$$R\left(\frac{\partial \ln c_o}{\partial\, 1/T}\right)_i = R\left(\frac{\partial \ln k_3/k_{-3}}{\partial\, 1/T}\right) - \frac{R}{2}\left(\frac{\partial \ln k_2}{\partial\, 1/T}\right) = \Delta H_{c,i} \qquad [22]$$

and

$$R\left(\frac{\partial \ln c_o}{\partial\, 1/T}\right) = R\left(\frac{\partial \ln c_o}{\partial\, 1/T}\right)_i + \frac{1}{2}\Delta H_\eta = \Delta H_{c,\eta} \qquad [23]$$

where ΔH_η is the heat of activation for the H.E.R. at overpotential η. Calculations on our results give $\Delta H_{c,i} = -1.33$ kcal/mole and $\Delta H_{c,-0.408\text{v NHE}} = 5.0$ kcal/mole, *i.e.*,

$$\Delta H_{c,-0.408\text{v}} - \Delta H_{c,i} = 6.33 \text{ kcal/gram mole} \qquad [24]$$

$$\tfrac{1}{2}\Delta H_{-0.408\text{v}} = 7.2 \text{ kcal/mole} \qquad [25]$$

This internal consistency in the results gives added proof to the fact that hydrogen on entering the metal goes through an adsorbed intermediate which is identical to that which leads to hydrogen evolution. This finding is in disagreement with the hypothesis of Bagotskaya (4), that two parallel paths exists for hydrogen discharge, (one which leads to entry to the

[5] Since θ is small <0.1 up to —1.02v a fast discharge-slow electrochemical reaction above —1.02v would give a Tafel slope of —0.040v.

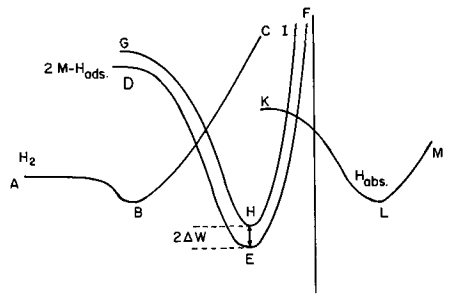

Fig. 13. Schematic representation of the potential energy curves for physical adsorption of molecular hydrogen, chemisorption of atomic hydrogen and absorption of atomic hydrogen.

metal, and the other which leads to hydrogen combination on the surface and evolution of hydrogen gas), each with widely different activation energies.

Mechanism by which anions and poisons increase the permeation rate.—Kabozev and Montblanova (12, 13) on the basis of the assumption that the rate-controlling step in H evolution on iron is recombination, have suggested that the increase in adsorption of anions is due to a lowering of the M-H_{ads} bond. Although the rate-determining step assumed by these workers is no longer an acceptable one for Fe (10), nevertheless, their idea can be incorporated in the mechanism of hydrogen evolution and entry into the metal, deduced in the present work.

In Fig. 13, the potential energy curves for physical adsorption of H_2 (A,B,C), chemisorption of H(DEF), and absorption of H in an octahedral interstitial cavity directly beneath the cathodic surface (KLM) are shown. GHI represents the curve for chemisorption of H when the M-H_{ads} bond strength is lowered by an amount ΔW.

Let J'_i be the permeation rate on lowering the M-H_{ads} bond energy by an amount ΔW. From Eq. [9] it follows that

$$\frac{J'_i}{J_i} = \frac{k'_{-3}k_3}{k_3k_{-3}}\left(\frac{k_2}{k'_2}\right)^{1/2} \qquad [26]$$

where k'_2, k'_3, and k'_{-3} are the rate constants when the potential energy curve for hydrogen adsorption is GHI.

On the basis of the model shown in Fig. 13

$$k'_3 = k_3e^{\alpha\Delta W/RT} \qquad [27]$$

$$k'_2 = k_2e^{2\beta\Delta W/RT} \qquad [28]$$

$$k'_{-3} = k_{-3}e^{(\alpha-1)\Delta W/RT} \qquad [29]$$

where α and β are the slopes of the potential energy curves at the points of intersection. From Eq. [26], [27]-[29] it follows that

$$\frac{J'_i}{J_i} = e^{(1-\beta)\Delta W/RT} \qquad [30]$$

Thus, since $\beta < 1$, it may be seen that a lowering of W by ΔW results in an increase in the hydrogen permeation rate, and on this basis the effect of adsorption of I^- on the permeation rate may be explained.

The question arises as to how adsorption of I^- decreases W. If one supposes, as have Frumkin and Slygin (14) for platinum, that the polarity of the Fe-H_{ads} bond is negative towards the solution, then the lowering of W could be due to electrostatic interaction between I^- and H^-. Interaction between the adsorbed I^- and the d-bond of the metal could lower W, as has been proposed by Bockris and Conway (15). Finally, if adsorption of I^- occurs at sites favorable for hydrogen evolution (*i.e.*, with large W), discharge will then occur at other sites, where W is weaker. The lowering of W may be due to any of the above three effects, or any combination of them, since they can occur simultaneously. Such a model successfully explains the increase in hydrogen permeation and the rise in hydrogen overpotential on absorption of I^-. The increase in the hydrogen permeation rate with concentration of I^- is due to an increased surface coverage with I^-.

The effect of CN^- in alkaline solution can be explained by a mechanism similar to that proposed for I^-. The fact that at low overpotentials the permeation rate is independent of the concentration of cyanide would indicate strong chemisorption of cyanide on the metal surface. This conclusion is in agreement with the findings of Beck *et al.*, who found strong adsorption of CN^- on iron (16). The concentration dependence of the permeation rate in alkaline cyanide solutions at higher overpotentials is due to the fact that here the desorption step is electrochemical instead of combination.

On the basis of the effect of the lowering of W on the permeation rate the increase in permeation on addition of naphthalene to 0.1*N* H_2SO_4 may be explained. Interaction between the π-bonds of naphthalene and the d-band of the metal could lower W and hence increase the permeation rate. This conclusion is in agreement with recent findings of Russian workers (17), who observed a positive shift in the point of zero charge on mercury on adsorption of naphthalene. The similarity in the effects observed in the case of I^- CN^- and naphthalene would suggest that the mechanism of Bockris and Conway is the best explanation for the lowering of the M-H_{ads} bond energy on the adsorption of impurities.

Mechanism of the lowering of permeation rate by organic nitriles.—The effects observed in the case of valeronitrile benzonitrile and naphthonitrile are mutually similar, but give permeation effects in the opposite direction to that observed for naphthalene. The similarity in the effects observed in the case of the aliphatic and aromatic nitrile would indicate that adsorption of the aromatic nitriles occurs vertically. If this were not the case, different effects would be expected in going from the aliphatic to the aromatic nitriles. Adsorption of these compounds in this fashion would thicken the double layer and preclude the interaction of the π-bonds of the aromatic nitriles with the metal. Vertical adsorption of these compounds would hinder the approach of hydrated hydrogen ions from the solution to the metal surface. Since energy would be expended on pushing the hydrogen through the adsorbed organic layer an increase in overvoltage would be expected (5). Thus, the decrease in hydrogen permeation would be due to a decrease in θ_H. At higher surface concentrations of the organic, the effect would be more drastic, and, hence, the concentration dependence of this effect can be explained.

The effects observed by Smialowski *et al.* (18) in the case of dibenzylsulfoxide may be explained by a similar mechanism.

Consistent interpretation of the work of Bagotskaya.—On investigations the permeation from mercury poisoned acid solutions. Bogotskaya (4) had found that the permeation time curve displayed a maximum. Similar results have been observed by us in acid solutions and the mechanism by which this maximum occurs is explained elsewhere (19), as being due to the blistering of the metal and the formation of surface cracks due to supersaturation of the metal with hydrogen. Bagotskaya (4) has found that poisoning the diffusion side with mercury in acidic solutions increases the permeation rate above that observed when only acid (0.1*N* H_2SO_4) was present: the diffusion side in each case was polarized at $i_c = 4 \times 10^{-9}$ amp/cm^2, while the polarization side was polarized at 50 ma/cm^2 in HgO saturated alkaline solutions. In the case of alkaline solutions it was found (4) that, on poisoning with mercury, polarization at $i_c < 4 \times 10^{-4}$ amp/cm^2 decreased the permeation while above $i_c = 4 \times 10^{-4}$ amp/cm^2 the permeation rate was increased, as

compared to that observed in pure alkaline solutions under similar conditions of polarization. Mercury, a strong poison, supersaturates the metal with hydrogen (as is evidenced by the observed maximum in the permeation rate transient). It is suggested, therefore, that, when the diffusion side is poisoned with mercury, fissures form on the surface. Such a damaged surface reduces the entry of hydrogen from the diffusion side. However, hydrogen atoms diffusing from the polarization side can recombine at the bottom of the fissures (out of contact with the electrolyte) and arrive as hydrogen gas at the diffusion side surface. Thus the mercury on the iron diffusion side surface will not affect the permeation. In the case of alkaline solutions it is possible that such damage will not occur until $i_c > 4 \times 10^{-4}$ amp/cm^2 is realized.[6] Below $i_c = 4 \times 10^{-4}$ amp/cm^2, mercury will influence the permeation rate as described here for other poisons, while above 4×10^{-4} amp/cm^2 a situation such as that described for mercury poisoned acid solutions will be operative.

The hypothesis that hydrogen recombines in fissures out of contact with the electrolyte is consistent with the findings of Bagotskaya in an earlier work (20), when it was found that diffusing hydrogen had no effect on the overpotential (η) on polarized mercury poisoned hydrogen electrodes in acid solutions. If the atomic hydrogen cannot reach the sites when hydrogen evolution takes place on the mercury poisoned iron surface, no effect of diffusion hydrogen on η would be expected.

It may be seen that the mechanism described in (19) for the observed maxima in permeation transients offers a rational explanation of the results of Bagotskaya; thus is not necessary to postulate that direct discharge of hydrogen into the metal takes place, in order to explain the observed results (4).

Summary

The investigation of the hydrogen evolution reaction (h.e.r.) on iron has been carried out as a function of ambient and temperature, using permeation rate-potential relationships as a diagnostic criterion for mechanism determination. The evolution on, and entry of hydrogen into single crystal Armco iron, has been studied.

Additions of I^-, CN^-, and naphthalene to the solutions increase, while additions of valeronitrile, benzonitrile and naphthonitrile decrease the permeation rate (J). J through Armco iron single crystals and polycrystals is similar for identical electrode conditions.

From the permeation-potential, permeation-current, and permeation-temperature relationships observed, it has been concluded that hydrogen on entering the metal passes through an adsorbed state on the metal surface which is identical to the intermediate which leads to hydrogen evolution. The similarity of the results obtained for Armco iron, single crystals, and polycrystals indicates that grain boundaries play no part in the hydrogen evolution kinetics or the mechanism of hydrogen entry to the metal.

The current-potential relationships and the dependence of the permeation rate on potential and current density are tenable only with a coupled discharge-recombination mechanism for hydrogen evolution on iron at low overpotentials in acid solutions. This mechanism does not change with temperature. In alkaline solutions the mechanism for hydrogen evolution is coupled-discharge recombination below −1.02v N.H.E. while at more negative potentials, it is slow discharge followed by fast electrochemical desorption.

The effect, of adsorption of I^-, CN^-, and naphthalene, on the permeation rate has been explained by a lowering of the M-H_{ads} bond, while the effect of valeronitrile, naphtonitrile, and benzonitrile is explained by there vertical adsorption hindering the discharge of hydrogen ions and thus lowering θ_H.

It has been shown that the results of Bagotskaya (4) for the effect of mercury poisoning on the permeation rate are not necessarily in disagreement with the hypothesis that hydrogen is adsorbed on the metal surface prior to entry to the metal.

[6] Since at $i_c < 4 \times 10^{-4}$ amp/cm^2 in mercury poisoned alkaline solutions the hydrogen concentration in the lattice will be insufficient to cause any damage of the metal surface.

Acknowledgments

The financial support of the Naval Air Engineering Center, Philadelphia, Pennsylvania, during the course of this work is gratefully acknowledged. The authors wish to express sincere thanks to Dr. H. Wroblowa and Dr. W. Beck for many helpful suggestions and discussions, and to Dr. D. F. Stein, of General Electric Corporation, Schenectady, for supplying the single crystals used in this work. Thanks are also due to Mr. F. S. Williams and Mr. E. Taylor of N.A.E.C. (Philadelphia) for their kind cooperation during the course of the present work. This paper is taken in part from the thesis presented to the University of Pennsylvania by one of the authors (J. McB.) in partial fulfillment of the requirements for the Ph.D. degree.

Manuscript received March 11, 1965; revised manuscript received June 21, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

An All-Metal Cell Technique for the Measurement of the EMF of Molten Metal-Metal Halide Solutions Corrosive to Ceramics

Harry R. Bronstein

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

A new technique is described which permits the measurement of emf using an all-metal cell. The applicability of the method to both aqueous systems and molten metal-metal halide systems is demonstrated. This technique will now permit measurements of the emf of systems such as the molten alkaline earth-alkaline earth halides and the rare earth-rare earth halides which are extremely corrosive to ceramics.

The measurement of equilibrium cell potentials has long been an important means of determining thermodynamic properties of systems. In addition, equilibrium emf measurements can yield information as to the species present and the number of electrons involved in the potential-determining process. The application of this fundamental measurement to a unique group of solutions, namely, the alkaline earth metals, and the rare earth metals dissolved in their respective molten halides (1, 2) has been reported for the lanthanum-lanthanum chloride (3, 4) and the cerium-cerium chloride (5) solutions. However, the results are subject to question because of the corrosiveness of these solutions to ceramic material (6, 7). If dependable emf measurements are to be made on these solutions, a technique must be employed which eliminates the use of ceramic containers and insulators.

This paper describes such a technique which permits the measurement of emf in an all-metal cell.

Discussion of Technique

Aqueous cells such as Hg^{o}, $Hg_2SO_4/H_2SO_4/Ag_2SO_4$, Ag^{o} are contained in glass apparatus. Each electrode compartment is in communication with the sulfuric acid bridging solution by means of a capillary or a sintered glass frit. Electrode leads are platinum wire in contact with the mercury of the $Hg\text{-}Hg_2SO_4$ half-cell and the silver wire of the Ag, Ag_2SO_4 electrode. The open-circuit potential of this cell is measured in the normal manner. The current is comprised of electron transport from the $Hg\text{-}Hg_2SO_4$ electrode, $2Hg \rightarrow Hg_2^{+2} + 2e^-$, via the platinum lead through the potential measuring instrument to the $Ag\text{-}Ag_2SO_4$ electrode, $2Ag^+ + 2e^- \rightarrow 2Ag^{o}$ with the sulfuric acid acting as the transfer medium for the sulfate ion. The over-all cell reaction being $2Hg^{o} + Ag_2SO_4 \rightarrow Hg_2SO_4 + 2Ag^{o}$.

If the same half-cell mixtures Hg^{o}, $Hg_2SO_{4(solid)}$, saturated aqueous solution and Ag^{o}, $Ag_2SO_{4(solid)}$, saturated aqueous solution are placed in separate tantalum tubes, these containers have now the same function as the platinum and silver wires of the glass cells. The tubes are partially immersed in a sulfuric acid solution and communication of the solution in each tube with the bridging liquid is provided by means of a sintered porous tantalum plug welded in the side of each tube. If there were no such communication, a current would not be expected to flow, since the potential difference between the two electrodes is much less than the potential necessary for decomposition of the sulfuric acid (H_2O) and that of the anodic dissolution of tantalum metal. Concomitant with this requirement is the absence in the bridging liquid of any redox process which can occur within the potential developed at the tantalum electrodes. With these requirements met and with the porous metal plug providing an ion path for transport of current, the potential between these all-metal cells should be the same as that measured in the conventional glass insulator apparatus.

The same analysis may be applied to a molten metal-metal halide system. A concentration cell contained in an all-metal system may be schematically illustrated as follows:

$$\underline{\text{Ta}} \quad \begin{matrix}\text{saturated} \\ \text{Cd-CdCl}_2\end{matrix} \quad \begin{matrix}\text{LiCl, KCl} \\ \text{eutectic}\end{matrix} \quad \begin{matrix}\text{unsaturated} \\ \text{Cd-CdCl}_2\end{matrix} \quad \underline{\text{Ta}} \qquad \text{[Cell 1]}$$

The solid line represents the metal tube containing the respective solution, and the dotted line the sintered porous metal frit. The symbol of the metal of construction is placed as shown and the bridging liquid written as normally. The conventional half-cell reaction may be written for each compartment.

The saturated anode

$$Cd \rightarrow Cd^{2+} + 2e^-$$

or [ref. (1), (2)]

$$Cd_2^{2+} \rightarrow 2Cd^{2+} + 2e^-$$

The unsaturated cathode

$$Cd^{2+} + 2e^- \rightarrow Cd^{o}$$

or

$$2Cd^{2+} + 2e^- \rightarrow Cd_2^{2+}$$

For transport of current and measurement of a potential, chloride ions must be able to migrate from the cathode compartment via the bridging liquid to the anode compartment.

As stated previously, if there were no communication of the solutions in the tantalum cells with the bridging liquid and if the decomposition potential of the bridging liquid were greater than the potential developed at the tantalum electrodes, no current could flow. The decomposition potential of the constituents of the molten eutectic mixture (8) is greater than any potential which can be developed in this system (9, 10), but with communication through the porous metal frit, chloride ion migration is possible, and the potential measured should be the same as measured in a conventional ceramic apparatus.

Experimental

For the evaluation of the applicability of this technique to aqueous systems, the following cell was used

$$\underline{\text{Ta}} \quad \begin{matrix}\text{Hg}^{o}, \text{Hg}_2\text{SO}_{4(\text{solid})} \\ \text{saturated solution} \\ \text{in } H_2O\end{matrix} \quad \begin{matrix}1N\ H_2SO_4, \\ H_2O\end{matrix} \quad \begin{matrix}\text{Ag}^{o}, \text{Ag}_2\text{SO}_{4(\text{solid})} \\ \text{saturated solution} \\ \text{in } H_2O\end{matrix} \quad \underline{\text{Ta}} \qquad \text{[Cell 2]}$$

Each mixture was contained in a ⅝ in. diameter tantalum tube 3 in. in height, with a sintered porous tantalum pellet ⅜ in. diameter by ¼ in. thick welded into the wall. The silver wire in contact with both the

solution and solid silver sulfate was clamped to the tantalum cell for good electrical contact. The tubes were suspended in 1*N* H_2SO_4 contained in a tantalum beaker.

For the high-temperature study, the molten Cd-$CdCl_2$ system was used. The inertness of these solutions to Pyrex and quartz has permitted emf measurements to be made in the normal manner. The reproducibility of the data by several investigators (9, 10) has established the reliability of the Cd-$CdCl_2$ system as a standard.

Figure 1a illustrates the apparatus employed for this test. Much of the design of the apparatus was for projected use in the rare earth metal-rare earth halide systems. For the cadmium-cadmium chloride system, three tantalum metal cells (Fig. 1b) were employed, one the saturated Cd(excess)-$CdCl_2$ reference electrode and the other two containing 2 and 10 mole % cadmium dissolved in cadmium chloride, respectively. The 15 mil wall tantalum cells were ⅜ in. ID by 2½ in. in length. One-half inch from the bottom of each electrode capsule, a depression was formed in the wall for placement of a sintered porous pellet of tantalum ⅜ in. diameter by ¼ in. thick. The tantalum pellet was welded to the body of the capsule as illustrated so that only the exposed end of the pellet would be in contact with the bridging liquid. The wall of the capsule in back of the porous tantalum pellet had two holes 0.007 in. in diameter for access of the electrode solution to the porous pellet. The porous pellets were made by the Kawecki Chemical Company from uniform size, 10μ, high capacitance type tantalum powder compressed to 80% of theoretical density. After loading, the cells were capped and welded shut. Loading and welding was performed in a helium dry box. Closure of the cells was necessitated by the volatility of cadmium metal at the temperature to be employed (above 600°C), and escape would be limited by slow diffusion through the porous tantalum plug. By means of threads in the cell caps, 3/16 in. tantalum rods were attached to serve both as electrode leads and as a means of lowering the cells into the melt. The melt, a carefully dehydrated eutectic mixture of LiCl and KCl, was contained in a 3½ in. high tantalum vessel which fitted inside the 5 in. ID by 14 in. high stainless steel tank as illustrated. For this experiment, the tank cover was assembled with the electrode cells and spacer plate positioned such that the cells would be above the eutectic mixture when the tank cover was attached to the tank. The apparatus was evacuated and then pressurized with dry argon by means of a nullmatic valve for maintenance of constant pressure inside the tank. The tank was heated by means of a 6 in. ID by 24 in deep Marshall furnace. Constant temperature of the system was maintained by conventional control devices. At temperature, the cells were lowered into the melt by means of the tantalum rods which extended through Teflon pressure seals in the top of the entry ports, care being taken that the cells did not touch the bottom of the tantalum vessel. Next, the tantalum-jacketed stainless steel thermocouple tube, to which the spacer plate is attached, was lowered into the melt. The temperature was measured with a chromel-alumel thermocouple. The potential of the thermocouple was read on a Brown Electronik recorder, the major part of the voltage being bucked by a Rubicon precision potentiometer. The recorder had a chart span of 3 mv, graduated in 0.01 mv.

Several hours at temperature, 635°C ± 2°, was sufficient for saturation of the reference cell and complete solution in the others as attested by the attainment of a constant potential *vs.* the reference cell. The stability of the system was demonstrated by the constancy of the potential during a period of 16 hr at temperature. Potential measurements were made with a Hewlett-Packard model 425DC microvolt-ammeter.

Results

The potential of the aqueous cell 2 was + 41.5 ± 0.1 mv at 25°C in excellent agreement both with the theoretical value + 42.3 mv and the experimental + 42.0 ± 0.5 mv (11).

Table I compares the values of the emf obtained for the molten system Cd-$CdCl_2$ in cell 1 with those of previous investigations of this system in conventional ceramic cells. The agreement is excellent.

Since pure cadmium chloride was used as the bridging liquid by both Mashovets-Poddymov (10) and Crawford (9) and the eutectic LiCl-KCl in this experiment, the agreement in the experimental data indicates a negligible or nonexistent liquid junction potential in the all-metal cell system.

Summary

It has been experimentally demonstrated, both in an aqueous system and a molten metal-metal halide system, that emf measurements can be made in an all-

metal apparatus by a technique which eliminates the need of ceramic containers and insulators. For the all-metal cell technique to function, the decomposition potential of the bridging liquid, as well as that of any redox process which may be present in that liquid, must be greater than the potential difference between the electrode cells. It will now be possible to measure the emf of systems such as the molten alkaline earth-alkaline earth halides and the rare earth-rare earth halides which are extremely corrosive to ceramics.

Acknowledgment

The author wishes to thank Dr. F. A. Posey of this Laboratory, not only for very helpful and encouraging discussions during the conceptual development of the technique, but also for his continued aid throughout the course of the investigation. The research was sponsored by the United States Atomic Energy Commission under contract with the Union Carbide Corporation.

The Electrochemical Reduction of Oxygen on Platinum Electrodes Partially Immersed in Sulfuric Acid

H. J. R. Maget and R. Roethlein

Fuel Cell Laboratory, Direct Energy Conversion Operation, General Electric Company, Lynn, Massachusetts

ABSTRACT

Reaction rates have been determined for the cathodic reduction of oxygen on submerged and partially immersed smooth and platinized platinum electrodes in 1*N* and 10*N* H_2SO_4. Measurements of local and total electrode currents for various thicknesses of electrodeposited platinum have shown the dependence of current on deposit thickness and surface roughness, observed in 10*N* H_2SO_4. The liquid film theory offers a partial explanation of the observed experimental results. Gas-liquid interfacial geometry relationships have been derived to describe menisci and liquid films obtained on glass, smooth and platinized platinum, and a value of the liquid film thickness immediately above the intrinsic meniscus has been obtained. In all cases, the current is mainly carried by the electrode surface immediately above the conventional "three-zone interface" and decreases rapidly above this level because of appreciable contribution of ohmic polarization to local electrode potentials. Limiting currents were shown to be linearly dependent and square-root dependent on oxygen partial pressure below the meniscus region and above the meniscus, respectively.

It was the general objective of this research program to conduct investigations leading to an understanding and eventual improvement of porous electrodes to be operated as oxidant cathodes in fuel cells. Due to the complexity of practical electrode structures, work was conducted on a simplified model of a single pore, but was expected to yield information regarding the behavior of practical porous electrodes. The simplest study model is a straight cylindrical pore. An early model proposed by Justi (1) suggested a surface diffusion of hydrogen as a rate-controlling step for the electrochemical oxidation of hydrogen, involving the concept of a three-zone interface. However, recent work by Will (2) has shown that the main source of current is confined to a narrow band close to the upper edge of the meniscus. Similar results were observed by Sama *et al.* (3) in the case of oxygen reduction on copper, silver, and nickel electrode sheets. These authors suggest that mass transport of oxygen may be rate limiting. This concept is intriguing since a two-zone thin film region could justify extremely large transport rates. Such a model has raised questions regarding the necessity of basing the diffusion current theory on large exchange currents, larger than usually accepted for gas reactions (4). In addition, meniscus and film stability for practical pore lengths are dependent on pore geometry, the pore material, and potential. Bonnemay (5) has shown for monotubular silver electrodes that applied potentials produce a modified surface state of the pore-wall metal, yielding variations in electrolyte-electrode surface tension, resulting in a dynamic behavior of the liquid in the capillary. As expected, the electrode activity is dependent on the pore diameter, increasing with pore diameters up to 0.3 mm, but abruptly decreasing for diameters greater than 0.3 mm. This result suggests large modifications of meniscus geometry and contact angle. If oxygen diffusion is rate controlling, an increase in contact angle results in a larger diffusion path and smaller gas concentration at the metal-solution interface.

Direct evidence of the existence of these films on metal surfaces has been obtained by Muller (6). A practical contribution to thin film studies was also

reported by Rozenfeld (7) in the case of electrolyte evaporation. Rates of oxygen transport through thin films were observed to increase with rate of evaporation, as a result of spontaneous mixing arising from changes in electrolyte concentration and surface tension. These results indicate that additional complications could be expected in thin film regions if concentration differences, *i.e.*, natural convection, can take place. Detailed and comprehensive calculations on transport processes in pores have been discussed by Wagner (8).

If mass transport of reacting species across the meniscus and film is rate controlling, as it has been shown for some electrochemical processes, it becomes necessary to know the gas-liquid interfacial geometry. Indeed, for extremely small contact angles between the electrolyte and the supporting electrode material, the thickness of the liquid layer near the meniscus-film boundary may become rather small, resulting in appreciable ohmic overvoltage between the electrolyte bulk and the narrow current-carrying region. This would change the local potential and current distribution, which in turn could possibly result in appreciably reduced contribution of the liquid film to the over-all reaction rate. A comprehensive study on such effects has been reported by Guillou (9). This author indicates that potential-concentration relationships are point functions of the current density, and that current-potential relationships have a significance only at discrete points of the electrolyte/electrode.

The following experiments were designed to investigate the effects of thin electrolyte films on the rate of oxygen reduction on platinum electrode surfaces. The results were expected to give a qualitative description of the reaction mechanism and current-potential distribution which occurs in the region immediately above the bulk electrolyte level.

Experimental

Experimental apparatus.—The experiments were carried out in a Pyrex glass cell consisting of five compartments, separate from each other by fine pore fritted glass disks. Two counter electrode compartments were arranged parallel to each other on either side of the central compartment. The counter electrodes have a large surface area composed of platinum-black electrodeposited on platinum mesh. Two other compartments which served as reference cells were joined symmetrically to the remaining sides of the central compartment. Each reference cell had a Luggin capillary extended into the main compartment, allowing the application of potentials near the test electrode. Hydrogen gas was bubbled through the reference compartments, and two platinum black screens served as hydrogen reference electrodes.

The test electrodes, see Fig. 1, were composed of platinum tubing (99.99% pure), 1.0 cm long, 1.5 cm in diameter, and 0.2 cm in wall thickness, sections A and A'. Another electrode, section B, of the same diameter and thickness but only 0.0127 cm (5 mils) in length was inserted between sections A and A'. Electrical connection was made by spot welding Teflon covered platinum wire to the inner wall of the platinum tubing. All three sections were mounted on a Teflon assembly and held rigid by a Teflon coated tantalum rod, which was threaded tightly into a Teflon stopper. This prevented the inner surface from coming in contact with the electrolyte. Insulation was accomplished by inserting 1 mil thick Mylar sheet of the same outside and inside diameter as the platinum tubing between each section.

The test electrode was raised and lowered into solution by means of a specially modified L. S. Starrett Vernier height gauge with an accuracy of $\pm 1.2 \times 10^{-3}$ cm.

Electrode preparation.—The electrode surface was pretreated in several ways: (*a*) finely polished, also electrodeposited with spongy platinum from chloroplatinic acid (with traces of lead acetate) at 10 ma/cm^2 for (*b*) 60 sec, (*c*) 12 sec, (*d*) 4 sec, and (*e*) 240 sec.

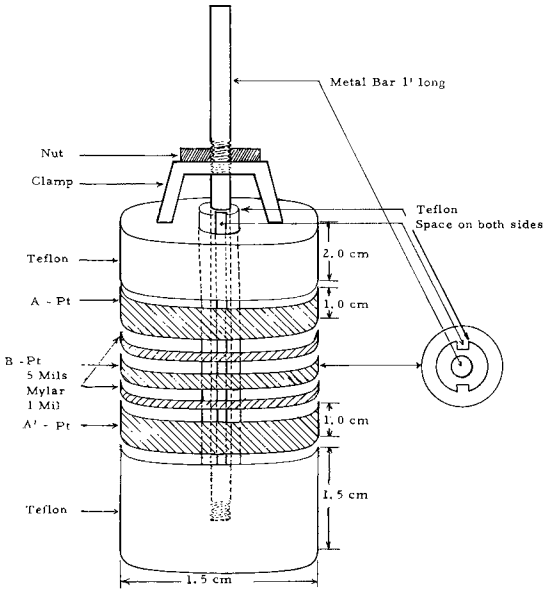

Fig. 1. Experimental cylindrical electrodes for the determination of current densities in meniscus and thin film region.

Measurements of the thickness of the electrodeposited platinum black layers were made by placing the platinum tubing vertically under a microscope and measuring the difference between the platinum substrate and the electrodeposited layers. The magnification was about 200X, with average deviation of $\pm 10\%$ for the thickness of the spongy layer.

Experimental procedure.—Polarization measurements were made by means for two "fast rise" Wenking potentiostats, (Model 61 TR) which have an operating potential source of ± 2v, a current measurement accuracy of 1.5% full scale, and a zero point stability of 5 mv/day.

Surface area measurements for the different electrode roughnesses were made by means of a constant current pulse used in conjunction with the Wenking potentiostat (10). The test electrode was held at a constant potential a few millivolts more positive than the reversible hydrogen potential; then by means of a switching device the potentiostat was disconnected from the circuit and replaced by a constant current anodic pulse. The potential change with time of the test electrode was measured simultaneously with the current variation across a standard resistance by means of a Tektronix type 551 dual-beam oscilloscope. The trace was photographed with a polaroid Tektronix C-12 oscilloscope camera. The number of coulombs required to remove hydrogen from the electrode surface in a N_2 purged, 1N H_2SO_4 solution was then used as a relative measure of the electrodes surface area.

Sulfuric acid of two different normalities (1N and 10N) was made from C. P. Reagent Grade stock solution using doubly distilled water containing less than 0.4 ppm impurities. The gases used in these experiments were of high grade prepurified quality. The temperature was maintained constant at $+23 \pm 1$°C.

The height and shape of meniscus and film formation on various surfaces (glass, smooth platinum, platinized platinum) were examined by optical and electrical methods. The measurements were conducted on cylindrical platinum tubing (99.99% Pt), 1.5 cm in diameter (in absence and presence of electrodeposited platinum black) and on 1.0 cm diameter glass tubing partially immersed in 1 and 10N H_2SO_4.

The meniscus geometry could be determined by projecting the image of the interface on a screen, allowing magnification of about 16X. The liquid film could not be observed clearly by this method.

Electrical resistance measurements were obtained by means of a semicircular platinum foil 1.0 cm in diameter and 1.27 x 10^{-2} cm thick, sealed between two cylindrical glass tubes and finely polished to form a continuous smooth surface. Electrical contact was made by spot-welding a platinum wire to the foil inside of the glass cylinder. The cylinder was raised and lowered into the electrolyte by means of the L. S. Starrett Vernier height gauge. Constant current pulses of less than 3 msec duration were applied between the foil and a counter electrode. The instantaneous potential decay was observed and measured on an oscilloscope and the ohmic resistance calculated therefrom. Similar measurements were also conducted by means of an a-c resistance bridge operating at 1000 cps.

Experimental Results

Interfacial liquid-gas geometry.—The maximum length, h, of the magnified observable meniscus was found to be 0.28 ± 0.01 cm for platinized platinum and glass and 0.27 ± 0.01 cm for polished platinum. The over-all meniscus geometry was similar in all cases. Figure 2 presents the observed geometry for platinized platinum cylinders.

Results obtained from resistance measurements on glass cylinders are reported in Fig. 3, for 1N and 10N H_2SO_4 electrolytes. The ohmic resistance is divided by the electrolyte resistivity, to account for the large variations in electrolyte conductivity. The linear part of the resistance curve is associated with the region of the thin film, allowing the calculation of electrolyte film thickness. Resistance values obtained by a-c measurements and constant current pulses were identical. The point from which a linear relationship between R/ρ and x/h is observed can be used to determine the length of the intrinsic meniscus. These values are in agreement with the measured length obtained from the magnified projected gas-liquid interface, that is 0.28 cm in 1N and 0.265 cm in 10N H_2SO_4.

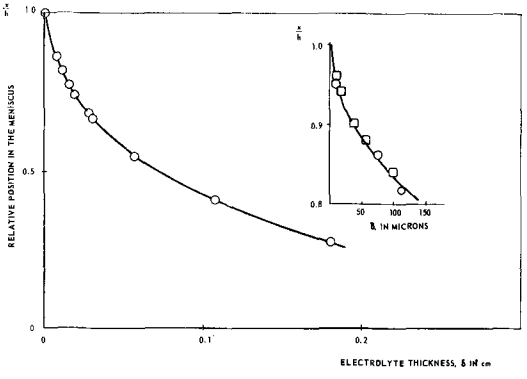

Fig. 2. Gas-liquid interfacial geometry: ○, experimental results; □, calculated values from Eq. [1a].

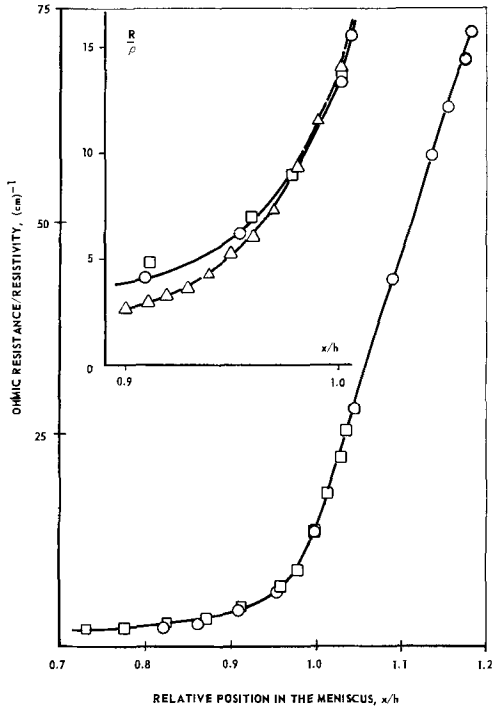

Fig. 3. Resistance in meniscus and thin film, 1N and 10N H_2SO_4. Experimental results: ○, 10N H_2SO_4; □, 1N H_2SO_4; △, calculated values from Eq. [5].

Since the experimental results have shown that relatively thin electrolyte films and relatively large resistance contributions to ionic flow occur for (x/h) values greater than about 0.9, all derivations have been established for (x/h) values near 1. Landau and Lifshitz (11) have derived equations [A1] and [A2] in Appendix A) for the interfacial liquid-gas geometry of menisci on flat surfaces. At the meniscus-film boundary, these equations for the electrolyte thickness, δ in cm, and the relative meniscus height x/h (x is the distance from the liquid level and h the length of intrinsic meniscus), become

$$\delta = \delta_h + A(1 - X)^2 \qquad [1]$$

where $X = x/h$ and A represents the theoretical value

$$A = \frac{1}{2}\frac{5 + 4\sqrt{2}}{4 + 3\sqrt{2}}\left(\frac{2\sigma}{gd}\right)^{1/2} \qquad [2]$$

where σ is the surface tension, g acceleration, d liquid density. For 1N H_2SO_4, $A \simeq 0.25$ cm. However, this value does not check well with the value obtained from the resistance measurements (Appendix B) for the boundary condition $X = 1$, at which the total meniscus resistance R_m should be

$$R_m = \frac{\rho h}{4b(A\,\delta_h)^{1/2}} \qquad [3]$$

where ρ is electrolyte conductivity and, 2b the diameter of the partially immersed cylindical glass tube.

The film thickness, δ_h, can be obtained from experimental results, since

$$\frac{dR_f}{dx} = \frac{\rho}{2\pi b \delta_h} \qquad [4]$$

if high order terms of δ_h are neglected. Indeed, the slope dR_f/dx in the linear region of Fig. 3, allows us to establish that $\delta_h = 2.7 \times 10^{-4}$ cm.

The value of A, thus determined from Eq. [3] and [4], is equal to 0.37 and not too appreciably different for 1 and 10N H_2SO_4. In fact $(A_{1N}/A_{10N})_{\text{theo.}} \simeq 1.14$, whereas the experimental values are $\simeq 1.05$.

Calculated values for the interfacial geometry and ohmic resistance were thus based on

$$\delta = \delta_h + 0.37\,(1 - X)^2 \qquad [1a]$$

and

$$\frac{R(x)}{\rho} = \frac{h}{2b\pi}\frac{1}{(A\delta_h)^{1/2}}\left[\frac{\pi}{2} - \tan^{-1}\left(\frac{A}{\delta_h}\right)^{1/2}(1 - X)\right] \qquad [5]$$

for $X \leq 1$, $A = 0.37$, and $2b = 1$.

Calculated values of δ are plotted against X in the exploded section of Fig. 2 and compared to experimental results obtained for partially immersed platinized platinum surfaces.

Calculated values of $R(x)/\rho$ in 1N H_2SO_4 are plotted against position in the exploded section of Fig. 3 and compared to experimental results obtained for partially immersed glass tubes in 1N and 10N H_2SO_4

Good agreement is obtained in both cases, with the largest deviations occurring at decreasing values of (x/h), as expected.

Current-voltage characteristics of partially immersed electrodes.—Electrode currents on platinum electrodes are greatly enhanced by raising the electrode partially out of solution as shown in Fig. 4. The data for this plot were taken potentiostatically on a platinized platinum surface of one of the larger sections, A or A′, (total area, 4.7 cm^2; height, 1 cm) of the segmented electrode in 1*N* H_2SO_4. At the limiting current there is, on the average, a fivefold increase in total electrode current from the submerged condition to the one of full meniscus and film formation. In the case of a platinum black electrode surface, drawing the electrode further out of solution does not increase the current past the point of meniscus and film formation. Bright platinum electrodes do show some current increase when partially immersed but large variations are observed with surface pretreatment. Figure 5 shows the effect of acid concentration on polarization behavior for a partially immersed platinum black electrode. This electrode was prepared by deposition of a thick layer of electrodeposited platinum. A fourfold increase in current is observed between 1*N* and 10*N* H_2SO_4. This increase in current for higher acid concentrations is partially explained by the increase in electrolyte conductivity.

Local current-voltage behavior was measured by raising or lowering the thin (5 mil) foil electrode, section B, into meniscus or film zones. Measurements were made with the use of two Wenking potentiostats, one connected to the test electrode and the other to the shorted sections A and A′. By this means the surface of the entire segmented electrode could be kept at relatively the same applied potentials. Figure 6 is representative of the local current-potential variation for the thin segmented electrode, section B, having a platinum black surface. Significant current increases are not realized until the electrode is raised into the highest portion of the meniscus region from 0.28 to 0.30 cm, where the liquid electrolyte layer surrounding the electrode becomes relatively thin. On further withdrawal of the electrode from solution, *i.e.*, displacing the electrode segment upward, the current drops sharply. This is due to the increased resistance to current flow encountered by entering into the thin film region.

Position dependence of the current in the meniscus region. Constant applied potential, —1N H_2SO_4. *Total currents.*—Figure 7 shows a typical behavior for a platinized platinum cylindrical electrode which has been drawn out of solution to various heights above the electrolyte level with an applied potential in the limiting current range. A constant potential of +0.400v *vs.* H_2 was chosen, since this represents a point of maximum oxygen reduction in absence of other reactions such as hydrogen deposition. At higher cathode potentials, the activation polarization represents a large contribution to over-all applied potentials. Thus, the chosen applied potential was representative and reproducible for mass transfer controlled currents for the diffusion of oxygen to the electrode.

The initial portion of the curve represents the currents obtained for a completely immersed electrode and shows very little increase in current until the upper portion of the meniscus is formed. In this region the current rises at an extremely high rate until the meniscus is fully formed. From this point on, the current remains relatively constant dropping slightly near the end of the electrode, since at about 1.0 cm the electrode is nearly completely withdrawn from the electrolyte.

This curve is also representative of the electrode behavior for any thickness of electrodeposited platinum black in 1*N* H_2SO_4 solutions. Three different

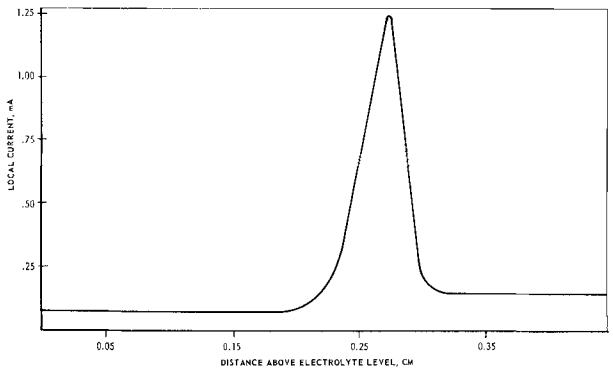

Fig. 8. Local current distribution in the meniscus and thin film at constant potential of +0.400v vs. H_2; 1*N* H_2SO_4.

thicknesses of spongy platinum surfaces were tested, namely 15, 30, and 60μ. The behavior was similar in all cases. Increasing surface roughness had no appreciable effect on electrode performance for this acid concentration. A somewhat different behavior was observed for 10*N* H_2SO_4, as will be described in another section of this paper.

Bright platinum was also tested and showed similar currents for the submerged condition with small increases in current when partially immersed. However, these currents were often transient in behavior and seemed to be largely dependent on surface pretreatment.

Local current.—To determine the local current profile in the meniscus, the height of the thin cylindrical electrode, section B, was varied in the meniscus by means of the Vernier height gauge. A constant potential was applied to the platinized test electrode, while section A and A' were held at the same potential by means of a second potentiostat. A typical curve is shown in Fig. 8. Again the current remains relatively constant until the upper edge of the meniscus zone is reached.

Here the slope rises rapidly until a maximum current is reached, which coincides with the maximum height of the meniscus as determined by optical methods, *i.e.*, approximately 0.28 cm. Further withdrawal of the electrode from the electrolyte displays a rapid current decrease, at approximately the same rate as previously observed for the local current increase. This behavior is due to a sharp increase in electrolyte resistance as the electrode is brought into the thin film region. The current should essentially drop off to zero but there is a small residual current due to stray currents obtained from electrolyte bridging from top to bottom electrode around the Mylar insulating sheet.

The shape of these curves also verifies a previous statement that the polarization potential decreases rapidly to zero in the thin film region.

* Liquid film.

Position-dependence of the current in the meniscus region. Constant applied potential, 10N H_2SO_4. Total currents.—Using the procedure described above, various thicknesses of electrodeposited platinum and polished platinum were tested in 10*N* H_2SO_4. Figure 9 shows the behavior of polished platinum and four platinized platinum electrodes each one of which was electrodeposited at 10 ma/cm^2 for four different periods of time, i.e., 4, 12, 60, and 240 sec. As shown from the curves there is a distinct increase in current with increasing surface roughness of the electrode. Measurements of the thickness of platinum black layers were made for three different deposition durations by microscopic methods. A relative measure of the surface roughness was also obtained by measuring the number of coulombs required to strip hydrogen from the electrode surface. Table I gives a summary of the data found for surface roughness and platinum black thickness.

Approximate analytical solutions based on two-dimensional oxygen diffusional processes in the spongy platinum layer allow prediction of total electrode currents as a function of electrodeposited platinum layer thickness, δ_{sp}, and a factor (Ψ) describing the state of dispersion of the platinum in the electrodeposited platinum layer. If it is assumed that the roughness, as determined by hydrogen stripping, is representative of this state of dispersion, a qualitative agreement, as presented in Fig. 10, can be obtained between I_T and $(\delta^2_{sp}\,\Psi)^{1/2}$.

Equations developed by Wagner (8) for mass transport controlled processes in an electrolyte-wetted spongy metal surface show that there is a linear relationship between total current, deposit thickness and platinum dispersion

$$I_T = \pi D \left[2 \frac{(\delta^2_{sp}\,\Psi)}{\rho} i_o \frac{RT}{\alpha n F} e^{\frac{\alpha n F}{RT}\eta} \right]^{1/2} \qquad [6]$$

where i_o is exchange current density, D diameter electrode, ρ electrolyte resistivity, ohm-cm, η = polarization, volts, $\frac{\alpha n F}{RT}$ usual electrochemical significance,

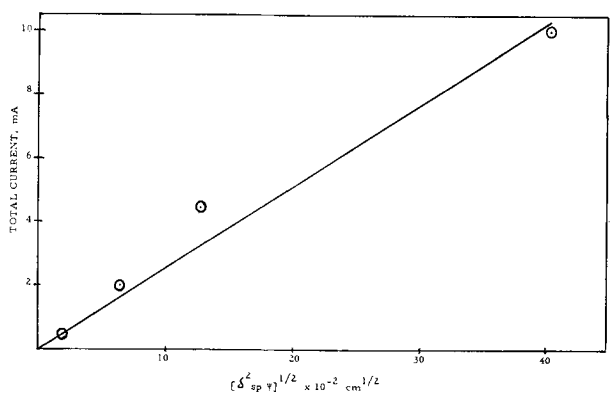

Fig. 10. Total electrode current as a function of platinum deposit thickness, δ_{sp}, and surface roughness Ψ: δ_{sp}, thickness of Pt deposit; Ψ, surface roughness.

and Ψ = (roughness factor/δ_{sp}), cm^{-1}. With appropriate values for the above parameters, calculated values of the current for the various platinum thickness are in close agreement with those obtained from experiment.

Local currents.—In an identical manner to that described for the case of a dilute electrolyte (1*N*), the local current distribution was investigated in 10*N* H_2SO_4.

The currents observed on three platinized electrodes, each one of which was subjected to a different deposition time, increase with increasing surface roughness, which parallels the current variations obtained on the large electrodes.

Effect of oxygen partial pressure.—The partial pressure of oxygen was varied by changing the atmosphere surrounding the electrolyte. The effects of partial pressure on electrode currents were measured potentiostatically. Beside pure oxygen, a mixture of 50% O_2-50% N_2, air, and pure N_2 were tested. In the submerged state there is a linear dependence of current on oxygen partial pressure. For the partially immersed electrode with full meniscus and film formation a square root dependence between current and oxygen partial pressure is observed. This square root relationship exists for both normalities and for all thicknesses of electrodeposited platinum black. Polished platinum tended to show a linear relationship with oxygen partial pressure for total electrode immersion. For partial immersion the results were rather scattered. The problem of getting meaningful results for polished platinum probably lies in the fact that it is so catalytically poor and therefore activation controlled, even at high applied potentials, that true diffusion controlled currents are never realized. When the gaseous atmosphere was changed to N_2 the current essentially dropped to zero. For the submerged electrode this could take more than an hour, however, if the electrode were partially immersed the decay in current occurred within a few minutes. This tends to show again that for the partially immersed condition the diffusion of oxygen across the thin film surface is far more predominant than diffusion from the bulk electrolyte. Table II shows the current variation with partial pressure at a constant applied potential of +0.400v *vs.* H_2 for two different normalities.

Conclusion

For platinized platinum structures the main source of current for the reduction of oxygen at high polarizations (on partially immersed electrodes) is localized to a relatively small region above the meniscus boundary. This fact is shown in a general manner, primarily by the steady increase in current associated with the gradual withdrawal of an electrode from an immersed condition until a full meniscus and liquid film are formed on the extended electrodes' surface. Furthermore, the local current variation in the meniscus exhibits a sharp maximum at a point where the height of the meniscus reaches its maximum length, approximately 0.28 ± 0.01 cm.

Above this region the local current decreases sharply because of large potential gradients, due to ohmic polarization, which are manifested in the thin film region. The sharp increase of resistance in the thin film was also verified by the direct measurement of resistance as a function of height in the meniscus. These measurements also gave a fairly accurate value for the thickness of the thin films, approximately 2.7 x 10^{-4} cm, which are formed above the intrinsic meniscus. Liquid phase continuity at the boundary between the upper edge of the meniscus and the film is obtained, and contact angles identical (or nearly identical) to zero degree can be assumed at the boundary. The height of the intrinsic meniscus decreases, as expected from theory, for decreasing ratios of surface tension/liquid density. However, the theoretical values of the intrinsic meniscus length do not adequately represent the experimental results. Modifications of this length yield quadratic relationships between the liquid electrolyte thickness and the meniscus position, at least near the top of the meniscus. The ohmic resistance, calculated from the interfacial liquid-gas meniscus geometry is linearly dependent on the electrolyte resistivity and can assume rather large values near the meniscus-film boundary.

The relationship obtained for the height-dependence of the meniscus and film can be used to determine if molecular mass transfer can be rate controlling in electrochemical processes. Since transport rates are also dependent on local electrode overpotential, the relationship obtained for the height dependent ohmic resistance, will allow the calculation of ohmic contribution to local potentials, determining to what extent the electrolyte film will contribute to the overall reaction rates.

The liquid film theory, as developed by Will (2), maintains that current depends on electrolyte film thickness. From the measured values of the film thickness, calculations of the current do not check well with those obtained from experiment. Results obtained in 10*N* H_2SO_4 exhibit a distinct electrode current dependence on the electrode surface roughness. The variation in platinum layer thickness, δ_{sp}, does not necessarily affect the thickness of the liquid film, δ_h, which could still form on the spongy metal surface. However since current increase is observed with increasing values of δ_{sp}, it is believed that the longitudinal electrolyte resistance in the spongy platinum layer is decreasing with increasing platinum layer thickness. These changes would vary the potential distribution considerably above the intrinsic meniscus level thereby providing a greater electrode length capable to sustain the electrode current.

If the transport rates are evaluated on the basis of a two-dimensional transport process in the spongy electrolyte-filled platinum layer as developed by Wagner (8), a relationship is obtained between electrode current and the geometric characteristics of the spongy layer, *i.e.*, layer thickness and platinum particle size or layer roughness. Indeed, the currents obtained in 10*N* H_2SO_4 show good agreement with those calculated for the various platinum layer thicknesses by the use of Eq. [6].

Since the values obtained at low acid concentration (1*N* H_2SO_4) show little variation with deposit thickness, it is believed that the lower conductivity value of the 1*N* H_2SO_4 solution does not provide for a long enough active film length above the intrinsic meniscus level to be affected to any great degree by increasing layer thickness. It is therefore concluded that a complete interpretation of the experimental results depends upon an adequate characterization of the electrodeposited platinum layer.

For a partially immersed electrode, which has a full meniscus and film, a square root relationship between oxygen partial pressure and limiting current was obtained. Equation [6] which predicts the diffusion currents for this condition shows that this relationship exists between current and oxygen concentration. The

exchange current, i_o, can be shown to be directly related to oxygen concentration. For fully immersed electrodes there is a linear relationship between current and oxygen partial pressure, which is indicative of a bulk diffusion-controlled process.

APPENDIX A

The equation presented by Landau and Lifshitz (11) to describe the liquid-gas interfacial geometry of menisci on flat surfaces

$$\delta = \frac{-a}{\sqrt{2}} \cosh^{-1}\sqrt{2}\frac{a}{x} + a\left[2 - \frac{x^2}{a^2}\right]^{1/2} + \delta' \quad [A1]$$

where

$$a = (2\sigma/gd)^{1/2} \quad [A2]$$

is also equal to h = length of the intrinsic meniscus and σ = surface tension; g = acceleration; d = liquid density, yields the following relationship, if a contact angle $\theta = 0$ is assumed

$$\delta = \frac{a}{\sqrt{2}}\left[\cosh^{-1}\sqrt{2} - \cosh^{-1}\sqrt{2}\frac{a}{x}\right] + a\left[\left(2 - \frac{x^2}{a^2}\right)^{1/2} - 1\right] \quad [A3]$$

The change of variable $X^* = 1 - x/a$ introduced in Eq. [A3] yields

$$\delta = \frac{a}{\sqrt{2}}\left(\cosh^{-1}\sqrt{2} - \cosh^{-1}\sqrt{2}\frac{1}{1 - X^*}\right) + a[(1 + 2X^* - X^{*2})^{1/2} - 1] \quad [A4]$$

or

$$\delta = \frac{a}{\sqrt{2}}\left(\frac{-X^*}{1+\sqrt{2}} + \frac{X^{*2}}{2(1+\sqrt{2})} + \frac{X^{*2}}{2(1+\sqrt{2})^2} - X^* - \frac{X^{*2}}{2}\right) + aX^* - \frac{aX^{*2}}{2} \quad [A5]$$

if Eq. [A4] is simplified for small values of X^*. Ultimately Eq. [A5] will yield a quadratic relationship between δ and X^* for values near the upper limit of the intrinsic meniscus

$$\delta = \frac{aX^{*2}}{2}\frac{5 + 4\sqrt{2}}{4 + 3\sqrt{2}} = A(1 - X)^2 \quad [A6]$$

If a liquid film of constant thickness δ_h is assumed to exist above the intrinsic meniscus, the following general relationship will yield geometry continuity between liquid level and interface geometry

$$\delta = \delta_h + A(1 - X)^2 \quad [A7]$$

where the theoretical value for A should be

$$A = \frac{5 + 4\sqrt{2}}{4 + 3\sqrt{2}}\frac{(2\sigma/gd)^{1/2}}{2} \simeq 0.25 \text{ cm} \quad [A8]$$

APPENDIX B

Since the largest contribution to the resistance to ionic flow is expected near the upper limit of the intrinsic meniscus and in the liquid film, calculations will be restricted to small values of X^*. Resistance variations can be, at least in a simplified manner, expressed by

$$\frac{dR}{dX} = \frac{\rho h}{\pi\delta(2b + \delta)} \quad [B1]$$

where ρ = electrolyte resistivity, $X = x/h$, $2b$ = diameter of the tube supporting the electrolyte, and δ = film thickness.

If $\delta << 1$, which is correct for values of $X > 0.7$, Eq. [B1] can be integrated to yield

$$R(x) = \frac{\rho h}{2b\pi}\frac{1}{(A\delta_h)^{1/2}}\left[\tan^{-1}\left(\frac{A}{\delta_h}\right)^{1/2} - \tan^{-1}\left(\frac{A}{\delta_h}\right)^{1/2}(1 - X)\right] \quad [B2]$$

and since $\delta_h << A$

$$R(x) = \frac{\rho h}{2b\pi}\frac{1}{(A\delta_h)^{1/2}}\left[\frac{\pi}{2} - \tan^{-1}\left(\frac{A}{\delta_h}\right)^{1/2}(1 - X)\right] \quad [B3]$$

where A can be evaluated from the total meniscus resistance, R_m through

$$R_m = \frac{\rho h}{4b(A\delta_h)^{1/2}} \quad [B4]$$

Since Eq. [B3] only applies up to $X = 1$, the total measured resistance will be

$$R(x) = \frac{\rho h}{2b\pi\delta_h}\left[\left(\frac{\delta_h}{A}\right)^{1/2}\left[\frac{\pi}{2} - \tan^{-1}\left(\frac{A}{\delta_h}\right)^{1/2}(1 - X)\right] + X\right] \quad [B5]$$

where the first term of Eq. [B5] applies to $X \leq 1$, and the second term to $X > 1$.

Thermodynamics of Ions: Consistent Standard States for Enthalpies and Free Enthalpies

Philip B. Lorenz

Bartlesville Petroleum Research Center, Bureau of Mines, United States Department of the Interior, Bartlesville, Oklahoma

and Albert Sprague Coolidge

Department of Chemistry, Harvard University, Cambridge, Massachusetts

ABSTRACT

Ions can be treated thermodynamically in the same way as neutral substances if the chemical elements are supplemented by an "element of charge" and if an electrical parameter is added to the variables defining "state." Possible choices for the element of charge are gaseous electrons, electrons in the Schottky state, aqueous hydrogen ion, and metallic electrons. A standard electrical state of zero Volta potential is implied in most discussions, but there are advantages in adopting grounded platinum as a basis for defining standard states.

The application of thermodynamics to electrochemistry would be facilitated if conventions for defining thermodynamic functions of ions were better standardized. Problems have arisen because the hydrogen scale for entropies of aqueous ions contains an internal inconsistency (1), and different standards of reference have been used for ions in gaseous and aqueous states (2). The entropy scale has been discussed critically by several authors (1-5). However, the subject of reference standards seems worthy of further examination.

To an extent greater than may be realized, thermodynamics can be extended to ions in a manner exactly analogous to the treatment used for neutral substances. For each substance C formed from elements A and B, there is a unique formation reaction.

$$aA + bB \rightarrow C \qquad [1]$$

The enthalpy of reaction for [1] when A, B, and C are in their standard states is the standard enthalpy of formation of C; the elements are zero states. If C is a charged species it cannot be synthesized from neutral elements alone, and in order to represent its "formation," there must be inserted into [1] some term playing the role of the element of charge, whose standard state is a zero state for electrically charged species. In the interest of simplicity and in order to conform to basic physical concepts, this term should appear on the left side of [1] and be the same for both cations and anions; therefore, either in one case or in the other, it must have a negative coefficient. It is the purpose of this paper to specify and compare possible choices for the element of charge and its standard state.

Gaseous Electron Standards

The most natural choice for the element of charge would be the electron, with formation reactions of the form

$$aA + bB \mp ze^- \rightarrow C^{z\pm} \qquad [2]$$

where z is the absolute value of the valence of the $C^{z\pm}$ ion. Reactions like this form the basis for tabulations of thermodynamic functions of ions in the gaseous state. However, there is some latitude in what can be taken as the standard state for the electron. The accepted standard enthalpy of formation for gaseous hydrogen ion, given in tabulations (6), is the value of ΔH° for the reaction

$$\tfrac{1}{2}H_2(g) - e^-(g) \rightarrow H^+(g) \qquad [3]$$

where the standard state for electrons and hydrogen ions is the ideal gas at 1 atm. The corresponding free enthalpy of formation is obtained by a straightforward computation using the precise values of entropy for $e^-(g)$ and $H^+(g)$ given by the Sackur equation, in combination with the third-law entropy of $H_2(g)$.

The tabulated value $\Delta H^\circ_f = 367.088$ kcal (6) for reaction [3] is the sum of three terms: the enthalpy of formation of monatomic hydrogen, 52.089 kcal; the ionization energy obtained from the Rydberg constant, 313.518 kcal; and the translational enthalpy 5/2 RT = 1.481 kcal arising from an increase in the number of particles. This latter term can be eliminated by another choice for the standard state of the gaseous electron, conveniently designated (2, 7) by $e^-(0)$. It is defined by

$$\left.\begin{aligned} &\Delta H^\circ = 5/2\,RT \text{ for } e^-(0) \rightarrow e^-(g) \\ \text{and} \quad &S^\circ = 0 \text{ for } e^-(0) \end{aligned}\right\} \qquad [4]$$

For the reaction

$$\tfrac{1}{2}H_2(g) - e^-(0) \rightarrow H^+(g) \qquad [5]$$

the value of ΔH° is then 365.607. In the state $e^-(0)$ the electron has a zero value for entropy and translational enthalpy; this is therefore an example of the "null" state proposed by Schottky (8). The Schottky state has also been described as a state of infinite dispersion with the particles at rest (9). The two descriptions correspond in respect to having zero energy (kinetic and potential), but a state of rest and infinite dispersion is not a unique thermodynamic state, since it can be approached as a limit by endless adiabatic expansion of states having different fixed entropies, the values of each of which will carry over to the limit. It is therefore convenient to specify that $S^\circ = 0$. This is not a definition of a physical state, but a recipe for imagining a reference state; Schottky called it a "harmless fiction."

The state of rest and infinite dispersion is related experimentally to the condition of electrons after gaseous ionization or photoelectric processes at ordinary temperatures. The entropy is unimportant here, as electron work functions for metals are low-temperature approximations which, along with ionization potentials, involve only energies. When the concept of the Schottky state is extended to ions, it becomes fictitious even in respect to the energy, being related to experiment only through neutral combinations formed with the electron. For this purpose it has been necessary to specify that any internal degrees of freedom have the energy that corresponds to statistical equilibrium for the temperature under consideration (9). It seems preferable to avoid a physical description of the fictitious gaseous state (0), but since it is used

in various guises, its numerical characteristics must be clearly recognized.

Aqueous Hydrogen Ion Standard

In aqueous solution, the "element of charge" customarily implied is the ion-molecule couple [$H^+(aq) - \frac{1}{2}H_2(g)$]. Formation reactions take the form

$$aA(\text{std. state}) + bB(\text{std. state}) \pm z[H^+(aq) - \tfrac{1}{2}H_2(g)] \rightarrow C^{z\pm}(aq) \quad [6]$$

Enthalpies and free enthalpies of formation of ions, based on this element of charge, are usually available from standard electrode potentials and their temperature coefficients (6). Naturally, since thermodynamic functions for gaseous ions and aqueous ions are based on different standards, they cannot be compared unless the enthalpy and entropy of hydration for hydrogen ion are known.

Standards Based on Electrons in Platinum

There is another possible standard state for electrons serving as the element of charge, namely the metallic state. It is less closely connected with ordinary conventions, but it has some advantages in helping to correlate gaseous and aqueous states and in clarifying the concepts of standard state in electrochemistry.

Platinum is a convenient choice for the metal because of its involvement in the standard hydrogen electrode (10), which serves as a basis for treatment of all other ions. If $e^-(Pt)$ is the standard (zero) state for the element of charge), it can be connected with the aqueous hydrogen ion standard through the half reaction

$$\tfrac{1}{2}H_2(g) \rightarrow H^+(aq) + e^-(Pt) \quad [7]$$

added $\pm z$-fold to reactions like [6] to give

$$aA(\text{std. state}) + bB(\text{std. state}) \mp ze^-(Pt) \rightarrow C^{z\pm}(aq)$$

Similarly, the connection with the gaseous electron standards is through the reactions

$$e^-(Pt) \rightarrow e^-(g) \quad [8]$$

$$e^-(Pt) \rightarrow e^-(0) \quad [9]$$

added $\mp z$-fold to reactions with the form of [3] and [5].

For reaction [9], the enthalpy change is given by the electron work function for platinum, and the entropy change can be calculated statistically.[1] Although the thermodynamics of reaction [7] has been much investigated, there are some points that have been overlooked. Strictly speaking, this reaction (along with other electrochemical reactions above) is incompletely defined. The parameters necessary to specify the state of electrically charged substances in a conducting medium, besides temperature, pressure, and ordinary composition, must include one that determines electrical condition. For example, a 1-v change in the potential of the platinum, with no other change, would alter the free enthalpy of reaction [7] by 23 kcal.

One way to define electrical condition is by means of the electrostatic (Volta) potential. A zero value of this potential is the standard state that is implied in most discussions. For example, in the calculation of the hydration energy of gaseous ions [*Cf.* (5), (7)] no work term is included for the process of bringing the ion up to the aqueous surface.

However, since it is notoriously difficult to reproduce, the Volta potential is unsatisfactory as a parameter of thermodynamic state. Because of this problem another way is suggested of defining electrical condition, based on electrochemical potentials ($\tilde{\mu}$). For metals, the electron potential, $-\tilde{\mu}_{e^-}/F$, which is a measure of the free enthalpy per mole of transfer of electrons from ground, is a natural parameter to represent electrical state. The standard state of electrons can therefore be taken as grounded platinum,[2] denoted by $e^-(Pt^*)$. An analogous experimental parameter for the electrical state of aqueous hydrogen ion must establish a value for its electrochemical potential $\tilde{\mu}_{H^+}$. For a solution in equilibrium with hydrogen and electrons (*cf.* reaction [7]), it is necessary that

$$\tilde{\mu}_{H^+} = \tfrac{1}{2}\mu_{H_2} - \tilde{\mu}_{e^-} \quad [10]$$

When the hydrogen is in its standard state, this reduces to $\tilde{\mu}_{H^+} = -\tilde{\mu}_{e^-}$. Thus the electrical state of any aqueous solution may be uniquely specified by the electron potential to ground of a standard hydrogen electrode in equilibrium with it. The standard state of the aqueous ion, denoted by $H^+(aq^*)$, may be taken as an acid in its standard state in equilibrium with a reversible standard hydrogen electrode that is grounded. This state is independent of the condition of any of the surfaces involved.[3] It is also independent of the anion associated with the hydrogen ion. In this latter sense it might be more appropriate to speak of $H^+(aq^*)$ as representing a standard electrochemical potential rather than a standard state. Nevertheless, all other thermodynamic functions of the hydrogen ion also have standard values under these conditions, even though only uncertain estimates of their values are available.

Electrical States for Gaseous Ions and Electrons

Electrons emitted from grounded platinum according to reaction [9] are at an electrostatic potential that differs by 0.8v from that of electrons emitted from grounded mercury. Consequently if the enthalpy of reaction [9] is given by the electron work function of platinum, it is not proper to say that the enthalpy of the reaction

$$e^-(Hg) \rightarrow e^-(0)$$

is given by the work function of mercury. An electrical parameter must be added to the conditions that define the state $e^-(0)$. The gaseous states for charged species are obtained by "paper and pencil operations" from experiments involving the removal of single particles from the influence of the opposite charges with which they were associated. Such states cannot be considered appreciably at equilibrium with condensed phases, at least at ordinary temperatures, and therefore the electrostatic potential is the only potential that can be used as an electrical parameter despite its disadvantages. The electrostatic potential of a gas with respect to ground is not an absolute experimental quantity, as it can be measured only relative to the Volta potential of some standard probe that is grounded. Now experimentally platinum is not the best reference material for Volta potentials, but for purposes of uniformity with standards for metallic and aqueous phases it is convenient to define standard gaseous states as having the electrostatic potential of grounded platinum. Symbols such as $H^+(g^*)$ and $e^-(0^*)$ may be used for these states.

Discussion

The word "equilibrium" in the definition of the standard state of $H^+(aq)$ automatically requires that the free enthalpy change for the reaction

$$\tfrac{1}{2}H_2(g) \rightarrow H^+(aq^*) + e^-(Pt^*) \quad [7^*]$$

[1] In platinum at 25°C, with approximately 0.6 free electrons per atom (11), the molar entropy of electrons is about 0.06 e.u.

[2] It is unnecessary to specify the metal that is grounded when only free enthalpy is considered, but entropy and other functions depend on the chemical composition.

[3] Strehlow (12) pointed out that variations in electron work function do not lead to different electrode potentials, but to different values of the Volta potential. At the metal-solution interface variations in the surface condition will be compensated by variations in the amount of adsorption in the electrochemical double layer.

is zero (Eq. [10]). This is not a numerical fiction, but a definition of electrical state.[4] With this definition it follows that $\Delta G^\circ = 0$ for reaction [7]. This statement may come as a surprise in view of the many attempts that have been made at calculation of the standard free enthalpy of reaction [7] (or related calculations) (7, 12-16). Now the most common method of calculation is based on a theoretical hydration energy for the ion and the electron work function of platinum. Consider a standard grounded platinum-hydrogen electrode in contact with a standard acid solution having the equilibrium Volta potential, Ψ°. Reaction [7*] is the sum of the processes

$\frac{1}{2}H_2(g) \rightarrow H(g)$	$\Delta G^\circ = a$
$H(g) \rightarrow H^+(g^*) + e^-(0^*)$	b
$H^+(g^*) \rightarrow H^+(g, \Psi = \Psi^\circ)$	$F\Psi^\circ$
$H^+(g, \Psi = \Psi^\circ) \rightarrow H^+(aq^*)$	$(-c + d)$
$e^-(0^*) \rightarrow e^-(Pt^*)$	$-Fw(Pt)$

The free enthalpies add to zero, and so the contact potential of the metal against the solution is

$$-\Psi^\circ = (a + b - c + d)/F - w(Pt) \qquad [11]$$

The notation is that of de Béthune (13) to show the parallel with his analysis. His value for $-\Psi^\circ$ is -0.459v.[5] The present value of zero for the standard free enthalpy is a consequence of the well-known equation of Lange (19)

$$\tilde{\mu}_i = \alpha_i + z_i F\Psi \qquad [12]$$

according to which the free enthalpy change for zero Volta potential difference is equal to the Volta potential difference for zero free enthalpy change.

The term $(-c + d)/F$ differs from the "real potential," α_{H^+}, by the free enthalpy of the reaction

$$H^+(0) \rightarrow H^+(g) \qquad [13]$$

which, using the Sackur entropy 26.011 kcal for $H^+(g)$, turns out to be -0.272v. Experimental values of the real potentials are limited in accuracy by the uncertainty in work functions and Volta potentials. Reproducible to only one or two significant figures, they are less popular than theoretical estimates of the same thing carried out to four figures. Nevertheless, values of real potentials and their temperature coefficients offer in principle an unexceptionable route for finding ionic entropies, and enthalpies and free enthalpies of formation that are based on a single standard for ions in both gaseous and aqueous states.

[4] It is well to emphasize that we are dealing with total ("electrochemical") free enthalpy change. We do not consider the "purely chemical free enthalpy change" which appears in many electrochemical discussions for the purpose of visualization.

[5] The value back-calculated from the contact potential (17) and standard electrode potential (18) of the standard calomel electrode is -0.447v.

Evaluation of a Pulse Charging Technique for Capacitance Measurements and Double Layer Studies

R. G. Barradas and E. M. L. Valeriote

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

A previously published pulse charging technique for measurements of capacity to derive surface areas of electrodes has been investigated to assess its suitability for studying electrochemical adsorption of inorganic and organic compounds at mercury. Reasonably acceptable results were observed with electrolytic capacitors and for a number of inorganic electrolyte solutions. The method was found to be less suitable for examining the adsorption of organic additives. Unusual dependence of capacitance on potential with varying resistances (R_s) was experienced. Results which conflict with reported data are discussed.

Experimental methods of investigating equilibrium properties of the electrical double layer (1) and electrochemical adsorption of organic compounds at electrodes (2) have recently been reviewed. In the course of our general investigations of electrochemical adsorption (3-9) we were attracted to the pulse-charging technique of measuring capacitance developed by Hackerman and co-workers (10, 11) because of their encouraging results. This method is a modern refinement of an earlier technique due to Bowden and Rideal (12), and differential capacity is determined by analysis of an R-C discharge circuit in which the

electrical double layer provides the capacitative component. The method appeared to be ideally suited to our principal objectives which were to complement the electrocapillary studies of an interesting new class of corrosion inhibitors (furfurylamine, its saturated analogue, and their respective derivatives and ions) on a mercury electrode (9) by capacitance measurements, and to extend the latter to comparison with solid electrodes. There is also the additional advantage of obtaining reliable measurements of electrode areas, which would aid other electrochemical studies, *e.g.*, the kinetics of anodic oxidation of silver (13, 14).

The purpose of this paper is to report on an experimental evaluation of the pulse charging method in terms of specific adsorption of inorganic electrolytes on mercury and also to show some preliminary results concerning its application to adsorption studies of the furfurylamine class of corrosion inhibitors. Certain unexpected behavior and apparently anomalous results were encountered in the course of the investigation and these are discussed below.

Experimental

With the exception of some minor experimental changes, which will be described, the method was essentially similar to that previously reported (10). To ascertain the reliable reproduction of our experimental arrangement and technique, capacity measurements on mercury in a 0.1*N* aqueous solution of Na_2SO_4 were repeated over a wider range of potentials to make better diagnostic comparison with published results (10, 15). The apparent lack of agreement led to further measurements on mercury in aqueous solutions of inorganic electrolytes of varying degrees of specific adsorbability.

A 150 henry choke was used to isolate the square wave from the potentiometer circuits and shielded wire was used for all connections. The cell is shown in Fig. 1 and contains a Ag-AgCl reference electrode which was initially used for potential calibration purposes only. All the reported potential measurements were made with respect to the saturated calomel electrode in order to facilitate comparison with other data (8, 10). A hypodermic syringe, fitted with a ground glass joint and equipped with a Chaney Adaptor (Hamilton Company, Whittier, California), was attached to the cell to supply mercury to the 2.5 cm diameter glass cup. A short platinum wire, sealed in the glass tubing, provided electrical connection between the mercury electrode and the external circuitry. Adjustment of the syringe provided stable and renewable mercury surfaces. The cup was surrounded by a cylindrical 45 x 45 mesh smooth platinum gauze electrode (Johnson, Matthey and Mallory Ltd., Toronto) with an apparent area of approximately 200 cm^2, which served as a counter electrode and as an electrostatic shield for the mercury pool. Although a platinized platinum counter electrode is desirable for reasons stated by McMullen and Hackerman (10), our counter electrode was not platinized in anticipation of the problems associated with its large adsorbent properties in dilute solutions of organic additives. A platinized electrode with a roughness factor of about 500 would increase the area of the counter electrode to such an extent that the bulk concentrations of organic adsorbates would be seriously affected, if not completely depleted, by adsorption on platinum at concentrations of 10^{-3}M or less. Other workers have avoided the use of platinized platinum for similar reasons (16).

Greaseless water-sealed vacuum stopcocks prevented ingress of air and eliminated the possibility of electrode contamination by stopcock lubricants. All solutions were deoxygenated by purified nitrogen gas which was admitted to the cell through sintered glass filters and water-filled presaturator. The solutions were also covered by an inert nitrogen atmosphere during the run by retention of a slight positive pressure of the gas within the cell.

Doubly distilled mercury was further purified by electrolysis in addition to a procedure outlined by Ives and Janz (17). All solutions were made up with "equilibrium water" prepared by redistillation of distilled water in a Barnstead EPR-1/2 still. The conductivity of the final "equilibrium water" was 8 x 10^{-7} mho/cm. The inorganic salts were of high analytical grade and were further purified, where necessary by recrystallization. Furfurylamine (Miles Chemical Company, Elkhart, Indiana) was twice distilled under nitrogen immediately before use. Only solutions of Na_2SO_4 were preelectrolyzed (at 2 ma for 14 hr) before the measurement of capacitances. Comparison between results obtained for solutions which are not preelectrolyzed have been found to show no significant differences within the limits of experimental errors (4, 18).

Results

Using electrolytic capacitors (in place of the cell solution) and a wide range of input wave amplitudes and resistances, R_s [this refers to the series resistance

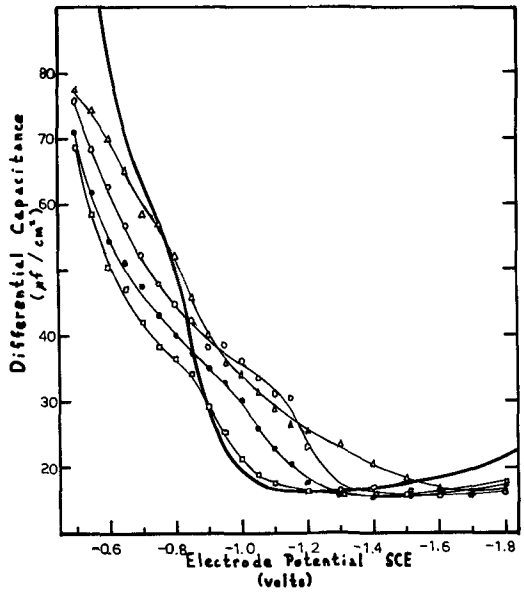

Fig. 4. Dependence of differential capacity on potential and resistance R_S at the mercury-0.1*N* KI interface. □, R_S = 26.7K; •, R_S = 10.8K; ○, R_S = 6.9K; △, R_S = 3.9K; ——— Grahame, Poth, and Cummings (20).

denoted by the same symbol in the circuit diagram reported by McMullen and Hackerman (10)], the capacities of several condensers ranging from 20 to 300 μf were determined at an applied square wave signal of 1000 cps and compared to values obtained using a General Radio Type 1608 A Independence Bridge. The percentage differences between the two sets of determinations had a maximum of 8% and an average of 3% for the eight capacitors tested. This compares favorably with previously reported results (10) of 7-8% differences for 37 and 58 μf electrolytic capacitors.

Differential capacities as a function of potential for various concentrations of aqueous solutions of Na_2SO_4, KF, KCl, and KI were determined by the square wave technique using the lowest amplitude possible so that the potential across the double layer changed by less than 10 mv over a half period of the square wave, and the IR drop in solution was minimized. The value of the series resistance, R_S, and electrode potential, E_{SCE}, was varied systematically, and the results for Na_2SO_4, KF, and KI solutions are displayed in Fig. 2-4. For the sake of clarity, some intermediate values of R_S have been omitted in Fig. 2 to 4 since they are consistent with those shown and do not contribute any further information.

For comparative purposes previously published data (10, 15, 19, 20) are also included on the same figures. Comparison between NaF and KF in Fig. 3 is justifiable because these two substances show similar capacity *vs.* potential behavior (C-E) at equal concentrations [cf. (19) and (20)]. The C-E curves for Na_2SO_4, KF, KI, and KCl (not shown diagramatically because some of the data are reported in Table I) have common characteristics with respect to the effect of varying R_S. Large and small values of R_S shift the curves to more anodic and cathodic potentials, respectively. The shifts of the potential are much more dependent on R_S than are the changes of capacity. This is most easily discernible in Fig. 3 where the C-E curves show clearly defined maxima and minima. It should be noted that the maximum R_S values are 16.3, 37.9, 26.7, and 15.4K for Na_2SO_4, KF, KI, and KCl, respectively, and the C-E curves which correspond to the maximum R_S values are in best agreement with previously published data. In general poorer agreement was observed at anodic potentials with respect to the pzc within a range of 200-300 mv. For Na_2SO_4 (Fig. 2) our C-E curve for R_S = 16.3K conforms more closely to that reported by Grahame than that of McMullen and Hackerman, except for the stated anodic region. The choice of the maximum R_S used was controlled by the magnitude of the highest expected capacitances for the various inorganic electrolytes examined and also by certain instrumental limitations. The variation of C-E curves with changes in R_S reflects the empiricism in assuming an electric analogue of the metal-solution interface.

Owing to the relatively small area of the counter-electrode used, an appropriate correction term was applied to every experimentally observed capacitance according to the following equation

$$1/C_{obs} = 1/C_{Hg} + 1/C_{Pt} \qquad [1]$$

where the terms C_{obs}, C_{Hg}, and C_{Pt} are the experimentally observed capacity and the capacities of the mercury-electrolyte and platinum-electrolyte components, respectively. C_{Pt} was assumed to be 22 μf/cm² on the basis of previously reported constancy of this value for platinum over a potential range from 0.0 to + 0.4v (SCE) in a sodium sulfate solution (10).

In addition a second positive correction of 2% was applied to all C_{obs} to allow for the systematic parallax effects between the photographic images of the oscilloscope graticule and screen. The value of 2% was estimated by comparison of traces on the time axis of the CRO screen, as recorded by the camera, with signals of known frequency (Hewlett-Packard Function Generator 202 A). All experimental values of capacitances reported for the solutions examined have been corrected as described above. To exemplify, the corrections for sodium sulfate (Fig. 2) were approximately 3% and 7% for the respective lowest and highest C_{obs} values. The applicability of Eq. [1], which is based on an assumed C_{Pt} value of 22 μf/cm², to electrolyte systems other than Na_2SO_4 is obviously questionable, but later discussion of this point will show that the correction is not too unreasonable in the absence of organic adsorbates.

Using an R_S value of 15.4K, differential capacities were measured as a function of potential for various concentrations of furfurylamine in aqueous 1.0*N* KCl base electrolyte. Graphical numerical double integration of the C-E curves was carried out to obtain surface tension values (15, 21). The integration constants were obtained from electrocapillary data for identical systems (22). The results of direct measurements of surface tension with those evaluated by double integration of C-E curves are tabulated (Table I). The two sets of surface tensions at various electrode potentials must, of necessity, coincide at the pzc's, but comparison

E_{pzc} and γ_{pzc} are the potentials and surface tensions, respectively, of the electrocapillary maxima. C_a is the concentration of furfurylamine.

at various anodic and cathodic potentials with respect to the pzc gives a good indication of suitability of the pulse-charging method for examining electrochemical adsorption.

Discussion

Reproducibility of results.—The general agreement between capacities of commercial electrolytic capacitors measured on an impedance bridge and that obtained by the square-wave pulse technique are comparable to those previously reported (10), which indicates that there is no significant difference in the electrical circuitry employed in the present work. However, both sets of results show that the pulse-charging method gave less accurate results than that of the impedance bridge. With R_s = 15.4K, the best precision with which we could measure differential capacities in the electrolyte solutions was approximately 4%. In regions of the C-E curves where dC/dE was large the lack of precision was as high as 11% (0.1*N* KI). Smaller values of R_s gave correspondingly poorer precision.

Inorganic electrolytes.—The uniform disparity between our best C-E plots with those of other workers for all inorganic electrolytes examined is obvious from inspection of Fig. 2-4. Hence it will be sufficient to discuss only the Na_2SO_4 case as a typical example. It was suggested by McMullen and Hackerman (10) that the observed discrepancy of results at cathodic potentials in comparison with Grahame's data (15) might be explained by a correction to the mercury surface area of about 1 cm^2 due to meniscus curvature effects. This correction of 20% seems unusually high, and it is not clear why such an effect would not be applicable to both anodic and cathodic branches of the capacity curves. In order to ascertain the magnitude of the area contribution due to meniscus curvature, the profile of our mercury pool electrode was determined using a travelling microscope with a micrometer scale eyepiece. The vertical displacement of the surface was plotted on an exaggerated scale compared to that of the horizontal coordinate. Using a standard analytical expression, the surface area was approximated by successive laminar segments of cones, and the total area found by adding the contributions of each of the laminar elements. A surface area correction of approximately 1% was calculated, which corresponds to an increase of 0.05 cm^2. Our measurements were made for the mercury/glass/air interfaces, but it has been reported (23) that the contact angle for mercury/glass is the same at the air or water interface. Therefore our area correction of about 1% is reasonably valid in the dilute aqueous solutions examined.

In comparison with the results of McMullen and Hackerman (10) for Na_2SO_4 our curves show much closer agreement to Grahame's data at cathodic potentials and greater divergence at anodic potentials.[1] There does not appear to be any simple explanation to resolve these contradictory experimental findings.

Capacitance correction, pzc, and relevant implications.—The correction for C_{Pt} of Eq. [1] is valid for Na_2SO_4 because of the constancy of C_{Pt} = 22 μf/cm^2 over a potential range of 0.0 to + 0.4v (SCE). The same correction for other solutions cannot be strictly applied unless two conditions are satisfied: (i) platinum behaves like mercury at cathodic potentials with respect to their corresponding pzc's; (ii) the pzc for platinum is 0.5 ± 0.2v (SCE). Since the capacity of mercury in most simple inorganic electrolytes is known to be relatively constant and independent of concentration and electrolyte species at extreme cathodic potentials (24) our application of Eq. [1] to electrolytes other than Na_2SO_4 should be justified. However, it is doubtful that the stated conditions are realistic: condition (i) is not supported by conclusive experimental evidence and condition (ii) is apparently erroneous (see Table II).

The value of 0.5 ± 0.2v (SCE) for the pzc of platinum in Table II has been deduced from an inadequately verified hypothesis (25) which relates the electronic work function to the pzc of various metals. It should be pointed out that Robertson (26) showed a capacitance minimum at 0.75v (NCE) for 1.0*N* HCl, but did not define this as the pzc for platinum. Should

[1] Cf. Riney *et al.* (33) using a single pulse method found good agreement with Grahame's data for 1.0*N* Na_2SO_4 (34) at cathodic potentials but poor agreement at anodic potentials.

Table II. Potential of zero charge (pzc) for platinum

Potential, v (Corrected to SCE)	Solution	Literature source
0.5 ± 0.2	1.0*N* Na_2SO_4	McMullen and Hackerman (10)

the real pzc for platinum be approximately 0.0v (SCE) as shown in Table II, the use of capacitance techniques to measure surface areas is not invalidated if a calibration procedure is adopted, whereby the area of at least one sample of each metal is determined by BET measurements. The areas of all other samples can then be derived by comparison of capacity values under similar appropriately chosen experimental conditions.

The discussion of pzc's of platinum does not support condition (ii) and the consequent correction factor of Eq. [1]. However, reported capacity values for platinum in various inorganic electrolytes (26-29) indicate that our corrections are in general slightly higher than necessary, but reasonable within experimental limitations.

Adsorption of furfurylamine in 1.0*N* KCl *solution.*—The doubly integrated capacity data in Table I is in moderately good agreement with the direct electrocapillary determinations of surface tension (22) for 1.0*N* KCl. When furfurylamine was present poorer agreement was observed. For 1.0*N* KCl the quantity

$$\Delta \equiv \left(\int\int_{E_{pzc}}^{E} C\,dE^2\right) - \gamma = 1.4 \pm 0.1 \text{ dynes/cm}$$

at the three most positive potentials, and -1.6 ± 0.5 dynes/cm at the three most negative potentials. Positive and negative values of Δ indicate high and low capacitance values, respectively. Hence we note that capacity values are slightly low at anodic potentials (consistent with the other inorganic electrolytes examined) and high at cathodic potentials for the base electrolyte. Although the Δ values are somewhat larger in magnitude than other published comparative differences (21), they are within the estimated experimental error of about 4% which was stated earlier.

In the presence of furfurylamine the average value of Δ is 5.8 ± 1.6 dynes/cm at the extreme potentials (-0.10 and -1.2v). These deviations are positive and greater than the above-mentioned experimental error, and they reflect consistently low capacitance values. The adsorption of some furfurylamine on the platinum counter electrode would reduce C_{Pt} in Eq. [1] to less than 22 μf/cm^2, and this leads to a corrected C_{Hg} which is smaller than its actual value.

Summary

1. A pulse charging technique for capacity and surface area measurements has been evaluated by investigating double layer properties of the mercury/solution interface in a variety of inorganic electrolytes.

2. To make the method suitable for the study of electrochemical adsorption of organic materials, a smooth platinum counter electrode was necessarily introduced. This led to a correction term which gave results only in fair agreement with previously published data for inorganic electrolytes.

3. It was found that the magnitude of the series resistance (R_s) had an appreciable effect on the variation of capacity with electrode potential.

4. Using furfurylamine as a test case the method proved to be less satisfactory in comparison with electrocapillary measurements.

Technical Notes

Beneficial Effect of Lithiated Electrolyte on Iron Battery Electrodes

Stanley Hills

Electric Storage Battery Company, Philadelphia, Pennsylvania

The beneficial effect of lithiated KOH electrolytes in nickel iron and nickel cadmium cells has been recognized for more than a half-century. It was obvious from the time that Edison patented its use (1) that incorporation of lithia in the alkaline electrolyte increased the efficiency of the nickel oxide electrode, since both of the aforementioned cells were and still are designed to be positive limiting. This fact oriented the major portion of the research concerning this phenomenon toward the nickel oxide electrode. Because of this emphasis one finds relatively few references in the literature with regard to the iron electrode (2), and more specifically there is nothing of significance with regard to an additive effect similar to that described previously.

A study of iron active material produced by various techniques, which is still in progress, has shown that the common practice of incorporating lithia in the 20% KOH electrolyte (50g LiOH/liter for formation which is then replaced by 25g LiOH/liter) is of greater benefit to the iron electrode than it is to the nickel oxide electrode. In the attempt to develop a standard procedure with which to evaluate new iron active materials, during the early phases of this investigation, pure 20% KOH was employed as an electrolyte as a result of the mistaken but still widely accepted belief that lithiated electrolytes were of benefit only to the latter electrode (3-5). A great deal of time was lost chasing down blind alleys because of the confusion which arose in the attempt to correlate the mass of seemingly meaningless and irreproducible efficiency data, before it was realized that the presence of lithia in the 20% KOH electrolyte was of greater significance than other variables such as precycling soak time, active material density, fabrication techniques (pressed powder of flat pocket), formation charge and discharge current densities, and extent of overcharge.

Table I. Efficiencies of iron active material stabilized in lithiated and unlithiated 20% KOH

Electrode	Mix weight, g	Weight iron, g	Stabilized Efficiency amp-hr/g Fe	Mean
102	8.11	6.98	0.392 ± 0.009	
103	8.10	6.97	0.392 ± 0.008	
104	8.13	6.99	0.388 ± 0.009	0.392
105	8.13	6.99	0.394 ± 0.010	
106	8.15	7.01	0.295 ± 0.007	
107	8.10	6.97	0.297 ± 0.007	
108	8.16	7.02	0.291 ± 0.007	0.292
109	8.17	7.03	0.288 ± 0.007	

Table I contains efficiency data for eight virtually identical single flat pocket iron electrodes, cycled until stabilization was assured in a pure and in a special lithiated 20% KOH employed solely for such single pocket evaluation (11g LiOH per liter of 20% KOH). These electrodes were fabricated from a batch of active material, prepared by the conventional Edison process described in the literature (6), which had been set aside as a quality control reference standard because of its excellent efficiency. The vast quantity of efficiency data collected with this batch of active material over a span of five years particularly suited it for such a study. Discharge was terminated at the first break in the voltage profile, designated by Salkind, Venuto, and Falk (2) to be the point where the useful capacity derived from the two electron Fe-Fe$(OH)_2$ transition was exhausted.

Theoretical efficiency for this transition is 0.96 amp-hr/g Fe. Individual electrode efficiencies are averages of the values observed over the last eight of the fifteen cycle regime and the excellent reproducibility obtained once stabilization was achieved is readily apparent. The difference in mean values represents a 34% increase in efficiency. Electrodes fabricated with less efficient grades of active material displayed differences of up to 50% when cycled in the same two electrolytes.

Stabilization of iron electrodes in pure 45% KOH yielded efficiencies equivalent to those obtained with lithiated 20% KOH, but use of such a concentrated electrolyte is incompatible with tubular nickel oxide electrodes as presently fabricated, since it results in rupture of the tube from excessive expansion of the active material. It is believed that the increased efficiency obtained with lithiated and more concentrated KOH electrolytes can most logically be explained by a delay in the onset of passivity. The cause of this phenomenon is, as yet, not readily apparent, but probably is related to the maintenance of a desirable crystal morphology.

Electrode Potentials in Fused Systems

IX. Liquid Junction Potentials in the AgCl-AgBr System

Kurt H. Stern

National Bureau of Standards, Washington, D. C.

Recent transport and liquid junction potential measurements (1) on a variety of molten salt systems indicate that the cationic mobilities in binary molten salt solutions are in general not equal over the entire composition range. Earlier results (2-4) in which zero liquid-junction potentials were obtained now appear as special cases.

Results published so far have included only systems of a single anion, the cation composition being different on the two sides of the junction. In the present paper we report a study of an anion concentration cell, *viz.*

$$\mathrm{Ag|AgCl}(X_1),\mathrm{AgBr}(X_2)\,||\,\mathrm{AgCl}(X_1'),\mathrm{AgBr}(X_2')\,|\mathrm{Ag} \qquad (A)$$

In this cell any nonzero emf is a liquid junction potential and must arise from differences in the anion mobilities and transport numbers.

Following Laity (2), we write for the cell emf

$$-FE/RT = \int_A^B t_1 d\ln a_1 + t_2 d\ln a_2 \qquad [1]$$

where t_1 and t_2 are the chloride and bromide transport numbers, and a_1 and a_2 are the AgCl and AgBr activities, respectively. Introducing the Gibbs-Duhem equation

$$d\ln a_2 = -\frac{X_1}{X_2} d\ln a_1 \qquad [2]$$

into [1] gives

$$-FE/RT = \int_A^B \frac{t_1X_2 - X_1t_2}{X_2} d\ln a_1 = \int_A^B \frac{\phi}{X_2} d\ln a_1 \qquad [3]$$

E can of course be zero only if $\phi = 0$, *i.e.*, $t_1 = X_1$, $t_2 = X_2$, but this is entirely possible even when $t_1 \neq t_2$ since the transport numbers are composition dependent. An explicit solution of Eq. [3] is possible only if some relation between t_1 and t_2 is assumed. This assumption is equivalent to choosing a reference with respect to which the transport numbers are to be measured. By choosing $t_1 + t_2 = 1$ we obtain transport numbers relative to silver ion, *i.e.*, $t_{Ag^+} = 0$. Making this substitution, and remembering that $X_1 + X_2 = 1$, gives

$$\phi = t_1 - X_1 \qquad [4]$$

Substituting [4] into [3] gives

$$-FE/RT = \int_A^B \left(\frac{t_1 - X_1}{X_2}\right) d\ln a_1 \qquad [5]$$

The corresponding expression for bromide ion is obtained by interchanging subscripts, *viz.*

$$-FE/RT = \int_A^B \left(\frac{t_2 - X_2}{X_1}\right) d\ln a_2 \qquad [6]$$

In the present work, using cell (A) the lower limit was fixed at a constant value of $X_1 = X_2 = 0.50$ and the upper limit was varied on both sides of this value.

Experimental

All measurements were carried out at 530°C in a furnace giving temperature control to ±1°. Cells were Pyrex U-tubes, 13 mm OD and 25 cm long, into whose center were sealed fine porosity (5-15μ hole size) quartz disks. These were capable of maintaining a considerable difference in liquid levels for several hours. Resistance measurements served to show that the pores of the frit were indeed wetted by the salt, since the resistance of unwetted glass is of course much higher. Some frits were cut open at the end of the run and examined microscopically to provide direct evidence that the pores were indeed filled with salt.

Twenty grams of each of the appropriate melt compositions were weighed out and melted together in a separate test tube to obtain uniform composition and then poured into the cell. Silver wire electrodes were placed into the cell compartments and the emf measured with a K-2 potentiometer. When a steady value had been reached, a weighed quantity of AgCl or AgBr was added to the variable side and the procedure repeated. Five or six such additions were made. In each run X_1' was both increased and decreased randomly by appropriate additions of AgCl and AgBr; only runs in which the emf varied reproducibly with composition were retained for mathematical analysis.

Results and Discussion

Plots of emf *vs.* the logarithm of AgCl and AgBr activity are shown in Fig. 1. The activities for the experimental compositions were computed from the data in reference (5). The slight curvature in the data suggested that ϕ/X_1 and ϕ/X_2 are not constant over the entire measured concentration range, and they were therefore fitted with a quadratic equation using

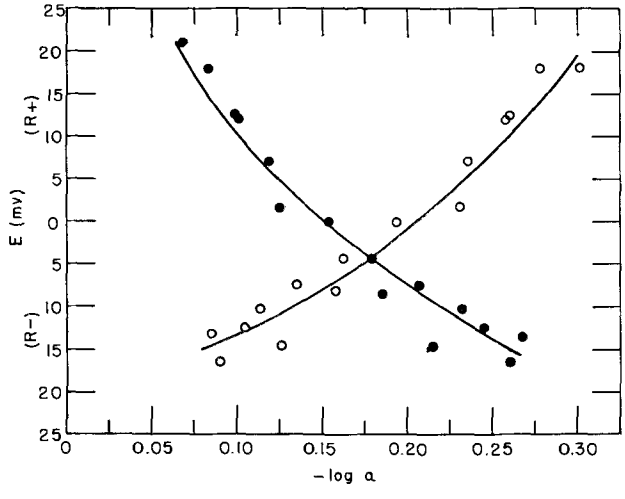

Fig. 1. Liquid junction potential of the cell Ag|AgCl(X_R = 0.5), AgBr| |AgCl(X), AgBr(1 − X)|Ag as a function of the logarithm of the activities of the right-hand compartment. • AgCl, ○ AgBr.

Table I. Relative transport numbers t_{Cl^-} and t_{Br^-} calculated from Eq. [7]. Activity data from (5)

X_{AgCl}	X_{AgBr}	a_{AgCl}	a_{AgBr}	t_{Cl^-}	t_{Br^-}	$(t_{Cl^-} + t_{Br^-})$
0.30	0.70	0.518	0.850	0.30	0.58	0.88
0.40	0.60	0.575	0.782	0.68	0.36	1.04
0.50	0.50	0.660	0.685	1.09	0.039	1.13
0.60	0.40	0.750	0.590	1.22	−0.36	0.86

a least-square procedure. The results of this calculation were used to compute the slopes $dE/d \log a_1$ and $dE/d \log a_2$. Substituting numerical values and solving for t_1 and t_2 gives

$$t_1 = (2.733 + 9.447 \log a_1) X_2 + X_1$$
$$t_2 = (-0.0365 + 5.392 \log a_2) X_1 + X_2 \quad [7]$$

The first term in Eq. [7] gives the deviation from ideality ($t_i = X_i$) which is quite concentration dependent. t_1 and t_2 are of course not independently calculable since (*a*) they are calculated from the same cell, (*b*) the condition $t_1 + t_2 = 1$ was used in deriving [5] and [6], and the activity of AgCl was obtained by a graphical integration of the Gibbs-Duhem equation using the cell Ag|AgBr, AgCl|Br_2 which gives AgBr activities directly (5). The results of the calculation are shown in Table I.

The increasing nonideality of the system with increasing AgCl concentration is quite noticeable. Thus as X_{AgBr} decreases, t_{Br^-} decreases even more rapidly and even becomes negative, suggesting some positive bromide complexes such as Ag_2Br^+. Outside the concentration range of Table I the sum $(t_{Cl^-} + t_{Br^-})$ increasingly drops below unity so that Eq. [7] apparently no longer describes the data adequately.

Although the present results do not yet justify extensive speculations on the nature of anion transport in molten salts, they suggest that the study of this phenomenon, by a variety of techniques, would prove as interesting as the corresponding study of cation transport has been.

The Preparation of Large-Area Silicon Cathodes for Use in Reactive Sputtering

M. Bloom and N. P. Sandler

TRW Space Technology Laboratories, Thompson Ramo Wooldridge Incorporated, Redondo Beach, California

The properties of films of silica (1-3) deposited by reactive sputtering and the conditions under which they are applied (4, 5) are such that these films have great potential value in the fabrication of semiconductor devices. We have had occasion to apply this technique and found ourselves hampered by the lack of suitable large-area silicon cathodes.

The area of the cathode must be larger than the area of the substrate in order to obtain a deposit of uniform thickness (4). Silicon slices are usually used as cathodes, but silicon ingots with diameters larger than 3 in. are difficult to obtain. By slicing an ingot lengthwise, one may obtain a rectangular slab whose length and width are limited by the length and diameter of the ingot. The thickness cannot be reduced below a certain minimum amount because of the necessity of fixing the cathode to its holder. Our attempts to build a large cathode from an assembly of small blocks of silicon have not been successful. The joints, which initially might be quite smooth, are preferentially attacked by the bombarding ions and are soon enlarged to the point where the deposit exhibits nonuniformity.

A similar lack of uniformity is contributed to by the mounting screws. We have used Sinclair and Peter's (5) method of mounting a silicon cathode to its holder with a recessed aluminum screw. In our experience, such a mount causes the deposit to be contaminated with aluminum oxide even at the voltage (1800v) which these authors used. Covering the recessed aluminum screw with an appropriately shaped piece of silicon eliminated the aluminum contamination, but produced a lack of uniformity in the deposit corresponding to the gap between the piece of silicon covering the screw and the remainder of the cathode. Clearly, uniform deposits demand a large cathode having a uniform surface.

It occurred to us that such large-area cathodes might be produced by depositing silicon on a graphite substrate. This has been found to be the case, and it is the purpose of this communication to describe how this was done. The cathode was machined from a piece of graphite so that the front side, the surface from which the silicon was to be sputtered, was flat. The type of graphite was considered to be unimportant since McAleer (6) and co-workers have pointed out that layers of silicon with crystallite sizes ranging from 2 to 200μ across can be deposited by chemical decomposition processes on virtually any type of graphite. The back side of the cathode was machined so that it could be mounted on its holder without interfering with the front side. Figure 1 illustrates a typi-

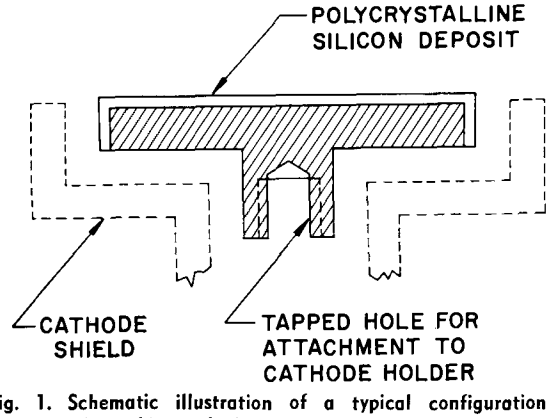

Fig. 1. Schematic illustration of a typical configuration for silicon-coated graphite cathode.

cal configuration. Except at the point of attachment, which was thick enough to allow drilling and tapping, the pieces were 8 mm thick but we know of no reason why the piece could not be thicker. The minimum thickness is determined by the fragility of the graphite.

Silicon was deposited on the cathode by the reduction of trichlorosilane by hydrogen at elevated temperatures in a deposition apparatus similar to that used by Bhola and Mayer (7). The only differences of note are that in our apparatus we used a graphite susceptor and vaporized trichlorosilane by bubbling hydrogen through it. In order to prevent silicon from depositing in the tapped attachment hole, a cathode holder was machined which masked the entire back surface of the cathode during deposition. The entire assembly was heated to 1250°C in the presence of only hydrogen for 30 min to drive off any adsorbed gases and reduce any residue to insure adequate adhesion of the deposited silicon to the cathode surface. This was followed by the deposition of silicon at a very slow rate to optimize complete coverage. The deposition parameters were then adjusted to obtain approximately 4μ of deposited silicon per minute at 1150°C. In this manner, we obtained a uniform layer of polycrystalline silicon whose thickness was approximately 10 mils in 1 hr and whose average grain diameter was approximately 10μ.

The economical use of a sputtering power supply requires that the cathode be shielded to suppress any glow discharge on those portions which do not contribute to the deposition (8). However, such shielding does not prevent oxidation of the exposed graphite during reactive sputtering in oxygen atmospheres when cathodes coated with silicon on only one side are used. During typical runs in 100% oxygen, the loss of graphite from the back side of the cathode, when using a shield, amounted to 0.01 mil/hr. Without a shield the loss was 0.7 mil/hr. For this reason it is better to cover the entire surface of the graphite with silicon. Only a minimal thickness is needed on the back side if a cathode shield is used. This problem might be obviated by depositing the silicon on a piece of polycrystalline alumina (9) which was provided with suitable metal conductors.

The surface of the silicon deposit is rougher and thus has a greater surface area than a lapped slab of silicon of the same diameter. Consequently, one might expect that the former would give a greater rate of deposition than the latter (10). However, after the latter has been used as a cathode for a short time its surface becomes roughened. As a result, the rate of deposition of the two cathodes is essentially the same.

The silica deposits obtained by the use of these silicon-coated graphite cathodes at a current density of about 3 ma/cm^2 appear to be identical to those obtained from cathodes made of slabs of polycrystalline or single crystal silicon.

A Concentration Gradient Profiling Method

Stacy B. Watelski, W. R. Runyan, and R. C. Wackwitz

Texas Instruments Incorporated, Dallas, Texas

Epitaxial depositions are usually such that a thin high resistivity layer is deposited on a low resistivity substrate. If it is desired to make a concentration profile through the interface region, conventional incremental lapping from the front surface is not appropriate because even the removal of thick layers will hardly change the resistance of the remaining sample since most of the carrier contribution comes from the substrate. To circumvent this difficulty, lapping from the back is necessary. Success of the standard incremental lap process hinges on the ability to remove successfully many small parallel sections from the sample. This is difficult to do even when sectioning relatively thin regions and is quite impractical when moving through several hundred microns of material.

These difficulties may be alleviated by beveling from the back at some small, roughly predetermined angle. Sheet resistance readings are made at regular intervals down the slope of the lapped surface using a four-point probe oriented so that the line of probes is perpendicular to their direction of motion (see Fig. 1). Studies of this method thus far have been made using angles as small as 8 min ($\tan \alpha = 0.0023$). The angle is usually determined by sectioning the slice after all electrical measurements are made. Nonuniformity in the angle across and along the face of the bevel is corrected by measuring the sample thickness at several positions along its length.

If the total thickness to be examined is greater than $L \tan \alpha$, where L is the sample length, a sequential process of incremental angle lapping and probing may be employed. When the incremental steps are properly chosen, some overlap of sheet resistance from step to step is possible. A typical sheet resistance profile for a case with three successive laps is shown in Fig. 2. Each sheet resistance curve has a region which decreases with decreasing thickness. This is an edge effect resulting from large probe spacing and was substantially

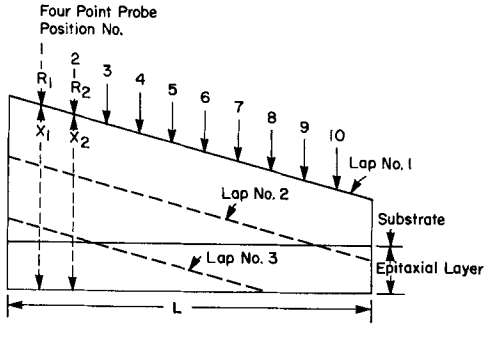

Fig. 1. Diffusion profile determination by incremental angle lapping.

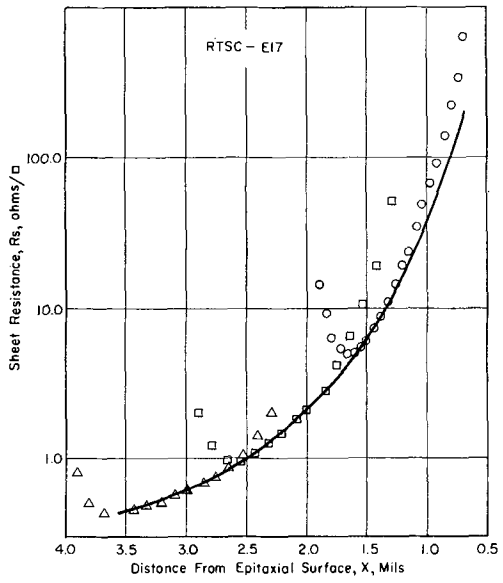

Fig. 2. Measured sheet resistance profile: △, lap No. 1; □, lap, No. 2; ○, lap No. 3.

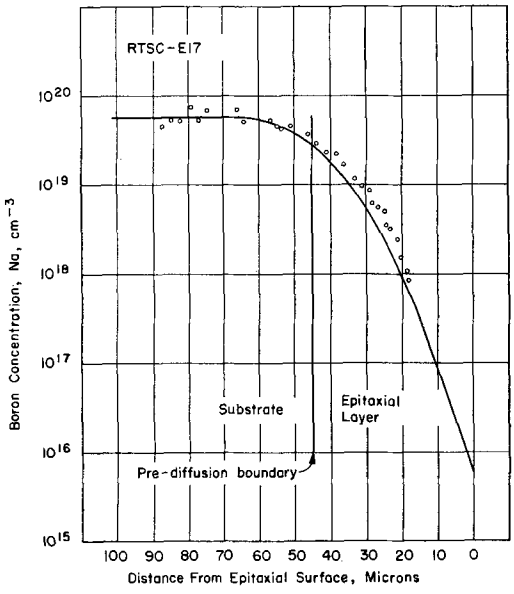

Fig. 3. Comparison of calculated and measured boron concentration profile: ——, calculated; ○ ○ ○, measured.

reduced in later studies by using 250μ probe spacings. An additional edge effect occurs at that portion of each curve corresponding to the thinner end of the blank and causes the apparent sheet resistance to increase at a faster than normal rate. The solid line shown in Fig. 2 compensates for these edge effects and was used for the profile calculations. When the lapped edge intersects the bottom of the slice, *e.g.*, No. 3 of Fig. 1, the readings near the thin edge are very sensitive to damage induced during beveling or by the probes. Probing damage is minimized by securing the sample to a silicon support with a dimensionally stable insulating epoxy layer. This epoxy layer is firm enough to prevent penetration of the probes even at the thin edge extreme. This laminate is also useful when sectioning the sample to correlate probe reading and sample thickness. Induced material damage usually results in readings higher than normal and may be minimized by careful lapping or grinding. Surface roughness comparisons of lapping with 1800 grit *vs.* grinding with an 800 grit diamond wheel show maximum surface excursions of 2.3μ and 0.38μ, respectively. Indeed, a measure of the proficiency of the operation may be obtained by profiling a uniform resistivity slice and observing how thin a section can be measured before the sheet resistance indicates an apparent increase in resistivity. Using 250μ spaced probe, errors $\gtrsim$10% may be realized at distance $\gtrsim$5μ from the surface; however, errors increase rapidly in the 0-5μ region. The technique is valid for substrate to layer resistivity ratios $\lesssim$1.

If R_1 and R_2 are the sheet resistances at x_1 and x_2, respectively, resistivity values in a small interval $(x_1 - x_2) = \Delta x$ may be calculated in the manner of Fuller and Ditzenberger (1) from

$$\rho = \frac{R_1 R_2}{R_2 - R_1} \Delta x \qquad [1]$$

Data reduction may be simplified by computer programing and plotting, in which case it has been found convenient to convert sheet resistance *vs.* thickness to bulk resistivity *vs.* thickness by a method which minimizes the effect of experimental error in the sheet resistance value and does not depend upon the value of Δx used (2). The method consists in relating the logarithm of the sheet conductance values to depth, from which the bulk resistivity ρ for any thickness x can then be found. If $G(x)$ is the sheet conductance for a thickness of material x, then the conductivity $\sigma(x)$ is given by

$$\sigma(x) = \frac{dG}{dx} \qquad [2]$$

The logarithm of sheet conductance has some functional dependence on depth which may be defined as $F(x)$, *i.e.*

$$\ln G(x) \equiv F(x) \qquad [3]$$

Differentiation with respect to x gives

$$(1/G)\,(dG/dx) = dF/dx \qquad [4]$$

so that by combining Eq. [2] and [4]

$$\rho(x) = 1/GF' \qquad [5]$$

The values of $\rho(x)$ thus calculated are converted to concentration values by use of Irvin's curves (3).

A Fortran program has been written for the IBM 7040 computer to calculate $\rho(x)$ *vs.* depth from sheet resistance *vs.* depth measurements using Eq. [5]. A piece-wise smoothing subroutine is first applied to the ln G *vs.* depth values to smooth out random experimental errors in sheet conductance. The smoothing subroutine used reliably follows the physical nature of the curve and does not "over-smooth." A spline subroutine is next applied to the smoothed ln G *vs.* depth values, from which values of $G(x)$ and $F'(x)$ can be calculated for use in Eq. [2] for any depth x desired. The spline subroutine used is based on the spline described by Theilheimer and Starkweather (4), and hence does not require *a priori* values of the first derivative for the first and last data points.

This method has been applied primarily to studies of substrate-epitaxial layer profiles after extended diffusion. For example, a 2.3 ohm-cm, 45μ thick p-type layer was epitaxially deposited on a 0.002 ohm-cm boron-doped substrate blank. The blank was then diffused for 25 hr at 1250°C after which it was beveled and profiled. A comparison of the measured boron concentration profile with one calculated by assuming a boron diffusion coefficient of 8.7 x 10^{-12} cm^2/sec is shown in Fig. 3. The lack of data for $x < 18\mu$ is due to the probe spacing edge effect mentioned earlier.

Residual Surface Recombination on Germanium Anodes

P. J. Boddy and W. H. Brattain

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

Capacity measurements on germanium electrodes which had been subjected to anodic dissolution in neutral aqueous electrolytes free from noble metal ion contaminants showed no evidence of charge trapping due to fast surface states (1) (*i.e.*, $N_t < \sim 10^{9.5}$ cm^{-2}). Similarly the value of surface recombination velocity (srv) was reduced to a very low level by the same treatment. In this communication we report measurements of the magnitude of the srv under the conditions which we have adopted as standard (*i.e.*, deoxygenated 10M K_2SO_4, buffered with 15M phosphate to pH 7.4) in several experimental studies of germanium electrodes (2-4). First note that in the Eq. [1] (5)

$$s = (\lambda + \lambda^{-1})(C_nC_p)^{1/2}\{2\cosh(v + \ln\chi) + 2\cosh(Y - \ln\lambda - \ln\chi)\}^{-1} \quad [1]$$

it is the quantity $s(\lambda + \lambda^{-1})^{-1}$, not s, which remains constant for all nondegenerate values of the bulk Fermi level if the other parameters are fixed. Consequently for electrodes which are close to intrinsic, *i.e.*, λ close to unity, the value of s is relatively small. Our previous measurements have been made with near-intrinsic samples to avoid pronounced minority carrier effects, *e.g.*, saturation at small currents. This has reduced the sensitivity of the srv measurements, but not the capacity measurements. A further factor reducing the sensitivity of the srv measurements has been the requirement that the filaments should be sufficiently thick that the ohmic drop between the center and ends of the filament caused by the current flow across the polarized interface is not greater than ~10 mv.

The measurements shown in Fig. 1 were made on a p-type bridge electrode (1) with $\lambda = 19.5$. The srv

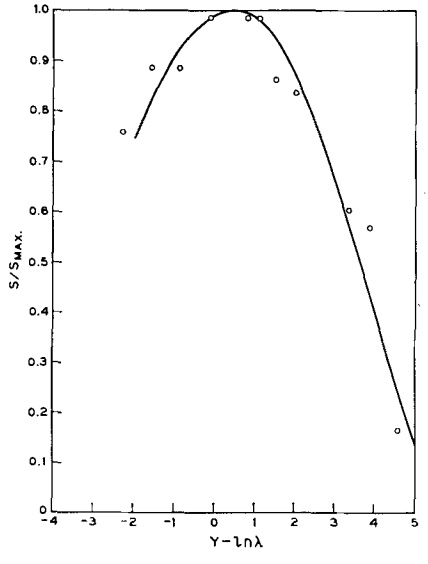

Fig. 1. Measurements made on p-type bridge electrode

was determined from the filament lifetime by the relationship

$$2s = (\tau^{-1}_{fil} - \tau^{-1}_{body})(t^{-1} + w^{-1})^{-1} \quad [2]$$

The surface potential, which was varied by changing the electrode potential, was derived from the interfacial capacity measured by ~1 μsec current pulses (1). The value of s_{max} at 25°C was 39 cm sec^{-1} and hence $s_{max}(\lambda + \lambda^{-1})^{-1}$ was ~2 cm sec^{-1}. As shown in Fig. 1 the data were fitted to a discrete state with parameters: $\ln\chi = 0.4$, $v = +2.6$ or -3.4 kT/e measured positive downward from the intrinsic level. We have no criterion for deciding at which of these two possible levels the state occurs. Within the sensitivity of our measurement we observe no additional capacity (*i.e.*, trapped charge) due to fast surface states. A combination of the uncertainty of about 10% in the surface roughness factor combined with the distortion of the capacity electrode potential curves due to changes in Helmholtz potential difference which occur as a result of polarization (6) precludes the observation of a state with a peak capacity of the same magnitude as the space charge minimum, unless fortuitously it should occur within about 25 mv of the potential of the minimum.

Since $s_{max}(\lambda + \lambda^{-1})^{-1} \approx 2$ cm sec^{-1}, and $(v + \ln\chi) = \pm 3.0$ then from Eq. [1]

$$2 = (C_pC_n)^{1/2}\{2\cosh 3 + 2\}^{-1} \quad [3]$$

since $\cosh(Y - \ln\lambda - \ln\chi) = 1$, when $s = s_{max}$. Hence

$$N_t(\sigma_p\sigma_n v_p v_n)^{1/2} \approx 44 \quad [4]$$

The average cross section $(\sigma_p\sigma_n)^{1/2}$ is taken as approximately equal to atomic dimensions, *i.e.*, 10^{-15} cm^2, on the assumption that an uncharged center has a cross section equal to its physical size while for a charged center the equal and opposite coulombic forces on the holes and electrons will tend to average out. Then taking $(v_pv_n)^{1/2} \approx 7 \times 10^6$ cm sec^{-1}, we have $N_t \approx 6 \times 10^9$ cm^{-2}.

The capacity per unit area due to surface states at a single energy is

$$C = N_t e^2 (kT)^{-1}\{2\cosh \tfrac{1}{2}(Y + v - \ln\lambda)\}^{-2} \quad [5]$$

and, for the N_t derived above, has a peak value of $\sim 1.0 \times 10^{-8}$ farads cm^{-2}. In Fig. 2 is shown the theoretical capacity of the electrode compared with the capacities for surface states of the density and energies we have calculated. The sum of the two is also shown by the dashed lines, and it is clear that, since the experimental curve tends to be broadened by changes in Helmholtz potential difference, the observation of states of these parameters would be quite difficult. For comparison purposes the capacities of surface states produced by contamination of the surface with cupric ion are shown using the energies and densities previously determined (7). In this case it is clear that the additional capacity due to the states is easily measurable. The nature of the residual states in uncontaminated solutions is not known, but the srv data

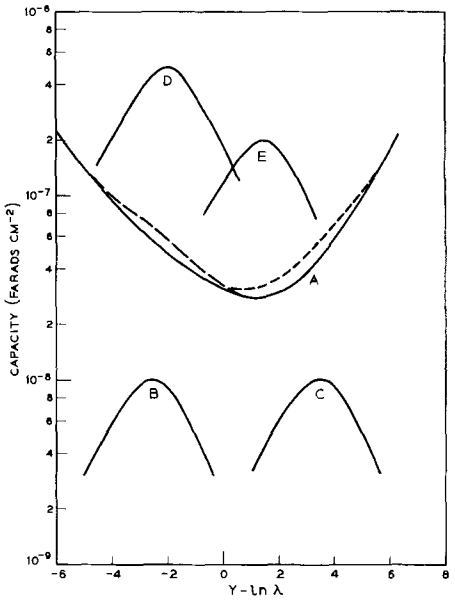

Fig. 2. Theoretical capacity of the electrode

described above have been observed repeatedly and are presumed to be an inherent property of this surface.

Summary

Measurements of srv of an appropriate electrode show that the residual value of $s_{max}(\lambda + \lambda^{-1})^{-1} \approx 2$ cm sec^{-1} on anodically etched surfaces. The parameters of the state are ln $\chi = 0.4$, $\nu = 2.6$ or -3.4 kT/e and $N_t \leq 6 \times 10^9$ cm^{-2} if $(\sigma_p\sigma_n)^{1/2} \leq 10^{-15}$ cm^2.

SYMBOLS

s	surface recombination velocity
p	bulk hole concentration
n_i	intrinsic electron concentration
λ	pn_i^{-1}
N_t	density of recombination centers
$v_{p,n}$	thermal velocity of holes, or electrons
$\sigma_{p,n}$	capture cross sections for holes, or electrons
$C_{p,n}$	$N_t v_p \sigma_p$, or $N_t v_n \sigma_n$
χ	$C_p^{1/2} C_n^{-1/2}$
ν	energy level of a recombination center measured positive downward from the intrinsic level
Y	potential difference across space charge region
τ	minority carrier lifetime
t	thickness of filament
w	width of filament

k, T, and e are the usual constants.

Reaction of Nickel Carbonyl with Carbon Disulfide

S. H. Pitts, Jr.

Chemistry Research and Development Laboratories, The Dow Chemical Company, Golden, Colorado

A program was undertaken to investigate additives which would alter the reaction rate or lower the decomposition temperature of nickel carbonyl. Other investigators have shown that hydrogen sulfide will catalytically lower the decomposition temperature from about 150°C down to 60°-100°C (1). Oxygen or water vapor are rate promoters in the H_2S-$Ni(CO)_4$ reaction (2). Silicon and titanium tetrachlorides are also rate promoters (3). This work revealed that carbon disulfide effects a rapid and unique room temperature reaction.

Figure 1 shows the experimental apparatus. It consists of a one-liter bell jar sealed to a steel base plate with an O-ring. The plate was fitted with the necessary connections to facilitate evacuations and gas chargings. The bell jar served as a precalibrated $Ni(CO)_4$ reservoir. Connected to it was a one-liter round bottom flask reaction vessel. Pressure readings were taken on mercury manometers with a cathetometer. A small reservoir of liquid CS_2 was separated from the flask by a needle valve. A heated decomposition chamber disposed the residual $Ni(CO)_4$ in the waste gases.

The system was designed so that the reaction could be followed through the pressure change. The following 1 to 4 pressure increase occurs in the complete thermal decomposition of $Ni(CO)_4$

$$Ni(CO)_{4(g)} \rightarrow Ni_{(s)} + 4CO_{(g)} \qquad [1]$$

In the CS_2-$Ni(CO)_4$ reaction, the final pressure is usually only 3 times that of the initial pressure. However, the pressure increase does vary by a factor of 2 to 3.5.

A typical run for maximum $Ni(CO)_4$ conversion using the experimental system is made by evacuating the system and charging the reaction flask with 3.5 mm of CS_2. The bell jar is charged with 50 mm of $Ni(CO)_4$. The connecting valve between the two vessels is opened for a minimum time to admit $Ni(CO)_4$ to the reaction flask to an equilibrium pressure of 21.4 mm. Pressure readings are taken after 1 min and as often as necessary thereafter. This procedure is mandatory because of the very fast initial reaction rate. Attempts to meter $Ni(CO)_4$ directly into the reaction flask and get a zero time pressure reading give erratic results. This is due to the simultaneous pressure increase from the CO being formed. After ap-

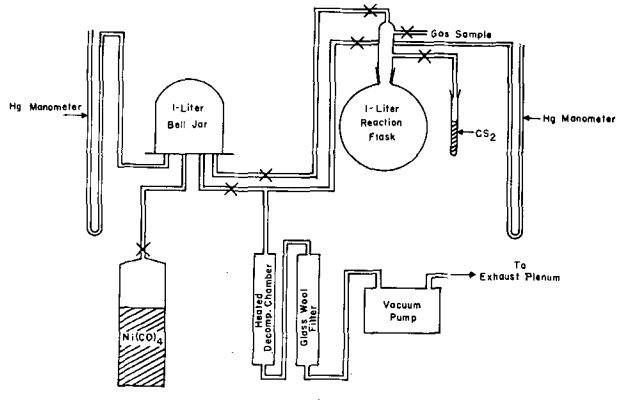

Fig. 1. Experimental system for the $Ni(CO)_4$-CS_2 reaction study

proximately 25 min, no further pressure changes occur.

The reaction can also be made in a modified system which eliminates the reaction flask. This is desirable when using the reaction in practical plating applications where precise measurement is not critical. Both the $Ni(CO)_4$ and the CS_2 can be metered directly into the bell jar. Since the gases react immediately upon contact and the subsequent pressure increase can give erroneous readings, the system in Fig. 1 was used for the experimental work. The CS_2-$Ni(CO)_4$ reaction is apparently not catalytic because of the consumption of CS_2 in the reaction. The maximum conversion is obtained using 13-15% (or higher) volume per cent CS_2. Infrared analyses of residual gases show both the CS_2 and $Ni(CO)_4$ are consumed. Figure 2 shows the effect of CS_2 concentration on the reaction. The $Ni(CO)_4$ conversion increases up to a maximum as the CS_2 concentration is increased to 15%. The rate of reaction and CS_2 concentration could not be correlated.

Sufficient data are not available to postulate a plausible reaction mechanism. It is different than that of thermal decomposition of $Ni(CO)_4$ as implied by the pressure change. Gas analysis shows that 95-100% $Ni(CO)_4$ conversion is obtained even though the pressure increase is only 2 to 3.5 times that of the initial pressure. Carbon monoxide is the major constituent in the residual gas.

Analysis of the nickel deposit is inconclusive because only the following elements were measured: Ni, 81.6%; S, 9.8%; C, 1.8%. It was not determined whether the sulfur exists as a compound or in elemental form, but it does explain the consumption of CS_2. Presumably, the remaining portion of the deposit is oxygen. X-ray diffraction patterns could not be obtained because the deposit is apparently amorphous or very fine grained. Electron microscopy shows the deposit as loosely packed spherical or polyhedral particles of consistent size, approximately 375Å in diameter. Dissolution of the nickel plate in nitric acid leaves an unidentified powdery brown residue. This indicates the deposit to be something other than pure nickel. There was no significant weight change on heating the deposit *in vacuo* to 500°C. After cooling and reheating in an oxygen atmosphere the sample increased in weight 16% and became green-black in color. This is indicative of oxide formation and the deposit is, at least in part, elemental nickel. The deposit imparts a bright, mirror-like finish to smooth surfaces. However, it is quite thin. In a one-liter flask with a 25 mm $Ni(CO)_4$ charge, interferometric measurements show the deposit to be 1700-2100Å thick.

In both the thermal decomposition of $Ni(CO)_4$ and the H_2S-$Ni(CO)_4$ reaction, the accumulation of the CO by-product has a retarding effect. The addition of CO to a CS_2-$Ni(CO)_4$ mixture prior to reacting did not inhibit the reaction. It did produce a 1-2 min induction period.

Both oxygen and water are reported to promote the H_2S-$Ni(CO)_4$ reaction (2). However, neither 6.4% water vapor nor 5.3% air in a CS_2-$Ni(CO)_4$ mixture had any significant effect.

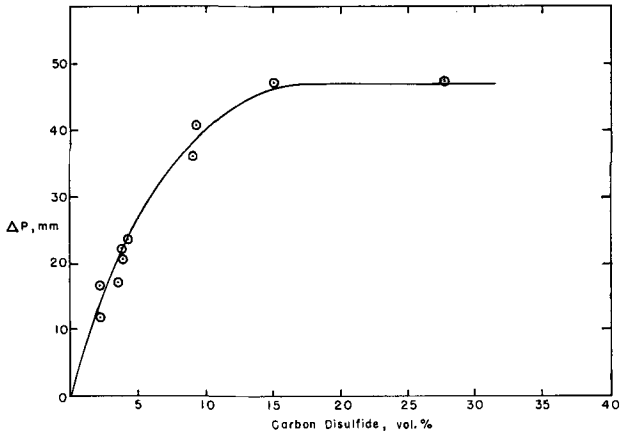

Fig. 2. Effect of CS_2 concentration on reaction with 25mm $Ni(CO)_4$ at 25°C after 25 min.

It is known that $Ni(CO)_4$ will decompose photochemically. However, room light had no apparent effect on the CS_2-$Ni(CO)_4$ reaction. CS_2 and $Ni(CO)_4$ reacted the same in clean glass as they did in a plated flask used 10-12 consecutive times. The metallic coating completely covers the reaction flask after 1-2 passes. The decomposition apparently is initiated and grows from particular surface nucleation sites. This is visually evident from the growth pattern on clean glass. A faster reaction rate was obtained by adding approximately 1-3g of 900 mesh nonactivated alumina. The alumina was loosely adherent to the surface of the reaction flask. Even though complete $Ni(CO)_4$ conversion was obtained, a smaller pressure increase occurs when using alumina. Carbon monoxide adsorption measurements on alumina did not account for this difference. Plating was preferential on the oxide particles. This suggests adsorption of one or both of the reactants on the particle surfaces. The coated particles caused the same effect as uncoated alumina. Powdered nickel oxide also causes a faster reaction rate.

The room temperature reaction of $Ni(CO)_4$ with CS_2 shows some potential for thin films and coating applications. Reaction mechanism studies are being pursued.

Brief Communications

PbS Diode Laser

J. F. Butler and A. R. Calawa

Lincoln Laboratory,[1] Massachusetts Institute of Technology, Lexington, Massachusetts

Diode laser action in the Pb salt semiconductors has previously been achieved in PbTe (1) and PbSe (2). Electron beam pumping has recently produced laser action in all three Pb salts (3). The PbS diode laser is described in this note.

Techniques for fabricating diodes of PbS, like those of PbTe and PbSe (4), were based on controlling deviations from stoichiometry. The starting material was a Bridgman grown, n-type single crystal of PbS with a carrier concentration of 3 x 10^{18} cm^{-3}. Wafers with flat planar surfaces were obtained from the boule by cleaving along {100} planes. To diffuse a p-layer into a wafer it was heated in an evacuated, sealed quartz ampoule with a vapor source consisting of a S rich, two phase ingot of PbS (51:49 a/o). A diffusion time of 1 hr at 550°C produced a p-n junction 50μ deep. Dice in the form of rectangular parallelopipeds were obtained from a wafer by further cleaving along {100} planes. Typical dimensions are 500μ between the end faces defining the Fabry-Perot cavity and 200μ in the other two directions. Ohmic contact was made to the p-side with evaporated Au and to the n-side with a Sn-In alloy. The dice were mounted in low inductance packages.

The diode lasers were mounted on the cold finger of a liquid helium dewar. Spectra were measured using a single-pass grating spectrometer and an InSb photovoltaic detector. The detector output was amplified by a lock-in amplifier system.

[1] Operated with support from the United States Air Force.

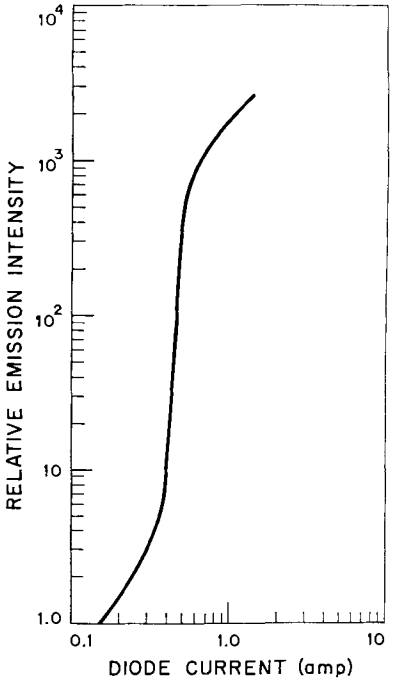

Fig. 1. Infrared emission from an end face of a PbS diode laser at 4.2°K as a function of forward current.

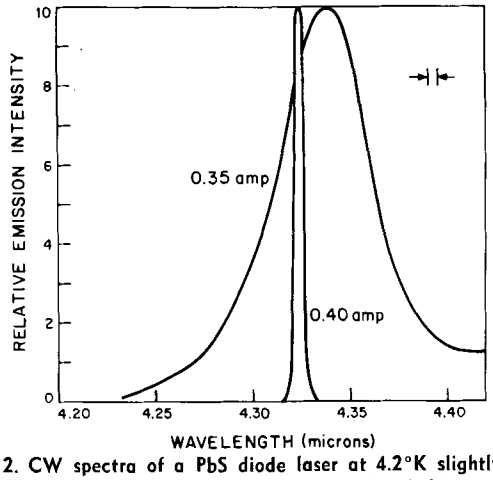

Fig. 2. CW spectra of a PbS diode laser at 4.2°K slightly below (0.35 amp) and slightly above (0.40 amp) threshold.

Figure 1 shows the intensity of the infrared emission from a laser end face as a function of diode forward current. At low currents the intensity is low and increases superlinearly. The sharp rise at about 0.38 amp indicates the onset of laser action and gives a threshold current density of 300 amp cm^{-2}. Since at this temperature the diodes do not overheat for direct current densities of over 1,000 amp cm^{-2}, CW operation at currents greater than three times threshold is possible.

In Fig. 2, CW spectra measured slightly below and slightly above threshold are normalized to the same

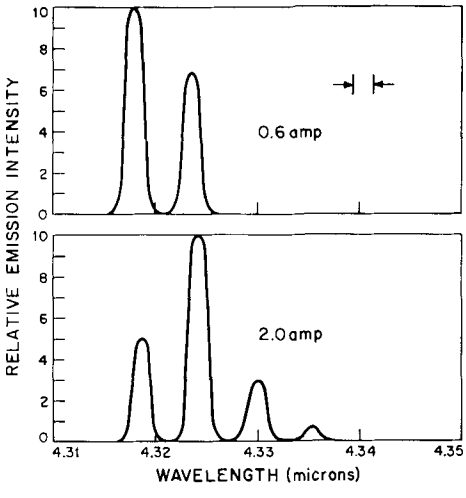

Fig. 3. Multimode emission from a PbS diode laser at 4.2°K forward biased with 0.6 amp direct current and 2.0 amp, 4μsec current pulses.

scale to illustrate the line narrowing associated with laser action. The absolute intensity of the laser peak is much higher than that of the spontaneous emission maximum. The width of the laser line is obviously resolution limited in this figure.

Figure 3 illustrates the multimode emission which occurs at higher currents. The separation between modes of 55Å satisfies the condition that the optical length of the cavity be an integral number of half-wavelengths if $dn/d\lambda = -0.3\ \mu^{-1}$, where n is the refractive index of the material and λ the wavelength of emitted radiation. This result was obtained by using a value of 4.7 for the refractive index of PbS at 4°K, extrapolated from unpublished measurements (5) covering a range down to 77°K. A resolution limited laser linewidth of 15Å has been measured.

Gallium Arsenide Surface Preparation

Jack Lowen

National Aeronautics and Space Administration, Cambridge, Massachusetts

The preparation of planar devices, for example, field effect transistors, requires polished damage-free surfaces. The following method has consistently yielded flat, polished, and damage-free gallium arsenide.

Material is cut into 0.002 in. thick slices and then into 5/16 in. squares. Heavy coats of wax must be used to avoid breakage. The 5/16 in. squares are removed from their block mounts using heat and then carefully dewaxed and degreased with three successive hot rinses of Solox, tricholorethylene, and methyl alcohol.

The A and B sides are then differentiated using an etch consisting of HF, H_2O_2, and H_2O (1:1:1) for from 1 to 2 min at room temperature. The A side shows up as shiny with rounded orange peel surface. The B or arsenic side has a matte finish and triangular etch pit pattern.

The squares are then mounted on a Teflon block, B side up and chemically polished, with rotation against a flat Teflon surface, in a solution of H_2SO_4, H_2O, H_2O_2, and H_2F_2 (250, 40, 50, and 25), for from 5 to 10 min.

Addendum

The following additional information is presented for the Technical Note "Notes on the Chemical Polishing of Gallium Arsenide Surfaces" by R. D. Packard which appeared on pp. 871-872 of the August 1965 issue:

"When nitric acid and glycerine are mixed, glyceryl trinitrate (nitroglycerine, a dangerous explosive) may be formed. It is a colorless-to-yellow liquid of specific gravity 1.6 g/cc, and when pure explodes at 260°C.

"The nitric and hydrochloric acids should be mixed first, and then poured into the glycerine slowly, with gentle stirring. The HNO_3-HCl interaction results in the formation of nascent chlorine, which is an oxidant aiding polishing.

"The solution should not be heated nor subjected to violent agitation. Use a constant temperature bath arount the polishing solution. It should be used in a well-ventilated area such as a fume hood, since it is irritating and toxic when breathed.

"The solutions are relatively unstable due to various reactions such as those described; they should be mixed fresh before each etching and discarded by flushing down an acid sink after use. They can be easily and rapidly mixed volumetrically."

Studies of the Molten Carbonate Electrolyte Fuel Cell

A. N. Webb, W. B. Mather, Jr., and R. M. Suggitt

Texaco Research Center, Beacon, New York

ABSTRACT

Fuel cells with $NaLiCO_3$ electrolyte contained in a porous MgO matrix have been operated at 650°C on synthetic, "realistic" fuels containing combinations of H_2, CO, CO_2, H_2O, and N_2. A mixture of air and CO_2 was used as the oxidant. Hydrogen reacted nearly reversibly when a completely oxidized state of the electrode was avoided. No reversible oxidation of CO was observed, and current-time data confirmed that electrode oxidation occurred preferentially. H_2 and CO were oxidized at oxidized electrodes with 0.6v activation polarization. Carbon deposition from the disproportionation of CO occurred even during the oxidation of H_2. The disproportionation can be prevented by addition of H_2O or CO_2.

The molten carbonate fuel cell has been and continues to be under intensive investigation and development (1-11). Rejection of CO_2 by the electrolyte and high operating temperatures of 500°-750°C give promise of practical operation on impure hydrogen and less reactive carbonaceous fuels. Distinct advantages are the reversibility of the silver oxygen electrode and the efficient dissipation of heat at a useful level. Disadvantages are slow starting and the severe testing of materials by the hot, corrosive environment. Considering that these factors are not overruling or can be overcome, there remain problems such as carbon deposition and low anode activity for CO. The objectives of this work were to examine the behavior of realistic fuel gases, especially impure H_2 with CO_2, to develop a working hypothesis of the anode reactions in order to discover and, if possible, remove limitations on cell performance, and to find an electrode catalyst for efficient oxidation of CO. Since CO is present in or formed from all fuel gases (even pure H_2) in the molten carbonate cell, efficient operation will require that CO be consumed at a cell voltage near that of H_2.

Experimental

Experimental cells were disk-type similar to those described by Trachtenberg (11). A binary electrolyte of the composition $LiNaCO_3$ was contained in a porous MgO matrix. Electrodes were of the porous diffusion type formed from silver powders sintered or brazed to silver flame-sprayed areas on either side of the MgO disk. In most cases a dual porosity electrode was prepared by sintering layers of −80 +100 mesh and −20 +40 mesh silver powders at 850°-920°C for 1 hr in a nitrogen atmosphere. The sintered structures were 2 in. diameter and weighed from 10 to 15g.

Anode catalysts were incorporated both by electroplating and as mixed or enclosed powders. Electroplating was performed "internally" by first soaking the porous Ag electrode in the plating solution and then cathodizing it in a similar solution without the reducible metal salt. To overcome limitations on the amount and kind of catalyst which could be introduced by electroplating and the inability to sinter electrode structures containing more than a few per cent of refractory materials, an enclosed powder structure was used. Either a ring of sintered Ag or an Ag gauze basket was filled with a mixture of powdered silver and catalyst, covered with Ag powder, and finally sintered. In some cases the enclosed oxides were "silverized" by coating with $AgNO_3$ and decomposing the nitrate at 500°C using the method of Chambers and Tantram (12). A sintered, uncatalyzed silver cathode was used in all cases.

Cells were heated to 650°C in 4-6 hr with CO_2 flowing through both compartments. The fuel gas then replaced CO_2 in the anode compartment and air at 100 cc STP/min was added to the 40 cc STP/min of CO_2 in the cathode compartment to provide stoichiometric ratio for the reaction

$$\tfrac{1}{2}\ O_2 + CO_2 + 2e^- \rightarrow CO_3^=$$

All operations, unless otherwise noted, were on this cathode mixture of air and CO_2. Electrolytic grade hydrogen, deoxygenated and dried, was used. Carbon monoxide was of C.P. grade; technical grade desulfurized butane and pentane were used. Pentane was picked up in a helium stream and water was injected. Suitable flow meters were used with all gases.

Current-voltage curves were obtained manually by changing the load resistance so that either cell current changed by 50 ma or the cell voltage changed by 50 mv every 2 min. The latter method was preferred since a nearly constant time was required for all cells. Curves were started at open circuit and, if the unloading curve fell appreciably below the initial sweep, retracing was continued until a reproducible path was obtained. Maximum power densities were obtained from the steady-state curve and were based on the area of catalyzed anode.

Measurements of current obtainable at a set voltage as a function of time provided a less tedious approach to steady-state values and a reliable method for distinguishing fuel and electrode oxidations. Anode potential-time curves used in polarization studies were obtained by recording separately current and voltage with time at each of several different cell loads. Voltage and time values for any particular cell current were determined from current-voltage curves (at various times) plotted from the original data. Voltages were not corrected for cathodic or ohmic polarization. Anode and cathode polarizations could not be individually measured since there was no reference electrode in this cell. From other related work, however, both cathode and ohmic polarizations were found to be directly proportional to the current but constant with time at each current density.

Cell Performance

On pure hydrogen.—Performances on H_2 at 650°C of several molten carbonate fuel cells, containing various types of anode structures and various catalysts, are given in Table I. Open-circuit voltages were quite uniform between 1.17 and 1.25v in the absence of anode reaction products. Maximum power densities occurred near 0.6v in all cases and were as high as 45 mw/cm². A more consistent value, however, was 32 mw/cm², and Table I indicates the range of values observed. In most cases 10-20% of the hydrogen entering the anode compartment was oxidized at maximum power.

No one anode type or catalyst was superior to the others although electroplated anodes gave the best performance per gram of catalyst, probably due to better catalyst distribution.

Table I. Fuel cell performance

Porous sintered silver cathodes supplied with air at 100 cc STP/min + CO_2 at 40 cc STP/min.
Cell resistance: 0.15-0.25 ohm.

Cell power could be increased by increasing the flow of hydrogen to the anode compartment probably because fresh fuel replaced reaction products more rapidly. As the H_2 flow was increased from 10 to 100 cc STP/min, open-circuit voltage increased from 1.09 to 1.31v, and cell power at 1.0v increased from 7.4 to 20.2 mw/cm^2. But cell maximum power (at 0.6v) went up by only 50%, from 18.6 to 28.2 mw/cm^2. Moreover, at the higher flow rates there was a considerable decline in per cent H_2 consumed, 5.5% consumed at maximum power at 100 cc STP/min *vs.* 44.0% at 10 cc STP/min. These observations were obtained with cells which had gas chambers of 60-90 cm^3 volume, electrode areas of 11.4-20.2 cm^2, and electrodes 0.2-0.25 cm thick. Since space velocity of the gas feed and the ratio of electrode area to gas volume are undoubtedly important parameters these results cannot be expected to apply directly to cells of different geometry.

On dilute hydrogen.—Pure hydrogen cannot be considered a practical fuel cell fuel. Hydrocarbons and carbon monoxide cannot be used directly in the fuel cell at 650°C because of coke formation (*vide infra*). Hydrogen-carbon dioxide mixtures resulting from steam reforming of hydrocarbons or shifting of carbon monoxide appear to be the most suitable fuel for the molten carbonate fuel cell.

Table II shows the results of using several H_2-CO_2 mixtures as the anode feed. In one case total anode feed rate was kept constant and concentrations of H_2 and CO_2 varied; in the second experiment the H_2 flow was constant and the total flow increased with CO_2. In each case addition of CO_2 lowered open circuit voltage considerably and had a large effect on cell power at 1.0v. Cell power at 0.6v was less affected, decreasing almost linearly with the concentration of H_2 in the gas stream. Increased flow improved cell power at a given concentration by sweeping reaction products from the electrode surface.

Cathode feed—air (100 cc STP/min) + CO_2 (40 cc STP/min).

These experimental results were anticipated from simple consideration of the Nernst equation as applied to the gas phase compositions of anode reactants and products. At open-circuit CO_2, a product of the anode reaction

$$H_2 + CO_3^{=} \rightarrow H_2O + CO_2 + 2e^-$$

decreased the anode potential. At 0.6v, however, the effect of the CO_2 in the fuel stream was lessened by the formation of H_2O and CO_2 at the anode.

Similar results were obtained for operation on mixtures of H_2 and N_2 except that N_2, an unreactive gas in this system, did not lower cell open-circuit voltage. There was again an almost linear decrease in cell power with decreasing H_2 concentration. These experimental results indicated that it was the concentration (or partial pressure) of H_2 in the anode compartment that determined performance. This fact must be considered when cells are operated on dilute hydrogen fuels and especially when determining the characteristics of battery packs in which feeds are passed serially through the unit. Although it may be possible to oxidize all the hydrogen in a given feed to a battery, the low concentration of H_2 in the fourth, fifth, etc., cells of such a unit may lead to very poor performance of these later cells.

Another problem with such downstream operation is the gradual shifting of residual H_2 in the feed to H_2O and CO by CO_2. To consume most of the H_2 supplied to the unit, CO must be oxidized. Some effort has gone into an attempt to develop an electrode catalyst for the oxidation of CO.

Carbon monoxide oxidation.—The cells with internally plated and enclosed powder catalysts, listed in Table I, were also operated on CO/2CO_2 and CO/3CO_2 mixtures. Maximum power densities were between 2 and 5 mw/cm^2, in most cases less than 10% of the maximum from H_2. At the lowest fuel rate, up to 30% of the fuel was consumed at maximum power. Although fairly high limiting current densities of 35 to 45 ma/cm^2 were attainable from CO, low cell voltage minimized the power. Maximum power was obtained at between 0.13 and 0.26v, in most cells at 0.20v.

The question arose of whether the small amounts of power obtained from CO come from direct oxidation of CO or from H_2 formed by the water gas shift reaction. Kronenberg (7) reported operation of a molten carbonate fuel cell on CO dried to contain less than several ppm H_2O and concluded that a "direct galvanic utilization appears to be the case." It was conceivable that some H_2 could remain for a long time in the cell cycling between H_2O and H_2 by electrode reactions and shifting with CO; however, a seventyfold variation in water input produced no detectable variation in current. Whether the fuel was dried over 4A molecular sieve to contain 0.05 vol % H_2O or was

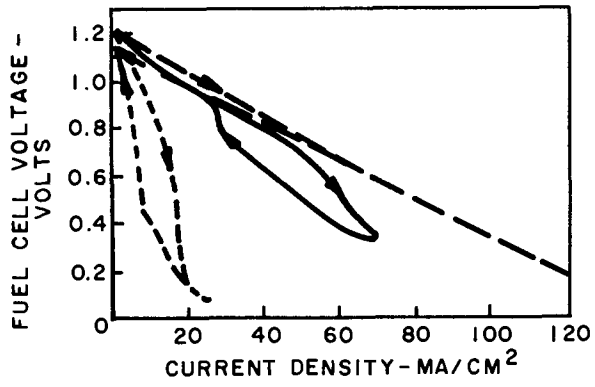

Fig. 1. Typical fuel cell current-voltage curves: —— —— —— cell N; ———— cell C; — — — cell J. Ohmic polarization included was about 0.3v at 107 ma/cm^2. → cell loading; ← cell unloading.

saturated to 3.4 vol % (when shifted to H_2, equivalent to 0.30 amp) the current remained constant with a maximum of slightly over 0.4 amp. This evidence supports Kronenberg's conclusion that CO is directly oxidized, but only at very low cell voltages.

Cell Polarization

Current-voltage curves.—Current-voltage curves have been used to characterize fuel cell performance. Typical current-voltage curves are shown in Fig. 1 for three different fuel cells operated on hydrogen and oxygen. These curves illustrate the range of performance observed in our molten carbonate cells. In each case the cathodes were the same and had a much less important effect on cell polarization than did the anodes. The sigmoid shape of both loading and unloading curves for cells J and C is similar to that of current-voltage curves reported by Broers (1) and Douglas (3) and indicates that at least two different anode reactions are occurring.

For cell N which exhibited no sharp voltage inflection in the hydrogen current-voltage curve, total cell polarization was 1.1v at 100 ma/cm^2. Of this total, ohmic polarization accounted for 0.35v, cathode polarization 0.25v, and anode polarization 0.50v. This same cell when operated on H_2/CO_2 mixtures showed even greater anode polarization. At 50 ma/cm^2 with a $1H_2/4CO_2$ fuel, ohmic polarization was 0.18v, cathode polarization 0.16v, and anode polarization 0.60v.

Table III. Standard potentials for reactions occurring within molten carbonate fuel cell at 650°C

A sigmoid H_2 current-voltage curve is seen for cell K in Fig. 2. For this cell the current at which the sharp voltage inflection occurred depended linearly on the concentration of H_2 in a mixed H_2-N_2 feed. This relationship between concentration and current is characteristic of a diffusion limited reaction which occurs at cell voltages above 0.8v The increase in current at low cell voltages indicates that a second reaction may be occurring. This cell contained a rhodium catalyst which would be oxidized at a standard potential of 0.287v (see Table III). The cell voltage of 0.2v at 70 ma/cm^2 should be corrected for ohmic polarization totaling 0.15v. The I-R free potential of the low voltage oxidation of 0.35v is not far from the standard potential of $Rh \rightarrow Rh_2O$. The increase in current at low voltages may have been due in part to the oxidation of rhodium and in part to oxidation of H_2 on the rhodium oxide surface. The curve at zero H_2 flow was taken following the others when the rhodium may already have been mostly oxidized.

The cathode reaction contributed less polarization than the anode reaction when stoichiometric feeds were supplied to the fuel cell. When the supply of air was limited, however, the cathode polarization increased. Figure 3 shows the effect of reducing the air content of the cathode feed on the cell current-voltage curve. Limiting currents at very dilute oxygen feeds approached the current equivalent to reduction of all the oxygen (4 electrons/molecule) in the gas feed. This experiment indicates that with the normal air and CO_2 feeds used, the cathode does not limit cell performance.

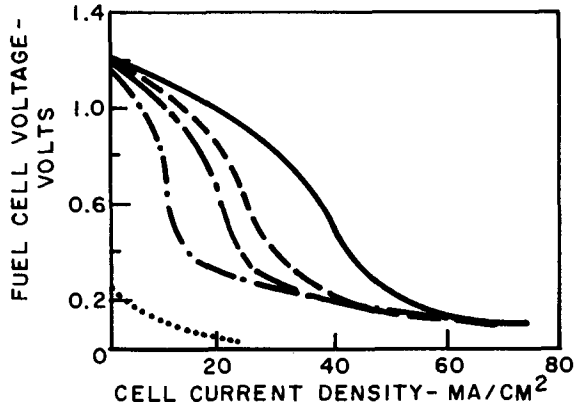

Fig. 2. Fuel cell current-voltage curves, cell K operation on dilute H_2 anode feeds: —— H_2 at 40 cc STP/min; — — — — — H_2 at 30 cc STP/min + N_2 at 10 cc STP/min; —— — —— H_2 at 20 cc STP/min + N_2 at 20 cc STP/min; —— · —— H_2 at 10 cc STP/min + N_2 at 30 cc STP/min; - - - - - N_2 at 40 cc STP/min. Cathode feeds: air at 100 cc STP/min + CO_2 at 40 cc STP/min; complete oxidation of H_2 at 10 cc STP/min would be 126 ma/cm^2. Ohmic polarization totaled 0.15v at 75 ma/cm^2.

Anode feed: H_2 at 40 cc STP/min. Ohmic polarization totaled 0.30v at 107 ma/cm^2.

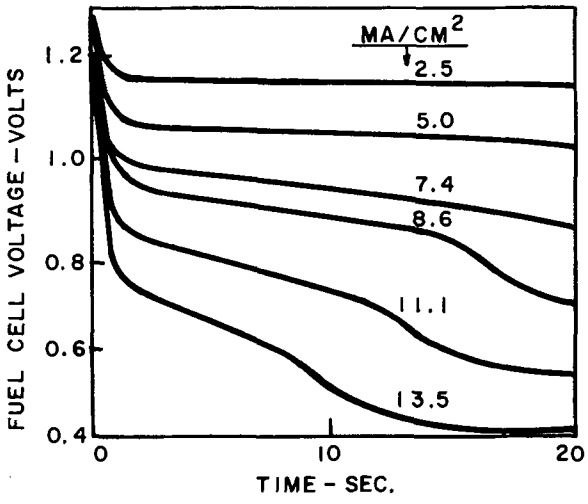

Fig. 4. Voltage-time curves at constant current, Cell A, H_2 at 40 cc STP/min.

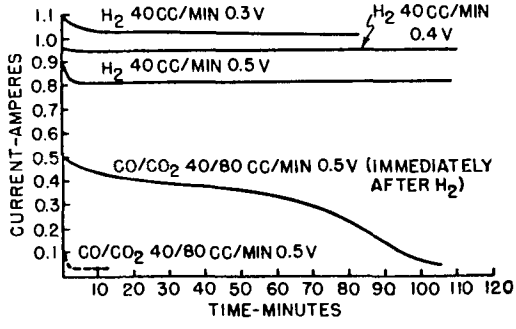

Fig. 5. Current-time curves at constant cell voltage, cell Q

Voltage-time curves.—Voltage-time measurements at constant current have been used to study electrode reactions. From current-voltage studies it was concluded that the anode reactions contributed most to cell polarization. Measurements of cell voltage changes with time reflected reactions occurring at the anode since other experiments indicated cathodic and ohmic polarization, while dependent on current, did not change with time.

A very poor cell was needed to observe any significant voltage time effects within 30 sec. Cell A was constructed with very poor distribution of the fuel gas to the nickel plated anode. Current-voltage curves for H_2, H_2/CO_2 mixtures and a CO/CO_2 mixture were sigmoid shaped. In the voltage-time curves shown in Fig. 4 a voltage inflection for H_2 was observed after 16 sec at 8.6 ma/cm^2 and after shorter times at higher currents. The voltage inflection was followed by a leveling out as a second reaction occurred. The second reaction, occurring about 0.2v lower than the first was probably the oxidation of nickel (standard potential 0.80v, Table III). The first reaction was the oxidation of hydrogen (standard potential 1.02v).

With a mixed H_2-CO_2 feed open-circuit voltage was lower and voltage inflections were observed at lower currents. Again the second reaction occurred about 0.2v lower than the first.

With a mixture of CO and CO_2 no voltage inflection was observed and cell voltage was the same as for the second part of the H_2 anode voltage-time curves. It is probable from this and other experimental evidence that the reaction observed with this feed was just the oxidation of the nickel electrode.

In these three voltage-time studies the only variable was the anode feed. Thus the transition time (dependent on current and H_2 concentration) observed only in the two studies involving hydrogen could not have been due to the cathode reaction or to the electrolyte. It could have been due to a hydrogen species which was dissolved in a thin film of electrolyte at the anode and was in equilibrium with the anode gas.

Current-time curves.—Current-time curves at constant cell voltages for various fuels in cell Q are shown in Fig. 5. With H_2 the stable current values were only slightly below corresponding points on the current-voltage curve indicating that steady-state values were achieved in both observations. With CO-CO_2 the current at 0.5v fell to 0.05 amp after 100 min. The area under this curve corresponds to 19.9 meq or 0.58 g of nickel. Since the electrode contained 2.4g of nickel it is probable that this portion of the nickel had been reduced during the immediately preceding operation on H_2. After the cell had been operated on CO-CO_2 for approximately 2 hr for plotting current-voltage curves the current at 0.5v very quickly fell indicating that very little reduced nickel was present.

Cell L, in which the effect of water on CO oxidation was studied, contained 2.06g of ZnO. Depending on the water content different open-circuit voltages were established: 0.93v for undried and 1.06v for dried fuel. The extent of electrode reduction (the ratio of Zn/ZnO) corresponding to these potentials are calculated by the Nernst equation and found to be in good agreement with the current generated by the cell before the voltage dropped sharply to below 0.3v. Calculated values were 1.6 and 42.6 coulombs compared to 6 and 48 coulombs observed. These experiments indicate that currents observed above 0.3v with CO feed are due to oxidation of the electrode rather than CO.

Discussion of Anode Reactions

Both chemical and electrochemical reactions occur in the anode compartment. Even with pure H_2 fuel there are at least five reactions likely to occur:

$$H_2 + CO_3^{=} \rightarrow H_2O + CO_2 + 2e^-$$

$$\text{Electrolyte} \rightarrow CO_2 \text{ (decomposition and diffusion)}$$

$$H_2 + CO_2 \rightleftharpoons H_2O + CO$$

$$CO + CO_3^{=} \rightarrow 2CO_2 + 2e^-$$

$$2CO \rightleftharpoons C + CO_2$$

These likely reactions, together with possible complications such as the reaction of carbon in the cell with CO_2, H_2, or H_2O in the Boudouard, methanation, and water gas reactions, do not permit detailed material balances to determine the extent of reactions occurring in the anode compartment. Instead current-voltage-time relationships were used to evaluate electrode performance and arrive at a working hypothesis of the electrode reactions. This hypothesis was then used to guide a search for improved electrode catalysts.

The shapes of current-voltage, current-time, and voltage-time curves are interpreted to mean that H_2 reacts nearly reversibly on reduced electrode sites, but, if all accessible sites become oxidized, H_2 reacts electrochemically only with a high activation overvoltage. Carbon monoxide does not react reversibly on either reduced or oxidized sites and most electrode materials are preferentially oxidized. As indicated by Table III only silver would not be oxidized at the potential of the operating anode. Carbon monoxide does appear to react on the oxidized electrode with an activation overvoltage not greatly different from that of H_2.

Stable currents exceeding the electrochemical equivalents of catalyst were obtained from CO only at cell voltages of 0.3v or lower. Activation rather than concentration polarization is invoked to explain the behavior of CO because relatively high current densities are sustained at low voltages.

The situation with regard to H_2, both pure and diluted, is more complex. Some electrodes were particularly susceptible to concentration polarization, and during periods of high current drain almost all the

hydrogen near the reduced electrode sites was consumed. When the cell voltage is reduced to about 0.6v many active electrode sites are oxidized. The cell voltage falls until hydrogen can be oxidized on the irreversible oxide sites. Still higher currents are available from electrode oxidation and, since the limiting current can be sustained indefinitely, from H_2 itself. The electrode recovers to its more active state only if the rate of electrode reduction exceeds that of oxidation. Reduction may be accomplished by increasing the H_2 concentration or by raising the potential above that at which oxidation can occur. The latter requires that the current be reduced to a level considerably below that at which deactivation occurs and results in a large hysteresis loop. The facts argue against operation of a corrosion mechanism which would require the rate of reduction to equal that of electrode oxidation and would preclude the observed hysteresis loop. Much higher power yields are produced by the electrode in the reduced state, but it is metastable, and with temporary overloading the electrode can become trapped in the oxidized state.

The facts that only oxidized electrodes showed appreciable activity for CO and that the high performance of reduced electrodes with H_2 is not stable lead to the conclusion that a reversible oxide anode catalyst would be most desirable. The anodes of cells M and N, which gave the best performance on CO fuel, contained ZnO with Co or Co_2O_3. The presence of a higher valent metal oxide should enhance the n-type conductivity of ZnO. The best impurities for enhancing the n-type conductivity of ZnO are Al_2O_3, Ga_2O_3, and possibly Cr_2O_3, and the firing temperatures should be 1000°C to insure proper doping (13, 14). For comparison purposes both n- and p-types of doped oxides were tried in cells Q and P. Lithia doped nickel oxide and alumina doped zinc oxide each containing 5 a/o of foreign ions were calcined at 1000°C for 3 hr, "silverized," and incorporated in the anodes of these respective cells. The p-type NiO was better at 4.7 mw/cm^2 than the n-type ZnO which yielded only 2.3 from CO, but neither catalyst was distinctly better than undoped materials.

Carbon Formation

Hydrocarbons introduced directly into the molten carbonate cell at 650°C would be expected to crack and form coke; however, pentane was briefly supplied to a cell with a Ag-Ni anode to determine the extent of coking and power production. After 5 hr on 10 cc STP/min of pentane the open-circuit voltage was 0.42v and a current of 0.12 amp was delivered at 0.3v. An exhaust gas sample showed that 87% of the pentane was converted to a distribution of products typical of thermal cracking. The amount of hydrogen in the products including water was within 1% of the input, but the carbon in the exhaust, including some from the electrolyte, was only half the amount entering. On examination of the cell the inlet line was found to be almost plugged, and a soft sooty deposit of carbon nearly filled the anode compartment.

The inlet tube of a cell operated on pure CO at 650°C became plugged in 30 min by carbon from the reaction $2CO \rightleftharpoons C + CO_2$, $K_{650°C} = 2.5$; however, with CO_2 present in the ratio of $2CO_2/1CO$ carbon deposition is prevented, and such fuel mixtures were generally used without difficulty. More serious is the fact that carbon formation can and did occur sufficiently to plug gas lines when H_2-CO, H_2-CO_2, and even pure H_2 fuels were being used. In addition to plugged lines and chemical analyses, evidence of carbon formation has been found in increased cell performance when CO_2 was substituted for a N_2 fuel stream. This effect can be explained by formation of CO by reaction of CO_2 with carbon deposits in the cell.

At 650°C almost any surface catalyzes the water gas shift reaction, $H_2 + CO_2 \rightleftharpoons CO + H_2O$, and CO disproportionation so that conditions thermodynamically favorable for carbon deposition must be avoided. Cairns, Tevebaugh, and Holm (15) have examined these conditions in detail. In general carbon deposition can be prevented by raising the temperature and by increasing the content of H_2O or CO_2 (if a certain minimum is exceeded). Extent of fuel consumption is also a factor. Increased pressure favors carbon deposition.

Addition of H_2O and CO_2, products of the anode reaction, suppresses the open-circuit voltage, but the effect on equilibrium potentials is not large at high levels of fuel consumption. In fact, since the effect of temperature on cell voltage is greater than the effect of the amount of water needed to suppress carbon formation, more power should be obtained from a cell operating at 500°C on a 2:1 H_2:H_2O feed mixture than on pure H_2 at 650°C. In practice the porous diffusion electrodes used in this work limited cell performance when products of the anode reaction were introduced.

Conclusions

It should be emphasized that the results reported in this paper were obtained with porous diffusion electrodes which were quite subject to concentration polarization. The conclusions reached, however, are generally applicable since the problems encountered are common to all molten carbonate fuel cells when the limitations of gas diffusion electrodes are approached.

1. Reduced metals are active and reversible electrodes for the oxidation of H_2 but are not active for CO. Most electrode materials are more easily oxidized than CO.
2. Oxidation of both H_2 and CO can occur on completely oxidized electrodes; however, all those tried (zinc, nickel, cobalt, rhodium, and manganese) showed about 0.6v activation polarization.
3. The reaction of CO on the oxidized electrode is direct and does not involve a water gas shift reaction.
4. Carbon does form in the cell and gas lines when thermodynamically permitted. Favorable conditions for carbon deposition can occur even with pure H_2 as the fuel.

Analysis of the Charge-Discharge Characteristics of Nickel-Oxide Electrodes by Infrared Spectroscopy

Frederick P. Kober

General Telephone & Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

Infrared spectroscopy is shown to be a sensitive tool in studies of the structure of electrochemically active materials and in elucidating the mechanism of charge and discharge. The spectrum of the sintered nickel-oxide electrode, impregnated using standard procedures, has been determined in the region between 4000 and 250 cm^{-1}. These spectral data show the discharged state to be $Ni(OH)_2$ having a hexagonal layer structure isomorphic with the space group D_{3d}^3. The hydroxyl groups are parallel to the c-axis of the crystal and are "free" in the sense that hydrogen bonding is absent. Associated with this structure is a relatively small amount of water which is trapped in the crystal lattice through the formation of coordinate-covalent bonds with the nickel ions. The charging process is accompanied by the formation of a hydrogen-bonded structure possessing a higher degree of crystal symmetry than is found in the discharged state. During discharge, these hydrogen bonds are continuously broken, and the structure transforms back to a free hydroxyl configuration.

Many attempts have been made to determine the structure of the active species in nickel-oxide electrodes for rechargeable alkaline batteries. Structure determinations have been based on the analysis of the x-ray diffraction patterns of the active materials (1-5). Because of the amorphous quality of the electrochemically active materials, particularly in sintered electrodes, the x-ray method has been limited to providing information concerning the phases present within the electrode during charge and discharge.

Infrared spectroscopy has been extensively used in the analysis of molecular structure because of the extreme sensitivity of the method to small changes in the vibrational energy states of a molecule. Therefore, infrared analysis of the nickel-oxide electrode should provide valuable information about the structure of the active material and about the changes in chemical bonding which occur during charge and discharge. In this paper the usefulness of this method is demonstrated. The structure of the discharge state of the nickel-oxide electrode is discussed in detail. The infrared data, in addition, provide valuable insight into the changes in chemical bonding which occur during the charging process and provide information about the nature of the charged state.

Experimental Procedure

Pure $Ni(OH)_2$ was prepared from a solution of the nitrate using the method of Glemser and Hartert (6). Electrodes were fabricated from sintered plaques impregnated with $Ni(OH)_2$ by the conventional impregnation technique (7). Samples of the charged and discharged materials were obtained from electrodes which had been cycled at least ten times in 31% KOH at the 3-hr rate. After cycling, the plates were thoroughly washed in hot water and dried at 60°C for 48 hr in an atmosphere of dry nitrogen. The electrodes were then ground to a fine powder (400 mesh).

The near-infrared spectra (2.25-14μ) were obtained using pressed KBr pellets with a Perkin-Elmer model 421 double-beam recording spectrometer. For the far-infrared measurements (14-40μ), samples were dispersed in Nujol, and the spectra obtained with a Beckman IR-7 double-beam instrument equipped with CsBr optics. Although identical results were obtained in the far-infrared using pressed CsBr pellets, Nujol mulls were used because of the ease in preparation.

It was necessary to determine whether the sample preparation technique in any way altered the electrochemical activity of the charged material. Samples of the charged electrode which had been washed, dried, and ground to 400 mesh powder were subsequently discharged in 31% KOH in a pocket-type electrode configuration. These samples yielded normal discharge voltage characteristics and delivered approximately 75% of the capacity obtained from sintered electrodes that were dried but not ground. Consequently, it is concluded that self-discharge of the "higher oxide" is evident to a relatively minor degree during processing of the samples.

Results and Discussion

It is generally assumed that the composition of the discharged state corresponds to $Ni(OH)_2 \cdot xH_2O$, where x has been given many values from zero to ten (1-5). X-ray data indicate that this assumption is essentially correct. However, examination of the literature shows that the structure of the discharge state is, as yet, unresolved.

Pure nickel (II) hydroxide crystallizes with the hexagonal layer structure having the space group D_{3d}^3 (8). Infrared analysis has confirmed this structure (9). In addition, the infrared spectrum shows that the hydroxyl group is "free" in the sense that hydrogen bonding is absent. Because of the absence of

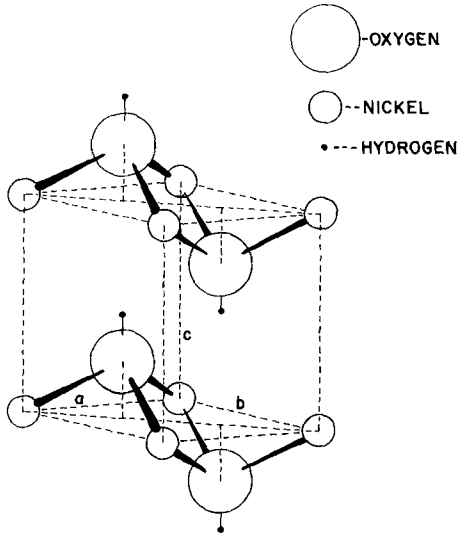

Fig. 1. $Ni(OH)_2$ unit cell showing the hexagonal D_{3d} symmetry. The Ni and O occupy equivalent sites having D_{3d} site symmetry.

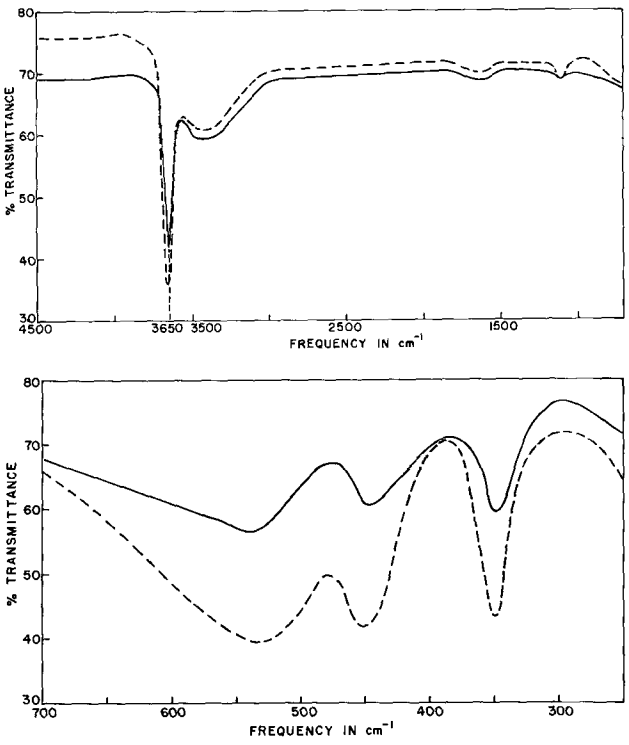

Fig. 2. Spectrum of an impregnated sintered electrode having undergone no cycling compared to that of pure $Ni(OH)_2$: ——, impregnated plate, no cycling; — — —, pure $Ni(OH)_2$.

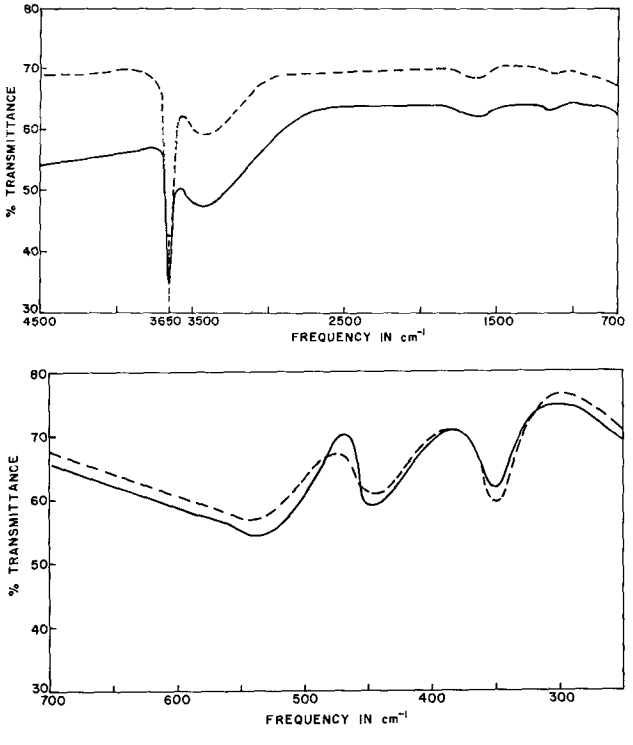

Fig. 3. Spectrum of a sintered electrode in the discharged state: ——, discharged state; — — —, impregnated plate, no cycling.

hydrogen bonding, the vibrational modes of the hydroxyl group do not interact with the lattice modes of the crystal. The hexagonal D_{3d}^3 layer structure of $Ni(OH)_2$ is illustrated in Fig. 1.

In Fig. 2 the spectrum of the pure $Ni(OH)_2$ is compared with that of the freshly impregnated plate which has not undergone any cycling. The spectra are identical, showing that the nickel (II) hydroxide structure is in no way altered during the impregnation procedure. The difference in relative absorption levels in the near infrared is due to dilution of the sample by the nickel matrix. The difference in absorption levels in the far infrared is due to varying sample concentrations in the Nujol mulls. Since the impregnation procedure does not change the structure of $Ni(OH)_2$, the spectrum of the impregnated plate will be used as a reference.

The spectrum of the discharged state is given in Fig. 3. The appearance of the sharp intense band at 3650 cm^{-1} is due to the antisymmetric stretching fundamental of the "free" hydroxyl group (10). With respect to the band centers, the spectrum of the discharged state is identical with that of the pure $Ni(OH)_2$. Therefore, the spectral data show that the discharged state is indeed nickel (II) hydroxide having the same crystal symmetry as the pure compound, *i.e.*, a hexagonal layer structure having the space group D_{3d}^3, and having nonhydrogen bonded hydroxyl groups parallel to the c-axis of the crystal. Although the discharged state may be a highly defect structure and susceptible of considerable disorder (11, 12), the basic hexagonal D_{3d}^3 site symmetry is preserved.

It is not possible to determine the symmetry of the nickel-to-oxygen coordination directly from the infrared spectrum. In lieu of a complete x-ray analysis of the nickel hydroxide molecule, we have estimated the nickel-to-oxygen bond distances from values of the Pauling ionic radii (13) although other data could be used for this estimate (6). From these estimated bond distances, we find that the nickel-to-oxygen coordination is slightly distorted along the c-axis of the crystal from true octahedral symmetry. This slight distortion from true octahedral coordination is consistent with the doubly degenerate nickel-oxygen stretching mode observed at 450 cm^{-1} (Fig. 2b) (9). If the nickel-to-oxygen coordination were truly octahedral, we should then expect to observe the nickel-oxygen stretching mode as a broad intense triply degenerate band in the far infrared (14).

Figure 3 indicates that there is a small amount of lattice water associated with the $Ni(OH)_2$ structure, *i.e.*, water molecules trapped in the crystal lattice by weak coordinate-covalent bonds to the nickel ions. The broad band having a center at 3450 cm^{-1} and the weak absorption at 1620 cm^{-1} can be attributed to the stretching mode and the bending mode of the lattice water, respectively (15). The broad band having a center at approximately 530 cm^{-1} has been attributed to the torsional mode of the lattice water (16). The role and nature of the water associated with electrochemically active $Ni(OH)_2$ will be discussed in detail in a future publication.

The spectrum of the charged state together with that of the discharged state is given in Fig. 4. Several differences are readily observable. The hydroxyl band at 3650 cm^{-1} is no longer present in the spectrum of the charged species. This absorption is replaced by a broad diffuse band having a center at 3450 cm^{-1}. In the far infrared we observe a broadening and shift to a higher frequency of the band at 535 cm^{-1} when going from the discharged to the charged state. These spectral shifts at approximately 3500 and 530 cm^{-1} are definite indications of hydrogen bond formation (17).

In the spectrum of $Ni(OH)_2$ a band at 350 cm^{-1} is observed (Fig. 2). This absorption has been attributed to the interaction of the nickel-oxygen stretching fundamental at 450 cm^{-1} with the librational lattice mode of the free hydroxyl group (< 100 cm^{-1}) (9). By librational mode is meant the torsional motion of the OH group about the Ni-O bond. In the spectrum of the charged material this combination band at 350 cm^{-1} is seen to disappear, accompanied by a broadening of the Ni-O stretching fundamental at 450 cm^{-1}. These spectral data indicate that the charged species is a hydrogen-bonded structure containing no "free" hydroxyl groups. In addition, the broadening of the

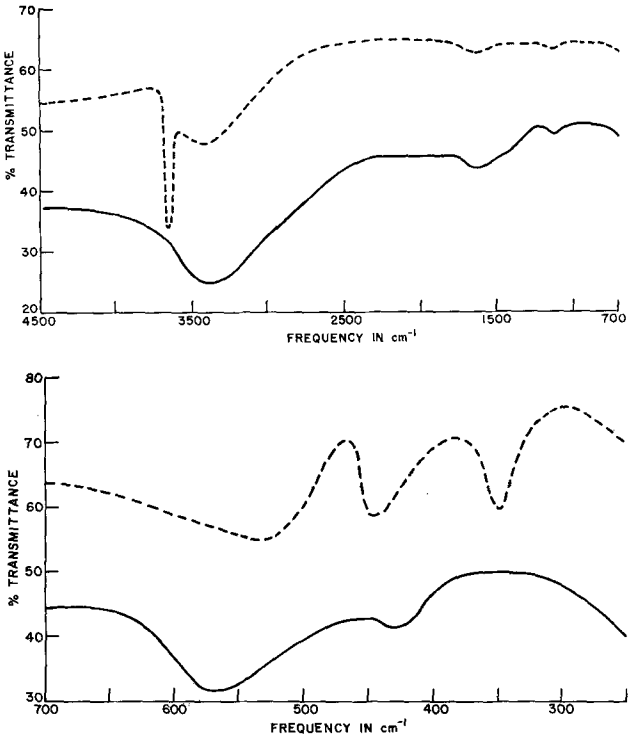

Fig. 4. Spectrum of the charged electrode compared to that of the discharged electrode: ——, charged electrode; — — —, discharged electrode.

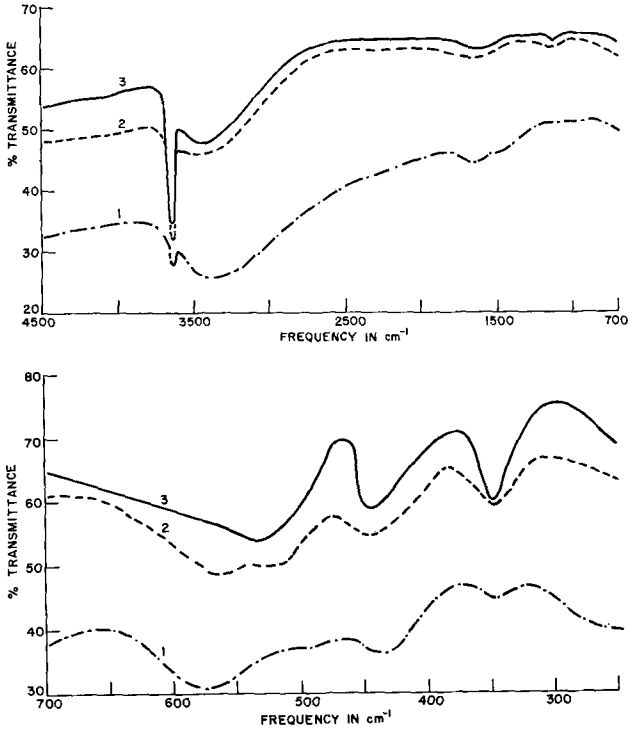

Fig. 5. Spectra of electrodes at various stages of discharge: curve 1, 50% discharge; curve 2, 90% discharge; curve 3, 100% discharge.

band at 450 cm^{-1} indicates that the Ni-O stretch is now triply degenerate (14). This increase in the degeneracy of the Ni-O stretch implies a higher degree of symmetry in the charged state with regard to nickel-oxygen coordination than is found in the discharged state. It is quite probable that the distorted octahedral nickel-oxygen coordination found in the discharge state tends toward regular octahedral coordination as the electrode is charged. This octahedral nickel-oxygen coordination in the charged state has been suggested previously by Tuomi (11). In light of the above evidence, the designation of β-NiOOH for the charged state is, at best, an oversimplification. Similar statements concerning any simple designation for the charged state have been made by others (18, 19).

Okada *et al.* (20), in their x-ray studies of the higher oxides of nickel, suggest that the oxidation of $Ni(OH)_2$ to the higher oxide proceeds through the formation of a series of solid solutions, and discharge of the higher oxide would also proceed through the formation of solid solutions of divalent and trivalent nickel. In Fig. 5 the spectra of the charged nickel positive electrode are shown at various stages of discharge. Curves 1, 2, and 3 differ only in the intensity of the "free" hydroxyl band at 3650 cm^{-1}, showing that $Ni(OH)_2$ is formed continuously during discharge of the higher oxide. Complementing the OH group formation is a continuous disappearance of H bonds as indicated by the changes in the far-infrared spectra. This is evidenced by the continuous shift in the librational water band from 575 to 535 cm^{-1}. If the discharge process involved the formation of solid solutions, the "solute-solvent" interactions should be observed in the spectra. We should expect to observe either a shift or broadening of the hydroxyl band or the appearance of combination bands in the region of 3650 cm^{-1} due to these interactions. Since these interactions are not observed, we conclude that only mixtures (distinct phases) of $Ni(OH)_2$ and the charged species are present. The possibility is not eliminated that the charged state is itself a solid solution of several higher oxides. Tuomi (11) proposes that $Ni(OH)_2$ is transformed into a second phase within which solid solutions of Ni(II) and NI(IV) could be formed. In light of the spectral data, however, this possibility seems unlikely. The formation of mixtures as opposed to solid solutions during charge and discharge has been proposed by Conway and Gileadi (21), Briggs and Wynne-Jones (4), and others (2). Care must be exercised while comparing the results of various investigations since the formation of mixtures as opposed to solid solutions may depend strongly on the method of electrode preparation and the conditions of polarization.

Summary

The sintered positive nickel oxide electrode has been investigated using infrared spectroscopy. The following conclusions can be drawn from the data obtained.

1. The discharged state is $Ni(OH)_2$ having a hexagonal layer structure isomorphic with the space group D_{3d}^3. The hydroxyl groups are parallel to the c-axis of the crystal and are "free" in the sense that hydrogen bonding is absent.

2. A small amount of crystalline lattice water is associated with the $Ni(OH)_2$ structure. The amount of water may be dependent on preparative techniques.

3. The charging process is accompanied by the formation of a hydrogen bonded structure possessing a higher degree of symmetry with respect to nickel-oxygen coordination than is found in the discharged state.

4. The discharge process is accompanied by the continuous formation of "free" hydroxyl groups. In addition, the nickel (II) hydroxide forms mixtures (distinct phases) with the charged species as opposed to solid solutions, *i.e.*, continuous solid solutions from the bivalent state to the higher oxide.

Acknowledgment

The author is indebted to Mr. E. R. Bowerman for his aid in illustrating the symmetry properties of the $Ni(OH)_2$ structure, and to Dr. P. Goldberg for many helpful suggestions during the course of the work. He is also indebted to E. P. Bulan, M. Tomkus, and J. F.

Cosgrove for their assistance in preparing the samples and obtaining the infrared spectra.

Manuscript received June 10, 1965. This paper was presented at the Buffalo Meeting, Oct. 10-14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Hydrogen Permeation Studies

I. Armco Iron and Iron-Molybdenum Alloys

Robert R. Heinrich, Carl E. Johnson, and Carl E. Crouthamel

Chemical Engineering Division, Argonne National Laboratory, Argonne, Illinois

ABSTRACT

Hydrogen permeation of Armco iron, 5 w/o (weight per cent) molybdenum-iron, and 10 w/o molybdenum-iron alloys was investigated over a temperature range of 350-800°C and at 1 atm hydrogen pressure. Activation energies have been calculated from the experimental data as $E_{(\text{Armco Fe})} = 10{,}260 \pm 29$ cal g-atom^{-1}, $E_{(5\text{ w/o Mo-Fe})} = 9472 \pm 140$ cal g-atom^{-1}, and $E_{(10\text{ w/o Mo-Fe})} = 9592 \pm 191$ cal g-atom^{-1}. Use of iron diaphragm electrodes, in lithium hydride cells under heavy current loads, has resulted in current densities which were 1.5 times greater than those obtainable from data on the permeability of hydrogen through an iron diaphragm at 1 atm hydrogen pressure across the diaphragm. Alpha activation of the hydrogen gas also increases the hydrogen permeation rate of iron. When ionization of the hydrogen gas with alpha particles was used, the activation energy for the process was reduced from -10.3 kcal g-atom^{-1} to -7.9 kcal g-atom^{-1}.

Hydrogen has the unique property of diffusing through certain metals at a rapid rate, and attempts have been made to exploit this property in a thermally regenerative cell system. The use of such a permeable metal diaphragm as an electrode in fused salt systems alleviates some of the problems associated with porous metal gas electrodes, namely, concentration polarization and "flooding" of the electrode with either electrolyte or gas. Materials, on the other hand, which are compatible with a lithium hydride cell environment consisting of liquid lithium, lithium hydride, and a molten alkali halide electrolyte, are somewhat limited. Although iron and some iron alloys have proved to be satisfactory under these conditions, their use as a hydrogen diffusion diaphragm-electrode limits the cell current density and therefore restricts the practical application of such a cell. The purpose of this investigation was to find a metal capable of high rates of hydrogen permeation and therefore capable of high cell current densities when used as a diaphragm-electrode in a lithium hydride cell.

The permeation of a diatomic gas through a metal barrier was considered to be a four step composite rate process; (*i*) the activated adsorption of the gas on the metal surface, (*ii*) the formation of a gas-metal solid solution, (*iii*) the diffusion of atoms through the metal crystal lattice, and (*iv*) the recombination of atoms and the desorption of the gas at the opposite surface. Much experimental evidence has been given to support such a mechanism (1-5). The surface conditions of a metal determine its affinity to adsorb hydrogen, and in the case of aluminum (6), where its oxide film is difficult to remove, this condition was the rate-determining step in the over-all mechanism.

Of great importance to gas permeation is the solubility constant of the gas-metal system. A metal which possesses a high gas solubility, providing optimum surface conditions exist, will in general exhibit a high rate of permeation.

The literature (7) indicates that the solubility of hydrogen in iron-molybdenum alloys reaches a maximum at a composition of about 6 w/o molybdenum. Although this hydrogen solubility differs little from that of pure iron, the iron-molybdenum alloy does occur, along with the silver-palladium alloy, in the same general classification (8) of alloys which exhibit a maximum hydrogen solubility. The silver-palladium alloy, of course, is very permeable to hydrogen, even more permeable than pure palladium. Consequently, it was anticipated that a similar phe-

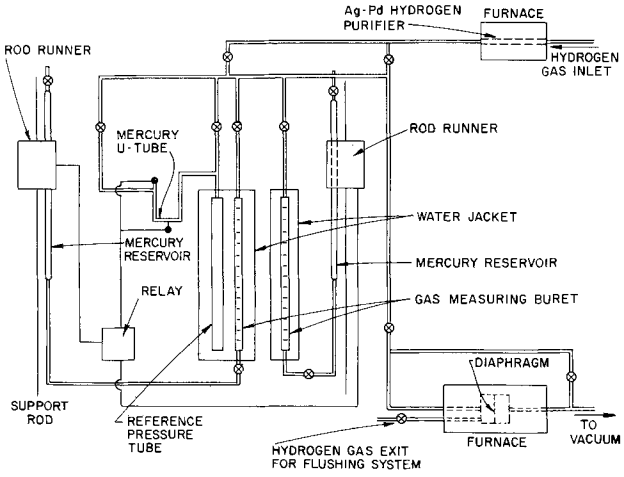

Fig. 1. Gas measuring apparatus

nomena might also exist, but to a lesser degree, for the iron-molybdenum alloy.

Experimental

Apparatus.—Because of greater sensitivity, most investigators have chosen to observe the change in pressure on the vacuum side of the specimen as hydrogen permeates the metal. For this work an apparatus was assembled to measure directly the change in volume of hydrogen permeating the metal. This approach was taken because of anticipated high permeation rates and the simplicity of the volume measuring technique under these experimental conditions. A schematic drawing of this apparatus is given in Fig. 1 and includes the hydrogen gas purifier and diaphragm assembly. The portion of apparatus comprising the gas measuring burets, reference pressure tube, and mercury U-tube and reservoirs was constructed of Pyrex. Stopcocks used in this section were, with one exception, entirely grease free in an effort to keep the introduction of gas impurities into the hydrogen to a minimum. The one exception was not located in the hydrogen flow stream to the diaphragm. This stopcock, isolating the reference pressure tube from the rest of the system, was of the conventional Eck and Krebs precision vacuum type. Other stopcocks were GYCO greaseless high vacuum type. The remaining portion of the apparatus containing the hydrogen purifier and diaphragm assembly was constructed of metal. Connection of these components to the Pyrex system was made by copper to glass seals. Valves used in the metal system were VEECO high vacuum bellows-type.

The hydrogen gas flow into the system was so arranged that the free volume in front of the diaphragm could be flushed with purified hydrogen (from a silver-palladium valve) at the temperature of the measurement. The permeation rates were measured at a constant pressure differential across the diaphragms of 1 atm. This was accomplished by setting the pressure in the reference tube at exactly 1 atm with the aid of a mercury barometer. Any small drop in hydrogen pressure in the system with respect to the reference pressure tube was quickly corrected by the electric motor driven rod runner. The rod runner responds to the closing of an electrical circuit in a U-tube filled with mercury. When the hydrogen pressure in the gas measuring buret dropped below that of the reference pressure tube, the electrical circuit closed by the movement of mercury in the U-tube and the rod runner quickly raised a mercury reservoir until the pressure in the gas measuring buret was exactly equal to that in the reference tube. The permeation rate through the diaphragm was measured directly as the change of gas volume in the measuring buret per unit time.

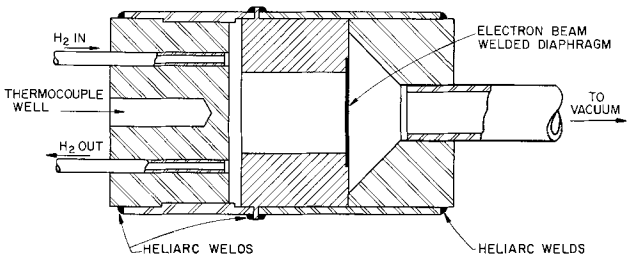

Fig. 2. Diaphragm assembly

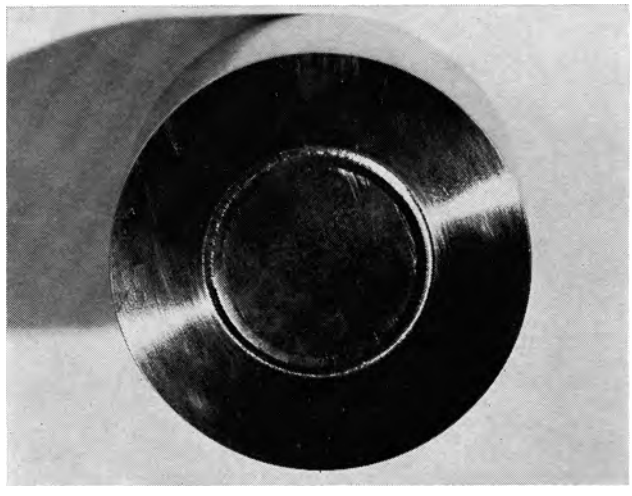

Fig. 3. A typical electron beam welded diaphragm

The design of the gas measuring apparatus does not restrict the presence of mercury vapor on the gas side of the diaphragm. Possible poisoning of the surface of the metal diaphragm could result from the mercury vapor, thereby directly affecting the rate of gas permeation through the diaphragm. A carbon trap was placed in the system to restrict the movement of mercury vapor. However, no differences in rates of permeation were noted either with or without the presence of the carbon trap in the system.

The diaphragm assembly is illustrated in Fig. 2. The diaphragm was first electron beam welded onto a 304 stainless steel support ring. This support ring was in turn heliarc welded into the rest of the assembly. To prevent oxidation of the surface of the metal diaphragm, the heliarc welding operation was carried out under an inert gas blanket. Figure 3 is a photograph of a typical electron beam welded specimen. The uniformity and small width of the electron beam weld enables an accurate measurement of the permeable area of the diaphragm.

To insure that the results were not biased due to hydrogen permeating the diaphragm metal support assembly, the following conditions were met. First, the material of construction of this support was 304 stainless steel which has a permeation rate ten times less than that of Armco iron or the iron-molybdenum alloy. In addition, the wall thickness of the assembly components was kept large compared to the thickness of the diaphragm, the smallest ratio being 10 to 1. Critical dimensions of the diaphragms are given in Table I.

Materials.—Armco iron was used as the pure metal diaphragm and also for the main constituent in the alloy diaphragms. Molybdenum used in the alloys was purchased from Fansteel Metallurgical Corporation, North Chicago, Ill.

Spectrographic analysis of the material is given in Table II.

Method.—Prior to any measurements, the gas measuring system was evacuated to about 10^{-4} mm of mercury and then filled with purified hydrogen gas.[1]

[1] Instrument containing an Ag-Pd valve was purchased from Milton Roy Company, St. Petersburg, Florida.

Table I. Diaphragm dimensions

Diaphragm	Armco Fe	5.04 w/o Mo-Fe	10.0 w/o Mo-Fe
Diameter, mm	24.21	24.00	24.00
Thickness, mm	0.254	0.140	0.140

Table II. Spectrographic analysis

Iron		Molybdenum			
Fe	99.94 (%)	Mo	99.9 (%)	As	0.02 (%)
S	0.025	Si	0.005	Al	0.003
Mn	0.017	Cu	0.002	Co	0.004
C	0.012	Mn	0.01	Pb	0.003
P	0.005	Ni	0.004	Ag	0.0002
		Cr	0.004	Ge	0.002
		B	0.005		

This process was repeated several times before the pressure was set at 1 atm and a measurement taken.

The diaphragm assembly was also evacuated and degassed at 800°C for 16 hr prior to any measurements. Leak rates, on the gas measuring system filled with helium, were undetectable over an 8-hr period. All diaphragm assemblies were leak checked with a helium mass spectrometer prior to connection with the gas measuring portion of the system. In addition, a helium leak check was made at temperature to ensure that the diaphragm or the diaphragm weld did not open on heating. After this testing, pure hydrogen was introduced to the assembly and flushed past the diaphragm for several hours to insure saturation of all the metal system with hydrogen. Reproducibility of successive measurements at temperature was used as an indication that equilibrium had been reached. No decrease in the rate being measured toward the end of a run was observed. A constant rate was taken as indicating that little or no surface contamination of the diaphragm by a reactive impurity occurred during an experiment.

Over-all experimental accuracy was estimated to be ± 2% with the maximum uncertainty occurring in defining the working area of the diaphragm. Accuracy of the burets was considered better than 1% and the reading precision about 0.1%.

Results and Discussion

The general equation for the permeation of a diatomic gas through a metal barrier can be expressed as

$$Q = \frac{KDAt}{d}(p_1^{1/2} - p_2^{1/2}) \exp - \left(\frac{E}{RT}\right)$$

where Q is the amount of gas permeating the diaphragm, cm³ (STP); K is the solubility constant of the gas-metal system; D is the diffusion constant; A is the area of barrier, cm²; d is the thickness of the diaphragm, mm; p_1 is the gas pressure on the upstream side of the diaphragm, atm; p_2 is the gas pressure on the downstream side of the diaphragm, atm; E is the activation energy for the process, cal g-atom^{-1}; R is the gas constant; T is the absolute temperature, degrees Kelvin; and t is the time, hr.

From the equation, it can be seen that the rate of permeation of a diatomic gas through a metal diaphragm varies directly as the area of the diaphragm and as the difference of the square roots of the pressure at each metal face; inversely as the thickness; and exponentially as the reciprocal of the absolute temperature.

In these experiments, the downstream side of the diaphragm was continuously evacuated and the upstream hydrogen pressure held constant at 1 atm which reduces the above equation to the following

$$Q = \frac{KDAt}{d} \exp - \left(\frac{E}{RT}\right)$$

Results of this work are summarized in Table III and are plotted in Fig. 4 as the logarithm of the rate of permeation *vs.* the reciprocal of the absolute temperature. The solid line represents a smoothing of the experimental data by a least squares analysis. Current densities listed in Table III are the equivalent current densities achievable in a cell operating at 100% electrode efficiency.

A comparison has been made in Table IV of the activation energy and permeability derived from this work with that of previous authors for the equivalent hydrogen-metal systems. The reported activation energy for iron was in excellent agreement with literature data (5, 6, 9, 10). No literature data were available for comparison on the 5 w/o Mo-Fe alloy. Rea-

sonable agreement was observed in the data on the 10 w/o Mo-Fe alloy. There was general agreement when comparing the rates of permeation between this work and previous data (11, 12).

Current densities achievable in a cell which utilizes an iron or iron-molybdenum alloy diffusion electrode are unfortunately low. Actual operation of lithium hydride cells under full load using Armco iron diffusion diaphragms as cathodes produced current densities which were equivalent to 1.5 times the permeation rates obtained with a 1 atm hydrogen pressure differential (1 atm to a vacuum). Apparently, when atomic hydrogen at the iron-fused salt interface was removed as a hydride ion, the over-all permeation rate is increased because of the elimination of the fourth step in the mechanism; namely, the recombination of hydrogen atoms and the desorption of the diatomic gas molecules from the diaphragm surface.

In an attempt to alter the first step of the rate process, *i.e.*, the activated adsorption of the gas on the metal surface, the ionization of the hydrogen gas by a radioactive source was studied. The same type of diaphragm assembly was used but an alpha source (U-233, 5 x 10^8 d/m) was positioned about 10 cm from the iron diaphragm. The same iron diaphragm was used for measurements with and without the alpha source. These results are illustrated in Fig. 5 and indicate that a slight increase in hydrogen permeation of iron was realized when the incoming hydrogen gas was ionized using the radioactive alpha source. At 450°C the increase in rate over that of the same iron diaphragm was 51%; at 550°C the increase 23%; and at 650°C the increase 13%. The activation energy was changed slightly from 10.3 kcal g-atom^{-1} for the plain iron diaphragm to 7.9 kcal g-atom^{-1} for the same diaphragm with the radioactive source.

In view of the above data, indications are that iron or iron-molybdenum alloys probably would not be suitable for use as a diaphragm electrode in a lithium hydride cell where reasonable current densities are required; *i.e.*, 100 ma/cm^2 or greater. In order to fulfill this requirement a material more permeable to hydrogen which is also compatible with the cell environment must be used. The possibility that the Group V-a transition metals may possess these properties will be investigated next.

Hydrogen Permeation Studies

II. Vanadium as a Hydrogen Electrode in a Lithium Hydride Cell

Robert R. Heinrich, Carl E. Johnson, and Carl E. Crouthamel

Chemical Engineering Division, Argonne National Laboratory, Argonne, Illinois

ABSTRACT

Hydrogen permeation of pure vanadium has been investigated over the temperature range of 450°-550°C and 1 atm hydrogen pressure. An activation energy of 14.2 ± 0.4 kcal g-atom^{-1} has been determined. A lithium hydride cell using a vanadium diaphragm electrode has been operated for a period of 540 hr. Current densities obtained during operation were 180 ma/cm^2 at one-half open-circuit voltage.

The success of a regenerative lithium hydride cell which employs a diaphragm type electrode will depend a great deal on the current density achievable when the cell is operated under load. Current densities in this type of cell are, for the most part, limited by the hydrogen permeation rates of the electrode diaphragm. The permeability of a metal to a diatomic gas has been discussed in a previous investigation (1). The steps in the process can be summarized as: (*i*) the activated adsorption of the gas on the metal surface; (*ii*) the formation of a gas-metal solid solution; (*iii*) the diffusion of the atoms through the crystal metal lattice; and (*iv*) the recombination of the atoms and the desorption of diatomic gas at the opposite surface.

In general, metals which possess high gas solubility, providing optimum surface conditions exist, will exhibit a high permeability to that gas. Transition metals of group V-a possess high hydrogen solubilities and have also been found to be compatible with the lithium hydride cell environment. However, these metals also have the undesirable property of forming very stable oxides and nitrides which are not reduced by hydrogen gas. Thus, pure hydrogen gas and precise control of cell environment must be employed if successful cell operation is to be realized.

In the group V-a transition metals, vanadium is among the highest in hydrogen gas solubility and permeability, is least sensitive to adverse surface effects, maintains good mechanical strength above 400°C in hydrogen atmospheres, and appears to be compatible with all alkali-halide electrolytes and lithium metal.

Experimental

Apparatus.—The diaphragm assembly is illustrated in Fig. 1. The entire apparatus, with the exception of the thin diaphragm, is fabricated from 304 stainless steel. The design of the apparatus is a modification of a basic concept by Brymner and Steckelmacher (2). The seal of the diaphragm is made by tightening the union nut onto the union body which forces the diaphragm to seat in the proper position. The seal itself is achieved by the surface-shearing action between the diaphragm and the male-female components of the assembly. Seals of this type have been shown to withstand several temperature cycles from —188°C to 800°C (2) and still remain gas tight. The technique yields excellent seals; several experiments actually produced cold welding of the diaphragm to the stainless steel.

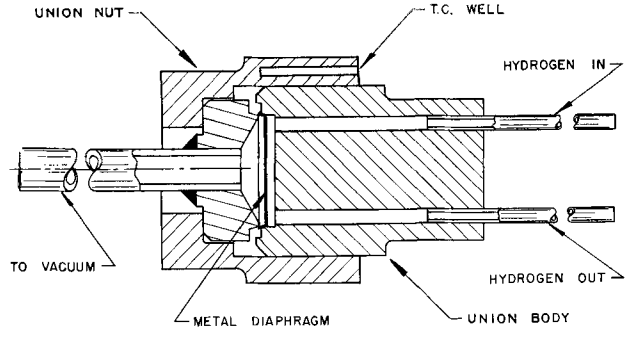

Fig. 1. Swage-type diaphragm holder

The critical diameter of the diaphragm is defined by the diameter of the seat in which the diaphragm fits. This diameter was designed and machined to be 25.40 mm. Diaphragm thickness was 0.254 mm. Wall thickness of the assembly components was kept large in comparison to the diaphragm, the smallest ratio being 10 to 1.

The permeation rates of the diaphragms were measured at 1 atm (absolute) hydrogen pressure by the gas measuring apparatus described previously (1). Pure hydrogen gas was obtainable by passing electrolytic tank hydrogen through a Ag-Pd alloy. The hydrogen gas flow into the system is so arranged that the free volume in front of the diaphragm can be flushed with purified hydrogen at the temperature of measurement.

Materials.—High-purity vanadium metal was purchased from Ames Laboratory, Iowa State University, Ames, Iowa. Our analysis of the material was: V, 99.81%, Fe, 0.019; C, 0.037; N_2, 0.028; H_2, 0.005; and O_2, 0.086.

Method.—Before any measurements were made, the diaphragm and diaphragm assembly were degassed at 850°C for a period of 16 hr. At the end of this time, pure hydrogen was introduced to the assembly and allowed to flush past the diaphragm. With hydrogen flushing past the diaphragm, the temperature was lowered to 450°C. After temperature equilibration had been reached, the first measurement was taken. During the period the diaphragm assembly was being cooled in hydrogen, the gas measuring apparatus was evacuated to 10^{-4} Torr and then filled with purified hydrogen. This process was repeated several times before the pressure in the constant pressure tube was set at 1 atm and connected to the diaphragm assembly.

Leak rates on the gas measuring portion of the system were undetectable over an 8-hr period. The diaphragm assembly was leak checked with a helium mass spectrometer and found to be gas tight. In addition, a helium check was made at temperature to assure that the shear-type seal on the diaphragm was still intact. Accuracy of the gas measuring burets is considered better than 1% and the reading precision about 0.1%.

Results and Discussion

The general equation

$$Q = \frac{KDAt}{d}(p_1^{1/2} - p_2^{1/2}) \exp - \left(\frac{E}{RT}\right)$$

for the permeation of a diatomic gas through a metal diaphragm was discussed previously. With the pressure on the downstream side of the diaphragm essentially a vacuum and the upstream pressure held constant at 1 atm, the equation reduces to

$$Q = \frac{KDAt}{d} \exp - \left(\frac{E}{RT}\right)$$

Results of this investigation are summarized in Table I and are plotted in Fig. 2 as the logarithm of the rate of permeation *vs.* the reciprocal of the absolute temperature. The solid line represents a smoothing of all the experimental data in a least squares sense. Current densities listed in Table I are equivalent current densities achievable in a cell whcih has 100% electrode efficiency and are calculated using the average permeation rate for the particular temperature range listed.

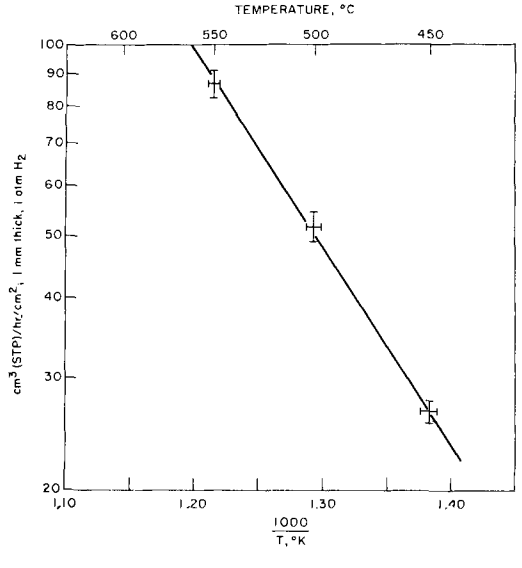

Fig. 2. Hydrogen permeation isobar of pure vanadium. E_a = 14.2 ± 0.4 kcal g—at.$^{-1}$.

Preliminary experiments indicated that, in order for the vanadium to become permeable to hydrogen initially, it was necessary to bake the diaphragm in a vacuum at high temperature (850°C) to eliminate as much surface contamination as possible. Hydrogen was then introduced and the diaphragm thermally activated. It was found that the permeation rate was optimized if the diaphragm was cooled in hydrogen to 450°C before any measurements were taken. Since vanadium absorbs hydrogen with a negative temperature coefficient, this increased permeability is undoubtedly due to the expansion of the vanadium metal lattice. The data of Fig. 2 were collected over a temperature range on four separate days and each time the same activation technique was used. Even so the scatter in the data is attributed to the difficulty in activating the vanadium on four separate occasions.

Difficulty in activating group V-a metals to hydrogen is well-known and for this reason permeation data in the literature are very sparse. Smith (3) has classified these metals as exothermic occluders of hydrogen and has listed a few interesting characteristics of the group. Briefly these are: (*i*) the metal must be raised to an "activation" temperature in order for it to exhibit a high permeability to hydrogen; (*ii*) this permeability may gradually decline due to aging; (*iii*) the metal, if heated and cooled in hydrogen, subsequently shows diminished permeability; (*iv*) reactivation of the metal can only be achieved with difficulty at a temperature higher than the initial activation temperature. These characteristics are interpreted by most investigators as being the result of the expansion and contraction of the metal lattice and possibly surface contamination of the metal. In view of these observations the scatter in our data is not surprising.

Contrary to the findings in the literature (4), vanadium, when used as an electrode material in a lithium hydride cell, was very compatible with the cell environment. A lithium hydride emf cell has been operated in this laboratory for a period of 540 hr using a 0.254 mm thick vanadium diaphragm as an electrode. The electrolyte used was a mixture of lithium chloride-lithium fluoride-lithium hydride. When the cell was operated under a resistive load at 540°C, the average current density obtained was 180 ma/cm² at one-half open-circuit voltage and 1 atm hydrogen pressure. Although this current density was only about one-third of the theoretical, it was achieved without making any attempt to activate the vanadium metal thermally before it was put into the cell. The slope of a plot of cell emf *vs.* the logarithm of hydrogen pressure corresponded to the expected Nernst slope of one, indicating the reversibility of the H_2,H^- couple at a vanadium electrode. Experiments using niobium metal flags as the cathode in a lithium hydride emf cell gave the same equilibrium potential as obtained in cells with pure iron or pure vanadium as the cathode metal flags.

With niobium and vanadium flag electrodes, the rate of achieving the equilibrium potential was very slow. The cell emf was monitored continuously on introduction of each new metal cathode into the cell electrolyte (LiH-LiCl saturated with LiH) operating at 500°C and 1 atm hydrogen pressure. With iron, the initial emf observed was the equilibrium value. However, with vanadium and niobium the equilibrium cell potential was reached only after equilibration in excess of 5 hr. Each of the three metal cathodes (Fe, V, Nb) gave the same equilibrium potential.

The hydrogen electrode in this cell is required to record the potential defined by the over-all equilibrium between molecular hydrogen and hydride ions in the cell electrolyte. But this equilibrium is not freely established in the absence of an active surface, so the electrode must serve in this capacity as well. This makes an additional demand on the electrode because of the reactions that must take place at the electrode surface. The establishment of an equilibrium popula-

tion of atomic hydrogen on the metal surface is achieved only after the bulk metal is saturated with hydrogen. In the case of niobium and vanadium, the hydrogen solubility in the metal is about four to seven thousand times greater than that of iron. At 500°C the slow rate of attaining hydrogen saturation of the bulk metal was reflected in the slow rate of achieving the equilibrium potential.

The following mechanism is consistent with the experimental results and delineates the important features in establishing the equilibrium potential at the hydrogen-hydride electrode.

1. $H_2(g)$	$\rightleftarrows$	2H (surface)	R_1 (moderate)
2. H (surface)	$\rightleftarrows$	H (bulk)	R_2 (slow)
3. H (surface)	$\rightleftarrows$	H^- (solution)	R_3 (very fast)

In this mechanism, rate 1 is the activated adsorption of hydrogen on the metal surface. Rate 2 combines the formation of the gas-metal solid solution and the diffusion of atoms into the metal into a composite rate. The diffusion of hydrogen through the metal lattice is the rate-controlling step. The slow rate at which hydrogen saturates the metal also controls the rate of attaining equilibrium potentials in the cell.

The reaction rate R_3 was assumed to be very fast with respect to rates R_1 and R_2. Atomic hydrogen on the electrode surface was rapidly stripped off as hydride ion by an electron exchange. Voltammetric studies (5) using a microelectrode in a lithium chloride potassium chloride electrolyte have confirmed the rapid rate of this reaction.

The diffusion of atomic hydrogen from the metal surface into the bulk metal lattice was considered the slowest rate. This was consistent with the fact that, when operating a metal diaphragm under a gas pressure differential of 1 atm, the permeation rate was inversely proportional to the diaphragm thickness. The unique feature of vanadium and niobium over that of iron was the extremely high hydrogen solubility in the former two metals. Thus it was not surprising that an equilibrium population of atomic hydrogen could not be maintained on the fresh vanadium or niobium surfaces until the bulk metal was saturated. Once equilibrium had been attained, the reverse was also observed in that the potential of a lithium hydride cell, using a vanadium cathode, dropped only slowly when hydrogen gas was removed from the cell compared to a very rapid drop when iron cathodes were used.

It is realized that more extensive testing of the vanadium diaphragm under severe load conditions must be made before any consideration can be given to its use in a practical cell. However, these hydrogen permeation measurements indicate the use of vanadium as a cathode material is certainly attractive.

The Voltage Increase of the Cuprous Chloride Electrode by the Addition of Sulfur

R. F. Amlie, H. N. Honer,[1] and P. Ruetschi[2]

The Carl F. Norberg Research Center, The Electric Storage Battery Company, Yardley, Pennsylvania

ABSTRACT

The addition of elemental sulfur to the cuprous chloride active material increases the electrode potential throughout discharge by approximately 0.4v when operated in neutral or acidic media. The greatest benefit is attained by the addition of approximately stoichiometric quantities of sulfur. Cupric sulfide, rather than metallic copper, is the final discharge product. As a result of the increased power density realized by this innovation, the CuCl-Mg water-activated battery constructed for a given power output can be reduced about 15% in weight while the volume is reduced approximately 20%. The effect of sulfur in other similar electrode couples was also investigated.

The cuprous chloride-magnesium water-activated battery is designed to operate under extreme environmental conditions in which most of the conventional dry batteries do not function efficiently. This investigation describes how the addition of elemental sulfur to the cuprous chloride electrode increases the potential during the entire discharge period by approximately 0.4v, which results in a higher energy output per unit weight and volume of the battery.

Since 1949 cuprous chloride-magnesium water-activated batteries have been produced commercially, and their general characteristics have been summarized by Pucher (1). These batteries are characterized by their ability to deliver moderately high current densities with good power output, and they are capable of being discharged at ambient temperatures as low as —50°C, after activation at 0° to 30°C with tap water or salt water. The high energy of hydration of magnesium ions causes internal heating after activation, making these batteries particularly suitable for low-temperature environments.

Cuprous chloride electrodes, either pasted on a supporting grid or pressed to form a flat pellet, are suitable for current densities in the range of 5-70 ma/cm^2 of apparent surface area. The assembled batteries must be stored in dry, sealed containers prior to activation due to the hygroscopic nature of the cuprous chloride. The CuCl-Mg battery has a considerable cost advantage over the silver chloride-magnesium water-acti-

[1] Present address: ESB Company, Ray-O-Vac Division, Special Products, Wonewoc, Wisconsin.

[2] Present address: Leclanché, S. A., Yverdon, Switzerland.

vated system, which has a greater energy output per unit volume because of the higher potential of the Ag/AgCl couple. Cuprous chloride magnesium cells normally produce 1.3-1.4v, while the analogous silver chloride cells give a potential of slightly over 1.5v. Cuprous chloride reserve batteries are used extensively in meteorological balloons and in marine navigation and emergency aids. The life requirements range from periods of about 10 min up to 72 hr for a life-jacket light.

One of the authors (H.N.H.) discovered in 1959 that the addition of sulfur to the cuprous chloride electrode mixture resulted in an operating potential increase of 0.35-0.45 v/cell. Further investigation showed this voltage increase to be completely reproducible even with widely different mix compositions, provided only that the sulfur and cuprous chloride were intimately mixed. It was established that the capacity which could be obtained at the higher voltage level depended on the quantity of sulfur present. The best effect was attained with the addition of about 33% sulfur. With this quantity of sulfur the cell voltage was maintained at a uniform high level during the entire discharge time. The number of cells required for a given battery voltage could thus be decreased with a corresponding reduction in manufacturing costs.

The inclusion of sulfur in the cuprous chloride cathode mix represents a very significant and unique development in the technology of the cuprous chloride-magnesium battery. A patent assigned to The Electric Storage Battery Company is pending.

Elemental sulfur has been employed previously as an additive to the positive electrode active material of the copper oxide-zinc alkaline battery. An early patent by Erwin (2) states that a potential increase of about 0.20v is realized when 1-5% sulfur is mixed with copper oxide for use in an alkaline system. A number of patents were issued to Benner and French (3-6) during the period 1918-1922 and to Armstrong (7) concerning the addition of sulfur to copper oxide electrodes in alkaline electrolytes. Although a sulfur addition as high as 40% is claimed in one patent (4), it was subsequently stated that a concentration in the order of 1% is preferable. More recently, other authors have stated that the potential of the copper oxide electrode can be raised 0.1-0.25v by the addition of a small amount of sulfur (8) or sulfur-containing material (9, 10). Flerov (10) has shown that the steady-state discharge potential of the cupric oxide electrode includes high polarization and the addition of a very small amount of sulfur in the oxide serves to increase the potential as a result of an improvement in the conductivity of the intermediate cuprous oxide layer. His results are discussed further in a later section. Selenium and tellurium are reported to have an effect similar to that of sulfur (9). Elemental sulfur has also been investigated as a cathode active material by itself in neutral electrolytes, but has not gained acceptance due to its low potential (—0.4v *vs.* S.H.E.) and other limitations (11-13).

Experiments with Cuprous Chloride-Sulfur Electrodes in Pile-Type Batteries

The batteries now being manufactured by The Electric Storage Battery Company are of the pile type. A sheet of battery grade magnesium is separated from the cuprous chloride cathode by a porous textile fiber separator material. The cells are stacked in series. Averaged discharge data for a number of CuCl-Mg cells, both with and without the inclusion of sulfur in the cathode, are summarized in Fig. 1. The cell stacks represented in Fig. 1 were discharged through a resistance equivalent to 47.7 ohms/cell after activation with tap water. The average current densities for cells with and without sulfur were 11.4 and 9.0 ma/cm^2, respectively.

Figure 1 shows that a voltage increase of about 0.37 v/cell is achieved by a 30% sulfur addition to the cuprous chloride electrode, and this higher voltage

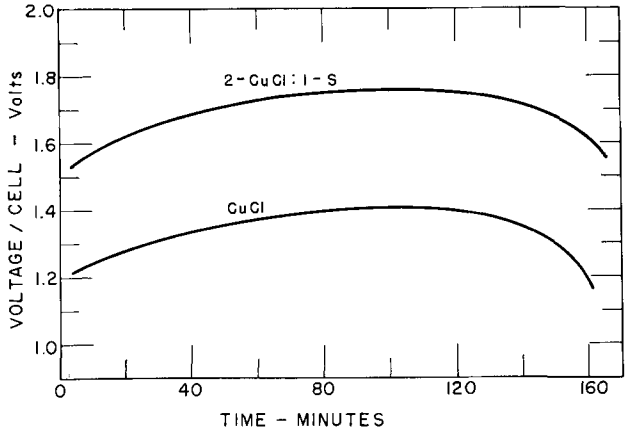

Fig. 1. Effect of sulfur addition to CuCl electrode; discharge through 47.7 ohms/cell; average current density: 11.4 ma/cm^2 w sulfur; 9.0 ma/cm^2 w/o sulfur.

level is maintained throughout the entire discharge. It has been found that, as a result of this innovation, the battery weight and volume for a given power density are reduced approximately 15% and 20%, respectively.

The effect of sulfur content on the discharge capacity is illustrated in Fig. 2, in which the capacity in minutes to the 1.56 v/cell endpoint is plotted against mole per cent of sulfur and cuprous chloride in a S-CuCl mixture. The cell stacks were activated and discharged as described above. It is apparent that the maximum capacity is realized with about 63 mole % sulfur (33% by weight), which approximates a 2:1 mole ratio of sulfur to cuprous chloride.

The effect of the sulfur addition to cuprous chloride is further illustrated in Fig. 3, where the potentials on discharge of single cathodes are measured against a saturated calomel reference electrode. Each cathode was attached to a graphite support and discharged at a constant current of 10 ma/cm^2 in a test cell containing a large excess of 1M magnesium chloride electrolyte. A graphite rod in a separate cell, connected by an electrolyte bridge, served as the counter electrode. The control electrode with no sulfur contained 0.639g of CuCl, equivalent to a theoretical capacity of 0.190 amp-hr, and delivered 74% of this capacity to a cut off of 0.3v below the maximum voltage attained. The electrode with 30% by weight of sulfur maintained a potential about 0.36v above the control throughout the discharge. An efficiency of 87% was realized to a comparable cut-off voltage, based on the weight of the cuprous chloride in the pellet. This single electrode study illustrates that, in addition to the increase in potential, the sulfur also promotes a better electrochemical utilization of the cuprous chloride.

Single Electrode Studies

Experimental.—The addition of sulfur to CuCl and other metal salts which might be employed as positive active materials in electrochemical cells was studied further with small single electrodes in order to achieve a better understanding of the voltage increase mechanism. All of these materials were metal halides or oxides and the measurements were made in a 0.5M $MgCl_2$ or a 30% (7.65M) KOH electrolyte. The experimental technique was discussed and illustrated in detail in the preceding paper (14).

Electrode potentials in 0.5M $MgCl_2$ solution were measured against a saturated calomel reference electrode, while a mercuric oxide reference was employed for the alkaline 7.65M (30%) KOH electrolyte. Initial open-circuit potentials were determined after immersing the sample and allowing the voltage to become constant; the sample pellets were discharged at progressively higher currents, ranging from 10 μa to 5 ma (0.032 to 16 ma/cm^2). A graphic illustration of the test procedure is given in Fig. 4. The ohmic parts of polarization were determined from the recovery of potential after interruption of the current drain and, in most instances, were found to be small enough to be disregarded. Only a small fraction of the total electrode capacity was consumed in making the discharge polarization measurements.

The results of these measurements are summarized in Table I. The difference between the open-circuit value potential and the potential attained at 1.6 ma/cm^2 (500 μa) discharge was selected as a relative measure of polarization for the various samples.

Behavior in neutral or slightly acid chloride electrolytes.—If a mixture of CuCl and sulfur is immersed in water or an aqueous solution, a spontaneous reaction with the formation of CuS occurs (15)

$$2CuCl + S \rightarrow CuS + Cu^{++} + 2Cl^- \quad [1]$$

It can be calculated that this reaction has a free energy change of —2.5 kcal if all the components are in their standard states at unit activity (16). The spontaneous formation of black copper sulfide, accompanied by blue coloration of the solution, can be readily observed. The formation of CuS was confirmed experimentally by x-ray diffraction analysis.

Although an electrode of pure sulfur, without cuprous chloride, attains a steady potential of 0.13v, it is strongly polarized on discharge. Thus, the couple S/H_2S in acidic medium will neither deliver a usable discharge capacity nor influence the potential of other reversible electrode processes.

The electrode mechanism responsible for the potential increase produced by the addition of sulfur was discussed by the authors, in the preceding paper (14). For the present discussion it need only be stated that the presence of solid CuS in the electrode is imperative for the attainment of the higher voltage level and the solid CuS functions as redox catalyst for the $(Cu^{++})/(Cu^+)$ couple which furnishes the discharge current. The theoretical maximum voltage-increase achievable with the addition of sulfur is 0.50v, determined by the free energy of formation of CuS.

As seen from Table I, similar results were also obtained when either cuprous bromide or cuprous iodide were admixed with sulfur.

The potential of the cuprous chloride electrode can also be increased by the addition of certain sulfur-containing compounds such as metal sulfides. Cupric sulfide produced a potential increase of 0.25-0.30v which is significantly less than the increase realized by the addition of sulfur. This increase can be correlated with the formation of cuprous sulfide, Cu_2S, in the electrode during discharge. The reaction responsible for the potential increase is

$$e^- + CuCl + CuS \rightarrow Cu_2S + Cl^- \quad [2]$$

It was found that the maximum electrode capacity at the higher voltage level was realized with a mole ratio of 1:1 between CuCl and CuS.

An experimental potential of —0.26v was observed for a CuO electrode in 0.5M $MgCl_2$. This value was increased by 0.24v with the addition of sulfur. The increase is in close agreement with the theoretical value of 0.25v, calculated from the free energy of formation of CuS. The couple $2e^- + CuO + S + 2H^+ \rightarrow CuS + H_2O$ is however easily polarized in $MgCl_2$ and cannot be utilized in a practical battery device.

When a mixture of silver chloride and sulfur is placed in the magnesium chloride electrolyte no spontaneous reaction can occur since

$$2AgCl + S \rightarrow Ag_2S + Cl_2 \quad [3]$$

has a positive free energy change. Metallic silver, and not Ag_2S, was formed when an electrode of AgCl + S was discharged in 0.5M $MgCl_2$.

The reaction between sulfur and discharged silver according to

$$2e^- + 2AgCl \rightarrow 2Ag + 2Cl^-$$

$$2Ag + S \rightarrow Ag_2S$$

$$2e^- + 2AgCl + S \rightarrow Ag_2S + 2Cl^- \quad [4]$$

appears to be slow. Thus the addition of sulfur will not affect the AgCl/Ag potential.

The addition of sulfur to highly reversible mercurous chloride electrodes has no significant effect on the Hg/Hg_2Cl_2 potential.

Behavior in alkaline electrolyte.—The effect of the sulfur on cupric oxide electrodes in alkaline solution

Table I. Addition of sulfur and sulfides to positive electrode active materials

Electrode composition, w/o, electrolyte	Discharge polarization measurements, v 500 μa (1.6 ma/cm²) (ma-min discharged)	Open-circuit voltage after interruption	Observations during open-circuit recovery
Sulfur			
75% sulfur 25% graphite 0.5*M* $MgCl_2$	−0.60v *vs.* SCE (31 ma-min)	0.13	Increase from −0.1 to +0.13 over 16 hr period (no step)
75% sulfur 25% graphite 30% KOH	−0.36v *vs.* HgO (106 ma-min)	−0.35	Good reversibility, potentials become more negative as sulfur dissolves
Copper compounds			
100% CuCl 0.5*M* $MgCl_2$	−0.22v *vs.* SCE (45 ma-min)	−0.136	Steady after 1 hr
67% CuCl 33% sulfur 0.5*M* $MgCl_2$	0.225 (100 ma-min)	0.230	Increase immediately to +0.230v and is steady for > 4 hr
60% CuCl 30% sulfur 10% graphite 0.5*M* $MgCl_2$	0.220 (30 ma-min)	0.230	Increase to +0.252v after 16 hr
100% CuBr 0.5*M* $MgCl_2$	−0.300 (15 ma-min)	−0.180	Increase to −0.195v after 30 min and −0.180v after 16 hr
75% CuBr 25% sulfur	0.186 (90 ma-min)	0.210	Constant after 1 hr and remains steady > 4 days
90% CuI 10% graphite 0.5*M* $MgCl_2$	−0.43 (59 ma-min)	Approx. −0.24 indeterminate	Slow recovery depending on extent of reduction
67% CuI (1-F.W.)* 23% S (2-F.W.) 10% graphite 0.5*M* $MgCl_2$	0.02 (141 ma-min)	0.21	Rapid rise to 0.15v, slow to final value
90% CuO 10% graphite 0.5*M* $MgCl_2$	−0.4v initial −0.78v after 16 hr	−0.26	−0.29v after 1 hr −0.26v after 5 hr
75% CuO 25% sulfur 0.5*M* $MgCl_2$	−0.55	−0.023	After 1 hr
100% CuO 30% KOH	−0.49v *vs.* HgO (60 ma-min)	−0.22	Steady after 1 hr
95% CuO 5% sulfur 30% KOH	−0.34 (30 ma-min)	−0.075	Steady after 1 hr
71.4% CuO (1-F.W.) 28.6% sulfur (1-F.W.) 30% KOH	−0.22 (186 ma-min)	−0.20	After approx. 1 hr No dissolved S/S⁻⁻
83.2% CuO (2-F.W.) 16.8% sulfur (1-F.W.) 30% KOH	−0.223 (122 ma-min)	−0.177	After 16 hr, sol'n light blue
86.5% CuO (10-F.W.) 3.5% sulfur (1-F.W.) 10.0% graphite 30% KOH	−0.22 (40 ma-min)	−0.170	After 16 hr; sol'n water-clear with sl. blue color
Other heavy metal salts			
90% AgCl 10% graphite 0.5*M* $MgCl_2$	−0.080 (20 ma-min)	−0.025	Increase from −0.50 to −0.025v over 16-hr period
100% AgCl 0.5*M* $MgCl_2$	−0.340 (90 ma-min)	−0.039 (>2 hr)	High resistance, likely due to poor contact
60% AgCl 30% sulfur 10% graphite 0.5*M* $MgCl_2$	−0.079 (50 ma-min)	0.150	−0.031v after 1 hr, increase to 0.150v after 48 hr
30% AgCl 40% Ag_2S 20% sulfur 10% graphite 0.5*M* $MgCl_2$	−0.090 (148 ma-min)	0.150	Remains at approx. −0.042v for 3 hr, increases to 0v at 3½ hr, 6 hr 0.135, 22 hr 0.150
79.5% AgO (1-F.W.) 20.5% sulfur (1-F.W.) 30% KOH	0.21 (538 ma-min)	0.250	Stable potential, finely divided black suspension
87.9% Ag_2O (1-F.W.) 12.1% sulfur (1-F.W.) 30% KOH	0.21 (87 ma-min)	0.300	After 24 hr recovery, OCV increased 50 mv
70.6% Ag_2O (1-F.W.) 9.8% sulfur (1-F.W.) 10.2% Ag_2S 30% KOH	0.215 (110 ma-min)	0.300	Ag_2S addition of no value. Black suspension (Ag_2S) forms
89.1% Ag_2O (2-F.W.) 6.1% sulfur (1-F.W.) 4.8% graphite 30% KOH	0.24 (72 ma-min)	0.315	Rapid final OCV recovery
98.6% Ag_2O (10-F.W.) 1.4% sulfur (1-F.W.) 30% KOH	0.205 (33 ma-min)	0.238	Initial OCV of 0.40v steady for 10 min, then dropped rapidly to 0.27v

Table I. Addition of sulfur and sulfides to positive electrode active materials (con't.)

Electrode composition, w/o, electrolyte	Discharge polarization measurements, v 500 μa (1.6 ma/cm²) (ma-min discharged)	Open-circuit voltage after interruption	Observations during open-circuit recovery
90% Hg_2Cl_2 10% graphite	−0.03 (123 ma-min)	0.00	Immediate recovery to 0v. Stable at 0v for over 16 hr
60% Hg_2Cl_2 30% sulfur 10% graphite 0.5*M* $MgCl_2$	−0.054 (30 ma-min)	0.0	Stable at 0.0v > 16 hr
30% Hg_2Cl_2 40% HgS 20% sulfur 10% graphite 0.5*M* $MgCl_2$	−0.06 (56 ma-min)	0.00	Steady at 0v > 3 days
98.6% HgO (1-F.W.) 1.4% sulfur (1-F.W.) 30% KOH	−0.025v (*vs.* HgO ref) initial OCV. After 4 days open-circuit stand OCV dropped to −0.4v as solution acquired yellow polysulfide color.		

Reference electrode potential *vs.* standard hydrogen electrode
$Hg/HgCl_2$, sat'd KCl + 0.243v
Hg/HgO, 30% KOH + 0.098v
* (F.W.) is formula weight or stoichiometric ratio of active components only.

is different from that in acidic electrolytes. The reaction

$$CuO + S \rightarrow CuS + (1/2)O_2 \qquad \Delta G_o = 18.7 \text{ kcal} \quad [5]$$

has a positive free energy, and consequently the spontaneous formation of CuS cannot occur on open circuit. Stable open-circuit potentials of CuO mixed with increasing amounts of sulfur (weight per cent) are shown in the following tabulation. The electrode potentials were measured in 30% KOH against a mercuric oxide reference electrode.

Electrode composition	Potential, v *vs.* Hg/HgO
CuO + 0% S	−0.22
CuO + 5% S	−0.07
CuO + 16% S	−0.18
CuO + 29% S	−0.23

These results indicate that the increase in electrode potential is greatest with relatively small additions of sulfur. With 30% sulfur the potential is the same as for pure CuO (—0.22v *vs.* Hg). A 40% sulfur addition would be equivalent to a 1:1 stoichiometric ratio. Electrodes of pure sulfur in KOH show a potential of about —0.4v *vs.* HgO, which depends also somewhat on the concentration of dissolved sulfur. The S/S^{--} couple is quite reversible in alkaline electrolytes. The experimental results can therefore be explained by the strong tendency of sulfur to form its own electrode potential in KOH, resulting in a mixed potential with electrodes containing both CuO and S. With very small amounts of sulfur, however, a voltage increase of nearly 0.2v is realized due to the electrode reaction $2e^- + CuO + S + H_2O \rightarrow CuS + 2(OH)^-$. The addition of sulfur to Cu_2O gives a greater voltage increase than that of sulfur to CuO, this in agreement with the free energy of the reaction $2e^- + Cu_2O + 2S + H_2O \rightarrow 2CuS + 2(OH)^-$. During discharge of sulfur-containing copper oxide electrodes at low current densities the duration at the higher voltage level never exceeded the time corresponding to the stoichiometric quantity of sulfur consumed according to the above reactions. However, with large quantities of sulfur present the S/S^{--} couple begins to impose its potential on the electrode, lowering it to —0.4v, which is impractically low.

The effect of the sulfur addition to Ag_2O and HgO positive materials in alkaline solutions was also investigated. Ag_2O is somewhat soluble in alkaline electrolytes and will react with sulfur since the reaction $Ag_2O + S \rightarrow Ag_2S + \frac{1}{2} O_2$ has a free energy of —7.0 kcal.

The electrode potential of Ag/Ag_2O in 30% KOH is 0.25v *vs.* Hg/HgO. The addition of small percentages of sulfur produced potentials as high as 0.35v *vs.* HgO for short periods of time, until the sulfur was substantially consumed at the surface of the electrode. Theoretically, the couple

$$2e^- + S + H_2O + Ag_2O \rightarrow Ag_2S + 2(OH)^- \quad [6]$$

would have a potential of 0.45v *vs.* HgO. With large sulfur additions the open-circuit voltage is about 0.30v *vs.* HgO and steady for several hours, before it decays to the potential of sulfur.

The voltage of the reversible Hg/HgO couple in 30% KOH is not noticeably affected by addition of small amounts of sulfur. With larger amounts of sulfur, the electrode potential is decreased due to the influence of the S/S^{--} couple. The reaction

$$HgO + S \rightarrow HgS + \frac{1}{2} O_2 \qquad \Delta G_o = 3 \text{ kcal} \quad [7]$$

has a positive free energy and does not proceed in the presence of oxygen at atmospheric pressure. The couple, $2e^- + HgO + S + H_2O \rightarrow HgS + 2(OH)$, does not exert a measurable influence.

Discussion

Thermodynamics of the sulfide formation.—An extensive investigation of metal sulfide electrodes in aqueous solutions was carried out by Wrabetz in collaboration with Noddack and Herbst (17-19). These investigators measured the electrode potentials of a large number of metal sulfides in solutions containing the respective cations and found that the sulfides have their own electrochemical potential series which is shifted toward more noble values than that of the respective parent metals. Many of the metal sulfides studied exhibited electrode potentials depending on the activity of the dissolved cation in conformity with the Nernst relationship (17). Wrabetz and co-workers conclude, as Piontelli (20) already had for galena (PbS), that the potential increase ΔE of the metal sulfide electrode over that of the metal is related by

$$\Delta G_o = -z_e F \Delta E \quad [8]$$

to the free energy of formation ΔG_o of the sulfide. According to Wrabetz (17), these sulfide potentials arise as a result of the nonideality, or the nonstoichiometry, of the metal sulfides. The excess of sulfur contained therein reacts according to

$$2e^- + S \text{ (sulfide)} + M^{++} \rightarrow MS \quad [9]$$

Since only a small quantity of excess sulfur or cation vacancies exist in the crystal lattice, very little capacity can be withdrawn in either direction. A comprehensive discussion of the electrode mechanism responsible for the potential of the cupric sulfide elec-

trode is given by Amlie and Ruetschi in the preceding paper (14).

Sulfur addition to the $Cu/CuO/OH^-$ *electrode.*—The electrode mechanism of the cupric oxide electrode during discharge in alkaline solution has been studied recently by Flerov (10). He found that the electrode discharges at two distinct potential levels corresponding to the cupric and cuprous oxide reduction, respectively. He also prepared an "activated" oxide containing about 0.15% sulfur which could be discharged almost entirely at the upper potential level at the 4 ma/cm^2 rate. Flerov suggests that the upper potential level corresponds to the reduction of Cu_2O according to

$$2e^- + Cu_2O + H_2O \rightarrow 2Cu + 2(OH)^- \quad [10]$$

with a potential of —0.35v *vs.* N.H.E. or —0.45v *vs.* Hg/HgO. The cuprous oxide likely exists in a hydrated form and is readily reducible at the Cu/Cu_2O potential. Cuprous oxide is formed by chemical reaction between CuO and Cu, and this formation is shown to be enhanced by intimate mixing, long rest periods, elevated temperature, and preliminary discharge.

Flerov attributes the lower potential level of the two-step discharge curve to the polarized electrochemical reduction of solid-phase CuO

$$2e^- + 2CuO + H_2O \rightarrow Cu_2O + 2(OH)^- \quad [11]$$

He omitted two experiments which would have given greater substantiation to his proposed mechanism. If the CuO electrode had been reduced at sufficiently low discharge rates to allow time for the simultaneous formation of Cu_2O, only the higher potential plateau should have been observed. Also, the discharge of an electrode containing Cu_2O as the only oxide would have provided further confirmation.

Flerov attributes the beneficial effect of the small quantity of sulfur added to an improvement of the conductivity of cuprous oxide. Sulfur is an effective electron acceptor which is said to increase the "hole" conduction of Cu_2O, a p-type semiconductor. Consequently, the reaction between Cu and CuO is accelerated since charge transfer across the intermediate layer of Cu_2O is now facilitated.

It should be emphasized that the higher potential level maintenance mechanism described by Flerov is entirely different from the potential increase phenomena described in the present study. His work explains the improved potential maintenance due to addition of small quantities of sulfur as described in the patent literature (2-7) and elsewhere (8). This mechanism requires that the sulfur be incorporated into the crystal lattice of the cuprous oxide to be effective throughout discharge. In contrast, our findings relate to a new electrode couple in which sulfur is electrochemically consumed, and a potential above that of the Cu_2O/Cu and CuO/Cu_2O electrodes is realized.

Conclusions.—1. The addition of sulfur to the cuprous chloride electrode was found to increase the voltage of the cuprous chloride-magnesium battery by 0.35 to 0.45v and to promote a more efficient utilization of the cuprous chloride active material. This discovery constitutes an important advancement in the technology of this system since a considerably greater power output per cell and is realized by the addition of a very inexpensive substance.

2. Generally, the addition of sulfur to electrochemical couples of the types metal/metal oxide or metal/metal halide may produce a voltage increase which is accounted for by the reaction

$$ne^- + M_xB_y + S \rightarrow M_xS + B_y^{-n} \quad [12]$$

whereby the corresponding metal sulfides are formed. However, this reaction is not always dominant over the component processes

$$ne^- + M_xB_y \rightarrow M_x + B_y^{-n} \quad [13]$$

$$2e^- + S \rightarrow S^{--} \quad [14]$$

Theoretically, the maximum potential increase attainable can be calculated from the free energy of formation of the metallic sulfide, although this increase is not always attainable experimentally.

Traces of free sulfur excess in metal sulfide electrodes in solutions of corresponding cations may produce electrochemical couples analogous to (12), namely

$$ne^- + xM^{n+} + S \text{ (sulfide)} \rightarrow M_xS \quad [15]$$

However, no sustained discharge is possible due to the limited amount of sulfur present.

3. The potential of the copper halide electrodes can also be increased by addition of certain sulfur-containing compounds such as metal sulfides. Cupric sulfide, added to cuprous chloride, produced an increase of 0.25-0.30v which is less than that attained by the addition of sulfur.

4. Sulfur is an electrochemically active material which attempts to establish its own potential when in a solution containing sulfide, polysulfide, or complexed sulfide ions. While the S/S^{--} couple is ineffective in neutral or acid solutions, it is quite reversible in alkaline electrolytes.

If large amounts of sulfur are added to a positive electrode in an alkaline electrolyte, the sulfur will tend to impose its own potential on the system and the electrode potential will approach that of the sulfur/sulfide ion couple, which is impractically low. With small amounts of sulfur present, an increased voltage may be observed over a short transient period on account of the mechanism (12).

5. Sulfur incorporated into the crystal lattice of Cu_2O may greatly decrease the polarization resistance during discharge of copper oxide electrodes, due to increased conductivity.

Oxidation Studies on Ni and on a 0.37 w/o Cr-Ni Alloy in CO_2 and in CO_2-CO Mixtures

K. Fueki[1] and J. B. Wagner, Jr.

Materials Research Center and Department of Materials Science,

The Technological Institute, Northwestern University, Evanston, Illinois

ABSTRACT

The linear oxidation of pure Ni and a 0.37 w/o (weight per cent) Cr-Ni alloy in reduced pressures of CO_2 was studied between 900° to 1300°C. It was found that the linear rate constants are proportional to the pressure of CO_2 and that the constants of the 0.37 w/o Cr alloy are several times larger than those of pure Ni. The linear oxidation in CO_2-CO mixtures was found not to obey the rate equation, $\overset{o}{n}/A = k' p_{CO_2} - k'' p_{CO}$. Disagreement of the observed results with the above rate equation is interpreted to be due to a nucleation and growth phenomenon whereby the oxide grains are discontinuous over the surface.

The over-all processes of metal oxidation involve the surface reactions at both interfaces and the material transport through the growing oxide layer. When the reaction is governed by the transport process through the compact oxide layer, the oxidation is parabolic, while the linear oxidation is observed when the reaction is controlled by a surface reaction, especially that at the oxide-gas boundary.

Since linear oxidation has been observed only in a few cases, the kinetics of linear oxidation have not been well established. The purpose of this paper is to present kinetic data for the linear oxidation of nickel, undoped and doped with chromium, in CO_2 and in CO_2-CO mixtures.

Linear oxidation in CO_2-CO mixtures has been studied on iron and cobalt. Hauffe and Pfeiffer (1) found the linear rate constant of iron to be proportional to $(p_{CO_2}/p_{CO})^{2/3}$ and have suggested a chemisorption mechanism. Pettit and his co-workers (2, 3) have shown that the linear rate of oxidation of iron obeys a rate equation

$$\overset{o}{n}/A = [k'p_{CO_2} - k''p_{CO}] \qquad [1]$$

where $\overset{o}{n}$ is the number of equivalents of oxide formed per unit time, A is the area, p_{CO_2} and p_{CO} are the partial pressures, and k' and k'' are constants. The second term in brackets of Eq. [1] accounts for the reverse reaction due to the presence of CO in the gas mixture. In general, the constants k' and k'' are functions of the composition of the oxide, in particular, the concentration of excess electrons or electron holes. In the case of the oxidation of iron to wüstite in CO_2-CO mixtures, Pettit and Wagner (3) have inferred that the Fe/O ratio in the wüstite is virtually fixed at that coexisting with metallic iron during the initial kinetics (for thin oxide layers). Accordingly, the concentration of excess electrons and electron holes is fixed and does not appear explicitly in the rate equation, Eq. [1]. Pettit and Wagner (3) have proposed the rate-determining step for the linear oxidation of iron to be the dissociation of carbon dioxide into carbon monoxide and adsorbed oxygen atoms or ions in accordance with a theory of C. Wagner (4).

The linear oxidation of cobalt in CO_2-CO mixtures has been studied by Pettit and Wagner (5). They found that oxidation proceeded by two successive regions of linear kinetics in the initial period of oxidation. It was also found that the rates during the first linear kinetics obeyed Eq. [1] but the second ones did not.

[1] Present address: Department of Industrial Chemistry, University of Tokyo, Tokyo, Japan.

Experimental and Results

Oxidation rate measurements.—Sheets, 0.15 mm thick, of pure nickel and nickel doped with 0.37 w/o chromium were used for the experiments. Their analyses are listed in Tables I and II. Specimens, 8 mm wide and 2 cm long, were cut from the sheets, polished with 1/0, 2/0, 4/0 emery papers and with Linde "A" alumina abrasives, washed with soap and water and then with acetone, and dried. The polished specimens were annealed in purified hydrogen overnight at 550°C to remove strain.

The oxidation rates were measured gravimetrically. The measurements below 1200°C were conducted using an Ainsworth automatic recording balance and its accessories described by Pettit and Wagner (5). The measurements above 1250°C were carried out by means of a quartz spring balance and high-temperature furnace described in a previous paper (6).

The reduced total pressures of the CO_2 and CO were produced by using pure argon as the diluent gas. Linear flow rates of 0.9 and 2.7 cm/sec were employed below 1200° and above 1250°C, respectively.

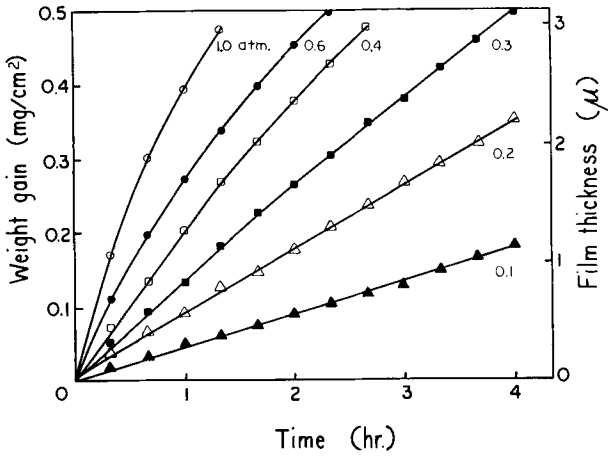

Fig. 1. Oxidation curves of pure Ni oxidized in different pressures of CO_2 at 1100°C.

Figure 1 shows the oxidation curves of pure Ni oxidized in different pressures of CO_2 at 1100°C. The distinct linear portion was observed in the initial period of oxidation, when the pressure of CO_2 was less than about 0.4 atm. The critical film thickness at which the transition from linear to parabolic oxidation rates occurs were found to be 2-5μ depending on the temperature and the pressure of CO_2.

Typical oxidation curves of the 0.37 w/o Cr alloy are shown in Fig. 2. As in the case of pure nickel, linear oxidation is observed for oxidation in reduced pressures of CO_2. The critical film thicknesses for the onset of linear kinetics were found to range from 4 to 36μ.

The linear rate constant, k_L (g-cm^{-2}-sec^{-1}), is determined from the slope of the weight gain *vs.* time plot. The dependence of the linear rate constants of both metals on the pressure of CO_2 is shown in Fig. 3 and 4. The linear rates are proportional to the pressure of CO_2 and are expressed by an equation

$$k_L = k' p_{CO_2} \qquad [2]$$

where k' is a constant and is numerically equal to k_L at 1 atm of CO_2. This result indicates that the rate-determining step of linear oxidation is the surface reaction at the oxide-gas interface.

Figure 5 shows the Arrhenius plots of k'. The plot for pure nickel is straight, while that for the 0.37 w/o Cr alloy has a break point at 1200°C. The rates for the oxidation of the 0.37 w/o Cr alloy are several times larger than those of pure nickel. The activation energies are given in Table III.

Because only a very small content of CO in the gas phase could be tolerated before the oxide would be reduced, the extensive measurements of rate as a function of CO/CO_2 ratio as reported for iron (2, 3) and for cobalt (5) could not be carried out. However, the effect of CO on the oxidation was studied at a pressure of 0.3 atm of CO_2. Typical oxidation curves

are shown in Fig. 6 and 7. The percentage of CO given in these figures shows the ratio of p_{CO} to p_{CO_2}. Both the linear rates and the parabolic rates decrease with an increase in the content of CO. Figures 8 and 9 show the plots of k_L *vs.* p_{CO}. In these figures, the notation, equil, denotes the dissociation pressures of nickel oxide in terms of the CO/CO_2 ratio. The linear rate constant, k_L, decreases nonlinearly with the increase

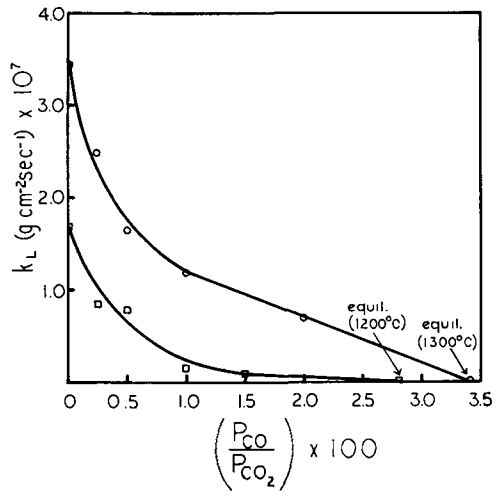

Fig. 9. Effect of CO on k_L of a 0.37 w/o Cr alloy; p_{CO_2} = 0.3 atm; ○, 1300°C; □, 1200°C.

in p_{CO}. These results show that Eq. [1] does not hold since k_L is proportional to n/A (2-4). A nonlinear relation between k_L and p_{CO} was found by Pettit and Wagner for the linear oxidation of cobalt (5) in CO_2-CO mixtures.

It is known that parabolic oxidation kinetics are related to the point defects in the oxide layers formed. In order to obtain information on the defects in nickel oxide doped with chromium oxide, parabolic oxidation was also studied as a function of temperature and oxygen pressure. Figure 10 shows the temperature dependence of parabolic constants at 1 atm of CO_2. In this figure, Ni (II) is the pure nickel used in the present study and Ni (I) is the one employed in the previous work (6). The rate constants of Ni (II) are very close to those of Ni (I). The parabolic rate constants of the 0.37 w/o Cr alloy are about 10 times larger than those of pure Ni. The Arrhenius plot of the data for the 0.37 w/o Cr alloy has a break at 1200°C. The activation energies are given in Table III.

Microscopic observation.—The surface of oxidized specimens was examined microscopically. The surface

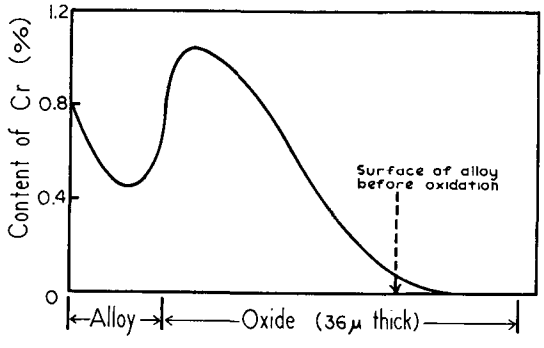

Fig. 13. Distribution of chromium in oxide formed on a 0.37 w/o Cr alloy, 1300°C, 6 hr, 0.3 atm of CO_2.

of nickel oxidized in pure CO_2 was found to be completely covered with well-faceted, coarse oxide grains, as shown in Fig. 11. When pure nickel is oxidized in CO_2-CO gas mixtures, a thin, continuous oxide film consisting of grains of irregular shape was formed. In addition, in some regions there were well-faceted, thick oxide grains. The covering with the well-faceted oxide grains seemed to be high when the content of carbon monoxide was low and the period of oxidation was long. The faceted oxide grains had corners of angles of 60° and 120°, as is seen in Fig. 11. Since nickel oxide is a cubic crystal, the facets are identified as having {111} planes parallel to the substrate.

The cross section of an oxidized alloy is shown in Fig. 12. The scale is thick and distinct oxide layers are not observed. Some apparent voids are present in the oxide. Some second phase (presumably Cr_2O_3) is present in the metal indicating internal oxidation.

Studies by electron microprobe.—In order to investigate the distribution of chromium in oxide film, the cross section of alloy specimens oxidized in 0.3 atm of CO_2 at 1100° and at 1300°C were examined by electron microprobe. A typical distribution of chromium in the oxide is shown in Fig. 13. The concentration of chromium is about three times higher than that in the unoxidized alloy near the metal-oxide interface and is very low at the oxide-gas interface.

The accumulation of chromium near the metal-oxide interface could be a result of the inward movement of particles of chromium oxide as markers. The low concentration at the oxide-gas interface could be due to the low solubility of Cr_2O_3 in NiO and the low diffusivity of chromium ions in NiO, as well as the inward movement of the chromium oxide particles.

Discussion

Nickel oxide is a metal deficit semiconductor exhibiting predominately electronic conductivity *via* electron holes. Excess oxygen may be dissolved in the crystal according to

$$\tfrac{1}{2}\,O_2 = (2-n)\oplus + (Ni_{\square''}\cdot n\oplus) + NiO \qquad [3]$$

where n has values of 0 to 2, and is usually an integer, $Ni_{\square''}$ denotes a cation vacancy and $(Ni_{\square''}\cdot n\oplus)$ denotes a cation vacancy with n trapped electron holes, $\oplus$. Under the usual assumption of dilute solution, the mass action relation is

$$K = [\oplus]^{(2-n)}\left[\left(Ni_{\square''}\cdot n\oplus\right)\right]/p_{O_2}{}^{1/2} \qquad [4]$$

where the brackets denote concentrations. When $n = 0$, the electron holes are completely dissociated from the cation vacancies, and the concentrations of vacancies and holes are proportional to the sixth root of the oxygen partial pressure. Such behavior has been reported at 1300°C for undoped single crystals of NiO by Mitoff (7). At 1000° and 950°C, Wagner and von Baumbach (8) report a pressure dependence of 1/4.5, and between 1200° and 850°C, Eror (9) finds the pressure dependence to be ¼. These data suggest that one electron hole is trapped on each cation vacancy ($n = 1$ in Eq. [4]).

The introduction of Cr_2O_3 in NiO changes the concentration of defects in the crystal. Mass action law consideration (10, 11) shows that the concentration of electron holes is decreased while that of cation vacancies is increased by the addition of Cr_2O_3. Conductivity studies of NiO doped with Cr_2O_3 have been carried out at 800°C by Hauffe and Block (10). Their studies show that the conductivity of doped crystals is 10^3 times smaller than that of the undoped one and therefore the concentration of holes in doped NiO is much smaller. The increase in the concentration of cation vacancies by the introduction of Cr_2O_3 is corroborated by oxidation studies. C. Wagner and Zimens (11) and Zima (12) have found that the parabolic oxidation rate of nickel doped with chromium is greater than undoped nickel. This was also found in the present study. These data show that the cation vacancy concentration in NiO is increased when chromium is added and consequently diffusion of nickel across the reaction product layer is increased during oxidation.

When the oxidation was conducted in pure CO_2, the linear rate constants of pure Ni and of the 0.37 w/o Cr alloy were found to be proportional to p_{CO_2}. It was also found by microscopic observations that the surfaces of specimens are completely covered with coarse grains of oxide during this linear oxidation. These results indicate that the rate-determining step is the surface reaction on the coarse grains of oxide. The surface reaction can be represented by the following elementary steps

$$CO_2 \rightarrow CO + O\ (ads) \qquad [5]$$

$$CO_2 + \ominus \rightarrow CO + O^- \text{ (ads)} \quad [6]$$

$$CO_2 + 2 \ominus \rightarrow CO + O^= \text{ (ads)} \quad [7]$$

If step [5] is predominant, the linear rate should be independent of the activity of electrons in the oxide at the oxide-gas interface, while the linear rate should depend on the activity of electrons, if either step [6] or [7] is predominant.

As discussed above, the concentration of electrons in doped NiO is higher than that in pure NiO. Although the concentration of chromium found at the oxide-gas interface of oxidized alloy is fairly low, a small amount of chromium would be present there. Therefore, the concentration of electrons at the surface of oxide formed on the 0.37 w/o Cr alloy would be higher than that formed on pure Ni. Since the linear rate constants of the 0.37 w/o Cr alloy is much higher than that of pure Ni, a correlation between the linear rate constant and the concentration of electrons is noted. In this case, either one of steps [6] and [7] could be the rate-determining one.

When carbon monoxide was present, the extent of the surface area which was covered with coarse grains of oxide was less than when pure CO_2 was used. Furthermore, the coverage decreased with the increase in CO content. The disagreement of the observed results with Eq. [1] could be due to the incomplete covering with coarse grains, especially since Pettit and Wagner (3) have shown that the linear rate of oxidation is a function of the crystal plane of the oxide that is exposed to the gas.

Summary

The oxidation of nickel and of a 0.37 w/o Cr alloy in reduced pressures of carbon dioxide is linear in the initial oxidation period. The linear rate constants of both metals are proportional to the pressure of CO_2. The rate-determining step is considered to be the surface reaction at the oxide-gas interface. The linear rate constants of the 0.37 w/o Cr alloy are several times larger than those of pure Ni. Thermodynamic consideration of the defects in nickel oxide with or without chromium oxide and the related experiments indicate there is a higher concentration of electrons in doped NiO. Either one of the reaction steps, $CO_2(g) + \ominus \rightarrow O^-$ (ads) + CO(g) or, $CO_2(g) + 2 \ominus \rightarrow CO(g) + O^=$ (ads), is proposed to be rate controlling. Disagreement of the results observed in CO_2-CO mixtures with the equation, $n/A = k' p_{CO_2} - k'' p_{CO}$, is attributed to the fact that the surface was not completely covered with coarse oxide grains which formed during the later stages of linear oxidation.

The Effect of Nitrogen on the Oxidation of Tantalum at High Temperatures

John Stringer

Metal Science Group, Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio

ABSTRACT

The effect of nitrogen on the oxidation of tantalum has been studied at 600°, 820°, and 925°C. In all cases, the oxygen partial pressure was close to 360 Torr; nitrogen partial pressures in the range 0 to 250 Torr were investigated. At all three temperatures, nitrogen reduces the rate of oxidation, the effect increasing with temperature. Although the oxidation in pure oxygen follows a linear rate law, with nitrogen present the reaction ceases to be linear. The interpretation of the results in terms of the existing kinetic models is discussed. It is suggested that the pressure drop associated with the flow of the gas through the porous outer scale cannot be neglected.

The oxidation of tantalum at pressures not too remote from atmospheric in the temperature range 500°-950°C has been studied in some detail over the past decade. There is now general agreement on the temperature dependence of the reaction rate, the variation of the reaction rate with oxygen pressure, and the general features of the reaction morphology (the physical distribution of the reaction products in space). In spite of this general agreement, the reaction mechanism remains unclear.

McLintock and Stringer (1) demonstrated that the oxidation of niobium was retarded by the presence of small amounts of nitrogen in the atmosphere, an effect later confirmed by Kolski (2). This effect was somewhat surprising. Mayo *et al.* (3) had oxidized niobium-chromium alloys in mixed atmospheres and found that the presence of nitrogen markedly increased the rate, a result which can easily be rationalized in terms of the Wagner-Hauffe model. It appeared therefore that the effect of nitrogen on the oxidation of

tantalum not only might be interesting in itself, but also might act as an additional experimental variable to assist in the elucidation of the reaction mechanism. This paper describes some results of an investigation of the effect. Before discussing the results of the experiments, it is necessary to describe the reaction of tantalum with oxygen in this temperature range and to outline briefly the kinetic models which have been developed to account for the experimental results.

Reaction of Tantalum with Oxygen

Kinetic Results

All the investigations of the reaction kinetics reported in the literature appear to have been performed on "coupon" specimens, rectangles cut from sheet. For specimens of this shape, the reaction rate over this temperature range is substantially linear

$$w = k_l t + a \qquad [1]$$

where w is the weight of oxygen absorbed at time t, k_l is the linear rate constant, and a is a reaction constant. In some temperature ranges the linear reaction is preceded by a nonlinear step, but this initial reaction is usually short. The empirical rate constant k_l must be regarded with some suspicion, because for coupon specimens the accumulation of oxide on the metal surface is not uniform, thicker layers being formed at the specimen edges and corners. This nonuniformity of oxide accumulation is reflected in the metal removal, which is also greater at the specimen edges and corners, although it has not yet been demonstrated that there is no lateral flow of oxide during the reaction. The nonuniformity is not marked until the temperature exceeds 600°C, and below 950°C the thickness at the corners is only about twice that at the centers of the faces of a specimen. Above this temperature, however, the effect becomes much more marked.

The absolute values of the empirical linear rate constants obtained by different investigations show substantial agreement. Figure 1 shows the rate constants from four investigations, normalized to an oxygen pressure of 760 Torr using the pressure-dependence data of Cowgill (4). Over the range 600°-800°C the temperature dependence of the reaction rate is very small. From 500° to 600°C and from 800° to 950°C, the temperature dependence can be described

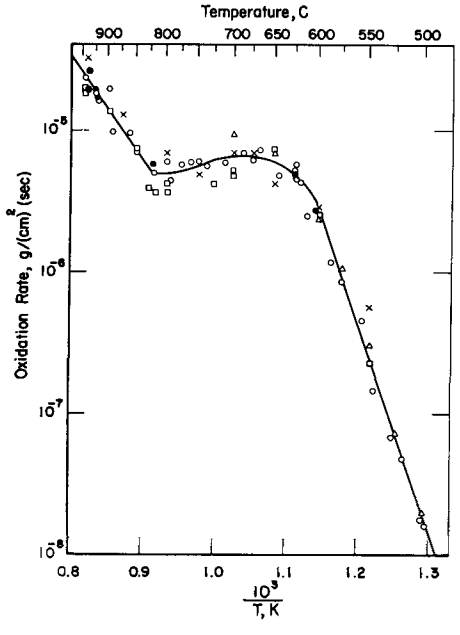

Fig. 1. Arrhenius graph of linear rate constants for the oxidation of tantalum. Rates are normalized to an oxygen pressure of 760 Torr, after Cowgill (4). ○, Cowgill (4); △, Kofstad (5); □, Albrecht (6); x, Peterson (7); •, present investigation.

by Arrhenius relations, although with different activation energies. However, in view of the uncertainty of the absolute significance of the rate constant k_l, this type of analysis is not justified.

The pressure dependence of the rate constant is also well documented. Peterson (7) first studied the pressure dependence over the temperature range 500°-800°C and at pressures from 0.5 through 40 atm. The results could be satisfactorily described in terms of an equation having the form of a Langmuir isotherm

$$k_l = \frac{k_1 k_2 p}{1 + k_2 p} \qquad [2]$$

where p is the oxygen pressure, and k_1 and k_2 are reaction constants. Cowgill and Stringer (8) studied the pressure dependence at lower oxygen pressures and suggested that theirs and Peterson's results would be better described by an equation of the form

$$k_l = k_1 \left(\frac{k_2 p^{1/2}}{1 + k_2 p^{1/2}} \right) \qquad [3]$$

Kofstad (5) has also studied the pressure dependence of the reaction, obtaining results in substantial agreement with Cowgill. More recently, in a study of the oxidation of niobium, McLintock (9) used the empirical equation

$$k_l = k_1 \left(\frac{k_2 p}{1 + k_2 p} \right)^{1/2} \qquad [4]$$

which, although very similar in form to Eq. [3], produced a slightly better fit to his results. Above approximately 750°-800°C, the available experimental results are fitted by the equation

$$k_l = k_3 p^{1/2} \qquad [5]$$

which is in fact the limiting form at high temperatures and low pressures of Eq. [3] and [4].

Morphological Results

The principal reaction product in this range is the low-temperature modification of tantalum pentoxide, Ta_2O_5. In addition, oxygen dissolves in the metal, and specimens cooled and sectioned for metallographic examination after oxidation show light gray, optically active platelets extending into the metal from the metal/oxide interface (5, 10-18). At lower temperatures (below 800°C) these appear to be a metastable tetragonal suboxide, which has been designated TaOz by Kofstad. Above this temperature there is some uncertainty; Kofstad (19) suggests that they may be TaO, with NaCl structure; Vaughan *et al.* (20) have observed similar plates precipitated from supersaturated solid solutions of oxygen in tantalum which were shown to be Ta_2O_5.

The gray suboxide platelets form parallel to prominent crystallographic planes in the tantalum, although there is some disagreement as to which plane they are parallel (10, 14-17).

Although in the very early stages of oxidation more than half the total oxygen absorbed dissolves in the metal, once the linear reaction is well established 95% or more of the oxygen absorbed is present as Ta_2O_5. The pentoxide appears to grow adherently on the metal surface, apparently under considerable compressive stress (21). These stresses eventually cause the oxide to break away from the metal (6), and oxidation starts immediately on the freshly exposed surface. The ruptured oxide forms a detached porous laminated layer. Below 600°C the detached oxide is loose and flaky, falling away from the metal on cooling. However, as the temperature increases, the scale becomes more continuous; at 950°C it has good mechanical strength, although it is still porous.

Figure 2 is a schematic diagram of the cross section of an oxidized tantalum sample after cooling to room temperature.

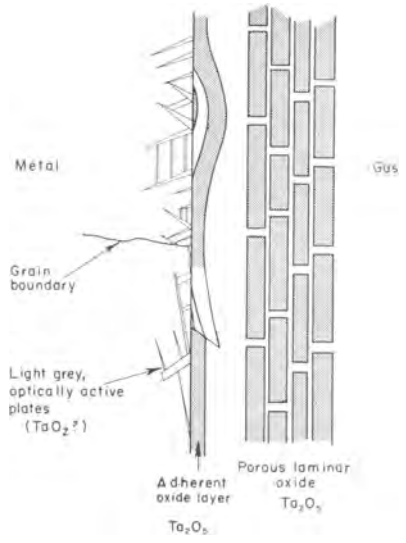

Fig. 2. Schematic drawing of the cross section of an oxidized tantalum specimen after cooling to room temperature.

Effect of Nitrogen

There have been few studies of the tantalum-nitrogen-oxygen system, either kinetic or equilibrium. Schönberg (22) has reported four metallic phases in the pseudobinary TaO-TaN system, and Wasilewski (23) has reported an oxy-nitride having the approximate formula $Ta_2(O_x\ N_{1-x})$. Nitrogen, like oxygen, dissolves interstitially in tantalum. The solubility is approximately 0.5 a/o (atomic per cent) at 950°C, falling to 0.25 a/o at 600°C (24). The oxygen solubility, for comparison, is 2.5 a/o at 950°C and approximately 1.2 a/o at 600°C (10). The diffusion of nitrogen in tantalum is described by the equation

$$D = D_0 \exp(-Q/RT)$$

where $D_0 \cong 0.006$ cm²/sec and $Q = 38.0$ kcal/mole (25) while for oxygen Peterson's (26) analysis of the data leads to $D_0 = 0.02$ cm²/sec, $Q = 27.6$ kcal/mole. At 600°C, this corresponds to a diffusivity of 2.1×10^{-12} for nitrogen and 2.7×10^{-9} for oxygen. At 950°C the figures are 1.1×10^{-9} and 2.5×10^{-7}, respectively. It appears therefore that before the specimen is saturated with oxygen, the amount of nitrogen that will diffuse in will be very small. For example, if oxygen and nitrogen are assumed to be diffusing simultaneously into a tantalum sheet at 950°C in such a manner that the surface concentration is always equal to saturation, then when the sheet has absorbed 90% of all the oxygen it can dissolve, the fractional saturation of nitrogen is 7%. Since the solubility of nitrogen is at least five times smaller than that of oxygen, inward diffusion of nitrogen into the metal is unlikely. Nitrogen apparently does modify the diffusion of oxygen at very low concentrations, but the effect is roughly similar to increasing the oxygen concentration (27).

Albrecht *et al.* (6) have studied the oxidation of tantalum in air but were unable to detect any change in the reaction products. In particular, the lattice spacing of Ta_2O_5 was unaffected, which suggests that any solubility of nitrogen in Ta_2O_5 is small.

Ta_2O_5 has been reported to be an n-type semiconductor containing oxygen vacancies (28), in which case the presence of the higher valent anion N^{3-} should increase the concentration of vacancies. However, Kofstad more recently (29) has reported that the defect structure is more complicated. The oxide is n-type at low oxygen concentrations, but p-type at higher pressures; Kofstad suggests that this implies the presence of reverse Frenkel defects, namely, oxygen interstitials and oxygen vacancies. In this case, the effect of nitrogen cannot be predicted with certainty.

Table I. Manufacturer's analysis of the tantalum sheet

Tantalum 99.90 min.

It appears therefore that the most likely effect of nitrogen will be to form metallic oxynitrides, presumably at the metal surface. The effect of such new phases on the oxidation reaction again cannot be predicted.

Experimental Materials and Methods

Specimen Preparation

Specimens were cut in the form of rectangles approximately 3 x 0.5 cm from 0.050-in. (0.127 cm) sheet produced by Fansteel. An analysis of the material as supplied by the manufacturer is shown in Table I. Although it appears that the oxidation kinetics are not affected by minor variations in surface preparation, some care was taken to achieve a good surface finish. After hand grinding through 600-grade metallographic polishing papers, the specimens were first chemically polished for 10 min in a 1:2:5 mixture of hydrofluoric, acetic, and sulfuric acids, and then electropolished for 30 sec at a potential of 20v in a sulfuric acid-10% hydrofluoric acid electrolyte at 45°C, using a carbon cathode. After this treatment, the specimen had a bright uniform polish, with a very slight grain-boundary etch. Talysurf measurements indicated that the surface roughness was approximately 2 μin. Immediately prior to the admission of oxygen to the oxidation apparatus, the specimen was vacuum annealed at a pressure of 10^{-6} Torr for 1 hr at reaction temperature. A microhardness traverse of the cross section of a specimen prepared in this way showed that the hardness was quite uniform at 140 DPN, with no tendency for the surface to be harder than the interior. This hardness corresponds closely to that expected on the basis of the manufacturer's analysis.

The specimens had a fine equiaxed grain structure, with a mean grain diameter of approximately 3×10^{-3} cm.

Apparatus

Volumetric methods are preferable to gravimetric for the study of the oxidation of tantalum, because of the loose powdery scale formed at the lower temperatures. Furthermore, volumetric methods are more flexible than gravimetric, although not quite so accurate. Preliminary experiments showed that very little nitrogen was absorbed by the specimen from a mixed atmosphere, so that the problem in a constant-pressure experiment becomes one of replacing the oxygen absorbed from the atmosphere without altering the nitrogen content. This was achieved by bubbling oxygen from the gas buret into the system through a mercury column so that the partial pressures of both gases in the reaction volume remained constant. The total reaction volume is approximately 150 cm³. Details of the design and operation of the apparatus will be published elsewhere.

Metallography and Analysis

In order to prevent the brittle oxide from crumbling during preparation and to prevent "rounding" of the specimen edges, the specimen was mounted between two pieces of glass in epoxy resin and then sectioned, using a diamond cut-off wheel. The cross section was

then prepared mechanically in the conventional manner and lightly etched.

The specimens and scales were analyzed for oxygen and nitrogen, using both vacuum fusion and micro-Kjeldahl methods. In general, the quantity of oxygen was so great that vacuum fusion methods would have been unable to detect quite substantial amounts of nitrogen; for example, in the extreme case of the oxide, 1000 ppm of nitrogen could easily have remained undetected. The micro-Kjeldahl method does not suffer from this disadvantage, but measures the nitrogen directly.

Microhardness traverses on specimen cross sections were performed. Both Knoop and diamond indenters were used, but the diamond indenter gave much more satisfactory results. For most measurements, a 25-g load was used. Because of the fine grain size, it was often difficult to obtain satisfactory microhardness results.

Results

The temperature range 625°-800°C, in which the linear rate constant varies only slightly with temperature, is difficult to interpret and may represent a transition region. Accordingly, for this investigation, temperatures in this range have been avoided. With the dimensions of the present apparatus, the study of very slow reactions is not easy, so low temperatures also have not been studied. These considerations determined three temperatures for detailed study: 925°, 820°, and 600°C. In addition, a small number of oxidations have been performed at 940° and 625°C. The oxygen pressure for most of the experiments was close to 360 Torr; a few experiments were performed with pressures as high as 400 Torr. The nitrogen partial pressure was varied from 10 through 225 Torr.

In addition to these constant-pressure experiments, some "constant volume" experiments of the type described by Stringer and Cowgill (8) were performed at 600° and 625°C.

Effect of Nitrogen at 600°C

The effect of nitrogen on the oxidation rate at 600°C is shown in Fig. 3. The effect is not great; the rate is diminished appreciably by nitrogen, but the appearance of the scale or the suboxide platelets is not appreciably affected. Micro-Kjeldahl analysis shows that neither the scale nor the metal contains any nitrogen. Figure 4 shows a typical cross section of the metal. In addition to the lateral fissures in the scale parallel to the metal surface, the chains of voids through the scale should be noted; these appear in most cases to originate above suboxide plates.

The pressure dependence of the reaction rate in the absence of nitrogen is shown in Fig. 5. As can be seen, the pressure-dependence curve is repeatable and agrees very closely with the constant-pressure results. Furthermore, the curve is reproduced closely from specimen to specimen. The curve drawn through the results is obtained by fitting Eq. [4] through two arbitrary points; the curve shown has

$$k_1 = 3.144 \times 10^{-6}$$

$$k_2 = 3.50 \times 10^{-3}$$

when the rate is given in g/(cm²)(sec). The value of the rate obtained from this equation by setting $p_{O_2} = 760$ Torr is plotted in Fig. 1; it agrees with the results obtained in constant-pressure experiments by other authors.

A number of similar experiments were performed using oxygen-nitrogen atmospheres. In this case, although the curve could be repeated over the same specimen, less satisfactory agreement was obtained with the constant-pressure results. This is scarcely surprising, since as Fig. 3 shows, the rate curves in the mixed atmospheres are not rectilinear. The effect of nitrogen is to increase k_1 and decrease k_2; when $p_{N_2} = 25.6$ Torr, $k_1 = 3.600 \times 10^{-6}$, and $k_2 = 2.00 \times 10^{-3}$; when $p_{N_2} = 112$ Torr, $k_1 = 4.659 \times 10^{-6}$, and $k_2 = 0.873 \times 10^{-3}$.

Effect of Nitrogen at 820°C

As Fig. 6 shows, the effect of nitrogen is much more marked at 820°C. Again, analysis of the scale and the metal showed no detectable amounts of nitrogen. Careful examination of specimen cross sections failed to show any difference in the suboxide morphology as the nitrogen content of the atmosphere increased. Figure 7 shows microhardness traverses performed on three specimens oxidized for the same length of time, but with different amounts of nitrogen present. The hardness profile is the same in each case, indicating that nitrogen does not modify the oxygen solution process.

It seemed possible that the curvature of the rate plots when nitrogen was present might be due to a slow approach to a new linear rate. If this is so, it follows that the slope of the curve, dw/dt, should

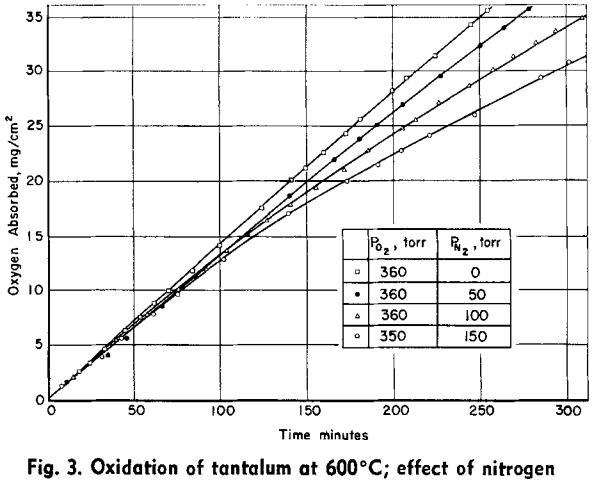

Fig. 3. Oxidation of tantalum at 600°C; effect of nitrogen

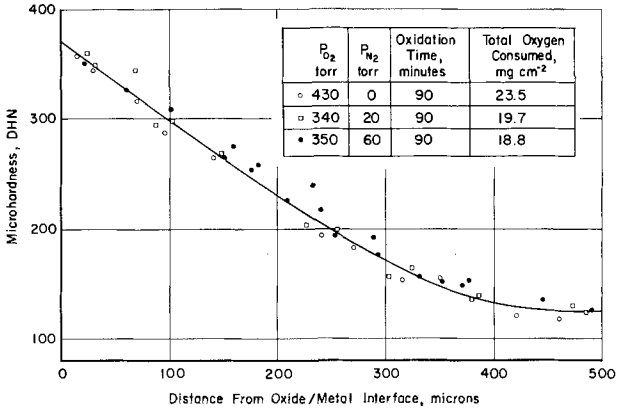

Fig. 7. Oxidation of tantalum at 820°C; microhardness traverses of oxidized specimens.

approach a constant value as t approaches infinity. Such a tendency is difficult to see graphically, but it follows that if dw/dt is plotted against the reciprocal of time, so that $t = \infty$ is the ordinate, a rate curve of any form tending to a straight line at long times should intersect the ordinate horizontally at a positive value. A graph of the rate curves at 820°C plotted in this fashion is shown in Fig. 8. It is clear that for partial pressures of nitrogen in excess of 50 Torr this interpretation is untenable. It cannot be said that the rate curves become linear at any time for nitrogen contents greater than this in the reaction times studied in this investigation.

Cowgill has demonstrated that at this temperature and in this pressure range the rate is proportional to

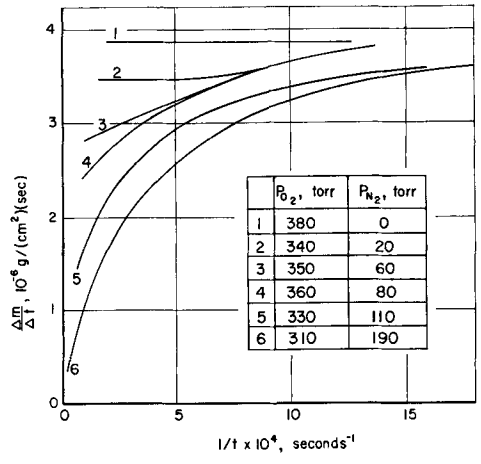

Fig. 8. Oxidation of tantalum at 820°C; effect of nitrogen

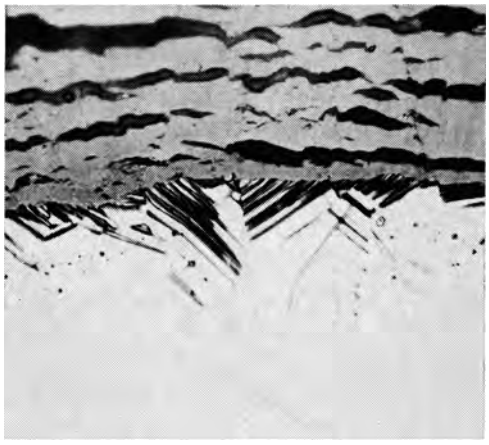

Fig. 9a. Cross section of specimen oxidized for 345 min at 820°C, showing adherent oxide layer; $p_{O_2} = 300$ Torr; $p_{N_2} = 160$ Torr. Normal illumination. Magnification 750X.

Fig. 9b. Same as Fig. 9a except with polarized light

the square root of oxygen pressure; points calculated on this basis from runs performed without nitrogen are included in Fig. 1. Again, the agreement with previous results is very good.

Apart from the change in the oxidation rate, nitrogen produced two effects. The scale appeared to adhere to the metal more strongly as the nitrogen increased, and (for a given weight of scale) the inequality in development of the scale increased, the edge growth becoming more pronounced. It was difficult to determine whether the adherent layer thickness (w_c) increased as the nitrogen content increased, since sufficient scale adhered only to specimens oxidized in atmospheres

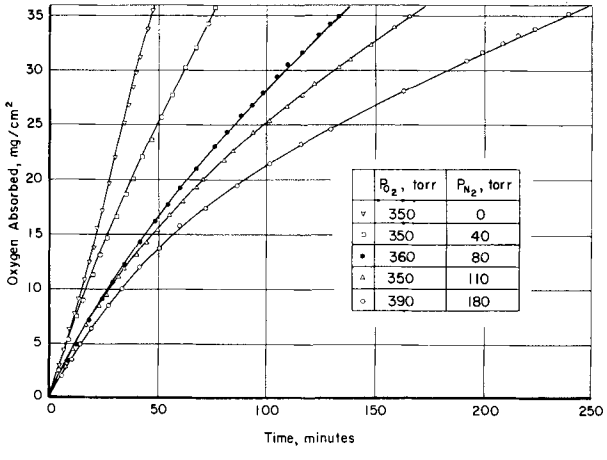

Fig. 10. Oxidation of tantalum at 925°C; effect of nitrogen

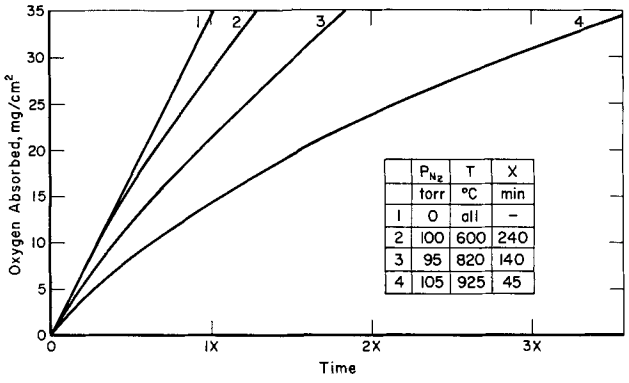

Fig. 11. Relative effect of 100 Torr nitrogen on the oxidation of tantalum at three temperatures; p_{O_2} = 360 Torr. X is chosen so that the curves p_{N_2} = 0 superimpose at all three temperatures.

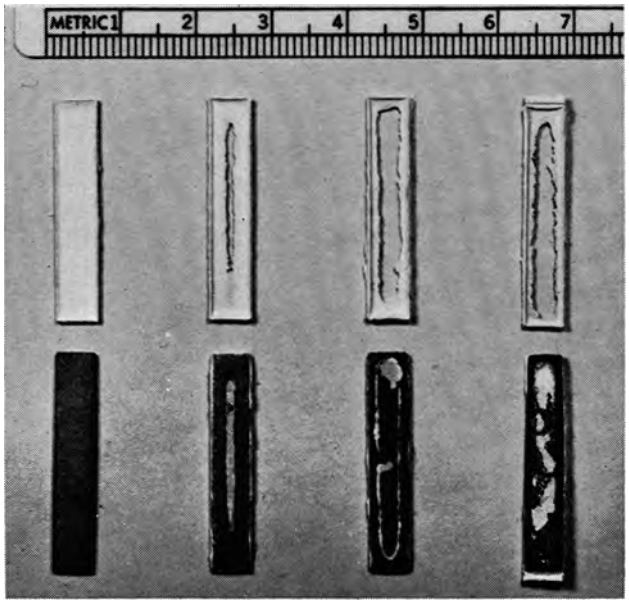

Fig. 12. Oxidation of tantalum at 925°C. The white scales (upper) have separated from the specimens (lower) on cooling. The holes in the separated layers correspond to the still-adhering oxide. All specimens were oxidized in an oxygen partial pressure of approximately 360 Torr to a total weight gain of 45 mg/cm². From left to right, the nitrogen partial pressures and oxidation times, respectively, are: 0 Torr, 54 min; 40 Torr, 100 min; 80 Torr, 180 min; and 180 Torr, 325 min.

containing a significant amount of nitrogen. The adherent layer is shown in Fig. 9a and b for a specimen oxidized in an atmosphere containing 160-Torr nitrogen. Tentatively, it appears likely that the thickness is less on specimens oxidized in atmospheres containing less nitrogen, but this conclusion is based on less than satisfactory metallographic evidence.

Effect of Nitrogen at 925°C

Figure 10 shows the effect at 925°C. Figure 11 shows the effect of 100 Torr of nitrogen on the rate at the three temperatures. The time scale is normalized so that the rate curves for pure oxygen at all three temperatures superimpose. This time the effect of the nitrogen on the oxide morphology and adherence is sufficiently marked to be evident on a photograph; Fig. 12 shows four specimens oxidized to the same total weight gain in atmospheres containing respectively 0-, 40-, 80-, and 180-Torr nitrogen.

Once again, the results in the absence of nitrogen are in excellent agreement with earlier investigations and are included in Fig. 1.

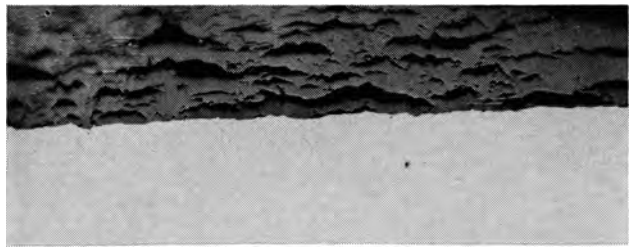

Fig. 13a. Unetched cross section of a specimen oxidized for 106 min at 925°C, showing adherent oxide layer; p_{O_2} = 400 Torr; p_{N_2} = 0. Normal illumination. Magnification 200X.

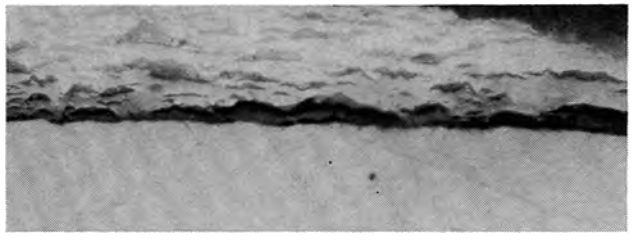

Fig. 13b. Same as Fig. 13a except with sensitive tint illumination

Fig. 14. Cross section of specimen oxidized 185 min at 925°C; p_{O_2} = 355 Torr; p_{N_2} = 110 Torr.

Now, definite differences appear in the scale and platelet morphology. Figures 13a and b show the adherent oxide layer in the absence of nitrogen. Figure 14 shows a specimen oxidized in an atmosphere containing 110-Torr nitrogen. In addition to the dark gray Ta_2O_5 and the light gray optically active platelets, large amounts of a light gray phase can be seen. Although this can only be distinguished with difficulty from the light gray suboxide in this figure, it has little or no optical activity in polarized light. Attempts to identify the phase have failed so far. It is present only in the scale formed on the centers of the large specimen faces, where the scale is adhering; the adherent scale looks dark on the specimen. This specimen contains significant amounts of nitrogen; it is likely therefore that the light gray phase is an oxynitride.

Discussion

A linear oxidation rate may be attained in two ways. The rate-controlling process may be an interface reaction whose rate is independent of the oxide thickness; in this case the rate is truly linear on a microscopic scale. Alternatively, the mechanism may be one of the so-called "paralinear" processes. Suppose that the oxide grows on the metal surface, its rate of growth being determined by the diffusion of one or both of the reactants through the oxide layer. The rate of growth of this adherent layer will in fact be parabolic

$$w^2 = k_p t + a \qquad [6]$$

where k_p is the parabolic rate constant. If the compressive growth stresses in the layer are high enough, the layer will fail, either in shear or by blistering from the metal surface, when the scale reaches a critical thickness ω_c. If the failure process is such that pores or other passage are formed through the separated layer, so that it presents little obstacle to the inward flow of molecular oxygen, a new adherent oxide layer will again grow parabolically on the freshly exposed surface. A thickness, ω_c, is added to the porous outer oxide layer every t_c seconds, where

$$t_c = \frac{\omega_c^2}{k_p}$$

and the over-all rate is therefore linear, with

$$k_l = \frac{\omega_c}{t_c} = \frac{k_p}{\omega_c} \qquad [7]$$

Of course, this description coincides exactly with the observed morphology of the oxidation process. But as Murphy (30) pointed out in 1923, even a coherently forming scale will grow according to a linear rate law if one of the interface processes is slower than the transport process; the scale morphology does not assist, therefore, in determining the reaction mechanism.

However, it is well established that k_l is a function of pressure and, at low enough pressures over this temperature range, varies as the square root of the oxygen pressure. Consequently, if the paralinear mechanism is to account for the reaction rate, either or both of k_p and ω_c must depend on the oxygen pressure. If Ta_2O_5 is an oxygen-vacancy n-type semiconductor, Wagner's mechanism would imply that k_p would be independent of the oxygen pressure provided

$$p_{O_2} >> p_{eq} \qquad [8]$$

where here p_{eq} is the equilibrium pressure for the reaction

$$\frac{4}{5}Ta + O_2 \rightarrow \frac{2}{5}Ta_2O_5$$

At 950°C, p_{eq} is approximately 10^{-25} atm, so that the inequality is satisfied for all attainable pressures. It is difficult to see how ω_c can depend directly on the oxygen pressure, since ω_c should be a function of the growth stresses, the scale adherence, and the scale fracture strength. None of these should depend strongly on the oxygen pressure at low pressures. However, if, as Kofstad suggests, Ta_2O_5 is n-type at low oxygen concentration and p-type at higher, it follows that the adherent scale layer will have an n-p or n-i-p junction within it. The relative position of this boundary, and hence the defect transport rate, will then be pressure dependent. Unless a most unusual ionization is postulated for the mobile species, it is difficult to see how the pressure dependence of k_p can exceed $p^{1/4}$. However, although ω_c is probably not a function of oxygen pressure, it is likely to be a function of the oxidation rate and hence of k_p: if one assumes that, as the rate falls, ω_c increases, then this will magnify the apparent pressure dependence of k_l (32). In fact, there is some evidence that ω_c does increase as the oxidation rate decreases (at constant temperature) in both tantalum (31) and niobium (32). Therefore, it is not impossible that a paralinear process could be compatible with the observed pressure dependence.

A linear reaction rate involving a slow interface process was suggested by Cowgill and Stringer (4, 8). They pointed out that, in order to account for the pressure dependence, the interface must be a solid/gas interface and that, since x-ray evidence suggested that Ta_2O_5 grows coherently on the metal surface, the only available interface was that between the coherent Ta_2O_5 layer and oxygen. In particular, they suggested that the slow step was one of the reactions

$$O_2)_{ads} + 2\,O^{2-}\,\square/Ta_2O_5 + 4e \rightarrow 2\,O^{2-}/Ta_2O_5$$

or

$$O)_{ads} + O^{2-}\,\square/Ta_2O_5 + 2e \rightarrow O^{2-}/Ta_2O_5 \qquad [9]$$

However, it is difficult on the basis of a single process to account for the observed temperature dependence of the reaction rate. In the oxidation of niobium, the change in temperature dependence is apparently associated with the disappearance of suboxide plates, and so it is tempting to locate the rate-controlling reaction at a suboxide/oxygen interface and to postulate that at high temperatures the suboxide either vanishes or changes form. Two models in these terms have been postulated, by Kofstad (19) and by Ong (33). However, no good evidence of the existence of these interfaces has so far been produced; metallography always indicates an adherent Ta_2O_5 layer on the surface of both the metal and the suboxides.

Below 750°C, the results of Peterson (7) and Kofstad (5) are reasonably well fitted by Langmuir adsorption isotherms of the form of Eq. [3] or [4]. However, because of the multiple-specimen technique used by these authors, the fit is less than wholly convincing. For a given pressure range, at high temperatures the Langmuir isotherm becomes

$$\theta \sim k_1 k_2 p^{1/2}$$

where θ is the surface coverage; at low temperatures it becomes

$$\theta \sim k_1$$

so that only in an intermediate temperature range will the results have the form of Eq. [4] and [5]. Most authors are limited to two or three orders of magnitude change in pressure, and for the oxidation of tantalum this restricts the intermediate temperature range to about 100°C. Ong (33) has collected the results of a number of authors over a much wider pressure range, and while the results are compatible with a Langmuir-type behavior, the scatter in the data makes the identification less than certain. Ong's data suggest that for the pressure range attainable in the present apparatus, the optimum temperature for obtaining a Langmuir-type curve should be 600°C; as Fig. 5 shows, the fit to the McLintock Eq. [4] is very good and agrees well with the available results in the literature. On the basis of these results, it seems likely that, at least below 625°C, the oxygen concentration at the reaction interface is determined by an equilibrium adsorption process.

It is important to stress that this adsorption step is compatible with both the linear and paralinear mechanisms; both are demonstrably dependent on the oxygen concentration, and in either case this may be enhanced by adsorption.

Effect of Nitrogen

If nitrogen dissolved in Ta_2O_5, replacing O^{2-} ions on the anion lattice and forming N^{3-} ions, one would expect an increase in the concentration of oxygen vacancies. This should increase the rate of diffusion across the scale for the paralinear model, thus increasing k_p; if the surface reaction in the linear model is a reaction such as [9] the increase in vacancy concentration should also increase this rate.

Both Smith (34) and Kling (35) have remarked that alloy elements which would be expected to increase the oxygen vacancy concentration in Nb_2O_5 nevertheless decrease the linear oxidation rate of niobium. Smith suggests that the increase in vacancies makes plastic deformation of the scale easier, thus increasing ω_c. Kling suggests that the vacancies result in a reduction in the lattice parameter of the oxide, thus improving the scale/metal fit; again, the effect is to increase ω_c. However, Ashbee and Smallman (36) have shown that in the case of TiO_2 increasing the concentration of oxygen vacancies makes the material less, rather than more, ductile; and no change in lattice parameter of the Ta_2O_5 due to the nitrogen has been

detected. In spite of this, nitrogen apparently does improve scale adherence. The effect may be indirect, however; it is known that reducing the rate increases ω_c and hence the scale adherence, so that the improved adherence may be a consequence of the slowing down of the rate, not a cause of it.

Since there is good reason to believe that the oxygen is adsorbed on an interface, nitrogen may affect the surface concentration of oxygen. Nitrogen may be preferentially adsorbed, so that fewer sites are available for oxygen. The effect of this would be to reduce the oxygen concentration and thus the rate. However, in this case the effect should increase as the temperature decreases, as the surface concentration of the adsorbate increases. In fact, the reverse is true. Further, one would expect the establishment of a new linear rate, but in fact the rate becomes nonlinear.

The slow step in the linear model is a surface reaction, and it is therefore possible that a necessary step in the reaction is the formation of a complex of the form $O^{2-}/Ta_2O_5 \cdot O_{ads}$ prior to the actual incorporation. Nitrogen could result in the disruption of this complex by mechanical bombardment with nitrogen molecules and thus, without affecting the adsorption process or the surface oxygen concentration, reduce the rate by reducing the complex lifetime. The chances of this are slight if the surface coverage is noticeably higher than the atmospheric concentration of gas, but they increase relatively as the surface concentration diminishes. The effect would therefore increase with temperature, in agreement with experiment. However, once again, one would expect the establishment of a new linear rate; this model does not lead to a nonlinear process.

The literature survey suggests that the principal effect of nitrogen should be to modify the suboxides; in fact, at 925°C a phase which appears to be an oxynitride is formed. This could affect the oxide fit at the metal surface, and hence modify ω_c. Further, if with Kofstad and Ong one supposes that the reaction interface is that between the atmosphere and a suboxide, a change in rate is not unexpected. The effect of nitrogen on the suboxides is clearly greater at higher temperatures, and although no nitrogen was detected in the specimens oxidized at lower temperatures, the volume fraction of the suboxides is sufficiently small that they still could contain a significant amount of nitrogen. While one would again expect a new linear rate, this is no longer certain; the composition of the suboxynitrides could change as the reaction proceeds. However, as noted above, the metallographic evidence casts some doubt on the existence of oxygen/suboxide interfaces.

Gas-Flow Model

The rate-controlling reaction, irrespective of its nature, occurs in the general vicinity of the metal surface, inside the porous laminated outer scale. It follows that the oxygen pressure p_1 "seen" by the reaction is lower than the external pressure p_o. The difference

$$\Delta p = p_o - p_1$$

is determined by the oxygen flux required by the reaction and the permeability of the outer scale. Since the outer scale is obviously fairly porous, typically containing about 30 v/o (volume per cent) voids, it is customary to assume that Δp is very small and to ignore it. Further, if it were not small, Δp should increase as the porous scale layer thickens, thus leading to a nonlinear reaction rate for constant p_o. However, most of the voids in the scale are the fissures between the scale laminations parallel to the metal surface, and these do not contribute to the permeability through the scale. Further, although the scale is formed in compression on the metal surface, it breaks away to a strain-free position and thereafter is pushed outwards by the newly forming layers. The outer layers of the scale thus fail in tension, with fractures lying normal to the metal surface. The permeability of the porous scale is thus determined by the effectively constant thickness unfailed layer; as a result, the oxidation rate would be linear, and Δp may not be small. Normally, this difference between the external pressure and the reaction pressure will not be evident.

However, if nitrogen is introduced into the atmosphere, the inward-flowing oxygen will transfer momentum to the nitrogen molecules by ordinary collision processes (provided flow through the scale is Poiseuille rather than Knudsen), thus driving it toward the metal surface. The nitrogen pressure between the reaction zone and the porous scale will therefore increase above the external value. This partial pressure difference will produce a dynamic flow of nitrogen outwards, and eventually the system will approach a steady state. Now, however, the transfer of momentum from the oxygen to the nitrogen (and from the outward-flowing nitrogen to the oxygen) will increase the resistance to inward flow of oxygen, thus decreasing the apparent permeability of the scale, increasing Δp, and thus (for a constant external partial pressure of oxygen) decreasing the oxygen pressure at the reaction interface. Again, since this is a steady-state situation, one would expect a new linear rate. However, it appears probable that ω_c increases with decreasing rate; this should lead to a decrease in scale permeability as the rate falls, which again should magnify the effects described above. The rate will therefore become nonlinear. Plainly, the effect also should increase more or less progressively as the nitrogen content increases, in agreement with experiment. Finally, it is clear that the scale permeability decreases as the temperature increases, so that the effect of a given amount of nitrogen also should be greater at higher temperatures. The model is then

1. The reaction process, which may be any process capable of giving a linear or square root pressure dependence, is located in the general vicinity of the metal/suboxide/adherent oxide zone, inside the outer porous oxide.
2. The oxygen concentration "seen" by the reaction is that inside the porous scale and may be enhanced by an adsorption process.
3. The oxygen pressure inside the porous scale is appreciably less than that outside; the difference may not be great, but it is not negligible.
4. Gas flow through the relatively small pores normal to the scale laminations takes place by Poiseuille flow.
5. Nitrogen slows down the rate simply by absorbing momentum, although the effect is enhanced by the rate dependence of the porous scale permeability.

Since the effect of nitrogen is simply to accept momentum, it follows that the model predicts that

1. Argon, since its molecular weight is similar to that of both oxygen and nitrogen, should have roughly the same effect as nitrogen.
2. Helium should also slow the rate down, but because of its smaller weight, the effect should be appreciably less.

These predictions have not been fully checked yet. Although no thermal separation of O_2-N_2 and O_2-Ar atmospheres in the apparatus can be expected, some separation of O_2-He atmospheres will take place, so that the results of these last experiments must be treated with caution. The results of preliminary experiments at 925°C are shown in Fig. 15. As can be seen, the effect of argon is almost the same as that of nitrogen. Varying argon pressures have been used, and in all cases the results lie very close to the results obtained with nitrogen. Relatively few experiments with O_2-He atmospheres have so far been performed, but the results to date are in agreement with the curve shown. A more detailed study of the effect of inert gases will be described in a later paper.

The effect of the inert gases seems to confirm the model. Unfortunately, the model does not help to de-

	P_{O_2} torr	P_X torr	X
1	345	–	–
2	360	225	He
3	370	220	N_2
4	365	220	Ar

Fig. 15. Effect of 220 Torr of helium, argon, and nitrogen on the oxidation of tantalum at 925°C; $p_{O_2} \simeq 360$ Torr.

termine the nature of the rate-controlling process. However, since the effect at 925°C can be interpreted entirely in gas-flow terms, although nitrogen clearly modifies the suboxide phases, it does suggest that the Ong mechanism involving suboxides is incorrect.

Clearly, the idea that the rate of oxidation is determined by the pressure the reaction "sees" explains the observed more rapid growth of oxide at the edges and corners of a rectangular specimen, since at these positions fractures penetrate the scale close to the metal. This aspect of the hypothesis is also currently being tested, and results will be published later.

Finally, at 600°C the outer scale is relatively loose and flaky, but at 800°C it is strong and "sintered"; it is possible therefore that since the permeability of the scale clearly falls drastically between these temperatures, the change in temperature dependence may be explainable in this way. This last point has been made in the case of the oxidation of niobium by Aylmore *et al.* (37).

Essentially similar results have been observed in the reduction of hematite by hydrogen by McKewan (38); there, however, the rate remains essentially linear. Helium has slightly less effect on the reduction than nitrogen. These results are well fitted by a modified adsorption equation.

Conclusions

It appears that the pressure drop associated with the flow of gas through the porous outer scale in the oxidation of tantalum in the temperature range 600°-950°C cannot be ignored. Further, the critical scale thickness apparently increases as the rate decreases. These properties account for the observed effect of nitrogen on the oxidation rate and predict that the effect of argon will be much the same. Preliminary experiments confirm this prediction. Although the results do not help much in elucidating the nature of the rate-controlling process, they suggest that models involving suboxide surface reactions are incorrect.

Acknowledgments

Thanks are due to a number of people who have sent me their results and comments on the model described in this paper, most notably Dr. John Sheasby of McMaster University, Hamilton, Ontario, and Dr. William McKewan of the Edgar Bain Laboratories of United States Steel, Monroeville, Pa. Preliminary experiments were performed by Dr. M. G. Cowgill and Dr. C. H. McLintock at the University of Liverpool, England. Mr. R. O. Dodds and Mr. C. R. Rarey assisted with the experimental work, and the metallography was done by Mr. C. H. Brady. The research was supported by Battelle Memorial Institute.

Manuscript received May 17, 1965; revised manuscript received July 30, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Erratum

In the Extended Abstract book of the Electrothermics & Metallurgy Division for the Buffalo Meeting, Oct. 10-14, 1965, there is an error in Abstract 150, "The Interaction of Iodine with Zircaloy-2" by H. S. Rosenbaum. Delete the last sentence of the first paragraph, the sentence beginning "Since iodine . . ." and ending, ". . . clad with zirconium alloys."

Rotating Disk Study of the Dissolution of Zirconium in $HF-H_2SO_4$

R. E. Meyer and Sandra Massey Zettl[1]

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

The dissolution of crystal bar zirconium in mixtures of hydrofluoric acid and sulfuric acid has been investigated by use of a rotating disk electrode system. The presence of the sulfuric acid in relatively large amounts considerably reduces the rates as compared to solutions of hydrofluoric acid and nitric acid. In addition, the reaction, which is normally first order, changes to second order in the presence of large amounts of sulfuric acid. A kinetic equation which accounts for these results can be derived if it is assumed that both the hydrofluoric acid and the sulfate ion are adsorbed.

Of the common aqueous dissolution media, only solutions of HF significantly attack zirconium metal. Therefore this reaction has been the subject of a number of investigations.

Smith and Hill (1) investigated the dissolution of Zr in various aqueous solutions containing HF by measuring the buildup of ^{95}Zr in a solution that was circulated past a radioactive Zr electrode. They reported that the rate of dissolution is controlled solely by the rate of mass transfer of undissociated HF to the electrode. Their results also showed that the reaction proceeds with a rate of hydrogen evolution exactly equivalent to the rate of dissolution of the metal.

Dissolution rates in mixtures of HNO_3 and HF were determined by Vander Wall and Whitener (2) by use of a tracer method similar to that used by Smith and Hill. According to their results, the reaction is first order with respect to HF and has an activation energy of 6.4 kcal/mole.

Measurements have also been reported by Straumanis, James, and Neiman (3) and by James, Custead, and Straumanis (4). These investigators determined the rate of dissolution by determining the volume of the hydrogen gas evolved. They proposed that the reaction is the result of direct chemical attack of HF molecules on the metal.

The electrochemistry of this reaction was investigated by use of steady state and transient polarization techniques (5) and by use of the rotating disk electrode (6). These investigations show that the reaction is electrochemical in nature and that it proceeds by the continuous formation and dissolution of a film. Rate constants for the surface reaction between HF and the film were determined by the rotating disk study (6).

The electrochemistry of the reaction was investigated by Gilman and Kolotyrkin (7), who also conducted polarization experiments and concluded that the reaction proceeds electrochemically by the formation and dissolution of a film.

In the rotating disk study of the dissolution of zirconium (6), the rate constants of the surface reaction between HF and the zirconium in mixtures of HF and HNO_3 were determined. Interpretation of the results was relatively simple, since the reaction was first order with respect to HF. When the same experiments were done with H_2SO_4 instead of HNO_3, the rates were much lower than the rates in HNO_3, all other factors being equal. Because all factors were identical except that H_2SO_4 was substituted for HNO_3, it appeared that this might be an example of a specific anion effect on a reaction which supposedly was under the influence only of HF. For this reason, a more complete study of the $HF-H_2SO_4$ system was undertaken with the rotating disk electrode. These measurements included the determination of the capacity of the electrodes as a function of rotational velocity.

[1] Oak Ridge Institute of Nuclear Studies Summer Student Trainee (1963) from Texas Wesleyan College, Fort Worth, Texas.

Theory

Derivations of the equations applicable to the rotating disk have been summarized by Levich (8). The current at a rotating disk is given by the expression

$$I = nFSA(C - C_i)\omega^{1/2} \qquad [1]$$

where

$$A = 0.62\, D^{2/3}\gamma^{-1/6}$$

and S is the electrode area, C is the concentration of the reactant in the bulk of the solution, C_i is the concentration of the reactant at the interface, ω is the rotational velocity (rad/sec), D is the diffusion coefficient, and γ is the kinematic viscosity. If the reaction at the surface follows the equation

$$I = nFSk\,C_i^m \qquad [2]$$

then for $m = 1$ (first order)

$$\frac{1}{I} = \frac{1}{nFSk\,C} + \frac{1}{nFSA\omega^{1/2}\,C} \qquad [3]$$

If the reaction is first order, plots of $1/I$ *vs.* $1/\omega^{1/2}$ will be linear, and the rate constant k can be determined by extrapolation of the line to infinite frequency of rotation ($1/\omega^{1/2} \rightarrow 0$).

The treatment for the cases in which the order is not equal to unity is more complicated, and in general, the constant A must first be evaluated in order to determine k. If the reaction is second order ($m = 2$), the current will be given by the following expression

$$I = \frac{A^2\,nFS\omega}{4k}\left[\left(1 + \frac{4kC}{A\omega^{1/2}}\right)^{1/2} - 1\right]^2 \qquad [4]$$

This equation has been plotted for values of C, A, and k which correspond roughly to the values observed in the work here. These plots are illustrated in Fig. 1 and 2. At low values of ω the plots are linear, but they tend to curve at higher values of $\omega^{1/2}$. For the lowest value of C, the term $(4kC/A\omega^{1/2})$ under the square root sign is small compared to unity and a first-order approximation gives $I = nFkSC^2$. The resulting plots do not show a large per cent change in the reciprocal current as the rotational velocity is changed. (Note the greatly expanded scale of the vertical axis on the bottom plot of Fig. 2.)

Experimental

The experimental details are essentially identical to those described in ref. (1) except that solutions were prepared with sulfuric acid instead of nitric acid.

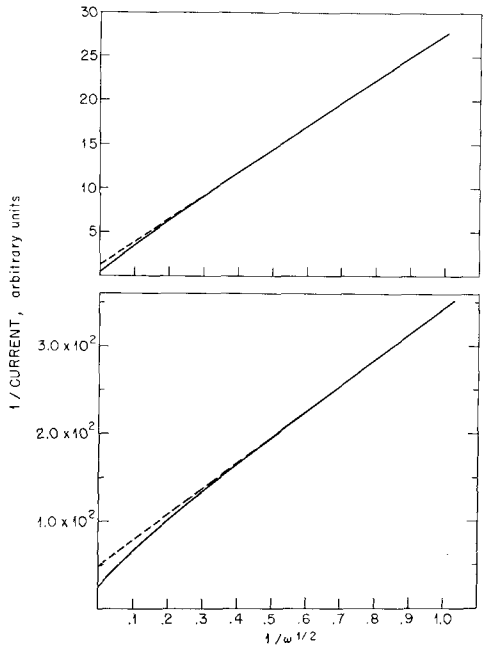

Fig. 1. Calculated $1/I$ vs. $1/\omega^{1/2}$ curves for a second order reaction. Top: C = 10^{-1}, A = 10^{-3}, K = 10^{3}; bottom: C = 10^{-2}; A = 10^{-3}; K = 10^{3}.

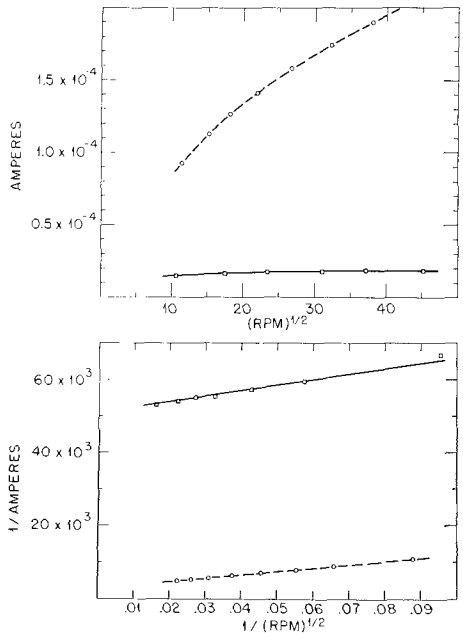

Fig. 3. Comparison of rotating disk plots for zirconium in HF-HNO_3 and HF-H_2SO_4. Electrode area = 0.318 cm^2: ——, 0.0011*N* HF, 1.8*N* H_2SO_4; — —, 0.0011*N* HF, 1.2*M* HNO^3, both —400 mv *vs.* S.C.E.

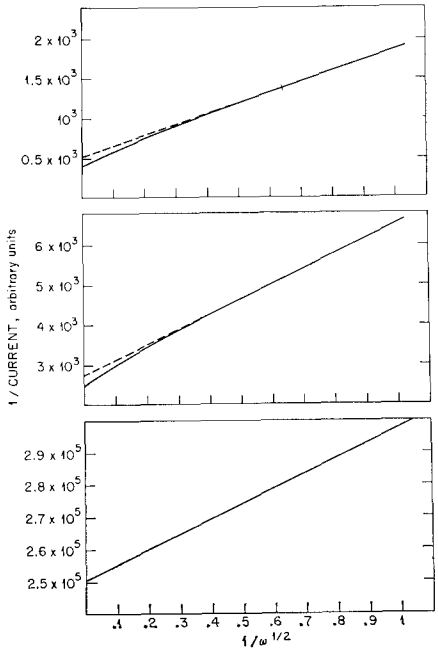

Fig. 2. Calculated $1/I$ vs. $1/\omega^{1/2}$ curves for a second order reaction. Top: C = 2.5 x 10^{-3}; A = 10^{-3}; K = 10^{3}; center: C = 10^{-3}; A = 10^{-3}; K = 10^{3}; bottom: C = 10^{-4}; A = 10^{-3}; K = 10^{3}.

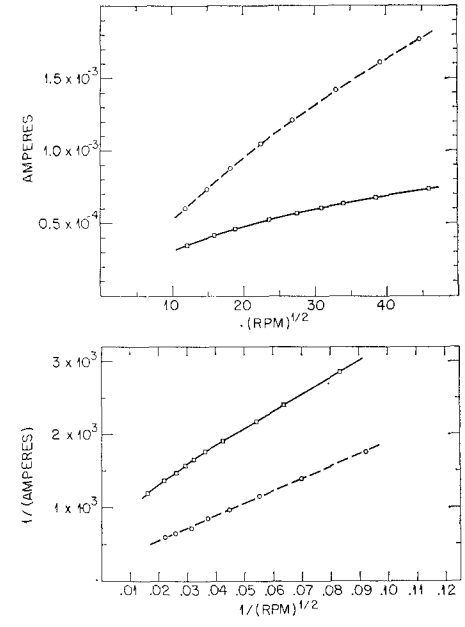

Fig. 4. Comparison of rotating disk plots for zirconium in HF-HNO_3 and HF-H_2SO_4. Electrode area = 0.318 cm^2; — —, 0.00532*N* HF, 1.2*M* HNO_3; ——, 0.0055*N* HF, 1.8*N* H_2SO_4, both —400 mv *vs.* S.C.E.

The capacity was measured by determining the slope of the plot of the electrode potential with time as a constant current pulse was applied. The capacity is then given by the current density divided by this slope, dV/dt. The apparatus used has already been described (5).

Results

The results of these experiments were obtained as a series of determinations of the current as a function of the potential, the rotational velocity, and the composition of the solutions. The potential was varied in steps of 100 mv from —600 to —300 mv *vs.* S.C.E. The concentration of HF was varied from 0.044*N* to about 0.001*N*, and the sulfuric acid concentration was varied from 1.8*N* to 0.0036*N*. The results obtained in HF-HNO_3 (6) are included here for comparison purposes. In Fig. 3-5, comparisons are made between the sulfuric acid and the nitric acid data for three concentrations of HF. Both the current as a function of the square root of the rotational velocity and the reciprocal current as a function of the reciprocal of the square root of the rotational velocity are shown. In each case, the currents for the HNO_3 solutions are greater, this effect being most pronounced for the solutions which contained the lowest concentrations of HF. Examination of the plots also shows that the relative difference increases as the rotational velocity is increased. In the lower sections of Fig. 3-5, com-

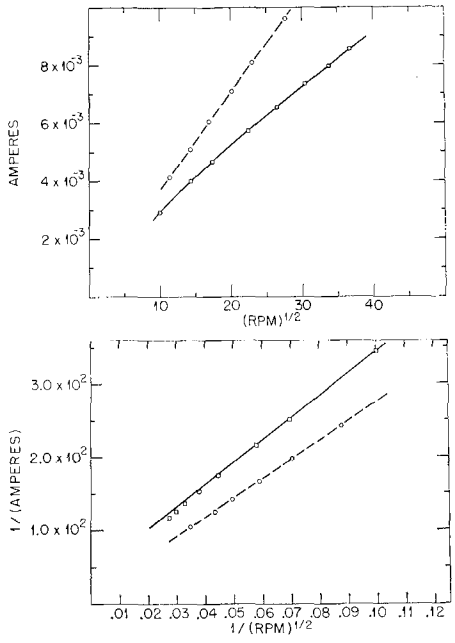

Fig. 5. Comparison of rotating disk plots for zirconium in HF-HNO_3 and HF-H_2SO_4. Electrode area = 0.318 cm^2; ——, 0.0440*N* HF, 1.8*N* H_2SO_4; — —, 0.0426*N* HF, 1.2*M* HNO_3, both —400 mv vs. S.C.E.

parisons are made of the plots of $1/I$ *vs.* $1/rpm^{1/2}$. The plots for the H_2SO_4 experiments are curved, but the plots for HNO_3 are linear.

The effect of potential on the current is illustrated in Fig. 6. At low values of the rotational velocity there is little effect, but at the highest values the current decreases slightly as the potential becomes more anodic, a somewhat unusual result. If a normal Tafel-like logarithmic relation held, a large increase in current as the potential becomes more anodic would be expected.

The effect of change of the concentration of H_2SO_4 is illustrated in Fig. 7. The currents for 0.036*N* and 0.18*N* H_2SO_4 are about the same, but the currents at the higher rotational velocities are markedly smaller for the 1.8*N* H_2SO_4 experiment. Similar patterns were observed in other experiments.

In some experiments, the capacity of the electrodes was also measured as a function of rotational velocity. The results of these experiments are shown in Table I, where it is shown that the capacity is quite small compared to double layer capacities. These results also

show that the capacity increases significantly as the current and rotational velocities increase.

Discussion

The effect of increasing the rotational velocity is to increase the concentration of the reactant at the interface and therefore to minimize the concentration difference between the interface and the bulk of the solution. If the reaction rate at the surface is fast enough, the reaction will be essentially under complete mass transfer control at the lowest velocities. As the rotational velocity is increased, the concentration at the interface is increased and consequently the rate of the surface reaction rapidly increases. Therefore, if a change in experimental conditions affects only the surface reaction, the effect will be most apparent at the higher rotational velocities. Any effects which change the mass transfer conditions will be present at the lower velocities. Since the effects of 1.8*N* H_2SO_4 were apparent only at the higher rotational velocities, it can be concluded that the sulfuric acid affects the surface reaction and has little or no effect on the mass transfer reaction.

Examination of the plots of $1/I$ *vs.* $1/\omega^{1/2}$ for the data in solutions of H_2SO_4 shows that the plots are not linear but resemble the second order plots shown in Fig. 1-2. In order to determine whether the reaction actually was second order, the logarithm of the concentration at the interface was plotted as a function of the logarithm of the current. The order is numerically equal to the slope of this line. The concentration at the interface was determined by rearranging Eq. [1],

which is valid generally for reactions of any order, to give

$$C_i = C - \frac{I}{nFSA\omega^{1/2}} \qquad [5]$$

The constant A in Eq. [5] was determined in these experiments from two different experiments at different values of C. Since the current is a function only of C_i, then if the currents are equal in two runs at two different values of C the values of C_i must be identical. Under these conditions, we may write

$$C_1 - I/nFSA\omega_1^{1/2} = C_2 - I/nFSA\omega_2^{1/2} \qquad [6]$$

where the subscripts refer to the two different runs. This equation may be solved to give A (or nFA if n is not known). When this was done, values of nFA between 28 and 29 were found.[2] These values were similar to those found in HF-HNO_3 where values from 28-33 were found.

By use of these techniques, plots of log of C_i *vs.* log I were made for all of the runs at 1.8*N* H_2SO_4 and all of the concentrations of HF. All of the data from 0.0055*N* HF to 0.022*N* HF lay on the same line, which had a slope of about 1.8. The 0.044*N* runs could be made to lie on the line by slight adjustment of the value of nFA. However, the values of the current for the 0.0022*N* and 0.0011*N* HF experiments fell well below the extension of the line. These lines were calculated for all potentials used, and an example of such a plot is shown in Fig. 8. Unfortunately it is difficult to say whether the reaction is exactly second order with experimental error accounting for the discrepancy or whether the order is actually 1.8 because of a complex mechanism or other complicating factors.

The capacity measurements showed that the values were small compared to the values one would expect from a solution double layer. It is difficult to interpret these low values in any other way than as a film capacity. The dissolution reaction, therefore, probably involves the continuous formation and dissolution of a film. As explained in ref. (5), the presence of the film can explain the lack of the dependence of the rate on the potential and also the increase in capacity with increasing current.

In the study of the HF-HNO_3 system, a first order dependence with respect to HF was found. In this study, however, a reaction order slightly less than two was found for high concentrations of H_2SO_4. As the concentration of H_2SO_4 was reduced, the plots of $1/I$ *vs.* $1/(\text{rpm})^{1/2}$ became more linear, indicating that the reaction was approaching first order. Further, the rate constants found by extrapolating these lines at the lower concentrations of H_2SO_4 were about the same as those found for the nitric acid case. The results obtained suggest, therefore, that the sulfate ion, if present in large quantities, is adsorbed on the surface of the film in such a way that the dissolution by HF is inhibited. The affinity of the fluoride and sulfate ions for the zirconium ion is well known and has been discussed extensively (9).

The second order dependence found in the sulfuric acid solutions may also be explained on the basis of adsorption of sulfate. Consider the following equations

$$HF + Zr_l^{+4} \rightarrow Zr(HF)_l^{+4} \qquad [A]$$

$$Zr(HF)_l^{+4} \rightarrow Zr_l^{+4} + HF \qquad [B]$$

$$HF + Zr(HF)_l^{+4} \rightarrow ZrF_2^{+2} + 2H^+ \qquad [C]$$

$$SO_4^{=} + Zr_l^{+4} \rightarrow ZrSO_4^{+2} \qquad [D]$$

$$ZrSO_4^{+2} \rightarrow Zr_l^{+4} + SO_4^{=} \qquad [E]$$

Equations [A] and [B] represent the reversible adsorption of HF; Eq. [D] and [E] represent the reversible adsorption of $SO_4^{=}$. The dissolution reaction is represented by Eq. [C] in which a complex containing two fluoride ions is formed; further complexing may occur in the solution.

The following kinetic expressions may be written

$$R_A = K_A(HF)(1 - \theta_1 - \theta_2) \qquad [7]$$

$$R_B = K_B\theta_1 \qquad [8]$$

$$R_C = K_C\theta_1(HF) \qquad [9]$$

$$R_D = K_D(SO_4^{=})(1 - \theta_1 - \theta_2) \qquad [10]$$

$$R_E = K_E\theta_2 \qquad [11]$$

Here θ_1 and θ_2 represent the fraction of the surface sites occupied by adsorbed HF and adsorbed $SO_4^{=}$, respectively. If steady state coverages in the θ's are assumed, the following expression for the over-all rate may be derived

$$R = \frac{K_AK_CK_E(HF)^2}{K_BK_D(SO_4^{=}) + K_CK_D(HF)(SO_4^{=}) + (K_CK_E + K_AK_E)(HF) + K_BK_E} \qquad [12]$$

If the sulfate ion concentration is very large, then it is possible for the first term in the denominator to dominate, so that

$$R \approx \frac{K_AK_CK_E(HF)^2}{K_BK_D(SO_4^{=})} \qquad [13]$$

Under these conditions, the reaction order with respect to the concentration of HF will be two, and there should be an inverse dependence in $SO_4^{=}$, as observed. If the sulfate ion is reduced, then the other terms containing HF will become significant, and the reaction will tend to approach first order. Again this assumes the appropriate values of the constants.

This explanation is undoubtedly simplified for there are other effects which will affect the rate of the reaction. Among these are possible variations in surface roughness and the influence of the thickness of the film. The zirconium electrodes were very easily passivated by slight anodic pulses in those solutions that contained small amounts of HF, and in extreme cases,

[2] In this computation of nFA, the units of concentration were moles per cubic centimeter and the units of ω were rpm.

this passivation produced visible films. It is quite possible that partial passivation may have occurred, in that only a portion of the surface was actively dissolving. It is also conceivable that the thicker films formed in the more dilute solutions were more resistant than the very thin films formed in solutions containing relatively large amounts of HF. Either of these effects may be the explanation for the very low rates found in the solution containing 0.0011*N* HF.

Manuscript received April 2, 1965; revised manuscript received July 30, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965. Research was sponsored by the United States Atomic Energy Commission under contract with the Union Carbide Corporation.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Devitrification of Tin Oxide Films (Doped and Undoped) Prepared by Reactive Sputtering

W. Robert Sinclair, F. G. Peters, D. W. Stillinger, and S. E. Koonce

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Tin oxide films doped with antimony oxide formed by reactive sputtering of tin-antimony alloy cathodes can be made conductive at room temperature by heating in air at elevated temperatures (*ca.* 710°C) if the atom per cent of antimony in the cathode is between 3.0 and 14%. The kinetics is quite complicated with room temperature resistance of quenched samples showing two minima as a function of time of heating. The kinetics is speeded up if carbon is applied to the sputtered film prior to firing. This treatment introduces oxygen vacancies and allows even indium doped films to be made conductive on firing. For 3500Å thick films of antimony doped tin oxide the highest conductivity obtained is 175 ohms $\square^{-1}$. The temperature coefficient of resistivity ranges from negative to +2000 ppm/°C, depending on composition.

Methods for preparing conductive tin oxide films have been known for some time, and the patent literature is rich on this subject (1). The films are usually prepared by hydrolyzing a volatile tin compound on a hot surface, *e.g.*,

$$SnCl_4 + 2H_2O \xrightarrow{500°\text{-}800°C} SnO_2 + 4HCl$$

In practice the volatile tin compound is dissolved in an organic compound such as ethanol, and the resulting atmosphere is reducing leading to oxygen deficient films.

Aitchison (2) has studied films made by the above reaction as well as films doped with 5% antimony oxide or 5% indium oxide. He found that the conductivity in all cases was electronic and that addition of antimony (presumably +5) ion increased the conductivity whereas addition of indium (presumably +3) ion decreased the conductivity as Verwey had also found (3).

Holland and Siddall (4) have prepared tin oxide films by reactive sputtering. Their technique involved activation of the cathode with oxygen before film deposition, and sputtering was then done in a 95% Ar-5% O_2 atmosphere. The objective was to obtain oxygen deficient conductive films. Heat-treatment of the film to 400°C was necessary, but the results were quite variable and impossible to predict.

We have previously shown (5) that tin oxide films prepared by reactive sputtering with deposition on unheated substrates are amorphous. These films are also electrically insulating. We, therefore, have the opportunity of separating the film deposition step and the crystallization reaction. It was our hope that we could thus obtain insight concerning the properties of conductive SnO_2 films which are far from being understood especially with respect to details involved with the preparation procedure (6).

Experimental Procedures

One of the possibilities for the variability in film resistance obtained by Holland and Siddall was lack of control of the concentration of oxygen vacancies. We decided to sidestep this difficulty as much as possible by completely oxidizing the film by sputtering in pure oxygen and introducing chemical defects by addition of indium or antimony by sputtering from an alloy electrode and/or subsequent reduction with carbon. This approach should allow for better reproducibility from experiment to experiment since precise control of the condition of the cathode or of the oxygen pressure in the system should not be required.

The apparatus used in the sputtering has been previously described (5). Deposition conditions were standardized as much as possible: 2-hr runs, 1500-1600v applied, 30 Mamp and 4 x 10^{-2} Torr of O_2. No attempt has been made yet to maximize the deposition rate which certainly can be increased greatly. Chemical descriptions of the films are in terms of the compositions of the electrodes used. For instance, what is termed a 10% antimony oxide film is prepared from an electrode containing 10 a/o (atom per cent) antimony and 90 a/o tin. The mole per cent of antimony oxide present in the resulting film assuming the products are Sb_2O_5 and SnO_2 is approximately one half of the electrode atom percentage, and in the particular example given is 5.26%.

Films were deposited onto cleaned fused silica rectangular parellelopipeds (1 in. x ca ¼ in. x 1 mm) cut from Amersil fused silica microscope slides and were about 3500Å thick. Film thickness was held approx-

imately constant to avoid effects of film thickness on resistivity noted by Aitchison. In general, six samples were coated on one side in a run. The process of cleaning the silica bars involved the following steps: (*a*) boiling in isopropyl alcohol to remove the wax used in cutting the pieces, (*b*) boiling 30 min in Dreft, (*c*) rinsing in hot tap water, (*d*) boiling in 10% H_2O_2, (*e*) several boilings in deionized water followed by an air dry and storage in a desiccator.

Electrodes (cathodes) were prepared from 99.998 + per cent pure tin (Vulcan Material Company) and Asarco indium (99.999 + per cent pure) and antimony (99.999 + per cent pure). Mixtures of the metals of desired composition were melted in graphite crucibles and poured into a glazed porcelain dish where the alloy solidified. The alloy does not stick to porcelain. During pouring an aluminum screw was suspended above the center of the dish so that the screw head was embedded in the solid alloy, but the threads were still available for attachment to an aluminum piece which served as vacuum seal and electrical conductor and was machined to allow circulating tap water to cool the electrode. The electrode diameter was about 2 in.; the thickness about ¼ in.

After the films had been deposited on the fused silica slides they were removed from the sputtering chamber and fired in air at a desired constant temperature for a given time. No attempt was made to control humidity. After removal from the oven and cooling to room temperature silver electrodes[1] were painted on and fired at 500°C. A separate sample was used for each firing time, *i.e.*, no sample was cooled and then reheated to get another point on the resistance *vs.* firing time curve. Each point in the resistance *vs.* time plots discussed in the next section is an average of about four samples. The room temperature measurements of resistance were made with a Keithley 610A Electrometer. A d-c Wheatstone bridge was employed for temperature coefficient measurements (T.C.R.). To obtain reproducibility in the T.C.R. measurements further heat-treatment was necessary as will be discussed later.

Some samples were coated with carbon previous to firing. The carbon coat was applied by evaporation using a commercial carbon evaporation apparatus (E. F. Fullam, Inc.). The carbon coats were approximately 125Å thick.

Results and Discussion

Structure and composition of films before and after heat-treatment.—The sputtered films as deposited on an unheated substrate are amorphous as indicated both by electron diffraction results on the unsupported film and by x-ray diffraction results on supported films. Upon sufficient heat-treatment these films crystallize to a rutile-like structure with an average crystallite diameter of about 400Å (cf. Fig. 1). If the films are coated with carbon previous to firing and then fired in air, the resulting films are indistinguishable from the uncoated fired film from the point of view of crystallite size, a result different from that of the devitrification of aluminosilicate glass films (7) where the application of carbon was necessary to obtain a very fine grained film of quite uniform crystallite size.

As the ratio of antimony to tin in the film increases the lattice parameters of the crystallized SnO_2 films increase until the 15% Sb-85% Sn film is reached which is nonconducting. The lattice parameters of this film are quite close to those of the pure SnO_2 film. X-ray fluorescence analysis of fired and unfired films shows that within analytical error no antimony or tin is volatilized in air at 710°C in 24 hr. Analysis also indicates that the cation ratio in the film is the same as the atom ratio in the alloy cathode.

These observations can be explained, we believe, by assuming that the true solubility of antimony oxide in tin dioxide films is less than 1 mole % and that such a film is a nonconductor (cf. Fig. 7). This solubility figure is in accord with Loch's measurements (8). The films containing between 1 and 14% Sb then are thermodynamically unstable with respect to exsolution of antimony oxide. We can expect to get supersaturated films easily because the crystallization process probably involves simply bond breaking and reforming with little or no diffusion. Diffusion and consequent exsolution should be slow because our firing temperature is low compared to the melting point of SnO_2. However, since there is no published phase diagram of the SnO_2-Sb_2O_5 system we have been forced here to assume that there is no SnO_2-Sb_2O_5 eutectic at about 1% antimony and at a low temperature of, say, 1000°C. In line with these statements we say that the exsolution of the 15% antimony oxide doped films occurs sufficiently fast at 710°C with the heating schedules employed that the supersaturation is removed and the resulting films are nonconductors.

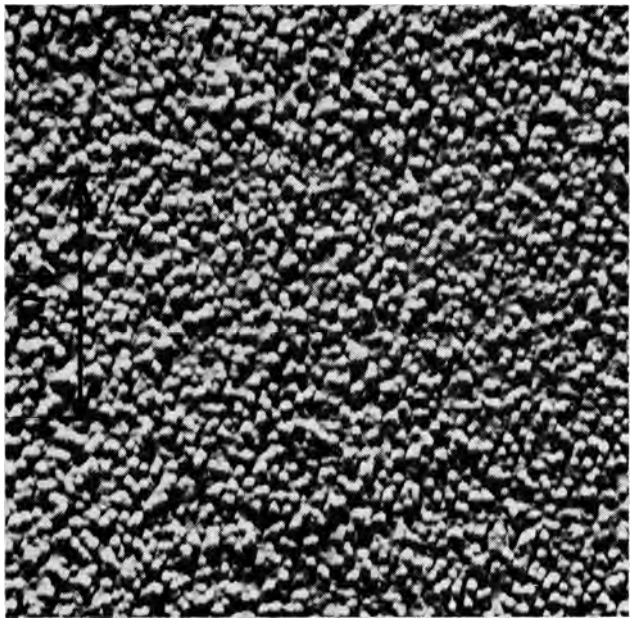

Fig. 1. Electron micrograph (replica) of SnO_2 film on fused silica substrate; fired 3 hr, 710°C in air.

Devitrification kinetics.—Preliminary experiments indicated that the firing temperature should be between 600° and 900°C, and somewhat arbitrarily 710° ± 10°C was selected as the standard firing temperature. The results of firing tin oxide films with various amounts of antimony oxide added are shown in Fig. 2. Obviously the kinetics is complicated and, somewhat surprisingly, the reaction is rather slow. Some light on

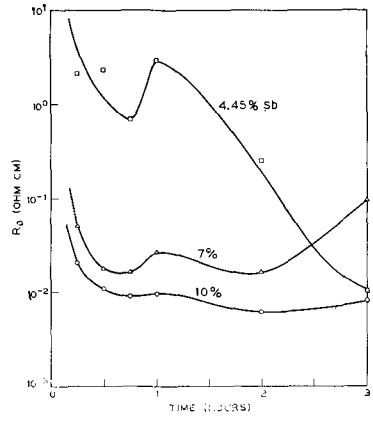

Fig. 2. R_0 in ohm-cm at room temperature of 3500Å thick SnO_2 films doped with indicated amounts of antimony oxide *vs.* firing time at 710°C in air. Films were not carbon treated.

the processes involved is shed by the results of devitrification of films which have been carbon coated previous to firing. Before discussing these results, however, we should remark on why this approach was chosen.

In the early stages of this work two difficulties were encountered, poor adhesion of the film after firing and poor reproducibility in resistivity. While these effects existed, considerable effort was applied to understand and overcome them. Although various possibilities such as mismatch of thermal coefficient between film and substrate could be suggested we decided first to investigate the possibility that variable microstructure in the crystallized film was the source of difficulty. It is well known that control of the microstructure is important in control of electrical and other properties of materials (9). As mentioned in the previous section no difference in microstructure with carbon coating could be determined. However, the improvements in reproducibility and elimination of adhesion problems were most dramatic. In addition, the effect of this treatment on the devitrification kinetics was quite noticeable. The results of these studies are indicated in Fig. 3 and 4.

Comparing the results in Fig. 2, 3, and 4 it is apparent that the devitrification reaction is speeded up by the addition of carbon before firing. To explain these results the following tentative reaction scheme is presented.

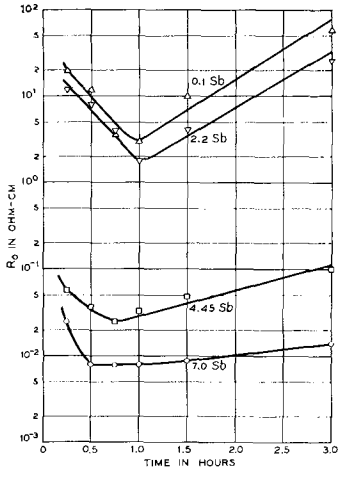

Fig. 3. R_0 in ohm-cm at room temperature of 3500Å thick SnO_2 films doped with indicated amounts of antimony oxide vs. firing time at 710°C in air. Films were coated with *ca.* 125Å carbon film before firing.

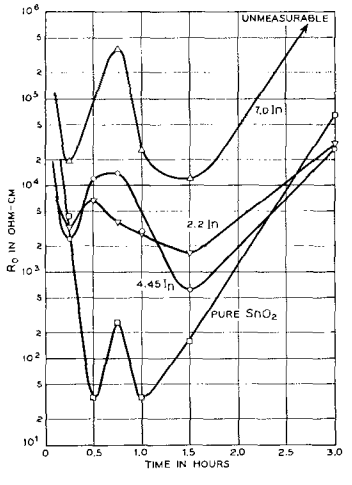

Fig. 4. R_0 in ohm-cm at room temperature of 3500Å thick SnO_2 films doped with indicated amounts of indium oxide vs. firing time at 710°C in air. Films were coated with *ca.* 125Å carbon film before firing.

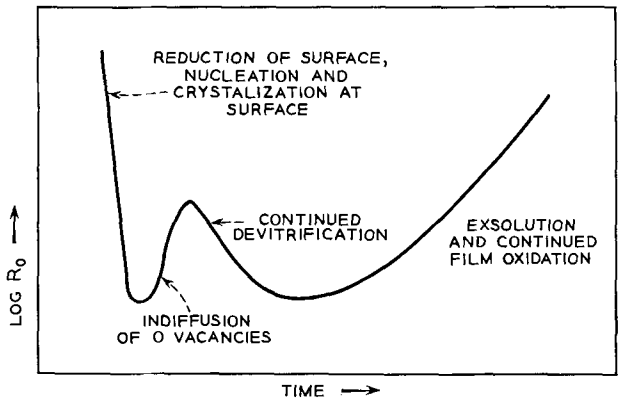

Fig. 5. Postulated reaction steps in heat-treatment of tin oxide films

Presumably the function of the carbon is to reduce the film by abstracting oxygen to form CO or CO_2. We then postulate the nuclei are formed at the surface possibly because the broken Sn-O bonds allow some necessary atomic movements to occur. This should occur more easily with the less stable tin oxide glass. In this picture, then, crystallization of the film starts at the air-film interface and requires breaking of some Sn-O bonds. This occurs more rapidly with a reducing agent like carbon present. In the initial stages of devitrification of the carbon coated stannate glass and to a lessened extent with the uncoated film the crystallized portion should have a high concentration of oxygen vacancies. As time increases there are two competing processes as far as effects on the room temperature resistivity of the film are concerned. Increasing thickness of the crystalline region of the film decreases the resistance whereas decreasing oxygen vacancy concentration due to diffusion into the film, oxidation at the air-film interface (because of the lower dissociation pressure of the crystalline phase), and reduction of Sb^{+5} to Sb^{+3} in the film would act to increase the resistance. Under these conditions one would not expect the resistivity to be a linear function of the vacancy or impurity concentration and, indeed, experimentally does not appear to be so (cf. Fig. 7). Thus as the vacancy concentration gets below a critical value it can be expected that the resistance may sharply increase again despite the continuing increase in the thickness of the crystalline region. Eventually, the resistance drops as the crystallization process continues. The film finally goes to a very high resistivity as the exsolution process becomes dominant. Of course, with the pure tin oxide film exsolution would not occur and reoxidation would be the only mechanism involved in this final upswing in resistance. These processes are summarized in Fig. 5.

In this picture then there is a delicate interplay of several reactions each with its own activation energy and the kinetics could be changed by a variety of influences. The effects of temperature change are indicated in Fig. 6. It is seen that at high temperatures (900°C) the exsolution process becomes dominant. At low temperatures the initial stages of the reaction which are influenced greatly by diffusion of oxygen vacancies are slowed sufficiently that even with carbon coated antimony doped films the first reaction minimum can be seen.

In Fig. 7 the specific resistivity at the second minimum has been plotted as a function of per cent antimony or indium added and the results compared with Aitchison's results. The second minimum was chosen because in our reaction picture the film should be about completely crystallized. In the case of the carbon coated antimony doped films the one minimum obtained was assumed to be the second minimum.

Temperature Coefficient of Resistance

The temperature coefficient of resistance of the nonreduced antimony doped films has been studied in the

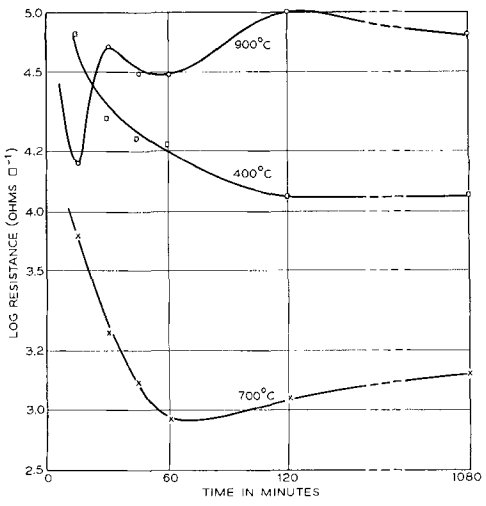

Fig. 6. Devitrification of SnO_2 films containing 4.45% antimony oxide as a function of firing temperature.

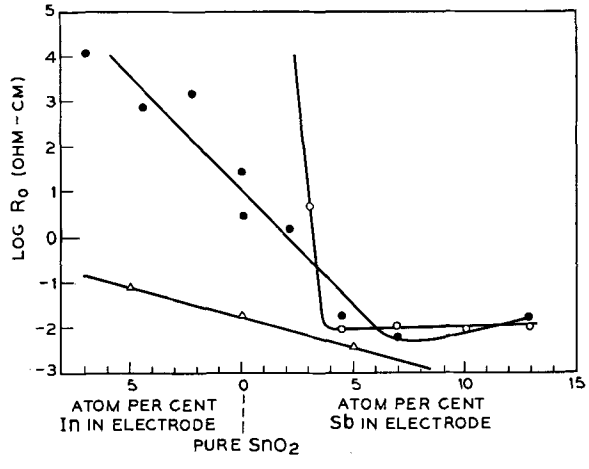

Fig. 7. R_0 (second minimum value) at room temperature of SnO_2 films prepared by reactive sputtering as a function of film composition and carbon treatment. range 25°-300°C and the results indicated in Fig. 8. It is seen that the T.C.R. increases monotonically from negative through zero to positive as we progress from insulating films to conducting films. A more detailed discussion of this behavior and of the T.C.R. of the reduced films will be presented in another communication (10).

It is important to note though that the T.C.R. is strongly influenced by the thermal history of the film. This is indicated in Fig. 9 where it is shown that if one cycles the film between 25° and 300°C the T.C.R. can change radically, mostly in the first few cycles. This is possibly due to the fact that initially the film has been quenched from 710° to 25°C and has frozen in a distribution of vacancies, etc., corresponding to a temperature near 710°C. It is known that the resistance of alkali halides is influenced by thermal history at temperatures below a value characteristic of the particular alkali halide and this is attributed to "frozen-in" distributions (11). If one assumes a melting point of 1900°C (12) for tin oxide[2] then one is clearly in a range where mobility of defects should be of importance. It follows also that the processes of quenching and annealing are important in obtaining reproducible resistance values. In general, the values presented in

[2] The melting point of tin oxide is variously reported in different handbooks between 1127° and 1900°C. The 1127°C value we have checked and it is certainly wrong.

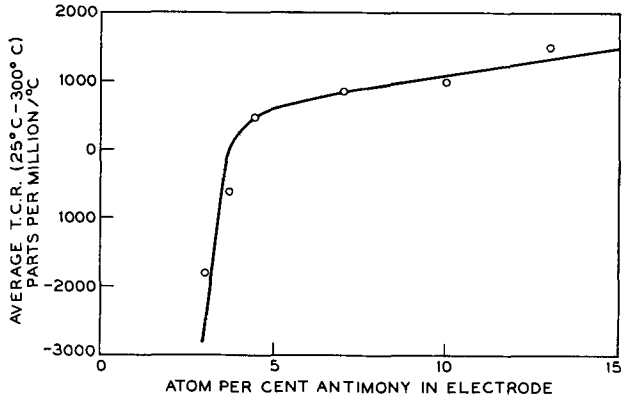

Fig. 8. Average temperature coefficient of resistance (25°-300°C) of tin oxide films at second minimum fired at 710°C in air (3500Å thick) as a function of added antimony oxide. Films were not carbon coated before heat-treatment.

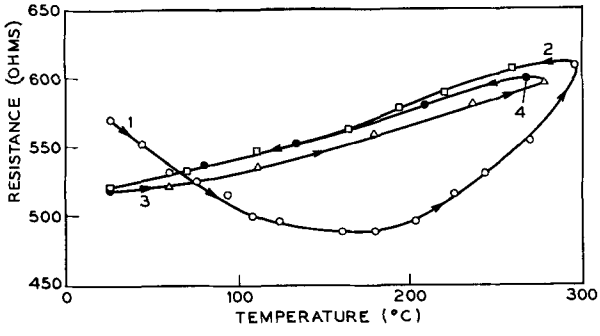

Fig. 9. Resistance of an SnO_2 film doped with 7% antimony oxide as a function of thermal history. Run 1, increasing temperature; run 2, decreasing temperature; run 3, increasing temperature; run 4, decreasing temperature.

Fig. 2 to 4 and 6 are obtained on unannealed samples. Enough corroborative work has been done to assure us that the general shape of these curves is correct. One cannot properly evaluate reproducibility in these systems with only four samples per point, but it appears at the present state of our work as if the resistances of equivalently prepared samples at the second minimum are reproducible to about ±20%, if not carbon treated, and somewhat better, if carbon treated. Preliminary indications are that annealing at 300°C improves the reproducibility.

Summary

We have shown that tin oxide films prepared by reactive sputtering in oxygen of tin or tin-antimony electrodes are crystallized to a rutile-like structure on heating. These films if they contain more than 3.0% Sb and less than 15% Sb are conductive if heated for an appropriate time at a high temperature (*e.g.*, 710°C) in air. The kinetics is complicated. Using the room temperature resistance of a fired film as an index, in general two minima in resistance are noted as a function of time. Films coated with carbon prior to firing devitrify more quickly and display lower conductivity at the second minimum for high antimony concentrations but considerably higher conductivity than the uncoated antimony doped tin oxide film at low antimony concentrations and, in fact, conductivity can be noted even in indium doped films under these circumstances. Long-term heating of these films at high temperatures (*e.g.*, above 900°C) leads to insulating films in all cases. A general picture to explain the kinetic results has been suggested.

The temperature coefficient of resistance of antimony doped tin oxide films which have not been treated with carbon ranges monotonically from negative through zero to +2000 ppm/°C as a function of antimony con-

tent. Annealing of the film at about 300°C is required to stabilize the temperature coefficient of resistivity for the interval 25°-300°C.

Impurity Redistribution Processes in Epitaxial Silicon Layers

B. A. Joyce, J. C. Weaver,[1] and D. J. Maule

Allen Clark Research Centre, The Plessey Company Limited, Caswell, Towcester, Northants., England

ABSTRACT

Impurity redistribution processes occurring during the epitaxial growth of silicon layers have been investigated using radiotracer techniques. The final impurity profiles obtained have been measured by the capacitance-voltage technique and the results compared with theoretically computed profiles. It has been shown that the occurrence of the previously postulated etch-back mechanism is unlikely, and that all of the redistributed impurity can be accounted for in terms of solid-state diffusion from the front of the substrate and outdiffusion from the rear. Certain anomalous diffusion rates have been observed in the case of phosphorus doped substrates.

During the growth of epitaxial silicon layers a process occurs whereby impurities initially present in the substrate are redistributed in the growing layer (or in downstream layers in a multislice system) as growth proceeds. This process is usually referred to as autodoping, and the impurity penetration is normally considered to be greater than could be accounted for by solid-state diffusion.

Three possible mechanisms have been suggested for the process, and they are briefly summarized below.

(*A*) The dopant is transferred from the back surface of the slice to the growing layer, the transfer taking place via the gas phase (1).

(B) Transfer occurs from the upper surface of the substrate (or the film after it has begun to grow) into the gas phase, with subsequent reincorporation of the impurities into the growing layer (2, 3). A mathematical treatment is then derived from this countercurrent extraction model by analogy with distillation theory.

(*C*) An extension of (*B*) in which an explicit time dependence for the reaction rate is derived kinetically, and details of the origin of the redistributed substrate impurity are postulated (4). Briefly, a single etch back mechanism is suggested as a natural consequence of the transient behavior involved in initiating a steady-state growth reaction.

The most significant factor in all of this work was the claim that impurity penetration was far greater than could be accounted for by a diffusion mechanism. Recently, however, Grove *et al.* (5) have convincingly demonstrated that normal solid-state diffusion processes are sufficient to account for most of the impurity redistribution observed, particularly with boron and antimony doped substrates, provided that system contamination is eliminated. Further, although they derive a rigorous solution to the diffusion equation based on a moving boundary model, they show that this reduces to a simple complementary error-function-type distribution for all practical growth conditions.

The purpose of this paper is to present results from radiotracer determinations which show that any transfer occurring via the gas phase happens during the substrate pretreatment with hydrogen or via the back of the substrate during growth if this is not adequately sealed. Results of differential capacitance measurements are also presented which confirm that the form of the redistribution profile can be accounted for in terms of solid-state diffusion, coupled with a slight contribution from outdiffusion.

Experimental

It was considered necessary to obtain information on two stages of the autodoping process, namely, the mechanism of any gas phase impurity transfer, and the nature and origin of the redistributed impurity profile. For this reason two experimental techniques have been employed, namely radiotracer methods to investigate gas phase transfer and capacitance voltage measurements on diodes fabricated very close to the epitaxial layer surface in order to determine the impurity profile (6). The details of layer preparation were basically similar for both techniques and are described briefly below.

The films were grown by the hydrogen reduction of trichlorosilane, using a multislice, horizontal, R.F. heated reactor, the susceptor being a block of high-purity graphite encapsulated in fused quartz. Film growth temperatures were in the range 1150°-1250°C, as measured with an optical pyrometer corrected for emissivity and wall transmission losses. The partial pressure of $SiHCl_3$ used was normally 8 mm Hg, and the total flow rate 4 l. min^{-1}.

The substrate slices had an impurity concentration of approximately 10^{19} at. cm^{-3} of either phosphorus, arsenic, or antimony, or approximately 5×10^{17} at. cm^{-3} of gallium and were chemically polished to remove work damage from the surface. Any layer doping was carried out with phosphine.

[1] Present address: Ferranti Ltd., Edinburgh, Scotland.

Table I. Isotope data

Isotope	Half-life	Sensitivity (by β-count) (counts min^{-1} g^{-1})
^{32}P	14.1 days	1.19×10^{10}
^{72}Ga	14.1 hr	1.4×10^{11}
^{76}As	26 hr	4.5×10^{11}
^{122}Sb	2.7 days	3.3×10^{11}

The radiotracer technique employed was to place a labelled slice (containing ^{32}P, ^{76}As, ^{122}Sb, or ^{72}Ga) as number two slice in the reactor, followed by a number of unlabelled substrates. The appropriate growth run or pretreatment was then carried out, and a β-count made on the epitaxial layers grown on the unlabelled substrates (or on the substrates themselves if no deposition was carried out). The isotope data is given in Table I.

Since the actual counts were made on 2.5 cm diameter slices, the calibration from solutions of known specific activity was designed to simulate experimental conditions as nearly as possible. A suitable quantity of solution containing the radio isotope, and of known specific activity, was therefore evaporated on the surface of an inactive silicon slice, the count rate determined using an end window Geiger-Müller counter and the decay rate followed.

In some instances it was ncessary to isolate the radioactive element from a solution, *i.e.*, where it was required to determine impurity concentrations in SiO_2 films formed by oxidation of an active slice. Normally after isotopic exchange had taken place an insoluble compound containing the radioactive element was precipitated, and after chemical, and where necessary radiochemical, purification, the compound was weighed and the count rate determined. Following this a quantity of solution of known specific activity was isolated directly and the count rate determined. The weight of the element in question was then obtained by comparison of count rates and a correction applied for the difference in chemical yields. Such determinations were carried out for ^{32}P, isolated as $(NH_4)_3\ PMo_{12}\ O_{40}$ and weighed as $MgNH_4PO_4 \cdot 6H_2O$ and for ^{72}Ga isolated as $Ga(OH)_3$ and weighed as Ga $(C_9H_6ON)_3$ (gallium oxinate).

Finally impurity profiles were determined by fabricating diodes in the n-type epitaxial layers [using a very shallow (0.3μ) boron diffusion] and measuring the capacitance of the depletion width of the junction as a function of applied reverse bias. The principles of the method have been described by Thomas *et al.* (2) and the technique used here is based on a series R-C network with an applied high-frequency emf. The capacitance in the network is supplied by the depletion region of the diode, whose width is a function of a low-frequency negatively biased emf applied to the junction. As this capacitance varies the change in circuit impedance is measured as a change in potential across the resistor. Since the capacitance is measured at 1 Mc/s, the output signal is modulated at this frequency. After amplification, it is therefore demodulated and applied to the Y plates of an oscilloscope, with the low-frequency bias applied to the X plates. The effective C-V trace thus obtained is calibrated from a single measurement of the capacitance at zero applied bias. Actual capacitance voltage data is then taken from the calibrated trace and processed using an English Electric KDF9 computer to obtain impurity concentration *vs.* distance values.

Gas Phase Transfer Processes, Radiotracer Results, and Discussion

The radiotracer technique was used specifically to study the nature of any gas phase transfer processes occurring under a variety of growth and pretreatment conditions. Basically the conventional epitaxial process may be considered as a pretreatment stage followed by a growth stage, and the back surface of the substrate may be oxidized or left exposed. Initially therefore experiments were devised to obtain information on the stage of the process at which any gas phase transfer occurred and on the effect of sealing the back surface of the substrate with an oxide film. Qualitatively similar results were obtained for all of the labelled impurity elements used in considering the transfer process, but significant differences in the efficiency of an oxide film as a barrier to outdiffusion were observed between group III and group V elements. In an attempt to make the pattern of the results more simple to follow, a brief qualitative picture is presented below of the approach used and the results obtained. The complete quantitative results are subsequently given in detail.

The gas phase transfer experiments were designed to check the possibility of the etch back hypothesis being correct and to find an alternative if this were not so. The only realistic etching mechanism which could be considered was one in which all of the impurities were released initially, since as soon as any low impurity concentration layer growth commenced, substrate impurities could only be released by diffusion through this layer, and under all normal conditions growth rates would be very much faster than diffusion rates. On this basis, therefore, essentially all of the transfer should occur during the very early growth stages and should then virtually cease. As shown in the results below, this did not occur, most transfer occurring during hydrogen pretreatment (to downstream slices) and finally reaching a steady-state level for any layer thickness. Significant differences in the amounts transferred were observed between labelled substrates with the rear surface oxidized and those left unoxidized, so it was apparent that some or all of the transport occurred via this source. Furthermore, some transfer was still observed with a labelled substrate oxidized on all surfaces, so evidently a thermally grown oxide cannot provide a complete barrier. These results in fact seemed to fit best a simple outdiffusion model for gas phase transfer processes, and this was further substantiated by measurement of the amount of impurity transferred via the gas phase from the back of an active substrate into a growing layer in a single slice system, both with the rear surface oxidized and unoxidized. It will in fact be shown that the amount of impurity transferred from the rear surface to the growing layer by outdiffusion closely corresponds to the divergence of the actual impurity profile from the profile derived theoretically, assuming only a solid-state diffusion process to occur.

For gas phase transfer, the results obtained using an arsenic doped substrate may be taken as typical and these will be presented in full. The procedure used was as follows. The substrate containing ^{76}As, doped to a level of 10^{19} at. cm^{-3} and with a 1μ thick oxide layer on the back surface was placed in the horizontal multislice reactor, and the release of impurities was measured by collection on a series of unlabelled substrates placed downstream from this source (slices A, A+1, A+2, A+3).

The various stages of the process which were investigated are shown in Table II. Each of the stages a, b, c, and d was carried out with separate source and collector substrates. The results are illustrated in Fig. 1. The four sets of points show the total amount of active impurity transferred to the four downstream substrates for each separate process stage. From these it may be seen that the bulk of the transport, at least to downstream slices, occurs during

Table II. Stages of the process

Stage	Pretreatment conditions and duration	Growth time and temperature

(b)	As (a)	1.5 min at 1200°C, (4 $l.min^{-1}$)
(c)	As (a)	2.5 min at 1200°C, (4 $l.min^{-1}$)
(d)	As (a)	6.5 min at 1200°C, (4 $l.min^{-1}$)

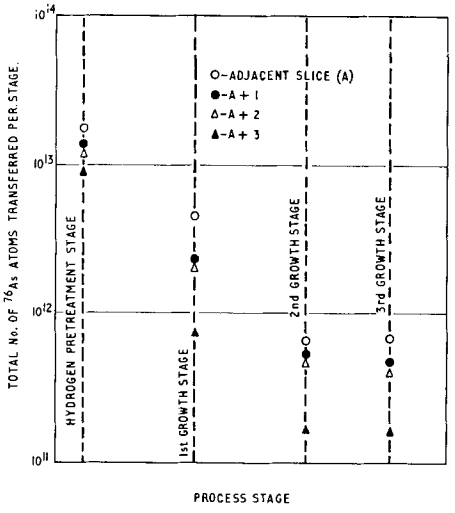

Fig. 1. Impurity transfer occurring during stages of epitaxial growth

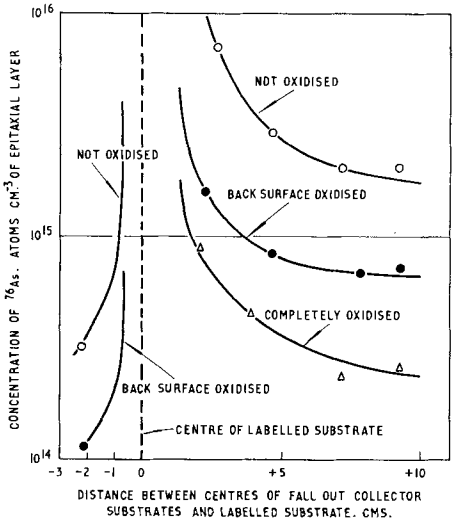

Fig. 2. Effects of oxide barriers on impurity transfer during epitaxial growth.

the hydrogen pretreatment stage. The small amount transferred during growth has been shown to equal, within experimental error, the amount transferred by outdiffusion through the oxide film on the rear surface. The results for this are given later in this section. The observed loss of impurity during hydrogen pretreatment can be correlated with normal outdiffusion processes from silicon, as described by Smits (7).

For comparative purposes the total transfer to the epitaxial layer on an adjacent substrate from substrates containing ^{32}P, ^{76}As, and ^{122}Sb is shown in Table III. The pretreatment and growth conditions were identical in all cases, and correspond to (d) above.

The second aspect of the radiotracer work was designed to study the efficiency of oxide films as barriers to outdiffusion and subsequent gas phase transport. Since significant differences were observed between group III and group V elements the results will be presented in two sections.

Results for Phosphorus, Arsenic, and Antimony

Again the results for the group V elements were qualitatively similar, and only those for arsenic will be presented in detail. The experimental sequence was as follows. Three ^{76}As labelled slices were used in successive runs; for the first the slice was completely unoxidized, for the second the slice had a 1μ oxide film on the back surface only, and for the third a 1μ film on all surfaces. The labelled slice was placed in No. 2 position in a multislice reactor, there being a total of six substrates. They were treated in hydrogen for 20 min at 1200°C, followed by deposition of a 10μ layer at 1μ min^{-1} at 1200°C. The β-activity of the layers on the unlabelled substrates was then measured, and the results are presented in Fig. 2. In this the relative position of the center of each slice is plotted on the distance axis, but the actual count was of course made over the whole of each slice, of 2.5 cm diameter. (The final downstream substrate was semicircular, but of the same diameter.) Thus it may be seen that while an oxide film has a considerable effect as an outdiffusion barrier for arsenic (and similar results were obtained for phosphorus and antimony), some transfer occurs even when the substrate is completely oxidized. This is in accordance with results obtained for the segregation of arsenic between Si and SiO_2 during thermal oxidation, when it was found that ratio of the average concentration of ^{76}As in SiO_2 to the average concentration in the Si was 0.51:1 (for an initial concentration of 1.1×10^{19} at. ^{76}As cm^{-3}, in the silicon, which was oxidized in steam at 1100°C). It should be pointed out that since the growth temperature was 100°C higher than the oxidation temperature some further redistribution of impurities between silicon and silica may occur during the growth of the layers. This compares approximately with the results of Grove *et al.* (8) and indicates that while some accumulation of arsenic in silicon does occur at the silicon-silica interface the extent of this accumulation is quite small. This point is of some importance in considering the surface concentration existing in a substrate which has been oxidized on all surfaces, and then the front surface oxide removed. It will be considered again in the section dealing with solid-state diffusion processes during epitaxial growth. However, the result also indicates that the concentration of arsenic in the silica film is sufficiently high in comparison with the original concentration in the silicon for a considerable amount to be lost by outdiffusion, provided that the diffusion coefficient is large enough, which appears to be the case.

In fact it is possible to make a comparison between the amount of impurity transferred during the actual growth process and the amount transferred by outdiffusion through the oxide film on the rear surface. From Fig. 1, the total number of ^{76}As atoms transferred to the adjacent slice during the growth of a 10μ layer (excluding the hydrogen pretreatment stage) equals 5.6×10^{12}. A labelled substrate with a 1μ oxide film on all surfaces was then used, and a 10-min deposition carried out at a growth rate of 1 μmin^{-1} and a temperature of 1200°C. No hydrogen pretreatment was used. A β-count was made on the adjacent downstream slice and the total number of ^{76}As atoms transferred found to be 5.1×10^{12}. It is considered that the only escape mechanism through an oxide film is outdiffusion, and almost all of this must be via the rear surface, as the front is rapidly covered with a layer of polycrystalline silicon. Thus it appears that transfer during growth can be equated, within experimental error, to transfer by outdiffusion through the oxide on the rear of the slice.

Table III. Pretreatment and growth conditions

Substrate impurity nature and concentration at. cm^{-3}	Substrate rear surface conditions	Adjacent layer contamination at. cm^{-3}
^{32}P, 4×10^{18}	Not oxidized	$<1.5 \times 10^{15}$ (detection
	Oxidized	$<1.5 \times 10^{15}$ limit)
^{76}As, 1×10^{19}	Not oxidized	7.2×10^{15}
	Oxidized	1.6×10^{15}
^{122}Sb, 7.5×10^{18}	Not oxidized	1.1×10^{14}
	Oxidized	4.2×10^{13}

Table IV. Results

Substrate impurity concentration ^{72}Ga at. cm^{-3}	Surface conditions	Concentration of ^{72}Ga in adjacent epitaxial layer, at. cm^{-3}
3.2×10^{17}	No oxide	1.8×10^{15}
3.2×10^{17}	Oxide on rear surface only	8.5×10^{14}
3.2×10^{17}	Oxide on all surfaces	5.6×10^{14}

Results for Gallium

Gallium is the only acceptor to have a suitable isotope, so radiotracer work for group III had to be confined to this element although it is quite possible that other acceptors may behave differently. Further, since the solubility of gallium in silicon is comparatively low the maximum impurity level available was 3.2 x 10^{17} at. cm^{-3}. A series of runs corresponding to those for arsenic doped substrates was carried out, except that in this case only one downstream slice was used to detect transfer because of the much lower impurity concentration in the active substrate. The results are shown in Table IV. (Growth conditions were the same as (d) of Table II.)

Two points are immediately apparent from these results; first, the amount of downstream transfer with respect to the substrate concentration is significantly higher for gallium than for group V impurities, and second, the efficiency of a thermal oxide film as a barrier to outdiffusion is very low in this case. This result is the expected one based on the results of Grove *et al.* (8, 9), who showed that although the segregation coefficient of gallium between silicon and silica favors a larger equilibrium concentration in the silicon, the diffusivity of gallium in silica is so high that it readily escapes into the gaseous ambient, and the over-all effect is a depletion of the impurity from the silicon. As a check, the actual segregation during thermal oxidation was measured radiochemically. It was found that for an oxide film 1μ thick grown at 1100°C in steam the ratio of the concentration of gallium in the silica to the concentration in the silicon was 6.2, for an initial concentration of 3.8 x 10^{17} at. cm^{-3} in the silicon. It appears, therefore, that the value of the segregation coefficient determined radiochemically differs from previously calculated values, and depletion of the silicon might arise from a combination of high diffusivity and higher solubility of gallium in silica. However, the over-all effect is still to allow escape of gallium from the oxide. Thus in a multislice system using gallium doped substrates significant amounts of downstream transfer will always occur, and if a substrate undergoes oxidation followed by partial removal prior to deposition, there will be a considerable depletion of gallium at the substrate surface.

The final transfer problem which was dealt with by radiotracer techniques concerned the transport of material from the rear of the substrate into the epitaxial layer grown on this same substrate. In order to do this a slightly different technique was used. Phosphorus was diffused into a silicon wafer from a phosphine source to give a surface concentration of 5 x 10^{18} at. cm^{-3}, and a junction depth of 7μ (the background concentration was 10^{14} B at. cm^{-3}). This slice was then irradiated and one surface and all sides were removed to a depth of approximately 25μ to yield a rectangle of silicon of area 1.9 cm^2, with phosphorus diffused into one surface. The geometry of this arrangement is shown in Fig. 3. After pretreatment in hydrogen (20 min at 1200°C) a 10μ thick epitaxial layer was deposited on the phosphorus free face (1 μmin^{-1} at 1200°C), and the active phosphorus in this layer, which arose by transport from the back surface, was measured. The experiment was carried out with and without a 1μ thick SiO_2 film over the phosphorus diffused area. The results are shown in Table V.

Table V. Results

Substrate		Epitaxial layer
N_S ^{32}P at. cm^{-3}	Rear surface condition	N ^{32}P at. cm^{-3}
5×10^{18}	Not oxidized	1.8×10^{16}
5×10^{18}	Oxidized	$<6 \times 10^{14}$

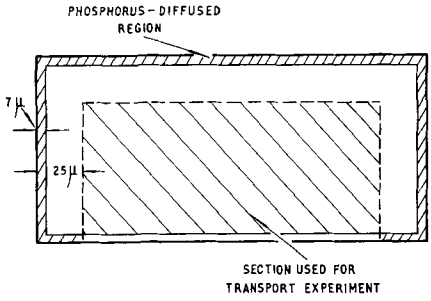

Fig. 3. Slice geometry for rear to front surface transfer experiments

Thus significant transfer from the back surface to the front does occur where no oxide film is present, but a 1μ thick film is sufficient to reduce the phosphorus transfer below the limits of detection of ^{32}P. However the amount of arsenic transferred through a similar film appears to be rather greater, reaching about 8 x 10^{14} at. cm^{-3} under corresponding conditions.

Thus the radiotracer results of gas phase transport effects may be summarized as follows:

(*a*). In a multislice system considerable downstream transfer of impurities is observed, but essentially it all occurs during any pretreatment in hydrogen, by a normal outdiffusion process. There is negligible transfer resulting from any possible etch back mechanism.

(*b*). Oxide films provide much better outdiffusion barriers for group V elements than for gallium, but they are not completely effective for any of the elements studied.

(*c*). A measurable quantity of impurity transfer from the rear surface to the epitaxial layer on the same substrate occurs via the gas phase, as a result of outdiffusion, but again this can be minimized by an oxide film, at least for group V elements.

It is apparent that item (*a*) is by far the most important result obtained from the radiotracer experiments and basically may be taken to mean that "autodoping" as a separate phenomenon based on an etch back mechanism does not occur. All gas phase transfer processes can be accounted for by normal outdiffusion, and in a single slice system where the back of the slice is oxidized, the impurity profile must be accounted for simply by solid-state diffusion, with the exception of a small amount of material which diffuses through the oxide film.

Comparison of Theoretical and Measured Impurity Profiles

Since the radiotracer experiments have shown that there is negligible gas phase transfer occurring from the front of the slice during growth, any redistribution must be accounted for in terms of solid-state diffusion (including outdiffusion through an oxide barrier). "Anomalous diffusion" in epitaxial silicon layers has been reported previously (10) where it was shown that the value of the diffusion coefficient can be as much as nine times greater in the interface region than in bulk material because of poor crystal perfection. However, here the diffusion was carried out after the growth process was complete, so the problem was one of normal diffusion.

It has been suggested by Rice (11) that for the case of concurrent diffusion and growth, *i.e.*, the normal epitaxial process, it is necessary to treat the diffusion as a moving boundary problem in order to obtain an accurate knowledge of the distribution profile. How-

ever, it has been shown by Grove *et al.* (5) that for all normal conditions of epitaxial growth, the solution approximates extremely closely to a simple complementary error-function-type distribution. In addition, it appears that the computations in Rice's paper only give the complementary error function distribution, and do not include the moving boundary effect. Therefore, briefly, the moving boundary solutions are given below, and it is shown, following Grove, how these reduce to the complementary error function distribution for all practical conditions.

The over-all solution is the sum of two component solutions, *i.e.*, (i) final distribution of impurities originally in the substrate and (ii) final distribution of impurities added with the growing layer. The same differential equation governs both cases, although boundary conditions are different.

$$i.e.,\ \partial C/\partial t = D(\partial^2 C/\partial x^2), -\infty < x < x_f, t > 0 \quad [1]$$

where C is the concentration and x the layer thickness at time t. The final thickness is given by $x_f = Vt$, where V is the layer growth rate.

The determination of the final distribution of impurity originally in the substrate is carried out by generating a solution of [1] with the following initial and boundary conditions.

(i) $C(x,O) = M$ (*i.e.*, original impurity concentration in the substrate is constant)
(ii) $\lim_{x\to\infty} C(x,t) = M$ (*i.e.*, concentration far from surface at which deposition occurred not depleted).
(iii) $-D\,(\partial C/\partial x) = (h+V)C$ at $x = x_1$, (*i.e.*, material diffusing to the surface of the layer either escapes or is incorporated into the layer. h is the coefficient of escape of impurities at the surface).

The solution in dimensionless form is then:

$$C(x,t)/M = \tfrac{1}{2}\,\mathrm{erfc}\,[x/2(Dt)^{1/2}] - [(h+V)/2h] \times \exp[(V/D)(Vt-x)] \times \mathrm{erfc}\,[(2Vt-x)/2(Dt)^{1/2}] + [(V+2h)/2h] \times \exp\{[(V+h)/D][(V+h)t-x]\} \times \mathrm{erfc}\,\{[2(V+h)t-x]/2(Dt)^{1/2}\} \quad [2]$$

However, for all normal values of growth rate, *i.e.*, $Vt/(Dt)^{1/2} >> 1$, [2] reduces to

$$C(x,t)/M \simeq \tfrac{1}{2}\,\mathrm{erfc}\,[x/2(Dt)^{1/2}] \quad [3]$$

In order to determine the final distribution of impurity added with the growing layer the following initial and boundary conditions are used

(i) $C_2(x,O) = O,\ x < O$ (*i.e.*, substrate initially contains none of the impurity added with the growing layer)
(ii) $C_2 \to O$ as $x \to -\infty$ (*i.e.*, no impurity added with deposited layer reaches points deep in the substrate)
(iii) $C_2(x_f,t) = K$ (concentration of this impurity is constant at film surface).

The solution is given by

$$C_2(x,t)/K = \tfrac{1}{2}\{1 + \mathrm{erf}[x/2(Dt)^{1/2}] + \exp[(V/D)(Vt-x)] \times \mathrm{erfc}\,[(2Vt-x)/2(Dt)^{1/2}]\} \quad [4]$$

but for $Vt >> (Dt)^{1/2}$, *i.e.*, practical growth conditions, and, in the film, for distances $x > 2(Dt)^{1/2}$ from the interface

$$C_2(x,t) \simeq K \quad [5]$$

Simple complementary error function distributions were therefore used to obtain theoretical impurity profiles.

Thus capacitance-voltage measurements were made on shallow diodes fabricated in n-type epitaxial layers grown on n^+ substrates and impurity profiles determined from these. The only growth variable was temperature, and values in the range 1150°-1250°C were used. The impurity concentration in the substrates was approximately 10^{19} at. cm^{-3}, using both phosphorus and antimony. The growth rate was 1 μmin^{-1}, and 10μ layers were grown. The impurity added with the growing layer was always phosphorus, and the back surface of the substrate was always oxidized in order to minimize transfer from that source.

Impurity profiles were determined from the capacitance voltage data and Fig. 4a to c show the profiles from layers on antimony doped substrates for growth temperatures of 1150°, 1200°, and 1250°C, respectively. The layers were all approximately 10μ thick and were grown at 1 μmin^{-1}. The theoretical profiles are also shown and indicate a reasonable level of agreement. It may be seen that penetration of impurity from the substrate is a function of temperature in the normal way to be expected for a diffusion process. [The theoretical profiles were computed using standard values of diffusion coefficients and activation energies of diffusion (12) and since the over-all agreement between theory and experiment is quite good, it may be assumed that approximately the same values hold in the practical system].

Previous workers (2, 3) have also attributed the comparatively sharp profile close to the substrate-layer interface to a solid-state diffusion process, the so-called diffusion tail, and the results presented here show that the measured profiles do in fact agree closely with those determined theoretically over most of the range.

However, the divergence between measured and computed profiles for impurity concentrations less than about 5 x 10^{14} at. cm^{-3} is probably too great to be accounted for by experimental error. These portions of the curves do in fact correspond closely to those regions which Thomas *et al.* interpreted as arising from an etch back mechanism. Since the radiotracer results have shown that this explanation is not tenable, an alternative must be sought. While no definitive evidence is available it is suggested that this extra impurity is incorporated after outdiffusion through the oxide mask on the back of the slice. It would only require the release of approximately 10^{12} at. of impurity to make up the difference between the observed and calculated values, and the radiotracer experiments have shown that amounts of this order are lost by outdiffusion through the oxide. One further set of results appears to provide evidence in favor of this mechanism. This concerns the radial redistribution of impurities in a slice; it is observed that if capacitance-voltage measurements are made on diodes fabricated across the diameter of an epitaxial layer, the impurity profiles so obtained are not consistent but vary well outside the limits of experimental error. The variation is not random, but is a function of the position of the diode across the slice, and of the temperature of

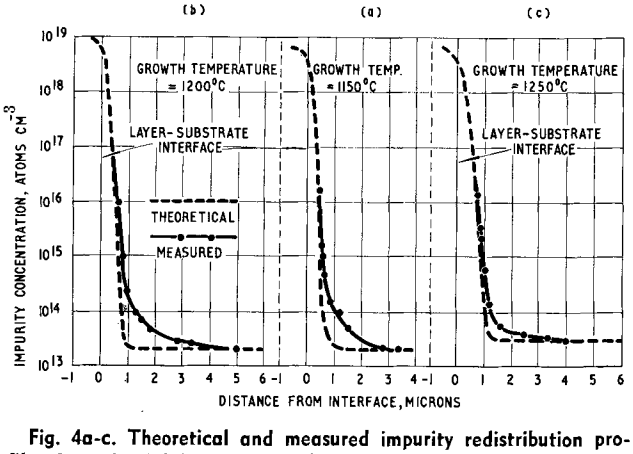

Fig. 4a-c. Theoretical and measured impurity redistribution profiles for epitaxial layers on Sb-doped substrates.

growth. It is found that penetration is greatest on peripheral devices, decreasing to a minimum at the center, and also that the final film doping level follows the same pattern. The effect of temperature is to effect the degree of variability, being very slight at 1150°C, and most pronounced at 1250°C. Some results for 10μ layers on antimony doped substrates (impurity concentration $\sim 10^{19}$ at. cm^{-3}) at three temperatures are presented in Fig. 5a and b. In both cases the ordinate represents the relative position along a radius of the layer, while in Fig. 5a the abcissa represents the penetration depth at which an arbitrarily chosen impurity concentration (5 x 10^{14} at. cm^{-3}) is reached and in Fig. 5b the final film doping level obtained with no deliberately added impurity. Obviously no significance should be attached to the actual shapes of the curves, nor to the absolute values of the ordinate, but the trend is quite apparent. A further point which is brought out by Fig. 5b is that the actual value of the finally achieved impurity concentration is also a function of temperature, irrespective of the position on the slice. Higher growth temperatures in fact lead to higher final doping levels. Qualitatively similar results were obtained for other group V impurities.

It appears that all of these results can be explained on the basis of outdiffusion through the oxidized rear surface. The effect of temperature would be simply to increase the total amount of impurity liberated, in accordance with the observed result, a dynamic equilibrium eventually being achieved for each temperature. The radial distribution would result from the gas flow patterns set up in the reactor, and something of the form illustrated in Fig. 6 seems a reasonable approximation, allowing for the comparatively poor contact which is known to exist between susceptor and slice.

The results so far presented do not show any cases of anomalous diffusion (*i.e.*, abnormally high diffusion rates), but such effects were observed particularly in the case of phosphorus doped substrates. In these circumstances it was necessary to adjust the value of the diffusion coefficient by amounts up to an order of magnitude over the bulk value in order to obtain a reasonable fit between theoretical and calculated profiles. However such values have been determined by Kahng *et al.* (10) and attributed by them to crystal imperfections. Because of the apparently random variations from the normal value of the diffusion coefficient observed during this work, the defect explanation does not seem to be the only plausible one, and system contamination may be responsible, with the possible proviso that phosphorus appears always to penetrate further than the true value of D would allow. A typical profile for a phosphorus doped substrate ($\sim 10^{18}$ at. cm^{-3}) is shown in Fig. 7, for a 10μ layer grown at a temperature of 1200°C.

To obtain the level of agreement shown the value of D was adjusted by a factor of ten, which is about average for phosphorus doped substrates. If the explanation for the anomalous diffusion lies only in terms of crystal defects or system contamination, then it is difficult to account for the behavior of phosphorus. While it is well known that diffusing phosphorus atoms can induce dislocations in silicon (13) the actual impurity concentration for the experiments discussed above is rather lower than the reported concentration necessary to produce a sufficiently high dislocation density to affect diffusion rates significantly. Further, other group V elements should also produce dislocations in the same way, at equivalent, or possibly lower concentrations. However, no evidence to account for this effect in any other way has been produced during this investigation, but it may be worthwhile pointing out one possibility. A good deal of evidence exists to show that the presence of a second impurity can greatly increase the diffusion rate of the first when both impurities are of like charge, and decrease it when they are oppositely charged (14). It has also been shown by one of the authors (J.C.W.), using radiochemical techniques, that epitaxial silicon layers grown from silicon chlorides contain between 10^{16} and 10^{17}

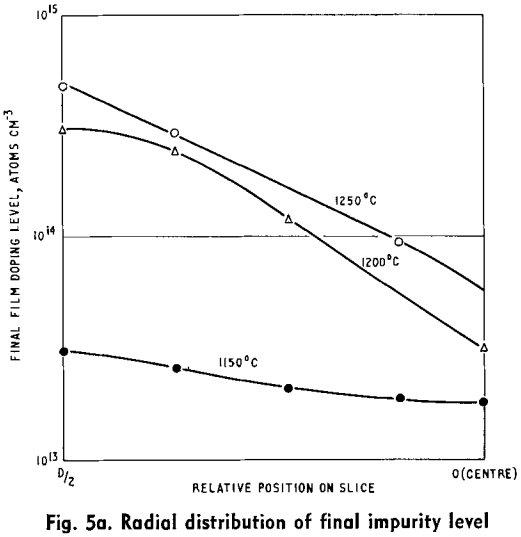

Fig. 5a. Radial distribution of final impurity level

at. cm^{-3} of chlorine (15) although it is not known in what form the chlorine is present. It is suggested, therefore, that chlorine may increase the diffusion rates of group V impurities, and that the effect is greatest for phosphorus. On this basis, of course, it would be expected to decrease the diffusion rates of group III impurities, but the rate of outdiffusion, at least of gallium, through the oxidized rear surface is so great as to mask any solid-state diffusion effects.

A second way of checking this hypothesis is to consider autodoping effects in silane grown layers, where obviously no chlorine can be present. However, available data are not sufficiently accurate to enable any conclusions to be drawn. The method of profile determination used by Mayer and Shea (16) was rather suspect, and although the capacitance voltage method was used by Bhola and Mayer (17), measurements were not extended sufficiently close to the interface to enable an assessment of the extent of anomalous diffusion to be made. (The diffusion coefficient of arsenic could be increased by a factor of about 60 and still include all of the experimental points shown.) Our own work on silane (18) used a low pressure rather than a hydrogen dilution system and, because of different outdiffusion effects, comparison between this and the chloride systems, is probably not valid.

Finally, in order to check the radiotracer results by means of profile determination, layers of varying thickness were grown and the impurity distribution through them measured. It was thought that, if the single etch back mechanism, in particular, was in any way valid, then the extent of autodoping should be greater in thinner layers, since all of the impurity would be liberated initially, and in thin layers there would be insufficient time for the deliberately added impurity to become the controlling parameter. On the other hand, if the mechanism as determined by radiotracer experiments was correct, and essentially no gas phase transfer occurred via the front of the slice during growth, then autodoping should only be time dependent in accordance with the appropriate diffusion equation. This was in fact found to be the case, and the result for a layer grown for 2 min at 1 μmin^{-1} and a temperature of 1200°C is shown in Fig. 8. The theoretical profile is also shown, and the agreement is extremely good. The substrate was arsenic doped to a level of $\sim 10^{19}$ at. cm^{-3}.

Summary and Conclusions

It has been shown, using radiotracer techniques, that impurity redistribution during the epitaxial growth of silicon does not occur from the front of the slice via the gas phase, but that some outdiffusion from the back does occur, even when this is covered by an oxide film. During any pretreatment in hydrogen at elevated temperatures, the normal outdiffusion processes occur from both surfaces, and impurities are transferred downstream in a multislice system. However, the etch back mechanism proposed in various forms by Thomas *et al.* (2, 3) and by Grossman (4) does not appear to take place.

The form of the final impurity distribution profile can be accounted for almost entirely by normal solid-state diffusion, with two possible exceptions. First, for impurity concentrations less than 5×10^{14} in the growing layer, the outdiffusion of impurities from the back surface, even if this is oxidized, can be the controlling factor. Second, in some cases, and particularly with phosphorus doped substrates, it is necessary to assume values of diffusion coefficients up to an order of magnitude larger than normal to obtain agreement between theoretical and measured profiles. Two possible explanations for this are in terms of enhanced diffusion rates associated with crystal defects or with the presence of a second impurity.

Acknowledgments

The authors are indebted to Mr. J. H. Neave for layer preparation, to Mr. J. Whitworth for some of the radiochemical analyses, and Mr. R. M. Ware for valuable criticism and discussion. Thanks are due to the Plessey Company for permission to submit this paper.

Mechanism of Anodic Germanium Oxide Film Formation

Joseph B. Story[1]

Materials Sciences Laboratory, Lockheed Missiles and Space Company, Palo Alto, California

ABSTRACT

Voltage transient studies were made on the Ge-GeO_2 electrode in a system of acetic anhydride containing small amounts of acetic acid, water, and lithium nitrate. These studies indicate that water diffuses into and through the GeO_2 film, that it reacts electrochemically at or near the Ge-GeO_2 interface, and that the hydrogen ion so produced moves back through the film as the current-carrying species. Increasing the concentration of water in the film increases the conductivity by increasing the jump distance of the hydrogen ion.

Anodic germanium oxide films have been produced by Zwerdling and Sheff (1) who used anhydrous sodium acetate in glacial acetic acid as an electrolyte, and by Wales (2) who used lithium nitrate in acetic anhydride containing small amounts of germanium dioxide, acetic acid, and water. Additional studies of a system similar to that of Wales have shown an unexpected voltage transient effect, an effect which this paper seeks to explain. In the course of the investigation, it was found that the information obtained is relevant to the mechanism of film formation.

Experimental Procedure

Cell.—The cell used for this study (Fig. 1) is almost identical to that used by Wales (2,3). The electrode was mounted outside the cell body, the effective electrode area of 0.50 cm^2 being defined by a circular hole in the cell wall or in the gasket. In voltage decay experiments, the germanium was cemented over the hole in the cell wall with a sodium silicate solution; in all other studies a neoprene gasket was used. The bottom of the cell contained a temperature control "finger" and an argon pump that provided an argon flush and a slow mixing of the electrolyte. A layer of mercury prevented the solution from leaking between the cell wall and cell bottom. For voltage decay work the temperature used was 23°C; for the other experiments, it was 25°C. The cathode was a tantalum sheet.

Flexible salt bridge and Luggin capillary.—The potential was measured between the germanium and the tip of a Luggin capillary placed near the oxide film. By filling a length of No. 22 AWG Teflon tubing with an agar gel of an aqueous potassium chloride solution, a flexible salt bridge and Luggin capillary was created. The aqueous agar gel was satisfactorily stable in contact with the acetic anhydride-based electrolyte. Because this form of flexible salt bridge could be readily manipulated, it was convenient for this application. The end used as the capillary was guided into position by being passed through a glass tube built into the cell, and the opposite end was immersed in a stoppered jar containing an aqueous potassium chloride solution and a commercial calomel electrode.

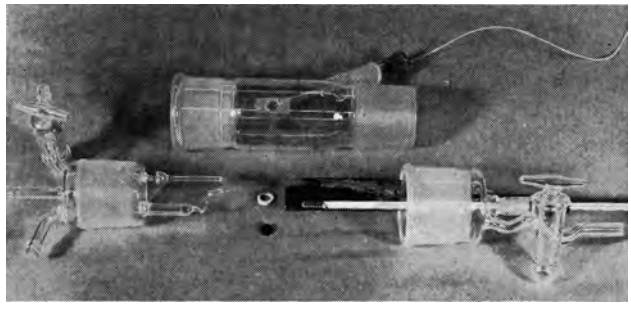

Fig. 1. Photograph of cell

Materials.—The electrolyte employed was acetic anhydride containing 6.0 x 10^{-3} mole/liter lithium nitrate, 0.10 mole/liter acetic acid, and 0.30 mole/liter water. The acetic anhydride, acetic acid, and lithium nitrate were of reagent grade. The germanium used was a single crystal 1-1-1 face p-type with a resistivity of 0.62 to 0.76 ohm-cm. It was etched with CP-4A [3HF (48%), 5HNO_3, and 3HAc, by volume].

Instrumentation.—The potential was measured with a Model 610 Keithley electrometer. Recording of the potential-time curves was made by connecting the electrometer output to an oscilloscope and photographing the trace.

The constant current source was based on the field-effect transistor (8) which contained five individual constant current sources (each variable) that could be connected in parallel in various combinations.

Organization of the study.—Several different kinds of measurement were used in this study. The investigation centers about a particular experimental observation which can be described as follows: (*i*) an anodic GeO_2 film is grown at constant current until the voltage across the film increases to a value V_1; (*ii*) the current is turned off for a few minutes; (*iii*) the constant current is turned on again; (*iv*) the voltage, however, does not immediately rise to V_1, a period of

Table I. Outline of sequence of experiments

Object	Experiment or plot	Result and conclusion
Determine importance of water in observed effect.	Add small amount of water to solution during film growth.	Major change observed; water assumed to be important in effect.
Determine whether effect occurs within GeO_2 film.	Plot intensity of effect as function of film thickness.	Plot is linear over wide range of film thicknesses; therefore, effect is uniformly distributed within film.
Describe changes occurring in electrical conductivity of GeO_2 film during effect.	At two different stages of effect (a and b) switch current rapidly through series of constant currents (I_1, I_2, etc.); observe voltages Va_1, Va_2, etc., and Vb_1, Vb_2, etc.	Va_1: Va_2: : Vb_1: Vb_2 Va_1: Va_2: : Vb_1: Vb_3, etc. Assuming oxide conduction model is valid, observed effect is result of change in activation distance.
Obtain additional evidence of change in activation distance.	Interrupt current briefly at two different stages; record voltage decay curves.	V *vs.* log t plots of potential decay curves show straight lines of somewhat different slope. Assuming potential decay occurs according to model, difference in slope indicates difference in activation distance.

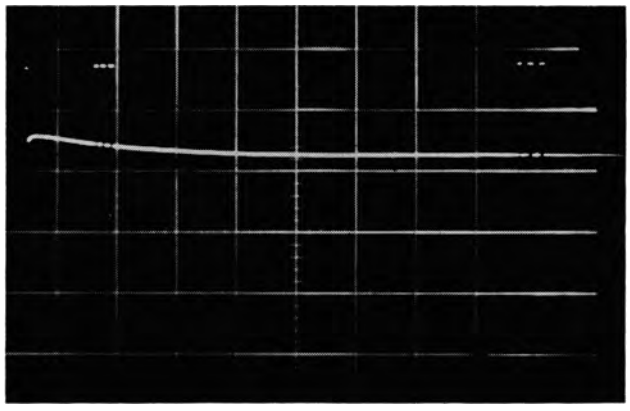

Fig. 2. Voltage transient of Ge-GeO_2 electrode after interruption at low potential. Vertical scale, 20 v/square (read top to bottom, zero potential indicated by dots); horizontal scale, 6.8 sec/square; current density, 120 $\mu a/cm^2$.

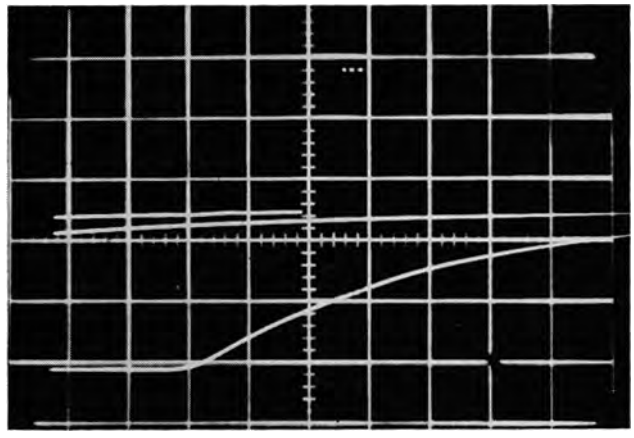

Fig. 3. Hydration of Ge-GeO_2 electrode by addition of 0.5 w/o H_2O to electrolyte. Picture covers 4 min. Vertical scale, 20 v/square; horizontal scale, 6.8 sec/square; current density, 120 $\mu a/cm^2$.

½ to 1 min being required (an oscilloscope trace showing this effect is presented in Fig. 2). Why does this phenomenon occur? Table I lists the sequence of investigational efforts employed to answer this question.

Results

An anodic germanium oxide film was grown in the acetic anhydride-acetic acid-water-lithium nitrate system at constant current. At intervals throughout the growth, the current was turned off for several minutes, then turned on again. Each time this occurred, ½ to 1 min was required for the voltage across the film to rise to its previous value. A typical oscilloscope trace of the voltage change is presented in Fig. 2. Voltage-time curves for interruptions at other voltages can be approximated by multiplying the ordinates of the curve by an appropriate factor, provided that the voltage at interruption is lower than about 60v (at 120 $\mu a/cm^2$). If the voltage is over 60v (at 120 $\mu a/cm^2$), the voltage may continue to rise for several minutes until it exceeds 100v (limit of the Keithley electrometer). If the rise is completed within 1 min, the voltage normally will not exceed the voltage observed before the interruption. If, however, the rise continues for more than 1 min, the voltage can reach values much higher than would be expected if no interruption had occurred.

In Fig. 2, there is an initial "overshoot" in potential. The subsequent decrease in potential appears to be caused by the generation of additional charge carriers as a result of the current. This increase in current carriers has been observed in oxide films on tantalum and several other metals (4). Apparently, a steady-state is reached within a few seconds. The magnitude of the overshoot and the time required for the steady-state to be reached seem to be proportional to the film thickness.

It is convenient to anticipate the results of this study by specifying a name, "dehydration voltage," for the voltage change observed on resumption of the constant current after its interruption. Dehydration voltage will be defined as the difference between the minimum voltage (observed just after the overshoot) and the voltage observed when the steady state is again attained. The dehydration voltage is not defined for cases in which greatly prolonged voltage rise occurs. The oscilloscope trace showing the observed effect will be called the "dehydration trace."

If the small amount of water [0.5 w/o (weight per cent)] present in the acetic anhydride-acetic acid-water-lithium nitrate system is significant in the formation of the germanium oxide film, then the addition of another 0.5 w/o water should have an appreciable effect on the voltage across the film. The effect of such an addition is shown in Fig. 3. The voltage across the film decreased from over 100 to 49v. A dehydration trace made after the addition of this larger amount of water was similar to that for a thinner film, except that the period required for the overshoot to decrease to its steady-state value remained that of the thick film.

In studying the constant current formation of anodic germanium oxide films in a system almost identical with that used in this study, Wales (2) has shown that both the voltage across the film and the film thickness increase linearly with time (after a brief initial period). Thus, the increase in film thickness is proportional to the increase in voltage across the film, and a plot of dehydration voltage *vs.* total voltage across the film at the time of interruption will be linear when the dehydration voltage *vs.* film thickness plot is linear. Such a plot is presented in Fig. 4. Other runs at the same current densities show the same trends, but the values scatter by as much as 20%. Thus, the dehydration voltage varies linearly with film thickness, within the limits of reproducibility of the data.

It was hoped that, by studying and comparing the instantaneous current-voltage properties of the film at two different points along the dehydration trace,

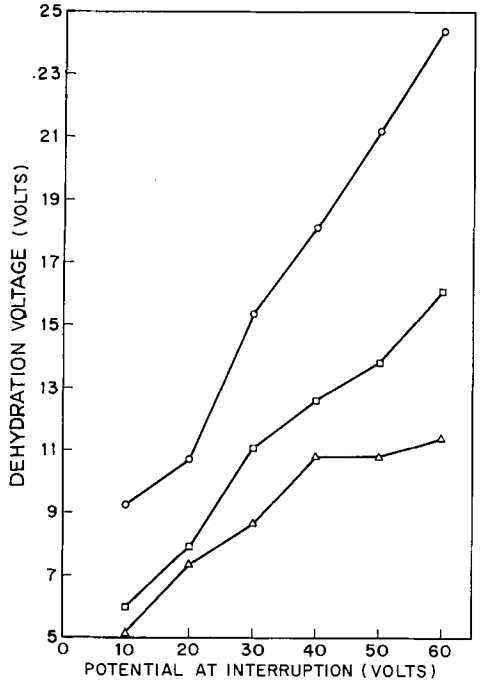

Fig. 4. Dehydration voltage as a function of potential at interruption: circle, 360 $\mu a/cm^2$; box, 120 $\mu a/cm^2$; triangle, 50 $\mu a/cm^2$.

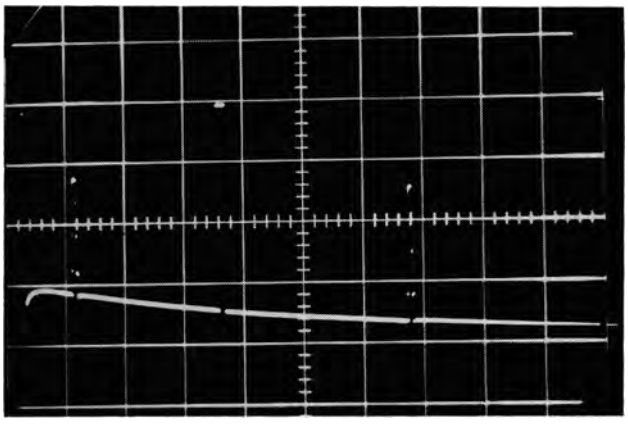

Fig. 5. Dehydration of Ge-GeO_2 electrode after interruption. Vertical scale, 20 v/square; at 7 and 60 sec current decreased in sequence 120, 80, 40, 20, 10 $\mu a/cm^2$, then increased in reverse sequence.

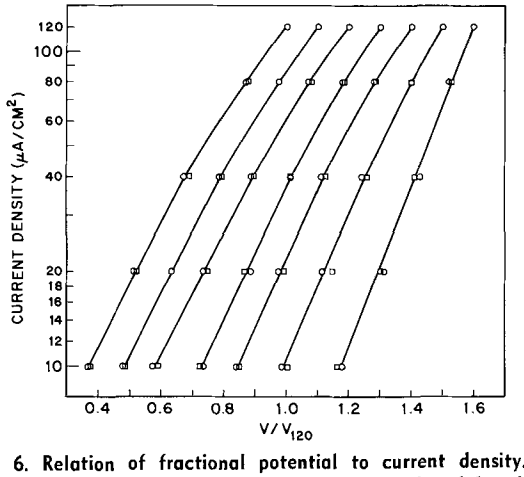

Fig. 6. Relation of fractional potential to current density. Potential at 120 $\mu a/cm^2$ defined as 1.00; curves displaced for clarity. (Dehydration for 7 sec, circle; for 60 sec, box.) From left to right, runs represent interruption 90, 80, 70, 40 30, 20, and 10v, respectively.

some understanding of the nature of the processes occurring within the film could be gained. The comparison was accomplished by switching the current very rapidly through a series of constant currents and observing the corresponding voltages. A trace obtained by this procedure is presented in Fig. 5. In such traces it is significant that there is a constant ratio of voltages for two currents. For example, if the current is switched from 120 $\mu a/cm^2$ to 80 $\mu a/cm^2$ (then quickly back to 120 $\mu a/cm^2$) 7 sec after film growth has been resumed and the voltages Va_1 and Va_2 recorded, then again switched from 120 $\mu a/cm^2$ to 80 $\mu a/cm^2$ 53 sec later and the voltages Vb_1 and Vb_2 recorded, it is observed that $Va_1 : Va_2 : : Vb_1 : Vb_2$. Figure 6 presents such data from a series of dehydration traces. As explained later, this is interpreted to mean that an increase activation distance is associated with the dehydration trace. As a further test of the idea that the activation distance changes during the course of the dehydration trace, voltage decay curves were recorded for the very brief interruption of the dehydration trace at two points. Voltage *vs.* log time plots of these curves are presented in Fig. 7. As discussed below, the difference in slope of the two lines so obtained is interpreted as indicating an increase in activation distance.

Discussion

The decrease in the voltage across the film from over 100 to 49v upon the addition of 0.5 w/o water to the solution suggests that water is important in the formation of the film. This decrease in voltage could not

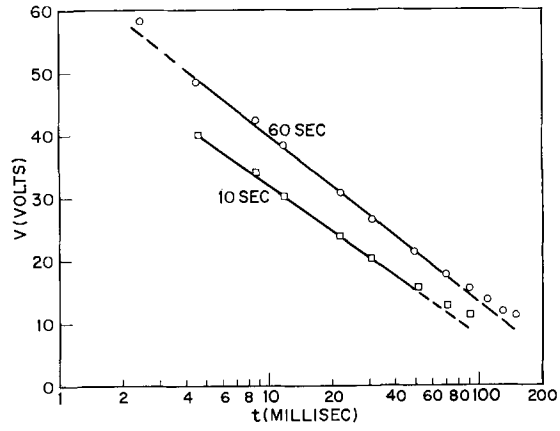

Fig. 7. Open-circuit voltage decay

possibly be the result of half of the film being dissolved because of the following:

1. The process was essentially complete at the end of 4 min. In order for the dissolution of the film to stop at the end of 4 min it would be necessary for the solution to become saturated with germanium oxide within this same period. Common laboratory experience indicates that one cannot saturate 100 ml of a solvent with a slightly soluble substance of limited contact area (0.50 cm^2) within such a short time.
2. It was observed that the addition of another 0.5 w/o water to the solution had a considerably smaller effect on the voltage across the film.
3. The voltage-time curve for the initial period of film growth (almost identical to that given by Wales) does not have the shape that would be expected if an appreciable amount of the germanium oxide being formed were being dissolved to saturate the solution.
4. The period required for the overshoot to decrease to its steady state value did not decrease to the value that would be expected for a thinner film.

The great effect of the small amount of water added can be explained only by assuming that the water penetrated the film and affected its conductivity. The penetration of water into amorphous germanium oxide has been reported (5).

Wales (2,3) has suggested that, because the oxygen in water would be more readily available than that in the acetic anhydride, in the acetic acid, or in the lithium nitrate, water is the source of the oxygen required for film growth and is necessary for such growth. Thus, the stoichiometry of anodic germanium oxide film formation can be represented.

$$Ge + 2H_2O \rightarrow GeO_2 + 4H^+ + 4e$$

It appears that the water within the film and at or near the germanium-germanium oxide interface would react in preference to the more remote water in the bulk of the film or at the germanium oxide-solution interface. If this is true, there will be a decrease in water concentration at the germanium-germanium oxide interface and a transport of water through the film by diffusion. The amount of the concentration decrease will depend on the resistance to mass transport. The major portion of this resistance could occur either in the germanium oxide film or in the stagnant liquid film (diffusion layer) adjacent to the oxide film. If the controlling resistance were in the oxide film, one would not expect the linear voltage-time curve for film growth that was found by Wales (2), since each added increment of film thickness would cause a decrease in the water content and conductivity of the underlying film. This suggests that the controlling resistance to mass transfer is to be found in the liquid phase. The common method used to test for liquid phase diffusional resistance is the stirring of the liquid. Such stirring decreases the thickness of the diffusion layer and thereby decreases the resistance to

mass transport. Such a test was made. It was found that the voltage across the oxide film decreased during stirring and rose to its initial value when stirring was stopped. Thus the controlling resistance to mass transport was in the liquid phase. This is not surprising, if one considers that the diffusion layer is probably more than a thousand times as thick as the film (2,7).

The linear increase in dehydration voltage with film thickness can best be explained by assuming that the dehydration voltage occurs within the film rather than at an interface, and that each element of film thickness (after the initial element) contributes equally to its magnitude. It is unlikely that the dehydration voltage could be an activation overpotential, since the mass transfer and electrode kinetics equations are of such complexity that one would not expect them to interact to produce a linear relation over such a wide range of dehydration voltages. The magnitude of the dehydration voltage is much greater than that usually encountered for activation overpotentials.

A consequence of the existence of a mass transfer resistance in the liquid phase is that the resumption of the current after interruption will not be accompanied by an immediate return of the voltage across the film to its value just prior to interruption. This voltage will be reached only after the mass transfer processes have again attained a steady state condition. Because water addition increases the electrical conductivity of the film, one would expect that the voltage observed shortly after resumption of the current would be lower than at the steady state condition and would then rise to the steady state value. This is what is observed in the dehydration trace. Thus, the reason for the selection of the terms "dehydration voltage" and "dehydration trace" becomes apparent, there is a decrease in water content of the film during the period in which these occur. The concentration of water in the germanium oxide film decreases until the concentration gradient across the diffusion layer is just sufficient to transport water to the film at the rate at which it is being consumed. An approximate calculation shows that the observed ½ to 1 min dehydration time is reasonable for this process.

Figure 6 represents the instantaneous current-voltage relations for a series of dehydration traces. To exhibit the constant ratio between the voltages corresponding to a particular pair of current values, each voltage is divided by the voltage observed at 120 μa/cm^2. The instantaneous current-voltage curves for 7 sec of dehydration are seen to be identical with those for 60 sec of dehydration. It is of interest to interpret these results according to the simple model for oxide film conductivity, although there is no assurance that this model is valid. The current-voltage relation for simple ionic conduction in a film [cf. (4)] can be represented by

$$i = 2eqamv \exp [-(W - eqaV/d)/kT]$$

where i is the current density, e is the electronic charge, q is the charge on the ion, a is the activation distance or half-barrier width, m is the concentration of mobile ions, v is the frequency factor, W is the height of barrier, d is the film thickness, k is Boltzmann constant, and T is the temperature.

Because a given dehydration trace is made at constant current, the voltage change that is observed will reflect a change in one or more of the other variables on the right side of the equation. The only variables that can change and leave the voltage fraction constant are those multiplying the voltage, specifically eqa/d. Because it is not reasonable to expect e, q, or d to change, the change must occur in a. Thus, the activation distance should vary as $1/V$.

It is of interest to plot $1/V$ *vs.* the square root of time ($t^{1/2}$) for: (*i*) the dehydration of the film, (*ii*) the hydration of the film by the addition of water to the solution during film growth, and (*iii*) the hydration of the film by decreasing the current density to a fraction of its initial value. Such plots are shown in Fig. 8, 9, and 10. It is evident that there is a linear relation. In the opinion of the writer, this linearity is a result of both activation distance (proportional to $1/V$) and $t^{1/2}$ being linearly related to the concentration of water at the film-solution interface. The linear relation between interface reactant concentration and $t^{1/2}$ is known from the unsteady state diffusion equation for a constant current process (6). Thus there appears to be a linear relation between the activation distance and the water concentration at the film-solution interface. The writer suspects that there is a linear relation between the water content of the film and the concentration of water at the film-solution interface, and a linear relation between the water content of the film and activation distance.

Additional evidence of a change in the activation distance during dehydration can be found by inter-

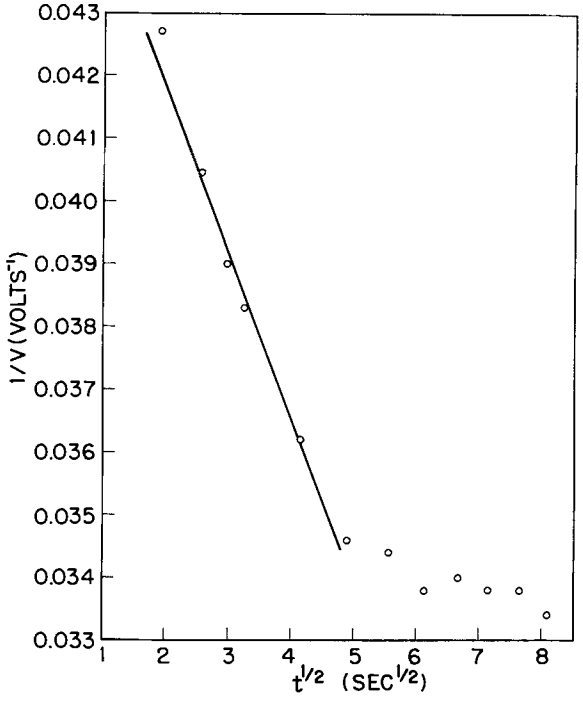

Fig. 8. Dehydration of the Ge-GeO$_2$ electrode (data from Fig. 2)

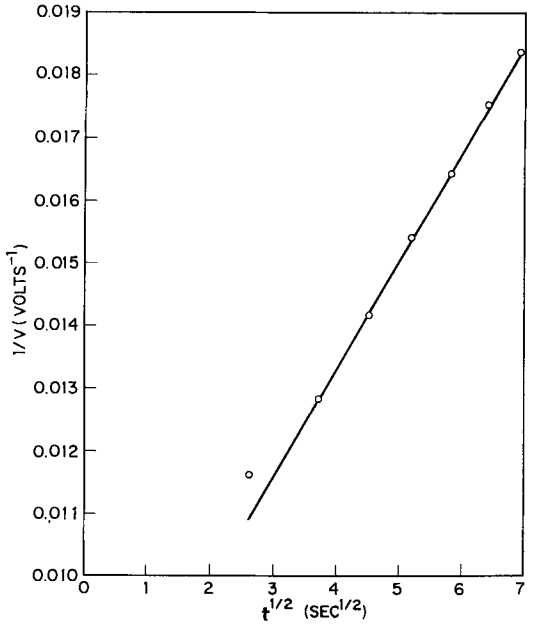

Fig. 9. Hydration of Ge-GeO$_2$ electrode by water addition (data from Fig. 3).

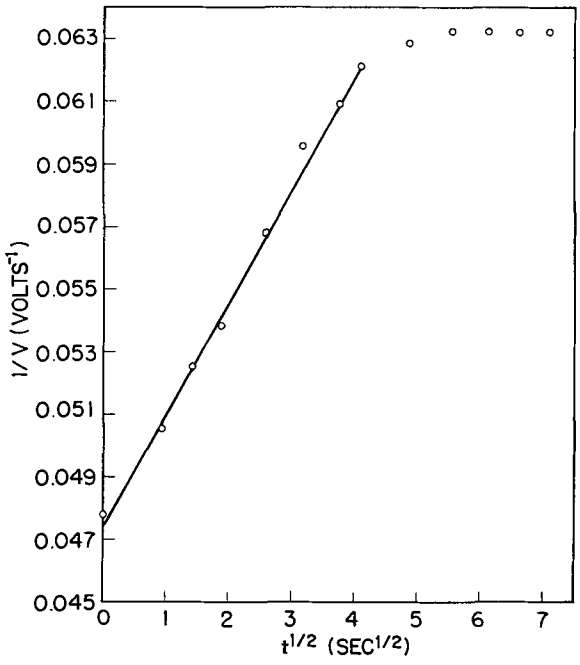

Fig. 10. Hydration of Ge-GeO_2 electrode by decrease in current density from 120 to 10 $\mu a/cm^2$.

preting the voltage decay curves obtained by interrupting the dehydration trace very briefly. If the voltage decay follows a particular simple model it can be represented [cf. (4)] by the equation

$$(1/AB)[\exp(-BV/d) - \exp(-BV_o/d)] = 4\pi \times 9 \times 10^{11}\, t/\epsilon$$

where $A = 2eqam\nu \exp(-W/kT)$; $B = eqa/kT$; and ϵ = dielectric constant.

If A and B are constant during the decay and if V is small compared with V_o, a straight line should be obtained by plotting V *vs.* log t. Such a plot is presented in Fig. 7 for interruptions at 10 sec and at 60 sec. The lines are straight during the major portion of the voltage decay. Measurement shows an increase in slope of about 10% during the dehydration between 10 and 60 sec. This corresponds to a decrease in the value of B. Again, the only apparent explanation is a decrease in activation distance. The displacement of the line toward greater time values is a result of the decrease in film conductivity.

If water moves through the film and reacts to produce germanium oxide at or near the germanium-germanium oxide interface, it is necessary that a mechanism exist whereby the hydrogen of the water can be removed from the film. The only apparent means by which this can happen is for the hydrogen to move through the film as hydrogen ion. The amount of this hydrogen ion would be electrically equivalent to the current producing the reaction

$$Ge + 2H_2O \rightarrow GeO_2 + 4H^+ + 4e$$

Since the germanium oxide is produced with about 80% current efficiency (2), most of the current in the film should be carried by hydrogen ion. Thus the decrease in activation distance on dehydration is a decrease in activation distance for hydrogen ion; that is, the removal of water from the film causes the hydrogen ion to jump between equilibrium positions that are closer together. In the opinion of the writer, this is a result of the water in the film occupying sites that can be used as equilibrium positions by the hydrogen ion when the water is not present.

Conclusions

The oxygen consumed in the formation of an anodic GeO_2 film using an acetic anhydride-acetic acid (0.10M)-water (0.30M)-lithium nitrate (6.0×10^{-3}M) solution, is supplied by the water. This water diffuses through the film and reacts electrochemically at or near the Ge-GeO_2 interface to produce GeO_2 and hydrogen ion. Diffusion of the water results in film growth at the Ge-GeO_2 interface rather than at the GeO_2-solution interface. The hydrogen ion carries the current through the film and jumps between successive available sites. The length of the jumps is increased by the presence of water in the film. It may be that the number of available sites is decreased by the presence of the water. Apparently, the mass transfer of water is controlled by diffusional resistance in the liquid phase, except after interruption of the current through a thick film. In this case, it may be that the diffusional resistance through the thick film dominates, with a severe depletion of water occurring at the Ge-GeO_2 interface.

Cross Substitution in InAs

J. C. Woolley, E. W. Williams,[1] and R. Gagnon[2]

Physics Department, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

The paper considers cross-substitutional alloys of InAs produced by replacing As by combinations of (Ge,Te), (Sn,Te), or (Ge,Se) so as to keep the ratio of valence electrons to lattice sites equal to four. Limits of solid solution have been determined by x-ray and photomicrograph techniques. All the alloys so produced are degenerate n-type semiconductors of very high carrier concentrations. Values of carrier density and optical energy gap have been determined as a function of composition and the results extrapolated to give data for the conduction band minima of InAs. It is found that at room temperature the <111> minima lie at 0.9 ev above the valence band maximum and that the (000) minimum will accept approximately 4 x 10^{19} electrons/cm^3 before an appreciable number of electrons enter the <111> minima.

It has been shown (1) that new semiconducting compounds can be predicted by using the method of cross substitution. This process, which can be applied to semiconducting elements or compounds, is the replacement in the chemical formula of two or more identical atoms of a given valency by the same number of different atoms, chosen so that the total number of effective valence electrons is unchanged. Thus, for materials of adamantine structure the ratio of valence electrons to lattice sites is kept equal to four. This is the condition of the Grimm-Sommerfeld law (2), and cross substitution is an extension of this law.

In the case of the adamantine structure, the simplest cross-substitutional derivatives are the binary compounds such as GaAs, InSb, etc., which are derived thus from the group IV elements. Further application of the process to such binaries leads to ternary compounds, *e.g.*, $CdSnAs_2$ from InAs. Continued application of the process predicts other ternaries, quaternaries, and more complicated compounds.

One limitation of the production of new materials by this method is the stability of the predicted compound. Thus, for the heavier binary compounds, *e.g.*, InSb, the derived ternaries are unstable and so do not form. However, it is possible to carry out the substitution to a limited extent, *i.e.*, in the case of InSb to replace a limited number of antimony atoms by combination of, say, tin and tellurium atoms. The resulting material may be considered as a solid solution of the derived ternary In_2SnTe in the $A^{III}B^V$ compound (InSb), *i.e.*, a composition in the alloy system InSb-In_2SnTe, even though the derived ternary is unstable. The limits of such solid solution of various ternary derivatives in InSb have been studied recently (3) and the Hall coefficient and optical energy gap measured for samples in the single phase ranges.

All of these InSb alloys are degenerate with high carrier concentrations. These latter occur because the alloys are not completely stoichiometric. For example, in the "anionic" InSb-In_2SnTe system (where anionic indicates substitution for atoms of the element in the $A^{III}B^V$ which has higher electronegativity) some solution of tin atoms in the indium sublattice is to be expected from thermodynamic considerations, leaving excess tellurium on the antimony sites. Both this tin and the resulting excess tellurium will act as donors giving n-type material of high carrier concentration. Very similar results are obtained with InSb-In_2Te_3 and InSb-In_2Se_3 alloys (4, 5).

The variation of Hall coefficient and optical energy gap with composition shows that as donor material is added to InSb, the (000) minimum of the conduction band is filled rapidly and that electrons enter the <111> minima. It is thus possible from the optical data to determine values for the height of the <111> minima above the valence band maximum and, from the Hall data, the approximate number of electrons entering the (000) minimum before appreciable numbers of electrons enter the <111> minima. Hence it is found (3) for InSb itself that at room temperature the <111> minima lie at 0.47 ev above the valence band maximum and that approximately 1 x 10^{19} electrons/cc enter the (000) minimum before the <111> minima are filled appreciably.

Here this work is extended to the cross-substitutional alloys of InAs. The data from these, plus that for the InAs-In_2Te_3 and InAs-In_2Se_3 alloys (6, 5) will give results for the conduction band of InAs similar to those for InSb described above.

Experimental Procedure

Three anionic alloy systems of InAs were investigated, *viz.*, InAs-In_2SnTe, InAs-In_2GeTe, and InAs-In_2GeSe. Standard x-ray powder photograph and photomicrograph methods were used to determine the ranges of solid solution in InAs, and measurements made at room temperature of Hall coefficient R_H and optical energy gap E_g.

The preparation of the alloys and the methods of measurement of R_H and E_g were as described previously (4, 5).

Results

Crystallographic data.—For each of the three systems investigated, samples in the range 0-40 mol. % ternary[3] were investigated. In each case it was found that x-ray photographs of the alloys quenched from the melt at 1050°C and of alloys subsequently annealed for one week at 400°C were practically identical, so that no further annealing was necessary. The variations of the lattice parameter of the zinc blende phase as a function of composition in the three systems are shown in Fig. 1. The curves for the In_2GeTe and In_2SnTe alloys [Fig. 1(a) and 1(b)] are typical of pseudobinary sections and indicate a range of solid solution of 12 mol. % in the case of In_2GeTe and of 3 mol. % for the In_2SnTe alloys. At higher concentrations of ternary, extra lines were observed in the x-ray photographs indicating the presence of other phases, but no attempt was made to investigate these, as the zinc blende type of solid solution was the only phase of interest.

In the case of the In_2GeSe alloys, the graph of lattice parameter against composition [Fig. 1(c)] is not that of a pseudobinary section. For alloys containing more than 5 mol. % In_2GeSe, extra x-ray lines were observed in addition to those of the zinc blende phase,

indicating the presence of a second phase, but the zinc blende lattice parameter a_o varies in this range. The sharp break in the a_o against composition curve was assumed to represent the limit of single phase behavior, giving a range of solid solution of between 2 and 3 mol. % In_2GeSe. This was confirmed by photomicrograph work.

Semiconductor data.—Measurements of Hall coefficient R_H and optical energy gap E_g were made only on those alloys which were known to be single phase from the data given above. In all cases the specimens were found to be n-type, and the effective carrier concentrations were calculated, assuming that $R_H = 1/ne$. The variation of log n with molecular per cent ternary for the three cases is shown in Fig. 2 while the corresponding variation of E_g is shown in Fig. 3. It is seen that the three sets of data for n and E_g are the same within the limits of experimental error.

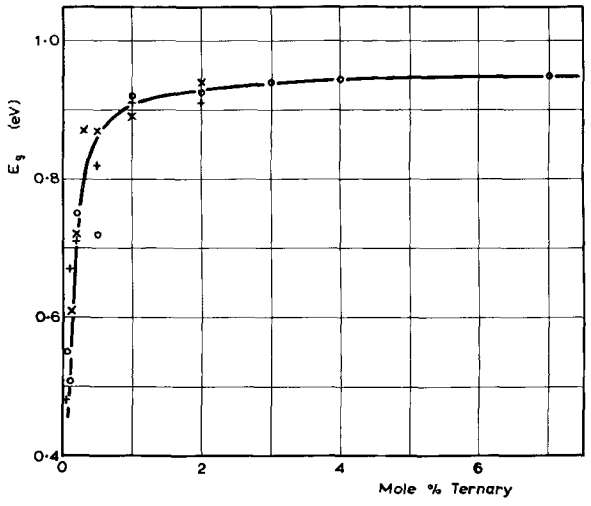

Fig. 3. Variation of room temperature optical energy gap E_g with mole percentage "ternary compound" added to InAs: O, In_2GeTe; x, In_2SnTe; +, In_2GeSe.

Discussion

The curves shown in Fig. 2 and 3 are very similar to the corresponding curves for the InSb cross-substitutional alloys, and they can be explained in the same way. As the ternary In_2 A^{IV} B^{VI} is added to InAs, some A^{IV} atoms enter the indium sites leaving uncompensated B^{VI} atoms on the arsenic sites. Both these A^{IV} and B^{VI} atoms act as donors, resulting in the rapid increase in n seen at low In_2 A^{IV} B^{VI} concentrations. Because of the low density of states in the (000) minimum of the conduction band, the Fermi level moves rapidly up the conduction band, resulting in the observed rapid increase in E_g (Burstein effect). In this region of the curves, the number of A^{IV} atoms occupying indium sites might be expected to vary from one ternary to another. However, the resulting rise in n and E_g is so rapid that it is not possible, within the limit of experimental error, to determine differences among the three cases.

When the Fermi level rises sufficiently in the conduction band, electrons begin to enter the <111> minima. Because of their much higher effective mass, these electrons contribute very little to the Hall coefficient, and to a first order approximation it is possible to assume that $R_H = 1/en_o$ where n_o is the electron density for the (000) minimum alone. Because of the much higher density of states in the <111> minima, the increase in n_o (*i.e.*, $1/eR_H$) with ternary concentration is greatly reduced, *i.e.*, the curve of log $1/eR_H$ against composition flattens out although the total number of electrons in the conduction band continues to increase. Also the Burstein effect in the <111> minima is very small, and so the value of E_g measured in this range is effectively the height of the <111> minima above the valence band maximum.

This behavior is observed in Fig. 2 and 3 at concentrations of ternary larger than about 0.75 mol. %. Here the results for the three cases should coincide unless the band structure of InAs is affected appreciably by the solid solution of small amounts of ternary compound. This coincidence is observed for both n and E_g curves.

Assuming some influence on the band structure due to solid solution, the values for pure InAs can still be obtained by extrapolating this region of the curves back to zero ternary content. On this basis it is found that in InAs at room temperature the <111> minima are 0.9 ev above the valence band maximum and that the number of electrons required to fill the (000) minimum to this level is approximately 4 x 10^{19}/cc. This is in good agreement with the corresponding results for the InAs-In_2Te_3 alloys (6). The values obtained for

the InAs-In_2Se_3 alloys are rather higher than this, but there is some indication that the InAs band structure is appreciably affected by addition of In_2Se_3 (5).

There appears to be no previous experimental data on the energy separation of the <111> conduction band minima and the valence band maximum for InAs. Hilsum (7) has made an empirical estimate of this value, but his figure of 1.5 ev is considerably higher than the value obtained here.

The Growth of α-SiC from Various Chromium Alloys by a Travelling Solvent Method

M. A. Wright[1]

Tyco Laboratories, Incorporated, Waltham, Massachusetts

ABSTRACT

Crystal growth of α-SiC from Cr-Si and Cr-Ta alloys has been accomplished using the travelling solvent method. No elaborate surface pretreatments are necessary although kinetic experiments indicate that diffusion is the crystal growth rate-limiting step only when the SiC surfaces are cleaned by electron beam heating or etching in a NaOH + Na_2O_2 salt mixture. At temperatures less than 1760°C the diffusion coefficient for SiC through a liquid chromium—12 w/o (weight per cent) Si alloy can be described by $D = 2.6 \times 10^{-3}\ e^{-1300/RT}$ cm²/sec. It is demonstrated that multiple zone passing results in crystal purification. Large single crytals can also be grown using this method.

The growth of crystals of α-SiC from chromium solution using the travelling solvent method has been reported recently (1). This variant of the temperature gradient zone melting technique (2) consists essentially of maintaining a temperature gradient across an assembly comprising a thin layer of solvent sandwiched between a seed and a source crystal of SiC. At the temperature of crystal growth SiC goes into solution; however, more tends to be dissolved at the hotter than at the cooler crystal-solvent interface. The concentration gradient which is formed provides a driving force to move solute from the hot through the liquid zone to the cooler interface. This latter interface eventually becomes supersaturated, and deposition of SiC occurs. The solvent zone effectively moves through the source crystal until it emerges at some external surface.

The requirements of a solvent are therefore that it should dissolve SiC, that this solubility should increase with increasing temperature, and that the solvent should be insoluble in solid SiC. Elemental chromium meets these requirements; however, it does not wet SiC readily. Cleaning of the SiC surfaces using electron beam heating in ultra-high vacuum, followed by evaporation of chromium *in situ* on the surfaces, produces good wetting and reproducible crystal growth.

Electrical contacting studies (3, 4) indicate that strong ohmic contacts can be produced if metals containing small amounts of Si or Ta are used as contacting material. The small alloying additions effectively react with and remove any contaminating surface film present on the SiC. Chromium alloys were fabricated therefore containing varying proportions of either silicon or tantalum; the following is an account of the growth of single crystal α-SiC from these alloys using the method outlined above.

Experimental Technique

Commercially available "S" type SiC supplied by the Norton Company was used in all the experiments. The specimen dimensions typically 1/4 x 1/4 x 1/20 in. were obtained by cutting and grinding this solid with water-cooled diamond wheels. The chromium alloys were prepared from high-purity materials in an argon arc furnace. The arc was allowed to traverse the specimen several times. Subsequent metallographic observations failed to reveal any segregation. Thin slices of the alloys were cut with a diamond saw, after which the final dimensions were obtained by conventional lapping techniques.

The apparatus used for the growth experiments is shown in Fig. 1. It consisted of an R. F. heated carbon block (A) on which the specimen was placed, contained in a quartz tube. The water-cooled copper end

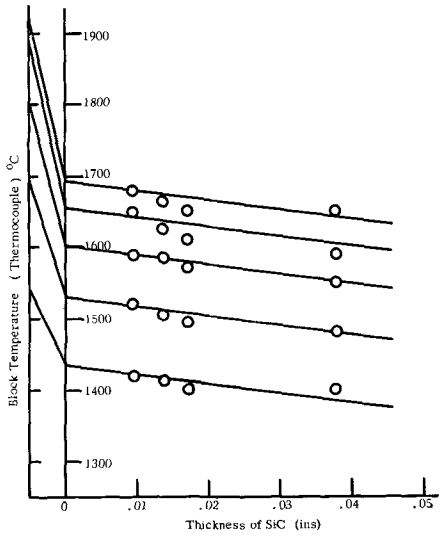

Fig. 2. Effect of block temperature on the temperature gradient through the SiC.

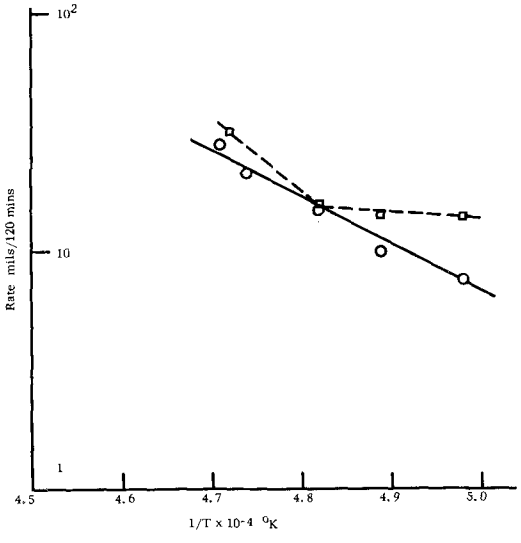

Fig. 3. Effect of temperature on zone movement; □ - - - □, specimens electron beam heated; O—O, specimens degreased only.

caps shown in Fig. 1 were vacuum sealed to the tube with apiezon wax. To prevent oxidation of the chromium at the high-growth temperatures, high-purity argon was passed continuously through the system after first evacuating and back filling three times.

Accurate optical measurement of the temperature of the molten zone proved experimentally difficult due, in part, to unknown emissivity corrections and to the small dimensions (0.005 in.) of the molten zone. The following preliminary experiments were therefore performed:

1. The temperature of the carbon block (A) was measured using both thermoelectric and optical methods.

2. SiC pieces having the same cross section but of different thickness were heated individually to different block temperatures. The surface temperature was measured optically and normalized using the preliminary results discussed above. The effect of specimen thickness is demonstrated in Fig. 2. Assuming that the emissivity of carbon and SiC are approximately equal it was possible with these results and with the continuously recorded temperature of the carbon block to compute the temperature of the molten zone.

Results

Alloys containing 1, 4, 8, and 12 w/o Si in Cr and one alloy containing 5 w/o Ta were used as solvent material. Zone movement was observed in all cases. Figure 3 shows the rate of zone movement *vs.* temperature for the Cr-12 w/o Si alloy.

The polarity observed between opposite (111) faces of zinc blende-type crystals (5) is also shown by the (0001) faces of α-SiC; each face terminates solely in atoms of one kind. The two faces can be identified by etching in a molten NaOH + Na_2O_2 mixture since the rates of dissolution are different. It was thought, therefore, that zone-passing experiments wherein dissolution and recrystallization rates were varied might enable the rate-determining step to be defined. Accordingly, zone-passing experiments were performed using Cr-12 w/o Si as the solvent in which the four possible combinations of face relationships were used. The rate of zone movement was found to be the same, *i.e.*, 5 mils/hr at 1760°C in all cases, suggesting that diffusion of SiC across the solvent zone is the rate-controlling step.

Normal back-reflection x-ray techniques were used to study the effect of growth temperature and zone thickness on the regrown layer. It was found that single crystal growth was achieved easily within wide variations of these parameters. In practice, optimum zone thickness was found to be between 0.006 and 0.015 in. to minimize any tendency of the zone to break up.

The rate of zone movement was studied as a function of zone thickness, but no dependence was observed for the temperature range reported here.

Effect of repeated zone passes.—The principle of multiple zone passing is a well-known technique for preparing ultra pure semiconductor materials. The degree of purification effected by a given number of passes depends only on the relative solubility of the impurity in the liquid and solid phases. Any impurity that exhibits a distribution coefficient much less than or much greater than unity will, therefore, be removed.

A Cr-12 w/o Si alloy zone was made to move through a crystal of SiC. The alloy was removed from the crystal by grinding, and a further zone was made to pass through the crystal in the reverse direction. This process was repeated until a total of six zones, three forward three back, had been passed through the original crystal. The crystal shown in Fig. 4 had then changed from opaque black to translucent green, a definite indication of impurity removal.

Effect of repeated additions of seed crystals.—The passage of a molten-solvent zone through the SiC source crystal results in an increase in size of the seed crystal. The slowest growing direction in the case of hexagonal SiC is the c-direction; thus, thin platelets of relatively pure SiC most commonly produced commercially have maximum dimensions in the c-direction of around 0.050 in.

An experiment was conducted in which one zone was passed through a source crystal, therefore, producing a crystal double the size of the seed crystal. A further source crystal was then added, and the zone was passed through it. This was repeated six times, after which the resultant crystal measured ½ in. in the c-direction (see in Fig. 5).

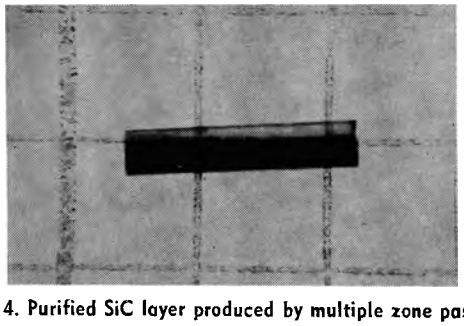

Fig. 4. Purified SiC layer produced by multiple zone passes

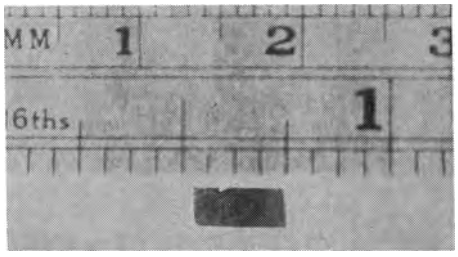

Fig. 5. Large single crystal of SiC produced by successive source crystal additions.

Discussion

SiC can be transported across the solvent zone by two mechanisms, convection and diffusion. The experimental heating geometry would lead one to suppose that convection should be the main transport process, *i.e.*, heat was supplied at the bottom surface of the molten zone; however, no effect of zone thickness could be observed. Since the temperature gradient through the specimen has been shown to be constant, (see Fig. 2), it can be concluded that convection effects are negligible and that diffusion effects predominate. The surface polarity experiments support this conclusion. These experiments also indicate that of the three processes, dissolution, diffusion, and deposition, diffusion is the slowest and is, therefore, rate controlling. The activation energy for the process, using only degreased specimens, computed from Fig. 3 is ~ 90 kcal/mole. This value is not typical of liquid diffusion. Further experiments were performed in which the surface was cleaned by electron bombardment in high vacuum, after which a layer of chromium was immediately evaporated onto the surfaces. Chromium 12 w/o Si was then used as the solvent zone. The effect of temperature on the rate is also shown in Fig. 3.

At temperatures lower than 1807°C the activation energy using these clean samples, is ~ 13 kcal/mole and can be taken as typical for a diffusion-controlled process. If this experiment is taken in conjunction with the surface polarity experiments, then it is apparent that either etching in salt solution or electron beam heating of SiC is sufficient to limit the induction period (presumably by cleaning the surfaces) observed when growth experiments are carried out using only degreased samples.

Above 1807°C a faster transport rate is observed than would be predicted if diffusion effects are still predominant. Since movement of the soluble species by convection has been shown to be negligible, the transport rate can be described by Ficks law, *i.e.*

$$R = -D\frac{dc}{dt}\cdot\frac{dt}{dx}$$

where R is the flux of solute passing through unit area of molten zone, D the diffusion coefficient, dc/dt the variation of concentration with temperature, and dt/dx the temperature gradient.

Figure 2 shows that the temperature gradient through the growing crystal is a constant thus any contribution to the growth rate by this gradient (Soret effect) would also be constant. In addition the variation of the diffusion constant (D) with both temperature and concentration would be expected to be small. It is reasoned, therefore, that the sharp increase in rate is produced by an increase in the value of dc/dt. In physical terms, it would appear that the equilibrium liquidus in the pseudobinary phase diagram (Cr + 12 w/o Si)-SiC begins to turn over quite sharply above 1807°C, however, the experimental data presented here is not sufficient to derive the actual curvature of the liquidus. The equilbrium solubility data for Cr-Si-SiC has not been reported in the literature; however, the pure chromium-SiC equilibrium diagram has recently been determined by Griffiths (6). Using points taken from his curve an accurate plot of dc/dt against $1/T$ for the temperature range reported here was determined. Below 1760°C, dc/dt was constant; above this temperature however, the value began to change quite rapidly until between 1807° and 1857°C an apparent activation energy of 93 kcal/mole was exhibited.

The solute diffusivity was computed by inserting the appropriate values in Ficks equation; thus

$$D = \frac{2.54 \times 13.5 \times 10^{-3} \times 600 \times 10.16 \times 10^{-2}}{120 \times 60 \times 6 \times 50 \times 10^{-2}}\ \text{cm}^2/\text{sec}$$

$$= 9.5 \times 10^{-5}\ \text{cm}^2/\text{sec at } 1700°\text{C}$$

This is a perfectly reasonable value for diffusion through a liquid.

If we insert the values computed above in the expression

$$D = D_o\, e^{-Q/RT}\ \text{cm}^2/\text{sec}$$

where Q is the activation energy for diffusion, R the gas content, and T the absolute temperature, we find that the temperature dependence of the diffusion coefficient below 1760°C can be described by

$$D = 2.6 \times 10^{-3}\, e^{-13000/RT}\ \text{cm}^2/\text{sec}$$

Wernick (7) attempted to measure diffusivities for aluminum-rich and gold-rich zones in silicon and germanium. He obtained reasonable values of D, but found a high activation energy and therefore concluded that true diffusivities were not being measured.

In the case of SiC, it is apparent that, providing rigorous surface cleaning is carried out, acceptable activation energies will be exhibited, and true diffusivities can be computed from zone movement measurements.

Summary

Using and travelling solvent method (A) silicon carbide single crystals can be grown from chromium 5 w/o Ta and various chromium-silicon alloys. In this way the wetting of the SiC surfaces by the solvent is more easily effected such that no elaborate surface cleaning techniques are necessary. (B) Large single crystals of SiC can be produced; (C) Purification of SiC can be achieved; (D) Providing clean surfaces are used, it is possible to measure diffusivities in liquids accurately.

A Study of the Phase Transitions in $PbZrO_3$

Victor J. Tennery

Department of Ceramic Engineering, University of Illinois, Urbana, Illinois

ABSTRACT

An investigation of the linear thermal expansion of high purity specimens of polycrystalline $PbZrO_3$ has revealed that a ferroelectric phase is stable in this compound between 226° and 236°C on heating. The same phase exists between 226° and 212°C on cooling. The data were all obtained at a constant heating and cooling rate of 1°C/min. The thermal expansion of high purity specimens containing about 200 ppm more calcium than those exhibiting the ferroelectric phase did not indicate the existence of such a phase. Hysteresis loop measurements of the low calcium containing materials showed well defined ferroelectric hysteresis loops with $E_c \simeq 2.5$ kv/cm and $P_s \simeq 23\mu$ coulombs/cm^2 at 215°C whereas similar measurements on the more impure material revealed a field induced antiferroelectric → ferroelectric phase transition. The substitution of 0.05 weight per cent of calcium for lead in the purer $PbZrO_3$ resulted in the disappearance of the ferroelectric phase.

The compound $PbZrO_3$ has been the subject of many investigations. Roberts (1) and Smolenskii (2) first reported a dielectric anomaly on the basis of measurements made on polycrystalline specimens. These authors found a peak in the dielectric constant which occurred at about 230°C. Shirane (3) and Smolenskii (4) reported that the sign of the volume anomaly on cooling was negative, in contrast with $BaTiO_3$ in which it is positive. Sawaguchi *et al* (5, 6) established that the phase occurring below 230°C was antiferroelectric, but that in the presence of high electric fields a ferroelectric phase could be induced at temperatures just below the transition temperature of 230°C.

Several systems of solid solutions involving $PbZrO_3$ and various other perovskite-type compounds have been investigated extensively. The system $PbTiO_3$-$PbZrO_3$ has been reported upon by Shirane *et al.* (7-9) and by Sawaguchi (10). These studies indicated that the substitution of even a few atomic per cent of titanium for zirconium in $PbZrO_3$ resulted in the appearance of a rhombohedral ferroelectric phase whose distortion from a cubic perovskite was similar to that observed in the low temperature phase of $BaTiO_3$. Detailed investigations of the piezoelectric properties of poled ceramics in this system have been reported by Jaffe *et al* (11) and by Kulcsar (12). Investigations of the solid solutions $PbZrO_3$-$BaZrO_3$ have revealed that the same rhombohedral phase appears when lead is partially replaced by barium as reported by Roberts (1), Shirane (13), and Shirane and Hoshino (14). On the other hand, investigations of the systems $PbZrO_3$-$SrZrO_3$ and $PbZrO_3$-$CaZrO_3$ reported by Shirane (13) and Krainik (15, 16) revealed that in these systems a ferroelectric phase did not appear when some of the lead ions in the structure were replaced by either strontium or calcium.

In the cases of other divalent ions being substituted for lead in $PbZrO_3$ it appears that the ionic radius of the substituted ion is a critical factor in determining whether or not the ferroelectric rhombohedral phase will appear. If the substituted ion is smaller than the lead ion which it replaced, then the ferroelectric phase does not appear. This is the case for strontium and calcium. In the case of barium, the barium ion is larger than the lead ion and when it is partially substituted for lead the ferroelectric phase is observed.

Experimental

This work consists of a study of the phase transition sequence observed on heating and cooling polycrystalline specimens of high purity $PbZrO_3$. Four different lead zirconates were prepared by using four different zirconium oxides, but the same lead oxide as the raw material from which the compound was synthesized. Two of the zirconias were micronized C. P. zirconium oxide[1] and came from different lots of the oxide. The other two zirconias[2] were somewhat different in that one contained 2% hafnium whereas the other contained only 50 ppm hafnium. The lead oxide used in all cases was an ultra high purity litharge[3] from the same lot and shipment.

The preparation conditions for the lead zirconates were held as constant as experimentally possible. The dried PbO and ZrO_2 were weighed on an analytical balance and the powders were dry mixed for 20 min on a vibratory mixer. Reagent methyl alcohol was then added to the powder and the batch was mixed by hand for 30 min with a mullite mortar and pestle.

After the alcohol was evaporated from the batch, the caked material was broken up to about —100 mesh with the mortar and pestle. This powder was calcined at 800°C for 2 hr in covered platinum crucibles. Measurements of the weights of the calcines prior to and after calcining indicated that negligible lead losses occurred during this stage of preparation. After calcining at 800°C the powders were passed through a 100 mesh screen, a small quantity of distilled water was added to the powder and specimens were pressed from this powder in the form of right cylinders 1.4 cm in diameter by 0.8 cm high. These cylindrical specimens were sintered to high density by placing them on platinum in covered theoretically dense magnesia crucibles and firing them at 1240°C for 1 hr. Weight loss records kept on all of the specimens indicated that about 2 to 3% of the PbO present initially was lost from the specimens when sintering them in this manner. It was apparent from a visual examination of the sintered specimens that most of the PbO loss occurred from a narrow region about the outer surface. After sintering, the specimens were weighed and the lead deficient area of each specimen was included in the weight. The lead deficient area of each specimen was then ground away prior to the thermal expansion measurement. Careful examination of the x-ray patterns of these specimens revealed that only the diffraction lines of $PbZrO_3$ were present. Thus the sintered specimens were not nearly as lead deficient as the weight losses indicated.

The thermal expansion of these specimens was measured by means of an automatic plotting fused quartz dilatometer. The thermal dilation of a specimen was detected by a linear displacement transducer whose output was fed to the Y axis of an X-Y recorder. The junction of a chromel-alumel thermo-

couple was imbedded in a 1 mm hole in the specimen. The emf output of this couple was fed to the X axis of the recorder. The relative electric permittivity or dielectric constant, loss tangent, and ferroelectric hysteresis loop properties were measured in the conventional manner.

Results and Discussion

The four lead zirconates which were prepared from the four different zirconias as discussed previously will be designated A, B, C, and D throughout the remainder of the text for convenience. The spectrographic analyses obtained for these materials will be given later. The thermal expansion $\Delta L/L$ *vs.* temperature for $PbZrO_3$-A is shown in Fig. 1 for both heating and cooling. The heating and cooling rate in all cases was 1°C/min. The thermal expansion behavior in this case is essentially identical with that reported by Shirane (13). On heating, the specimen underwent a large expansion between 220° and 230°C. This expansion was associated with the transition from the antiferroelectric orthorhombic structure to a paraelectric cubic structure (17). On heating, a discontinuity in the thermal expansion is apparent between 226° and 228°C indicating that a phase transformation takes place. On cooling the paraelectric → antiferroelectric transition occurred at 229°C, whereas the reverse transformation occurred at 234°C on heating.

The thermal expansion of $PbZrO_3$-B is shown in Fig. 2. In this case, on heating, the specimen underwent a sharp contraction between 226° and 227°C. The thermal expansion was then essentially independent of temperature between 229° and 235°C, whereupon it increased essentially linearly with temperature. In this case it appeared that the antiferroelectric phase originally present transformed to some other phase at about 227°C which subsequently transformed to a paraelectric phase at 235°C. On cooling this specimen to 224°C, a very large expansion occurred with $\Delta L/L$ attaining a maximum value of 4.8×10^{-3} at 210°C. At 209°C this intermediate phase transformed to the antiferroelectric phase and a rapid decrease occurred in the thermal expansion.

The thermal expansion of $PbZrO_3$-C was very similar to that of $PbZrO_3$-D shown in Fig. 3. In this case, on heating, the thermal expansion exhibited the usual large increase above 220°C, exhibited a sharp change at 228°C, was temperature independent to 230°C then increased linearly with temperature. On cooling, the thermal expansion exhibited an abrupt increase at 226°C, was temperature independent from 222° to 213°C, and then decreased very rapidly.

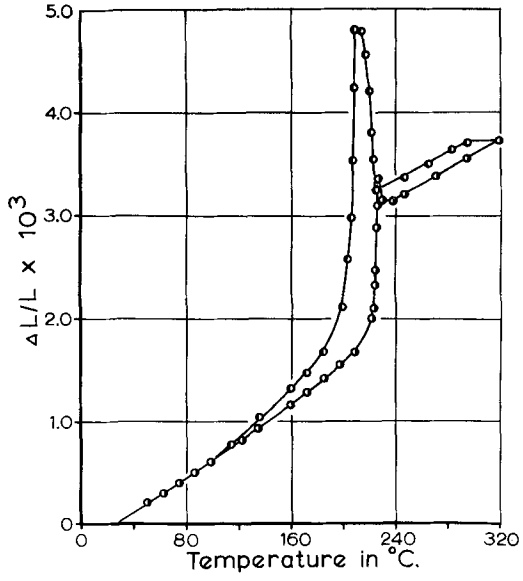

Fig. 2. Linear thermal expansion vs. temperature for $PbZrO_3$-B, half dark circle, right side, heating, half dark circle, left side, cooling.

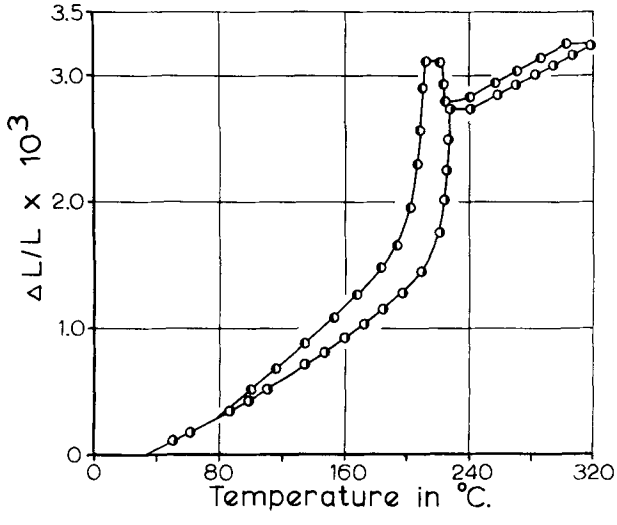

Fig. 3. Linear thermal expansion vs. temperature for $PbZrO_3$-D, half dark circle, right side, heating, half dark circle, left side, cooling.

The thermal expansion of $PbZrO_3$-D is shown in Fig. 3. In this case the thermal expansion on heating was very similar to that observed in $PbZrO_3$-B. There was a slight contraction at 226°C, then a temperature independent region from 226° to 236°C, then the expansion increased linearly with temperature. On cooling there was a large expansion at 226°C, an essentially temperature independent region to 212°C, and then an abrupt contraction at this temperature.

Spectrographic analyses were obtained of all four of the lead zirconates discussed. The analyses agreed reasonably well with those estimated from the analyses obtained from the suppliers of the starting oxides. The analyses of the eleven major impurities present in the four lead zirconates discussed previously are shown in Table I.

It was apparent from the thermal expansion data that there was some critical difference between $PbZrO_3$-A and the others. The spectrographic analyses indicated that $PbZrO_3$-A differed from the others primarily in that it contained higher concentrations of calcium and silicon. However, $PbZrO_3$-D contained nearly as much silicon as did A, but it still exhibited expansion properties very similar to those of B and

* Concentrations are in ppm except where otherwise noted.

C. Thus, silicon did not appear to be a critical impurity. In order to experimentally evaluate the conclusion that calcium was the critical impurity in $PbZrO_3$, experimental compositions were prepared in which some calcium was intentionally substituted for lead. The following compositions were prepared: $Pb_{0.99965}Ca_{0.00035}ZrO_3$, $Pb_{0.999}Ca_{0.001}ZrO_3$, $Pb_{0.995}Ca_{0.005}ZrO_3$, $Pb_{0.99}Ca_{0.01}ZrO_3$. It was not felt that it would be possible to experimentally provide a homogeneous distribution of the calcium at such small concentrations, but it was thought that some indication of the dependence of the appearance of the intermediate phase on the calcium concentration would be gained. The zirconia used to prepare $PbZrO_3$—D was used for all of these compositions. The thermal expansion of the composition $Pb_{0.99965}Ca_{0.00035}ZrO_3$ differed very little from that shown in Fig. 3. One of these specimens was then crushed, repressed, refired, and measured. The expansion curve of this specimen revealed that the temperature range in which the intermediate phase existed was much narrower than in the previous case where the specimen had been sintered only once. The thermal expansion curves of some of the other compositions noted above are shown in Fig. 4 and 5. It is apparent from these figures that even small concentrations of calcium in $PbZrO_3$ have a profound effect on the phase transition sequence in this compound. In Fig. 5 it is shown that as little as 0.05% by weight of calcium present in the zirconate will completely prevent the intermediate phase from appearing. These data corroborate the results obtained for $PbZrO_3$—A. From Table I it is apparent that $PbZrO_3$—A also contained more magnesium and less hafnium than did B, C, or D. The $PbZrO_3$—A material contained about 25 ppm more magnesium than did $PbZrO_3$—D. It is difficult to access the significance of such a small concentration difference in the presence of other impurities. Because of the small size of the Mg^{+2} ion relative to Pb^{+2}, the amount of magnesium which can substitute for Pb^{+2} in the $PbZrO_3$ structure is probably very limited. Any magnesium ions which do substitute for lead in the structure probably tend to influence the phase transitions of the zirconate in the same way as do calcium ions, since calcium and magnesium are from the same periodic family. The hafnium concentration in $PbZrO_3$—A was slightly less than the lower limit of 100 ppm necessary for reasonably accurate quantitative spectrographic results. $PbZrO_3$—B and D contained somewhat more hafnium than this limit. This difference in hafnium appears to be insignificant as substitutions of hafnium for zirconium in $PbZrO_3$ would be expected to make the appearance of ferroelectricity less likely due to the fact that $PbHfO_3$ is an antiferroelectric crystal at 25°C, and a ferroelectric phase has not been observed in this compound even when it is subjected to intense electric fields at high temperatures.

The electric flux density was examined as a function of electric field and temperature for specimens of $PbZrO_3$—A, B, C, and D to establish if the intermediate

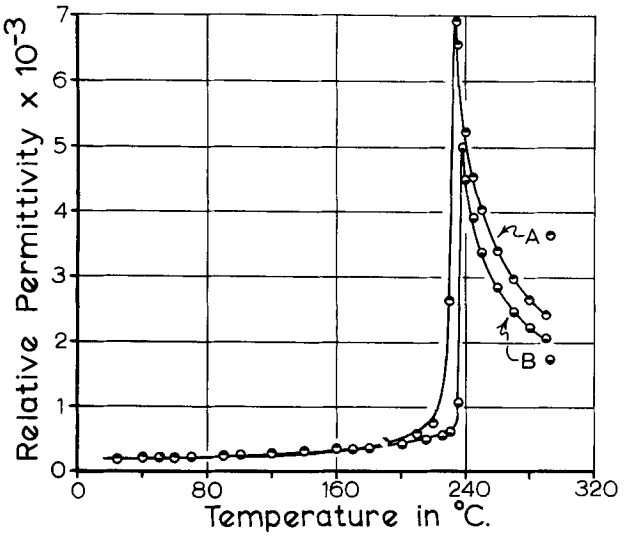

Fig. 7. Dielectric constant *vs.* temperature for $PbZrO_3$-B, curve A, half dark circle, top; and for $Pb_{0.995}Ca_{0.005}ZrO_3$, curve B, half dark circle, bottom.

phase observed in $PbZrO_3$—B, C, and D was ferroelectric. The data obtained for $PbZrO_3$—A are shown in Fig. 6 (a). The trace shown in Fig. 6 (a) is very similar to that reported by Sawaguchi (18) illustrating the transition from an antiferroelectric phase to a ferroelectric phase at some critical field which is temperature dependent. Figure 6 (b) shows that the intermediate phase observed in all of the lead zirconates containing low concentrations of calcium impurities is indeed ferroelectric with a coercive field of about 2.5 kv/cm and a spontaneous polarization of about 23 μcoulombs/cm^2 at 218°C. Just below this temperature the hysteresis loop vanished and was replaced by the linear relationship expected for the antiferroelectric phase.

The relative dielectric constants of specimens of $PbZrO_3$—B and $Pb_{0.995}Ca_{0.005}ZrO_3$ are shown in Fig. 7. The densities of both specimens were approximately 93% of the theoretical for $PbZrO_3$. It is evident that the occurrence of the ferroelectric phase in the material $PbZrO_3$—B was accompanied by a much higher maximum dielectric constant than was the case in $Pb_{0.995}Ca_{0.005}ZrO_3$ where the ferroelectric phase did not appear.

Acknowledgments

The author would like to express his appreciation to Mr. R. M. Brown who helped prepare many of these materials and to Mr. K. Hang and N. Harris for helping with the measurements. This work was supported under contract NONR 1834 (38).

Diffusion-Controlled Attack of Glass Surfaces by Molten Hydroxides

Roger F. Bartholomew

Research and Development Laboratories, Technical Staffs Division,

Corning Glass Works, Corning, New York

ABSTRACT

The attack of soda-lime-silica, alkali borosilicate, zirconia-silica and alumina-silica glasses by sodium hydroxide and potassium hydroxide melts at temperatures just above their melting points has been studied. Sodium hydroxide attack resulted in a frosty layer bound to the surface; potassium hydroxide left a clear surface. Kinetic measurements were made of the weight loss per unit area as a function of time. Diffusion-controlled mechanisms were indicated in both salts for immersion times equal to or less than 5 min.

The problems associated with the weathering and chemical durability of glass surfaces have been studied extensively (1,2). The rate of attack depends on the nature of the attacking medium. Douglas and Isard (3) studied the attack of a soda-lime and a sodium borosilicate glass in acid and neutral solutions. They showed that the rate was determined by the rate at which the cations diffuse in the glass. A study of the rate of attack of glass surfaces by alkaline solutions made by Schumacher and Schwiete (4) lead to the conclusion that in such systems the weight loss per unit area was proportional to the time of immersion.

The attack of glass surface by molten salts has received little attention in comparison. Many workers in the molten salt field have commented on the attack of glass containers by such media at high temperatures. Lundén (5) has summarized, in a qualitative manner, his experiences of the resistance of glass to various molten salt baths. Elyard and Rawson (6) studied the effect of sodium vapor on the simple Na_2O-SiO_2 system. At 350°C they found that the higher the soda content, the higher the resistance to attack of the glass.

Table I. Major constituents of glasses

	A	B	C	D

Li_2O	—	—	1.0	3.4
CaO	5.2	—	—	—
MgO	3.5	—	—	1.5
ZrO_2	—	—	16.5	—

Metal corrosion by molten salts has received more attention because of the use of such systems in nuclear technology. Much of this work has been concerned with equilibrium studies in molten halides (7).

Experimental Procedure

The major components of the glass compositions studied are given in Table I. These compositions will be referred to afterwards as glasses A, B C, or D. Slabs of glasses A, B, and C with approximate dimensions of ½ x ½ x ¼ in. were ground and polished to give a smooth finish. Glass D was similarly treated to give slabs of ½ x ½ x ⅛ in. The chemicals used in this work were Baker Analyzed Reagent grade pellets. The sodium hydroxide was 98.6% pure (0.29% Na_2CO_3), and the potassium hydroxide was 86.0% pure (0.94% K_2CO_3). The major impurity was water. The salts were fused without further purification and left molten for several hours before use, to drive off the water. Nickel crucibles were attacked to a certain extent by fused potassium hydroxide; so all runs were made with the salts fused in zirconium crucibles having a capacity of approximately 50g of salt.

The salts were fused in a tube-type furnace whose temperature could be controlled to within a degree. The sodium hydroxide runs were made at 350°C, the potassium hydroxide at 425°C. The temperature of the furnace was measured by means of a shielded chromel-alumel thermocouple attached to a L&N potentiometer. The slabs were placed in a nichrome wire basket, washed in an ultrasonic cleaner with a detergent, rinsed with distilled water and acetone, and dried in an air oven at 140°C. The samples were then placed in a dessicator, cooled, and weighed. The dimensions of each slab were determined using calipers. The basket plus slabs were preheated in the furnace for at least 2 min, then quickly transferred to the fused salt, and completely immersed. The time of immersion was noted using a stop watch graduated in tenths of a second. The samples were removed from the salt, allowed to cool for 5 min, and then rinsed with tap water. For final cleaning they were placed in an ultrasonic cleaner, and the procedure outlined above was repeated to obtain the loss in weight. The nichrome baskets were attacked to a small extent by the molten salts. Potassium hydroxide melts were observed to be slightly brown in color after several immersions of a basket in the melt. It was assumed that any such impurity would not interfere with the glass attack. These baskets were not exposed to the salt for long times, so while nickel crucibles were badly attacked after several days, the attack of the baskets was very slight. When the brown color was apparent the melt was discarded. The baskets themselves showed no sign of deterioration, beyond a slight blue coloration.

The surface attack was also studied using a Leitz "Ortholux" microscope fitted with an "Aristophot" camera equipped to take 4 x 5 in. Polaroid Land film.

Results and Discussion

There was a major difference in the appearance of a glass sample attacked by sodium hydroxide and one attacked by potassium hydroxide. Sodium hydroxide attack always resulted in a frosty appearance of the surface, making the sample opaque; potassium hydroxide attack left a transparent surface. Photomicrographs were taken of the surfaces after attack. Sodium hydroxide attack is characterized by the topography shown in Fig. 1. This shows the raised character of the frosty layer which causes the samples to be opaque. Close examination of this type of surface shows no crystalline features. This was confirmed by surface x-rays, and by x-ray studies of the surface of glass D which flaked off when dried. In both studies the surface was found to be amorphous. Potassium hydroxide attack, in comparison, gives rise to a featureless surface as shown in Fig. 2. There were slight differences in topographical features between the different compositions treated in the same melts. For instance, the size of the features formed by sodium hydroxide attack on glass A at any one time were much smaller than on glass B.

Fig. 1. Glass B, NaOH, 5 min, 350°C. Magnification approximately 55X.

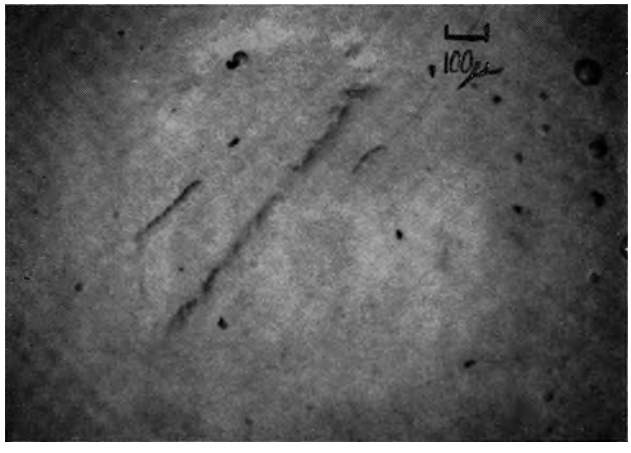

Fig. 2. Glass A, KOH, 1 min, 425°C. Magnification approximately 55X.

Weight Change Studies

The change in weight per unit area was measured as a function of time for all the glass compositions in both molten sodium hydroxide and potassium hydroxide. These runs were made at 350°C in molten sodium hydroxide (mp 322°C) and in molten potassium hydroxide at 425°C (mp 410°C).

The attack of the glasses by molten potassium hydroxide may be considered to proceed by dissolution of the glass. The dissolution of a solid in a liquid may be treated by the method used by Cooper and Kingery (8) in their studies of the dissolution of sapphire in molten calcia-alumina-silica slags. They showed, that in the region where molecular diffusion governs the rate of dissolution, their results could be expressed by the equation

$$Y = 2\alpha\,(Dt)^{1/2} \qquad [1]$$

Y is the change of solute thickness for a semi-infinite slab, D the effective binary diffusion coefficient, and the constant α can be obtained from the expression

$$f(\alpha) = \pi^{1/2}\alpha \exp \alpha^2 \operatorname{erfc} \alpha \cong - \left(\frac{W_1 - W_\infty}{1 - W_1} \right) \quad [2]$$

The function $f(\alpha)$ has been plotted (9), so that α can be obtained once the right-hand side of Eq. [2] has been evaluated. The saturated weight fraction W_1 represents the saturation concentration of the solute in the solvent, and W_∞, the bulk weight fraction, represents the concentration of solute in the solvent before dissolution, and is equal to zero in these systems.

The weight change per unit area, $\Delta W/A$ is related to the change in thickness Y by the expression

$$\frac{\Delta W}{A \cdot \rho} = Y \quad [3]$$

where ρ is the density of the glass. Combining Eq. [3] and Eq. [1] leads to

$$\frac{\Delta W}{A} = 2\alpha \cdot \rho \cdot (Dt)^{1/2} \quad [4]$$

Plots of $\Delta W/A$ against $t^{1/2}$ are shown in Fig. 3. The potassium hydroxide data are represented by the triangles; the sodium hydroxide data by the circles. The bars indicate the spread in the values of the weight change per unit area at a given time. The times of immersion are restricted to 5 min or less, as deviations from linearity were larger for longer immersion times, indicating that diffusion is no longer rate controlling. The data show a certain amount of scatter due to the difficulty in preparing reproducible glass surfaces. A least mean square analysis was applied to all the data. The Student t test, using a 5% confidence level, indicated that in the potassium hydroxide/glass systems there was no significant difference between the calculated intercept and zero, except for the system potassium hydroxide/glass D. The same test applied to the sodium hydroxide/glass systems indicated a significance in the calculated intercept, except for the sodium hydroxide/glass D system, which was not significantly different from zero. It was reported earlier in this discussion that in this system the surface layer flaked off on drying the sample. The points indicate the change in weight per unit area after this layer had been removed. The reason for a significance in the intercept in the potassium hydroxide/glass D system is not too clear. The samples after treatment had the same appearance as the other three compositions treated in potassium hydroxide. A possible explanation is that the diffusion controlled mechanism breaks down before 5 min, in which case the first four points only should be considered. If this is so, then using the statistical treatment outlined earlier, an intercept not significantly different from zero is obtained. The initial slope obtained by this method was used to calculate the effective diffusion coefficient shown in Table II. However, it should be taken as indicating only an approximate value.

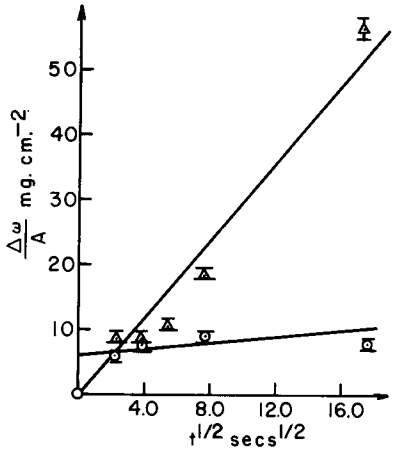

Fig. 3A. Weight loss per unit area as a function of the square root of time. Glass A: ⊙, NaOH, 350°C; △, KOH, 425°C.

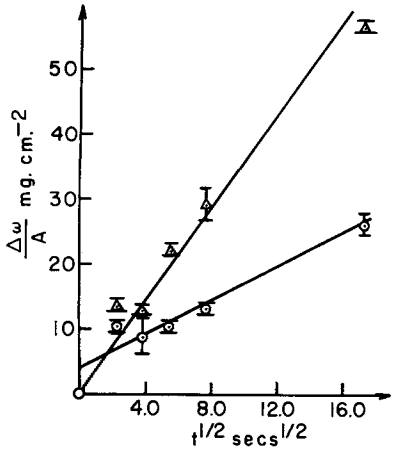

Fig. 3B. Weight loss per unit area as a function of the square root of time. Glass B: △, KOH, 425°C; ⊙, NaOH, 350°C.

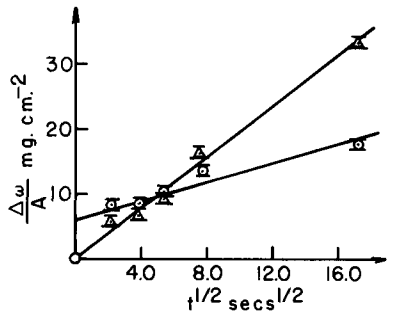

Fig. 3C. Weight loss per unit area as a function of the square root of time. Glass C: △, KOH, 425°C; ⊙, NaOH, 350°C.

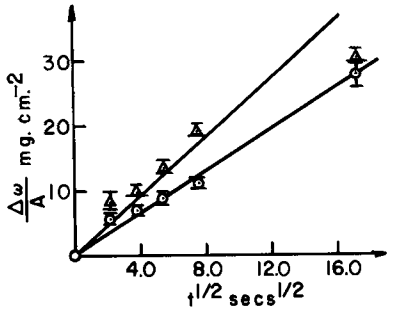

Fig. 3D. Weight loss per unit area as a function of the square root of time. Glass D: △, KOH, 425°C; ⊙, NaOH, 350°C.

The mechanism for surface attack of a glass by sodium hydroxide does not appear to be supported by a simple dissolution process as is found for potassium hydroxide attack. After immersion in sodium hydroxide one, or several, of the reaction products are left strongly bound to the surface, giving rise to the frosted look, and except for glass D are difficult to remove. A diffusion-controlled mechanism is still indicated in these systems by the linear relationship between the weight change per unit area and the square root of the immersion time. The boundary conditions required to apply the treatment of Cooper and Kingery, however,

Table II. Diffusion coefficients in the KOH/glass systems at 425°C

Glass	W_1	ρ, g cm^{-3}	α	D, cm^2 sec^{-1} 10^5
A	0.26	2.47	-0.15_5	1.5
B	0.18_6	2.23	-0.11	5.4
C	0.21_1	2.61	-0.12_5	0.9_2
D	0.22_7	2.44	-0.13	1.3

do not hold. The potassium hydroxide/glass systems, on the other hand, appear to obey these boundary conditions.

A value for the diffusion coefficient in Eq. [4] can be found once W_i, the saturation weight fraction, is known. This latter quantity was obtained by adding known weights of powdered glass slowly to the bath until the melt solidified. The weight of glass in a given weight of salt was then used to obtain W_i. Although this is not an exact measure of W_i, it gives a value which is close enough for calculating diffusion coefficients. The values of D obtained are given in Table II.

All the systems give a value of D of the same order of magnitude, *i.e.*, 10^{-5} cm^2sec^{-1}. This is very similar to values obtained for cation and anion self-diffusion in fused salts at these temperatures (10). However, it should be pointed out that Eq. [4] holds only for molecular diffusion in a binary system. In the dissolution of glass, the system is probably more complicated than a binary system, although one could consider it as a diffusion of potassium hydroxide to the glass surface, followed by the diffusion away from the surface of the reaction products.

Acknowledgments

The author wishes to thank Stanley Lewek for obtaining the weight change data. He also wishes to thank Dr. J. S. Olcott, Dr. R. M. Tichane, Dr. H. M. Garfinkel, and Mr. P. B. Adams for their suggestions and constructive criticism of this paper.

ABSTRACT

Thin film deposits of Cu, Ni, and Rh were obtained by hydrogen reduction of $Cu(tfa)_2$, $Cu(hfa)_2 \cdot H_2O$, $Ni(hfa)_2 \cdot 2H_2O$, and $Rh(tfa)_3$ from the gas phase (tfa = trifluoroacetylacetonate anion; hfa = hexafluoroacetylacetonate anion). The chelates are well suited for gas plating purposes by virtue of their high volatility and ease of reduction by hydrogen. The deposition process can be conducted at atmospheric pressure and at temperatures as low as 250°C. The process is potentially cyclic, free chelating agent being regenerated by the reduction reaction.

Chemical vapor deposition processes are the subject of increasing interest for applications in which it is difficult or impossible to use conventional methods for coating objects with metals or metal compounds. Perhaps the greatest obstacle to the widespread use of vapor deposition methods in the past has been the unavailability of suitable volatile metal compounds. Examination of the properties of certain fluorocarbon-β-diketonate metal chelates indicated that these compounds are remarkably well suited for vapor deposition purposes.

This paper discusses a vapor plating technique for the deposition of thin metallic films utilizing hydrogen reduction of volatile metal chelates. Thin films of metallic Cu, Ni, and Rh were obtained by reduction of metal chelates formed from trifluoroacetylacetone and hexafluoroacetylacetone. Although some of these compounds have been known for several years, their potential in chemical vapor deposition has not been previously recognized. The chelates are highly volatile, thermally stable, and readily reduced at atmospheric pressure at temperatures as low as 250°C.

Experimental

Reagents.—1, 1, 1-Trifluoro-2, 4-pentanedione, H(tfa), and 1, 1, 1, 5, 5, 5-hexafluoro-2, 4-pentanedione, H(hfa), were purchased from Peninsular Chemical Research, Inc. The former reagent was used without further purification; the latter was redistilled prior to use. The rhodium nitrate was obtained from Alpha Inorganics, Inc., and was used without further purification.

Sample preparation.—The chelates *bis*(1, 1, 1, 5, 5, 5-hexafluoro-2, 4-pentanedionato) copper (II) hydrate $Cu(hfa)_2 \cdot H_2O$, *bis*(1, 1, 1-trifluoro-2, 4-pentanedionato) copper (II) $Cu(tfa)_2$, and *bis*(1,1,1, 5, 5, 5-hexafluoro-2, 4-pentanedionato) nickel (II) dihydrate

Table I. Analytical and melting point data for the metal chelates

Compound	Exp. mp, °C	Lit mp, °C	Carbon, % Theo.	Carbon, % Exp.	H, % Theo.	H, % Exp.	Metal, % Theo.	Metal, % Exp.

$Ni(hfa)_2 \cdot 2H_2O$	209-210	207-208 (3)	23.60	23.64	1.19	1.22	11.54	11.19
$Rh(tfa)_3$	180-184	*cis* 148.5-149 (1) *trans* 189.5-190 (1)	32.05	31.88	2.15	1.74	18.31	18.15

$Ni(hfa)_2 \cdot 2H_2O$ were prepared by mixing an aqueous solution of the metal chloride with an aqueous solution of H(hfa) or H(tfa) in the proper mole ratios. The ligand solutions were slightly acidic, having been almost neutralized by NaOH prior to addition to the solution of the metal salt. The precipitate resulting from mixing the solutions was isolated by filtration, washed with water, allowed to dry, and then purified by recrystallization from benzene.

The *tris*(1, 1, 1-trifluoro-2, 4-pentanedionato) rhodium (III) $Rh(tfa)_3$ was prepared by the method of Fay and Piper (1).

Elemental analyses were obtained for each of the metal chelates. The analytical results shown in Table I indicate good agreement with the theoretical values. Experimental and literature values of the melting points are also tabulated. Fay and Piper (1) have shown by nuclear magnetic resonance spectroscopy that rhodium (III) trifluoroacetylacetonate exists in two geometrically isomeric forms, the *cis* and *trans* isomers. They were able to separate the isomers by column chromatography and found that the melting points of the pure isomers differ by about 40°. In the present study the isomeric mixture was used without separation, which explains why the melting point does not agree with the values given previously.

Plating equipment.—To test the thermal stability, volatility, and plating characteristics of the metal chelates, a simple apparatus was constructed in which two different temperatures could be maintained simultaneously in two different sections. A schematic of this equipment is shown in Fig. 1.

The function of the "vaporization zone," a Pyrex glass tube 3.2 cm OD and 70 cm long, was to provide a means of volatilizing the metal chelate. This gaseous chelate was then transported by hydrogen, the carrier gas, to the "reduction zone," where it reacted and was reduced to a metal plating on the test specimens. The vaporization zone was maintained between 95° and 150°, depending on the chelate being studied. The temperature of the reduction zone was varied over a broad range to determine the optimum temperature at which reaction occurred.

A thick-wall copper tube 44 cm long wrapped with heating and asbestos tapes was used as a furnace to heat the Pyrex tube. A thermocouple embedded in the copper wall was used to monitor the wall temperature. One end of the Pyrex tube was connected through a Pyrex glass joint to a Predictability Flowmeter, Model FM 1042B, while the other end was used as the exit

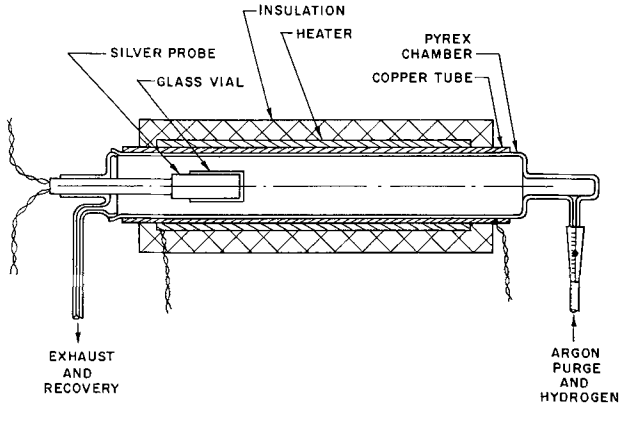

Fig. 1. Schematic of the plating equipment

for the byproducts of the reaction. A 9.5-cm-long, thick-walled, pure silver tube, heated internally by a cartridge heater, was used to heat the test specimens. At steady-state operation there were very small temperature gradients in this silver probe. A thermocouple embedded in this probe measured the reduction zone temperatures. The test specimens were flint glass vials 1.8 cm OD and 7 cm long which securely fitted over the silver probe. These vials were cleaned by dipping them in concentrated nitric acid, rinsing with water and then acetone, and drying in the air.

The heating of both zones was controlled by automatic temperature-regulating equipment capable of maintaining a selected temperature. These vaporization and reduction zone temperatures were continuously monitored and recorded by strip-chart recorders.

Sublimation equipment.—An auxiliary apparatus was used to determine the temperature range which could be used to volatilize the metal chelate at an appreciable rate without causing it to decompose. The lower limit of this range is referred to as the sublimation temperature in Table II. The temperature at which the vaporization zone was actually operated is shown in the second column. Although even higher temperatures can be used, these were judged to be the most satisfactory.

The equipment consisted of a heating bath 22 cm OD and 46 cm high, filled with heating oil. In the oil bath was a coil of glass tubing 4.8 m long. Hydrogen entered one end of the tubing at a carefully controlled flow rate of 16 ml/min and the outlet of the tubing vented to a fume hood. The bottom of the coil contained a glass joint in which the chelates were placed.

The oil bath was agitated vigorously with two stirrers, and the temperature of the bath was continuously recorded. The sublimation temperature recorded in Table II was obtained by very slowly increasing the temperature of the oil bath and observing the value at which crystal growth in the cool part of the glass tubing exposed to the ambient surroundings first became apparent.

Plating experiments.—In each plating experiment the reduction zone was brought to a steady-state temperature, the system was purged with argon and then hydrogen, and the vaporization zone was heated to an appropriate temperature that resulted in reasonably rapid volatilization of the chelate. About 0.01g of the chelate was placed in the vaporization zone of the reaction tube apparatus for each experimental run. The reduction temperature was varied from 200° to 350°C in increments of 10°, while the hydrogen flow rate was varied from 8 to 28 ml/min in increments of 2 ml/min. The best appearing deposits for all four metal complexes were obtained at a reduction temperature of 250° ± 10°C and a hydrogen flow rate of 16 ± 1 ml/min.

Table II. Sublimation, vaporization, and reduction temperatures of the chelates[a]

Compound	Sublimation temp, °C	Vaporization zone, temp, °C	Reduction zone, temp, °C
$Cu(tfa)_2$	85	150	250
$Cu(hfa)_2 \cdot H_2O$	65	90	250
$Ni(hfa)_2 \cdot 2H_2O$	100	135	250
$Rh(tfa)_3$	110	130	250

Results and Discussion

The reaction of a metal salt with H(hfa) or H(tfa) to form the diketonate complexes may occur by several reactions summarized as follows (1-8)

$$MX_n + n\text{H(tfa) or } n\text{H(hfa)} \rightarrow \text{M(tfa or hfa)}_n + n\text{HX} \quad [1]$$

where X may be Cl^-, NO_3^-, CO_3^{2-}, OH^-, etc. The number n depends on the valence and coordination number of the metal ion. Frequently sodium hydroxide or ammonium hydroxide is used in the synthesis to neutralize the ligand. The structure of a representative complex, the *trans* isomer of $Cu(tfa)_2$, is shown in Fig. 2.

The unusual properties of the metal fluorocarbon-β-diketonates arise from the disposition of the fluorine-containing ligands about the metal ions. The organic ligands with highly electronegative fluorine atoms act as a shroud that surrounds the metal atoms, imparting extraordinary volatility to the complexes (4). The chelates studied all sublime at rates satisfactory for deposition purposes at temperatures much lower than those at which thermal decomposition is appreciable. The compounds are easily prepared and handled and are stable indefinitely to atmospheric hydrolysis, unlike many of the compounds used previously for gas plating purposes. As a matter of fact, the complexes are sufficiently volatile and thermally stable to be subjected to quantitative gas phase chromatography. A recent book (9) summarizes the advances made in this interesting field. The data presented in this paper have direct bearing on problems associated with the gas chromatography of the complexes. Thermal stability, volatility, and ease of reduction are considerations of prime importance. The data in Table II, for example, indicate that unnecessarily high column temperatures and injection port temperatures should be avoided, particularly if hydrogen is used as the gas chromatographic carrier gas, or in conjunction with the flame ionization detector, so that decomposition of the chelates will not occur.

The vaporized chelates were reduced by the hydrogen in the reduction zone according to the following:

$$Cu(tfa)_2 \xrightarrow{H_2} Cu + \text{H(tfa)} \quad [2]$$

$$Cu(hfa)_2 \cdot H_2O \xrightarrow{H_2} Cu + \text{H(hfa)} + \text{HY} \quad [3]$$

$$Ni(hfa)_2 \cdot 2H_2O \xrightarrow{H_2} Ni + \text{H(hfa)} + \text{HY} \quad [4]$$

$$Rh(tfa)_3 \xrightarrow{H_2} Rh + \text{H(tfa)} \quad [5]$$

where HY is 1, 1, 1, 5, 5, 5-hexafluoro-2, 2, 4, 4-tetrahydroxypentane (8, 10).

In a separate experiment a large amount of $Cu(tfa)_2$ was completely vaporized and then reduced by hydrogen. The effluent reaction products were trapped in a U-tube cooled by dry ice and were then analyzed by gas chromatography. The analysis showed that H(tfa), the chelating agent, was regenerated, which suggests that it could be re-used in a cyclic process. HY can be dehydrated to regenerate H(hfa) by treatment with phosphorus pentoxide or concentrated sulfuric acid (8, 10). This step is unnecessary for the regenerative synthesis of the copper chelate, however, because both H(hfa) and HY react with copper (II) salts to form the desired complex.

The thin metallic deposits that were obtained adhered very well to the glass tubes, even though the tubes had not been subjected to any special cleaning or etching treatment other than rinsing with concentrated nitric acid, water, and acetone. Although the experimental plates were very thin, there is, of course, no limit to the thickness that can be obtained since this depends only on the deposition rate and time the reaction is allowed to proceed.

All plates were shiny mirrors on both surfaces and all were electrically conductive. The plates were very ductile and, when scraped from the substrate, could be folded to a sharp crease without breaking. No impurities could be detected by x-ray diffraction measurements on the samples. Lattice constants for the metallic deposits are shown in Table III.

As expected, the thickness of the metal plate was found to be a function of both the surface temperature and the concentration of the metal chelate in the gas contacting the surface. Temperature gradients in the surface caused uneven plating. Also, thinner plates resulted in zones where the chelate concentration in the gas phase was depleted.

Although most of the plating experiments were conducted with flint glass substrates, stainless steel substrates were used in a few cases. As expected, adhesion to the metal was even better than to the glass. Any material, for example, plastics, wood, ceramics, etc., could be plated by this method if the object can be heated to the temperature required for plating. Since the temperature required for the reduction is relatively low, heating could be accomplished with a variety of sources, *e.g.*, resistance, infrared, or induction.

Conclusions

Vapor deposition by hydrogen reduction of metal chelates of fluorocarbon-β-diketones provides a new method of obtaining pure, thin film deposits of various metals. Cu, Ni, and Rh were studied in this investigation, and undoubtedly several other metals can be deposited by reduction of similar chelates possessing the required volatility.

Hydrogen was used both as a carrier gas and as a reducing agent. For complexes of some metals, *e.g.*, copper and rhodium, an inert gas may be used as the carrier, and the chelates will undergo self-reduction to yield the elemental metal via thermal decomposition (11). This method appears to yield a less pure deposit, but like the hydrogen reduction method, it occurs at atmospheric pressure, obviating the problems of operating in a vacuum. Because the reduction occurs at any heated surface, both methods offer significant advantages over line-of-sight plating processes.

A Chronopotentiometric Study of the Silver-Silver Chloride and Silver-Silver Bromide Systems

John D. Van Norman

Brookhaven National Laboratory, Upton, New York

ABSTRACT

The dissolution of silver in its molten chloride and bromide was studied using a chronopotentiometric technique. The solubility of silver in molten AgCl and AgBr was evaluated by adding small amounts of silver to the salts until saturation was reached, as measured *in situ*, by anodic chronopotentiometry. The solubility of silver in its chloride at 520°C was 0.0123 mole % and in its bromide, 0.0118 mole % at 500°C. Analyses of the anodic chronopotentiogram wave shapes indicated that the oxidation of the soluble silver species in the chloride and bromide was a reversible one-electron process. Diffusion coefficients for this species were determined to be 2.0 x 10^{-5} cm^2/sec in AgCl at 520°C and 4.2 x 10^{-5} cm^2/sec in AgBr at 500°C.

The dissolution of metals in their own molten salts is of considerable interest from both the theoretical and practical viewpoints (1,2). Metal-metal halide systems have been examined in detail by using a variety of techniques. In most cases the systems which have been reported are those with appreciable solubility of the metal, *e.g.*, solutions of alkali metals, alkaline earth metals, transition metals, and inner transition metals in their salts. In these cases the solubility of the metal generally exceeds 1 mole % where techniques such as measurement of freezing point depression, vapor pressure, conductivity, and emf, are quite useful. Solubilities have been determined chemically with a fair degree of accuracy, and the phase diagrams in many cases are known.

However, there are certain metal-metal halide systems where the solubility of the metal is small, considerably less than 1 mole %. Examples of such systems are the Pb-$PbCl_2$ (3), Mg-$MgCl_2$ (4), Sb-$SbCl_3$ (5), and the Ag-AgCl (6) systems. In such systems the previously mentioned techniques are not always applicable, while electrochemical techniques have been used with considerable success. Egan (3) utilized a polarographic technique to elucidate the mode of dissolution of lead in its chloride. Van Norman and Egan (4) used a chronopotentiometric technique to study the magnesium-magnesium chloride interaction while Corbett *et al.* (5) employed an emf technique in their study of the Sb-$SbCl_3$ system. In each of these systems the solubility of the metal had been determined chemically. An *in situ* electroanalytical technique may well prove more accurate for determining the metal solubilities while also offering additional information on these systems.

This investigation uses such a technique, anodic chronopotentiometry. The Ag-AgCl and the Ag-AgBr systems were chosen because of their low metal solubility to demonstrate the usefulness of the developed technique. Corbett and von Winbush (6) determined the solubility of silver in its chloride at 490°C by equilibrating the molten salt with excess silver, filtering at temperature through a fine quartz frit, and subsequently analyzing the excess silver content in the AgCl by dissolution of the salt in ammonium hydroxide and weighing the free silver. Since silver recrystallizes in molten silver chloride at these temperatures, finely divided silver not in solution may have passed through the fine quartz frit. For this reason they placed a maximum value of the solubility of 0.03 mole %.

The technique developed in this investigation to determine accurately the solubility of silver in its chloride and bromide is an extension of that used by Van Norman and Egan (4) in their study of the Mg-$MgCl_2$ system. Small amounts of silver were added to the molten silver salts and anodic chronopotentiograms were taken after each addition. From the basic equation of chronopotentiometry

$$i_o\tau^{1/2} = \frac{nF\pi^{1/2}D^{1/2}C}{2} \qquad [1]$$

where i_o is the current density, τ the transition time, D the diffusion coefficient, and C the concentration, it can be seen that the product $i_o\tau^{1/2}$ is directly proportional to concentration. Thus a plot of this product *vs.* the amount of silver added will be a straight line until saturation is reached where $i_o\tau^{1/2}$ becomes constant. The diffusion coefficient D can be calculated from the slope of this plot.

Experimental

Materials.—The silver chloride and the silver bromide used in this investigation were supplied by the Amend Drug and Chemical Company and were of C. P. grade. The AgCl was further treated by passing chlorine gas through the powder while raising the temperature slowly above the melting point, at which point the chlorine was passed through the molten salt for four additional hours. The salt was then cooled, transferred to a filtration apparatus, and filtered in the molten state through a fine quartz frit to remove any insoluble materials. The salt was stored in the

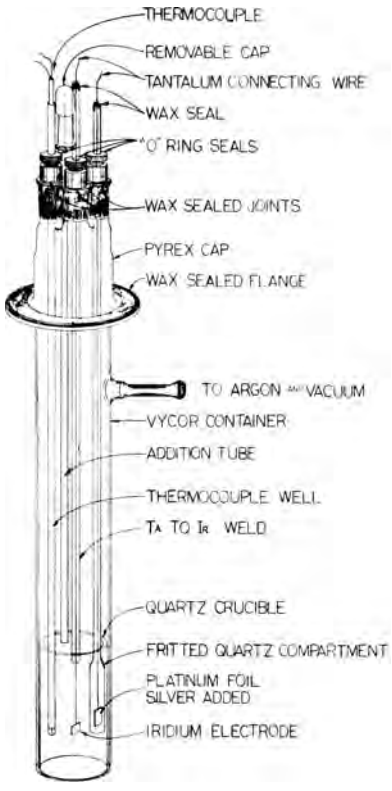

Fig. 1. Experimental cell used for the study of the Ag-AgCl and Ag-AgBr systems.

dark under argon until it was used. The silver bromide was treated in a similar manner with bromine gas. The silver metal used was high-purity foil.

The indicator electrodes used were either tungsten or iridium. It was found that tantalum reacted with molten silver salts to give volatile tantalum salts and silver. Molybdenum oxidized before the soluble silver species was completely oxidized and hence was useless. Tungsten proved satisfactory, but iridium was found to be the best electrode material for both systems.

Apparatus.—The experimental cell shown in Fig. 1 consists of a flanged Vycor jacket sealed with Apiezon wax to a Pyrex cap which has standard tapered joints for insertion of electrodes, a thermocouple well, and an addition tube. The silver salts were contained in an inner quartz crucible. The reference electrode was a platinum foil suspended in a fritted quartz compartment filled with the silver salt and excess silver metal. The indicator electrode was either a tungsten or iridium foil suspended in the main body of silver salt by a fine wire of the same material spot-welded to the foil. Electrical contact was made by a tantalum wire spot-welded to the tungsten or iridium wire. The tantalum wire ran through the quartz tubing which was held by the O-ring seals waxed into the cap. The O-ring seals permitted vertical positioning of the electrodes and thermocouple well. The temperature was measured by a chromel-alumel thermocouple positioned in the well, below the surface of the salt.

The addition tube, sealed through the Pyrex cap, allowed opening of the cell while it was under an argon atmosphere for the addition of small amounts of silver. The cell was contained in a resistance furnace maintained at the proper temperature.

Method.—Pure silver salt was placed in the quartz crucible and the cell assembled and sealed. The cell was then evacuated to a pressure of $<10^{-5}$ mm Hg. Argon was admitted to the cell and the temperature raised to the operating temperature. The fritted quartz compartment, indicator electrode, and thermocouple well were lowered below the surface of the molten salt. Anodic chronopotentiograms were taken of the pure salt by passing a constant current between the reference electrode (which served as the cathode) and the indicator electrode (which served as the anode) while measuring the potential as a function of time. The reference electrode was nonpolarizable as silver was being deposited from a pure silver salt.

The constant current was supplied by an all electronic circuit designed by the Instrumentation Division of Brookhaven National Laboratory and the potential-time curves were recorded on a L&N High Speed Speedomax G recorder which had a pen speed of 0.25 sec, full scale, and a chart speed of 2.0 ips. Transition times for the chronopotentiograms were read directly from the chart recordings with an estimated accuracy of ± 0.025 sec. Transition times were kept between 0.5 and 1.5 sec. Below 0.5 sec the error in reading the transition times became significant, and above 1.5 sec convection due to thermal gradients became important.

A small weighted piece of silver was then added to the pure silver salt and the system equilibrated for at least 20 hr. More anodic chronopotentiograms were taken, and the process was repeated until saturation was achieved. After saturation was established the electrodes and the thermocouple well were withdrawn, and the salt was cooled and weighed.

Results

Anodic chronopotentiograms for the oxidation of the soluble silver species in AgCl at 520°C were obtained at various concentrations; Fig. 2 shows typical examples. Transition times were measured from current onset to the potential break corresponding to the rapid shift of the potential to that of the limiting potential, *i.e.*, the dissolution of the electrode material. In practice, the potential at which this break occurred was determined at each concentration for 4 to 5 waves and subsequent transition times measured to that point.

The product $i_o\tau^{1/2}$ at a given concentration was independent of current density, indicating the validity of this technique for analysis. Final $i_o\tau^{1/2}$ values used in evaluating the solubilities were averages of 8 or more measurements and had an average deviation of $\pm 3\%$. Figure 3 shows a sample plot of $i_o\tau^{1/2}$ *vs.* silver added to silver chloride at 520°C. The diffusion coefficient D for the soluble silver species was calculated from the slope of this plot (see Eq. [1]).

Analysis of the shape of chronopotentiograms can in the ideal case give the number of electrons transferred in an oxidation or reduction process. For the case of the oxidation of silver dissolved in its salts, a plot of potential E *vs.* $-\log(\tau^{1/2}-t^{1/2})$ should be a straight line with a slope of $2.3(RT/nF)$. The quantity t is the time along the chronopotentiogram. A number of such plots gave a straight line with slopes close to that of

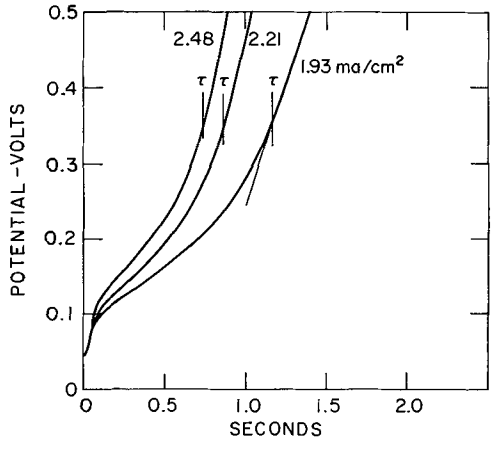

Fig. 2. Typical anodic chronopotentiograms obtained in the Ag-AgCl system using an iridium electrode; temperature, 520°C.

a single-electron process at 520°C, namely, 157 mv. Figure 4 shows such a plot.

Table I summarizes the solubility data, the calculated diffusion coefficients, and the slopes of plots of E vs. $-\log(\tau^{1/2}-t^{1/2})$ for the Ag-AgCl system.

The silver-silver bromide system was studied in the same manner. Anodic chronopotentiograms obtained for the oxidation of the silver species in AgBr were quite similar to those obtained in the chloride. The slopes of the solubility plots varied considerably when tungsten was the electrode material, but were constant when iridium was used. Hence diffusion coefficients were calculated from the iridium results. Plots of E vs. $-\log(\tau^{1/2}-t^{1/2})$ were not straight lines when tungsten was the electrode, but were when iridium was used. Table II summarizes the results obtained for the silver-silver bromide system at 500°C.

Table I. Ag-AgCl (520°C)

Electrode material	Solubility, mole %	Diffusion coefficient, cm²/sec	Slope of plot, E vs. $-\log(\tau^{1/2} - t^{1/2})$, mv
Tungsten	0.0121	1.33×10^{-5}	149
Tungsten	0.0131	1.13×10^{-5}	148

Discussion

The solubility of silver in its chloride at 520°C was found to be 0.0123 mole % as compared with the maximum value set on the solubility at 490°C by Corbett and von Winbush of 0.03 mole %. The observed difference can be accounted for by the inability of the filtration technique to distinguish between dissolved silver and very finely divided silver which may have passed through the quartz frit.

The discrepancy in diffusion coefficients obtained using tungsten as an electrode and that obtained using iridium as an electrode remains a mystery. However, the behavior of the tungsten electrode in the bromide system leads one to suspect these values in the chloride. The probable value of the diffusion coefficient of the soluble silver species in AgCl is 2.0×10^{-5} cm²/sec, quite similar to diffusion coefficients of ions in fused salts.

The plot of E vs. $-\log(\tau^{1/2}-t^{1/2})$ shows a reversible one-electron oxidation process. This can be accounted for by several mechanisms:

$$Ag^0 \text{ (solution)} \rightarrow Ag^+ + e^- \quad [2]$$

$$Ag_2^+ \rightarrow 2Ag^+ + e^- \quad [3]$$

or, in a more general form,

$$Ag_n^{(n-1)+} \rightarrow nAg^+ + e^- \quad [4]$$

where n represents a number of silver ions sharing the excess electron as in an F center. Equation [2] can be rejected as most evidence indicates that metals dissolve in their salts with the formation of an ionic species (1, 2). It is perhaps most meaningful to discuss this system in terms of Eq. [4], where $Ag_n^{(n-1)+}$ represents an F-(color) center with a delocalization of the electron. The number of solute cations, Ag^+, considered bound to the mobile electron is of considerable interest and needs clarification.

The solubility of silver in its bromide at 500°C, approximately the same number of degrees above its melting point as for AgCl, was 0.0118 mole %, which is quite similar to that in AgCl. The diffusion coefficient for the soluble silver species was found to be 4.2×10^{-5} cm²/sec, about twice that found for the chloride system; this is quite reasonable in view of the larger size of the bromide ion. Once again there is a reversible one-electron oxidation process.

The chronopotentiometric technique developed for this study of the Ag-AgCl and the Ag-AgBr systems can easily be extended to other systems where metal solubility is low and difficulties are encountered using other techniques. Valuable information can also be derived concerning diffusion processes in these systems and the nature of the metal-metal salt interaction.

Acknowledgments

The author would like to express his appreciation to Dr. Carl Wagner for suggesting the application of the technique to solubility studies, and to Drs. James Egan and Richard Wiswall, Jr., for many helpful discussions and suggestions. This work was performed under the auspices of the United States Atomic Energy Commission.

Manuscript received July 6, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Oxygen Overvoltage on Bright Palladium in Acid Solutions

James P. Hoare

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

Oxygen overvoltage measurements were made both galvanostatically and potentiostatically on bright Pd electrodes in O_2-saturated $2N$ H_2SO_4 solutions. The anodic evolution and the cathodic reduction of oxygen were investigated, and, in general, the two measuring techniques gave the same kinetic results. The overvoltage curves exhibited a mixed potential region followed by a Tafel region. In the anodic curves these two regions were separated by a limiting current or passivation region. It was found that Pd is a poorer peroxide-decomposing catalyst than Pt, that a film of adsorbed PdO is a poor electronic conductor, that oxygen is evolved on a Pd anode through an oxide mechanism, the decomposition of PdO_2 to PdO and O_2, and that oxygen is reduced from the adsorbed oxygen molecules on a Pd cathode.

In acid solutions, it appears that the best catalysts for the reduction of oxygen are platinum and palladium. However, in the case of Pd, the metal becomes active in a potential region between 900 and 1100 mv according to Vetter and Berndt (1). Because of this solubility of Pd in H_2SO_4 solutions, the potential-determining mechanism on open circuit does not seem to involve the O_2/H_2O reaction

$$O_2 + 4H^+ + 4e \rightleftharpoons 2H_2O \qquad [1]$$

To explain the observed phenomena that the rest potential is independent of pH but dependent on the partial pressure of oxygen, and that an over-all two-electron process is potential-determining, a mixed potential mechanism composed of the Pd/Pd^{++} and the PdO_2/Pd^{++} half-reactions

$$Pd \rightleftharpoons Pd^{++} + 2e \qquad [2]$$

and

$$O_2 + Pd^{++} + 2e \rightleftharpoons PdO_2 \qquad [3]$$

was proposed (2). The potential is controlled by Eq. [3].

Two oxides are formed by Pd (3), PdO, and PdO_2 but PdO_2 is unstable in acid solutions (3, 4). After a Pd electrode had been anodized above 1500 mv, it was found that, in the absence of peroxide, a steady rest potential of 1470 mv was observed (2) which was assumed to be associated with a Pd/PdO_2 electrode. Since this potential coincides with the point on the charging curves (1, 5, 6), where oxygen is first evolved, it was noted (2) that possibly oxygen is evolved on Pd by a mechanism involving the unstable PdO_2.

In this report an account is given of the oxygen overvoltage measurements obtained on bright Pd both galvanostatically and potentiostatically for the cathodic reduction and the anodic evolution of oxygen in oxygen saturated solutions of $2N$ H_2SO_4.

Experimental

Small beads (0.1 to 0.15 cm in diameter) melted at the end of pure Pd wires (99.97%) in an oxygen torch were cleaned by heating white hot in a hydrogen flame followed by quenching in concentrated HNO_3 in a manner described before (7). As checks, three beads were mounted with Teflon spaghetti over the lead wires (polyethylene was avoided, since it may be attacked by peroxides produced in the polarization procedures) in one side of a dual Teflon cell (7). An α-Pd-H reference electrode (8) was mounted in the other side. All purification techniques and all cell and electrode preparations were the same as before (7).

The galvanostatic measurements were determined by the method already described (9) in which the potential was determined with a General Radio electrometer, Model 1230-A. Potentiostatic measurements were determined with a Model 61R Wenking potentiostat. The value of the current was recorded after the current had remained steady for 60 sec using a Weston microammeter. With an electronic current interrupter, it was found that up to a current density of 1 ma/cm^2 the iR correction to the measured potential was less than a millivolt.

Partial pressure of oxygen, P_{O_2}, experiments were carried out in the same way that was done in the case of Pt (7, 9) using a Beckman Oxygen Analyzer to determine the value of P_{O_2} in the N_2-O_2 gas mixtures. The system was stirred with gas flows of at least 350 cc/min to minimize the effects of mass transfer. In all cases, with this stirring rate mass transfer effects were absent. The overvoltage was determined from 1229 mv, the reversible oxygen potential (10), and all potentials are quoted with respect to the normal hydrogen electrode (NHE) unless otherwise noted. These experiments were carried out at a temperature of 25° ± 1°C.

Finally, it was observed that the Pd bead was still bright after the polarization measurements were taken.

Results

After a Pd/PdO electrode, as prepared in ref. (2), had come to a steady rest potential (~870 mv), the galvanostatic polarization at very low current densities was obtained. A plot of these data is given in Fig. 1. As long as the current density range shown in Fig. 1 was not exceeded, these data could be reproduced within ± 0.5 mv. Each point on the curve is the average value of those obtained from three cycles of increasing and decreasing current through the rest potential.

The cathodic overvoltage for the reduction of oxygen on Pd (galvanostatic) is shown in the bottom curve of Fig. 2. The arrows indicate the direction of polarization. There was some hysteresis observed be-

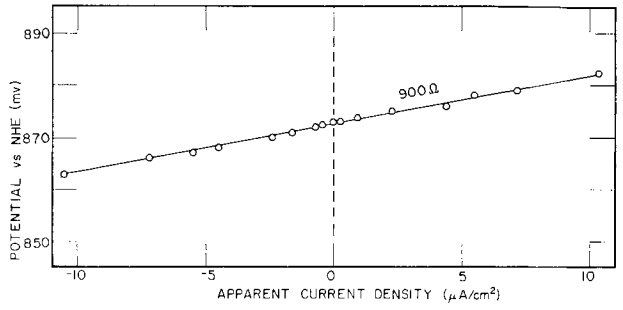

Fig. 1. Plot of potential against apparent current density for a Pd/PdO electrode at very low current densities.

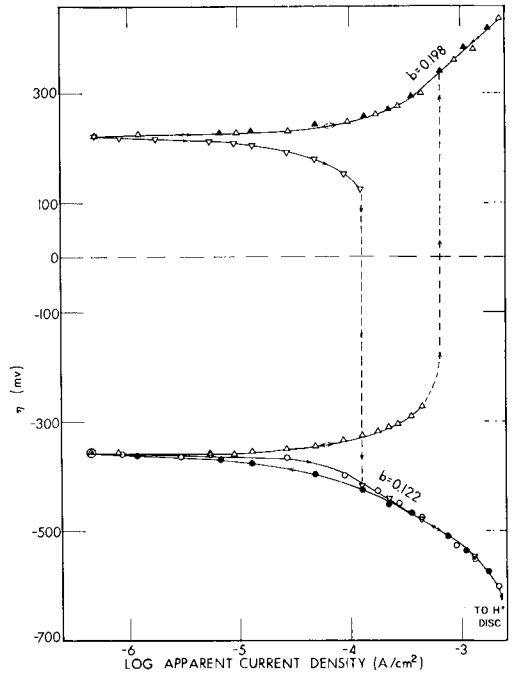

Fig. 2. Oxygen overvoltage curves for the reduction of oxygen (○) and the evolution of oxygen (△) on bright Pd electrodes in O_2-saturated 2*N* H_2SO_4 solution, obtained galvanostatically. The arrows give direction of polarization and, in general, open symbols represent data obtained with increasing current and filled symbols, those with decreasing current. The reduction curve for a Pd/PdO_2 electrode (▽) is also shown.

tween 10^{-4} and 10^{-5} amp/cm². Each point represents the average value of the data obtained from three cycles of increasing and decreasing current, and the deviation from the mean value is within ± 6 mv.

Also in Fig. 2 are presented the anodic overvoltage curves for the evolution of oxygen on Pd. Below a current density value of about 0.7 ma/cm², the curve was highly reproducible (within ± 1 mv) as indicated by the double arrows. Above this point, the potential moved very rapidly (from 960 to 1550 mv within 60 sec) which is depicted by the broken line in Fig. 2 from $\eta = -270$ to $\eta = 320$ mv. Now, a very reproducible curve was obtained in which the points averaged over three cycles of increasing and decreasing polarization deviated within only ± 3 mv from the average value. The steady open-circuit potential value was 1451 mv. When this electrode was cathodized, an irreproducible curve, indicated by the single arrows, was obtained which went into a limiting current above 0.11 ma/cm² (broken line in Fig. 2). Steady state cathodic polarization data after the limiting current was reached gave results identical to the original cathodic overvoltage curve. The complete cycle of events described by the curves in Fig. 2 could be repeated with the same results.

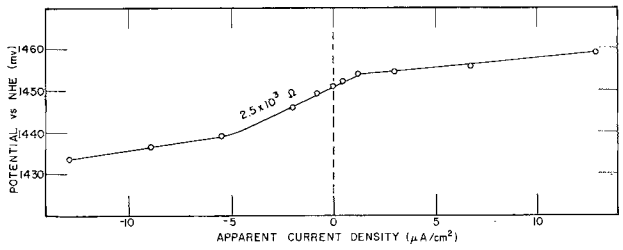

Fig. 3. Plot of the potential against the apparent current density for a Pd/PdO_2 electrode at very low current densities.

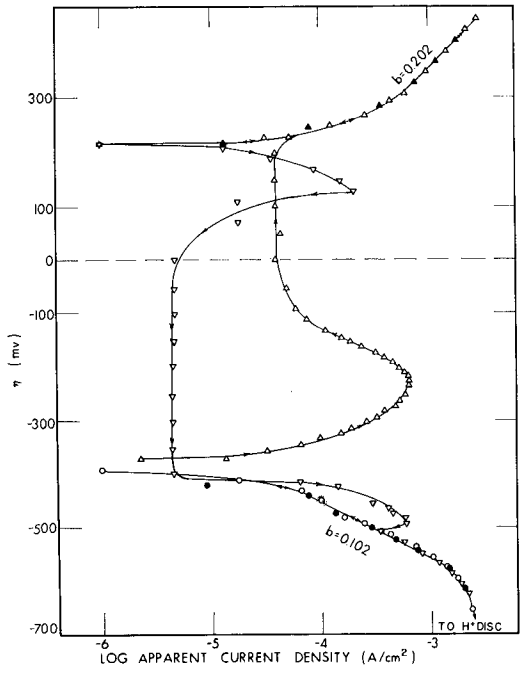

Fig. 4. Oxygen overvoltage curves obtained potentiostatically. The electrode system is the same, and symbols have the same meaning as in Fig. 2.

Polarization data, at very low current densities, obtained on the Pd/PdO_2 electrode are given in Fig. 3. These data are obtained from the anodic polarization curves in Fig. 2 for the electrode with an open-circuit potential of 1451 mv.

The overvoltage curves shown in Fig. 4 were obtained on Pd electrodes potentiostatically. Both the cathodic overvoltage curves below 870 mv ($\eta = -360$ mv) and the anodic overvoltage curves above 1450 mv ($\eta = 220$ mv) are nearly identical to those obtained

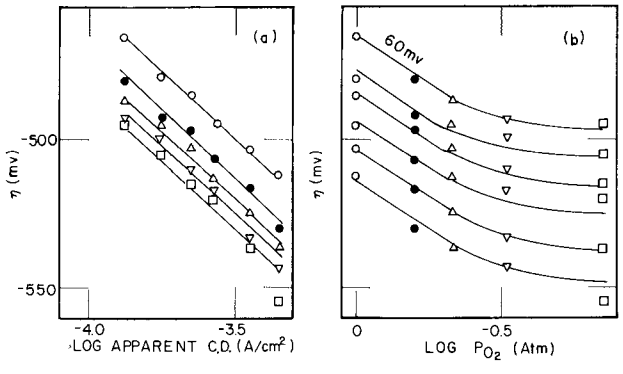

Fig. 5. (a) Oxygen overvoltage curves for the reduction of oxygen on bright Pd obtained galvanostatically with various values of P_{O_2}. P_{O_2} = 1, ○; 0.63, ●; 0.47, △; 0.30, ▽; 0.14, □. (b) Oxygen overvoltage as a function of log P_{O_2}. Lines with a slope of 60 mv were drawn through the first points to show that the data are consistent with a one-electron transfer step.

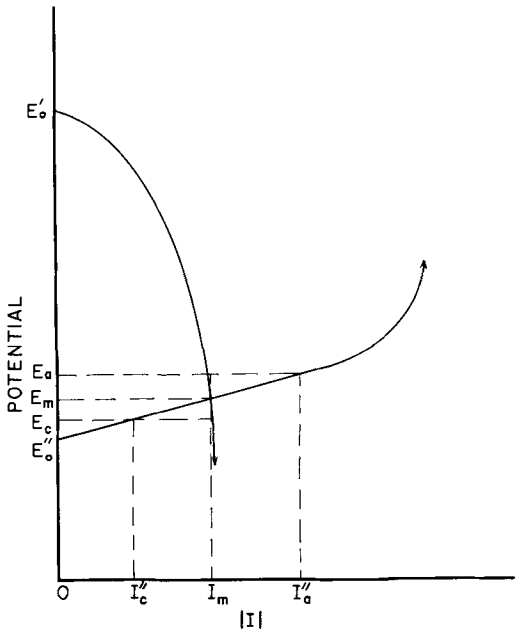

Fig. 6. Sketch of the mixed potential diagram for the Pd-O_2-acid system as a plot of the potential against the absolute value of the local cell current.

galvanostatically. In the potential range between 870 and 1450 mv, where the galvanostatic curves exhibit limiting currents, the potentiostatic curves display typical passivation phenomena. The maximum current density values observed in this potential range correspond well with the limiting current density values observed in the galvanostatic measurements.

Figure 5 contains data showing the variation of the overvoltage with P_{O_2} in the Tafel region for the galvanostatic reduction of oxygen on a Pd cathode. The overvoltage as a function of the current density for various values of P_{O_2} is given in Fig. 5a and as a function of the log P_{O_2} in Fig. 5b. The data in Fig. 5b were obtained from that in Fig. 5a. Similar measurements in the Tafel region for the galvanostatic evolution of oxygen on a Pd anode indicated that the overvoltage is independent of P_{O_2}.

Discussion

Mixed potential region.—As mentioned above, data have been obtained (2) which support the conclusion that the rest potential of a Pd/O_2 electrode is a mixed potential composed of the Pd/Pd^{++} and PdO_2/Pd^{++} half-reactions, with the potential controlled by Eq. [3]. A sketch of a mixed potential diagram that can explain these rest potential observations as well as the polarization data obtained here is given in Fig. 6. E_o' is the equilibrium potential, E_o, for the Pd/Pd^{++} reaction which is 987 mv (10). The E_o for the PdO_2/Pd^{++}, E_o'', is not known, but since the rest potential is 870 mv (2), E_o'' must be less noble than 870 mv, as shown in Fig. 6. To satisfy the requirement that the potential be determined by the PdO_2/Pd^{++} reaction, the Pd/Pd^{++} reaction must be at a limiting current condition at the mixed potential, E_m.

When the system is polarized in the cathodic direction to the potential E_c, the observed external current, I_c, equals the difference between the half-cell currents, I_c' and I_c''. As seen in Fig. 6, I_c' is almost identical to I_m. In like manner, anodic polarization of the system to E_a produces an anodic current $I_a = I_a'' - I_a'$, and again $I_a' \sim I_m$. It may be seen, then, that at very low current densities the system behaves as a reversible PdO_2/Pd^{++} electrode, as shown in Fig. 1. A plot of the reproducible polarization data passes through the open-circuit potential, E_m, without a change of slope. The slope, $di/d\eta$, may be taken as the rate of the electrode process (11) which is 1.1×10^{-3} mho for the PdO_2/Pd^{++} reaction from the data in Fig. 1. It has been shown (9) that the local cell current density, i_m, at open-circuit conditions may be expressed as

$$i_m = \frac{I_m}{A} = (di/d\eta_p)\frac{RT}{F} \qquad [4]$$

where A is the effective electrode area, $\eta_p = E - E_m$, and the other symbols have their usual meaning. From Eq. [4], $i_m = 28.5$ μa/cm^2. Vetter and Berndt (1) found a maximum corrosion current for the dissolution of Pd in N_2-stirred $2N$ H_2SO_4 of about 1 μa/cm^2. It is interesting that in the presence of oxygen a local cell is set up under the driving force of which the dissolution of Pd is increased by an order of magnitude.

Reduction of oxygen region.—With an increase in cathodic polarization, the potential becomes less noble than E_o'', and the mixed potential process can no longer maintain the demanded current density. At this point, the current is obtained from the reduction of oxygen adsorbed on the Pd surface, and a Tafel region is observed (Fig. 2) with a slope of about 0.12. The overvoltage is sensitive to P_{O_2}, and as seen in Fig. 5, a value of 60 mv is obtained as the coefficient of the log P_{O_2} term. As in the Pt/O_2 case, the step favored as the rate-limiting step is

$$O_2(\text{ads}) + e \rightarrow O_2^-(\text{ads})$$

According to an analysis of various mechanisms for the evolution of oxygen (12), it may be shown that a Tafel slope of 0.12 is associated with a mechanism in which the rate-determining step is an electron transfer step.

From Fig. 5b, it is seen that below a P_{O_2} value of about 0.4 the curves deviate from the 60-mv slope by flattening out. Probably this is caused by mass transfer effects. At low values of P_{O_2}, oxygen diffusion becomes rate-determining.

A reproducible hysteresis is observed in the cathodic overvoltage curve in Fig. 2, the values of potential being more noble for increasing than for decreasing current densities. This observation could be explained if the Pd surface were a poor peroxide-decomposing catalyst. The presence of relatively large amounts of peroxide produced at the higher current densities in the neighborhood of the electrode could lower the potential at lower current densities bringing about the hysteresis. By the time a steady open-circuit potential is obtained, this excess peroxide is decomposed, and increasing current densities reproduce the top curve again. This indicates that Pd is a poorer peroxide-decomposing catalyst than Pt, since the overvoltage curves on Pt(9) did not show this hysteresis. The data in Fig. 2 give an $i_o = 5.0 \times 10^{-8}$ amp/cm^2, which is about an order of magnitude larger than that found on Pt (9). Although Pd may be a poorer peroxide-decomposing catalyst than Pt, it may also be a better catalyst for the electron transfer process.

Evolution of oxygen region.—When the system is anodized at progressively higher current densities, a point is reached, as seen in Fig. 6, where the PdO_2/Pd^{++} reaction goes into a limiting current region. At this point, the potential of the system rises rapidly to a more noble value where a new electrode process can supply the demanded current. This behavior is reflected in the anodic overvoltage curve presented in Fig. 2. As long as one remains below a current density of about 0.4 ma/cm^2, steady state reproducible data may be obtained, as shown by the double arrows. Above this point, the system goes into a limiting current region described by the broken line in Fig. 2. Steady state, reproducible, polarization data are obtained again at potentials above 1450 mv ($\eta = 220$ mv).

The overvoltage curve at the top of Fig. 2 has a Tafel region with the very high slope of 0.198. MacDonald and Conway (13) state that anodic electrode mechanisms in which surface oxides play a part are

often accompanied by Tafel slopes of high value. It has been shown (3-6) that PdO_2 is unstable in acid solution. The chemical decomposition of PdO_2 probably proceeds according to the reaction

$$PdO_2 \rightarrow PdO + 1/2O_2 \quad [5]$$

The observed open-circuit potential value of 1451 mv for this anodized electrode is very near the value of 1470 ± 10 mv assumed (2) for the equilibrium potential of the Pd/PdO_2 reaction

$$PdO_2 + 4H^+ + 4e \rightleftharpoons Pd + 2H_2O \quad [6]$$

The small discrepancy between these rest potentials may be due to the presence of peroxides in the electrolyte (2, 7). It was observed that both the rest potential and the overvoltage are independent of P_{O_2}. In Fig. 3, it is seen that the polarization curve for a Pd/PdO_2 electrode, at very low current densities, passes through 1450 mv at zero current density without a change of slope. In view of these experimental observations, it is concluded that the electrode process determining the evolution of oxygen on a Pd/PdO_2 electrode is the chemical decomposition of PdO_2 according to Eq. [5]. The current goes into the conversion of PdO to PdO_2 by the reaction

$$PdO + H_2O \rightleftharpoons PdO_2 + 2H^+ + 2e \quad [7]$$

Over the very low current density range shown in Fig. 3, the electrochemical reaction is the anodic formation and the cathodic reduction of PdO_2 either by Eq. [6] or Eq. [7]. Since it appears that there are two different slopes in the curve of Fig. 3, possibly Eq. [6] predominates in the very low region, ± 2 $\mu a/cm^2$, and Eq. [7] in the higher regions, > ± 2 $\mu a/cm^2$. When the Pd/PdO_2 electrode is cathodized, a polarization curve for the reduction of PdO_2 is obtained until all of the oxide is reduced, after which the system reaches a limiting current as described by the second broken curve in Fig. 2. The system goes rapidly to the reduction of oxygen, and a cathodic polarization curve is found identical to the reduction of oxygen on Pd which was obtained before.

Potentiostatic measurements.—Additional evidence to support the mechanisms described above may be obtained from overvoltage measurements determined potentiostatically on bright Pd electrodes. As seen in Fig. 4, the cathodic overvoltage curve for the reduction of oxygen is almost the same as that found galvanostatically. The Tafel slope seems to be smaller. Possibly this is caused by the influence of peroxide since the hysteresis, observed in the galvanostatic case, was not observed here. With constant current measurements, the rate of the electrode reaction is fixed, and because of the activation energies involved, concentrations of peroxide may build up, producing variations in the potential. The observed effect is the appearance of hysteresis phenomena. With constant potential measurements the rate of the electrode reaction adjusts to the experimental conditions under which the system finds itself, and the effect of the presence of peroxide is added into the over-all electrode kinetics. In this case, the observed effect is the modification of the value of the Tafel slope. Where the build-up of an intermediate is not present, such as in the anodic evolution of oxygen on a Pd/PdO_2 (top curves in Fig. 2 and 4), the constant current and constant potential measurements give identical curves with the same Tafel slope.

The initial part of the anodic potentiostatic curve is almost identical with the corresponding part of the galvanostatic overvoltage curve and may be referred to as the mixed potential region. As the potential is made more anodic, the PdO_2/Pd^{++} reaction enters a limiting current region, as shown in Fig. 6, and a point is reached where a film of PdO begins to form on the Pd surface. The coverage of the surface with PdO is a function of the potential. From the shape of the curve in Fig. 4, it is assumed that this film is a poor electronic conductor, and as the surface becomes covered with PdO with increasing anodic potential, the current decreases. After the surface becomes completely covered with at least a monolayer of PdO, the current falls to a very low value. When the potential has reached values greater than 1450 mv (η = 220 mv), the layer of PdO is converted to one of PdO_2. It is felt that in this region most of the PdO sites have become PdO_2 sites. At higher anodic potentials, the chemically unstable PdO_2 sites decompose to form PdO and O_2, but the newly formed PdO sites are immediately oxidized electrochemically to PdO_2. In this way, oxygen is evolved on a Pd anode by means of an oxide mechanism. There is not enough evidence obtained here to distinguish the nature of the rate-determining step for this mechanism.

When the Pd/PdO_2 electrode is cathodized potentiostatically, a reduction curve similar to that in Fig. 2 is obtained up to the point where all the PdO_2 is removed. Afterward the current falls to a very low value because the surface is covered with the poorly conducting PdO film. Finally, at a low enough potential (about 820 mv, η = —410 mv), a polarization curve for the cathodic reduction of PdO is obtained. When the PdO is used up, the current goes into the reduction of adsorbed oxygen on the Pd surface. This is shown in Fig. 4 by the kink in the curve at about 0.6 ma/cm^2, after which the curve becomes identical with the cathodic overvoltage curve.

Conclusions

From these data, it appears that oxygen may be adsorbed on a bright Pd surface under at least three forms; as adsorbed oxygen atoms, as PdO, and as PdO_2. Oxygen, most likely, is also dissolved in the surface layers of the Pd metal (14,15) but could not be distinguished from the other adsorbed oxygen in this work. Oxygen may be adsorbed as atoms at high negative overvoltages. Reduction of oxygen occurs through the adsorption of molecular oxygen. As in the case of Pt (9), peroxide formed in this process is catalytically decomposed to form oxygen which is adsorbed to complete the cycle. Palladium appears to be a poorer peroxide-decomposing catalyst than platinum.

At low overvoltages, both anodic and cathodic, and at open circuit, the oxygen adsorbed on the surface is in the form of PdO and PdO_2, formed through the mixed potential mechanism. The direction of the local cell is such that the surface should become covered with PdO_2. Since PdO_2 is unstable in this potential region, it decomposes to PdO. However, a complete layer of PdO is also unstable under these conditions, and consequently, bare Pd sites are always available to participate in the local cell reaction. The PdO may be removed from the surface by chemical decomposition, by dissolution in the electrolyte, possibly as a complex ion, or by dissolution in the Pd metal. At open circuit, the over-all result is the corrosion of Pd metal.

In the limiting current region, the Pd surface is completely covered with a monolayer of PdO. The film of PdO is a poor electronic conductor, and the Pd surface is passivated. At high enough potentials (above 1450 mv), the PdO sites may be converted to PdO_2 sites, and in the region above this potential, the surface is considered to be covered mainly by PdO_2. Oxygen is evolved by the chemical decomposition of PdO_2, and the anodic current goes into the formation of PdO_2 from PdO. On open circuit, the Pd/PdO_2 electrode acts like a metal-metal oxide electrode with an electrode reaction corresponding to Eq. [6].

Oxygen Reduction at Silver and Silver-Based Alloy Electrodes

S. Z. Beer and Y. L. Sandler

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Current-voltage characteristics for the reduction of oxygen at silver and alloy electrodes formed with silver and elements having oxides of low electron affinity were studied in pre-electrolyzed and in ordinary 15% KOH solution. In impure solutions or at the alloy electrodes straight Tafel lines were obtained, but with pure silver in pure solutions no such behavior was found. This is taken to indicate a dynamic surface of varying catalytic activity. With silver-magnesium oxide surfaces, a potential about 100 mv higher than with pure silver was obtained at open circuit as well as under current drain. The possible mechanistic significance of the results is discussed in terms of the physical properties of the material and the behavior of the constituents in gas-solid reactions.

Much of the effort in current electrochemical research is directed toward the elucidation of the mechanism of the oxygen electrode. Despite the reduction of the oxygen to water, the theoretical emf corresponding to the oxygen-water reaction is rarely observed. The mechanism of the oxygen reduction is not at all simple, and various processes can interfere to yield potentials below the theoretical 1.229v.

In the present work the effect of gases and additions to a silver electrode on the oxygen dissolution reaction was examined. A study of the silver electrode is of special interest because the mode of oxygen adsorption on the dry surface is now better understood (1-3). Chemisorbed oxygen atoms can exist in different binding states. One such state, a molecular weakly bound precursor state, presumably in form of an O_2^- ion, is likely to be involved in the first steps of the oxygen reduction reaction. Pretreating the silver with hydrogen strongly modifies the reversibility of the oxygen adsorption (3). To relate better the electrochemical behavior to knowledge gained in adsorption studies, silver electrodes pretreated in oxidizing and reducing atmospheres were examined with the view of determining the effect of such pretreatments on electrode properties.

The influence of additions on the catalytic oxidation properties of silver has been investigated frequently (1), and their effect has been attributed to a change in the work function of the surface. Changes of this kind thus might be expected to have an influence on the rate of electron transfer in the adsorption of oxygen, or other intermediate steps in the oxygen reduction reaction. Silver alloys containing elements, which themselves or as oxides have superior electron emissive properties (low electron affinity), were examined, and their properties compared with the similarly treated silver electrodes mentioned above. The approach led to the discovery of a new oxygen electrode alloy which operates in basic solutions at much higher potential and considerably lower polarization than silver alone.

Experimental

All the experiments reported here were done in 15% KOH solutions, prepared from chemically pure KOH and degassed, double-distilled deionized water. Some of the effects were examined both in ordinary and pre-electrolyzed KOH solutions.

Two relatively simple cells were used in these investigations. One was of Teflon and the other of thoria. The cells, about 3 in. in diameter, had concentric cylindrical hydrogen reference cells in the center from which emerged the Luggin capillary. The hydrogen electrode was surrounded by an inner porous thoria cup.

Experiments were performed with ordinary KOH and KOH pre-electrolyzed for 20 hr with 2 platinum wire electrodes of about 0.3 cm^2 area at 40 ma. All handling of chemicals, solutions, and electrodes was done in a glove box under a flowing nitrogen atmosphere.

The working electrodes were squares, ½ in. each side and 10 mils thick. They were made at Westinghouse or elsewhere as stated. The electrodes were all lightly etched in dilute nitric acid, washed, and steamed. They were then annealed as described later. The counter electrode was a platinum wire coil of about the same area. The purification train for the gases consisted, for the oxygen and helium, of BTS catalyst (B.A.S.F., Inc., a form of finely divided copper oxide) at 300°C, $CaSO_4$ (Drierite), magnesium perchlorate, and Ascarite CO_2 absorbent, followed by well-baked molecular sieves (Linde 13X) cooled with a CO_2-methanol bath. For hydrogen, a similar train was used except for the substitution of Pd-asbestos at 250°C for the BTS catalyst and the molecular-sieves trap was cooled with liquid nitrogen. The gas lines were of Teflon tubing.

Current measurements were made with a Kiethley Electrometer 200B equipped with a current shunt and the potential with a Kiethley 660 Null Voltmeter. The current source was a set of mercury cells in series with large step and variable resistors.

The oxygen partial pressure in the various rare gas-oxygen mixtures was measured with a Westinghouse oxygen gauge, operating on the principle of a solid electrolyte fuel cell (4).

Cathodic galvanostatic scans were made by manually setting the driving current between values of 10^{-7} to 10^{-3} amp and waiting approximately 2 min to ascertain that a steady state had been attained. An upper limit of current was determined by the onset of fluctuations which always preceded the sudden drop in potential to the hydrogen evolution region.

Results

Pure silver electrodes.—Silver foils (Handy and Harman, 99.99%) were cleaned as described above and annealed at 500°C in an argon-1% oxygen flowing mixture. One foil was quenched and transferred to ordinary KOH solution, and the cathodic galvanostatic sweep was taken. The other foil was heated in an atmosphere of hydrogen at 400°C. This foil was then quenched and transferred to a KOH solution for the same purpose. In this as in the later cases, rapid flow of oxygen was bubbled over the surfaces of the electrodes, agitating the electrolyte vigorously. The resulting curves are shown in Fig. 1; the arrows show the order in which the individual points were measured. Linear portion of each curve extends over one decade or more with Tafel slopes of about —80 mv for the oxygen-treated foil and —70 mv for the hydrogen-treated foil. The potentials of the hydrogen-treated foil are seen to be somewhat lower than those of the oxygen-treated foil.

Another set of experiments was carried out with pre-electrolyzed solutions. The silver electrodes were annealed in oxygen to remove organic impurities and were then either degassed in helium or reduced with hydrogen. In the first experiment a cleaned silver foil was lightly oxidized in a flowing mixture of helium and oxygen (approximately 0.1%) and then degassed for four days at 500°C in pure helium. The foil was inserted into the pre-electrolyzed KOH solution with oxygen bubbling over the electrodes.

The immediate open-circuit potential, o.c.p., was as low as 0.11v, but after 4 hr rose to 0.980v. The cathodic galvanostatic sweep taken at that time is shown as curve 1 in Fig. 2. After anodizing and cathodizing,

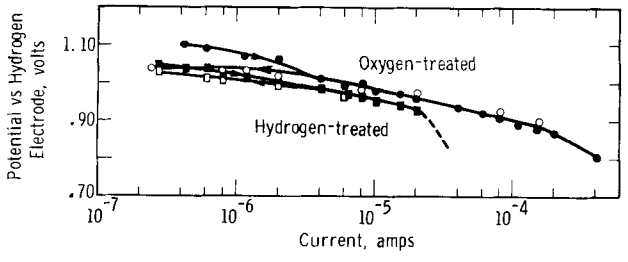

Fig. 1. Cathodic galvanostatic characteristics of silver in ordinary KOH solutions. The arrows indicate the directions in which the points were measured.

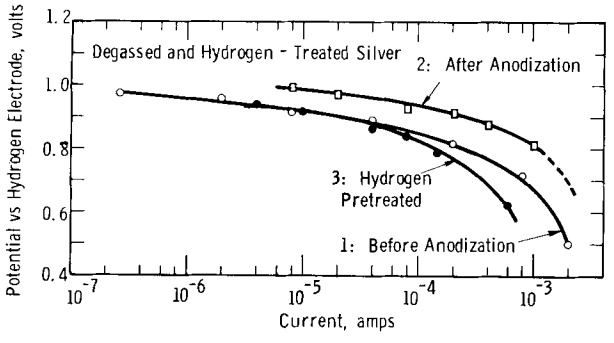

Fig. 2. Effect of pretreatment on cathodic galvanostatic characteristics of silver in pre-electrolyzed KOH solutions.

the o.c.p. rose to 1.034v. The new cathodic galvanostatic sweep taken is shown as curve 2 of the same figure. This galvanostatic characteristic curve corresponds to the highest potentials attained with the silver electrodes regardless of further oxidation and reduction or additional resting in solution. The potentials are now very close to those shown for the oxygen-treated foil as shown in Fig. 1, suggesting that the state of oxygen enrichment of the electrode and the peroxide concentration in solution are about the same for both cases.

The cathodic galvanostatic characteristics of a hydrogen-treated foil can be seen in curve 3, Fig. 2. The foil was treated twice with 20 Torr oxygen in a vacuum system at 500°C, pumped for 16 hr, and then treated with hydrogen at 550°C at 15 Torr pressure before immersion into the pre-electrolyzed solution with oxygen bubbling vigorously over the electrode surface. The o.c.p. was now 0.955v, and the curve is seen to be little different from the degassed electrode (curve 1). Thus, the potentials of electrodes of low oxygen content generally appeared to be somewhat lower than those of the oxygen-pretreated electrodes. A more pronounced effect of this kind was found with platinum in acid solutions (5).

No linear Tafel line portions were obtained in these experiments with pure silver, in contrast to what was found with ordinary KOH solutions. This is seen to be the case even after the potentials have reached the maximum attainable after anodization, where it can be inferred that the peroxide was reduced in concentration comparable to that found in the ordinary KOH solution. It seems possible that some surface property, such as the content in more reversibly adsorbed oxygen, changes continuously with current density. Alternately, this may indicate a change in the dissolution mechanism. This property or mechanism appears to be stabilized by the presence of the impurities which may be present in greater concentration in the ordinary KOH solutions. The possibility of surface stabilization through impurities is seen again later in the results obtained with silver alloys.

Silver-magnesium alloy.—Of the alloys investigated, a silver-1.7 w/o (weight per cent) magnesium alloy yielded the most interesting results. This alloy is used for Dynodes in the construction of phototubes because of its high secondary electron emission (6). In these devices, before the alloy foils are inserted, they are lightly oxidized in an atmosphere containing oxygen in the form of water vapor. The alloy foil, made by Handy and Harman, was annealed in a flow system at 500°C in an argon mixture of low oxygen content for four days. The galvanostatic curve for this foil (Ag-Mg-I) was taken and is shown in Fig. 3. Curve 1 is the curve taken in the direction of increasing currents; curve 2 is the return curve. The open-circuit

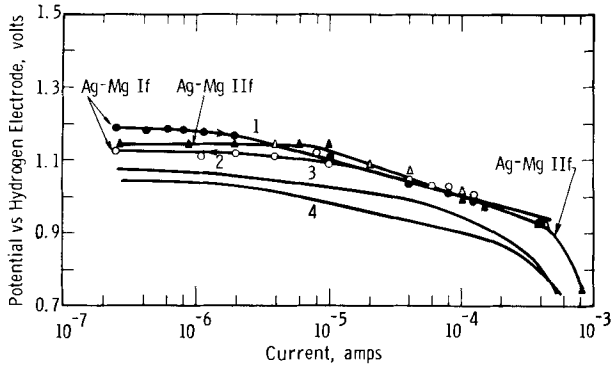

Fig. 3. Cathodic galvanostatic characteristics of silver-1.7 w/o alloy electrodes in ordinary and pre-electrolyzed KOH solutions. The arrows indicate the directions in which the points were measured. Curve 3 of silver in pre-electrolyzed KOH and curve 4 of silver in ordinary KOH are given for reference.

potential stabilized at 1.16v. Straight-line portions are found in these curves over a range of about two decades of current. These yield Tafel slopes of —120 mv.

Another foil of the same composition (Ag-Mg-II) was cleaned and annealed in a helium-0.1% oxygen mixture at 500°-550°C followed by degassing in pure helium. The open-circuit potential in pre-electrolyzed KOH stabilized at 1.14v. Cathodic galvanostatic sweeps were then taken. These results are also shown in Fig. 3 as Ag-Mg-II. Significantly, the potentials are not markedly different from the previous case. Also, contrary to the findings on pure silver in pre-electrolyzed KOH, straight-line portions of the curve are now found. Tafel slopes of —120 mv can be measured.

For comparison purposes, cathodic galvanostatic curves for pure silver are presented in Fig. 3. Curve 3 is that of a silver electrode after anodization in a pre-electrolyzed solution; curve 4 is the same as shown in Fig. 1 for the oxygen-treated silver in ordinary KOH. The over-all potential levels for both Ag-Mg-II and Ag-Mg-I are considerably higher than the highest obtained with pure silver.

To determine whether the open-circuit potentials of 1.16 and 1.14v, found for the electrodes Ag-Mg-I and Ag-Mg-II, respectively, were related in some way to the 1.18v reported for the Ag_2O phase, anodic and cathodic chronopotentiometric measurements were made.

The potentials encountered on anodizing pure silver have been much studied (7). On anodization, the potential rises rapidly, to the first potential plateau of 1.18v, at open circuit, accompanying the formation of Ag_2O. On further oxidation, the potential of the postulated AgO-Ag_2O_3 reaction is encountered at 1.53v, at open circuit. On continued anodization, a third plateau at 1.43v, at open circuit, is attained. This is thought to correspond to the Ag_2O-AgO equilibrium. On cathodization, the voltage falls directly from the 1.43v plateau to the 1.18v level. On anodization, until the 1.53v level is reached it was found by us and others that the current efficiency producing Ag_2O is 100%.

The silver-magnesium alloy electrode Ag-Mg-II was driven anodically to the 1.43v level. On cathodization, more than twice the number of coulombs were driven across the cathode at currents of 10 ma/cm^2. The final open-circuit potential was still 1.135v.

On driving the foil cathodically from the 1.43v level no separate break was found to occur at what might be construed to be a separate 1.18v level. Thus, the 1.14 o.c.p. potential level appears to be some form of stabilized 1.18v level, presumably modified by the presence of MgO in the surface.

Other alloys.—The outstanding behavior of this alloy suggested that other alloying agents having either low work functions or high secondary electron emission characteristics might also be of interest. Thorium, indium, and barium seemed to offer these advantages and so were tried.

A silver 1 w/o thorium alloy was prepared by levitation melting and rolling. Most of the thorium was in the form of the oxide; a photomicrograph showed precipitation at grain boundaries. The foil was cleaned and annealed at 500°C in a helium-oxygen mixture ($P_{O_2} = 0.001$ atm) and was transferred in this state to the pre-electrolyzed KOH. In another set of experiments, a silver 1 w/o indium foil and a silver 1 w/o barium foil, made by William Gold Refining Company, were treated in the same way as the silver-thorium alloy and were then transferred to separate solutions.

The first cathodic sweeps gave rather low potentials. Alternate anodization and cathodic sweeps were performed on each of the alloy electrodes. With each anodization, potential levels of subsequent cathodic polarization curves were higher. The behavior and potentials of these electrodes were much like those of the degassed and hydrogen-treated silver electrodes discussed previously. Thus, no improvement over pure silver was obtained in this last group of alloys. It is, however, of interest to note that linear Tafel regions were found and that these were similar to those found for pure silver in nonpre-electrolyzed solutions, *i.e.*, the slope was about —80 mv.

Discussion

The continuously changing slope found with pure silver in the cleaner solutions may simply indicate that no single step in the reduction reaction is rate determining. The occurrence of distinct Tafel slopes in impure solutions or with alloys, however, indicates that a changing surface may cause this behavior of pure silver. The catalytic properties of the surface may change as a result of a changing oxygen content of the surface, which probably is accompanied by a rearrangement of the surface. Such effects were noted by Germer and his associates in the case of oxygen on nickel (8). Adsorption or incorporation of impurities should reduce the mobility of the surface and may thus cause a more constant activity for the various transfer and chemical steps occurring on the surface.

The fact that the potential of the silver-magnesium oxide surface is higher throughout a relatively broad range of potentials is noteworthy from a practical as well as a mechanistic point of view. The increased activity may be connected with the stabilization of oxygen in the silver lattice by the presence of the magnesium oxide. Alternately, it may be the (silver doped) magnesium oxide that is responsible for acceleration of electron transfer steps. The high activity of this oxide with respect to the recombination of oxygen atoms on surfaces (9) and in the oxygen isotope exchange reaction (10) $O_2^{16} + O_2^{18} \rightarrow 2\,O^{16}O^{18}$ may be related to the superior electron emission properties (6) of the material (low electron affinity) and may explain the higher electrochemical activity.

The outstanding secondary electron emission characteristic of this alloy is well known. The characteristic depends much on the electron mean free path and is somewhat less dependent on surface conditions (11) than is the work function (as a measure of primary emission). The dependence on the latter in the oxygen evolution reaction was studied by Rüetschi and Delahay (12) who concluded that no relationship exists. The same conclusion appears to be warranted on the basis of our results with the Ag-Th, Ag-In, and Ag-Ba alloy electrodes. It must be recognized, however, that the work function is extremely sensitive to surface conditions. The lack of correlation between the work function of the dry solid and related properties of the same solid as an electrode in an electrolyte is not surprising. In the study of this type of dependence, a property such as secondary electron emission might be more useful than the work function. In the light of the unusual behavior of this alloy both in the dry solid-gas state and in an electrolyte, the possibility of an overvoltage dependence on a measurable electron emissive property cannot be dismissed.

The foregoing suggests that other alloys with similar physical properties might show interesting properties as oxygen electrodes. For example, silver-beryllium appears to be promising on the basis of the excellent properties of copper-2 w/o beryllium also much used because of its outstanding emission properties (11). No doubt other alloys of equal promise are possible, however, the paucity of data on these properties makes the selection of other alloys and the comparison with other known systems difficult.

Further work is needed and is at present being carried out to determine the rate-determining step in the reduction reaction on pure silver as well as on the Ag-Mg and other alloys. The analogy with the oxygen isotope exchange reaction indicates that the first adsorption step $O_2 + e^- \rightarrow O_2^-$ might be the slow step in the reaction which is accelerated by the lower electron affinity of the alloy.

Acknowledgment

One of the authors (S. Z. B.) wishes to thank Dr. N. T. Melamed for bringing to the former's attention the availability of the silver-magnesium alloy and Dr. E. J. Sternglass for his stimulating discussions on secondary electron emission.

Electrochemistry in Fused Alkali Thiocyanates

Richard E. Panzer and Michael J. Schaer[1]

United States Naval Ordnance Laboratory, Corona, California

ABSTRACT

Detailed polarographic and chronopotentiometric investigations were conducted in molten potassium thiocyanate and the eutectic mixture of 70 mole % KSCN and 30 mole % NaSCN. Between 150° and 325°C, electrochemical oxidation occurred at a potential of +0.25v (vs. Ag/AgCl) to produce thiocyanogen, $(SCN)_2$, which polymerizes to parathiocyanogen, $(SCN)_x$. At the cathode, the SCN^- ion was reduced to sulfide and cyanide ions at a potential of —1.75v. At higher potentials, the half-wave potentials were —2.35v for Na^+ and —2.92v for K^+. In a continuing series of fractional factorial experiments with laboratory prototype pill cells (laminar, 1-3 mm thick, 1 cm in diameter), thiocyanate electrolytes were used with a variety of alkali metal anodes and various cathode materials such as transition metal oxides, silver salts, and organic nitro compounds. At current densities approaching 100 ma/cm², closed-circuit voltages ranged from 1.50 to 2.50v for at least 5 min. At a temperature of 200°C, this performance is approximately equivalent to that of the best previous thermal cells in LiCl-KCl operating at 450°C.

Ionic melt investigations were conducted in both molten potassium thiocyanate and the eutectic mixture of 70 mole % KSCN and 30 mole % NaSCN. Conductivities were measured at various temperatures, polarographic and chronopotentiometric techniques were applied, and a detailed study was made of suitable reference electrode systems.

Only a few investigations have been conducted in molten alkali thiocyanates. Paterno and Mazzuchelli observed the blue coloration of KSCN when it is heated to its decomposition point (1). Kordes, Bergmann, and Vogel were concerned with the manner in which the freezing point was lowered by various transition metal salts in KSCN (2). Greenberg, Sundheim, and Gruen investigated the spectra of sulfur dissolved in molten KSCN (3); Harrington and Sundheim reported the spectra of various transition metal complex ions in that medium (4); and Baddiel and Janz investigated the Raman spectra and structure of molten thiocyanates (5). Frame, Rhodes, and Ubbelohde have summarized the properties of many single molten salts, including alkali thiocyanates (6). Harrington and Tien have written an article on a reference electrode for use in molten salts, including KSCN (7).

Investigations of ionic melts in the range from 80° to 300°C, which have been conducted at NOLC for several years, are continuing in an effort to discover and develop electrolyte systems usable in high energy-density thermal batteries. Approaching the problem from an applied research viewpoint, energy-density requirements are based on a future need for a battery with 100 ma/cm² at 2.00v per cell and 1600 joules per gram of final packaged battery. This objective limits the available materials, since many previously used thermal cell materials do not perform well in this temperature range because their reactivities are drastically reduced at the lower temperatures.

In keeping with the applied research perspective, the method used at NOLC employs a preliminary screening of prospective materials in a beaker-cell environment. Before incorporation into a practical cell, an electrolyte must meet four criteria: (*a*) a melting point within the 80°-300°C range; (*b*) a minimum specific conductivity of 0.1 mho/cm; (*c*) compatibility with anode and cathode materials; and (*d*) absence of surface effects, such as the formation of an insoluble material that might inhibit further reaction. Although other criteria could have been chosen, these four were considered the most important. Failure to meet any one of these, with no discoverable remedy, is considered sufficient reason for halting work on that electrolyte. Several electrolytes have failed to meet the last three criteria in ways unpredictable from any previously existing data.

After an electrolyte has met all four criteria, it is more thoroughly investigated in a laboratory prototype voltaic cell configuration. Statistically designed sets of fractional factorial experiments are used to determine the best operating conditions, anodes, cathodes, electrolyte combinations, absorbents, and resistive loads. Finally, techniques of polarography and chronopotentiometry are used to answer questions of electrochemistry or reaction mechanisms arising during voltaic cell experimentation. Evaluation of responses from

[1] Present address: Department of Chemical Engineering, Montana State University, Bozeman, Montana.

the statistically designed cell experiments is facilitated by a FORTRAN computer program for analysis of variance and by F (level of confidence) tests for significance, using the Laboratory's 7074 IBM digital computer.

Experimental Procedures

Conductivity measurements were made in molten thiocyanates in beaker-cell quantities, using a dipping-electrode system patterned after Crook and Bockris (8) and Van Artsdalen and Yaffe (9). This assembly consists of platinum-bead electrodes 3 mm in diameter that have been somewhat flattened to a wedge shape. Each rests on the top end of a 1 mm ID capillary about 3 cm long. The capillaries are attached to a center Pyrex tube 7 mm ID and 25-35 cm long, which serves as a thermowell and a holder for the electrode assembly. This dip cell was calibrated using 0.1M aqueous KCl solution. Readings were made on a General Radio Model 1650A bridge. Platinized platinum electrodes were used to reduce polarization effects. Conductivities were determined at several frequencies up to 100 kc to determine inductive effects, but the reproducibility of results at 1 kc was satisfactory and it facilitated comparison with data from other investigators.

Conductivities were also determined in a pill-cell environment. The configuration of these cells, the heating apparatus, and the experimental techniques have been described previously (10). The anolyte mixture consists of the electrolyte salt mixed with a sufficient amount of an inert adsorbent, such as kaolin or alumina to immobilize the electrolyte when it is molten. The catholyte mixture consists of the electrolyte salt with at least 65% of the active cathode material, which also serves as the adsorbent to immobilize the molten electrolyte. Carbon was often added to the catholyte mixture for better conduction between the cathector and the active cathode material.

Anolyte or catholyte pills are prepared by pressing 0.10-0.15g of the desired mixture in a steel die under a pressure of 3500 kg/cm^2 to form wafers 1-3 mm thick and 1 cm in diameter. The assembled electrolyte pill stack between strip electrodes is placed between the platens of a heater fixture, which applies approximately 1100g weight to the cell stack.

For conductivity measurements, the electrodes were platinized Pt strips 2 mm wide. Using single pills of anolyte or catholyte composition, the relative conductivity of different compositions could be determined. Temperatures were controlled within ±1°C using a chromel-alumel thermocouple placed in direct contact with the pill-cell stack and regulated by either a Brown Electronik recorder-controller or a Wheelco Amplitrol anticipating controller.

Instrumentation.—The instruments used for polarographic investigations were a Sargent model XXI polarograph, a Keithley model 210 electrometer, and a Moseley model 135 X-Y recorder. The polarograph was used only as a source of slowly varying potential and not as a recorder. The electrometer was used to measure potential because of the reference electrode's high impedance. Current was recorded as the IR drop across a precision resistor. Figure 1 shows the polarographic setup.

Instrumentation for voltammetry at constant current (chronopotentiometry) consisted of a 270v battery pack with several variable resistors in series to provide a constant current of any desired value from 10 μa to 200 ma. Alternatively, an electronic power supply was used, but more spurious transients were observed on the Tektronix type 545A oscilloscope screen with this setup. A Keithley electrometer was used with the high-impedance reference electrode. Voltage-time curves were recorded on the cathode-ray oscilloscope (CRO) with a Dumont type 450 camera, using Polaroid-Land 3000 ASA film. Figure 2 shows the chronopotentiometric circuit.

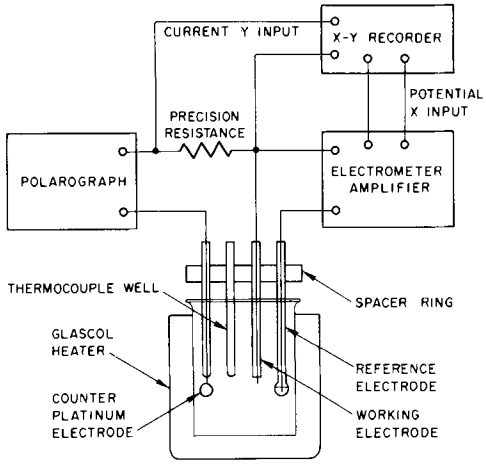

Fig. 1. Polarographic setup

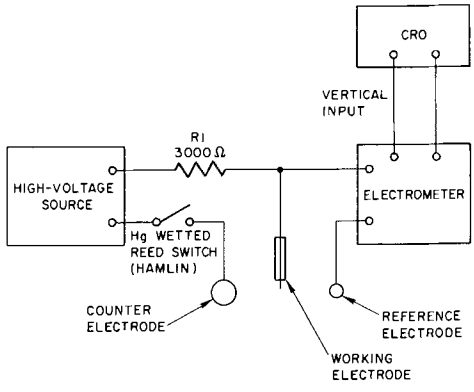

Fig. 2. Chronopotentiometric circuit

All instruments were standardized against a L&N K-3 potentiometer, and all electrode potentials are recorded according to the IUPAC 1953 Stockholm convention.

Reference electrode.—Development of a reproducible, stable, reversible, reference electrode for investigating untried electrochemical systems is almost a research project in itself. The development of a suitable reference electrode for a pill-cell environment has been described previously (11). The electrode mentioned at that time was Mg/MgO, and it was used in LiCl-KCl eutectic at 450°C. However, that electrode was found to be unusable in molten thiocyanates. In this research, the electrodes used and their characteristics were as follows:

Ag-AgCl/$LiNO_3$-KNO_3 *eutectic + sat'd* KCl/*Pyrex glass bulb.*—This electrode consists of a silver wire immersed in a saturated solution of AgCl and KCl in the nitrate eutectic within a thin-walled Pyrex bulb. It is similar to the one described by Inman (12), except for the use of $LiNO_3$ in place of $NaNO_3$. The electrode in this study is stable and reversible within ±2 mv, but an unknown junction potential exists at the external glass interface when the bulb with nitrate on the inside was immersed in the thiocyanate melt. A very large impedance (on the order of 10 meg at 180°C) militates against any fast measurements of polarization and requires the use of an electrometer to avoid loading the electrode during measurements.

5 mole % Na in Hg/soda-glass bulb or capillary.—This electrode, described and discussed by Delimarskii and Markov (13), was found to be stable and reversible when inadvertently loaded. Contact with the sodium amalgam is made with a tungsten wire. Because of the presence of Na^+ ions in the glass, as well as in the melt and amalgam, this electrode behaves as a sodium electrode, reversible to sodium ions. If KSCN is used,

the minute concentration of Na^+ ions required (10^{-5} mole %) may be easily added without changing the melt conditions (14). The bulb-type electrode was used in beaker-cells, and the capillary-type was used in pill-cells 1-2 mm thick. The impedance of the Na-Hg electrodes is quite high, on the order of 1 to 4 meg, depending on the type of glass used. Pyrex glass may also be used with little change in voltage. Against the Ag/AgCl electrode, the amalgam electrode gave 2.11v, measured with an electrometer.

Co/0.1 m $CoCl_2$ in molten KSCN/glass frit or glass bulb.—Harrington and Tien (13) have utilized a similar electrode, but later work by these investigators indicates that the electrode may not be stable enough over reasonably long (24 hr) periods of time (14). The cobalt electrode system contained behind a medium glass frit has a much lower impedance than the glass bulb electrodes, but it is not readily adapted to future use in a pill-cell environment because the small cell precludes use of a fritted separator.

Voltammetric cells.—Beaker-cell investigations were always conducted in the drybox, using three electrodes clamped rigidly in the melt. The chronopotentiometric electrodes were: (*a*) a large platinum counter electrode of about 2 cm^2 area; (*b*) a very small platinum working electrode made of a wire with a cross-sectional area of 8.0×10^{-6} cm^2, fused into a glass tube, and ground flush; and (c) Ag/AgCl chloride reference electrode, previously described.

Polarographic electrodes consisted of the Ag/AgCl reference electrode and the small Pt wire microelectrode only.

When cell investigations outside the drybox were considered desirable, a three-compartment cell with ball joints and medium glass frit separators was loaded in the drybox and then transferred out of the box with the electrodes already in place. The electrodes were essentially the same as for the beaker-cells used in the drybox, but adapted to the smaller column of the tubular compartmented cell.

Voltaic cells.—The configuration of the voltaic cells, called variously pill, wafer, or laminar cells, has been described above.

Fractional factorially designed voltaic-cell experiments were set up in a 2^5 arrangement (five factors were investigated at two levels each). This arrangement has proved convenient for this work and is readily analyzed for variance by the least-squares technique. The independent variables of the statistically designed cells are listed in Table I, but the dependent variables were chosen in order to evaluate the cell performance from various viewpoints. For example, the first set of tests was evaluated on the basis of the change of voltage, ΔE, from peak to final closed-circuit voltage, the cells being activated under load. However, it is possible for a cell starting at a low peak voltage to have a nearly flat discharge and hence a low ΔE. Although a low ΔE would be a desirable criterion, the operation of this cell would not be favorable on an over-all basis because of its generally low voltage. Similar situations arise when considering peak open- or peak closed-circuit voltage, the final closed-circuit voltage level, or some figure based on wattage output.

Table I. Independent variables of statistically designed voltaic-cell experiments

Anodes	
(Lithium metal)	
Li-Ca alloy	80-20 w/o
Li-Zn alloy	80-20 w/o
Li-Mg alloy	75-25 w/o
Li-Mg alloy	50-50 w/o
Li-Pb alloy	Li_4Pb
Cathodes	
$CaCrO_4$	
AgBr	
UO_3 (anhydrous)	
$H_4UO_6(UO_4 \cdot 2H_2O)$	
V_2O_5	
Na,-3,5 dinitrobenzoate

KSCN	
KSCN-LiBr	90-10 w/o
KSCN-NaSCN eutectic	73.7 to 26.3 w/o
KSCN-NaSCN eutectic + 10 w/o NaCl	
Atmosphere	
Laboratory ambient	
Dry argon (drybox)	
Resistive load	
10, 25, 34, 43 ohms	
Temperature	
150°, 175°, 200°, 250°, 300°C	
Electrolyte absorbent	
Kaolin (Edgar, Florida)	
Alumina (Micria AD, Monsanto Chemical Company)	

The error variance was established directly by replicating one of the series of cell tests, rather than by estimating from the effects of factorial combinations or of interactions that were not considered to be significant. By establishing the error variance in this manner, it was learned that the effect of small temperature changes makes close temperature control desirable. Scrutinizing the variances directly also helped in finding how the operational error of uncontrolled (unknown) variables could be reduced. An extremely useful exposition of these statistical methods is given by Davies (16), and the reader is referred to that work for details on the design and analysis of experiments.

The significance of results from the sets of fractional factorially designed experiments is determined by the analysis-of-variance technique. The Laboratory's IBM 7074 computer has been programmed to run this analysis, and the labor involved is thus drastically reduced.

Preparation of materials.—Reagent grade chemicals were used throughout the experimentation and were routinely weighed, transferred, crushed, or melted in a Vac/Atmospheres Company drybox. Potassium and sodium thiocyanates were dried separately in a vacuum oven at 150°C, and the resulting salts poured freely without lumping. No further purification was deemed necessary, since the polarographic residual current on these melts was on the order of 0.5 μa. A definite aging effect on these melts in the drybox was observed as a light yellow color. The polarographic observation of aging will be described in the discussion of polarography. A steel-blue color has been reported by numerous investigators when thiocyanates are heated to temperatures above 300°C, and this color can be obtained readily at any lower temperature in the melt by adding powdered sulfur. The reason for the light yellow color is not known, although the aging effect is reported by Frame *et al.* to cause a large variation in the change of surface tension per degree centigrade (18).

Depleted UO_3 was obtained from Nuclear Materials and Equipment Company, Apollo, Pennsylvania. Hydroxyperuranic acid, H_4UO_6, was prepared from this UO_3 by the method given by Urey (19). The sodium salt of 3,5 dinitrobenzoic acid was prepared by mixing stoichiometric quantities of the acid and sodium hydroxide in water and then evaporating to dryness under vacuum. A portion of the resulting salt was dissolved in water and found to have a *p*H value between 6.5 and 7.0. The salt would not melt, but it decomposed when heated above 500°C.

Lithium alloyed with 20% calcium, with 20% zinc, or with 25% magnesium, respectively, was obtained from Maywood Chemical Works (a Division of Stepan Chemical Company). An alloy of 50-50 w/o (weight per cent) lithium and magnesium was prepared by melting the two metals in an Armco iron crucible. The furnace and crucible were used in the Laboratory's argon-atmosphere drybox, since lithium reacts directly with nitrogen, which was previously used in the drybox.

Kaolin, supplied by the Edgar Kaolin Corporation, Edgar, Florida, was used as an electrolyte immobilizer in pill-cells. Alumina, produced by Monsanto Chemical Company under the trade name Micria AD, was used as an absorbent in some pill-cells.

Analysis of sulfide and cyanide in the presence of excess thiocyanate.—Polarographic techniques were employed to analyze aqueous solutions of sulfide and cyanide in the presence of a large excess of potassium thiocyanate. Because of the difficulties of analyzing for sulfide, cyanide, and thiocyanate in the presence of one another (specially excess thiocyanate), we are presenting in some detail the results of our experience with this method. A Lingane-Laitenen type of H-cell was prepared with the usual dropping mercury-electrode and saturated calomel half-cell separated by a freshly precipitated agar-agar KCl bridge. The supporting electrolyte was a 0.1M solution of NaOH. Prior to the polarographic runs, the solutions were bubbled with nitrogen gas to remove dissolved oxygen.

The method was standardized by taking aliquot portions of prepared solutions of NaCN and Na_2S, determining the half-wave potentials, and then determining the effect of adding various concentrations of KSCN. The latter effect is shown in Fig. 3. It was observed that the KSCN tended to move the limit of analysis (*i.e.*, the decomposition potential of the supporting electrolyte) to more negative values, and this made the analysis of cyanide somewhat more difficult, since the half-wave potential of cyanide occurs very close to the end potential.

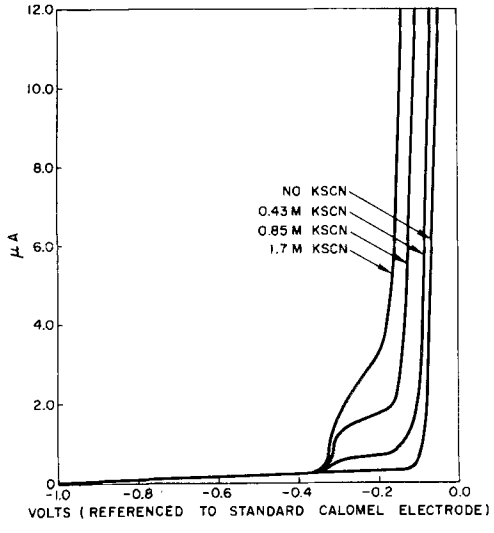

Fig. 3. Polarographic effect of varying the quantity of KSCN in a solution of 0.1M NaOH.

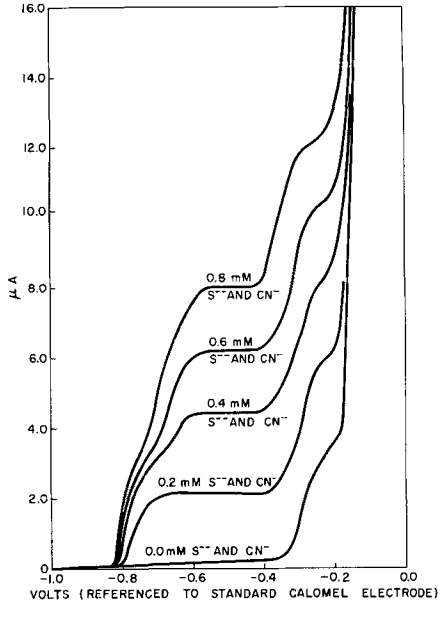

Fig. 4. Polarographic standardization: equal molar concentrations of S^{--} and CN^- in a solution of 1.7M KSCN, 0.1M NaOH.

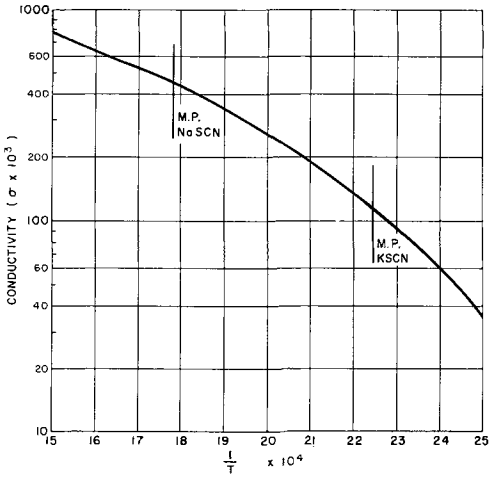

Fig. 5. Specific conductivity as a function of temperature for KSCN-NaSCN eutectic.

When equal molar concentrations of CN^- and S^{--} were used, the curves shown in Fig. 4 resulted. The first wave is caused by the reaction

$$Hg^o \pm S^{--} = HgS + 2e^- \quad [1]$$

The second wave is caused by the reaction

$$Hg^o + 2CN^- = Hg(CN)_2 + 2e^- \quad [2]$$

The final wave is caused by the reaction

$$Hg^o + 2\,OH^- = Hg(OH)_2 + 2e^- \quad [3]$$

which marks the decomposition of the supporting electrolyte. The wave attributable to SCN^- was not observed, because its value is beyond that of the supporting electrolyte.

After this method of analysis had been standardized, it was applied in determining the reaction products that result from the electrolysis of thiocyanate melts, which will be described below in the following section.

Fundamental Results and Discussion

Conductivity.—Conductivities were determined for several electrolytes, namely, KSCN, KSCN-NaSCN eutectic (73 w/o KSCN), KSCN-NH_4SCN (50-50 w/o). Conductivity of the potassium-sodium thiocyanate eutectic, which had not been reported previously, was investigated from 123.5° to 360°C. When the logarithm of the specific conductivity is plotted against the reciprocal of the absolute temperature, the resulting curve is essentially straight until the melting point of NaSCN is reached; with a further temperature drop, the curve is sharper (Fig. 5). This behavior corresponds with that predicted by Delimarskii and Markov for ideal eutectic salt mixtures (20).

It was expected that conductivity of the thiocyanate melts could be increased with additives, so various materials were combined with the melts and the conductivity determined. Additive salts were AgBr, NaI, NaCl, NaBr, KCl, LiCl, and LiSCN. Measured quantities of water were also introduced. Effects of these additives were minimal. There was no great conductivity increase in any case, and in some mixtures there was a decrease.

Addition of water to the eutectic before melting and while molten would be expected to cause some hydrolysis and the formation of such products as H_2S and HCN. While this proved to be true, hydrolysis was minimal because most of the water boiled out during heating. Conductivity was increased only slightly, however, and gassing occurred at the electrodes during polarographic experiments in "wet" melts.

Sodium chloride seemed to cause a slightly increased conductivity. This and the following reasons led to its subsequent addition to the eutectic for cell

electrolytes: (*A*) The Cl^- ion tends to aid anodic depolarization. (*B*) The Na^+ ion has a much smaller charge-to-radius ratio than does the Li^+ ion, and the Na^+ ion does not so readily attract oppositely charged ions, hence its mobility is not reduced.

The conductivity of KSCN-NaSCN-alumina pills (1.4 mm in thickness and 1 cm in diameter) was determined. When subsequent voltaic-cell tests showed that pill cells with kaolin for an absorbent contributed to better performance, further investigation of the anolyte pill conductivity was carried out, using a composition of 65 w/o salt mixture and 35 w/o absorbent at 200°C. Specific conductivities were 0.0606 mho for KSCN-NaSCN-Al_2O_3 and 0.127 mho for KSCN-NaSCN-kaolin. It is believed that the improved cell performance with kaolin results from less ohmic polarization. Possibly the laminar structure of kaolin allows easier passage of the conducting ions than does that of alumina, which has a platelike but irregular structure that grossly lengthens path distance across the cell. In other words, conducting ions may pass through the kaolin particles but must detour around the alumina particles.

Polarography.—Polarographic investigations were conducted in both the pure KSCN and KSCN-NaSCN eutectic melts, electrode reactions were verified by analysis of the melts after prolonged electrolysis, and the effect of aging the melts was determined. All potentials are referenced to the Ag/AgCl reference electrode, unless otherwise stated.

For the pure KSCN, two definite waves occur in the cathodic direction. The first potential increase begins at —1.60v, rising to —1.92v, and the half-wave value ($E_{1/2}$) is —1.75v. The current then decreases to a stable value until the potential reaches a value of —2.93v, whence the current increases without limit. In the anodic direction, the current begins to decrease at a potential of about —2.00v and reaches the residual value at about —1.60v. The current remains at the residual value until the potential reaches a value of approximately +0.20v, whence the current increases for a short span and then returns to the residual value.

The thiocyanate eutectic melt gives essentially the same polarographic waves as the pure KSCN, but with one additional wave, for which $E_{1/2}$ is —2.35v. The current then decreases to an equilibrium value until the potential is approximately —2.93v, where the current rises without limit. Summarized curves of the polarograms for these two melts are plotted in Fig. 6.

These investigations proved that an electrochemical reduction takes place in both these melts at a more positive potential than would be predicted solely on the basis of the reduction of the sodium or potassium ions. The reduction occurring at the half-wave potential of —1.75v is postulated as

$$2\,e^- + SCN^- = S^{--} + CN^- \qquad [4]$$

Experimental proof of this reaction was obtained by analysis of the melt after a prolonged electrolysis,

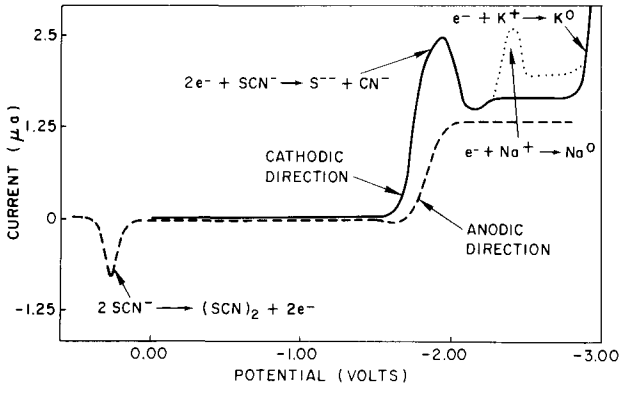

Fig. 6. Characteristic polarographic curves from the KSCN-NaSCN melt.

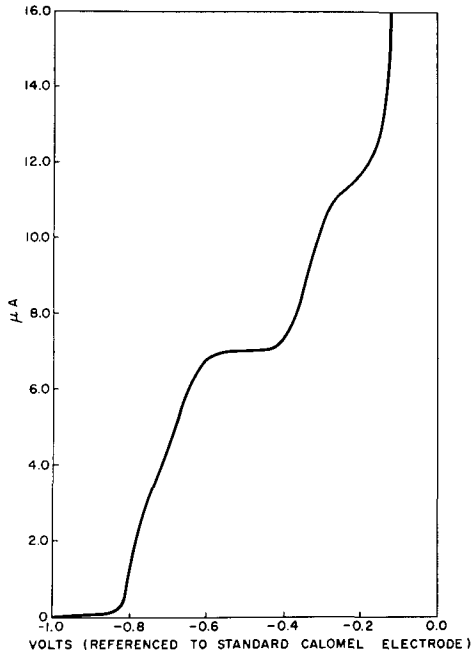

Fig. 7. Polarographic curve of a sample from molten thiocyanate electrolysis in an aqueous solution of 0.1M NaOH.

using the polarographic method in an aqueous 0.1M solution of NaOH, as previously described for the analysis of sulfide and cyanide. The melt electrolysis was carried out between two platinum electrodes, each having an area of 2 cm^2, which were separated by a medium-fritted glass disk. The cathode was enclosed in a known small volume in order to obtain the highest possible concentration of sulfide and cyanide. After electrolyzing the melt with a constant current of 1.6 ma at 1.80v for 20 min, the melt was allowed to cool and was then removed from its container to weighing bottles.

A 1-g sample of the electrolyzed KSCN was dissolved in 12 ml of a 0.1M aqueous solution of NaOH and placed in the H-cell. The resulting polarogram is shown in Fig. 7. These results proved that the total moles of S^{--} and CN^- produced in the electrolysis were faradaically equivalent to the total expected from analysis of the aliquot sample. The results also indicate that these two anions are produced in a one-to-one ratio during electrolysis of the melt. A small error observed in the CN^- determination is probably due to the interference of the KSCN as mentioned previously. Although a strong odor of sulfide is always noted after electrolysis of these melts, the polarographic method was needed to verify its formation.

The second wave observed in the eutectic mixture polarogram is postulated as resulting from the reaction

$$e^- + Na^+ = Na^o \qquad [5]$$

Finally, in the cathodic direction, a third wave in the eutectic-mixture polarogram (it occurs as the second wave in pure KSCN) is apparently due to the reaction

$$e^- + K^+ = K^o \qquad [6]$$

In both depositions of the alkali metals, the metal is not observed in a long-term electrolysis because of the reaction

$$2\ \text{metal} + SCN^- \rightarrow 2\ \text{metal ion}^+ + S^{--} + CN^-$$

The waves resulting from the alkali metal deposition can be observed only because the thiocyanate ion concentration is being lowered by the formation of sulfide and cyanide ions at the cathode-electrolyte interface. At the moment of depletion, current drops to an intermediate value until the potential is reached at which the sodium ion Na^+ is reduced until depleted.

When the Na^+ is depleted, deposition of the potassium begins at its reduction potential.

The anodic polarograms are essentially the same for both types of thiocyanate melts. The increase in anodic current, beginning at a potential of +0.20v, is apparently caused by the reaction

$$2SCN^- = (SCN)_2 + 2e^- \quad [7]$$

The dimeric thiocyanogen, unstable above +2°C, immediately undergoes polymerization to parathiocyanogen $(SCN)_X$. This material is reported by Walden and Audrieth as a yellow-orange solid that is insoluble in most solvents (21). This reported reaction was confirmed in experiments in which much higher currents than those obtaining in polarography were passed across two tungsten electrodes. The anode required a yellow-orange deposit, which formed in bubbles as a gas was given off, and this solid was found to have properties almost identical with those attributed to $(SCN)_X$ by Söderbäck (22). The anode product served as an insulating film on its parent electrode, causing the current to peak at +0.25v before dropping to a very small residual value. On reversing the current (toward the negative direction), the $(SCN)_X$ was not removed at any definite potential, but the film deteriorated with time, probably diffusing away into the melt, in which it has a limited solubility. The vapor that collected over the anode deposited in a cold tube as a light yellow solid that was very inert to solvents and strong mineral acids. No visible signs of reaction were seen on the negative electrode.

Other observations include an effect on the potential caused by aging of the melt. The fresh melts produced a more negative potential at the start of the first wave (*i.e.*, formation of S^{--} and CN^-), but the half-wave potential was essentially the same. Older melts tended to produce varying slopes in the polarographic waves.

Runs made in the ambient laboratory atmosphere produced heavy gassing at the electrodes, even in the low humidity prevailing, while runs in the argon-drybox atmosphere produced comparatively little gas. We analyzed samples of the gas mixture above the electrolysis melt with a mass spectrograph, but this showed only the presence of argon (from the drybox atmosphere), a trace of nitrogen, and very small traces of oxygen and hydrogen.

As the final revision of this manuscript was being prepared, an abstract of a report by Metzger (23) on a similar subject was released. It appears that Mme. Metzger has detected cyanogen above a melt of KSCN. Further investigations may be necessary for a complete determination of the gases evolved in this electrolysis.

Chronopotentiometry.—Chronopotentiometric results in pure KSCN melts verified the polarographic data. All potentials are referenced to the Ag/AgCl electrode. The cathodic current results in two potential plateaus, as shown in Table II. Extrapolation of the first plateau to zero current gives a potential of —1.68v, while extrapolation of the second plateau to zero current gives a potential of —2.90v. The anodic current results in only one plateau, as shown in Table III. Extrapolated to zero current, this potential becomes +0.25v. The time at which the potential remains on the plateau is inversely proportional to the current density.

This method verified the existence of the parathiocyanogen *film*, which appeared to be of constant thickness at the current densities used.

Table II. Cathodic potentials

Current, μa	First plateau, v	Second plateau, v
2.15	−1.72	—
18	−1.99	−2.93
25	−2.08	−2.89
40	−2.12	−3.12

Table III. Anodic potentials

Current, μa	Plateau, v	Time, sec
20.3	+0.27	0.657
100	+0.32	0.301
200	+0.36	0.169

Applied Results and Discussion

Rather extensive preliminary voltaic cell tests, first in beaker cells and then in pill cells, preceded the voltammetric studies in fused alkali thiocyanates. These exploratory cells proved that the thiocyanates would be usable in high energy-density voltaic cells, but did not point conclusively to optimum parameters. However, enough information was gained to proceed with statistically designed sets of fractional factorial tests of voltaic cells at the same time that detailed polarographic and chronopotentiometric investigations were conducted into fundamental characteristics of molten alkali thiocyanates as electrolytes.

Very satisfactory results have been obtained in the search for the optimum operating conditions, anode-cathode-electrolyte combinations, electrolyte absorbents, and resistive loads. Various cell components and operating parameters were used in five series of fractional factorial cell tests. While it manifestly is impossible to list all results obtained from this work, the main results, typical cell configurations, and representative outputs under given conditions can be reported at this time.

As results of each series of factorially designed cell experiments were obtained, developmental work with thiocyanate electrolytes proceeded accordingly. For example, data from the preliminary tests indicated that the mixture of KSCN-LiBr would improve cell performance, *i.e.*, open-circuit performance was good, and closed-circuit performance was acceptable at current densities greater than 50 ma/cm². Because of its melting point at about 175°C, comparison tests were run with this mixture and with the KSCN-NaSCN eutectic. The eutectic proved superior, and the addition of NaCl further improved cell performance, as previously explained in the discussion of conductivity.

The main result that determined the pattern of experimentation and the acceptable limitations of cell components was the optimum operational temperature of 200°C. The effect of temperature was clearly defined. As expected, cells operating at higher temperatures produced higher peak open-circuit (POCV) and peak closed-circuit (PCCV) voltages and higher current densities for longer lifetimes to a given cutoff voltage, but conductivity experiments revealed gassing in beaker melts of alkali thiocyanates above 325°C. Whether this gassing would occur in pill cell configurations is unknown, but some variation in pill-cell performance at high temperatures was observed, and this may have resulted from decomposition of the electrolyte. However, results were found to be consistently good in the temperature range from 200° to 325°C.

Since all of the likely anode materials melted below this temperature, it was necessary to prepare alloys that could be used above 200°C. A mixture of Li 50 w/o Mg melted at about 275°C, and this was used in a factorially designed set of tests for comparison with the Li 25 w/o Mg alloy that had been previously used. While it is thermodynamically predictable that the 50-50 w/o alloy would give a lower potential level, it was actually found that the difference between the potentials of the two was only a few hundredths of a volt. Other results from the 50-50 w/o alloy tests essentially duplicated those from the tests with the 75-25 w/o alloy. In view of these findings, the Li 50 w/o Mg anode material was adopted.

It is in the realm of investigations of cathodic materials that the use of statistically designed cells

[a] Electrolyte used on the cathode side of cells is the same as that listed on the anolyte side, but with no absorbent except the active cathode material (*i.e.*, UO_3, V_2O_5, etc.).
[b] PCCV is the peak closed-circuit voltage.
[c] FCCV is the final closed-circuit voltage measured 300 sec after the cell output reached the PCCV voltage.
[d] Dry inert atmosphere, all others were operated in ambient atmosphere.

proved most advantageous since there is such a large number of materials that might prove useful.

Preliminary tests showed that AgBr produced potentials on the order of 2.28v (with Li-Mg anodes) at an apparent current density of 45 ma/cm². The first set of statistically designed cells incorporated AgBr, $CaCrO_4$, and UO_3 for the various levels of the cathode factor. Results from this set indicated UO_3 performed significantly better than calcium chromate and slightly better than silver bromide. Since silver bromide has a significant solubility in the electrolyte and could migrate to the anode, it was apparent that UO_3 would be the better cathode material for practical applications.

In later sets of cells, hydroxyperuranic acid, H_4UO_6, and the sodium salt of 3,5 dinitrobenzoic acid (DNBA), were used as cathode materials. Peak open- and closed-circuit voltages were in the range of 1.58 to 1.92v at 200°C. The Na-DNBA gave good performance at all levels of the other factors in the cells (anode, electrolyte, and temperature). However, when the Na-DNBA was then used in a set of cells with UO_3 as the other level of the cathode factor, the latter material again proved its superiority in terms of voltage and current densities achieved.

In work reported previously, V_2O_5 has been used in cells at 450°C, but in the LiCl-KCl eutectic melts (24). The same cathodic material has been used in this research in molten thiocyanates, comparing it with UO_3. Generally, voltage and current levels were about the same as those from UO_3 and in some cases slightly higher. However, V_2O_5 reacts with the electrolyte to an undetermined but obvious extent and is therefore restrictive in cells that must operate for more than a few minutes. Possible reactions of V_2O_5 with the solid salts have not been investigated.

The effect of varying the load resistance was determined so that the cell behavior in a practical battery could be predicted. As the load resistance is lowered for a given electrochemical system, the closed-circuit voltage lowers but the current density rises. In comparing various electrochemical systems, as was done in the statistically designed experiments, the voltage drop for a given time under a high current drain may be much different for one system than it is for another. Thus, the variation under a given load resistance may be used to predict the level of discharge from a given electrochemical system. Although load resistance was used as an independent variable when these series of cell tests were initiated, some other factor of more immediate importance was substituted in later series.

Among the variables that were not significant, it was of interest to note that the atmosphere apparently made little difference; indeed, most cells operated slightly better in ambient atmosphere than in the drybox. This was probably because of a beneficial effect of the slight moisture content of the pill-cell electrolyte.

Summary and Conclusions

Fundamental electrochemistry.—Results of this study indicate that the electrochemical decomposition of thiocyanate melts is bounded on the anodic side by the reaction given in Eq. [7] and on the cathodic side by the reaction given in Eq. [4]. All materials having potentials outside the range of +0.25 to −1.75v (using Ag/AgCl reference electrode) will be thermodynamically unstable in molten thiocyanates and will, ultimately, decompose the SCN^- to either $(SCN)_X$ or sulfide and cyanide ions. Although this study gives a more complete understanding of the basic electrochemistry of fused alkali thiocyanates, we have not investigated the kinetics of such reactions. It is manifestly impossible to predict voltaic-cell performance exclusively from fundamental investigations. For this reason, we have conducted extensive voltaic-cell investigations involving materials that have potentials lying outside the predicted decomposition range of the fused electrolytes. A summary of these results is given in the following section.

Applied electrochemistry.—The configurations and operating parameters of cells selected from the factorially designed sets are given in Table IV. Additionally, discharge curves of representative voltaic cells from the factorial series are shown in Fig. 8. These are cells that have operated presumably at their optimum rate under controlled conditions.

Two things should be kept in mind when evaluating the results of the applied portion of this investigation. In all these tests, more than one factor was changed at a time, and a significant result or difference must be directly attributable to the component under consideration; *i.e.*, there must be no predictable interactions. The other item to remember is the difficulty in extrapolating the results of electrochemical studies made in beaker or laboratory prototype cells into the performance of mass-produced cells or batteries. While screening techniques such as the factorial design of experiments save time and materials, the results cannot be considered final until batteries have been operated and evaluated in the required environment.

Technical Notes

Recrystallization of Anodic Alumina Films

D. J. Barber[1]

National Bureau of Standards, Washington, D. C.

Oxide films on metal surfaces are used increasingly in modern technology. Films formed by anodic or thermal oxidation deviate from stoichiometric composition because of lattice defects and impurities. The electrical, chemical, and mechanical properties of the films depend on stoichiometry, the presence of various phases, grain size, and porosity. This note describes some electron microscope observations on the recrystallization of one type of Al_2O_3 anodic film. Keller *et al.* (1), Franklin and Stirland (2), and Heine and Sperry (3) have already used electron microscopy to study other types of as-grown Al_2O_3 films.

The films were made by the method of Hauser and Kerler (4), as modified by Johnson and Deslattes (5). These samples were conveniently available, but other methods of preparation would have been equally suitable since only small samples were required. The anodizing solution was ammonium citrate and citric acid in distilled water. To avoid charging in the electron beam, the films were backed with a layer of evaporated carbon.

As-grown films are amorphous; grains cannot be resolved and the cellular structure found in some anodic films [for example, those of Keller *et al.* (1)] is absent. Diffraction experiments reveal an intense cloud of scattered electrons about the direct beam but no diffraction rings. The grain size is deduced to be < 30Å. The films are not structureless but show markings related to the rolling direction in the parent aluminum foil. Rolled foil is known to have a fibrous structure (6). The markings in the samples may arise from surface irregularities or rolled-in impurities in the aluminum, or because the apparently amorphous film has a fine crystallinity related to the fibrous structure. Hauser and Kerler (4) showed that their method

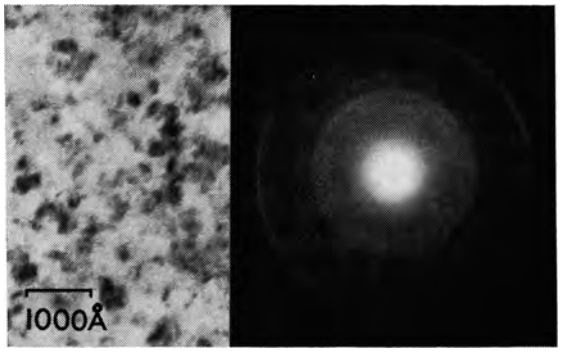

Fig. 1. Aluminum oxide film after type (A) recrystallization, and selected area diffraction pattern.

[1] Present address, Physics Department, the University of Essex, Colchester, England.

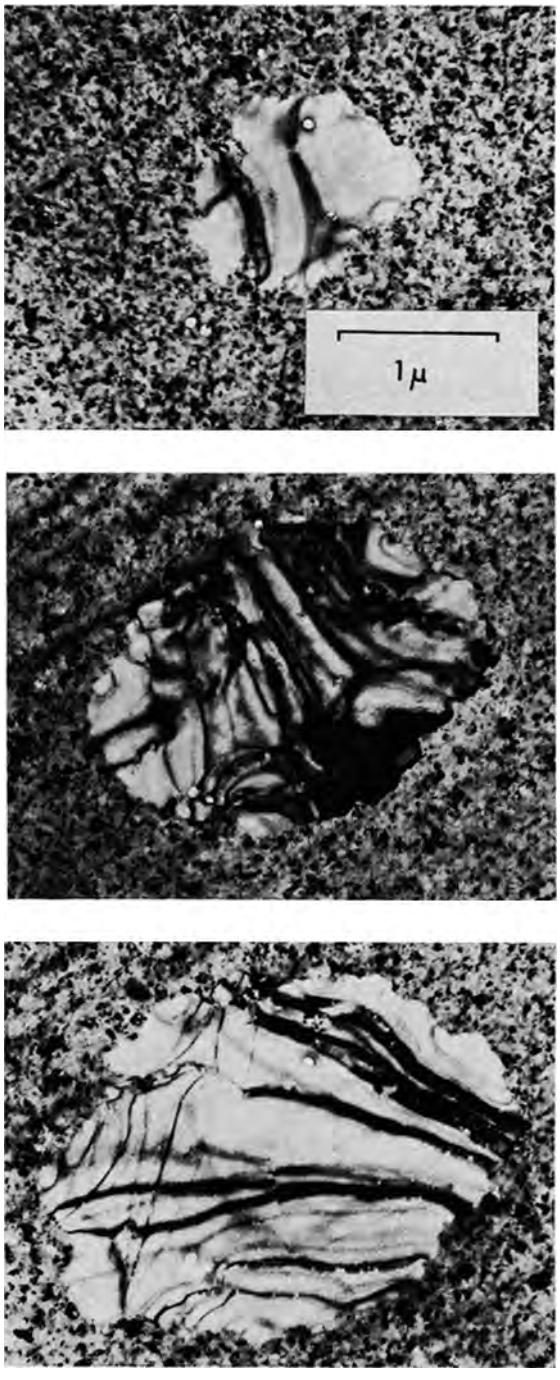

Fig. 2. Successive stages in the development of type (B) recrystallization in the electron beam.

produces films which are gas tight, *i.e.*, free from penetrating pores. Nevertheless, the present samples exhibit many pore-like defects which often nearly penetrate the foil. They apparently result from bubbles which form in the anodizing bath and are incorporated in the growing film. Their occurrence can be substantially reduced by containing the bath in an ultrasonically vibrated vessel. As an added advantage the films are cleaner, showing that there is dross rolled into the aluminum and that some is shaken free during anodization.

Films could be recrystallized by heat treatment at ~ 1250°C in a tube furnace. It was more instructive, however, to cause recrystallization with the electron beam and thus follow its progress. Intense local heating was achieved by using a large condenser aperture and momentarily switching off the second condenser lens.

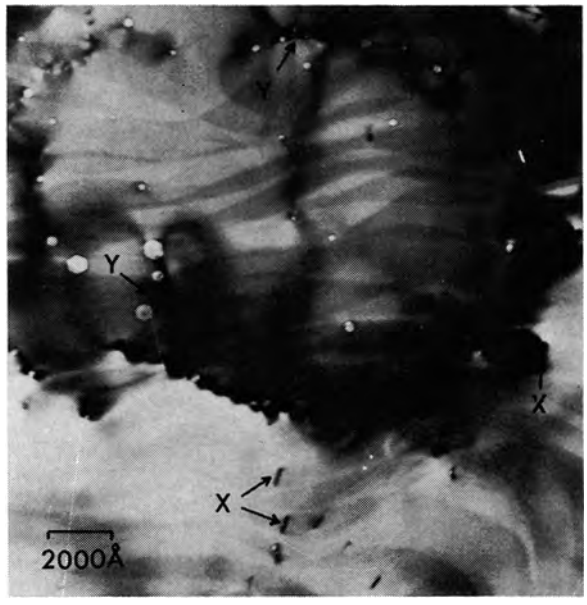

Fig. 3. Completely recrystallized film exhibiting pores, surface terraces (caused by thermal etching in the electron beam), and short dislocations in subgrain boundaries and at pores.

Recrystallization of films in the beam occurs in two stages, which will be referred to as A and B. At an estimated temperature, ~ 1150°C, the film becomes finely polycrystalline (A) with a grain size ~ 250Å. The recrystallization front propagates through the sample like a wave. Further changes (B) occur at ~ 1400°C, and this is shown by the migration of grain boundaries and the rapid growth of large grains. Higher temperatures are needed to cause recrystallization in the beam than in the uniform heat of a furnace. Figure 1 shows a transmission micrograph and selected area diffraction pattern from a sample which had barely undergone (A) recrystallization. The small grains are apparently α-Al_2O_3. Further heating improves the crystallinity and improves the Bragg contrast. Successive views of (B) recrystallization are shown in Fig. 2; these frames were obtained by subjecting the area to short hot pulses from the beam and photographing it between each pulse. The characteristics of stage (B) are typical of normal recrystallization processes.

It is well known that anodic films of Al_2O_3 may contain several phases, including γ-Al_2O_3. In our case the nature of the unrecrystallized films could not be determined by either x-ray or electron diffraction. It is believed, however, that (A) is principally a phase transition to the α-form accompanied by some grain growth; this process leaves the films in a state of high internal strain. Figure 3 demonstrates that dislocations can occur within grains after stage (B) recrystallization. This sample was given prolonged heating in the beam, which explains the surface terraces and equilibrated shape of the pores. Most of the dislocations are nearly perpendicular to the foil (as at X) and thus have minimum energy. Those lying in the plane are usually caught up around pores (as at Y); apparently the pores also impede grain boundary migration. Sub-grain boundaries are somewhat rare and those observed have been of tilt character.

Defects in the Structure of Electrodeposited Copper

E. M. Hofer,[1] L. F. Chollet, and H. E. Hintermann

Laboratoire Suisse de Recherches Horlogères, Neuchâtel, Switzerland

The scope of this paper is to describe, compare, and discuss three methods used to obtain characteristic microstructural quantities important for a better understanding of the mechanical properties and the behavior of electrodeposited metals. These techniques are the electron microscopy, the Fourier analysis of the x-ray diffraction line profiles, and the small angle x-ray scattering. In certain cases some of the structural parameters can be measured by two of these methods. Thus the results can be compared.

Electron microscopy permits one by direct counting to determine the dislocation density, the density of inclusions, and the grain size. Its disadvantage is that the results are obtained on a small area which may not be representative of the specimen as a whole.

The x-ray methods do not have this disadvantage. They provide better statistical values for the determination of the crystallite size. However, with these techniques the dislocation density can be calculated only indirectly (1).

The investigated electrodeposits contained inclusions of the additive or a reaction product. The number of inclusions per unit volume can be determined by counting them on an electron micrograph. The inclusion density can also be determined by small angle x-ray scattering provided only that the size of the inclusions is sufficiently small, *i.e.*, smaller than about 100Å. The investigated electrodeposits actually contain inclusions which satisfy this condition (2).

Experimental

Copper deposits, 30μ thick, were produced on laminated and annealed copper sheets, 50μ thick, in an electrolytic cell with a rotating cylindrical cathode (1). The initial composition of the plating bath was 1*N* $CuSO_4$, 1*N* H_2SO_4, prepared and purified as described by Fischer and co-workers (3, 4). Gelatin (mol. wt. $\approx$ 180,000) was used as the additive in concentrations of 80 and 200 mg/l. A fresh solution was used for each deposition. The current density was 20 ma/cm^2 and the temperature was kept constant at 25°C. One portion of each sample was thinned electrolytically perpendicular to the growth direction in a phosphoric acid/ethanol solution, and examined by transmission electron microscopy (Elmiskop I) at electron optical magnifications between 22,000 and 160,000 times using an acceleration voltage of 80 kv. The average grain diameter $\bar{D}$ of these electrodeposits was determined from the formula of Braun (5), which relates the average volume $\bar{V}$ of the grains to its average linear dimensions $\bar{L}$ measured on the electron micrographs, *i.e.*, $V = 2.57\ (\bar{L})^3$. The dislocation density ρ_{el} at the surface of the specimens, the inclusions mean diameter $(\bar{D}^{-3})^{1/3}{}_{el}$ were counted and calculated from 5 or more greatly enlarged electron micrographs (2). The specimen thickness was estimated from extinction fringes at grain boundaries and boundaries of microtwins, to 100-1000Å.

The x-ray diffraction patterns were recorded with a Philips proportional counter diffractometer. Filtered Co Kα radiation (voltage 30 kv, current 10 ma, Fe filter) was used, thus eliminating the copper fluorescent radiation from the sample. The width of the divergence slit was 1°, that of the receiving slit 0.2 mm. The scanning speed was ¼ degree 2θ/min, the chart speed 800 mm/hr.

The background was determined from a sample annealed at 750°C and subtracted from each diffraction pattern of the samples to be analyzed. The electrodeposits were mounted in a stainless steel specimen holder in order to provide reproducible experimental conditions during the recording of the various diffraction patterns. The heat-treatment was performed while the specimen was kept in the holder.

The analytical treatment of x-ray diffraction line profiles has been reviewed by Warren (6). The following quantities can be determined by this method.

The probability α of finding a stacking fault between two (111) layers determined from the relative shift of the 111 and 200 diffraction peaks of the sample as deposited and the same sample annealed for 1 hr at 750°C (7).

$$\Delta(2\theta^0_{200} - 2\theta^0_{111}) = -\frac{45\sqrt{3}\alpha}{\pi^2}\,(\tan\theta_{200} + \tfrac{1}{2}\tan\theta_{111})$$

The probability β of finding a twin fault between two (111) layers determined by the method of Cohen and Wagner (8) from the asymmetry of the diffraction peaks, measured as the relative displacement of the center of gravity (ΔCG) in regard to the peak maximum

$$\Delta CG\,(2\theta^0)_{111} - \Delta CG\,(2\theta^0)_{200} = \beta(11\tan\theta_{111} + 14.6\tan\theta_{200})$$

The Fourier coefficients and the correction of Stokes for the instrumental line broadening are calculated on an electronic computer IBM 1620. From these coefficients the average dimension of the coherently diffracting domains, $\langle D\rangle_{\text{eff hkl}}$, can be obtained.

$$\frac{1}{\langle D\rangle_{\text{eff hkl}}} = -\left[\frac{dA_L{}^S}{dL}\right]_{L\to 0} = \frac{1}{\langle D\rangle} + \frac{(1.5\,\alpha + \beta)}{a_o}\,c_{hkl}$$

The cosine-coefficient A_L can be considered as the product of two coefficients, $A_L{}^S$ and $A_L{}^D$ whereby the former relates to the size (index S) of the crystallites and the latter to the microdeformations, *i.e.*, rms strains (index D). L is a distance perpendicular to the reflecting planes; c_{hkl} has the value of $\sqrt{3}/4$ for the 111 and 222 reflections. The expression $a_o(1.5\,\alpha + \beta)/c_{hkl}$ is defined as $\langle D\rangle_{\text{F hkl}}$, the calculated crystallite dimension due only to the presence of faults. By plotting ln A_L as a function of $h_o{}^2$ where $h_o{}^2 = (h^2 + k^2 + l^2)$ for different values of L, a set of straight lines is obtained whose intersections with the ordinate furnishes the values $A_L{}^S$ and whose slope is proportional to the rms strain $\langle\epsilon^2{}_L\rangle$.

The small angle x-ray scattering diagrams were obtained according to Jan (9). The photometrically measured intensity $I(h)$, where $h = 4\pi\theta/\lambda$, is plotted

[1] Present address: Research Division, American Radiator & Standard Sanitary Corporation, New Brunswick, New Jersey.

as a function of h^2 on a double logarithmic scale, θ being the diffraction angle, λ the wavelength. This experimental curve is superimposed on a network of $I(h)/I(O)$ curves calculated for different values of the parameter $\gamma(\gamma = 1, 2, 3. . .)$ and plotted as a function of $R_o^2h^2$, where R_o is the most probable radius of gyration. From this the $I(O)$, R_o, and γ values can be deducted. It is then possible to calculate the number of scattering centers, N, per unit volume, V_o, according to

$$\frac{N}{V_o} = [I(O)/P_o] \cdot r^2[t\eta\rho^2\kappa^2R_o^6f(\gamma)]^{-1}$$

where P_o is the power of the incident beam, r the distance from the specimen to the film, t the specimen thickness, ρ the electron density of the scattering centers, η a constant equal to 7.94×10^{-26} cm^2, κ a form factor. The function $f(\gamma)$ is calculated using the relation

$$f(\gamma) = \frac{1}{8\gamma^6\sqrt{\pi}}\left[\frac{2\gamma \exp(-\gamma^2)}{1+\Theta(\gamma)}(4\gamma^4 + 28\gamma^2 + 33) + \sqrt{\pi}(8\gamma^6 + 60\gamma^4 + 90\gamma^2 + 15)\right]$$

with $\Theta(\gamma)$ being the Kramp-Laplace error function

$$\Theta(\gamma) = \frac{2}{\sqrt{\pi}}\int_o^\gamma \exp(-x^2)\,dx$$

which can be found tabulated in mathematical tables. The function $f(\gamma)$ takes the values of 23.4, 3.62, and 1.97 for γ equal to 1, 2, and 3, respectively. The radius R of the scattering centers can then be obtained from

$$\overline{R^3} = R_o^3\left[\frac{3+2\gamma^2}{2\gamma^2} + \frac{\exp(-\gamma^2)(1+\gamma^2)}{\gamma^2\pi^{1/2}[1+\Theta(\gamma)]}\right]$$

from which the average diameter $(\overline{D^3})^{1/3}$ of the inclusions can be deducted.

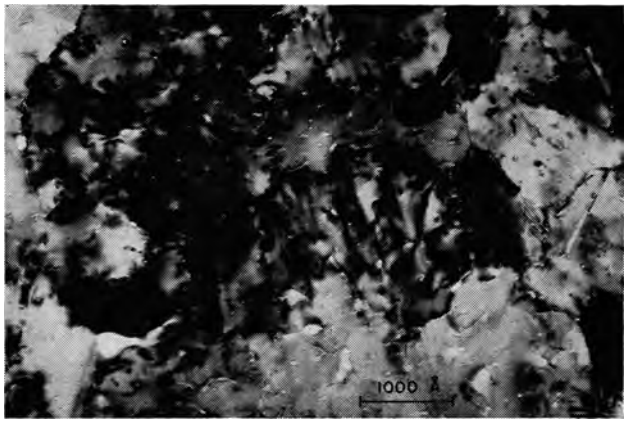

Fig. 1. Electron micrograph of a copper deposit (conditions: 1N H_2SO_4, 1N $CuSO_4$, 20 ma/cm^2, 25°C, 200 mg/l gelatine) showing dislocations and inclusions.

Fig. 2. Electron micrograph of a copper deposit (conditions: 1N H_2SO_4, 1N $CuSO_4$, 20 ma/cm^2, 25°C, 200 mg/l gelatine) showing microtwins, grain boundaries, dislocations, and inclusions.

Results and Discussion

Typical electron micrographs from which the crystallite size and the inclusions and dislocation densities were determined are shown in Fig. 1 and 2. Figure 1 contains more of the randomly distributed inclusions, but only a few microtwins. The dislocations are often seen to interact with the inclusions thereby accounting for the high mechanical strength generally observed in these deposits. The grain boundaries are not always well defined. (Fig. 2).

In general, the crystallite size determined by electron microscopy is larger than that measured by the Fourier analysis. In the first case, an average distance from grain boundary to grain boundary is measured, whereas in the latter case, it is the distance of coherence in the interior of the crystal which may be interrupted by defects such as dislocations and twin faults. Furthermore, with the Bragg-Brentano focalization conditions encountered in the counter diffractograph technique, only the crystallites whose $\{hkl\}$ planes lie parallel to the surface of the sample participate to an hkl reflection. Therefore, the coherence distance is measured perpendicularly to the surface of the sample by the x-ray diffraction technique. Whereas in the electron microscope, the distance corresponds to a cross section of the grains parallel to the surface of the sample, but some electron micrographs taken perpendicularly to the sample surface did not differ essentially from those taken parallel.

The results of the three methods are summarized in Tables I and II. The twin fault density in these electrodeposits is small indeed and a shift of peaks indicating the presence of stacking faults has not been observed. Knowing the values of the rms strains $\langle\epsilon^2_L\rangle_{hkl}^{1/2}$ and assuming a maximal separation and a minimal interaction of the dislocations, it is possible to calculate the dislocation density ρ_{WS} in the sample from the formula proposed by Williamson and Smallman (10)

$$\rho_{WS} = \frac{16\langle\epsilon^2_L\rangle}{b^2}$$

where b is the Burgers vector of the dislocation. This value ρ_{WS} agrees fairly well with the dislocation density ρ_{el} obtained from the electron microscopical study.

The diameters of the inclusions obtained by the small angle x-ray scattering method are in general slightly smaller than those determined with the electron microscope. This is due to the fact that the very smallest inclusions are difficult to observe on the electron micrographs and thus easily escape the counting. As a whole, however, the average sizes of inclusions determined according to the two methods agree reasonably well. The results obtained from the three methods show that each technique is useful in the study of the

Fluorescent Properties of Terbium-Activated Alkaline Earth Alkali Borates

W. L. Wanmaker, A. Bril, and J. W. ter Vrugt

N. V. Philips'Gloeilampenfabrieken, Eindhoven, Netherlands

In recent years several new rare earth activated phosphors have been prepared, especially with europium and terbium as an activator. For instance Van Uitert (1) studied the fluorescence of Tb in many different host materials (scheelites). It was shown in a previous paper (2) that terbium-activated alkaline earth borates are phosphors of medium efficiency, the highest quantum efficiency found being 42%. In this paper we describe the preparation and some fluorescent properties of terbium-activated phosphors which are even more efficient, viz., alkaline earth alkali borates such as, *e.g.*, calcium sodium borate activated with terbium.

The type of host lattice mentioned above was previously used by Tomaschek (3), in the preparation of Eu-activated calcium sodium borate glass. We have not found in the literature any other examples of phosphors with this type of host lattice. In our first paper (2) we presented a short survey of Tb-activated phosphors. Since then, Borchardt (4) has described the preparation of Tb-activated rare earth tungstates and molybdates, and Brixner (5) has prepared phosphors such as $Tb_{0.5}Nb_{0.5}W_{0.5}Ca_{0.5}O_4$ and $Tb_{0.5}Nb_{0.5}Mo_{0.5}Ca_{0.5}O_4$, of which the last was the most efficient one.

The ingredients used in the firing mixtures were luminescent grade $CaCO_3$, $SrCO_3$, $BaCO_3$, $MgCO_3$, and H_3BO_3; Li_2CO_3 ("reinst"), Na_2CO_3, and K_2CO_3 (both A.R.) from the firm Merck (Darmstadt), and the rare earth oxides Tb_4O_7 and Gd_2O_3 which were obtained from the Lindsay Chemical Division of American Potash and Chemical Corporation in purities of 99.9%

In all cases the preparation was carried out in such a way that no glass melts were prepared but polycrystalline powders only. From x-ray analysis it followed that in nearly all cases (except with the compounds $MgLiBO_3$, $MgNaBO_3$, and $BaKBO_3$) well crystallized solids were formed. The powder diagram of calcium sodium borate was in accordance with those found by Lehmann (6). The hitherto unpublished d-spacings of the other compounds will be published elsewhere.

It is important to point out that the phosphors which are discussed in this paper cannot be considered as phosphors comparable to those prepared by us before (2), by merely adding alkali ions for charge compensation. This follows from the fact that, for instance in a compound such as $3CaO \cdot B_2O_3$-Tb, no increase in brightness was observed when adding equimolar amounts of Na and Tb. Only with a high amount of sodium added, accompanied by the appearance of a distinct new phase, a strong increase in brightness could be achieved.

In the case of the preparation of phosphors with varying amounts of activator added, the ratio of the number of cations and anions was kept constant, *e.g.*, $(Ca, Na)_{1-x}Tb_xBO_3$. A small excess of the anions was added, as is common practice in the preparation of most phosphors.

The formula of the phosphors prepared are given as the molar compositions of the firing mixture. One should keep in mind, however, that after the firing, the composition may be different, *e.g.*, due to the volatilization of part of the boric acid added. Moreover an uncertainty of maximum 2% exists in the exact Tb concentration, as we assumed that the Tb-oxide used has the formula Tb_4O_7, and it is known that this compound may have some deviation from this formula.

The excitation, diffuse reflection, and emission spectra, efficiency, and decay times were determined by procedures already described by us (7, 8). All the phosphors investigated show emission lines characteristic of terbium (9), corresponding to transitions from the $^5D_4$ to ^7F_j levels. They resemble those found for the alkaline earth borates, described by us (2) earlier.

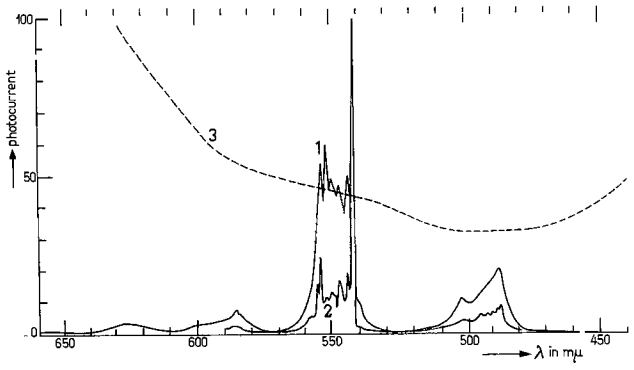

Fig. 1. Spectral energy distribution curves of the emission of $CaNaBO_3$-Tb; molar ratio Tb/B_2O_3 = 0.06. Curve 1, measured at room temperature, 20°C; curve 2, measured at liquid nitrogen temperature, —196°C; curve 3, correction factor with which the ordinates have to be multiplied in order to get relative radiant power.

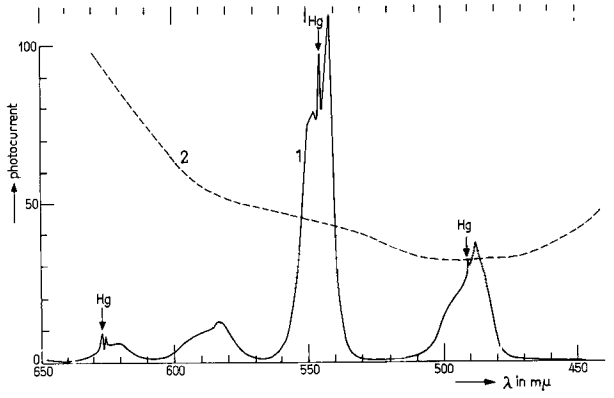

Fig. 2. Spectral energy distribution curves of the emission of $SrLiBO_3$-Tb, molar ratio Tb/B_2O_3 = 0.06 (curve 1). The same correction factor as in Fig. 1 is given in curve 2.

Examples of the emission spectra are given in Fig. 1 and 2, showing uncorrected recorder curves of the photocurrent as a function of wavelength λ. In $CaNaBO_3$-Tb we found that for a low Tb concentration the emission peaks are much sharper than for higher concentrations. The diffuse reflection spectra of the phosphors are similar to those found for the terbium-activated alkaline earth borates, reported before (2). The wavelength dependence of the quantum output (denoted by *L*) of the Tb-fluorescence (excitation spectrum) has been determined for several Tb-activated phosphors. That of calcium sodium borate-Tb is given in Fig. 3. The total intensity of the Tb emission (with $\lambda > 450$ mμ) was continuously monitored as a function of the exciting wavelength in the region from 220 to about 400 mμ Possible changes in the excitation spectra as a function of the fluorescent wavelength were thus not considered. The excitation spectra consist of a continuous part and of a line spectrum. In $CaNaBO_3$-Tb the continuous part of the excitation spectrum becomes somewhat broader with an increasing Tb concentration. This favors the efficiency with 253.7 mμ excitation, as present in a mercury discharge. With the borates containing Sr the peak in the excitation spectrum is located at a shorter wavelength (at about 235 mμ) than in the corresponding Ca-compounds (about 240 mμ). Both in the Ca- and Sr-alkali borates, the continuous bands in the excitation spectra are found to be narrower with the potassium compounds. For many of the latter phosphors the efficiency at 253.7 mμ is already considerably reduced.

Considering the lines found in the excitation spectra, one can distinguish between two groups of lines, *viz.*,

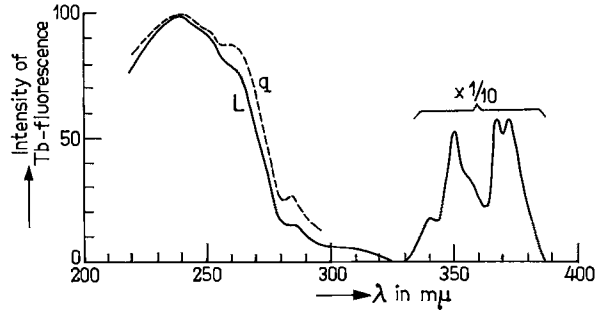

Fig. 3. Relative excitation spectra of the Tb fluorescence of $CaNaBO_3$-Tb (Tb/B_2O_3 = 0.15). Curve denoted with L, quantum output; curve denoted with q, quantum efficiency.

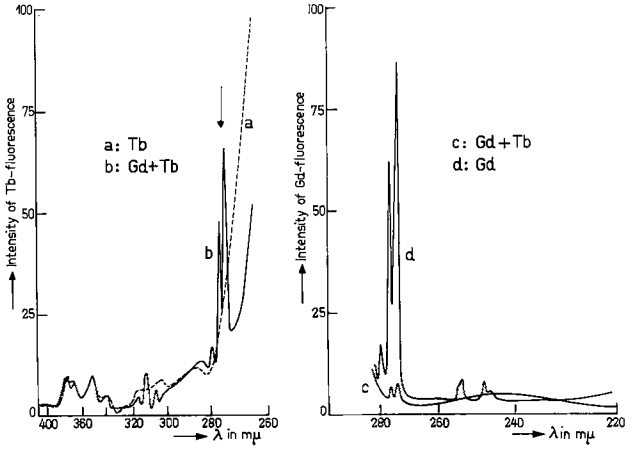

Fig. 4. Relative excitation spectra of the $2CaO \cdot Na_2O \cdot B_2O_3$ phosphors.

Curve	Molar ratio Tb/B_2O_3	Molar ratio Gd/B_2O_3	
a	0.06	0	Tb—fluorescence
b	0.06	0.24	Tb—fluorescence
c	0.06	0.24	Gd—fluorescence
d	0	0.24	Gd—fluorescence

those due to the presence of Tb and Gd, respectively, in the same way as was already discussed by us for the Tb-activated alkaline earth borates (2). When the phosphor contains both Gd and Tb, excitation of the Gd^{3+} ions results in the green Tb fluorescence due to transfer of energy from Gb to Td. (Fig. 4b). The sharp Tb fluorescence peaks indicated by an arrow are due to absorption in the Gd ions. Curves c and d give the excitation spectra of the Gd output (total fluorescent intensity in the 310 mμ region). From d it can be seen that the Gd emission of the phosphor activated with Gd only can indeed be excited in the 275-280 mμ region due to absorption by Gd ions. When incorporating Tb, it is obvious from curve c that the intensity of the Gd fluorescence is very much reduced. An interesting question is whether the observed transfer of energy is due to a quantum-mechanical resonance process or to a radiant process (absorption of the 310 mμ radiation emitted by Gd).

Radiative energy transfer seems rather unlikely, because it follows from the excitation spectra of the Tb emission that the efficiency of this emission is very low for excitation by 310 mμ radiation (see curve C).

Table I presents a survey of the radiant and quantum efficiencies of some terbium-activated borates for excitation in the 250-270 mμ region. These efficiencies are corrected for the reflection of the exciting radiation. In this way the quantum efficiency (the ratio of the number of emitted quanta and the number of absorbed quanta) is obtained. As follows from Fig. 5 the most efficient phosphors are prepared with a molar

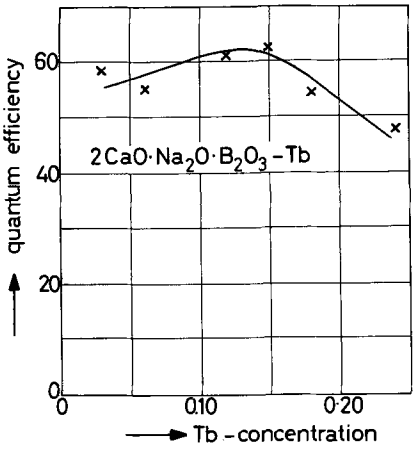

Fig. 5. Quantum efficiency (250-270 mμ excitation) of $2CaO \cdot Na_2O \cdot B_2O_3$-Tb phosphors as a function of the Tb concentration. The Tb concentration is expressed as the mole ratio Tb/B_2O_3.

ratio Tb/B_2O_3 of about 0.12. Concerning the effect of the molar ratio $(Ca + Na + Tb)/B_2O_3$, it was found that the best phosphors are made with a small excess of B_2O_3 added, *viz.*, with about a molar ratio $(Ca + Na + Tb)/B_2O_3$ of 3.75.

As regards the molar ratio Na/Ca of the $CaNaBO_3$-Tb phosphors, it was found that efficient phosphors can also be made with a large excess of sodium, *e.g.*, with a molar ratio Na/Ca = 1.50. From x-ray diffraction analysis it followed, however, that in these cases, apart from the pure $CaNaBO_3$-Tb phosphor, an unknown second phase is present, probably $NaBO_2$. With decreasing values of the molar ratio Na/Ca a gradual decrease in brightness occurs.

In general, the Sr-containing alkaline earth alkali borates are less efficient than the corresponding Ca compounds under excitation with 250-270 mμ radiation. This is in accordance with the shape of the excitation curves of the Ca- and Sr-alkali borates. Since no attempt was made to determine exactly the optimum chemical composition and firing conditions, it may well be possible to make phosphors that are more efficient than those listed in Table I.

Table I. Efficiencies of terbium-activated alkaline earth alkali borates

r = reflection; η = radiant efficiency; q = quantum efficiency; T = relative brightness at 500°C (brightness at room temperature = 100)

Host lattice	Molar ratio Tb/B_2O_3	Molar ratio Gd/B_2O_3	Excitation 250-270 mμ r (%)	η (%)	q (%)	T
$2CaO \cdot Na_2O \cdot B_2O_3$	0.15	0	21	31	65	80
$1.53CaO \cdot 1.15Na_2O \cdot B_2O_3$	0.15	0	43	16	33	—
$1.40CaO \cdot 1.05Na_2O \cdot B_2O_3$	0.15	0.15	30	20	42	—
$2CaO \cdot Li_2O \cdot B_2O_3$	0.06	0	46	4	7	190
$2CaO \cdot Li_2O \cdot B_2O_3$	0.06	0.06	44	11	22	105

$2MgO \cdot Na_2O \cdot B_2O_3$	0.24	0	36	19	40	—

Table II. Decay times in milliseconds (1/e — values) Excitation: short wavelength ultraviolet.

Host lattice	Molar ratio Tb/B_2O_3	Molar ratio Gd/B_2O_3	Decay time (ms) at 20°C	at −196°C
$2CaO \cdot Na_2O \cdot B_2O_3$	0.03	0	5	5
$2CaO \cdot Na_2O \cdot B_2O_3$	0.15	0	3.5	3.5
$2CaO \cdot Na_2O \cdot B_2O_3$	0.24	0	3	3
$2CaO \cdot Na_2O \cdot B_2O_3$	0.06	0.06	4	4

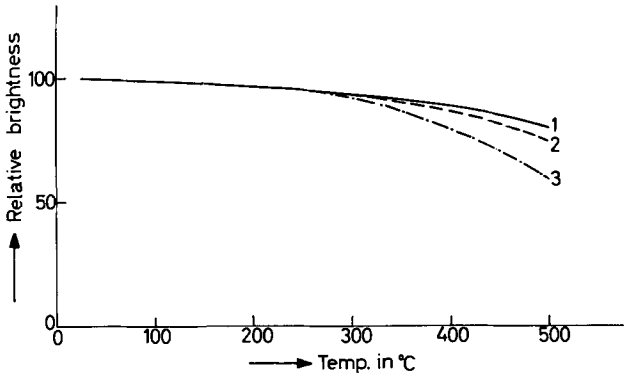

Fig. 6. Variation of brightness with temperature of $2CaO \cdot Na_2O \cdot B_2O_3$-Tb phosphors (with varying Tb concentration). Excitation with germicidal lamp (mainly 254 mμ radiation). The phosphors were twice fired, *viz.*, at 750° and 850°C. Tb/B_2O_3: curve 1, 0.03, 0.12, and 0.15; curve 2, 0.18; curve 3, 0.24.

The radiant efficiency with cathode-ray excitation of some of the phosphors was determined also, in a way described already (10). The highest radiant efficiency, *viz.*, 2.2%, was observed in a sample of $2CaO \cdot Na_2O \cdot B_2O_3$-0.15Tb.

The decay times (*i.e.*, the times in which the intensity of the emission falls to 1/e of the original value) of some of the phosphors prepared are given in Table II. The decay curves were found to be exponential within the accuracy of measurement. At the temperature of liquid nitrogen the decay time is about the same as at room temperature, indicating that the number of radiationless transitions at room temperature is not high.

It may be seen from Fig. 6 and also from the data given in Table I, that the phosphors, like the previously prepared terbium-activated alkaline earth borate phosphors, show a relatively high brightness at elevated temperatures. With a molar ratio $Tb/B_2O_3 = 0.06$, the relative brightness at a certain elevated temperature decreases in the sequence: $CaLiBO_3$-Tb, $CaNaBO_3$-Tb, $CaKBO_3$-Tb. In many cases the phosphors investigated show a stronger absorption of the incident ultraviolet radiation at 500°C than at room temperature. A higher ultraviolet absorption means an increase in brightness, especially for those phosphors having a low ultraviolet absorption at room temperature. This effect may partially explain the increase in brightness at elevated temperatures found for some phosphors.

Acknowledgment

The authors wish to express their thanks to Mr. J. G. Verlijsdonk and Mr. A. A. L. Sleutjes for preparing the phosphors; to Mr. J. A. A. Bertens, Mr. C. D. J. C. de Laat, and Mr. C. J. Loyen for carrying out the measurements of the optical properties of the phosphors investigated, and to Mr. W. Parchen for the x-ray diffraction analysis.

Optical Absorption Edges of ZnO and CdS

W. Lehmann

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

The optical absorption edge of n-type InSb has been reported to move to higher quantum energy (*i.e.*, shorter wavelength) with increasing impurity concentration (1). The effect is explained by assumption of an, in k-space, relatively narrow conduction band which fills rapidly with free electrons up to an appreciable height above the bottom of the conduction band. Optical absorption corresponding to an electron transition from the top of the valence band is then possible only into higher, empty conduction band states (2). We observed a qualitatively similar dependence on the impurity concentration of what appeared to be the optical absorption edges of n-type ZnO and n-type CdS.

Measurements so far were restricted to powders. Luminescent or electronic grade ZnO or CdS, respectively, were doped with Al, Ga, or In of various concentrations, prefired in appropriate atmospheres (air for ZnO, H_2S for CdS) to insure well crystallized particles of roughly 10μ mean diameter, and refired in hydrogen gas at relatively low temperatures (700°C for ZnO, 500°C for CdS). The hydrogen reacts slightly with the materials

$$ZnO + H_2 \rightarrow Zn + H_2O$$

$$CdS + H_2 \rightarrow Cd + H_2S$$

so that a slight excess of free Zn or Cd, respectively, remains and the tendency of self-compensation by formation of cation vacancies is reduced. The H_2 firing may also be replaced by firing the powders with a slight excess of the metal in evacuated and sealed quartz tubes with similar results. It is shown by Kröger and co-workers that the n-type conductivity of CdS crystals prepared under such conditions corresponds to approximately one free electron per added impurity atom (3).

Compact but thin (quasi-monoparticle) layers of the powders were stuck with little binder on a piece of aluminum metal and illuminated with the unfiltered light of an incandescent lamp. The light reflected from the samples was passed through a monochromator into a photomultiplier. The readings were normalized on solid $MgCO_3$ (= 100%). Some reflection curves so obtained are shown in Fig. 1 and 2. The reflection remains at a fairly constant, low level at short wavelengths up to a certain point where on it increases rather rapidly. It is estimated from the geometry of the samples that the bulk absorption coefficient of the materials at the "edge" of the absorption curve is in the order of 100 cm^{-1}.

ZnO and CdS crystallize both in the wurtzite structure, and their optical properties are slightly anisotropic. Hence, a determination of the absorption edge on a powder with randomly oriented particles gives only an average between the values corresponding to the directions parallel and perpendicular to the c-axis. This difference is not very large, however. Some values of the optical absorption edge measured by various authors on powders and on single crystals of CdS are collected in Table I.

We observed that the quantum energy corresponding to the optical absorption edge determined as described above increases steadily with increasing impurity concentration up to a certain limit, then on it remains constant. The effect is strong enough in CdS to be noticed on the body color of the sample with the unaided eye. Measured values of the optical absorption edges as functions of the added impurity concentrations are shown in Fig. 3 and 4. They increase up to 2.51 ev at room temperature and to 2.62 ev at 77°K for CdS, and up to 3.33 ev at room temperature and to 3.42 ev at 77°K for ZnO. These values for CdS are higher than any so far reported for CdS (Table

I). The situation with ZnO is less clear since considerable controversy exists concerning its optical absorption edge (11). However, most authors agree to a strong onset of absorption of powdered ZnO, at room temperature, in the neighborhood of $\lambda = 385$ nm ($= 3.22$ ev) (12-16).

The variation of the optical absorption edges with the impurity concentrations shown in Fig. 3 and 4 probably can be explained in essentially the same way as proposed by Burstein for InSb (2) with one difference. The density of allowed energy states near the bottom of the conduction band of an ideally perfect crystal clearly is a discontinuous function. However, no crystal is perfect, and any disorder may cause a tailing-off of the density of allowed states below the bottom of the conduction band (17). This tail is probably strong in all conventional II-VI compounds as indicated by the commonly observed exponential (rather than parabolical) dependence of the absorption constant on the quantum energy near the absorption edge (18). Hence, a measured absorption constant in the order of 100 cm^{-1} probably does not correspond to an electron transition into the conduction band but into the tail below the conduction band, and different workers observed different values for the optical absorption "edge" (Table I) because of different degrees of perfectness of their crystals. It appears from Fig. 3 and 4 that increasing n-type conductivity first fills up only the tail below the conduction band, and that the conduction band itself is reached only for high impurity concentrations. Hence, the high energies of the absorption edges, approaching constant values for high impurity concentrations, in Fig. 3 and 4 probably are the true values of the forbidden band gaps of near-perfect ZnO and CdS.

Acknowledgment

The writer wishes to express his thanks to Mr. H. H. Dorman for much good work in preparations and measurements.

Electron Beam Exposure of Photoresists

R. F. M. Thornley and T. Sun

IBM Watson Research Center, Yorktown Heights, New York

The conventional visible or ultraviolet exposure of photoresists is well suited to the parallel exposure of large fields and for resolutions above 3μ. For serial exposures, such as may be required in printed circuit generators, the maximum exposure rates are limited by the sensitivities of presently available resists. For high resolution work, problems of focus adjustment and control of the level of illumination become more critical, making it difficult to carry out routine operations with resist patterns less than 3μ wide. Electron beam exposure can be expected to overcome these problems, at the expense of introducing new ones. The power densities obtainable in electron beams are several orders of magnitude higher than those from conventional optical light sources, permitting exposures to be carried out in well below 1 msec. The diameter

of an electron beam can easily be made less than 0.1μ and the depth of focus for such a beam will be of the order of $\pm 25\mu$. The significant new problems are the need for a high vacuum system and the removal of the resist after etching.

Interaction Mechanism

A negative-working resist is essentially a material which can be caused to polymerize when irradiated with light of a suitable wavelength. The energy of a light quanta is such that it is only able to initiate the polymerization process at certain sensitive points in the resist molecule, and the composition of the resultant polymer is fairly well defined. When an electron, typically with an energy of 20 KeV, enters the resist, the interaction is much less subtle. The electron has so much energy that it opens most of the chemical bonds in its path, permitting a complete reorganization of the molecular structure. Such a process broadens the range of molecular weights in the resist but does not necessarily increase the average molecular weight (1). Experimentally, it is found that the effect of electron exposure is similar to that of light on the negative-working resists. Overexposure with electrons continues the cross linking process and eventually forms a layer which, although a good resist, cannot be stripped after etching in any of the solvents normally used for this operation.

Resist Exposure Characteristics

The resists tested were Kodak Photoresist (KPR), Kodak Metal Etch Resist (KMER), Kodak Ortho Resist (KOR), and Kodak Thin Film Resist (KTFR). The resists were tested on oxidized silicon wafers, coated with an evaporated aluminum layer 1μ thick. Before coating with resist, the wafers were given a 3 min dip in 10% potassium dichromate solution at 65°C to improve the adhesion of the resist to the aluminum surface. The resists were applied, after dilution, by a filter-equipped syringe to the surface of the wafer. KTFR, KOR, and KPR were diluted 1:1 and KMER was diluted 2:1 with the manufacturer's thinner. The wafer was then spun at 7000 rpm for 3 min, producing film thicknesses in the range 1500 to 2500Å. The wafer was then inserted into the vacuum system and pumped down to 10^{-6} Torr, completing the drying process. Prebaking at 45° for 10 min before exposure did not change the sensitivity characteristics.

Exposures were made at 14 and 20 kv using a 1μ diameter beam carrying 1.29 x 10^{-9} amp, which was scanned to cover a 5 x 20 mil area in 50 mS, the line

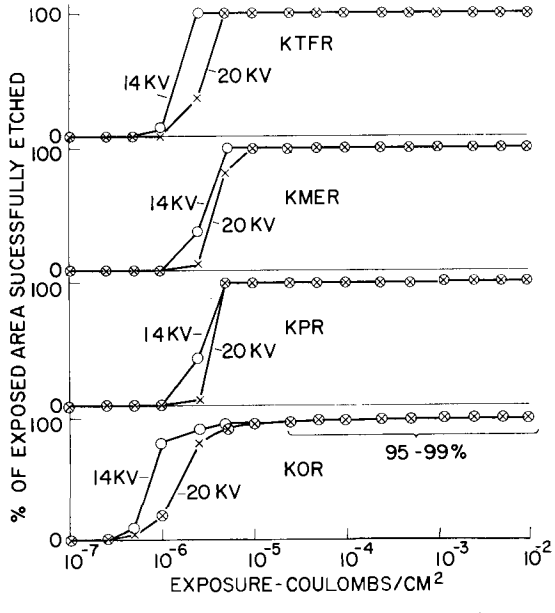

Fig. 1. Exposure characteristics at 14 and 20 kv

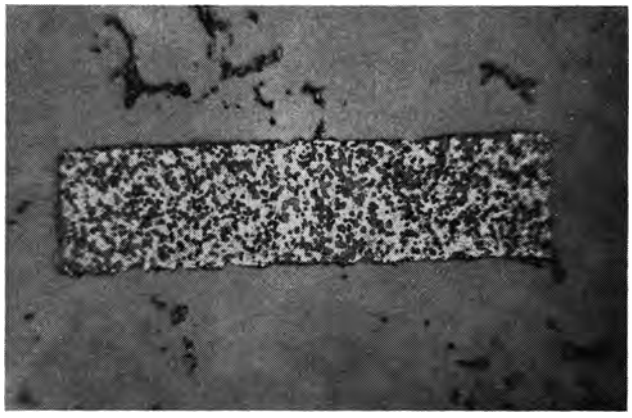

Fig. 2. Pinhole formation in KOR sample exposed with 10^{-5} coulombs/cm^2 at 20 kv.

frequency being adjusted to prevent the scan lines from being resolved. Variations in exposure over a 1000:1 range were achieved by repeated scanning over the same area. A further factor of 100 in range was obtained by increasing the beam current to 1.29 x 10^{-7} amp in a slightly larger beam diameter.

After exposure, the resists were developed, KPR and KOR with the manufacturer's developers, KMER and KTFR with a mixture of three parts toluene, three parts xylene, and one part benzene by volume. The patterns were photographed, baked at 130°C for 30 min, and etched in 20% NaOH at 65°C. No change was found between the areas of the resist patterns of KTFR, KMER, and KPR after development and the areas of the etched aluminum patterns. With KOR, etching revealed the existence of numerous pinholes in the resist image (Fig. 2). The efficiency of resist formation as a function of charge density for 14 and 20 kv electrons is given in Fig. 1. It can be seen that for KTFR, KMER, and KPR, the characteristics are substantially identical, the sensitivities at 20 kv being about 25% less than 14 kv. This is expected since electrons of both energies pass completely through the resist layer and the energy loss/unit length is less for the higher energy beam.

The KOR is about five times more sensitive than the other materials but does not form a satisfactory resist, even with very high exposures. The failure is ten-

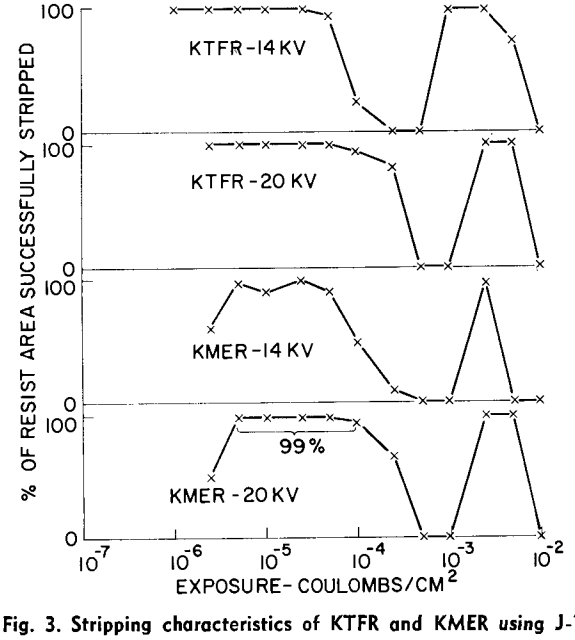

Fig. 3. Stripping characteristics of KTFR and KMER using J-100 at 90° for 4 min.

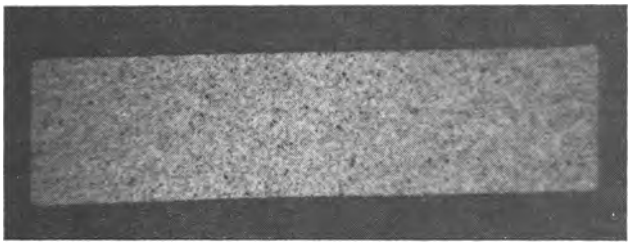

Fig. 4. KTFR exposure, using 10^{-5} coulombs/cm^2 at 20 kv, after etching and stripping.

tatively attributed to the formation of minute bubbles of gas during exposure.

Stripping Characteristics

In most resist operations, the resist must be removed after etching. A very wide variety of solvent mixtures are used for this operation. To restrict the range to be investigated, stripping was attempted for each resist using solvent mixtures that were known to be satisfactory for the same resist exposed with ultraviolet light.

The results for KTFR and KMER, using the commercial stripping solution J-100[1] are shown in Fig. 3. KOR did not strip using a mixture containing 80% trichlorethylene and 20% Stripper 77[2] for 30 min at 70°C. KPR stripped successfully using chromic acid but the aluminum was also attacked, raising doubts as to whether the resist was dissolved off or simply released by the removal of the aluminum. An optimally exposed, etched, and stripped KTFR sample is shown in Fig. 4.

An unexpected feature of the stripping characteristics was the existence of a second area between 10^{-3} and 10^{-2} coulombs/cm^2 for which stripping was possible. The possibility that the effect is due to thermally induced changes during exposure was eliminated by repeating the exposure tests with the beam current reduced by two orders of magnitude. No change was observed.

[1] Litho Aluminum Product Co., Chicago, Illinois.
[2] Shipley Co., Wellesley, Massachusetts.

Exposure Rates

The exposure of any of the resists considered requires the specimen to absorb about 0.1 joules/cm^2. Since this quantity of energy cannot be confined to the irradiated volume without causing an excessive temperature rise, the exposure rate must be low enough to permit most of this energy to diffuse away. For thick (approximating to semi-infinite) substrates, this rate is set by the thermal diffusivity of the substrate and varies from about 10^{-3} for glass or methacrylate plastics up to about 1 cm^2/°C/sec for copper. Experimentally, satisfactory exposures have been made on 0.005 in. thick silicon wafers in 0.25 mS. No upper limit for the exposure rate was reached with the available equipment and silicon wafers.

Conclusions

For applications, requiring high speed, high resolution exposure of resist patterns, electron beams can be usefully employed. There is a range of approximately 10:1 using KTFR for which the resist formation and stripping characteristics are both excellent.

Vapor Phase Equilibria in the Gallium-Chlorine and Gallium Arsenide-Chlorine Systems

M. A. Zuegel

Systems Development Division, International Business Machines Corporation, Boeblingen, Germany

In the vapor growth process, layers are formed by chemical reaction between the substrate and a gas phase which contains compounds of the material deposited on the substrate. The events occurring at the substrate result from the tendency of this reaction toward the establishment of thermodynamic equilibrium. For the process to be practical, the equilibrium conditions must be known.

The importance of III-V compounds, especially of gallium arsenide in the modern technology of semiconductors, was the reason for an experimental investigation of the equilibrium composition in the gallium arsenide-chlorine system. Chlorine, elemental or in form of the compound HCl, is often used as a transporting agent in the vapor growth process of gallium arsenide. To check the stability of the various gallium chlorides at the conditions of the process the gallium-chlorine system was also investigated. The corresponding iodine systems were the object of an earlier study by Lyons and Silvestri (1). A theoretical treatment of the chlorine systems by Fergusson and Gabor (2) makes a comparison of the experimental results with theoretical data possible.

Experimental

The experimental procedure was the same as that used by Lyons and Silvestri (1). The total pressure (P_t) in a sealed quartz ampoule filled with a known amount of chlorine and excess gallium or gallium arsenide, respectively, was measured as a function of temperature.

Figure 1 shows the apparatus used for the experiments. The arrangement of a quartz ampoule prepared for the run is shown in Fig. 2.

The pressure in the reaction vessels was measured with Bodenstein manometers. These manometers (Heraeus Quarzschmelze, Hanau, Germany) are made from a very thin-walled, flat quartz tubing by coiling them into helical spirals. Differences of pressure between the inside of the spirals and the surrounding atmosphere cause a twisting of the spirals from their equilibrium positions. Distortions of the spirals are completely reversible, if they do not become too large and if stresses in the spirals have been removed by annealing at 1000°C. The twisting of the spirals is made visible by a light beam projected on to a scale via a small mirror mounted at the indicator end of the spirals. If a pressure difference causes a distortion of such a spiral, the light mark can be reset to the zero point of the scale by adjusting the pressure surrounding the spiral. This pressure was measured with precision manometers (Wallace & Tiernan, Belleville, New Jersey). With spirals of normal sensitivity, the measuring arrangement permits a clear resolution of pressure differences down to 0.1 mm Hg. To protect the very fragile quartz spirals from glass splinters, a frit was melted into the capillary tubing connecting the reaction vessel and quartz manometer.

In preparing the runs, the reaction vessel was loaded with a quartz hammer and an ampoule which had been sealed in high vacuum after filling it with gallium (99.99%) or gallium arsenide (high resistivity, uncom-

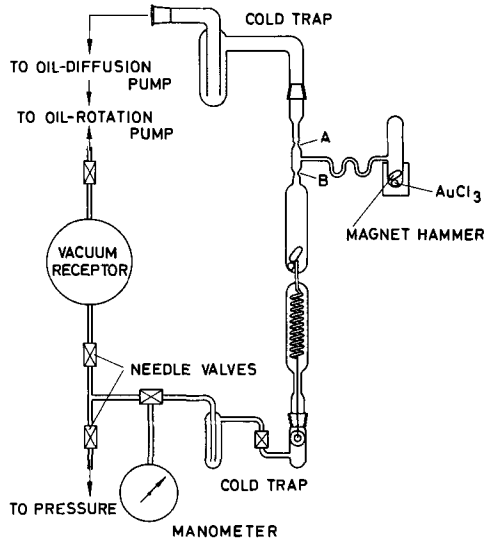

Fig. 1. Apparatus used for the experiments

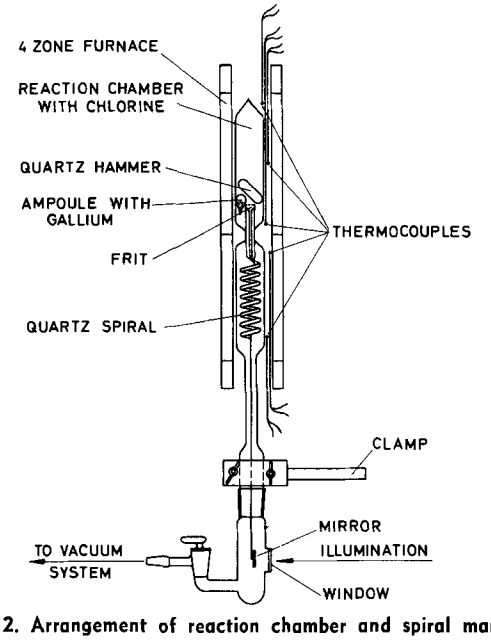

Fig. 2. Arrangement of reaction chamber and spiral manometer in the furnace.

pensated material). The reaction vessel, spiral manometer, and the part of the apparatus in which chlorine was generated were evacuated to 10^{-6} mm Hg, and where possible heated with a torch. The apparatus was sealed at point A, and chlorine was generated by thermal decomposition of gold trichloride ($AuCl_3$) at 250°C. The approximate desired quantity of chlorine was led into the reaction chamber which was then sealed at point B.

For the determination of the initial chlorine concentration, $\frac{n_{Cl}}{V}$, the reaction vessel was placed upside down in a water bath of known temperature, and the pressure in the vessel was determined. The initial chlorine concentration was calculated from the measured pressure and temperature using the ideal gas law.

The small ampoule containing gallium or gallium arsenide was then broken with the quartz hammer by tilting the reaction vessel. Finally, a four-zone furnace was positioned over the reaction vessel and spiral manometer. The voltages of the Pt-Pt/Rh (10%) thermocouples checking the temperatures at the positions shown in Fig. 2 were measured with a L & N millivolt potentiometer.

To prevent a deposition of condensed substances in the spirals, the temperature of the spiral was always

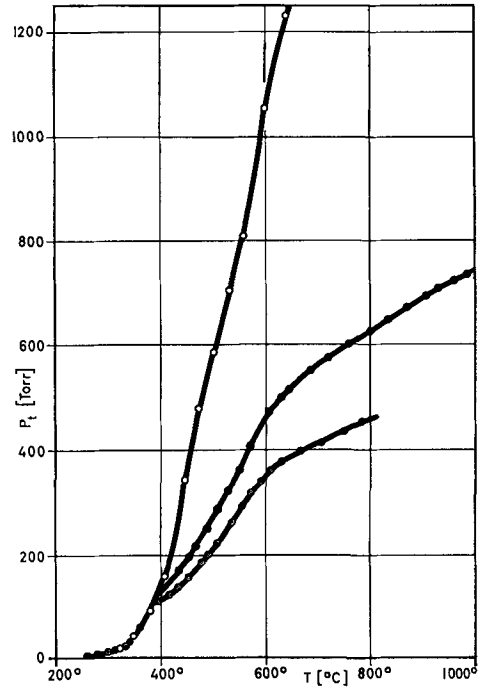

Fig. 3. Gallium-chlorine system: total pressure P_t as a function of temperature for three runs with different initial chlorine concentrations $\frac{n_{Cl}}{V}$

⊙, Run 1, $\frac{n_{Cl}}{V} = 6.92 \times 10^{-3}$ g-at. of Cl/liter

•, Run 2, $\frac{n_{Cl}}{V} = 9.60 \times 10^{-3}$ g-at. of Cl/liter

○, Run 3, $\frac{n_{Cl}}{V} = 2.44 \times 10^{-2}$ g-at. of Cl/liter

kept a few degrees higher than that of the reaction vessel. In most cases, the pressure was measured in the direction of increasing temperature. Since the same pressure values were obtained with decreasing temperatures, this indicates that thermodynamic equilibrium was established during the pressure reading.

Results and Discussion

The gallium-chlorine system.—The reaction between chlorine and gallium occurs at approximately room temperature. A white crystalline material forms with a strong evolution of heat. At 170°C, the crystals melt to a colorless liquid with a high refractive index.

Figure 3 shows the pressure in the reaction chamber as a function of temperature for three runs with different initial chlorine concentrations.

Up to about 400°C the pressure is independent of the chlorine concentration and depends only on temperature. In this range the gallium-chloride system is univariant, and, since it is composed of two components, gallium and chlorine, it consists of three phases, two condensed phases, gallium and a gallium-chlorine compound, and the gas phase. In this temperature range, the pressure in the vessel corresponds to the equilibrium pressure between gallium dichloride and its vapor as measured by Laubengayer and Schirmer (3). Since the physical properties of the compound aforementioned agree with those of gallium dichloride [see ref. (3)], this indicates that chlorine reacts with excess gallium at low temperatures to form gallium dichloride.

At about 400°C, a kink in the pressure curves can be observed. It corresponds to the dew point of gallium dichloride and shifts, as expected, to higher temperatures with increasing initial chlorine concentration. Above the kink the system is divariant and consists of only two phases, a condensed phase of liquid gallium and the gas phase.

From 400° to approximately 600°C, the molar concentration of the gas phase increases with tempera-

ture. An indication of the reaction occurring in this temperature range may be obtained by comparing the molar concentration of the gas phase with the initial chlorine concentration at the kinks of the curves and at high temperatures. At the temperature of the kinks, the molar concentration is only a little higher than one-third of the initial chlorine concentration. Here gallium trichloride ($GaCl_3$) seems to be the predominant vapor species. With increasing temperature, the concentration of the gas phase approaches the initial chlorine concentration indicating the formation of gallium monochloride (GaCl), and it remains constant at temperatures higher than approximately 650°C.

The chlorides, $GaCl_3$ and GaCl, correspond to the iodides, GaI_3 and GaI, as found by Lyons and Silvestri (1) in the gallium-iodine system. In accordance with the gallium-iodine system, the reaction proposed for the gallium-chlorine system is

$$2Ga(l) + GaCl_3(v) \rightleftharpoons 3GaCl(v) \qquad [1]$$

With the pressure data measured above the kinks, the corresponding equilibrium constant

$$K_P(\text{atm}^2) = \frac{p^3_{GaCl}}{p_{GaCl_3}} \qquad [2]$$

was calculated. The partial pressures of GaCl and $GaCl_3$ expressed in terms of total pressure P_t and initial chlorine concentration $\frac{n_{Cl}}{V}$ are

$$p_{GaCl} = \frac{1}{2}\left(3P_t - \frac{n_{Cl}}{V} \cdot RT\right)$$

$$\text{and } p_{GaCl_3} = P_t - p_{GaCl} \qquad [3]$$

The plot $\log K_p$ *vs.* $1/T$ for the three runs of Fig. 3 is shown in Fig. 4. Since the equilibrium constant proves to be independent of the initial chlorine concentration the validity of Eq. [1] is confirmed experimentally.

From the slope of Fig. 4, the enthalpy of reaction was calculated and found to be $\Delta H = 54.2$ kcal/mole.

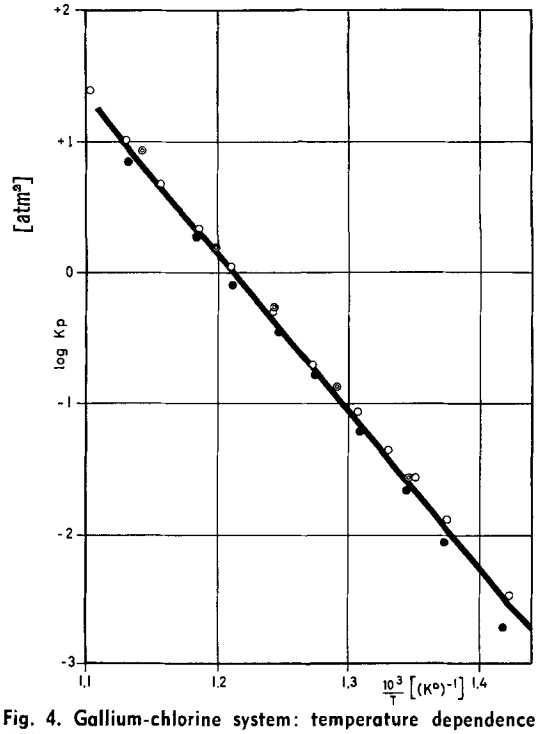

Fig. 4. Gallium-chlorine system: temperature dependence of the equilibrium constant.

○, Run 1, $\frac{n_{Cl}}{V} = 6.92 \times 10^{-3}$ g-at. of Cl/liter

●, Run 2, $\frac{n_{Cl}}{V} = 9.60 \times 10^{-3}$ g-at. of Cl/liter

◉, Run 3, $\frac{n_{Cl}}{V} = 2.44 \times 10^{-2}$ g-at. of Cl/liter

This value is in good agreement with a theoretical value of $\Delta H = 48.9$ kcal/mole (mean value for the temperature range of Fig. 4) calculated with the aid of the heats of formation of GaCl and $GaCl_3$ (2). The temperature dependence of the equilibrium constant for Eq. [1] can be described by the equation

$$\log K_p\ (\text{atm}^2) = -\frac{1.19 \cdot 10^4}{T} + 14.42 \qquad [4]$$

valid between 420° and 630°C.

In the calculation of the partial pressures of the gallium chlorides, the dimerization of $GaCl_3$ was not considered. As can be shown with the data of Fischer and Jubermann (4), Ga_2Cl_6 is almost completely dissociated in the temperature and pressure range of the measurements, and in the most unfavorable case, the Ga_2Cl_6 contents is not higher than a few per cent.

The gallium arsenide-chlorine system.—Chlorine reacts with gallium arsenide already at room temperature. Cooling the top part of the reaction vessel with liquid nitrogen condenses the product of reaction as a colorless liquid which flows down the walls of the vessel and solidifies. Since the substance has a higher vapor pressure than the gallium chlorides, it is presumed to be arsenic trichloride ($AsCl_3$) or more likely a mixture of $AsCl_3$ with gallium di- or trichloride. The pressure curves of four runs with different initial chlorine concentrations are shown in Fig. 5.

At low temperatures, the system is univariant and the pressure is defined by a vaporization equilibrium, probably, of the rather volatile $AsCl_3$. After the complete evaporation of this substance, the slope of the curves decreases suddenly. From the plot dips up to approximately 300°C, the molar concentration of the gas phase increases steadily. At around 300°C, an irreversible reaction takes place indicated by a sudden

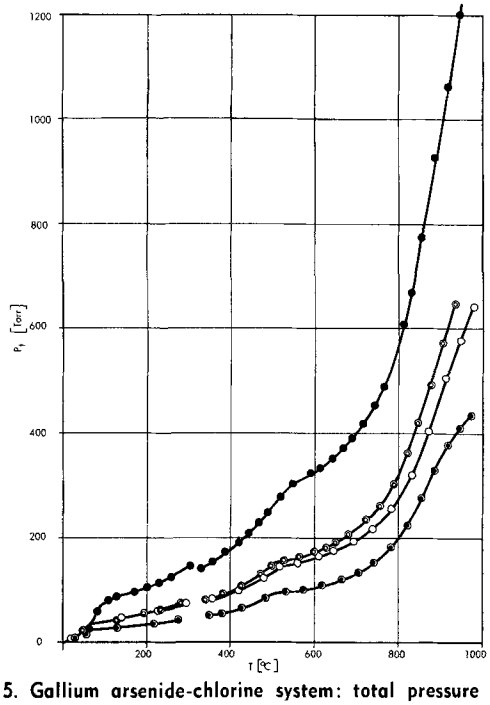

Fig. 5. Gallium arsenide-chlorine system: total pressure P_t as a function of temperature for four runs with different initial chlorine concentrations.

◉, Run 1, $\frac{n_{Cl}}{V} = 4.32 \times 10^{-3}$ g-at. of Cl/liter

◎, Run 2, $\frac{n_{Cl}}{V} = 7.18 \times 10^{-3}$ g-at. of Cl/liter

●, Run 3, $\frac{n_{Cl}}{V} = 1.41 \times 10^{-2}$ g-at. of Cl/liter

○, Run 4, $\frac{n_{Cl}}{V} = 7.03 \times 10^{-3}$ g-at. of Cl/liter

pressure change. Perhaps $AsCl_3$ reacts here with GaAs forming arsenic and gallium trichloride, and the dimerization of $GaCl_3$ causes the observed drop of pressure. The pressure then increases continuously up to the second kinks of the curves at approximately 500°C. The pressure measured here equals that calculated from the ideal gas law, *if* a quantitative formation of completely evaporated $GaCl_3$ and As_4 from the available amount of chlorine is assumed according to the equation

$$2GaAs + 3Cl_2 \rightarrow 2GaCl_3 + \frac{1}{2}As_4 \qquad [5]$$

A further rise of temperature increases the molar concentration of the gas phase more strongly than can be explained by the beginning dissociation of tetrameric arsenic (As_4) into dimeric arsenic (As_2). Therefore, a reaction of the gas phase with unreacted GaAs must be taking place which increases the concentration of the gas phase.

As in the gallium-chlorine system, the pressure at sufficiently high temperatures is the same as would be expected from a quantitative reaction between chlorine and gallium arsenide with formation of only gallium monochloride and arsenic, the latter being partially dissociated. The temperature dependence of the equilibrium constant for the arsenic dissociation is tabulated by Stull and Sinke (5) and obeys the equation

$$\log K_p(\text{Torr}) = \log\left(\frac{p^2_{As_2}}{p_{As_4}}\right) = -\frac{1.31 \cdot 10^4}{T} + 10.99 \qquad [6]$$

From these observations it is likely that the formation of GaCl at temperatures above 500°C is due to a reaction between GaAs and $GaCl_3$ according to the equation

$$2GaAs(s) + GaCl_3(v) \rightleftharpoons 3GaCl(v) + \frac{1}{2}As_4(v) \qquad [7]$$
$$\Updownarrow$$
$$As_2(v)$$

Equation [7] corresponds to the reaction found by Lyons and Silvestri (1) in the gallium arsenide-iodine system.

The partial pressures of the vapor species necessary for the calculation of the equilibrium constant for Eq. [7]

$$K_p = \frac{p^3_{GaCl} \cdot p^{1/2}_{As_4}}{p_{GaCl_3}} \qquad [8]$$

are expressed in terms of total pressure P_t and initial chlorine concentration $\frac{n_{Cl}}{V}$ and dissociation constant for arsenic K_pAs

$$p_{As_4}(\text{Torr}) = 0.2P_t + 0.18K_{pAs} - [(0.2P_t + 0.18K_{pAs})^2 - 0.04P_t^2]^{1/2} \qquad [9a]$$

$$p_{GaCl_3}(\text{Torr}) = \frac{1}{2}\left(\frac{n_{Cl}}{V} \cdot RT - P_{As} - P_t\right), \quad \text{with } P_{As} = p_{As_4} + p_{As_2} \qquad [9b]$$

$$p_{GaCl}(\text{Torr}) = P_t - P_{As} - p_{GaCl_3} \qquad [9c]$$

The partial pressures p_{As_4}, p_{As_2}, p_{GaCl_3}, and p_{GaCl} and the corresponding K_p values were calculated by an IBM 1401 computer using the P_t values measured above the second dips of Fig. 5.

The temperature dependence of the equilibrium constant for the proposed Eq. [7] for four runs with different initial chlorine concentrations is shown in Fig. 6.

Although the temperature dependence of the reaction enthalpy ΔH should be very small in Eq. [7] as calculated from the data of ref. (2) (ΔH 600°C = 104.1 kcal/mole, ΔH 1000°C = 101.4 kcal/mole), the slope of the plot log K_p *vs.* $1/T$ is not even roughly constant for the runs 1-3 of Fig. 6. During these runs dry air or nitrogen was used for the counterpressure. At the high temperatures of the measurements, fused quartz becomes noticeably permeable to the above gases. The permeability of fused quartz for several gases has been measured by Johnson and Burt (6) and Barrer (7).

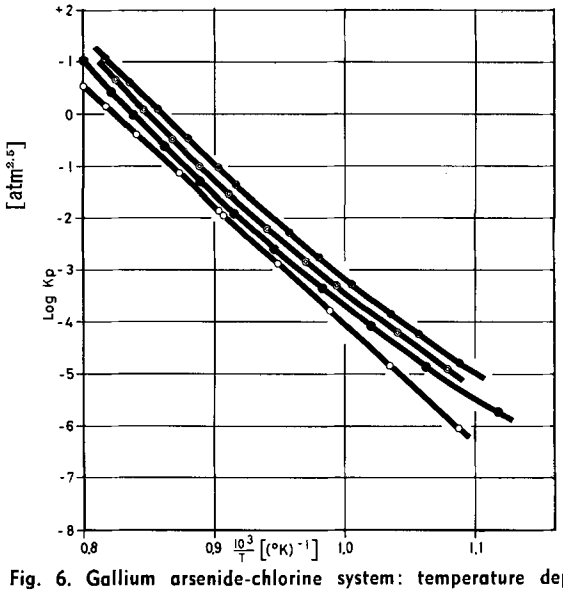

Fig. 6. Gallium arsenide-chlorine system: temperature dependence of the equilibrium constant.

⊙, Run 1, $\frac{n_{Cl}}{V}$ = 4.32 x 10^{-3} g-at. of Cl/liter

⊙, Run 2, $\frac{n_{Cl}}{V}$ = 7.18 x 10^{-3} g-at. of Cl/liter

●, Run 3, $\frac{n_{Cl}}{V}$ = 1.41 x 10^{-2} g-at. of Cl/liter

○, Run 4, $\frac{n_{Cl}}{V}$ = 7.03 x 10^{-3} g-at. of Cl/liter

The value for nitrogen at 900°C, *e.g.*, is about 10^{-10} cm^3/sec of nitrogen gas at normal pressure and temperature related to a sample area of 1 cm^2, a sample thickness of 1 mm, and a pressure difference of 1 Torr across the sample. Thus, with a pressure difference of about 1 atm, with the dimensions of the reaction chamber and the very thin-walled quartz spiral, approximately 0.2 cm^3 of nitrogen would diffuse per hour into the reaction chamber at 900°C. The permeability of quartz glass for air will be approximately the same since its mean molecular weight is similar. The diffused-in gases can react with the contents of the reaction chamber and thereby affect the pressure of the system. In such a case, the pressure will not be due only to the reacting species, $GaCl_3$, GaCl, As_4 and As_2, as has been assumed for the calculation of the equilibrium constant.

During run 4, for which the slope in Fig. 6 is constant in an extended temperature range, argon (99.9%) was used for compensating the deflections of the spiral. The permeability of quartz glass for argon is much smaller, approximately 5 × 10^{-12} cm^3/sec at 900°C. Besides this advantage, argon does not react with the contents of the reaction chamber, so that its effect on the pressure is only an additional partial pressure which can be subtracted from the measured total pressure. The obtained corrected pressure arises then only from the participants of Eq. [7]. As another precaution, the walls of the reaction chamber were made thick for run 4 to keep the penetration of air into the system as small as possible. The amount of diffused-in argon was determined by measuring the pressure in the reaction vessel at a temperature at which the partial pressures of the other constituents are negligibly small. After run 4, the partial pressure of argon was 1.6 Torr at room temperature. Considering the much higher diffusivity of nitrogen or air, it is obvious that no reliable measurements could be made with air or nitrogen as compensating medium.

From the slope of run 4 in Fig. 6, the enthalpy of Eq. [7] was calculated and found to be $\Delta H = 104$ kcal/mole. The temperature dependence of the equilibrium constant for Eq. [7] can be described with the following equation

$$\log K_p\ (\text{atm}^{2.5}) = \frac{-2.28 \cdot 10^4}{T} + 18.79 \qquad [10]$$

which is valid between 640° and 980°C.

Conclusions

The reactions establishing the thermodynamic equilibrium in the gallium-chlorine and gallium arsenide-chlorine systems and the temperature dependence of the corresponding equilibrium constants can be described by the following equations:

Gallium-chlorine system

$$2\text{Ga(l)} + \text{GaCl}_3\text{(v)} \rightleftharpoons 3\text{GaCl(v)} \qquad [1]$$

$$\log K_p\ (\text{atm}^2) = -\frac{1.19 \cdot 10^4}{T} + 14.42 \qquad [5]$$

valid between 420° and 630°C. Gallium arsenide-chlorine system

$$2\text{GaAs(s)} + \text{GaCl}_3\text{(v)} \rightleftharpoons 3\text{GaCl(v)} + \frac{1}{2}\text{As}_4\text{(v)} \qquad [7]$$

$$\Updownarrow$$

$$\text{As}_2\text{(v)}$$

$$\log K_p\ (\text{atm}^{2.5}) = -\frac{2.28 \cdot 10^4}{T} + 18.79 \qquad [10]$$

valid between 640° and 980°C. The mean reaction enthalpy for Eq. [1] or [7] in the above temperature ranges is 54.2 or 104 kcal/mole, respectively.

The Voltage Sweep Method

Electronic Device for Producing Triangle Pulses and Ramps

F. G. Will

Research and Development Center, General Electric Company, Schenectady, New York

Voltage Sweep Method and Its Application

The application of a voltage that changes slowly and linearly with time is well known in polarography (1) and serves to determine the concentration of some oxidizable or reducible species in electrolytes. The linearly varying voltage is usually produced by a motor-operated potentiometer. In oscillographic polarography, periodic sawtooth (2-4) or triangular voltages (5) of much faster rise time are applied to increase the sensitivity of the concentration measurement.

Later, a similar method of applying periodic triangular voltages by means of a potentiostat was introduced (6) to the study of adsorption phenomena and reaction kinetics on solid electrodes. An electronic triangle voltage generator is required to produce the large range of voltage amplitudes and sweep rates that are desired for this purpose. Furthermore, a potentiostat is required to ensure proper control of the potential between the test electrode and an unpolarized reference electrode while the current flows through the test electrode and a counter electrode. In cases where a fixed sweep rate is sufficient and where the currents are small, a conventional polarograph may be used (7,8.)

Originally, the method was applied to measure accurately the amounts of hydrogen and oxygen that are chemisorbed on platinum (9) and other noble metal electrodes (10). Later, the heat of adsorption of hydrogen on polycrystalline platinum (11) and on single crystal platinum (12) was determined by this method. Under the names surface coulometry, cyclic voltammetry, and potentiodynamic method, the voltage sweep method has been used extensively in past years to study the adsorption and oxidation of organic molecules on noble metal electrodes. Examples are investigations on methanol (13-16), formic acid (14-19), and on a number of other organic molecules (15,20). The method has also been used to study the adsorption of carbon monoxide (21) and halide ions (22) on platinum. Recently, an attempt was made (23) to develop a theory that would allow the determination of kinetic parameters with the voltage sweep method.

Application of Periodic Waves vs. Single Pulses

One of the advantages in the study of adsorption phenomena by applying a periodic triangular voltage lies in the periodic removal of impurities ("activation") from the electrode surface (9). This is similar but not equivalent to the periodic renewal of the electrode surface in the case of the dropping mercury electrode. Unfortunately, however, the application of a periodic voltage changes the state of the electrode surface, for example, its roughness (9). In many cases this may not be disturbing as long as the extent of the changing surface roughness is known. In studies of the effect of the surface structure of the electrode on adsorption phenomena, however, the changing surface state is quite undesired. This problem is pointed out in a recent study of hydrogen adsorption on different platinum single crystal faces (12).

In investigations of this kind it is desirable to apply single triangular voltage pulses or ramps that start from controlled d-c voltage levels. In cases where one likes to study the reduction of some adsorbed species immediately following its oxidation, a triangular pulse is applied. In other cases it is preferable either to reduce or oxidize some species and then to wait until a new steady state is obtained. Here, the application of a

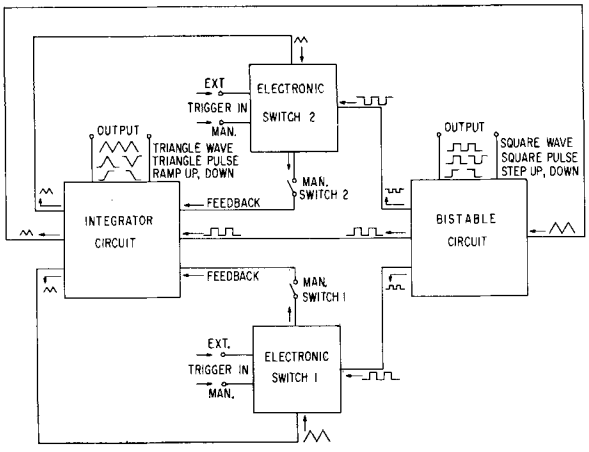

Fig. 1. Block diagram of bistable circuit, integrator circuit, and electronic switches.

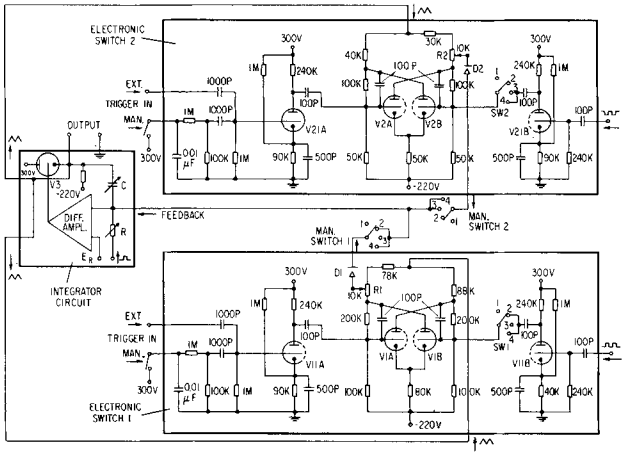

Fig. 2. Circuit diagram of electronic switches in conjunction with integrator circuit. V1, V2, V11, V21 = 12 AX 7; D1, D2 = 1N459.

ramp is required that leads from one controlled d-c voltage level to another. A commercial device[1] is available that produces triangular and sawtooth waves and pulses. However, the d-c level from which these pulses start is not controlled, nor does this instrument produce ramps. In the following, an electronic device is described that is capable of producing triangular pulses, ramps, square pulses, and steps from periodic triangular and square waves. The periodic waves have to be provided by a customary bistable circuit and integrator circuit.

Basic Function of the Electronic Device

Figure 1 shows a block diagram of the new device, consisting of the electronic switches 1 and 2, in conjunction with the bistable circuit and the integrator circuit. The basic operation of the whole instrument is as follows. With both manual switches 1 and 2 open, electronic switches 1 and 2 are also open, and the device produces periodic triangular and square waves in the usual way. The square wave that is produced in the bistable circuit is integrated in the integrator circuit to produce the triangular wave. The triangular wave, in turn, triggers the bistable circuit every time the voltage reaches a predetermined lower and upper voltage reference level. These two voltage levels constitute the positive and the negative turning point of the triangular wave.

With manual switch 1 closed, the electronic switch 1 remains open until the triangle reaches its next negative turning point (lower voltage level). At this point, a negative pulse is produced that closes the electronic switch and stops the triangle. The lower voltage level is controlled by strong negative feedback from the output of the integrator to its input. If a manual or external trigger signal is applied, the electronic switch opens and a single triangular pulse is produced. At the negative turning point, the switch closes again and the voltage is kept at the lower reference level. Concurrently with the triangular pulse, a single square pulse is obtained.

The operation of electronic switch 2 is equivalent to that of switch 1. With manual switch 1 open and 2 closed, the upper voltage level is controlled, and downward triangle and square pulses can be generated by opening electronic switch 2 with a manual or external trigger signal. An internal trigger signal at the positive turning point of the triangle closes electronic switch 2 again and stops the triangle.

With both manual switches closed, electronic switch 1 is always closed when electronic switch 2 is open and conversely. In the former case, the lower voltage level is controlled. When a manual or external trigger signal is applied to electronic switch 1, an upward ramp is generated. During the duration of the ramp, both electronic switches are open until a negative trigger signal is produced at the positive turning point of the triangle that closes electronic switch 2 and causes the upper voltage level to be controlled. In this state, therefore, electronic switch 1 is open and 2 closed. A trigger signal applied to electronic switch 2 opens this switch, too, and a downward ramp is generated. The internal trigger signal that occurs when the ramp voltage reaches the lower reference level closes electronic switch 1 again and results in the control of this voltage level. Concurrently with the upward and downward ramp, at the output of the integrator circuit, an upward and downward step occurs at the output of the bistable circuit.

[1] Exact Electronics function generator.

Description and Operation of the Circuit

Figure 2 shows a circuit diagram of the two electronic switches in conjunction with the integrator circuit. The main part of electronic switch 1 is a bistable circuit V1A/V1B and a diode D1. The manual switches 1 and 2, and SW1 and SW2 are ganged. With these switches in position 1, the bistable circuits are just an additional cathode load to V3 of the integrator circuit, and a periodic triangle wave appears at the output. With the switch in position 2, the bistable circuit 2 continues to be inactive. However, electronic switch 1 becomes closed as soon as the triangle reaches its first negative turning point. At this point, V11B, which is usually nonconducting, becomes momentarily conducting by virtue of the positive flank of the square pulse applied to its grid. The negative pulse that occurs at the plate of V11B makes V1B, which was hitherto conducting, nonconducting. The plate voltage of V1B rises to such a value that the diode D1 becomes conducting, and strong negative feedback is applied from the cathode of V3 to the input of the differential amplifier. In fact, the integrator circuit now operates as a regulated power supply. The magnitude of the controlled d-c voltage that appears at the output depends on the setting of the potentiometer R1 and the magnitude of the reference voltage E_R. If the manual trigger is operated or if a positive trigger signal of at least 30v is applied to the trigger input, V11A becomes momentarily conducting. Hence, V1A becomes nonconducting and V1B conducting. The plate voltage of V1B drops and the diode D1 becomes nonconducting. Consequently, the integrator circuit generates a linearly increasing voltage. The voltage at the plate of V1B has to stay at such a low value that D1 remains nonconducting even at the positive turning point of the triangle pulse. It is only at the negative turning point of the triangle that V11B produces a negative pulse that makes V1B nonconducting and D1 conducting again and, hence, stops the linearly decreasing voltage.

With the switches in position 3, electronic switch 1 becomes inactive and electronic switch 2 functions in an equivalent manner as described for switch 1. The upper voltage level is now being controlled, and a trigger signal produces a downward triangle pulse. The grid of V21B receives the positive flank of the square wave at the positive turning point of the triangle, at which point the triangular sweep is stopped.

With the switches in position 4, both electronic switches are active. A trigger signal applied to electronic switch 2 makes the diode 2 nonconducting. Hence, the voltage at the output decreases from the upper voltage level linearly with time until it reaches the lower voltage level. At this point, the diode 1 becomes conducting and the voltage stops decreasing. A downward voltage ramp has been produced. Accordingly, a trigger signal applied to electronic switch 1 produces an upward ramp.

Conclusions

The electronic device that has been described here broadens the range of applicability for the voltage sweep method and should make this method an even more valuable tool in the study of adsorption phenomena. Further applications are seen in studies of the corrosion (24-27) and electrodeposition of metals. The device also performs as an extremely versatile, fully electronic polarograph. A device of this kind producing ramp amplitudes up to 60v with ramp rise times from 50 μsec to 500 sec (28) has been built and applied to the study of adsorption phenomena.

Acknowledgment

Studies of Hydrocarbon Fuel Cell Anodes by the Multipulse Potentiodynamic Method

I. Behavior of Ethane on Conducting-Porous-Teflon Electrodes

L. W. Niedrach, S. Gilman, and I. Weinstock[1]

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

The adsorption of ethane on semimicro Teflon-bonded, platinum black fuel cell electrodes in the presence of $HClO_4$ electrolyte is both mechanistically and kinetically similar to that on smooth platinum after normalization to "real" (hydrogen adsorption) area. Polarization data obtained under the same conditions as the adsorption experiments allow a comparison of oxidation current with surface coverage over a range of potentials. Additional results obtained with methane and propane are also presented.

The behavior of ethane on smooth platinum microelectrodes in the presence of a perchloric acid electrolyte has been investigated with the multipulse potentiodynamic (MPP) method in this Laboratory (1). This type of study has now been extended to fuel cell anodes of more complex structure. For this purpose a miniature version of a previously described (2) conducting-porous-Teflon fuel cell electrode (containing platinum black as catalyst) has been employed.

Particular attention has been given to the rates of adsorption and the nature of the species that form on the surface of the electrode. Both of these aspects have, in turn, been related to the over-all polarization curve for the fuel electrode. Ethane has been the subject of the most detailed investigation to date in order to obtain maximum correlation with the earlier work with the smooth microelectrodes. However, some work has also been done with several other fuels.

Experimental

The three-compartment, Teflon electrochemical cell is shown schematically in Fig. 1. The anode, a miniature version of a fuel cell electrode, consisted of a 0.20 cm diameter Teflon-bonded platinum black electrode (2). This electrode, which was formed in the center of the thin (approximately 0.012 cm) platinum washer, was mounted horizontally in the cell, with connections for admitting fuel and venting products made from below. The support washer was electrically insulated from the electrolyte by bonding to it a thin, nonporous Teflon film. The electrical connection from the electrode to the external circuitry was made through the bottom of the cell.

A reversible hydrogen reference electrode communicated with the anode through a Luggin capillary. A porous Teflon plug in this leg minimized diffusion of hydrogen to the anode chamber. The counter electrode was also separated from the anode chamber via a porous Teflon plug. Both electrodes were platinized platinum flags. The cell was operated in an air thermostat, enabling control of temperature to ± 0.1°C.

The electronic instrumentation and circuit have been described previously (3).

The 4.3*N* perchloric acid electrolyte solution used for the work was prepared from reagent grade perchloric acid and quartz-distilled water. Electrolytic grade hydrogen was used in the reference electrode chamber, and Phillips research grade hydrocarbons were used as the fuels. Tank argon, deoxygenated by passage over heated copper turnings, was used as the "fuel" for obtaining solvent blanks. Tank argon was also used for de-gassing the solution.

The potential-time sequence applied to the anode for adsorption studies at constant potential is shown in Fig. 2. The significance of the steps is covered below.

A. Pretreatment step (15 sec) to remove oxidizable impurities and to produce a layer of "adsorbed oxygen" which serves to block fuel adsorption. The solution is vigorously stirred and purged with argon to remove molecular oxygen and oxidation products formed.

B. Potential step, during which the oxygen layer formed in *A* is maintained, and the solution is purged for an additional 1 min. The solution is then allowed to become quiescent for 1 min.

C. Reduction step (15 sec), during which the "adsorbed oxygen" layer is reduced. At this low potential

[1] Present address: Battery Product Section, Capacitor Department, General Electric Company, Gainesville, Florida.

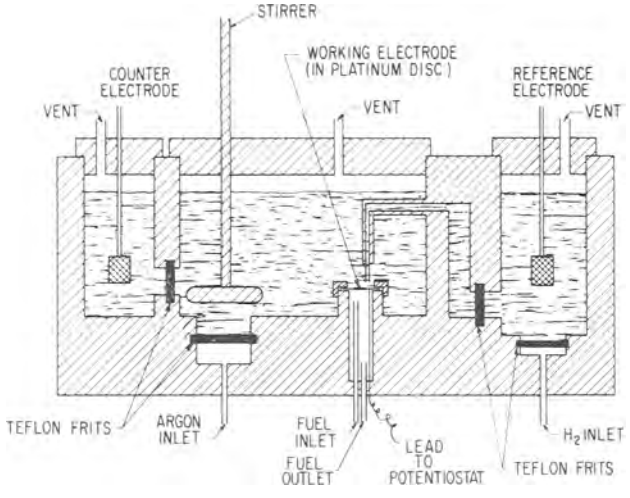

Fig. 1. Schematic diagram of cell

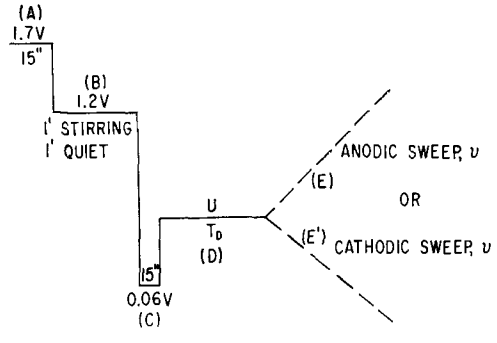

Fig. 2. Potential sequences applied to the test electrode

(0.06v) the adsorption of the hydrocarbons is blocked. This step was included so that the reduction of the surface and the adsorption of the hydrocarbon would not occur simultaneously. However, omission of this step was found to have no detectable effect on the equilibrations.

D. Adsorption step, during which the hydrogen from *C* is rapidly oxidized, exposing a reproducibly clean surface for adsorption. The duration of this step is the adsorption time, T_D.[2]

E. Anodic sweep at 0.1 v/sec. The adsorbed fuel is oxidized and the surface covered with a layer of "adsorbed oxygen." Subtraction of the charge due to surface oxidation from the total charge yields the charge required to oxidize the species derived from the adsorbed fuel.

E'. Alternative to *E*, a cathodic sweep at 0.025 v/sec which is used for determination of the charge $_sQ_H$ corresponding to hydrogen deposition. In this case, argon is substituted for the hydrocarbon fuel.

Steady-state polarization curves such as that in Fig. 12 were obtained in two ways. The first method involved application of steps A-D of Fig. 2 before each measurement of current (after $T_D = 10$ min) at a particular potential *U*. In the second method, steps A-C of Fig. 2 were applied only once, at the lowest value of *U*. The potential was changed in increments and the current recorded for each potential after an apparent constant value was established. The two methods gave essentially identical results.

Results and Discussion

Measurement of $_sQ_H$.—When the sequence of Fig. 2 is terminated in step *E'* (linear cathodic sweep) and applied to a smooth platinum microelectrode, a "hydrogen-deposition" trace may be obtained during step *E'* (3). By drawing the proper construction lines (which make approximate correction for double-layer charging and for hydrogen-evolution) an area $_sQ_H$[3] is defined, which is equivalent to approximately a monolayer of hydrogen, and may be used as a measure of relative surface area. For a smooth platinum microelectrode in an argon saturated solution the charge $_sQ_H$ was found to remain constant (to within a few per cent) for values of the sweep speed up to $v = 800$ v/sec. At much higher values of v, the trace loses "definition" and it is difficult to estimate $_sQ_H$. In the present work, the hydrogen deposition traces obtained with the Teflon-bonded electrodes were similar to those observed previously for smooth microelectrodes, but the traces begin to lose "definition" at much lower values of v. This probably reflects the diffuse structure of the electrode and its resulting inherent internal voltage drops.

Table I records the values of $_sQ_H$ measured on the Teflon-bonded electrode for values of v from 0.01 to 0.25 v/sec. The trace for $v = 0.25$ v/sec was already ill-defined. Over the useful range of $v = 0.01$ to 0.1 v/sec, $_sQ_H$ was found to be reproducible to within 5% according to Table I. A sweep speed of $v = 0.025$ v/sec was subsequently used routinely in making comparative surface area measurements.

If $_sQ_H = 0.21$ mcoul/cm^2 is taken as equivalent to a monolayer of hydrogen on an atomically smooth surface (4), then the value of $_sQ_H$ measured for our electrode corresponds to a roughness factor of approximately 1,800.

Measurement of Q_E.—For these experiments, the sequence of Fig. 2 terminating in step *E* (linear anodic sweep) was employed. When argon is fed to the electrode application of the pulse sequence to the Teflon-bonded electrode results in "oxygen adsorption" traces such as those shown in Fig. 3. The portion between 0.7 and 1.5v on the traces correspond mainly to the oxidation of the platinum surface. At 25°C the trace

[2] The subscript here and for other time intervals refers to the step involved according to Fig. 2.

[3] Previously used symbol was Q_{SH}.

was found to remain essentially invariant for values of T_D upwards of 3 hr without any purification of the solution. This is illustrated by the two superimposed oscilloscope traces in Fig. 3, one made after $T_D = 15$ sec and the other after over 10,000 sec. At 60°C similar reproducibility of the traces was observed.

This behavior contrasts sharply with the approximately 100 sec "clean time" observed for smooth platinum without solution purification (3). The variation of the "oxygen adsorption" trace with time was previously ascribed (3) to the adsorption of impurities from the solution. For the highly "roughened" surface under study here, the rate of flow of impurities to the surface per unit of real area is much diminished. The per cent contamination per unit time is hence also much diminished, and a longer time is required before contamination is noticeable.

The reproducibility of these solvent blanks is important in the determination of the charge associated with the oxidation of adsorbed hydrocarbon species to CO_2 since the latter is derived from the area enclosed by the blank and the corresponding curve for the electrode after equilibration with the hydrocarbon (1). This is illustrated by the data in Fig. 4 where trace A is a solvent blank and traces B through D were obtained when ethane was fed to the electrode and the

adsorption time, T_D, was varied. The measured charge, Q_E', may include several terms:

$$Q_E' = Q_{E\text{tot}} + Q_E'' + \Delta Q_{\text{cap.}} + \Delta Q_o \qquad [1]$$

where $Q_{E\text{tot}}$ is the charge corresponding to oxidation of the ad-layer formed from ethane during step D; Q_E'' is the charge corresponding to ethane not adsorbed during step D but which oxidizes during step E with or without a preceding adsorption step; $\Delta Q_{\text{cap.}}$ is the difference in capacitive charges included under the "oxygen adsorption" and "ethane" traces due to differences in initial surface states; and ΔQ_o is the difference in charges due to surface oxidation, included under "oxygen adsorption" and "ethane" traces.

It has previously been demonstrated, for smooth platinum (1), that $Q_E' \simeq Q_{E\text{tot}}$ if $v < 20$ v/sec. At higher values of v, $Q_E' < Q_{E\text{tot}}$, at least partially because some of the adsorbed ethane is retained on the surface during sweep E. At the other end of the scale, it is important that the sweep speed not be so slow that appreciable re-adsorption of ethane occur during step E, cause $Q_E'' > 0$. For the present electrode the useful range of v was examined by adsorbing a fixed amount of ethane (corresponding to $T_D = 600$ sec) and measuring Q_E' for a range of sweep speeds. Some results appear in Table II. Below $v = 0.092$ v/sec, a "background" current (corresponding to Q_E'') is distinctly present. Above 0.92 v/sec, the traces tend to lose definition, probably due to the large internal voltage drops in the electrode. A decline in the charge required for the oxidation of the ad-layer is also evident. The range of constancy of Q_E' for the Teflon-bonded electrode extends only from approximately 0.1 to 0.4 v/sec, and in this range we assume $Q_{E\text{tot}} = Q_E'$. Accordingly, a sweep speed of $v = 0.1$ v/sec was used routinely in making the measurements discussed below.

Behavior of ethane.—The general form of the current-voltage trace obtained during the oxidation of adsorbed ethane with a linear potential sweep is shown for a range of equilibration times, potentials, and temperatures in Fig. 4-6. For each experimental condition, trace 2 was obtained in the presence of ethane, while trace 1 was obtained in the presence of argon. Trace 1 serves as the "oxygen adsorption" or "solvent" correction.

From Fig. 4-6, it can be seen that, if ethane is adsorbed at potentials below 0.7v, and a linear anodic

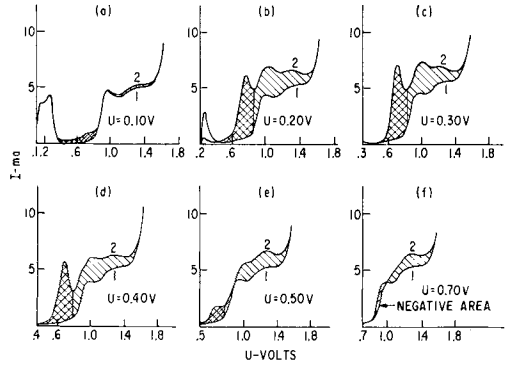

Fig. 5. Current-potential (time) traces for ethane adsorbed at several potentials: 4.3*N* $HClO_4$; 60°C; μ = 0.1 v/sec; T_D = 10 min; 1, Ar blank; 2, ethane; ME-11.

sweep (l.a.s.) applied to the electrode, the ad-layer is oxidized over a range of potentials part of which is a continuum and part more sharply differentiated as discrete waves. This can be taken as evidence for the existence of a range of reactivities for the individual ad-species which can have their origins in gross differences in chemical composition as well as subtle differences in the activities of individual adsorption sites. Only one sub-division of the ethane ad-layer will be attempted here, since it is suggested by voltammetric and chemical considerations. The various "ethane" traces of Fig. 4-6 reveal that some of the adsorbed ethane is removed at sweep potentials below those (approximately 0.8v) at which the surface itself is normally oxidized. This first wave generally exhibits a well-defined peak. The second wave exhibits a flat maximum which stretches all the way from approximately 0.8v to oxygen evolution potentials. It has already been demonstrated that species associated with wave 2 may be eliminated by cathodic hydrogenation (1, 5) whereas wave 1 is relatively unaffected. Hence waves 1 and 2 represent chemically different species, with the reservation that further sub-divisions are likely also possible.

As previously, Q_E' ($\simeq Q_{E\text{tot}}$ under these conditions) will be used to refer to the entire charge measured

on applying a l.a.s. to the ethane-covered surface (entire shaded area of Fig. 5 and 6). The charges Q_{E1} and Q_{E2} will now be taken as the areas of wave 1 and 2 (dark and light-shaded areas of Fig. 5 and 6), respectively. All values of charge reported have been normalized to "real area." For the normalization, the quantity sQ_H was measured for each electrode used, and 0.21 mcoul/cm² was chosen to correspond to 1 cm² of true area (4).

Variation in Q_{Etot} and Q_{E1} with time, temperature, and potential are recorded in Fig. 7 to 10 and in Table III. (The charge Q_{E2} can be readily derived from

Q_{Etot} and Q_{E1}.) From Table III and Fig. 9 it is apparent that the ratio of the charge associated with the two ethane "waves" is not a sensitive function of the adsorption time or potential (up to 0.5v). The ratio is sensitive to the adsorption temperature. According to Fig. 10, higher temperatures favor higher relative surface coverages with wave 1 species.

In Fig. 7 and 8, values of Q_{Etot} are plotted against the log of adsorption time for the comparison of results obtained for the Teflon-bonded electrodes with similar results obtained with smooth platinum microelectrodes (1). For both types of electrodes at 60°C, the results are qualitatively similar. The maximum rate of increase of surface coverage occurs in the close vicinity of 0.3v for both systems. At low potentials (<0.3v) adsorption is hindered because the required dissociation of the adsorbing hydrocarbon is repressed by the low potential and/or the presence of atomic hydrogen on the surface. At potentials above 0.3v the surface coverage again declines as the rate of adsorption fails to keep pace with the increasing rate of oxidation of the ad-layer. At 0.3v, the rate of adsorption is initially constant and then falls on a linear semilog plot until quite high surface coverages are achieved. The maximum (initial) adsorption rate is approximately 0.010 mcoul/sec/cm² of "real" area for both the Teflon-bonded and smooth electrodes. Considering the assumptions involved in normalizing the two types of electrode structures to the same real area, the results must be said to represent remarkably good agreement in the adsorptive properties of two platinum surfaces prepared in quite different ways.

With the information presently available, it is not possible to identify firmly the individual species involved on the surface. It is reasonably certain that just as in dry systems (5) the ad-layer does not correspond to undissociated ethane. More than likely, several species are involved. The results of hydrogen codeposition experiments suggest that an average C:H ratio of 1 prevails (1). Additional inferences can be made from the observed temperature effects and other data.

Considering first the data of Fig. 6 and 10 showing the effect of temperature on the oxidation curves for adsorbed ethane, it is noted that wave 1 becomes more prominent as the temperature is raised. An attractive explanation of this phenomenon based on past observations is that this wave is associated with a species derived from the reaction of a primary adsorption species with water. This might be via a direct chemical reaction or via an electrochemical route; the species might itself be either a necessary reaction intermediate along the major route involved in the over-all oxidation of ethane or it could be a by-product that reaches a steady state on the surface.

This new species might thus be the "CO-like" surface species previously suggested by Niedrach (6) or the "reduced CO_2" of Giner (7), both of which appear to refer to identical materials. To obtain additional information bearing on such an interpretation, ex-

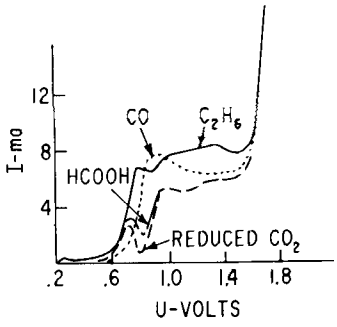

Fig. 11. Current-potential (time) traces for several carbonaceous materials adsorbed on platinum: 4.3*N* $HClO_4$; 60°C; u = 0.1 v/sec; ME-16.

periments were performed at 60°C in which the electrode, after the standard activation procedure, was equilibrated with CO (at 0.3v), CO_2 (at 0.06 and 0.2v), and argon saturated with formic acid vapor at 25°C (at 0.06 and 0.2v) prior to a potential sweep. The results of these experiments are shown in Fig. 11.

The positions of the oxidation waves for the three oxygenated materials relative to that of wave 1 from ethane strongly suggest that a species closely related to them is involved in the oxidation of ethane. This idea is further supported by the observation that wave 1 for ethane is resistant to removal by cathodic hydrogenation of the electrode. As has been previously noted, carbon monoxide behaves in a similar fashion (6), and the waves for reduced CO_2 and formic acid were, of course obtained after equilibrations at hydrogenating potentials, *i.e.*, 0.06v. Additional evidence that wave 1 represents an oxygenated species derives from related galvanostatic and analytical studies of hydrocarbons (8). While the nature of the species associated with wave 1 appears to be narrowed down to a partially oxidized species related to CO and formic acid, additional work will be required to identify it more specifically and to define its role as an active intermediate or by-product. Resolution of the latter point is of particular importance in view of the fact that the "CO-like" species already strongly manifests itself at potentials as low as 0.15v.

As far as the second wave for ethane is concerned, the present work sheds no light in this area. It would appear likely, however, that this wave involves a partially dehydrogenated ethylenic species (1).

In the discussion so far, the effect of temperature on the rate of adsorption has not been considered. The

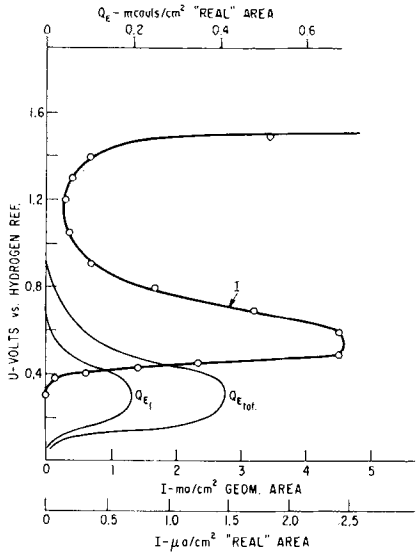

Fig. 12. Polarization and surface charge curves for ethane: 4.3*N* $HClO_4$; T = 60°C; ME-16.

data in Fig. 7 show that the over-all adsorption at 25°C, when expressed in terms of millicoulombs per square centimeter of real electrode area, follows a pattern similar to that observed at 60°C. Similar results were also obtained at 42°C (not shown). Although the equilibrations at the lower temperatures were not continued to "saturation," it is significant that higher total surface charges were realized in both these cases than in the equilibration at 60°C. This appears to reflect the influence of the partially oxidized "CO-like" species on the surface at the higher temperatures.

One additional point for consideration is the relationship between the adsorption data and the polarization curve for the electrode operating on ethane. Such a polarization curve obtained at 60°C is shown in Fig. 12. The abscissa is expressed in terms of the current density per unit of "real" and "geometrical" area of the electrode. Therefore, the data may be related to the adsorption studies as well as performance curves for operating fuel cell devices. Also shown in Fig. 12 are the measured surface coverages, Q_{E_1} and $Q_{E_{tot}}$, from Fig. 9. The form of the polarization curve is typical of those for a variety of fuels when the data are obtained potentiostatically. Even hydrogen shows the minimum in the region from 0.9 to 1.4v on smooth platinum. Over the potential range from 0.3 to 0.45v, the curve has a linear Tafel region with a slope of 0.066 v/decade of current.

It is of interest to compare the value of the maximum current in Fig. 12 with that calculated from the observed adsorption rate on the "clean" surface as measured at 0.3v. In converting the adsorption rate to equivalent current density, it must be recalled that the former is expressed in terms of the change in surface charge with time, $\Delta Q_{E_{tot}}/\Delta t$. Allowance must therefore be made for any oxidation that occurred during the adsorption step itself, *e.g.*, immediate oxidation of dissociated hydrogen. This may be done by multiplying $\Delta Q_{E_{tot}}/\Delta t$ by the ratio of the charge associated with the hydrocarbon fuel molecule to that of the adsorbed species.

While the precise composition of the ad-layer has not been established for ethane, especially after short equilibrations, it is possible to calculate a range of limiting currents from the adsorption data at 0.3v. For ethane it is reasonable to bracket the composition of the ad-layer between one corresponding to C_2H_2 radicals and one corresponding to CO. The observed value of $\Delta Q_{E_{tot}}/\Delta t$ = 0.010 mcoul/sec then corresponds to a range of current densities from 14 to 35 μa/cm². The observed maximum current of 2.5 μa/cm² is much lower than the calculated value. This, as well as the fact that the "maximum" occurs when there is yet an appreciable concentration of adsorbed material on the electrode surface, indicates that the maximum current is established in this case neither by a limiting rate of mass transport nor by a limiting over-all rate of adsorption on a "clean" surface. It could, however, reflect a limiting adsorption rate on a surface partially covered with refractory hydrocarbon residues, oxygen (at 60°C the surface oxide starts to form between 0.6 and 0.7v), and adsorbed ions. Additional work will be required for a definitive understanding of this limiting step.

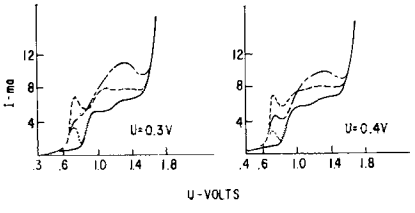

Fig. 13. Current-potential (time) traces for several hydrocarbon fuels after equilibrations at different potentials: 4.3*N* $HClO_4$; 60°C. —— ——, C_2H_6; ----, CH_4; — · —, C_3H_8; ——— Ar blank, ME-16.

Behavior of other fuels.—A limited amount of data have been obtained for fuels other than ethane. Examples of l.a.s. traces obtained after equilibrations with methane and propane at 0.3 and 0.4v are shown in Fig. 13. These data indicate that propane is quite similar to ethane in that the ad-layer on the electrode surface shows two oxidation waves when the l.a.s. is applied. Methane differs markedly, however, in that only wave 1 can be detected during oxidation of the ad-layer. A detailed discussion of the behavior of methane will be the subject of a forthcoming publication (9).

Conclusions

The adsorption and surface behavior of ethane, as a representative hydrocarbon fuel, on semimicro, Teflon-bonded fuel cell electrodes parallels that on wire electrodes. In both cases during adsorption at intermediate potentials a linear law relating measured surface charge and adsorption time is followed at low coverages. At higher coverages the surface charge varies with the logarithm of time. Numerous properties of the first of two waves seen during the oxidation of adsorbed ethane with a linear sweep suggest that one of the surface species is partially oxygenated and related to carbon monoxide and/or formic acid. The behaviors of methane and propane resemble that of ethane, but important differences are seen. In particular adsorbed methane gives only a single wave on oxidation.

An Experimental Study of the Operation of a Porous Oxygen Cathode

ABSTRACT

A special oxygen cathode was designed to investigate the film model for operation of porous gas electrodes. This electrode consists of a bed of ~55μ silver spheres behind a thin electroformed mesh facing. The thickness of the bed can be adjusted, and the structure permits holding the electrolyte meniscus out of the electrode body. Measurements in 6.9*N* KOH (23.5°C) confirmed the operation of the film mechanism. The overpotential/current density behavior of the electrode was in agreement with film model analysis with a film thickness of 0.05μ.

It was noted as early as 1839 by Grove that electrodes using a gaseous reactant performed better when only partially immersed in a liquid electrolyte and partially in contact with the gas phase than when totally submerged in the liquid (1). However, the importance of electrolyte films on the surface of those parts of an electrode which are exposed to a gas phase has been clearly recognized only recently (2-7). Now considerable interest has developed in the effect of such films in determining the performance of the porous gas electrodes of fuel cell systems. In this investigation, the behavior of a porous oxygen cathode operating in potassium hydroxide solution was measured and compared with the predictions of a theoretical model based on the film coverage concept. This served to indicate the existence of the films in a porous structure and to confirm the applicability of the model to such systems.

The performance of a porous electrode involving a gas phase reactant supply is determined largely by the location and configuration of charge transfer reaction sites within the pore structure, by the local reaction kinetics, and by the transport of reacting species and electric current to and from the sites. The theoretical models that have been proposed to describe the reaction zone of such electrodes can be broadly classified according to the distribution of reaction relative to the position of the electrolyte meniscus in a pore (usually assumed cylindrical) and the method of gas reactant transport to the points where reaction takes place:

1. Reaction along the pore wall in the liquid filled portion of pore; transport of gaseous reactant by dissolution at the meniscus and diffusion through liquid filled pore to reaction sites (8-9).

2. Reaction along pore wall near the meniscus in the liquid filled portion of pore; transport of gaseous reactant by adsorption on walls of the gas filled section of pore and surface diffusion along pore wall to reaction sites (10-11).

3. Reaction under a liquid film covering pore walls in the gas filled portion of pore; transport of gaseous reactant by dissolution at the surface of the film and

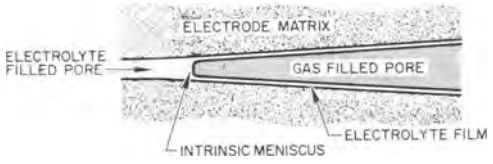

Fig. 1. Idealized pore of gas electrode

diffusion across the thin film to reaction sites along pore wall (2-7).

4. Reaction in liquid filled micropores which intersect walls of the gas filled portion of macropores; gaseous reactant transport by dissolution in electrolyte at mouths of micropores along the macropore walls and diffusion into micropores to reaction sites (12-13).

The first of these models can frequently account for only very low superficial current densities because of the relatively long diffusion paths involved; it cannot explain observed electrode performance in most cases. It can easily be calculated that the contribution of such a mechanism to the operation of the other models listed above is almost always negligible. The last mentioned model may apply to electrodes with a wide range of pore sizes, actually a superimposed coarse and fine pore structure, if the distribution of reaction in the flooded micropores is properly characterized.

For electrodes with a narrow pore size distribution (a single scale of porosity in the bulk of the electrode), or for partially immersed solid electrodes, the "surface diffusion" and "film" models could be considered. However, calculations for the former method indicate that surface diffusion cannot support observed currents for the hydrogen anode (5); similar results can be expected for oxygen cathodes. Thus, the film mechanism remains, perhaps, the most likely explanation for the operation of these gas electrodes. In this model, a thin film of electrolyte covers the walls of the gas filled portion of each pore, extending a very long distance (in relation to pore dimensions) from the intrinsic meniscus (see Fig. 1). Dissolved gas diffuses across this film to reaction sites on the pore wall. Ionic species involved in the reaction move from (or to) the site by diffusion and migration along the film to (or from) the intrinsic meniscus and electrolyte filled part of the pore. The electrons involved are carried by the conducting pore walls. In 1957, Wagner described such a model for the oxygen cathode in molten salt electrolyte (2). He developed overpotential-current density expressions for several limiting cases under the assumption of constant electrolyte conductivity. Will, in conjunction with experimental investigation of a hydrogen electrode, formulated a film model assuming absence of kinetic effects (equilibrium reaction) and uniform conductivity in the film (3). Later, Grens, Turner, and Katan (4), and, independently, Rockett (6), developed film models incorporating electrode kinetic limitations and accounting for variation in electrolyte composition with position along the film. Iczkowski also presented a film model for the hydrogen electrode in sodium hydroxide which included the refinement of considering variation in transport properties with electrolyte concentration (5). One of the significant features of the more refined film models is that they predict active reaction zones extending along the film thousands of film thicknesses from the intrinsic meniscus, particularly when ionic species are formed in the reaction. This phenomenon, among others, is subject to experimental verification.

Measurements by Will using the hydrogen anode in sulfuric acid electrolytes demonstrated the validity of a film mechanism for this system (3). The electrodes employed in that work were exterior surfaces of partially immersed platinum tubes. A later investigation, by Bennion and Tobias, of oxygen reduction at the surface of silver and nickel rods protruding from aqueous potassium hydroxide electrolytes not only established that this reaction occurred under an electrolyte film but also determined the distribution of the reaction along the film above the intrinsic meniscus (7). Further, Muller demonstrated by optical methods the existence and stability of such films on the surface of nickel plates partly immersed in potassium hydroxide solutions and measured film thicknesses on the order of $1 \times 10^{-5} - 5 \times 10^{-5}$ cm (14). Recently, Mazitov found a film mechanism operative for oxygen reduction on silver rod electrodes dipping into KOH solutions (15, 16). However, little in the way of experimental verification of the film model in actual porous structures has been reported.

It was the intent of the present study to examine the operation of a well defined porous gas electrode with a single scale of porosity under conditions where the film model could be expected to apply. By operating in a manner such that electrolyte, except in the form of surface films, was excluded from the body of the electrode, the variation of the performance of the system with electrode thickness could confirm the presence of the film and provide a measure of its active length. Comparison of overpotential-current density relationships for the electrode with those predicted by the film theory would permit verification of the principal assumptions of the model and evaluation of the one parameter not available *a priori*, the effective film thickness on the pore walls.

Experimental

The system selected for study was the oxygen cathode operating in 6.9*N* aqueous potassium hydroxide solution at near ambient temperature. This reaction is important in low temperature fuel cells and has the advantage that it can be conducted, at least for purposes of these experiments, on silver electrode surfaces without use of deposited catalysts. Basic kinetic data for this particular system had been recently determined and were available for use in evaluation of results (17).

Apparatus.—The electrode, shown in Fig. 2, had a superficial area of 1.19 cm^2 and consisted of a thin electroformed silver mesh, which constituted the face in contact with the electrolyte, backed by a bed of 55μ silver spheres. The silver mesh diaphragm was as supplied by the Buckbye Mears Company, ruling number 107, and had regularly spaced 15.8μ square openings with 10.9μ walls between openings and a thickness of 12.0μ. Its porosity was 35%. A single layer of this

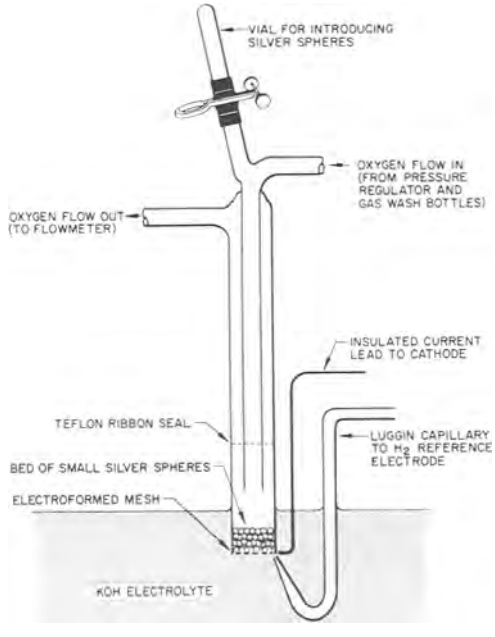

Fig. 2. Experimental oxygen cathode consisting of a bed of silver spheres.

material was cemented across the end of a 15 mm Pyrex tube (cut flat) 45 mm long which served as a carrier for the electrode. Electrical contact existed between the rim of this diaphragm and a gold wire ring which in turn connected to the external circuit through sealed, Teflon insulated leads. Total electrical resistance from the external lead to a silver disk placed on the mesh was 0.14 ohm. The bed of silver spheres, arranged as poured in the carrier tube and nonsintered, comprised the main body of the electrode matrix. The spheres were obtained from the American Platinum Works, and were of 55 $\pm 4\mu$ diameter and visually spherical configuration under 200× magnification. Surface roughness was not measured; however, the surfaces appeared smooth at 3000× magnification. Resistivity of uncompressed beds of these spheres (between silver plates) was measured as 18 ohm-cm.

The Pyrex tube carrying the electrode assembly was fitted flush against a Pyrex gas chamber of similar diameter and sealed with Teflon tape. The gas chamber included an oxygen supply duct extending to within about 2 cm of the electrode bed and a gas outlet leading to a flow control valve and meter. A glass vial could be attached to the gas chamber through a neoprene coupling, equipped with pinchcock, for addition of weighed samples of silver spheres during operation. Oxygen supply to the gas chamber was equilibrated with potassium hydroxide electrolyte at the same concentration and temperature as that in the cell by sparging through this solution. A water column pressure regulator on the supply line allowed control of gas chamber pressure.

The test electrode was mounted in a cell consisting of a glass Dewar flask of 1.4 liters working volume as shown in Fig. 3. Cell contents were held at 23.5°C and continuously sparged with nitrogen to eliminate dissolved oxygen from the bulk electrolyte. The counter electrode consisted of a double layer of 80 mesh platinum screen 7 × 7 cm, and was mounted in the bottom of the cell and connected to the external circuit through an insulated lead. A hydrogen reference electrode, operating in the same electrolyte, with a Luggin capillary leading close to the face of the test electrode furnished voltage reference. The external circuit provided for both galvanostatic (through an Electronic Measurements C612 constant current supply) and potentiostatic (with a Wenking potentiostat) electrode operation. Test electrode potential could be monitored with a Sargent MR potentiometric recorder and cell current measured with a sensitive ammeter (Western Electrical Instrument Corporation 931 or Greibach 500).

The electrolyte solutions used were prepared from reagent grade potassium hydroxide and distilled water.

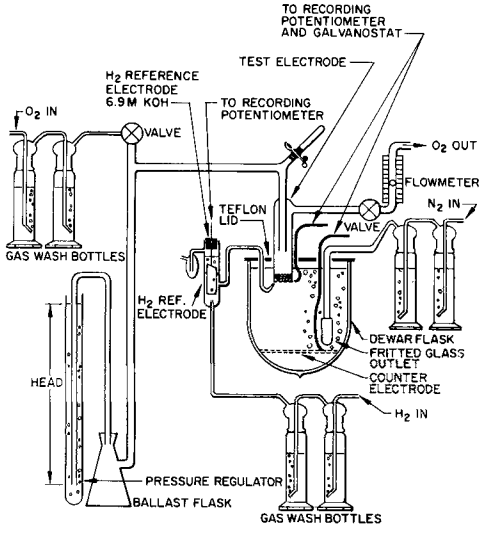

Fig. 3. Arrangement of experimental apparatus

Procedure.—Before each experimental run, the electrode was disassembled, cleaned and dried, and resealed to the gas chamber section. Before immersion, oxygen supply was set to obtain the desired chamber pressure and positive gas flow through the mesh facing; then the electrode was inserted approximately 10 mm into the electrolyte. In this way, the interior of the electrode assembly remained free of liquid. The desired initial quantity of silver spheres was added by means of the attached sample vial and the vial gently tapped to detach adhering particles. During subsequent operation of the electrode, further samples of spheres were introduced in the same way to increase electrode thickness where this effect was under investigation. This procedure yielded sphere beds for which deviations from flatness of the bed surfaces were not visually detectable.

After establishing the initial sphere bed (for some tests, no bed was added initially) the desired current was applied and electrode operation monitored until steady state was reached. Then changes could be made in cell current, oxygen pressure or flow rate, or in sphere bed depth (increases only) as the test series required, and the transient and steady-state effects of these changes observed. Response was recorded as test electrode potential against the hydrogen electrode reference. This value was, in turn, converted to test electrode overpotential by comparison with electrode potential at open circuit.

Characteristics of test electrode.—The test electrode described above was designed to incorporate three principal characteristics:

1. The capability of exclusion of electrolyte, except as surface films, from the body of the porous electrode.
2. A porous electrode thickness which could be easily changed.
3. A porous matrix for the electrode which was sufficiently well described to allow ready determination of specific surface, average wetted perimeter,[1] and other geometric factors.

The pore size of the electroformed mesh was sufficiently smaller than that in the sphere bed that the electrolyte meniscus could be held in the thin mesh face by use of suitable gas pressures in the electrode. The "blow through" pressure of the mesh was measured at 33 ± 1 in. of water while that of the bed was less than 13 in. Thus, the first condition could be satisfied over a wide range of gas chamber pressures.

The ability to establish sphere bed thicknesses as desired has been mentioned earlier. These matrices have properties typical of random packed beds of spheres (18). Measured bed density was 6.6 g/cm² corresponding to a porosity of 0.37, compared to 0.26 for a close-pack arrangement. The specific surface area was calculated, from this observed density, as 690 cm^{-1} and the equivalent wetted perimeter as 390 cm/cm². The average surface tortuosity of the bed,[2] however, could not be directly evaluated.

Results

Effect of sphere bed thickness.—The oxygen cathode overpotential at a current density of 2.1 ma/cm² was measured as a function of sphere bed thickness over a range of bed depths from 0 to ~3 mm. These experiments were conducted under conditions where the electrolyte meniscus was held in the mesh face of the electrode and not allowed to penetrate the bed (23 in. water O_2 pressure). Figure 4 illustrates the effect of bed thickness at steady state. The mesh facing itself was not effective as an electrode. As bed depth was increased, the overpotential decreased markedly up to

[1] Average wetted perimeter is film surface area per unit film length, which here is taken as bed surface area per unit length along sphere surfaces. The actual wetted perimeter will be reduced somewhat below that calculated in this simplified manner by film thickening at points of contact between spheres. As long as film thickness is small compared with sphere radius, this thickening affects the average perimeter by only a few per cent.

[2] Surface tortuosity is average path length along particle surface through a bed of unit depth.

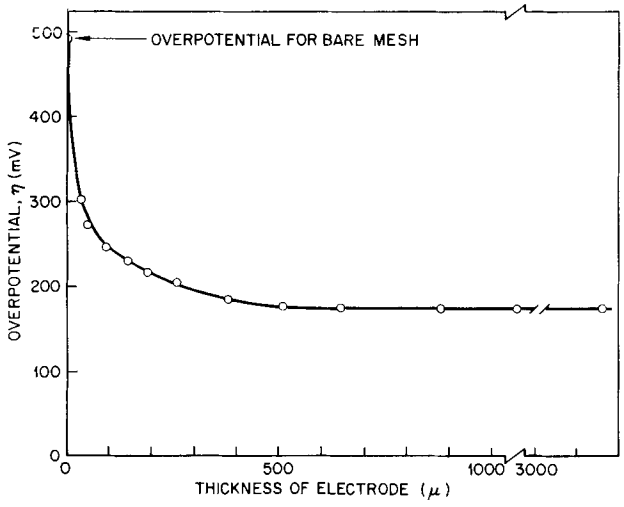

Fig. 4. Effect of increasing electrode thickness on overpotential of oxygen cathode. 6.9*N* KOH, 23.5°C, O_2 at 23 in. H_2O pressure, current density 2.1 ma/cm^2.

a depth of about 0.5 mm. Beyond this, no further improvement in electrode operation was noted. This behavior could be consistently reproduced with electrodes using other electroformed mesh and sphere samples, and corresponding effect of bed depth on current density was observed for potentiostatic operation at an overpotential of 450 mv. Thus, the portion of the bed within 0.5 mm of the electrode face constituted the active part of the electrode. In subsequent experiments investigating effects of other parameters, beds sufficiently deep (3 mm) to exclude effects of bed thickness were used.

When increases in depth were made for beds considerably thinner than the 0.5 mm active depth, the cathode overpotential decreased over a time period of order 1 min to a value perhaps 10% less than its stationary value at the new depth and then increased over a period of order 10 min to its new steady state.

Effect of gas pressure.—The effect of oxygen pressure in the gas chamber on electrode overpotential for a current density of 8.4 ma/cm^2 was determined for a 3-mm thick sphere bed. The performance of the test electrode for gas chamber pressures between 5 and 23 in. of water is shown in Fig. 5. When oxygen pressure was reduced below that necessary to exclude electrolyte (except as films) from the sphere bed (about 13 in.) electrode overpotential increased. For pressures of 7 in. of water or below, capillary action caused complete flooding of the sphere bed and electrode performance became extremely poor.

After a reduction of gas pressure below 13 in., that is after some penetration of bulk electrolyte into the bed

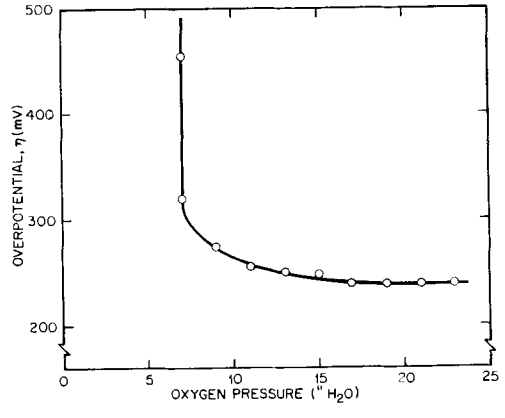

Fig. 5. Effect of oxygen pressure on overpotential of oxygen cathode. 6.9*N* KOH, 23.5°C, 3 mm electrode thickness, current density 8.4 ma/cm^2.

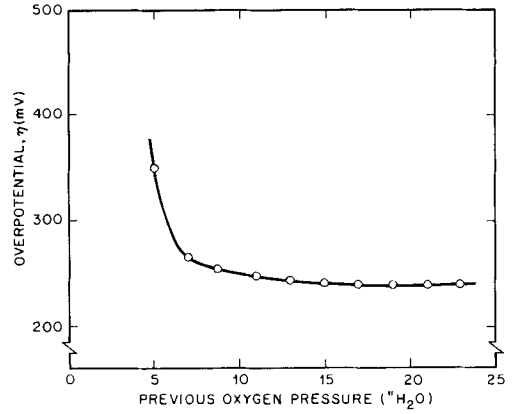

Fig. 6. Effect of previous reduction in oxygen pressure on overpotential of oxygen cathode operating at 23 in. H_2O pressure. 6.9*N* KOH, 23.5°C, 3 mm electrode thickness, current density 8.4 ma/cm^2.

had occurred, later return to original (23 in.) oxygen pressure did not restore electrode performance. This effect is presented in Fig. 6. It is to be expected for such a sphere bed since certain regions, particularly those near points of contact between spheres, cannot be cleared of electrolyte by gas pressure after being flooded.

Variations in oxygen flow rate at 23 in. pressure over the range of 0 to 5 cm^3/min had no measurable effect on electrode behavior.

Effect of current density.—Overpotential-current density relationships were determined for test electrodes under conditions where bulk electrolyte was excluded from the sphere beds (23 in. O_2 pressure) and where these beds were much thicker than their active regions (3-mm thick). These data are shown as the experimental points in Fig. 7. Galvanostatic currents in the range of 0 to 35 ma/cm^2 were applied and overpotential recorded after steady state was reached. The upper limit of currents investigated was set at the point where the resistive potential drop in the sphere bed itself clearly entered as an important effect. This condition would be determined by the linearity of the overpotential-current density curve caused by the resistive loss and was expected above about 20 ma/cm^2 because of the fairly high specific resistivity of the loose packed bed.

Discussion

The observed behavior of the electrode used in this study is in good agreement with the film model for porous gas electrodes (4). With a surface tortuosity factor on the order of 3 to 6 in the sphere bed[3] and a

[3] The tortuosity (path length/bed thickness) of void paths in a random packed sphere bed is about 1.5 and the further tortuosity of the surface, and thus the film, along such a path is $\pi/2$. This gives a minimum film tortuosity of 2.4 which is certainly considerably increased by lack of continuity of pore walls.

* Using Volmer type kinetic expression [Equation 2, ref. (4)].

film thickness of order of magnitude 10^{-5} cm, the measured active reaction zone extends more than 10^4 film thickness (more than 2 mm) along the surface away from the intrinsic meniscus. This constitutes strong evidence for the film mechanism; active lengths for surface diffusion should be two orders of magnitude less (5). Extreme degradation in electrode performance noted when the meniscus was allowed to enter the sphere bed is also consistent with the film process. The almost negligible residual activity of the flooded electrode indicates the magnitude of the contribution of the mechanism involving reaction under the meniscus itself or in the flooded portions of pores.

For quantitative comparison of measured electrode performance with predictions of the film model, the analog computer implemented computational procedure developed previously by two of the present authors (4) was applied to the electrode system of these experiments. In these calculations, the kinetic parameters for the oxygen reaction were taken from recent measurements for oxygen reduction at silver cathodes in potassium hydroxide solutions (17). Transport properties of the ionic species were derived from transference numbers and conductivities for similar solutions (19-20). The solubility and diffusion coefficient of oxygen in the electrolyte were interpolated from available data for aqueous KOH (21). These values are listed in Table I.

The remaining parameter necessary for film model computations, the film thickness, could not be directly measured. It was determined from the limiting slope of the overpotential-current density relationship for the sphere bed electrode at vanishing currents.[4] The measured limiting slope of 250 mv/ma/cm² yields a film thickness of 0.5×10^{-5} cm. This is of reasonable magnitude; it should be expected that the films on the convex surfaces of spheres of small radii would be thinner than the 1 to 5×10^{-5} cm films observed on flat plates (14).

From the parameters cited above, the overpotential-current density curve and the reaction distributions were calculated for the sphere bed electrode. Figure 7 shows the predicted overpotential compared with experimental values. The model agrees reasonably well with the measured data except for currents large enough for the resistive potential drop in the sphere bed itself to become important. This effect causes an increase in overpotential of about 10 mv at 20 ma/cm² and proportionately higher deviations at higher currents.[5] The resistance of the matrix was not considered in the development of the film model and is negligible where sintered electrodes are involved. The calculations give an active film length of 10^5 film thicknesses or about 0.5 cm for this electrode, a number of the same order as that found experimentally.

For the oxygen cathode under the conditions of these experiments, the reaction distribution and the polarization are determined almost entirely by the electrode reaction kinetics and the transport of ionic species along the film.[6] The transport of dissolved gas across the film does not limit reaction rate nor materially influence electrode performance. This conclusion is supported by the transient behavior observed following increases in bed thickness for beds thinner than the active depth. As the film is very thin when it first forms and increases gradually to its final thickness (14), the overpotential of an electrode whose performance was determined by gas transport across such a film should drop sharply during formation of such new film. Only small temporary decreases in overpotential (<10%), however, were observed. These can be attributed to the elimination of film area by flooding of small regions near the contacts between spheres during film thickening. Exchange current would have to be several orders of magnitude greater than that for oxygen reduction on silver before dissolved gas transport could become a significant factor.

Conclusions

From the experiments with the sphere bed electrode and the comparisons made to film model calculations, several important conclusions can be drawn concerning the operation of porous gas electrodes in KOH electrolytes.

1. The principal mechanism active in gas electrodes with a single scale of porosity is reaction under an electrolyte film on the walls of the gas filled parts of the pores.
2. The electrode reaction is distributed over a length of film extending many thousands of film thicknesses from the intrinsic meniscus.
3. Electrode reactions occurring under the meniscus itself or in the flooded portions of pores do not contribute significantly to the performance of gas electrodes.
4. Those analyses based on the film model which include effects of electrode kinetics and concentration changes in the film (*e.g.*, 4-5-6) provide useful predictions of the performance of gas electrodes of a single scale of porosity.
5. The thickness of aqueous KOH electrolyte films existing on the walls of pores in electrodes composed of spherical or near spherical particles on the 10-100μ size range is on the order of 10^{-6} — 10^{-5} cm at ambient temperatures.

The type of cell used in this work can serve as a tool for investigation of many factors in gas electrode design. Spheres of different materials or of different sizes can be used to examine the influence of matrix material or pore size. The spheres can be uniformly treated with catalyst before being added to the bed for investigation of catalyst activity. In such experiments, the well characterized structure of the electrode and the exclusion of electrolyte menisci from the bed facilitate interpretation of the measurements. Moreover, the applicability of the film model calculation to this electrode permits interpretations in terms of fundamental parameters of the system.

An Electrochemical Model for the Oxidation of Zirconium

D. H. Bradhurst,[1] J. E. Draley, and C. J. Van Drunen

Metallurgy Division, Argonne National Laboratory, Argonne, Illinois

ABSTRACT

A simple electrochemical model for gaseous oxidation is derived and applied to the oxidation of zirconium at 700°C. It is concluded that the part of reaction involving electron transport is rate-controlling. The factor determining the difficulty of ion transport has not been identified; passage through the oxide film does not seem to be limiting. Half-cell potentials for oxidation and reduction have been calculated to be approximately equal. Some variation in the oxide film defect structure with oxidation time has been deduced. Details are lacking.

The existing theories of oxidation suffer from the disadvantage of limited application. Within the extensively studied class of film-forming metals a number of oxidation theories have been built upon such simplifying assumptions as equilibrium existing at the reacting interfaces, or that the thin film of oxide has properties identical to the corresponding material in bulk. In two of the accepted oxidation theories, those of Cabrera and Mott (1), and Wagner (2), it is implied that a potential gradient exists across the growing oxide such that the metal is positive with respect to the oxide-gas interface. The fact that these assumptions do not always hold limits the applicability of the theories.

In a typical oxidation process it is impossible to measure, using existing methods, the instantaneous values of all the variables which can affect the reaction rate, let alone to predict the values on theoretical grounds. A more reasonable approach in developing a comprehensive theory seemed to be to use a simple model for the reaction in which the number of assumptions is minimal and to measure parameters which are characteristic of a particular reaction. Subsequent analysis of these parameters might be expected to yield useful information from a theoretical viewpoint.

In this paper, evidence is presented in support of a simple electrochemical model for the reaction between zirconium and oxygen at elevated temperatures. However, the model is generally applicable to film-forming oxidation reactions.

Theoretical.—Wagner first applied an electrochemical model to solid-gas reactions involving film formation and published the results in a series of papers in the early thirties. In one of these papers on sulfidation of Ag (2) he derived the familiar expression for the ionic transport number for ions diffusing through a protective layer of silver sulfide, *viz.*

$$\frac{/E/}{E_o} = n_a + n_c \qquad [1]$$

where n_a and n_c are the transport numbers of anion and cation, respectively. E is the potential across the film, and E_o the electrical potential equivalent to the free change for the reaction.

In this treatment the expression derived is independent of the polarity of the potential E developed across the growing layer, while it seems implicit in the derivation that the polarity of E is such that the metal is positive with respect to the outer surface of the growing layer.

In experiments by Misch (3) it was shown that in the oxidation of zirconium, a potential was developed in which the metal was negative with respect to the oxide-gas interface. The following electrochemical model for the oxidation of zirconium was developed in an attempt to allow for the existence of a potential of either polarity.

In the absence of an electric field across an oxide film it can generally be expected that the rates of the ionic and electronic processes will be different. Ionic movement (whether anion or cation moves is for the present purposes immaterial) can be considered to be part of the anodic process since both oxidation of zirconium and ion transport through the oxide produce a negative potential on the metal relative to the exterior of the oxide. The primary anodic driving force is the free energy change in the half-cell reaction which can be written

$$Zr + nZrO_{2-x} \rightleftarrows \left[(n+1)ZrO_{(2-x)} \frac{n}{n+1} \right]^{+4} + 4e^- \qquad [2]$$

[1] Present address: Australian Atomic Energy Commission, Lucas Heights, N.S.W., Australia.

where n is the number of zirconium ions in the oxide film and x is the result of oxygen vacancies. The charge produced in the oxide is distributed in an unspecified manner.

The electrical equivalent of this free energy change is called E_a, and $i_{ionic} = E_a/R_{ionic}$, where R_{ionic} represents the kinetic difficulty of the entire anodic process, including the diffusion of ions. Similarly, $i_{electronic} = E_c/R_{electronic}$, where E_c is for the half-cell reaction which can be written as follows

$$\left(1-\frac{x}{2}\right)O_2 + \left[(n+1)ZrO_{(2-x)}\frac{n}{n+1}\right]^{+4} + 4e^- \rightleftarrows (n+1)ZrO_{(2-x)} \quad [3]$$

So long as the ionic and electronic currents are unequal, a potential will be developed between the metal and the exterior surface of the oxide. For example, ionic flow tends to establish a field which opposes further ionic movement (metal negative). Electronic movement is encouraged by this field and tends to reduce it. A steady potential is established as a result of these processes when their rates are equal. Under these conditions it is expected that for some cases electrons migrate through the oxide against an electric field (but with an electron concentration gradient); for the remaining cases ions migrate against an electric field (but with an ion concentration gradient).

The following equations summarize the situation, where E is defined as the potential of the metal with respect to the exterior oxide surface.

$$E_a + E = iR_i \quad [4]$$

$$E_c - E = iR_e \quad [5]$$

Adding [4] and [5]

$$E_o = E_a + E_c = i(R_i + R_e) \quad [6]$$

which is identical to the equation obtained by Hoar and Price (4).

Also obtainable from Eq. [4] and [5] is the following expression for the potential existing during oxidation

$$E = \frac{\frac{R_i}{R_e}E_c - E_a}{\frac{R_i}{R_e} + 1} \quad [7]$$

The potential is determined by the ratio of the two R's and the values of the half-cell thermodynamic potentials. The possible range of values for E is from $-E_a$ to $+E_c$.

Equation [4] predicts that the reaction rate can be altered by the external application of a potential: if a more positive E is maintained, the oxidation rate will increase, and if a more negative E is applied, the rate will decrease. The rate should decrease to zero when $E = -E_a$.[2]

The unknowns, R_e, R_i, E_a, and E_c can be obtained by experimental means during the course of the reaction, if it is assumed that R_e and R_i act in parallel during a measurement in which a small external current flows. It is also necessary to measure the area effective during the measurement, and the contact resistance. The resistance R is then given by

$$R \cdot \alpha = \frac{R_e \cdot R_i}{R_e + R_i} \quad [8]$$

where α is the fraction of the film area which conducts during the resistance measurement.

Simultaneous solution of Eq. [6] and [8] yields a quadratic equation, providing conjugate expressions for R_e and R_i. It is possible to select which are correct on two bases: (*a*) if applied cathodic current of the same magnitude as the oxidation current causes substantial reduction in oxidation rate (see results), then R_i cannot be much larger than R_e; (*b*) in the case of the present research, calculated values of E_c and E_a seemed reasonable only for one of the two conjugate choices.

Such selection provides the following solution

$$R_e = \frac{E_o}{2i}\left(1 + \sqrt{1 - \frac{4iR\alpha}{E_o}}\right) \quad [9]$$

A knowledge of R_e enables the remaining unknowns to be calculated; values of R_i and R_e indicate the relative importance of the ionic and electronic processes in controlling the reaction rate.

Experimental

Specimen preparation.—Zirconium specimens were prepared in the form of disks approximately 1.3 cm diameter x 0.2 cm thick. "Grade I" Van Arkel crystal bar (iron content 300 ppm) was argon arc melted three times and cold rolled to form sheet from which the disks were machined. The specimens were wet ground to 600 grade SiC paper, rinsed in hot water for 15 min, etched for 2 min in 45:5:50 HNO_3, HF, H_2O mixture, then rinsed in cold water for 30 min, degreased in ethyl alcohol, and swabbed dry.

Weight gain measurements.—The Ainsworth recording balance, together with the furnace and vacuum system are shown in Fig. 1. The balance operates continuously throughout each oxidation experiment and enables weight gain measurements to be made to within ± 10 μg. Samples were brought to temperature under a vacuum of about 10^{-6} mm Hg before the commencement of a run. The reaction was started by admission of oxygen to the furnace, and was stopped after a given period by evacuation of the system. "Blank" experiments were done without a specimen to determine both the buoyancy correction and the small but significant weight gain of the oxide powder used as an electrical contact.

Potential measurements.—The specimen was sometimes immersed in, and at other times rested on the surface of, 100-150 mesh lithium-doped nickel oxide powder (3, 5) contained in a platinum bucket. Comparison of weight change rates and appearances demonstrated that the powder did not seriously limit access of oxygen to the specimen, or otherwise influence reaction rate. This powder approximates an inert electron-conductor in this system.

Electrical contact was effected by means of two platinum wires, one spot-welded to the zirconium specimen (or to a short Zr wire from it) and the other to the platinum bucket. All contacts between dissimi-

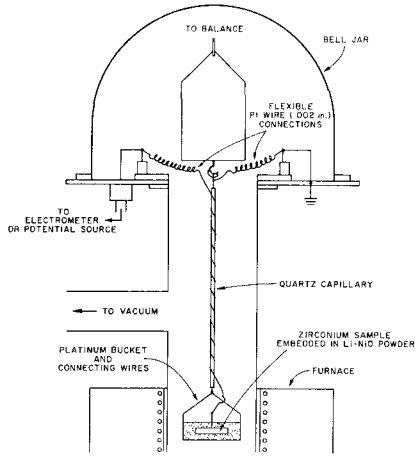

Fig. 1. Apparatus for simultaneous measurement of emf and weight gain.

[2] The value of E_a can be expected to depend on the defect structure of the oxide film (see Eq. [2]), which might be changed by an applied potential; thus the potential just sufficient to stop oxidation might be somewhat different than the E_a applying during unpolarized oxidation. However, oxidation should stop at a negative potential less than E_o.

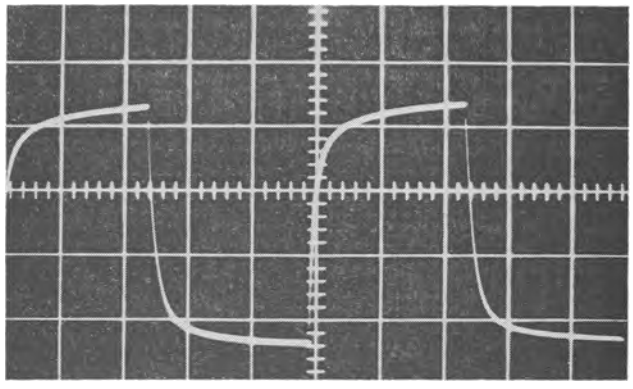

Fig. 2a. Oscilloscope trace of potential across oxide film and contact; 3.33 x 10^{-6} amp square wave; 0.1v (vertical) and 1 msec (horizontal) per large division.

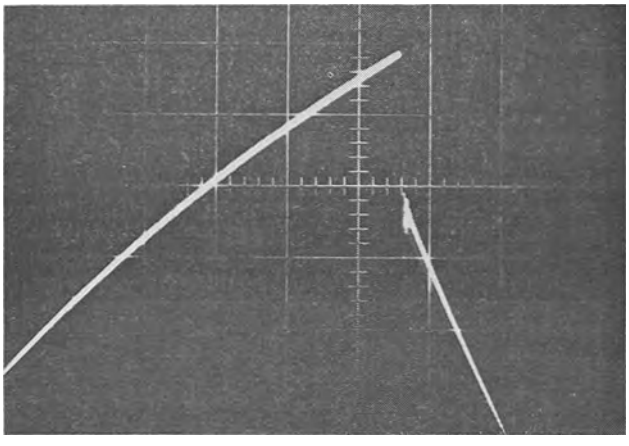

Fig. 2b. 0.01v (vertical) and 0.01 msec (horizontal) per large division.

lar materials were at the same temperature. Two coils of 0.002 in. platinum wire were used to make the connection from the balance to the external circuits for measurement of potential, current, and resistance. The sensitivity of the balance was adjusted prior to each run to compensate for the small damping effect of the coils. Potentials were measured with a Keithley electrometer, Model 610R, having an input impedance of 10^{13} ohms. Typically the output of the electrometer was recorded continuously.

Resistance measurements.—The basic method was to apply small currents, of both polarities, and to determine the slope of the E *vs.* I curve at zero current (polarization resistance). It proved convenient to use a bucking potential and to read only the unbalance produced by the applied current. Currents causing potential changes up to about 20 mv proved suitable for obtaining resistances without giving evidence of long-time disturbance of the oxidizing specimen. Nonlinear response resulted when considerably higher potential changes were used.

Resistances determined in this way required corrections from two causes: (*a*) there was an unknown series resistance consisting of the oxide powder resistance (trivial) and a contact resistance; (*b*) the area of the oxide film which conducted the applied current was unknown.

The series resistance correction was estimated from the oscilloscope trace of an applied square wave alternating current. Such traces for a platinum specimen showed that the potential at the contact points and across the oxide powder decayed rapidly ($<10^{-6}$ sec) and was ohmic. For an oxidizing zirconium specimen there was the iR drop and a more slowly decaying portion, ascribed to the oxide film. Typical traces of this type are shown in Fig. 2. The discontinuity in the

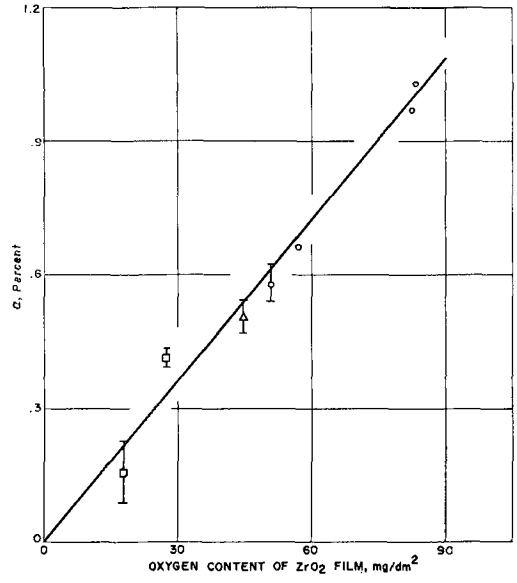

Fig. 3. Calibration curve for alpha: ○, 700°C; △, 650°C; □, 600°C.

decay curve made possible ready measurement of the contact resistance. In practice, a constant current square wave was chosen to give a total potential change in the range 15 to 50 mv. Equivalent results were obtained between 100 and 1000 cps.

The fraction of the film area conducting, α, was determined at the conclusion of the oxidation as the ratio of the resistance (per unit area) immersed in a molten (oxygenated) bath of 28% Li_2CO_3, 33% Na_2CO_3, 39% K_2CO_3 to that obtained in oxygen with the powder contact at the same temperature. In order to obtain the variation in α with film thickness, several tests were terminated at less than typical total exposure. These values were plotted against the film thickness to provide a calibration curve (Fig. 3). To determine film thickness, the amount of oxygen diffused into the metal, as estimated from the data of Pemsler (6), was subtracted from total weight gain.

For small film thicknesses, oxidation rates at 700°C were sufficiently rapid that significant film growth occurred between the last resistance measurement in oxygen and that in the carbonate bath. In order to eliminate this problem, some determinations were made at lower temperatures. Uncertainties were sometimes substantial, but a straight line through the origin is indicated.

Confirmation of the type of calibration curve was obtained with an analogue system. This consisted of a thin layer of 1M $CuSO_4$ solution in a shallow vessel, having a flat copper base. The resistance between a single small-point copper tip just touching the solution surface and the plate is given by: $R = \rho t/A$, where ρ is the measured resistivity of the solution, t its thickness, and A the area effective in conducting the current. The ratio of A to the area of the plate was taken as α for this system.

The thickness to area ratios for these experiments were larger than for the oxidation specimens, the smallest being slightly larger than the largest in Fig. 3. Results approximated a straight line through the origin, providing credence to the calibration curve of Fig. 3.

Results

Preliminary experiments. Potential measurements on zirconium and niobium.—Figure 4 shows a typical measurement of the emf developed during the oxidation of zirconium at 700°C. Before admission of oxygen, when the system is at a pressure of 10^{-6} mm Hg and 700°C, the emf is zero; it rises quickly to a steady value as oxidation proceeds. Finally, when the system is

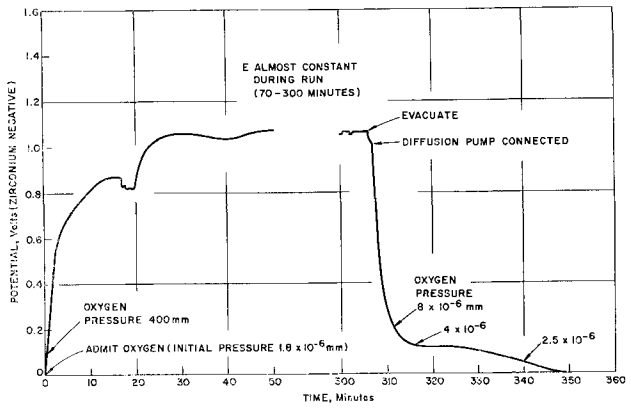

Fig. 4. Behavior of potential developed during oxidation of zirconium at 700°C.

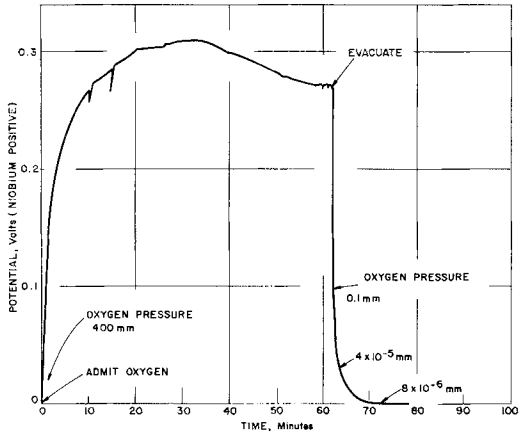

Fig. 5. Behavior of potential developed during oxidation of niobium at 450°C.

evacuated, the emf decays once again to zero. During oxidation of zirconium under these conditions, the emf is slightly greater than 1v with the zirconium negative with respect to the oxide-gas interface.

Figure 5 illustrates that the behavior in emf for niobium at 450°C is similar, except that for this reaction the sign of the emf is reversed.

Forty-six experiments of this type were done for zirconium and all showed the same polarity for the emf. The value of the emf was typically in the region of 1.0 to 1.1v at 700°C, which was in agreement with previous measurements by Misch (3) and Kirkbride and Thomas (7). The emf was steady throughout the experiment in the better runs. There was a small reduction in the value of the emf at longer times of oxidation (from 300 to 5000 min). The majority of measurements were made in the range 0 to 306 min.

Polarization experiments.—A series of specimens were polarized during oxidation in order to determine whether an alteration in rate could be effected as described by Eq. [4]. It was shown that the oxidation rate could be reduced by at least a factor of two by the application of a cathodic potential approximately equal to the reversible emf of the reaction. This is illustrated in Fig. 6 in which the reaction rate (taken as the weight gain during the time interval from 100 to 300 min) is plotted as a function of the applied voltage. The rate decreases as the applied potential becomes more negative, whereas much less change in rate is evident with anodic polarization. The deviation from the prediction from Eq. [4] can be explained from the following. Microscopic examination revealed that the surfaces of the cathodically polarized samples were covered with indentations separated by a distance approximately equal to that between particles of the semiconducting oxide powder used as the contact.

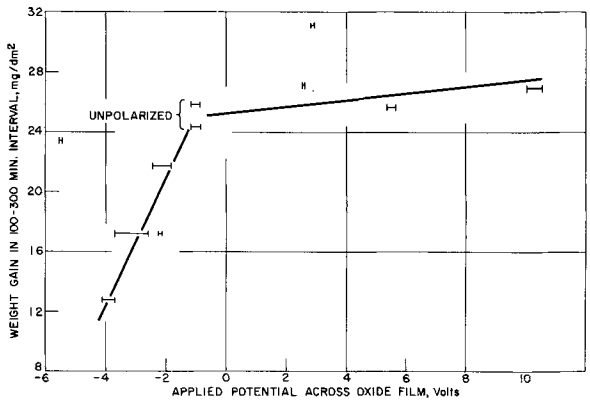

Fig. 6. Variation in oxidation rate with applied voltage: zirconium in oxygen at 700°C.

Unpolarized samples also had some darkened areas corresponding to points of contact, but without depth. The anodically polarized samples had small mounds at points of contact.

These observations suggest that relatively large changes in oxidation rate did occur near the contact points, where the potential was controlled, but that the local changes were not truly represented by the overall weight gain of the specimen. This was more noticeable in the anodic case, since the area of influence was restricted to point contacts as the film grew there, giving rise to a quite small area where the potential was controlled. In the cathodic experiments, the area of contact progressively increased as the oxide thickened around the base of each particle, and the potential was controlled over a significant fraction of the total area.

Experiments using porous metal film contacts.—In an effort to obtain an increased area of contact to the oxide surface, experiments were done in which a layer of gold (approximately 200Å thick) was evaporated onto the surface of the zirconium specimens. A twenty-fold increase in oxidation rate resulted and polarization proved ineffective in changing the oxidation rate. Figure 7 is a photomicrograph of a cross section of an oxidized zirconium specimen, showing the difference between the "normal" oxide thickness (after 300 min) and that achieved beneath the gold layer.

It seems reasonable to expect that an increase in rate might result from contamination of the oxide product by gold, since it is known that zirconium-gold alloys have relatively poor oxidation resistance. The effect was larger than might have been anticipated on this basis. Whether there was a galvanic effect is not known. One face of a single crystal was gold-plated and showed about the same accelerated reaction on that face only. Similar behavior was exhibited during oxidation after evaporating gold on a pre-oxidized specimen.

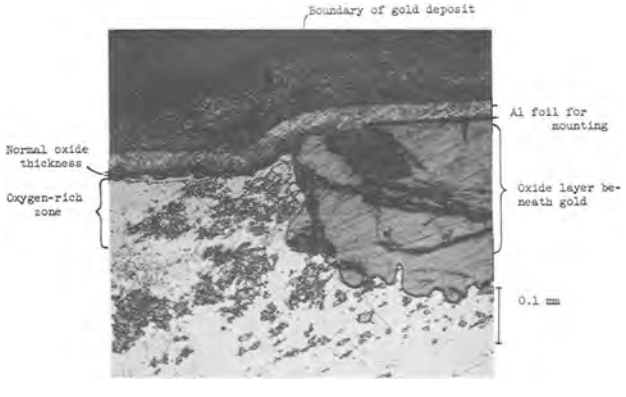

Fig. 7. Cross section of zirconium specimen after 300 min oxidation at 700°C.

In a second series of experiments evaporated films of copper were used in place of the gold. The oxidation rate of unpolarized copper-coated samples was slightly less than that for pure zirconium, after the copper had completely oxidized in about an hour. Variable copper thicknesses apparently caused some irregularity in results, but the oxidation rate changed substantially with applied potentials; positive potentials accelerated oxidation to about the same extent as negative potentials reduced it. The controlled potential at the oxide film surface was apparently more uniform in this case than for the experiments with uncoated zirconium.

Electrochemical Analysis of Oxidation

The reaction rate at 700°C was found to be essentially independent of oxygen pressure in the range 10 to 400 mm Hg, as may be seen from Fig. 8. Kinetics roughly followed the cubic rate expression, although deviation was evident at early and later stages (Fig. 9). The deviation after 100 to 200 min varied from case to case, in some instances being substantial. Detailed examination of the reaction kinetics will be deferred; at this time only the approximate cubic behavior will be used for convenience.

For a number of experiments of about 300 min duration, the potential and weight gain were continuously recorded and the film resistance was determined periodically, using the methods outlined above. Because of some irregularities in the weight gain curves, it was difficult to determine instantaneous slopes (or oxidation "currents") with good precision. It is not clear how much of the irregularity has been due to

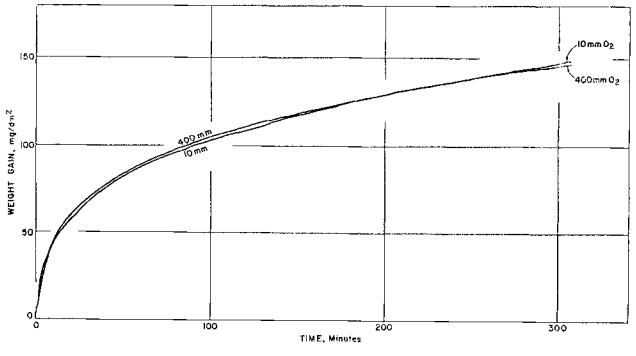

Fig. 8. Weight gain curves for Zr: 700°C and different oxygen pressures.

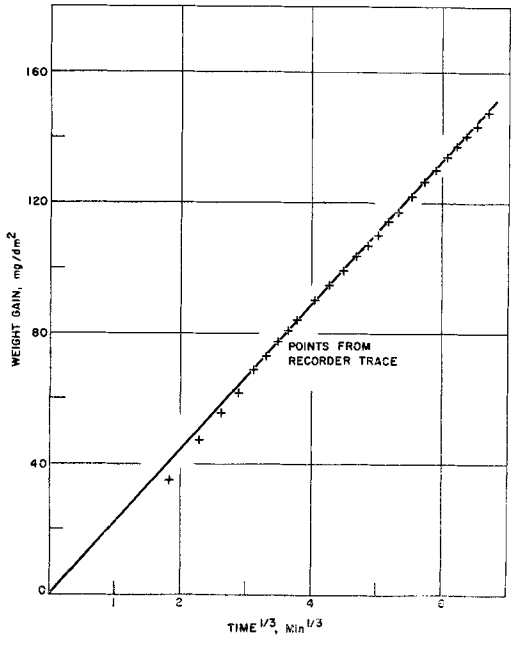

Fig. 9. Cubic plot for oxidation at 700°C

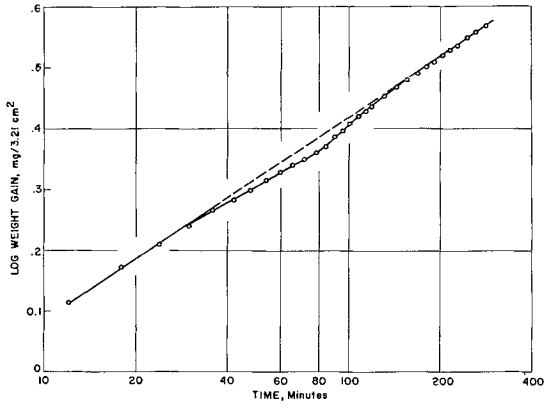

Fig. 10. Weight gain for specimen 69

deficiencies in the apparatus (such as slight balance movement caused by turbulence of the gas in the tube furnace) and how much represents actual irregularity in the oxidation process. Examination of recorder traces has indicated that both of these effects have been significant.

In order to analyze the data effectively, the logarithm of the weight gain was plotted against the logarithm of time. Generally, a straight line was observed; one of the most notable exceptions is shown in Fig. 10. Oxidation currents at times corresponding to resistance measurements were then calculated from slopes of lines such as that in Fig. 10. Values for E_c, E_a, R_e, and R_i were calculated at these times, assuming a constant E_o of 2.344v (at 400 mm O_2 and 700°C) (8).

Results for one specimen are given in Fig. 13; comparison with three other specimens is made in Table I. E_a and E_c were found to be approximately equal. E_a was generally found to have a downward trend with time, and E_c the converse.

R_e and R_i varied smoothly with time, with R_e always considerably the greater. Under these circumstances, and with the knowledge that $\Delta W \approx Kt^{1/3}$, it can be expected (from Eq. [6]) that $i = \dfrac{d(\Delta W)}{dt} \approx \dfrac{K}{3t^{2/3}} \approx \dfrac{E_o}{R_e}$; thus, that $R_e \approx k_e t^{2/3}$.

Figure 11 shows that this is true, with the variation in the middle of the plot peculiar to this specimen (noted in Fig. 12). In spite of this peculiarity, R_i varied smoothly with $t^{1/2}$ for a period, then became erratic. The parabolic rate constants for this increase and the times for which no further regular increase were observed are recorded in Table I. Since R_e and R_i obeyed different rate laws, their ratio changed continuously with time. The ranges of these ratios are also presented in Table I.

Discussion

The rise and fall of the emf across the oxide film with admission and removal of oxygen from the system provide good support for the concept that the potential is produced by the processes occurring. Under

Table I. Calculated electrical constants

	Specimen No. 51	52	69	70*
E_c at 300 min., v	1.25	1.34	1.28	1.48
E_a at 300 min., v	1.09	1.00	1.06	0.86
k_e, ohm-cm^2-min$^{-2/3}$	166	195	181	165
k_i, ohm-cm^2-min$^{-1/2}$	16.5	16.9	32.4	28.5

R_e/R_i before break	17-25	13-33	9-14	9-15

* This specimen exhibited an unusually low potential (0.70-0.76, compared to more typical values of 1.0); after an initial period of severe scatter, calculated values of R_i varied with $t^{1/2}$ through the last reading at 290 min.

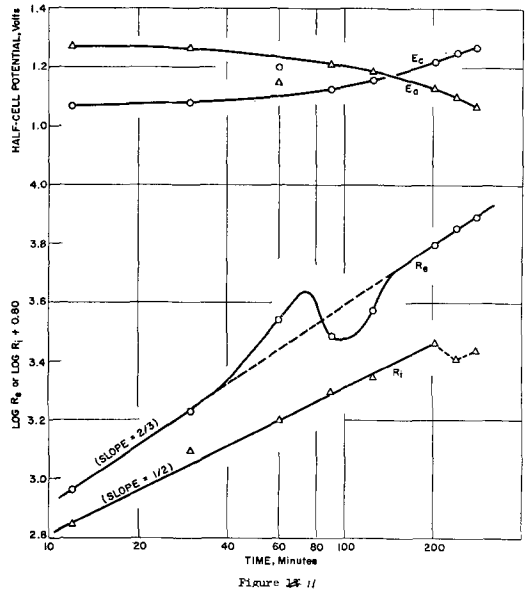

Fig. 11. Calculated constants for specimen 69

these circumstances it is probably wrong to consider the potential as a primary driving force for the reaction.

The appreciable changes in reaction rate which were effected by polarization of zirconium samples during oxidation support the electrochemical model summarized by Eq. [4] and [5]. That this might be a general phenomenon is suggested as well by the work of Jorgensen (9, 10) and of Lacombe *et al.* (11). The fashion in which control of reaction rate by applied potentials was essentially restricted to points of contact demonstrates the need for care in interpreting such results. Reaction rates can be expected to vary with time in a fashion difficult to interpret as the oxide grows into interstices and increases the area of contact, even with constant cathodic polarizing potential (or current).

There are some complications in the application of the theoretical treatment developed here:

1. If there is a potential difference between oxide surface and a zone in the gas phase which is influential in the oxidation process, this will not be included in our measurements and our results for E_a and E_c will be in error. For the present research this error is estimated to be trivial.

2. The R's in Eq. [4] and [5] are integral quantities in that they measure kinetic difficulties in the change from $i = o$ to i. The R_i and R_e in Eq. [8] are differential quantities (for small incremental current values). Assuming that these are the integral R's (in the derivation of Eq. [9]) leads to errors. These have not been evaluated; that the situation is not too bad can at least be hoped from the observations that R (Eq. [8]) remained constant over a fairly wide range of currents, and Eq. [9] was rather insensitive to the value of R.

3. If metal oxidation were not occurring, that portion of an applied current transported through the oxide by electrons would not be involved in an oxidation or reduction reaction. The R_e (and R_i) which would apply for that case would be different from those which are effective during oxidation (and Eq. [1] would hold). However, if applied currents are small compared to an oxidation current, it is believed that such currents can be considered partly to change the ionic current in Eq. [4] and partly to change the electronic current in Eq. [5]. Under these circumstances, the effective R_i and R_e would appear to be nearly those set up by the oxidation reaction. The error due to oversimplified treatment will then be significant only if the kinetic difficulty due to an activation energy in the reduction of oxygen to ions is a significant fraction of R_e.

The results of this investigation suggest (Table I and Fig. 13) that the free energy driving forces for the two half-cell reactions in the oxidation of zirconium at 700°C are approximately equal. Their variation with time is not known, because the variation of E_o with time is not known. Since these quantities can be expected to depend on the defect structure (or nonstoichiometry) of the oxide, it is indicated that there is a variation in this property during oxidation. If knowledge of the free energy of formation and the partial pressure of oxygen in equilibrium with zirconium oxide can be made available as a function of stoichiometry [such as has been reported for the latter by Aronson (12)] it should be possible to determine the stoichiometry of the growing oxide.

The ratio of R_e to R_i ranged from 9 to 33 during this investigation, for times up to 300 min. This indicates the reaction at 700° to be predominantly controlled by an electronic process. Within the meaning of R_e, this process could be any of the following: transport of electrons through the oxygen-rich layer in the metal; entry into the oxide; transport through the oxide; or the surface reaction in which oxygen is reduced. Of these, transport through the oxide seems the most likely, considering both magnitude and variation with time.

The process controlling R_i is apparently not closely related to that controlling R_e, as judged by the different rate law, and the different behavior in experiments showing peculiarities; *e.g.*, the deviation illustrated for R_e, but not R_i, and the irregularity in R_i after some period of exposure (but not in R_e). The process controlling R_i apparently does not reside in an obvious way in the oxide film. Where the weight gain for the specimen illustrated in Fig. 10 was approximately equal to $22.4t^{0.33}$, the estimated oxygen content of the film was $21t^{0.30}$, and R_i was $32.4t^{0.50}$. The diffusion of oxygen into the metal is apparently parabolic (6), and this suggests that this process determines R_i. There appears to be little evidence on this point.

After a period of oxidation, if a sample is evacuated the resistance to the passage of external current is rapidly and sharply reduced (by a factor of a few hundred). Since this resistance is approximately equal to R_i (Eq. [8], where $R_e >> R_i$), it is indicated that this quantity responds quickly in this fashion. The explanation is not clear, but some process at the metal-oxide interface, such as entry of oxygen ions into the metal, is suggested. The failure of R_i to continue to increase (after about 200 min in Fig. 11) might logically be expected on this basis, if the surface layers of the metal became saturated with oxygen at that time.

The calibration curve for α (Fig. 3) indicates that for a film of constant resistivity the measured value of the external resistance should be constant, independent of film thickness. This was observed for the $Cu/CuSO_4$ experiments. During the oxidation of zirconium, however, this resistance increased with time, although sometimes irregularly. This demonstrates that R_i is not a direct measure of some property of a uniform total oxide film.

Under the conditions of the present investigation, the oxide films contain many fine cracks. Interpretation of these results in terms of detailed mechanisms does not seem feasible at this time. It appears desirable to study oxidation under conditions where cracking does not occur before hoping to interpret controlling factors for growing and cracking films.

It is observed (Eq. [9]) that the value of the potential across the growing oxide need not be known in order to calculate R_e and R_i. With measurement of the oxidation rate and the resistance to external current, and knowledge of E_o, it is possible to derive values for the electronic and ionic retardances. These quantities should be quite valuable as an aid in deducing the difficult steps in the oxidation. Their response

to changes in experimental parameters might be quite instructive. Measurement of the potential then makes possible the calculation of E_a and E_c. With these quantities available it might be hoped that interpretation of reaction mechanisms will become possible.

The value of the present treatment appears primarily to be to focus attention on the processes which are most important in determining oxidation behavior. Further analysis of such processes will very possibly involve the use of other techniques. The analogy to electrochemical consideration of corrosion in liquid electrolytes suggests that procedures applicable to such systems might also be applicable to gaseous oxidation.

Effect of Impurities in Iron on Corrosion in Acids

Z. A. Foroulis and H. H. Uhlig

Corrosion Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

The corrosion rate of annealed pure iron in 0.12*N* deaerated HCl is increased by alloying several hundredths per cent of various nonmetallic elements in the sequence B, N, As, C, S, P. The addition of 0.02% N increases the rate by a factor of only 1.3, whereas for 0.02% S or P the corresponding factors are 23 and 31, respectively. Small amounts of As up to about 0.1% increase the rate; larger amounts, up to at least 0.27%, decrease it. Tin in the amount of 0.1% or more decreases the corrosion rate below that of iron itself; it similarly decreases corrosion of iron in citric or malic acid. Cold work alone has relatively little effect on the corrosion rate except with iron containing carbon, for which the effect is large. Polarization measurements show that hydrogen overvoltage of the added element itself, or as associated with Fe, is the generally important factor controlling corrosion; in some cases change of anodic polarization also enters.

In a previous paper (1), detailed data were presented on the effect of carbon and nitrogen in iron, and of cold work, on the corrosion rate in deaerated 0.12*N* HCl of *p*H 1.01. The present investigation extends these results to iron alloyed with boron, phosphorus, sulfur, arsenic, and tin. The effects on corrosion of some of these elements differ markedly from those induced by nitrogen or carbon. Also cold working of iron containing these elements tends to accelerate corrosion less than in the case of carbon or nitrogen. The reasons for these differences are discussed in relation to the electrochemical mechanism of corrosion.

Experimental Procedure

The procedure was the same as that described previously. Rectangular specimens about 4-6 cm^2 total exposed area were immersed in 1.5 liters of H_2-deaerated 0.12*N* HCl with H_2 continuously bubbling through the acid at a low rate. For the tin alloys, additional runs were made in citric and malic acids. Corrosion rates were determined by periodic colorimetric analyses of the acid for Fe^{++} using the orthophenanthroline method, the rate being taken from the slope of metal dissolution *vs.* time of exposure. Checks were made by weight-loss determinations at the end of each run. Exposure time was usually 4-6 days. The effect of cold work was investigated for all the alloys with the exception of the sulfur alloys which, being brittle, were tested in the as-cast and homogenized condition.

All the alloys were prepared in a vacuum furnace starting with remelted electrolytic iron supplied by courtesy of Westinghouse Electric Corporation (<0.001% Cu, <0.001% Ni). This was further decarburized to 0.002% C by treatment in wet H_2 at 760°C for 48 hr. The alloys were cast in an atmosphere of purified helium (passed over Ti at 850°C) by drawing into ¼ in. Vycor tubing and water quenching. Each specific alloy, encapsulated in evacuated quartz tubes, was homogenized for 48 hr at 1050°C, air cooled, and then cold-rolled to 50% reduction in thickness.

Phosphorus was added in the form of Bureau of Standards ferrophosphorus alloy containing 26.2% P. Other components were added as the purest available form of the element. The alloys were analyzed chemically after the homogenization treatment.

Polarization measurements were conducted in a three compartment glass cell as described earlier (2). Because of slow attainment of steady-state values, anodic polarization values were recorded after constant current flow for 15 min; for cathodic polarization the required time interval was less. Data for tin alloys were especially sensitive to time of previous immersion in the electrolyte.

Results

Iron-boron alloys.—Four alloys prepared for this series contained 0.01-0.099% B with carbon and nitrogen contents of 0.006 and 0.0014%, respectively. An alloy containing 0.15% B was too brittle to cold-roll. Corrosion data are shown in Fig. 1 showing negligible effect of boron on corrosion in 0.12*N* HCl, and with cold-rolled alloys corroding at slightly higher rates

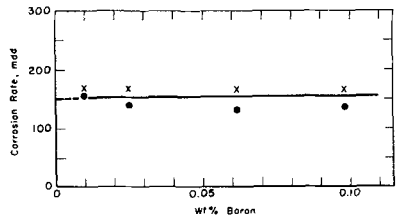

Fig. 1. Effect of alloyed boron on corrosion of iron in deaerated 0.12*N* HCl. • Annealed 2 hr at 950°C; X cold-rolled.

than annealed alloys. The small effect of cold rolling, if any, can probably be ascribed to residual C and N as much as to B.

The cold-rolled B alloys show a maximum in corrosion rate after heat-treating at about 100°C for 2 hr, the maximum rate being almost twice that for the initial cold-rolled material. In view of the fact that a similar effect is found for carbon and nitrogen alloys but not for pure iron (1), the maximum for the present B alloys may also be caused mostly by residual C and N. A similar maximum in corrosion rate of cold-rolled iron alloys containing 0.01-0.105% C and 0.1-1.04% Si was reported by Foroulis (3) after heat-treatment of the alloys at 100°C for 2 hr.

Iron-phosphorus alloys.—Three alloys were prepared containing 0.05-0.15% P, and with C and N contents of 0.002 and 0.005%, respectively. Phosphorus produced the highest corrosion rate in HCl (Fig. 2) compared with any of the other components presently investigated, sulfur also having a marked accelerating effect. Cold rolling produced still higher rates, the effect increasing with phosphorus content. At 0.15% P, for example, 50% reduction in thickness increased the rate by 30%. Heat-treatment of cold-rolled alloys at 100°C decreased the rate instead of increasing it as for C and N alloys.

The marked accelerating effect on corrosion of iron by alloyed P confirms previous results of Endo (4), Edwards *et al.* (5), and of Stern (6).

Iron-arsenic alloys.—Three alloys were prepared containing 0.09-0.29% As and with C and N contents of 0.002% and 0.005%, respectively. The corrosion rate of the 0.09% As alloy is higher than that of alloys containing more, or less, than this amount of As (Fig. 3). Cold working of the alloys has a negligible effect; heat-treatment at 100°C of cold worked alloys neither increases nor decreases the rate.

Iron-sulfur alloys.—Three alloys contained 0.015-0.078% S, with C and N contents of 0.002% and 0.005%, respectively. The corrosion rate of the cast alloys increases linearly with sulfur additions, the increase being appreciable for small amounts (Fig. 4). The effect on corrosion in HCl for a given weight per cent sulfur up to about 0.08% is about 25% less than for the same weight per cent addition of phosphorus. Endo (4) found that the corrosion rate of iron in 5% HCl or 5% H_2SO_4 increased almost linearly with alloyed S up to about 3%. For Fe alloyed with P, on the other

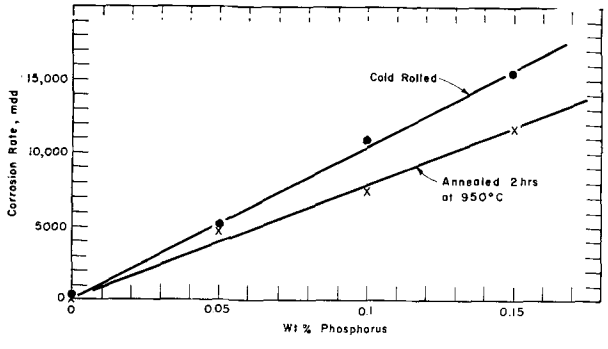

Fig. 2. Effect of alloyed phosphorus on corrosion of iron in deaerated 0.12*N* HCl.

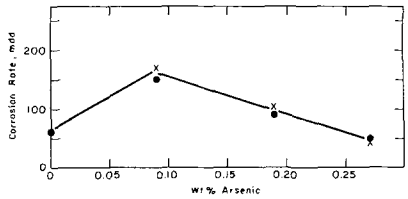

Fig. 3. Effect of alloyed arsenic on corrosion of iron in deaerated 0.12*N* HCl. • Annealed 2 hr at 950°C; X cold-rolled.

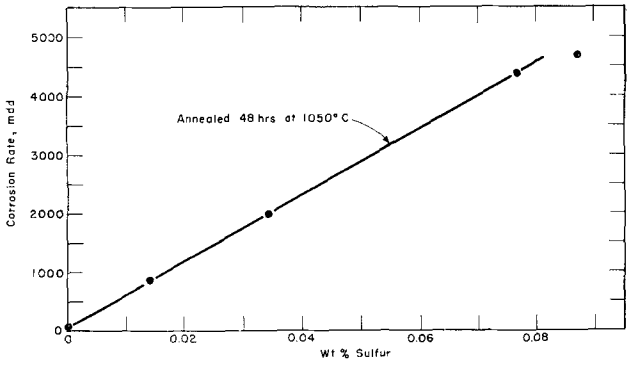

Fig. 4. Effect of alloyed sulfur on corrosion of iron in deaerated 0.12*N* HCl.

hand, he found corrosion to increase up to about 2% P; larger amounts again decreased the rate to appreciably lower values. Edwards *et al.* (5) found alloyed S up to about 0.15% to have little or no effect on corrosion of Fe in 6% H_2SO_4, but their alloys also contained appreciable Cu which counteracts the effect of S. The effect of Cu to reduce the accelerating effect of S on corrosion of iron in nonoxidizing acids was demonstrated by Bardenheuer and Thanheiser (7) and by Stern (6). The latter found Cu to be greatly beneficial in S-Fe alloys exposed to HCl and citric acid, but not to malic acid.

Iron-tin alloys.—Five tin alloys were prepared ranging from 0.039 to 1.38% Sn. Carbon and N contents were 0.002 and 0.005%, respectively. The alloys were cold-rolled except for the 1.38% Sn alloy which was too brittle. Corrosion rates in HCl are given in Fig. 5.

For all alloys in HCl, the initial corrosion rate was higher than the final rate. The cause was either redeposition of tin on the alloyed surface or perhaps build up of a tin-rich surface by preferential dissolution of iron. The decrease of corrosion rate with time is caused by change of alloy surface rather than by change in composition of the acid as shown in Fig. 6. The upper curve represents the weight loss of the 0.039% Sn alloy as a function of time. A steady-state corrosion rate of 25 mdd is reached after 36-40 hr. During this time, a visible black coating forms. If the solution is renewed at the end of six days, the continuing corrosion follows the lower curve of Fig. 6. After an initial period of 3 to 4 hr, the slope is the same as the steady-state upper slope for the initial immersion. Lack of immediate steady-state conditions on

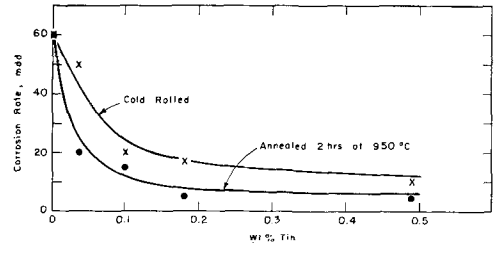

Fig. 5. Effect of alloyed tin on corrosion of iron in deaerated 0.12*N* HCl.

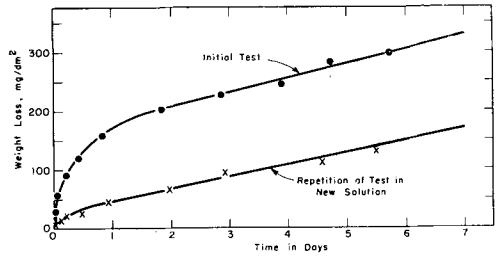

Fig. 6. Weight loss vs. time in deaerated 0.12*N* HCl for cold-rolled 0.039% Sn-Fe. Specimen at the end of corrosion test, upper curve, was introduced into a new solution for repetition of test, lower curve.

transfer of the specimen to the second solution is probably caused by a structural change, or by incipient oxidation of the metal surface during washing, drying, and weighing of the specimen.

It is of interest that the induction time observed in Fig. 6 was reduced in the case of citric and malic acids, with steady-state conditions being achieved within the initial 3-6 hr of the test. Alloyed tin lowered the corrosion rate in the organic acids as well as in HCl.

Rates given in Fig. 5 are steady-state values after exposure to HCl for several days. Tin additions up to 0.1% decrease the rate to about one-sixth the rate for tin-free iron, with little further change for higher Sn additions. The effect of cold-rolling is to increase the rate slightly; subsequent heat-treatment at 100°C had only a small effect either to increase or decrease the rate. Corrosion rates in 0.1*N* citric acid, *p*H 2.05, are similar to those in 0.12*N* HCl, both acids being deaerated (Fig. 7). The rates in deaerated 0.11*N* malic acid, *p*H 2.08, on the other hand, are about one-tenth the rates in either citric acid or HCl (Fig. 8).

Discussion

In our previous paper (1) we showed that zone-refined iron when severely cold-worked corrodes no more rapidly in 0.1*N* HCl than when annealed. In other words, imperfections, such as dislocations, produced by cold work in pure iron have no discernible effect on rate of acid attack. For iron containing carbon, however, cold work markedly accelerates corrosion in the same acid medium, presumably because low hydrogen overvoltage sites form by association of C atoms with imperfections. Nitrogen also markedly increases the rate but more so after heat-treating the alloy at about 100°-200°C at which temperature but not below nitrides readily dissociate allowing N atoms to reach imperfection sites. Carbon or N atoms segregated at imperfections lower hydrogen overvoltage; anodic polarization, on the other hand, is not affected.

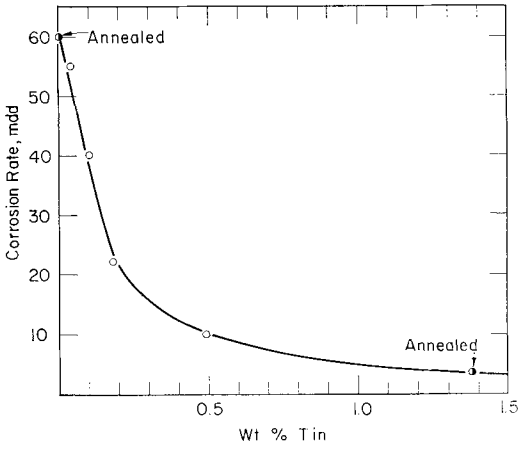

Fig. 7. Corrosion of cold-rolled (or annealed as shown) tin-iron alloys in deaerated 0.1*N* citric acid.

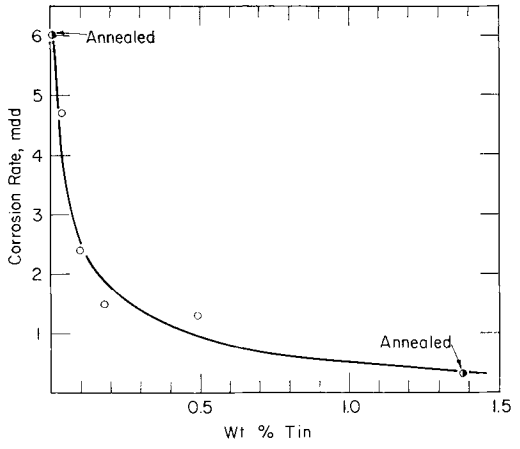

Fig. 8. Corrosion of cold-rolled (or annealed as shown) tin-iron alloys in deaerated 0.11*N* malic acid.

The slight effect of alloyed B up to 0.1% on corrosion of iron indicates that any interstitial impurity substituted for carbon in the iron lattice is not sufficient to reduce hydrogen overvoltage and to accelerate corrosion. Foroulis' results similarly show [Fig. 3, 4, ref. (3)] that alloyed Si up to 0.58% has very little effect on corrosion of cold-worked Fe in 0.1*N* HCl; although in the annealed state Si alters the form of iron carbide to a needle-like precipitate which in turn accelerates corrosion. Hence, chemical properties of the interstitial atoms and their chemical interplay with the surrounding iron atoms are important factors. Cold work apparently accelerates corrosion in nonoxidizing acids like HCl only if the additional imperfections generated by cold work are associated with specific impurity atoms, *e.g.*, C and N atoms, which lower hydrogen overvoltage. In presence of Si and B atoms alone, cold work has little if any effect.

As is noted, phosphorus and sulfur additions accelerate corrosion much more than any of the other elements added to iron. Polarization measurements for phosphorus alloys in Fig. 9 show that increasing P content lowers especially cathodic polarization with simultaneous reduction, although to a lesser extent, of anodic polarization. The corrosion potential moves toward more noble values as the P content of Fe increases in accord with the expected effect of decreased cathodic polarization. The cathodic sites of markedly reduced hydrogen overvoltage may consist of imperfections associated with P atoms but, were this entirely true, the effect on corrosion of cold work, which increases imperfection density, should probably be more pronounced. Instead, the low overvoltage sites probably also consist of iron phosphides.

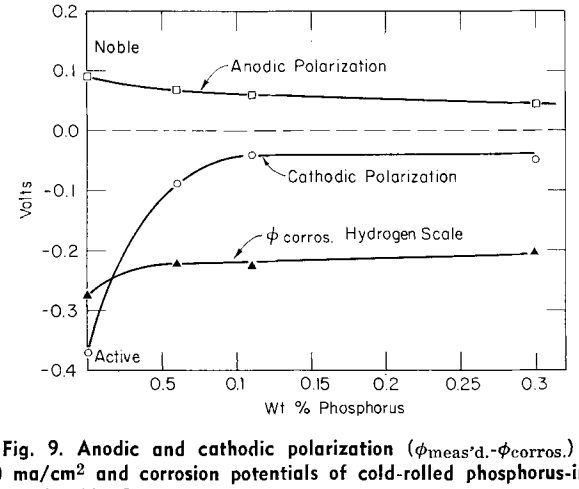

Fig. 9. Anodic and cathodic polarization ($\phi_{meas'd.}$-$\phi_{corros.}$) at 10 ma/cm² and corrosion potentials of cold-rolled phosphorus-iron alloys, 0.12*N* HCl, 25°C.

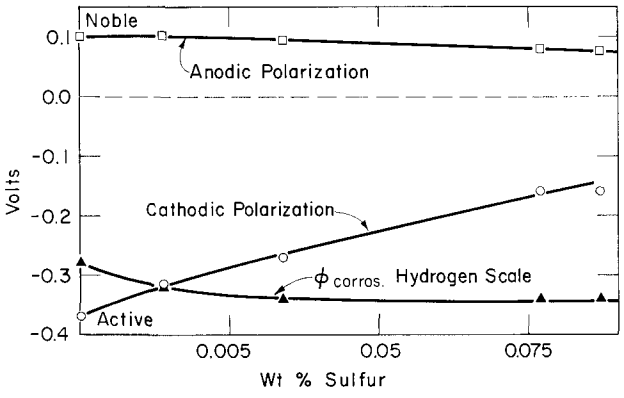

Fig. 10. Anodic and cathodic polarization ($\phi_{meas'd.}$-$\phi_{corros.}$) at 10 ma/cm^2 and corrosion potentials of annealed sulfur-iron alloys, 0.12*N* HCl, 25°C.

Similarly in the case of sulfur additions, the low overvoltage sites very likely consist in large part of iron sulfides. Segregation of S at grain boundaries accounts for the tendency of S-Fe alloys to corrode locally in the form of pits. This effect was previously observed by Stern (6). The corrosion potentials for iron with increasing S content move toward more active values (Fig. 10), opposite to the expected effect accompanying a decrease of cathodic polarization. The reason is not certain, but it is plausibly related to an increasing anode to cathode area ratio as the sulfur content increases (6).

Although the present data show that P increases corrosion of Fe in HCl somewhat more than does an equal weight per cent of S, previous data of Stern showed that the relative effects of S and P depend to some extent on the corrosive medium. In HCl + 4% NaCl at *p*H 1, he found that 0.017% P-Fe alloy (1000 mdd) corroded less rapidly than 0.015% S-Fe alloy (2830 mdd), but the reverse effect applied at *p*H 2, namely the P alloy (480 mdd) corroded at a higher rate than the S alloy (244 mdd). In 0.1*N* citric and malic acids he found that the S alloy corroded much more rapidly, by factors of 4 and 30, respectively, than did the P alloy. It is probably difficult to establish precise relations in this regard because both S and P alloys corrode at increasing rates with time of immersion and never reach true steady-state values. Both gradual change of metal surface composition and structure, and accumulation of P or S corrosion products in solution have an appreciable effect on the rate.

Arsenic added to iron in amounts up to about 0.1% presumably forms a solid solution of As in iron having low hydrogen overvoltage. Above 0.1%, free arsenic of known high hydrogen overvoltage either accumulates on the metal surface or it is redeposited from a solution of reaction products of the Fe-As alloy with HCl.

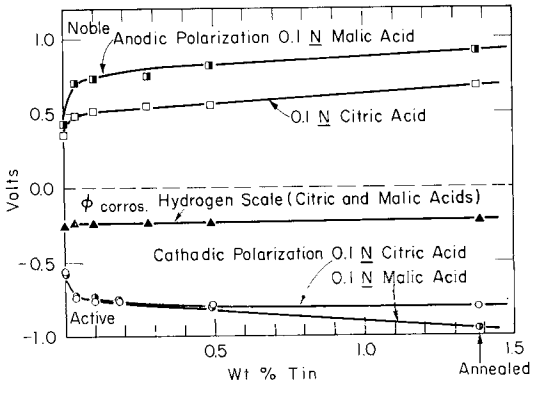

Fig. 11. Anodic and cathodic polarization ($\phi_{meas'd.}$-$\phi_{corros.}$) at 10 ma/cm^2 and corrosion potentials of cold-rolled tin-iron alloys, 25°C.

Tin in solid solution is remarkably effective in reducing the corrosion rate of iron. The steady-state corrosion rate of the 0.1% Sn alloy in 0.1*N* HCl (10 mdd) for example, is below that of zone-refined iron in the same medium (20 mdd) (1). This reduction parallels both an increase of hydrogen overvoltage as well as an increase of anodic polarization with increasing tin content. The lower corrosion rate in 0.1*N* malic acid, compared to 0.1*N* citric acid, is a result largely of increased anodic polarization in malic acid (Fig. 11). Cathodic polarization is about the same in both acids. These facts suggest that malate ions, or their reaction products with iron, adsorb on anodic sites much more, and with stronger bonding, than do citrate ions, thereby more effectively impeding the dissolution of Fe^{++} ions. The effect increases with tin content of iron, parallel to the observed decrease of corrosion.

Recently Greene and Saltzman (8) reported a marked increase in corrosion rate in 1*N* H_2SO_4 or 0.1*N* HCl for zone-refined iron wires torsionally deformed. They ascribed the large effect of cold work which they found to their application of more drastic mechanical deformation in comparison with our 50% cold-reduced material for which no effect was observed. They interpreted their results to indicate, therefore, that plastic deformation increases the number and/or activity of surface dislocations which act as sites for anodic dissolution. Our own work, on the other hand, has not shown an effect of plastic deformation on anodic or cathodic polarization; only in the presence of carbon, for example, is cathodic polarization reduced. Thermodynamic calculations based on residual energy of severely cold-worked iron (approximately 5 cal/g) support the conclusion that change of open-circuit anode potential cannot be more than about 6 mv, a value which is too small to account for a significant increase of corrosion. In agreement with this calculation, Straumanis and Wang (9) found that very severe deformation did not increase the corrosion rate in 1*N* HF of pure aluminum cold reduced 90% in thickness. Similarly Bonnet (10) found no appreciable effect of cold work on the corrosion rate of Ni in deaerated 2*N* HCl of pure Ni sheet cold reduced 70% in thickness. Many lattice imperfections must have been present in both materials. The increase noted by Greene and Saltzman, therefore, may have another explanation which only further experiment can resolve. It is possible in their experiments that torsional straining produced an increase of true surface area with accompanying higher corrosion rates. Their reported increase in rate of corrosion with time suggests that such an effect may have been occurring. Also the discontinuity in the relation between carbon content of their iron and the corrosion rate, instead of a continuous relation (1), suggests that surface contamination may possibly have occurred during the heat-treatment schedules. Our work showed that a few thousandths per cent pick up of carbon easily occurs and can produce large effects. It remains our conclusion, therefore, pending further data, that imperfections, as such, do not have a large effect on corrosion characteristics of relatively soft metals like iron; only when such imperfections are associated with specific impurities, in particular carbon, is the effect marked, and in this case the increase in corrosion results from a lowering of hydrogen overvoltage at such sites.

Logarithmic Oxidation Kinetics of Zinc

Vincent O. Nwoko and H. H. Uhlig

Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Oxidation rates of cold-rolled zinc are reported at 0.2-0.8 mm O_2 pressure in the temperature range 125°-206°C. Oxide thickness *vs.* time follows a two-stage logarithmic equation similar in behavior to Cu, Ni, and Fe. Activation energies for first- and second-stage oxidation are 0.34 and 0.35 ev, respectively. The data are interpreted in terms of a uniform density space charge oxide, corresponding to first-stage oxidation, underlying a diffuse space charge oxide corresponding to second-stage oxidation, with the rate being controlled in each instance by electron transfer from metal to oxide. The high density of trapped charge in ZnO ($2 \times 10^{17}/cm^3$ at 200°C) explains in part the low initial oxidation rate of Zn compared to Cu and Ni. Second stage logarithmic oxidation kinetics is ascribed to thermal dissociation of trapped charge in the outer regions of oxide when the latter reaches a critical thickness, giving rise to a diffuse space charge.

The oxidation of zinc in accord with parabolic oxidation kinetics has been studied by several investigators (1-4). The initial or low-temperature oxidation rate obeying logarithmic kinetics has also received some attention. Tammann and Köster (5) studied the initial oxidation rate in air in the temperature range 375°-412°C. They were the first to show that the logarithmic equation is obeyed for their particular experimental conditions. An extensive investigation was carried out by Vernon *et al.* (6) who measured the oxidation rate in air between 25°-400°C by weight gain of zinc sheet specimens. They found that the oxidation rate was sensitively affected by method of surface preparation. Abraded or etched surfaces yielded self-consistent but not necessarily the same results. The logarithmic equation was obeyed typically above but only approximately below 225°C, the discrepancy increasing on lowering the temperature or decreasing the time of oxidation.

Previous reports on the initial or thin-film oxidation rate of copper (7-11), Ni (12, 13), and Fe (14) show a two-stage logarithmic behavior. This behavior is also found in data for cobalt by Gulbransen and Andrew (15). Oxides such as NiO and Cu_2O are p-type semiconductors in which cation vacancies characterize the important lattice imperfection sites. It is of interest to learn whether Zn also follows a two-stage logarithmic equation since Zn forms an n-type semiconductor oxide, ZnO, the characteristic lattice imperfections of which are thought to occur as excess interstitial zinc ions. As previously mentioned, Vernon *et al.* (6) found that oxidation of Zn at low temperatures follows a single stage logarithmic equation, but with some discrepancies arising below 225°C. The present measurements on pure Zn cover the thin film oxidation rate at 0.2 to 0.8 mm Hg oxygen pressure in the temperature range 125°-206°C.

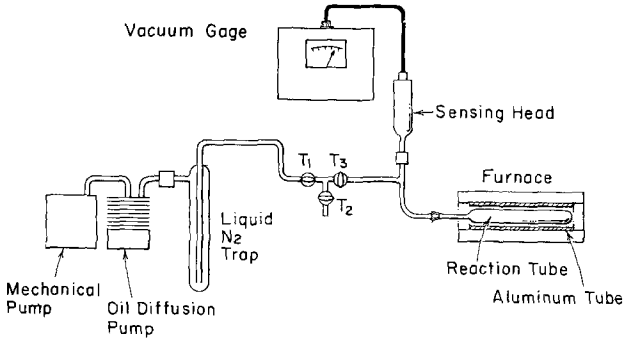

Fig. 1. Apparatus for measuring oxidation rate

Experimental

The oxidation rate was studied using a manometric method. Specimens in the form of thin sheet were contained in a closed glass tube about 60 cm long and 5 cm OD. The glass reaction tube, in turn, was inserted into a heavy wall aluminum tube of slightly larger internal diameter which fitted into an automatically controlled furnace (±1.5°C). The aluminum tube insured a better temperature gradient along the specimen length. The glass tube was connected through a ground glass joint to the vacuum system with details as shown in Fig. 1. The pressure gauge was an "Alphatron" unit which operated by measuring the amplified current in an electrically biased ionization chamber containing the gas and 100 microcuries of radium. The gauge covered seven pressure ranges from 0-100 down to $0\text{-}10^{-4}$ mm Hg; the range used for the present measurements was usually 0-1 mm Hg. The metallic sensing head of the pressure gauge was attached to the vacuum system by means of an O ring connector.

Pure zinc sheet, 0.1 cm thick, was supplied by courtesy of the New Jersey Zinc Company who provided the following analyses: 99.99+% Zn, 0.0009% Pb, 0.0028% Fe, 0.0018% Cd. Specimens 4 x 10 cm were prepared from the original sheet cold rolled to 0.05 cm thickness. These were degreased in benzene and abraded with 2/0 emery paper. A few dimples were then punched in each specimen in order to keep adjoining surfaces separate during oxidation. Specimens were etched in 2*N* HCl at room temperature for 3 min, washed in distilled water, alcohol, and finally benzene. Using clean gloves, the specimens were rolled into spirals having an outer dimension allowing them to be inserted into the glass reaction tube. Twelve and one-half specimens in all were provided for each run

with total apparent area of 1000 cm². The volume (940 ml) of the reaction tube plus specimens, pressure gauge, and connecting glass tubing up to stopcock T_3 was determined by allowing air of known pressure and volume between stopcocks T_3, T_2, and T_1 to expand into the evacuated system and noting the final pressure.

The procedure during a run was to heat quickly the evacuated reaction tube to temperature by inserting the tube into the previously heated furnace. When temperature was established, a specific amount of O_2 dried over $CaCl_2$ was allowed to enter the system. The amount of O_2 reacting with zinc was then determined by pressure decrease. Blank runs were used to establish the extent of slow pressure build-up in the system, particularly from gases adsorbed on the metal sensing head of the pressure gauge which could not be previously degassed by heating. It was found in this way that the pressure increased linearly with time at a rate of about 0.002 mm Hg in 5 hr. This rate of pressure build-up required correction to observed pressures in the latter stages of oxidation for some of the runs. On the basis that ZnO is formed of density 5.47 g/cm³, each 0.01 mm O_2 pressure drop was equivalent to a film of oxide 1.49Å thick, uncorrected for metal roughness factor. Reported values are for oxide thickness overlying a thin air-formed oxide at room temperature.

Results

In view of decreasing pressure during a single run, it was necessary to estimate the effect, if any, of oxygen pressure on the oxidation rate. Two runs were conducted at 157°C, one starting at 0.763 mm O_2 pressure and the other at 0.208 mm. The data, included in Fig. 2 and 3, show that the rates are the same within experimental error despite a threefold change in initial pressure. Hence the normal decrease of pressure during a single run reaching a maximum of 8% of the initial pressure at 125°C and 60% at 206°C did not influence the observed oxidation rates. Oxidation data at various temperatures are plotted in Fig. 2, the initial O_2 pressure being 0.85 mm at 125°C, 0.782 mm at 175°C, and 0.56 mm at 206°C.

Although the data fall on smooth curves in Fig. 2, when plotted semilogarithmically as in Fig. 3, they conform to a two-stage logarithmic equation similar in form to the initial or thin film oxidation behavior of several other metals including Cu and Ni. Earlier data of Vernon *et al.* (6) omitted points for short times of oxidation suggesting that the reported values are for second stage oxidation only. Their observation that deviation from logarithmic behavior increased at temperatures below 225°C and for short oxidation times may have been due to first stage oxidation data lying on a different slope than second stage data for higher temperatures or longer times. They also reported a

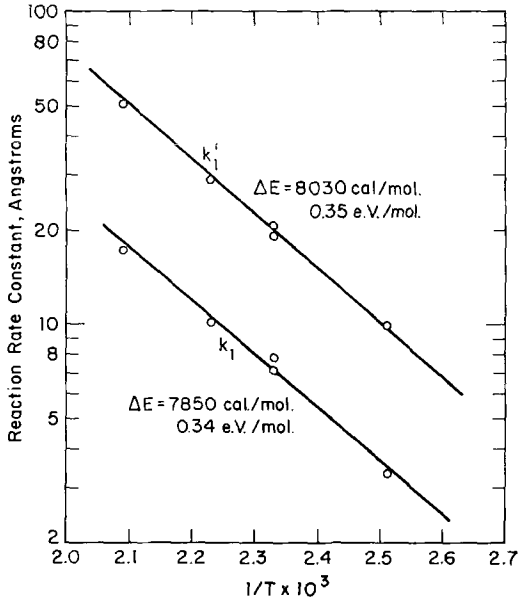

Fig. 4. Logarithm of reaction rate constant of Zn in O_2 as a function of reciprocal absolute temperature. Corresponding activation energies ΔE are inscribed.

maximum in oxidation rate between 25° and 225°C occurring at about 130°C which, however, is not confirmed by the present work. Surface contamination of their specimens, which the authors themselves mention as a cause of irreproducible results, may have been a factor. For the reported data at present, the logarithm of the oxidation rate constant decreases linearly with reciprocal absolute temperature in accord with the Arrhenius equation (Fig. 4). Activation energies ΔE for first and second stage oxidation are found to be nearly the same. Constants based on data of Fig. 3 for the equations:

$$y = k_1 \log\left(\frac{t}{\tau} + 1\right) \qquad \text{(1st stage)}$$

$$y - L = k'_1 \log\left(\frac{t}{\tau'} + 1\right) \qquad \text{(2nd stage)}$$

are listed in Table I where y is the thickness of oxide in Angstrom units, t is time in minutes, τ, τ', k_1, and k'_1 are constants, and L is the thickness of oxide at the beginning of second stage oxidation. Values for τ are obtained by extrapolating to $y = 0$, and for τ' by taking times at which second stage oxidation begins.

Discussion

The data show clearly that a two-stage logarithmic equation is obeyed by zinc which forms an n-type semiconducting oxide, of the same form as is obeyed by Ni and Cu which form p-type oxides. The basis for a two-stage logarithmic oxidation behavior has been described by Uhlig (10). Two kinds of space charge are presumably formed in thin film oxides in contact with metal, the oxidation rate being controlled by rate of electron transfer from metal to adjoining oxide. The first formed constant density space charge consists of electrons trapped (or electrons lost) at all available imperfection or impurity sites in the oxide, whereas the second stage corresponds to a diffuse space charge with a decreasing fraction of the available sites exhibiting charge as the oxide thickens. Electron transfer is impeded by the increasingly negative (or decreasingly positive) space charge of the oxide which grows, as calculations show, in accord with logarithmic oxidation kinetics. The formation of a diffuse space charge overlying a uniform space charge layer is accompanied by a higher oxidation rate constant because of the lower average charge density per unit oxide thickness acting to slow down electron transfer. For thickness of oxide beyond space charge dimensions, other processes become controlling such as diffusion of ions or ion vacancies through the oxide as described by Wagner (16) to account for parabolic oxidation kinetics.

The theory of logarithmic oxidation kinetics makes it possible to calculate density of imperfections in the oxide at which charge is trapped and relates activation energy for oxidation to metal work function and to electron affinity of oxygen. Information of this kind has been calculated for Cu (10) and Ni (13). The theory furthermore ascribes the observed change in oxidation rate of Ni and of alloys of Ni-Fe and Cr-Fe at the Curie temperature as being caused by changes in metal work function. Similarly the observed change in oxidation rate at the α-γ transformation temperature of iron alloys, and the variation in oxidation rate with crystal face for metals in general are ascribed to changes in work function which affect rate of electron transfer controlling the oxidation process.

The above-described theory was criticized by Fromhold (17) on several grounds, including an implied misinterpretation of Poisson's equation and our alleged ignoring of ionic transport in the oxidation process. However, Poisson's equation can be employed using any set of self-consistent boundary conditions so that our use in the equation of total oxide thickness y to calculate potential at the metal-oxide interface is not considered to be a misinterpretation. In any event, the final equation we obtain appears to be similar to that derived by Fromhold on other assumptions. Furthermore, ionic transport was justifiably ignored in our treatment because it is considered to be the faster process during initial oxidation, with electron transfer being controlling. Perhaps the main difference of Fromhold's treatment from ours is his assumption that the energy of electron transfer from metal to oxide refers only to a tunneling distance equal to the oxide lattice constant, and by further thermal excitation to a distance δ presumably as large as 50Å. In our opinion there is no physical or theoretical reason to believe that an electron entering the oxide at the metal-oxide interface cannot migrate through the conduction band of the oxide to the oxide-oxygen interface in order to ionize adsorbed oxygen, where indeed the electron must eventually go if oxidation is to proceed. In a p-type oxide, a positive hole migrates through the oxide thickness in the opposite direction. We consider that the activation energy for oxidation is equivalent to transfer of an electron from metal to oxide to oxygen adsorbed on oxide, given by $e\ (\phi - v)$ where e is the electronic charge, ϕ is the metal work function ϕ_0 modified by amount χ through contact with the oxide such that $\phi = \phi_0 - \chi$, and v is related to the electron affinity of adsorbed oxygen (approx. 3.6 ev). The total energy of electron transfer is increased by the growing more negative space charge in the oxide accounting for a decreasing oxidation rate as the oxide grows. Fromhold prefers to consider that this energy applies only over thickness δ, beyond which the electron affinity of adsorbed oxygen no longer operates. However, this assumption, besides being unjustified, leads to values of space charge density inconsistent with observed values as is pointed out in his own discussion. Hence the model he describes cannot be considered correct for oxide thickness over which the logarithmic equation applies. His treatment for growth of oxides to thickness values below the tunneling thickness may be valid, but the equations he develops apply largely to growth of air-formed films and not to films forming subsequently at elevated temperatures of the kind represented by practically all available oxidation data.

In accord with the mechanism of logarithmic oxidation kinetics previously described (10), the first stage activation energy ΔE for oxidation of metal is equal to

$$\Delta E = e(\phi_0 - \chi - v)$$

the terms of which have already been defined. For the numerical evaluation of the above expression, the published values of work function for zinc unfortunately show wide scatter. Michaelson (18) considered the average value for polycrystalline zinc to be 3.74v, but for the 0001 face it was reported to be higher, namely 4.26v (19). Since the zinc used in the present experiments was textured by the normal rolling process so that the 0001 face lay in large part parallel to the metal surface, it is probably not unreasonable to accept 4.0v as the value for the Zn sheet used at present. Inserting this number into the above equation and the value of $\Delta E = 0.34$ ev, it is found that $\chi = 0.06$ ev. This value is at best an arbitrary estimate; perhaps the only reasonable conclusion to be made is that χ is small based on values of work function reported at present. As pointed out in an earlier paper (13), the corresponding value of χ for Cu-Cu_2O coincides with the energy necessary to excite an electron from the filled band of Cu_2O to the conduction band. The same coincidence may be noted here for zinc where in this case the small value of χ is apparently the energy required to promote an electron from the donor band of the oxide to the conduction band. Values reported in the literature are 0.02-0.05 ev (20, 21).

The imperfection site density n at which electric charge is trapped in the constant charge density layer of ZnO and the corresponding maximum density n_o in the diffuse space charge layer at which charge may be trapped but not all sites of which exhibit charge, are calculated from the following relations

$$k_o = \frac{\epsilon kT}{4\pi n e^2 l}; \quad v = \frac{4\pi n e l^2}{2\epsilon} = \frac{3.6}{300} \text{ volt}$$

$$k'_o = \frac{\chi_o}{2}\left(\frac{kT}{-C_o e}\right) \text{ where } \chi_o = \left(\frac{\epsilon kT}{2\pi n_o l^2}\right)^{1/2}$$

k is Boltzmann's constant, k_o is $k_1/2.3$, k'_o is $k'_1/2.3$, T is the absolute temperature, ϵ is the dielectric constant of ZnO [approximately 10 (20, 22)], e is the charge on the electron (4.8×10^{-10} e.s.u.), l is the theoretical maximum thickness of the uniform space charge layer, $C_o = -4\pi n e l L/\epsilon - (\phi - v)$ where ϕ, v, and L have

Table II. Calculated values of charge density n in uniform space charge of ZnO, available density of sites n_o in diffuse space charge, and thickness L of ZnO at which 2nd stage oxidation begins

Temp, °C	nl, cm^{-2}	n_o, cm^{-3}	n, cm^{-3}	L, Å
125	1.3×10^{13}	5.0×10^{17}	4.5×10^{18}	13
157	0.64	1.6	1.03	26
175	0.49	0.82	0.60	34
206	0.31	0.33	0.24	53

already been defined, and $-C_o e$ is the activation energy for second stage oxidation.

Values of n and n_o are listed in Table II. It is obvious that n decreases with increase of temperature corresponding to displacement of the following equilibrium to the left

Imperfection site + free electron ⇆ bound electron

A similar apparent shift was also found previously to occur in Cu_2O based on interpretation of thin film oxidation rate data for Cu. The density n_o of available sites for trapped charge in the diffuse layer of ZnO is found to be lower than density n in the constant density layer. Perhaps only higher lying and hence fewer energy levels in ZnO are available for trapped electrons in second stage oxidation. These also decrease with increase of temperature.

The nature of donors and traps in ZnO has been discussed by several investigators at some length (20, 21, 23). The density n of traps here interpolated for the constant density space charge equal to 2×10^{17} at 200°C is certainly larger than the equilibrium concentration of excess zinc atoms in ZnO calculated by Thomas (23) from conductivity measurements (5×10^{13} extrapolated to 200°C). On the other hand, the density of traps estimated by Harrison (20) from low temperature conductivity and Hall effect measurements equal to $3\text{-}8 \times 10^{18}$ is higher, but seemingly still lower than the densities of Table II extrapolated to lower temperatures. Harrison favored oxygen vacancies or paired zinc and oxygen vacancies as contributors to available traps. Impurities, of course, may also be important and would add to other type imperfections, making the total number larger.

It is of interest to know why zinc oxidizes relatively less rapidly at above-room temperatures compared to Ni, Fe, or Cu. For example, the value of k_1 for Ni (13) at 390°C is 350Å, the extrapolated value for Cu (10) is 3650Å, but the extrapolated value for Zn is only 160Å. The oxide thickness formed after 1 hr at 200°C is 70-115Å for iron (24,25) but is only 18Å for Zn. The lower oxidation rate of Zn must be ascribed to a higher density of trapped charge in ZnO (n at 200°C = 2×10^{17}) compared for example to Cu_2O (n at 200°C = 2.5×10^{14}). The value of τ is also higher for Zn than for Cu (approximately 6 *vs.* 0.1 min). Since $\tau = (k_o/A) \exp e(\phi - v)/kT$, the higher value for Zn is related to a higher value for $e(\phi - v)$ which for Zn is 0.34 ev and for Cu is 0.28 ev, and to a lower value of A equal to 8×10^{-7} cm/sec for Zn compared to 6×10^{-4} cm/sec for Cu. The constant A enters the expression for electric current flowing across the metal-oxide interface for a given applied voltage V' as follows:

$$i = (A/\beta) \exp \frac{-e(\phi - V')}{kT}$$

where β is a proportionality constant.

Cause of Two-Stage Oxidation Behavior

Why does a metal oxidizing initially to form a uniform space charge oxide relatively suddenly oxidize at a different rate with formation of a diffuse space charge oxide? The reason apparently resides in a balance within the oxide largely between the electrostatic energy of trapped charge at favorable sites and the thermal energy tending to dissociate trapped charge. The energy of trapped electrons, for example, in the constant space charge layer is a function of the potential exerted by the metal in contact with oxide. The electrostatic energy is largest for electrons trapped in oxide near the metal surface; it becomes less in outer regions of the oxide mostly because of trapped negative charge interposed between outer and inner regions. At a critical thickness of oxide L, the electrostatic energy in the outer oxide approaches the thermal energy kT. Trapped electrons at distance L from the metal surface dissociate increasingly as electrostatic energy decreases in the growing oxide, accounting for the diffuse space charge and a higher oxidation rate constant. As has been shown by others (26), classical statistics apply to this situation.

The approximate oxide thickness L corresponding to balance between kT and the electrostatic energy of an electron in the outer oxide can be calculated from available data as follows: The potential C_o at the metal-oxide interface for an oxide of thickness L corresponding to constant density space charge, is derived in the earlier reference (10).

$$C_o = \frac{-4\pi nelL}{\epsilon} - (\phi - v) \qquad [1]$$

The value of C_o for oxide thickness less than L becomes more negative as the oxide grows. On the other hand, the potential at the oxide-oxygen interface becomes less negative as the oxide grows, and the above expression for thin oxide films becomes

$$C'_o = \frac{4\pi nelL}{\epsilon} - (\phi - v) \qquad [2]$$

Multiplying by electronic charge $-e$ and setting the above expression equal to kT,

$$L = \frac{[e(\phi - v) - kT]\epsilon}{4\pi ne^2 l} \qquad [3]$$

and since $k_o = \dfrac{\epsilon kT}{4\pi ne^2 l}$

$$L = k_o \left[\frac{e(\phi - v)}{kT} - 1 \right] \qquad [4]$$

Equation [4] indicates that the thickness of oxide L at which second stage oxidation begins depends on the initial oxidation rate constant k_o, the activation energy for first stage oxidation $e(\phi - v)$, and temperature. At 125°C, $k_o = 1.43$Å and $e(\phi - v) = 0.34$ ev; hence $L = 13$Å. This value can be compared with the empirical value 4.5Å given in Table I. Corresponding calculated values at other temperatures are listed in Table II, showing that L increases with increase of temperature, as is observed. For Cu, taking data from ref. (10), the observed values of L at 150°, 175°, 225°, and 250°C are 360, 750, 1540, and 1630Å, respectively, compared to calculated values of 600, 990, 1720, and 1510Å, respectively. Considering the approximations that are made in the calculations, and only fair reproducibility of empirical values for L, agreement with experiment is considered reasonable.

The Valency of Aluminum Ions and the Anodic Disintegration of the Metal

M. E. Straumanis and K. Poush

Department of Metallurgical Engineering and Graduate Center for Materials Research, University of Missouri at Rolla, Rolla, Missouri

ABSTRACT

It appears from coulometric measurements that Al in Al-amalgam may go into solution in basic electrolytes exclusively as a trivalent ion. Experiments made in aqueous solutions of NaOH, HNO_3, KNO_3, and $K_2Cr_2O_7$ showed that at anodic current densities between 20 and 300 ma/cm^2 dark, nearly black films, which constantly broke down, are formed on the Al electrode. Microscopic examinations revealed the presence of a multitude of metallic particles entangled in the hydrated Al-oxide flakes, causing the dark color of the latter. Depending on the conditions, the diameter of the metallic particles and leaflets varied from almost 10^{-5} to 10^{-2} mm. Such a disintegration of Al was also observed when the partially amalgamated metal merely came in contact with distilled H_2O: dark flakes of hydroxide, containing a multitude of smallest Al particles, were formed. There are indications that the disintegration of Al is caused by the forcible breakdown (*e.g.*, by the current or Hg) of the oxide layers firmly sticking to the surface of the metal. On breaking down of the film the smallest Al particles which remain on the film are torn from the meal. The observed deviation from Faraday's law and the negative difference effect, may be explained in terms of this behavior, without recourse to the hypothesis of lower valency Al ions.

The discoverer of metallic Al, Wöhler, and Buff found in 1857 (1) that, on the anodic dissolution of Al, more metal dissolved than calculated from Faraday's law (that is, from the number of coulombs which passed the anode). Since that time, the search for the reasons for this deviation has continued. Wöhler himself rejected the idea that Al could initially go into solution as an ion of lower valency, *e.g.*, in the form of Al^+

$$Al \rightarrow Al^+ + e \qquad [1]$$

because he could not synthesize Al-lower valency compounds. However, on the assumption that Al^+ is very unstable and immediately reacts outside the anode

$$Al^+ + 2H^+ \rightarrow Al^{3+} + H_2 \qquad [2]$$

the deviation from Faraday's law can well be understood. Therefore, no Al^+ ions are expected to be present in the solution after electrolysis. However, the idea of lower valency ions became less probable when it was found that a dark gray deposit was observed in the electrolyte, especially in the presence of oxidizers (3). It has been assumed for quite a while that the gray color of the deposits is due to metallic Al formed by a disproportionation reaction

$$3Al^+ = 2Al^o + Al^{3+} \qquad [3]$$

Just as in the case of Be (4, 5), reaction [3] appears to be highly improbable; it assumes growth of Al particles in an aqueous solution from nuclei free from an oxide layer. Nevertheless, Al was found later in anodic deposits by Plumb (6). Although he rejected the formation of Al according to reaction [3], he did not mention anodic disintegration, which might well have provided an explanation. Aluminum in anodic deposits and films was also found by McCune (7) and Dmitriev *et al.* (8). Formation of comparatively large, quite regular Al blocks by dropout from an Al piece dissolving in HCl was observed by Roald and Streicher (9).

The reducing power of the anolyte was investigated by many authors (10-16). However, the possibility that the Al particles themselves (rather than Al^+) could act as reducers, was not considered until recently (2).

The intention of the present article is to show that Al during anodic dissolution partially disintegrates into particles and leaflets of irregular shape embedded in an oxide layer, that the particles are much smaller than the blocks previously observed (9), that disintegration of Al also occurs while it is reacting with

H_2O in the presence of Hg, and that Al goes into solution only as Al^{+3} ion.

Anodic Disintegration of Al

Disintegration experiments were made in solutions of NaOH, HNO_3, KNO_3, and $K_2Cr_2O_7$ as electrolytes.

NaOH.—In 1*N* NaOH the Al electrode (99.99% pure) dissolved slowly, evolving H_2 according to the reaction

$$Al + OH^- + H_2O = AlO_2^- + 1.5H_2 \qquad [4]$$

As soon as the switch connecting the Al with the Pt electrode through the battery and resistance was closed, the self-dissolution rate of the Al anode dropped (positive difference effect), and H_2 was evolved on the Pt (17). At anodic current densities between 20 and 300 ma/cm the Al surface became black, and black flakes fell to the bottom of the beaker. The flakes were rinsed in distilled water, then treated with acetone and collected on a slide for microscopic examination. Only at high magnifications, about 1500X, using oil immersion objectives and reflected light, bright shiny metallic particles of various sizes could be seen in a milky looking layer of Al oxide beta trihydrate, as revealed by x-ray powder patterns. The shape of the particles was irregular (Fig. 1). In transmitted light, the same particles were opaque, thus establishing their metallic nature. The black color of the anodic flakes was caused by the presence of the finely divided metal in the oxide layer, in agreement with the theoretical expectations of Ketelaar (18).

HNO_3.—Al does not dissolve in this acid because of formation of a tight oxide layer on the surface of the metal. However, an anodic current of about 300 ma/cm^2 produced in 0.25*N* HNO_3 results similar to those in NaOH. Gray clouds of particles and flakes fell to the bottom of the beaker from the dark anode surface under slight gas evolution at the electrodes. Ultrasonic vibrations of the electrolyte accelerated the breakdown of the flakes. The finest particles dissolved slowly in the HNO_3. Microscopic examination of the flakes revealed groups of fine particles and of objects with plane surfaces having a bright metallic luster, embedded in a milky substance (Fig. 2), which consisted of aluminum oxide. The large plane surfaces exhibited tiny dark spots.

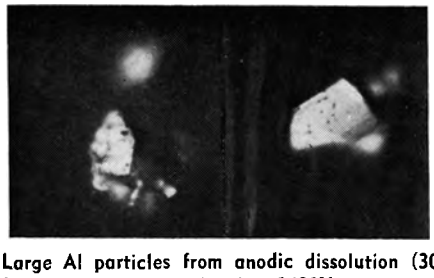

Fig. 2. Large Al particles from anodic dissolution (300 ma/cm) of Al in 0.25*N* HNO_3. Magnification 1430X.

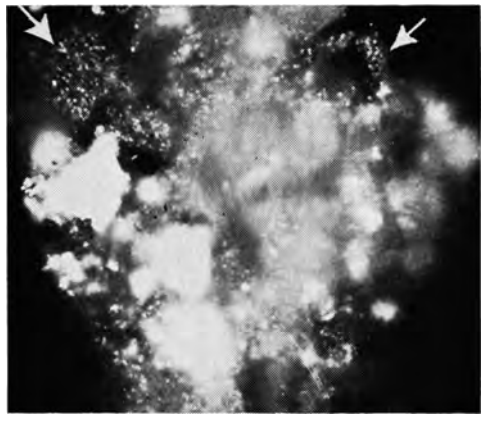

Fig. 3. Bright Al particles, small (arrows) and large ones (with plane surfaces) formed anodically in 3% KNO_3, embedded in Al-oxide. Magnification 1430X.

Fig. 4. Electron micrographs of Al particles formed during anodic dissolution of an Al anode in 3% KNO_3. Round objects are latex spheres. Magnification 2700 to 10000X.

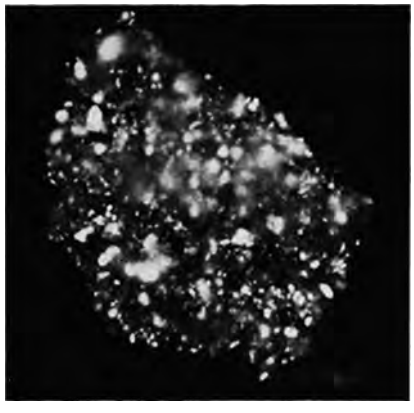

Fig. 5. Al hydroxide flakes containing metallic Al particles formed during anodic dissolution of Al in 3% $K_2Cr_2O_7$. Reflected light. Magnification 1430X.

3% Aqueous **KNO_3.**—Al anodes in this electrolyte behaved very similarly; except that the white oxidic material was more abundant (Fig. 3). To study the shape of the particles, electron microscopic pictures were made. The collected flakes were suspended in ethyl alcohol with an ultrasonic vibrator, and then drops of the suspension were allowed to dry on a small piece of a 200 mesh Cu screen. The magnification was determined from the size of latex spheres which had a diameter of 0.557μ. As can be seen from Fig. 4, the particles look like leaflets torn off the Al surface.

3% **$K_2Cr_2O_7$** *aqueous solution.*—In this solution, the initial current dropped very quickly from 150 to 2 ma, but on adding a few ml of 1*N* NaOH to the solution, a current of 3 ma could be maintained for about 1 hr. Black, finely divided particles accumulated beneath the anode. The microscope revealed aggregates of shiny particles held together by a thin network of Al oxide or hydroxide (Fig. 5). X-ray diffraction patterns

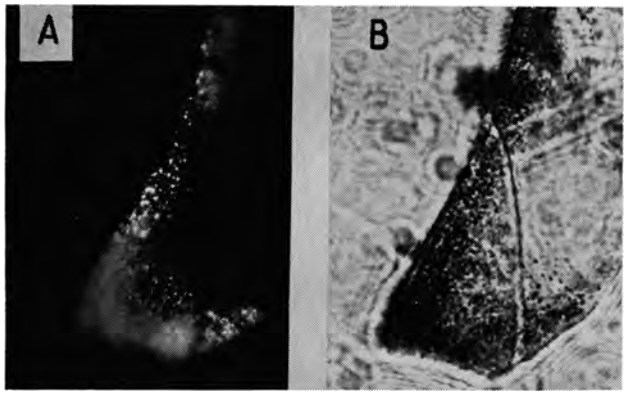

Fig. 6. Al particles embedded in a bayerite flake; particles formed due to disintegration of Al in presence of Hg during reaction [5]. A—in reflected and B—in transmitted light. Magnification 1430X.

showed the presence of faint 200 and 111 lines of metallic Al in addition to the usual oxide pattern.

Disintegration of Al *in* H_2O *in Presence of* Hg

It was observed that on Al pieces (wire or foil) floating on Al-amalgam under distilled H_2O, some dark gray substance was formed around and on the unamalgamated portions in about 0.5 hr. The H_2 (no current was applied) developing according to the reaction

$$Al + 3H_2O = Al(OH)_3 + 1.5H_2 \qquad [5]$$

partially carried the dark gray particles to the water surface. However, particles of gray color did not form after complete amalgamation of the pieces. Large quantities of fluffy, white hydrated Al oxide beta trihydrate (bayerite), as revealed by x-ray diffraction pictures, were also obtained as a consequence of reaction [5]. The nearly black material was carefully removed with a suction tube to avoid mixing with the white oxide and was examined with an optical microscope after drying. Bright spots with metallic luster of the magnitude of about 10^{-5} mm in diameter, embedded in the oxide flakes, appeared in reflected light. The spots became opaque in transmitted light (Fig. 6). Furthermore, as the particles were flat and faded in time, they could only be of metallic Al. These results show that Al can also disintegrate in the presence of Hg.

Trivalency of Al *Ions from Coulometric Measurements*

Clearly, the observed anodic disintegration of Al causes a deviation from Faraday's law. Hence, it may be that Al goes into solution only in form of Al^{3+} ions. In order to test this hypothesis, coulometeric experiments were undertaken by a technique similar to that used with Ga (19): Al amalgam was chosen as an anode. The amount of Al that went anodically into solution was determined by titration with EDTA (20). The apparent valency V of Al ions could then be calculated from Eq. [6] in which a is the number of coulombs

$$V = a/A \text{ (moles)} \times 96490 \qquad [6]$$

However, because H_2 developed in acids on the Pt cathode, as well as in small amounts on the amalgam (self-dissolution), only alkaline solutions (1.0 or 0.1*N* NaOH or KOH) were used, as the self-dissolution rate was much lower there. The anodic dissolution follows the reaction

$$Al + 4\,OH^- = AlO_2^- + 2H_2O + 3e \qquad [7]$$

Aluminates (soluble) are formed at the anode and H_2 is developed at the Pt cathode. Results are given in Table I. The apparent valency fluctuates from measurement to measurement and occasionally approaches 3. The factors which cause the deviation from three are the self-dissolution rate which lowers the apparent valency, and the disintegration of Al. Since the metal floats on the Hg surface (but under the electrolyte) and becomes locally quite "dry" of Hg, disintegration of Al occurs as already mentioned. Experiments with thin amalgamated Al foils which nearly dissolved in Hg gave apparent valencies of 2.93, indicating that there was a minimum of disintegration. Thus, measurements in strong bases are consistent with the assumption that Al goes anodically into solution only as Al^{3+}. The same may also occur in acids, although this is not directly provable.

Table I. Valency of Al ions anodically dissolving from Al amalgam in basic solutions

Electrolyte	Coulombs	Moles Al	*V*, apparent
KOH, 1*N*	27,680	0.1025	2.80
KOH, 1*N*	34,310	0.1241	2.86
KOH, 1*N*	41,855	0.1511	2.87
KOH, 1*N*	30,200	0.1094	2.86
NaOH, 0.1*N*	9,992	0.0352	2.94
NaOH, 0.1*N*	9,705	0.0411	2.45
NaOH, 0.1*N*	24,611	0.0940	2.71
NaOH, 0.1*N*	11,553	0.0450	2.66
NaOH, 0.1*N*	9,992	0.0343	3.02

Discussion and Conclusions

Since the apparent valency lower than 3 may be accounted for by the facts just mentioned, it is unnecessary to assume the formation of lower valency Al ions, either from amalgam or from a pure Al anode.

The presence of metallic Al was also previously found in the anodic flakes (6-8). However, nobody observed the very fine particles (down to about 5 x 10^{-5} mm in diameter) in the deposits, only occasional large chunks and the cubes as found by Streicher *et al.* (9). The mechanism of formation of these entities is, however, quite different from the disintegration described in this paper, because all the particles observed here were embedded in a film consisting of Al oxide (Fig. 3, 5, 6), mainly beta bayerite (21). In NaOH as an electrolyte these oxides dissolve and the particles may appear free (Fig. 1).

The mechanism of formation of such particles is, therefore, as follows. If an active metal (Al) is anodically polarized in aqueous solutions, the oxide film present can thicken. The composition and, therefore, the properties of these films will depend largely on the electrolyte and the applied voltage (22). For one or another reason, these films do not cover the metal anodes uniformly and the anodic current will follow the path of least resistance. At places where the film is thin, or not formed at all (*e.g.*, on inclusions), the current density will be high and anodic dissolution will occur around such high resistance spots, undermining them. After some time, the respective spots, still containing some metal adhering to the protective layer, may drop out. If the protective film is not dissolved by the electrolyte, the metallic particles will appear embedded in the film. Of course, the ions going anodically into solution exert some pressure on the oxide layer and aid the separation. The shape of the metallic particles must, therefore, be irregular and of various sizes as determined by the places of least resistance of the adhering film. This conclusion is confirmed by Fig. 3, 4, and 5. A new oxide film is formed on places where the metal dropped out and the drop-out can occur again after some time. It is clear that with such a mechanism of disintegration, its rate and the particle size and shape will depend on the composition of the electrolyte, temperature (4), and current density (23). In electrolytes which do not further formation of strongly adhering protective films, there may be, with other reasons also excluded, no anodic disintegration at all.

The disintegration of Al, partially amalgamated, proceeds in H_2O in a similar manner: Hg atoms spreading between the oxide film and the metallic surface forcibly loosen the former. The film, on breakdown, takes with it tiny Al particles cracking off the bulk material, as they stick firmly to the film (Fig. 6).

These particles cause the nearly black color of the flakes (18) separating from Al or other metals (4, 5, 23, 24). If the particles are well protected by a film from the action of H_2O, as in case of Al embedded in bayerite, the residue keeps its dark color even in water for a comparatively long time (several days), but where the protection is weak, as with Mg, the dark flakes become white in the presence of moisture much faster (24).

The reducing ability of the anolyte, or of parts of the electrolyte in close vicinity to the anode, is explained simply by the action of the fine metallic dispersion of the active metal coming in contact with an oxidizer, which may be added to the electrolyte, or which may be the solvent itself, *e.g.*, H_2O. In fact, metallic dust (*e.g.*, of Al, Zn, Fe, etc.) is well known as a reducer of organic substances. Whether this reduction proceeds indirectly through the atomic H formed (25) or directly by transfer of the valence electrons from the metal is of lesser importance. The question how this transfer occurs, whether all 3 electrons pass over to the oxidizer molecules simultaneously or in succession, is also insignificant, because at present there is no possibility to check the guess anyway.

Acknowledgment

This investigation was supported by the Office of Naval Research and also partially by the Corrosion Research Council. The authors would like to thank Mr. J. A. Rowland, Director of the U.S. Bureau of Mines at Rolla and Mr. J. W. Jensen for the permission to use the electron microscope of the Bureau.

Manuscript received Jan. 22, 1965; revised manuscript received July 22, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Low-Energy Electron Diffraction Studies of Oxygen Adsorption and Oxide Formation on a (001) Iron Surface

A. J. Pignocco and G. E. Pellissier

Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania

ABSTRACT

The technique of low-energy electron diffraction (LEED) has been used to study oxygen adsorption and oxide formation on a (001) surface of iron. The LEED data indicated that the atomically clean iron (001) surface was an unreconstructed surface. The chemisorbed oxygen layer formed on exposing the clean face of iron to very low oxygen partial pressures consisted of half a monolayer of oxygen atoms arranged in a Fe (001) c(2x2)-O two-dimensional array. With continued oxygen exposure and annealing, a thin layer of FeO was observed to form on the iron crystal with its (001) face oriented parallel to the (001) face of the iron substrate, and with the [110] direction of the FeO parallel to the [100] direction of the iron. These FeO films that were formed and maintained at very low oxygen partial pressures were stable at room temperature.

A thorough understanding of the oxidation behavior of a metal requires a careful study of the manner and rate of growth, the composition, the character, and the structure of the oxide phase from its initiation as a chemisorbed layer to the formation of the thick bulk oxide. Much of the work dealing with the oxidation of metals has been directed toward achieving a better understanding of the formation of thick oxide layers. Vacuum microbalance measurements, transmission and reflection electron microscopy, optical methods, and x-ray and electron diffraction techniques have been utilized successfully in studying this phase of the oxidation process. Despite the great interest in the initial stages of oxidation, studies of the character and mode of growth of the chemisorbed layer, and the subsequently formed very thin oxide layer, have been largely neglected because of the lack of experimental techniques capable of providing such information. Most classical studies of chemisorption have consisted of determinations of adsorption isotherms and isobars, which involve measurements of the quantity of gas taken up or measurements of the changes in various

physical properties of the metal surface that occur as the chemisorption proceeds.

Relatively little has been reported on the arrangement of surface atoms of the metal, or about the conditions and cleanliness of the surfaces under investigation. Although it was well-known since the early Davisson-Germer experiments (1, 2) that low-energy electron diffraction (LEED) is well suited to such studies, only Farnsworth (3-9) and his associates extensively applied the technique to surface and gas sorption studies. Recently Germer (10), Lander (11), and others have perfected a much simpler and more rapid LEED technique. The method, first devised by Ehrenberg (12) in 1934, displays the diffraction pattern of a fluorescent screen. This diffraction pattern can be observed and measured directly, or photographed from the screen for permanent record. In addition to ease of experimentation, this method permits direct observation of many detailed features of a rapidly changing diffraction pattern. Thus, utilizing this improved technique Germer (13-15), MacRae (14, 15), Lander (16-18) and others have generated, in a relatively short time, large amounts of information on the manner in which several kinds of foreign atoms stick and arrange themselves on different faces of many crystalline solids.

This paper describes the results of a LEED study of chemisorption of oxygen on a clean (001) face of a high-purity iron crystal and the subsequent formation, epitaxy, and stability of the thin oxide phase formed under very low oxygen partial pressures.

Material and Experimental Work

Material.—Because the effects of many of the impurity elements found in iron on the oxidation behavior are not well understood, several specimens of the highest purity iron available were used in this investigation. It was possible to achieve an atomically clean surface only on a crystal having a very low carbon content (14 ppm). This was an iron sample obtained from Battelle Memorial Institute in the form of a small polycrystalline section of zone-refined ingot. The analysis of this iron, presented in Table I, indicated that the material had a maximum purity of 99.94%. Other iron specimens, containing carbon in concentrations exceeding 30 ppm, could not be cleaned by conventional techniques. A similar deleterious effect of carbon in the preparation of an atomically clean surface also was encountered by Farnsworth (19) in earlier work on nickel.

Table I. Purity of the iron foil used in the oxidation study (Solids mass-spectrographic analysis)*

Impurity	Parts per million present (1 ppm = 0.0001%)
Arsenic	13
Boron	12
Calcium	2.5
Carbon	14
Chlorine	12
Chromium	19
Cobalt	53
Copper	102
Gallium	50
Germanium	30
Magnesium	5
Manganese	20
Nickel	42
Nitrogen	3
Oxygen	19
Phosphorus	55
Potassium	<20
Silicon	101
Sodium	<20
Sulfur	34
Zinc	2.5
All others**	<0.2-0.7

Maximum purity = 99.941% Fe.
* After all treatments prior to crystal-growing operation.
** Only H, He, Li, Be, F, Al, C, N, and O are not detectable by this method. Of these, C, N, and O were determined by a vacuum-fusion method, while the others are believed to be present in insignificant amounts.

Preparation of the (001) iron crystal surface.—The iron specimen used in these LEED experiments was in the form of a thin platelet (1.0 by 0.5 cm in cross section, and 0.04 cm thick) that consisted of a bicrystal. This bicrystal was prepared from a piece of the polycrystalline Battelle iron by the strain-anneal method. The platelet was oriented and thinned mechanically, ground on a series of successively finer grit emery papers, and then fine-polished with levigated alumina on rotating laps; the polished surface was parallel to the (001) crystal face of one of the grains to within 1 degree. The polished platelet was mounted on two 0.020-in.-diameter clean tungsten support rods, electropolished, washed in absolute methanol, thoroughly dried, and sealed into the LEED tube with the [001] direction of the crystal aligned approximately parallel to the drift tube axis of the electron gun. After the LEED tube was evacuated and "baked out," following conventional ultra-high-vacuum techniques, the residual gas pressure was about 5×10^{-10} Torr.

LEED apparatus.—The LEED apparatus used was of the display type described by Germer *et al.* (10); it had an acceptance angle of approximately 70°, and utilized a planer grid and fluorescent screen assembly. The tube envelope was fabricated of 100-mm OD Pyrex glass tubing, and formed an integral part of an ultra-high vacuum system. Figure 1 is a schematic diagram of the LEED apparatus, showing the fluorescent screen assembly, the iron crystal, and the sputter gear assembly. The energy of the incident electron beam was varied over the range of 50 to 350 ev.

Cleaning of the iron (001) face.—Although a surface prepared by electropolishing has been described as atomically smooth, with relatively little oxide overgrowth, chemisorption studies require that the surface under investigation be atomically clean at the outset. Among the most successful surface cleaning techniques employed by Germer (14), Lander (16, 17), and Farnsworth (19) in their LEED experiments were (*i*) extended high temperature annealing under ultra-high vacuum conditions, (*ii*) alternate oxygen-hydrogen treatments, and (*iii*) low-energy argon ion bombardment. Because high temperature annealing or the oxygen-hydrogen treatments either destroy the single crystal nature of the iron specimen or produce a very unsatisfactory, rough surface, the technique of low-energy argon ion bombardment was used in preparing atomically clean surfaces for these LEED experiments. The (001) iron platelet was subjected to repeated ion bombardment for times ranging from 30 to 60 min. An argon discharge voltage of from 50 to 200v was maintained between the crystal and an anode. The current density at the crystal face was maintained near 50 μamp/cm^2. After bombardment, the LEED tube was evacuated, and the crystal was annealed in high vacuum at 500°C for periods of time ranging from 5 to 15 min. Several such ion bombard-

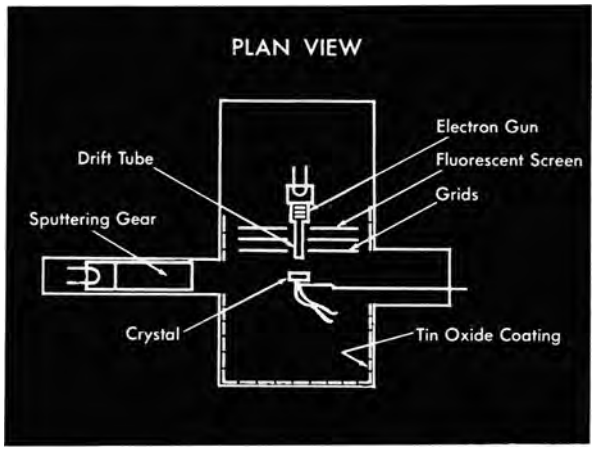

Fig. 1. Schematic diagram of LEED tube

ment-annealing cycles were usually required to prepare a clean (001) crystal face.

LEED nomenclature.—In the energy range of from 50 to 300 ev, the diffraction of electrons from diperiodic surface structures is of paramount importance. Because the arrangement of sorbed atoms on a surface often is related to that of the atoms in a parallel crystal plane of the substrate, a convention of terminology for LEED has been proposed by Wood (20) in which a surface structure is described in terms of a substrate cell; that is, the diperiodic structure of the substrate surface, which initially is known, is taken as the base of reference. In such a diperiodic structure, equivalent points form two-dimensional nets in which the unit areas are unit meshes. A surface structure with the identical mesh of the substrate is then denoted a (1 x 1) mesh; one with its sides equal to twice those of the substrate and with the same orientation as the substrate, a (2 x 2) mesh. A prescript (p) denotes a primitive mesh; and when a mesh contains a centered atom, a (c) precedes the description of the mesh.

For a more complete identification of the structure, Wood further suggests that this term be preceded by the name and orientation of the substrate and followed by the chemical symbol of the sorbed layer. Other notations, such as Miller indices of reflections and indices of a crystallographic direction, generally follow the triperiodic conventions, with the omission of the final index. Such terminology is used to describe the LEED patterns and structures observed in this study.

Observation of Laue diffraction beams.—Under the experimental conditions used in this study, all the sets of diffraction beams obtained from an atomically clean (001) face of iron appear in either the [10] or [11] azimuths. The [10] azimuth beams lie in the planes containing the incident beam and the [100] or the [010] crystal directions; the [11] azimuth beams appear in the planes containing the incident beam and the [110] or [$\bar{1}$10] crystal directions. The first experiments on the clean (001) iron face were made to locate the positions of the LEED beam maxima. The wavelength of the incident beam was varied from 0.6 to 1.6Å, while the azimuths were scanned for beam maxima. When a set of diffraction beams reached maximum intensity, the LEED pattern on the fluorescent screen was photographed, and the electron beam energy was measured to the nearest volt. In addition to these data, a more complete analysis of these beams, revealing the fine structure in the maxima, was desired; for this purpose, a photometer was used to monitor and measure the relative intensity of the 10 diffraction feature as the wavelength of the incident electron beam was varied over the experimental voltage range.

Chemisorption of oxygen on the iron (001) face.—The identification of the two-dimensional lattice structures obtained on exposing the clean (001) crystal face to oxygen for different times and pressures was objective of this series of experiments. The crystal platelet at room temperature was exposed to oxygen at pressures ranging from 1 x 10^{-8} to 5 x 10^{-8} Torr for periods of time ranging from 15 to 60 sec. The exposures (product of time and pressure) were varied from 1.5 x 10^{-7} to 30 x 10^{-7} Torr-sec. After each exposure, the screen was scanned for new diffraction features.

Oxide formation on the iron (001) surface.—According to work reported in the literature (21), the relatively fast chemisorption of oxygen on iron at room temperature is followed by a slow stage that corresponds to the nucleation and growth of crystalline oxide. Nucleation of the oxide has an activation energy that can be overcome by increasing the oxygen pressure. The process of growth of nuclei into a crystalline oxide film also involves an activation energy. This latter activation energy can be overcome by increasing the temperature of the specimen; that is, oxide crystal growth can be facilitated by promoting diffusion of the iron ions to the nucleation sites by annealing the crystal in an ultra-high vacuum after a suitable oxygen exposure. After an oxygen exposure of 55 x 10^{-6} Torr-sec, the LEED features obtained from the (001) surface of an iron crystal were weak and poorly defined. A well developed oxide phase was obtained, however, by subsequently annealing this crystal at 550°C under ultra-high vacuum conditions. The resultant LEED patterns were photographed, and the relative intensity-voltage data were obtained for the 10 beam.

Stability of FeO.—Much of the reported data (22-26) on the wüstite-magnetite transformation ($4FeO \rightleftarrows Fe_3O_4 + Fe$) were obtained under relatively high oxygen partial pressures. The studies generally were performed at the prevailing atmospheric pressures, or under relatively poor vacuum conditions. It was concluded from these data that FeO transformed to Fe_3O_4 at temperatures below 570°C. Gulbransen *et al.* (22) noted some retardation of this transformation with lower oxygen partial pressures; at oxygen pressures near 10^{-6} Torr, the presence of FeO on an iron substrate was observed at temperatures as low as 412°C. An extension of this work to much lower oxygen partial pressures (less than 10^{-10} Torr) was included in this phase of the present LEED study. An iron crystal surface covered with a thin layer of FeO was annealed for 65 hr at each of three temperatures under ultra-high-vacuum conditions, that is, at 480°C [the temperature at which Chaudron and Forestier (26) reported the decomposition rate to be at a maximum], at 100°C, and at room temperature. The LEED patterns and intensity-voltage relationships were determined before and after each experiment.

Results and Discussion

The Clean Iron (001) Crystal Face

Alpha-iron has a body-centered-cubic structure with a lattice constant a_o = 2.86Å. Figure 2 is a solid sphere model of the atomic arrangement in the (001) face of iron. The unit cell of iron is outlined by the square near the top of the figure, and the principal azimuths of the (001) face, that is the [10] and [11] azimuths, are depicted by arrows in the lower part of the figure. The LEED patterns presented in this paper can be brought into register with Fig. 2 by rotating them approximately 5° in a counter-clockwise direction.

The first argon-ion bombardment-annealing cycle sequence did not produce a clean iron surface. A photograph of a LEED pattern taken at 102 ev at this stage of the cleaning process is reproduced in Fig. 3. In addition to the integral-order features in the [10] and [11] azimuths, bright and sharp half-order features {½ ½} were observed. This LEED pattern has been interpreted in terms of a 2-dimensional (2-D), centered two-by-two structure (Fe(001) c(2 x 2)—?).

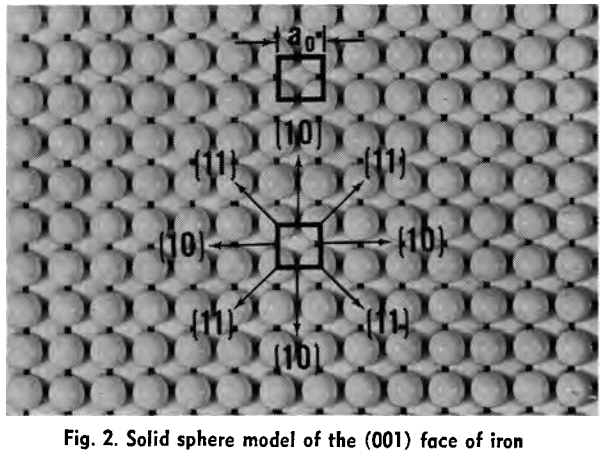

Fig. 2. Solid sphere model of the (001) face of iron

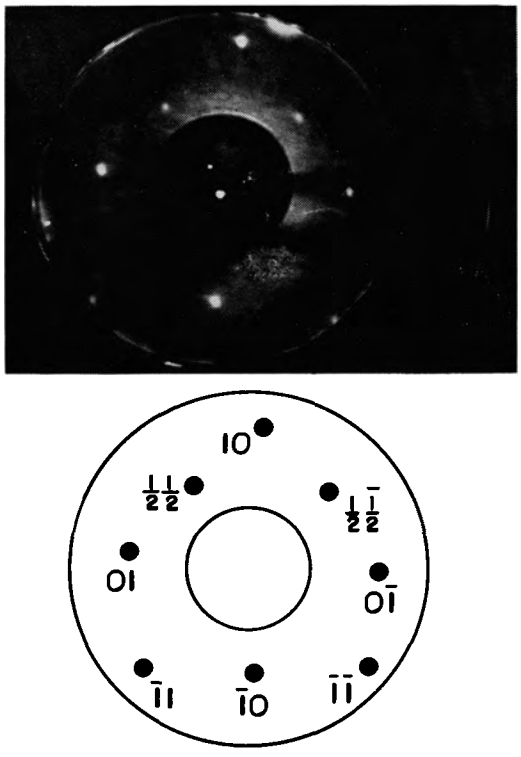

Fig. 3. Photograph of LEED pattern of a contaminated iron surface. The wavelength of the incident electron beam was 1.21Å.

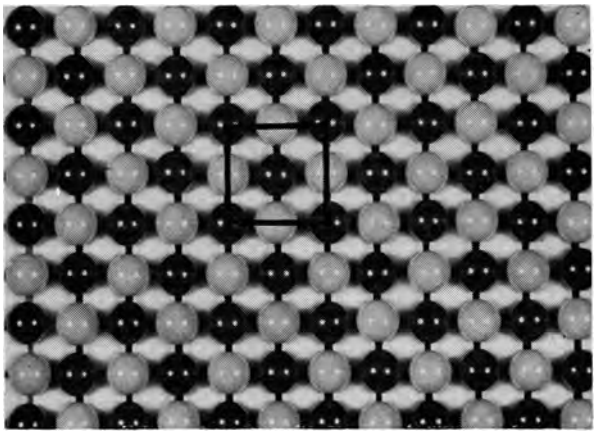

Fig. 4. Suggested solid sphere model of a Fe(001) c(2 x 2)—? structure.

This structure, according to LEED nomenclature, is a superposed net consisting of foreign atoms situated at the corners and at the center of a 2-D mesh. The sides of the mesh are equal to twice the length of the unit mesh of the substrate (iron) with the same orientation as the substrate. The relatively high intensity and sharpness of the half-order beams as compared to that of the integral-order features further suggests that this structure consists of a full monolayer of atoms containing both iron atoms, which occupy the open positions in the c(2 x 2) mesh, and impurity atoms. A suggested model of this structure is illustrated in Fig. 4. The dark spheres represent the impurity atoms and the light spheres the iron atoms. The 2-D unit mesh is outlined in this figure.

Repeated application of low-energy, argon-ion bombardment and annealing removed all fractional order features from the LEED pattern. Figure 5 is a photograph of the LEED maxima in the [10] azimuths obtained at 104 ev from a clean (001) iron surface, where only the integral-order features expected for a clean iron (001) surface, Fe (001) p(1 x 1), are evident.

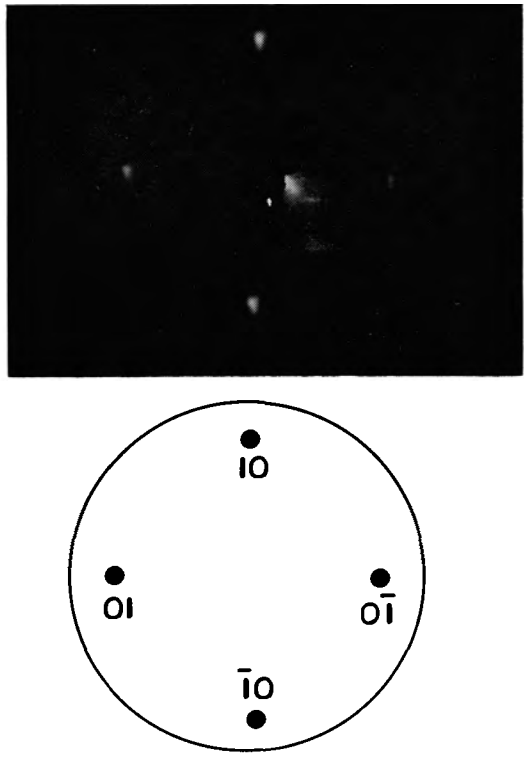

Fig. 5. Photograph of a LEED pattern of a clean iron surface. The wavelength of the incident electron beam was 1.20Å.

All LEED beams back-reflected from a clean iron (001) surface under the conditions of these experiments appear in either the [10] or the [11] azimuths. The surface diffraction grating relationships that apply in these azimuths are

$$\lambda = 2.86 \operatorname{Sin} \phi \text{ (for the 10 reflections)} \quad [1]$$

$$\lambda = 2.03 \operatorname{Sin} \phi \text{ (for the 11 reflections)} \quad [2]$$

These relationships plot as straight lines in Fig. 6, and the calculated positions of the intensity maxima (Laue beams) as deduced from simple kinematic diffraction theory are plotted as circles. The experimental data consisting of the applied electron accelerating voltages and measurements of the resulting LEED patterns (Fig. 5) appear as squares. The relative intensity-voltage data for the 10 beam from a clean iron surface are plotted in Fig. 7. The positions of the Laue beams appear on this plot as inverted arrows. The differences between the experimental and the calculated values of the wavelengths of the beam maxima have been attributed to the interaction of the

electron beams with electrostatic fields existing within the crystal surface, causing refraction of the diffracted beams (the wavelength of the electron beam within the crystal is not the same as that in vacuo outside the crystal), and consequent displacement of the diffraction maxima. These considerations indicate, therefore, that the wavelength characteristic of a diffracted beam is more accurately represented as $[150.4/(V + \psi)]^{1/2}$, where V is the accelerating voltage for the incident electron beam in vacuo and ψ is the inner potential of the surface.

The experimentally observed maxima, appearing at 106 and 210 ev in Fig. 7, are in agreement with the calculated Laue beams (arrows), if an average value of 23v, uncorrected for contact potential, is assumed for the inner potential of this surface. The smaller peaks and/or shoulders appearing at the calculated Laue beam positions, 124 and 230 ev, respectively, generally have been attributed to the interaction of surface beams diffracted from steps on the crystal surface. Because under these conditions the beams do not penetrate into the surface, no inner potential shift is expected. It was concluded from these data, the sharpness of the diffraction features, and the relatively low background, that this surface was clean and that a clean (001) iron surface is an unreconstructed surface; that is, the clean (001) iron surface consists of iron atoms in the positions expected of a mathematical model of atoms arranged in a (001) surface of a body-centered cubic lattice.

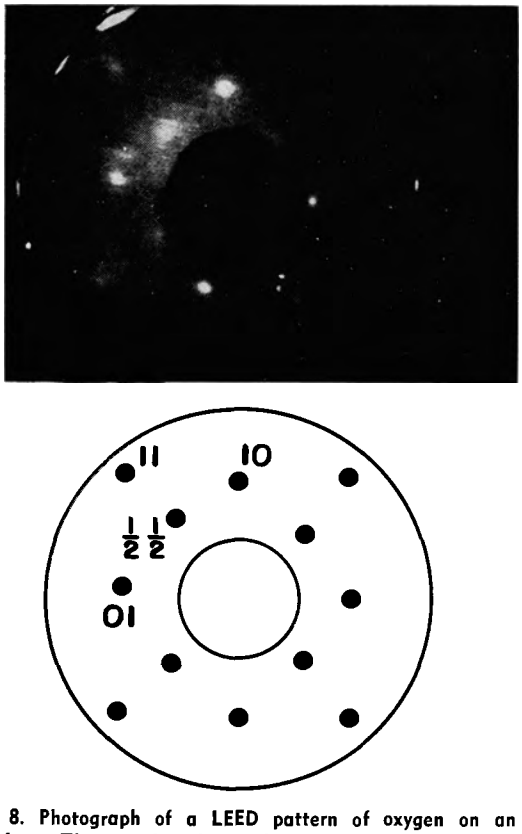

Fig. 8. Photograph of a LEED pattern of oxygen on an iron (001) face. The wavelength of the incident electron beam was 1.03Å.

Chemisorption of oxygen on a clean iron (001) surface.—The first experiments performed on the clean iron surface consisted of the observation and interpretation of LEED patterns obtained on exposure to low pressures of oxygen at room temperature. The initial, relatively slight oxygen exposure (1.5×10^{-7} Torr-sec) served only to weaken somewhat the clean iron surface diffraction features. After a greater exposure of 5×10^{-7} Torr-sec, a weak pattern characteristic of a 2-D, Fe(001) c(2 x 2)-O was observed. This c(2 x 2) pattern reached maximum intensity after an exposure of about 8×10^{-7} Torr-sec. A photograph of the pattern, taken at 140 ev, is presented in Fig. 8; the diffraction features are identified according to their 2-D Miller indices. A photograph of the proposed model of this c(2 x 2) structure, deduced from the LEED pattern, is shown in Fig. 9. The dark spheres represent the chemisorbed oxygen atoms in the top layer; the 2-D unit mesh of the oxygen lattice is outlined in this photograph.

The relatively low intensities of the half-order features, ½ ½, compared to those of the features attributable to the iron substrate 10, suggest that the top surface immediately after an oxygen exposure of 8×10^{-7} Torr-sec probably consists of half a monolayer of chemisorbed oxygen arranged in a c(2 x 2) structure (rather than a full monolayer) containing both iron atoms and oxygen atoms. From these data and the calculated number of oxygen molecules that struck the surface during the exposure, it was evident that essentially every molecule of oxygen that struck the surface dissociated into atoms and was chemisorbed on the surface.

Oxide formation on the iron (001) face.—On further exposure to oxygen at room temperature, the intensities of the beams from the c(2 x 2) structure gradually weakened, with an accompanying increase in background intensity. Also the intensity-voltage relationships for the 10 feature became more complicated with continued exposure. After an exposure of 55×10^{-6} Torr-sec, no diffraction beams were discernible on the screen. However, as a result of a subsequent ultra-high vacuum anneal at 550°C, LEED patterns were obtained that exhibited integral order features only in the [10] and [11] azimuths, and corresponded to the calculated pattern of FeO. The formation of

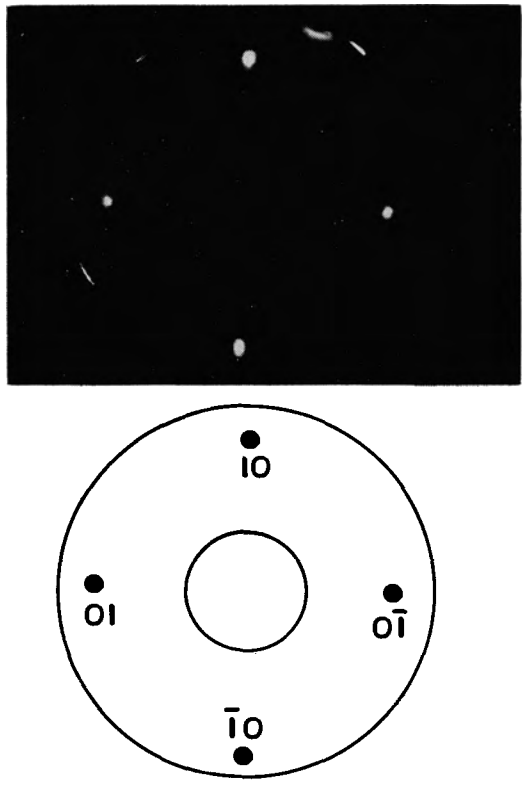

Fig. 10. Photograph of a LEED pattern of iron oxide (FeO) on an iron (001) face. The wavelength of the incident electron beam was 1.33Å.

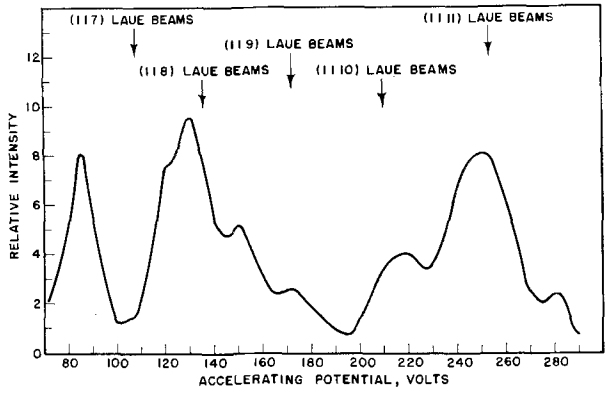

Fig. 11. Relative beam intensity-voltage data for the 10 reflection from a FeO (001) surface.

FeO also was observed to occur at room temperature and very low oxygen partial pressures on a clean (001) face of iron that had been allowed to dwell in an ultra-high vacuum for an extended period of time (~5 days). A photograph of a typical LEED pattern of FeO obtained at 85 ev after an oxygen exposure of 55 x 10^{-6} Torr-sec and subsequent anneal is presented in Fig. 10. The intensity-voltage relationships for the 10 feature are plotted in Fig. 11. The voltages for occurrence of intensity maxima, calculated from a simplified model of FeO (lattice parameter $a_o = 4.32$Å) oriented on the iron substrate with its (001) face parallel to the (001) face of the iron, and with its [110] direction parallel to the [100] direction of iron, are indicated by the arrows.

The maxima appearing at 85 and 150 ev correspond to (117) and (119) Laue beams, respectively, which have been displaced toward lower voltages by approximately 23v, the assumed inner potential of the surface. No correction for the contact potential was employed in these calculations. The large peak appearing at 250 ev is attributed to the (1 1 11) Laue beam, and the smaller peak appearing at 172v, to coherent diffraction from surface steps in the oxide. The intensity maxima observed at 130 and 220 ev, respectively, occur near the voltages calculated for the "forbidden" (118) and (1 1 10) reflections. Because electron scattering phenomena in the low energy range are imperfectly understood, this analysis represents only a first approximation in the calculation of the positions of the occurrence of the intensity maxima. Thus, it is perhaps not surprising that more maxima are observed than can be accounted for by this simple treatment.

Stability of FeO

The thin film of FeO formed on the (001) face of iron was annealed at each of three temperatures (25°, 100°, or 480°C) for 65 hr, at oxygen partial pressures below 10^{-10} Torr. The LEED patterns and the voltage-intensity relationships for the 10 feature, before and after annealing, were identical. Additional features expected for a cubic oxide, such as Fe_3O_4, were not observed under these conditions. Thus, it is concluded that the FeO film, formed and annealed at oxygen partial pressures below 10^{-10} Torr, did not transform to Fe_3O_4, and probably continued to grow as FeO. No evidence of transformation of the FeO to Fe_3O_4 was observed at these low oxygen partial pressures.

There are at least two explanations for this observed stability of FeO. The first assumes that the reaction, 4 FeO $\rightleftarrows$ Fe_3O_4 + Fe, takes place. The equilibrium constant for this reaction calculated from properties of bulk oxide, prepared and investigated at atmospheric pressure, predicts that FeO is unstable at temperatures below 575°C. Gurry and Darken (27), in their investigations of FeO at elevated temperatures, indicated, however, that the free energy of FeO was dependent on oxide composition (that is, on the number of cation vacancies in the oxide) and hence on the manner in which the oxide was prepared. Such variations in the values of the free energies of FeO and/or Fe_3O_4, prepared and maintained at very low pressures, could alter the equilibrium constant and thereby account for the increased stability of FeO at lower temperatures. A second explanation, suggested by Gulbransen (22, 23), is that the nucleation of Fe_3O_4 is rate determining and that the activation energy for the nucleation of Fe_3O_4 is dependent on oxygen pressure, since oxygen concentration should have an influence on the number of vacancies in the FeO lattice, and presumably, therefore, on the number of Fe_3O_4 nucleation sites. This activation energy should become larger at lower oxygen pressures; hence, lower oxygen pressures should inhibit the reaction. Once the activation energy is overcome, the reaction can proceed readily to form the Fe_3O_4 phase. Thus, the very low oxygen pressure utilized in the present experiments may have effectively arrested the reaction through its affect on the nucleation activation energy of Fe_3O_4. Either of these mechanisms satisfactorily account for the observed stability of FeO at room temperature under ultra-high vacuum conditions.

Summary

The LEED technique has been used to investigate the chemisorption of oxygen on an atomically clean (001) iron surface and the subsequent formation and stability of a thin oxide film formed on the iron surface. The surface cleaning treatment consisted of a low-energy argon ion bombardment and a final short period of ultra-high-vacuum annealing at 500°C. It was possible to achieve an atomically clean surface only for crystals obtained from a zone-refined sample having a relatively low carbon content (about 14 ppm or less). The LEED patterns and the intensity-voltage relationships for a clean (001) face of iron indicated that this surface was an unreconstructed surface.

The effects of exposing an atomically clean cube face of iron to low oxygen pressures for different time intervals indicated that after an exposure of 8 x 10^{-7} Torr-sec, formation of the chemisorbed layer was es-

sentially complete. This layer consisted of half a monolayer of oxygen sorbed in a Fe(001) c(2 x 2)-O structure. Germer and Hartman (13) observed a similar structure for the chemisorption of a half of a monolayer of oxygen on the nickel (001) face. A thin layer of FeO was detected on the crystal after an exposure of 55 x 10^{-6} Torr-sec and subsequent annealing at 550°C. FeO also was observed to form at room temperature on a clean (001) face of iron, when the specimen was allowed to dwell under ultra-high-vacuum conditions for an extended period of time. The (001) plane of this film was oriented parallel to the (001) face of the iron substrate, with the [110] direction of the oxide parallel to the [100] direction of the iron which is the usual epitaxy of FeO on iron reported in the literature. Under similar conditions of oxidation Farnsworth (3) and Germer and MacRae (13) also observed the formation of a cubic oxide, NiO, on a nickel crystal. Farnsworth reported that the NiO phase formed at room temperature after a suitable oxygen exposure (10^{-5} Torr) while Germer observed that with lighter oxygen exposures (10^{-6} Torr) heat was generally required to form NiO. In view of these data it appears that it is extremely difficult if indeed not impossible to prepare and maintain for any appreciable time an oxide free surface for such reactive metals as iron and nickel in systems where the oxygen partial pressure is of the order of 10^{-6} Torr or higher.

These LEED studies on iron have also presented data on another phase of the oxidation process; the transformation of FeO to Fe_3O_4. Earlier studies by others had indicated that oxide (FeO) films formed and examined at relatively high oxygen partial pressures, decomposed to form Fe_3O_4 at temperatures below 570°C. The present LEED experiments have demonstrated that FeO films formed and analyzed at very low oxygen partial pressures do not transform to Fe_3O_4 at an appreciable rate at temperatures below 570°C and instead continue to grow as FeO.

Acknowledgments

The authors are indebted to Dr. L. H. Germer for many helpful suggestions and discussions. We also wish to thank Mr. F. J. Malloy and Mr. F. M. Roth for their valuable assistance in the construction of the experimental equipment.

Epoxy Dielectric Films Produced by Electron Bombardment

A. E. Brennemann and L. V. Gregor[1]

International Business Machines Corporation, Watson Research Center, Yorktown Heights, New York

ABSTRACT

Thin dielectric films have been produced by low energy electron bombardment of a surface which is simultaneously exposed to an evaporating epoxy resin. The rate of film growth is dependent only on the evaporation parameters when the electron flux at the surface is much larger than the molecular flux in the evaporant beam. The polymerized epoxy films are good insulators with d-c dielectric breakdown strengths greater than 10^6 v/cm. The films are stable in normal room atmosphere and may be cycled thermally from room temperature to 77°K many times without damage to their mechanical or electrical properties. A number of multilayer electrical structures consisting of alternating evaporated Pb films and epoxy films have been prepared successfully and tested.

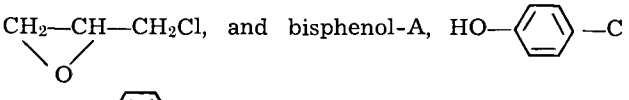
Organic molecules adsorbed on a surface can be converted to solid polymeric films by low energy electron bombardment. Because of the dielectric properties of such films, their use has been suggested as insulation for thin film circuits (1). It has been shown that adsorbed residual pump oil vapor (DC-704) in a vacuum system can be converted by electron bombardment into polymer film with good insulating properties (2). Other investigations have been concerned with the electron bombardment of butadiene (3),

[1] Present address: Systems Development Division, International Business Machines Corporation, Poughkeepsie, New York.

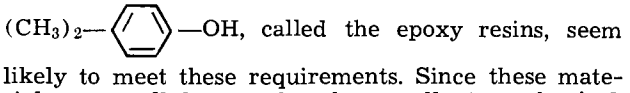
methyl methacrylate, and various conjugated organic monomers (4) with less promising results. The electron bombardment process for producing thin dielectric films is of particular interest for the fabrication and study of cryogenic circuits, since polymer films are not as highly stressed as most evaporated inorganic dielectrics (5) and are more resistant to the additional stresses caused by cooling to very low temperatures. A disadvantage of electron bombardment processes for producing dielectric films is the relatively low rate of film deposition.

In order to be highly compatible with vacuum evaporation techniques for producing multilayer thin film circuits, the material to be used in the electron bombardment process should possess these properties:

1. It should be convertible by bombardment to a solid dielectric.
2. It should have a vapor pressure at room temperature which is negligible compared to the working pressure of the vacuum system, yet which rises to $\sim 10^{-3}$ mm Hg on heating.
3. It should be sufficiently reactive to be polymerized by low energy electron bombardment to the point where essentially no further chemical reactions occur in the film after bombardment. The low molecular weight condensation polymers of epichlorohydrin,



and bisphenol-A,



called the epoxy resins, seem likely to meet these requirements. Since these materials are well known for the excellent mechanical, thermal, adhesive, and dielectric properties in bulk, they were chosen for this study.

Experimental Procedures

Evaporation system.—The apparatus for depositing epoxy polymer films was installed in a conventional CVC 18-in. vacuum system operating from 5 x 10^{-5} to 5 x 10^{-6} mm Hg. The schematic diagram (Fig. 1) shows the substrate, electron source or "gun," the epoxy evaporation source, and the magnetic deflection coils for the electron beam. Not shown are the conventional metal evaporation heater and shutter. The epoxy source is mounted 8 in. directly below the substrate, while the electron gun is mounted alongside the epoxy source at an angle to the vertical center line. The deflection coils are positioned between the sources and substrate in such a manner as to allow the evaporating epoxy beam to pass unhindered. The electron beam, aimed at the center of the coils, is deflected on passage through them to become colinear with the molecular beam on arrival at the substrate.

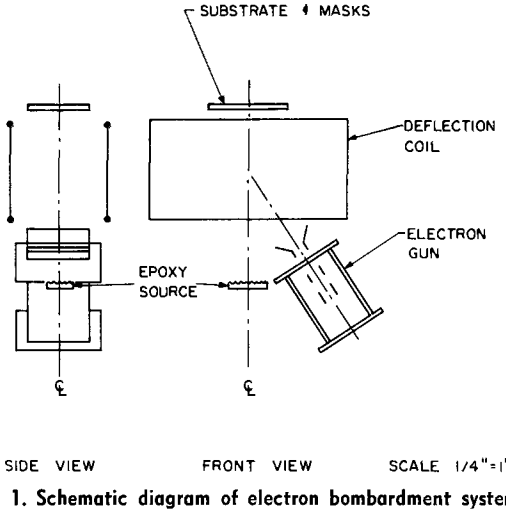


Fig. 1. Schematic diagram of electron bombardment system, side and front views. The electron gun is offset from the center line connecting the epoxy evaporation source and the substrate. Not shown is the vacuum chamber in which the apparatus is situated.

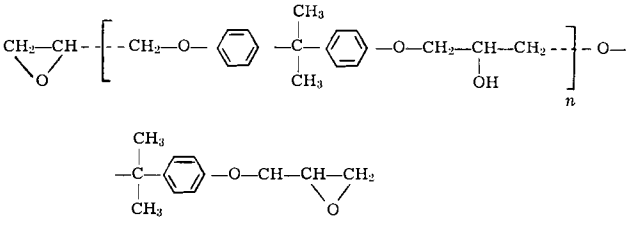
The electron gun is a modification of the Pierce type of electron beam source. The beam can be focused to the shape of a rectangle 4 x ⅜ in. and is capable of static beam current densities up to 5 ma/cm². The focused electron beam is swept across the substrate area, 2 x 2 in., by applying a 60 cycle a-c voltage or other suitable sweep voltages to the deflection electrodes of the gun. The beam current density was maintained at 1.5-2.0 ma/cm² during polymerization, and the accelerating potential was 1200v. The static beam current density was determined by dividing the total target current by the beam area. On sweep deflection, the average dynamic beam density is of course somewhat less than the static value. However, attempts to measure average beam current density during sweep by means of target electrodes or a Faraday gauge at the substrate area did not give consistent results. Thus, the values given for current density can represent only upper limits to the actual current density during polymerization. The rectangular Helmholtz coils used for magnetic deflection of the beam were wound on 5 x 10 in. forms spaced 5 in. apart. A 200-turn coil of No. 32 wire was wound on each frame to produce a 60-amp turn field.

The epoxy resin used in all experiments was Eccomold L-28 manufactured by Emerson and Cummings Inc. It has the molecular structure



where $n < 10$. The resin is a highly viscous liquid whose vapor pressure is less than 1 x 10^{-6} mm Hg at 25°C. The evaporation source was a shallow trough made of copper sheet or copper tubing, mounted from 6 to 10 in. below the substrate. It was heated by a tungsten or nichrome heater attached to its underside; power input during evaporation was from 5 to 30w for a source temperature from 60° to 130°C, maintained constant to ±1°C. Sources were designed to provide rapid heating, and rapid cooling to room temperature was achieved by means of a copper heat sink.

Evaporation procedure.—The substrate and masks were maintained at room temperature and shielded from the source and electron gun by a movable shutter. At the beginning of a typical run the evaporant source was heated from 25°C to the desired temperature. During the heating period the electron beam was turned on, and the beam current density was adjusted. The beam position and sweep voltages were adjusted by viewing the beam on a phosphor-coated screen on the bottom of the shutter. When the source temperature was stabilized, the shutter was opened to commence film deposition. At the end of deposition, the shutter was closed before either the source or electron gun was turned off. The gun and source were then turned off in no particular sequence. The point to be stressed here is that the substrate should never be exposed to the vapor stream without the presence of the electron beam. Failure to observe this procedure results in unpolymerized epoxy resin on the substrate which is too thick to be polymerized by subsequent scanning with the electron beam.

The temperature of the substrate was monitored during the evaporation. The electron beam power input of 0.5-2.0 w/cm² caused an increase in the substrate temperature from 20° to 40°C after bombardment times of 15-20 min. For longer bombardment times or for larger current densities it was necessary to provide a heat sink and cooling coil for the substrate to

insure that the substrate temperature did not become excessively high.

During the initial experiments, in which a glass bell jar was used, no noticeable polymerization of the epoxy resin in the trough heater was observed. However, subsequent experiments in an all-metal vacuum system resulted in a rapid polymerization of the source epoxy resin and hence a drastic decrease in evaporation rate. The effect may have been due to random bombardment of the source by secondary electrons; in any case, it was prevented by shielding the source with a chimney made of copper.

An undesirable condition is the accidental electrical connection to ground of any metal layer on the substrate. It was observed that if a previous evaporated metal layer became grounded, by shadowing or other means, the subsequent metal layers often became short-circuited to the grounded layer during a subsequent epoxy evaporation. It appears that the short circuit occurs because the ungrounded metal film is charged to some large potential during the electron bombardment. The insulation layer between the grounded and ungrounded layer will then break down due to the large voltage across the film. It is recommended that all metal layers be floating from ground or that all be tied to some fixed potential.

Results

Film growth rates.—Insulating films were produced which were initially reliable (free from short circuits) in a thickness range of 200-10,000Å. Deposition rates were observed from 100 to 900 Å/min on substrates of glass, aluminum, or cast epoxy. Figure 2 shows the rate of film formation as a function of the epoxy evaporation source temperature, with source area as an additional parameter. The substrate temperature was maintained at 25° ± 15°C. The source areas are for shallow open source designs which minimize any collimating or "chimney" effects in the evaporating epoxy resin beam.

The rate of film formation is relatively independent of beam current density between 1.0 and 2.0 ma/cm^2. However, below 1.0 ma/cm^2, the electron beam was difficult to control and the films began to show signs of degradation at current densities above 2.0 ma/cm^2.

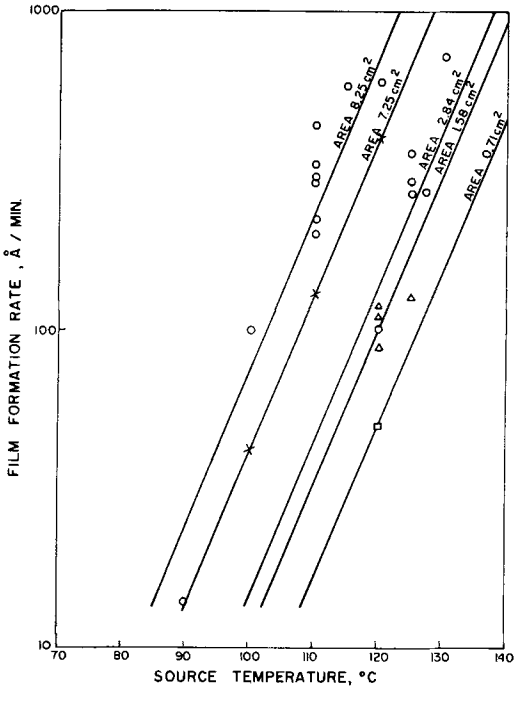


Fig. 2. Polymer film deposition rate (logarithmic scale) vs. temperature of epoxy resin evaporation source for various source areas. Constant accelerating voltage 1200v; constant current density 0.5 ma/cm^2.

Table I. Some dielectric properties of polymerized epoxy resin films at 23°C and 1 kc

Sample No.	Measured thickness, Å	Capacitance, pf	Dielectric constant, k	Dissipation factor, tan δ	Dielectric strength, v/cm
2-44-3	2400	581.8	5.7	0.0063	– (n.m.)
3-47-3	2680	563.4	6.2	0.0070	– (n.m.)
4-50-3	1980	652.2	5.3	0.004	$\geq 1.9 \times 10^6$
2-42-3	1630	1368	5.4	0.0062	$\geq 1.2 \times 10^6$

The degradation consisted of brownish discoloration, increased d-c conductivity, and a much higher incidence of catastrophic failure. Likewise, the rate is relatively independent of the accelerating potential of the gun up to 1200v, but the beam was not controllable for the particular gun design below several hundred volts, setting a lower limit on operating voltage. The upper limit is determined by the voltage at which gas discharge and arcing begin to occur; there appears to be no advantage in operating above 1200v in any case.

Dielectric properties.—The low-frequency dielectric constant k of the polymer film was determined by measuring the capacitance of a structure which embodied the thin film of polymerized epoxy resin as the dielectric medium between two evaporated Pb films approximately 0.5μ thick. The substrate was glass or cast epoxy. The polymer film thickness was measured directly to ±250Å by a Taylor-Hobson Talysurf surface profile instrument. The uniformity of film thickness across a 2 in. substrate deviates less than 2%; the reflection interference color of the film was unchanged across the entire film. Table I summarized the average values for k, tanϑ, and breakdown voltage for films approximately 2000Å thick. The dielectric constant and dissipation factor, tanϑ, were measured from 100 cps to 100 kc, and typical results are shown in Fig. 3. There was no observed variation of either k or tanϑ with a-c signal voltage up to fields of 2 x 10^6 v/cm (rms).

The insulation reliability of epoxy polymer films was examined by fabricating 90 capacitors whose areas ranged from 0.013 to 0.051 cm^2 with the insulating thickness approximately 2000Å. No initial short circuits were found in any of these samples. Thermal cycling between room temperature and 77°K caused no physical damage or short circuits even after hundreds of cycles. Multilayer capacitors with four superimposed metallic films were fabricated with no short

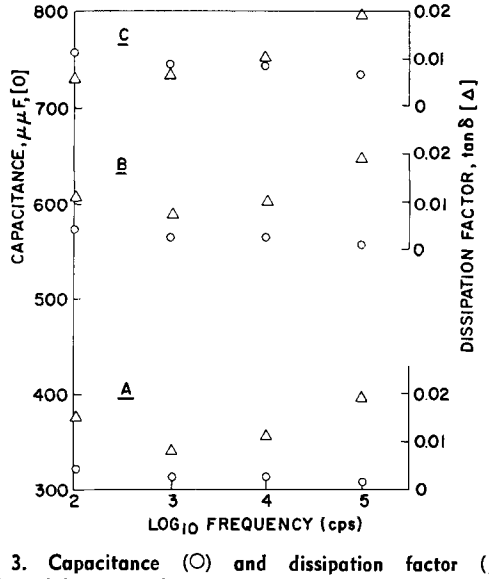

Fig. 3. Capacitance (○) and dissipation factor (△) vs. logarithm of frequency for typical capacitors A (bottom, area 1.37 x 10^{-2} cm^2), B (middle, area 2.76 x 10^{-2} cm^2), and C (top, area 4.03 x 10^{-2} cm^2). Average polymer film thickness 1200-1500Å; measured in air at 23°C.

Table II. D-C breakdown voltage of polymerized epoxy films at 23°C

Film thickness, Å	Breakdown voltage, v
1700	25
1900	40
2100	45

circuits. The dielectric breakdown strength in all samples examined exceeded 1 x 10^6 v/cm (Table II).

Preliminary tests of the epoxy polymer films under conditions of elevated temperature and humidity (85% relative humidity at 85°C) have indicated the occurrence of deleterious effects, such as film buckling and separation from substrate. However, at room temperature and normal humidity (~50%) the capacitors are stable over periods of several months, there being no detectable change in capacitance, dissipation factor, or physical appearance.

The degree of "shadowing," or insulation creepage beyond the edge of the masked areas of the substrate, was found to be comparable to conventional thermally evaporated films. Talysurf measurements of the step width of film approximately 2000Å thick showed the width to be 0.001-0.002 in. The extent of shadowing was determined electrically by varying the width of the insulation mask with respect to the capacitor plate widths until the metallic films were shorted; by this method the extent of electrical shadowing was determined to be $\leq$0.005 in.

Discussion of Results

When used as insulation for capacitors and more complex multilayer thin film structures, the polymerized epoxy films described in this paper have a high degree of initial reliability and are not affected adversely by low-temperature thermal cycling. This implies that the polymer films are homogeneous and adhere well to the surfaces investigated. The structure of the polymer has not been determined, but it is probably a randomly cross-linked network structure; at each end of the molecule the  group can be opened to give a reactive site (*e.g.*, a carbonium ion group ), and in the center of the molecule there is the labile —CH_2—CHOH—CH_2— group. In addition to the trifunctional nature of each resin molecule, there is also the possibility of random bond scission and reformation at other points during the bombardment. Many more electrons strike the surface than are required to activate the end or middle reactive groups. For instance, assuming a current density of 1.0 ma/cm^2 and a deposition rate of 150 Å/min, the ratio of electrons to resin molecules reaching the surface is

$$\frac{n_e}{n_m} = \frac{(1.0 \times 10^{-3}\ \text{amp})\,(60\ \text{sec/min})\,(6.2 \times 10^{18}\ e/\text{coul})}{(1\ \text{cm}^2)\,(1.5 \times 10^{-6}\ \text{cm})\,(1.2\ \text{g/cm}^3)\,(6.02 \times 10^{23})\left(\frac{1}{1000\ \text{g/m}}\right)} = \frac{3.7 \times 10^{17}}{1.0 \times 10^{15}} = 370$$

assuming a polymer density of 1.2 g/cm^3 and an average resin molecular weight of 1000 (6). Although the epoxy resins in bulk form are noted for their resistance to electron bombardment after being "cured" (7), the polymer films are apparently adversely affected by prolonged exposure to electron bombardment when the ratio n_e/n_m exceeds ~ 750, corresponding to 2 ma/cm^2 at 1 kv.

The rate of deposition is essentially independent of electron energy and electron flux density within the ranges of these variables which were investigated, since $n_e >> n_m$. The rate of deposition increases exponentially with increasing evaporation source temperature and is proportional to evaporation source area. The film growth rate is essentially determined by the product of the rate of arrival of epoxy resin molecules and the sticking coefficient of the molecules, provided the surface temperature is constant. No accurate epoxy vapor pressure data were available for an attempt to correlate film deposition rate with the rate of epoxy evaporation.

The experimental arrangement allows opportunity for electron-molecule interaction during the time of transit from source to target. In order to estimate the magnitude of this effect, if any, experiments were performed in which the deflection coils were not energized. Under these conditions, the number of electrons striking the surface is greatly reduced; nevertheless an insulating polymer film is formed on the surface at approximately the same rate as during direct bombardment, although the evaluation of the dielectric properties of such indirectly produced polymer films is not complete (8).

The major advantages of epoxy polymer films prepared by electron bombardment appear to be the high degree of insulation reliability, the relatively high rate of film growth, and the compatibility of the process with vacuum evaporation techniques. In addition, the nucleation properties of the surface of the deposited epoxy polymer film can be affected quite strongly by further electron bombardment after deposition. Well-defined patterns have been produced by bombarding selected areas to create nucleation sites, followed by selective growth of metallic films subsequently evaporated onto the polymer surface (9).

Magnetically Shaped R. F. Discharge for Polymer Film Formation

R. A. Connell[1] and L. V. Gregor[2]

International Business Machines Corporation, Watson Research Center, Yorktown Heights, New York

ABSTRACT

A magnetically contained glow discharge has been developed for production of thin polymer insulating films. The glow discharge is maintained by an electrodeless radio-frequency source external to the system. Film growth rates of 1200Å/min of polystyrene have been achieved with very little substrate heating or shadowing of the polymer films. The controlled glow discharge has been used to make thin film capacitors whose plates are evaporated metal films. Insulating films as thin as 100Å have been produced from several organic monomers.

The formation of thin polymer films on surfaces by means of a gas discharge in an organic vapor has been accomplished by several investigators (1-4). In general, the use of an electrical discharge in a reactive atmosphere is related to the fields of (*a*) chemical plasma reactors for the synthesis of certain compounds (5, 6), and (*b*) electron beam polymerization of absorbed organic or organo-silicon vapors to form insulating films (7-10). The glow discharge source described in this paper attempts to achieve a greater degree of flexibility and control of the discharge and the reaction products evolved than do previous glow discharge polymerization processes.

The analysis of the physical and chemical processes occurring in a discharge involving complex molecules is generally extremely complicated. In such a situation, one wishes to remove as many uncontrolled variables as possible while maintaining maximum control over all other parameters which may influence the results. Accordingly, it was decided to construct a source with the following features: (*a*) rf electrodeless excitation to avoid sputtering and other electrode effects; (*b*) the use of d-c magnetic fields to contain and control the resulting plasma; (*c*) the use of a dynamic flow system to control the relative percentages of constituents of the plasma and the population temperatures within the discharge; and (*d*) the restriction of the target to a passive role in the discharge process.

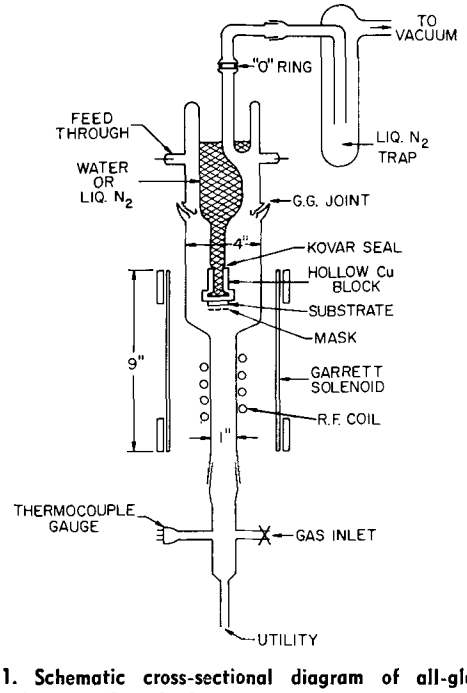

Fig. 1. Schematic cross-sectional diagram of all-glass magnetically focused glow discharge system I.

Apparatus

Cross-sectional diagrams of two versions of the rf discharge apparatus are shown in Fig. 1, a drawing of the original all-glass model for simple experimental work (system I), and Fig. 2, a schematic diagram of the incorporation of such a source into an existing evaporator system (system II). In both models, the monomer vapor is fed into the excitation region through a needle valve and then through a drift zone to the target substrate. In both cases the substrate is attached to a copper block. In system II the block can be alternatively rotated into the discharge stream or faced downward for vacuum evaporation of metal films. A water-cooled rf coil, operating at 0.5 Mc/sec and capable of generating peak fields of the order of 2 oe, was used to excite the gas. The containment coils used in both models provided d-c magnetic fields up to 500 oe. A pinch coil was introduced in the second model as an embellishment to further reduce unnecessary losses by the establishment of a so-called "magnetic mirror" whereby electrons below a certain energy will be reflected by the bunching of magnetic flux. The pinch coil generated a local field intensity of about double the containing field. A separate collimating coil was used for the drift region in system II.

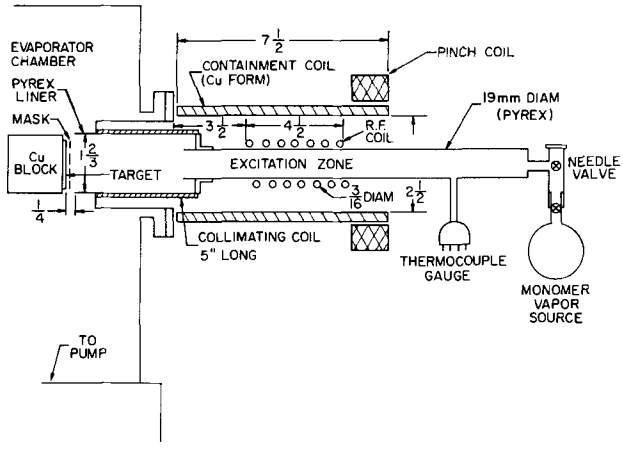

Fig. 2. Schematic cross-sectional diagram of magnetically focused glow discharge system II. Apparatus shown incorporated into the side of a metal bell jar of a vacuum evaporation system.

This coil provided relatively uniform fields up to about 150 oe.

Analysis of the Discharge

An rf electrodeless discharge is essentially diffusion limited (11), and hence the power that must be coupled into the plasma to sustain it in an equilibrium state is determined by the rate at which charged particles are lost from the plasma. Electron drift in a plasma is easily restricted by the application of a modest magnetic field. Under the operating conditions just described, the cyclotron frequency of the electrons, $\omega_e = eB/m$, is of the order of 10^{10} rad/sec with a Larmor radius $\rho_e = mv/He \sim 10^{-2}$ cm. For a typical monomer ion, whose mass number may exceed 100, $\omega_i \sim 10^4$ rad/sec and $\rho_i \sim 5$ cm. The constraint exercised on the heavy ions with the present geometry and fields is therefore indirect, arising from a charge build up on the container walls or a restraining space charge (12).

In a magnetic field, the mean distance and electron moves in a direction perpendicular to the field for an electron-ion collision is l_e (11). For a pressure of 100μ and no applied field, the electronic and ionic mean free paths l_e and l_i are of the order of 1 cm and 1 mm, respectively. The diffusion coefficients of the two species will also be altered accordingly (11, 12). It is obvious that the nature of the discharge will be altered considerably by this field and, in particular, that it may be maintained at pressures and rf field intensities below those which are otherwise possible. Furthermore, it establishes an anisotropy in diffusion losses with a preferred direction parallel to the d-c field.

Magnetic reflection will occur in the pinch field region when the charged particle kinetic energy $W \leq \mu B_m$, where

$$\mu = \tfrac{1}{2}\, mv_c^2/B_0$$

μ is the magnetic moment of the charged particle, B_m is the peak field in the pinch zone (12), and v_c is the velocity component perpendicular to the magnetic field. For an electron energy of 1 ev, the field necessary for electron reflection is of the order of 10^3 gauss.

Two other points should be made before passing on to results of the actual operation of the apparatus. According to Lax *et al.* (11), the mean energy gain of an ion from an rf field between collisions is inversely proportional to the square of the d-c magnetic field. Thus, not only is it possible to sustain a discharge at a low rf power level, but at this level the low-lying excited states and particularly the lowest energy process leading to ionization or excitation should be preferred. This amounts to the exclusion of high energy processes which tend to give rise to a greater variety of reaction products. In this respect, many of the reactions taking place in this discharge should closely resemble those encountered on ultraviolet gas-phase irradiation (14), which can be highly selective. This is in contrast to other discharge sources (1-4), which utilize relatively high energy excitation.

The second point has to do with collimation of the ionized stream impinging on the target surface. The existence of a magnetic field normal to the target surface will severely restrict lateral electronic motion. This applies not only to the primary plasma electrons, but also to any secondary electrons or photoelectrons which might conceivably be ejected from the target or intervening structure, such as a mask. This collimation should reduce shadowing (*i.e.*, unwanted polymer formation) underneath the masked area. In the event that polymerization is achieved via uncharged species such as free radicals (15), the magnetic field would cease to be effective in this respect. However, decreased shadowing would still result from the reduction in the minimum operating pressure and concomitant increase in molecular mean free path, as opposed to the mask-target separation.

Results and Discussion

The observed behavior of the system conforms remarkably well to what might be predicted from the discussion above. Considering system I first, it was found that a pale blue glow could be sustained at a monomer pressure in the range of 20-100μ, as registered on a thermocouple gauge, when $H_{d\text{-}c} \geqq 300$ oe and H_{rf} (peak) ~ 1 oe. A reduction in the d-c field extinguished the glow. For higher rf fields, higher pressures, and decreased d-c field, a bright white, arc-like discharge mode was obtained. (It was observed that it was not possible to strike or sustain a discharge in gases possessing relatively high ionization potentials, such as nitrogen or argon, with this apparatus.) The monomer used most extensively was a mixture of the isomers of divinylbenzene, $CH_2 = CH - C_6H_4 - CH = CH_2$, (DVB), whose vapor pressure at 25°C is approximately 4×10^{-1} mm Hg.

During the blue glow discharge in DVB a tough, coherent, colorless, transparent polymer film was formed on the substrate. The rate of deposition was relatively insensitive to monomer pressure in the glow discharge range. On the other hand, the bright arc-type discharge was characterized by the generation of a great deal of heat, the consumption of comparatively large quantities of monomer (as attested to by a drastic decrease in pressure), and the formation of a thick, brownish deposit on all adjacent surfaces. Some of this is believed to be due to thermal polymerization since it occurred chiefly in the areas heated most strongly, irrespective of magnetic field orientation, and with little or no film formation at the cooler target surface.

The magnetically controlled glow discharge films resembled those formed by ultraviolet polymerization of DVB in many ways (14). There were some differences in physical properties; films prepared by the former process were mechanically much harder with a higher softening temperature, indicative of a higher degree of cross-linking (15). This suggests that the electrons in the discharge may be contributing to cross-linking during polymerization, a conjecture also supported by the absence of almost any shadowing when the target surface was masked off by an aluminum template. For mask-to-substrate spacings as much as 0.020 in, the shadowing, as determined from Talysurf contours, was not more than 0.002 in. This is to be compared to other discharge sources, where the shadowing may extend ten times as far (3).

The average film growth rate, d/t, where d is the

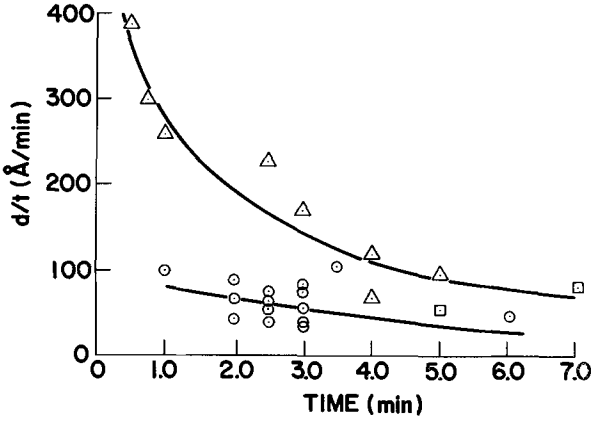

Fig. 3. Rate of deposition of polymer film vs. time for divinylbenzene vapor. Inlet pressure 50μ except for points shown as squares. The decrease in rate is more pronounced for the vertically mounted system in which the thermal contact between substrate and holder is less efficient (system I). Open triangle with dot, vertical mount water-cooled substrate; open circle with dot, horizontal mount; open box with dot, $P_{(DVB)} = 20\mu$.

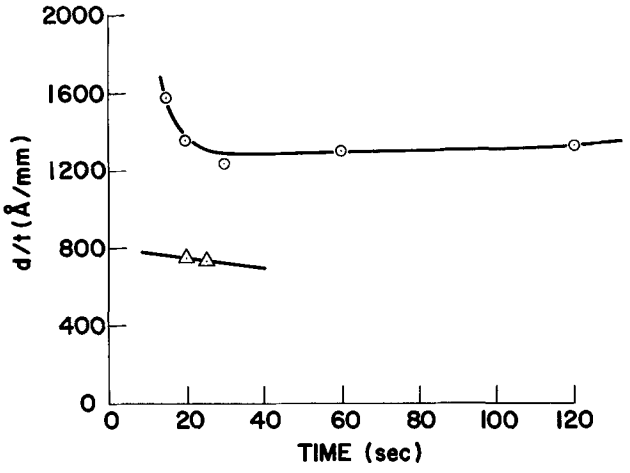

Fig. 4. Rate of deposition of polymer film vs. time for styrene vapor. Inlet pressure 50-75μ, system II; Open circle with dot, Pb film substrate; open triangle with dot, Cu film substrate.

film thickness and t is the deposition time, is plotted as a function of deposition time in Fig. 3 and 4. Thicknesses were ascertained by means of a Talysurf for the thicker films. These readings were then correlated with capacitance measurements of structures comprising films of Pb electrodes above and below the polymer film. For polymer films <1000Å, thicknesses were determined from capacitance measurements alone, assuming the constancy of the polymer dielectric constant (K = 2.8 at 1 kc) as determined from the thicker films. This approach was necessitated by the insensitivity of the Talysurf for thickness values below 1000Å.

Figure 3 shows the deposition rates observed in the all-glass system (I) with DVB as the monomer gas. The triangular points represent values taken with the discharge axis mounted vertically and water cooling of the copper block holding the substrate. The circled points were obtained with the apparatus mounted horizontally with no substrate cooling. Figure 4 shows the rate of deposition as a function of exposure time for films made from styrene, $CH_2 = CH$, in system II. The rate in this case is considerably higher than shown in Fig. 3 and levels off more rapidly. This is probably because the substrate was in better thermal contact with its holder in system II. Included also are two points showing the rate of deposition of polystyrene on an evaporated Cu film in system II.

Although most of this paper concerns itself with divinylbenzene, other monomers such as butadiene, glycidyl methacrylate, and allyl glycidyl ether were also tried, with varying degrees of success. Styrene, deposited via system II, gave the best results to date. With appropriate adjustment in monomer flow rate through the system, deposition rates of the order of 1200 Å/min are readily achievable. Films were deposited on a variety of surfaces, including glass, cast epoxy, evaporated metallic films on glass (Ag, Cu, Pb), polished aluminum and Ni-Fe alloy plated Mylar tape. There did not appear to be any limitation on film thickness up to 10,000Å, the thickest film prepared. Adherence of the polymer film to all substrate materials was excellent. A thick film (7000-9000Å) was deposited on aluminum (25 cm^2 area) and showed no observable deterioration after storage in air at room temperature for nine months.

The capacitor configuration normally used had a rectangular plate area of 7.6 mm^2. The capacitors were fabricated on glass substrates 2.5 x 1.2 cm. The uniformity of polymer film thickness across a circular area 3 cm in diameter is a function of deposition rate, gas flow rate, and thickness. For thick films (> 1μ) deposited at high rates, the decrease in thickness from the center of the circle to the edge was approximately 30%.

In Fig. 3, the apparent drop off in rate with time is believed to be a heating effect at the target surface. The target substrate is only loosely coupled with the cooling block in system I. The cooling block thus serves only to establish an initial surface temperature (approximately 18°C). Under these conditions the most plausible explanation of the observed drop in rate is local heating of the surface. This would be in accordance with rate measurements made as a function of substrate temperature for polymer films formed by both ultraviolet and electron beam irradiation (9, 14), (excluding surfaces so hot as to spontaneously polymerize the vapor).

The use of this type of glow discharge sometimes provides polymer films free of pinholes down to 100Å thickness, although this lower limit will vary somewhat from one monomer to another. Because these films are so thin, electronic conductivity (due to tunneling and Schottky emission) is observed when the electric field across the capacitor is sufficiently high.

The Effect of Thiourea on Alkaline Electroless Deposition

J. Kivel[1] and J. S. Sallo

Honeywell Research Center, Hopkins, Minnesota

ABSTRACT

C_{14} or S_{35} tagged thiourea were used to follow the uptake of C and S into the electroless nickel deposit and to determine adsorption curves for thiourea on nickel and cobalt. Enhancement of the rate of deposition is observed for cobalt but not for nickel. A Raney nickel type of mechanism and an electron transfer mechanism are proposed to explain the results.

The effect of thiourea and other sulfur-containing compounds on the rate of the electroless deposition process for acid nickel has previously been described (1, 2). Radiochemical studies of this process utilizing sulfur and carbon tagged thiourea have also been reported (3). None of this previous work has dealt with the effect of thiourea on the electroless deposition of nickel or cobalt from alkaline media. The purpose of the present paper is to broaden these studies into the alkaline region for cobalt and nickel and also to report the results of studies utilizing sulfur and carbon tagged thiourea in this type of deposition system.

Experimental

The following systems were studied (i) $NiCl_2 \cdot 6H_2O$, 30 g/l; NH_4Cl, 50 g/l; $NaH_2PO_2 \cdot H_2O$, 20 g/l; Na citrate$\cdot 2H_2O$, 100 g/l. (ii) $CoCl_2 \cdot 6H_2O$, 30 g/l; NH_4Cl, 50 g/l; $NaH_2PO_2 \cdot H_2O$, 20 g/l; Na citrate$\cdot 2H_2O$, 100 g/l. The *p*H of the system was adjusted to the desired levels with NH_4OH.

The temperature of the plating systems was maintained at 85° ± 2°C by means of an electric heating mantle. The substrates used in this investigation were 1 x ½ in. nickel strips. These substrates were sensitized by previously described techniques (4). Deposits were made at 1-hr periods; agitation of the system was accomplished by mechanical stirring. Measurements of *p*H were carried out for all experiments using high temperature glass and calomel electrodes.

In each experiment the desired amount of C^{14} or S^{35} thiourea was added to the system. The activity of the solution during deposition and the activity of deposited samples were determined using previously described techniques (3). All nickel substrates were weighed prior to and following deposition to determine the weight of the deposit. All results are reported as the average of several experimental runs.

Results

The effect of thiourea concentration on the rate of nickel and cobalt deposition from alkaline systems is shown in Fig. 1. Previous work in acid systems has shown a gradual increase in the rate of nickel deposition up to a concentration of about 0.5 mg/liter of thiourea (2). Thiourea concentrations greater than 0.5 mg/liter result in a gradual decrease in the rate until at 1.4 mg/liter, the rate goes to 0. Figure 1 shows that for the electroless deposition of nickel from an alkaline medium, the rate steadily decreases until about 1 mg/liter of thiourea, where there is a very rapid decrease to 0. There is no enhancement of the plating rate due to the addition of thiourea in the alkaline electroless deposition of nickel. The addition of thiourea to an alkaline cobalt electroless system as also seen in Fig. 1 leads to a rate maximum at about 0.2 mg/liter of thiourea. Further increase in the thiourea concentration leads to a rapid falloff in the rate of electroless cobalt plating from alkaline media. This behavior is similar to the behavior previously observed for acid nickel systems; however, the maximum for cobalt occurs at a much lower thiourea concentration. The results of Fig. 1 are obtained at a *p*H of 8. Similar results are obtained at other alkaline *p*H values.

The results of the radioactive uptake of carbon from carbon tagged thiourea are shown in Fig. 2 for both nickel and cobalt deposition from alkaline media. The

[1] Present address: Atlantic Research Corporation, Alexandria, Virginia.

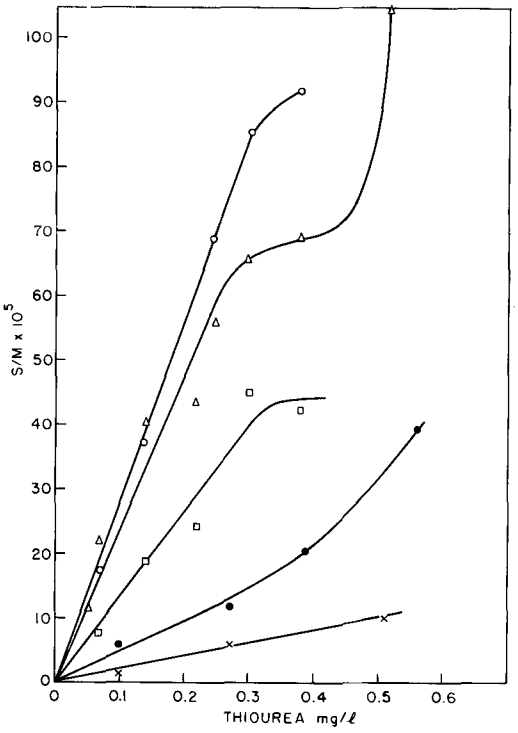

Fig. 3. Sulfur-to-metal (Ni or Co) ratios in the deposit vs. thiourea concentration. ○, S/Co at pH 8.0; △, S/Co at pH 8.5; □, S/Co at pH 9.0; •, S/Ni at pH 7.5; X, S/Ni at pH 9.0.

results are shown as carbon-to-cobalt and carbon-to-nickel ratios. The carbon uptake in the cobalt deposition is virtually independent of pH, whereas in the nickel deposition system the amount of carbon uptake decreases as the pH increases.

The uptake of sulfur in the deposits, shown as sulfur-to-nickel and sulfur-to-cobalt ratios, is seen in Fig. 3. As was previously reported for the acid nickel system (3), there is about a hundred times as much sulfur in the deposit as there is carbon, indicating a high rate of cleavage of the thiourea molecule. It is seen that for both cobalt and nickel more sulfur occurs in the deposit at low pH than at high pH. It is also seen that in the case of cobalt a plateau in the curve occurs which is similar to that which was previously observed in the acid nickel system (3).

Figure 4 shows the results of thiourea uptake on active nickel and cobalt surfaces. The data were taken utilizing a technique which has been previously described (5), in which the nickel surface is slowly withdrawn from a solution of thiourea, dried, and counted. The shapes of these curves are similar to the usual adsorption curve obtained for adsorption from solution, with the plateau representing a monolayer of the adsorbent on the surface. Similar data for adsorption of thiourea on nickel from an alkaline medium fail to show a clear monolayer region. In this case less adsorption is observed than is found from an acid thiourea solution.

Discussion

It is seen from Fig. 1 that cobalt deposition from alkaline media resembles nickel deposition from acid media in that a maximum occurs at a small thiourea concentration followed by a rapid decrease in the rate. This behavior is not followed for nickel in alkaline media where the rate of deposition gradually falls off and no peak or increase in rate is observed at any thiourea concentration. Enhancement in rate is also observed in alkaline cobalt systems.

In the previous work done for nickel in acid media, a plateau in the uptake of sulfur was observed at approximately the same thiourea concentration at which a maximum rate was observed (3). In the case of

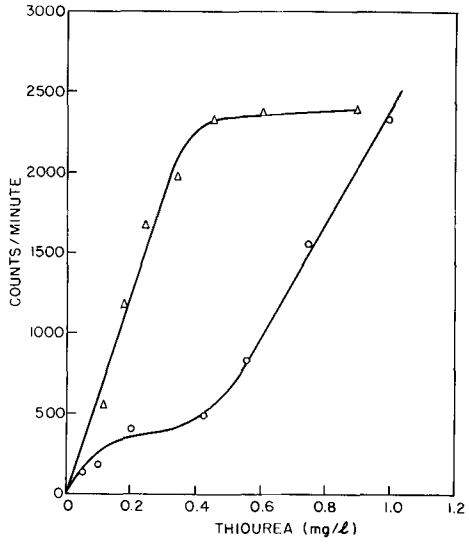

Fig. 4. Adsorption of thiourea. ○, Co surface pH 8; △, Ni surface pH 5.

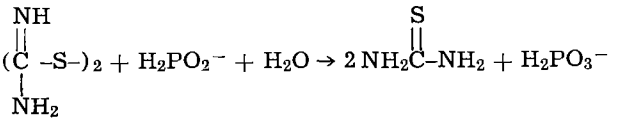
cobalt deposition a very similar behavior is observed as is seen in Fig. 3. In this case the maximum occurred at 0.3 to 0.4 mg/liter of thiourea. Maxima occurred at higher concentration with thiourea in the acid-nickel system; however, the maximum in the rate also occurred at a higher concentration. In the case of nickel deposition from alkaline media a gradual increase in sulfur uptake into the deposit is observed with no plateau and the curve shapes are entirely different.

The sulfur-to-carbon ratios in the deposit are in the order of 100/1 in all cases. This shows a strong tendency for the thiourea molecule to cleave, leading to the deposition of sulfur, and a very small tendency for carbon to deposit, possibly due to the occlusion of an entire molecule of thiourea. In the acid-nickel system, a volatile sulfur fragment was found (3). When the system was agitated, some of the sulfur counts were lost, presumably in the form of a volatile species. It was speculated that this was hydrogen sulfide which was being lost from the acid system. If this is the case, the alkaline system should show no such loss. A careful investigation has shown that complete sulfur balance is obtained in alkaline systems, and no sulfur is lost during the course of the reaction, even from agitated systems. Furthermore, at the end of the run the system was made acidic and then agitated violently with nitrogen gas and no sulfur loss was observed. It would appear from this result that water soluble sulfide ion forms in the acid system, but not in the alkaline system. This lends support to the suggestion (3) that the sulfide ion in solution results from hydrolysis of nickel sulfide in the deposit. In the alkaline pH region, this nickel sulfide would not hydrolyze, and no sulfide would be found in solution. This finding lends support to the previously suggested Raney mechanism, since one of the previous difficulties was to explain the origin of the sulfides.

In the previous work on this subject, it was suggested that the thiourea acts to enhance the rate of deposition through an electron transfer mechanism. It has been reported (6) that thiourea exists in a redox equilibrium with formamidine disulfide at a potential of —0.42v. It seems quite possible that this reaction between thiourea and its dimer could be the electron transfer mechanism which is used to deposit nickel and cobalt. The reaction suggested is shown below

$$2\,H_2N\text{–}\overset{\overset{S}{\|}}{C}\text{–}NH_2 + Ni^{++} \rightarrow Ni + \left(\overset{\overset{NH}{|}}{C}\text{–}S\text{–}\right)_2 + 2H^+$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \underset{\underset{NH_2}{|}}{}$$



The dimer has been shown in the literature to be unstable with respect to sulfur formation if the *p*H is much above 3 (6). It would seem that the decomposition of this dimer to sulfur and an organic fragment could be one mechanism by which sulfur appears in the deposit. The sulfur uptake data in Fig. 3 show that more sulfur appears in the deposit from the alkaline-cobalt system, where enhancement is occurring, than in the deposit from the alkaline-nickel system where there is no enhancement of the rate. Decomposition of the dimer could explain the excess sulfur formation which is observed when the rate of nickel deposition and cobalt deposition are enhanced.

As a partial check on the possibility that the dimer of thiourea functions as an electron transfer agent, a quantity of the dimer was synthesized (6) and utilized in the reaction as if it were thiourea. In all experiments performed in this way the dimer behaved as if it were thiourea and the normal enhancement of the rate was observed. While this is not proof of the dimer's involvement in the enhancement mechanism, it does lend support to this electron exchange mechanism for the thiourea enhancement of nickel and cobalt deposition.

It would seem that two mechanisms are required to explain the sulfur uptake and the increase in rate in those systems where enhancement of the rate takes place. A Raney mechanism leading to the formation of metal-sulfide and formamidine at the active nickel or cobalt surfaces has previously been suggested (3). The present data lend further support to this notion. The Raney mechanism will not, however, explain the increase in rate which is observed in some of these systems. It is suggested that the large increase in sulfur uptake which is observed after the maximum of the rate of reaction is due to this Raney reaction. This Raney reaction would begin when adsorption beyond the monolayer begins and would explain the large increase in sulfur uptake in the deposit which occurs in these higher thiourea concentrations. In this picture, all of the sulfur uptake in the alkaline-nickel system, where no rate enhancement is observed, is due to the Raney nickel mechanism.

The adsorption data shown in Fig. 4 offer a further insight into the mechanism of the reaction. It is seen that the plateau indicating monolayer formation occurs at about 0.3 mg/liter thiourea for the alkaline cobalt media, and at about 0.5 mg/liter thiourea for the acid nickel media. These points correspond almost exactly to the maximum rate obtainable when thiourea is added to the cobalt or nickel system, respectively. Furthermore, the break upwards in the cobalt curve indicating adsorption beyond the monolayer also corresponds to the thiourea concentrations which begin to inhibit the rate of the reaction. In addition, these adsorption curves are almost identical to the sulfur uptake curves. There is a strong implication from these data that the increase in rate in those systems where enhancement occurs is closely tied to the adsorption of thiourea on the surface.

The reason for the failure of thiourea to enhance the rate of deposition of nickel from alkaline media is not known. Complexation with thiourea appears to occur readily for both nickel and cobalt in alkaline media (7), and there is no reason to believe that the complexes differ in stability. The present work shows that thiourea does not appear to form a monolayer on nickel when adsorption occurs from alkaline media. This monolayer formation seems related to rate enhancement and its absence may explain the failure of thiourea to enhance the rate of alkaline nickel deposition.

Conclusions

Thiourea is shown to increase the rate of cobalt deposition from alkaline media to a maximum at 0.3 mg/liter thiourea. No such enhancement of the rate occurs in the alkaline-nickel deposition systems. It is suggested that the enhancement of the rate which occurs in the alkaline cobalt system and in the acid nickel system is due to an electron transfer mechanism involving the dimer of thiourea and that the excess sulfur which appears in the deposit when enhancement of the rate is taking place is due to the breakdown of this thiourea dimer to give sulfur. It is further suggested that the sulfur appearing in the deposit when excess thiourea is present and during the entire range of thiourea concentration for alkaline nickel systems is due to a Raney mechanism. It is also shown that the region of enhancement of the rate of nickel and cobalt deposition by thiourea is also the region of monolayer formation for thiourea adsorption on nickel and cobalt surfaces. The region where the rate begins to decrease as thiourea concentration is further increased corresponds to adsorption beyond monolayer formation.

An Evaluation of the Bismuth-Tellurium Phase System

Alfred C. Glatz

Carrier Research and Development Company, Syracuse, New York

ABSTRACT

Phase equilibria studies of the bismuth-tellurium system have been performed by differential thermal analysis (DTA), x-ray diffraction, and metallography. These studies have shown that congruent melting γ-phase (Bi_2Te_3) is stable as a single phase over a very narrow composition range and is separated from a bismuth-rich peritectic β-phase by a narrow two-phase field. DTA studies on annealed samples indicate that there are probably several other peritectic compounds in the region from 30 to 50 mole % tellurium. The departure from equilibrium below the liquidus is considered responsible for some of the previous discrepancies for this system.

The unique electrical properties of bismuth telluride have stimulated many investigations of the physical properties of this compound. However, in spite of these efforts the exact form of the phase diagram below the liquidus appears obscure. In particular, there is considerable disagreement between the reported phase diagrams in the region near the compound Bi_2Te_3 (60 mole % Te) and in the region from 30 to 50 mole % Te. For example, Brown and Lewis (1) and Hansen (2) report a single compound in the system with widely different ranges of compound stability, while Abrikasov and Bankina (3) report a very narrow range of compound stability for Bi_2Te_3 with several other compounds in the system. These apparent discrepancies have indicated that a more detailed investigation of the bismuth-tellurium phase system is required in order to elucidate the true "equilibrium" phase diagram. The study being reported in this paper is concerned primarily with the region near the congruent melting compound with systematic observations in the region from 5 to 50 mole % tellurium and represents a portion of the effort of the thermoelectric materials group of Carrier Research and Development Company to determine the equilibrium phase diagram of the bismuth-tellurium system.

Phase equilibria studies on the bismuth-rich side of Bi_2Te_3 are complicated by the fact that both bismuth and bismuth telluride have the hexagonal C33-type crystal structure with the $R\bar{3}m$ unit cell space group symmetry. This fact limits the use of x-ray diffraction as the only experimental method for interpreting the phase diagram. Consequently, we have employed a combination of x-ray diffraction, differential thermal analysis (DTA), and metallography in these studies.

Although the phase diagram is, by definition, a representation of equilibrium phase boundaries, evidence will be presented to show that in some of the previous studies the samples apparently did not attain thermodynamic equilibrium, which resulted in some erroneous conclusions. For this reason, studies have been made of the effect of "equilibrium" on the phase diagram in the composition ranges mentioned above.

Experimental Procedures

Materials.—Bismuth metal shot (99.9999+%) and elemental tellurium (99.999+%) were obtained from Cominco Products, Inc., and American Smelting and Refining Company, respectively. These elements were used directly in the preparation of the samples.

Preparation of the samples.—For the phase equilibria studies three-gram samples of the appropriate compositions were sealed in evacuated quartz ampoules. The samples were placed in a "Hevi-Duty" tube furnace provided with a rotating mechanism, and the temperature was raised above the liquidus temperature of the alloys for approximately 30 min and then cooled to room temperature. The samples were then placed in a high thermal capacity annealing furnace and initially annealed below the solidus temperature for two weeks. In general, alloys containing greater than 37 mole % tellurium were annealed at 400°C and those containing less than 37 mole % tellurium were annealed at 250°C. After this initial annealing period, the alloys were removed from the ampoules, ground up with a vibrator, and sieved to −50 mesh. Then they were replaced in evacuated, sealed quartz ampoules and annealed at the annealing temperature for approximately two more weeks. In addition, at periodic intervals the powdered samples were removed from the furnace and shaken with the vibrator to ensure homogenization of the composition. To study the effect of "equilibrium" on the phase diagram, alloys having compositions ranging from 5 to 50 mole % tellurium were annealed for varying periods of time up to six months at various annealing temperatures.

The samples prepared in this manner provided annealed powders suitable for x-ray diffraction and DTA measurements. It has been shown by Sato (4) that annealed powders must be used to obtain sharp x-ray diffraction patterns of bismuth telluride.

The compositions of the samples were determined from the constituents. The compositions were verified on representative samples by chemical analysis. In all cases the analyzed compositions indicated that the sample had lost tellurium, but the loss did not exceed 0.05 mole % tellurium.

Phase equilibria examination.—The samples were examined by DTA, x-ray diffraction, and metallographic techniques.

The DTA thermograms were obtained by the conventional technique of plotting the difference in temperature between an aluminum oxide standard and the sample on an X-Y recorder (Honeywell Function Plotter—Model 153X33). The DTA samples were prepared by adding 750 mg of the alloy composition to 250 mg of α-Al_2O_3 (both sieved from −100 to +200 mesh). The aluminum oxide was added to the sample to minimize base-line drift. The standard and the sample were contained in sealed Vycor ampoules with concentric thermocouple wells and placed symmetrically in a high thermal capacity Kanthal furnace. The heating rate of the furnace was controlled at 5°C per min with a cam-type program controller (Honeywell—Model 152).

Alloy compositions in the range from 56 to 62 mole % tellurium were examined by conventional x-ray powder diffraction techniques. The x-ray powder photographs were taken at room temperature with a 14.3 cm Debye-Scherrer camera and nickel filtered $CuK\alpha$ radiation, using the Straumanis method with the samples held in thin-walled silica tubes. The line positions were measured with a Norelco film reader accurate to 1/20 mm. Approximately 25 reflections were indexed for each composition on the basis of

hexagonal lattice employing the data published by Francombe (5). The lattice parameters were determined by extrapolation using Cohen's least squares method (6) with the function, $1/2[(\cos^2\theta/\sin^2\theta) + (\cos^2\theta/\theta)]$, programmed in "Fortran" on a computer. For the calculation of the lattice parameters, 1.54051 and 1.54433Å was assumed for the wavelengths of the $K\alpha_1$ and $K\alpha_2$ radiations, respectively, and 1.54178Å was assumed for the wavelength of the unresolved doublet.

The measured hexagonal lattice parameters of Bi_2Te_3 using the above procedure are $a_{hex} = 4.384 \pm 0.001$Å and $c_{hex} = 30.495 \pm 0.006$Å. The values published by Francombe (5) are in agreement, within the reported precision, with those obtained by this investigation.

Some of the samples were examined by metallography, both at room temperature and as a function of temperature. The metallograph used for these studies was a Bausch and Lomb Research Metallograph, which was equipped with a Unitron HHS-3 Vacuum-Heating Stage. The powdered samples were polished using a Fisher Vibramatic Polisher employing 0.05μ β-Al_2O_3 as a final abrasive. Samples for the hot stage were grown in a Bridgman furnace and polished electrolytically. Vaporization from the surface was reduced during a hot-stage run by introducing approximately 3 atm of argon gas at about 200°C.

Results

Phase equilibria studies by DTA, x-ray diffraction, and metallography, which have been correlated for compositions extending from 56 to 62 mole % tellurium, have established that Bi_2Te_3 exists as a single phase over a very narrow composition range. This congruent melting single-phase field (herein called the γ-phase) is separated from a peritectic phase (herein called the β-phase) by a narrow two-phase field. The phase diagram in this region is shown in Fig. 5, which will be discussed in more detail later.

The range of existence of the single-phase field for the γ-phase and the two-phase field between the β- and γ-phases has been established at room temperature by x-ray diffraction using the parametric method. Shown in Fig. 1 are the hexagonal lattice parameters (a_{hex} and c_{hex}) at room temperature for Bi-Te compositions in the range from 56 to 62 mole % tellurium. It may be observed from the compositional variations of the lattice parameters that at room temperature the γ-phase exists as a single phase from 59.70 ± 0.10 to 60.35 ± 0.15 mole % tellurium and the two-phase

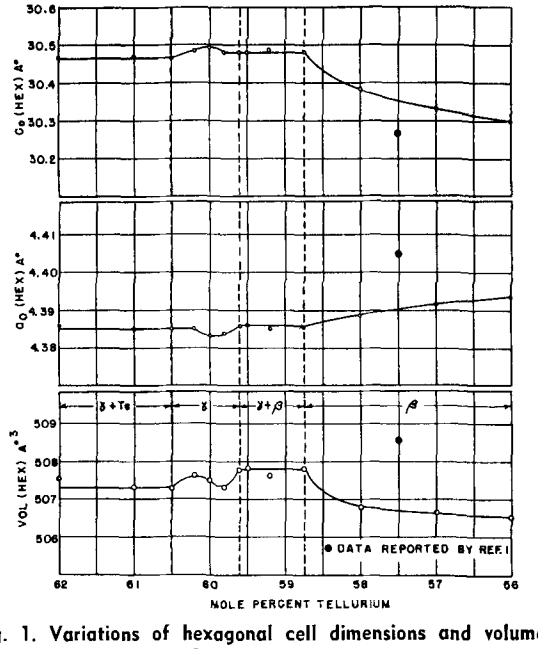

Fig. 1. Variations of hexagonal cell dimensions and volume of Bi-Te compositions at 25°C.

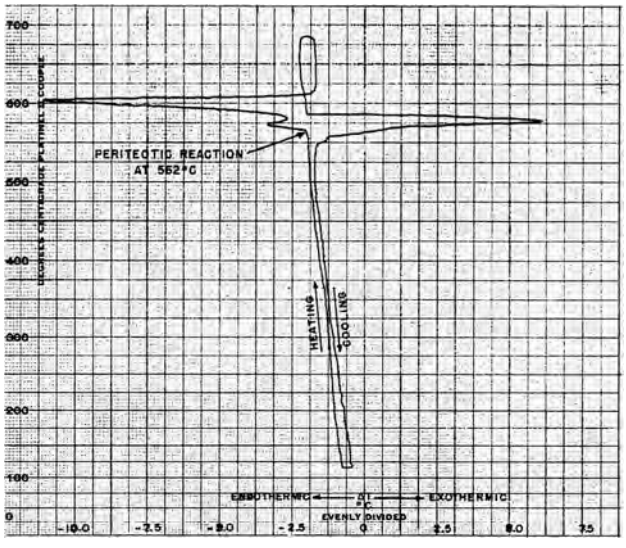

Fig. 2. DTA thermogram for $Bi_{41}Te_{59}$

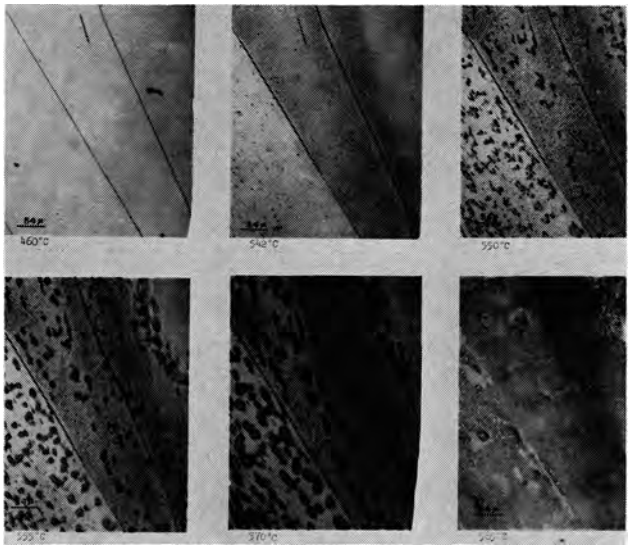

Fig. 3. Photomicrographs at various temperatures for $Bi_{40.4}Te_{59.6}$

field between the β- and γ-phases extends from 58.75 mole % tellurium to the bismuth-rich phase boundary of the γ-phase. The phase boundaries drawn in Fig. 1 represent the maximum ranges for the γ- and β-phases.

The β-phase peritectic with a peritectic reaction temperature of 562° ± 2°C has been observed by both DTA and high-temperature metallography. Shown in Fig. 2 is a DTA thermogram for the composition $Bi_{41}Te_{59}$ and shown in Fig. 3 are photomicrographs of an electrolytically polished section taken at various temperatures for the composition $Bi_{40.4}Te_{59.6}$ (sample 921-B). The existence of the peritectic at 562°C is clearly evident from the DTA thermogram and allowing for the uncertainty in the temperature measurement during a hot stage run, the photomicrographs verify the formation of a liquid phase below the normal melting point of the γ-phase. The peritectic reaction is observed on DTA thermograms extending from the phase boundary of the γ-phase to the liquidus at 50 mole % tellurium. The peritectic reaction was reported by Abrikasov and Bankina (3) at a slightly lower temperature and has apparently been observed by Bolling (7) as the appearance of a liquid below the normal melting point of Bi_2Te_3.

The peritectic point of the β-phase was established at approximately 55 mole % tellurium by metallographic examination of polished sections of alloys quenched from below the peritectic reaction tem-

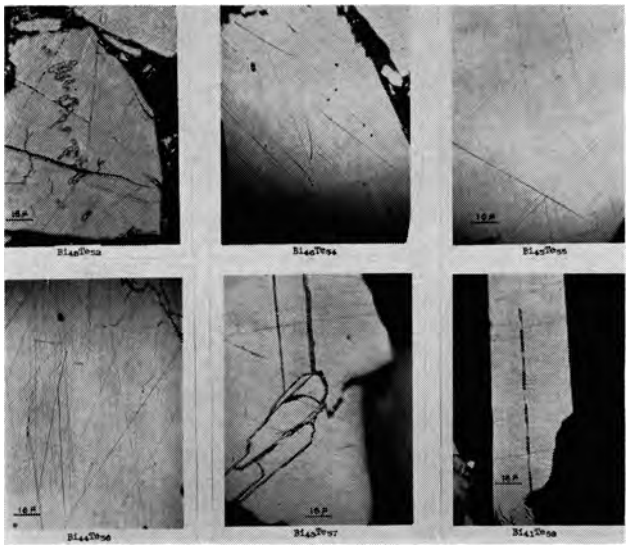

Fig. 4. Photomicrographs of specimens quenched from 553°C

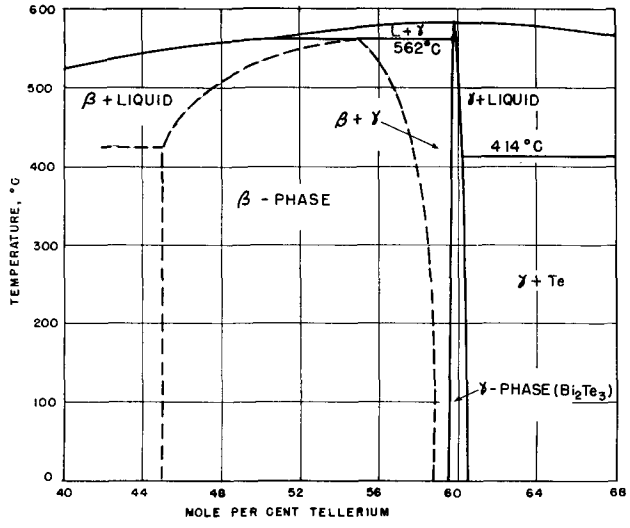

Fig. 5. Phase diagram of the bismuth-tellurium system in the region near the congruent melting compound.

perature. Six powdered alloys having compositions 52, 54-57, and 59 mole % tellurium were maintained at 553° ± 3°C for one week in a "Hevi-Duty" tube furnace mounted in the vertical position and were quenched in ice water. Visual examination of these quenched specimens indicated the appearance of a quenched liquid phase for compositions 52 and 54 mole % tellurium, a sintered mass for compositions 55-57 mole % tellurium, and unaltered powdered sample for 59 mole % tellurium. Employing a mounting technique for powders described by Skinner (8), the peritectic point was established by metallographic observation of polished sections of these alloys. Shown in Fig. 4 are several photomicrographs of these quenched and polished specimens indicating that the peritectic point of the β-phase lies at approximately 55 mole % tellurium. It is of interest to note that the β- and γ-phases are not distinguishable on these photomicrographs in the region between these phases. This is apparently due to the structural similarities between these phases as shown by the x-ray studies. It appears from the photomicrographs that incomplete peritectic reaction or envelopment can be detected in this region.

The β-phase extends over to approximately 45 mole % tellurium as determined by the disappearance of a thermal effect at 430°C. This thermal effect at 430°C will be discussed later.

The range of existence of the γ-phase as a single-phase field at elevated temperatures has been established by DTA studies. On the bismuth-rich side the peritectic reaction at 562°C is observed from the liquidus at 50 mole % tellurium to 59.7 mole % tellurium, and on the tellurium-rich side the eutectic reaction at 414°C is observed from pure tellurium to 60.2 mole % tellurium. The maximum melting composition was determined by the DTA method as the composition having the maximum area under the curve associated with melting. The maximum melting composition determined by this method is $Bi_{40.2}Te_{59.8}$. The existence of the maximum melting point on the bismuth-rich side of the stoichiometric composition is consistent with that reported by other investigators (9, 10).

On the basis of these studies, the equilibrium phase diagram for the Bi-Te system in the region near the congruent melting compound, extending from 45 to 68 mole % tellurium, is shown in Fig. 5.

DTA studies of samples having compositions from 5 to 50 mole % tellurium, that were annealed for periods of time up to six months at various temperatures, indicate that equilibrium is not easily attained for alloys in this composition range. This may be observed on the DTA thermograms shown in Fig. 6.

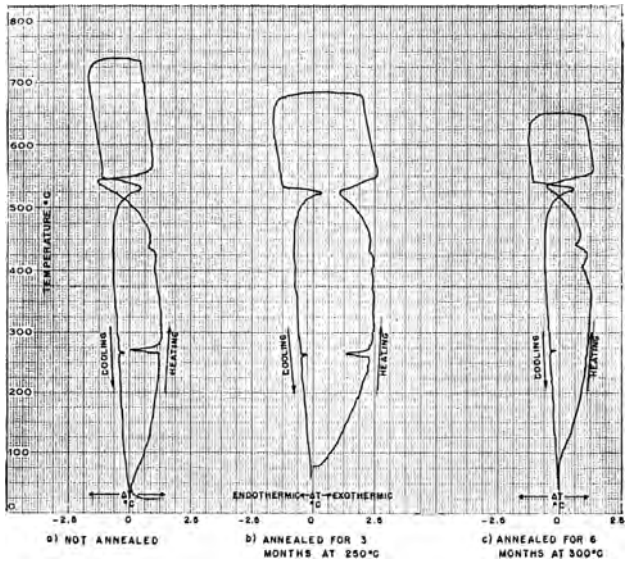

Fig. 6. DTA thermograms of composition, $Bi_{56}Te_{44}$, annealed at various temperatures and periods of time.

This figure illustrates the effect of annealing time and temperature on the observed thermograms for the composition, $Bi_{56}Te_{44}$. It may be observed that the bismuth-eutectic at 266°C can be eliminated by annealing at 300°C for six months; whereas, annealing at 250°C for three months will not eliminate the eutectic reaction, which is also observed on the unannealed sample. DTA studies on unannealed samples indicate that the bismuth eutectic at 266°C is observed on all alloys up to 52 mole % tellurium. For samples annealed at 400°C for one month and at 300°C for six months, the bismuth eutectic is observed on all alloys having compositions less than 40 mole % tellurium. In addition, Fig. 6 shows the appearance of at least two enthalpic effects, occurring at approximately 430° and 375°C. These effects are magnified when the samples are annealed several degrees below these transition temperatures indicating that a closer approach to equilibrium is being achieved. DTA studies of samples annealed at 400°C for one month and 300°C for six months have shown that these enthalpic effects extend over to the liquidus. It is believed that they are probably due to peritectic reactions, but further work is required to validate this point. It may be recalled that Abrikasov and Bankina (3) reported two peritectic compounds in this region of the phase diagram.

Discussion

The results of this phase equilibria study on the Bi-Te system clearly indicate that the congruent melting γ-phase exists as a single phase over a narrow composition range with maximum limits extending from 59.6 to 60.5 mole % tellurium at room temperature. This congruent-melting, single-phase field is separated from a peritectic β-phase by a narrow two-phase field extending from 58.75 to the bismuth-rich phase boundary of the γ-phase at room temperature. The β-phase, which has a peritectic reaction temperature of 562°C, extends from 58.75 to approximately 45 mole % tellurium. Additional studies across the bismuth-rich-phase field from 5 to 50 mole % tellurium have demonstrated the importance of "equilibrium" and have indicated the probable existence of several additional peritectic compounds in this region of the phase diagram.

The samples used in this investigation were annealed below the liquidus for various lengths of time and at various temperatures to investigate the effect of departure from equilibrium upon the phase diagram. These studies have shown that in the region from 30 to 50 mole % tellurium, equilibrium below the liquidus is difficult to attain and requires long annealing time at the proper temperature. This behavior is also observed for some mineral systems (11). It appears that in the region from 55 to 100% tellurium, equilibrium can be easily attained in the laboratory.

Our phase study in the region from 45 to 68 mole % tellurium has demonstrated the importance of using several analytical techniques simultaneously in doing phase studies on this system. For example, Brown and Lewis (1) using only the x-ray method were unable to distinguish between the γ- and β-phases, because these solid solutions have similar symmetries and lattice parameters. Also, their x-ray investigations did not include samples with compositions between the γ- and β-phases so that they erroneously concluded that the β-phase extended up to 60 mole % tellurium. For comparison, the x-ray data reported by Brown and Lewis (1) is shown in Fig. 1. For this reason we have employed both DTA and metallography to corroborate x-ray measurements in this region. It is of interest to note that our phase studies in this region of the phase diagram are consistent with the existence of the mineral phases tellurbismuth and wehrlite as distinct phases (12).

In samples that have not been properly annealed, the bismuth eutectic can be observed on DTA thermograms up to 52 mole % tellurium. This would yield a phase diagram similar to that published by Hansen (2). It is important to note that in systems in which equilibrium is difficult to achieve, thermal methods of analysis must be treated with caution because equilibrium is not attained at each temperature. It is better to corroborate thermal analysis studies with equilibrium studies, *e.g.*, x-ray diffraction at each temperature for establishing phase boundaries. For this reason, our investigations in the region from 5 to 50 mole % tellurium, are presented, only to give an indication of the importance of "equilibrium" in this region of the phase diagram. However, these studies have been performed on carefully annealed samples and probably represent equilibrium at these temperatures. Additional phase equilibria studies on properly annealed samples are required in order to verify the observations mentioned above, and elucidate the equilibrium phase diagram in this region. These studies are in progress and will be reported later.

In conclusion, we have found that the assurance that the sample has reached equilibrium is extremely important in establishing the "true" equilibrium phase diagram for the Bi-Te system. The previously reported phase diagrams for this system appear to be valid representations under the stated conditions. The discrepancies seem to arise due to differences in sample preparation and the limited number of analytical methods that were employed by each investigator.

Solubility and Electrical Behavior of Group IV Impurities in Solution Grown Gallium Phosphide

F. A. Trumbore, H. G. White, M. Kowalchik, C. L. Luke and D. L. Nash

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Gallium phosphide crystals doped with silicon, germanium, or tin were grown from solution by using a thermal gradient technique. At low doping levels nearly all of the tin or silicon atoms act as donors, *i.e.*, substitute on gallium sites. At higher doping levels the number of tin and silicon atoms substituting on phosphorus sites increases to about 30% and almost 50%, respectively. In contrast, doping with germanium yields p-type material at the lower doping levels and n-type material at higher doping levels with nearly equal numbers of germanium atoms on both sites at all doping levels.

The purpose of this paper is to present the results of experiments dealing with the concentration dependence of the electrical activities and solid solubilities of silicon, germanium, and tin in GaP crystals grown from gallium solution. This work is an extension of similar studies on zinc, sulfur, selenium, and tellurium in GaP (1), while the behavior of tin in crystals grown from solutions of GaP in pure tin was discussed in an earlier paper (2). Of particular concern here is the amphoteric nature of the Group IV impurities, *i.e.*, the substitution of these impurities on either gallium or phosphorous sites, thus leading to self-compensation.

Experimental

The crystals were grown from doped gallium solutions by using the same sealed tube thermal gradient technique described previously (3) for the growth of germanium or silicon from solution. After crushing and digesting to remove any occluded material, the samples were analyzed using spectrophotometric techniques (4) and, in the case of silicon, emission spectroscopy. Excess donor or acceptor concentrations were determined from surface barrier capacitance measurements involving the evaporation of gold dots on the GaP crystals (5). In order to test for precipitation a few crystals were heated to about 1000°C for several minutes, quenched, and remeasured after etching to eliminate surface effects. Details of the experimental procedures are the same as described previously (1-5).

Results

The results of the chemical analyses and the capacitance measurements are summarized in Table I and plotted in Fig. 1, 2, and 3. The data in Fig. 1 show that for the tin-doped samples the excess donor concentration, $(N_D - N_A)$, is equal to the tin concentration, within experimental error, at the lowest doping level of about 1×10^{17} atoms/cc. At higher tin concentrations the samples remain n-type but the doping efficiency drops until, in the most heavily doped samples grown from a solution of GaP in pure tin, $(N_D - N_A)$ is less than half of the tin concentration. Quenching experiments on crystals grown from pure tin yielded no evidence of precipitation (2). The agreement between duplicate capacitance measurements was especially good for this series of samples.

Although the silicon-doped crystals were grown at a number of different temperatures between 1015° and 1085°C, the scatter in the data masks any temperature dependence of the solid solubility and hence all of the data are plotted in Fig. 2. It is seen that, in the silicon concentration range from about 10^{18} to 7×10^{20} atoms/cc, all the crystals are n-type, although at the higher doping levels the excess donor concentration is only a small fraction of the silicon concentration. No conclusive evidence concerning the presence or absence of precipitation was obtained from quenching experiments, since the capacitance measurements become unreliable at $(N_D - N_A)$ values $\gtrsim 10^{19}$ cm^{-3}. It seems reasonable to assume that there is no significant pre-

* The results of the individual analyses or capacitance measurements are given in order to indicate the reproducibility of these data. All of the $\lvert N_D - N_A \rvert$ values correspond to excess donor concentrations (n-type material) unless noted otherwise. The growth temperatures are uncertain to ±20°C. The value of C_L for the least heavily tin-doped crystal is uncertain but lies between 0.01 and 0.1 a/o as indicated.

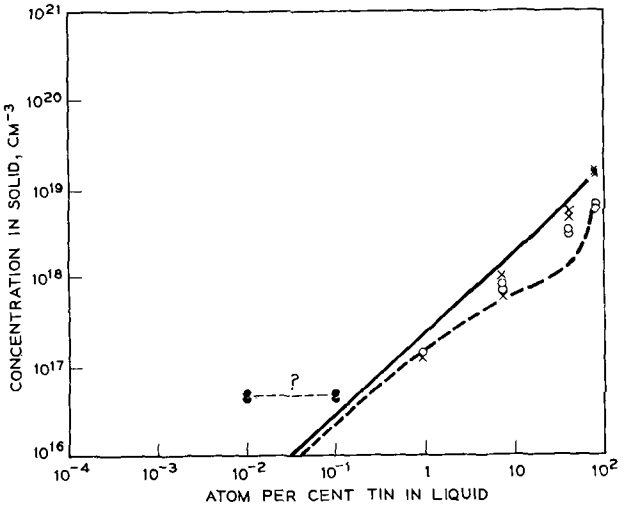

Fig. 1. Tin and excess donor (acceptor) concentrations as a function of the concentration of tin in gallium solution at ~1070°C. The solid and dashed curves are the theoretical curves obtained by fitting the chemical and capacitance data, respectively, for the most heavily doped sample assuming a value of n_i of 3 x 10^{17} cm^{-3}. The p-type behavior at the lowest doping level is believed to be due to a background acceptor. X, Sn concentration, photometric; ○, $(N_D - N_A)$ n-type; ●, $(N_A - N_D)$ p-type.

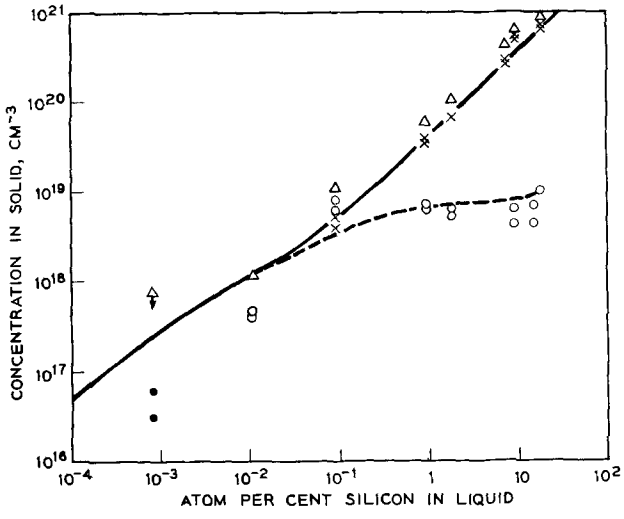

Fig. 2. Silicon and excess donor (acceptor) concentrations as a function of the concentration of silicon in gallium solution at ~1040°C. Actually, points are included for crystals grown at various temperatures between ~1015° and 1085°C (see text). The solid and dashed curves are the theoretical curves obtained by fitting the chemical and capacitance data, respectively, for the most heavily doped sample assuming a value of n_i of 2.5 x 10^{17} cm^{-3}. △, Si concentration, spectroscopic; X, Si concentration, photometric; ○, $(N_D - N_A)$ n-type; ●, $(N_A - N_D)$ p-type.

cipitation in view of the results for tin and germanium (see below). Concerning the chemical analyses, it is seen in Fig. 2 that the spectroscopic results are higher than the photometric values, especially at the lower doping levels. Unfortunately, the scatter in the capacitance data does not help to decide which analyses are more reliable. In general, photometric methods are more accurate and these points are weighted more heavily.

The behavior of germanium (Fig. 3) is quite different from that of tin and silicon. At the higher doping levels of up to about 2 × 10^{20} atoms/cc, the samples are n-type with $(N_D - N_A)$ values between one and two orders of magnitude lower than the germanium concentrations. (No evidence of precipitation was found in quenching experiments.) However, when the

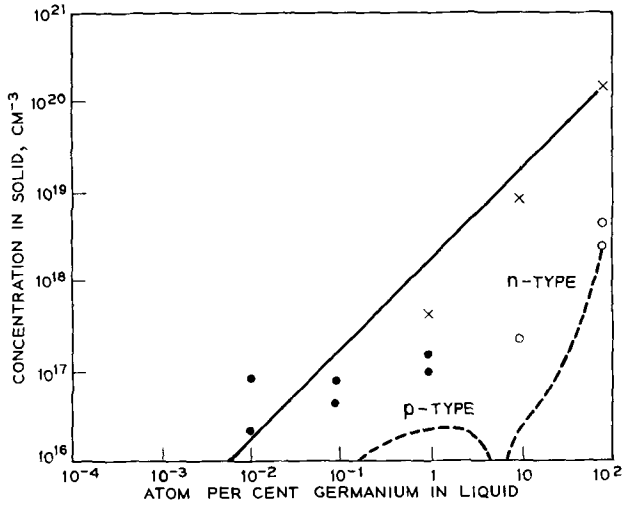

Fig. 3. Germanium and excess donor (acceptor) concentrations as a function of the concentration of germanium in gallium solution at ~1040°C. The solid and dashed curves are the theoretical curves obtained by fitting the chemical and capacitance data, respectively, for the most heavily doped sample assuming a value of $n_i = 2.5 \times 10^{17}$ cm^{-3}. The lowest $(N_D - N_A)$ point is used for fitting to theory. X, Ge concentration, photometric; ○, $(N_D - N_A)$ n-type; ●, $(N_A - N_D)$ p-type.

doping level falls below about 10^{18} atoms/cc p-type material is obtained. The preparation of p-type GaP using Ge as a dopant has also been reported by Weinstein and Mlavsky (6). Data are given in Table I for crystals grown from solutions of GaP in pure Ge at temperatures of ~1040°-1050°C as well as for a crystal grown at ~950°C. There is apparently little temperature dependence of the solid solubility in this temperature range and the distribution coefficient is essentially constant at 4×10^{-3}.

The preceding discussion has included only those samples for which photometric analyses are available. At lower concentrations, where the photometric method is not applicable, capacitance measurements have been made. Crystals grown from the most lightly doped melts are all p-type with $(N_A - N_D)$ values scattering about 5×10^{16} cm^{-3}. This behavior is believed to be due to some unidentified background acceptor impurity or defect. (Crystals grown from undoped gallium solutions were either p- or n-type at the 10^{16}-10^{17} cm^{-3} level.)

Discussion

The incorporation of group IV elements in III-V compounds has been considered by many authors. Kröger (7) gives a detailed discussion and references to most of this work. In considering the incorporation of a group IV element, M, into GaP from a liquid phase we may write the following equations and equilibrium constants involving the gallium and phosphorus vacancies, V_{Ga} and V_P, and the free electrons and holes, e^- and e^+:

$$M(l) + V_{Ga} = M^+ + e^-; \quad K_1 = \frac{(M^+)n}{(M_L)\gamma^{M_L}(V_{Ga})} \qquad [1]$$

$$M(l) + V_P = M^- + e^+; \quad K_2 = \frac{(M^-)p}{(M_L)\gamma^{M_L}(V_P)} \qquad [2]$$

$$O = e^+ + e^-; \quad K_i = np = n_i^2 \qquad [3]$$

$$Ga(l) + V_{Ga} = Ga_{Ga}; \quad K_4 = 1/(V_{Ga})(Ga_L)\gamma^{Ga_L} \qquad [4]$$

$$P(l) + V_P = P_P; \quad K_5 = 1/(V_P)(P_L)\gamma^{P_L} \qquad [5]$$

$$(M^+) + p = (M^-) + n \quad \text{(neutrality condition)} \qquad [6]$$

where the quantities in parentheses denote the concentrations of the respective entities, n and p are the free electron and hole concentrations, n_i is the intrinsic electron or hole concentration, and $\gamma^{M}{}_{L}$, $\gamma^{Ga}{}_{L}$, and $\gamma^{P}{}_{L}$ are the activity coefficients of the respective elements in the liquid phase. Here, we have assumed M to be completely ionized[1] and the solid solutions to be ideal dilute solutions in which all of the entities (M^+, e^-, V_{Ga}, etc.) obey Henry's law. We have also assumed the departures from stoichiometry to be small so that (Ga_{Ga}) and (P_P) are constant. Inherent in this treatment is the assumption that ionized vacancies or other defects or impurities are present in negligible concentrations and the assumption of Schottky type disorder.

The above equations may be solved for (M^+), (M^-), and n to give

$$(M^+) = \frac{K_1 \gamma^{M}{}_{L}(M_L) Q}{n_i} \left\{ \frac{K_i + K_2 \gamma^{M}{}_{L}(M_L) Q^{-1}}{K_i + K_1 \gamma^{M}{}_{L}(M_L) Q} \right\}^{1/2} \quad [7]$$

$$(M^-) = \frac{K_2 \gamma^{M}{}_{L}(M_L)}{n_i Q} \left\{ \frac{K_i + K_1 \gamma^{M}{}_{L}(M_L) Q}{K_i + K_2 \gamma^{M}{}_{L}(M_L) Q^{-1}} \right\}^{1/2} \quad [8]$$

$$n = n_i \left\{ \frac{K_i + K_1 \gamma^{M}{}_{L}(M_L) Q}{K_i + K_2 \gamma^{M}{}_{L}(M_L) Q^{-1}} \right\}^{1/2} \quad [9]$$

where it is convenient to define the quantity Q

$$Q \equiv \left\{ \frac{\gamma^{Ga*}{}_{L}\,(Ga^*{}_{L})}{\gamma^{Ga}{}_{L}\,(Ga_L)} \right\} \quad [10]$$

Here the asterisks denote the values of these quantities in the binary Ga-GaP liquidus alloys. At 1040°C ($Ga^*{}_L$) is about 97 a/o (atom per cent) (8) and $\gamma^{Ga*}{}_{L}$ should be very close to unity (assuming a standard state of pure liquid gallium). In dilute liquid solutions, where (M_L) is low, Q will be approximately unity. It is only in the neighborhood of (M_L) equal to about 10 a/o or more that Q may be expected to depart significantly from unity, at least in the temperature range of interest here ($\leq$ 1070°C). In order to derive values of K_1 and K_2 from the experimental data we may use Eq. [7], [8], and [9] to derive the expressions

$$K_1 = \frac{(M^+)n}{\gamma^{M}{}_{L}(M_L) Q} \quad [11]$$

and

$$K_2 = \frac{(M^+)(M^-)K_i}{K_1 (M_L)^2 (\gamma^{M}{}_{L})^2} \quad [12]$$

Also

$$K_i = n^2 - n\,[(M^+) - (M^-)] \quad [13]$$

The chemical analyses yield $[(M^+) + (M^-)]$ and the capacitance measurements give $[(M^+) - (M^-)]$ so that one can solve for (M^+) and (M^-) assuming, of course, that the concentrations of all other electrically active defects or impurities are negligible. As a first approximation, we may assume both $\gamma^{M}{}_{L}$ and $\gamma^{Ga}{}_{L}$ to be unity, *i.e.*, Raoult's law is obeyed in the liquid phase, and a value for Q can then be calculated.[2] The value of n is assumed to be equal to ($N_D - N_A$), a valid assumption only as long as $n >> n_i$, at the growth temperature. This is a necessary condition since ($N_D - N_A$), measured at room temperature, corresponds to $[(M^+) - (M^-)]$, which in turn only equals n to a good approximation when $[(M^+) - (M^-)] >> n_i$. Therefore, in order to use Eq. [11] to get K_1, it is necessary to use data on a heavily doped sample. This value of K_1 can then be substituted in Eq. [12] to get K_2, if we know K_i. Practically speaking, Eq. [13] is useless in determining K_i since ($N_D - N_A$) or Hall effect data are needed at the growth temperature. In the treatment that follows, values of n_i of 2.5 and 3 $\times$ 10^{17} cm^{-3} were used for the temperatures 1040° and 1070°C, respectively. These values are found to give reasonably good fits to the data and compare with values of between 1 and 3 $\times$ 10^{17} cm^{-3} based on extrapolation of effective mass and band gap data from lower temperatures (9).

The curves in Fig. 1, 2, and 3 are the curves obtained by fitting the photometric and capacitance data on the most heavily doped sample for each system to Eq. [11] and [12] to obtain K_1 and K_2 assuming the above values of n_i. The curves were then calculated from Eq. [7], [8], and [9] assuming the liquid solutions to be ideal, *i.e.*, the activity coefficients were assumed equal to unity.

The agreement between theory and experiment in the case of tin is seen in Fig. 1 to be rather good, especially considering the assumption of Raoult's law for the liquid solutions. The predicted tin solubilities are higher than the measured solubilities, a feature common to germanium and silicon as well. It is interesting that the lower ($N_D - N_A$) values agree well with the predicted values while an intermediate point lies much further off the theoretical curve.

The fit in the case of silicon (Fig. 2) is also good, especially down to a doping level of about 5 $\times$ 10^{18} cm^{-3}, the lowest photometric value. At lower doping levels, if the capacitance measurements at ~5 $\times$ 10^{17} cm^{-3} are taken to be more reliable than the spectroscopic values, the theory predicts a higher solubility than is observed. It is of interest that the predicted concentration of acceptor silicon atoms (on phosphorus sites) is less than 10^{16} atoms/cc at less than about 5 $\times$ 10^{-3} a/o silicon in the liquid phase. Yet, in crystals grown from undoped melts there are strong Si-S (type IA) pair spectra (10). These spectra presumably involve silicon as the acceptor and one concludes that there are less than 10^{16} pairs/cc involved. It would also be expected that Si-Si pair spectra would be observed in these crystals but no such spectra have yet been identified.

In the case of germanium (Fig. 3) the agreement between predicted and observed solubilities is poorer than in the case of tin or silicon. However, the change from n- to p-type is predicted. It should be noted that the magnitude of ($N_D - N_A$) and the concentration at which the crystals change from n- to p-type are extremely sensitive to small changes in the values of ($N_D - N_A$) and n_i used to fit the theory. This is to be expected in view of the very close compensation in these crystals. Liquid phase departures from ideality may be partly responsible for the relatively poor quantitative agreement. Thurmond and Kowalchik (11) showed that the binary Ga-Ge liquidus alloys obeyed Raoult's law closely, at least insofar as the germanium activity is concerned. However, they used a heat of fusion for Ge of 8.1 kcal/g-atom, considerably lower than the recent values of about 8.9 kcal/g-atom obtained by Orr and Sommelet (12) and by Perbix and Tarwater (13). Using the latter values, negative departures from ideality are obtained which are in the direction needed to obtain closer agreement.

Conclusion

The behavior of tin in acting as a relatively strong donor is not unexpected in view of the fact that the tetrahedral radius of tin is 1.40Å while the radii of gallium and phosphorus are 1.25 and 1.10Å, respectively (14). Thus, one would not expect tin to substitute on the phosphorus site nearly as readily as on the gallium site. The behavior of germanium, with a tetrahedral radius of 1.22Å, may be rationalized on

[1] The assumption of complete ionization neglects the possible presence of neutral M atoms due to Fermi level effects; this assumption seems reasonable in view of the close compensation at high doping levels. However, application of this mass action treatment at high doping levels is certainly to be considered only a first approximation.

[2] The values of (Ga_L) and (M_L) were calculated from the binary or pseudobinary Ga-GaP, Sn-GaP, and Ge-GaP liquidus curves (8) assuming the solubilities of GaP in the liquid alloys to vary linearly between the solubility in pure gallium and that in pure tin or germanium. In the case of silicon the solubility of GaP in pure (supercooled) silicon was assumed to be zero and the same linear interpolation was used.

the basis that at low doping levels, due to factors other than size, there is a very slight preference for the phosphorous site, with the increase in gallium vacancy concentration at higher doping levels leading to a preference for the gallium site. From the standpoint of size silicon, with a tetrahedral radius of 1.17Å, would be expected to substitute more predominantly on phosphorous sites than germanium whereas just the opposite is true. This result is also in disagreement with the approximate calculations of Scott and Fredericks (15) who considered the effects of bond and strain energies on the site distribution of group IV elements in III-V compounds. They estimated the free energy of transfer of germanium from a phosphorous to a gallium site to be —10 kcal/mole as opposed to —9 kcal/mole for silicon.

Low-Temperature Epitaxial Growth of Si (Inverted Transport in Close-Spaced Technique)

J. Bloem and J. W. A. Scholte

Semiconductor Development Laboratory, N. V. Philips' Gloeilampenfabrieken, Nijmegen, Netherlands

ABSTRACT

The transport of silicon in a temperature gradient via the vapor phase between two neighboring silicon slices has been analyzed for the chloride system ($SiCl_4$-$SiCl_2$-HCl-H_2). Normal transport of silicon is directed toward the low-temperature side. A reversal of the transport, however, is possible at lower temperatures and at higher $SiCl_4$ partial pressures. Epitaxial layers of good quality can be grown at temperatures as low as 1000°C, an additional advantage is found in the observation that in this case disturbing oxides are transported away from the growing layer. This method offers advantages for the growth of high-resistivity layers on low-resistivity substrates.

The vapor transport of silicon in a temperature gradient between two neighboring silicon surfaces can be realized in a high vacuum (1) or in the presence of silicon halides (2-5) and possibly oxides (6). In most cases the transport of silicon takes place from the higher toward the lower temperature side, as in thermal gradient crystal-growing across a solution (7).

According to Schäfer (2) we may assume that there is equilibrium between the gas phase and the silicon surfaces at both the higher and the lower temperature, giving different vapor pressures of the various reaction partners. By diffusion between the two interface regions in the chloride system a transport of, *e.g.*, $SiCl_2$ from the high to the lower temperature region takes place. At the lower temperature the arriving $SiCl_2$ reacts according to

$$2SiCl_2(g) \rightarrow Si(s) + SiCl_4(g) \qquad [1]$$

$SiCl_4$ again diffuses toward the high-temperature side and the net result is a transport of silicon without a fresh supply of chlorides being necessary.

If the two silicon slices are closely spaced, the rest of the apparatus has little influence, so that high resistivity layers can be grown. A disadvantage of this sandwich system (3), as it is called, is the observation that epitaxial silicon layers with rather high stacking-fault densities are formed. Efficient reduction of surface oxides is difficult in closely spaced structures, and transport of SiO_2 to the lower temperature side interferes with the epitaxial growth of silicon. For the chloride system Steinmaier (8) calculated the resulting equilibrium vapor pressure of HCl, $SiCl_2$, $SiCl_4$, and H_2 in contact with silicon at various temperatures, starting with $SiCl_4$ in H_2 for a system of 1 atm total pressure. For the epitaxial growth of silicon by the sandwich method, use is often made of $SiCl_4$ in H_2 with an open system. Steinmaier's results might be useful in understanding the transport reactions, especially if, as Schäfer suggests, equilibrium vapor pressures can be assumed.[1]

Steinmaier introduced a hypothetical silicon vapor pressure P_{Si}. If the value of P_{Si} is greater than the maximum silicon vapor pressure at that specific tem-

[1] In Schäfer's experiments the distance between the two reaction regions has been so great that diffusion constitutes the rate limiting step. For the close spaced structures this no longer holds, here probably etch and nucleation rates are rate limiting. Near equilibrium in both temperature regions will be postulated nevertheless, as the main interest is in the direction and not in the rate of the transport.

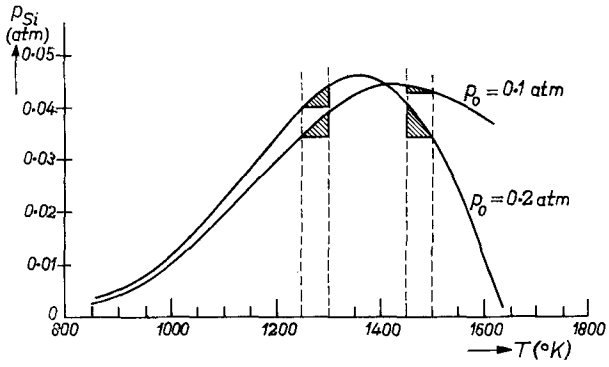

Fig. 1. Variation of p_{Si} with temperature for two initial partial pressures (p_O) of $SiCl_4$ in H_2. The value of p_{Si} refers to a hypothetical silicon vapor pressure, which can be related directly to the growth rate of silicon.

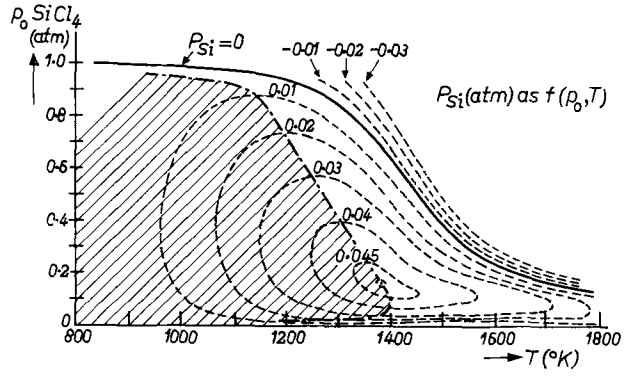

Fig. 2. Variation of p_{Si} (proportional to the growth rate of silicon) with temperature and initial $SiCl_4$ partial pressure (p_O) in the $SiCl_4$-H_2 system. Contours of equal values of p_{Si} are given, together with the line connecting maximum values of p_{Si} vs. temperature. In the shaded area p_{Si} increases with T and reversed sandwich growth is expected.

perature deposition will occur, for a lower value etching will be observed. Figure 1 gives a curve of P_{Si} as a function of temperature for an initial $SiCl_4$ vapor pressure of 10 and 20% in H_2 ($p_O = 0.1$ and 0.2).

In a system with two temperatures of, *e.g.*, 1450° and 1500°K it will be seen that the lower of the two temperatures has the higher value of P_{Si} and thus will give a higher silicon growth rate. In a close-spaced system with the same temperatures it can be expected that the difference in deposition rate between the two interface regions, as deduced from Fig. 1, will constitute the driving force of the transport reaction, the lower temperature side being the receiving part. This being so, then at lower temperatures, *e.g.* 1250°-1300°K in Fig. 1, the transport direction must be reversed, and epitaxial growth of silicon at the high temperature side is to be expected. If some oxide is present a possible transport of SiO_2 toward the low temperature side will not be reversed, but will continue as before. It was, therefore, considered that inverted sandwich growth giving low stacking-fault densities might be

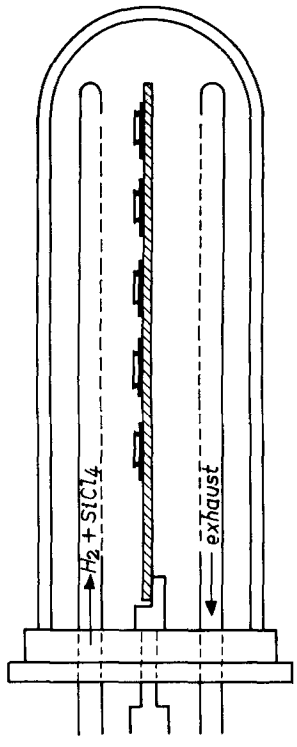

Fig. 3. The horizontal, resistance-heated apparatus used for the sandwich experiments.

possible at relatively low temperatures if the experiments were done in a region where the deposition rate (or rather P_{Si}) increased with temperature. In Fig. 2 values of P_{Si} as given by Steinmaier are depicted as functions of p_O, the initial partial pressure of $SiCl_4$ in H_2, and temperature. The shaded area is the field where transport toward the high temperature side, *i.e.*, the reversed sandwich growth, is expected. Table I gives some numerical results of the calculations of Steinmaier.

Experimental

Apparatus.—The close-spaced sandwich experiments were performed in a horizontal water cooled reactor in which a resistance-heated molybdenum heating element, covered with a quartz glass plate, served as a support for the silicon slices. Gas inlet and outlet tubes were situated as given in Fig. 3. (Figure on side by error.) The silicon sandwich consists of two silicon slices separated by a thin silicon ring or a few silicon chips. The silicon surface temperatures were measured by an optical pyrometer, calibrated by measurement of several melting and alloying temperatures. In the following only the corrected temperatures will be given.

Normal growth.—For normal sandwich growth at higher temperatures (1240°-1300°C) Fig. 4 shows the variation of the growth rate on the low temperature side with the $SiCl_4$ partial pressure of the incoming gas for three different spacer thicknesses (S). The growth rate of silicon not only depends on the spacer thickness and the $SiCl_4$ partial pressure, but also on the total gas flow rate (Fig. 5). For small gas flow rates,

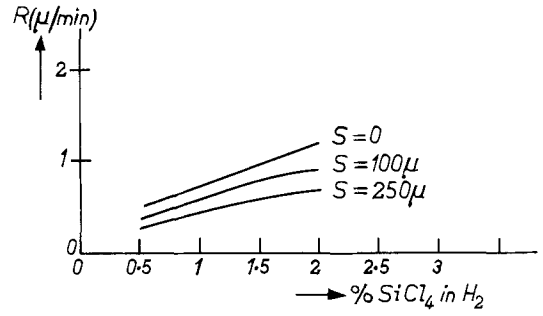

Fig. 4. Growth rate of silicon (R) on the low temperature side of the sandwich vs. initial partial pressure of $SiCl_4$ in H_2. S denotes the thickness of the spacer between seed and source slices. T = 1240°-1300°C.

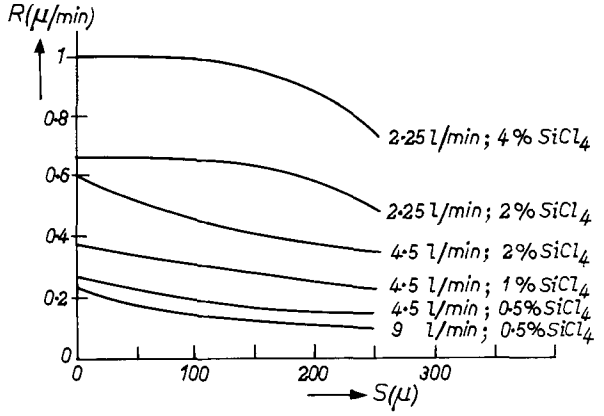

Fig. 5. Influence of the gas flow rate on the sandwich growth rates

however, there is no difference in growth rate for $S = 100\mu$ and $S = 0$ (no spacer).

Reversed growth.—With 1% $SiCl_4$ in H_2, decreasing the heater temperature results in a decreased sandwich growth rate (Fig. 6). In order to obtain reversed sandwich growth lower temperatures and higher $SiCl_4$ partial pressures were studied and results are given in Fig. 7, as can be seen a region indeed exists where reversed growth is observed.

In order to obtain a reasonable temperature gradient at the lower over-all temperatures, the spacing of the slices had to be increased to 200-500μ, otherwise the growth rate was found to be smaller than 0.1 μ/min. With adequate cooling, however, the growth rate at these low temperatures can be increased. The crystallographic quality of the resulting layers is very good, especially if the low growth temperature is considered (9).

It is also possible to start with H_2 + HCl instead of H_2 + $SiCl_4$. In the former case some Si is etched to obtain the necessary $SiCl_4$ and $SiCl_2$ concentration; the same equilibrium concentrations are thus reached from the other side. Reversed epitaxial sandwich growth calls for high HCl concentrations, resulting in a rapid etching of those silicon surfaces that are exposed to the gas phase.

For these experiments, $SiCl_4$ + H_2 was therefore preferred.

Layer quality.—The limited exchange between the close-spaced system and the rest of the apparatus has an advantage in so far as layers with very high resistivity can easily be grown. A disadvantage is the poor reduction possibility prior to growth, giving a high stacking fault density (>3000/cm^2) (3).

In the reversed sandwich growth the growth temperature is lower, but the number of stacking faults is much lower too (<2000/cm^2). This observation gives strong support to the suggestion that transport of SiO_2 toward the low temperature side of the sandwich is one of the major reasons for the growth irregularities.

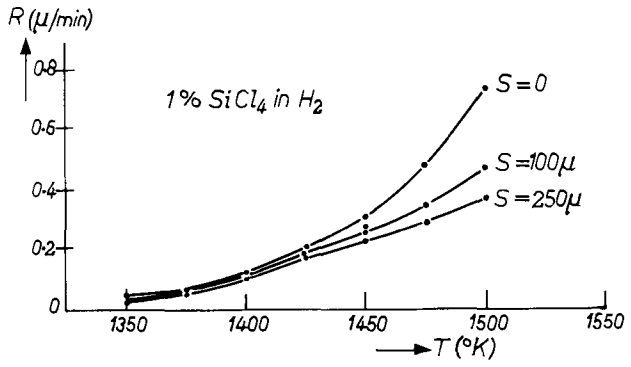

Fig. 6. Influence of the temperature on the sandwich growth rate for 1% $SiCl_4$ in H_2.

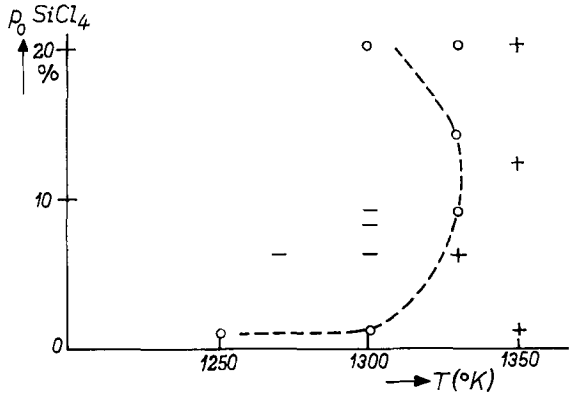

Fig. 7. Regions of normal (+) and inverted epitaxial sandwich growth (—) separated by a neutral zone (O) where no apparent growth on either side of the sandwich structure is observed (compare with Fig. 2). The temperatures given refer to the lower temperature side of the sandwich.

Both in the normal and the reversed sandwich growth the resistivity of the resulting layers mainly depends on the substrate doping level, a refining action being present due to the space between the slices which has to be filled with the gaseous chlorides of the doping elements until ultimately a balance is established between incoming and outgoing dope. The gas phase segregation coefficients for n-type impurities (P, As, Sb) are close to unity. After about 1μ of growth the original resistivity is found again. At greater distances between source and seed crystal the transfer ratio decreases because of a greater loss of dope into the rest of the apparatus. For p-type impurities (B, Al, Ga) the segregation coefficient of B is somewhat smaller than unity. For Al and especially for Ga, the coefficients are very small, *i.e.*, high resistivities result in grown layers of not too great a thickness (see Fig. 8).

Discussion

Equilibrium considerations.—The equilibrium of solid silicon with an atmosphere containing chlorides has been calculated by Steinmaier (8), starting from the following equilibrium reactions

$$SiCl_4(g) + Si(s) \leftrightharpoons 2SiCl_2(g) \qquad [2]$$

giving

$$K_1 = \frac{(p_{SiCl_2})^2}{p_{SiCl_4}}; \quad \log K_1 = 10.081 - 16427/T \qquad (10)$$

and

$$SiCl_4(g) + 2H_2(g) \leftrightharpoons Si(s) + 4HCl(g) \qquad [3]$$

with

$$K_2 = \frac{(p_{HCl})^4}{p_{SiCl_4}(p_{H_2})^2};$$

$$\log K_2 = 13.9 - 13170/T - 1.664 \log T \qquad (11)$$

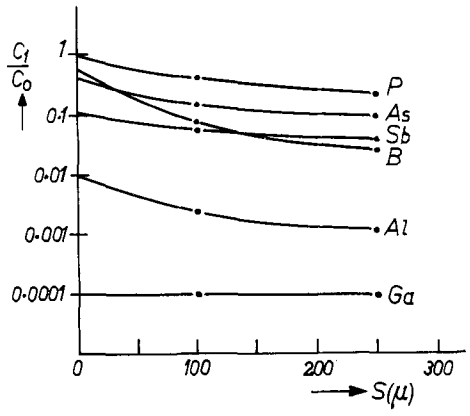

Fig. 8. Some examples of the variation of the segregation coefficient $\frac{C_1}{C_0}$ with distance in sandwich experiments. 1% $SiCl_4$ in H_2, T_1 = 1300°C, T_2 = 1240°C, growth rate 0.8 μ/min, layer thickness 16μ. C_1 = dope concentration in grown layer, C_0 = dope concentration in silicon source.

Further for an open system the sum of all partial pressures is 1 atm

$$p_{SiCl_4} + p_{H_2} + p_{HCl} + p_{SiCl_2} = 1 \quad [4]$$

The total chlorine balance gives

$$p_{SiCl_4} + \tfrac{1}{4}p_{HCl} + \tfrac{1}{2}p_{SiCl_2} = p_0 \quad [5]$$

where p_0 denotes the initial $SiCl_4$ partial pressure.

From [2] and [3] a "silicon partial pressure" p_{Si} is formulated as

$$p_{Si} = \tfrac{1}{4}p_{HCl} - \tfrac{1}{2}p_{SiCl_2} \quad [6]$$

With Eq. [2]-[6] the equilibrium values of the various components can be deduced for any starting concentration of $SiCl_4$ in H_2. Recently Lever (12) has expanded the calculations by introducing also other reaction products of which $SiHCl_3$ proved to be present in greater concentrations, especially at lower temperatures. The arguments used here, fortunately, remain valid, only the maxima in p_{Si} will shift somewhat to lower temperatures.

Direction of transport.—The equilibrium concentrations of the various reaction partners will be different at different temperatures. In a sandwich experiment these different temperature regions are closely spaced and transport occurs because of the existing concentration gradients between the two silicon slices. The transport of n moles of HCl toward any silicon face gives rise to the formation of $\frac{1}{4}n$ mole $SiCl_4$ and the etching of $\frac{1}{4}n$ mole of silicon from the solid (Eq. [3] in reverse direction). On the other hand transport of m moles of $SiCl_2$ toward the same face gives rise to the deposition of $\frac{1}{2}m$ mole of silicon and the formation of $\frac{1}{2}m$ mole $SiCl_4$ on that face (Eq. [2] reverse). The $\frac{1}{4}n + \frac{1}{2}m$ moles of $SiCl_4$ are now present in excess and diffuse back to the other side; here in turn n mole of HCl is formed, $\frac{1}{4}n$ mole of silicon is deposited, also m moles $SiCl_2$ are formed and $\frac{1}{2}m$ mole of silicon is etched away there and the circle is closed.

If the transport of silicon toward the low temperature, T_L, side is called positive and transport toward the high temperature, T_H, negative, then the total transport of silicon is found to be proportional to

$$\tfrac{1}{2}(p_{SiCl_{2H}} - p_{SiCl_{2L}}) - \tfrac{1}{4}(p_{HClH} - p_{HClL}) \quad [7]$$

where the subscripts H and L refer to high and low temperature equilibrium vapor pressure. Equation [7] can also be read as

$$(\tfrac{1}{4}p_{HClL} - \tfrac{1}{2}p_{SiCl_{2L}}) - (\tfrac{1}{4}p_{HClH} - \tfrac{1}{2}p_{SiCl_{2H}}) \quad [8]$$

or, with Eq. [6]

$$p_{SiL} - p_{SiH} \quad [9]$$

It is thus demonstrated that the relative values of p_{Si} can be used anyway to predict the direction of the silicon transport, that side of the sandwich with the highest value of p_{Si} is the receiving side. The magnitude of the growth rate, however, is not strictly proportional to the difference in p_{Si} as for the small diffusion lengths encountered here nucleation rates and perhaps heat transfer difficulties are rate limiting, more than the rate of transport via diffusion as in the experiments of Schäfer.

In the experiments described the total pressure in the open system is kept at about 1 atm, for a closed system the direction of transport is not only temperature dependent as shown here, but also a pressure dependence can be expected analogous to the experiments of Schäfer and Morcher (13).

Under near equilibrium conditions this value of p_{Si} determines the growth rate in normal epitaxial growth and according to Eq. [9] also in sandwich growth; comparison of the experimental Fig. 7 with the calculated Fig. 2 shows that the calculated boundary between the regions of normal and reversed sandwich growth has to be shifted toward the low temperature side by about 100°, dependent also on the actual value of the temperature gradient between the slices. As the presence of $SiHCl_3$ has been neglected in the gas phase in the present calculations, the agreement may be called very satisfactory.

Oxide transport.—The reactions

$$Si(s) + SiCl_4(g) \leftrightharpoons 2SiCl_2(g)$$

and

$$Si(s) + SiO_2(s) \leftrightharpoons 2SiO(g)$$

are comparable to the extent that in both cases transport of silicon toward the low temperature side occurs; for the second system at the high temperature side silicon and SiO_2 react to give SiO, this SiO diffuses toward the low temperature side, the reaction is reversed and solid silicon and solid SiO_2 are deposited again, whereas in the former reaction solid silicon and gaseous $SiCl_4$ are formed. This makes the oxide transport a one way process, the transport stops as soon as the oxide at T_H is used up. As the gas atmosphere is essentially free of oxygen, no new oxide is formed at the high temperature side.

Conclusion

It has been demonstrated that it is possible, using the close-spaced sandwich method, to reverse the growth direction in the epitaxial growth of silicon resulting in a layer of good quality, grown at relatively low temperatures (1000°C). Because of the limited out-diffusion at the low temperatures used, this type of growth has interesting prospects, especially for the growth of high resistivity layers on low resistivity substrates.

Electrochemical Behavior of the Quinone-Hydroquinone System in Pyridine

W. Richard Turner[1] and Philip J. Elving

The University of Michigan, Ann Arbor, Michigan

ABSTRACT

The electrochemical behavior of quinone, hydroquinone, and quinhydrone in pyridine solution at the stationary pyrolytic graphite electrode has been studied by conventional and cyclic voltammetry. In the absence of available protons, quinone is somewhat reversibly reduced in a probable 1*e* process to a free radical anion; in the presence of protons, the free radical produced on 1*e* reduction is thought to be oxidized to an N-dihydroxyphenyl pyridinium ion. The latter is also a likely product from the oxidation of hydroquinone. The quinone-hydroquinone system itself is irreversible, *e.g.*, quinhydrone behaves as a mixture of quinone and hydroquinone, the potentials of whose waves are 0.5v apart.

Since the oxidation-reduction behavior of the quinone-hydroquinone system is often used as a test system for electrochemical technics and approaches, its behavior at the pyrolytic graphite electrode was investigated as a part of a systematic investigation of electrochemistry in pyridine as solvent. Previous papers have described the general use of pyridine for polarography with the dropping mercury electrode (1-3), voltammetry with graphite indicating electrodes (4), and an orientative investigation of electrochemical oxidation (5).

Pyridine has a very low proton availability (much lower than the commonly used so-called "aprotic" solvents such as dimethylformamide and acetonitrile), so that reactions carried out in it, *e.g.*, those involving organic compounds, can be compared in the absence of protons and in the presence of known concentrations of available protons present in the form of pyridinium ions.

The results obtained in the present study by both conventional direct-current constant-potential voltammetry and relatively low-frequency cyclic voltammetry indicate the importance of pyridine as a stabilizer of free radicals and carbonium ions, as well as some interesting synthetic possibilities.

Experimental

Reagents.—Analytical reagent grade pyridine (Mallinckrodt) was used without further purification, since it showed the same voltammetric behavior as pyridine, which had been dried over barium oxide and fractionally distilled. Anhydrous lithium perchlorate (G. Frederick Smith) was dried at 200°C. Quinone (Eastman yellow label) was recrystallized from benzene after the benzene solution had been treated with Norit. Hydroquinone and quinhydrone (Eastman white label) were used without further purification. Pyridinium nitrate was prepared by adding cold, concentrated nitric acid to cold pyridine; cooling the resulting solution produced a precipitate, which was filtered and recrystallized from hot acetone, yielding white, nonhygroscopic needles. A colorless, transparent conducting gel, which is excellent for salt bridges, was prepared by heating 5g methyl cellulose (Dow "Methacel," 15 cps viscosity) with 100 ml of 0.5*M* lithium perchlorate in pyridine and cooling.

Apparatus.—The cell, maintained at 25.0° ± 0.1°C, and electrode used have been described (5). The sides of the pyrolytic graphite cylinder (4.0 mm diameter) were insulated by coating with polyethylene; the *ab* plane formed the base of the cylinder. Prior to each run, the electrode was resurfaced by sanding the end with a disk sander using 600A silicon carbide paper.

Procedures.—Conventional voltammograms were obtained with a Sargent Model XV polarograph. The IR drop across the cell was corrected electronically, using an operational amplifier circuit (6). Cyclic voltammograms were obtained by means of a three-electrode polarograph operational amplifier circuit (7), a triangular sweep function supplied by a Hewlett-Packard Model 202A function generator, and an Electro Instruments Model 320 X-Y recorder. All potential measurements are *vs.* the Ag-1.0*M* $AgNO_3$ pyridine reference electrode [$E = +0.09$v *vs.* aqueous S.C.E. including liquid junction potentials (1)].

Behavior of Quinone-Hydroquinone System

The oxidation and reduction of hydroquinone, quinhydrone, and quinone at the stationary pyrolytic graphite electrode were investigated in pyridine solutions, which were 0.5*M* in $LiClO_4$ as background electrolyte.

Cyclic voltammetry.—Typical results of cyclic voltammetry (span: 0.6 to −0.4v; scan rate: 20 mv/sec) are illustrated in Fig. 1.

Oxidation of hydroquinone (4 m*M*) produces a single anodic wave [peak current (i_p) = 83 μa; half-peak potential ($E_{p/2}$) = +0.30v]. On the reverse sweep, only a small wave of 6 μa is observed at a $E_{p/2}$ of −0.12v. The latter wave, which does not appear on the forward sweep and is therefore not a solution impurity, is due to the reduction either of a small amount of the oxidation product of hydroquinone or of a trace amount of quinone, which could be formed by air oxidation of hydroquinone. In either case, the oxidation of hydroquinone is completely irreversible. The product or products of the electrooxidation probably undergo a chemical reaction to form a species which cannot be electroreduced, at least within the potential range involved.

Quinone (4 m*M* solution) is reduced, producing a cathodic wave ($i_p = 45$ μa; $E_{p/2} = -0.18$v). On the reverse sweep, an anodic wave appears in the same region. Since this wave is superimposed on the cathodic process, it is difficult to assess the voltammetric parameters, i_p and $E_{p/2}$, which appear to be very similar to

[1] Present address: Technical Center, Atlas Chemical Industries, Wilmington, Delaware.

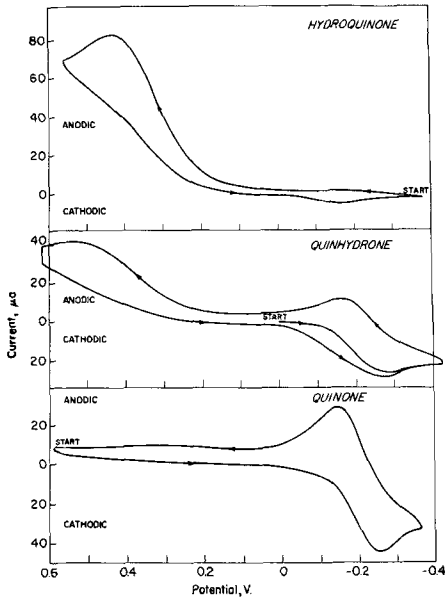

Fig. 1. Cyclic voltammograms at pyrolytic graphite electrode of 4 mM hydroquinone, 2 mM quinhydrone, and 4 mM quinone in 0.5M $LiClO_4$-pyridine solution; scan rate, 20 mv/sec.

those for the cathodic wave. Since a reversible 1e process requires a peak current separation of 57 mv and the present separation is 90-100 mv, the behavior is somewhat irreversible, although in comparison to the hydroquinone oxidation this deviation is minor.

The peak current for the hydroquinone oxidation is almost twice that for the reduction of the same quinone concentration. If the small reduction wave ($i_p = 6$ μa) observed for hydroquinone is due to partial air oxidation of hydroquinone, then i_p for the latter can be corrected to about 89 μa. The ratio of peak currents at a stationary electrode for two reversible processes, one of which is 2e and the other 1e, is 2.8, since the current is proportional to $n^{3/2}$. However, since the oxidation of hydroquinone is quite irreversible so a ratio smaller than 2.8 would be expected. Since the ratio of i_p for the two processes is near 2 and since the ratio of reversible 3e and 4e processes to reversible 1e processes would be 5.2 and 8, respectively, the oxidation of hydroquinone would seem to involve twice as many electrons as the reduction of quinone, and the postulation of a 2e oxidation of hydroquinone and a 1e reduction (and reoxidation) of quinone is quite reasonable.

Similar behavior is observed in the voltammetry of quinhydrone. Although quinhydrone is a 1:1 molecular addition compound of hydroquinone and quinone, cyclic voltammetry clearly shows that the two compounds react independently of each other. The i_p ratio for hydroquinone oxidation and quinone reduction in a quinhydrone solution is 2, *i.e.*, the same as when the two species are independently oxidized and reduced.

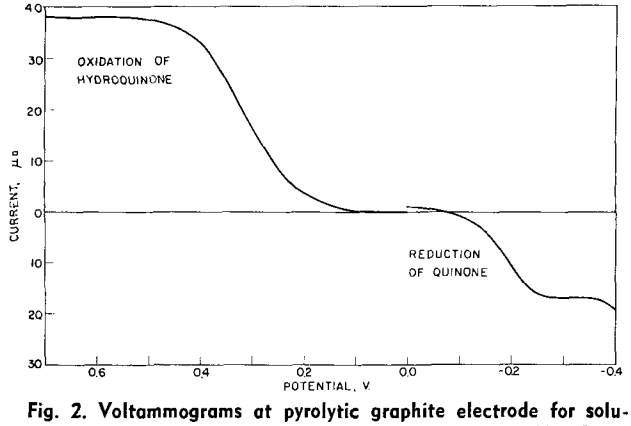

Fig. 2. Voltammograms at pyrolytic graphite electrode for solutions of 4 mM hydroquinone and of 4 mM quinone in 0.5M $LiClO_4$-pyridine solution. Polarization rate, 1.67 mv/sec. The figure is constructed from two voltammograms, one for each compound.

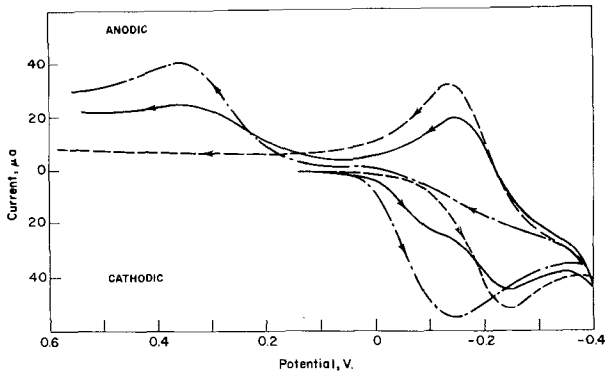

Fig. 3. Cyclic voltammograms at pyrolytic graphite electrode for 4 mM quinone in 0.5M $LiClO_4$-pyridine solution. Dashed line, no pyridinium nitrate added; solid line, 2.0 mM pyridinium nitrate; broken line, 4.0 mM pyridinium nitrate.

Voltammetry.—Typical conventional voltammograms for quinone and hydroquinone are shown in Fig. 2. Hydroquinone produces an anodic wave of 38 μa ($E_{p/2} = 0.31$v); quinone gives a cathodic wave of 17 μa ($E_{p/2} = -0.19$v); these results are in good agreement with the cyclic voltammetry data. The currents, when compared on the basis of current per unit concentration per unit area, correspond to those found for known 2e and 1e electrochemical redox reactions [*cf.* ref. (5).]

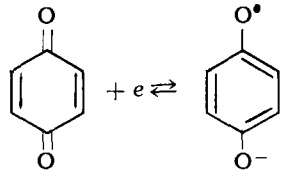
Effect of proton addition.—Helpful information in respect to elucidation of the electrode processes involved is obtained on reducing quinone in the presence of available protons or hydrogen ions, *e.g.*, cyclic voltammetry of quinone in the absence of pyridinium ion and in the presence of 0.5 and the same concentrations of pyridinium ion (Fig. 3).

The height of a cathodic wave, which appears at an $E_{p/2}$ of −0.15v, increases with pyridinium ion concentration up to a 1:1M ratio, at which ratio the original quinone wave at −0.18v is no longer visible. In addition, the original anodic reoxidation wave ($E_p = -0.15$v) decreases, and a second anodic wave ($E_{p/2} = +0.25$v) appears, which increases with increasing pyridinium ion concentration up to a ratio of one pyridinium ion per quinone molecule; at this concentration ratio, the anodic wave ($E_p = -0.15$v) has disappeared. Moreover, the ratio of cathodic to anodic peak currents is approximately one and a 1e process is indicated from the magnitude of the peak currents compared with i_p for reduction in the absence of pyridinium ion. Further increase in pyridinium ion has no effect, *e.g.*, a cyclic voltammogram for a solution, in which the molar ratio of pyridinium ion to quinone is 2, is identical to that for a solution, for which the ratio is 1.

Probable Electrode Processes

The voltammetric data can be rationalized on the basis of the following series of electrode reactions, which, as subsequently discussed, involve known reactions of pyridine:

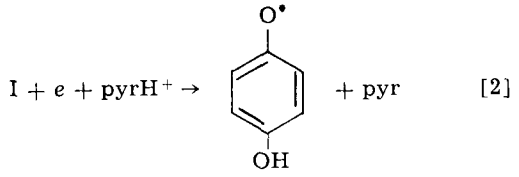
1. Voltammetry of quinone in the absence of pyridinium ion; cathodic wave ($E_{p/2} = -0.18$v; 1e process)



[1]

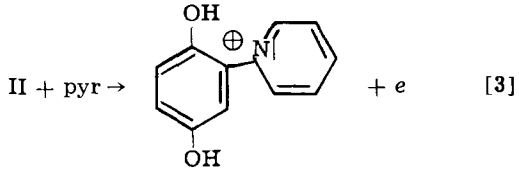
I

2. Voltammetry of quinone in the presence of pyridinium ion; cathodic wave ($E_{p/2} = -0.05$v; 1e process)



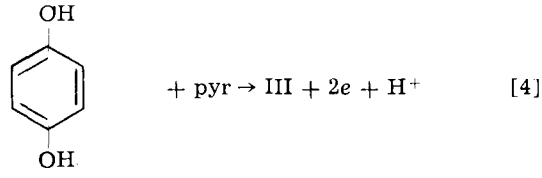
II

For anodic wave ($E_{p/2} = +0.25$v; 1e process)



III

3. Voltammetry of hydroquinone; anodic wave ($E_{p/2} = +0.30$v; 2e process)

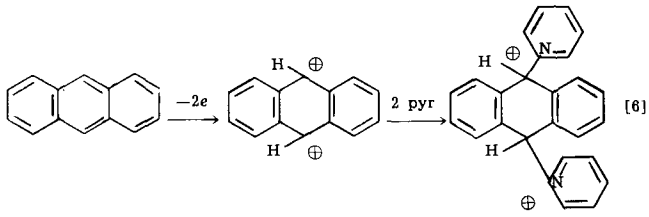


The semiquinone anion radical (I), postulated as the product of the reduction of quinone in the absence of added protons, has also been postulated by Wawzonek *et al.* (8) for the reduction of quinone in anhydrous acetonitrile and dimethylformamide, which are more likely to react with free radicals than pyridine, since they contain hydrogen atoms which are more labile than the hydrogen in pyridine. In addition, one would hardly expect the anodic and cathodic waves to be as close together as shown in the bottom panel of Fig. 1 if there were an intervening chemical reaction such as a dimerization.

Although the N-dihydroxyphenyl pyridinium ion (III) has not been isolated from the reaction, it is a likely product since the following chemical reaction has been observed and the products characterized (9)

The latter reaction proceeds slowly at room temperature and does not compete with the electrochemical reduction. However, when the hydroquinone radical (II) is oxidized, the removal of an electron might produce a protonated quinone in an activated state, which would be readily attacked by pyridine producing (III). In other words, the rate-determining step for the chemical reaction of quinone and pyridinium ion is the protonation of the quinone. The activation energy for this step is decreased, when a protonated quinone is produced during the oxidation of hydroquinone, and the protonated quinone would react rapidly with pyridine.

The reaction of pyridine with positively charged organic oxidation products is by no means unusual, *e.g.*, Lund (10) observed the following reaction in acetonitrile-pyridine mixture:



As far as reversibility of the quinone-hydroquinone system in pyridine is concerned, the over-all system is totally irreversible, *e.g.*, Fig. 2 and 3. However, the system involving quinone and the free radical anion resulting from its 1e reduction (Eq. [1]) approaches reversible behavior in the absence of available protons. Wawzonek *et al.* (8) report that 1e reduction of quinone in acetonitrile and dimethylformamide to be reversible.

Discussion

The results of the study of the voltammetric behavior of the quinone-hydroquinone system in pyridine demonstrates the value of the solvent in providing a controlled hydrogen ion environment, where the availability of hydrogen ions for participation in the electrode process is precisely known. The ability of pyridine to react with positively charged organic ions, which may be transient intermediates, is indicated by the oxidation of hydroquinone. This reaction is potentially useful both in trapping reaction intermediates for mechanism elucidation and in synthesis.

An Electrode Mechanism for the Electrochemical Reduction of M-dinitrobenzene

G. W. Jackson and J. S. Dereska

Consumer Products Division, Research Laboratory, Union Carbide Corporation, Cleveland, Ohio

ABSTRACT

This is an integrated polarographic and potentiostatic study on the mechanism of the cathodic reduction of m-dinitrobenzene for various *p*H values of aqueous electrolytes. The polarographic results confirmed previous results of a two-stage reduction involving four electrons in each step. The supporting coulometric work was performed potentiostatically at a graphite cathode under a nitrogen atmosphere at a controlled potential of —0.48v on a solution of *p*H 6.00. The product of the first step, 3-nitrophenylhydroxylamine, was quantitatively isolated and identified for coulometric equivalencies of 25, 50, 75, and 90% reduction.

There have been a number of theoretical and practical experiments on the electrochemical reduction of m-dinitrobenzene. Some of these reductions have been carried out electrolytically where no attempt was made to control the potential. These reductions have had as their goal the synthesis of a given product such as 2, 4-diaminophenol, m-nitroaniline, 3, 3'dinitroazoxybenzene, and 3-nitrophenylhydroxylamine (1-5). Even though these reductions were carried out in strongly acidic and basic solutions, the *p*H was left doubtful because of the use of large amounts of alcohol.

Pearson (11) polarographically examined a series of dinitro aromatic compounds and concluded that these compounds reduced in two separate stages with each stage equivalent to a four-electron reduction. Such a reaction path has also been postulated by other workers on the basis of polarographic evidence (7-11). Ehlers and Sease (6) used a combination of potentiostatic reduction and polarographic techniques to elucidate the reaction path for the reduction of m-dinitrobenzene and other polynitro aromatic compounds. Their result was the same as above in that a two-step reduction occurred with each step coulometrically equivalent to four electrons. These workers, however, were unsuccessful in obtaining 3-nitrophenylhydroxylamine.

In an effort to more convincingly confirm and describe the representative cathodic process, it appeared advantageous to relate identified isolated products with process-characterizing potentials and the Faradaic amount of electricity required. Polarographic techniques were employed to correlate potentials with reduction processes, while Faradaic equivalence was determined by coulometric measurements at the selected potentials. Finally, confirmation of the reaction path was sought in the isolation and identification of the products. For better interpretive significance in relating potentials to reduction mechanisms, alcohol solvents were avoided and only aqueous solutions of the sparingly soluble m-dinitrobenzene were used in this work. Quantitative isolation and identification of the intermediates were accomplished to confirm the reaction path for the reduction process.

Experimental

Equal importance was placed upon the polarograph, potentiostat, and isolation phases of the experimental work. The specialized polarograph employed in this phase of the nitro compound studies was the one described by Kelly, Jones, and Fisher (12) of the Oak Ridge National Laboratory and made by the Indiana Instrument and Chemical Corporation, Bloomington, Indiana. The polarographic cell was kept at 25°C and used a separate S.C.E. as reference electrode and platinum wire as the anode. The unique feature of this experiment was that no alcohol or other special solvent was used to dissolve the m-dinitrobenzene.

For the potentiostatic work this required that larger volumes of solutions be used; therefore, a special electrolytic cell was designed (Fig. 1). The electrolytic cell for potentiostatic work was a 4000 ml beaker which used three electrodes. The anode compartment consisted of a cylindrical glass tube, 2 in. in diameter, which was separated from the cathode by a cellophane membrane. The anode was silver-silver chloride. The cathode or working electrode was a graphite disk covering the entire bottom of the 4-liter beaker. The reference electrode was a saturated calomel electrode. Adjustment of the reference potential of the graphite electrode with respect to a corresponding S.C.E. was made.

Modification of the electronic circuitry in the standard Wenking model potentiostat was necessary to achieve the higher currents required for this work where substantial amounts of intermediates were isolated and identified. The *p*H meter was a Beckman *p*H meter, Model N.

The m-dinitrobenzene obtained from the Matheson Company, Inc., was first recrystallized from distilled water. The m.p. of the recrystallized material was 89°-89.5°C. All buffer solutions were made from reagent grade materials.

Solutions of m-dinitrobenzene were then prepared by weighing 1g of recrystallized solid into 2 liters of the given buffer. This was heated and vigorously stirred until all of the solid went into solution. The final volume was measured in order to calculate the concentration, since some evaporation took place on

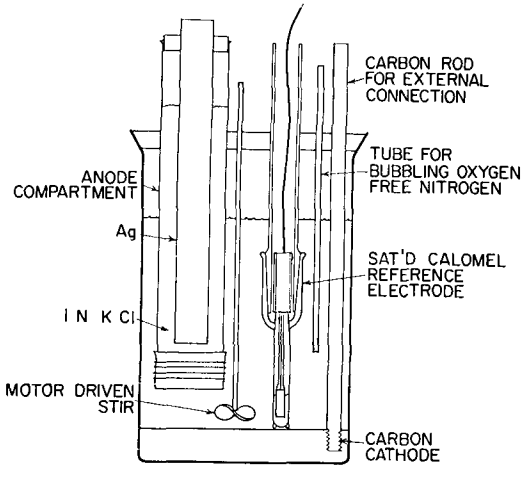

Fig. 1. Drawing of electrolytic cell

heating. The pH of all final solutions was taken on the Beckman pH meter. Solutions of pH 6.00 were used in the potentiostatic experiments.

Dissolved oxygen was removed from the solutions for both polarographic and potentiostatic work by bubbling oxygen-free nitrogen through the solutions for 10 min and 1 hr, respectively. The drop weight was taken at a potential on the limiting current plateau. The values of m and t were 2.53 mgm-sec^{-1} and 3.34 sec. The value of mt was 8.45 mg and $m^{2/3}t^{1/6}$ was 2.27. The diffusion current, I_d, varied slightly for each solution because of the slight differences in the concentration, while the diffusion current, constant, I^*, remained constant.

$$I^* = \frac{I_d}{Cm^{2/3}t^{1/6}} = \frac{I_d}{C \times 2.27} \qquad [1]$$

The potentiostatic reduction was run for a prescribed period of time coulometrically approximated to give 25, 50, 75, and 100% reductions. Siphoning of supernatant ether extracts while under nitrogen was successfully employed to remove products and unreacted meta-dinitrobenzene. After separation and purification of products and any unreacted meta-dinitrobenzene, identification was made by infrared spectra and quantitative chemical analysis. The n values were obtained by coulometric techniques.

Polarographic and Potentiostatic Measurements

Solutions of m-dinitrobenzene were made as described above at all integral values of pH from 1 through 10. These solutions were then diluted by a factor of ten and polarograms were run on the initial and resulting solutions. It will be seen from the polarograms that the half-wave potential, $E_{1/2}$, varies with the pH and in some cases approximately 60 mv per pH unit. A plot of the diffusion current *vs.* the height of the mercury column raised to the one-half power gave a curve that was proportional. A plot of log $I/(I_d - I)$ *vs.* potential gave a straight line whose slope was 0.065. This slope agrees with the experimental findings of Pearson (11). Table I gives the half-wave values and n values as a function of pH. Polarograms are shown in Fig. 2-5. Figure 5 shows a derivative polarogram with peak indicating half-wave values.

The potentiostatic reduction was carried out at preset electronically controlled potentials, and the current was followed on an ammeter. In this case the experiments were run on solutions of pH 6.00, and the potential was set at a potential just below the knee of the first wave as shown on the polarographic curve. This potential was —0.48v *vs.* S.C.E. The amount of current was determined by planimeter integration of the current-time curves and from a copper coulometer. The reduction was carried out under a blanket of nitrogen to insure that no oxygen would become involved in the reaction. This was done because it had been observed in our previous experiments that oxygen could drastically change the products. For example, it was observed that if a reduction was already in progress and oxygen was intentionally added, visible color changes took place and a product was obtained which contained 3, 3'dinitroazoxybenzene. Since the rate of reduction was followed polarographically by determining the amount of m-dinitrobenzene present after a given reduction, a double check was obtained because the rate of reduction of m-dinitrobenzene was also followed coulometrically.

After the reduction, the catholyte was extracted with anhydrous ether while still under the nitrogen atmosphere. To accomplish this, the solution was vigorously

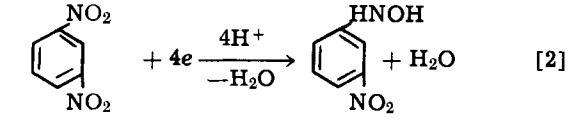
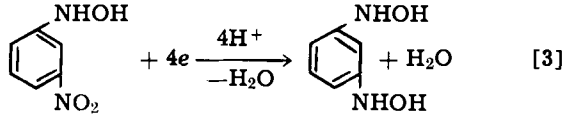
stirred with a mechanical stirrer and bubbling nitrogen. The ether layers were siphoned off and dried over anhydrous sodium sulfate. The ether was evaporated while still making sure a dry nitrogen atmosphere prevailed. The dried products were weighed and the components separated using a solvent mixture composed of one part chloroform and three parts benzene. This seemed to separate the mixed product into two principal products which were identified as m-dinitrobenzene and 3-nitrophenylhydroxylamine. Table II gives the results of the reduction. Figure 6 shows an infrared curve for the compound formed and identified as 3-nitrophenylhydroxylamine. The medium used for the infrared determination was a KBr disk. Repeated efforts to electrolyze to 100% of the first step in the reduction failed to give all 3-nitrophenylhydroxylamine.

Discussion

From the data listed above and from work of other investigators (1-11), a reaction path for the reduction of m-dinitrobenzene is well established. Above *p*H of 2, the reduction takes place in two steps, polarographically and coulometrically, each wave is of equal height and is equivalent to four electrons. This would mean that the reduction goes as follows



[2]



[3]

This reaction path is consistent with experimental results and is inconsistent with the mechanism proposed by Morehouse and Glicksman (13) of a two-step reduction each involving six electrons. Isolation and identification of products in galvanic cells, although somewhat more complex than for the isolated conditions published here, have confirmed at least the initial representative steps and mechanisms described

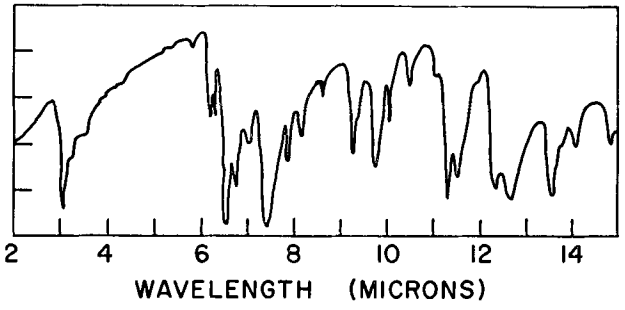


Fig. 6. Infrared spectrum of 3-nitrophenylhydroxylamine on KBr disk.

here. Below *p*H of 2, the reduction goes via 12 electrons as proposed. Even though electron spin resonance evidence (14-19) indicates that the polarographic four electron step is in reality a series of steps involving a free radical, the over-all picture is as shown above.

The results in Table II show no product at 100% reduction. The expected product was all 3-nitrophenylhydroxylamine, but instead of obtaining this compound a mixture was found. This lack of pure product indicates that reduction of the first nitro group does not occur completely before reduction of the second group begins. Several runs gave similar results at 100% reduction.

The product, phenyl dihydroxylamine, which resulted from the complete reduction was not isolated. One reason was the occurrence of a mixture that would not cleanly separate. In alkaline solution, the products were very sensitive to the atmosphere and always contained 3, 3'dinitroazoxybenzene.

Conclusion

1. In a macro sense at least, the initially observable phase of reduction of m-dinitrobenzene above *p*H 3.0 goes in two steps with each step equal to a four electron reduction.

2. The product of a controlled reduction of m-dinitrobenzene equivalent to four electrons is 3-nitrophenylhydroxylamine which is quite reactive and readily undergoes condensation, rearrangement, disproportionation, and oxidation depending on the environmental conditions imposed, *e.g.*, the electrolyte *p*H, temperature, time of its exposure, and competitive side reactions.

3. Alkaline solutions and oxygen tend to increase the probability of the coupling process; *i.e.*, the formation of stable 3, 3'dinitroazoxybenzene, and cause a mixed product; therefore, the presence of this compound and its reduced products, such as the hydrazo, is a result of side reactions and is not to be considered a part of its true reaction path.

Electrochemical Studies on Zirconium and Hafnium in Molten LiCl-KCl Eutectic

R. Baboian,[1] D. L. Hill,[2] and R. A. Bailey

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York

ABSTRACT

Electrode potential and polarographic studies have been made on solutions of zirconium and hafnium ions in molten LiCl-KCl eutectic at 450°-550°C. Anodic dissolution of Zr at 450°C yielded Zr(IV), but at 550°C, chiefly Zr(II). Only Hf (IV) was observed over this range. Apparent standard electrode potentials were (mole fraction scale, Pt(II)/Pt(0) reference)

Zr(II)/Zr(0); —1.77v at 550°C

Zr(IV)/Zr(0); —1.86v at 450°C

Hf(IV)/Hf(0); —1.88v at 450°C; —1.92v at 550°C

The electrochemical behavior of zirconium and hafnium in molten salt systems has received only slight attention. Yang *et al.* (1, 2), studied the electrode potentials of zirconium and hafnium in fused LiCl-KCl eutectic at 500°-550°C. They found Hf(IV) and Zr(IV) to be the predominant species in equilibrium with the metals, although there was some uncertainty in the latter case (2). More concentrated solutions of $ZrCl_4$ were studied in the same melt by Inman *et al.* (3) at 400°-500°C, but here volatilization of the solute prevented satisfactory potential measurements. It was found that $ZrCl_2$ was the major product of electrolysis at the cathode. Anodization of the metal produced Zr(IV). Work at higher temperatures has been carried out in molten equimolar NaCl-KCl by Grechina and Barchuk (4) and Smirnov *et al.* (5). The former found that at 700°C anodic dissolution of zirconium metal gave Zr(II) as the predominant product, but this disproportionated to Zr(IV) and Zr(0). Chronopotentiometric measurements have been carried out on both the zirconium and hafnium systems at 700° to 800°C in the above melt by Baraboshkin *et al.* (6).

This paper describes potentiometric and polarographic studies of zirconium and hafnium in the LiCl-KCl eutectic at 450°-550°C which yielded values of electrode potentials and information on the oxidation states produced by anodization. Electrode potentials refer to the cell

Metal	Metal Ion, Concentration C, LiCl-KCl Eutectic	Glass Frit	Reference Electrode

[1] Present address: Department of Metallurgical and Material Science, University of Toronto, Toronto, Ontario.

[2] Present address: Department of Chemistry, University of Hong Kong, Hong Kong.

The reference electrode was either the Pt(II)/Pt(0) or the Ag(I)/Ag(0) couple. The apparent standard potential of the metal ion—metal couple, $E^{0\prime}_{M(n)/M(0)}$, is given by the equation

$$-E'_{cell} = E^{0\prime}_{M(n)/M(0)} + \frac{2.303\,RT}{nF}\log C$$

where E'_{cell} is the cell potential with the reference electrode in its standard state of unit mole fraction or molality. $E^{0\prime}_{M(n)/M(0)}$ differs from the true standard potential by the activity coefficient which is included in it, and is constant only if the activity coefficient is constant over the range of concentration studied.

From the free energy of formation of the pure metal chloride, it is possible to calculate the standard potential of the couple, and hence the activity coefficient for the metal ion if that of the reference is known. That of Ag(I) is unity in this melt (7, 8). Other thermodynamic quantities can be found from standard relationships.

Experimental

The purification of the LiCl-KCl eutectic, the electrochemical cell and reference electrodes, and other aspects of the experimental procedure were as described in a previous publication (9). Solutions of zirconium and hafnium were prepared by anodic dissolution of the metal rods using a constant current source (about 10 ma/cm^2). Only low concentration solutions were investigated—generally less than 5 x 10^{-4} mole fraction of zirconium or hafnium.

The zirconium metal used was > 99.9% pure, while the hafnium had a zirconium content of 1-2%, but less than 0.1% of other impurities. The rods were polished with fine emery cloth and slightly etched with HF before use; they were then immediately placed in the

cell where they were maintained under vacuum as the temperature was raised slowly to the desired point. During the electrochemical measurements, the cell was flushed with purified argon which was also used for stirring.

Anodic dissolution of both zirconium and hafnium produced an immediate black precipitate if the melt was inadequately purified, although there was no visible attack of the metal before electrolysis as is the case with titanium under similar conditions. With properly purified melts, this effect was not noticeable. It is evidently due to the formation of oxide and/or oxychloride by reaction of oxide or hydroxide impurities (3). Solubility studies of both metals and their dioxides showed that no detectable amount of material entered solution from them.

Results

The products obtained from anodic dissolution of zirconium depended on temperature. At 450°C, plots of E'_{cell} *vs.* log (zirconium concentration) gave good straight lines with slopes corresponding to a 4-electron process; the average slope of all experiments was 0.037v, while that calculated for a 4-electron transfer at this temperature is 0.0359v. Weight-loss measurements of the rod also indicated that zirconium was dissolved as Zr(IV). At 550°C, a linear plot of the above quantities was also obtained, but with an average slope of 0.073v. This is close to the calculated value for a 2-electron process, 0.0817v, and again weight-loss measurements indicated dissolution as Zr(II). At 500°C, no linear plot could be obtained. At 450° and 550°C, apparent standard potentials were obtained by extrapolating the plots to unit mole fraction; these are given in Table I. The results obtained from different experiments agreed to within 0.01v.

The temperature dependence of the Zr(II)/Zr(0) couple over the range 550°-600°C, given in Table II, was linear and reproducible. This coefficient was used to estimate the potential of the above couple at 450°C which is given in Table I. On the other hand, solutions prepared at 450°C and heated to 550°C and cooled, gave different potentials for increasing and decreasing temperatures. This may have been due in part to loss of Zr(IV) from the melt at higher temperatures, although it is probable that the chief cause was an irreversible reaction such as

$$Zr(IV) + Zr(0) \rightarrow 2Zr(II)$$

Figure 1A shows polarograms recorded at 450°C for different concentrations of Zr(IV) at a platinum microelectrode. No anodic wave was observed, and only a single cathodic wave at about —1.9v appeared. The limiting currents from these polarograms yield an approximate straight line, intersecting the abscissa near zero concentration, when plotted against the concentration of Zr(IV). The slope of this line (the limiting current constant) is about 0.08 amp/mm² per unit mole fraction. In these polarograms, and the others to be discussed, considerable uncertainty is involved in the values of the limiting currents per unit microelectrode area. In part this may be due to the slope of the plateau of the polarogram, but also significant is the fact that measurement of the true microelectrode area is difficult. The limiting current constants quoted, which are the best values from several runs, are reliable to within about 0.01 amp/mm². On reversing the direction of polarization, as in Fig. 1B, the curve is retraced up to the deposition potential, then passes through the zero current axis and changes sign (dotted line). However, the current quickly decreases to nearly zero.

Polarograms in Fig. 2(a), (b), and (c) are for solutions prepared at 450°, 500°, and 550°C, respectively. At 500°C, two cathodic waves occur, at —1.8 and —1.9v. At 550°C, the two waves are at —1.6 and —1.9v. The current of the second wave is quite large with a marked increasing current effect. At 550°C, anodic oxidation waves could be observed; at a fixed potential, the current was more negative with successive additions of Zr(II), but otherwise these polarograms were not reproducible.

Potential measurements in the hafnium system at both 450° and 550°C gave straight lines when E'_{cell} was plotted against log (hafnium concentration). The slopes calculated for a 4-electron process at these temperatures are 0.0359 and 0.0408v, compared with observed values of 0.037 and 0.040v. Weight-loss measurements of the metal rod also agreed with dissolution as Hf(IV). Apparent standard potentials are given in Table I, and the temperature dependence, which was

linear over this range against a Ag(I)/Ag(0) reference electrode, in Table II.

Polarograms at 450°, 500°, and 550°C showed only a single reduction wave, and no oxidation wave. Figure 3A shows examples at 450°C; those at higher temperatures were similar. Figure 3B shows the curve obtained when the direction of polarization of curve c was reversed (dotted line) but this quickly fell to nearly zero. As in the case of Zr(IV), plots of limiting current *vs.* concentration of Hf(IV) were approximately linear through the origin. The limiting current constants were 0.06, 0.08, and 0.11 amp/mm^2 per unit mole fraction at 450°, 500°, and 550°C, respectively. A plot of log i_d *vs.* $1/T$ (where i_d is the limiting current) was linear also, with a slope corresponding to an activation energy for diffusion of 7 kcal. This may be compared with a value of 10.1 kcal at 800°C in the NaCl-KCl melt reported by Baraboshkin *et al.* (6).

Polarograms at solid microelectrodes may be expected to fit either the Kolthoff-Lingane equation if the reduced metal forms a deposit on the electrode surface, or the Heyrovsky-Ilkovic equation if it alloys with the electrode material. The former predicts a linear relation between the microelectrode potential E_{me} and log $(i_d - i)$, while the latter predicts a linear plot of E_{me} *vs.* log $i/i_d - i$. Here, i is the current on any part of the wave. As shown in Fig. 4, the data for the reduction of Zr(IV) at 450°C, and Hf(IV) at 450°, 500°, and 550°C, fit the Heyrovsky-Ilkovic plot fairly well. The Kolthoff-Lingane plots showed much greater curvature. The slopes observed were: curve (a), 0.040v; curve (b), 0.040v; curve (c) 0.044v; and curve (d), 0.047v. The calculated slopes are 0.036v, 0.036v, 0.038v, and 0.041v. The implication that alloy formation is taking place is supported by the observation that not all the deposited metal could be stripped from the electrode when the current was reversed. The current approached zero before sufficient coulombs had passed to account for the amount of metal deposited originally. However, in the absence of other information, the case is not proved (10).

Discussion

Results of polarographic and potentiometric measurements indicate that Zr(IV) is the stable species in this melt at 450°C. The free energy change and equilibrium constant for the reaction

$$Zr + Zr(IV) \rightleftarrows 2Zr(II) \qquad [1]$$

(in 10^{-5} mole fraction solutions, extrapolated to unit mole fraction) are +9.2 kcal and 1.6 x 10^{-3}, respectively, as calculated from our data. Thus the equilibrium lies to the left at this temperature. The activity coefficient calculated for this solute, utilizing the data of Hamer *et al.* (11), is 9.6 x 10^{-6} (Table III), in agreement with that estimated by Yang *et al.* (1), 10^{-5} to 10^{-6}. This very small value, and the value of the partial molal free energy in Table III, may be interpreted as indicating a high degree of complexing of Zr(IV) in this melt.

At 550°C, Zr(II) is the predominant species produced by anodic dissolution under our conditions. This is indicated by the Nernst plot and the polarographic waves. The first reduction wave at this temperature may be attributed to reduction of the small amount of Zr(IV) in the melt to Zr(II), and the second, larger

Table III. Activity coefficients and partial molal free energies of solutions of metal chlorides in the LiCl-KCl eutectic

Compound	Range of concentration, mole fraction × 10^6	Activity coefficient 450°C	Activity coefficient 550°C	ΔG_s (kcal/mole) 450°C	ΔG_s (kcal/mole) 550°C
$ZrCl_2$	5-50	6.4×10^7	3.1×10^6	+25.7	+24.4
$ZrCl_4$	3-25	9.6×10^{-6}		−16.5	
$HfCl_4$	3-25	24.8	3.1	+4.60	+1.84

wave to reduction of Zr(II) to the metal. These waves were always observed, although their forms were often indistinct. With time, when solutions of higher concentration were used, $ZrCl_4$ could be detected in the argon gas used for stirring, and finely divided zirconium metal appeared in the melt. Evidently Zr(II) disproportionates according to the reverse of reaction [1] above, as it does at higher temperatures in KCl-NaCl (3).

No evidence was found for the existence of a Zr(III) species in this melt. This is in accord with the work of Larson and Leddy (12) on the pure zirconium chlorides, which showed that the equilibrium for the reaction

$$3Zr(III) \rightleftarrows 2Zr(IV) + Zr(0) \qquad [2]$$

lies far to the right at 450°C.

In contrast to the zirconium system, hafnium yielded only Hf(IV) in this melt over the temperature range investigated.

While the activity coefficient for Zr(IV) is very small, the activity coefficients of Zr(II) and Hf(IV) are greater than unity (Table III). Their validity of course depends on the correctness of the free energies of formation of the pure chlorides from which the standard electrode potentials were calculated (11). It does not follow that Zr(II) and Hf(IV) are not complexed in the melt. Flengas and Ingraham (13) have interpreted the activity coefficients of Cr(II) and Sn(II) in KCl-NaCl melts, which were also greater than unity, in terms of a "bond-loosening" effect. If the pure chlorides were composed of more complicated species which break up on dissolution in the melt, an activity coefficient greater than unity could be accounted for in an analogous manner.

A New Class of Molten Salt Mixtures
The Hydrated Dipositive Ion as an Independent Cation Species

C. Austen Angell[1]

Argonne National Laboratory, Argonne, Illinois

ABSTRACT

On the basis of solubility and electrical conductance measurements, a new class of molten salt mixtures involving hydrated multivalent cations as independent cation species is proposed. It is shown that these ions confer essentially the same properties on the solutions as expected theoretically from hard sphere cations of the same charge:radius ratio. The solutions are of considerable potential interest since they have especially low liquidus temperatures for molten salt systems and, as a result, are frequently glass forming. The investigation of ionic liquid behavior at low free volumes (high densities) should, therefore, be possible in a variety of systems. By way of an example, KNO_3 is found to dissolve to the extent of some 70 mol % at 100°C in the "hydrate melt" $Ca(NO_3)_2 \cdot 4H_2O$. The application of free volume transport theory equations to the analysis of electrical conductance data for this system produces striking correlations with electrical conductance behavior in the anhydrous system $Ca(NO_3)_2 + KNO_3$.

Following an account of electrical conductance in the $Mg(NO_3)_2 + H_2O$ system at very high concentrations, it has recently been suggested (1) that aqueous solutions of polyvalent ions in which the water content is insufficient to satisfy more than a first co-ordination sheath for the cation, may most profitably be regarded as molten salts of weak field cations, $M(H_2O)_n^{m+}$. By treating this species as a hard sphere

[1] On leave from Department of Metallurgy, University of Melbourne, Australia.

dipositive ion of radius ($r_{M2+} + 2r_{H_2O}$) it was found that the electrical conductance of these melts could be correlated with that in water-free molten salt systems. The usefulness of this concept was supported by its application in finding tetrahedral $NiCl_4^=$, *i.e.*, 4-coordinated Ni^{++} in aqueous systems for the first time (2).

Extending this idea, it would be expected that "hydrate melts"[2] will dissolve other (unhydrated) salts, in the same way that ordinary molten salts usually dissolve one another. So far we find this to be the case, *e.g.*, KNO_3 whose saturation solubility in water at 100°C corresponds to an 11M (30 mol %) solution, will dissolve in molten $Ca(NO_3)_2 \cdot 4H_2O$, mp 42.7°C, [which is already a 7.2M (20 mol %) solution] to the extent of about 68 mol % at 100°C. Some brief observations on other solutions of this class are noted below.[3] It will be apparent that because of their low liquidus temperatures, these systems may be of considerable value in permitting physicochemical investigations of molten salt behavior in a temperature range otherwise not readily accessible. In this short paper an attempt is made to establish the over-all validity of this view of the aqueous liquids by showing that electrical conductance in the system $Ca(NO_3)_2 \cdot 4H_2O + KNO_3$ is completely analogous to that in other mixed molten salt systems. This particular system is a logical choice for initial study since its anhydrous salt analogue $Ca(NO_3)_2 + KNO_3$ has been studied in some detail (3-5), and the electrical conductance of molten $Ca(NO_3)_2 \cdot 4H_2O$ has recently been measured (1).

We have already reported that electrical transport in molten hydrated Ca^{+2} and Mg^{+2} nitrates is exponentially dependent on $1/(T - T_o)$ in formal accord with the free volume model general equation for conductance (5)

$$\Lambda = AT^{1/2} \exp\left(-\frac{k}{T - T_o}\right) \qquad [1]$$

where Λ is the equivalent conductance, T_o is the theoretical glass transition, or zero free volume, temperature (6), and A and k are constants. The values of k found for the hydrate melts were virtually the same as the value, 690°K, for the molten salt system $Ca(NO_3)_2 + KNO_3$. The same value of k may, therefore, be anticipated for the mixed molten salt-hydrate melt mixtures. Furthermore, since the T_o value for molten KNO_3 (by extrapolation) is greater than the experimental value for $Ca(NO_3)_2 \cdot 4H_2O$ (1), then in the mixed nitrate-hydrate melt T_o should increase with KNO_3 content if the mixed system behaves like a normal molten salt mixture. T_o, which seems to be determined by the electrostatic field strengths of the ions, would thus vary in the opposite manner with KNO_3 content to that in the anhydrous system $Ca(NO_3)_2$-KNO_3. Such a variation of T_o would cause the "activation energy" at a given temperature to increase with KNO_3 content.

[2] For convenience, we will adopt the term "hydrate melts" for a class of molten salts involving independent hydrated cations as constituent species.

[3] *Some General Comments on Hydrate Melts*

1. *Chlorides.*—Molten $MgCl_2 \cdot 6H_2O$ (14.3 mol % $MgCl_2$ or 7.2M at 83.5°C) dissolves considerable amounts of LiCl (saturated solution in H_2O at 100°C = 35 mol % LiCl or ≈ 18M) and somewhat smaller amounts of KCl. As in pure molten $MgCl_2$-$6H_2O$, additions of $NiCl_2$ to this liquid produce blue solutions due to $NiCl_4^=$, *i.e.*, to 4-coordinated Ni^{++}, when hot, changing to yellow on cooling, apparently due to $NiCl_6^=$ or 6-coordinated Ni, through a tetrahedral → octahedral coordination change. Of possible value is the observation that the organic salt, pyridinium chloride, is completely miscible with $MgCl_2 \cdot 4$-$5H_2O$, most compositions being glass forming.

2. *Chloride-nitrates.*—$CaCl_2$ and $MgCl_2$ hydrate melts are completely miscible with the corresponding hydrate nitrates. Where the pure chloride hydrates crystallize on cooling at normal rates, the mixtures with hydrate nitrates generally yield stable viscous liquids at ambient temperatures, and glasses on cooling to lower temperatures, *e.g.*, in liquid nitrogen.

3. *Nitrates.*—The molten hydrate nitrates of Mg and Ca dissolve each and all of the alkali nitrates. In each system there appear to be composition ranges which are glass forming, these presumably corresponding approximately with eutectic regions in the (undetermined) phase diagrams.

Experimental

A. R. grade $Ca(NO_3)_2 \cdot 4H_2O$ was carefully fused without loss of water, and filtered into a Pyrex glass conductance vessel. The latter was seated in the cork of a 1 liter Dewar flask. When filled with water or paraffin at the desired temperature, the Dewar flask restricted the temperature fall rate in the immersed conductance vessel to about 2°C per hour. This rate of change was quite insufficient to affect adversely the accuracy required for the present survey. The temperature of the melt was measured by a precision mercury thermometer and was checked by a fine gauge Cr/Al thermocouple fixed alongside the conductance cell.

The resistances of the melts were measured using a silica dip-type cell (cell constant = 61.85) with platinized electrodes, in conjunction with an Industrial Instruments Inc. Model RC 18 precision conductance bridge. The resistance was measured at 3 kc and 1 kc, but calculations were based on the 3 kc readings since, provided the cell resistance was greater than 1000 ohms, the polarization errors were not sufficient to affect the results plotted in the accompanying graphs, Fig. 1 and 2, detectably.

Composition changes were made by weighed additions of A. R. grade KNO_3, which was used without further purification.

Results

The specific conductances, κ, of the solutions in this system are given in Table I and are shown as a function of composition in the isotherms of Fig. 1 (i). Because of the very low values of conductances recorded in this system at low temperatures a logarithmic scale has been employed in Fig. 1(i) so that the reversal of the composition dependence will be apparent. For a given composition, the "Arrhenius coefficients" (5),

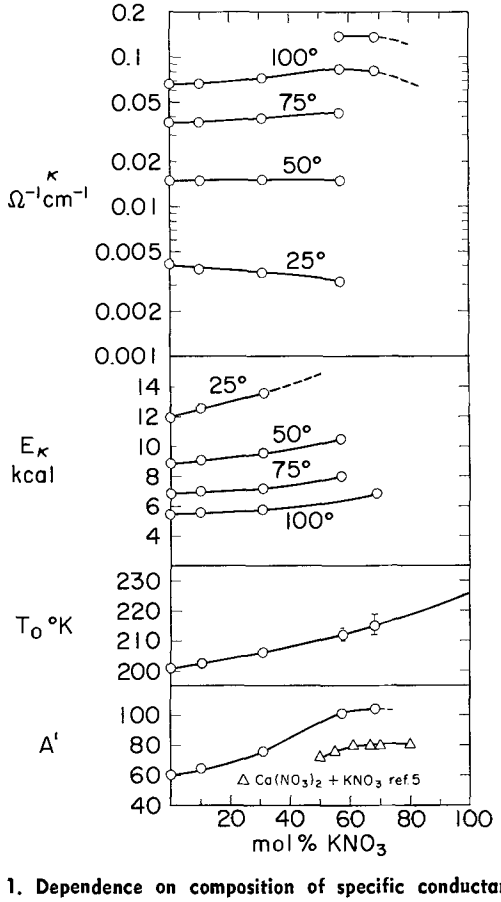

Fig. 1. Dependence on composition of specific conductance, κ, Arrhenius coefficient, E_κ, theoretical glass transition temperature, T_o, and pre-exponential constant, A', in the system $Ca(NO_3)_2 \cdot 4H_2O + KNO_3$.

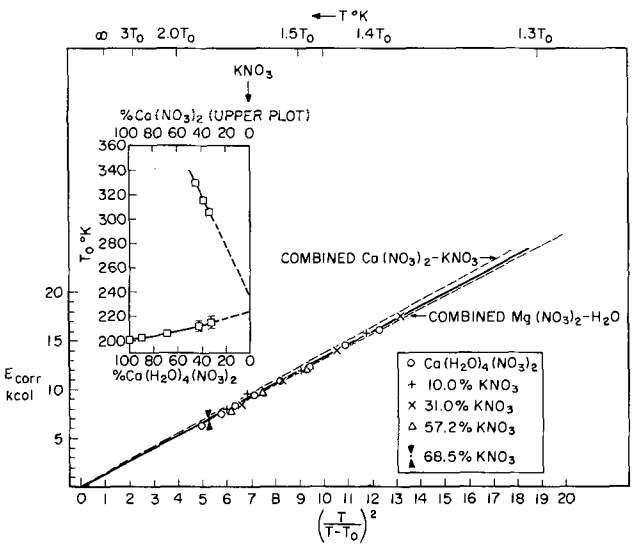

Figure 2. Test of free volume model predictions for the system $Ca(NO_3)_2 \cdot 4H_2O$ + KNO_3, and comparison with other systems. Inset: best fit values of T_o as function of composition for $Ca(NO_3)_2 \cdot 4H_2O$ + KNO_3, and $Ca(NO_3)_2$ + KNO_3 systems.

i.e., "activation energies" E_K, increase rapidly with falling temperature in a manner which has been described in previous publications (5, 1), and which we interpret as due to the probability of ionic movement going to zero at T_o rather than at 0°K as required by the Arrhenius, or other rate process theory, equations. The behavior of the "Arrhenius coefficients" with temperature and composition is summarized in Fig. 1 (ii), where it is seen that at a given temperature the "Arrhenius coefficients" increase with increasing KNO_3 contents as anticipated.

Unfortunately, due to the combination of low temperatures and low conductances in this system, measurements were ceased before E_K reached values as high as were realized in the systems previously studied. As a result, the constants k and T_o of Eq. [1] are in principle more difficult to determine precisely by the graphical method previously employed, since the plot E_{cor} *vs.* $(T/T - T_o)^2$ whose linearity depends on the correct choice of T_o, loses sensitivity to T_o at lower E_{cor} values. This loss of sensitivity was compensated to some extent by an improvement in precision in the measurements, and the value of T_o for $Ca(NO_3)_2 \cdot 4H_2O$ [4] is considered correct to ± 3°K. For the other compositions we have adopted a treatment of results which involved taking the plot for pure $Ca(NO_3)_2 \cdot 4H_2O$ as a reference and making the assumption, based on the similar slopes of these plots for $Mg(NO_3)_2$-H_2O and $Ca(NO_3)_2$-KNO_3 solutions (see Fig. 2), that the other compositions in the present system would have the same value of k. The values of T_o then required to fit the E_{cor} values on the $Ca(NO_3)_2 \cdot 4H_2O$ line were determined for each composition and the validity of the treatment judged by both the degree of fit over the whole T/T_o range, and the behavior of the T_o values with composition. These data are shown in Fig. 2. It seems clear that the assumption of constant k is justified at least up to 31% KNO_3, and, from the continuing regular change of T_o with composition, it is most probably valid at the other compositions. This is consistent with the finding that k for the pure $Ca(NO_3)_2 \cdot 4H_2O$ melt is the same as for the $Mg(NO_3)_2$-H_2O series and about the same as for the anhydrous system KNO_3 + $Ca(NO_3)_2$.

[4] In view of the present finding this composition could be written more informatively as $Ca(H_2O)_4 \cdot (NO_3)_2$ as in the diagrams.

Discussion

Figures 1 and 2 show that the temperature dependence of conductivity in this system is in complete qualitative accord with the expectations based on the notion that the average cation field strength in the mixtures rises in a regular manner with KNO_3 additions, as K^+ ions ($z_+/r_+ = 0.75$), mix with $Ca(H_2O)_4^{++}$ ions ($z_+/r_+ = 0.53$),[5] *i.e.*, that the hydrated calcium nitrate behaves like a molten salt of a weak field cation. There is a quantitative discrepancy in that the T_o values determined for the present system seem to extrapolate to a value of 225° ± 5°K for pure KNO_3 whereas extrapolation from the data in the anhydrous system $Ca(NO_3)_2$+ KNO_3 indicated T_o = 237° ± 12°K. A comparison of these two sets of data is given in Fig. 2, inset. When the length, and consequent uncertainty, of the latter extrapolation is considered, a discrepancy is not too surprising, and the fact that the same value is approached this closely from opposite directions is enough to give considerable confidence in the general validity of the theoretical approach used in the analysis of these results.

One observes also (Fig. 2) that the application of Eq. [1] has reduced almost to a single straight line plot so-called "activation energies" for conductance varying from 3.5 to 30 kcal in the range 0°-350°C in three different systems whose only common feature is the nitrate anion. This is an impressive correlation.[6a]

While recognizing the danger of circular arguments, the author believes that the general coherence of these observations not only supports the claim that the hydrate melts are no less than molten salts in their important properties,[7] but also indicates the potential usefulness of binary systems with hydrate components, such as the present system, to explore free volume-

[5] The effective radius of the H_2O molecule employed in the estimation of r_- is the generally accepted value of 1.39Å.

[6] Note that the correlation applies only to the slope of the Arrhenius plot, the factor A of Eq. [1] having been eliminated by the logarithmic differentiation. We are thus using two parameters, K and T_o, to describe and unify E_K *vs.* T curves for the form of Fig. 1, ref. 5a, Figure 2 of this paper shows that these curves are all of the family derived from $E_{corr} = K\left(\frac{T}{T - T_o}\right)^2$, which can be written more informatively as $(E_A + \frac{1}{2}RT)^{1/2} = K/(1 - T_o/T)$. Since k seems to have a constant value, this equation indicates that $E_A + RT$ (representing $E_{diffusion}$) depends only on T/T_o, at least for $T/T_o \gtrsim 2$ (5b). The suggestion of a corresponding temperature scale is therefore strong.

[6a] *Note Added in Proof*: A new and attractive theory by Adam and Gibbs (*J. Chem. Phys.*, 43, 139, 1965), which suggests that configurational entropy rather than free volume is transport limiting, provides an alternative explanation of Eq. [1]) ($S_c \to 0$ at $T = T_o$). From the Adam-Gibbs equations it is possible to show that the corresponding temperatures T/T_o (see footnote 6), represent liquid states of equal configurational entropy (suggesting the term "isoentropic states"). To a large extent comments in the present paper on free volume effects can be rephrased in terms of entropy effects without loss of meaning. The quantities concerned should, in fact, be quite closely related.

[7] A discussion of whether or not water at these compositions should be considered completely "bound," is given in a separate publication (1).

determined properties of ionic liquids. We now consider that the high viscosities frequently reported for concentrated aqueous solutions are in general a direct consequence of the reduced free volume in the liquid due to the combination of moderately high charge concentration (and hence T_o) and very low liquidus temperatures.

Because of the long relaxation times for ionic movement, this condition obviously favors glass formation by reducing the probability of nucleation of the crystalline phase during cooling at a given rate. Generally, however, low mobilities due to reduced free volumes will not in themselves be a sufficient condition for glass formation except at extreme quenching rates. A proposal such as that of Urnes (4a) [whose work on the $Ca(NO_3)_2$-KNO_3 system we overlooked in an earlier publication (5)] that the thermal energy at very low temperatures is not sufficient to raise the ions from potential energy minima in the liquid to regroup as crystal nuclei, seems a more acceptable explanation than the chain and network schemes frequently invoked to explain glass formation.[8] Whatever the precise explanation may be, it seems that a large variety of aqueous glasses should exist, some of which may have interesting properties. Mostly, however, the glass transition for these liquids will lie below room temperature.

We have, as yet, no clear idea of why the constant, k, in the exponential of Eq. [1] (*i.e.*, the slope of Fig. 2 x $1/R$) should have almost the same value, 675° ± 15°K, in the three very different systems so far examined in detail (and summarized in Fig. 2). According to Cohen and Turnbull (7) k should be inversely proportional to the expansion coefficient with a proportionality constant of 0.5-1.0 depending on free volume overlap. As seen previously (5), for molten salts k proves to be too small to support the Cohen and Turnbull assumption that the free volume is randomly distributed. Ion-sized holes are apparently much more common than would be expected. If the as-yet-undetermined expansion coefficients of the hydrate melts have about the same value as in the $Ca(NO_3)_2$-KNO_3 melts, then the constant value of k will indicate a rather specific pattern in the distribution of hole sizes in these liquids. On the other hand, if the expansion coefficient increases as the charge concentration decreases, as indicated by a study of the system K, Na, NO_3, NO_2 eutectic + 0-70 mol % H_2O (8), then the constant value of k would indicate that the volume randomness increases proportionately with decrease in binding strength, which would seem reasonable.[8a] The key to this problem may well be in the suggestion of Gruen (9) for the case of the alkali chlorides that the local structure in fused salts is determined by a mobile equilibrium between tetrahedral and octahedral coordination schemes. Such an arrangement could impose considerable uniformity both on the hole size distribution and on the manner in which "diffusion sites" in the liquid or "critical voids" are presented to potential "jumping" ions. The tendency to maintain such electrostatically favored symmetry groups would naturally become less as the coulombic interactions decreased in intensity[9] with, for instance, increasing water content; thus an increasingly random free volume distribution would result.

The behavior of the pre-exponential constant, A, in this system, and particularly the proximity of its value to that found in the anhydrous $Ca(NO_3)_2$-KNO_3 system [Fig. 1(iv)],[10] are not easy to interpret. The slopes of both plots increase when allowance is made for the double charge on the Ca-containing species. The fact that the constants A and k are much the same in the complete absence of the KNO_3 component seems to rule out the possibility (5) that it is a single species (K^+) which determines the conductance behavior in each case.

The reversal of the composition dependence of the isothermal conductance at lower temperatures, Fig. 1 (i), is due to the opposing effects of A and T_o. While the temperature is well above T_o, E_κ changes little with composition, and the increase of A with KNO_3 content leads to a similar dependence of κ. As the temperature falls toward T_o, however, the form of Eq. [1] requires that the exponential term becomes rapidly predominant, so that at low temperature the direction of the T_o change with increasing KNO_3 content imposes a steady decrease on the isothermal conductance.

We conclude that, although there are difficulties in accounting for the values of the constants A and k, the correlations resulting from the use of Eq. [1] in the analysis of conductance data are very significant and indicate that the overlap region between molten salts and polar solvents in general, may prove an interesting field for investigation. In particular it seems that the expansion coefficients of these liquids deserve more systematic study than they have received in the past.

[8] Although it may appear obvious, it is worth re-stating that an explanation of glass formation should focus attention on the failure to crystallize rather than on the resulting amorphous solid. From the present model, rigidity, *i.e.*, glassiness, follows inevitably on the effective disappearance of free volume, which must occur somewhat before the continued contraction of the liquid can produce a close-packed structure [see, e.g., Turnbull, (6)].

[8a] *Note Added in Proof:* Expansion coefficients for liquid $Ca(NO_3)_2 \cdot 4H_2O$ and $Mg(NO_3)_2 \cdot 4H_2O$ by recent measurements are 5.1×10^{-4} and 5.2×10^{-4} at 100°C, respectively [c.f. the smaller value of 3.5×10^{-4} at 100°C for liquid 38% $Ca(NO_3)_2 \cdot 62\%$ KNO_3 (3)].

[9] This is seen, for example, in the two-dimensional magnetic disk ionic liquid model, described by Angell and Gruen (10).

[10] The quantity plotted in Fig. 1 differs from A of Eq. [1] in that it is calculated from specific conductance rather than from equivalent conductance values.

The Theoretical Effect of Electrode Ohmic Losses on the Performance of Diffusion Membrane Electrodes

Ralph Brown

Pratt & Whitney Aircraft, East Hartford, Connecticut

ABSTRACT

Ohmic losses in diffusion membrane electrodes can be significant because current is distributed over the membrane area and must be collected through contacts having considerably smaller area. Explicit mathematical expressions for the ohmic distribution in the electrode, the local current density distribution, and the current-polarization characteristic can be obtained if there is a linear relationship between the local current density and local metal-solution potential difference. A discussion of the kinetics of hydrogen diffusion anodes considers under which conditions the linear approximation is valid. The approximation can apply to each the gas adsorption controlling, diffusion controlling, and electron transfer controlling cases. Three membrane geometries are considered: a hollow tube with external contact at one end, a circular membrane with external contacts around the periphery, and a rectangular membrane with external contacts at the edges. One example shows that ohmic losses in a 10 cm long, 0.005 cm thick tubular membrane will triple the polarization when compared to a membrane with no ohmic losses.

In certain fuel cell electrodes, the ohmic losses in the electrode can be the same order of magnitude as the metal-solution potential. This is particularly true for hydrogen diffusion anodes. In this case the current is distributed over a thin palladium membrane or tube and is collected at the edge of the electrode where the cross-sectional area is relatively small.

There has been some previous work on similar problems in the study of electrolytic cells (1, 2). The problem has also been investigated in reference to a thin wire or tube in contact with an external circuit at one or both ends (3, 4). In the present work, the current distribution and ohmic distribution in both tubes and membranes of various geometries are investigated. Although the analytical solutions consider approximations which are of practical value when applied to the kinetics of hydrogen diffusion anodes, these approximations apply also to a variety of other cases. The effect of electrode ohmic losses are shown by comparing current-polarization characteristics with zero and finite electrode resistivities.

Model.—The model shown in Fig. 1 is for the one-dimensional case of a tubular membrane connected with an external circuit at one end. The external circuit is connected at $x = 0$ to a tube of length L, diameter D, and thickness δ. Consider the current in the tube J, going in the negative x direction. This is related to the local current density on the membrane by taking a balance about an element Δx.

$$\frac{dJ}{dx} = \pi D i \qquad [1]$$

The current in the tube is also related to the ohmic potential, ϕ, in the x direction. This is simply Ohm's law with the conductivity of the metal specified by σ.

$$J = -\pi D \delta \sigma \frac{d\phi}{dx} \qquad [2]$$

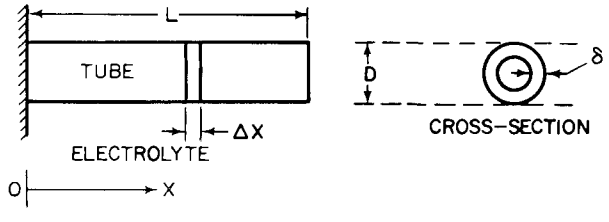

Fig. 1. Model of one dimensional case of tubular membrane

Equation [2] is differentiated with respect to x and substituted into Eq. [1] to obtain a second order differential equation in ϕ.

$$-\delta\sigma \frac{d^2\phi}{dx^2} = i \qquad [3]$$

The electrode is considered to be at a polarization from open circuit of E. If the conductivity of the electrolyte is sufficiently high, the potential in the electrolyte is constant in the x direction. This means that the solution potential can be chosen at zero, and the difference between the metal potential and solution potential at any point is $E - \phi$. The local current density at any point is a function of this local metal-solution potential difference, the specific function being defined by the kinetics of the electrochemical reaction.

$$i = \text{function } [E-\phi] \qquad [4]$$

A boundary condition is given at the connection to the external circuit.

$$x = 0, \quad \phi = 0 \qquad [5]$$

Since there is no current generated beyond the location x_o where ϕ is large enough so that the local current becomes zero, the other boundary condition is

$$x = x_o, \frac{d\phi}{dx} = 0 \qquad [6]$$

The value of x_o will depend on the functional dependence of the local current density on the local metal-solution potential difference, $E-\phi$. If this is a linear dependence, an integration of Eq. [3] will show that x_o is infinite. This means that the value of x_o is given simply by the geometric limitation such as that for the tube, $x_o = L$.

The ohmic distribution, current distribution, and tube current can be found by solution of the differential Eq. [3] if we have knowledge of the kinetics-dependent function in Eq. [4]. Whether or not an analytic solution can be found depends on the specific function. The statement of the problem can be generalized to the two-dimensional membrane.

$$-\delta\sigma\left(\frac{d^2\phi}{dx^2} + \frac{d^2\phi}{dy^2}\right) = \text{function } [E-\phi] \qquad [7]$$

Specific locations for the boundary conditions would depend on the geometry. The boundary conditions

would be $\phi = 0$ at external contacts to the membrane, and

$$\frac{d\phi}{dx} = \frac{d\phi}{dy} = 0$$

at either the ends of the membrane or at the axes of symmetry.

Kinetic Approximations

Mathematically, the solutions to the equations are straight forward when there is a linear local current-potential relationship

$$i = k\,(E - \phi) \qquad [8]$$

These linear current-polarization characteristics are observed experimentally to high current densities when employing membranes at high temperatures (~200°C) and with adequate surface activations (5). This discussion of the reaction kinetics is intended to show these limits on the polarization to which this linear behavior can be expected.

The kinetic relations assume the following sequence of steps: (I) Dissociative adsorption of the hydrogen molecules at the gas-metal surface; (II) desorption of the hydrogen atoms from the gas-metal surface into the metal; (III) diffusion of the hydrogen atoms through the metal to the liquid-metal surface; (IV) adsorption of the hydrogen atoms onto the liquid-metal surface, and finally, (V) transfer of electrons from the hydrogen atoms at the liquid-metal surface.

In alkaline electrolytes, the reaction of the proton with a hydroxyl ion to form water also takes place. This additional step is generally rather fast so is assumed to have no effect on the kinetic relations. Dissociative adsorption and subsequent dissolution of hydrogen in its atomic form is assumed because hydrogen permeability through palladium-silver is proportional to the square root of hydrogen pressure if the surfaces are sufficiently active. A consistent adsorption model must be applied on both sides of the surface in order to maintain the square root dependence in the permeability *vs.* pressure function. Langmuir adsorption kinetics are assumed for the surface both with respect to the fluid and with respect to the bulk metal. The rate equations are as follows:

H_2 adsorption from gas

$$i = K_1P\,(1-\theta)^2 - K_2\theta^2 \qquad [I]$$

H desorption into solid

$$i = \alpha_1\theta - C\alpha_2\,(1-\theta) \qquad [II]$$

H diffusion through solid

$$i = I_D\,(C - C') \qquad [III]$$

H adsorption from solid

$$i = C'\,\beta_2\,(1-\theta') - \beta_1\theta' \qquad [IV]$$

Electron transfer

$$i = k_1\theta' e^{\frac{F(E-\phi)}{2R_oT}} - k_2(1-\theta')\,e^{-\frac{F(E-\phi)}{2R_oT}} \qquad [V]$$

The solid to surface desorption and adsorption reactions are fast so that Eq. [II] and [IV] are assumed to approximate their forms at equilibrium. The hydrogen atom concentrations can then be written in terms of surface coverages and the diffusion equation becomes:

$$i = I_D\frac{\alpha_1}{\alpha_2}\left(\frac{\theta}{1-\theta} - \frac{\beta_1\alpha_2}{\beta_2\alpha_1}\frac{\theta'}{1-\theta'}\right) \qquad [III']$$

At equilibrium, the currents are equal to zero so that θ can be written in terms of K_1P and K_2; and θ' can be written in terms of k_1 and k_2. In order that the equilibrium relationship between θ and θ' given by Eq. [III'] be consistent with the equilibrium values of θ and θ', some simple algebra shows that

$$\frac{\beta_1\alpha_2}{\beta_2\alpha_1} = \frac{k_1}{k_2}\sqrt{\frac{K_1P}{K_2}}$$

The result is substituted into the diffusion equation

$$i = I_D\frac{\alpha_1}{\alpha_2}\left(\frac{\theta}{1-\theta} - \frac{k_1}{k_2}\sqrt{\frac{K_1P}{K_2}}\frac{\theta'}{1-\theta'}\right) \qquad [III'']$$

The kinetic relation for the local current-polarization characteristic is now given in terms of three equations ([I], [III"], [V]) which express the current in terms of θ, θ', and $E - \phi$. The three equations in terms of these three parameters can be rearranged to give one equation for current in terms of $E - \phi$. The algebraic manipulations are not very tractable; for example, a cubic equation is involved when one equates [I] and [III"] in order to solve for θ in terms of θ'. The rate expressions for specific controlling mechanisms can be readily solved, however, by assuming the noncontrolling steps approximate their forms at equilibrium. The results are shown below:

(*A*) *Gas Adsorption Control*

(*i*) High initial coverage $K_1P >> K_2$

$$i = K_2\left[e^{\frac{F(E-\phi)}{R_oT}} - 1\right]$$

$$i \cong K_2\frac{F}{R_oT}(E-\phi) \quad \text{if} \quad E - \phi < \frac{R_oT}{F}$$

(*ii*) Low initial coverage

$$i = K_1P\left[1 - e^{\frac{-F(E-\phi)}{R_oT}}\right]$$

$$i \cong K_1P\frac{F}{R_oT}(E-\phi) \quad \text{if} \quad E - \phi < \frac{R_oT}{F}$$

(*B*) *Diffusion control*

$$i = I_D\sqrt{\frac{K_1P}{K_2}}\left[1 - e^{\frac{-F(E-\phi)}{R_oT}}\right]$$

$$i \cong I_D\sqrt{\frac{K_1P}{K_2}}\frac{F}{R_oT}(E-\phi) \quad \text{if} \quad E - \phi < \frac{R_oT}{F}$$

(*C*) *Activation (Electron Transfer) Control*

$$i = \frac{k_2}{1 + k_2/k_1}\left[e^{\frac{F(E-\phi)}{2R_oT}} - e^{\frac{-F(E-\phi)}{2R_oT}}\right]$$

$$i \cong \frac{k_2}{1 + k_2/k_1}\left[\frac{F}{R_oT}(E-\phi)\right] \quad \text{if} \quad E - \phi < \frac{R_oT}{F}$$

The results show that the linear current-potential expression can be written for the three possible controlling steps in the diffusion membrane. This is subject to satisfying the condition that $E - \phi < R_oT/F$. It has been pointed out that well activated membranes satisfy this condition at typical fuel cell operating current densities.

Hollow Tube with External Contact at One End

The differential equation is given by substituting the linear current-potential characteristic into Eq. [3].

$$\frac{d^2\phi}{dx^2} - \frac{k}{\delta\sigma}\phi = -\frac{k}{\delta\sigma}E \qquad [9]$$

This is a linear, second order equation with constant coefficients for which a solution can be written as a linear combination of hyperbolic sines and cosines. The boundary conditions of Eq. [5] and [6] are applied.

$$\phi = E[1 - \cosh \alpha x - \tanh \alpha L \sinh \alpha x] \quad [10]$$

where: $\alpha = \sqrt{k/\delta\sigma}$. This shows the variation of ohmic potential along the length of the electrode. Substitution of the ohmic relation into Eq. [8] gives the current distribution along the electrode.

$$i = kE(\cosh \alpha x - \tanh \alpha L \sinh \alpha x) \quad [11]$$

The total current from the electrode is given by either integrating the local current over x between 0 and L or by evaluating $\pi D\delta\sigma \frac{d\phi}{dx}$ at x equal to 0.

$$J = kE\left(\frac{\pi D}{\alpha} \tanh \alpha L\right) \quad [12]$$

In order to show the effect of the ohmic losses, the total current can be written as the fraction of the current obtained when there are negligible ohmic losses by dividing by $\pi DLkE$.

$$f = \frac{\tanh \alpha L}{\alpha L} \quad [13]$$

Circular Membrane with External Contacts at the Periphery

The differential equation can be solved most easily if written in cylindrical coordinates

$$\frac{d^2\phi}{dr^2} + \frac{1}{r}\frac{d\phi}{dr} - \frac{k\phi}{\delta\sigma} = -\frac{k}{\delta\sigma}E \quad [14]$$

The boundary conditions are

$$r = 0, \qquad \frac{d\phi}{dr} = 0$$

$$r = R, \qquad \phi = 0 \quad [15]$$

The solution to the equation can be written in terms of Bessel functions

$$\phi = E\left[1 - \frac{I_0(\alpha r)}{I_0(\alpha R)}\right] \quad [16]$$

The current distribution is

$$i = kE\left[\frac{I_0(\alpha r)}{I_0(\alpha R)}\right] \quad [17]$$

The fraction of the current obtained with a zero-resistance membrane is given by

$$f = \frac{2\pi R\delta\sigma}{\pi R^2 kE}\frac{d\phi}{dr}\bigg|_{r=R} \quad [18]$$

and

$$f = \frac{1}{\pi R^2 kE}\int_0^R 2\pi r i dr \quad [19]$$

$$f = \frac{2}{\alpha R}\frac{I_1(\alpha R)}{I_0(\alpha R)} \quad [20]$$

Rectangular Membrane with External Contacts at the Edges

A membrane is considered for which the dimensions are M and L. The differential equation is written in two dimensions

$$-\left(\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2}\right) = \frac{k}{\delta\sigma}(E - \phi) \quad [21]$$

The geometric center of the membrane is chosen as the center of the coordinate axes so that one quadrant of the membrane is considered. The boundary conditions are shown on Fig. 2:

$$\phi(L/2,y) = 0 \quad [22a]$$

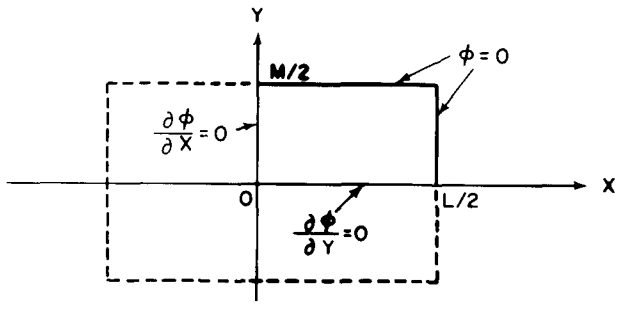

Fig. 2. Boundary conditions of membrane

$$\frac{\partial\phi}{\partial x}(0,y) = 0 \quad [22b]$$

$$\phi(x, M/2) = 0 \quad [23a]$$

$$\frac{\partial\phi}{\partial y}(x,0) = 0 \quad [23b]$$

A solution of the equation is assumed to be in the form

$$\phi(x,y) = \phi_x(x) + \phi_{xy}(x,y) \quad [24]$$

The x-dependent solution is given by solution of the ordinary differential equation in x with $\phi(L/2)$ and $d\phi/dx(0)$ equal to zero.

$$\phi_x = E\left(1 - \frac{\cosh \alpha x}{\cosh \alpha L/2}\right) \quad [25]$$

The result is substituted into the original differential equation to obtain an equation for ϕ_{xy}. The corresponding boundary conditions are also given.

$$\frac{\partial^2\phi_{xy}}{\partial x^2} + \frac{\partial^2\phi_{xy}}{\partial y^2} = \alpha^2\phi_{xy} \quad [26]$$

$$\phi_{xy}\left(\frac{L}{2}, y\right) = 0 \quad [27a]$$

$$\frac{\partial\phi_{xy}}{\partial x}(0,y) = 0 \quad [27b]$$

$$\frac{\partial\phi_{xy}}{\partial y}(x,0) = 0 \quad [27c]$$

By assuming that the solutions take the form of a product of a function of x and a function of y, and applying boundary conditions [27a], [27b], and [27c], the solutions can be written as an infinite series.

$$\phi_{xy} = \sum_{m=0}^{\infty} A_m \cos\left[\frac{2(m + \tfrac{1}{2})\pi x}{L}\right] \cosh\left[\sqrt{\alpha^2 + \frac{4\pi^2(m + \tfrac{1}{2})^2}{L^2}}\, y\right] \quad [28]$$

The complete solution for ϕ is

$$\phi = E\left(1 - \frac{\cosh \alpha x}{\cosh \alpha L/2}\right) + \sum_{m=0}^{\infty} A_m \cos\left[\frac{2(m + \tfrac{1}{2})\pi x}{L}\right] \cosh\left[\sqrt{\alpha^2 + \frac{4\pi^2(m + \tfrac{1}{2})^2}{L^2}}\, y\right] \quad [29]$$

The boundary condition of Eq. [23a] is now employed

$$E\left(\frac{\cosh \alpha x}{\cosh \alpha L/2} - 1\right) = \sum_{m=0}^{\infty} A_m \cosh\left[\sqrt{\alpha^2 + \frac{4\pi^2(m + \tfrac{1}{2})^2}{L^2}}\left(\frac{M}{2}\right)\right]$$

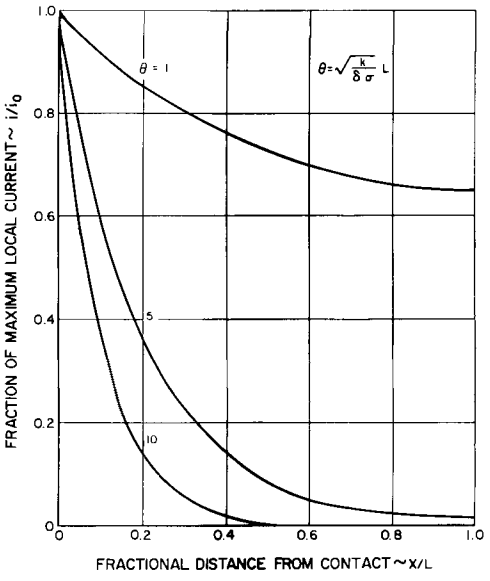

Fig. 3. Local current distribution on tubular membrane

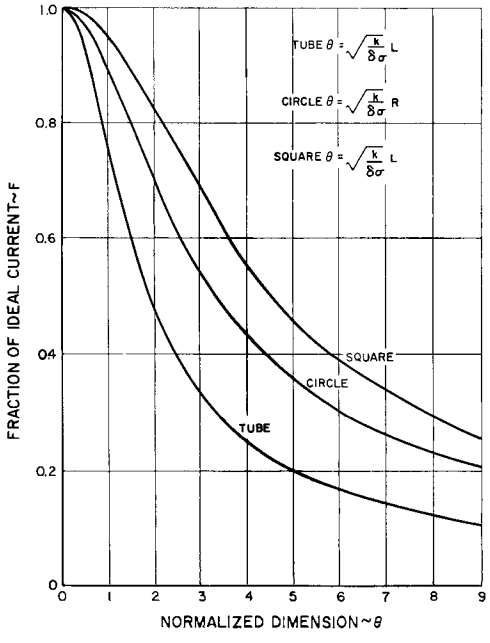

Fig. 4. Effect of ohmic losses on membrane performance

$$\cos\left[\frac{2(m+\tfrac{1}{2})\pi x}{L}\right] \qquad [30]$$

This represents a Fourier cosine series in x. The appropriate coefficients of $\cos[2(m+\tfrac{1}{2})\pi x/L]$ can be evaluated so that the series will converge to the function on the left-hand side. The final solution in x and y is

$$\phi = E\left(1 - \frac{\cosh \alpha x}{\cosh \alpha L/2}\right)$$

$$-\frac{2E}{\pi}\sum_0^\infty (-1)^m \left[\frac{1}{m+\tfrac{1}{2}} - \frac{4(m+\tfrac{1}{2})^2\pi^2}{L^2\alpha^2 + 4(m+\tfrac{1}{2})^2\pi^2}\right]$$

$$\left[\frac{\cosh\sqrt{L^2\alpha^2 + 4(m+\tfrac{1}{2})^2\pi^2}\;(y/L)}{\cosh\sqrt{L^2\alpha^2 + 4(m+\tfrac{1}{2})^2\pi^2}\;(M/2L)}\right]$$

$$\left[\cos\frac{2(m+\tfrac{1}{2})\pi x}{L}\right] \qquad [31]$$

This gives the variation of ϕ, and therefore, of the local current density along the surface of the membrane. The fraction of the total current to that of a zero-resistance membrane is found by integration of i over the quadrant.

$$F = \frac{4}{MLkE}\int_0^{L/2}\int_0^{M/2} i\,dy dx \qquad [32]$$

$$F = \frac{2}{\alpha L}\tanh\frac{\alpha L}{2}$$

$$+\frac{2}{\pi}\sum_0^\infty \left[\frac{1}{m+\tfrac{1}{2}} - \frac{4(m+\tfrac{1}{2})^2\pi^2}{L^2\alpha^2 + 4(m+\tfrac{1}{2})^2\pi^2}\right]$$

$$\left[\frac{\tanh\sqrt{L^2\alpha^2 + 4(m+\tfrac{1}{2})^2\pi^2}\;M/2L}{(m+\tfrac{1}{2})\pi\sqrt{L^2\alpha^2 + 4(m+\tfrac{1}{2})^2\pi^2}\;M/2L}\right] \qquad [33]$$

Discussion

There are certain characteristics of the solutions for the ohmic potential and local current densities that are common to each the linear, circular and rectangular geometries. As governed by the boundary conditions, the ohmic potential has its maximum value at the end or axis of symmetry of the electrode and is zero at the external contacts. This means that the local current is at a minimum near the end or axis of symmetry and at a maximum at the external contacts. The local currents never go to zero leaving part of the electrode inactive, but the local current near the end can be rather small. This is illustrated in Fig. 3 where the fraction of maximum local current density is plotted *vs.* the fractional distance from the external contact. This is plotted for parameters of $\sqrt{k/\delta\sigma}\,L$, this factor being inversely proportional to the square root of membrane thickness and conductivity. Figure 3 illustrates that local currents are reduced in greater proportion as $\sqrt{k/\delta\sigma}\,L$ is larger.

The electrode ohmic losses have a direct influence on the current-polarization characteristic of the electrode. This influence is quantitatively expressed in Eq. [13], [20], and [33] as the ratio of current of the membrane to the current of a zero-resistance or "ideal" membrane. The net current of an actual membrane is then

$$J = f\,A\,k\,E \qquad [34]$$

The reference case of an "ideal" membrane can be approached in practice by employing external circuit contacts along the membrane often called "current-collectors." Small membranes, that is, those with relatively low length or diameter to thickness ratios, also will approach an ideal membrane. The correction factor is independent of the electrode polarization because of the linear current-potential relation. This correction factor is illustrated in Fig. 4 where it is plotted *vs.* a dimensionless parameter defined for each geometry:

$$\text{Tube} \quad \theta = \sqrt{\frac{k}{\delta\sigma}}\,L$$

$$\text{Circle} \quad \theta = \sqrt{\frac{k}{\delta\sigma}}\,R$$

$$\text{Square} \quad \theta = \sqrt{\frac{k}{\delta\sigma}}\,L = \sqrt{\frac{k}{\delta\sigma}}\,M$$

An example of the effect of this ohmic drop is given by considering a tube 10 cm long with a membrane thickness of 0.005 cm. A well activated membrane would show about 20 mv polarization at 0.2 amp/ft^2 when operated at 200°C. The conductivity of a palladium-silver alloy at this temperature and in the presence of hydrogen is about 2 x 10^4 (ohm-cm)$^{-1}$. For this case,

θ is 3.16 and the correction factor from Eq. [13] or Fig. 4 is 0.315. In this example, about three times as much polarization can be expected at a given current density as compared to a tube with current collectors.

Nomenclature

A	Geometric surface area of membrane, cm^2
A_m	Coefficients of Fourier cosine series
C	Concentration of hydrogen atoms in metal at gas side, mole/cm^3
C'	Concentration of hydrogen atoms in metal at electrolyte side, mole/cm^3
D	Outside diameter of tube, cm
E	Polarization from open circuit potential, v
f	Ratio of actual current to the ideal current with no ohmic losses
F	Faraday constant, 96,500 coulomb/equivalent
i	Local current density, amp/cm^2
I_0	Modified zero order Bessel function of the first kind
I_1	Modified first order Bessel function of the first kind
I_D	Diffusion rate constant, amp-cm/mole
J	Current at any location in the tube, amp
k	Proportionality constant between local current and metal-solution potential difference, amp/cm^2-v
k_1	Anodic rate constant for electron transfer, amp/cm^2
k_2	Cathodic rate constant for electron transfer, amp/cm^2
K_1	Hydrogen adsorption rate constant, amp/cm^2-atmosphere
K_2	Hydrogen desorption rate constant, amp/cm^2
L	Length of tube or rectangular membrane, cm
M	Width of rectangular membrane, cm
m	Integer
P	Hydrogen partial pressure, atmosphere
R	Radius of circular membrane
R_0	Gas constant = 8.314 joules/mole-°K
r	Radial distance from center, cm
T	Absolute temperature, °K
x	Linear distance from origin, cm
x_0	Location at which local current equals zero
y	Linear distance from origin, cm
α_1	Hydrogen atom desorption rate constant, amp/cm^2
α_2	Hydrogen atom adsorption rate constant, amp-cm/mole
α	$\sqrt{k/\delta\sigma}$ — cm^{-1}
β_1	Hydrogen atom desorption rate constant, amp/cm^2
β_2	Hydrogen atom adsorption rate constant, amp-cm/mole
Δ	Denotes difference
δ	Membrane thickness, cm
θ	Normalized distance
θ	Fraction coverage of gas-side surface active sites with hydrogen atoms
θ'	Fraction coverage of electrolyte-side surface active sites with hydrogen atoms
ϕ	Ohmic potential, v
ϕ_x	x-dependent solution of ϕ
ϕ_{xy}	x and y dependent, or homogeneous solution of ϕ
σ	Electrical conductivity of membrane, (ohm-cm)$^{-1}$

Electronic Conduction in Anodic Films: The Role of the Forming Solution

D. A. Vermilyea

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

The electronic conductivity of anodic Ta_2O_5 and Nb_2O_5 film depends strongly on the forming solution. Hydrogen peroxide is especially effective; small additions (<1%) may decrease the electronic conductivity by several orders of magnitude. The effect of hydrogen peroxide on conductivity can sometimes be removed by application of large fields in the forward direction. Such major effects of forming bath on conductivity have not been observed with other anodic films or with Ta_2O_5 and Nb_2O_5 films formed on substrates which introduce many flaws into the films.

A previous paper (1) presented current-voltage data for electronic currents in anodic films on several metals. It was found that flaws in the films were very important for all oxides, but that for Nb_2O_5, WO_3, and Ta_2O_5 films electronic currents were passed through films which were nearly flaw free. For those studies only dilute aqueous solutions were used in forming the films, and the results were essentially independent of forming solution. This paper reports studies of the effect of the forming solution on current flow in Ta_2O_5 and Nb_2O_5 films. All films were tested at room temperature using conventional equipment, and the test solution was 0.1M $CeSO_4$ + M H_2SO_4.

It was found that for very thin films (below 100Å) there was little dependence of the electronic current flow on the forming bath or procedure. As the film thickness increased, however, marked differences were observed between films formed in different solutions, and in addition the behavior depended on the rate and temperature of formation. Figure 1 shows some typical data for films formed 2 min at 28v at room temperature on chemically polished zone refined tantalum; the films are essentially flaw free. The data for 1% H_2SO_4 are typical of the behavior of films formed in a variety of dilute aqueous solutions of variable *p*H. The behavior of films formed in 85% H_3PO_4 was not very different, a remarkable fact in view of the report by Randall *et al.* (2) that the films formed on tantalum under similar conditions contain about 0.18 mole of phosphorus per mole of tantalum ions.

Other concentrated forming solutions yield films showing widely different behavior, as shown in Fig. 1. The effect of hydrogen peroxide is especially startling. A film formed in 1% HNO_3 shows a current voltage

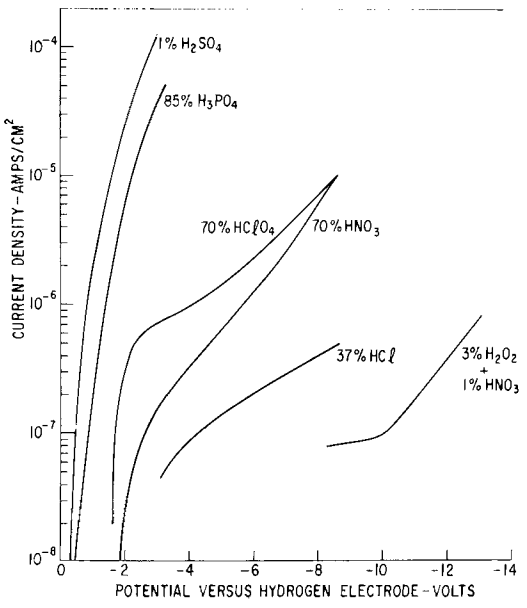

Fig. 1. Films formed at 28v for 2 min at 25°C on chemically polished zone refined tantalum.

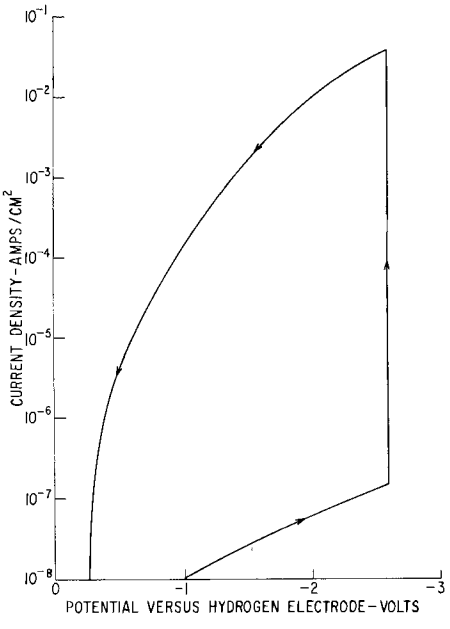

Fig. 2. Film about 200Å thick formed in 1% HNO_3 + 30% H_2O_2 at 25°C.

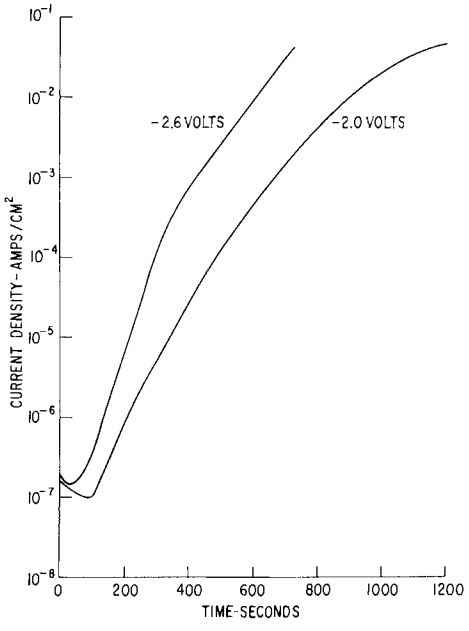

Fig. 3. Films formed as for Fig. 2, held at different negative potentials.

curve like that for 1% H_2SO_4, but the addition of as little as 0.01% H_2O_2 results in a curve similar to that for the 3% H_2O_2, 1% HNO_3 solution. A solution containing 30% H_2O_2, 1% HNO_3 yielded similar films, and the behavior is essentially the same for films formed in 1% H_2O_2 plus a variety of salts in solutions with pH from 1 to 13. It was found that the HF dissolution rates (as measured by changes of interference colors) of the outer portions of films formed in even very dilute H_2O_2 solutions were as much as a factor of two greater than those of the inner portions, a behavior typical of films which contain materials from the forming solution (2, 3). It therefore appears that tantalum oxide has a very strong tendency to occlude hydrogen peroxide or some product of hydrogen peroxide. Niobium oxide is similarly sensitive to H_2O_2, and also, to a lesser extent, to $HClO_4$.

In order to be effective the H_2O_2 must be in the forming bath during film growth. Post formation treatments of any kind do not result in incorporation of H_2O_2 and reduction in current flow. Double formations in which H_2O_2 containing solutions are used for forming part of the film are less effective than when H_2O_2 is present throughout the formation period. It is not possible to remove the H_2O_2 by subsequent long anodization at the same forming potential in a solution which is free of H_2O_2. The H_2O_2 effect is not associated only with the rapidly etching outer layers, for when these are removed with HF the inner portion of the film also has an abnormally low electronic conductivity.

The use of H_2O_2 in forming films is not effective when the metal contains flaw-forming defects (4), films formed with H_2O_2 on such specimens giving nearly unchanged current-voltage curves. On good specimens at sufficiently negative potentials local breakdown occurs and very high currents can be carried at one or a few sites. Attempts to detect uniform conduction in H_2O_2 formed films by gold deposition have not been successful, and it appears that the effect of H_2O_2 is to reduce greatly the conduction in the bulk of the film without changing conduction at flaws.

The high resistivity films produced by H_2O_2 can be altered to low resistivity films by the application of steady negative potentials below those required to cause local breakdown. Figure 2 shows data for a Ta_2O_5 film about 200Å thick formed with H_2O_2 and then held at —4v. The upper portion of the curve is typical for films formed in dilute aqueous solutions, and once the film conductivity has reached that high level it is not possible to regain the initial low conductivity state by any treatment including hour-long formation at the original forming voltage in the original H_2O_2 containing solution. After the conductivity change the outer portion of the film still etches faster than the inner portion, so all the effect of H_2O_2 has not been removed. This "unblocking" is faster at a more negative potential, occurs as readily in mercury as in aqueous solution, and is relatively uniform as shown by gold deposition on the altered specimen. Figure 3 shows data for the current as a function of time for the "unblocking." The curve has a shape very nearly like that for the concentration at one film interface of a substance diffusing across the film from the opposite interface where its concentration is constant.

In summary, it appears that substances from the forming bath which are incorporated into the films may greatly reduce the electronic conduction of the

films. The effects of rate and temperature of film formation may be to change the amounts of such incorporated materials. The effects seem to be primarily associated with bulk conduction and not flaw conduction. The blocking effect is unstable, being removed by long negative polarization, possibly when diffusion adds something to or removes something from the film. Finally, no similar effects of H_2O_2 on conduction in Al_2O_3 and ZrO_2 films was observed; it is believed that conduction in such films occurs mainly at flaws.

Technical Notes

Direct Observation of the Anodic Oxidation of Aluminum

H. A. Francis

Arthur D. Little, Inc., Cambridge, Massachusetts

Recently, the ionic transport kinetics of the anodic oxidation of aluminum have been investigated using radioactive tracer methods by Davies *et al.* (1). They found that, in the current density range 0.1-10 ma/cm^2, the cation transport fraction (*i.e.*, fraction of total ionic current which is cationic) was 0.6 independent of current density for a nonaqueous electrolyte and increased with current density from 0.4 to 0.7 for an aqueous electrolyte. Transmission electron microscopy has been employed by Doherty and Davis (2) to determine the kinetic mechanisms of the thermal oxidation of aluminum. They found that above 500°C, crystalline oxide forms at the oxide-metal interface by anion transport through the existing amorphous oxide film. Evidence was presented indicating that the thermal amorphous film grows largely by cation transport controlled at the oxide-metal interface. The present investigation utilizes transmission and replica electron microscopy of the oxide in the vicinity of vacancy pits on the metal to investigate the growth mechanisms of anodized amorphous oxide films.

Experimental Technique

Electropolished single crystals of 99.992+% aluminum were grown horizontally from the melt and electropolished in a methanol-perchloric acid solution in the same manner as those used by Doherty and Davis (2). The experiments were performed on (100) and (110) surfaces.

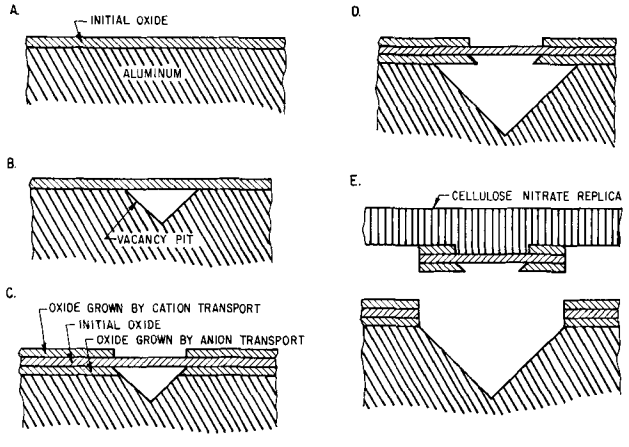

Fig. 1. Schematic representation (not to scale) of experimental technique. (A) Initial surface. (B) After first heating and cooling. (C) After anodizing. (D) After second heating and cooling. (E) Removal of oxide fragment.

The basic experimental technique is illustrated schematically in Fig. 1. The initial oxide film (A) was either the as-electropolished oxide or a thicker film grown either thermally in air or anodically. When the crystal was heated to an elevated temperature (ranging from 400° to 575°C) and cooled (B), micron-sized pits bounded by low-index crystallographic planes nucleated and grew under the oxide in the metal by the condensation of lattice vacancies (3). Oxide was then grown anodically (C) under various controlled voltage conditions to be described later. In all cases the electrolyte was 1% respectively of ammonium citrate and citric acid in distilled water and the cathode was electropolished aluminum of the same purity as the specimens. It is seen that, at the edge of a vacancy pit, a step is produced at the oxide-metal interface whose height is equal to the thickness of oxide grown by anion transport, and a step of height equal to the thickness of oxide grown by cation transport is produced at the oxide-electrolyte interface. Then the crystal was heated a second time, and, on cooling, a fraction of the vacancy pits grew to a larger size (D). An adherent cellulose nitrate replica was used then (E) to remove the oxide over the pits, and these oxide fragments were viewed in normal transmission in the electron microscope. The topography of the oxide-metal interface was observed by shadowing the fragments with platinum after their removal from the crystal. The topography of the oxide-electrolyte interface was observed either by shadowing the surface of the crystal prior to application of the replica or by using conventional techniques to replicate the surface before the second heating without removing any oxide. In all cases, the shadowing angle of incidence was 18°.

The specimens exhibit a slight surface roughness which is observable optically. Hence, it cannot be assumed that the surface in the immediate vicinity of a vacancy pit is precisely parallel to the over-all surface of the specimen or replica which is used as the shadowing angle reference. This and the fact that the oxide over a vacancy pit often bows in either direction prohibit determination of step height from apparent shadow length.

Results

Figure 2 shows a shadowed replica of a (100) surface in the vicinity of a square vacancy pit, the oxide over which was not removed. In this case, the crystal

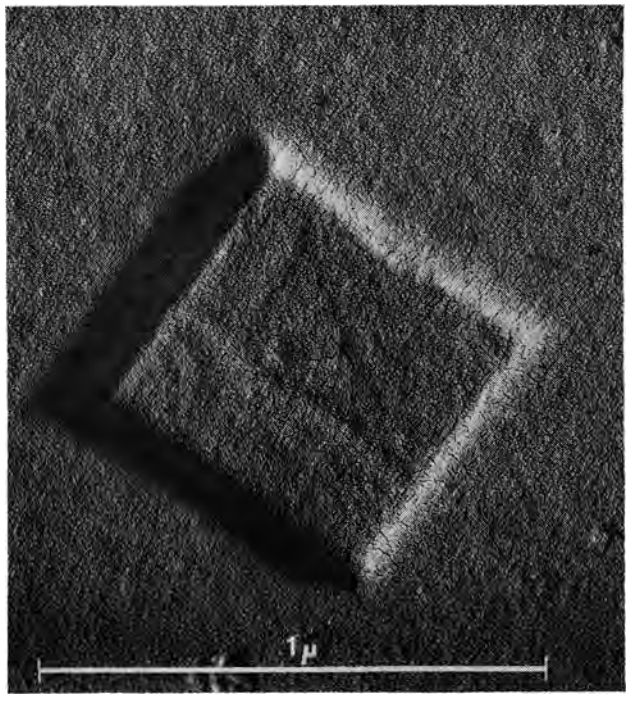

Fig. 2. Shadowed replica of (100) oxide-electrolyte interface showing step along perimeter of vacancy pit.

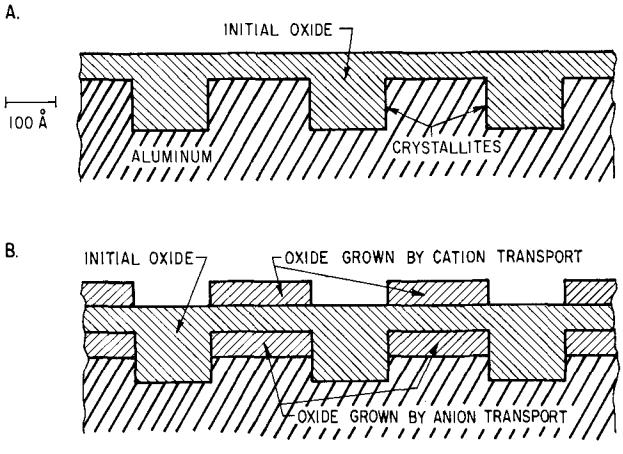

Fig. 3. Schematic representation of surface after nucleation of crystalline oxide. (A) Before anodization. (B) After anodization.

was anodized to 8v, vacancy pitted, and anodized to 27v by instantaneously applying the entire voltage, resulting in a mean current density (averaged over oxide thickness) of 3 ma/cm^2. In addition, (100) surfaces were anodized to voltages ranging from 27 to 42v with the following voltage rates (and mean current densities): 0.24 v/min (0.01 ma/cm^2), 4 v/min (0.3 ma/cm^2), and 15 v/min (1.4 ma/cm^2). The results of replication without oxide removal were identical for the four average current densities. It is seen in Fig. 2 that a step exists along the perimeter of the vacancy pit indicating that cation transport occurred during anodizing.

Doherty and Davis (2) have shown that the high temperature stage of thermal oxide growth consists of the nucleation of oxide crystallites at the oxide metal interface which then grow into the metal. This stage is shown schematically in Fig. 3(A). At room temperature, anodic oxide growth will not occur if the field in the oxide is less than about 1/14 v/Å (4). Thus, if a crystal with this oxide-metal interface topography is anodized by slowly increasing the voltage, growth will not occur at the crystallite sites until the oxide thickness is uniform (Fig. 3B). Growth by cation

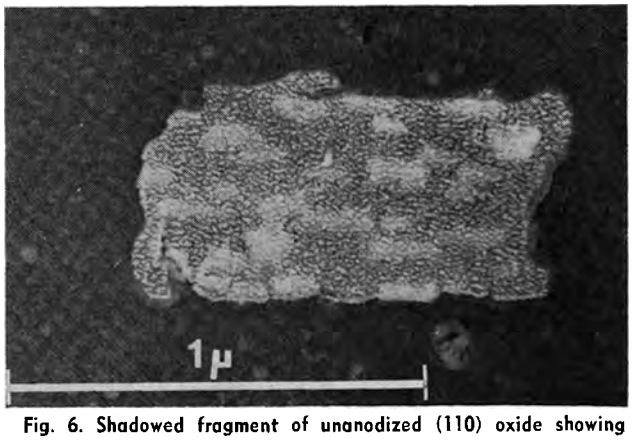

Fig. 6. Shadowed fragment of unanodized (110) oxide showing smooth oxide-electrolyte interface.

transport will result in depressions in the final oxide-electrolyte interface over the crystallite sites. Growth by anion transport will tend to "swallow up" the crystallites.

A crystal was heated to 575°C for 15 min to grow crystallites, cooled to form vacancy pits, and anodized to 20v at about 4 v/min. The mean current density was about 0.3 ma/cm^2. Figure 4 shows a shadowed replica of the (110) surface in the vicinity of a rectangular vacancy pit. The unanodized oxide over the pit has bowed into the pit, and the left half of it has been removed with the replica, directly displaying the crystallites at the oxide-metal interface. The right half

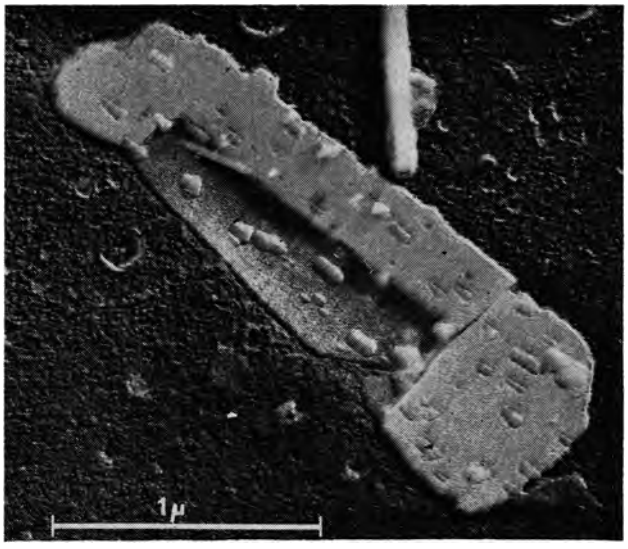

Fig. 7. Fragment of (110) oxide whose oxide-metal interface has been shadowed demonstrating oxide growth by anion transport.

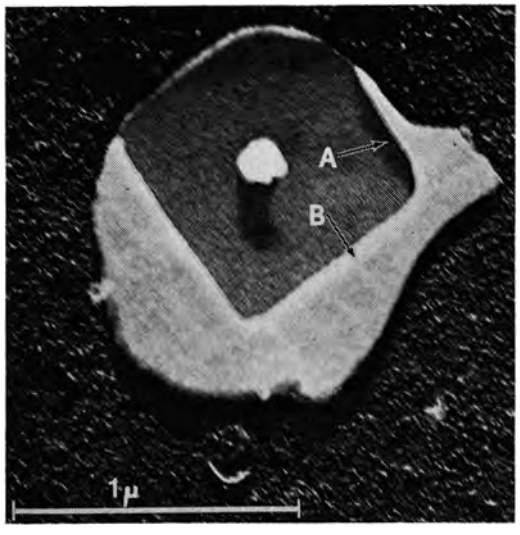

Fig. 8. Fragment of (100) oxide whose oxide-metal interface has been shadowed. Step along original perimeter of vacancy pit is revealed by its cast shadow (A) and platinum build-up on its face (B).

remained in place over the pit, and the replica shows its oxide-electrolyte interface to be smooth. The oxide-electrolyte interface of the anodized oxide surrounding the pit site is seen to contain depressions (rises on the replica) corresponding to the crystallites, indicating growth by cation transport.

Another crystal was treated as described in the preceding paragraph and, after anodizing, heated and cooled a second time to enlarge the existing vacancy pits (see Fig. 1D and 3). Figure 5 shows an oxide fragment removed from the (110) surface, the oxide-electrolyte interface having been shadowed prior to removal. The depressions over the crystallite sites are revealed by the shadowing. For comparison, a fragment of unanodized oxide removed from a pit that did not enlarge is shown in Fig. 6. Its oxide-electrolyte interface is seen to be smooth. The light areas (lower transmitted intensity) correspond to the oxide crystallites. Figure 7 shows an oxide fragment whose oxide-metal interface was shadowed after removal from an enlarged pit. The unanodized region is not in the center of the fragment because either one side of the original pit did not grow or part of the oxide over the pit was not removed. A step can be seen separating the anodized and unanodized regions at the original perimeter of the pit. In addition, the oxide grown by anion transport has surrounded the sides of most of the crystallites, as evidenced by the fact that they do not cast a noticeable shadow. Thus Fig. 5-7 show that for this treatment the anodized oxide grew by both anion and cation transport.

Figure 8 shows an oxide fragment removed from an enlarged pit (see Fig. 1E) on the (100) surface of a crystal which had been anodized to 8v, vacancy pitted, anodized to 27v at 0.24 v/min (0.01 ma/cm^2), and heated and cooled a second time to enlarge the pits. Both a cast shadow and shadowing material (platinum) build-up show that a step exists on the oxide-metal interface along the original perimeter of the pit, hence anion transport occurred. Identical observations were made under experimental conditions differing only in that the 27v was instantaneously applied and the mean current density was 3 ma/cm^2.

Discussion

For the anodizing treatments investigated, which encompass a range of mean current densities from 0.01 to 4 ma/cm^2, we may conclude that both anion and cation transport occur. On one anodized crystal (Fig. 5, 6, 7; 0.3 ma/cm^2) both anion and cation transport were observed. On all others, one or the other was investigated and always observed. There was no observable dependence of the results on surface orientation. The results of the present investigation thus confirm by a new technique previous results which showed that cation and anion transport can occur simultaneously.

For mean current densities of 0.1 ma/cm^2 and 3.0 ma/cm^2 on a (100) surface, 0.3 ma/cm^2 on a (110) surface, and about 30 ma/cm^2 on a (111) surface the oxide grown did not diffract an electron beam. This encompasses the range of current densities for which ionic transport mechanisms were investigated. Thus, while thermal oxide grown at the oxide-metal interface is crystalline (2), apparently anodic oxide grown by anion transport is not. Since anodic oxidation takes place essentially at room temperature, it is reasonable that for kinetic reasons long range order is not produced in the oxide grown at the oxide-metal interface.

One of the most interesting results of the recent work of Davies *et al.* (1) is the apparent dependence of the ionic transport kinetics on the nature of the electrolyte, an effect largely neglected in the literature.

They bombarded unanodized aluminum foils with Xe^{125} and used β-spectroscopy to measure the mean depth of the tracer after anodizing at various constant current densities in the range 0.1-10 ma/cm^2. Independent measurements of the amount of aluminum dissolved in the electrolyte were made for each current density using a neutron activation technique. The final barrier oxide thickness δ was calculated from Bernard and Cook's (5) empirical relationship $i = \alpha \exp(\beta V/\delta)$. The measurements of tracer depth d, dissolved Al a, and δ were converted to equivalent μg/cm^2 of oxide, and the cation fraction t_m (cationic fraction of total ionic current) was calculated from the relationship $t_m = (d + a)/(\delta + a)$. It was found that t_m was 0.6 independent of current density for a sodium tetraborate/ethylene glycol electrolyte and increased with current density for an aqueous 3% ammonium citrate electrolyte.

They inferred that the observed dependence of t_m on current density for the citrate electrolyte may be attributed to pore formation in the oxide. It should be emphasized that the Al in solution may result from either or both of two processes: (*i*) pure cationic leakage (as assumed by Davies *et al.* in their analysis), and (*ii*) dissolution of oxide in the electrolyte to form an electronically conducting porous layer on top of the nonconducting barrier layer (6, 7). Both cases are equivalent with respect to barrier layer growth rate, barrier layer thickness δ, and the field in the barrier layer. For case *ii*, the data must be interpreted in a slightly different fashion. Assuming the density of the porous layer to be homogeneous and independ-

ent of current density, the mass/cm^2 of the porous layer is Ka where K is a constant. The total oxide growth (total ionic current) is thus given by $\delta + a(K + 1)$. The observed Xe^{125} depth d will be less than the actual depth by a "distance" equivalent to the mass/cm^2 of the dissolved oxide. Thus the numerator of t_m will be the same as for case i, and

$$t_m = \frac{d + a}{\delta + a(K + 1)}$$

Although K is not known for this electrolyte, we can predict that the fractional variation in t_m with current density will lie within a certain range. $K = 0$ is case i, for which Davies' values hold. As K becomes very large, the fractional variation in t_m with current density becomes that of the numerator $d + a$. It may be seen from Davies' Table IV that this variation, although less than the variation in t_m for case i, is in the same direction and still well outside of its 10% experimental error. If both cationic leakage and pore formation occur, the fractional variation in t_m will be that for an intermediate value of K. Thus, regardless of the amount of porous oxide formed, the increase of the cation fraction with current density is a real effect for this electrolyte.

It is to be noted that, barring the difficulty of step height measurement, the vacancy pit technique could be used to determine t_m regardless of the amount of pore formation, providing any cationic leakage current is known. The step height at the electrolyte-oxide interface includes both the cationically grown barrier layer and the porous layer.

The nature of the rate-determining steps and the field, temperature, and thickness[1] dependences (*i.e.*, the constants in the appropriate rate equations) of the cation and anion transport rates i_c and i_a remain to be investigated for the various electrolytes. This requires that the total ionic current density $i_t(E, T, \delta)$ be accurately known for the particular electrolyte, even though an approximation is sufficient to determine δ and hence t_m by Davies' method, since δ is probably a relatively insensitive function of the nature of the electrolyte. In addition, if pore formation occurs, the density and growth rate of the porous layer must be known. The fact that $t_m(i_t)$ differs between the two electrolytes investigated by Davies *et al.* strongly suggests that $i_t(E)$ depends on the nature of the electrolyte. For Davies' citrate electrolyte, $i_t(E, T, \delta)$ is not accurately known, so a comparison of $i_c(E, \delta)$ and $i_a(E, \delta)$ between the two electrolytes is not possible.

[1] A thickness dependence is possible according to Dewald's theory for diffusion-limited ionic transport (8).

Assuming Benard and Cook's $i_t(E)$ (5) for an ammonium pentaborate/ethylene glycol electrolyte to hold for Davies' glycol electrolyte, we may conclude from the invariance of t_m that for this electrolyte both $i_c(E)$ and $i_a(E)$ are exponential functions with the same Tafel slope as $i_t(E)$. Since, for the citrate electrolyte, t_m is a function of E, the rate-controlling step of at least one of the two species must be in some way altered between the two electrolytes. Three possible rate-limiting processes for either species are transport across either of the two interfaces of the barrier layer and diffusion within the barrier layer. It is difficult to imagine the structure of the oxide-metal interface to be dependent on the electrolyte. However, it is possible that the nature of the electrolyte could influence the structure of the oxide-electrolyte interface or the structure of the cationically grown oxide, since its growth occurs at the oxide-electrolyte interface (1). If a porous layer exists, anion transport might be limited by oxygen diffusion through the pores to the surface of the barrier layer.

Miles and Smith (9) have anodized aluminum and other metals in an oxygen plasma electrolyte which offers a third, rather different electrolyte for which to investigate the anodic oxidation kinetics. It would be illuminating to know which of the rate equations for i_t, i_c, and i_a differ among the two "wet" electrolytes and the plasma.

An Electrically Latched EL-PC Memory Panel

B. Sunners and B. Narken

International Business Machines Corporation, Components Division,

East Fishkill Facility, Hopewell Junction, New York

Electroluminescent memory and display panels have been described by many authors and were reviewed by Henisch (1). They range from a simple EL-PC couple to the very complicated "ELF" (electroluminescent-ferroelectric-photoconductor) display panel. Zim and Krolak recently described an electrically addressed electroluminescent memory panel using hysteretically conducting cadmium selenide as the control element (2).

In its simplest form, a light addressed memory panel is prepared by placing an electroluminescent layer and a photoconductor layer in series and in optical contact, as shown in Fig. 1a. When light strikes the photoconductor, the resistance of the photoconductor falls, and the voltage drop increases across the electroluminescent layer, which then emits light characteristic of the electroluminescent material. Some of this triggering light is fed back to the photoconductor, thus holding it in the "on" position even when the exciting light is removed. The panel remembers the triggering light and can be extinguished only by removing the applied voltage.

In order to display a pattern, the conventional panel (generally in a more complex form) (3) must become one unit in an X-Y matrix (Fig. 1b). The pattern definition is limited by unit size and cross talk between adjacent lines, and the over-all size is limited by the greatly increasing complexity as the number of X and Y drive lines is increased. In addition, this optically latched couple cannot be constructed or used in

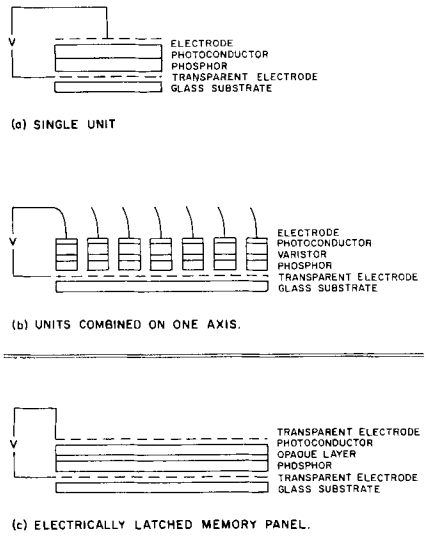

Fig. 1. Schematics of memory panels

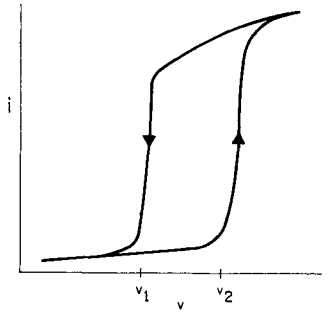

Fig. 2. Current-voltage hysteresis in powder photoconductors (after Nicoll).

a way as to expose the photoconductor to a high ambient light level that would trigger it into the "on" state.

This note describes a panel that does not have the complexity, limited size, and limited resolution of the conventional XY matrix. It is prepared in a continuous sheet (Fig. 1_c), and it has the further advantage of being able to operate in a high ambient light level.

The panel operates on a principle first reported by Nicoll in his work on an image storage device (4). He observed a hysteresis loop in the current/voltage curves of plastic embedded power photoconductors (Fig. 2). Such materials can be triggered into the high conduction state by light when the value of the applied voltage is between V_1 and V_2, and will remain in this state until the voltage drops below V_1. This then forms the basis for a bistable device, switched on by light and switched off by removing (or lowering) the applied voltage.

It is now possible to produce this effect in sintered layer photoconductors. In addition to the usual advantages of sintered layers compared to power photoconductors (*e.g.*, photosensitivity, mechanical strength, ease of fabrication), these sintered photoconductors permit a memory panel that is continuous in structure and does not require the usual complex XY matrix in order to store a pattern. Figure 1c clearly shows the simplicity inherent in this type of construction. As the latching is electrical, not optical, an opaque layer is necessary to prevent feedback from the photoconductor. This construction permits operation of the panel in high ambient light levels, limited only by the desired output contrast level.

The structure is prepared as follows. The semitransparent electrode and the glass electroluminescent and opaque layers are made in the usual ways. The photoconductor is next deposited on top of the opaque layer. In Nicoll's paper, the hysteresis effect was observed in powered materials; these are usually of lower sensitivity than single or polycrystalline materials. The photoconductor discussed here is prepared by sintering CdSe under carefully controlled conditions to yield a material of high sensitivity.

The method of preparation of such a sintered layer is as follows: pure cadmium selenide is thoroughly mixed with glycol, glycerol, an aqueous solution of cupric chloride, and cadmium chloride flux (from 5 to 10% by weight), so as to give a mixture or suspension suitable for depositing by a doctor blading, or similar technique that results in a texture-free layer (thus, screen printing is not entirely satisfactory). The concentration of copper will determine to a large extent many properties (response time, sensitivity, etc.) of the completed photoconductor. As a guide, a suitable concentration of copper under the conditions of our preparations is about 500-1000 ppm by weight. The flux concentration is critical but it is strongly dependent on experimental conditions, such as firing cycle, ambient flow rates, furnace volume, etc.

After depositing the photoconductor in the required grometry, it is slowly dried in air at 200°-300°C and subsequently fired. All samples at present have been fired in a quartz-lined horizontal-tube furnace at 525°-575°C for periods up to 30 min. The ambient is carefully controlled and consists of 98% nitrogen and 2% oxygen by volume, slightly humid, flowing over the sample at a rate of 30 cm/min.

Obviously, these conditions can be varied; sintered layer photoconductors can be prepared under a wide variety of conditions but to obtain a material with the optimum hysteresis properties, a combination of conditions must be chosen so that the sintering action of the cadmium chloride flux is minimal and yet does not lead to typical powder photoconductor properties (e.g., nonlinear current-voltage relationship). The presence of oxygen in the ambient improves adhesion and the mechanical properties of the layer, which otherwise, due to the low flux concentration, would be poor; in addition, it may improve particle-to-particle contact through the formation of a conducting CdO layer (5).

The hysteresis can be greatly enhanced by baking the fired photoconductor at temperatures up to 300°C in an oxygen-containing atmosphere. This process is known to decrease the effective number of donor species in the material (*i.e.*, reduce the number of selenium vacancies). The photoconductor may also be baked in a sulfur or selenium atmosphere, and indeed, some of the better results were obtained with sulfur treatments.

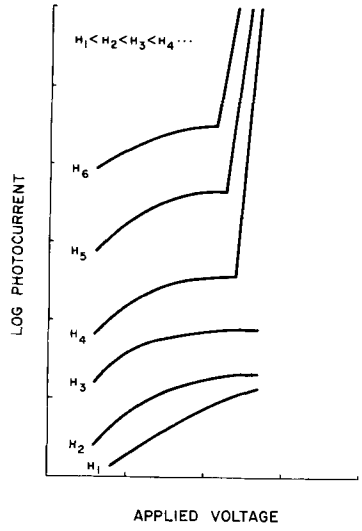

Fig. 3. Photocurrent voltage curves

Preparative techniques that increase hysteresis in general shift the photocurrent-voltage curve to higher voltage levels at a constant light intensity. The voltage breakdown shown has been made to persist in these photoconductors even in the absence of light and thus provide the second stable dark state of the device (Fig. 2).

A layer so prepared has the mechanical properties and sensitivity of the conventional sintered layer and has a linear voltage-current relationship, but, in addition, it shows dark current hysteresis.

Problems have been encountered in applying electrically continuous semitransparent electrodes to the relatively rough surface of this photoconductor, and experiments have been conducted with a view to applying the photoconductor in a glass binder to provide a smooth surface. It is known that photoconductive layers may be prepared in this way and show many advantages over the conventional plastic binder (6), but the required property of hysteresis has not yet been observed in such a structure. Although no panels greater than about 1 in.^{2} have been prepared, no limits to the size are known, nor has any limit to the definition been observed. Ideally, this limit may be the grain or crystallite size of the photoconductor and phosphor; thus the layer should be deposited by doctor blading rather than screen printing to develop optimum resolution. Spreading of the image would, of course, limit the definition and also limit the storage time of the memory. To date, experimental units do not show any spreading or fading of spots about 1 mm in diameter over periods up to 18 hr. The sensitivity of most of the photoconductive layers is such that they are readily triggered by the light from a cathode ray tube, and the intensity of the image is limited only by the performance of existing phosphors.

It is felt that the great advantages of simplicity and consequent ease of manufacture of this type of panel will be of interest to those engaged in fields of display, storage, and opto-electronics.

Phase Stability Regions of Boron Phosphides in the Ni-B-P System

Robert I. Stearns

Central Research Department, Monsanto Company, St. Louis, Missouri

and Paul E. Greene

—hp associates—, Palo Alto, California

A procedure for the preparation of BP was reported (1) in which mixtures of Ni and B were heated to about 1400°C and then allowed to cool under a phosphorus atmosphere. BP and/or $B_{12}P_2$ (2) was recovered by dissolving away the unwanted material with aqua regia.

In an effort to optimize the preparative procedure, work was undertaken independently by the two laboratories contributing this article. The procedures used were slightly different and are described separately.

The data obtained, although far short of completely defining the system, are sufficient to construct a preliminary phase diagram of the Ni-B-P system, Figure 1.

Experimental

Procedure I.—Mixtures of powdered Ni (A. D. Mackay, carbonyl powder, 99.9%), B (Cooper Metallurgical Associates, Grade AA-325, 99.5%), and red P (American Agricultural Chemical Company, semiconductor grade, ground under distilled water) were made by weighing the individual elements and mixing them thoroughly in a capped bottle. About a half gram of the mixture was sealed under vacuum (about 10μ) in a small quartz ampule and heated to melting and then solidified by quenching. The melting occurred in the same temperature range noted in procedure II below. The weights of the resulting solid masses corresponded to the elements weighed in the small ampules and it was therefore assumed that the vapor pressures at the melting points were small and of the same order given in procedure II. The solidified mass was treated with warm aqua regia until dissolution ceased. The resulting boron phosphides were easily identified by examination. BP is red, transparent, face centered cubic material and $B_{12}P_2$ is black to colorless, rhombohedral material. These identifications were spot checked by x-ray diffraction examination

Procedure II (3).—Weighed samples, 0.2-0.4g of 4.00 w/o B (99.9999% Leytess Metal and Chemical Corporation) in Ni (99.999% Leytess Metal and Chemical Corporation) alloy were taken from a homogenous 20.0g alloy ingot and placed in an alumina crucible in a R. F. heated graphite furnace. These Ni-B samples were then allowed to equilibrate with P_2 at 3.8 Torr partial pressure in H_2 flowing at one 1 l/min. with a total system pressure of 1 atm. Equilibrations were carried out at constant temperatures (± 5°C) ranging from 1085° to 1320°C for 2 hr.

Table I. Tabulation of data

Procedure	At. % Ni	At. % B	At. % P	Phase remaining after acid treatment
I	49.1	8.4	42.5	BP
I	53.4	9.0	37.6	BP
I	54.7	9.1	36.2	BP

I	80.0	13.0	7.0	None

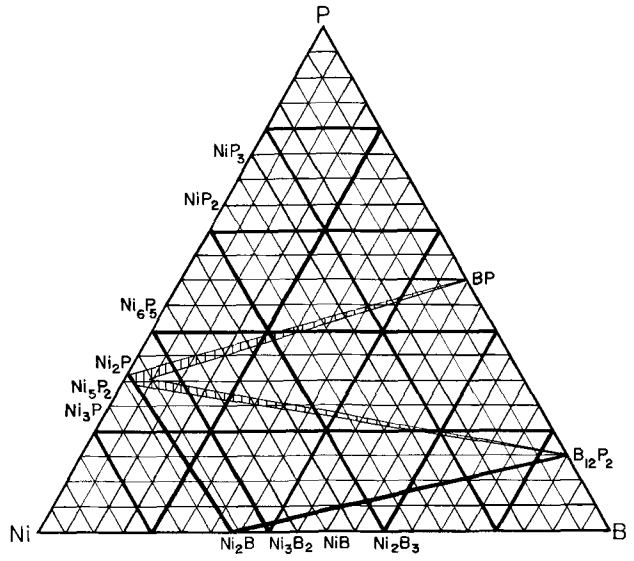

Fig. 1. Phase stability regions of BP and $B_{12}P_2$ in the Ni-B-P system.

The melts were quenched to room temperature, reweighed to within 0.1 mg, and subjected to hot HNO_3 treatment to dissolve the metallic phases and leave the BP and/or $B_{12}P_2$ as residues. The aqueous solutions were analyzed by standard methods (4-6) for Ni, P, and B, while the residues were determined gravimetrically giving a material balance. Identification of the boron phosphides were carried out in the same manner as procedure I.

Discussion

Table I tabulates the data. Figure 1 shows the phase stability regions of BP and $B_{12}P_2$ in the Ni-B-P system. It was constructed (7) by plotting on the binary legs the known binary compounds (1, 2, 8), the data of Table I and then drawing the tie lines from BP and $B_{12}P_2$. The hatched areas represent uncertainty in locating the tie-lines. That a ternary compound in the neighborhood of Ni_2P is indicated corroborates the findings of Rundquist (9) that Ni_2P dissolves B and Ni_3P does not.

The areas outside the area bounded by the four corners Ni_2B, $B_{12}P_2$, BP and the ternary compound cannot be defined by the method employed. Only detailed x-ray work could definitely establish these areas. Nevertheless certain predictions might be made. If no further ternary compounds exist, tie lines from $B_{12}P_2$ to Ni_3B_2, NiB, and Ni_2B_3 are expected, as would be tie lines from the indicated ternary compound to Ni_5P_2, Ni_2P, Ni_6P_5, NiP_2, Ni_3P, and P.

Acknowledgment

The Monsanto portion of this work was performed under a subcontract of MIT Lincoln Laboratory, which is operated with support from the United States Air Force, and the hpa portion under a Wright-Patterson Air Force Base contract (2, 3).

Preparation and Properties of Lead Hydroxy-Iodide in Single Crystal Form

J. Dennis and H. K. Henisch

Materials Research Laboratory, Pennsylvania State University, University Park, Pennsylvania

and P. Cherin

Fundamental Research Laboratory, Xerox Corporation, Webster, New York

It has been shown (1-3) that a variety of crystals suitable for solid state experimentation can be grown in silica gel. The method is especially useful for substances which, because of their low solubilities or low dissociation temperatures (or both, as in this case), cannot readily be grown in other ways. While preventing turbulence and remaining chemically inert, the gel provides a three-dimensional structure (of silica) which permits reagents to diffuse. It yields mechanically to the growing crystal and, in this way, gross constraining forces which otherwise might arise in a crucible are avoided.

The growth of lead di-iodide in gel media has already been described by Holmes (4) and Hatschek (5). A casual reference to the monoiodide (PbI) has been given by Niewodniezanski (6), but without any kind of detail concerning the circumstances of its formation, its structure, or its properties. Another appears in published tables (7), but without reference to origin and supporting evidence. The crystals here described were indeed the outcome of an attempt to check whether PbI can be obtained. They were grown as follows: Equal volumes of 0.86M sodium metasilicate and 0.68M acetic acid were mixed, and the resulting solution made 0.05M with respect to potassium iodide, giving a pH of 8.0. This was allowed to gel in a heat bath at 40°C. The process takes about 4 min. A raised temperature is necessary to maintain a high degree of hydrolysis and hence the alkaline nature of the gel medium. The top of the gel was covered with a 0.25M solution of lead acetate. Subsequent growth was allowed to take place in darkness. The size and

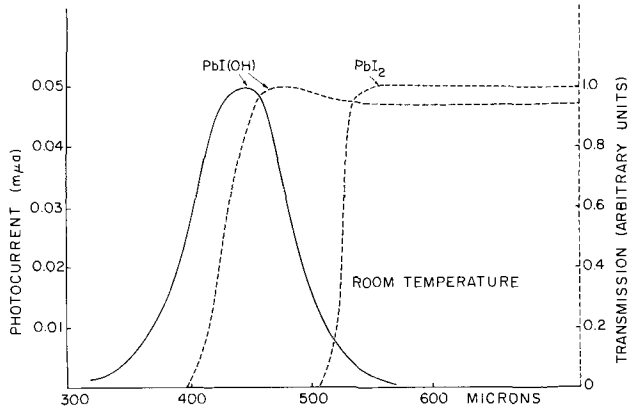

Fig. 1

clearness of the crystals obtained was found to be very sensitive to the *p*H changes of the reagents. Preliminary studies have shown that nucleation is not affected much by light (1) or temperature. However, a decrease in the *p*H causes a decrease in the number of nuclei, until at a *p*H of 7 the crystals which nucleate are PbI_2.

The crystals which result from this procedure are of the order of 1 mm^2 in cross-section, up to 5 mm long, clear, and pale yellow in color. Their appearance is thus entirely different from that of the more familiar PbI_2 which grows in the form of orange-colored hexagonal platelets. X-ray fluorescence, by comparison with PbI_2, showed the ratio Pb:I to be 1:1, within an accuracy of about 1.5%. A result of this kind may have been responsible for the impression that PbI exists. However, PbI(OH) and $PbI_2 \cdot PbO$ satisfy the same criterion while, at the same time, being much more plausible from the valence point of view. Neutron activation studies (by General Dynamics) showed the amount of oxygen to correspond to PbI(OH). The measured lattice parameters of the orthorhombic crystals were $a = 10.43 \pm 0.01$Å [10.41Å], $b = 7.79 \pm 0.004$Å [7.80Å], $c = 4.19 \pm 0.004$Å [4.19Å], the numbers in square parentheses being the parameters for PbI(OH) taken from Wyckoff (8) for the purpose of comparison. The space group is Pbnm, with four molecules per unit cell. The x-ray density is 6.85 g/cc.

As far as is known, PbI(OH) has not previously been prepared in single crystal form. Silicon was known to be present as a contaminant, to the extent of 200 to 500 ppm, no doubt originating from the gel medium. On heating (200°C) in oxygen, the crystals turn to Pb_2O_3.

An exhaustive investigation of properties has not yet taken place, but a few basic results are available. Figure 1 shows that there is an optical absorption edge at about 430μ. It also gives the spectral response of the photoconductivity. The low frequency (10^4 c/s) dielectric constant is about 10.5, and the magnetic susceptibility (averaged over all directions) is -0.256×10^{-6}/g.

The material was shown to be a p-type semiconductor under thermoelectric test. When examined under a scanning electron probe, most of the specimens were found (with a sensitivity of ½%) to be homogeneous as regards Pb:I ratio, and free from gross contaminations by foreign matter. They showed a faint but stable bluish-white cathodoluminescence, in contrast with PbI_2 which luminesces in the green region.

Cathodic Crossed Hydrocoupling

II. γ-Hydroxy-γ-Methylvaleronitrile and Its Hydrolysis Product from a Mixture of Acetone and Acrylonitrile

Kiichiro Sugino and Tsutomu Nonaka

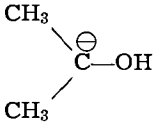
Department of Applied Electrochemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo, Japan

In a previous paper (1), we mentioned an electrolytic method for the preparation of δ-cyanovaleric acid ester by cathodic crossed hydrocoupling of acrylonitrile with acrylic acid ester.

We have now attempted to extend this to the crossed hydrocoupling of two entirely different types of compounds which can be reduced at the cathode. As a result, we found that a mixture of γ-hydroxy-γ-methylvaleronitrile and its hydrolysis product, γ, γ-dimethylbutyrolactone, could be obtained in a good yield when a mixture of acetone and acrylonitrile was reduced in aqueous sulfuric acid. The yield and the current efficiency were both as high as 70% when calculated on the basis of the amount of acrylonitrile used.

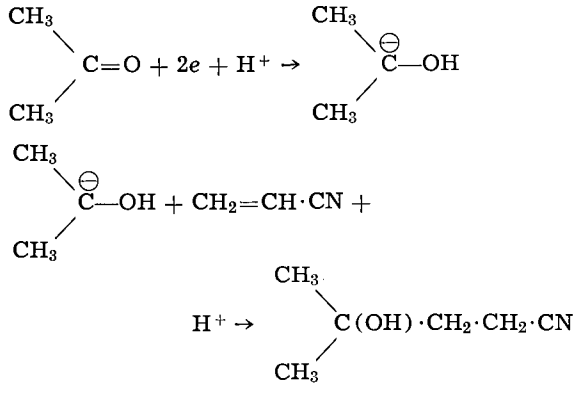
It is interesting to note that the reaction could be obtained even at a potential as low as −1.20v (*vs.* S.C.E.) in a simple electrolyte containing sulfuric acid.[1]

It is well known that acetone is easily reduced in aqueous sulfuric acid at around −1.3v (*vs.* S.C.E.) (2). However, acrylonitrile itself cannot be reduced under the same conditions. It seems to us, therefore, that this crossed hydrocoupling may be the reaction of

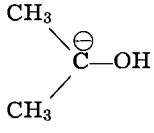


[1] In a neutral electrolyte containing quaternary ammonium salt at −2.3 to −2.4v, the reaction also proceeded smoothly and γ-hydroxy-γ-methylvaleronitrile was obtained without the formation of hydrolysis product. However, the yield was not as good because of the formation of other products.

anion with acrylonitrile. This can be formulated as follows.



These results have a bearing on the mechanism of pinacol formation by the electrolytic reduction of acetone. This has been considered as the mutual reaction of the radical ($(CH_3)_2\dot{C}OH$) formed at the cathode. However, the result of this research led us to suppose that the usual mechanism might be erroneous and the formation of pinacol from acetone should be the reaction of



anion with acetone molecule. This gains support from the result of another research (3), which shows that the reduction wave of acetone in tetramethylammonium p-toluenesulfonate has been interpreted as representing a two-electron reduction. The details will be reported in a separate paper.

Experimental

The cell used was the same as described earlier (1): cathode, mercury pool; area, 12.6 cm^2; anode, Pt disk. The electrolysis was carried out by controlling the cathode potential at —1.20v (*vs.* S.C.E.). The electrolysis conditions were: anolyte, 20% sulfuric acid; catholyte, (*a*) 32g acetone and 24g acrylonitrile in 16g 20% sulfuric acid and (*b*) 43g acetone and 3.2g acrylonitrile in 23g 20% sulfuric acid; amperage, (*a*) 0.35-0.24 amp and (*b*) 0.60-0.30 amp; cathodic current density, (*a*) 2.8-1.8 amp/dm^2 and (*b*) 4.8-2.4 amp/dm^2; temperature, (*a*), (*b*) 29°-32°C; amount of current, (*a*) 4.14 amp hr (0.154 Fr) and (*b*) 3.21 amp hr (0.120 Fr, theoretical based on acrylonitrile)

The catholyte turned pale yellow during electrolysis, and a small amount of gas was generated at the cathode.

After the reduction, the catholyte was neutralized with anhydrous potassium carbonate, and the resulting solution was thoroughly extracted with ether. The dried ether extract was analyzed by vapor phase chromatography[2] for isopropyl alcohol[3] and pinacol[4]: (*a*) 0.4g, (*b*) 0.6g of the former and (*a*) a trace, (*b*) 0.2g of the latter were found in it. The extract was then concentrated at diminished pressure, and the resulting concentrate was again analyzed by vapor phase chromatography[2] for γ-hydroxy-γ-methylvaleronitrile[4] (I) and also for its hydrolysis product, γ,γ-dimethylbutyrolactone[4] (II). It consisted of (*a*) 2.5g, (*b*) 1.9g of I and (*a*) 3.7g, (*b*) 2.6g of II. Current efficiency for coupling products was about (*a*) 70% and (*b*) 66%, respectively.

Identity was further confirmed by isolating each compound in nearly pure state by fractional distillation of the concentrate at reduced pressure.

γ-Hydroxy-γ-methylvaleronitrile seemed to be an unknown compound. The fraction corresponding to this compound has the following properties: b.p. 87°-88°C (5 mm Hg), n_D^{24} 1.4351, (molecular refraction 31.05; calculated from the sum of the atomic refractivities, 31.20), d_4^{24} 0.9512; analysis calculated for $C_6H_{11}NO$: C, 63.7; H, 9.8; N, 12.4; found: C. 63.5; H, 10.1; N, 12.3.

Infrared spectrum indicated a very distinct absorption at 2250^{-1} pointing to the presence of nitrile group. It also showed the principal absorption bands at 3400 cm^{-1} (OH), 2950 cm^{-1} (CH_3), and 1468 cm^{-1}($-CH_2-$).

This compound was converted into γ,γ-dimethylbutyrolactone (described below) by hydrolysis with acid.

The γ,γ-dimethylbutyrolactone fraction has the following properties: b.p. 81°C (12 mm Hg) [lit. (4) 208°C], solidify by cooling with ice [lit. (4) mp 10°C], $n_D^{14.5}$ 1.4342 [lit. (5) $n_D^{14.9}$ 1.4349], soluble in water. An infrared spectrum indicated the presence of lactone (C=O) group at 1775 cm^{-1}. It also showed the principal absorption bands at 2960 cm^{-1} (CH_3) and 1460 cm^{-1} ($-CH_2-$). No absorption for CN group was observed in this case. Identity was further confirmed by converting it to γ-hydroxy-γ-methylvaleric acid hydrazide, mp 65-66°C. A mixed melting point with authentic sample[5] showed no depression.

Acknowledgment

This investigation was promoted by a grant for fundamental scientific research from the Ministry of Education of Japan and also a grant from Nippon (Japan) Carbide Industries Inc., for which the authors wish to express their deep appreciation. The authors also wish to acknowledge the collaboration given by other members of this laboratory, especially Dr. K. Shirai, in helping us to carry out this research.

Czochralski Growth of Iron-59 Doped Calcium Tungstate Crystals and the Determination of Iron Retention by Radiochemical Analysis

V. J. Cobb and J. R. Coleman

Titanium Division, Research Laboratory, National Lead Company, Sayreville, New Jersey

The technique of pulling single crystals from the melt was first used by Czochralski (1) in 1918 to measure the speed of crystallization of different metals. More recently, the technique has been modified for the growth of silicon and germanium single crystals which have found wide use as semiconductors. The first successful application of the Czochralski method to multiple oxide systems was by Nassau and Van Uitert (2, 3). They applied the pulling technique to the growth of both pure and rare earth doped calcium tungstate single crystals. Nassau and co-workers (4, 5) have done extensive research on the growth of calcium tungstate, both pure and with trivalent rare earth substitutions, the latter being useful for laser applications.

The present study has utilized a radioactive tracer to investigate the behavior of iron during the growth of calcium tungstate single crystals by the Czochralski technique. The study was designed to yield information regarding the retention, concentration, and distribution of iron in the finished single crystals.

Initial melts were prepared by dry mixing the calculated amounts of calcium tungstate, radioactive ferrous tungstate containing Fe-59, normal ferrous tungstate, and a 4% excess of tungsten trioxide added as tungstic acid. The mixtures were dry blended until repetitive samples gave equal specific activities (c. min^{-1} g^{-1}) indicative of uniform iron distribution.

The apparatus used for the Czochralski growth of calcium tungstate was similar to that used by Nassau (3). The only significant difference being the use of a Minneapolis-Honeywell "Heat Eye" utilizing a ⅛ in. sapphire rod sighted on the bottom of the iridium crucible, instead of a Pt-PtRh thermocouple immersed in the melt.

A Baird-Atomic Gamma Scintillation Spectrometer, Model 8200, was used to determine the concentration of iron in the initial melts, cold finger samples, and finished single crystals.

All crystals were pulled using a seed crystal oriented in such a way that the a-axis was perpendicular to the melt. The seed was attached to the end of a ⅛ in. diameter rhodium rod by platinum wire. The seed, rotated at a speed of 50 rpm, was lowered into the iron-doped calcium tungstate melt which was held at a temperature of 1625°-1675°C. The seed was allowed to melt slightly, after which the withdrawal mechanism was started and a single crystal pulled from the melt at a rate of 5-15 mm/hr. Samples of the melt were removed at 30-min intervals, during growth of the single crystals, by a cold finger technique and tested for iron content by radioassay. The cold finger sampling involved the immersing of a ⅛ in. rhodium rod in the melt for a few seconds and then withdrawing it. Molten material solidifying on the rod was used as melt samples. Crystals ranging in weight from 8 to 15g were pulled over a period of 2½ to 4¼ hr (~3.3 g/hr).

Table I. Analytical data showing iron retention of calcium tungstate crystals

			Specific activity, c./min/g	Iron content, w/o	Iron distribution coefficient
Run No. 1	Starting material		1046	0.60	
	Cold finger samples	(30 min)	935	0.55	
$K = 5.88 \times 10^{-6}$		(60 min)	918	0.54	
		(90 min)	852	0.50	
		(120 min)	914	0.54	
		(180 min)	904	0.53	
	Average of cold finger samples			0.53	
	Final melt		905	0.53	
	Crystal samples (Top)		28.7	0.017	
			27.0	0.016	
			23.9	0.014	
		(Bottom)	27.3	0.016	
	Average of crystal samples				0.031

Table II. Iron retention of calcium tungstate crystals

Run No.	Melt concentration, w/o	Crystal concentration, w/o	Iron distribution coefficient
1	0.53	0.016	0.031
2	0.55	0.016	0.029
3	0.58	0.016	0.028
4	0.39	0.011	0.028
5	0.41	0.009	0.022
6	0.42	0.014	0.030
7	0.25	0.005	0.020
8	0.25	0.0038	0.015

Calcium tungstate crystals were grown from feeds containing from 0.26 to 0.60 w/o (weight per cent) iron added as iron tungstate. As can be seen from Table I, the concentration of iron in the melt remained essentially constant over the course of the run.

In making material balances for the various runs, both unaccounted weight losses and unaccounted activity losses were found. It was first assumed that the activity loss resulted from loss of iron by volatilization during the melting operation. A careful survey of the operating area gave no indication of radioactivity which might result from condensation of volatilized radioactive iron, however. It was later discovered that the bubble alumina adjacent to the crucible showed the presence of radioactive iron. From the calcium tungstate weight loss and the activity of the contaminated alumina it was estimated qualitatively that the missing iron was present in the alumina asso-

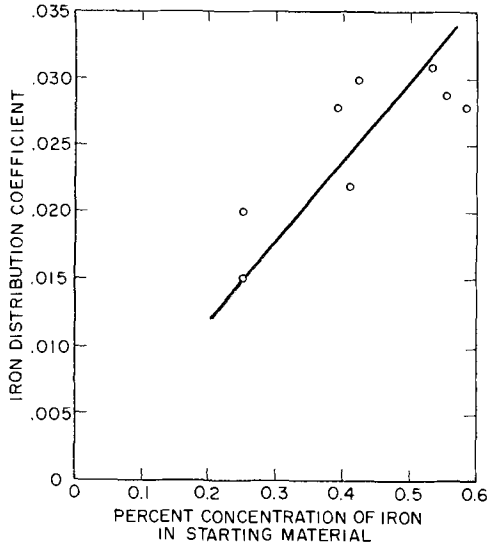

Fig. 1. Effect of change in concentration of iron in the melt on iron retention in the crystal.

ciated with the "lost" calcium tungstate but in a higher concentration than in the starting material.

Careful observation indicated that during growth the calcium tungstate crept up the side and over the lip of the crucible. If iron in molten calcium tungstate is assumed to be a surface active agent, the loss of a disproportionate amount of iron can be explained in this way.

Analytical data for the iron content in the crystals are also shown in Table I and Table II. Samples were taken from the top (first-grown portion) and at intervals of about 3 mm to the bottom (last-grown portion) of the crystal. No significant variation in iron content was observed from place to place, and the iron content was judged to be uniform, as might be expected for this growth technique, over the length of the crystal.

The per cent iron in the crystal increased in a roughly linear fashion with distribution coefficients of iron in the melt as shown in Fig. 1 and ranged from about 0.015 at a melt concentration of about 0.25% Fe (run No. 8) to 0.029 at a melt concentration of 0.55% Fe (run No. 2). Paramagnetic resonance studies by Mergerian (6) disclosed that the majority of the iron was present in the trivalent state. Since these studies were made on a crystal annealed in air at 1200°C for 20 hr, no definitive conclusions can be made with regard to the state of the iron ions at the growth temperature.

Manuscript received May 25, 1965; revised manuscript received Sept. 9, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

On the Use of Galvanostatic Transients for the Study of Fuel Adsorption on Platinum

M. W. Breiter

Research Laboratory, General Electric Company, Schenectady, New York

Galvanostatic or potentiostatic transients have been used in recent years to study the adsorption of formic acid (1-6) and of similar species (7-13) on platinum from aqueous solutions. It is the purpose of this note to compare and evaluate results (1, 4, 5) on the coverage with formic acid as defined subsequently. These results were obtained by two different galvanostatic techniques (1, 4) in N $HClO_4$ with additions of HCOOH. The discussion of the formic acid coverage does not depend on the nature (1, 3-6) of the adsorbed species. Unpublished results of the author on the limitation of the second technique (4) are presented. The conditions for the determination of fuel adsorption from the decrease of hydrogen adsorption are specified for potentials in the hydrogen region.

Anodic charging curves exhibit (1,3) a plateau between about 1.0 and 1.2v in formic acid solutions. The plateau is attributed to the oxidation of adsorbed formic acid. It was found difficult (1) to determine the length of the plateau accurately because of its gradual transition to the subsequent electrochemical process, the formation of the oxygen layer on platinum. Therefore the difference between the anodic charges Q and $Q_{o,an}$, which are required to reach the same potential at the beginning of the O_2 evolution in the presence and absence of formic acid, was suggested (1) as an estimate of the adsorbed amount Q_F of formic acid

$$Q_F = Q - Q_{o,an} \qquad [1]$$

An equivalent procedure was used for potentiostatic transients in other systems (8, 9). It is assumed with Eq. [1] that (*a*) the extent of the formation of the oxygen layer during the fast anodic transient is the same in the presence as in the absence of adsorbable species, (*b*) the double layer charging is the same in each case, (*c*) all the adsorbed species are oxidized, and (*d*) the contribution from species, diffusing to the electrode during the transient, is negligible. The validity of the assumptions (*b*) and (*d*) was demonstrated (1, 3, 4, 8, 9).

The technique was criticized (3, 4) because of the assumptions (*a*) and (c) although experimental findings suggest that they hold approximately. The shape of potential-time curves (U-t curves) or current-time curves (I-t curves) is practically independent of the bulk concentration of the fuel up to 1M in the potential region of O_2 evolution. Oxygen evolution starts on platinum during fast anodic transients after about a monolayer Pt-O has been formed. Another technique which is independent of the assumptions (*a*) and (*c*) was employed (4). The anodic current pulse which is applied during the time τ_a is followed by a cathodic pulse. The charge Q is obtained from the anodic pulse while the charges $Q_{o,cath}$ and Q_H are determined from the cathodic one. Here Q_H designates the charge equivalent of the hydrogen coverage under the given conditions. The charge equivalent of the adsorbed fuel is taken (4) as the difference between Q and $Q_{o,cath}$.

The coverage θ_F is calculated from Q_F and ${}_sQ_F$ where ${}_sQ_F$ represents the saturation value corresponding to the maximum coverage with adsorbed species.

$$\theta_F = Q_F/{}_sQ_F \qquad [2]$$

The hydrogen coverage θ_H

$$\theta_H = Q_H/{}_sQ_H \qquad [3]$$

which coexists in the presence of adsorbed fuel serves as a measure of the part of the surface on which fuel adsorption does not occur.

Comparable results on formic acid adsorption are shown in Fig. 1. The hydrogen coverage is plotted *vs.* the formic acid coverage. Curve a represents the straight line through the data taken from Fig. 5 of ref. (4). The linear extrapolations on both sides are indicated by dashed lines. The ${}_sQ_F$ value of 0.356 mcoul/cm^2 was used in the computation of θ_F. Curve b was constructed from the data in Fig. 5 of ref. (1). These data were obtained by separate anodic and cathodic charging curves at a given formic acid coverage. In general the agreement between the two sets of results may be called fair, taking the reproducibility of about 5% for each of the measurements into account.

Curve b which lies systematically below curve a for $\theta_F \leq 0.85$ consists of a linear portion for $0 < \theta_F < 0.5$

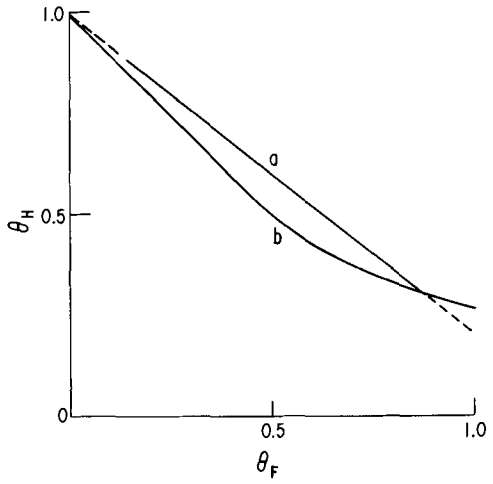

Fig. 1. Hydrogen coverage θ_H as a function of formic acid coverage θ_F on platinum: curve a, ref. (4); curve b, ref. (1).

and a curved portion for $0.5 \leq \theta_F < 1$. It was claimed (4) that a curvature was not found in the case of curve a. However, the experimental points in Fig. 5, and especially in Fig. 6 of ref. (4), indicate the beginning of a curved portion at $\theta_H \approx 0.8$. This suggests that the extrapolated ${}_sQ_F$ values in ref. (4) are too small. Indeed the linear extrapolation of the straight line in Fig. 6 where the curvature is clearly pronounced leads (4) to a ${}_sQ_F$ value of 0.327 mcoul/cm^2 instead of 0.356 mcoul/cm^2.

Larger ${}_sQ_F$ values would lead to a better agreement between the curves a and b of Fig. 1. Thus it is suggested that the two galvanostatic techniques lead to the same results in the case of formic acid adsorption on platinum.

An attempt had been made in 1961 by the author to determine the methanol adsorption on smooth platinum from aqueous solutions by the second technique. However, the technique was abandoned because $Q_{o,an}$ and $Q_{o,cath}$ were not the same in the absence of methanol. The ratio $Q_{o,an}/Q_{o,cath}$ in Table I represents an average of five measurements for each column. The results in Table I demonstrate that $Q_{o,cath}$ is by about 18% smaller than $Q_{o,an}$. A larger effect of this type had been observed (14, 15) previously at smaller values of I_{an} and I_{cath} than here. Although the interpretations (14-16) of the effect are divergent it constitutes a limitation of the second technique. By subtracting $Q_{o,cath}$ from Q an error of unknown magnitude is introduced if $Q_{o,cath}$ and Q are comparable. The error is negligible as in the case (4) of formic acid adsorption if $Q_{o,cath} << Q$.

Table I. Ratio $Q_{o,cath}/Q_{o,an}$ under different conditions in N $HClO_4$

I_{an}, ma/cm^2	160	160	160	140	120
I_{cath}, ma/cm^2	20	60	100	60	60
$Q_{o,cath}/Q_{o,an}$	0.79	0.82	0.84	0.84	0.82

It was suggested (13) to determine the methanol adsorption on platinum solely from the measurements of the hydrogen coverage by cathodic transients. This procedure leads to θ_F values which are too small in the potential region of hydrogen adsorption. The hydrogen coverage which exists at a certain potential in the hydrogen region is not measured by the cathodic transient starting at that potential. The deviations will be the larger the smaller θ_F is. Both an anodic and a cathodic charging curve are required for the determination of fuel adsorption at potentials in the hydrogen region. The discrepancies between the methanol coverage of ref. (8) and (13) in the hydrogen region result from a disregard of the above condition in ref. (13).

Oxidation of Hydrogen on Nickel Electrodes in Sodium Hydroxide Solution

R. N. O'Brien[1] and K. V. N. Rao

Chemistry Department, University of Alberta, Edmonton, Alberta, Canada

The mechanism of the electrochemical oxidation of hydrogen on nickel in alkaline solutions, a reaction of possible fuel cell use, has not been established yet. Several authors observed a limiting anodic current in this system, but different explanations have been offered for the occurrence of the limiting current. Thus Lukowzew, Lewina, and Frumkin (1) suggested that the limiting current is due to the concentration polarization of the hydrogen dissolved in solution and also due to the oxidation of the nickel anode beginning when hydrogen becomes deficient on the surface as a result of concentration polarization. They concluded this on the basis of the observation of the coincidence of the polarization curves obtained on the initial electrodes and on the electrodes subjected to repeated, successive oxidation and reduction, assuming that oxidation-reduction cycling increased the true area of the electrode. However, Weininger and

[1] Visiting Scholar, College of Chemistry, University of California, Berkeley, California.

Breiter (2) reported recently that successive anodic-cathodic sweeps did not increase the surface area of nickel electrodes in KOH by their experimental procedure. Makrides (3), on the other hand, obtained different polarization curves for electrodes of different pretreatment and attributed the limiting current on "initial" electrodes to diffusion control and to activation control of the step $H_2 = H_{ads} + H_{ads}$ on electrodes subjected to anodic-cathodic cycling. However, according to Kandler, Roemer, and Häusler (4), the limiting current obtained potentiostatically on porous electrodes, is due to diffusion control of molecular hydrogen in the solution. Weininger and Breiter (2) concluded that the anodic limiting current cannot be attributed to the Tafel step $H_2 = H_{ads} + H_{ads}$, based on the observation that practically the same current-potential curves resulted for solutions stirred with hydrogen or with argon. Instead, they suggested from the observation of a peak at about —100 mv overvoltage in the differential capacity-potential curve that anodic formation of adsorbed hydroxide due to the reaction $Ni + OH^- = NiOH + e$ might be taking place between —100 and +100 mv overvoltage. It is the purpose of the present study to investigate the cause of the anodic limiting current, which elucidates the mechanism of the electrochemical oxidation of hydrogen.

Experimental

Spectrographically pure nickel rod supplied by Johnson, Matthey, and Company was used for electrodes. A small piece of this rod was tapped, threaded, and attached to a steel rod which served as the electrical lead. The nickel end of this rod was forced into a hole in a small piece of Teflon rod. A thick walled glass tube fitted over the Teflon isolated the steel from the electrolyte. With the aid of a Teflon ring, brass cap, and a nut over the glass tube the electrode was made leakproof (5). A 19/38 ground glass joint was attached to the glass tube to insert the electrode into the cell. The electrode was machined flat so as to expose only the cross section of 0.19 cm^2 area of nickel to the solution. Anodic and cathodic charging curves were obtained with such electrodes. For steady state polarization measurements cylindrical electrodes of large area were used. These electrodes were also constructed in the same manner as described above except that the cylindrical nickel rod was covered with Teflon both at the top and the bottom exposing the middle portion (4.9 cm^2) to the solution.

The electrolytic cell was made of Pyrex glass and consisted of three compartments. Hydrogen or Hg/HgO electrodes placed in one side compartment were used as reference electrodes. Provision was made for bubbling hydrogen or helium in the reference and working electrode compartments. Bright platinum was used as a counter electrode in the other side compartment which was separated from the central compartment by a sintered disk. During the anodic potential-current measurements a cylindrical platinum gauze surrounding the working electrode was used as a counter electrode. Measurements were made in NaOH solutions prepared from Fisher certified electrolytic pellets. Hydrogen purified by passing it through a Serfass hydrogen purifier was bubbled through the solution for at least 3 hr before the start of the experiment. Grade A helium was bubbled through during the pre-electrolysis period of 15-20 hr. The electrodes were abraded with 4/0 emery paper and cleaned with chromic sulfuric acid solution followed by washing with conductivity water. They were made anodic for 5 min at 0.1 ma/cm^2 and then cathodic for at least 10 min at 1 ma/cm^2 in the working cell prior to measurements. Pretreatment of the electrodes at 0.2 ma/cm^2 anodic and 2.0 ma/cm^2 cathodic for 5 min did not produce any difference in results.

Steady state polarization measurements were made using a fast rise Wenking potentiostat. Currents were calculated from the iR drop measured across General Radio Standard resistances with the Keithley Model 660 Differential voltmeter. Charging curves were obtained by employing this potentiostat and a Western Electric 275 B relay. The required potential between the working electrode and the reference electrode was impressed by the potentiostat for 5 min and then the potentiostatic circuit was broken while applying the galvanostatic circuit simultaneously by the relay. The resulting potential-time curve was registered on the Tektronix Type 535 A oscilloscope. A 90v battery was used as a power source for the galvanostatic circuit. All the charging curves were obtained in 1.0*N* NaOH solution at 35° ± 1°C and the data reported refer to apparent surface area.

Results and Discussion

Polarization curves obtained potentiostatically at 35°C in 0.1*N*, 0.5*N*, and 1.0*N* sodium hydroxide solutions stirred vigorously, are shown in Fig. 1. All the potentials reported here refer to the reversible hydrogen electrode in the same solution unless otherwise mentioned. Steady currents were obtained in less than a minute in cathodic measurements (not reported here), whereas time variation of the current was observed in anodic measurements. The current readings taken at the end of 10 min at each potential are reported here. Figure 1 reveals that polarization is higher the smaller the concentration of sodium hydroxide which is likely for the over-all reaction

$$H_2 + 2OH^- = 2H_2O + 2e$$

It can also be seen from Fig. 1 that the current increases first with potential, reaches a limiting or peak value, and then decreases with further increase of potential. This clearly indicates that the oxidation of hydrogen reaction is not limited by either activation control of the step $H_2 = H_{ads} + H_{ads}$ or by diffusion control of hydrogen dissolved in solution because the current is not expected to decrease but level out with increase of potential in both these cases. The anodic limiting current of 14 $\mu a/cm^2$ in 0.1*N* NaOH obtained galvanostatically by Makrides (3) corresponds with the peak current obtained here potentiostatically in 0.1*N* NaOH. If the galvanostatic limiting current can be identified with the potentiostatic peak current, then the peak current, contrary to the results obtained here, should increase with decrease in NaOH concentration according to diffusion as well as activation control mechanisms, because the concentration of dis-

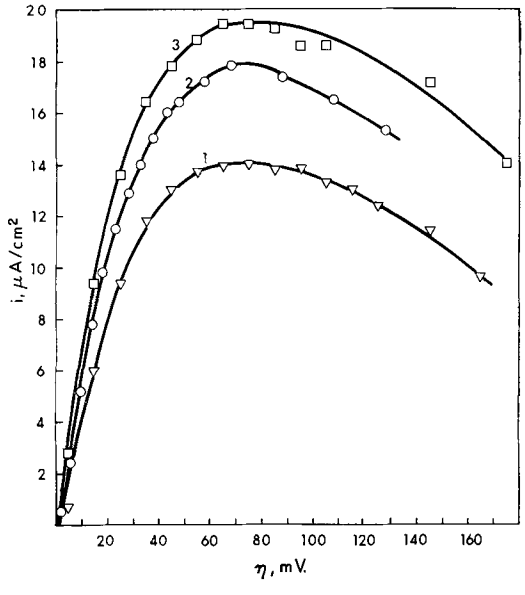

Fig. 1. Anodic polarization curves of the oxidation of hydrogen on nickel in sodium hydroxide solutions: 1, 0.1*N* NaOH; 2, 0.5*N* NaOH; 3, 1.0*N* NaOH.

solved hydrogen increases with decrease in NaOH concentration. As the decrease in current with potential beyond a certain critical value is a phenomenon typical of metal passivity, and since this decrease in current also begins about 35 mv cathodic to the equilibrium potential for the formation of oxide according to the reaction

$$Ni + 2H_2O = Ni(OH)_2 + 2H^+ + 2e$$

at all concentrations of sodium hydroxide investigated, it may be inferred that the decrease in current here is due to oxide film formation on the nickel electrode surface. Frumkin and Aikazyan (6) observed a decrease in current with potential in the studies of oxidation of hydrogen on platinum and suggested that the decrease in hydrogen ionization current is connected with passivation of platinum by adsorbed anions with increasing anodic polarization. Franke, Knorr, and Breiter (7) also observed in the anodic oxidation of hydrogen on platinum that the current decreases as oxidation of the surface occurs.

In order to see whether oxide film forms on the nickel surface, and if so whether the film formation begins from the potential where the anodic current begins to decrease or from lower positive potentials, the surface coverage at different potentials was determined by the method of cathodic charging curves. The galvanostatic reduction curves obtained at 10 ma/cm^2 in 1.0*N* NaOH after potentiostatically oxidizing the electrode at various potentials are shown in Fig. 2 and 3. It can be seen from Fig. 2 and 3 that kinks are present in all the reduction curves. Kinks or

overshoots have been frequently noted in the literature, but so far no single view on their nature exists (8). Kinks were not pronounced in the reduction curves obtained at 1 ma/cm^2 and disappeared completely from curves obtained at still lower current densities. Figure 4 is the reduction curve obtained at a current density of 48 μa/cm^2, showing the absence of kink. The appearance of overshoots in the chronopotentiograms makes it difficult to estimate the transition times accurately. Tangents were drawn as shown in Fig. 2, 6A and transition times λ, were measured from origin to the points of intersection of the dashed lines. The cathodic charge ($i\lambda$) which corresponds to surface coverage, was deduced from Fig. 2 and 3 and is shown in Fig. 5 as a function of over-potential. The charge involved as plotted in Fig. 5 may be due to the reduction of the oxide and/or hydroxide formed during potentiostatic oxidation and due to the deposition of hydrogen atoms. As it is not easy to make a distinction between whether oxide or hydroxide is formed on the surface it is assumed here that oxide is formed. Since the shape of the reduction curves, as can be seen from Fig. 2 and 3, starting from various potentials except from +525 mv (graph 5, Fig. 3) is similar and since the charge associated with the reduction step increases with increasing anodic potential, it is likely that most of the charge is involved in the reduction of oxide but not deposition of hydrogen atoms. Hydrogen evolution might be occurring beyond the peak in the chronopotentiograms. The different shape of the chronopotentiogram starting from +525 mv may be attributed to the modification of the surface when potentiostatically oxidized at this potential, the modification being such that it is reduced mostly at the hydrogen evolution potential.

Weininger and Breiter (9) found in the oxidation of nickel in 0.2*N* KOH from potential-current curves that a potential of about +320 mv *vs.* the hydrogen elec-

trode in the same solution is reached on coverage equivalent to about one monolayer of hydroxide. Approximately 600 μc is taken as equivalent to one monolayer. The charge (about 670 μc) at +300 mv obtained here from potential-time curves is in fair agreement with their value. Figure 5 reveals that about 1/6 of a monolayer of surface is covered with oxide even at +25 mv (whereas peak current is at +70 mv) and this increases with increasing potential, reaching a limiting value at about 200 mv. This suggests that the rate of oxidation of hydrogen decreases with increasing potential because of the decrease in area available uncovered with oxide where the rate of electrochemical oxidation of hydrogen is higher, rather than the view that oxidation of the nickel anode begins when hydrogen becomes deficient as a result of concentration polarization.

Although Weininger and Breiter (2), as mentioned earlier, reported that practically the same current-potential curves were obtained for solutions stirred with either hydrogen or argon, it was found that the steady state polarization curves were different for solutions stirred with hydrogen or helium in the region reported here. The currents taken at the end of 10 min were, for instance, 18.2 and 0.5 μa/cm^2 at an overpotential of +85 mv in 1.0N NaOH solutions stirred with hydrogen and helium, respectively. The difference in the results may be attributed to the difference in the techniques employed. Weininger and Breiter (2) obtained the current-potential curves by impressing potentiostatically a linearly increasing potential at a sweep rate of 5 mv/sec. Sato and Okamato (10) reported a difference in the polarization curves of the oxidation of nickel in alkaline solutions at a pH of 11.7, obtained by the transient state method with a 0.33 mv/sec rate of change of potential, and the stationary state method; the currents being about 10.0 and 0.08 μa/cm^2, respectively at —500 mv potential with reference to the standard hydrogen electrode. Hence it may be concluded that polarization is lower in solutions stirred with hydrogen than in solutions stirred with helium due to participation of dissolved hydrogen in the electrode reaction.

Detection and Removal of Traces of Water from Alkali Halides

Irving Warshawsky

Lewis Research Center, National Aeronautics and Space Administration, Cleveland, Ohio

It is well known that analytical reagent grade alkali halides are contaminated with traces of water. The presence of this impurity is a source of difficulty in the following studies:

1. In the preparation of "F" centers in alkali halides, the presence of an impurity such as water or hydroxide may lead to colloid formation (1).
2. When an alkali halide is added to an alkali metal ammonia solution, the water impurity is a source of decomposition of the blue solution (2).
3. In the preparation of solutions of alkali metals in molten salts, the presence of water in the melt not only is a source of decomposition (3), but also leads to corrosion of the container (4).

The purpose of this note is:

1. To present a quantitative method for the detection of traces of water in alkali halides; and
2. To indicate the effectiveness of two methods of removing traces of water from analytical reagent grade alkali halides: (*a*) pumping on the salt at room temperature, and (b) washing with dry liquid ammonia.

Quantitative Method for Detection of Traces of Water

A method for the quantitative detection of traces of water in an alkali halide consists of measuring the amount of hydrogen evolution from the reaction

$$H_2O_{(salt)} + Na_{(NH_3)} \xrightarrow[-78°C]{} NaOH_{(ppt)} + \tfrac{1}{2} H_{2(g)}$$

There is an additional source of hydrogen evolution: the reaction of the blue solution with adsorbed water at the glass-liquid interface (5). At —78°C the homogeneous reaction of sodium with ammonia is negligible.

Experimental

Pumping on the salt at room temperature to remove water impurity.—A small weighed quantity of analytical reagent grade alkali halide was placed in an open vial. The vial was placed into an impule (ID 10 mm) along with a small quantity of sodium. The ampule was then glass-blown to the vacuum line. (The glass-blowing was carried out using a drying tube to minimize the introduction of a new source of moisture.) The salt was dried by pumping on it at room temperature and at pressures less than 10^{-6} mm Hg. For purposes of comparison, one sample of each salt was pumped on for about 20 hr and a second sample of the same salt for about 125 hr. During the final 2 hr of pumping, a liquid nitrogen bath was placed around a trap between the calibrated McLeod gauge and the ampule containing the salt in order to minimize mercury contamination. The latter is believed to catalyze the decomposition of the blue solution (6).

After the drying operation was completed, 3.20 cc of degassed liquid ammonia (previously dried over sodium) were distilled into the ampule which contained the reagent grade salt and sodium at —78°C. This resulted in the formation of a dark blue solution containing an excess of salt. After the saturated solution had been allowed to sit at —78°C for 6 hr, the quantity of hydrogen evolved was determined with a calibrated McLeod gauge, as described previously (5, 7). In one "run" with reagent grade lithium bro-

Table I. Summary of the quantitative data for detection of water in analytical reagent grade alkali halides

Salt	Grams of salt	Hours pumped	*Moles of H_2 evolved $\times 10^7$	*Per cent water by weight

KI	0.100	142	2.9	0.013

* Corrected for the heterogeneous reaction between the blue solution and adsorbed water.

mide (which had been pumped on for 18 hr), the original dark blue solution faded completely in 5 hr. Blank determinations in the absence of the salt were made in order to correct for the quantity of hydrogen evolved from the heterogeneous reaction during the 2 hr. Results are summarized in Table I.

Washing with dry liquid ammonia to remove water impurity.—An ampule containing 0.10g reagent grade sodium iodide with a sidearm holding sodium was glass-blown to the vacuum line. The system was pumped on for 24 hr at room temperature and at a pressure less than 10^{-6} mm Hg. Liquid ammonia, dried over sodium, was distilled into the ampule containing the salt; a saturated solution formed, which was allowed to sit at —78°C for 24 hr. The solvent was then distilled back into a reservoir containing sodium, and the sodium iodide was pumped on for another 24 hr to remove the residual ammonia. This purification procedure was repeated two more times.

In order to test for the presence of water, $\sim 10^{-6}$ moles of sodium was transferred into a saturated solution of the salt in liquid ammonia at —78°C, as previously described (5). This did not result in any additional hydrogen evolution within experimental error (7). Similar results were obtained for the ammonia treatment of lithium chloride (reagent grade) and potassium chloride (reagent grade).

Conclusion

It has been observed quantitatively that extended pumping on analytical reagent grade salts (as described) is not sufficient to remove the last traces of water. However, it is noted that extending the time of pumping on the lithium salts from about 18 hr to about 125 hr does lead to a considerable decrease in the per cent of water impurity present, while for the potassium salts tested, extending the time of pumping (as above) has very little effect on the removal of the water impurity. On the other hand, treatment with liquid ammonia has been shown to be a more effective method for removing traces of water.

Brief Communications

The $Zn_xCd_{(1-x)}SnAs_2$ Semiconducting Alloy System

B. R. Pamplin, J. S. Shah, and R. A. L. Sullivan

Department of Physics, Bristol College of Science and Technology, Bristol, England

Recent work on semiconducting alloys has shown that a large number of tetrahedrally bonded compounds are isomorphous in pairs. It is found that if two such compounds share a common atom they usually exhibit complete solid solution (1). Ternary compounds $ZnSnAs_2$ and $CdSnAs_2$ which have chalcopyrite structure El 1 (space group $D_{2d}^{12} - I\bar{4}2d$) have been shown to form complete solid solution with InAs (2, 3). The work reported in this note was undertaken to see if the two compounds $ZnSnAs_2$ and $CdSnAs_2$ are also capable of complete solid solution. The compositions chosen for study are those predicted by simple structural arguments to be most likely to show complete or partial ordering (4).

The different compositions used were prepared by reacting the elements of semiconductor grade purity *in vacuo* in quartz ampoules and holding in the molten state for several hours. The ingot so produced was then powdered, annealed at temperatures above 600°C for several weeks, and finally quenched in water. X-ray powder photographs were taken using a Philips 11.46 cm diameter camera and Ni filtered $CuK\alpha$ radiation. The films were interpreted by reference to the end components as being of chalcopyrite structure.

The lattice parameters were determined by the method of least squares. A program was written for the Elliot 803 computer which calculated the lattice parameters with their standard errors. The procedure of Mueller *et al.* (5) was followed in that various correction terms were introduced into the calculation, one at a time. A solution was also calculated using no correction term. However, it was found that the lattice parameters obtained did not differ significantly whichever correction term was used. For consistency Taylor and Sinclair's (6) correction term $\sin^2 2\theta(1/\sin\theta + 1/\theta)$ was used for all results quoted. Since only reflections with a Bragg angle greater than 60° were used weighting each reflection did not significantly affect the results either. Results quoted here were obtained using unweighted reflections.

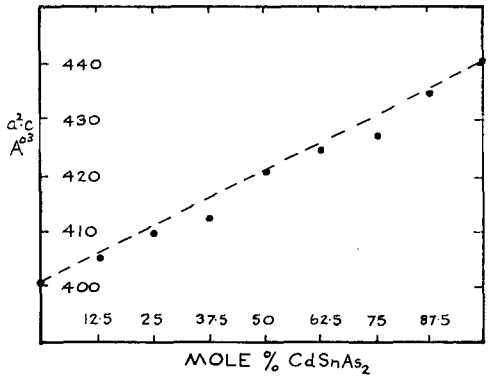

Fig. 1. Variation of unit cell volume (a^2c) *vs.* composition in the system $Zn_xCd_{(1-x)}SnAs_2$.

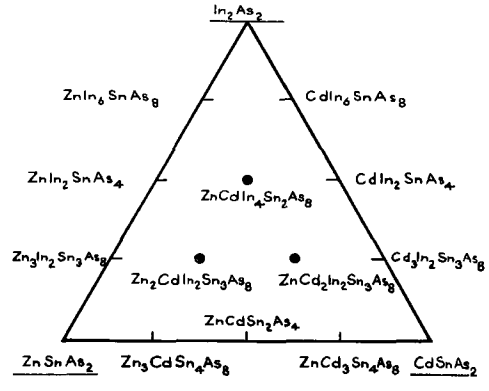

Fig. 2. Pseudoternary system $(Zn_xCd_{(1-x)})_y\ In_{1-2y}Sn_yAs$. Formulas along coordinates and in the diagram indicate compositions rather than ordered phases or compounds.

In the $Zn_xCd_{(1-x)}SnAs_2$ system all the compositions with $x = n/8$ were found to be chalcopyrite. The high angle alpha doublets were clearly resolved in the film of every annealed sample. No convincing evidence for superlattice lines due to further ordering was found. A few weak extra lines found on some photographs were identified as due to As which presumably deposited from the vapor phase on quenching. The "a" and "c" parameters (with their standard errors) of the various alloys in this system are given in Table I. It is worth noting that for all alloys the standard errors in the parameters are larger since the high angle lines in the powder photographs of these were not as sharp as those for pure $CdSnAs_2$ and $ZnSnAs_2$. Figure 1 shows the variation of the unit cell volume (a^2c) as a function of composition. Such departures from Vegard's law as are seen in Fig. 1 are not uncommon in semiconducting alloy systems (1). They are due presumably to the fact that the alloys under study may not quite have achieved their true equilibrium state.

The 50% alloy $ZnCdSn_2As_4$ was found to possess also a disordered sphalerite structure when quenched after anneal above 630°C. It thus seems likely that all zinc rich alloys in the system undergo an order-disorder transition as does $ZnSnAs_2$ itself (7, 8).

It has been shown (9) that the three compositions $ZnCdIn_4Sn_2As_8$, $ZnCd_2In_2Sn_3As_8$, and $Zn_2CdIn_2Sn_3As_8$ in the pseudoternary system $(Zn_xCd_{(1-x)})_y\ In_{1-2y}Sn_yAs$ (Fig. 2) can be obtained single phase with disordered sphalerite structure. Since in the pseudobinary system In_2As_2, $CdSnAs_2$ chalcopyrite structure is found only for the compositions in the vicinity of $CdSnAs_2$ (3), it would be fair to predict that in the phase triangle of the pseudoternary system (Fig. 2) compositions in the vicinity of the base line of the pseudoternary system ($ZnSnAs_2$ — $CdSnAs_2$ line) may possess chalcopyrite structure. All other compositions are likely to have sphalerite structure.

Preferential Etching Techniques for Removing Dendrites from Silicon Dendritic Web Material

David W. Ing

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania

and Thomas Hunt

Semiconductor Division, Westinghouse Electric Corporation, Youngwood, Pennsylvania

A new, nonmechanical technique for removing dendrites from silicon dendritic web material is described here.

Silicon dendritic web material is produced by growing a silicon sheet between two dendrites. The sheet faces are perpendicular to the [111] direction and possess few dislocations or other surface imperfections. In many applications it is preferable to use only the web portion of the webbed dendrite material. The standard mechanical methods for removing the dendrites often produce undesirable effects. A technique has been developed in which the dendrites are removed by heating dendritic web in KOH or NaOH solutions. Due to the difference in crystal orientations, these solutions preferentially etch the dendrites while leaving the web material relatively unaffected. The etching solution will attack surface imperfections on the web, but this problem is eliminated by oxide masking the sheet prior to etching.

In the new procedure, an oxide film is formed over the entire surface of the webbed dendrite by steam oxidation at 1200°C. Wax is applied to the sheet surface and the oxide coating is removed from the dendrites by an HF etch. Boiling trichloroethylene is used to clean the wax from the web surface. After this preparation, the webbed dendrites are heated in a solution of sodium or potassium hydroxide (10-20% by weight). The solution reacts strongly with the dendrites but the web surface is completely protected by the oxide coating. The web is removed from the solution as soon as the dendrites are completely etched away.

If surface flatness is not a prime requirement, the oxide step may be omitted. The etching solution will react only slightly with the crystallographically perfect sections of the sheet, while it will vigorously etch the dendrites and any surface imperfections on the web. This will result in shallow dimples in the web surface at imperfection sites, but the dendrites will be removed before a significant amount of silicon is etched from the sheet. The resultant web surface is not as flat as that obtained by including the oxide film step but still may be suitable for certain applications.

Thin Films Grown on Silicon Surfaces by Excess Nitric Acid Process

William B. Glendinning, Sidney Marshall, and Albert Mark

United States Army Electronics Command, Fort Monmouth, New Jersey

One often observes that following the use of routine laboratory procedures for etching or staining polished silicon wafers the samples are covered with a colored residue or stain film. Several workers have studied this effect and have reported the growth of such films in etchants rich in HF (1-5). Archer concludes that the films are a silicon hydride or another silicon rich form.

This note describes experimental work in which stain films on silicon were produced by both liquid and vapor phase reaction of etchants and silicon wherein the nitric acid concentration of the etchant was exceedingly high.

In the method used in our work a 0.050 in. bead of nitric acid is formed between the tip of a capillary tube and the silicon surface. A polyethylene nozzle directs a mixed stream of HF vapors and oxygen flowing at approximately 7 cc/min at the juncture of the HNO_3 drop and the silicon surface. The silicon substrate is heated to a temperature of 35°-40°C as measured by a Cu-Const thermocouple placed on the upper surface of the sample. When the capillary tube, which can be translated by a micrometer stage, is moved across the surface of a 0.01 ohm-cm p-type sample at a speed of 7 mils/sec a series of ringlike stain film growths occur (Fig. 1). A distilled water rinse was used to quench the etching and film growth reactions.

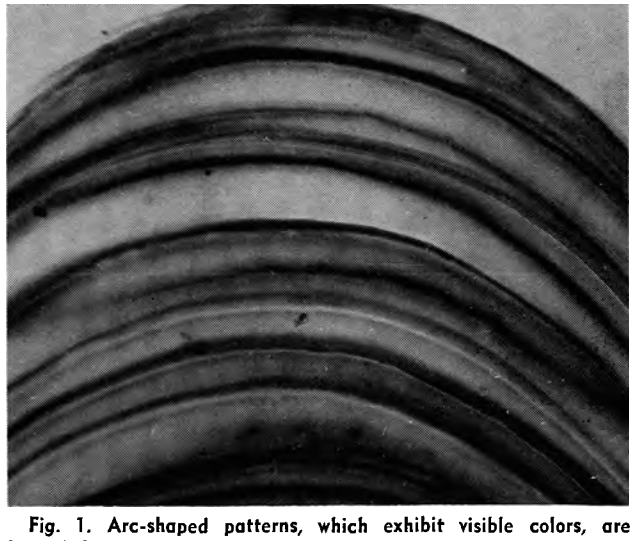

Fig. 1. Arc-shaped patterns, which exhibit visible colors, are formed from liquid HNO_3-vapor HF process.

We observed that the stain films were not noticeably attacked by treatment in a 47% HF solution, but that they could be removed by immersion in a 10% solution of NaOH for 3 min and were also dissolved by concentrated HNO_3.

The surface topology of the silicon samples in the vicinity of the film growth was examined by removing a part of the growth with the 10% NaOH solution, overcoating the sample with aluminum, and studying the fringe pattern obtained with a multiple beam interference technique. Film thickness obtained in this manner ranged from 900 to 1400Å. The surface in the region where the stain film was removed was corrugated and was depressed below the original surface of the silicon sample.

In a variation of the experimental procedure an angle-lapped silicon sample having a nine layer epitaxial structure with two resistivity levels was employed. The HNO_3 bead was formed as before, but this time it remained stationary in the angle-lapped region while the HF vapor stream flowed around it. Film growth was observed here also, but in this case the growth was in the lateral direction outward from the droplet. The extent and rate of growth under these conditions varied with the layer resistivity level and conductivity type. Film growth was most rapid on the 10 ohm-cm n-type, 0.05 ohm-cm p-type, and 10 ohm-cm p-type surfaces. The surface as well as two other 0.05 ohm-cm n-type layers reacted very little during the growth reaction.

Film growths obtained both with the moving HNO_3 bead and with the stationary bead on the angle-lapped surface could be readily scratched, and when this was done small irregularly shaped pieces of the film broke away from the silicon substrate surface.

Further correlation between stain film growth and silicon conductivity type and impurity concentration is being sought. In addition, the potential use of the film growth reaction in a silicon etching process is being evaluated.

The Crystal Structure and Polarity of Beryllium Oxide

(D. K. Smith, H. W. Newkirk, and J. S. Kahn, pp. 78-87, Vol. 111, No. 1)

Walter C. Allen[1]: In their paper, the linear and angular dimensions of the unit cell of beryllium oxide were given as:

$a_o = 2.6979 \pm 0.0002$Å
$c_o = 4.3772 \pm 0.0002$Å
$c/a = 1.622$
Be-O = 1.659 ± 0.003Å (parallel to C-axis)
Be-O′ = 1.645 ± 0.003Å (to 3 oxygens, O′ in basal plane)
O-Be-O′ = 108° 47′
O′-Be-O′ = 110° 51′

The structure is essentially close-packed hexagonal, but c/a is slightly less than the ratio 1.633 for the ideal HCP structure. Interatomic distances are therefore slightly distorted, and the angles deviate from the true tetrahedral angle of 109° 28′. Each beryllium ion is tetrahedrally coordinated with four oxygens, nesting in the hollow between a triangle of oxygens (O′) in the basal plane with the fourth oxygen straight overhead in a direction parallel to the C-axis.

Preparatory to constructing a model of the beryllia structure, these angles were checked by trigonometry. The angle O-Be-O′ is correct at 108° 47′, but the other angle O′-Be-O′ is incorrect as reported.

From the Law of Cosines,

$$\text{Cos A} = \frac{b^2 + c^2 - a^2}{2bc}$$

$$= \frac{(1.645)^2 + (1.645)^2 - (2.6979)^2}{2(1.645)\ (1.645)}$$

$$= -0.3449$$

$$\text{A} = 110° 10½′$$

The other pair of equal angles in this isosceles triangle was also checked:

$$\text{Cos B} = \frac{(1.645)^2 + (2.6979)^2 - (1.645)^2}{2(1.645)\ (2.6979)}$$

$$= \frac{2.6979}{3.290} = 0.8200$$

$$\text{B} = 34° 55′$$

$$\text{A} = 180\text{-}2\text{B} = 110° 10′$$

The literature value of 110° 51′ can probably be ascribed to an error in reading the trigonometric tables. This revised value of 110° 10′ is herewith presented for the record.

Figure 1 represents a stereoscopic view of the structure model, as made by Mr. Hervey Greenwood and the author. The eyes can be trained to see a three-dimensional image, without a special viewer, by parallel lines of sight instead of focussing convergently.

Correlation of Limiting Currents; Electrodeposition of Copper in Microelectrolytic Cells

R. N. O'Brien and L. M. Mukherjee[2] (pp. 1358-1362, Vol. 111, No. 12)

Ursula Böhm and **N. Ibl**[3]: The main conclusion of the paper by O'Brien and Mukherjee is that natural convection is still effective in microcells of the type used by one of the authors in his optical experiments. This is in general agreement with the results of a recent investigation of natural convection in narrow spaces open at their upper and lower ends and bounded either by a vertical electrode and a diaphragm or by two vertical electrodes.[4] The latter case corresponds to that studied by O'Brien and Mukherjee. It was found that, depending on the distance d between the electrodes, three regions can be distinguished:

(*A*) For values of d smaller than about 0.5 mm the limiting current reaches a well-defined steady state after some time which varies with d. The steady-state current decreases with increasing d, yielding on a log-log-plot a straight line with a slope of −0.85. The theoretical value of this slope would be −1 for the case that mass transfer from one electrode to the other takes place only by linear steady-state diffusion and migration. The somewhat smaller experimental value of the slope is due to some extent to the nonlinear diffusion toward the ends of the electrodes, and also probably to the fact that there is still some convection. However, the latter is very weak, and, in the region $d < 0.5$ mm, mass transfer occurs almost exclusively by diffusion and migration. The virtual absence of convection is confirmed by the fact that the Nusselt number is here independent of the Grashof number (when both numbers are based on the electrode height).

(*B*) With d lying approximately between 1 and 6 mm [5] the limiting current fluctuates with time, but is almost independent of d. Obviously, in this region, natural convection is already effective and prevents a further decrease of the limiting current with increasing d. The hydrodynamic boundary layers formed at the two electrodes probably interact in a complicated manner, thus causing the unstable character of the mass transfer.

(*C*) For d larger than about 6 mm the usual steady-state limiting current of natural convection was observed.

The thickness of zone (*A*) (virtual absence of convection) was found to increase somewhat with increasing electrode height and decreasing bulk concentration, *i.e.*, with decreasing density differences in

[4] Unpublished experiments of U. Böhm, Facultad de Ciencias Exactas y Naturales, Buenos Aires, Argentina; see also *Electrochim. Acta*, in press.

[5] For $0.5 < d < 1$ mm the limiting currents are substantially larger than for diffusion alone, but no instability was observed.

the solution. The electrode heights were larger and the density differences smaller than in the investigation of O'Brien and Mukherjee because they worked with $CuSO_4$ solutions whereas in the above-mentioned experiments a redox system was used (reduction of ferricyanide to ferrocyanide at the cathode, oxidation of ferrocyanide at the anode). However, the influence of the height and of the density differences is small. The study of O'Brien and Mukherjee and that reported here are therefore comparable in spite of the differences of electrode heights and of density variations and the two sets of experiments complement each other. Both show that natural convection is quite tenacious when the available space narrows and that it decays substantially only when the distance between the electrodes approaches the thickness of the diffusion layer.

R. N. O'Brien: The comments of Böhm and Ibl and the information given are in good agreement with experiments we have subsequently performed. Their remarks are given systematic consideration below.

(*A*) Confirming Böhm and Ibl's view that convection is present when d is very small we have recently published[6] some data in which three orientations of electrodes have been used, cathode-over-anode, deep vertical and shallow vertical (in all cases including the experiments referred to by Böhm and Ibl, the cell was full, bounded by electrode and glass flats on all sides, allowing no gas-electrolyte interface), and it appears that at small separation the various cell geometries approach each other in electrolytic transport properties suggesting that convection, although tenacious, becomes insignificant finally. An interferogram showing the interelectrode concentration contour at small d has been published.[7] We have also postulated the existence of field effects. In another experiment, the height of the cell and the vertical electrodes were reduced to 0.2 mm.[8] It was impossible to say whether convection was present or not, but when the same cell and electrodes were oriented so that the anode was above the cathode, convection was clearly visible. The effect of laminar and turbulent convection on concentration gradients as seen on an interferogram has been published.[8, 9]

(*B*) As Böhm and Ibl suggest the interaction of convection whorls at 1 mm $< d <$ 6 mm is quite complicated and employing a technique originated in Professor Ibl's laboratory[10] the pattern of convection has been obtained by observing the movement of suspended solids. At a distance of about 0.75 mm in 0.1*N* $CuSO_4$, electrode height 2 mm, there appears to be a transition from one whorl to two whorls with over and underflow between them. The interaction between the whorls seems to be at a maximum for these conditions and geometry at about $d = 2.5$ mm where transport efficiency reaches one of at least three maxima. The more or less circular whorls leave a fairly large volume of solution at the top and bottom of each electrode which is out of the main stream of convection and unpredictable turbulence occurs here. Since this instability affects an appreciable area of the electrode surface, instability would be expected. None of the interferometric data was obtained at greater than 1.5 ma/cm^2 current density, which is far from the limiting current.

(*C*) At c.d.'s much lower than limiting and $d > 6$ mm we also observed no anomalous effects in the interferograms.

N. Ibl: In this interesting investigation it has been found that with cathodes of small height the limiting currents are up to 1.8 times larger than those predicted by the now well established correlation for natural convection at vertical electrodes (Eq. [2]). This is interpreted as being due to an increase in electrode area owing to metal deposition. There is, however, another effect of importance here. The derivation of Eq. [2] from the fundamental differential equations of convective mass transfer implies the usual boundary layer assumptions, *i.e.*, it is assumed that the dimensions of the electrode are very large as compared to the thickness of the diffusion layer and of the hydrodynamic boundary layer. In the present case, with the electrodes of a height of 0.05 mm for instance, this condition is quite far from being fulfilled, the calculated thickness of the diffusion layer being approximately 0.05 mm and that of the hydrodynamic boundary layer of the order of 1 mm. This can lead to substantial departures from Eq. [2] for several reasons, one of which can be easily visualized as follows: near the lower and upper edge the diffusion toward the cathode is no longer perpendicular to the interface and the cross section for diffusion increases with increasing electrode distance, so that the limiting current at small electrodes is larger than that predicted by Eq. [2].

The metal deposition can indeed lead to an increase of electrode area in the region of the limiting current, where very rough or powdery deposits are formed. However, this effect is strongly time dependent and also present (although perhaps to a somewhat smaller degree) with large electrodes. We have studied this phenomenon in some detail with a rotating disk electrode 1 cm in diameter.[11] The increase of electrode area in the limiting current region causes, at constant current, a strong variation of the electrode potential with time. In potentiostatic experiments it leads to an increase of the limiting current. For instance, at a potential of −600 mv (*vs.* a copper reference electrode)[12] the limiting current increased by 20% within 1 min after switching on the current. It increased further to about 4 times its original value during the following 4 min.

R. N. O'Brien and **L. M. Mukherjee**[2]: Professor Ibl's remarks are noteworthy. Indeed, we have not considered any possible explanation on the basis of spherical diffusion in the type of microelectrolytic cells used by us in testing the Tobias equation (Eq. [2]). As suggested by Professor Ibl, it is probably true that as the ratio of the electrode area to the cell wall area decreases the problem approaches one of spherical diffusion. This may completely explain our results, although we believe, from observation of the electrodes following an experiment, that "edge effects" were also important; moreover, the current was practically independent of the position (height) of the electrode along the vertical plane of the cell wall contrary to what would be expected in the case of spherical diffusion. Professor Ibl further points out that the edge effects are strongly time-dependent. We believe that the rate of increase of area of a thin electrode should not be directly proportional to the time of electrolysis, but should decrease rapidly as the electrolysis proceeds. Because of the technique used in our experiments it is unlikely that we would have been able to distinguish this time-dependence, if any, from the normal experimental error.

Extremely Intense Light Sources with Narrow-Band Emission

J. E. Rosenthal and C. F. Eyer (pp. 68-70, Vol. 112, No. 1)

H. F. Ivey[13]: This paper concerns a sodium-seeded flame subjected to a microwave field. It is stated that

in this way "an over-all operating efficiency approaching 50%" is obtained. The value of efficiency calculated in the paper is 140 lpw, but it is claimed that with improved coupling to the microwave field this should be increased to 220 lpw. For purposes of comparison, xenon short-arc lamps with efficiency of 30-40 lpw were selected.

The writer would like to make two points concerning this paper. First, since the C.I.E. visibility function for the wavelength of the sodium D lines (5893Å) has the value 0.765[14], the theoretical maximum luminous efficiency at this wavelength is (0.765) (681) = 521 lpw. The observed (calculated) value of 140 lpw therefore corresponds to an over-all efficiency of 27%, while the predicted value of 220 lpw corresponds to 42.5%. It does not appear that either of these figures "approaches 50%"; the most that can conservatively be said is that the extrapolated value exceeds 40%.

Second, it seems that the efficiencies obtained experimentally in this case should be compared not with xenon lamps but with other sodium sources. With conventional low-pressure sodium-vapor lamps efficiencies of 125-140 lpw have been obtained experimentally, while values of 150-200 lpw have been predicted for improved designs.[15] Efficiencies of 100-145 lpw have also been reported for high-pressure sodium-vapor lamps.[16] It therefore appears that the efficiencies obtained with the apparatus described in this paper do not exceed those obtained with more conventional and simpler sodium sources.

As pointed out by the authors, the intensity and the ability to modulate the type of source described in this paper at high frequencies may be an advantage over conventional sodium lamps in some applications.

J. E. Rosenthal and **C. F. Eyer:** It is obvious that a sodium seeded flame is a very rudimentary light source and that the work described in the article represents only the first stages of development. It is therefore particularly interesting that we have already obtained an efficiency of 140 lpw, which according to Dr. Ivey's references[14,15] is the best that can be obtained with a fully developed sodium lamp operating at one-tenth of our power level. This indicates that the basic principle of our operation is one of high efficiency. Self-absorption is greatly reduced as shown in Fig. 4 of the article so that operation can proceed efficiently at very much higher temperatures and sodium pressures than indicated by van de Weijer[15] for a conventional sodium lamp.

The microwave arrangement used in the original experiments was of the simplest possible type that could be used to demonstrate the existence of the enhancement effect. Replacing it with a properly designed microwave cavity immediately boosts the efficiency of the rudimentary source at least to 220 lpw, or higher with a more efficient magnetron, while still maintaining the same high power output. Using the value of the least mechanical equivalent of light from the 1962-63 edition of the Handbook of Chemistry and Physics which gives 621 lpw at the wavelength of maximum visibility, we obtain 475 lpw as the maximum theoretical luminous efficiency at the wavelength of the sodium D-lines. This gives an efficiency in excess of 46%, which for practical purposes we consider approaching 50%. However, we should like to point out that any improvement in the design of the torch, to say nothing of its eventual replacement by an electrically powered simulated flame, will boost the efficiency.

Following van de Weijer we might try to anticipate the extent of possible improvements. He considers that redesign will boost the efficiency of his lamp from 140 to possibly 200 lpw. We do not anticipate as good an improvement factor. However, the figure of 280 lpw should be a reasonable estimate for the final model. This figure not only approaches but actually exceeds 50% efficiency on the basis of any calculation one may choose. None of these improvements will cause a deterioration either in the power level of the modulability of the source.

The Active Iron Electrode, I. Iron Dissolution and Hydrogen Evolution Reactions in Acidic Sulfate Solutions

E. J. Kelly (pp. 124-131, Vol. 112, No. 2)

W. J. Lorenz[17] and **Günter Eichkorn**[17]: Kelly showed by electrochemical investigations with stationary methods the Bockris mechanism of anodic dissolution of iron to be valid. His results agree with data, previously published by Bockris *et al.*[18, 19, 20]

The rate-determining step of transfer reaction if the Bockris mechanism is

$$Fe(OH)_{ads} \rightarrow FeOH^+ + e^- \qquad [1]$$

On the other hand the rate-determining step of transfer reaction given by Heusler,[21, 22, 23] Gerischer,[24] Lorenz *et al.*[25, 26, 27] is

$$Fe(FeOH)_{ads} + OH^- \rightarrow FeOH^+ + (FeOH)_{ads} + 2e^- \qquad [2]$$

Before this transfer reaction of the Heusler mechanism occurs there happens a slow catalytic reaction for the formation of $Fe(FeOH)_{ads}$

$$Fe + Fe(OH)_{ad} \rightleftharpoons Fe(FeOH)_{ad} \qquad [3]$$

In our opinion both mechanism can be found. We explain it in the following way: If there exists a great concentration of active iron sites on the electrode surface, so the equilibrium of Eq. [3] is shifted to the right side. Therefore preferential formation of $Fe(FeOH)_{ad}$ takes place and the following step is the transfer reaction (Eq. [2]), representing the Heusler mechanism. On the other hand, if the concentration of the active places is relatively low, the formation of $Fe(FeOH)_{ads}$ is negligible and the direct transfer reaction of $(FeOH)_{ads}$ happens at once (Eq. [1] of Bockris mechanism).

The proof of this explanation we found by comparing x-ray line width methods and electrochemical anodic dissolution measurements†.

Responsible for the mechanism of anodic dissolution is the substructure, the density of subgrain boundaries, that means the density of dislocations, which act as active places on the surface.

By tempering specimens of Ommet-iron we changed the density of subgrain boundaries in a definite way. On the same material as well the kinetic data of the Heusler mechanism that of the Bockris mechanism could be found. If the density of dislocations is high

(nontempered specimens), the Heusler mechanism is valid. By reducing the number of dislocations that is the density of active places (tempered specimens), we found the kinetic data of the Bockris mechanism. The difference between both mechanism is not due to influences of atomic imperfections, external conditions, or defects of measurements.

E. J. Kelly: In the paper under discussion, it was shown that, subject to appropriate steady-state conditions, the mechanism proposed for the anodic dissolution of iron in acidic sulfate media, Eq. [41]-[45], reduces to a kinetic equivalent of the Bockris mechanism, Eq. [9]-[11]. The objections of Lorenz, Yamaoka, and Fisher[26] to the Bockris mechanism were examined and rejected, and the author is pleased to find that, rather than reiterate these objections, Lorenz and Eichkorn appear to accept the validity of the mechanism. However, they now suggest that both the Heusler mechanism, as modified by Lorenz, Yamaoka, and Fisher {Eq. [53]-[56] of ref. (1), and hereafter referred to as the HLYF mechanism}, and the Bockris mechanism are operative, with the former predominating "if there exists a high concentration of active sites." To be specific, they would add the rate-determining reaction of the Bockris mechanism, Eq. [10], to the system of reactions comprising the HLYF mechanism, while simultaneously invoking the "active site" concept. An examination of the kinetics of the resultant hybrid mechanism reveals that the total steady-state anodic current density corresponding to the iron dissolution process may be represented as a sum of two partial current densities, i_B and i_H, attributable to the Bockris and HLYF mechanisms, respectively, with

$$i_B/i_H \approx \bar{k}_{44}/s \left(\frac{k_{54}}{k_{-54}} \right) \bar{k}_{55} A_{(OH-)},$$

where s represents the concentration of active sites and the other symbols have their customary significance. Therefore, with

$$A_{Fe(FeOH)_{ads}}/A_{(FeOH)_{ads}} \approx s \left(\frac{k_{54}}{k_{-54}} \right),$$

a shift in the equilibrium of Eq. [54] to the right, or an increase in s, would indeed favor the HLYF mechanism. Thus, as an artifice, the hybrid mechanism proposed by Lorenz and Eichkorn is not without merit. However, as a necessary consequence of the nonvalidity of the component HLYF mechanism, a fact already established by a detailed examination, the hybrid must be rejected.

Although Lorenz and Eichkorn refer to ref. (12) for the "proof of this explanation," only the first eleven references were included in the copy of their discussion sent to the author. In the absence of this reference, one is constrained from commenting upon this proof beyond suggesting that, in view of the nonvalidity of the HLYF mechanism, it should prove very interesting.

With regard to the last statement of the discussion of Lorenz and Eichkorn, it has been the experience of the author that in those environments in which the Bockris mechanism has been found to apply, contamination of the electrode surface, as evidenced by the presence of slow polarization hysteresis phenomena, can result in illusory steady-state Tafel behavior, with "apparent" Tafel slopes less than 40 mv/decade and "apparent" hydroxyl ion reaction orders greater than unity, *i.e.*, in data of the type that the HLYF mechanism was devised to explain. When such anomalous behavior was observed in acidic sulfate solutions, the experimental procedure described in this paper was repeated, with the result that the same electrodes then exhibited behavior corresponding to the Bockris mechanism. Hence, there is reason to believe that the Heusler mechanism and its modifications fail because, aside from their faulty constructions, they attempt to explain anomalous electrode behavior without recognizing that this is the case.

Fluorescent Emission Spectra in II-VI Compounds

R. E. Halsted, M. Aven, and H. D. Coghill (pp. 177-181, Vol. 112, No. 2)

W. Lehmann[28]: Emission bands in (Zn, Cd) (S, Se, Te) phosphors do not always shift as monotonously over the spectrum with a variation of the composition of the host lattice, as assumed by Halstead, Aven, and Coghill. Indeed, a steady shift, almost equal to the variation of the band gap, is well established only within the (Zn, Cd) S system. It may occur also with (Zn, Cd) Se and (Zn, Cd) Te, *i.e.*, in all cases where the cation of the host lattice varies from Zn to Cd. However, a strong deviation from such simple behavior does definitely exist within the Zn(S, Se, Te) system, and it may be expected also within the Cd(S, Se, Te) system, *i.e.*, in cases where the anion varies from S to Se to Te. The authors seem to have overlooked the complex influence of an anion variation on the luminescence of II-VI compound phosphors because it may have been not sufficiently stressed in previous reports [29,30,31,32] and because of the apparent restriction of their own work to single crystals of the pure binary compounds.

The situation may be demonstrated for the case of Zn(S, Se, Te) phosphors activated by the incorporation of small amounts of silver and chlorine. Some emission spectra measured at 77°K are shown in Fig. 1, in terms of d (number of quanta)/d (quantum energy) as a function of the quantum energy. This is the physically most senseful presentation because luminescent processes are quantum processes. The spectra are arbitrarily shifted up and down on the logarithmically calibrated ordinate in order to provide a clear picture. Cubic ZnS:Ag,Cl emits primarily in a single emission band in the blue, at about 2.76 ev (somewhat lower than in hexagonal ZnS:Ag, Cl). Replacement of only

(nontempered specimens), the Heusler mechanism is valid. By reducing the number of dislocations that is the density of active places (tempered specimens), we found the kinetic data of the Bockris mechanism. The difference between both mechanism is not due to influences of atomic imperfections, external conditions, or defects of measurements.

E. J. Kelly: In the paper under discussion, it was shown that, subject to appropriate steady-state conditions, the mechanism proposed for the anodic dissolution of iron in acidic sulfate media, Eq. [41]-[45], reduces to a kinetic equivalent of the Bockris mechanism, Eq. [9]-[11]. The objections of Lorenz, Yamaoka, and Fisher[26] to the Bockris mechanism were examined and rejected, and the author is pleased to find that, rather than reiterate these objections, Lorenz and Eichkorn appear to accept the validity of the mechanism. However, they now suggest that both the Heusler mechanism, as modified by Lorenz, Yamaoka, and Fisher {Eq. [53]-[56] of ref. (1), and hereafter referred to as the HLYF mechanism}, and the Bockris mechanism are operative, with the former predominating "if there exists a high concentration of active sites." To be specific, they would add the rate-determining reaction of the Bockris mechanism, Eq. [10], to the system of reactions comprising the HLYF mechanism, while simultaneously invoking the "active site" concept. An examination of the kinetics of the resultant hybrid mechanism reveals that the total steady-state anodic current density corresponding to the iron dissolution process may be represented as a sum of two partial current densities, i_B and i_H, attributable to the Bockris and HLYF mechanisms, respectively, with

$$i_B/i_H \approx \bar{k}_{44}/s \left(\frac{k_{54}}{k_{-54}} \right) \bar{k}_{55} A_{(OH-)},$$

where s represents the concentration of active sites and the other symbols have their customary significance. Therefore, with

$$A_{Fe(FeOH)_{ads}}/A_{(FeOH)_{ads}} \approx s \left(\frac{k_{54}}{k_{-54}} \right),$$

a shift in the equilibrium of Eq. [54] to the right, or an increase in s, would indeed favor the HLYF mechanism. Thus, as an artifice, the hybrid mechanism proposed by Lorenz and Eichkorn is not without merit. However, as a necessary consequence of the nonvalidity of the component HLYF mechanism, a fact already established by a detailed examination, the hybrid must be rejected.

Although Lorenz and Eichkorn refer to ref. (12) for the "proof of this explanation," only the first eleven references were included in the copy of their discussion sent to the author. In the absence of this reference, one is constrained from commenting upon this proof beyond suggesting that, in view of the nonvalidity of the HLYF mechanism, it should prove very interesting.

With regard to the last statement of the discussion of Lorenz and Eichkorn, it has been the experience of the author that in those environments in which the Bockris mechanism has been found to apply, contamination of the electrode surface, as evidenced by the presence of slow polarization hysteresis phenomena, can result in illusory steady-state Tafel behavior, with "apparent" Tafel slopes less than 40 mv/decade and "apparent" hydroxyl ion reaction orders greater than unity, *i.e.*, in data of the type that the HLYF mechanism was devised to explain. When such anomalous behavior was observed in acidic sulfate solutions, the experimental procedure described in this paper was repeated, with the result that the same electrodes then exhibited behavior corresponding to the Bockris mechanism. Hence, there is reason to believe that the Heusler mechanism and its modifications fail because, aside from their faulty constructions, they attempt to explain anomalous electrode behavior without recognizing that this is the case.

Fluorescent Emission Spectra in II-VI Compounds

R. E. Halsted, M. Aven, and H. D. Coghill (pp. 177-181, Vol. 112, No. 2)

W. Lehmann[28]: Emission bands in (Zn, Cd) (S, Se, Te) phosphors do not always shift as monotonously over the spectrum with a variation of the composition of the host lattice, as assumed by Halstead, Aven, and Coghill. Indeed, a steady shift, almost equal to the variation of the band gap, is well established only within the (Zn, Cd) S system. It may occur also with (Zn, Cd) Se and (Zn, Cd) Te, *i.e.*, in all cases where the cation of the host lattice varies from Zn to Cd. However, a strong deviation from such simple behavior does definitely exist within the Zn(S, Se, Te) system, and it may be expected also within the Cd(S, Se, Te) system, *i.e.*, in cases where the anion varies from S to Se to Te. The authors seem to have overlooked the complex influence of an anion variation on the luminescence of II-VI compound phosphors because it may have been not sufficiently stressed in previous reports [29,30,31,32] and because of the apparent restriction of their own work to single crystals of the pure binary compounds.

The situation may be demonstrated for the case of Zn(S, Se, Te) phosphors activated by the incorporation of small amounts of silver and chlorine. Some emission spectra measured at 77°K are shown in Fig. 1, in terms of d (number of quanta)/d (quantum energy) as a function of the quantum energy. This is the physically most senseful presentation because luminescent processes are quantum processes. The spectra are arbitrarily shifted up and down on the logarithmically calibrated ordinate in order to provide a clear picture. Cubic ZnS:Ag,Cl emits primarily in a single emission band in the blue, at about 2.76 ev (somewhat lower than in hexagonal ZnS:Ag, Cl). Replacement of only

[32] F. F. Morehead, *J. Phys. Chem. Solids*, **24**, 37 (1963).

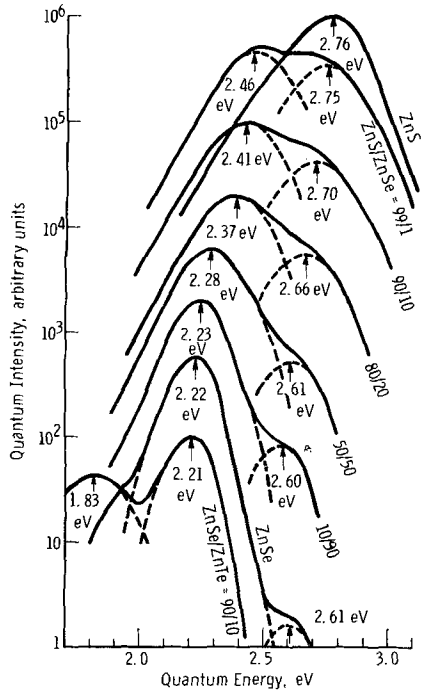

Fig. 1. Some emission spectra of cubic ZnS, Zn (S, Se), ZnSe, and Zn(Se, Te) phosphors made with 0.01 mole % of Ag and 0.1 mole % of Cl, excited to luminescence at 77°K.

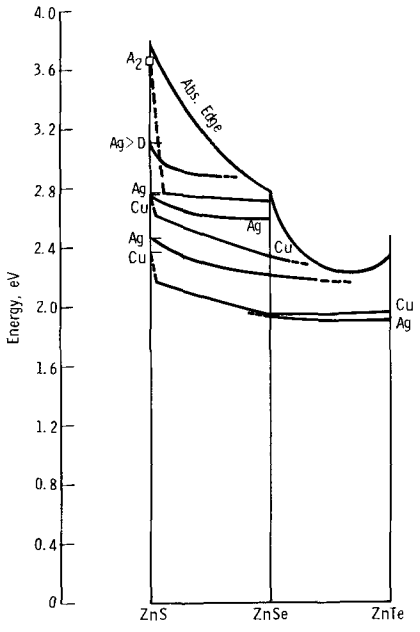

Fig. 2. Fluorescent emission energies in the Zn(S, Se, Te) system (as measured at 77°K).

1% of the ZnS by ZnSe causes a strong green emission band (peak ~ 2.46 ev) besides the blue, and both bands can then be followed through the entire range up to ZnSe.Ag, Cl, Hence, the 2.76 ev band (blue) of ZnS:Ag, Cl corresponds to a band at ~2.61 ev (blue-green) in ZnSe:Ag, Cl, while the 2.22 ev band of ZnSe:Ag, Cl (yellow) corresponds to the (ordinarily almost or completely absent) green emission band of ZnS:Ag, Cl located at ~ 2.46 ev. A similar appearance of a new emission band is to be observed if some of the ZnSe is replaced by ZnTe (also shown in Fig. 1).

This behavior with a variation of the host lattice from ZnS over ZnSe to ZnTe may vary considerably depending on the particular defect or impurity producing the emission. For instance, the complex "A_2-emission" near the optical adsorption edge of ZnSe is no direct continuation of the, also complex, near-edge emission of ZnS, and the two well-known Cu-emission bands in ZnS (blue and green) exhibit a distinct "jump" toward lower quantum energies if only a few per cent of the ZnS are replaced by ZnSe. Except for these irregularities, however, all peak positions vary considerably less than the band gap does over the same variation of the host lattice composition. Hence, if Fig. 4 by Halsted, Aven and Coghill is redrawn in a way as to correspond to experimental evidence in between ZnS and ZnSe, and in between ZnSe and Te, one obtains Fig. 2 here which clearly shows that a simple interpolation can be dangerous.

R. E. Halsted, M. Aven, and H. D. Coghill: W. Lehmann's 77°K results on ZnSSe:Ag provide a worthwhile addition to the literature. They appear to be in accord with the cited 300°K data of Leverenz and of Klasens. The recent analysis of these data by W. H. Fonger[33] is also relevant. The "jumps" apparent in the ZnSSe:Cu data of Lehmann are not evident in the work of Morehead. The jump in his edge emission data is particularly striking, if confirmed. Lehmann's results do indeed suggest that estimates of the positions of spectra derived by simple extrapolation from "analogous" end points may be invalid in ZnSSe:Ag, and perhaps more generally. This would appear to be an important point meriting further study. Our paper was motivated in part by the desire to raise this very question. We clearly distinguish between experimental data and possible implications of the data.

It should be noted, however, that the problem of sample preparation and emission band identification in such investigations is not simple. Trace impurities can exert a profound influence. It is interesting that Bundel's results on self-activated ZnSSe phosphors coincide closely with Morehead's data on the ZnSSe:Cu system. No evidence for the 2.46 ev ZnS:Ag band cited by Lehmann has been found at this laboratory in Cu-free material. We are impressed by Lehmann's conviction that the ZnS edge emission exhibits a 0.8 ev shift with small Se additions. We hope that additional experimental data on the ternary compounds may soon resolve these questions.

Hydrogen Evolution at a Solid Indium Electrode

J. N. Butler and M. Dienst (pp. 226-232, Vol. 112, No. 2)

R. Piontelli and **B. Mazza**[34]: The reference given by the authors to the work done in our Laboratory[35] on the cathode behavior of indium, completely overshadows the main result, which may deserve to be recalled also in view of the study of the hydrogen discharge on indium. This consists in the abrupt increase of the cathode overvoltage (in the order of: 0.4-0.5v), encountered when plating indium from some concentrated baths, and long before attaining the "limit current conditions" (for instance at current densities in the order of 10 amp/m^2).

This phenomenon is typical for: sulfate, sulfamate, perchlorate baths, while in chloride, or by adding adequate chloride amounts to the baths above, the insurgence of this "cathodic passivity" effect is very much displaced toward high values of the current density.

This phenomenon has been successively recognized by Kangro and Weingärtner,[36] who appear to consider it to be correlated with the participation of In^+ to the cathode processes.

In spite of the very extensive work carried out in this laboratory on this matter, some important aspects remain still unexplained, and they will require supplementary effort.

In any case, our results indicate the essential part taken by the hydrogen interference in the electrode processes, and suggest the indium behavior toward hydrogen to be largely different from the mercury one.

Once more the explicit and thorough consideration of the structural properties of the metallic phase and of its surface appears to be an indispensable step to make the kinetic theories some thing more than a formalistic game.

J. N. Butler and **M. Dienst:** Drs. Piontelli and Mazza have pointed out the importance of the hydrogen evolution reaction in the electrodeposition of indium from solution. Although there may be complex interactions between the hydrogen evolution and indium deposition reactions, we hope that studies of each of these processes, under conditions where the other does not occur, will further the understanding of those phenomena observed in practical situations.

Kinetics of the Silicon-Silicontetrachloride Reaction in a Flow System

Ole Alstrup and C. O. Thomas (pp. 319-323, Vol. 112, No. 3)

S. E. Craig, Jr.[37]: The interesting and timely work of Alstrup and Thomas conclusively proves that Mon-

champ et al.[38] did not measure true kinetic data as they believed but, instead, measured mass transport rates in the gas phase.[39]

Alstrup notes this error in Monchamp's work and then fails to consider mass transport in relation to his own work. Such a failure is always serious in work dealing with a heterogeneous reaction in a laminar flow reactor for such reactors have notoriously slow mass transfer rates.

It is especially unfortunate that Alstrup failed to evaluate the effect of mass transfer on his system since many of his observations are typical of mass transfer controlled reactions. For example, the rate was found to be independent of the surface condition and crystal orientation. The rate was also found to depend on the reactor type, the reactor geometry (above a certain volume), and the velocity of flow. Thomas has adequately explained this last effect as resulting from a difference in composition between the inlet gas and the bulk gas in the reaction mixture caused by the reaction itself. Nevertheless, it is appropriate to examine the gas phase mass transport.

Alstrup's Eq. [5] and [6] are a mass balance on $SiCl_4$ and may be arranged in the following form

$$r = \frac{1}{AM_0}\left(\frac{-dm_0}{dt}\right) = \frac{v_0\rho_0}{A}\left(\frac{y^0_4 - y_4}{1 + y_4}\right) \qquad [1]$$

where r (gram atoms Si removed $-cm^{-2}\text{-}sec^{-1}$) is the rate of reaction, A (cm^2) the active surface area, M_0 the atomic weight of silicon, m_0(g) the mass of the sample, v_0($cm^3\text{-}sec^{-1}$) the volume flow rate, ρ_0 (g moles-cm^{-3}) the molar density at which the volume flow rate is measured and y^0_4 and y_4 are the mole fractions of $SiCl_4$ in the inlet gas and in the reaction chamber, respectively.

A difference in composition will also exist between the bulk gas in the reaction chamber and the gas adjacent to the solid gas interface. This composition gradient is required to transport $SiCl_4$ to the interface and $SiCl_2$ away from the interface. The composition difference is related to the rate of transport by a mass transport coefficient, k'_G (g moles-$cm^{-2}\text{-}sec^{-1}$)

$$r = \frac{k'_G\,(y_4 - y_{4i})}{1 + \dfrac{y_4 + y_{4i}}{2}} \qquad [2]$$

where y_{4i} is the mole fraction of $SiCl_4$ in the gas phase at the solid interface. The numerator of Eq. [2] is derived from the film pressure factor and accounts for the net flow of gas away from the interface.[40] Therefore, k'_G includes only the effects of geometry, flow, and physical properties of the fluid. An equation similar to [2] can be written for the transport of $SiCl_2$. Equations of this form should have been used to calculate the interfacial compositions which could then be used in correlations similar to Alstrup's Eq. [4].

Mass Transfer Controlled Assumption

If the rate of reaction is controlled by the rate of mass transfer in the gas phase, then equilibrium is approached at the solid-gas interface. Since the mass transfer coefficient for $SiCl_4$ will be approximately equal to the mass transfer coefficient for $SiCl_2$, it can be shown that y_{4i} will be equal to the mole fraction of $SiCl_4$ which would remain if the feed gas mixture were brought to equilibrium with the sample at the temperature and pressure of the reactor.

$$y_{4i} = \frac{y^0_4(1 - z)}{1 + zy^0_4} \qquad [3]$$

[38] R. R. Monchamp, W. J. McAleer, and P. I. Pollack, *This Journal*, 111, 877 (1964).

[39] S. E. Craig, *ibid.*, 112, 647 (1965).

[40] O. A. Hougen and K. M. Watson, "Chemical Process Principles," Part III, Chap. 20, John Wiley & Sons, Inc., New York (1949).

where z is the fraction of the $SiCl_4$ in the feed which would be converted at equilibrium.

The general equation for the rate of reaction, assuming mass transfer controlled kinetics, is obtained by combining Eq. [1], [2], and [3].

$$r = \frac{k'_G\left(y^0_4 z - \dfrac{Ar}{v_0\rho_0}\right)}{1 + \dfrac{y^0_4 z}{2} + \dfrac{Ar}{2v_0\rho_0}} \qquad [4]$$

Since for this reaction, $1 >> y^0_4 z/2 + Ar/2v_0\rho_0$ the rate equation may be simplified to

$$\frac{Ar}{v_0\rho_0} = \frac{Ak'_G}{v_0\rho_0}\left[\frac{y^0_4 z}{1 + \dfrac{Ak'_G}{v_0\rho_0}}\right] \qquad [5]$$

Figure 1 is a logarithmic plot of Eq. [4] and is approximately equivalent to Alstrup's Fig. 2. The mass transfer number, $Ak'_G/(v_0\rho_0)$, was taken as 0.3 in order to have the curves fall in the general range of Alstrup's data. The equilibrium conversion, z, was computed from Schafer and Nickl's [41] equation for the equilibrium constant with the assumptions of ideal gas behavior at 1 atm total pressure. Increasing the mass transfer number moves all of the curves upward toward asymptotic values of

$$\frac{Ar}{v_0\rho_0} = y^0_4 z$$

This asymptote is shown for the temperature of 1170°C. Decreasing the mass transfer number merely translates the curves downward as shown for $T = 1170$°C and $Ak'_G/v_0\rho_0 = 0.022$.

An apparent activation energy, E_a, for the reaction can be obtained numerically from Fig. 1 and the definition.

$$\frac{E_a}{R} = \frac{\partial(\ln r)}{\partial(1/T)}$$

The apparent order of the reaction with respect to $SiCl_4$ can be obtained directly from the slope of the curves in Fig. 1.

Two limiting regions can be seen in Fig. 1. The high equilibrium conversion region (high temperature, low y^0_4) and the low equilibrium conversion region (low temperature and high y^0_4). In the high equilibrium conversion region ($z \geq 0.9$) the rate of reaction is controlled by the rate at which $SiCl_4$ gets to the surface. This yields an apparent first order reaction with a very

[41] H. Shafer and J. Nickl, *Z. anorg. u. allgem. chem.*, 274, 250 (1953).

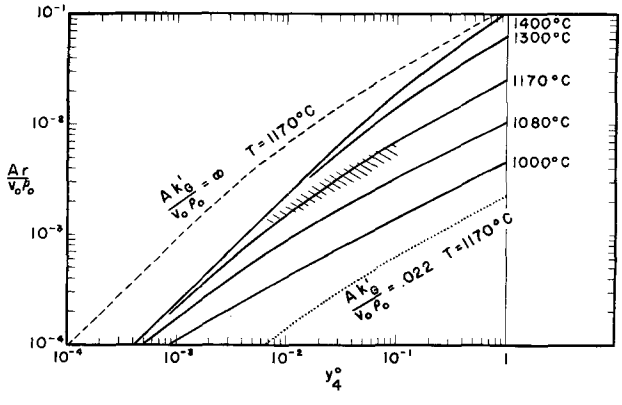

Fig. 1. Reaction rate for the system $SiCl_4$-$SiCl_2$-Si assuming mass transfer controlled kinetics in a well-mixed reactor with no $SiCl_2$ in the feed gas. Solid lines are for $Ak'_G = 0.3$; dashed line is for $Ak'_G/v_0\rho_0 = \infty$ at 1170°C; dotted line is for $Ak'_G/v_0\rho_0 = 0.022$ at 1170°C; shaded area represents the general range of Alstrup's data.

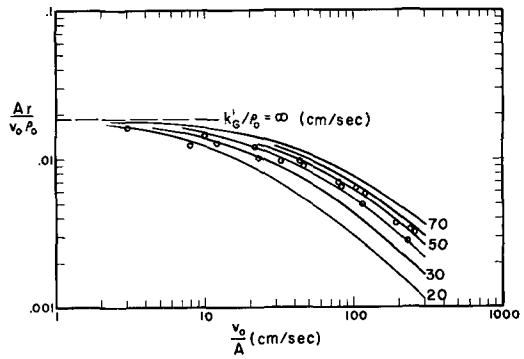

Fig. 2. Effect of velocity on the rate of the $SiCl_4$-$SiCl_2$-Si system assuming mass transfer controlled kinetics. Solid lines are computed from Eq. [4]; data points are from Alstrup's Fig. 5; $y^o_4 = 0.045$.

small apparent activation energy. In the low equilibrium conversion region ($z \leq 0.2$) the reaction kinetics are controlled by the rate at which $SiCl_2$ diffuse into the bulk gas phase. This results in an apparent ½ order reaction with an activation energy equal to ½ the standard free energy of reaction, ΔH^o (in this case about 38 kcal/mole). Both of these regions are fully represented by Eq. [4] and [5]. The apparent order of the reaction and the apparent activation energy are direct results of chemical equilibrium. The mass transfer controlled assumption is therefore able to explain why in a flow reactor, Monchamp[38] and Heinecke[42] obtained results so different from those of Alstrup and Thomas.

The effect of velocity on the mass transfer rate at constant y^o_4 is shown in Fig. 2. The lines are calculated from Eq. [4] while the points are Alstrup data taken from Fig. 5 of his work. From Fig. 2, we see that k'_G is not constant with velocity of flow but increases as the flow rate increases. This is consistent with the mass transfer controlled assumption.

Mass Transfer Coefficient

The mass transfer coefficient used in this discussion is the true local coefficient based on the actual local mole fraction difference driving force. Since the flow is doubtlessly laminar, the mass transfer coefficient can be correlated by the dimensionless equation.[43]

$$\frac{k'_G t}{D\rho} = f\left(\frac{v_o \rho_o}{D\,L\,\rho}\right) \qquad [6]$$

where t is a dimension characteristic of the channel thickness, D is the mass diffusivity (cm²/sec), ρ is the actual molar density of the gas in the reaction chamber (g moles/cm³), and L is the length measured downstream from the start of the reaction zone to the local point on the substrate.

Since Alstrup used a rather unusual reactor geometry, the exact form that the mass transfer correlation should take is unknown for his reactor. Nevertheless, we can infer the form and estimate the values from known solutions for the standard cylindrical tube. For unidirectional flow through a cylinder, $k'_G t/(D\rho)$ is equal to 3.66 if the approach to equilibrium is greater than 90% (very low flow rates or very long lengths). Alstrup's low flow rate region approached this region but did not fully enter it. If the approach to equilibrium is less than 60%, the relationship becomes

$$\frac{k'_G t}{D\rho} = 1.17\left(\frac{v_o \rho_o}{DL\rho}\right)^{1/3} \qquad [7]$$

If k'_G were taken as the mean transfer coefficient based on the average driving force, then the constant in Eq. [7] would be 1.75.[44] Equation [7] is almost

[42] W. J. Heinecke and S. Ing, *J. Appl. Phys.*, 32, 1498 (1961).

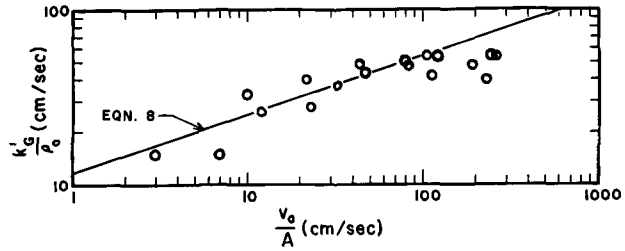

Fig. 3. Comparison of Alstrup's data with the estimated curve for mass transport controlled kinetics; $y^o_4 = 0.045$.

temperature independent. If natural convection is important, an additional temperature dependent term must be added. This additional term increases the mass transfer coefficient and is responsible for a small (0-10 kcal) apparent "activation energy." From the above considerations, we would expect Alstrup's mass transfer relation, neglecting natural convection, to be approximated by Eq. [7]. Additional information on mass transfer coefficients is most easily found in heat transfer texts [43,44] where by rigorous analogy, the group $k'_G t/D\rho$ may be substituted for the Nusselt number and the group $v_o\rho_o/(DL\rho)$, may be substituted for the Graetz number.

Figure 3 is a comparison of Alstrup's data, as interpolated by Eq. [4], with Eq. [7]. In order to plot Eq. [7], estimates had to be made of D, t, L, ρ and ρ_o. The molar densities were calculated from the ideal gas law. D was estimated using the Chapman-Enskog formula.[45] Since the flow in the reactor chamber is bidirectional, t was taken as ½ the tube diameter. One-half the sample length was taken as the average value of L and the width of the sample was assumed to be ½ cm.

The estimated transport relationship becomes

$$\frac{k'_G}{\rho_o} = 1.16\left(\frac{v_o}{A}\right)^{1/3} \qquad [8]$$

Discussion

The fit between Alstrup's data and the estimated transport relationship is surprisingly good in view of the uncertainties in Eq. [8] which may be in error by as much as a factor of 5. Nevertheless, Alstrup's data is definitely in the range where mass transport is important and where it may be controlling.

The mass transfer controlled assumption explains all of the observed phenomena except two; the high activation energy and apparently uniform etching rate. Equation [7] predicts that the upstream edge of the sample will etch faster than the downstream edge. Alstrup does not report whether this occurs or not (it should occur for most kinetic models). In fact, Eq. [7] predicts $k'_G = \infty$ for the extreme upstream edge. This certainly cannot occur. The unreasonably high prediction for $L = 0$ is caused by a simplifying assumption in the derivation of Eq. [7] which makes it invalid for extremely small L's.

As shown earlier, the mass transport assumption yields an apparent activation energy of ½ ΔH^o plus any temperature effects due to natural convection in the reactor. We estimate that the apparent activation energy due to natural convection should not exceed 10 kcal/mole. This would give a total activation energy of 48 kcal/mole which is considerably less than the reported value of 67 kcal/mole. This difference cannot be easily explained. It may be a real difference, indicating mass transport is not fully controlling, or it may be merely an indication of the difficulty in obtaining precise rate data.

Apparently Alstrup's data represents one of those frustrating cases that can be equally well explained by two widely different kinetic models. These models are not identical and extrapolate to different values. Alstrup's model predicts a rate which is uniform over the whole sample surface and which increases as the total pressure increases (y^{o}_4 held constant). The mass transfer model predicts a rate which will taper the sample and a rate which is essentially independent of the total pressure (y^{o}_4 held constant).

Based on the data presented by Alstrup, it is impossible to choose decisively between the two models. I prefer the mass transport model, however, since with it the correct magnitude for the reaction rate can be predicted a priori.

Ole Alstrup: It is natural to assume that the reaction is limited by diffusion in the gas phase, *e.g.*, because one will not expect a process at the surface to depend on the $SiCl_4$ pressure in a fractional power. A critical analysis of the experiments, however, will show that a diffusion model gives results which deviate so much from the experimental data that one has to reject it.

The diffusion process can take place in two different ways. In the first model we assume laminar flow in the reaction chamber and the mass transport taking place by diffusion across the gas flow. It is apparently this model Craig assumes. If this model is correct, the etch rate should depend on the orientation of the sample in the reaction chamber. Some initial experiments showed that this was not the case. Considering the geometry of the reaction chamber I also find it unlikely to assume laminar flow. We can therefore reject this model.

In our case it is more obvious to assume turbulence in the reaction chamber. The rate-limiting step might then be diffusion through a thin gaseous film at the surface of the sample. From this model one would expect the same etch rate all over the sample surface, in agreement with the experiments. From elementary calculations one obtains an expression for the etch rate which is similar to Craig's Eq. [5]. Both equations can be written

$$\frac{Ar}{v_o\rho_o} \propto \frac{K}{8} \frac{\sqrt{1 + 16\,(P^{o}_4/K)} - 1}{1 + \frac{v_o}{A}\frac{\rho_o}{k'_G}}$$

At 1170°C the equilibrium constant $K = 0.050$ atm, while P^{o}_4 varies from 0.005 to 0.1 atm. From a plot like Craig's Fig. 1 one would expect the etch rate dependency on P^{o}_4 to vary from proportionality to square-root dependency as the $SiCl_4$ pressure increases, and to be independent of the v_o/A value. The experiments however give as shown in our Fig. 2 that the etch rate is proportional to $P^{o}_4{}^{1/2}$ in the whole pressure region, but only for high flow rates ($v_o/A \geqq 3$ cc/sec). This is consistent with our model as we find the etch rate to be proportional to $P_4{}^{1/2}$, and for high flow rates $P_4 = P^{o}_4$ as shown in Eq. [20].

Perhaps more striking is the difference in temperature dependency between the diffusion model and the experiments, a difference which Craig also is aware of. From the above rate expression it is seen that when P^{o}_4 is large the apparent activation energy has its upper limit which is half of the value of that of the equilibrium constant (plus a minor amount from the diffusion constant). The experiments give an activation energy of almost twice that value.

In the diffusion model k'_G depends on v_o since the film thickness decreases with increasing v_o. The reaction rate therefore depends on the absolute value of the flow rate. Craig uses this dependency to explain his Fig. 2. He plots the etch rate *vs.* v_o/A. However this is not the same as plotting the etch rate *vs.* v_o. To verify that, we carried out experiments in which v_o and A were varied, while keeping v_o/A constant. From such experiments we found the same etch rate, whereas from the diffusion model we should get a higher etch rate for the experiments with the higher flow rate.

The conclusion of these considerations is that the diffusion model does not explain any of the parameter dependencies found. So I do not think that for this purpose it is necessary to increase the experimental material. On the other hand we have only been able to give a mathematical treatment that fits the experiments. This analysis makes it evident that the rate-limiting step is located at the surface. To find out what really happens at the surface presumably calls for a considerable expansion of the experimental data.

Studies of the Oxidation of Nickel in the Temperature Range of 900° to 1400°C

Kazuo Fueki and J. B. Wagner, Jr. (pp. 384-388, Vol. 112, No. 4)

Stanislaw Mrowec[46]: Studying kinetics and mechanism of oxidation of nickel at high temperatures, K. Fueki and J. B. Wagner found that dependence of calculated from the kinetic measurement $\sqrt{s}$ values of the self-diffusion coefficients of nickel in nickel oxide on the oxygen pressure can be described by the general equation

$$D_{Ni} = \text{const.}\ p_{O_2}{}^{1/n} \qquad [1]$$

Table I gives the values of the exponent $1/n$ of Eq. [1] computed by these authors for various temperatures.

Table I. Values of exponent $1/n$

Temperature, °C	$1/n$
1000	1/5.6
1100	1/6.0
1200	1/5.1
1300	1/4.0
1400	1/3.5

The data summarized in Table I show that the exponent at first decreases slightly in the temperature range 1000° to 1100°C and then in the temperature range 1100°-1400°C distinctly increases. In order to explain the above given relationship between the calculated values of D_{Ni} and oxygen pressure, Fueki and Wagner considered dependence of the defects concentration in NiO lattice on oxygen pressure on the basis of the mass action law. Results of these considerations did not lead however to the elucidation of the dependence of the $1/n$ exponent on temperature. In the opinion of the author of the present remarks there exists a possibility of interpretation of this dependence.

Let us consider the limiting cases of the ionic and electronic defects of the NiO lattice. On the basis of the studies on self-diffusion of nickel and oxygen in nickel oxide, reported by Moore [47,48] and the marker studies done by Fueki and Wagner one can assume that ionic defects occur practically exclusively in the cation sublattice. As nickel oxide is a metal deficit p-type semiconductor,[49] formation of such defects can be described schematically by the following equations

$$\tfrac{1}{2}\,O_2 \rightleftarrows Ni_{\square''} + 2\oplus + NiO \qquad [2]$$

$$\tfrac{1}{2}\,O_2 \rightleftarrows Ni_{\square'} + \oplus + NiO \qquad [3]$$

$$\tfrac{1}{2}\,O_2 \rightleftarrows Ni_{\square} + NiO \qquad [4]$$

where $Ni_{\square''}$, $Ni_{\square'}$, and $Ni_{\square}$ represent dinegative, uninegative, and neutral cation vacancies respectively, and $\oplus$ is an electron hole. Equation [2] describes the limiting case wherein the dissociation degree in the system electron hole-cation vacancy is equal to 1, whereas Eq. [3] illustrates the case in which the electronic defects are 50% associated with cation vacancies. Finally Eq. [4] represents the other limiting case in which dissociation degree of the ionic and electronic defects is equal to zero, *i.e.*, the defects are entirely associated. As the degree of defects dissociation increases with temperature, one can expect gradual changes of the equilibrium [4] via [3] into [2]. Applying the mass action law to the equilibria given in Eq. [2], [3], and [4], one can obtain the following expressions for the concentrations of cation vacancies as a function of oxygen pressure

$$n_{Ni_{\square''}} = \text{const.}\ p_{O_2}^{1/6} \quad [5]$$

$$n_{Ni_{\square'}} = \text{const.}\ p_{O_2}^{1/4} \quad [6]$$

$$n_{Ni_{\square}} = \text{const.}\ p_{O_2}^{1/2} \quad [7]$$

As the rate of selfdiffusion is directly proportional to the concentration of cation vacancies, one can anticipate in the p-type semiconductors the same dependence of D_{Me} on p_{O_2} as between the concentration of cation vacancies and oxygen partial pressure. The exponent in Eq. [1] should therefore decrease with increasing temperature from 1/2 to 1/6.

As has already been mentioned, dependence of the exponent $1/n$ on temperature indicated, that in the region of lower temperatures, 1000°-1100°C, the dissociation degree of ionic and electronic defects was practically equal to 1, Eq. [5], whereas the degree of dissociation of the defects decreased with increased temperature, reaching at 1400°C a value lower than 0.5. Such dependence of the dissociation on temperature is highly improbable, resulting in Fueki and Wagner abandoning the explanation of this dependence.

Considering the model of the defect structure of semiconductors, one usually neglects the intrinsic defects which involve transfer of electrons from the valence to the conductance bands. Formation of such defects can be illustrated by the equation

$$\text{zero} \rightleftarrows \oplus + \ominus \quad [8]$$

In the region of the moderate temperatures, < 1000°C, participation of the intrinsic electronic defects in the n- and p-type semiconductors is neglected, since it is very small. This is justified particularly when departure from stoichiometric composition is comparatively high. Recent studies, however, showed that nickel oxide exhibits in the high-temperature region very small departures from the stoichiometric composition.[50] Concentration of acceptors in the forbidden energy zone of the oxide is thus small and in the high temperatures one must take into account the increasing participation of the intrinsic defects of NiO lattice with increasing temperature. Formation of the electron holes in the valence band of NiO in these conditions involves superimposing of two processes: (*a*) transfer of electrons from the valence band to the conduction band as a result of reaction [8] and (*b*) transfer of electrons from valence band to acceptor levels according to Eq. [2]. In contrast to reaction [2] formation of the electron holes in valence band in process [8] is independent of oxygen pressure. Therefore one can anticipate that in the very high-temperature region, > 1400°C, total concentration of holes in the valence band of NiO lattice will be practically independent of oxygen pressure, this concentration being determined by reaction [8]. Applying in this case the mass action law to reaction [2] one can get

$$n_{Ni_{\square''}} = \text{const.}\ p_{O_2}^{1/2} \quad [9]$$

as concentration of the electron holes can be taken as being constant. Coming to lower and lower temperatures, participation of reaction [8] in the process of formation of the holes decreases, and at some temperature concentration of these defects in the lattice is determined almost entirely by reaction [2] which consequently gives the dependence of the cation vacancies concentration on oxygen pressure as expressed by Eq. [5].

The discussion given above leads to the following conclusions:
In the region of the not too high temperatures, exponent $1/n$ in Eq. [1] decreases gradually with temperature due to the increase of the dissociation degree of the ionic and electronic defects. In this region, concentration of the electron holes depends almost exclusively on the concentration of acceptor levels resulting from departure from stoichiometry in nickel oxide. In this temperature range one can expect the gradual decrease of the exponent $1/n$ from 1/4 to 1/6 due to the increase with temperature, of dissociation degree of defects. In the high-temperature region the concentration of the electron holes is less and less dependent on the oxygen pressure, as reaction [8] participates more and more in the formation of these defects. In this region of temperatures then, the $1/n$ exponent should increase with increasing temperature from 1/6 to 1/2. Data summarized in Table I indicate that the boundary between those two regions of temperature lies in the vicinity of 1100°C. Below this temperature one can still observe the drop of the value of $1/n$ with rising temperature, whereas above 1100°C the further increase of temperature results in the gradual increase of this exponent.

Kazuo Fueki and **J. B. Wagner, Jr.:** The authors thank Dr. Mrowec for his contribution. We agree with his discussion. We suggested a decreasing amount of association between cation vacancies and electron holes with increasing temperature. Because the value of the exponent, n, in the oxygen partial pressure dependence ($p_{O_2}^{1/n}$) of the diffusion coefficient or the electronic conductivity depends not only on the temperature but on the nickel to oxygen ratio, an additional test of Dr. Mrowec's proposal would be to compare the values of the exponent, n, at different temperatures for constant nickel to oxygen ratios.

Further studies in this laboratory[51] have shown that the isothermal electronic conductivity of single crystalline NiO in oxygen pressures of 10^{-4} to 1 atm and in the temperature range 800°-1200°C is proportional to the 1/4 power of the oxygen pressure. Slight differences in the exponents, $1/n$, of the pressure dependence for the diffusion and for the conductivity studies at the same temperature may be due to differences in the impurity level between the two different materials.

Poisoning and Gettering Effects in Silicon Junctions

E. J. Mets (pp. 420-425, Vol. 112, No. 4)

A. N. Knopp[52] and **R. Stickler**[53]: It is interesting to note that you found significant softening of the blocking characteristics tested on the diffused p-n-p's after exposing them to nitrogen at temperatures above 800°C. We assumed that your nitrogen ambient consisted of approximately 100% nitrogen. In addition, you stated that the resulting silicon nitride formation probably caused the downgrading. We have carried

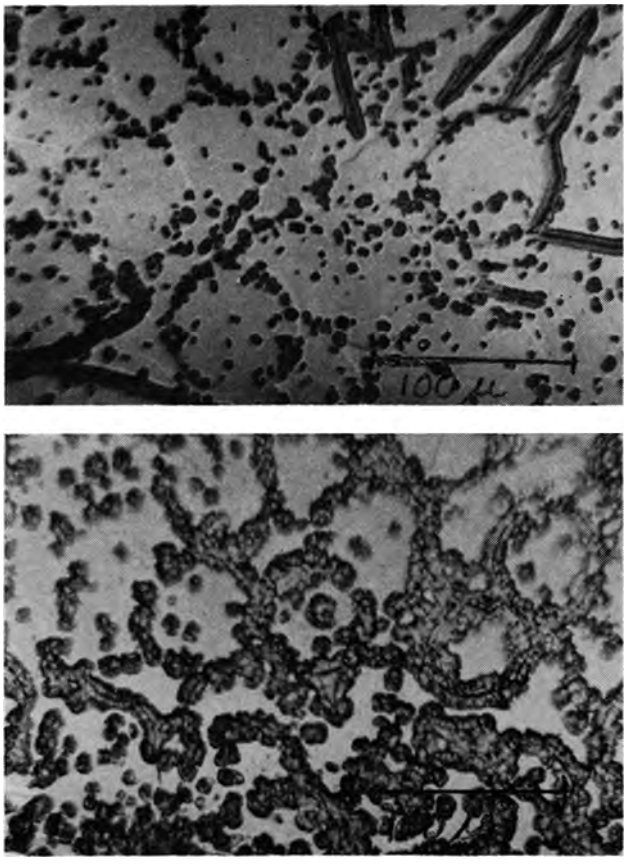

Fig. 2. Silicon nitride on diffused pnp's. (a, top) Silicon nitride on pnp's diffused in run A electrical data See (1a). (b, bottom) Silicon nitride on pnp's diffused in run B electrical data See (1b). Diffusion parameters were the same for run A and run B. Magnification 250X.

out similar studies.[54] In our case, the tested p-n-p structures maintained sharp avalanche breakdown characteristics as shown in Fig. 1a and 1b. Typical surface areas of p-n-p's used for testing are shown in Fig. 2a and 2b which stemmed from two different runs. Si_3N_4 can be clearly distinguished from the silicon substrate.[54] Thus, the silicon nitride formation needs not be responsible for any softening effects.[54]

On the Equilibrium Properties of Single Crystalline Copper Electrodes

L. H. Jenkins and U. Bertocci (pp. 517-520, Vol. 112, No. 5)

W. W. Harvey[55]: It was gratifying to note that previous work, which indicated a dependence on crystallographic orientation of the equilibrium potential of copper electrodes in copper sulfate solution, has been refuted by the recent experimental results of Jenkins and Bertocci. Certainly their results are in accord with principles of electrochemical thermodynamics. Thus, if the copper-cupric ion equilibrium has been established, then

$$Cu\,(metal) = Cu^{++}\,(in\ CuSO_4\ solution) + 2e^-\,(metal) \quad [1]$$

whence

$$\mu_{Cu} = \mu_{Cu^{++}} + 2e\psi_{electrolyte} + 2\mu_{e^-} - 2e\psi_{electrode} \quad [2]$$

Equation [2] indicates that for massive copper electrodes (*i.e.*, of a size and topography such that the surface free energy is a negligible fraction of the total), and providing there are no extraneous effects such as significant residual strains, the electrode-electrolyte potential difference (p.d.) will be independent of the crystallographic orientation of the surface exposed to the solution.

Arguments in support of seemingly contradictory experimental results, to the effect that observed differences in electrode potential are analogous to the variation of the electronic work function with surface orientation are erroneous. The work function is defined and supposedly measured for the condition of zero net charge on the metal, whereby the metal-vacuum p.d. is made up entirely of the so-called surface potential. By contrast, while the contribution of interfacial dipoles and space charge to the total electrode-electrolyte p.d. may be different for different crystallographic orientations of the electrode surface, the potential due to net charge must adjust itself so as to satisfy Eq. [2] if equilibrium is to be maintained.

R. Piontelli and B. Rivolta[56]: The results and conclusions of the work of Jenkins and Bertocci are in substantial agreement with those of the research carried out in this laboratory[57], concerning the following single-crystal electrodes

$Cu\,[(111), (110)\ (100)]/Cu(ClO_4)_2$
$Ag[(111), (110), (100)]/AgClO_4$
$Pb\,[(111), (110), (100)]/Pb(NH_2SO_3)_2$
$Cd\,[(10\bar{1}0), (11\bar{2}0), (0001)]/Cd(NH_2SO_3)_2$
$Sn\,[(001), (110), (100)]/SnCl_2$

at 25°C, in various conditions, as far as the metal and free acid content of the solutions are concerned.

By a very careful control of the surface conditions of the electrodes and of the purity of the solutions, and with only glass and metal cells, no influence of the crystallographic orientation of the working electrode surface on the equilibrium electrode voltages was encountered (in the accuracy range of the measurements, as a rule less than 1 mV). These equilibrium voltages, in the medium and high metal concentration range, are rather quickly attained and then scarcely influenced by agitation.

The equilibrium electrode voltages thus appear to be strictly independent of the crystallography orientation, in agreement with the requirements of the macroscopic thermodynamics.

On the contrary for the system

$$Zn\,[(11\bar{2}0), (0001)]/Zn(ClO_4)_2$$

which was found very sensitive to agitation [especially for the orientation (0001)] and continuously changing in time, appreciable differences are met with differently oriented electrodes. This last behavior appears to be clearly correlated with the nonequilibrium conditions of the electrode.

L. H. Jenkins and **Ugo Bertocci:** The research was undertaken by the authors because of contradictory reports in the literature. Hopefully, some causes for such conflicts were established and the differences better understood. The authors are aware of the extensive study of Piontelli and co-workers on the electrochemical properties of single crystals and are gratified that our equilibrium data are in agreement with those of this distinguished group.

The authors believe themselves to be in substantial agreement with most of Harvey's conclusions. However, it is not clear to them whether he believes potential differences between orientations must be ruled out as a matter of principle, or only that they are not measurable in the case of large crystals. At any rate, his comments are welcome since they initiate discussion of some matters of interest.

First of all, it seems worthwhile to consider the "massive" electrode. At most, the spacings between atoms in no more than 10 atom layers immediately below a surface would be expected to differ significantly from those of atoms deeper in the interior of the crystal. Even if the electrode were as much as 0.1μ thick, only about 1% of the total atoms present would be contained in these first 10 atom layers. Therefore, since the ultimate concern is the detection of necessarily small differences in the contributions of various surfaces to the total free energy of the system, it is extremely unlikely that potential differences arising from dissimilar surface orientations would be large enough to be observed. Consequently any singularly oriented metal electrode presently capable of experimental realization is either "massive," or an ultra thin specimen of such inherent imperfection, high strain, etc., as to render an unambiguous interpretation of experimental results highly problematical. It appears, then, that failure to observe potential differences between crystal orientations only sets a limit on their possible magnitude, but does not establish definitely the fact they do not exist.

However, the authors feel that the lack of any detectable surface faceting in noncorroding systems, even after extended periods of time, is probably a more sensitive test of potential differences than the measurements themselves. Nevertheless, they do not believe they have established unequivocally that the polar plot of surface energy as a function of orientation of a copper crystal exposed to aqueous copper sulfate is spherical or of such shape that all orientations are stable. It is almost certain that the large surfaces used practically preclude attainment of an equilibrium orientation. So many microscopic transport processes would have to occur to accomplish such a small decrease in free energy that the kinetic process should be immeasurably slow. Even if such is not the case, it is possible that (*A*) although the surface free energies of each of the orientations observed did differ slightly, each was located at a cusp in the Wulff plot. Therefore, any possible decrease in free energy due to spontaneous change from one orientation to another would be more than compensated by the inevitable increase in surface area. Or (*B*) in terms of a Wulff diagram, some or all the orientations studied could have been unstable. In such a case the decrease in free energy due to faceting could be balanced by the increase due to the formation of edges bounding the facets.

Thus the authors agree that failure to measure a potential difference or to observe the formation of facets of preferred orientation in systems at chemical equilibrium is, quoting Piontelli, "in agreement with the requirements of macroscopic thermodynamics." They also agree with Harvey's view that the analogy between electrode potentials and work functions is improper, but would like to point out the following: In vacuum a crystal is in electrical equilibrium regardless of the work functions of the surfaces bounding it (see, for example, Piontelli[58]), but it can be in thermodynamic equilibrium only when it has the Wulff shape. Whereas in an electrochemical system (a metal crystal in contact with a solution of its ions), if the crystal does not have the Wulff shape and is bound by differently oriented surfaces, it is in neither thermodynamic nor electrical equilibrium. Therefore, different orientations should exhibit different potentials, however small the differences might be.

Cryoscopic Studies of the Melting Point of Silver in High Pressure Oxygen

J. K. Johnstone[1]

Institute for Atomic Research and Department of Ceramic Engineering, Iowa State University, Ames, Iowa

The behavior of gases in metals is becoming increasingly important. Although this subject has received extensive attention for solid metals at pressures up to 1 atm, less emphasis has been placed on liquid metals at pressures above 1 atm.

The purpose of this work is to obtain data on the dissolution and behavior of oxygen in liquid silver at higher pressures. The system was chosen owing to the high solubility of oxygen in the liquid metal. Observations were made on the depression of the freezing point of silver as the oxygen pressure over the silver was increased.

Sieverts and Hagenacker (1) used the silver-oxygen system to show that the solubility of a diatomic gas in a liquid metal is proportional to the square root of the gas pressure, thereby proving that the gas dissolves as atoms rather than molecules (Sieverts' law for dilute solutions). This work was later confirmed by Stacie and Johnson (2) with respect to the solubility of oxygen in solid silver.

The only investigator who has studied the oxygen solubility in liquid silver at pressures substantially greater than 1 atm is Allen (3). The maximum pressure reported by Allen is 13.9 atm. The work also confirmed approximately Sieverts' law up to this pressure. The work reported here extends the pressure range to slightly more than 147 atm.

Since only the freezing point depression was measured, the discussion that follows will be based on the solubility data reviewed in Lumsden (4).

Experimental

The apparatus consisted of a resistance furnace mounted concentrically in a cylindrical, water-cooled pressure-vessel. The apparatus was essentially the same as that used by Baker (5) in a study of calcium carbonate where it is described in detail.

The furnace incorporated a porcelain tube with an inside diameter of 12 mm and a wall thickness of 2 mm. The tube was wound to a length of 9½ in. with 20 gauge 9:1 platinum-rhodium wire.

The pressure-vessel, which has been described previously, was constructed from a section of auto-frettaged gun-barrel with an inside diameter of 5.5 cm and a wall thickness of 2.75 cm. The space between the furnace and the vessel wall was packed with alumina powder.

The pressure and heating (cooling) rate were controlled manually. By this method, the pressures were accurate to ±0.5% and the freezing point temperatures were accurate to ±1°. Three Bourdon test gauges of 10 in. diameter were required to cover the pressure range of 1-147 atm.

Granular silver (— 20 mesh) of 99.9% purity and silver foil 0.004 in. thick and better than 99.9% purity were used for samples. Oxygen gas of 99.5% purity was used. The remaining 0.5% was argon. The available oxygen pressure was the limiting factor in this series of experiments. The oxygen was supplied from standard 2000 psi bottles from which 147 atm was the maximum attainable pressure. All thermocouples were made of Pt-Pt 13% Rh wire.

[1] Mr. Johnstone is the second recipient of the F. M. Becket Memorial Award of the Electrothermics and Metallurgy Division of the Society. See p. 120C of the May 1964 JOURNAL. The research was conducted under the supervision of Dr. E. H. Baker, Nuffield Research Group, Imperial College of Science and Technology.

The general procedure involved placing the sample in a crucible which was then placed in the furnace. The pressure-vessel was sealed in a nearly horizontal position to help eliminate convection currents caused by high-density gases at elevated temperatures and the furnace was heated at a rapid rate—15° to 20°/min —to 600°. At this temperature, the vessel was pressurized to the desired value after several flushings with oxygen at 20 atm pressure. From this point, the procedure was varied according to one of three methods used for the actual freezing point determination.

The first method employed was that of noting the thermal arrest in the cooling curve at the freezing point of the silver. The sample consisted of slightly more than 7g of granular silver placed in a silica crucible. A thermocouple encased in a silica tube was centered in the mass of silver. The sample was raised to a temperature approximately 30° above the expected freezing point of the silver and maintained at this temperature for 40 min. It was then cooled at a rate of 1°/min and the arrest temperature determined.

The method produced satisfactory results up to a pressure of 10 atm. At this pressure, the heat losses, owing to the high gas density, were of such magnitude that the arrest was very indistinct.

The second method involved the use of a D. T. A. technique. A strip of silver foil, 1 mm wide and 5-8 mm long was substituted for the junction of a thermocouple. (The best results were obtained when each end of the silver strip was welded to one of the thermocouple leads.) A standard thermocouple sealed in an alumina sheath was fixed next to the sample to insure an accurate measure of the temperature of the silver strip. The two thermocouples were then placed in a silica crucible and packed with — 10 mesh alumina granules. The alumina particles insured that the silver strip did not come into contact with the crucible as well as helping to eliminate further any convection currents in the gas.

The sample was heated to within 20° of the expected melting point where the heating rate was reduced to approximately 1.5°/min. At the melting point of the silver, the strip broke thus destroying the differential trace; this provided a well defined melting point.

This method provided accurate and consistent results up to a pressure of 50 atm. At this pressure the welds of the differential thermocouple leads to the silver strip oxidized causing an erratic emf.

The third and most reliable method involved the use of an independent electric circuit. The arrangement of the sample and the temperature thermocouple was identical to the D. T. A. method. However, rather than welding the sample to thermocouple leads, it was welded to two pure gold wire leads. The gold leads completed an electric circuit which consisted of a 1.5v dry cell battery, a 5000 ohm series resistance and a milliammeter, thereby providing an independent circuit.

The procedure for heating the sample was described in the previous method. When the silver strip melted, the electric circuit was broken as indicated by the milliammeter.

This method provided an extremely sharp and well defined melting point. Furthermore, at oxygen pressures up to 147 atm, there was no evidence of any oxidation of the welds between the silver strip and

gold wire or of the gold itself. This method was used to check several lower pressure results obtained by the previously described methods and good agreement was found.

At the conclusion of the test series, the thermocouples were checked to see if the surface oxidation of the thermocouple wire reported previously affected the emf which would result in faulty temperature measurement. The thermocouples were tested by determination of the melting point of potassium chloride in an oxygen pressure of 90 atm. Comparison of the observed and known melting point indicated that the thermocouple junctions were not measurably affected by the oxygen gas.

Results and Discussion

The experimental results are presented graphically in Fig. 1, where P is the oxygen pressure and T is absolute temperature. Due to the extremely small solubility of oxygen in solid silver (2), the curve can be regarded as representing the freezing point depression of pure silver.

The inset in Fig. 1 shows the relationship between the freezing point depression (curve A) and the silver oxide dissociation equilibrium (curve B). The equilibrium dissociation pressure of silver oxide was derived experimentally by Lewis (6) and confirmed by Keyes and Hara (7). The curve is defined by the equation

$$\log P = -\frac{2859}{T} + 6.2853$$

and covers a pressure range of from 20.5 atm to 388.3. atm. Brewer (8) has expressed doubt as to the reliability of the work done by Lewis (6) and Keyes and Hara (7) but offers no argument to support his position.

Allen extrapolated his work to intersect the silver oxide dissociation curve to determine a possible eutectic point for the Ag-Ag_2O system. This extrapolation (as well as a summary of past work involving the Ag-O_2-Ag_2O system) has been presented graphically by Vacher (9) and yields a eutectic with a temperature of 507°C and an oxygen pressure of 414 atm (point a,

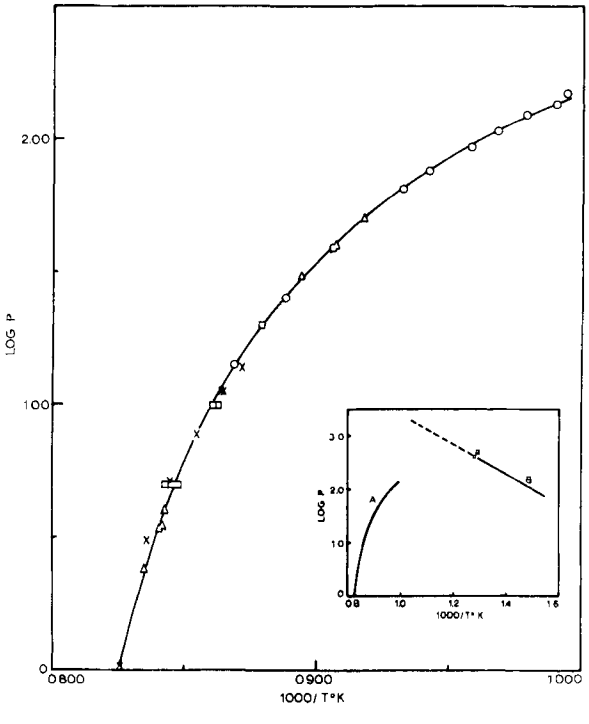

Fig. 1. Pressure-temperature diagram of freezing point depression: □, thermal arrest method; △, D. T. A. method; ○, independent electric circuit method; X, results obtained by Allen (3). Inset: Pressure-temperature diagram of freezing point depression (curve A) in relation to dissociation of Ag_2O (Curve B).

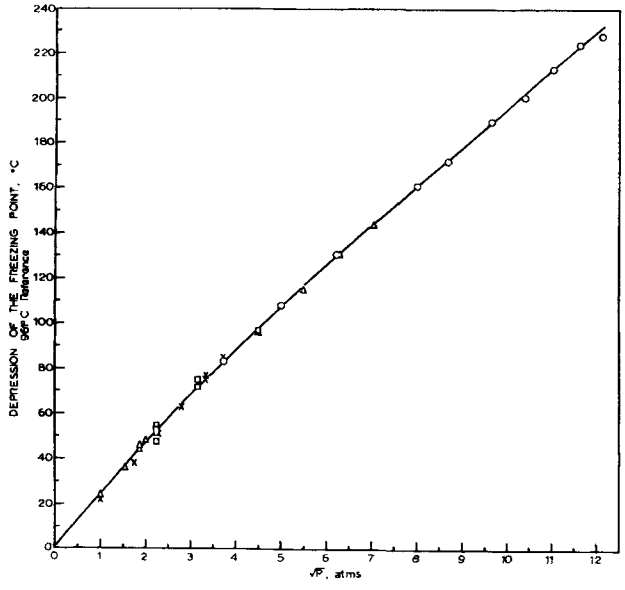

Fig. 2. Freezing point depression — $\sqrt{P}$ diagram

Fig. 1-inset). At the present, this work neither confirms nor disproves the values obtained by Allen. However, the freezing point depression data is tending toward the point suggested.

Allen showed for his range of pressures and temperatures (*i.e.*, to 13.9 atm and 876°C) that the depression of the freezing point was proportional to the $\sqrt{P}$. It is of interest to plot $\sqrt{P}$ against the freezing point depression for the results from the present work (Fig. 2). For pressures up to 4 atm a fair linearity is observed. At higher pressures and correspondingly higher concentrations of oxygen, deviation from the initial slope is apparent. This is to be expected at high concentrations and temperature changes.

The activity of the silver on the freezing point curve can be calculated by the van't Hoff equation in the form of

$$\ln a_{Ag} = \frac{\Delta H_{fus}}{R}\left[\frac{1}{T} - \frac{1}{T_{M.P.}}\right]$$

where $\Delta H_{fus} = 2855$ cal/mole (9) and $T_{M.P.} = 1234$°K. (By application of the Clausius-Clapeyron equation at the maximum pressure observed, it was calculated-assuming that the volume for liquid silver containing dissolved oxygen is not greatly different from the volume of pure liquid silver—that the lowering of the freezing point due to the pressure alone was less than 2°. Therefore, it is valid to consider the lowering of the freezing point of silver to be due solely to the solution of oxygen in the melt.) Using the eutectic temperature given by Allen, the activity of silver is calculated to be 0.508.

If the solution were roughly an ideal solution of oxygen atoms $N_o \cong 0.492$, where N_o is the atom fraction of oxygen in solution. This is greater than the oxygen content of pure liquid Ag_2O ($N_o = 0.333$). It is apparent that the oxygen at higher concentrations is present in some form other than oxygen atoms so that a greater depressive effect could be obtained for a given amount of dissolved oxygen. The possibility of the oxygen combining with silver to form Ag_2O is worth consideration. Such compound formation would certainly explain the observed temperature depression but, unfortunately, said formation can not be confirmed by the present work.

If the oxygen were present solely as oxygen atoms, the eutectic temperature would need to be higher than 642° (obtained through application of the van't Hoff equation for $N_o = 0.333$). It is difficult, however, to assign a reasonable equilibrium pressure at such a eutectic point limit which would fall on the silver-silver oxide line. Consequently, since the true state of

the dissolved oxygen at high concentrations is not known, it is preferable at this stage to regard the system as one involving Ag_2O.

From the above, it can be seen that it is essential to determine the compositions of the melts along the freezing point depression curve and to evaluate the pressure-temperature relation at the true eutectic point. Apparatus is being constructed for the last studies which will be made by Dr. E. H. Baker.

Acknowledgments

The author wishes to thank The Electrochemical Society for the F. M. Beckett award which made his participation in this work possible. Appreciation is also due Dr. E. H. Baker for his patient and invaluable guidance and Professor F. D. Richardson for his cooperation.

Manuscripts and Abstracts for Fall 1965 Meeting

Papers are being solocited for the Fall Meeting of the Society, to be held at the Statler-Hilton Hotel in Buffalo, N. Y., October 10, 11, 12, 13, and 14, 1965. Technical sessions probably will be scheduled on: Batteries (including Symposia on Charging Characteristics of Batteries and Characteristics of Electrodes during Charging), Corrosion, Electrodeposition (including Symposium on Thin Film Technology), Electronics-Semiconductors, Electrothermics and Metallurgy (including a Symposium on Zirconium and Its Alloys).

To be considered for this meeting, **triplicate copies of the usual 75-word abstract, as well as of an extended abstract of 500-1000 words** (see notice on page 29C of this issue), must be received at The Electrochemical Society, 30 East 42 St., New York, N. Y., 10017, *not later than May 17, 1965.* (Papers solely sponsored by the Corrosion Division **do not** require an extended abstract.) *Please indicate on 75-word abstract for which Division's symposium the paper is to be scheduled, and underline the name of the author who will present the paper.* No paper will be placed on the program unless one of the authors, or a qualified person designated by the authors, has agreed to present it in person. Clearance for presentation of a paper at the meeting should be obtained before the abstract is submitted. An author who wishes his paper considered for publication in the JOURNAL or ELECTROCHEMICAL TECHNOLOGY should send triplicate copies of the manuscript to the Managing Editor of the appropriate publication 30 East 42 St., New York, N. Y., 10017. Concerning papers to be published in the JOURNAL, see notice on per page charge on page 32C of this issue.

Presentation of a paper at a technical meeting of the Society does not guarantee publication in the JOURNAL or ELECTROCHEMICAL TECHNOLOGY. However, all papers so presented become the property of The Electrochemical Society, and may not be published elsewhere, either in whole or in part, unless permission for release is requested of and granted by the Editor. Papers already published elsewhere, or submitted for publication elsewhere, are not acceptable for oral presentation except on invitation by a Divisional program Chairman.
