

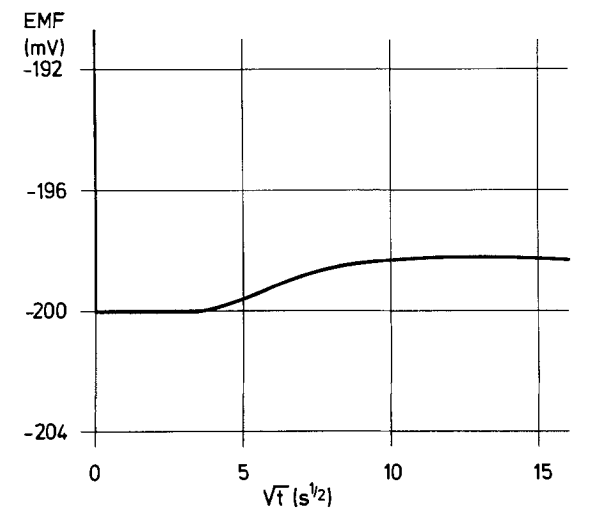

Fig. 10. Time response of emf after pressure decrease corresponding to Fig. 9.

That this is the case can be seen from the values given in Table II which were calculated with Eq. [12] and [13] for hole concentrations a factor 10 higher or lower than the standard value used in all calculations as the starting condition. We see that the transport numbers also contribute to make the error small at lower oxygen pressures; t_{ion} is closer to unity then.

So far the presence of a second phase has been introduced into the model in the form of a layer of mixed conductor properties at some distance from the surface only. The surface itself was considered free from such a contamination. In Fig. 11 and 12 the opposite case is shown; a mixed conductor layer of the same properties and thickness as before is now thought to be present on the surface only. Since the concentration

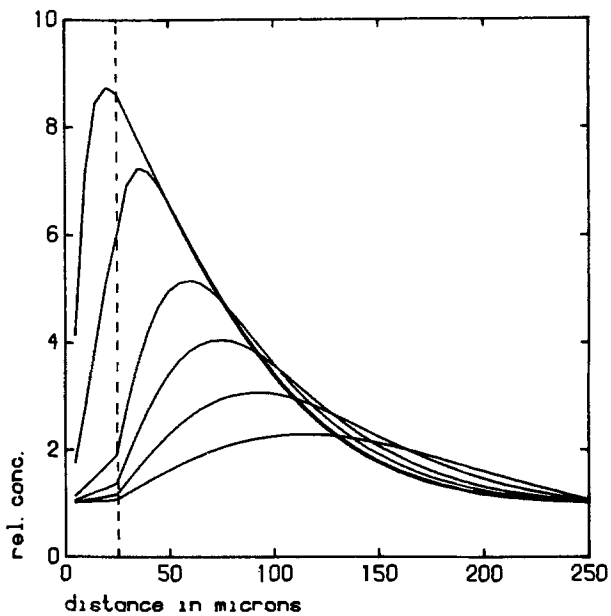

Fig. 12. Concentration profiles in electrolyte with mixed conductor region near the surface 2, 4, 10, 20, 40, 80, 160, and 320 sec after return to original pressure at left electrode following the last profile of Fig. 11.

changes occur in the mixed conductor region right from the beginning, the emf curves represented in Fig. 13 start with deviations from Nernst's law. These diminish in the course of time when the gradient flattens out, and the curves display a typical slow response. This contrasts with the overshoot behavior found before when the second phase is present in the interior of the sample. If the surface layer had been given such properties that no contribution was made to the emf at all (t_{ion} very small), it would have acted as a plain diffusion barrier. Qualitatively the emf response curves would not have changed in this case as calculations, not presented here, showed. The deviation from the ideal response can then be considered as the polarization of a surface layer belonging to the electrode. In fact the foreign layer on top of the electrolyte might be the electrode metal itself, which in that case is no longer considered as ideally porous. In this way the

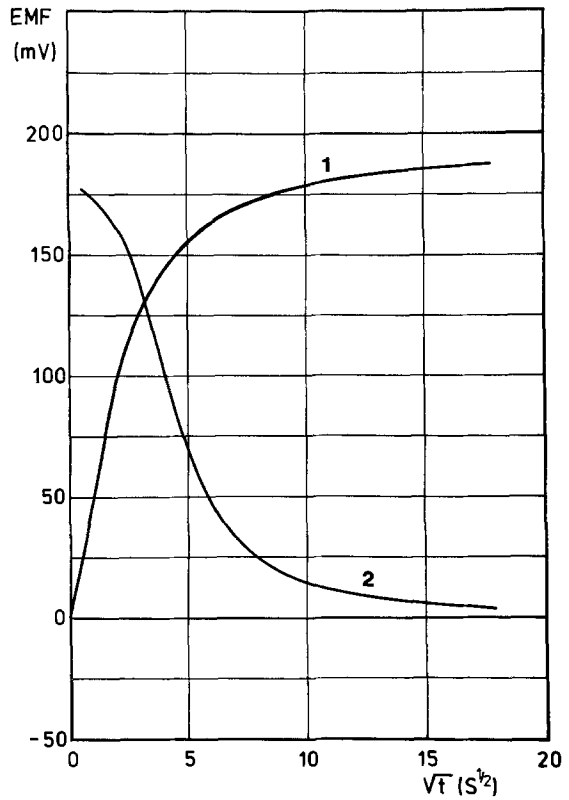

Fig. 13. Time response of emf after pressure increase, curve 1, and return to original, curve 2, corresponding to the profiles of Fig. 11 and 12. Curves of similar shape are found in the case that the surface layer is a mere diffusion resistance, for instance a metal (electrode).

nonreversible electrode qualitatively discussed before in connection with the oxygen uptake, can be introduced into our method of analysis in a quantitative manner.

The results given so far represent only a small part of the computations actually carried out. These covered a wider range of material parameters; also a pressure dependence corresponding to n-type conductivity (low pressure for zirconia) was included. However, since only changes in the magnitude but not in the character of the effects were encountered, the material was restricted to that given above. It demonstrates all typical features.

Discussion

The calculations presented in the previous section clearly illustrate several typical aspects of voltaic measuring cells with solid electrolytes, which, although recognized by those who have practical experience in building such galvanic cells, have never been discussed in much detail in the literature. One of the main points is that there is a large difference in the speed of the emf response and the speed by which processes inside the electrolyte lead to a steady state. That in satisfactorily working cells the output voltage reaches a stationary value very soon does not say that the diffusional process of adaptation of the interior of the electrolyte to the gas atmosphere has come to an end. In practical cells the latter process may take several hours. During the internal diffusion in zirconia, an oxygen flux is present in order to supply the amount of oxygen required for the readjustment of the local deviation from stoichiometry. This oxygen flux is a combination of a flow of oxygen vacancies and electron holes as described in the section Basic Equations. It gives rise to secondary effects, which may result in an emf deviating from Nernst's theoretical value.

We next discuss the following secondary effects: gas uptake (or release), electrode polarization, and intergrain polarization. To be able to do this we first discuss the parameters which determine the intensity of the flux in the final stationary state as well as during the transient.

In heterogeneous systems with only a small amount of second phase between the grains of solid electrolyte, the material flow is mainly determined by the latters' properties. Since t_{ion} is very close to unity, only the concentration and diffusion coefficient of the electronic charge carriers are relevant, see Eq. [3]. The effective diffusion coefficient equals the electronic one, so that no concentration dependence exists. It determines the time scale of the diffusion process.

The steady-state permeation flux density is proportional to the electronic component of the conductivity and can be written as (10)

$$j(\infty) = eD_h(h_o - h_{st})/l \qquad [16]$$

where the flux is expressed in terms of the equivalent electrical current.

The transient flow follows from the concentration profile existing at a certain moment. If we use the error function approximation, which is valid at short times (13) we have

$$h_\xi(t) - h_{st} = (h_o - h_{st}) \operatorname{erfc} \xi/(2\sqrt{D_h t}) \qquad [17]$$

By differentiation with respect to ξ and multiplication by eD_h we obtain the flux which for $\xi = 0$ corresponds to the gas uptake

$$j(t) = e\sqrt{D_h}\,(h_o - h_{st})/\sqrt{(\pi t)} \qquad [18]$$

We see a different functional dependence of the steady state, [16], and the transient, [18], gas flows. This difference allowed to determine both D_h and h separately in the past (10), so that their values, as given in Table I, can be used in the present calculations with faith.

Since the transient processes of gas uptake or release are large in magnitude and last over extended periods, they may be more disturbing in many practical applications than the steady-state penetration. Measures to reduce the latter, for instance by increase of the wall thickness l, see Eq. [16], or by the use of a guard atmosphere (14), therefore help only in such cases where only very slow pressure variations take place, so that the steady state is approached closely.

Gas uptake.—In the beginning it was stressed that the speed of response of cells is determined by the combination of the amount of gas required, and the ease by which the required amount can be supplied. So it depends on the medium to be measured, and on its connection to the galvanic cell, whether this gas uptake will give rise to measuring errors or not. If the geometry is unfavorable or the concentration low, so that the supply by diffusion is hampered, such errors occur. They are large in the beginning (see Fig. 6) but may be negligible in the steady state when only the steady-state gas permeation value counts. In such a case the speed of response is determined by the slow internal diffusion processes.

Electrode polarization.—The same type of slow response occurs if the limitation in the gas supply rate is not situated in the medium to be measured, but in the cell proper in the form of a polarizable electrode. This case was discussed in connection with Fig. 13. It explains the well-recognized experimental fact that the type, thickness, and way of application of the metal electrode are of utmost importance for the speed of response of the type of cells discussed (9, 15). In this respect it is not relevant if the polarization results from a diffusional or reaction kinetic type of limitation. From a practical point of view it is important to be aware of this requirement of reversibility. It means that the quality of electrodes for emf cells can be checked by electrical current techniques (9, 16, 17) such as voltage recording after a galvanostatic pulse

or impedance measurement at the low frequency end of the frequency domain.

Intergrain polarization.—Intergrain polarization gives rise to overshoot effects rather than to delay in the response, see Fig. 5. Such effects have been observed in practical cells with zirconia (9) and were originally appreciated as long termed creeping effects in the emf or drift in the zero voltage. The usually small effects seem irreproducible as long as it is not recognized that very long time constants are involved and that pressure variations of hours ago, or even of previous days if cells are cooled down in between, still exert their effect. These effects are typical results of the combination of the mixed conductor properties of the second phase between the grains and the chemical diffusion characteristics of the electrolyte proper. No effect is observed at all if the ionic transport number in the second phase is also near unity, or if the effective diffusion coefficient is much larger than that of the grains. In the latter case no concentration gradient is built up over the second phase. On the other hand, if the oxygen diffusivity is very low, the sample would show a high electrical resistance and would be disregarded as a suitable electrolyte right from the start. Thus, only if the ionic transport number is sufficiently different from zero to give a reasonable effective diffusion constant, Eq. [3], and at the same time sufficiently different from unity to yield emf errors, the phenomena are exhibited. It appeared that the silicate-rich phases that are often found in commercial zirconia samples have parameters in this range. The values used in the calculations, see Table I, were intentionally chosen to demonstrate the effect. From the discussion above it will be clear that the values are not as arbitrary as they might seem at first glance. This is also illustrated by the great change in the magnitude of the effects when a different average oxygen pressure range is used, modifying the parameters only slightly (Fig. 9 and 10).

Influence of doping.—From the previous discussion it is clear that if the flux is appreciable all types of polarization discussed (concentration, electrode, and intergrain polarization) are comparatively high. The question arises what material parameters can be varied to reduce the flux.

The electronic charge carrier concentration can in principle be modified by doping. However, it must be borne in mind that in many solid electrolytes this has been done already, with the aim to increase the concentration of mobile ionic defects. For instance, from the defect chemistry of stabilized zirconia it can be inferred that the adding of more acceptor-type dopants (Ca or Y for example) increases both the oxygen vacancy and the free hole concentrations (18). Consequently, at moderate oxygen pressures, which means p-type electronic conductivity, a smaller dopant concentration would be favorable for low fluxes in both the transient and the steady-state situation. However, in a pressure region with n-type electronic conductivity a high doping would be better because this would at the same time reduce the electron concentration and increase the vacancy concentration. Moreover, high doping also shifts the detection limit to lower pressures. The optimum doping thus depends on the requirements imposed by the type of application.

We now consider the influence of additional dopants of other elements, possibly inadvertently present as impurities, in concentrations low as compared to the main dopant discussed above.

Here, and also in electrolytes with a high intrinsic structural disorder, we do not expect an appreciable effect on the free carrier concentrations. However, such impurity content may be important for "trapping" phenomena. As was shown earlier (10) in zirconia, the capture of holes by multivalency impurity centers like Fe^{2+}, converting them into Fe^{3+},[3] reduces the diffusion coefficient $\tilde{D}$ by a large factor, the so-called "trapping" factor, which is proportional to the trap concentration. This is so because the deviation from stoichiometry now corresponds to the sum of both free and trapped electronic carriers and, at a given free carrier concentration, is consequently enlarged. The fluxes are still determined by the free carriers and their concentration gradients and are therefore not affected by trapping phenomena. Since more material has to be transported (gas absorbed) by fluxes of the same magnitude, this automatically means slowing down of the transient processes under influence of trapping.

Concluding, it can be stated that the use of "purer" zirconia, which in this context means containing fewer traps, results in cells exhibiting the same steady-state oxygen permeation rate. If transient effects are observable they have the same magnitude but occur on a shorter time scale.

[3] Free ion notation is used here. In Kroger and Vink's defect notation the centers should be indicated by Fe_{Zr}^{2-} and Fe_{Zr}^{1-}, respectively.

Conclusion

Although the discussion referred mainly to stabilized zirconia in a certain oxygen pressure range, the method of calculation, as well as the physicochemical interpretation, have a much wider scope. They can be extended to systems with any other type of solid electrolyte for which data on defect concentrations and diffusion coefficients are available. We think of sensors using silver or lead halides, calcium or lanthanum fluoride, etc.

In all such systems a small electronic conductivity component gives rise to a material (gas) flux which, depending on electrode and intergrain properties, may cause secondary effects observable in the emf behavior. In the transient situation this flux is higher than in the steady state, so that deviations from the ideal emf are more pronounced shortly after abrupt pressure changes. Such deviations take the form of a slow response when the electrodes show some degree of polarization; overshoot behavior can be expected from intergrain phases with mixed conductor properties.

The time behavior of these secondary effects is determined by that of the flux and thus is a function of the solid-state properties of the electrolyte material itself. These properties depend on purity and doping. The magnitude of the secondary effects depends also on the special properties of the electrode or the intergrain phase.

Kinetics of the Thermal Oxidation of Silicon in O_2/HCl Mixtures

D. W. Hess* and B. E. Deal*

Fairchild Camera and Instrument Corporation, Research and Development Laboratory, Palo Alto, California 94304

ABSTRACT

The thermal oxidation kinetics of silicon in O_2/HCl mixtures were studied as a function of HCl concentration, oxidation temperature, and silicon orientation, and the results compared to those obtained for oxidation of silicon in dry oxygen. The effective parabolic rate constant B generally showed a linear increase with increasing HCl concentration, while the effective linear rate constant B/A showed essentially no increase after a substantial increase for a 1% HCl addition. Possible explanations for such effects are considered. Activation energy plots for the rate constants were not linear, suggesting that several reaction mechanisms may be operative during silicon oxidation in O_2/HCl mixtures.

One of the most significant developments in the passivation of silicon surfaces during the fabrication of integrated circuits over the past several years has been the addition of a chlorine species during thermal oxidation. It has been demonstrated (1-3) that such additions result in improved threshold stability and increased dielectric strength. In addition, it has been observed that chlorine additions increase the rate of silicon oxidation (4-6), but extensive data for widely varying oxidation conditions have not been reported. Therefore, in this investigation the thermal oxidation kinetics of silicon in O_2/HCl mixtures are characterized as a function of oxidation temperature, HCl concentration, and silicon orientation, and the results are compared to those obtained from silicon oxidations performed in a dry oxygen atmosphere.

Experimental

The silicon wafers used in this study were 4-6 Ω-cm, phosphorus doped, with (100) and (111) orientations. The cleaning procedure as well as the oxidation system utilized has been previously described (7). The HCl was of 99.99% purity and was used as obtained from the manufacturer. The oxygen and nitrogen were from a liquid source and were further dried and filtered by passage through a Matheson Model 451 gas purifier. The wafers were rapidly pushed into the furnace in oxygen at the oxidation temperature, preheated for 15 sec, and a certain volume percent HCl added. After the allotted oxidation time, the O_2/HCl was turned off, and after a 2 min nitrogen purge, the wafers were pulled out of the furnace at the rate of ~15 cm/min.

The flowmeters utilized in this investigation were calibrated as described in Ref. (7). For the HCl, the flowmeters were calibrated with nitrogen, and the flows subsequently corrected for the density and viscosity of HCl.

The oxide thicknesses were measured with a Rudolph Model 436-200E ellipsometer with a helium-neon laser source. The reproducibility of the oxide thickness over the range investigated was ±3%.

The contamination level in the oxides was determined by bias-temperature stressing MOS capacitor structures under fields of $+5 \times 10^5$ and -3×10^5

* Electrochemical Society Active Member.
Key words: HCl/O_2 oxidation, silicon oxidation kinetics, silicon dioxide.

V/cm at 300°C for 3 min. The mobile ion charge density was typically found to be $<2 \times 10^{10}$ cm^{-2}.

Data Evaluation

The oxidation rate data were evaluated using the general relationship for the thermal oxidation of silicon as developed by Deal and Grove (8)

$$x_o^2 + Ax_o = B(t + \tau) \quad [1]$$

where x_o = oxide thickness in μm, A = constant in μm, B = parabolic rate constant in μm^2/hr, B/A = linear rate constant in μm/hr, t = oxidation time in hr, and τ = correction factor which accounts for an observed initial accelerated growth rate in dry oxygen, in hr.

Since the parabolic rate constant B depends on the partial pressure of oxidant in the oxidizing ambient, the solubility of the oxidizing species in SiO_2, and the effective diffusion coefficient of the oxidizing species in SiO_2 (8), there should be no variation of B with silicon orientation. On the other hand, the linear rate constant B/A involves the reaction rate constants at the SiO_2 surface and at the silicon surface, so that any orientation dependence of the oxidation rate should appear in this term via the constant A.

Since the method of analysis utilized depends on the correction factor τ, which is determined by extrapolation (8) and is thus prone to some error, oxidation times at least three times greater than the τ value for any set of oxidation conditions were generally used for the determination of B and B/A. In this way, any error in τ should have little effect on the calculated values of B and B/A.

Activation energies were obtained by fitting the data for B and B/A to an Arrhenius equation of the form

$$k = k_o e^{-E_a/RT} \quad [2]$$

where E_a = activation energy, T = temperature in °K, and R = gas constant.

Results and Discussion

Rate constants.—Log-log plots of oxide thickness *vs.* oxidation time for the thermal oxidation of (100) and (111) oriented silicon in O_2/HCl mixtures at temperatures of 900°, 1000°, and 1100°C, are shown in Fig. 1, 2, and 3, respectively. It is clear from the figures that the (111) silicon always oxidizes faster than does the (100). Also, it can be seen that the effect of HCl addition is to increase the oxidation rate relative to oxidation in dry oxygen. In particular, a relatively large increase in the oxidation rate occurs with the initial 1% HCl addition. Subsequent additions have a somewhat smaller effect, but the over-all rate is systematically increased. In addition, it can be observed in Fig. 1-3 that the over-all increase in oxide thickness for a particular oxidation time upon increasing the HCl concentration from 0 to 10%, is larger for (100) than for (111) oriented silicon. Although we can presently offer no explanation for this observation, it may be related to the silicon etching phenomenon mentioned below. It should be noted that very few data points are plotted for oxidations carried out at 1100°C with HCl concentrations greater than 1%. This is due to silicon etching and oxide bubble formation which occurs at the Si-SiO_2 interface during silicon oxidation with O_2/HCl mixtures at 1100°C (5, 6, 9, 10).

In order to separate the effects of HCl on the parabolic B and linear B/A rate constants, and thus obtain some indication of the role HCl plays in silicon oxidation, Eq. [1] was utilized. It should be mentioned that during the determination of τ, x_i was assumed to be essentially constant at 160 ± 40Å for all oxidation conditions investigated ($x_i = x_o$ at $t = \tau$). Although x_i should decrease with HCl addition due to water vapor generation as per the reaction of O_2 and HCl

$$4HCl + O_2 \rightarrow 2H_2O + 2Cl_2 \quad [3]$$

the extrapolations performed to determine x_i and thus τ could not detect small changes in x_i. Nevertheless, since τ depends upon x_i, B, and B/A, a decrease in τ was observed upon HCl addition, probably in part as a result of water generation, since x_i and therefore τ are zero for oxidation in a steam ambient (8).

The results of least squares analyses on the data shown in Fig. 1-3 are summarized in Fig. 4 and 5, which are semilog plots of the effect of HCl concentration on the parabolic and linear rate constants, respectively. It should be noted that the rate constants generated via Eq. [1] and plotted in Fig. 4 and 5 are effective rate constants, in that they represent the combined effects of oxygen, water, and chlorine species on B and B/A.

Figure 4 shows that essentially no orientation effect is observed in the parabolic rate constant B, in accordance with theory. Also, increasing the HCl concentration above 1% results in a linear increase in B (the plots are put on a semilog scale for convenience). The increase in B going from 0 to 1% HCl in dry oxygen is not as consistent among the three temperatures, however. For 1000° and 1100°C, a large increase in B due to 1% HCl addition occurs, whereas this trend is not observed at 900°C. These observations are in agreement with previous work which showed a linear increase of B with 0-9% HCl addition at 900°C (6) and a large increase in B due to 1% HCl addition at 1100°C (5). Presumably, the large increase in B, as well as the linear increase with subsequent HCl additions are at least in part due to water generation as described in Eq. [3], since it is well known that small amounts of water in oxygen increase the thermal oxidation rate of silicon relative to that of dry oxygen (11). However, as pointed out by van der Meulen and Cahill (6), gas phase thermodynamic equilibrium calculations indicate that the amount of water generated via Eq. [3] cannot account for the observed increase in oxidation rate. This is consistent with the published results that Cl_2 addition to a dry oxygen atmosphere yields a considerably higher silicon oxidation rate than the same volume percent HCl addition at 1150°C (14), suggesting that the chlorine species, rather than the water generated, may be primarily responsible for the increase in oxidation rate at high temperatures. However, since it is difficult to obtain Cl_2 which contains less than 3 ppm water, some effect, although small, would be anticipated from the water present.

In regard to the above argument concerning the amount of water generated via Eq. [3], it should be pointed out that thermodynamic calculations such as those in Ref. (6) give only the idealized gas phase equilibrium conditions. The presence of a surface

(especially one such as SiO_2 which is useful for catalytic purposes) could shift the equilibrium, and thus alter the amount of water generated and incorporated into the oxide surface.

Some insight can be gained into the silicon oxidation regime affected by water or chlorine (as generated via Eq. [3]) from consideration of the definitions of the parabolic (B) and the linear (B/A) rate constants. The definitions are as follows (8)

$$B \equiv 2D_{\text{eff}}C^*/N_1 \qquad [4]$$

where D_{eff} = effective diffusion coefficient, C^* = maximum solubility of oxidant in oxide, and N_1 = number of oxidant molecules incorporated into a unit volume of oxide

$$B/A \equiv \frac{C^*}{N_1\left(\frac{1}{k}+\frac{1}{h}\right)} \qquad [5]$$

where k = surface reaction rate constant, and h = gas phase transport coefficient.

Inspection of these definitions along with comparison of Fig. 4 and 5 suggests that the monotonic increase in B with HCl concentration is related to the effective diffusion coefficient D_{eff}, since this term does not appear in the expression for B/A. Likewise, it appears that the rapid initial increase in B and B/A might be related to the solubility of the oxidizing species in the oxide film. Although the latter conclusion could be explained by water addition, this explanation would not account for the increase in D_{eff}, since this parameter is known to decrease with water addition (8).

In light of the above arguments, the gradual increase of the parabolic rate constant with increasing HCl concentration could be partially related to a chlorine species, since it has been established that a higher concentration of chlorine is incorporated into the silicon dioxide film as the HCl concentration and/or the silicon oxidation temperature are increased (12). Consequently, it might be anticipated that increasing the chlorine concentration would cause the SiO_2 lattice to be strained (especially near the interface), thus allowing diffusion of oxidant to occur more easily, and thereby increase the oxidation rate as observed in the oxidation of heavily boron-doped silicon (13). Since the ionic radius of boron when substituted for silicon in a silicon lattice (which should be close to the radius of boron substituted for silicon in SiO_2) is 0.88Å (14), while the ionic radius of chlorine is 1.8Å (15), it would be expected that the SiO_2 lattice expansion would be even greater in the case of chlorine as compared to boron. This speculation is also consistent with the previously mentioned observation that Cl_2 additions result in higher silicon oxidation rates than do HCl additions at high temperatures, since more chlorine is apparently incorporated into the SiO_2 with O_2/Cl_2 than with O_2/HCl mixtures (12).

Inspection of Fig. 5 reveals a strong orientation effect on the linear rate constant B/A, which apparently decreases with increasing temperature. This observation is discussed in more detail in the next section. Also, as generally found for B, an initial rapid increase in B/A is observed upon increasing HCl concentration in the oxygen atmosphere from 0 to 1%. However, further increase of the HCl concentration resulted in essentially no change in B/A. Although an explanation for these observations is not apparent, it is conceivable that the breaking of Si-Si bonds could be promoted by etching of the silicon substrate which is known to occur with the use of HCl (5, 6, 9, 10) so that an increase in the linear rate constant might result. However, increased HCl concentrations should then further increase B/A, unless an equilibrium between oxidation and etching is established. Clearly, additional investigation of this phenomenon is needed if we are to understand the mechanism involved. It should be mentioned that preliminary results obtained in this laboratory with O_2/Cl_2 oxidation atmospheres substantiate the above interpretation, in that relatively large increases in B/A due to Cl_2 addition at 1100°C were observed, with considerably smaller increases noted for B.

Activation energies.—An Arrhenius plot of the parabolic rate constant B for the thermal oxidation of silicon in O_2 and several O_2/HCl mixtures is shown in Fig. 6. Since essentially no orientation effect was observed for B, only the (111) orientation is plotted. A least squares analysis of the data for dry oxygen (0% HCl) gave a value of 1.2 eV (28 kcal/mole), which agrees well with previously determined values for the thermal oxidation of silicon in dry oxygen (8, 16), as well as for the diffusivity of oxygen through fused silica (17). It can be seen from Fig. 6 that HCl addition to the dry oxygen atmospheres resulted in a convex curvature (relative to dry oxygen oxidation) of the Arrhenius plot.

An Arrhenius plot of the linear rate constant B/A for the thermal oxidation of silicon in O_2 and several O_2/HCl mixtures is shown in Fig. 7. A least squares analysis of the data for dry oxygen (0% HCl) oxidation of (111) oriented silicon yielded a value of 2 eV (47 kcal/mole), which is in close agreement with the energy required to break a Si-Si bond (18). However, determination of the activation energy for (100) oriented silicon affords two choices as seen in Fig. 7. If the data from 900° to 1200°C are analyzed, and the low temperature points neglected due to less certainty of the data which might result from the long oxidation times necessary to obtain kinetic data at these low temperatures, a value of 2.5 eV (57 kcal/mole) is obtained, *i.e.*, an increase of ~25% over that for (111). This increase was predicted by Ligenza from consideration of steric hindrance in the (100) and (111) planes of silicon during thermal

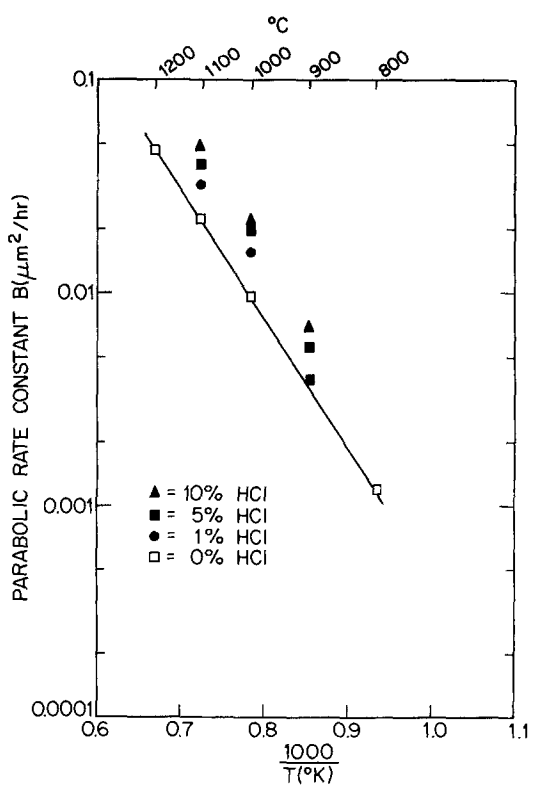

Fig. 6. Arrhenius plots of the parabolic rate constants for silicon oxidized in various O_2/HCl mixtures. Silicon orientation is (111).

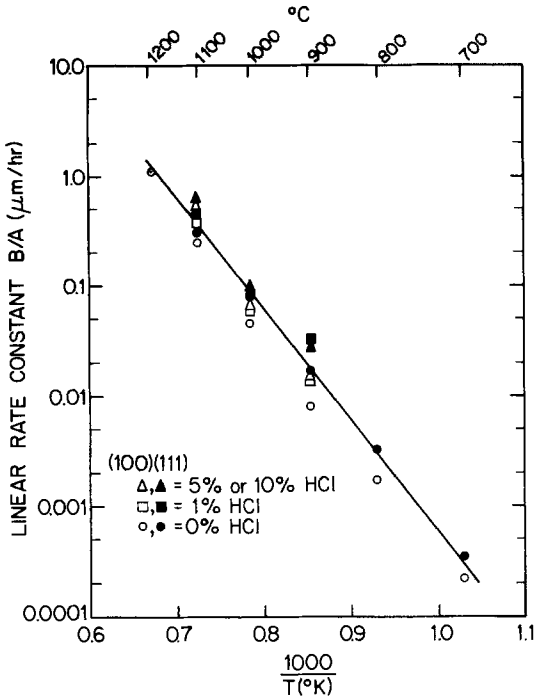

Fig. 7. Arrhenius plots of the linear rate constants for (111) and (100) oriented silicon oxidized in various O_2/HCl mixtures.

oxidation (19). On the other hand, if the data from 700° to 1200°C are analyzed, the 900°, 1100°, and 1200°C points could be considered as scatter from a line drawn parallel to the one for (111) orientation, passing through the 700°, 800°, and 1000°C points, thereby resulting in the same activation energy as (111) oriented silicon. Indeed, some faith could be put in such an assumption, since the 700°C data give B/A directly from a plot of x_o *vs.* t, which was found to be linear for this temperature. Thus, one could argue that the higher temperature analyses might be in error due to the inaccuracy in determining A from a plot of x_o *vs.* $(t + \tau)/x_o$. The slopes of these lines (B) are quite large, therefore a small change in the slope would shift the intercept (A), and thus B/A, considerably. At present, it is not known which of the above alternatives is the better one.

As in the case of the parabolic rate constant, the Arrhenius plot of the linear rate constant for HCl/O_2 mixtures (Fig. 7) is curved. In this instance, the curvature is concave relative to dry oxygen oxidation. Upon consideration of Eq. [3], it is not surprising that Arrhenius plots of the rate constants for the oxides grown in HCl atmospheres should result in curved lines. Certainly more than one activated process is occurring, *e.g.*, the oxidation due to oxygen and water vapor, along with several possible effects due to chlorine, as mentioned above. As the oxidation temperature is changed, the relative importance of these activated processes may also change. Thus it becomes necessary to separate out the effects of water and chlorine on the silicon oxidation rate. Toward this end, experiments are currently being performed to investigate the oxidation rate of silicon in O_2/H_2O and O_2/Cl_2 mixtures.

Summary

The thermal oxidation kinetics of silicon in O_2/HCl mixtures were characterized as a function of HCl concentration, oxidation temperature, and silicon orientation, and in each instance were compared to results obtained for the oxidation of silicon in dry oxygen. The effective parabolic rate constant B was found to increase linearly with HCl additions, except for an initial large increase when comparing oxidation in dry O_2 to a 1% HCl/O_2 mixture at 1000° and 1100°C. The observed increase in B could be due in part to water generation from the reaction of O_2 and HCl which would increase the solubility of oxidant in the oxide and in part to a straining of the SiO_2 lattice due to the presence of chlorine. The linear rate constant B/A showed an initial increase due to the addition of 1% HCl to the dry oxygen atmosphere, but further HCl additions had essentially no effect on B/A. Such behavior might be related to enhanced Si-Si bond breaking due to etching by a chlorine species. Arrhenius plots of the rate constants for the O_2/HCl oxidations were not linear, suggesting that more than one process was occurring during silicon oxidation in these mixtures.

Effect of Chlorine on the Negative Bias Instability in MOS Structures

Dennis W. Hess*

Fairchild Camera and Instrument Corporation, Research and Development Laboratory, Palo Alto, California 94304

ABSTRACT

The effect of the chlorine concentration in silicon dioxide films thermally grown in HCl/O_2 or Cl_2/O_2 atmospheres on the negative bias instability of the effective oxide charge ($Q_{ss} + N_{st}$) has been investigated at elevated temperatures. Also considered were the effects due to silicon orientation, silicon conductivity type, and silicon oxidation temperature. The effective oxide charge increased with increasing chlorine concentration, the Cl_2/O_2-grown oxides showing larger increases than the HCl/O_2-grown oxides. Distortions in the capacitance-voltage curves were found to be more prevalent for structures prepared using n-type silicon substrates than for p-type. For the (100) oriented samples, essentially the entire increase observed was eliminated by a heat-treatment at 500°C in nitrogen with aluminum present on the oxide surface, whereas only 90% of the effect was removed in the case of (111) oriented wafers which underwent the same treatment.

One of the current trends in the manufacture of silicon integrated circuits is toward thinner gate dielectrics (1). This trend necessitates improved breakdown characteristics, particularly for the most widely used gate dielectric, silicon dioxide. In order to attain the dielectric strength needed to meet these requirements, as well as to getter and passivate against mobile ions, a chlorine species is often added to the silicon oxidation atmosphere (2, 3). Such additions typically result in a chlorine concentration "peak" in the silicon dioxide near the $Si-SiO_2$ interface (4). Thus, it might be anticipated that the density of certain oxide charges originating in the region near the silicon surface could be affected by the chlorine species. For instance, the negative bias instability observed primarily with p-channel MOS devices at slightly elevated temperatures has been well characterized in the case of thermal oxides without chlorine incorporation (5-11). A proposed model for this instability involves an increase in fixed oxide charge (Q_{ss}) and in interface state density (N_{st}) arising from additional bond breakage at the already strained interfacial region (10,12). A large concentration of chlorine near the $Si-SiO_2$ interface could enhance such an effect, and, indeed, flatband shifts have been found to increase with increasing chlorine concentration in the thermally grown silicon dioxide layer of MOS capacitor structures during room temperature stress measurements under negative bias (4). The present study characterizes the effect of chlorine concentration on this negative bias instability at elevated temperatures. The effects of silicon orientation, silicon conductivity type, and silicon oxidation temperature were also considered.

Experimental

The silicon wafers used in this investigation were 4-6 Ω-cm phosphorus or boron doped, with (100) and (111) orientation. The cleaning procedure, as well as the oxidation system utilized, has been previously described (13). The HCl and the Cl_2 were of 99.99% and 99.9% purity, respectively, and were used as obtained from the manufacturer. The wafers were rapidly pushed into the furnace in oxygen, preheated for 15 sec, and a certain volume percent (v/o) HCl or Cl_2 was added. After oxidation at 1100°C to a thickness of ~1100Å, the O_2/HCl or O_2/Cl_2 flow was discontinued, the wafers were annealed in nitrogen for 15 min, and were subsequently allowed to cool in nitrogen.

After the anneal, the oxide thicknesses were measured using a Rudolph Model 436-200E ellipsometer with a helium-neon source. The oxides were then stripped from the backs of the wafers. Aluminum dots (0.076 cm diameter) were evaporated through metal masks, and the backs of the slices were coated with aluminum, using an unheated-substrate electron beam evaporation. The wafers were then annealed for 5 min in dry nitrogen at 500°C, and the MOS capacitors were evaluated using the capacitance-voltage technique at

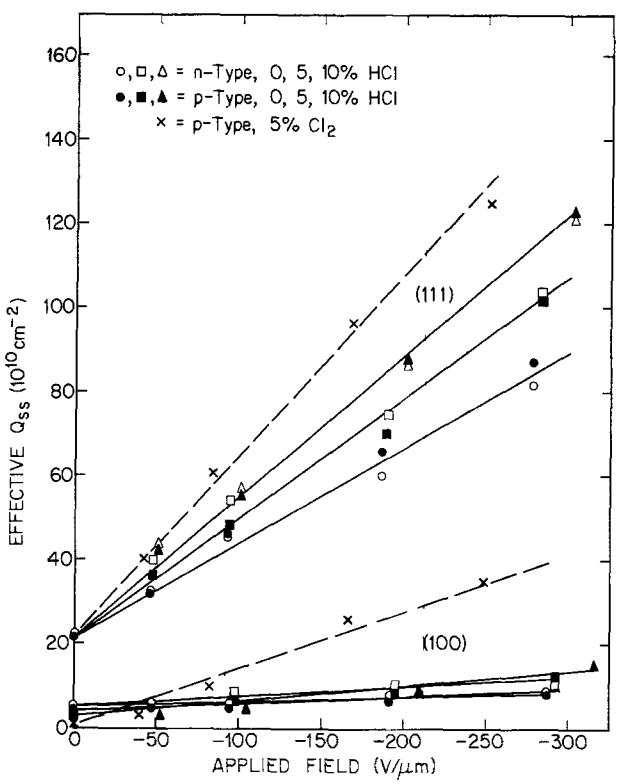

Fig. 1. Saturation values of effective oxide charge ($Q_{ss} + N_{st}$) as a function of applied negative fields for oxides thermally grown on (100) and (111) oriented silicon at 1100°C in various chlorine-containing dry oxygen atmospheres. Solid lines are for oxides grown in HCl/O_2 atmospheres, while the dotted lines are for oxides grown in Cl_2/O_2 atmospheres. The ($Q_{ss} + N_{st}$) value at zero applied field is the value prior to negative bias stressing.

Key words: chlorine oxidation, negative bias instability, oxide charge, interface states, MOS.

a frequency of 1 MHz (14). The work function differences for n- and p-type silicon were taken to be +0.1 and −0.6V, respectively (15). The mobile ionic contamination (Q_o) present in the samples was found to be less than 3×10^{10} cm^{-2} in all cases.

The MOS capacitor structures were stressed under negative fields at 400°C for 5 min in air [which was a sufficient time for the fixed charge (Q_{ss}) and interface state density (N_{st}) to reach saturation], and the samples were cooled under bias. This latter procedure was found to be necessary, since even a very short time (<5 sec) at 400°C without bias resulted in a decrease of effective Q_{ss}, *i.e.*, $Q_{ss} + N_{st}$. The reproducibility of the effective Q_{ss} values was found to be $\pm 3 \times 10^{10}$ cm^{-2}.

Results and Discussion

A plot of the effective Q_{ss} *vs.* applied negative field for oxides grown in 0, 5, or 10 v/o HCl or 5 v/o Cl_2 is shown in Fig. 1. Only results for p-type silicon substrates in the case of oxides grown in O_2/Cl_2 atmospheres are plotted in Fig. 1 due to distortions observed in the *C-V* characteristics for n-type samples. This observation is discussed in more detail below. For the (111) silicon orientation, it may be observed that the negative bias instability increases with HCl concentration, and is even greater for 5% Cl_2 than for 10% HCl atmospheres. Although this trend is not as apparent for (100) oriented substrates, it is still present as can be seen in Fig. 2-5. The negative field effect observed is consistent with the breaking of Si-Si or Si-O bonds near the interfacial region, since the presence of chlorine in this region might be expected to promote bond breaking due to a straining of these bonds. Thus, larger concentrations of chlorine show larger effects. Also, it is not surprising that O_2/Cl_2 atmospheres result in a larger effect than O_2/HCl atmospheres, since apparently more chlorine is incorporated in the oxide in the case of O_2/Cl_2 (4). In addition, it should be noted that very little difference is observed between n- and p-type silicon so that the major effect is due to chlorine concentration, at least when the oxides are grown at 1100°C. When the oxides were grown at 1000°C, the chlorine concentration was found to have little or no effect. In this instance, the negative bias instability as measured by the flatband shift was consistently 10-15% less for n- than for p-type silicon. Such behavior is probably related to the types of interface states present on n- and p-type silicon surfaces. This point will be discussed further in a later section. In any case, the small effect observed at 1000°C upon chlorine addition is most likely due to the smaller concentration of chlorine in SiO_2 films grown at 1000°C than in those grown at 1100°C (4).

It can be seen in Fig. 1 that the negative bias instability is considerably less for (100) oriented silicon surfaces than for (111). This is in agreement with previous data which have demonstrated the dependence of this effect on initial fixed oxide charge (and thus generally on silicon orientation) and gives further indication that this phenomenon is related to bond breaking (8-12).

As indicated above, interface state generation can play a large role in the negative bias instability. Insight into the importance of these states can be gained from inspection of Fig. 2-5. Figures 2 and 3 show the capacitance-voltage (*C-V*) curves resulting from the negative bias stressing of MOS capacitor structures fabricated on (100) n- and p-type silicon substrates, respectively, where the oxides were grown at 1100°C in a 10% HCl/O_2 atmosphere. Figure 2 shows that

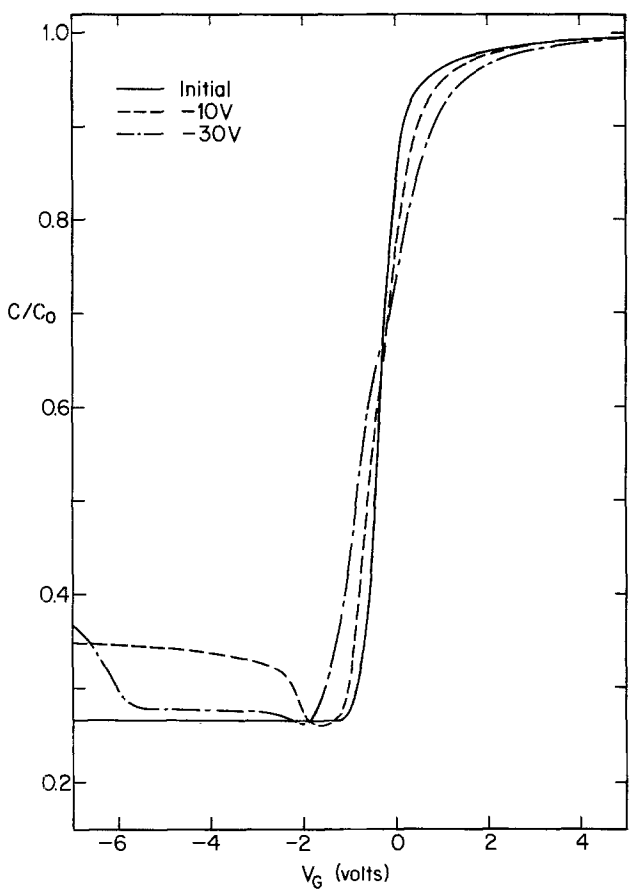

Fig. 2. Capacitance-voltage plots after negative bias temperature stress at the indicated voltages. The voltage applied to the aluminum electrode is V_G and the oxide capacitance is C_o. Oxides were grown at 1100°C in 10% HCl/O_2 on (100) oriented n-type silicon. The oxide thickness is 0.1 μm.

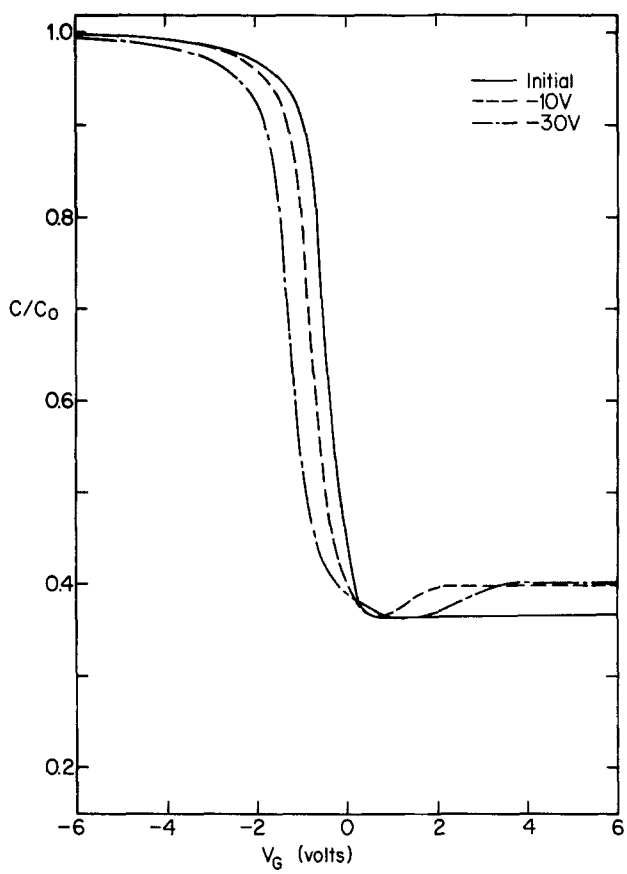

Fig. 3. Capacitance-voltage plots after negative bias temperature stress at the indicated voltages. Oxides were grown at 1100°C in 10% HCl/O_2 on (100) oriented p-type silicon. The oxide thickness is 0.1 μm.

essentially no flatband shift ($V_{FB} \simeq 0.7\ C/C_o$) occurs with the n-type substrate during bias temperature stressing, but the distortion of the C-V curves increases with applied field. However, the p-type structure (Fig. 3) exhibits a more parallel shift in the C-V characteristics, with some rounding of the curve near inversion still apparent. Although an explanation of these observations is not obvious, a qualitative description can be invoked if one assumes that at least some of the interface states formed by negative field stressing are acceptor states (electron traps) in the upper half of the silicon bandgap. These states would thus be negatively charged for n-type silicon and uncharged for p-type due to the location of the Fermi level. Therefore, these interface states would generate a shift to positive voltage (negative interface charge) for n-type silicon which would oppose any donor states (hole traps) and/or Q_{ss} generated, and a distortion of C-V curve would result. In the case of p-type silicon, the states in the upper half of the bandgap would be uncharged, so only a shift to negative voltage would be observed in the C-V curve.

It may also be noted that the inversion portion of the C-V curves has generally increased with increasing applied negative fields. This is probably due to the increased number of interface states created by the bias-temperature stress, which could act as generation sites for minority carriers.

Preliminary measurements of the interface state density utilizing the Gray-Brown technique (16) at a frequency of 1 MHz were performed on both (100) and (111) oriented n- and p-type silicon substrates which had oxides grown in 10% HCl/O_2 or 5% Cl_2/O_2 at 1100°C, and were stressed at 400°C under a negative field of ~300 V/μm. In each case, the samples showed very low concentrations of interface states ($<5 \times 10^{10}$ cm^{-2}). These results suggest that the energy levels of the interface states observed in these experiments by distortions in the C-V curves, are not located close to the silicon conduction or valence band edges. Also, the low concentration of interface states observed may be consistent with charge trapping in the oxide which occurs where bonds have been broken by negative bias-temperature stressing.

A few experiments were carried out in which positive bias (corresponding to ~200 V/μm) was applied to the MOS capacitors at 400°C. Even on (111) oriented substrates, only a very small (<0.4V) flatband shift toward positive voltage was observed, and this shift was independent of the silicon conductivity type or chlorine concentration. However, small distortions of the C-V curve were noted, primarily near the inversion point.

Figures 4 and 5 show the C-V curves resulting from the negative bias stressing of MOS capacitors fabricated on (100) n- and p-type silicon, respectively, where the oxides were grown at 1100°C in a 5% Cl_2/O_2 atmosphere. Clearly, the trends observed are identical to those for HCl oxides (Fig. 2 and 3), but are considerably more pronounced. As indicated above, this is in agreement with the larger concentration of chlorine incorporated into Cl_2/O_2-grown oxides than into HCl/O_2-grown oxides (4).

In order to determine the approximate portion of the shift in the C-V curves observed under negative bias-temperature stressing which is due to interface states, and/or oxide trapped charge which is annealable, some of the MOS capacitors were stressed under −30V at 400°C and the C-V curves recorded. The samples were subsequently heat-treated in nitrogen at 500°C for 5 min with the aluminum dots present on the oxide (anneal), since such treatments are known to reduce

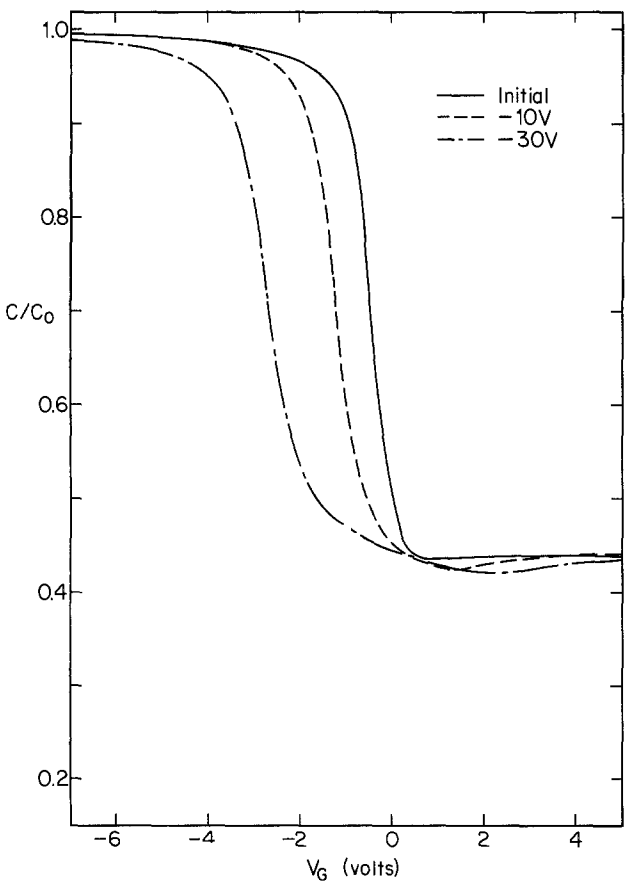

Fig. 4. Capacitance-voltage plots after negative bias temperature stress at the indicated voltages. Oxides were grown at 1100°C in 5% Cl_2/O_2 on (100) oriented n-type silicon. The oxide thickness is 0.12 μm.

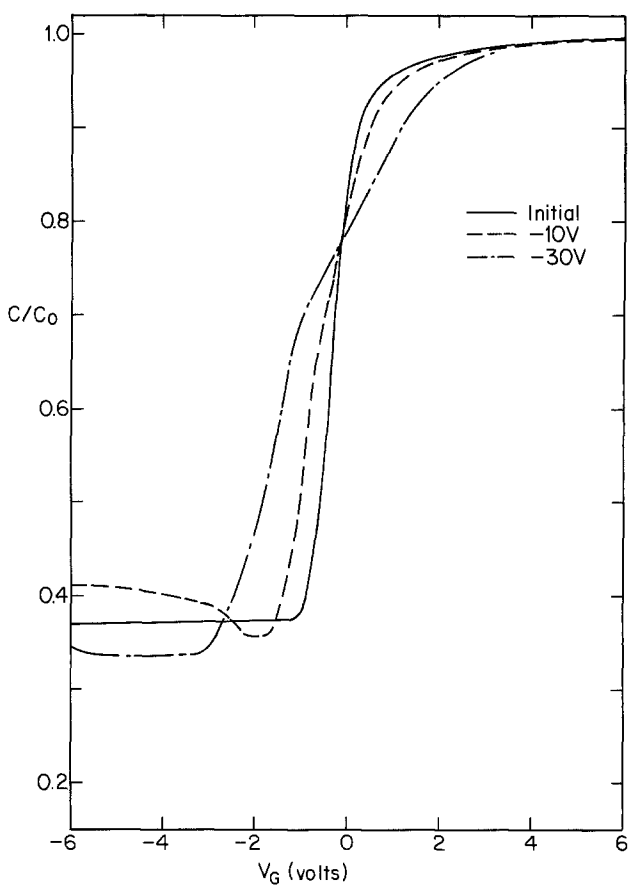

Fig. 5. Capacitance-voltage plots after negative bias temperature stress at the indicated voltages. Oxides were grown at 1100°C in 5% Cl_2/O_2 on (100) oriented p-type silicon. The oxide thickness is 0.12 μm.

the intrinsic state density (17). The resultant C-V curves indicated that essentially all of the distortions and flatband shifts had been eliminated on (100) capacitors, while ~10% of the flatband shift remained for the (111) capactiors, but all distortions had been eliminated. Also, it should be mentioned that the flatband shift was not appreciably changed with an additional 10 min N_2 treatment at 500°C. These results were independent of silicon type or chlorine concentration.

Summary

It has been demonstrated that the negative bias instability observed on MOS capacitors at elevated temperatures increases with increasing chlorine concentration in the thermally grown oxide. The effect was larger for oxides grown in Cl_2/O_2 atmospheres than for oxides grown in HCl/O_2 atmospheres. Such observations are consistent with a bond-breaking model of this phenomenon. Distortions of the C-V curves which were indicative of interface state generation and/or oxide trapped charge were most prevalent for n-type silicon, but were also observed on p-type substrates. For the structures fabricated on (100) oriented silicon, essentially the entire effect of the negative bias instability could be eliminated by a heat-treatment in nitrogen at 500°C with aluminum present on the oxide surface. However, only 90% of this effect was removed in the case of (111) oriented silicon wafers which underwent the same heat-treatment.

Photoconductive CdS Films by a Chemical Bath Deposition Process

N. R. Pavaskar, C. A. Menezes, and A. P. B. Sinha

National Chemical Laboratory, Poona 411008, India

ABSTRACT

A new technique for the preparation of CdS thin films by chemical bath deposition is described. The CdS films prepared by this method have many of the advantages of those made by the spray deposition method, such as the ease of coating large areas and simplicity of the process. The stoichiometry is easy to maintain in both these methods. The films are formed on rotating substrates from a bath containing cadmium salt in a complex form. Electrical, photoconducting, and optical properties such as I-V characteristics, decay of photoconductivity, spectral response of photoconductivity, and optical absorption were studied. Addition of cations like Ag, Cu, In, and Zn to the deposition bath makes the films amorphous. Such amorphous layers have a density of state of the order of 10^{19}-10^{20}/cm^3/eV near the Fermi level, as determined by photodecay and field effect measurements. The films produced are strong, adhering tightly to the substrates, show little or no degradation, and are photosensitive as deposited.

Current interest in direct energy conversion devices has led to renewed research in the area of materials for such devices. In the context of the need for a simple yet reliable technique for producing large area cells of CdS of high stoichiometry, this report on the preparation of chemically bath deposited films would appear to be topical. Various factors affecting the deposition process, as well as the effect of addition of cations, have been studied in order to understand the process of deposition and thus to improve the characteristics of the films.

Key words: amorphous CdS, photoconductive decay, field effect.

We have attempted to give in some detail the procedures followed by us for the preparation of the chemically bath deposited films. The basic outline of the method is that described in Ref. (1). We have standardized the conditions under which these films can be produced with a high degree of reproducibility with respect to thickness, structure, and electrical behavior.

We must stress the fact that the chemical bath deposition technique described here is substantially different from the better known chemical spray deposition technique of Chamberlin and Skarman (2).

The chemical bath deposition technique, well known for its use in forming films of lead chalcogenides, involves a slow film deposition from a solution which contains cadmium in a complex form and an organic sulfur-containing reducing agent which react to give cadmium sulfide in thin film form. Two essentials mark the difference between the two techniques: (*i*) In the bath deposition method, the cadmium is in a complex form; in the spray method, it is ionized Cd salt solution. (*ii*) In the bath deposition method, the film forms comparatively slowly with the advantages of better orientation of crystallites and improved grain structure unlike in the spray technique where the film formation is almost an instantaneous process.

However, the bath deposition method has a limitation regarding the temperature of deposition. By its very nature, this temperature is normally restricted to about 100°C, while in the spray technique, the initial temperature may be as high as 400°C.

Experimental

Preparation.—In this study, thin films of cadmium sulfide have been prepared by reaction of thiourea with cadmium tetraammonium sulfate.

The apparatus shown in Fig. 1 consists, in essence, of an oil bath whose temperature can be controlled, and an electrically driven stirrer, using a synchronous motor to obtain constant speed. The glass substrates to be coated are suspended in pairs from the stirrer shaft. It was found that the following conditions were most suitable for obtaining uniform and sensitive films:

1. The temperature of the oil bath was maintained at 100°-110°C so as to keep the temperature of the mixture at about 80°-90°C.

2. Freshly prepared doubly distilled water was used to prepare the solutions and to clean the glass slides used as substrates. These slides were initially cleaned by "Niogen C. S." detergent solution and were boiled several times in doubly distilled water. Some metal substrates were also used, *e.g.*, nickel, aluminum, copper, Kovar, etc. These were initially cleaned with dilute acid and then were boiled several times in doubly distilled water. Finally the substrates were cleaned for a few minutes in an ultrasonic cleaner. Careful cleaning is essential for obtaining uniform films.

3. The pair of substrates was kept rotating in the reaction mixture at a constant speed of 100 rpm. This stirring action which continuously exposes the substrates to a fresh body of reactants is important for uniform deposition of the films.

For each deposition, 10 cm^3 of 1 mole cadmium sulfate solution and 50 cm^3 of 2 mole ammonia solution were mixed in a 150 cm^3 beaker to form the complex compound. To this solution was added 10 cm^3 of 1 mole thiourea solution. The reaction vessel was heated to 80°-90°C for 30 min. The cleaned pair of substrates was kept rotating approximately 2.5 cm below the surface of the solution. The films formed were washed several times with distilled water, dried, and preserved in a dark dessicator.

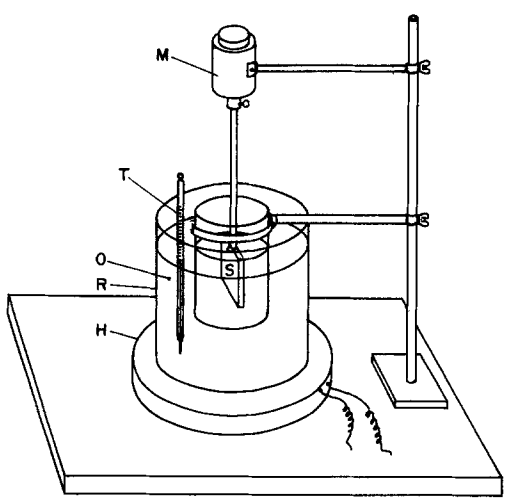

Fig. 1. Experimental setup for the deposition of the CdS layers. H, Heater; R, reaction vessel; S, substrate; O, oil bath; T, thermometer; M, synchronous stirrer motor.

A reaction mechanism for the formation of CdS based on the deposition kinetics of thin films of PbSe by Lundin (3), is suggested below:

1. Cadmium salt reacts with ammonia to form the complex compound

$$CdSO_4 + 4(NH_3) \rightarrow (Cd(NH_3)_4)SO_4$$

2. Diffusion of the complex ion, OH^-, and thiourea to the catalytic surface of CdS.

3. Dissociation of the thiourea on the CdS catalytic surface in an alkaline medium

$$\begin{matrix} H_2N & & NH_2 \\ & \diagdown \quad \diagup & \\ & C & \\ & \| & \\ & S & \end{matrix} + OH^- \rightarrow CH_2N_2 + H_2O + HS^-$$

4. Formation of bivalent sulfide ions

$$HS^- + OH^- \rightarrow S^{--} + H_2O$$

5. Formation of CdS

$$Cd(NH_3)_4^{++} + S^{--} \rightarrow CdS + 4NH_3$$

The sensitivity and the dark resistance of CdS films have traditionally been controlled by the addition of copper, which acts as electron acceptor. In our process copper is incorporated in two ways: (*i*) by addition of a copper salt (CuI, 0.1% by weight) to the bath solution, or (*ii*) by embedding the film in CdS powder to which approximately 0.1% CuI was added and baking at 100°C for 4 hr in a dry and oxygen-free nitrogen atmosphere. Films prepared by double deposition and doped with copper by the second method were used for the Hall measurements. For the study of the other properties, Cu was introduced in the films by the first method.

The thickness of the films was estimated by a method in which the area and the weight of the film were determined; the thickness deduced from this is between 0.8 and 1 μm. The surface structure of these films was examined by x-ray and electron diffraction methods.

Contacts.—It is known that In and Ga make good ohmic contacts with CdS. In and Ag were successively evaporated in vacuum (10^{-5} mm of Hg) onto a masked sample plate. The portion of the film where the contacts were to be made was kept exposed. Leads of 46 gauge silver-copper wires were soldered to the silver deposit.

The nature of the contacts was checked by the potential probe method and by measuring the current-voltage characteristics for a number of samples in the dark as well as with different illumination intensities. The potential probe method utilizes the principle that if the contacts are ohmic no abrupt potential drop should exist at the metal-semiconductor contacts.

About 3-4 mm wide electrode (In-Ag) strips were deposited at both ends of the sample. Also perpendicular to its length were deposited 1 mm wide (In-Ag) electrode strips at a distance of approximately 3 mm, leaving the CdS strip open at the center. Leads of 46 gauge silver-copper wire were soldered to each electrode strip. The sample was mounted in a shielded metal box and was connected to a multipoint rotary switch. A 90V d-c battery with a resistance in series was used as a voltage supply. Voltage drop across the length of the sample at different points was measured with a high impedance Cary 31 electrometer amplifier.

Rise and decay transients.—The rise and decay of photoconductivity includes the contributions of trap filling and emptying. The photoconductive rise and decay transients were studied with a view to finding the nature of the traps or trap levels.

The general procedure is to induce a change in the signal at a set repetition rate and observe it by a detector which is sensitive to that frequency. For this measurement of rise and decay transients the following method has been used (4).

A chopped light having chopping frequency of 14 Hz and intensity 2.4×10^{20} photons cm^{-2}-sec^{-1} was used to illuminate the sample. Consequently the current in the circuit is modulated in the same way, inducing a modulated voltage across a load resistor. The induced voltage corresponding to the change in the sample's conductance was fed to an oscilloscope (Tektronix Model 515-A) directly. An all-metal cryostat was used to mount the sample. This sample cryostat and the optical box were properly grounded to avoid stray electrical signals.

Field effect measurement.—The arrangement of the field effect experiment is presented in Fig. 2. A thick Teflon block was used as a base for mounting the sample. A layer of silver was deposited over the central portion of this which was used as a field electrode B. Electrodes A and A' are In-Ag electrodes to which aluminum pressed contacts were applied. A sweep voltage $V_{AA'}$ was applied across these electrodes and the sweep current through this circuit may be measured by a series ammeter. Sandwiched between the film surface and the field electrode B is a dielectric, such as a thin mica sheet (0.0025 cm thick). All these were maintained in position by means of side screws through the Perspex block placed on the sample. The whole assembly was fixed in a thick sheet-aluminum box to minimize stray electrical signals. A glass window was provided to illuminate the sample.

The field effect is the conductance change observed in the semiconductor when it is subjected to a transverse field (V_B). This conductance change in the sweep circuit is sometimes very small because of a large density of localized states which makes it difficult to move the Fermi level through more than a few kT. Thus detecting the field effect by measuring the conductance change is not a sensitive technique. Hence a sensitive field effect bridge was designed by us. Here the sample forms one of the arms of the bridge. With V_B kept at zero, the bridge is balanced by the variable ten-turn resistor so that the electrometer (Orion) reads zero voltage. As soon as V_B is applied to the field electrode (B, in Fig. 2), the sample conductance changes and the bridge becomes unbalanced. This imbalance voltage read by the electrometer is fed to a strip chart recorder (Varian, G-10) and may be related to the conductance change.

Spectral response of photoconductivity and optical absorption.—For the spectral response measurement, the sample was mounted in the cryostat mentioned earlier. Spectral response was measured as a photocurrent change in arbitrary units by an electrometer (EA 810 A). A calibrated Hilger monochromator with 500W projection lamp was used as a light source. Measurements were carried out at 300° and 93°K. The optical absorption was studied in the range 4000-7000Å, using a Unicam SP-600 spectrophotometer at 300°K. The absorption coefficient was calculated.

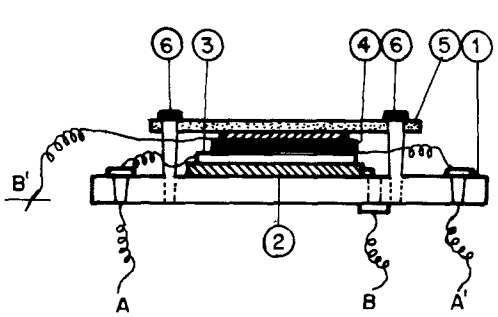

Fig. 2. Experimental arrangement of field effect specimen. 1, Teflon block; 2, silver electrode; 3, mica spacer; AA', sweep field; 4, sample; 5, Perspex block; 6, fixing screws; BB', transverse field.

Hall measurements.—As the films have high resistivity and low mobility, Hall measurements were possible only under white light illumination (10^{20} photons/cm^2/sec). The electrode arrangement required was obtained by deposition of the electrodes through a molybdenum mask which gave a distance of 10 mm between end electrodes and a length to breadth ratio of ~ 4. A special all-metal cryostat was used in which two soft iron pole pieces entered through O ring seals in the wall. Thus a small pole gap of ~ 1.5 in. could be maintained across the sample. Light coming from the source was focused on the sample by lenses. The magnetic field used was about 9000G.

Results

Preparation and structure.—CdS films prepared by the chemical bath deposition technique are uniform, adhere tightly to the substrate, and resist abrasion. These films appear to have some advantages over those prepared by other techniques, *e.g.*, their properties are relatively insensitive to oxygen and moisture. They are reproducible in structure, thickness, and electrical and photoconducting properties. We studied undoped films and films doped with indium, silver, arsenic, and copper in the form of halides, for their structure. Films deposited without dopants are polycrystalline. Films grown with dopants present during deposition are amorphous, while the precipitate obtained during the reaction is always polycrystalline irrespective of whether it is doped or undoped. Variation of temperature, speed of rotation, and composition of electrolyte do not affect these results. The ratio of resistivity in dark to that under illumination is lower for films doped with indium, silver, and arsenic than copper-doped or undoped films.

Study of the x-ray diffraction patterns shows that undoped films consist of a mixture of approximately 90% β-cubic and approximately 10% α-hexagonal forms of CdS, which was confirmed by electron diffraction measurements.

In-Ag evaporated contacts studied by the potential probe method show no major contact resistance. Current-voltage characteristics show linear behavior in the dark as well as with illumination which is characteristic of good ohmic contacts. No self-capacitance is observed at the frequencies at which the measurements were carried out.

Photoconductivity rise and decay was studied as a function of temperature in the range 130°-310°K. The dark conductivity and the steady-state photoconductivity curves as a function of temperature are given in Fig. 3. Here the steady-state photoconductivity is the conductivity corresponding to the initial value of the decay curve. The decay curves are exponential in nature over the temperature range studied. The density of states near the Fermi level was computed from the decay curves at various temperatures using the following expression (5)

$$N(E_F) = F\tau_0/kT \qquad [1]$$

where $N(E_F)$ is the density of traps at the quasi-Fermi level, F is the photoexcitation rate, and τ_0 is a photoconductivity decay response time. The density of states thus calculated is of the order 10^{19}-10^{20} cm^{-3} eV^{-1}.

The analysis of the field effect data for the estimation of the density of states at the Fermi level follows the method suggested by Arnoldussen (6, 7) with the assumption that the density of states at the surface is not very much different from that in the volume. The den-

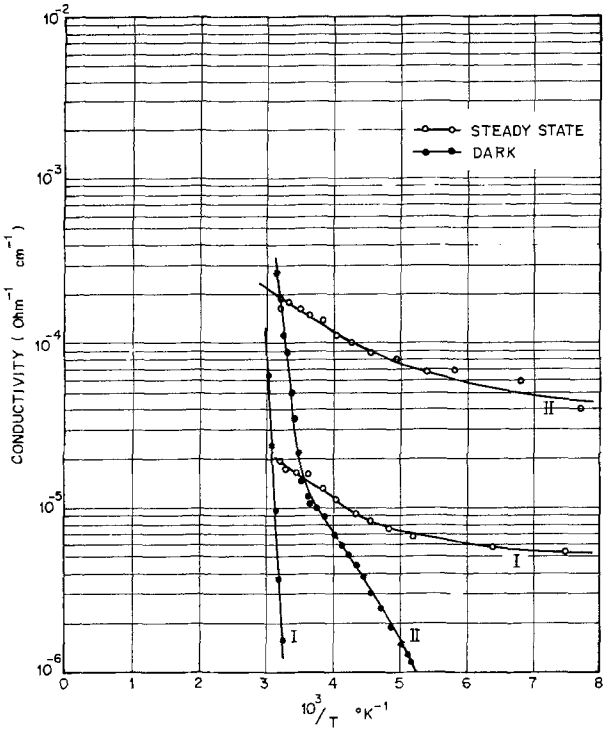

Fig. 3. Temperature dependence of dark conductivity and steady-state photoconductivity obtained from transient decay curves for CdS chemically deposited thin film: I, undoped and II, doped.

sity of states at the Fermi level, as it is moved by the applied field V_B, was calculated from

$$N[E_F(V_B)] = \frac{Q}{eDKT} \cdot \frac{G_o}{\Delta G} \qquad [2]$$

where Q is the induced charge by V_B, D is the thickness of the film, G_o is the sweep conductance measured with no field voltage applied, and ΔG is the change in the sweep conductance when the field voltage V_B is applied. This above formula is valid only in the case when $V_B \to 0$, and the shift in E_F is of the order of kT or less than kT.

The density of states at the no-field Fermi level E_{F_o} (*i.e.*, $V_B \to 0$) calculated for both the doped and the undoped films is of the order 10^{20} cm^{-3} eV^{-1}.

Figures 4 and 5 show the field effect conductance change, ΔG, as a function of field voltage V_B in the dark and under illumination for the undoped and the doped films.

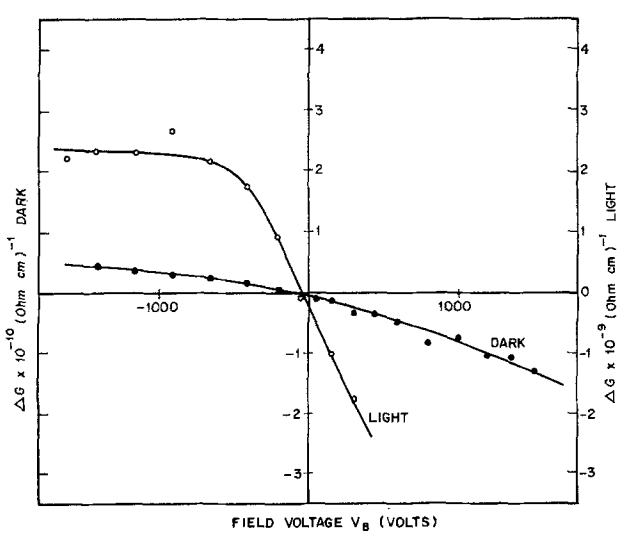

Fig. 4. Field effect conductance change as a function of field voltage in undoped CdS chemically deposited thin film.

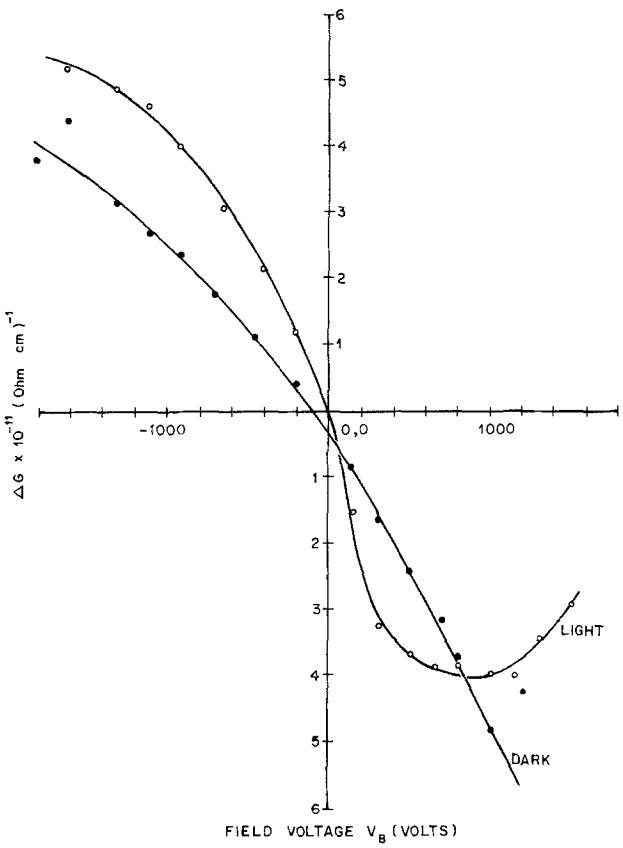

Fig. 5. Field effect conductance change as a function of field voltage in doped CdS chemically deposited thin film.

The field effect signals were recorded for different light intensities keeping the field voltage constant. Thus the density of states at the quasi-Fermi levels was calculated, which is found to remain more or less constant at 10^{20} cm^{-3} eV^{-1}.

From the observed absorption data it is found that plots of $(\alpha h\nu)^2$ *vs.* $h\nu$ (Fig. 6) for undoped and doped films gave fairly good straight lines indicating that the

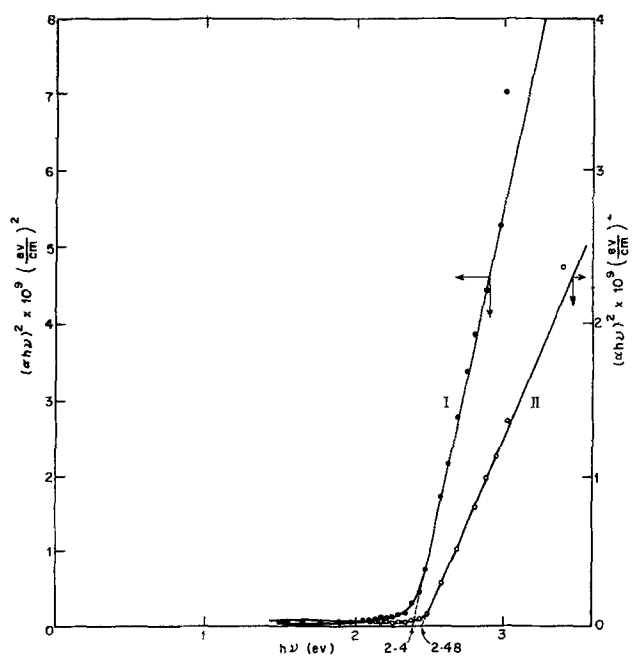

Fig. 6. Variation of $(\alpha h\nu)^2$ as a function of $h\nu$ for CdS chemically deposited thin film: I, undoped and II, doped.

transitions were direct and allowed. Besides the absorption coefficient, α, was high, of the order of 10^{-4} cm^{-1}, suggesting direct transitions. These observations are in agreement with the fact that the material is known to be a direct gap material. The plot of $(\alpha h\nu)^2$ against $h\nu$ for undoped film extrapolates to $(E_g)_{opt.} = 2.40$ eV, while that for the doped amorpous film extrapolates to $(E_g)_{opt.} = 2.48$ eV.

Spectral dependence of these films for excitation of photoconductivity at 300° and 93°K are presented in Fig. 7 and 8, respectively. At 93°K it shows a peak in the region of 480 nm for undoped samples and at 460 nm for copper-doped films. The values show that these films have a greater blue response than the corresponding CdS crystal, doped or undoped. The spectral response at 300°K gives a peak at 520 nm for undoped films and at 456 nm for doped films.

The Hall voltage for these CdS films was measured at room temperature under photoexcitation with white light (2.4×10^{20} photons/cm^2/sec) for three different magnetic fields and the Hall constant R and the mobility μ_H, were calculated; μ_H and n thus obtained are 5 $cm^2/V \cdot sec$ and $\simeq 10^{14}/cm^3$, respectively.

Discussion

One of the most interesting observations related to this study is that the trace addition of cations like copper, silver, indium, etc. make the layers amorphous (as judged from x-ray and electron diffraction data). This phenomenon can be explained on the basis of adsorption and its effects on crystal growth as observed by Kennan and France (8). Thus we attribute the lack of polycrystalline form when copper (for example) is added during deposition, to the adsorption of copper ions at the surface of a growing CdS microcrystal. This then prevents the microcrystals from growing larger along the plane of the substrate (and perpendicular to it). This is also substantiated by the observed fact that layers made with copper addition during deposition are thinner than those made without it.

This result makes it possible to grow and study both amorphous and polycrystalline photoconductive chemically deposited layers. This is particularly relevant to the current interest in the preparation and properties of amorphous materials. A further inference of the mechanism of deposition may be made: that it is the slow growth of the film on the substrate alone that is controlled by the addition of cations like copper or silver. This we deduce from the observation that even when the deposited film is amorphous in structure, the precipitated cadmium sulfide which is a by-product of the process is still crystalline. Thus the adsorption mechanism which inhibits crystal growth through the agency of cations like copper etc. must involve the substrate surface and not the crystal growth face itself. This aspect has not been pursued further in this work, but left open as an avenue of future investigation.

Let us now consider the decay of photoconductivity when the photoexciting radiation is interrupted. Though the decay curves, when replotted as a function of time give nearly a straight line plot of log $\Delta\sigma$ against time indicating that the decay process is more or less exponential, the plot of log τ_0 against $1/T$ gives a straight line with very small slope indicating nearly temperature-independent behavior. This suggests that there is a uniform distribution of traps close to the conduction band. The experimental data also indicate that though a uniform distribution of traps exists, the time constant of decay is nearly the same for all the trap levels. The density of states distribution in the bandgap calculated from the decay of photoconductivity confirms those obtained by the field effect measurement.

Study of the field effect conductance ΔG as a function of field voltage in the dark shows that the conductance increases with negative field voltage and decreases with positive field voltage for undoped as well as doped samples. This indicates that: (*i*) The material is n-type; either the free electron concentration or mobility is very much greater than the free hole concentration or mobility or both. (*ii*) The bands are flat at the surface. (*iii*) ΔG against field voltage curves are close to linear which suggests that the field effect is due to change in electron concentration and not due to change in mobility μ. If the field effect were due to the change in mobility, these graphs would be sharply nonlinear since mobility depends exponentially on ϕ, the barrier height (9). This is contrary to the observation by Waxman *et al.* (10) who observed a field dependence of mobility in the case of evaporated CdS thin films.

The photofield effect conductance as a function of field voltage indicates that in the presence of light the electron and hole concentrations and/or the mobilities are not greatly different.

A plausible explanation for a shift in bandgap (2.40 for crystalline and 2.48 for amorphous) is along the lines suggested by Lehman (11). He studied optical absorption as a function of impurity concentration for In-doped CdS. He found that the quantum energy corresponding to the edge increases steadily with increasing impurity concentration up to a certain limit, then

onwards it remains constant. The explanation suggested is as follows. Any disorder in crystal causes a tailing-off of the density of allowed states below the bottom edge of the conduction band. This tail is probably strong in all conventional II-VI compounds as indicated by the observed exponential dependence of the absorption constant on the quantum energy near the edge (12). Hence a measured α in the order 100 cm^{-1} probably does not correspond to an electron transition into the conduction band but into the tail below the conduction band. Thus the band-to-band transition energy is increased due to splitting off of the levels from the conduction band.

The highlights of our experimental investigations of the study of CdS chemically deposited films are: (*i*) a photo-Hall mobility of 5-10 cm^2/V-sec at 300°K, and (*ii*) an electrical conductivity of 10^{-8} Ω^{-1}-cm^{-1} at 300°K. We now proceed to the description of a suitable model for the situation of the gap states and the relation between the conduction band and the valence band and these states, based on our experimental data.

In discussing the behavior of such a material, the role of traps and trapping centers assumes great importance, especially because of the active part which these play in determining free lifetimes. The values of carrier densities which we have found, 10^{14}-10^{15} cm^{-3} and the mobility, 5-10 cm^2/V-sec seem appropriate to a picture of a polycrystalline material with a high density of interband states and a mobility limited by intergrain boundaries.

The high density of state at the Fermi level ($\simeq$ 10^{19}-10^{20} cm^{-3} eV^{-1}) indicates that the Fermi level is effectively pinned somewhere in the bandgap and that the distribution of states between the Fermi level and the conduction band is more or less uniform. We now consider the additional support to this model from the field effect and photofield effect data.

Field effect measurements carried out on the two types of specimens have shown that one can sample the localized states by moving the Fermi level through a few kT using either an electric field or light. This, therefore, offers a means of checking our earlier hypothesis that the Fermi level is pinned in the bandgap close to the bottom of the conduction band.

Field effect data show that the density of state at E_F is 10^{19}-10^{20} cm^{-3} eV^{-1} when E_F is moved by $\simeq$ 3 kT from its equilibrium value.

The field effect also indicates that the bands are flat at the surface which further supports our model. We now come to the problem of determining the quasi-Fermi level. Assuming an electron effective mass ratio $= 0.2$ and taking a free carrier concentration $n = 1.04 \times 10^{14}$ cm^{-3} as obtained from the photo-Hall effect, the quasi-Fermi level is found to be 0.25 eV below the conduction band at an excitation intensity of about 10^{20} photons/cm^2/sec at 300°K.

This again gives additional support to our model in which we assumed that the Fermi level was effectively pinned down by a cluster of gap states, with a high density, at the Fermi level. The amount that the quasi-Fermi level moves up in response to the photoexcitation is easily known from the ratio of light to dark conductivity and was found to be of the order of 0.08 eV. Thus, to a first approximation, we may determine the position of the Fermi level by adding the amount of light-activated Fermi level shift (0.08 eV) to the value of quasi-Fermi level as determined by photo-Hall measurements. This places Fermi level of $\simeq$ 0.33 eV below the conduction band.

Having determined that the Fermi level lies fairly close to the conduction band, the high density of state would then appear to be more of a tail of conduction band states caused by localization of these states.

The merit of this model is that it satisfactorily reconciles the data obtained on our chemically deposited layers through photo-Hall, decay characteristics, field effect, and optical absorption measurements.

Dependence of WO_3 Electrochromic Absorption on Crystallinity

O. F. Schirmer, V. Wittwer, G. Baur, and G. Brandt

Fraunhofer-Gesellschaft, Institut für Angewandte Festkörperphysik, D-7800 Freiburg, Federal Republic of Germany

ABSTRACT

The optical absorption of amorphous WO_3 electrochromic display layers is explained as small polaron absorption. The necessary W^{5+} 5d-electron localization is favored by the lattice disorder. This is concluded from the change of the optical properties to free-electron-like behavior upon crystallization of the layers. The increased electrocoloration stability of amorphous layers and the blue shift of the absorption peak in Mo-doped WO_3 films can also be explained within the model given.

It is established by now that the electrochromic coloration of evaporated WO_3 layers (1) to be used for display applications proceeds by the formation of tungsten bronzes A_xWO_3 (2, 3) (A = H°, Li°, etc.). The electrons entering the layers from the cathode are distributed over the WO_3 part of the lattice and are accommodated in W^{5+} 5d orbitals (2). The coloration is due to a broad absorption band peaked at energies near 1.2 eV (1), somewhat depending on the method of layer preparation and coloration. Such a peak is not typical for the optical behavior of crystalline tungsten bronzes; their reflectivity spectra can be explained roughly by assuming Drude-type behavior of electrons predominantly having banding character (5). On this basis one would expect to observe no or a less pronounced peak in the absorption of the electrons in the tungsten bronze of an electrochromic device. It is shown here that the optical absorption of such layers can still be understood as that of W 5d electrons in the tungsten bronzes if the disorder present in amorphous layers generally used for electrochromic display devices is considered. This will favor localization (4) of the electrons, breaking the translational symmetry of the lattice. In this way, the formation of W^{5+} d-electron bands will be hindered and the electron-phonon interaction can then cause an additional stabilization at the respective tungsten sites.

The electron together with its accompanying lattice distortion can be called a small polaron. It will be shown that the optical absorption of the amorphous films can be explained as that of small polarons. If such layers are transformed to a crystalline state, a different absorption with less pronounced peak structure is observed which shows features of banding electrons. Thus, the amorphous state is a necessary condition for the observation of electrochromic absorption bands near 1.2 eV in the tungsten bronzes. The increased stability of electrocoloration in amorphous layers can also be attributed to the disorder present. The experiments herein support an earlier proposal by Faughnan *et al.* (2) that the band absorption in electrochromic WO_3 is caused by intervalence transfer (6). The underlying physics of this model is simlar to that of small polaron absorption.

Experimental

WO_3 layers were evaporated at room temperature onto glass substrates, which were either covered with a SnO_2 film or uncovered. Layer thicknesses were between 0.4 and 1 μm, leading to weak interference structure in the optical spectra. Electrolytic coloration of the SnO_2-covered specimens with a H_2SO_4 solution as anode and the SnO_2 film as cathode resulted in the absorption and reflection spectra shown in Fig. 1; coloration of the SnO_2-free layers by applying an electric field along the plane of the film (1) led to the somewhat narrower absorption curves of Fig. 2.

Heating the WO_3 layers to 340°-400°C in air or N_2 gas and cooling in the same ambience resulted in crystallization of the layers, as demonstrated by their x-ray diffraction peaks shown in Fig. 3a. Such reflexes were completely absent in as-evaporated material, Fig. 3b. From the crystallized specimens, electrolytically colored in H_2SO_4, absorption and reflection spectra as shown in Fig. 4 were observed.

After coloration, the absorbance of the crystallized layers decreased with time and shifted to longer wave-

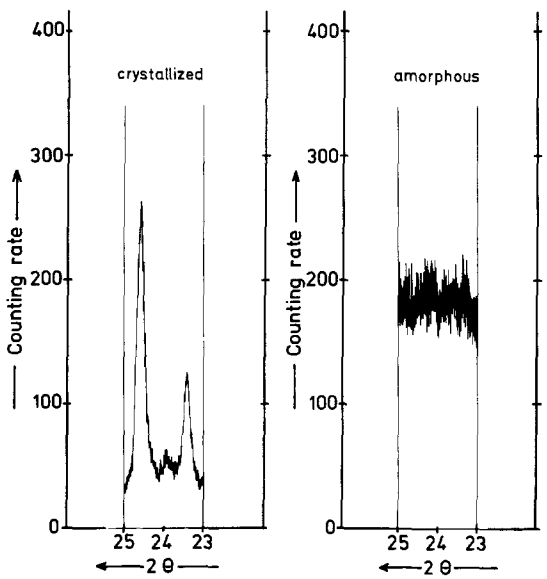

Fig. 3. Characteristic x-ray diffraction peaks observed from crystallized (left) and amorphous (right) WO_3 layers.

length as indicated in Fig. 5. The samples annealed in N_2 atmosphere were bluish before electrolytic coloration; in this state the absorption was lower but of the same wavelength dependence as after coloration (Fig. 6). After coloration layers annealed in N_2 or air essentially showed the same wavelength dependence of the absorption. Figure 6 also demonstrates the striking difference in absorbance between crystallized and amorphous layers.

The oxygen content of the layers changed upon annealing in air and N_2 atmosphere, respectively. This was checked with x-ray fluorescence: the counting rates for O and W, respectively, showed a ratio of 2.75 for air-treatment and 2.60 for N_2 annealing, *i.e.*, 5% change in the oxygen content. Since there are some ambiguities in calibrating the relative counting rates to the absolute O/W content of the layers, these ratios do not necessarily correspond to the actual stoichiometry of the specimens. The oxygen content of evaporated WO_3 layers apparently is increased by air-treatment and not lowered by N_2 annealing, as might be inferred from the above ratios; for specimens annealed in N_2 after air-treatment did not show a change in the O/W counting rate ratio.

Discussion

Amorphous material.—We shall explain the narrower band in Fig. 2 as small polaron absorption. A small polaron is formed if the interaction of a charge carrier with the surrounding lattice localizes the carrier to essentially one lattice site (7-9). The corresponding breaking of translational symmetry is favored, if the charge carrier banding, determined by the transfer integral J, is small or if its effect is suppressed by

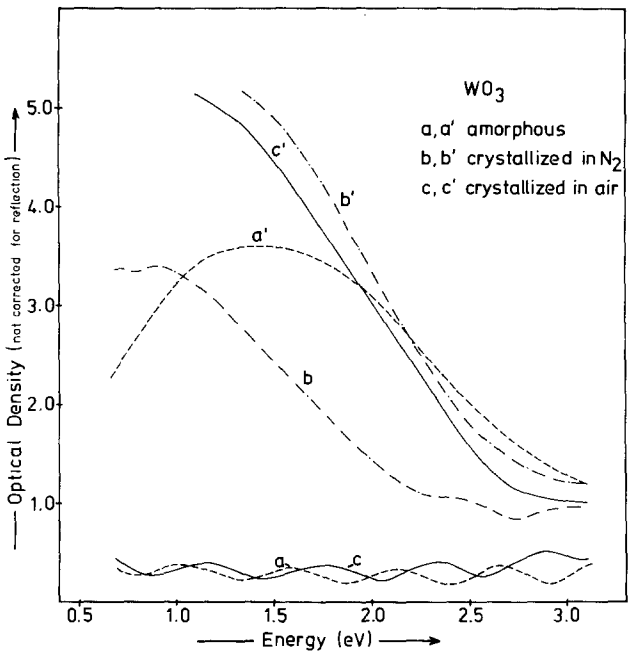

Fig. 6. Optical density (uncorrected for reflection) of WO_3 layers under the following conditions: a, a' amorphous, as-evaporated; b, b' annealed in N_2 gas; c, c' annealing in air. Primed letters refer to electrolytically colored samples, unprimed ones to the respective states before coloration.

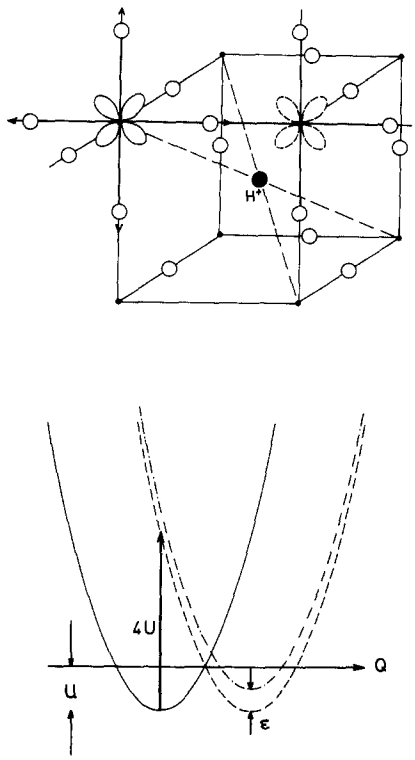

Fig. 7. Upper part: Expected effect of accommodating an electron into the shown W^{5+} 5d orbital on the lattice of an H_xWO_3 bronze. Lower part: Electronic energy vs. lattice configuration coordinate. Upon trapping the electron, the energy U is gained. A possible inequivalence of lattice sites may lead to the potential difference ϵ. The arrow marks the expected optical transition.

fluctuating local potentials. Disorder in the lattice reduces the mean free carrier path length to one lattice constant (4), if the energy range within which the local potential fluctuates is large compared to J. In the most simple approach, the carrier-induced lattice distortion is represented in a diagram showing the potential energy of electron and lattice depending on a single, one-dimensional lattice configuration coordinate, Fig. 7. The fluctuation of the local electron potential is considered by the inclusion of its difference, ϵ, between the two sites shown in Fig. 7. It has long been realized (9, 10) that optically induced transitions between two such sites can be considered as Franck-Condon transitions, indicated by the vertical arrow in Fig. 7. Recently, a simple formulation for the optical absorption band shape expected from such a system has been given (11)

$$\alpha(\hbar\omega) \propto \hbar\omega \exp\left(-w(\hbar\omega - \epsilon - 4U)^2\right) \qquad [1]$$

with $w^{-1} = 8U \cdot \hbar\omega_0$, $\hbar\omega_0$ being the energy of the representative vibration quantum. A least squares fit of this expression to the low energy onset of the optical absorption is shown in Fig. 8, where $\epsilon = 0$ was assumed. The case where $\epsilon \neq 0$ is considered below. It is seen that the low energy wing of the band is well reproduced with the parameters $U = 0.275$ eV and $\hbar\omega_0 = 0.098$. Discrepancies at energies beyond the peak energy like that in Fig. 8 have generally been noticed in small polaron absorptions (12, 13). Formerly, they have been attributed to electron transfer transitions into higher lying orbitals at neighboring sites (11, 12). They can occur since transitions are allowed to all orbitals having finite admixture to the original one by the corresponding transfer integral (11). It seems likely that the same explanation applies also here. The vibrational energy $\hbar\omega_0$, 0.098 eV, is close to that of LO phonons in WO_3 (14). This is reasonable because it is expected that the corresponding W-O spring in the lattice is strained by the electron-phonon interaction forming the small polaron. The polaron stabilization energy U, 0.275 eV, obtained from fitting the spectrum in Fig. 8, is somewhat higher than in other d-electron systems, typically 0.2 eV (12, 13). It must be considered, however, that the influence of ϵ will make the

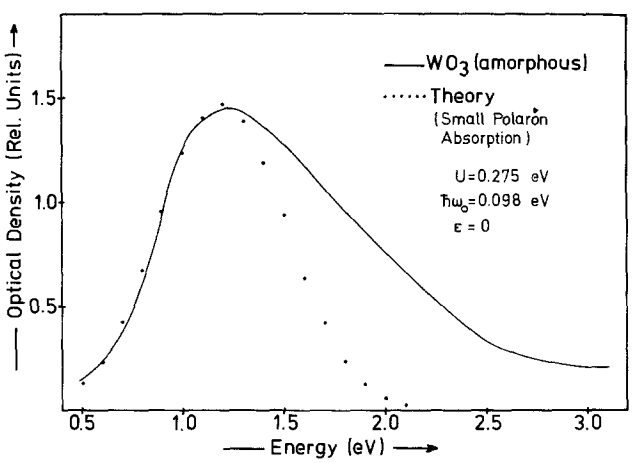

Fig. 8. Least squares fit of the low energy onset of the narrow band in Fig. 2 with the expression in Eq. [1], resulting in the fitting parameters in the upper right.

U determined for $\epsilon = 0$ an upper limit to the actual one. Since the trapped electron will tend to settle at the lowest possible potential, ϵ in Eq. [1] will be positive and U will be lower than that derived above. The observed absorption curve will then in fact be a superposition of a multitude of Gaussian bands. Since part of the apparent width of the absorption band will be caused by this superposition, the determined representative vibration frequency will also be somewhat too high.

It should be added that the rather high intensity of the electrochromic absorption band is also in accord with the model. Resonance admixture of orbitals at neighboring sites to the original one can lead to considerable transition moments (10, 11).

The appearance of a corresponding absorption band in the transmission spectrum of finely ground sodium tungsten bronze powder, pressed in thin pellets (5), can also be attributed to the presence of potential fluctuations, caused by mechanical damage during grinding.

Crystallized material.—The absorption and reflection spectra observed from crystallized layers show features different from those of amorphous specimens. The absorption now reaches a less pronounced maximum at lower energy (Fig. 4) than in the amorphous case, and the reflection spectra now show more narrow minima and an over-all behavior reminiscent of that of a plasma of free electrons. In fact the gross features of these optical properties can be explained under this assumption, provided the scattering of the electrons by optical phonons and/or lattice defects is taken into account. Expressions for absorption and reflection are obtained from the real, n, and imaginary, k, part of the complex refractive index of a plasma (15)

$$n^2 - k^2 = \epsilon_\infty - \frac{\omega_p{}^2 t^2}{1 + \omega^2 t^2}$$

$$2nk = \frac{\omega_p{}^2 t}{\omega(1 + \omega^2 t^2)}$$

ω_p being the plasma frequency.

In order to include scattering by impurities and/or phonons, we introduce a frequency-dependent relaxation time $t \propto \omega^x$, where x has to be determined from the experimental spectra. The absorption coefficient is given by (15)

$$\alpha(\omega) = \frac{2nk\omega}{c}$$

whereas

$$R(\omega) = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2}$$

determines the reflectivity. With these expressions, the absorption and reflection spectra in Fig. 4 could be fitted simultaneously using the following parameters. ϵ_∞ was set equal to 4.4, consistent with the refractive index WO_3 in the relevant frequency range (1). Depending on the coloration intensity, $\hbar\omega_p$ lies between 0.5 and 2.4 eV. Assuming an effective mass of $\sim 1 m_e$, this corresponds to carrier densities in the correct order of magnitude ($\sim 10^{21}$-10^{22}/cm^3). Plasma energies in the same range have been found by Scott *et al.* (16) for crystalline tungsten bronzes. The best simultaneous fits of reflection and absorption curves were obtained with $x = 1.1$, which leads to a high frequency asymptotic behavior of the absorption $\omega^{-3.1}$. This exponent lies between those characteristic for LO phonon scattering, $\omega^{-2.5}$ (17), and ionized defect scattering, $\omega^{-3.5}$ (18). So one might infer that the charge carriers in the crystallized layers interact both with defects and LO phonons. This result is reasonable since LO phonon interaction is also responsible for the observed formation of small polarons.

So it turns out that the optical behavior of 5d electrons, electrically injected into crystallized WO_3 layers, is consistent with the electronic properties of crystalline tungsten bronzes. 5d electrons in nonstoichiometric WO_3 crystals have been found to behave as large polarons with a coupling strength $U/\hbar\omega_0$ of ~ 3 (19). The upper limits of the corresponding values of U and $\hbar\omega_0$ inferred above from the small polaron absorption of the amorphous material with $\epsilon = 0$ are consistent with this ratio Since $\epsilon \neq 0$ will lead to a reduction of both values (see above), the actual ratio in amorphous material will still be of the same order. This means that in this intermediate coupling range the introduction of sufficiently large potential fluctuations can transform a large polaron to a small one with essentially the same coupling strength.

As shown above, the electrochromic coloration of crystallized WO_3 layers is independent of the annealing conditions, oxidizing, or reducing. Therefore, oxygen deficiency alone cannot be the cause of the 1.2 eV band in amorphous layers, as proposed in Ref. (1). The influence of disorder on the formation of this band is accounted for in a natural way by the model given above.

Additional Observations

The model presented above is supported by the observation that the addition of MoO_3 to the evaporating WO_3 material causes a blue shift of the electrochromic absorption (Fig. 9). From ESR investigations (20), one knows that electrons in such a mixed MoO_3/WO_3 compound are preferentially trapped at Mo sites. For low Mo concentrations these will be surrounded mostly by W ions. The electron capture at a Mo site will thus lead to an additional lowering of the initial state, *i.e.*, a larger effective ϵ (Fig. 7), and consequently to an absorption band peaked at higher frequency, *i.e.*, in a region of higher display efficiency. The same observation has been made independently by Faughnan (21).

The increased stability of electrochromic coloration in amorphous layers can be made plausible with the same model. Due to the potential fluctuations, electrons in not too high concentration will be more tightly bound in such layers. Oxidation of the layers by the surrounding O_2. *i.e.*, a removal of H^o, will thus be hindered, because a proton will have to capture an electron out of a deeper level, before it can escape as H^o. Of course, it is also expected that proton or H^o diffusion in an amorphous layer will be slower than in a crystalline compound.

Electrolytic coloration of amorphous WO_3 layers leads to broader absorption bands (Fig. 2) than coloration by an electric field in the layer plane. This is apparently due to a superposition of several bands corresponding to the occurrence of a higher spread of ϵ values. One must then conclude that electrons injected into WO_3 in an electrolytic experiment are accommodated in regions of high local disturbance. Since they will be captured close to the protons entering from the electrolyte, proton diffusion along highly disturbed parts of the amorphous network seems to take place. Electron injection by an electric field parallel to the layers apparently is compensated by protons sitting at less disturbed sites of the structure.

Conclusion

We have shown in this paper that the amorphous structure of evaporated WO_3 layers is a necessary

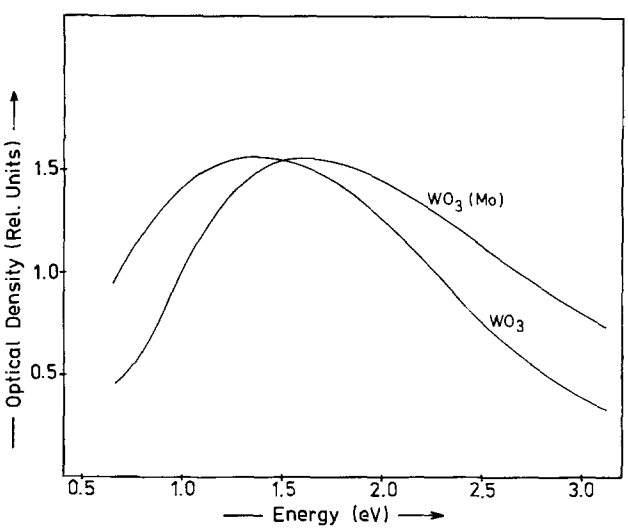

Fig. 9. Effect of adding 25 m/o MoO_3 to the WO_3 evaporating material on the electrochromic absorption.

condition for the appearance of stable electrochromic absorption bands, to be explained by intervalence or small polaron optical transfer. Otherwise an unstable free-electron-like absorption and reflection is observed, consistent with the known electronic properties of crystalline tungsten bronzes. The special behavior of the amorphous layers can be attributed to the potential fluctuations in the material caused by its disorder.

The Al-Ga-Sb Ternary Phase Diagram and Its Application to Liquid Phase Epitaxial Growth

K. Y. Cheng[1] and G. L. Pearson

Stanford Electronics Laboratories, Stanford University, Stanford, California 94305

ABSTRACT

The ternary phase diagram of the Al-Ga-Sb system was established in the Ga-rich region. Liquidus isotherms at 400°, 450°, 500°, and 550°C and solidus isotherms at 500° and 550°C were determined experimentally. Under the assumptions that the ternary liquid is a simple solution and that the AlSb-GaSb solid forms an ideal solution, excellent agreement was obtained between the calculated liquidus and solidus isotherms and experiment. The compositional variation of the $Al_xGa_{1-x}Sb$ epitaxial layers during growth was delineated.

The $Al_xGa_{1-x}Sb$ system, which has a close lattice match between the AlSb and GaSb binary compounds, is a potential candidate for various optoelectronic applications. However, only limited experimental pseudobinary data (1-3) and liquidus and solidus data at 600°C (4) have been reported. In order to control the composition of mixed crystals grown by liquid phase epitaxy (LPE), the Al-Ga-Sb ternary phase diagram must be established in the region of interest. In this work, the liquidus data along the 400°, 450°, 500°, and 550°C isotherms were obtained by the saturation technique and the corresponding solidus data at 500° and 550°C were determined. A simple thermodynamic model (5, 6) was used to analytically fit the measured liquidus and solidus results, and then to generate the Al-Ga-Sb ternary phase diagram in the Ga-rich region. Such a semiempirical approach was used since no theoretical model can exactly describe the thermodynamic behavior of the ternary system without some adjustments. The phase diagram was then applied to LPE growth to predict conditions such as the liquid and solid compositions at given temperatures and the variation of composition in grown layers.

Experimental Procedures and Results

A saturation technique was used to determine the liquidus data along the 400°, 450°, 500°, and 550°C isotherms in the Ga-rich region of the Al-Ga-Sb system. In this study, a vertical LPE dipping system similar to that described by Wu and Pearson (7) was used to obtain the liquid compositions as well as

[1] Present address: Electrical Engineering Department, Chung-Cheng Institute of Technology, Ta-Hsi, Tao-Yuan, Taiwan (335), Republic of China.

Key words: thermodynamics, simple solution, liquid phase epitaxy.

for LPE growths. Essential components of the system are a vertical tubular furnace, a quartz reaction tube through which a palladium-purified H_2 flow is maintained, and a quartz dual seed holder.

In each saturation cycle, the ternary solution was prepared by accurately weighing appropriate amounts of 6-9's Ga and Al into the Al_2O_3 crucible along with polycrystalline GaSb. Typically, 5g of Ga were used for each run. In order to remove surface oxides from the Ga solution, it was baked out in the crucible under H_2 flow at 850°C for several hours prior to adding Al and GaSb. An additional GaSb source and a pair of back-to-back substrates, with polished (111)B surfaces oriented toward the outside, were clamped in the seed holder and positioned in the cold zone of the furnace. Prior to raising the temperature, the system was evacuated and repeatedly backfilled with purified H_2. After the system had been heated and stabilized at the desired saturation temperature, which was monitored with a calibraed Pt *vs.* Pt-13% Rh thermocouple situated beneath the crucible, the GaSb source was dipped into the solution for at least 30 min to provide saturation. The dipping time was long enough to reach true equilibrium in the ternary melt. This was verified by dipping for longer periods of time and noting that the weight loss of the GaSb source changed very little. Upon completion of the saturation cycle, the GaSb source was retracted. At this time, the growth cycle was initiated by dipping the substrates into the saturated solution and the system was cooled several degrees at a rate of 0.25°C/min. Growth was terminated by raising the substrates out of the ternary solution.

The liquid composition at the saturation temperature was determined by measuring the weight loss of the GaSb source material along with the amount of Ga, Al, and GaSb in the presaturated solution. At these low temperatures no corrections were made for evaporation of Sb from the solution. The experimental solubility data of Sb at 400°, 450°, 500°, and 550°C are listed in Table I and presented in Fig. 1 as a function of Al concentration. The solid lines are calculated isotherms to be discussed in the following section. The over-all accuracy of the liquidus data is estimated to be better than ±2°C.

The solid compositions were determined on cleaved and polished edges of $Al_xGa_{1-x}Sb$ layers, which had been grown on GaSb substrates, by electron microprobe analyses. Measured intensities of the Al-Kα, Ga-Lα, and Sb-Lα lines were converted to compositions with a correction computer program (8). In all Ga-rich layers, the Al concentration was found to decrease from its maximum value near the $Al_xGa_{1-x}Sb$-GaSb interface toward the surface as a result of the depletion of Al in the solution during growth. On the other hand, when $x \geq 0.60$, the Al concentration increased from the interface toward the surface. Thus the Al concentration measured near the $Al_xGa_{1-x}Sb$-GaSb interface was taken to be the equilibrium solid composition with an accuracy of the order of 2% (absolute). The experimental solidus results at 500° and 550°C are listed in Table I and displayed in Fig. 2 together with the calculated isotherms.

Calculation and Discussion

The calculation technique for determining the Al-Ga-Sb ternary phase diagram is based on the thermodynamic model established by Ilegems and Pearson (5) and Panish and Ilegems (6). When applied to the Al-Ga-Sb system, the basic model equations are

$$\gamma_{AlSb}{}^{x} = \frac{4\gamma_{Al}\gamma_{Sb}}{\gamma_{A}{}^{sl}\gamma_{Sb}{}^{sl}} N_{Al}N_{Sb} \exp\left[\Delta S^{F}_{AlSb}(T^{F}_{AlSb} - T)/RT\right] \quad [1]$$

and

$$\gamma_{GaSb}{}^{(1-x)} = \frac{4\gamma_{Ga}\gamma_{Sb}}{\gamma_{Ga}{}^{sl}\gamma_{Sb}{}^{sl}} N_{Ga}N_{Sb} \exp\left[\Delta S^{F}_{GaSb}(T^{F}_{GaSb} - T)/RT\right] \quad [2]$$

where γ is the activity coefficient of the indicated element in the liquid or compound in the solid, T^F and ΔS^F are the temperature and entropy of fusion of the indicated pure binary compound, x is either the mole or atomic fraction of AlSb in the solid, and N is either the mole or atomic fraction of the indicated element in the liquid which follow the relation

$$N_{Al} + N_{Ga} + N_{Sb} = 1 \quad [3]$$

The superscript sl refers to the stoichiometric liquid. By solving these equations the ternary liquidus and solidus isotherms can be calculated, provided the parameters γ, ΔS^F, and T^F are known or can be satisfactorily estimated.

The activity coefficient γ, which is a measure of nonideality of the liquid or solid solution, is expressed in terms of interaction parameters and concentrations in this model. In the Ga-Sb binary liquid, γ_{Ga} and γ_{Sb} are related to the interaction parameter α_{GaSb} by equations of the form

$$RT \ln \gamma_{Ga} = \alpha_{GaSb}N_{Sb}{}^{2} \quad [4]$$

and

$$RT \ln \gamma_{Sb} = \alpha_{GaSb}N_{Ga}{}^{2} \quad [5]$$

and similarly for the liquid solution of Al and Sb. In the ternary solid solution, the activity coefficients have the same forms as Eq. [4] and [5] with an interaction parameter $\alpha^{s}_{AlSb\text{-}GaSb}$. For the ternary liquid solution the activity coefficients are related to the interaction parameters by (9)

$$RT \ln \gamma_{Al} = \alpha_{AlSb}N_{Sb}{}^{2} + \alpha_{AlGa}N_{Ga}{}^{2} + (\alpha_{AlSb} + \alpha_{AlGa} - \alpha_{GaSb})N_{Ga}N_{Sb} \quad [6]$$

$$RT \ln \gamma_{Ga} = \alpha_{GaSb}N_{Sb}{}^{2} + \alpha_{AlGa}N_{Al}{}^{2} + (\alpha_{GaSb} + \alpha_{AlGa} - \alpha_{AlSb})N_{Al}N_{Sb} \quad [7]$$

and

$$RT \ln \gamma_{Sb} = \alpha_{AlSb}N_{Al}{}^{2} + \alpha_{GaSb}N_{Ga}{}^{2} + (\alpha_{AlSb} + \alpha_{GaSb} - \alpha_{AlGa})N_{Al}N_{Ga} \quad [8]$$

In a previous study (5), the Al-Ga system was found to be near-ideal and the interaction parameter was approximated by a strictly regular solution in which $\alpha_{AlGa} = 104.0$ cal/mole. The ternary solid solution is considered to be ideal based on the fact that the lattice constants of AlSb and GaSb are nearly equal (10). Therefore the solid interaction parameter $\alpha^{s}_{AlSb\text{-}GaSb}$ was taken to be zero (11) and both γ_{AlSb} and γ_{GaSb} were set equal to 1.

The liquidus interaction parameters for III-V binaries have been observed to be slowly varying functions of temperature of the form $a + bT$ (12). We follow Vieland (13) in treating the GaSb binary solution which yields

$$\alpha_{GaSb} = -RT[\ln 4N_{Ga}N_{Sb} + \Delta S^{F}_{GaSb}(T^{F}_{GaSb} - T)/RT]/[2(0.5 - N_{Ga})^{2}] \quad [9]$$

Taking $\Delta S^{F}_{GaSb} = 15.80$ eu/mole (14), $T^{F}_{GaSb} = 985°K$ (14), and the experimental liquidus data, which are consistent with the recent redetermined liquidus of Maglione and Potier (15), the best linear fit for α_{GaSb} is $3425 - 5.13T$ cal/mole.

For the Al-Sb system, the same procedures for obtaining the liquidus interaction parameter as in the Ga-Sb system were followed. Using the experimental liquidus data of Urazov (16), the best linear fit for α_{AlSb} is $12{,}300 - 10.0T$ cal/mole as reported by Panish and Ilegems (6). Recently measured AlSb liquidus data at temperatures below 950°C give $\alpha_{AlSb} = 19{,}400 - 15.6T$ cal/mole (17). In both cases, the experimentally determined $\Delta S^{F}_{AlSb} = 14.74$ eu/mole (14) was used. With this value of α_{AlSb} together with other pertinent thermodynamic parameters, calculated ternary phase diagrams are in apparent disagreement with experiment. These discrepancies can be understood easily. Since the temperature range used in this study was below the heats of fusion of the two constituents Al (660°C) and Sb (630.5°C), the derivation of α_{AlSb} from Sb solubilities in Al as shown above was inapplicable. It was decided, therefore, to obtain α_{AlSb} by fitting the experimental ternary data of Panish *et al.* (6). In view of the usual trend in III-V binaries with the simple solution approximation, an α_{AlSb} of the form $a + bT$ was assumed in the calculations. Furthermore, ΔS^F, T^F, and the other interaction parameters are either good experimental results or well-established values, and they can only be adjusted in a limited range. Based on these assumptions, the calculated ternary phase diagram showed systematic deviations from the experimental data. Ilegems *et al.* (18) found that ΔS^{F}_{AB} and α_{AB} are interdependent values for a binary system A-B, and that they can be adjusted by changing the value of either one. In this case, ΔS^{F}_{AlSb} is the good experimental value. We decided to retain ΔS^{F}_{AlSb} and adjust α_{AlSb} only. We then found that a concentration-dependent term must be added to α_{AlSb} in order to obtain a calculated-experimental matched ternary phase diagram. A similar form of composition-dependent α has been used to describe In-Ga (7) and several other III-V binary systems (19). The experimental data were put into Eq. [1] through [8] in order to calculate α_{AlSb} at various temperatures and compositions. The best fit value was found to be $\alpha_{AlSb} = 1590 - 4.0T - 18.0T\,N_{Al}$ cal/mole.

The best fit parameters together with the other thermodynamic constants used in calculating the ternary phase diagram are listed in Table II. With the aid of a computer, the liquidus isotherms were obtained by eliminating x between Eq. [1] and [2] while elimination of T between these same equations gave the solidus isotherms. The resulting calculated liquidus and solidus isotherms at 400°, 450°, 500°, and 550°C are plotted together with the experimental data in Fig. 1 and 2, respectively. The agreement between the calculated and experimental data in the Ga-rich region of the Al-Ga-Sb ternary phase diagram is significant. However, incorporation of the semiempirical composition-dependent α_{AlSb} in the calculations contradicts the basic requirement of the simple solution model where α's are constant or a function of temperature only. Moreover, the inter-

Table II. Parameters for calculation of the Al-Ga-Sb phase diagram

	T^F (°K)	ΔS^F (eu/mole)	α(cal/mole)
Ga-Sb	985 (13)	15.80 (13)	$3425 - 5.13T$
Al-Sb	1330 (13)	14.74 (13)	$1590 - 4.0T - 18.0TN_{Al}$
Al-Ga			104 (5)
AlSb-GaSb			0

action parameter of the form $a + bT$ in the simple solution model is nonphysical (11). Thus, we conclude that although the simple solution model and the curve fitting technique are adequate to describe the Al-Ga-Sb system in the Ga-rich region, the parameters determined by curve fitting have no thermodynamic significance.

Application to Liquid Phase Epitaxy

A major application of the Al-Ga-Sb phase diagram is in predicting conditions for LPE growth. Based on the ternary phase diagram, a desired crystal composition can be obtained from an equilibrium solution at a specific growth temperature. In this work, following the calculated liquidus and solidus isotherms, reproducible homogeneous $Al_xGa_{1-x}Sb$ layers with composition $0 \leq x \leq 0.92$ were grown on (111) oriented GaSb substrates. In general, as-grown surfaces were shiny and smooth. Under the microscope, the cleaved edges of the $Al_xGa_{1-x}Sb$ epitaxial layers with large values of x appear darker than the GaSb substrate. Layers with Al composition $x > 0.8$ have a hygroscopic property similar to pure AlSb. The surface turns brown when exposed to air and must therefore be stored in a desiccator. This property is similar but less serious than that in $Al_xGa_{1-x}As$. For $x < 0.27$, the epilayer can be delineated by etching in a 10% A-B solution (20) for a few seconds.

An Al concentration gradient exists in the grown layer as a result of Al depletion in the solution during growth. This can be evaluated from the phase diagram. Under the assumptions that the growth rate is slow enough such that the liquid and solid remain in continuous equilibrium and that the solid precipitates only on the growth surface of the substrate, the compositional variation during the growth can be calculated. For a 5g Ga solution and a 0.5 cm^2 substrate growth area, the variation in layer composition as a function of normalized layer thickness during cooling from 550° to 450°C was calculated and is shown in Fig. 3. From this figure we can predict the layer thickness and composition during growth between these given temperatures. The composition in the growth direction was determined by electron microprobe analyses on cleaved and polished epilayers. The measured Al composition *vs.* distance from the $Al_xGa_{1-x}Sb$-GaSb interface in seven samples grown at starting temperatures of 500° and 550°C are compared with theory as shown in Fig. 4. The calculations were normalized to 5g of Ga solution

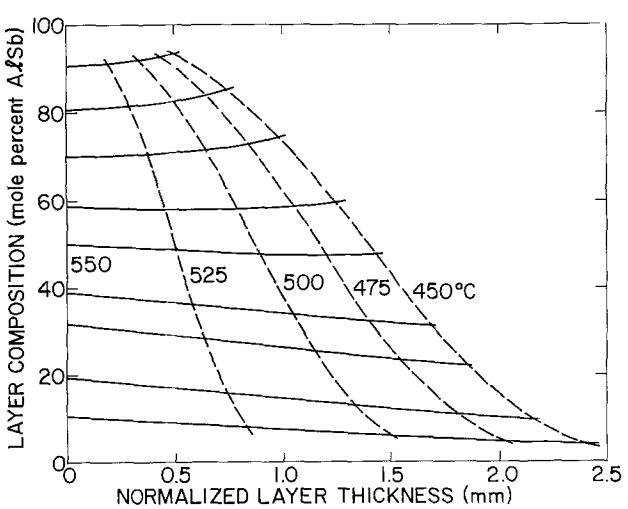

Fig. 3. Layer composition as a function of layer thickness normalized to a 5g Ga solution and a 0.5 cm^2 substrate area. Dashed lines are liquidus isotherms. The 550°C isotherm is superimposed on the ordinate axis.

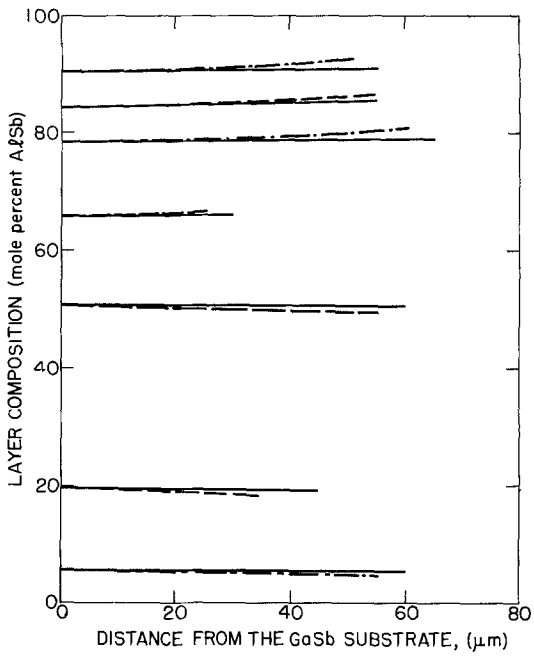

Fig. 4. Variation in layer composition for seven $Al_xGa_{1-x}Sb$ samples. Solid lines are calculated variations and dashed lines are experimental results at starting growth temperatures of 500° (– – –) or 550°C (—· —·).

and a 1 cm^2 substrate which are close to those used in this study. It was found that the Al concentration along the growth direction is constant only when $x \cong 0.6$ and increases or decreases as x becomes larger or smaller than 0.6, respectively. This property is due to the compositional dependency in the distribution coefficient of Al in the Al-Ga-Sb ternary solution.

The differences between experimental and computed values are attributed to the following two main factors neglected in the calculations. First, under the assumption of continuous equilibrium growth, the cooling rate is set equal to zero and the melt must be perfectly stirred. In this study, a cooling rate of 0.25°C/min was used and a depletion layer was formed near the interface. For Ga-rich layers, the distribution coefficient of Al is greater than or of the same order of magnitude as the Sb coefficient, so that Al segregation governs the growth. This leads to a decrease in the Al composition of the ternary solid as compared with the perfectly stirred case. The situation is reversed for Al-rich layers. This same property was observed in $Al_xGa_{1-x}As$ (21) and $Ga_xIn_{1-x}Sb$ (22). Second, we assumed that the solid precipitates only on the growth surface of the substrate. However, preferential growth on the edges of the substrate (23) and nucleation in the ternary liquid (24) cannot be neglected in LPE growth. These extra growths decrease the compositional gradient of solutes in the melt and the growth rate (24). Thus the variation of solid composition tends to be large at the end of the growth. In Al-rich layers, this property is much more severe due to the larger distribution coefficient of Sb which depletes very fast. In conclusion, the experimental results are generally in good agreement with the calculations.

A New Preferential Etch for Defects in Silicon Crystals

Margaret Wright Jenkins*

Motorola Incorporated, Motorola Semiconductor Products Group, Phoenix, Arizona 85008

ABSTRACT

A new preferential etch for (100) and (111) oriented, p- and n-type silicon has been developed. Oxidation-induced stacking faults, dislocations, swirl, and striations are clearly defined with minimum surface roughness or extraneous pitting. A relatively slow etch rate (~1 μm per min) at room temperature provides etch control. The long shelf life of this etch allows the solution to be stored in large quantities.

The development of a rapid and reliable method of evaluation of defects in silicon crystals is of major importance to crystal growth technology, wafer preparation, and processing. The electrical effects of crystal imperfections on device characteristics have recently been reviewed by Lawrence (1). Chemical etching is the simplest means of detecting the presence of defects in silicon crystals. An improved preferential etch which reveals defects precisely and in a more controlled manner has been developed.

The most common preferential etches presently in use are those of Sirtl (2), Dash (3), and Secco (4). Sirtl etch has been used to delineate defects on most crystal orientations, however, it favors the (111) orientation. Although the Dash etch reveals defects on all planes, the 4-16 hr etch time required is unsuitable for rapid evaluation of material. The Secco etch produces elliptical shaped dislocation pits on both (100) and (111) planes making orientation determination by etch pits more difficult.

The need for an etch which delineates defects on most orientations at a reasonable etch rate and with good definition gave rise to the development of the present etch. This etch solution preferentially delineates defects on (100) and (111) orientations of p- and n-type crystals over a wide range (0.02-20 Ω-cm) of resistivities.

A comparison of common defects delineated by this etchant and previously established etchants is given. The variation in etch rates among different material types and among the available preferential etchants is also discussed.

* Electrochemical Society Active Member.
Key words: silicon, preferential etch, defect delineation.

Experimental

The silicon material used in this work was cut from Czochralski and float zone crystals with (100) and (111) growth orientations. Both p- and n-type crystals were used with resistivities ranging from 0.02 to 20 Ω-cm. All wafers were chemically thinned on both sides and chemically slurry polished on one surface. All wafer cleaning consisted of the following steps: (*i*) 30 sec dip in 50:1, H_2O:HF; (*ii*) 5 min rinse in ultrapure deionized (UPDI) H_2O; (*iii*) 10 min boil in 7:3, H_2SO_4:H_2O_2 at 110°C; and (*iv*) 5 min rinse in UPDI water. All oxidations were performed at 1200°C in steam for 75 min. Etch rates were determined by measuring the loss in weight of the sample after each etch period (increment) and calculating to corresponding surface removal in micrometers as follows

$$\text{mass} = \text{volume} \times \text{density} \quad [1]$$

The volume of a wafer is determined by the expression

$$V = \pi r^2 t \quad [2]$$

thus

$$m = \pi r^2 t \rho \quad [3]$$

where m is the mass, π is a constant, r is the radius of the wafer, t is the thickness, and ρ is the density of Si. The change in thickness, Δt, is expressed as

$$\Delta t = \frac{\Delta m}{\pi r^2 \rho} \quad [4]$$

The actual etch rate, which is the change in thickness from one surface, is determined by the expression

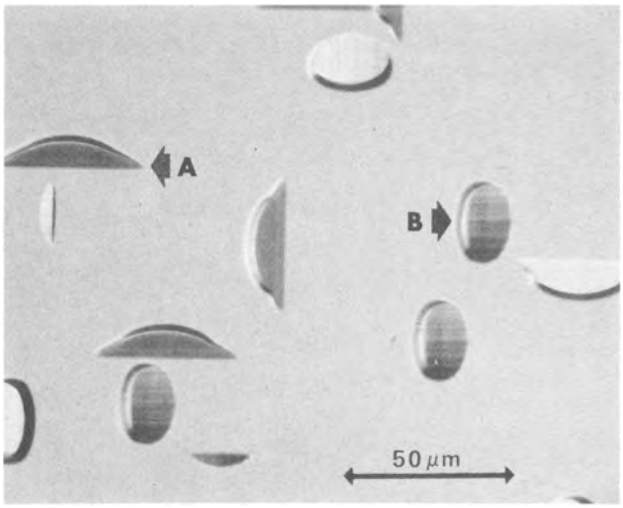

Fig. 1. Oxidation-induced stacking faults on a (100), 7-10 Ω-cm, boron-doped wafer after 30 min Wright etch. (A) Surface faults, (B) bulk faults.

$$\text{etch rate} = \frac{\Delta t}{2} = \frac{\Delta m}{2\pi r^2 \rho} \qquad [5]$$

The composition of this etch, which is known as Wright etch, is as follows: 60 ml conc HF (49%), 30 ml conc HNO_3 (69%), 30 ml of 5*M* CrO_3 (1g CrO_3/2 ml H_2O), 2g $Cu(NO_3)_2 \cdot 3H_2O$ (reagent grade), 60 ml conc acetic acid (glacial), and 60 ml H_2O (deionized). In mixing the solution, the best results are obtained by first dissolving the $Cu(NO_3)_2$ in the given amount of H_2O, otherwise the order of mixing is not critical.

Some of the etching processes were conducted according to the ASTM standard method (5). The wafer was placed with the polished surface upward, in the bottom of a plastic beaker. The etchant was added until the surface was covered with approximately 1 cm of solution. The wafer was etched with manual agitation (in a manner such that the dissolved silicon is moved away from the wafer surface) for the desired length of time (1-5 min or the removal of 1-5 μm of material for surface defects, and ~20 min or the removal of ~1 mil of material for bulk defects). The etchant was flushed from the beaker with distilled water and the wafer was rinsed thoroughly (~5 min). Batch etching was used when two or more wafers were being compared and when extended etch periods were required to reveal bulk defects. The wafers were loaded vertically into a Teflon cleaning boat and placed in an HF resistant container. The amount of etchant added was sufficient to cover the wafers (the wafers may also be immersed in the etch solution). The wafers were etched for the desired length of time and rinsed by quickly removing wafers from the etch solution and placing them under running deionized (DI) water or in a DI rinsing tank for ~5 min. Agitation was not deemed necessary in the batch etching process due to the vertical position of the wafers. However, when the wafers are in a horizontal plane, agitation is necessary to prevent the formation of surface deposits which result in etch artifacts. After rinsing, the wafers were dried and examined with the optical microscope using Nomarski differential interference contrast.

Results and Discussion

Robbins and Schwartz (6-8) described chemical etching of silicon in detail using an HF, HNO_3, and H_2O system and an HF, HNO_3, H_2O, and $HC_2H_3O_2$ system. Briefly, during chemical etching the silicon is dissolved by the etchant in a two-step process. First, the silicon is converted into a soluble oxide by a suitable oxidizing agent(s). Then the resulting oxide is removed from the surface by dissolution in a suitable solvent, usually HF. In order to delineate a crystal defect, the defect area must be oxidized at a faster or slower rate than the surrounding area forming a pit or mound.

In the present system, the silicon is oxidized with HNO_3, CrO_3 solution ($Cr_2O_7^=$), and $Cu(NO_3)_2$. The $Cr_2O_7^=$, a strong oxidizing agent, is considered to be the principal oxidizing species. The ratio of HNO_3 to CrO_3 solution stated in the formula produces a superior etched surface. Other ratios and the use of larger quantities of one of the oxidizing agents produce less desirable finish. With the addition of a small amount of $Cu(NO_3)_2$, the definition of the defect was enhanced. Therefore, it is believed that $Cu(NO_3)_2$ affects the localized differential oxidation at the defect site. The addition of the acetic acid gave the background surface of the etched silicon a smooth finish. It is theorized that this effect is attributed to the wetting action of the acetic acid which prevents the formation of bubbles during etching.

There are several characteristics of the Wright etch which offer distinct advantages over the existing preferential etchants: (*i*) improved defect delineation which facilitates defect identification, (*ii*) background surface smoothness after etching which also aids in defect identification and distribution determination, (*iii*) crystallographic etching which provides for orientation

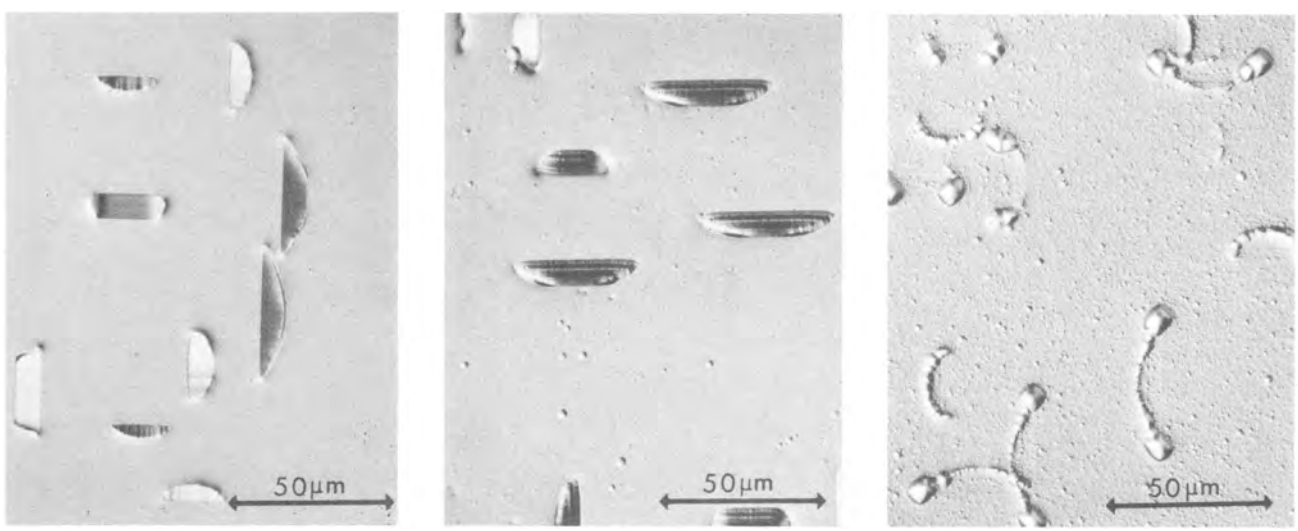

Fig. 2. A comparison of stacking fault delineation and surface condition of a (100) oriented, 1-5 Ω-cm, phosphorus-doped wafer after preferential etching. (a) After 15 min Wright etch, (b) 10 min Secco etch, and (c) 6 min Sirtl etch. Etch times were selected according to etch rates to remove similar amounts of silicon.

determination by the geometric shape of the etch figure, and (*iv*) a relatively slow etch rate which provides for etch control.

Oxidation-induced stacking faults, dislocations, swirl, and striations are clearly defined by this etchant with minimum surface roughness or extraneous pitting. It works exceptionally well in revealing stacking faults. Figure 1 shows surface and bulk stacking faults on a (100) oxidized surface. The stacking fault and the partial dislocation around the fault are etched at approximately the same rate, producing a flat, well-defined figure. The morphology of the faults revealed by this etch is geometrically similar to the diffraction contrast images of stacking faults obtained with the transmission electron microscope (TEM). The surface faults produce an etch figure similar to an extended partial disk while bulk faults are revealed as full loops. Bulk stacking faults that are 1 mil in diameter are shown. This is considered to be an advantage over TEM analysis where the geometry of the fault as viewed is limited to the thickness of the sample, which is typically 0.5 μm for a 100 keV beam.

A comparison of stacking fault delineation and surface condition after preferential etching is shown in Fig. 2. Portions of a (100) oxidized wafer were etched as follows: (a) Wright etch, (b) Secco etch, and (c) Sirtl etch. The definition of the defects and the background surface quality of sample (a) which was treated with Wright etch are superior to those of the Secco and Sirtl etched samples. In using this new etch, there is no excessive gas evolution (bubbles) which usually re-

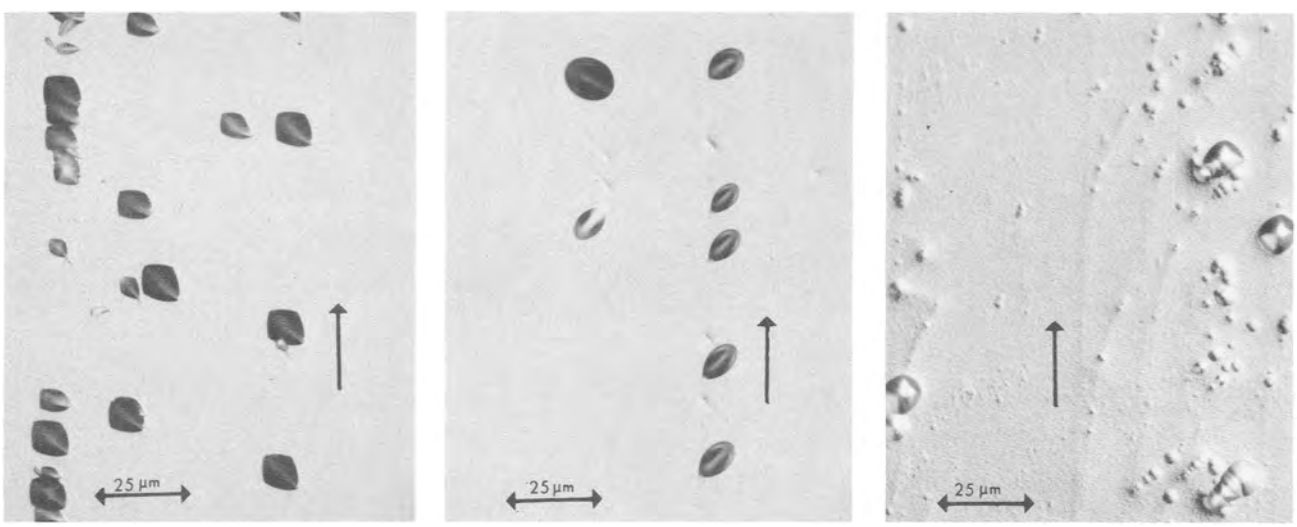

Fig. 4. A comparison of dislocation delineation on a (100) oriented, 10-20 Ω-cm, phosphorus-doped wafer after oxidation and preferential etching. (a) After 20 min Wright etch, (b) 10 min Secco etch, and (c) 6 min Sirtl etch. Arrows indicate slip directions.

sults in nonuniform surface etching. This is often observed on Secco etched samples.

There are no surface copper deposits detected after Wright etching. Auger analyses of etched surfaces were performed to evaluate surface contamination. Figure 3 shows Auger spectra of Wright etched samples before and after cleaning. A copper peak (at 920 eV) was not revealed. The minimum detectable limit of copper by Auger analysis is 10^{12} atoms/cm^2. Other contaminants (Cl, S, N, and Cr) were removed during cleaning.[1] Heat generation is also minimized which allows large numbers of wafers to be etched in batches. In batch etching however, it should be noted that the etch rate increases with the number of wafers being etched in a given amount of solution. This is due to the exothermic nature of the etching process. As the number of wafers being etched is increased, the amount of heat generated is also increased. This raises the temperature of the solution which in turn increases the apparent etch rate. When 10-3 in. wafers (20 mils thick, n-type 7-10 Ω-cm) were batch etched in 2 liters of Wright etch for 10 min, the temperature of the solution increased only 2°C, from 25° to 27°C, and the etch rate remained constant. When 25-3 in. wafers were batch etched in 2 liters of Wright etch for 20 min continuously, the temperature of the solution reached 102°C and 2 mils of surface were removed. In this case, the over-all etch rate is more than a factor of two greater than that at room temperature. A sufficient volume of etch solution

to wafer surface ratio, 200 ml of solution per 3 in. wafer, will minimize heat generation and the corresponding increase in etch rate. In revealing bulk defects (*i.e.*, dislocations) where long etch periods (~20 min) are required, step etching is encouraged. Step etching (~5 min increments) will prevent over etching which may be encountered due to the variation in etch rates between different material types. Generally, boron-doped material etches faster than phosphorus-doped material. Low resistivity material tends to etch faster than that of higher resistivity for the same dopant type. However, this does not necessarily mean that the preferential differentiation of defects is greater. High index oriented planes, *e.g.*, (111), tend to etch faster initially than planes of a lower index, *e.g.*, (100).

The anisotropic crystallographic characteristics of Wright etch is demonstrated in Fig. 4a and 5a. Dislocations along slip lines on a (100), phosphorus-doped surface (4a) reveal well-defined pits with a square geometry with no extraneous pitting or surface roughness. The slip dislocations on the (111) surface (5a) show approximately triangular geometry. The Secco etch reveals the dislocations on both (100) and (111) surfaces as elliptical shaped pits (4b and 5b). The Sirtl etch reveals dislocations on a (100) surface as mounds with approximately square geometry (4c). The background surface is also shown to be textured. However, dislocations on (111) surfaces are revealed as well-defined triangular pits by Sirtl etching (5c). The background surface is also smooth.

Figure 6a and b show oxidation-induced stacking faults on (111) surfaces after 5 min of Wright etch. Figure 6a is of antimony-doped material to 0.02 Ω-cm while 6b shows boron-doped material of the same resistivity. Both samples received the same oxidation cycle. The enlarged size of the stacking faults and the textured background surface of the boron-doped sample indicate a faster etch rate than the antimony-doped sample.

Figure 7a and b show stacking faults in epitaxial layers of (100) and (111) orientations, respectively, after 5 min of Wright etch. Figure 8a shows a swirl distribution of defects on a float zone, (111) oriented, 1-3 Ω-cm oxidized wafer. Figure 8b reveals swirl and striations at higher magnification. Figure 8c reveals stacking faults and dislocations in the swirl pattern.

The relatively slow rate of this etchant provides more etch control. In Fig. 9, the etch rate is compared to that of Sirtl etch. The etch rate of Sirtl etch is shown to be approximately three times greater than that of Wright etch. The former solution etches at a rate of 3 μm per min while the latter has a rate of 1 μm per min. These etch rates were determined by weight loss measurements as described above. Etching for these measurements was performed at room temperature with manual agitation. The slope of the etch rate curves, Fig. 9, is linear with relatively no scatter in data points. These etch rates are reproducible and correspond within 10% of those determined by the direct thickness measurement method. The etch rate of Secco etch, which is not shown, is reported to be approximately 1.5 μm per min (4)

The Wright etch has a long shelf life (~6 weeks). The chemical stability of the solution permits mixing and storing in large quantities. It provides highly reproducible etch results and allows the solution to be reused. Used etch may be stored in a separate container and reused until it becomes saturated with silicon. A saturated solution is characterized by discoloration (4) and the formation of artifacts on etched surfaces. Artifacts are noncrystallographic etch features that are not reproduced on clean surfaces when properly etched in a fresh solution. Figure 10a-c show portions of a wafer that were etched with a freshly mixed solution, a 4 week old solution, and a 6 week old used solution. There is no noticeable difference in defect delineation and surface condition among the three samples. However, the etch rate of 1μ per min for the freshly mixed solution and the 4 week old solution is approximately 40% higher than that for the 6 week old used solution which contained ~4 mg of dissolved silicon per milliliter. The difference in etch rates is also evinced by the width of the stacking fault etch figures after a 5 min etch period for each solution.

Summary

The Wright etch consistently produces well-defined etch figures of common defects on silicon surfaces. It has been demonstrated that Wright etch is superior in revealing oxidation-induced stacking faults. Dislocation etch figures on (100) surfaces are shown to have superior crystallographic etch features when compared with

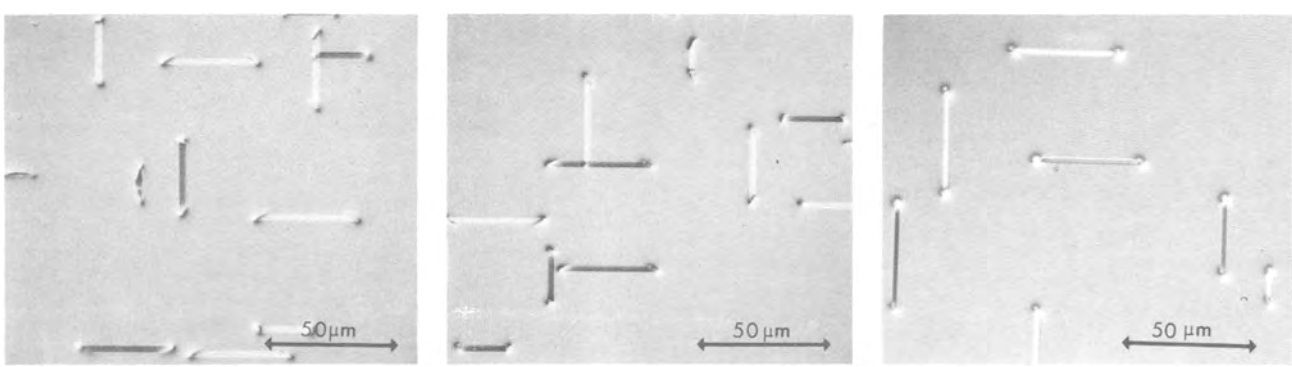

Fig. 10. Stacking faults on a (100), 1-3 Ω-cm, n-type wafer after 5 min Wright etch. (a) A freshly mixed solution, (b) a 4 week old solution, and (c) a 6 week old used solution. Stacking fault delineation and surface quality are not degraded by aging of the solution.

those revealed by Sirtl and Secco etching. The dislocation etch figures on (111) surfaces are comparable to those revealed by Sirtl etching and superior to those revealed by Secco etching. The etch rate of Wright etch (approximately 1 μm per min at room temperature) is slower than that of Sirtl and Secco etchants which provides for more etch control. The background surfaces after etching are smoother than those produced by the previous etchants. Large numbers of wafers may be etched in batches, in a sufficient amount of solution, without excessive heat generation, and the etchant may be reused without loss of defect definition.

Diffusion and Incorporation of Aluminum in Silicon

P. Rai-Choudhury,* F. A. Selim,* and W. J. Takei

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Aluminum is used as a p-type dopant in the manufacture of high power devices. The results of thermodynamic and experimental studies of the Al-Si-H-O system are discussed. Reaction with the quartz wall and moisture in the closed tube diffusion of aluminum causes the source to oxidize and reduces the aluminum partial pressure. Solutions to these problems are discussed. Heat-treatment of diffused wafers under various temperature-time conditions followed by Hall effect and resistivity measurements are performed to study possible formation of donor complexes.

The interest in Al diffusion into Si is primarily because of its use as a p-type dopant for the fabrication of high voltage junctions, and due to its role in silicon-on-sapphire film processing. For high power device fabrication, Al is preferred due to its fast diffusion in Si. The ionic radius of Al^- is close to the tetrahedral covalent radius of Si and it has a low solubility limit, and therefore dislocation generation is reduced. Also, Al does not form any intermetallic compounds with Si. Al diffusion, however, suffers from a few disadvantages because of its high reactivity with oxygen, moisture, and quartz walls. When diffusion is carried out in a sealed system under vacuum or an inert ambient, the presence of oxygen and moisture in the closed tube causes the Al source to oxidize, thus preventing transport of the dopant atoms. Reaction of the quartz walls further reduces the Al partial pressure in the system. The diffusion often results in a low surface concentration and nonreproducible shape of the impurity profile.

The diffusion of aluminum in silicon has been studied by Goldstein (1), Fuller *et al.* (2-4), Miller *et al.* (5), and Y. C. Kao (6). The surface concentrations of aluminum in silicon, found in both the experiments of Fuller *et al.* (2) and Goldstein (1) are in rough agreement but are two orders of magnitude less than the solid solubility of Al in Si. The aluminum (Al) surface concentrations in Fuller's results are below the aluminum solid solubility as their diffusions were made in quartz tubes. This permits the aluminum and quartz to react and reduce the partial pressure of aluminum significantly below the pressure to be expected in the absence of quartz. The interaction between oxygen and aluminum in silicon crystals giving rise to donor complexes and the stability of these complexes at various temperatures have been discussed by Fuller *et al.* (3, 4). Results showing electrical inactivity of Al in Si were reported by other workers. Schink and Warrick (7) have found by wet chemical methods in several silicon crystals an aluminum content of 10^{17} cm^{-3} without any influence on the n-type conductivity. In view of these discrepancies and uncertainties, it is worthwhile to reinvestigate the problem of Al diffusion in Si. The purpose of this study is to discuss sealed-tube Al diffusion and the formation of Al diffused junction, and the conditions under which the Al source remains effective throughout the diffusion cycle, to study the relevant thermodynamic data for the Al-O-H-Si system, and to determine the role and electrical activity of Al in Si.

Experimental Procedures

The silicon wafers used for sealed-tube Al-diffusion were 60-150 Ω-cm, n-type, float-zoned (111) crystals. The lapped wafers were cleaned with detergents, degreased, chemically etched, and chelated before loading in the sealed tube. The diffusion source consists of high purity aluminum pellets that are degreased, etched in NaOH, rinsed in acids and methanol. Quartz tubes were baked under heat lamps or in a 1000°C furnace before loading the source and wafers. Sealing of the quartz ampul was done either under vacuum or argon backfilled conditions. Diffusion was carried out for the desired temperature and time. At the end of the diffusion cycle the furnace was slow cooled at 0.2°-2.0°C/min to about 600°C and then the ampule was with-

* Electrochemical Society Active Member.

Key words: aluminum, junction, silicon, thermodynamics, Hall effect.

drawn from the furnace. The impurity profiles were then measured by the spreading resistance technique.

To study the reactions of Al with oxygen in silicon crystals we used both homogeneously Al-doped Czochralski silicon crystals (Al added to the melt) and Al-diffused wafers after being oxidized at different temperatures. The Al concentration in these Czochralski grown crystals varied from 5.4×10^{16} to 1×10^{18} cm^{-3}. Heat-treatment of these samples was done in N_2 atmosphere for different temperatures (400°-1100°C) and annealing times (16-300 hr), followed by either quenching or slow cooling. In a number of runs the samples were heat-treated at 1270°C for 20 min then rapidly cooled to room temperature. Thus, the high temperature equilibrium is frozen in. This was done to remove any "growth history," *i.e.*, to eliminate processes which may cause atomic defect formation, *e.g.*, precipitates, during the cooling following crystal growth. Hall effect and resistivity measurements on these samples before and after heat-treatment were conducted to check the change in carrier concentrations, conductivity type, and resistivity. Transmission electron microscopy was used to reveal the presence of any precipitates.

Sealed-Tube Aluminum Diffusion and Thermodynamics of the System Al-O-H-Si

In a sealed-tube aluminum diffusion we are dealing with quartz walls, aluminum diffusion source, oxygen and moisture (residual after high vacuum), and the silicon wafers to be diffused. Some of the possible reactions at a typical diffusion temperature in such a system are

$$2Al(g) + \frac{3}{2}O_2(g) \rightarrow Al_2O_3(s), \quad \Delta G_{1500°K} = -286 \text{ kcal} \qquad [1]$$

$$4Al(g) + 3SiO_2(s) \rightarrow 2Al_2O_3(s) + 3Si(s), \quad \Delta G_{1500°K} = -170 \text{ kcal} \qquad [2]$$

Reactions [1] and [2] have negative free energies and show that in the presence of oxygen and quartz the aluminum will be oxidized to form a stable Al_2O_3 (oxide) skin to seal or consume the aluminum source, *i.e.*, aluminum will not be available to transport and diffuse into the silicon wafers.

An examination of the thermochemistry of the Al-O-H-Si system provides information regarding the transporting species, their vapor pressures, and the feasibility of using those volatile species as diffusion sources. Figure 1 shows the thermochemical data for the aluminum-oxygen-hydrogen system at a typical diffusion temperature of 1500°K. The necessary free energy data for these calculations were obtained from the JANAF Thermochemical Tables (8). The ordinate shows the pressures (in atmospheres) of the various volatile species on a log scale while the abscissas show the equilibrium oxygen pressures (upper scale) and the equilibrium hydrogen-water vapor ratios (lower scale) on a log scale. The vertical line in the figure shows equilibrium data for liquid aluminum and solid aluminum oxide (Al_2O_3), while horizontal lines show simple vapor pressure data. The lines of various slopes to the left of the vertical line for the solid oxide show equilibrium data for the volatile oxides, hydrides, and hydroxides over liquid aluminum. The lines to the right of the vertical lines show equilibrium data for the volatile species over solid aluminum oxide. To the right of the vertical line, transport of Al is feasible in the presence of water vapor in the low parts per million range only. As the water vapor content reaches the parts per million level or higher, the partial pressures of the volatile species become extremely low and the liquid aluminum source will form an oxide skin. Under these conditions the aluminum source remains active only during the initial period of the diffusion cycle. To the left of the vertical line (*i.e.*, water vapor in the parts per billion range), liquid Al is stable, and the primary transporting species are Al and AlH. The Al source remains active throughout the diffusion cycle.

Since aluminum diffusion is normally carried out in a sealed quartz tube system, an examination of the silicon-oxygen-hydrogen system is also necessary. Figure 2 shows the thermochemical data for the silicon-quartz-water vapor system. Here again the vertical line defines equilibrium between solid silicon and solid silicon dioxide. If we operate to the left of the vertical line, oxidation of silicon wafers is not favored and the quartz would tend to reduce to SiO. In regions of practical interest, SiO is the dominant species which will react with aluminum when it is present as a diffusion source. The ideal procedure for aluminum diffusion is, therefore, not to use any quartz but instead materials such as alumina and zirconia.

When aluminum is included in the silicon-oxygen-hydrogen system, the equilibrium is shifted toward lower partial pressures for the oxides of silicon. Figure 3 shows the thermochemical data for this system at different temperatures. Here the system is allowed to reach equilibrium so that both liquid aluminum and solid alumina can coexist at a given temperature, which then determines the required ratio of p_{H_2}/p_{H_2O}. Figure 3 indicates that if the residual water vapor can be reduced to below 0.01 ppm (log $p_{H_2}/p_{H_2O} \sim 8$), a lower diffusion temperature is favored. This would maintain a low SiO pressure and minimize source oxidation. If, on the other hand, the quartz diffusion system has a high water vapor content, a higher diffusion temperature is preferable, although the aluminum source will oxidize and create a reproducibility problem.

Results and Discussions

Sealed tube aluminum diffusion.—In general, the surface concentration of aluminum diffused in silicon is about two orders of magnitude less than that at the

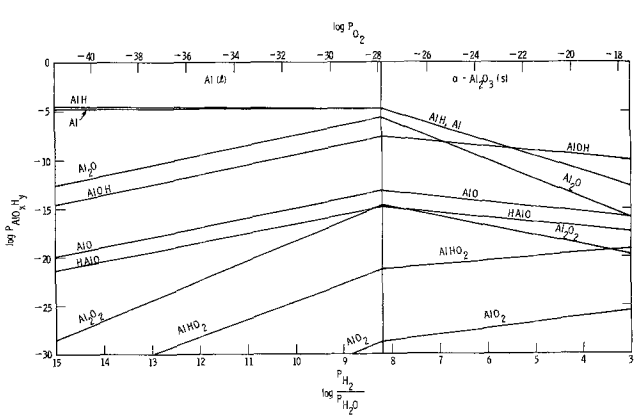

Fig. 1. Thermochemical data for aluminum-oxygen-hydrogen system at 1500°K.

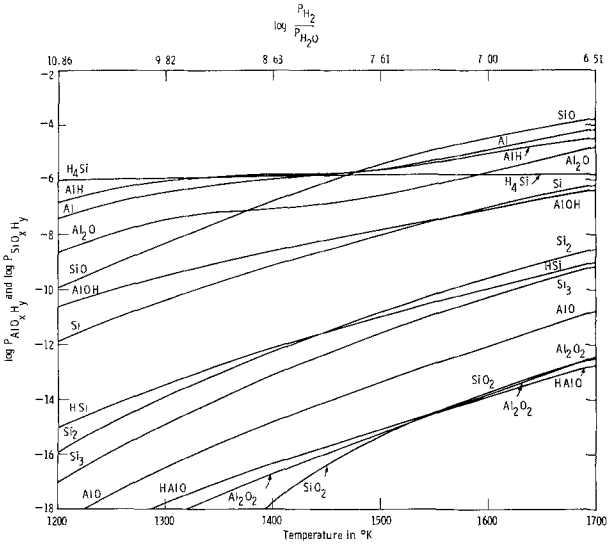

Fig. 3. Thermochemical data for silicon-oxygen-hydrogen-aluminum system at different temperatures.

solubility limit. Such a result may be expected when the experiment is carried out in a quartz system. Goldstein (1), Fuller and Ditzenberger (2), and Pavlov *et al.* (9) all performed their diffusions in quartz systems and were limited to a surface concentration of aluminum below 10^{17} cm^{-3}. Kao (6) has achieved surface concentrations near the solid solubility limit in a quartz system by allowing the quartz to be passivated by the formation of a layer of silicon and Al_2O_3. The aluminum source was maintained active during the passivation process by alloying aluminum with silicon so that no impervious skin is formed at the surface of the diffusion source.

In a quartz system, aluminum and quartz are certain to react and reduce the partial pressure of aluminum below the pressure expected in the absence of the quartz phase. In this regard, the total pressure at which diffusion is carried out is important. Under vacuum conditions the evaporated Al molecules leaving the crucible (assuming the crucible material does not react with Al) could travel considerable distances without undergoing any collisions, most of which occur at the quartz tube wall. Thus a layer of Si and Al_2O_3 builds up on the quartz wall, which becomes passivated. This is only possible if the system has a sufficiently low oxygen and moisture content, so that no impervious skin is developed at the aluminum source surface. When the quartz tube is filled with argon (necessary to prevent the tube from collapsing) to provide about 1 atm pressure at the diffusion temperature, the mean free path of the evaporated aluminum molecules is reduced to about 1 μm. Thus, the Al molecules suffer numerous collisions in the gas phase and with the crucible walls. Interaction with the quartz walls is only possible by Al transport through molecular diffusion. Since there is sufficient SiO partial pressure in equilibrium with quartz (see Fig. 2), Al will react with SiO in the crucible and not be available either to passivate the wall or to deposit on a silicon wafer.

In order to explore the effects of crucible material, quartz, polysilicon, and alumina crucibles were examined. In runs JS-3 and O218Q, aluminum pellets were placed inside a cavity in a silicon disk which were then placed in a quartz crucible. In runs O218S and O223S, aluminum pellets were in direct contact with the polysilicon crucible, whereas in Al3A, the pellets were in contact with an alumina crucible. Unfortunately, diffusions were performed under different conditions because of the need to fabricate different types of devices. Table I summarizes some typical results. The surface concentration (C_o) of aluminum is lowest (1.5×10^{16} cm^{-3}) when an argon backfilled quartz system is used. C_o increases to about $3\text{-}4 \times 10^{16}$ cm^{-3} if argon is replaced by vacuum. Use of a polysilicon liner together with flame baking of the quartz tube provided a higher C_o. When alumina is used as a liner and crucible material, C_o's as high as 8×10^{17} cm^{-3} are obtained under otherwise poor conditions, *i.e.*, argon backfilled. Experiments under vacuum conditions using an alumina liner were not performed because of practical limitations at the time. These results are consistent with the thermodynamic expectations. One of the possible reasons for lower surface concentration in run O2185 with polysilicon liner is that the aluminum source and the silicon wafers were not isolated as effectively from the quartz as in run A13A. The aluminum concentrations in these runs should be compared with the solid solubility limit of about 1×10^{19} cm^{-3}.

The analysis of the phases present in the diffusion sources was made by glancing incidence x-ray diffraction. A portion of the source was mounted in a 114.6 mm powder camera in such a position that the beam struck the diffusion source surface. Thus the technique is primarily sensitive to the phases present within about 0.1 mm of the surface. The only phases which could be detected were polycrystalline silicon, aluminum, and the corundum form of Al_2O_3. The polycrystalline silicon would arise from the formation of a Si-Al eutectic by reaction between the Al source and the Si support disk (except run AL3A where Al was placed directly on the alumina crucible). Typical patterns are shown in Fig. 4 and the results are listed in the last column of Table I.

In run AL3A, the Al source was placed in an alumina crucible, which, in turn, was placed inside an alumina cylinder open at one end only. The silicon wafers were loaded in the cylinder and an alumina cup was used to close the cylinder fairly tightly in an argon ambient. The conditions were apparently sufficiently good to provide fairly high Al surface concentrations. Figure 5 shows the impurity profile from such a run. As can be seen from Table I, the source Al remained unoxidized during the diffusion cycle. For comparison purposes, a typical profile from an all-quartz system under vacuum is shown in Fig. 6. Diffusion sources from such runs frequently will be covered with Al_2O_3.

Table I. Sealed-tube aluminum diffusion conditions

Source	Ambient	Liner inside quartz	Quartz bakeout conditions before sealings	Diff. temp (°C)	Diff. time (hr)	Surface concentration (cm^{-3})	Junction depth (μm)	Phases present in source after diffusion
JS-3	Ar, 1/3 atm	None	Dried under heat lamp	1245	8	1.5×10^{16}	49	Si, Al_2O_3, Trace Al

Electrical activity of aluminum in silicon.—Aluminum is known to give p-type conductivity in silicon. Heat-treatment studies by Fuller *et al.* (3, 4) show that in the presence of oxygen (10^{18} cm^{-3}) aluminum-doped silicon (3×10^{17} cm^{-3} Al) converts from p- to n-type upon reaction at a temperature 500°-900°C. The formation of aluminum-oxygen donor complexes, *i.e.*, ($SiO_4^+Al^-SiO_4^+$) or ($AlO_4SiO_4^+$), was suggested as a possible explanation in the study.

In principle, Al in Si can form two basic defects (10): interstitial aluminum atoms (Al_i), a single, double, or triple donor; or substitutional aluminum atoms (Al_{Si}), a single acceptor. In addition, complexes of these species with ionized defects such as SiO_4 donors may occur, giving rise to complexes such as ($SiO_4^+Al^-SiO_4^+$) or ($AlO_4SiO_4^+$); or neutral complexes, *e.g.*, ($Al^-SiO_4^+$).

Our studies on Al-doped samples have not revealed any conversion in conductivity from p- to n-type upon heat-treatment for different temperatures and times, indicating no formation of such donor complexes as majority species. A comparison of acceptor concentrations before and after annealing of Al-doped silicon is shown in Table II. It is seen that all samples remained p-type with no large change in resistivity after heat-treatment. In few cases we found the resistivity of some samples (No. 1) to increase by more than a factor of two. The acceptor concentrations of

*** Float-zoned crystal, Al diffused, and then oxygen diffused.

these samples changed from 3.2×10^{17} to 1.3×10^{17} cm^{-3}. This change corresponds to a formation of 9.5×10^{16} cm^{-3} donors compensating an equal number of acceptors reducing the acceptor concentration by an amount of 1.9×10^{17} cm^{-3}. This reduction could also be due to Al precipitation during cooling or to formation of 1.9×10^{17} cm^{-3} Al neutral complexes or deep levels. Slow or fast cooling of such samples showed no effect on resistivity, and transmission electron microscopy studies showed no evidence of observable precipitates. This suggests that the reduction in acceptor concentrations in this sample is due to formation of aluminum neutral complexes or deep levels or donor complexes as a minority species which cannot be revealed by room temperature Hall measurements.

Summary

When Al is diffused into silicon in an all-quartz system, the surface concentration of aluminum is low ($\sim 10^{16}$ cm^{-3}) due to an effective reduction of aluminum partial pressure through interactions with SiO_2, SiO, residual moisture, and oxygen. When alumina is used as a liner and crucible material, surface concentrations as high as $\sim 10^{18}$ cm^{-3} are obtained under otherwise poor conditions (*i.e.*, argon backfilled). No evidence of the interaction between Al and O giving rise to Al-O donor complexes as majority species was found.

Phase Diagram of the $(CuGaTe_2)_{1-x}$-$(2CdTe)_x$ System and Semiconducting Properties of $CuCd_2GaTe_4$

A. Aresti, L. Garbato, P. Manca, and A. Rucci

ABSTRACT

The system $(CuGaTe_2)_{1-x}$-$(2CdTe)_x$ was investigated by microstructure, DTA, and x-ray examinations. The analysis of the phase diagram shows, in the range $0.33 \leq x \leq 1$, the existence of a continuous series of solid solutions of sphalerite-type structure, the lattice parameter of which varies coherently with microhardness. The main physicochemical and transport properties of the $CuCd_2GaTe_4$ composition are reported.

Structural and microscopic examinations, carried out on the middle composition of $A^{I}C^{III}D_2^{VI}$-$B_2^{II}D_2^{VI}$ systems (A^I = Cu, Ag; B^{II} = Zn, Cd; C^{III} = Ga, In; and D^{VI} = Se, Te), have shown that the characteristics of homogeneity and single phase seem to be restricted to copper ($CuB_2^{II}C^{III}D_4^{VI}$) and silver ($AgCd_2InTe_4$) based compositions, the main physicochemical properties of which have been investigated (1). Experimental research in this field is generally concerned with the determination of regions of mutual solubility in tetrahedral four-component systems of the type $A^{N-1}C^{N+1}D_2^{8-N}$-B^ND^{8-N} (N = 2, 3) (2-19) or, more particularly, with the synthesis and crystal growth techniques of quaternary phases with general composition AB_2CD_4 (19-26), which can be considered as the structure analogous to binary and ternary normal tetrahedral compounds.

In this paper, as a part of intensive and systematic studies on synthesis processes, stability, and structural

Key words: diamondlike quaternary semiconducting phases.

characterization of $A^IB_2^{II}C^{III}D_4^{VI}$ quaternary phases, we report the phase diagram of the $(CuGaTe_2)_{1-x}$-$(2CdTe)_x$ system, in order also to define the region of interest for semiconductor-device metallurgy.

Experimental Procedure and the Phase Diagram

The alloys in the system $(CuGaTe_2)_{1-x}$-$(2CdTe)_x$ were obtained both by direct synthesis of elements (Johnson-Matthey "Specpure") and by starting from varying amounts of the terminal points of the diagram. Samples, sealed in quartz ampuls under high vacuum (10^{-5} Torr), were heated for 3 days at about 1160°C with a continuous mechanical vibration and then quickly quenched in an ice water bath. The synthesis process was carried out with an accurate temperature program, because of the relatively high vapor pressures of cadmium and tellurium (a heating rate of about 1°C/min was found to be the most suitable). In these conditions there was no evidence of distillation and thus the starting composition was insured for all samples.

The phase diagram (Fig. 1) is the result of microstructure, DTA, and x-ray investigations, carried out systematically on different samples, taking 0.08 as the average step in x. No differences were observed in the ingots obtained by the two above-mentioned synthesis methods. The left-hand side of the diagram ($x < 0.33$), with an exception of a small range of solubility in the chalcopyrite structure, is characterized as a heterogeneous region with two distinct phases melting at about the same temperature (850°C). All DTA transitions below the solidus curve disappear near the $x = 0.33$ composition. Microstructural examinations on etched surfaces of samples of this range provided a constant value of microhardness (about 340 kg/mm²) on both phases and x-ray diffractograms clearly revealed a mixture of tetragonal (chalcopyrite) and cubic (sphalerite) structures. The latter result, at least for the range $0 < x < 0.33$, agrees with a previous roentgenographic investigation (11).

In the single phase region ($0.33 \leq x \leq 1$) the analysis of thermograms points out that no detectable heat effects due to solid-solid phase transitions appear for these alloys. X-ray diffractograms can be systematically indexed as a cubic cell of sphalerite structure. This latter result suggests that the cationic sites, for all compositions of the solid solutions, are randomly occupied by the A^I, B^{II}, and C^{III} atoms, the disorder leading consequently to an isotropic sphalerite-type cell.

Figure 2 shows the variation of both microhardness and lattice parameter *vs.* composition. It is interesting to note that the lower limit of solubility occurs for the nominal composition $CuCdGaTe_3$ (equimolar ratio of $CuGaTe_2$ and CdTe), which exhibits the maximum

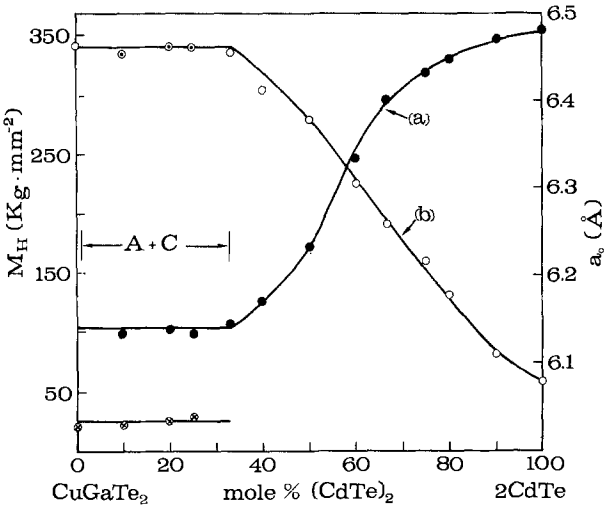

Fig. 2. Lattice parameter (a) and microhardness (b) *vs.* composition. ● zinc blende; ⊗ chalcopyrite [$a_o = (a^2c/2)^{1/3}$]. The symbol ⊙ of curve (b) refers to microhardness prints of cubic and tetragonal phases.

value of microhardness and the minimum one of lattice parameter. Such behavior seems to be characteristic of alloys whose anions are on the average surrounded by an equal number of cations (14).

Fundamental Properties of the $CuCd_2GaTe_4$ Phase

We consider the composition $x = 0.5$ ($CuCd_2GaTe_4$) in the $(CuGaTe_2)_{1-x}$-$(2CdTe)_x$ system as a relevant term of the phase diagram, because of its close analogy with $B^{II}D^{VI}$ semiconducting compounds of sphalerite structure.

Thermal conductivity (K) and thermoelectric power (α) measurements (80°-300°K, Fig. 3) were carried out on cylindrical polycrystalline samples (1.75 cm long and 1.0 cm in diameter) by using a previously reported (27) steady-state method (28). The room temperature values (Table I) are of the same order of those reported (14, 25) for some homologous quaternary phases and represent an average between the K and α values (29-31) of the terminal points of the phase diagram. A similar conclusion can be drawn for the value of magnetic susceptibility (χ_{mol}), which can be compared with the sum of the values of $CuGaTe_2$ (32) and CdTe (33). The samples grown are p-type, as shown by thermoelectric emf measurements.

The figure of merit $Z = \alpha^2\sigma/K$ at room temperature is found to be about 10^{-5} °K^{-1}. The optical gap at room

1.1	7.7	1.5	$5 \cdot 10^{18}$	11	260	28	10^{-5}	−246

temperature, as deduced from absorption and reflectivity spectra (Fig. 4), is 1.1 eV. This result is in agreement with the values obtained by Woolley and Williams (11) for other quaternary phases of the Cu-Cd-Ga-Te system, but sensibly deviates from the data reported (25) for some $A^{I}B_2^{II}C^{III}D_4^{VI}$ homologous compositions. The gap 1.1 eV of $CuCd_2GaTe_4$ can be compared with the values 1.3_1 and 1.4_7 eV found (1) for the isocationic phase $CuCd_2GaSe_4$ in the zinc blende and wurtzite structures, respectively.

Electrical conductivity measurements were made by a conventional d-c method, with ohmic contacts obtained by spark-soldering thin Pt wires or by four pressed graphite probes. The experimental results, obtained on a number of different samples in the range 170°-630°K, reveal the existence of an impurity level at about 0.1 eV. All $\sigma = \sigma(T)$ curves are reproducible up to 370°K. The high concentration of impurities and the probable onset of an irreversible change above 370°K make it impossible to determine the electrical energy gap of these samples. However, thermogravimetric analysis does not show loss of weight up to 750°K and microscopic examinations do not reveal any phase change in samples after electrical conductivity measurements. Therefore, the difference in electronic properties of recycled samples might be due to a random rearrangement of the Cu, Cd, and Ga atoms in the cationic sites of the sphalerite structure.

Oxidation Behavior of Chromium Between 300° and 600°C

D. J. Young* and M. Cohen*

National Research Council of Canada, Division of Chemistry, Ottawa, Ontario, Canada K1A 0R9

ABSTRACT

Oxidation kinetics of high purity polycrystalline Cr were measured at $p_{O_2} = 0.53$ Pa and $300° \leq T \leq 600°C$. The reaction proceeded in two stages: an initial period of growth, in which the kinetics could be described with the Cabrera-Mott theory, was followed by an abrupt transition to a lower growth rate and parabolic kinetics. The kinetic transition was accompanied by a change in diffraction pattern of the oxide from that characteristic of a random orientation of very fine grained Cr_2O_3 to a pattern indicating a strongly preferred fiber texture. The oxide film formed in the pretransition region was flat whereas that formed in the posttransition region was composed of ridges and nodules separated by a very thin oxide film. Activation energies in both kinetic regions were much less than that found for self-diffusion in Cr_2O_3. It is concluded that the rate-controlling process throughout the reaction is metal transport via preferred pathways, such as grain boundaries, through the oxide film. In the pretransition region the density of such pathways is high, leading to uniform film thickening. In the posttransition region the density of such pathways is low, leading to localized transport and hence localized oxide growth.

The reaction of chromium with oxygen has been studied extensively. Attention has been directed to two aspects: thick scale formation at high temperatures, and initial oxygen uptake on bare metal surfaces at relatively low temperatures. Thermogravimetric and marker studies (1-4) of the high temperature reaction have established that chromium grows a scale of Cr_2O_3 by outward diffusion of cations with some contribution from inward anion diffusion (2, 3, 5). Kinetics are parabolic until the temperature exceeds 900°C where Cr vaporization becomes important (6).

Investigations of initial oxygen uptake on clean, single crystal surfaces have focused on structural aspects (7-9) and the observation of Cr_2O_3 nucleation. Changes in surface potential (10, 11) have been measured during oxygen uptake on evaporated metal films, indicating that a potential drop was set up between the metal (positive) and adsorbed oxygen. Subsequent oxide film growth at low and intermediate temperatures has receiveed relatively little attention.

Alessandrini and Brusic (12) examined the oxidation of polycrystalline Cr at temperatures of 400°-600°C and at a pressure of 1 atm O_2. Their ellipsometric measurements indicated kinetics which were described as initially linear and finally parabolic. Depending on temperature, the initial linear period was up to 10 min long and the thickness of oxide formed in that time varied between ~40 and ~100Å. The subsequently observed parabolic reaction had an activation energy of 96 ± 2 kJ. These results were interpreted in terms of an initial stage in which oxide nucleation was rate determining, followed by diffusion limited growth.

Hope and Ritchie (13) have studied the oxidation of vacuum-deposited Cr films in 1 atm O_2 and $250° \leq T \leq 450°C$. Resistance marker experiments indicated that mass transport through the oxide was achieved by metal movement. An electrostatic field was applied across the growing oxide using a vacuum-deposited porous Pt counterelectrode. When the Cr-oxide interface was made positive with respect to the oxide-counterelectrode interface, the rate was enhanced; reversal of the field polarity led to a reduction in rate. The authors interpreted this result as indicating rate control by ion transport. The technique employed by Hope and Ritchie of measuring the rate of increase of resistance of a thin evaporated film, while sensitive to relative changes in reaction rate, does not yield accurate kinetics.

* Electrochemical Society Active Member.

Key words: oxidation kinetics, Cabrera-Mott equation, morphological development, ion transport.

It is evident from the above that a thorough understanding of the Cr oxidation mechanism cannot be achieved until more precise kinetic information is available. This paper presents new data in the 300°-600°C region together with a structural and morphological description of the oxide. A mechanism for oxide growth is proposed.

Experimental

Kinetics were measured manometrically in an ultrahigh vacuum system which has been described previously (14). Experiments were initiated by heating the Cr sample to temperature in a dynamic vacuum ($\sim 10^{-5}$ Pa). After times of up to 20 min, the sample was isolated from the pumps. An oxygen dose at a known pressure was then allowed to expand into the reaction chamber. Subsequent pressure changes were measured with a differential capacitance gauge which yielded a sensitivity corresponding to less than a monolayer coverage of the sample. Successive doses of oxygen were used to maintain the pressure within ±10% of the nominal value. Because the gas admission valve was relatively slow opening, the kinetics of gas uptake in the first 1-2 sec were lost.

The temperature of the metal sample was measured and controlled to within ±2°C. Representative samples were examined before and after reaction by reflection electron diffraction and electron microscopy. Moderately thick oxide films (>300Å) could be dry-stripped from the metal. Thinner films could not, and their morphology was studied by replica electron microscopy. A two-stage carbon replication technique was used.

Materials.—Polycrystalline chromium sheet was supplied by the Australian Aeronautical Research Laboratories. On analysis it was found to contain as major impurities (in parts per million atomic) O 800, C 39, N 31, Si 18, Fe 13, and S 10. This material contained inclusions which were identified by electron diffraction as Cr_2O_3. Rectangular samples of surface area ~5 cm^2 were prepared by mechanically polishing all surfaces to a 3 μm diamond finish and subsequently electropolishing in 5 volume percent (v/o) solution of $HClO_4$ in CH_3COOH at 16°C at a current density of ~0.5 A-cm^{-2}, in 10 sec bursts. The thickness of material removed mechanically was about 10 μm and electrochemically about 8 μm. The grain size of the Cr was ~0.1 mm, elongated slightly in the rolling direction. Spectroscopically standardized oxygen (<70 vpm impurities) supplied by the Baker Chemical Company was employed.

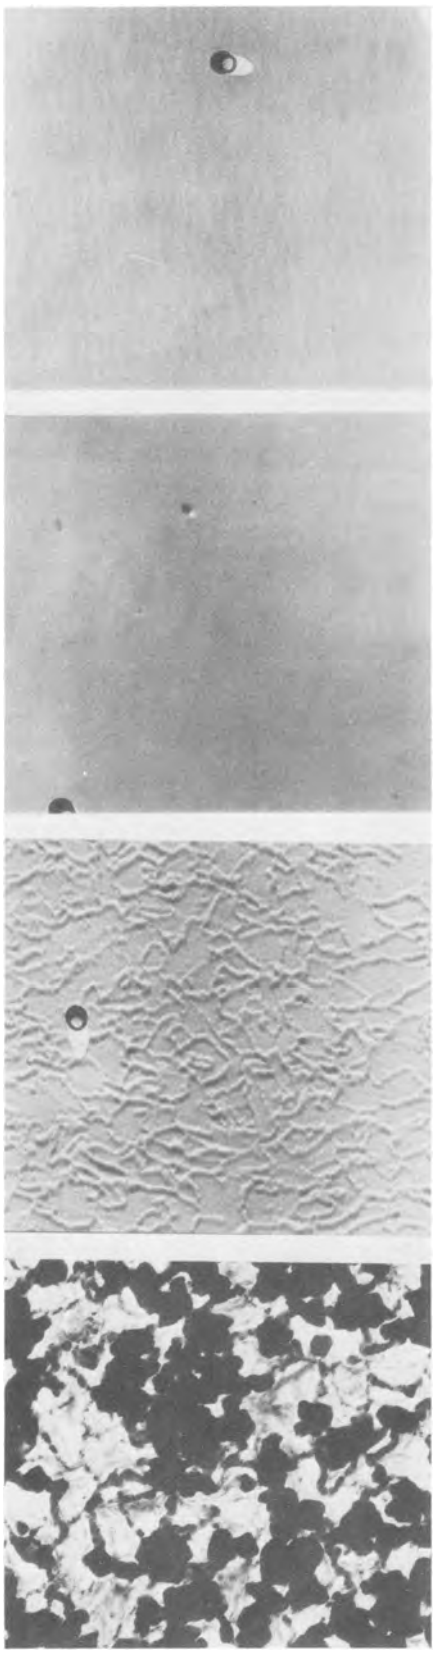

Fig. 1. Electron micrographs of oxide surface replicas. Top to bottom: (a) Replica of electropolished Cr prior to oxidation. (b) Replica of oxide grown in 150 sec at 330°C; $X = 50$Å. (c) Replica of oxide grown in 325 min at 400°C; $X = 115$Å. (d) Dry-stripped oxide grown in 395 min at 490°C; $X = 410$Å. All micrographs 30,000X; latex spheres are 910Å in diameter.

Results

Kinetics.—All kinetic experiments were carried out on samples which had already grown an oxide film during and after the electropolishing step. The thickness of this prior oxide film was measured by soft x-ray excitation (15) and found to be 16 ± 2Å. The only significant impurity was C at a concentration corresponding to ~1 monolayer. Examination of the film surface by replica transmission electron microscopy revealed the smooth, slightly rippled topography shown in Fig. 1a. Reflection electron diffraction revealed no structure at all. It is concluded that the prior oxide film is amorphous Cr_2O_3. Alessandrini and Brusic (12) estimated the thickness from ellipsometric measurements as 20 ± 4Å, while an earlier report (16) estimates the thickness of air-formed oxide as 15Å.

The rate of gas uptake at a pressure of 0.53 Pa and $300° \leq T \leq 600°C$ is shown in Fig. 2. Gas uptake has been converted to increase in average oxide film thickness on the assumption of a roughness factor equal to one and a Cr_2O_3 density of 5.25 g-cm^{-3}. The quantity plotted, X, is the actual film thickness, *i.e.*, the sum of the prior film thickness and the measured increase. The kinetics at all temperatures are characterized by an initial period of very rapid reaction followed by a much slower rate. This effect is shown more clearly in the semilogarithmic plots of Fig. 3 where an abrupt transition between the two regimes of kinetic behavior is apparent. As the temperature is increased, the transition occurs sooner but at greater film thicknesses. The

Table I. Pretransition kinetics as described by the various rate equations

T/°C	Standard deviations in film thickness in A			
	Eq. [1]	Eq. [2]	Eq. [3]	Eq. [4]
300	3.2	2.4	2.1	2.0
330	2.6	1.7	1.4	1.5
363	2.1	1.6	0.8	0.8
400	1.6	2.3	0.6	0.6

two regimes will be referred to as pre- and posttransition.

Only at the lower temperatures are extensive data available for the early stage kinetics. Regression analysis has been performed on pretransition data obtained at temperatures up to 400°C for a logarithmic rate equation

$$X = A_1 + B_1 \ln (t + 1) \quad [1]$$

a parabolic rate equation

$$X = A_2 + B_2 t^{1/2} \quad [2]$$

and two modified (17) forms of the Mott-Cabrera rate equation

$$dX/dt = A_3 \sinh (B_3/X) \quad [3]$$

$$dX/dt = (A_4/X) \sinh (B_3/X) \quad [4]$$

where A and B are constants. A comparison of the resulting standard deviations in film thickness is shown in Table I and reveals that the best description is found in either Eq. [3] or [4]. Regression lines for Eq. [4] are shown in Fig. 4. Arrhenius plots for A_3 and A_4 were constructed and that for A_4 is shown in Fig. 5.

The posttransition kinetics are best described by a modified parabolic rate equation

$$X = k_p^{1/2}(t - t_T)^{1/2} + C \quad [5]$$

where k_p and C are constants, and t_T is the time at which the transition occurs between kinetic regimes and is determined from Fig. 3.

Data for the second stage kinetics are plotted according to Eq. [5] in Fig. 6. Parabolic rate constants found from Eq. [5] are displayed in an Arrhenius plot in Fig. 7. The activation energy is deduced therefrom to be 150 ± 13 kJ.

Morphology and structure.—In a series of experiments conducted at 330°C, samples were oxidized for different periods of time. Growth kinetics observed in these experiments are shown in Fig. 8 where the reproducibility is seen to be good. The thickness, morphology, and structure of the resultant oxide films were subsequently examined.

Average oxide thicknesses were determined by oxygen K_α x-ray excitation (15). Thicknesses determined in this way are plotted against net oxygen uptake (as

measured manometrically) in Fig. 9 where the linearity of the results is seen to be excellent. The straight line shown was found by regression, and corresponds to a prior air-formed oxide film thickness, X_o, of 16 ± 2Å.

RHEED patterns were obtained for a Cr sample which had been held at 330°C for 30 min in a dynamic vacuum and for oxidized samples for periods indicated as A-E in Fig. 8. The vacuum heat-treatment and the two short-term oxidation treatments, A and B, all produced structures which exhibited two diffuse halos attributable to Cr_2O_3. Each of samples C, D, and E produced the same diffuse spot pattern in which the diffuse spots changed to arcs as the extent of oxygen uptake increased (see Fig. 10 a-c). The pattern corresponds to two fiber orientations of Cr_2O_3: in one the (006) plane is parallel to the metal surface, in the other it is the (0.2.10) plane.

Thicker oxide films grown at higher temperatures were also examined. A film grown at 400°C to an average thickness of 50Å (*i.e.*, oxide growth was terminated in the pretransition region) yielded a diffuse halo pattern identical to the one found from samples oxidized in the pretransition region at 330°C. A RHEED pattern obtained from a 115Å film grown at 400°C is shown in Fig. 10d. The fiber orientations found at 330°C are again present although the arcs are now much broader. This orientation was preserved in all thicker oxide

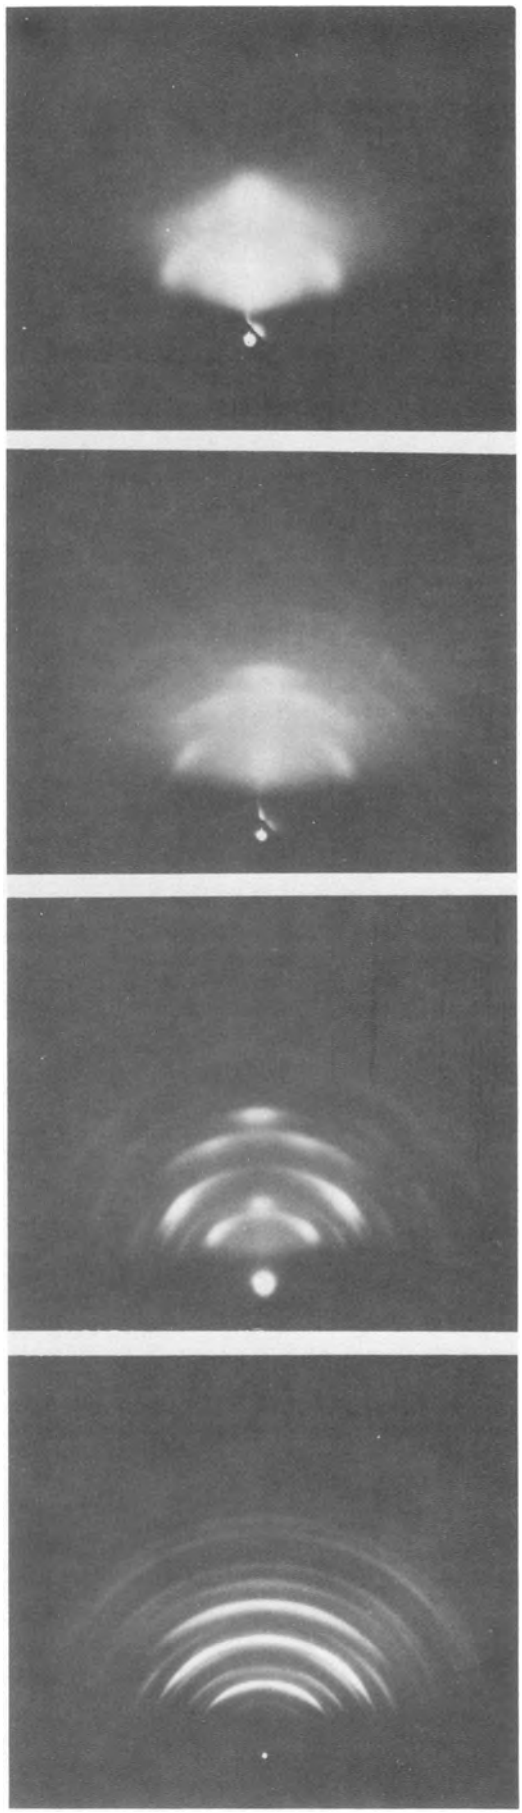

Fig. 10. Reflection high energy electron diffraction patterns. Top to bottom: (a) sample C of Fig. 8; (b) sample D of Fig. 8; (c) sample E of Fig. 8; (d) oxide grown at 400°C, X = 115Å.

films examined (up to $X \sim 1000$Å): the arcs became no broader and the only change observed was the development of higher order diffraction lines with increase in oxygen uptake.

Replica transmission micrographs showed all the oxide films produced at 330°C to have flat, featureless surfaces. An example is shown in Fig. 1b. A film grown at 400°C in the pretransition region had the same appearance. Another film grown at 400°C to an average thickness of 115Å is seen in Fig. 1c to have developed a structure of raised oxide ridges separated by regions of flat-surfaced oxide. A film of average thickness 395Å grown at 490°C was dry-stripped from the metal and a transmission micrograph is shown in Fig. 1d. The ridges seen at 400°C are again apparent and, in addition, thick nodules of oxide are now evident. The flat-surfaced oxide film which covers the metal between these features appears to be very thin.

For the reaction times used (up to 4 hr), the surface area fraction covered by ridges and nodules was approximately constant at a given temperature and varied from 0.5 at 400°C to 0.7 at 600°C. From a measurement of shadow lengths it was found that the thin portion of these posttransition oxide films accounted for <5% of the total oxygen uptake.

Discussion

The pretransition and posttransition domains of chromium oxidation behavior differ in their reaction rates, in kinetic functional form, in the activation energy of their kinetics, and in the morphology of the oxide film produced. It is evident that the two regions are characterized by different reaction mechanisms. They will therefore be discussed separately.

Pretransition kinetics.—Oxide films formed in the early stage reaction were found to possess a uniformly flat surface. The diffuse halo diffraction pattern which they yielded indicates a very fine grain structure. The film is therefore a close approximation to the theoretical model of a parallel-sided, essentially structureless oxide slab. Under these conditions and for the film thickness range in question ($X < 60$Å), the most generally useful kinetic theory of oxidation is that of Cabrera and Mott (18). This theory assumes that electronic equilibrium is established across the growing film. The resultant electrostatic potential drop across the film provides the driving force for transport of ionic defects through the film and hence for film growth. It may be shown (17) that space charge effects in such a system will generally be small. The expression for the rate of film thickening predicted by this model is

$$dX/dt = 4a\nu n_0 \Omega \exp(-U/kT) \sinh(|qa\phi|/kTX) \quad [6]$$

where Ω is the volume of oxide formed per ion, n_0 the concentration of mobile ionic defects at the interface at which they are generated, U the height of the activation barrier to their movement, a the activation distance, ν the attempt frequency on the barrier, q the charge on the ions, and ϕ the electrostatic potential drop across the film.

The evaluation of the quantity n_0 above has been treated elsewhere (17) via a steady-state kinetic approach in which n_0 is related to the surface concentration of species responsible for defect injection. In the case of metal interstitials, these latter species are taken to be metal atoms (concentration N cm^{-2}) at the metal-oxide interface, and in the case of transport by cation vacancies they are taken to be adsorbed anions (concentration σ cm^{-2}) residing on the gas-oxide interface. It seems likely that in the case of interstitials, n_0 is nearly independent of film thickness and is given by

$$n_0 \simeq [N \exp(-W/kT)]/2a \quad [7]$$

where W is the heat of solution of an interstitial cation. Combination of Eq. [6] and [7] leads to Eq. [3] with

$$A_3 = 2\Omega\nu N \exp[-(W+U)/kT] \text{ and } B_3 = |qa\phi|/kT \quad [8]$$

In the case of cation vacancy migration, no such simple relationship exists as σ_0 is proportional to $|\phi|/X$ and hence varies with film thickness. A general relationship between n_0 and σ_0 has been derived (17), but for present purposes it is sufficient to take the limiting case where X is small which leads to Eq. [4] with

$$A_4 = \Omega\nu\epsilon\phi [\exp(-Q/kT)]/2\pi q_0 \quad [9]$$

where ϵ is the dielectric constant of the oxide, Q is the height of the activation barrier to ionic movement at the oxide-gas interface, and q_0 is the charge on the surface adsorbed species.

In fitting kinetic data to Eq. [3] and [4], it has been assumed that ϕ is independent of X. It may be shown (17) that this is a reasonable approximation for $X >$ 20Å. The parameter values A_3, B_4, and A_4 derived from these fits are to be compared with the predictions of Eq. [8] and [9]. It will be assumed that the effective charge of the mobile ionic defect is ± 3 and an average value of $a = 1.47$Å will be adopted.

In principle, a value for ϕ may be calculated from an equilibrium adsorption model but the requisite thermodynamic data are lacking. However, surface potential measurements (10, 11) yield values of 2.1-2.4V at 25°C and at oxygen pressures between 1.3×10^{-3} and 13.3 Pa. Data fitting to Eq. [3] produce an estimate of 2.8 ± 0.8V, and to Eq. [4] of 2.4 ± 0.5V, both estimates being temperature independent. Since the potential drop is expected (17) to exhibit negligible temperature dependence, these values are in reasonable accord with the surface potential measurements. In view of the fact that the oxide thickness present during those measurements was unknown, the agreement is regarded as satisfactory.

Arrhenius plots for A_3 and A_4 yielded

$$A_3 = 2.21 \times 10^3 \exp[-177 \pm 24\,(\text{kJ})/RT] \text{cm sec}^{-1}$$

$$A_4 = 7.78 \times 10^{-5} \exp[-187 \pm 43\,(\text{kJ})/RT] \text{cm}^2 \text{sec}^{-1}.$$

Substituting the values $\Omega = 4.81 \times 10^{-23}$ cm^3, $\nu = 10^{12}$ sec^{-1}, $\phi = 2.4$V and the estimate $\epsilon = 5$ into Eq. [9] yields a value for the preexponential factor in A_4 of 6.4×10^{-4} cm^2 sec^{-1} on the assumption of singly charged adsorbed anions. Agreement with the empirical value is reasonable. Comparison of the theoretical expression and experimental value for A_3 results in an estimate of $N \simeq 5 \times 10^{13}$ cm^{-2}. This implies that about 5% of the surface metal atoms is in a position to enter the oxide if Eq. [3] represents the mechanism. Again, this is a reasonable result.

The activation energies deduced from the application of the two models are now considered. Since excess metal cations and cation vacancies are probably accommodated on the same sublattice in Cr_2O_3 (octahedral interstices in an approximately hexagonal close-packed array of oxygen), the activation energy for their movement will be the same. Self-diffusion data obtained (19, 20) at temperatures above 1100°C show an activation energy of 420 kJ. The very much lower value observed in the present work suggests that ionic motion is not occurring via sites in the Cr_2O_3 lattice but rather along favorable paths for transport through the film. The very small grain size of the oxide suggested by its diffuse diffraction pattern would provide a very high concentration of grain boundaries which would act as preferred transport paths. Under these conditions, it is not possible to distinguish between mass transport via excess cations or via cation vacancies.

Posttransition kinetics.—Films formed in the posttransition or parabolic growth stage are characterized by the existence of thick nodules and ridges of oxide separated by areas of very thin film. The oxygen uptake measured in this region is an approximate mea-

sure of the extent of growth of the nodules and ridges since the intervening film remains very thin. It follows that it is the nodules and ridges which grow according to parabolic kinetics. Since the surface area fraction occupied by nodules and ridges is approximately constant through the course of the reaction, the observed parabolic kinetics describe oxide thickening.

Parabolic kinetics can arise through diffusion under an activity gradient when local equilibrium is attained or, in the absence of local equilibrium, it can arise through migration under an electrostatic potential gradient. In the latter case which is expected to obtain in relatively thin films (18), the preexponential portion of the parabolic rate constant is given by $2\Omega_v s q a \phi / kT$ where s is the surface concentration of species responsible for defect injection, *i.e.*, either N or σ. Comparison with the quantity deduced from an Arrhenius plot yields $\phi s \simeq 1 \times 10^{11}$ V-cm^{-2}. As this is a reasonable result, the possibility of this model being applicable cannot be dismissed. Thus the kinetic measurements do not provide a basis on which to distinguish between diffusion under an activity gradient and migration in an electric field as the mode of mass transport.

The activation energy of 150 kJ found for the parabolic rate constant is much less than that for self-diffusion in Cr_2O_3 and is also less than the estimate of ~250 kJ found (5, 21) for oxidation at higher temperatures. It is concluded that preferred transport paths facilitate mass transport in the posttransition region of behavior also.

Structural development.—The transition between the two regions of kinetic behavior is accompanied by changes in the structure and morphology of the film. The initial fine-grained randomly oriented oxide begins to show preferred fiber texture at the time of the kinetic transition. During subsequent oxide growth this epitaxial relationship is preserved while the oxide grain size increases, as evidenced by the sharpening of the diffraction patterns and the appearance of higher order diffractions. Ridges and nodules of oxide are developed during this phase of growth.

During the pretransition period of growth, the very fine-grained structure provides a large number of grain boundaries which may serve as preferred transport paths. The density of these paths is so high that an approximately uniform film thickening results. This stage of oxidation terminates abruptly when the oxide undergoes a transformation. One of the products of this transformation is the very much more perfect fiber-oriented oxide seen in Fig. 10. Mass transport through this oxide will be much slower than along grain boundaries and oxide growth will virtually cease in the areas where this oxide covers the metal. It is therefore concluded that the thin film regions observed in posttransition oxides are areas of this more perfect oxide. Another product of the oxide transformation is polycrystalline oxide. The grain boundaries present in this material provide preferred pathways for mass transport. Thus metal ion transport and hence oxide growth will occur in the regions of polycrystalline oxide. Since these are localized, the development of oxide ridges and nodules is explained.

The transformation in oxide structure is explicable if the pretransition oxide is regarded as amorphous and therefore metastable. The provision of sufficient energy to the oxide will therefore bring about its crystallization. Although the present experiments do not reveal the source of this energy, we may surmise that stress within the growing oxide is the cause.

Summary

The oxidation kinetics of chromium show an abrupt transition between two distinct regions of behavior. The pretransition reaction proceeds according to the model of Mott and Cabrera. The evidence for this conclusion is as follows:

The kinetics of the reaction conform closely to those predicted by the model.

An assumption of the model is that electronic equilibrium is established across the growing film. The agreement between estimates for the potential drop across the film obtained from fitting kinetic data to the Mott-Cabrera equations and from independent, direct measurements of the quantity provides considerable support for the assumption.

The preexponential factors deduced from fitting data to the Mott-Cabrera model are in reasonable accord with those calculated from physical and system constants.

Posttransition kinetics are parabolic and reflect the growth of oxide ridges and nodules.

In both kinetic regimes, mass transport occurs via preferred paths through the film. In the pretransition regime the density of such paths is high, resulting in the growth of a uniform film. In the posttransition regime the density of grain boundaries is much lower, leading to the localized growth of ridges and nodules. The transition in kinetic behavior is ascribed to a transformation in oxide structure.

Pressure Effects in the Oxidation of Chromium

D. J. Young* and M. Cohen*

National Research Council of Canada, Division of Chemistry, Ottawa, Ontario, Canada K1A 0R9

ABSTRACT

The effect of oxygen pressure in the range 5.3 × 10^{-2}-13.3 Pa on the oxidation kinetics of polycrystalline Cr was investigated at temperatures of 300°, 400°, 490°, and 600°C. Results were obtained by comparing reaction rates of samples oxidized at different pressures and also by observing the effect of abrupt changes in pressure during the course of a reaction. The two types of experiment yielded the same result. At 300°C the pressure exponent in the expression: rate $\propto p^r$, is small and positive, decreasing in magnitude with increasing film thicknesses. At T = 400°, 490°, and 600°C it was found that $r = -0.34 \pm 0.19$, -0.36 ± 0.10, and -0.40 ± 0.08, respectively. The positive pressure exponent at low temperature which accompanies thin film formation, is consistent with the Mott-Cabrera theory of oxidation, as modified to include adsorption equilibria. The negative pressure exponent, which accompanies parabolic kinetics, is described in terms of an adsorption model in which different adsorbed species are responsible for electrostatic field production and for point defect formation within the oxide.

It has been shown (1) that the oxidation of polycrystalline chromium in the range 300° ≤ T ≤ 600°C is characterized by an abrupt transition in kinetic behavior. The pretransition kinetics may be described with the aid of a Mott-Cabrera model (2, 3) which states that the rate is controlled by ion migration in an electric field

$$dX/dt = 4a\nu n_o\Omega \exp(-U/kT) \sinh(|qa\phi|/kTX) \quad [1]$$

where X is the average oxide film thickness, t the time, Ω the volume of oxide per ion, n_o the concentration of mobile ionic defects at the film interface at which they are generated, q their charge, U the activation energy for defect movement, a the activation distance, ν the kinetic frequency term, ϕ the potential drop across the oxide film, and k and T have their usual meanings. Posttransition kinetics are parabolic and are described by

$$X = k_p{}^{1/2} (t - t_T)^{1/2} + C \quad [2]$$

where t_T is the time at which the transition occurs between kinetic regimes, k_p and C are constants. Again, mass transport was deduced to be rate controlling but the possibilities of diffusion under a concentration gradient or ohmic conduction could not be distinguished.

The oxide morphology changes at the time of the transition in kinetic behavior (1). In the pretransition region a uniform film of oxide is formed whereas in the posttransition region oxide nodules and ridges grow, the intervening metal surface being covered by a thin, uniform oxide film. A diagrammatic cross section of the latter film is shown in Fig. 1. Since the fraction of total oxide accounted for by the regions of thin film is small it may be ignored and the approximation $X_n \propto X$ employed.

In order to probe further the nature of the oxidation mechanism, a study of the effect of oxygen pressure variation has now been made. Only one other study on chromium oxidation appears to have been reported for the presently considered temperature range. Hope and Ritchie (4) report a small, positive pressure effect within the range 250° ≤ T ≤ 450°C.

The results of pressure effect studies for both kinetic regimes are here reported. Pressure effects on posttransition kinetics were investigated at temperatures of 400°, 490°, and 600°C. For pretransition kinetics, experiments were carried out at 300°C.

Key words: kinetics, adsorption, ion transport.

Experimental

High purity, polycrystalline chromium was oxidized in dry oxygen in the pressure range 5.3 × 10^{-2}-13.3 Pa and at temperatures of 300°, 400°, 490°, and 600°C. Kinetic measurements were made manometrically. Details of the technique and the materials used have been described previously (1).

Pressure effects on the reaction rate were investigated using two different methods. The first method was the standard one of oxidizing different Cr samples at different oxygen pressures. During the course of these experiments, the oxygen pressure was maintained within 10% of its nominal value except for the initial few seconds of an experiment when oxygen was being admitted to the reaction vessel and the pressure change was consequently very rapid. Due to the uncertainty arising from this initial period of ill-defined pressure, and also in order to investigate the possibility that pressure effects are dependent on the extent of reaction, an alternative technique was adopted.

In the second technique the oxygen pressure was altered rapidly to a new value during the course of a reaction. After a period of 20-40 min during which the reaction rate was measured, the pressure was again altered suddenly. Alternate increases and decreases in pressure were continued throughout the experiment, the higher pressure being from 10 to 40 times the lower value. Instrumental blanks were performed in which the sequence and duration of the different oxygen exposures were carefully duplicated. This technique of comparing reaction rates obtained in the course of a single experiment largely eliminates the difficulties commonly experienced in attempting to compare results obtained on different samples. However, the need to achieve a large number of pressure changes during the course of an experi-

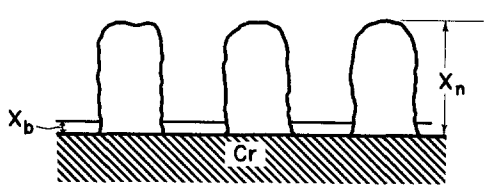

Fig. 1. Diagrammatic representation of a cross section of the oxide film formed in the posttransition reaction. The regions of thin film have a low density of favorable paths for transport whereas the thick nodules have a high density of such paths.

ment means that the periods of isobaric conditions are necessarily short. The precision with which the kinetics are measured is consequently lessened.

Results

Pretransition kinetics.—Isobaric experiments at 300°C showed the pressure effect to be smaller in absolute magnitude than the experimental errors. The reaction rate is very slow at this temperature and the reproducibility could not be improved enough to resolve any pressure effect with this technique. Pressure change experiments, however, revealed a small effect.

An increase in pressure during the course of a reaction at 300°C always caused an increase in rate and a decrease in pressure always caused a decrease in rate. If the kinetics of isobaric periods in this experiment are approximated as linear, then it is found that

$$\ln(R_1/R_2) = r \ln (p_1/p_2) \qquad [3]$$

where $R = dX/dt$, p is the oxygen pressure, and the subscripts 1 and 2 indicate successive periods of reaction. Values of r deduced therefrom are plotted as a function of X in Fig. 2. Experimental scatter is large but it may be concluded that r is small and positive, and decreases in magnitude with increasing X. A value of $r \simeq 0.35$ was found by Hope and Ritchie (4) at 300°C.

Posttransition kinetics.—Isobaric experiments were carried out at 400°, 490°, and 600°C. Parabolic rate constants were obtained from linear regression on Eq. [2] and are displayed as a function of oxygen pressure in the log-log plots of Fig. 3. From the empirical relationship

$$k_p = k_p' p^r \qquad [4]$$

where k_p' is a constant, it was found that at 600°C $r = -0.40 \pm 0.08$, and at 490°C $r = -0.36 \pm 0.10$. Data obtained at 400°C were of much lower quality and yielded $r = -0.34 \pm 0.19$.

Pressure change experiments confirmed that the pressure exponent is negative. Figure 4 shows the rate of oxygen uptake as affected by sudden changes in oxygen pressure at 600°C. It is evident that, after a short delay period, an increase in pressure always causes a decrease in rate and that a decrease in pressure always causes an increase in rate. This pattern of behavior was observed at 490°C also. The pressure effect produced by a sudden change in pressure was deduced from the reaction rates and pressures before and after the change as follows.

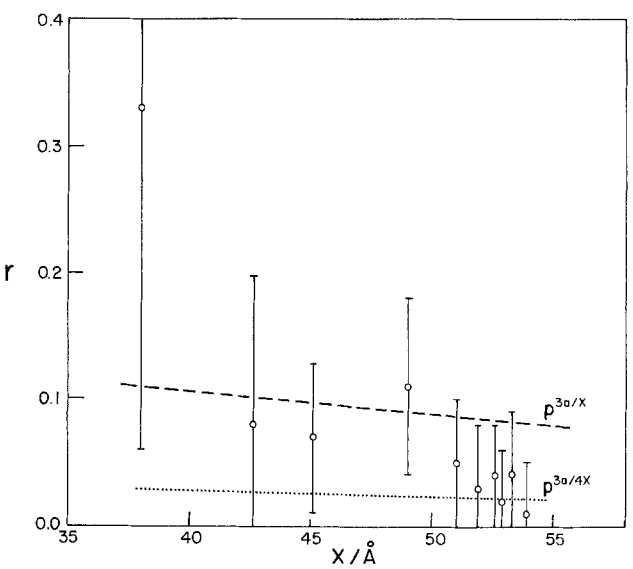

Fig. 2. Pressure exponent, r, as a function of oxide film thickness at 300°C. Also shown are pressure dependencies predicted from the Mott-Cabrera model of thin film oxidation where it has been assumed that $z = 3$ and that the predominant adsorbed species is O'' ($p^{3a/4X}$) or O_2' ($p^{3a/X}$).

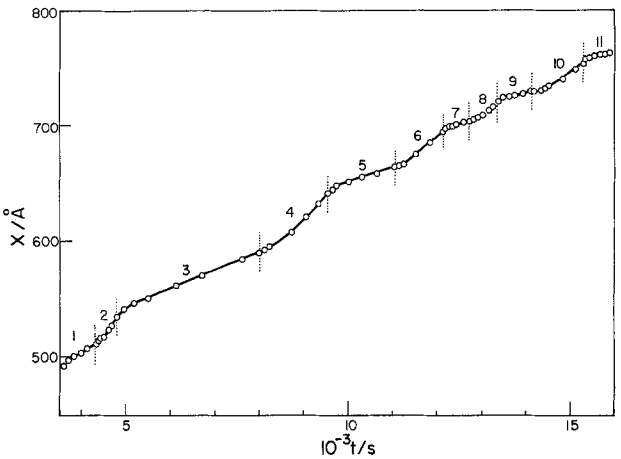

Fig. 4. Oxygen uptake with time at 600°C showing the effect of pressure changes. Numbers indicate the following pressures: 9.07, 8.5 × 10^{-1}, 8.93, 5.9 × 10^{-1}, 9.13, 6.0 × 10^{-1}, 9.07, 5.2 × 10^{-1}, 11.12, 5.1 × 10^{-1}, 12.23 Pa.

Substitution of [4] into [2] followed by differentiation yields for the reaction rate

$$R = \frac{dX}{dt} = \frac{k_p'}{2(X - C)} p^r \qquad [5]$$

Denoting by subscripts 1 and 2 the reaction before and after the pressure change, then, to a first approximation

$$\ln(R_1/R_2) = \ln[(\overline{X}_2 - C)/(\overline{X}_1 - C)] + r \ln(p_1/p_2) \qquad [6]$$

where the bars indicate average values for the periods of reaction concerned. For the short reaction periods employed, it was sufficient in evaluating dX/dt to approximate the rate as linear.

Values of the pressure exponent, r, found in this way are shown as a function of average oxide film thickness for temperatures of 600° and 490°C in Fig.

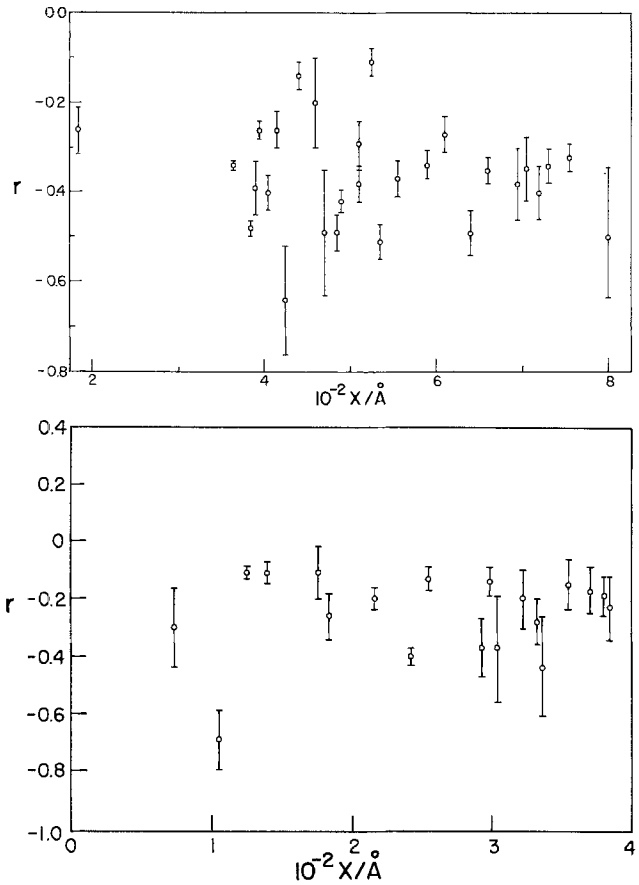

Fig. 5. Pressure exponent, r, as a function of average oxide film thickness at 600°C (upper graph) and 490°C (lower graph).

5. The results of several experiments have been summarized in this figure. Average values were found for r of -0.35 ± 0.12 at 600°C and -0.25 ± 0.14 at 490°C. These values are in reasonable accord with those deduced from the isobaric experiments. Data obtained at 400°C was again of lower quality, yielding $\bar{r} = -0.13 \pm 0.28$.

The thickness dependence of r was investigated by linear regression on the empirical equation

$$r = bX + c$$

where b and c are constants. Values of $b = (1.4 \pm 1.6) \times 10^{-4}$ and $(1.3 \pm 3.4) \times 10^{-4}$ Å^{-1} were found for data obtained at 600° and 490°C, respectively. It is therefore concluded that $r \neq f(X)$ at these temperatures.

Discussion

The previously deduced (1) mechanism for chromium oxidation of rate control by mass transport across the growing oxide film necessarily implies that both electron transport across the film and gas adsorption achieve equilibrium. Since pressure effects arise through the interaction of oxide and gas, these equilibria will now be examined.

Adsorption equilibria.—A description of adsorption equilibrium has been provided by Grimley and Trapnell (5) who considered the surface equilibria processes

$$\tfrac{1}{2}\,O_2(g) + S = O|S \qquad [7]$$

$$O|S + e' = O'|S \qquad [8]$$

$$O'|S + e' = O''|S \qquad [9]$$

where $O|S$ represents an adsorbed atom, together with the assumption of electron equilibrium across the growing oxide film

$$[e] = K_e \exp(-q_e\phi/kT) \qquad [10]$$

Here square brackets denote concentration, K_e is a constant, and q_e the electron charge. This model, together with the assumption of a fixed concentration, M, of surface adsorption sites, yields, to a close approximation (3), the results

$$[O'|S] = MK_7K_8K_ep^{1/2}[\exp(-q_e\phi/kT)]/(1 + K_7p^{1/2}) \qquad [11]$$

$$[O''|S] = [O'|S]K_9K_e \exp(-q_e\phi/kT) \qquad [12]$$

where K_7, K_8, K_9 are the equilibrium constants for the processes [7], [8], [9]. Substitution of [11] and [12] into Gauss' theorem

$$E = 4\pi|q_e|([O'|S] + 2[O''|S])/\epsilon \qquad [13]$$

where E is the electric field in the direction of metal transport and ϵ the oxide dielectric constant, together with the homogeneous field approximation

$$E = -\phi/X \qquad [14]$$

leads to an expression for ϕ. Two limiting cases are of interest: for $[O'|S] >> [O''|S]$ and $q_e\phi \gtrsim 4kT$

$$\exp(-q_e\phi/kT) = \frac{\epsilon kT(1 + K_7p^{1/2})}{4\pi(q_e)^2XMK_7K_8K_e\,p^{1/2}} \qquad [15]$$

whereas for $[O''|S] >> [O'|S]$ and $q_e\phi \gtrsim 4kT$

$$\exp(-q_e\phi/kT) = \left\{\frac{\epsilon kT(1 + K_7p^{1/2})}{16\pi(q_e)^2XMK_7K_8K_9(K_e)^2\,p^{1/2}}\right\}^{1/2} \qquad [16]$$

If adsorption involves the charged molecular species $O_2'|S$ and $O_2''|S$ then the required solutions are obtained by substituting p for $p^{1/2}$ in [11]-[16]. It is evident that at high coverages ($K_7p^{1/2} > 1$) no pressure dependence of ϕ is found. Accordingly, low coverages ($K_7p^{1/2} < 1$) will be assumed and Eq. [15] and [16] approximated accordingly.

Concentrations of adsorbed species are obtained by substitution from [15] or [16] (or the molecular oxygen analogues) into [11] and [12]. Examination of the various possibilities reveals an inverse p-dependence for the concentration of a species having more charge per atom than does the predominant adsorbed anion. Consider, for example, the case of $O'|S$ and $O''|S$, where $[O'|S] >> [O''|S]$ is assumed. An increase in p causes an increase in $[O'|S]$ and, according to Gauss' theorem, an increase in $|\phi|$. The concentration of free electrons obeys the Boltzmann distribution law and is therefore greatly reduced. The net result, as seen in Eq. [12], is a reduction in $[O''|S]$.

Pretransition kinetics.—The Mott-Cabrera model applies to the pretransition reaction and kinetics are described by Eq. [1]. The pressure dependence is therefore found from the way n_0 and ϕ are related to p. In the case of a metal excess oxide, defects originate at the metal-oxide interface and their concentration, n_0, is likely constant (3) and therefore pressure independent.

In the case of a metal deficit oxide, vacancy defects originate at the gas-oxide interface where they are formed in the region of a surface adsorbed anion species (3, 6). In the range of film thickness applicable to the pretransition region, injection of vacancies at the interface is likely rate controlling. A steady-state treatment (3) of this situation yields

$$n_0 = s/2a \qquad [17]$$

where s is the concentration of the particular surface anion species responsible for vacancy injection and is, in general, pressure dependent. In deriving [17] it has been assumed that the energy barrier to defect

movement across the interface is of the same height and width as the analogous barriers separating sites within the oxide lattice.

Pressure effects on reaction rate arising through the dependence of ϕ on p are found as follows. For small values of X the hyperbolic function in Eq. [1] may be approximated as

$$2\sinh(qa\phi/kTX) \simeq \exp(qa\phi/kTX) \qquad [18]$$

Substitution in [1] of [18] and [15] or [16] yields, for low surface coverages, pressure dependencies of the form

$$dX/dt = n_0 f(X) p^{za/lX} \qquad [19]$$

where $z = |q/q_e|$ and the value of l is characteristic of the predominant adsorbed anion species. For a metal excess oxide $n_0 \neq f(p)$ and the kinetic p-dependence is given directly by Eq. [19]. For a metal deficit oxide the p-dependence is found from Eq. [17] and [19] together with the appropriate expression for s given by the adsorption equilibria above. Results for both types of oxides are summarized in Table I.

Figure 2 shows a comparison of experimental results with the pressure dependencies $p^{3a/X}$ and $p^{3a/4X}$ where the value $a = 1.47$Å has been assigned. It is evident that the data can be described by any of the metal excess oxide models and by those of the metal deficit oxide models which involve as defect injecting anions and as predominant adsorbed anions species having the same number of electrons per atom. The other possibilities may be rejected. The only other model known to the authors which predicts a film thickness dependent pressure exponent is that of rate control by a surface ionization process (7) in which case

$$r = \frac{b}{X} - \tfrac{1}{2}$$

where b is an activation distance. This possibility must also be rejected.

It is therefore concluded that the pretransition reaction proceeds according to the Mott-Cabrera model as modified to include surface adsorption effects. The identity of the surface adsorbed species cannot, however, be determined.

Posttransition kinetics.—The oxide morphology characteristic of the posttransition regime is shown in Fig. 1 and it is to be noted that the nodules and ridges constitute ~95% of the total amount of oxide and cover *ca.* 50% of the surface. The observed kinetics, therefore, reflect the growth of these localized regions. The parabolic nature of the oxidation kinetics suggests that the reaction may be diffusion controlled. However, the Wagner model (8) of ambipolar diffusion coupled with local equilibrium cannot explain a negative pressure exponent. An alternative description is now proposed.

It was deduced earlier (1) that the posttransition oxide film shown in Fig. 1 consists of ridges and nodules of polycrystalline oxide separated by very thin film regions of a more perfect oxide. It was concluded that mass transport was confined to the grain boundaries of the polycrystalline oxide. It will now be assumed that electron equilibrium is achieved across the thin film portions of the oxide layer but not across the thick oxide nodules. In that case the adsorption equilibrium model employed above describes the concentration of species on the thin film surface. Assuming now that surface diffusion is rapid, it follows that the concentration of species adsorbed on the surface of nodules, where oxide growth is occurring, is also controlled by the electron equilibrium across the thin oxide film regions. Thus charge transfer between the underlying metal and the nodule surface occurs via the thin film region and subsequent surface diffusion of anions. Mass transport is assumed to occur via cation vacancy movement through the nodule. For the nodule thicknesses in question, the linear transport equation is appropriate

$$J = -D\frac{\partial n}{\partial x} - nu\frac{\partial \phi}{\partial x} \qquad [20]$$

Here J is the flux of defects having diffusion coefficient D and mobility u, and x is the position coordinate such that $x = 0$ at the oxide gas interface and $x = X$ at the oxide-metal interface. It may be shown (9) that for $|q\phi| \gtrsim 4kT$, the electrical potential gradient constitutes the major part of the driving force for ionic transport and Eq. [20] may be adequately approximated by

$$dX/dt = \Omega J = \Omega n_0 u|\phi|/X \qquad [21]$$

and parabolic kinetics are predicted.

The concentration of vacancies near the oxide gas interface, n_0, is found from the assumption of local equilibrium between adsorbed anions, $A^{m'}|S$, and the oxide

$$iA^{m'}|S = iS + jV^{mi'/j}Cr \qquad [22]$$

and hence

$$n_0 = K_{22}([A^{m'}|S]/[S])^{i/j} \qquad [23]$$

where the defect notation of Kroger and Vink (10) has been employed, and i and j serve to define the reaction stoichiometry. According to the postulate of rapid surface diffusion, the surface concentrations of species adsorbed on the nodules are proportional to those of species adsorbed on the thin film regions. Since the thickness of this film is practically constant, surface concentrations are a function of p but not of X. Substitution for n_0 in [21] from [23] and from the adsorption description of Eq. [11]-[16] yields the p-effect on the reaction. Results are summarized in Table II. As noted before, when the defect-producing species has more electrons per oxygen atom than

Table II. Values of pressure exponent, r, for posttransition kinetic model

Defect-injecting species	Predominant adsorbed anion $O' \mid S$	$O'' \mid S$	$O_2' \mid S$	$O_2'' \mid S$
$O' \mid S$	0	$\frac{i}{4j}$	$-\frac{i}{2j}$	0
$O'' \mid S$	$-\frac{i}{2j}$	0	$-\frac{3i}{2j}$	$-\frac{i}{2j}$
$O_2' \mid S$	$\frac{i}{2j}$	$\frac{3i}{4j}$	0	$\frac{i}{2j}$
$O_2'' \mid S$	0	$\frac{i}{2j}$	$-\frac{i}{j}$	0

does the predominant adsorbed anion, then the required negative pressure exponent results.

Comparison of experimental results with the predicted values for n shown in Table II yields estimates for i/j for the different cases. One reasonable possibility is the reaction

$$O''|S = S + O_o^x + V_{Cr}'' \quad [24]$$

together with either $O'|S$ or $O_2''|S$ as the predominant adsorbed anion species. The predicted pressure exponent is -0.5, in fair agreement with observation. However, independent evidence of the applicability of Eq. [24] is lacking.

In order to explain the change in pressure dependence which accompanies the transition in kinetics, it has been necessary to invoke a change in the nature of the surface equilibrium process. Since this transition is accompanied by a change in oxide structure (1), the requisite change in surface properties of the oxide may well be occurring, but no detailed description can as yet be formulated.

Summary

The pressure effects observed in the pretransition kinetic regime are in accord with the predictions of the Mott-Cabrera model thereby confirming the applicability of that model. However the data do not allow a distinction to be made between metal excess and metal deficit oxide.

The negative pressure exponent found in the posttransition kinetic regime is ascribed to an equilibrium process which is controlled by electron equilibrium across the thin portions of the film. Since these thin regions do not thicken appreciably during the posttransition reaction, the adsorption equilibrium is independent of time. The surface anions thus produced migrate rapidly to the surface of growing oxide nodules where they control the concentration of cation vacancies within the oxide. Nodule growth is controlled by conduction of these vacancies through the oxide and parabolic kinetics result.

LIST OF SYMBOLS

X	average oxide film thickness
t	time
a	activation distance for movement of cation defect in Cr_2O_3
ν	kinetic frequency term for cation defects
n	concentration of cation defects
Ω	volume of Cr_2O_3 per cation
U	activation energy barrier to cation movement in Cr_2O_3
k	Boltzmann's constant
q	charge on cation defect
ϕ	electrostatic potential drop across oxide films
k_p	parabolic rate constant
p	pressure of O_2
r	kinetic pressure exponent
S	oxide surface site
$A\|S$	species A adsorbed on S
e	electron
K	equilibrium constant
E	electrostatic field strength
ϵ	dielectric constant of oxide
q_e	charge on electron
M	total concentration of surface adsorption sites
s	concentration of surface anion species responsible for defect injection
z	effective valence of cation defect
D	self-diffusion coefficient for cation defect
u	mobility of cation defect
x	position coordinate within oxide film
J	flux of cation defects
V_{Cr}	vacancy on Cr site in Cr_2O_3
i, j	constants defining stoichiometry of defect injection equilibrium

ABSTRACT

The thermodynamic equilibria established in fused silica oxidation tubes operated at 1000°C are analyzed. Transparent fused silica tubes used for thermal oxidation of silicon contain about 10 ppm sodium impurity. At oxidation temperatures sodium diffuses in fused silica, evaporates into the oxidation ambient, and reacts with residual water contaminating the oxidation atmosphere. During the oxidation cycle enough sodium is incorporated into the growing oxide film to be detected later by capacitance measurements in metal oxide semiconductor (MOS) structures. Reactions taking place during currently used *in situ* furnace cleaning procedures are analyzed. Calculations indicate that the amount of sodium removed from the fused silica tube wall through chlorine or hydrogen chloride cleaning is substantial. The reaction rate is regulated by diffusion of sodium in the fused silica. The use of iodine and hydrogen iodide as cleaning agents is discussed.

Oxidation of silicon has been the subject of many investigations aimed at understanding metal oxide semiconductor (MOS) device instabilities caused by the action of mobile ion impurities localized in the oxide film (1). Test vehicles in the form of simple MOS capacitors built on silicon dioxide films 50-100 nm thick are frequently used to study ionic contamination in thermal silicon dioxide. The mobile ion density in the oxide film can be calculated from capacitance measurements after thermal cycles have been applied to the device (2).

Several contamination sources may contribute impurities to the oxide film. Due to their high natural abundance, alkali species are the most common impurities likely to contaminate silicon dioxide. Sodium, potassium, and lithium may cause ionic-type instabilities in the oxide. Sources of alkali contamination can be classified according to their origin as: (*i*) bulk and surface impurities already contained in the silicon wafer before oxidation, (*ii*) impurities introduced into the oxide film during silicon high temperature oxidation and annealing, and (*iii*) impurities introduced after oxidation through metallization (3).

Considerable research has been done to determine the presence of impurities in microelectronic process materials. Analytical techniques such as flame emission, atomic absorption, resonance fluorescence, neutron activation, and others have been used for trace contamination detection (4-6). Metallization of microelectronic devices has also received a great deal of attention regarding the introduction of ionic contamination in the oxide film from both the evaporation process used and contamination in the metal (7). These results show that impurities may be introduced through several processing steps and play a significant role in determining the electrical properties of the device.

During oxidation of silicon, sodium impurity contained in fused silica oxidation tubes evaporates from the tube wall into the oxidation ambient. In typical oxidation facilities, furnaces employing fused silica tubes are operated at about 1000°C (or 1300°K for the purpose of this paper). The oxidation atmosphere generally consists of pure dry oxygen flowing along the tube with laminar flow at about 4 cm^3/sec (equivalent to 0.5 std ft^3/hr). Transparent commercial fused silica tubes currently used for this purpose generally have an average sodium content of 10 ppm (8-9). Sodium in the tube bulk diffuses easily [diffusion coefficient in SiO_2: 2×10^{-6} cm^2/sec (10)] to the tube wall surface. This in turn causes the appearance of contamination in silicon dioxide films grown in the oxidation tube (11).

The purpose of this work is to study the oxidation atmosphere used to grow thermal silicon dioxide films as a source of sodium contamination introduced into the film during the growing cycle. The thermodynamic equilibria established in fused silica oxidation tube atmospheres at 1300°K were considered.

Reactions Occurring in Fused Silica Oxidation Tubes

The thermodynamics of sodium vaporization from sodium silicate-silica glasses has been previously studied in the temperature range of 1200°-2000°K where the equilibrium constant of the reaction $Na_2O \cdot SiO_2$ (in SiO_2) $\rightarrow 2Na(g) + \frac{1}{2} O_2(g) + SiO_2$ (c or glass) has been measured (12). Values of $K = p^2(Na) \cdot p^{1/2}(O_2)[\alpha(SiO_2)/\alpha(Na_2O \cdot SiO_2)]$ were reported for molar ratios of SiO_2 to Na_2O varying from 1.69:1 to 3.88:1, where the α's (activities) were expressed in terms of mole fractions. The results indicated Raoult law behavior was approximated in the higher ratio solutions. On this basis, extrapolation to larger ratios, *i.e.*, 10^5 (about 10 ppm sodium in the silica) leads to the value $K = 2.5 \times 10^{-19}$ at $T = 1300$°K. Using this value and thermodynamic data from Table VII we obtain $\Delta H°_{f298}(Na_2O \cdot SiO_2[10^{-5}$ mole fraction in SiO_2 gls]) $= -376.8$ kcal/mole. This value is in reasonably good agreement with the corresponding JANAF (13) value for $Na_2O \cdot SiO_2$(gls) of -373.2 kcal/mole. The difference between these values can be considered a measure of the solution effects, such as formation of $Na_2O \cdot x\ SiO_2$ species, and the difference between the properties of the simple compound as a glass and the same species in solution. For this reason the use

Table 1. Equilibrium atmosphere in fused silica dry oxidation tube at 1300°K. Sodium content in fused silica bulk is 10 ppm, oxygen at 1 atm.

	Reaction	K	p(atm)	N(cm^{-3})
[1]	$\frac{1}{2}O_2(g) \rightarrow O(g)$	1.76×10^{-7}	$p(O) = 1.76 \times 10^{-7}$	
[2]	$Na_2O \cdot SiO_2$ (in SiO_2) $\rightarrow Na_2O(g) + SiO_2(c)$	7.9×10^{-20}	$p(Na_2O) = 7.9 \times 10^{-25}$	
[3]	$Na_2O \cdot SiO_2$ (in SiO_2) $\rightarrow 2Na(g) + \frac{1}{2}O_2(g) + SiO_2(c)$	2.5×10^{-19}	$p(Na) = 1.6 \times 10^{-12}$	9×10^{6}
[4]	$Na_2O \cdot SiO_2$ (in SiO_2) $\rightarrow Na(g) + NaO(g) + SiO_2(c)$	9.1×10^{-20}		
[5]	$Na_2O(g) + \frac{1}{2}O_2(g) \rightarrow 2NaO(g)$	0.42	$p(NaO) = 5.7 \times 10^{-13}$	3.2×10^{6}
[6]	$Na_2O \cdot SiO_2$ (in SiO_2) $+ \frac{1}{2}O_2(g) \rightarrow 2NaO(g) + SiO_2(c)$	3.3×10^{-20}		

Total sodium density: 1.2×10^{7}

of the former value (−376.8 kcal/mole) derived from measurements (12) was preferred, assuming that any systematic errors in the calculations would be partially compensated.

A number of reactions take place in fused silica oxidation tubes operated at 1300°K. Table I shows the equilibrium[1] atmosphere resulting from 1 atm dry oxygen reacting with the tube wall. The partial pressure corresponding to atomic oxygen resulting from equilibrium dissociation of the oxygen molecule is shown through reaction [1][2] as $p(O) = 1.76 \times 10^{-7}$ atm indicating that reactions with atomic oxygen are not significant. The evaporation reactions [2], [3], and [4] show that sodium in the oxidation atmosphere is present as both atomic (Na) and molecular (Na_2O, NaO) species. Reaction [5] shows the conversion of Na_2O into NaO through interaction with oxygen. These results indicate that in a dry oxidation atmosphere atomic sodium is about three times more abundant than molecular sodium compounds. The total number of sodium atoms in the equilibrium oxidation atmosphere is 1.2×10^{7} cm^{-3} (both atomic and molecular species included).

Table II shows the equilibrium atmosphere resulting in fused silica oxidation tubes at 1300°K when water is added.[3] The reaction system [7] shows that water is more stable than OH by factors ranging from 20 to more than 100 times as humidity in the oxidation ambient increases. For increasing water content the most significant changes are seen in $p(Na_2(OH)_2)$ and p(NaOH) as resulting from reactions [8] through [11]. The sodium number density for 1 ppm water impurity goes to 3.3×10^{8} cm^{-3} or a factor 27 higher than the dry oxidation condition. If 30 ppm water is present in the oxidation ambient the sodium number density at equilibrium raises to 1.7×10^{9} cm^{-3} or a factor 142 higher than the dry oxidation condition. Table III and Fig. 1 summarize these results.[4]

The above calculations show that sodium contamination developed in oxidation atmospheres could be explained in terms of contamination in the bulk fused silica even if the furnace tube wall surface were perfectly clean. To reduce sodium density in oxidation atmospheres, it is necessary that the bulk tube material itself be sodium free. Two different approaches have been tried: (*i*) use of a sodium-free tube wall, or (*ii*) use of sodium-leaching agents to deplete a region just under the inner wall surface prior to oxidations. The first approach is based on the well-known fact that polycrystalline silicon tubes can be produced with 1000 times less sodium content than found in silica tubes (17). Empirical results indicate that oxide films grown on silicon using recently installed silicon oxidation tubes produce cleaner films (lower sodium content) than similar oxides prepared in fused silica tubes.

Polycrystalline silicon tubes develop, however, observable sodium contamination after being in operation for several months, when the use of sodium-leaching agents is then required. This contamination, developed under strictly controlled production-oriented environments, could be explained by assuming that during tube operation at oxidation temperature sodium arising from external sources reaches the oxidation chamber by diffusion through the tube wall. The contamination source could be located in furnace refractories surrounding the oxidation tube (11). Once the tube wall becomes loaded with sodium above a critical level, evaporation into the oxidation atmosphere starts to predominate. This is a slow process that may take a long time (several months) in continuous operation depending on environmental conditions (18).

Reactions Occurring When Cleaning Fused Silica Tubes

Cleaning of oxidation tubes is a frequent operation in processing facilities. At room temperature, the clean-

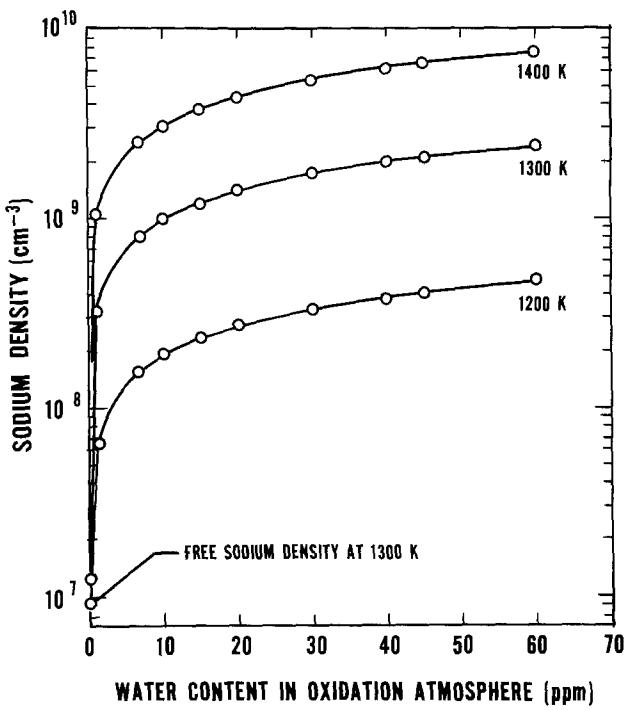

Fig. 1. Total sodium density [cm^{-3}] at equilibrium in fused silica oxidation tube atmosphere as a function of temperature and water impurity. The sodium concentration in silica is assumed 10 ppm, $p(O_2)$ is 1 atm.

[1] All calculated values presented in this work refer to equilibrium conditions and represent limiting values for the actual systems because of kinetic and diffusion factors.

[2] Data used to calculate reaction equilibrium constants are listed in Table VII. The actual calculation scheme is illustrated in the Appendix.

[3] Experimental evidence shows that in a typical "dry" oxidation atmosphere the water content is in the 20-30 ppm range (14). Moreover at oxidation temperatures in the range 900°-1300°C it was reported that water and/or hydrogen from the external ambient can diffuse through the silica tube wall into the oxidation chamber (15).

[4] Because of errors and approximations involved in thermodynamic data used to evaluate the equilibrium results, an absolute error of ±50% could be expected in these calculations. The relative error is much smaller. Resonance fluorescence measurements showed that in open fused silica oxidation tubes no free sodium was detected (16). This experimental result can be understood in terms of calculations shown in Fig. 1. For sufficiently high water content in the oxidation atmosphere the amount of free sodium detectable through resonance fluorescence technique could be substantially reduced due to sodium reactivity with excess water. Thus, free sodium is converted into compound sodium and consequently becomes not detectable by the above-mentioned technique.

Table II. Equilibrium atmosphere in fused silica oxidation tube at 1300°K. Sodium content in fused silica bulk is 10 ppm, oxygen at 1 atm.

	Reaction	K	Water content in oxygen:1 ppm		Water content in oxygen:30 ppm	
			p(atm)	N(cm^{-3})	p(atm)	N(cm^{-3})

ing can be accomplished using conventional acid solutions. At oxidation temperatures, the cleaning is made *in situ* by using 5-10% chlorine or hydrogen chloride diluted in an inert gas carrier. This treatment removes sodium contained in the tube inner "skin" down through a convenient depth. A typical cleaning action of this kind requires up to 20 hr of continuous treatment flushing the cleaning gas at about 4 cm^3/sec (0.5 std ft^3/hr). The several reactions taking place during this process are summarized in Table IV.

Reactions [16], [17], and [18] are solved as a simultaneous system. The resulting sodium number density at equilibrium in the tube atmosphere goes to 8.8×10^{16} cm^{-3} or a factor 7.3×10^{9} higher than the equilibrium sodium number density in a dry oxidation atmosphere. Reactions [16], [19], and [20] show similar results due to hydrogen chloride cleaning. The increase in sodium number density with respect to the dry oxidation condition is also in the 10^9 range. Microdroplets of liquid sodium chloride, if formed on the tube wall hot zone, would be removed by the gas stream and transported to a cooler tube zone where sodium chloride precipitates on the wall (sodium chloride melts at 801°C). This "transpiration mechanism" continues while sodium in the hot zone is available for reaction. It should be mentioned that sodium chloride formed in the gas phase is carried down the flushing gas stream and condenses also at the cooler zone where the temperature is appropriate. The cleaning action can be interpreted in terms of relocating sodium in the tube, depleting the hot zone, and enriching the exhaust tube end where the wall temperature is appropriate for condensation.

Stoichiometric equilibria in reactions [17] through [20] require the use of about 1.5g of chlorine or hydrogen chloride per gram of extracted sodium. Assuming that the oxidation tube wall surface is about 4000 cm^2 and the reaction depth in the wall is 10^{-3} cm, the total reacting volume is 4 cm^3 or about 10g fused silica. Assuming 10 ppm sodium content in the fused silica, the amount of sodium reacting is 10^{-4}g which requires the use of 1.5×10^{-4}g of chlorine or hydrogen chloride for complete reaction equilibrium. The density of 10% chlorine at 1300°K is 6.74×10^{-5} g/cm^3. At 4 cm^3/sec flow, the chlorine mass transported through the oxidation tube is 2.7×10^{-4} g/sec. This shows that the reaction rate is regulated by diffusion of sodium in the fused silica. When sodium in the wall bulk diffuses to the wall surface, the reaction with chlorine takes place immediately. In practice, a cleaning period of about 20 hr is used to deplete the tube wall. The longer the cleaning period, the longer the oxidation tube can later be operated under acceptable oxide growing conditions. These calculations indicate that the amount of sodium removed from the fused silica tube wall through chlorine or hydrogen chloride cleaning is substantial and that such cleaning certainly reduces the sodium content in the inner tube wall surface.

Iodine or hydrogen iodide can also be used for *in situ* oxidation tube cleaning. The relevant reactions taking place are summarized in Table V. Reactions [25] through [28] show the effectiveness of this type of cleaning indicating that iodine or hydrogen iodide could be used instead of chlorine or hydrogen chloride. However, due to economic reasons, the latter are more extensively used in practice. Since thermodynamic data are not available to the desired extent, similar calculations are not presented here for bromine and hydrogen bromide. However, bromine should have an intermediate behavior between chlorine and iodine according to the pattern of the members of the halogen family.

The Oxidation Atmosphere as a Sodium Contamination Source

An experimental test was made to check the validity of assuming that sodium becomes trapped in an oxidation tube due to the evaporation-transpiration-condensation cycle mentioned above. In a fused silica tube operated at 1000°C "dry" oxygen[5] was allowed to flow at a rate of 4 cm^3/sec for 120 hr. The exhaust gas was passed through a 5% hydrochloric acid solution. After this period the solution was analyzed by flame emission spectrometry. The detection limit for sodium in the solution was 10^{-10} g/cm^3. No evidence of sodium was detected in the solution after correcting for evaporation of the liquid. This test was repeated twice with consistently negative results. Consequently, it was concluded that sodium is not carried out of the oxidation tube.

There is no apparent way of extracting from a furnace tube a representative sample of the oxidation atmosphere. Other analytical techniques operating on gas samples removed from the oxidation atmosphere, such as mass spectrometry, are not appropriate to detect sodium due to condensation as the temperature decreases. On the other hand, any analytical instrumentation if introduced into the oxidation tube could change the oxidation atmosphere equilibrium adding extra contamination, thus perturbing the measurements.

[5] Electronic grade oxygen typically contains about 5 ppm water and 20 ppm hydrocarbons measured as methane.

Contamination of Thermally Grown Silicon Dioxide Films

The results of Tables I and II indicate that in typical fused silica oxidation tubes the equilibrium atmosphere contains atomic and molecular sodium species resulting in a sodium number density in the 10^7-10^9 cm^{-3} range, depending on the amount of water present. Due to the low density, sodium atoms and molecules contained in the oxidation ambient can be considered as ideal gases. The number of collisions per unit time sodium executes per unit area on the wafer surface is expressed as (19)

$$\nu = 0.25\, Nv$$

where N is the sodium number density in the oxidation atmosphere, $v = (8\ kT/\pi m)^{1/2}$ is the average molecular velocity at temperature T, k is the Boltzmann constant, and m is the weight of the sodium species. The resulting value of ν for $T = 1300$°K is 10^{12} cm$^{-2} \cdot$ sec^{-1} for $N = 5 \times 10^7$ cm^{-3}. The presence of oxygen (1 atm) in the tube slightly modifies this number due to collisions with sodium atoms and molecules.

A number of reactions can take place between the growing silicon dioxide film and the impinging sodium molecules as shown in Table VI. Sodium silicate is formed by reactions [29] through [35] which have high equilibrium constants. As sodium from the oxidation atmosphere becomes incorporated into the oxide

Table VI. Impurity reactions with SiO_2 films in fused silica oxidation tube atmospheres at 1300°K

film, more sodium from the tube wall evaporates into the atmosphere, maintaining the equilibrium.

There are not enough kinetic data available to estimate precisely the actual amount of sodium incorporated into the silicon dioxide film during the oxidation cycle. The typical dry oxidation period used to grow a 100 nm thick oxide film on a (100) sample of silicon at 1000°C is about 200 min. During this period the oxide film is subjected to about 10^{16} sodium collisions per square centimeter. Parameters such as the wafer temperature, oxygen flow, and the water content in the tube certainly influence the oxide film contamination level. At equilibrium, the sodium concentration in the oxide film grown on silicon should be similar to that in the oxidation tube wall bulk, *i.e.*, 10 ppm ($\sim 10^{17}$ cm^{-3}). This consideration clearly establishes that dry oxidation of silicon made in fused silica tubes produces oxide films with a significant amount of sodium included; the upper limit is determined by the impurity level in the fused silica bulk. Whether or not this sodium which has chemically reacted with silica to form sodium silicate in the film (Table VI) influences the electrical and radiation properties of MOS devices is a matter that needs detailed examination.

It has been reported that structurally included sodium atoms in silicon dioxide films behave like immobile ionic contamination. Capacitance measurements on MOS capacitors with a dielectric of silicon dioxide doped with sodium to density of 10^{20} cm^{-3} showed that most of the included sodium is inactive from the viewpoint of both surface-state density and ionic migration under high electric field at elevated temperature (15). However, instability of semiconductor devices due to sodium mobility in thermal silicon dioxide films has been largely recognized as a central problem in semiconductor technology. Sodium was shown to cause instability under bias-temperature stress in silicon devices made by planar technology. Thermally stimulated ionic conductivity measurements made on MOS capacitors using aluminum or gold as the gate metal have shown that in sodium-doped gate oxide films with surface concentrations in the 10^{11}-10^{13} cm^{-2} range, sodium moves at temperatures above 200°C under electric fields as low as 1.2×10^5 V/cm (20).

In practice instabilities due to sodium can be eliminated either by stringent cleanliness during oxide processing or by the formation of a protective layer such as phosphosilicate glass which can trap sodium (20).

An experimental test was made in a carefully controlled fused silica tube operated at 1000°C and periodically cleaned *in situ* with chlorine. Silicon dioxide films 50-100 nm thick were grown on (100) n-type silicon surfaces using dry electronic grade oxygen and annealed *in situ* after oxidation in dry nitrogen for 30 min. The metal gate was applied by evaporation of 1 μm thick aluminum film in an electron-gun evaporator. MOS capacitors were prepared and capacitance measurements were made at room temperature before and after stressing the capacitors at 300°C for 5 min with electric field of 10^6 V/cm (2). The results indicate a clear correlation between cleaning of the fused silica oxidation tube and the total mobile ion surface density in the oxide film. These measurements indicate that oxide films grown in recently cleaned tubes show mobile ion densities in the 10^{10} cm^{-2} range.

Assuming uniform contamination film in the measurements, these "clean" oxides exhibit an impurity number density in the 10^{15} cm^{-3} range. This contamination level is caused by impurities accumulated during the device preparation process. It has been shown that radiation sensitivity of gate oxide films has no correlation with the mobile ion content in the oxide as measured by MOS capacitance measurements after bias temperature stressing or high temperature ramping (21). However a correlation of total sodium content with radiation sensitivity in the oxide of various MOS devices has been reported (22). These considerations suggest that sodium contamination introduced in the oxide film during oxidation and metallization may play a prominent role in determining the device radiation resistance. Phosphorus gettering of the gate region or hydrochloric acid passivation increases the radiation sensitivity of MOS devices. Hence to obtain reliable, radiation-stable MOS devices in the absence of gettering it has been suggested that high standards of cleanliness should be maintained (21). This is specially applicable to the oxidation step. Alkali impurity introduced through metallization should also be minimized by careful investigation of the mechanisms through which such contamination is introduced.

Conclusions

The results of the present thermodynamic calculations show that sodium included in the bulk of fused silica oxidation tubes is a significant source of contamination in oxidation atmospheres, even if sodium surface contamination produced by external agents in the tube is negligible. The presence of water in the oxidation atmosphere produces a rapid buildup of the sodium number density from the 10^7 cm^{-3} range, corresponding to dry oxidation, of up to two orders of magnitude greater for water concentrations of a few parts per million. During the oxidation cycle, sodium is incorporated into the oxide film as sodium silicate developing a significant contamination level which can be potentially harmful for MOS device radiation resistance. Water may be incorporated in the oxidation atmosphere through trace water or hydrogen from hydrocarbon impurities included in oxygen, and by ambient water that diffused into the oxidation chamber through the fused silica tube wall.

Preparation of clean oxide films requires the control of sodium impurity in the oxidation atmosphere. This in turn imposes a strict control of the tube material and appropriate care concerning the environmental conditions during wafer processing.

APPENDIX[6]

Calculation of Equilibrium Reaction Constant from JANAF Data

For a reaction $xX + yY \rightarrow wW + zZ$ the thermodynamic equilibrium constant may be written as

$$K = \frac{\alpha^w(W) \cdot \alpha^z(Z)}{\alpha^x(X) \cdot \alpha^y(Y)}$$

where $\alpha(X)$ is the activity of compound X. For calculations involved in this work (dealing with very dilute gaseous species), the activity may be taken as the partial pressure of the vapor phase (measured in atmospheres). The activity of a solid phase such as $SiO_2(c)$ is taken by convention as unity. For Na_2SiO_3 solid solution in SiO_2 the activity is taken as the mole fraction (10^{-5} in the present work). For the reaction

$$Na_2O \cdot SiO_2(gls) + \tfrac{1}{2}O_2(g) \rightarrow 2NaO(g) + SiO_2(c)$$

the equilibrium constant is expressed as

$$K = p^2(NaO) \times 10^5/p^{1/2}(O_2)$$

To evaluate K at a particular temperature T (measured in Kelvin) the following relations are used

$$\Delta G_T = -RT \ln K$$

$$\Delta G_T = \Delta H^\circ_{298} + T(\Sigma(G^\circ_T - H^\circ_{298})/T)$$

where ΔH°_{298} is the heat of reaction, calculated from standard heats of formation as

$$\Delta H^\circ_{f298} = \Sigma\, \Delta H^\circ_{f298}(\text{products}) - \Sigma\, \Delta H^\circ_{f298}(\text{reactants})$$

[kcal/mole]

and $\Sigma(G^\circ_T - H^\circ_{298})/T$ is calculated from Gibbs energy function in the standard state at temperature T

$$\Sigma(G^\circ_T - H^\circ_{298})/T = \{\Sigma(G^\circ_T - H^\circ_{298})/T\}_{\text{products}} - \{\Sigma(G_T - H_{298})/T\}_{\text{reactants}} \quad [\text{cal}/^\circ\text{K mole}]$$

[6] This calculation follows standard thermodynamic formalism [see Ref. (23)].

Analysis of the Chemical Vapor Deposition of Titanium Diboride

I. Equilibrium Thermodynamic Analysis

Theodore M. Besmann[1] and Karl E. Spear[2]

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

A thermodynamic analysis of the chemical vapor deposition (CVD) of TiB_2 from gaseous $TiCl_4$, BCl_3, and H_2 was performed using a general computer program for the calculation of heterogeneous equilibrium compositions. The conditions for the deposition of single phase TiB_2 and for the codeposition of TiB_2 plus boron were determined. Condensed TiB and titanium metal phases were determined to be unstable when the above reactants are used. The gas composition in equilibrium with the deposited solid was computed as a function of the CVD parameters of deposition temperature, total pressure, and B/(B + Ti) and Cl/(Cl + H) fractions in the reactant gas. The gaseous species generally present in greatest abundance were $TiCl_3$, $TiCl_4$, BCl_3, H_2, $HBCl_2$, and HCl. Theoretical TiB_2 deposition efficiencies were also calculated as a function of CVD parameters. The most efficient deposition was calculated to occur (*i*) at temperatures <1500°K, (*ii*) under reduced pressures, and (*iii*) in the presence of an excess of hydrogen. Equilibrium calculations coupled with experimental results were also used to determine limits on the enthalpies of formation of TiB and TiB_2.

The diboride of titanium is a refractory material with metallic properties such as high thermal and electrical conductivity. It is quite stable with respect to oxidation and chemical attack and, like all boron-containing substances, has potential for use as a neutron absorber. Present commercial interests in TiB_2 center on its use as an abrasive, as a protective coating, as a potential high temperature electrode in the refining of aluminum, and as a component in TiB_2-BN composites used for aluminum evaporator boats.

The refractory nature of TiB_2 makes the synthesis of samples with a specified composition and purity difficult. Possible means of production are discussed by Powell (1), and include synthesis from the elements, fused salt electrolysis, reduction of metal oxides with boron, carbothermic reduction of metal oxide-boron mixtures, reduction of boron halides or pyrolysis of borohydrides on a metal substrate, and finally, the technique discussed in this work, the reduction of boron and metal halides on an inert substrate.

All methods of preparation tend to have problems such as interactions with container materials and background gases, preferential vaporization of titanium or boron, or inclusion of solvent when the boride is precipitated out of solution. Chemical vapor deposition (CVD) was investigated to produce well-defined specimens of high purity. In CVD gaseous reactants pass over a heated substrate where chemical reactions occur and condensed phases deposit. The technique controls reactant concentrations through manipulation of reactant partial pressures. Because relatively low temperatures are required, problems of container interactions and sample evaporation are reduced.

Diboride shapes are now produced by powder metallurgy techniques (1), but are limited in size, shape, and density. In many cases, CVD may substitute for powder metallurgical techniques to prepare dense TiB_2 coatings and bulk materials. Its feasibility has already been investigated to some extent (2-8).

Tailoring of a CVD process to yield a desired product under optimum operating conditions requires the use of a predictive model developed from a basic understanding of the chemistry of the system, the equilibrium thermodynamic limits of the process, possible chemical kinetic rate-limiting mechanisms, and mass transport limitations. An equilibrium thermodynamic analysis provides the limiting equilibrium composition of the gas phase, limiting deposition rates, and an identification of the phase(s) which can deposit under this limiting equilibrium state.

Chemical kinetic mechanisms have often been found to limit deposition rates and influence the morphology of the deposit. These mechanisms can be elucidated only from the experimental results obtained by operating the CVD system of interest. The transfer of reactants from the bulk gas to the substrate surface, and the transfer of reaction products back into the bulk gas stream also influence both the efficiency of deposition and the deposit morphology. A complete predictive model of a CVD system must therefore consider chemical, thermodynamic, chemical kinetic, and mass transfer relations.

The present comprehensive study of the CVD of TiB_2 is described in three separate papers. The morphology of CVD TiB_2 has been described and correlated with specific deposition conditions in a previous paper (9). The present paper describes an equilibrium thermodynamic analysis of the system as a function of the same deposition conditions. An accompanying paper (10) discusses the mass transport and chemical kinetics involved, and compares the experimental rates with those calculated using a predictive model.

Except for the present study, the only other equilibrium thermodynamic analysis of the CVD of TiB_2 was a very limited attempt by Peshev and Niemyski (7). They computed the standard free energy change for the over-all reaction

$$TiCl_{4(g)} + 2BCl_{3(g)} + 5H_{2(g)} = TiB_{2(s)} + 10\,HCl_{(g)} \quad [1]$$

as a function of temperature. These values were compared to the standard free energy changes for similar CVD reactions forming elemental titanium and boron. Thus they considered only the gaseous species $TiCl_4$, BCl_3, H_2, and HCl and the three condensed phases.

In contrast to Peshev and Niemyski's (7) work, the present study is a complete equilibrium thermodynamic analysis of the CVD process. All conceivable gaseous species, a total of 21, are included with the

Key words: chemical vapor deposition, titanium diboride, equilibrium thermodynamic analysis.

condensed phases in calculating the equilibrium composition of the system as a systematic function of the CVD variables of temperature, total pressure, and reactant concentrations.

Calculational Technique

Chemical equilibrium calculations involve the computation of the composition of a system, subjected to certain constraints, which contains the minimum free energy. The constraints in CVD systems are the preservation of the masses of each element present, constant temperature, and constant total pressure.

Numerous methods have been reported for computing thermodynamic equilibrium compositions, but all the techniques are based on the methods of either Brinkley (11-12) or White *et al.* (13). The method first outlined by Brinkley (11-12) is the older and more indirect technique. It requires the writing of a series of chemical reactions and the computation of their respective equilibrium constants. These are then used with the constraints mentioned above to solve for the equilibrium composition.

White *et al.* (13) developed a relatively simple and direct method for computing chemical equilibria. Their technique involves minimizing the summation of the free energies of all the species. Eriksson (14) extended the method to include systems containing more than one condensed phase and developed a computer program, SOLGAS, for performing the calculations. To prevent the omission of an important species, the program can consider all conceivable gaseous species and condensed phases in a single calculation. Unstable condensed phases are rejected from the calculation. The computer program SOLGAS was modified for convenient use with CVD systems and then used to perform the calculations in the present study.

Results

The thermodynamic analysis which follows considers equilibrium in a system in which condensed phases are deposited from initial gaseous reactants of $TiCl_4$, BCl_3, and H_2. The equilibrium was calculated as a function of the CVD variables of deposition temperature, total pressure, and the fractions B/(B + Ti) and Cl/(Cl + H) in the reactant gas. All conceivable gaseous species in the Ti-B-Cl-H system were included and are listed in Table I along with their respective thermodynamic values. The only condensed phases confirmed to exist in the binary Ti-B system (18) are Ti, TiB, TiB_2, and B.

The equilibrium calculations were initially used to develop what are termed CVD phase diagrams, of which Fig. 1 is an example. These plots of computed phase boundaries as functions of CVD variables show ranges of input conditions under which specific condensed phases are the equilibrium products.

The deposition of either $Ti_{(s)}$ or $TiB_{(s)}$ was not predicted under any of the CVD conditions investigated. This is a result of the high stabilities of TiB_2 and gaseous titanium chlorides as compared to Ti and TiB, and the fact that only fully chlorided titanium and boron were used as reactants.

Detailed information on the system's equilibrium gas composition as a function of the CVD parameters is given in Fig. 2. In each plot, both the reactant gas species partial pressures and the computed equilibrium partial pressures are graphed *vs.* a specific CVD parameter while all other parameters were held constant at an arbitrary set of standard conditions.

The standard conditions chosen were: temperature = 1523°K, total pressure = 0.263 atm, B/(B + Ti) = 0.667, and Cl/(Cl + H) = 0.333.

The four graphs in Fig. 2 show that $TiCl_3$, $TiCl_4$, BCl_3, $HBCl_2$, H_2, and HCl are the major gaseous species. The equilibrium partial pressures of the titanium- and boron-containing species are greater than 10% initial input reactant gas values even at high temperatures. The relationships shown in Fig. 2 are of importance in understanding the kinetics and mechanisms of deposition (10).

† Derived from the values for $TiCl_{3(g)}$, $\Delta H°_{298°K} = -40.6$ kcal/mole, and $\Delta S°_{298°K} = -36.4$ kcal/mole-°K and $\Delta C°_p = 4$ kcal/mole-°K determined by Sibbing and Schäfer (16) for the reaction $2TiCl_{3(g)} = Ti_2Cl_{6(g)}$.

‡ The value of $\Delta H°_{f,1600°K}$ (TiB_2) was derived from $\Delta H°_{f,298°K}$ (TiB_2) = −77.4 ± 0.9 kcal/mole determined by Huber (17) and the heat capacity, $C°_p$, reported in the JANAF Tables (15).

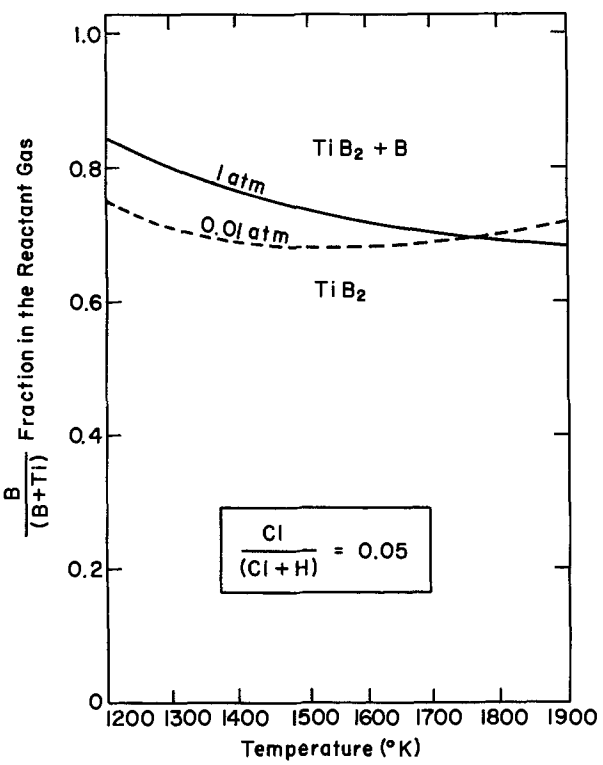

Fig. 1. CVD phase diagram based on thermodynamic equilibrium calculations. The B/(B + Ti) fraction in the reactant gas is plotted vs. the deposition temperature at two different pressures, 0.01 and 1.0 atm, and a Cl/(Cl + H) = 0.05 fraction in the reactant gas. The phase boundaries separate ranges of conditions under which either TiB_2 + B codeposits or single phase TiB_2 forms.

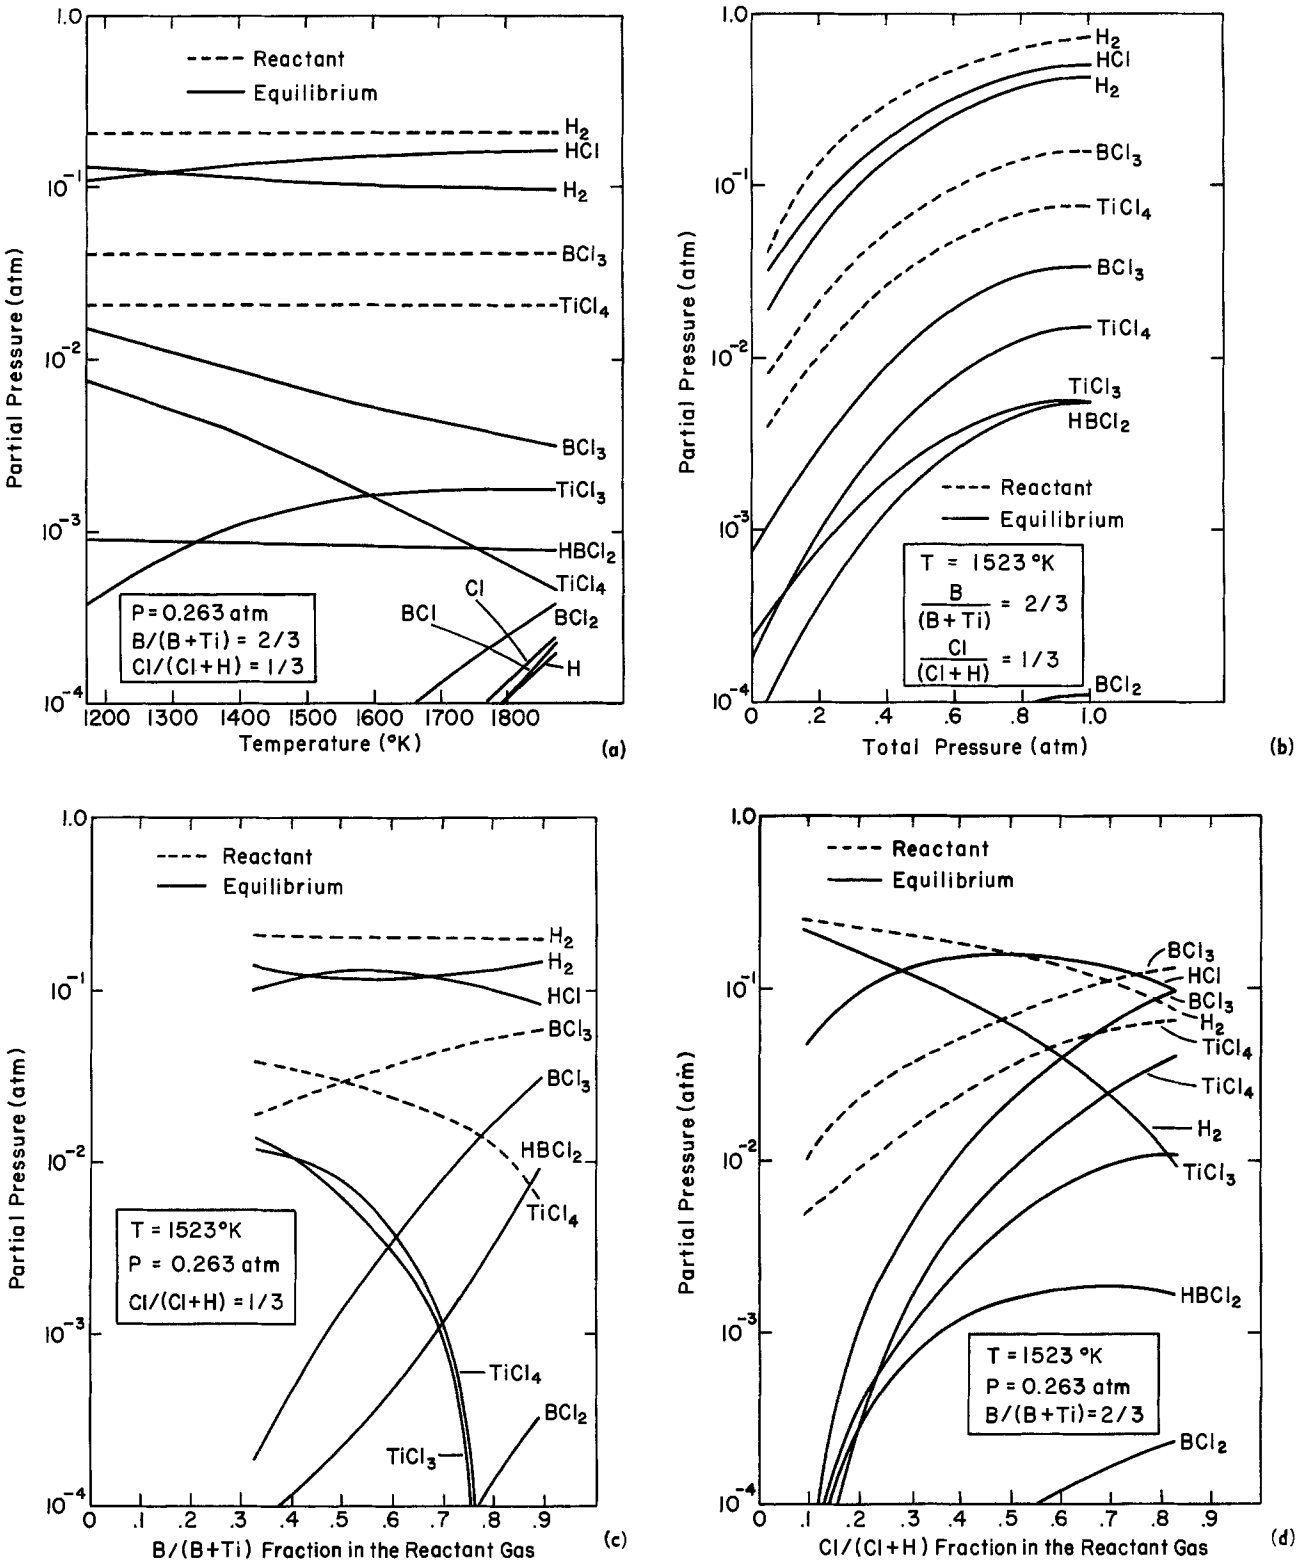

Fig. 2. Reactant and equilibrium partial pressures of the species present in the CVD system as a function of temperature (a), total pressure (b), B/(B + Ti) fraction in the reactant gas (c), and Cl/(Cl + H) fraction in the reactant gas (d).

The thermodynamic equilibrium calculations can also be used to determine theoretical deposition efficiencies. These efficiencies are defined as the moles of TiB_2 computed to deposit at equilibrium divided by the moles of diboride which could deposit if the reactants formed the maximum amount of TiB_2, *i.e.*, the amount which can form independent of any kinetic or thermodynamic limitations. Figure 3 contains plots of theoretical efficiency *vs.* deposition temperature for a series of deposition conditions. The CVD of TiB_2 is thermodynamically favored at elevated temperatures, reduced pressures, and low Cl/(Cl + H) fractions.

The equilibrium rate of formation of TiB_2 is sensitive to the value of the enthalpy of formation of TiB_2. The JANAF Tables (15) report the rather uncertain value of $\Delta H°_{f,298°K}(TiB_2) = -66.8 \pm 4$ kcal/mole. Their value is considerably more uncertain and based on older and less precise sources than is the value $\Delta H°_{f,298°K}(TiB_2) = -77.4 \pm 0.9$ kcal/mole reported by Huber (17). This more negative value is also in agreement with the recent value of Akhachinski and Chirin (19) of -76.1 ± 0.85 kcal/mole, and the values of -78.0 and -80.3 kcal/mole tabulated by Wagman *et al.* (20) for the analogous phases ZrB_2 and HfB_2, respec-

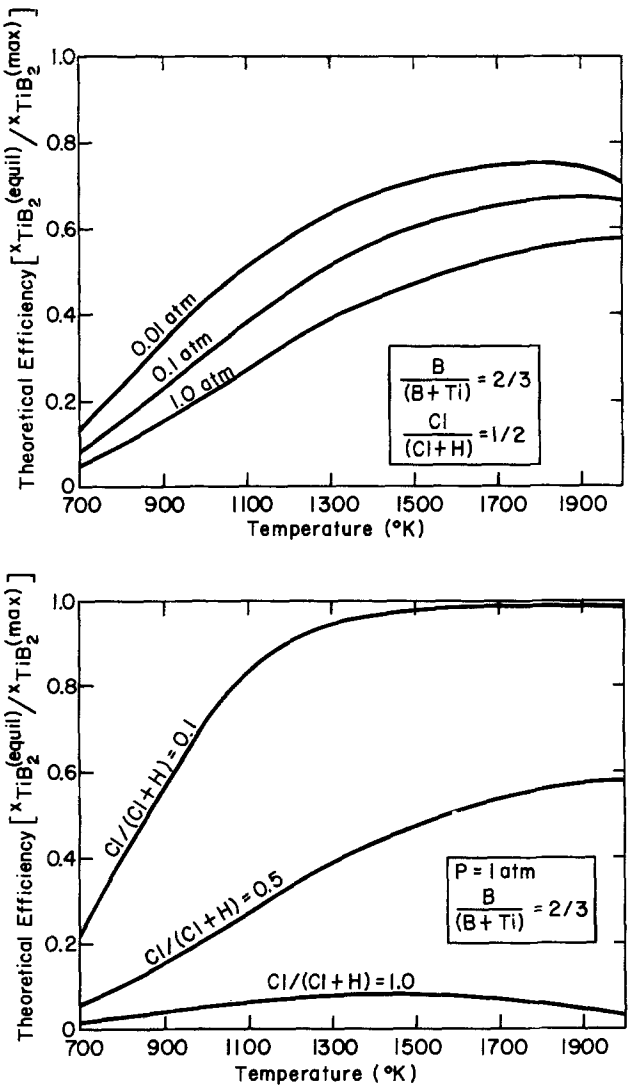

Fig. 3. Theoretical efficiencies of deposition vs. deposition temperature for total pressures of 0.01, 0.1, and 1.0 atm (a, top) and Cl/(Cl + H) fractions of 0.1, 0.5, and 1.0 in the reactant gas (b, bottom).

tively. Thermodynamic equilibrium calculations on the CVD of TiB_2 performed using the −66.8 kcal/mole value result in equilibrium deposition rates almost equal to several experimentally observed rates (10). This more positive JANAF value can therefore be considered the most positive limit for the enthalpy of formation since more positive values would yield calculated equilibrium rates lower than those observed experimentally.

The JANAF Tables (15) give an even larger uncertainty in the reported enthalpy of formation for TiB, $\Delta H°_{f,298°K}(TiB) = -38.3 \pm 9$ kcal/mole. Under experimental conditions favoring the formation of the monoboride, *i.e.*, a low B/(B + Ti) fraction in the reactant gas, the phase was not observed to form (10). These CVD conditions [$T = 1523°K$, $P = 0.263$ atm, $B/(B + Ti) = 0.333$, and $Cl/(Cl + H) = 0.333$] were used as data in thermodynamic equilibrium calculations in which the enthalpy of formation of TiB was allowed to vary. The enthalpy at which the TiB was computed to just begin to form is considered the maximum negative enthalpy of formation for the phase. This calculated limit of $\Delta H°_{f,1523°K}(TiB) > -55$ kcal/mole is consistent with the high temperature value of $\Delta H°_{f,1523°K}(TiB) = -41.0$ kcal/mole derived from the JANAF Tables (15).

Discussion

The oversimplified thermochemical logic used by Peshev and Niemyski (7) can yield misleading results. They state that if the standard free energy change ($\Delta G°$) for Eq. [1] is negative, and if the over-all reactions forming titanium and boron have more positive $\Delta G°$'s, TiB_2 should form readily. If Eq. [1] had not been the dominant over-all reaction, *e.g.*, $TiCl_3$ rather than TiB_2 had been the major product, their calculations would not have been meaningful. Only a complete thermodynamic analysis similar to that presented here would indicate the most important species. Additionally, Peshev and Niemyski ignored the possibility of the deposition of more than one condensed phase. For the conditions shown in Fig. 1, boron can codeposit with the diboride at a B/(B + Ti) as low as 0.65 in the initial reactant gases.

The trends in theoretical efficiency exhibited in Fig. 3 are easily explained by simple thermochemical logic since only one chemical reaction (Eq. [1]) is dominating. Assuming the condensed phase activity for TiB_2 is unity, the equilibrium constant, K, for Eq [1] is expressed by

$$K = \frac{p^{10}_{HCl}}{p_{TiCl_4} p^2_{BCl_3} p^5_{H_2}}$$

where the partial pressures, p's, are in atmospheres. The equilibrium constant can also be written as a function of the mole fraction of each species, x, and the total pressure, P

$$K = P^2 \frac{x^{10}_{HCl}}{x_{TiCl_4} x^2_{BCl_3} x^5_{H_2}} \qquad [2]$$

K is a constant defined by

$$K = \exp\left(\frac{-\Delta G°}{RT}\right)$$

where $\Delta G°$ is the standard free energy change for Eq. [1], R is the ideal gas law constant, and T is the absolute temperature. The data in Table I yield

$$\ln K = 31.32 - \frac{35{,}330}{T} \qquad [3]$$

The trend toward increased deposition efficiency with increasing temperature seen in Fig. 3 is now apparent from Eq. [3]. Higher temperatures yield larger values of K resulting in increased deposition.

The requisite that K in Eq. [2] must equal a specific constant at a specific temperature explains the pressure-dependent behavior of deposition efficiency observed in Fig. 3a. As P decreases, the ratio of the moles of product to the moles of reactants in Eq. [2] must increase to maintain K at the constant value. Increasing deposition efficiency thus accompanies decreasing total pressure, as seen in Fig. 3a.

Figure 3b can be explained similarly since increased amounts of hydrogen, a reactant, must cause increased amounts of product to form if K is to remain constant.

From Fig. 3 it appears that maxima in efficiency occur which shift toward lower temperatures under reduced pressures and increased Cl/(Cl +H) fractions. This is caused by the increased stability of gaseous species which form at the expense of TiB_2 at higher temperatures and under reducing conditions. Figure 2a shows that the partial pressure of $TiCl_3$ increases with increasing temperature, and thus suppresses the formation of TiB_2 at high temperatures. These phenomena cannot be predicted by the simplified thermodynamic analysis of Peshev and Niemyski (7).

Conclusions

Under all CVD conditions investigated, the thermodynamic equilibrium calculations indicate that TiB_2 and boron are the only solids which can deposit from the reactant gases of $TiCl_4$, BCl_3, and H_2. The theoretical efficiency of deposition appears to generally increase with increasing deposition temperature, although maxima appear to exist at high temperature.

Small Cl/(Cl + H) fractions in the reactant gas and small total pressures also favor higher efficiencies.

The gaseous species present in greatest abundance at equilibrium are $TiCl_3$, $TiCl_4$, BCl_3, H_2, $HBCl_2$, and HCl, and these probably play the most important mechanistic roles in the CVD of TiB_2. The present studies indicate that a $\Delta H°_{f,298°K}(TiB_2)$ of about −66 kcal/mole is the most positive value for the diboride that is still consistent with the experimental results. This limit is in agreement with later reported values which yield a $\Delta H°_{f,298°K}(TiB_2) \approx -77$ kcal/mole. Employing experimental results (10) and thermodynamic equilibrium calculations, a maximum negative limit of $\Delta H°_{f,298°K} = -55$ kcal/mole was computed for the enthalpy of formation of TiB.

The conclusions demonstrate the value of thermodynamic calculations in determining which equilibrium phases can form in a CVD system and in pointing the way toward optimizing deposition conditions. Published papers on CVD show that most studies omit such calculations or do not include all important species in their analysis. The procedures outlined in this paper are equally applicable to other CVD systems, as is the modified version of the computer program SOLGAS.

Analysis of the Chemical Vapor Deposition of Titanium Diboride

II. Modeling the Kinetics of Deposition

Theodore M. Besmann[1] and Karl E. Spear[2]

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

Deposition rates and efficiencies for the chemical vapor deposition (CVD) of TiB_2 from $TiCl_4$, BCl_3, and H_2 were experimentally determined as a function of CVD variables. These results, coupled with previously determined thermodynamic equilibrium compositions and deposit morphologies, were used to develop models for the deposition process. At high temperatures the principal rate-limiting mechanism is the diffusion of gaseous species through a gas boundary layer above the deposition surface. However, low Cl/(Cl + H) or high B/(B + Ti) fractions in the reactant gas cause a chemical kinetic mechanism to become rate limiting. At lower deposition temperatures equilibrium no longer appears to exist at the substrate surface and a chemical kinetic rate-limiting mechanism becomes important. A simple linear rate expression was used to calculate an activation energy of 40 ± 12 kcal/mole for the chemical kinetic mechanism.

As has been previously discussed (1-2) there is considerable interest in the process of chemical vapor deposition (CVD) and in TiB_2 as a material. The CVD of TiB_2 has been successfully attempted by several researchers (3-9), but little has been done to elucidate the deposition processes and in CVD in general. This is not surprising since developing an understanding of complex CVD processes involves understanding chemical thermodynamic, mass transfer, and chemical kinetic

[1] Present address: Oak Ridge National Laboratory, Chemical Technology Division, Oak Ridge, Tennessee 37830.

Key words: chemical vapor deposition, titanium diboride, kinetics, gaseous diffusion.

phenomena. Studies of the deposition of silicon, gallium arsenide, and tungsten represent the major published attempts to thoroughly understand CVD processes (10).

An earlier paper in the present series on the CVD of TiB_2 has described the thermodynamic analysis for the deposition of TiB_2 from the reactant gases $TiCl_4$, BCl_3, and H_2 (1). The identity of the condensed phases which form and the equilibrium partial pressures of the various gaseous species were calculated as a function of the CVD variables of temperature, total pressure, and the fractions B/(B + Ti) and Cl/(Cl + H) in the reactant gas. Only TiB_2 and boron were predicted to deposit under the conditions investigated. At equilibrium the most abundant gaseous species present are $TiCl_3$, $TiCl_4$, BCl_3, H_2, $HBCl_2$, and HCl. Equilibrium calculations were also used to determine theoretical TiB_2 deposition efficiencies, *i.e.*, the TiB_2 deposition rate at equilibrium divided by the deposition rate in the absence of any thermodynamic or kinetic limitations.

The morphologies of the TiB_2 deposits were previously correlated with the deposition parameters of substrate temperature, total pressure, total gas flow rate, and the B/(B + Ti) and Cl/(Cl + H) fractions in the reactant gas (2). Most diboride deposits were adherent, coherent coatings with preferred orientations such that the c-direction of the hexagonal TiB_2 was parallel to the substrate surface. As the deposition temperature increased, the deposits transformed from relatively smooth, nodular surfaces to faceted coatings. Increased B/(B + Ti) fractions in the reactant gas caused the growth of platelike crystallites several square millimeters in area fixed normal to the substrate surface. Low Cl/(Cl + H) fractions yielded irregular crystallites with decreased preferred orientation. Reduced total pressure yielded coatings having increased crystallite size, and higher gas flow rates resulted in decreased perfection in the crystallite faces of faceted coatings.

This paper describes a kinetic study of the CVD of TiB_2 in which deposition rates were systematically determined as a function of the deposition variables of temperature, total pressure, total flow rate, and the B/(B + Ti) and Cl/(Cl + H) fractions in the reactant gas. These results, along with equilibrium calculations (1) and observed deposit morphology (2), are used to model the deposition processes in an attempt to comprehend the underlying principles involved in CVD.

Peshev and Niemyski (8) also reported kinetic data on the CVD of TiB_2. Their study likewise used the over-all reaction

$$TiCl_{4(g)} + 2BCl_{3(g)} + 5H_{2(g)} = TiB_{2(s)} + 10\,HCl_{(g)} \quad [1]$$

They investigated the efficiency of deposition as a function of substrate temperature, total gas flow rate, and reactant gas Cl/(Cl + H) fractions. Their results are compared to the present study in the discussion section.

Modeling CVD Kinetics

The ultimate limit on the rate of CVD of any material is the rate of input of the reactants coupled with the system's thermodynamic equilibrium composition. This limit is rarely achieved in dynamic CVD systems and kinetic factors usually govern the deposition rate behavior. In a general review of CVD, Jones and Shaw (10) have delineated the general mass transfer and chemical kinetic processes involved in CVD. These include the flow of reactants and gaseous products through the system, the transport of chemical species from the bulk gas to the deposition surface, the transport of product gases from the surface to the bulk gas, and the chemical reactions occurring at the deposition surface.

A relatively simple model has been assumed for the transport of gaseous species between the bulk gas (where the gas flow is parallel to the substrate surface) and the deposition surface. It is envisioned that between the turbulent bulk gas and the deposition surface lies a laminar boundary layer, and that the diffusion of gaseous species through the laminar boundary layer is a possible rate-limiting step.

It is useful to assume that the diffusion of species i through the boundary layer is equivalent to the diffusion of i in a binary gas mixture containing the carrier gas j. Fick's first law yields

$$J_i = D_{ij}\left(\frac{{}_bp_i - {}_sp_i}{\delta RT}\right) \quad [2]$$

where J_i = flux of species i through the boundary layer, D_{ij} = binary diffusion coefficient for the species, ${}_bp_i$ = partial pressure of species i in the bulk gas, ${}_sp_i$ = partial pressure of species i at the deposition surface, δ = boundary layer thickness, R = ideal gas constant, and T = absolute temperature.

The functional relationships of the various parameters in the diffusion relation provide a valuable model for understanding the effects of experimental variables on the deposition rates. Jones and Shaw's (10) expression for the binary diffusion coefficient is

$$D_{ij} = \frac{AT^{1.75}}{P}\left(\frac{1}{M_i} + \frac{1}{M_j}\right)^{1/2} \quad [3]$$

where A = proportionality constant, P = total pressure, and M = molecular weight.

Bennett and Myers (11) show that for flow across a semi-infinite flat plate, laminar boundary conditions yield

$$\delta = 5\left(\frac{\mu L}{\rho v}\right)^{1/2}$$

where μ = fluid viscosity, L = distance from the leading edge of the plate, ρ = fluid density, and v = linear velocity of the fluid.

Assuming the flow across the CVD substrate region is analogous to flow across a flat plate, the functional relationship

$$\delta \propto \left(\frac{\mu}{\rho v}\right)^{1/2} \quad [4]$$

can be used. Jones and Shaw note that

$$\mu \propto T^m \quad [5]$$

where m is an empirical constant which varies between 0.6 and 1.0. Density is, assuming the gas is ideal, proportional to the total pressure and inversely proportional to temperature, and linear velocity is proportional to the volumetric flow rate and inversely proportional to density. Substituting the above relationships including Eq. [2]-[5] into Eq. [2] yields

$$J_i = \frac{ZF^{1/2}T^{(3/4-m/2)}}{P}({}_bp_i - {}_sp_i) \quad [6]$$

where Z = mass transfer coefficient (proportionality constant), and F = input volumetric flow rate at STP.

Since the diffusive flux, J_i, is directly proportional to the deposition rate, Eq. [6] can be considered as also containing the functional relationships for the CVD rate.

In applying Eq. [6] to a CVD system it is necessary to predict or experimentally determine both ${}_bp_i$ and ${}_sp_i$. A simplifying assumption is that ${}_bp_i$ is the species partial pressure in the reactant gas, although a knowledge of ${}_bp_i$ as a function of the distance from the leading edge of the substrate would yield more accurate results.

The partial pressures of species at the deposition surface, ${}_sp_i$, can be governed either by thermodynamic equilibrium or by chemical kinetic mechanisms. The equilibrium partial pressures can be calculated relatively easily. The kinetically fixed partial pressure dependencies must be experimentally determined for each system.

Table I. Standard TiB_2 CVD conditions

	This study	Peshev and Niemyski (8)
Deposition temperature, °K	1523	1673
Total pressure, atm	0.263	1.0
Total input flow rate (STP), cm³/min	462	2580
B/(B + Ti)	0.667	0.667
Cl/(Cl + H)	0.333	0.143

Two limiting cases can be of interest. The first case is where equilibrium exists at the deposition surface and the partial pressures of the reactant species at equilibrium are very small. The rate-limiting process for deposition is the diffusion of the reactant gases through the boundary layer. The diffusion rates, and thus deposition rates, are directly proportional to the bulk partial pressures.

The opposite situation arises when chemical kinetic steps are slow and the concentrations of reactants at the surface approach the partial pressures in the bulk. Diffusion is very slow due to small partial pressure gradients between the bulk gas and deposition surface and the slowest chemical kinetic step is rate limiting.

Experimental Procedure

Experimental deposition rates of TiB_2 as a function of temperature, pressure, total flow rate, and B/(B+Ti) and Cl/(Cl + H) fractions in the reactant gas have been determined. One parameter was varied while all other parameters were held constant at the arbitrary set of standard conditions listed in Table I. Also listed are the standard conditions used by Peshev and Niemyski (8) in their similar study. Individual flow rates can be easily derived from total flow rates and B/(B + Ti) and Cl/(Cl + H) fractions.

Figure 1 is a schematic of the CVD system which is similar in design to those employed by other researchers (6-8). Boron trichloride[3] and hydrogen[4] gases were metered into the system through float-type flowmeters. The $TiCl_4$,[5] which is a liquid at room temperature, was injected into a vaporizer at a constant predetermined rate by a syringe pump equipped with a gas-tight syringe. The corrosive gases were only in contact with Teflon lines and Monel valves and connections. Helium was used to purge the system.

The vaporizer was a round-bottom flask covered by a heating mantle maintained at temperatures greater than 409.4°K, the atmospheric boiling point of $TiCl_4$. The hydrogen stream flowed to the vaporizer where it mixed with the tetrachloride and passed on to a Pyrex-Vycor nozzle to mix with the BCl_3 stream. The line between the vaporizer and nozzle was wrapped with heating tape to maintain the $TiCl_4$ as a vapor.

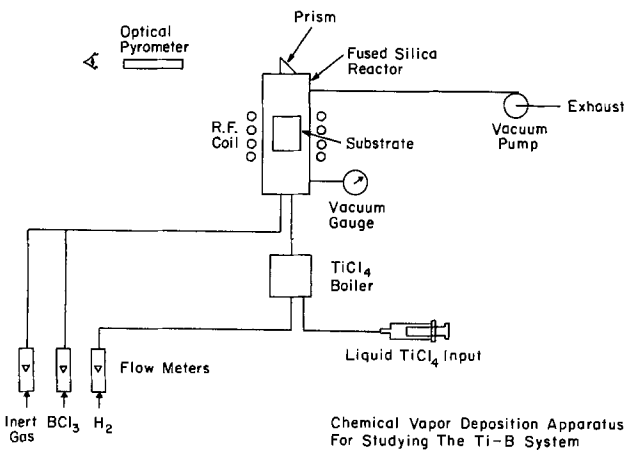

Fig. 1. Flow chart of the TiB_2 CVD system

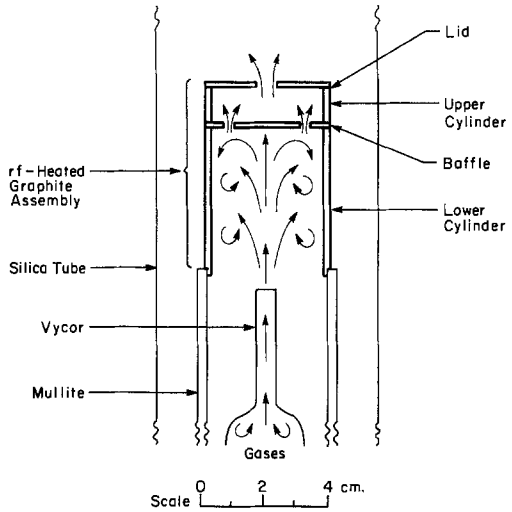

Fig. 2. Schematic of the graphite assembly in position in the CVD system. Not included in the sketch is a second mullite cylinder containing molybdenum foil shields whch surround the graphite assembly, and two molybdenum foil shields positioned on top of the lid.

Figure 2 is a sketch of the nozzle and CVD reactor setup. The gases flowed into a lower graphite cylinder which was supported by a mullite cylinder. The graphite was heated to temperature by a 10 kW, 450 kHz rf induction generator. To increase mixing and to help maintain a constant temperature in the lower cylinder, a baffle with exhaust holes was placed on top of the cylinder, a short graphite cylinder (upper cylinder) with a lid was positioned above the baffle, and a larger mullite cylinder and molybdenum foil thermal radiation reflectors were placed around the cylinders. Unreacted and product gases departed the system through a liquid-jet vacuum pump.

The CVD reactor consisted of a fused silica tube 6 cm in diameter and 25 cm tall with a Monel plate 2 cm thick and 15 cm in diameter sealing each end. The plates were held in place by four nylon dowels positioned around the periphery of the plates and outside the fused silica tube. The nozzle entered the reactor through a 2.5 cm diameter hole in the bottom plate. The top plate contained a 2.5 cm diameter Pyrex tube with a window for viewing the top of the graphite assembly. This plate also had two lines penetrating it, one leading to the vacuum pump and the other to the vacuum gauge. All penetrations of the Monel plates were sealed by compressed Teflon O-rings, and the plates were sealed to the main silica reactor tube with intervening Teflon gaskets.

For each experimental run a fresh graphite assembly was positioned above the nozzle. The system was then sealed and evacuated. Next a flow of helium was started and the substrate was brought to temperature. After the temperature had stabilized at the desired level, the helium was shut off and the reactant gases were allowed to flow through the graphite assembly. The system was usually operated for about 1 hr with constant monitoring and occasional adjustment of temperature, flow rates, and total pressure.

The deposition temperature was measured with a disappearing filament-type optical pyrometer by viewing the inner surface of the graphite cylinder through a small hole in the lid which was in line with a small hole in the baffle. The temperature of the graphite assembly was maintained by adjusting the power to the induction coil. The temperature was uniform over the length of the cylinder from the baffle to within a few millimeters above the mullite cylinder. The pressure was measured with diaphragm-type vacuum gauge and was held constant by manually opening or closing a valve in the line between the reactor and the vacuum

pump. Maintaining the total pressure constant often required adjustments during a run because the chloride species tended to condense in the exhaust line. The flow rates were set by adjusting a valve on the exit side of each flowmeter and by presetting the $TiCl_4$ injection rate. At the end of a run the gases were shut off and the system purged with helium. The induction generator was turned off and the assembly cooled to below red heat in about 5 min.

The deposition rates were determined by difference in mass of the lower graphite cylinder and baffle before and after a run. The mass in milligrams was divided by the run duration in minutes and by the inner surface area of the cylinder and baffle in square centimeters. The deposition rates ranged from about 0.5 to 1.5 mg/cm^2-min. The uncertainties associated with the measurement of temperatures, total pressure, and input flow rates were determined to average between 0.02 and 0.03 mg/cm^2-min. The mass of material deposited on surfaces not in the deposition zone and the change of mass of the graphite substrate were experimentally determined to be insignificant.

Results and Analysis

To try to elucidate the mechanisms involved in the CVD of TiB_2, the observed deposition rates have been compared with those due to strict compliance with (*i*) complete thermodynamic equilibrium, or (*ii*) gaseous diffusion (Eq. [6]) where equilibrium is assumed to exist at the deposition surface. Similar comparisons have been made using deposition efficiencies to provide another means for looking at the data. Efficiency is defined as the deposition rate divided by the rate at which the diboride would deposit in the absence of any thermodynamic or kinetic limitations. Changes in morphology correlated with rate and efficiency data aided in understanding deposition mechanisms.

In all cases, the experimental TiB_2 deposition rates were less than those calculated for thermodynamic equilibrium. Other mechanisms must therefore be limiting the deposition rates.

Temperature.—Figure 3 contains an Arrhenius plot of the logarithm of the observed deposition rate as a function of reciprocal temperature. As the temperature increases the rate goes from a strong to a weak function of temperature with a large change in slope.

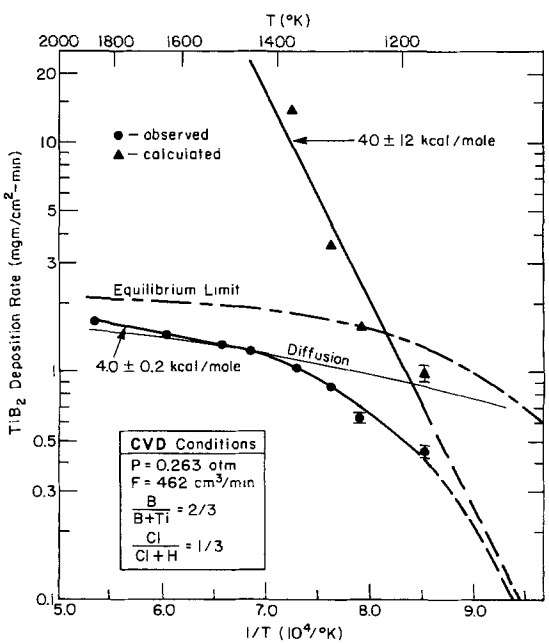

Fig. 3. Arrhenius plot for the deposition of TiB_2, including observed rates and calculated equilibrium-limited, diffusion-limited, and chemical kinetic-limited rates.

This indicates that more than one mechanism is likely to be rate controlling in the temperature range studied.

Chemical reaction rates usually increase exponentially with increasing temperature, and eventually become faster than mass transport rates. Figure 3 indicates that the present system changes from chemical kinetic to mass transport rate-limiting processes with increasing temperature. Above 1373°K the mechanism has an apparent activation energy (E_a) of 4.0 ± 0.2 kcal/mole which is significantly smaller than the 10-50 kcal/mole typical of a chemical kinetic process, but is characteristic of a gas diffusion rate-limiting process.

The experimental conditions of the present study would result in laminar flow if the substrate were an idealized smooth tube of infinite length. However, temperature gradients cause thermal convection, and the baffle in the present system and substrate end effects cause turbulence. In developing a mass transport model for the present experimental system, it is assumed that the bulk gas is turbulent, but that a laminar boundary layer exists adjacent to the substrate surface.

The mass transport model described by Eq. [6] was used to calculate diffusion-controlled deposition rates. It was assumed that the bulk gas partial pressures were equivalent to those in the input reactant gas. Thermodynamic equilibrium was assumed to exist at the deposition surface and the surface partial pressures were found from the equilibrium pressures calculated previously (1). Utilizing the partial pressures of titanium-bearing species, the temperature dependence of diffusion-limited deposition can be derived from Eq. [6] as

$$r \propto T^{(3/4-m/2)}({}_{rn}p_{Ti} - {}_{eq}p_{Ti}) \qquad [7]$$

where r = deposition rate, ${}_{rn}p_{Ti}$ = partial pressure of $TiCl_4$ in the input reactant stream, and ${}_{eq}p_{Ti}$ = sum of the equilibrium partial pressures of Ti-bearing species.

The use of boron-bearing species partial pressures would yield equivalent results.

Using the mean value of 0.8 for m, Eq. [7] is normalized to the observed deposition rate at the standard conditions and then plotted in Fig. 3. This diffusion curve generally follows the observed temperature dependence above 1373°K.

Below 1373°K the deposition rate is more dependent on temperature. A chemical rate-limiting mechanism is assumed to significantly influence the over-all rate since equilibrium is not established at the substrate surface. It is believed that the deposition rate is a function of the inherent rates of diffusion and of the slowest chemical kinetic process occurring at the deposition surface. The partial pressures at the surface are governed by the rate-limiting chemical kinetic process. This governs ${}_sp_i$ in Eq. [6] and, in turn, determines the diffusion rate. The over-all deposition rate can thus be expressed by the diffusion relation and the rate expression for the controlling chemical kinetic process.

Experimental data on the dependencies of the deposition rate on the partial pressures of the various species are not available in the lower temperature region, and so the diffusion and rate relations cannot be defined. A simple linear model can be used to sum the contributions of diffusion and chemical kinetic rate-limiting processes at temperatures below 1373°K. This model assumes that the rate is limited by (*i*) the diffusion of a reactant species through a boundary layer to the equilibrated deposition surface, and/or (*ii*) a chemical kinetic step that is a linear function of the partial pressure of the limiting species, *i.e.*, a first-order reaction. Thus it is possible to write the expression

$$\frac{1}{r} = \frac{1}{r_1} + \frac{1}{r_2}$$

where r_1 is the deposition rate controlled by the diffusion of reactants to an equilibrated deposition surface, and r_2 is the deposition rate controlled by a

chemical kinetic process when the reactant species partial pressures at the deposition surface are equal to those in the input gas.

Using the deposition rates experimentally determined at 1373°K and lower (r), and the respective diffusion-controlled deposition rates plotted in Fig. 3 (r_1), four points for r_2 were calculated and are also shown in Fig. 3. A straight line least squares fit to these points is the temperature dependence of the chemical kinetic process and from its slope an $E_a = 40 \pm 12$ kcal/mole was calculated. This relatively high E_a is typical of a chemical kinetic process.

Total pressure.—The high temperature region has been studied more closely and the influence of the total system pressure on the observed deposition rate and efficiency at 1523°K is shown in Fig. 4. From Eq. [6] and the assumptions described above, the total pressure dependence of diffusion-controlled deposition is

$$r \propto \frac{({}_{rn}p_{Ti} - {}_{eq}p_{Ti})}{P} \qquad [8]$$

Equation [8] normalized to the observed deposition rate at 0.263 atm, the standard value, is also plotted in Fig. 4 along with the equivalent curve for diffusion-controlled deposition efficiency. Agreement with the observed rate and efficiency curves indicates that gaseous diffusion through a boundary layer, with equilibrium at the deposition surface, is probably the rate-limiting mechanism.

Flow rate.—The gas flow rate influences diffusion by changing the laminar boundary layer thickness (Eq. [4]). Again from Eq. [6] the flow rate dependence of the deposition rate can be found and is

$$r \propto F^{1/2}$$

Observed deposition rates and efficiencies agree reasonably well with the diffusion curves normalized to the observed deposition rate and efficiency at the standard conditions as shown in Fig. 5.

B/(B + Ti).—Figure 6 exhibits plots of deposition rates and efficiencies *vs.* the B/(B + Ti) fraction in the reactant gas. The diffusion rate-limiting curves were

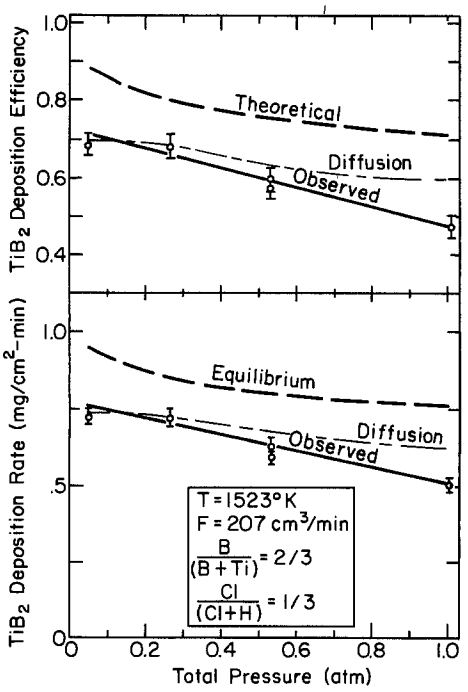

Fig. 4. Deposition rate and efficiency *vs.* total pressure including observed data plus calculated equilibrium-limited and diffusion-limited curves.

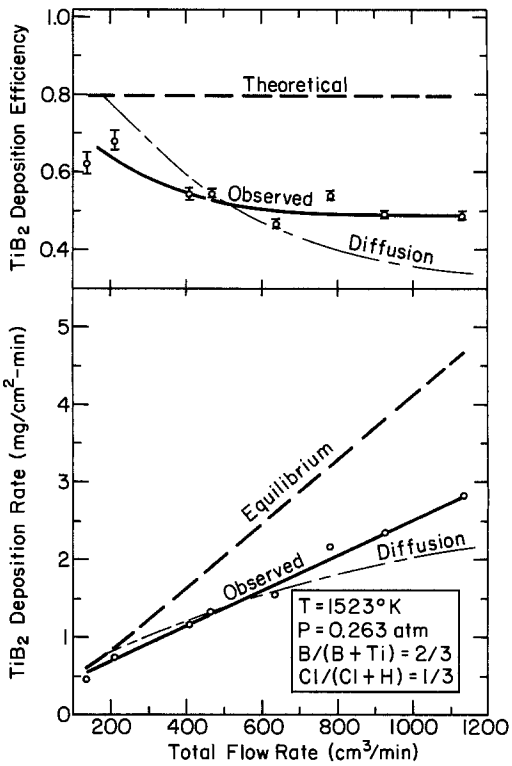

Fig. 5. Deposition rate and efficiency *vs.* total reactant gas flow rate including observed data plus calculated equilibrium-limited and diffusion-limited curves.

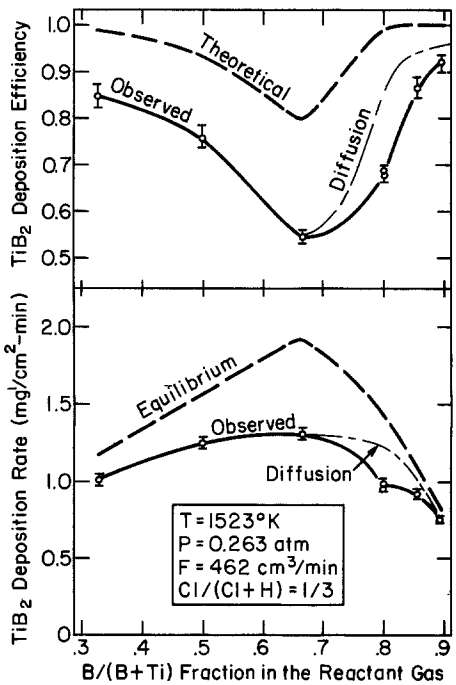

Fig. 6. Deposition rate and efficiency *vs.* reactant gas B/(B + Ti) fraction including observed data plus calculated equilibrium-limited and diffusion-limited curves.

calculated from the equation

$$r \propto ({}_{rn}p_{Ti} - {}_{eq}p_{Ti}) \qquad [9]$$

normalized to the deposition rate at the standard conditions. It is observed that the experimental deposition rate generally follows the calculated diffusion-controlled rate until B/(B + Ti) > 2/3. At these boron-rich compositions the experimental rate becomes significantly less than the diffusion rate. At B/(B + Ti)

> 2/3 it is also observed that TiB_2 no longer grows as a coherent coating. At B/(B + Ti) = 0.8 a small area of the substrate exhibits platelike crystallites oriented normal to the substrate surface, with the c-direction normal to the platelet surface (2). For B/(B + Ti) > 0.8 the TiB_2 grows exclusively as platelets indicating that a chemical kinetic mechanism is rate limiting by suppressing growth in certain crystallographic directions. At these high B/(B + Ti) fractions, boron or boron-containing species may adsorb on the crystal faces normal to the c-direction and poison the growth on these faces. The deposition surface is no longer at equilibrium and the resulting drop in deposition rate and efficiency is observed.

The shoulder in the plot of deposition rate *vs.* B/(B + Ti) in Fig. 6 is due to the change in deposit morphology. The platelike crystallites promote growth by protruding into the boundary layer, disturbing it, and increasing the reactant concentrations near the growth surface. A simple calculation of the average boundary layer thickness using Eq. [2], a typical deposition rate of about 1 mg/cm²-min, and standard conditions for determining the partial pressures of the input gas and equilibrium gas at the substrate yields a thickness of about 1 mm, which is about the same as the dimensions of many of the platelet crystallites.

Cl/(Cl + H).—Figure 7 shows the deposition rates and efficiencies as a function of the Cl/(Cl + H) fraction in the reactant gas. Equation [9] normalized to the deposition rate at the standard conditions was again used to calculate the diffusion curves. At Cl/(Cl + H) < 1/3 the experimental deposition rate is anomalously greater than that predicted from the gaseous diffusion model with equilibrium at the deposition surface. Apparently, at low Cl/(Cl + H) fractions this simple model is no longer sufficient. The large changes in average molecular weight of the gas which accompany variations in the Cl/(Cl +H) fraction change the flow characteristics of the gas. If molecular weight terms were included in Eq. [9] (and Eq. [6]), the system would be more accurately modeled.

At low Cl(Cl + H) fractions the observed deposition efficiency decreases as the theoretical efficiency continues to increase. Under these conditions a chemical kinetic process may be rate limiting and equilibrium may not exist at the deposition surface. This idea is enhanced by the fact that at low Cl/(Cl + H) fractions the coating formed is no longer faceted and coherent, but is made up of irregular crystallites which have little preferred orientation (2). Partially reduced molecular species or hydrogen may strongly adsorb on the reaction surface and slow growth. Equilibrium calculations indicate that the partial pressure of $HBCl_2$ approaches that of BCl_3 at low Cl/(Cl + H), and $HBCl_2$ may play a role in a chemical kinetic step.

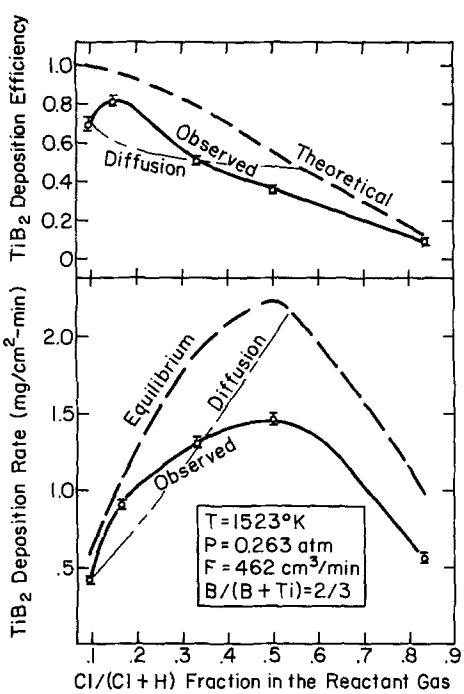

Fig. 7. Deposition rate and efficiency *vs.* reactant gas Cl/(Cl + H) fraction including observed data plus calculated equilibrium-limited and diffusion-limited curves.

Discussion

Peshev and Niemyski (8) have also reported efficiency data for the CVD of TiB_2. Although their system differed significantly, a comparison of the results is possible. The higher temperature and lower Cl/(Cl + H) fraction in the reactant gas used by Peshev and Niemyski (see Table I) increased their standard condition efficiency over that of this study, as expected. The influence of the different flow rates is difficult to compare because of different reactor and substrate configurations.

Figure 8 is a plot of efficiency *vs.* deposition temperature for the data generated in both studies. Peshev and Niemyski's (8) results indicate that the diffusion rate-limiting region, where equilibrium is presumed to exist at the deposition surface, occurs at temperatures greater than 1673°K as compared to a transition temperature of 1373°K for the present system. Lower Cl/(Cl + H) fractions in the reactant gas probably caused their system to remain chemical kinetic rate limited to higher temperatures. Their two highest temperature data points, however, yield an apparent activation energy of about 6.8 kcal/mole, which may indicate that both mass transport and chemical kinetic effects are important.

Deposition efficiencies for both studies are plotted *vs.* total flow rate in Fig. 9. The relation for calculating the efficiency curves was derived from Eq. [6]

$$\text{efficiency} = \frac{J(\text{diffusion})}{J(\text{input})} \propto \frac{F^{1/2}}{F} = F^{-1/2}$$

The curves were normalized to the deposition rates at the respective standard conditions. Agreement between the diffusion-limited and observed deposition efficiencies is fair and the efficiency of Peshev and Niemyski appears linear rather than proportional to $F^{-1/2}$.

The efficiencies as a function of reactant gas Cl/(Cl + H) ratio for both studies are compared in Fig. 10. Peshev and Niemyski (8) increased the hydrogen flow rate to vary the Cl/(Cl + H) fraction instead of varying input flow rates of $TiCl_4$, BCl_3, and H_2. To compare results it is necessary to remove the total flow rate dependence from Peshev and Niemyski's data by dividing each point by its experimental efficiency for the corresponding total flow rate. The results multipled by the efficiency at 2580 cm³/min are shown in Fig. 10.

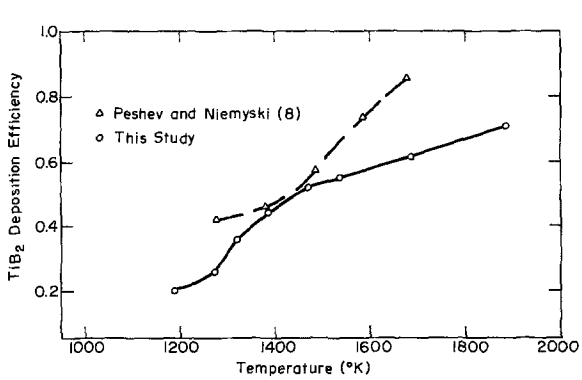

Fig. 8. Deposition efficiency *vs.* deposition temperature for Peshev and Niemyski's (8) data and that of the present study.

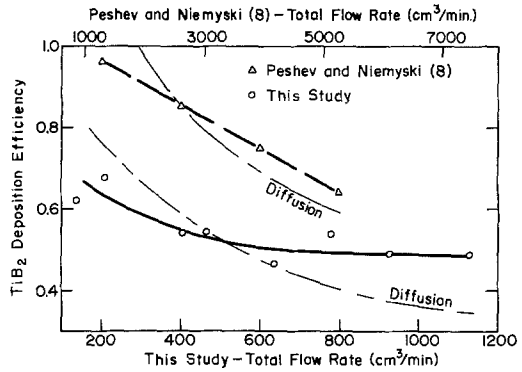

Fig. 9. Deposition efficiency vs. reactant gas flow rate for Peshev and Niemyski's (8) data and that of the present study. Included are diffusion-limited curves normalized to the deposition rates at the standard conditions of each respective study. The differences in flow rate scales should be noted.

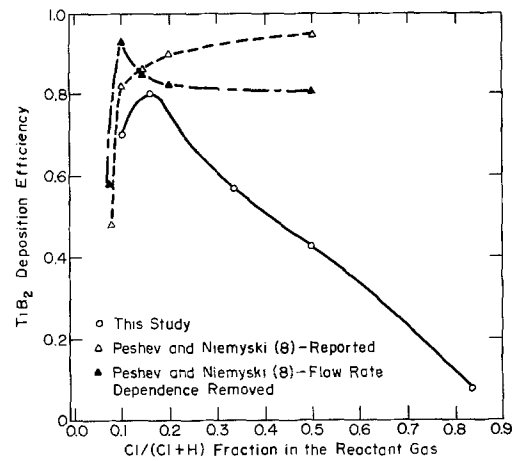

Fig. 10. Deposition efficiency vs. reactant gas Cl/(Cl + H) fraction for Peshev and Niemyski's (8) data and that of the present study. A curve derived from Peshev and Niemyski's data by removing the total flow rate dependence from their efficiencies is also shown.

The general shape of the derived flow rate-independent curve of Peshev and Niemyski (8) is similar to that found in the present study. Both curves show a significant drop in efficiency at low Cl/(Cl + H). This supports the conclusion that a chemical kinetic mechanism becomes rate limiting and reverses the trend toward increasing efficiency that is expected from equilibrium calculations (theoretical curve in Fig. 7).

Mehalso and Diefendorf (12) have recently reported a study of the CVD of boron by the hydrogen reduction of BCl_3. Their analysis was similar to that presented here, but they only considered the gaseous species BCl_3, H_2, and HCl. Their substrate consisted of a heated filament oriented parallel to the gas flow. Deposition rates were determined as a function of deposition temperature, total flow rate, and HCl concentration at, apparently, 1 atm total pressure.

They agree with the model of mass transfer across a laminar boundary layer described above and postulate the diffusion of HCl is rate limiting at lower gas flow rates. As the gas flow rate was increased to a maximum of ~4000 cm³/min they noted that the boundary layer became smaller and the rate of gaseous diffusion thus increased. At gas flow rates > 1000 cm³/min the deposition rate appeared limited by a chemical kinetic mechanism. They believe that the mechanism is the first-order desorption of HCl from the deposition surface and have calculated from an Arrhenius plot an activation energy of 52 kcal/mole. This value is similar to the

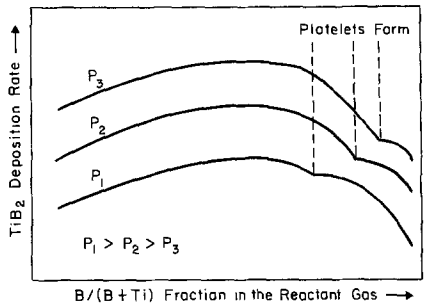

Fig. 11. Predicted relative curves for the TiB_2 deposition rate vs. reactant gas B/(B + Ti) for three different pressures.

40 ± 12 kcal/mole presently determined for the first-order, low temperature chemical kinetic rate-limiting mechanism in the CVD of TiB_2. It is possible that a single mechanism common to both the deposition of boron and the diboride of titanium, such as the desorption of HCl, may be an important rate-limiting process in the CVD systems.

The various rate relationships experimentally determined in the present study can be used to develop families of curves such as those in Fig. 3-7. As an illustration, a group of curves was developed for predicting the deposition rate as a function of reactant gas B/(B + Ti) ratio at three different total pressures. Figure 11 shows that the general shape of the predicted deposition rate curves follows that of the observed deposition rate curve in Fig. 6. From the pressure dependence of the deposition rate it was observed that the rate increases with decreasing pressure and the predicted curves show lower relative rates for higher pressures.

At high B/(B + Ti) fractions the observed rate drops below that predicted to be due to gaseous diffusion with equilibrium assumed to exist at the deposition surface, although a shoulder appears with increasing B/(B + Ti). The appearance of TiB_2 platelike crystallites, which accompanies the decreasing deposition rate, indicates that a chemical kinetic mechanism has become rate limiting. It is hypothesized that the TiB_2 platelets are formed by the adsorption of species on certain crystallite faces. At high pressures the concentrations of the gaseous species are greater and, therefore, adsorption takes place to a larger extent. As a result, at higher pressures the chemical kinetic mechanism becomes rate limiting at smaller B/(B + Ti) fractions yielding the TiB_2 platelets. The shoulder thus appears at lower B/(B + Ti) fractions and this is indicated in Fig. 11. In this manner a relationship determined with parameters held constant at specific values can be extended to other values of those fixed parameters.

Conclusions

The CVD of TiB_2 was studied by determining the deposition rates as a function of deposition temperature, total pressure, total reactant gas flow rate, and B/(B + Ti) and Cl/(Cl + H) fractions in the reactant gas. Either or both of the possible rate-limiting mechanisms of mass transfer and chemical kinetics appeared limiting under various deposition conditions. Above 1373°K rates often appeared to be limited by the diffusion of reactant species through a gas boundary layer to the deposition surface where chemical equilibrium was achieved. Below 1373°K a chemical kinetic mechanism dominates the TiB_2 deposition. An activation energy of 40 ± 12 kcal/mole was calculated for the process by using a simple linear rate expression. Changes in the composition of the reactant gas changed the rate-limiting mechanisms at 1523°K. Indications are that at B/(B + Ti) > 2/3 or at Cl/(Cl + H) < 1/3, the deposition surface is not at thermodynamic equilibrium and chemical kinetic mechanisms govern the deposition.

The model developed for the nigh temperature CVD of TiB_2 appears applicable to CVD systems operated under conditions in which chemical kinetic processes are rapid in comparison to gaseous diffusion. Mass transport models, such as the one discussed in the present paper, can be quantitatively applied to other CVD systems. The model presented here is simple, however, and involves a significant number of assumptions. The assumptions include the use of a simple expression for the binary diffusion coefficient, even though the present system contains more than two gaseous species. Hydrogen was generally present in excess, so the approximation that the other species are diffusing through pure hydrogen is probably good. The model also considers the boundary layer thickness to vary in a manner similar to that for flow across a semi-infinite flat plate.

The conclusions about the rate-limiting mechanisms and the effect of the deposition parameters on the deposit character made it possible to develop a preliminary model of the deposition processes. Such a model may allow the prediction of optimum conditions for the production of a desired deposit. Studies like this one can help provide the necessary knowledge to more thoroughly understand CVD processes in general.

ABSTRACT

An adherent film of TiN up to 160 μm was obtained on an iron substrate by chemical vapor deposition (CVD) in an ultrasonic field in the temperature range of 900°-1100°C, using a reactant gas mixture of $TiCl_4 + N_2 + H_2$. Ultrasonic vibrations of the iron substrate were found to improve adherence and toughness of the film, but had a minor effect on the growth rate and the deposition temperature. The Vicker's microhardness of TiN obtained in the ultrasonic field was 1600-2000, and the film was confirmed to have a strong <220> orientation. The CVD of TiN on iron was considered to proceed by a two-step mechanism.

Titanium nitride (TiN), one of the typical interstitial compounds, has a melting point of 2950°C, a microhardness of 1400-2000, and a high chemical stability in acid or alkali solution (1). Films or whiskers of TiN have been noted in recent years as a protective and decorative coating material on metals, or as a reinforced composite material (2, 3).

Film growth and whisker growth of titanium nitride on a graphite substrate by chemical vapor deposition (CVD) from the reactants $TiCl_4 + N_2 + H_2$ were reported in detail by Synielnikowa *et al.* (4), the authors (5), and Kato and Tamari (6). Münster and Ruppert (7) studied the CVD of TiN coatings with the same reactants on an induction-heated iron substrate and obtained a TiN film of about 100 μm thick. The adherence of the deposited TiN on an iron substrate is weak when the thickness exceeds 100 μm (4). A stress is developed at the interface between TiN and Fe due to the difference in their thermal expansion coefficient. Preelectrodeposition of cobalt on an iron substrate prior to the CVD of TiC (8) or TiB_2 (9) was investigated by the authors to improve the adherence between the deposited layer and the substrate. Similar techniques to form such an interlayer have been developed by others (10).

Application of an ultrasonic field to CVD processes has not been reported. Some chemical uses of ultra-

sound have been investigated in the field of ultrasonics in electroplating (11), metallurgy (12), and crystallization (13). In the present study, we investigated in detail the effect of ultrasonics on CVD of TiN using a gas mixture of $TiCl_4 + N_2 + H_2$. The goal was to obtain an adherent and dense thick film of TiN on an iron substrate and to investigate the growth mechanism of the TiN film.

Experimental

The flow system of the experimental apparatus is shown in Fig. 1. An oscillator and vibrator with frequency 19 kHz and power 10-20 W/cm², were used as an ultrasound source. The ultrasonic vibrations were applied to the substrate in the reactor through a cone and horn mechanical system. The reactant gas mixture is composed of $TiCl_4$, N_2, and H_2. The $TiCl_4$ vapor is carried with hydrogen gas from the $TiCl_4$ saturator which is heated at room temperature to 70°C. Hydrogen and nitrogen gases are purified by passing them through activated copper and silica gel columns. The flow rates of H_2 and N_2 gases at room temperature are measured by flowmeters.

Figure 2 shows the schematic diagram of the vertical reactor. The ultrasonic vibration horn is inserted into the quartz reactor (inside diameter: 25 mm), and a low carbon steel substrate (carbon content: about 0.3%) is silver-soldered at the tip of the horn. The tip diameter of a nailheaded substrate is 7 mm. The vinyl chloride flange between the horn and the reactor helps to prevent the ultrasonic power from being absorbed by the reactor wall. The substrate was polished by 800 mesh emery paper and cleaned in CH_3OH and HCl aqueous solutions, before being heated for a reaction run by an rf induction coil in the temperature range of 700°-1150°C. Hydrogen gas (flow rate: 7.0 ml/sec) is introduced at the top of the reactor to prevent overheating of the horn, and the reactor wall is water-cooled by copper pipe. The temperature of the substrate is measured by an optical pyrometer through the observation window. The reactant gas is introduced at the bottom of the reactor, and the residual gases are exhausted above the sample.

Results

Deposition condition of titanium nitride.—According to the authors' study (5), the deposition process of TiN is less affected by the gas flow rates of $TiCl_4$, N_2, and H_2 than by deposition temperature. The flow rates were fixed in the present experiment in a narrow range: $TiCl_4$, 0.9-1.0 ml/sec; H_2, 7.4 ml/sec; and N_2, 2.0-5.0 ml/sec.

Figure 3 shows the relation between the growth rate of the TiN film and the substrate temperature at constant gas flow rates with and without ultrasound. The

growth rate is apparently zero at temperatures less than 900°C. The growth of titanium nitride is initiated rapidly at 950°C, above which the growth rate increases progressively with the increase of temperature. A film of about 180 μm was obtained at a substrate temperature of 1100°C with a reaction time of 60 min. The film growth rates are not significantly changed when ultrasound is applied.

Structure of vapor-deposited titanium nitride.—Figures 4a and b show the surface appearances of the deposits on a carbon steel substrate which were obtained at a substrate temperature of 1050°C, with and without ultrasound. Normally the deposited film tends to peel off partially from the substrate even with a little pat of the surface (see Fig. 4a). This probably occurs because of the stress at the TiN-Fe interface in the cooling process of the specimen. In the case of CVD with ultrasound the deposit is quite adherent to the substrate, as shown in Fig. 4b. This can be verified by

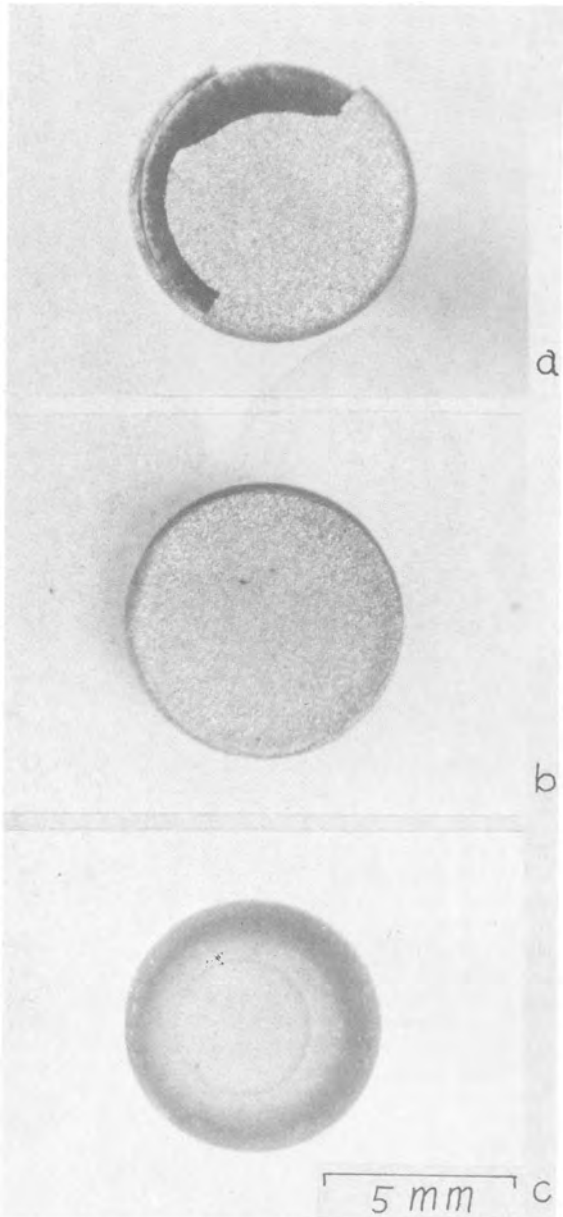

Fig. 4. Micrographs of surface appearance. (a) Temperature, 1050°C; reaction time, 60 min; no ultrasound. (b) Temperature, 1050°C; reaction time, 60 min; ultrasound applied. (c) Temperature, 950°C; reaction time, 13 min; ultrasound applied.

a hammering test, when only the rimmed part of the deposited film has some small cracks.

Figure 5 shows a typical microstructure of the vapor-deposited TiN film obtained at 950°C. A thick, golden yellow film of TiN is obtained with a 60 min reaction time. For CVD with no ultrasound, a sharply cracked line is observed as in Fig. 5b, and relatively large crystallites having glossy facets are obtained. A smooth deposit results from applying ultrasonic vibration to the substrate (see Fig. 5a).

Micrographs of cross sections etched by nital solution ($C_2H_5OH:HNO_3 = 100:5$) are shown in Fig. 6. Cracks or pores normally can be observed at the nonadherent film of TiN on the carbon steel substrate (see Fig. 6a). By CVD in an ultrasonic field a uniform and adherent film with a thickness of 100-160 μm can be obtained in a wide temperature range: 950°-1050°C (see Fig. 6b and c).

Figure 7 shows the variation of x-ray diffraction patterns of the surface of specimens deposited at substrate temperatures of 950°, 1000°, and 1050°C with ultra-

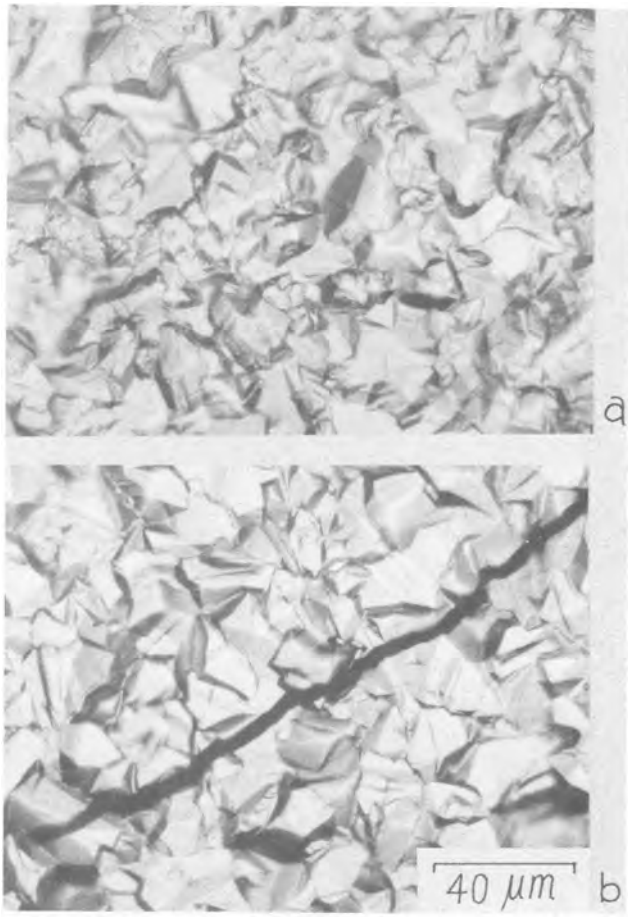

Fig. 5. Micrographs of vapor-deposited TiN. (a) Ultrasound applied. (b) No ultrasound. Substrate temperature, 950°C; reaction time, 60 min.

sound. The film had a <220> crystallographic preferred orientation (4) in the temperature range of 950°-1050°C. This result differs from vapor-deposited TiN films on graphite substrates (5), where a strong (220) line was observed only above a deposition temperature of 1200°C. Münster and Ruppert (7) found a <100> or <111> preferred orientation on an iron substrate which was considered to depend on the substrate texture. The x-ray Laue pattern of our TiN films showed a strong (220) diffraction ring which was composed of homogeneous fine Laue spots. This suggests that the crystallites are aggregated at random, independent of the orientation of the base material. The x-ray patterns having a <220> orientation were similar for specimens obtained without ultrasound.

Some properties of TiN film grown in the ultrasonic field.—Figure 8 shows a cross section of a TiN film obtained at a temperature of 1000°C in an ultrasonic field. A large microhardness indentation (300g load) at the interface between TiN and the carbon steel substrate confirms the improved adherence, since the TiN film is not peeled off from the substrate. The toughness of the deposited film seems to be high, since no cracks can be observed between five small indentations (100g load) on the cross section of TiN layer. The Vicker's microhardness was 1600-1750, comparable with the reported values (1, 15). The microhardness of the surface was 1900-2000 which is higher than that of the cross section. The hardness may be considered to be affected by the anisotropy of the TiN texture.

Figure 9 shows the etching figures of a cross section of the TiN film deposited in an ultrasonic field. Nital etching (Fig. 9a) for 30 sec shows that the texture of the carbon steel substrate near the interface does not

change (ferrite + perlite), but a 2-3 μm thick layer can be observed at the boundary region. Similar layers were obtained under ordinary CVD, although the adherence was not good. Figure 9b shows the TiN layer after etching by a hot aqua regia solution for 10 min. The carbon steel was etched entirely away, and very minor attack of the TiN film indicates a high chemical stability of TiN layer for hot aqua regia. The fine columnar texture can be seen in the TiN layer, which demonstrates the dense aggregation of crystallites, while a broad columnar texture was observed on the etching figure of the TiN deposited by CVD with no ultrasonic field (see Fig. 9c).

Discussion

Effect of ultrasound on CVD process.—From thermodynamic (7) and the experimental (5) data, the chemical reaction is the determining step in the formation of TiN in the temperature range of 900°-1100°C. Therefore, the effect of ultrasound on the reaction process is considered to be minor. Figure 3 shows that ultrasonic vibration does not affect the growth rate or the deposition temperature. If the process was diffusion limited such as at higher temperatures, the growth rate could be affected by ultrasonic vibration.

The development of film toughness and adhesion, however, was improved by using the ultrasonic field, as shown in Fig. 4, 5, 6, 8, and 9. The nucleation process may be promoted by activated molecular motion in the boundary region, so that the crystallite size is smaller and a dense layer of TiN was grown. Some similar characteristics of the crystallization process in an ultrasonic field have been found in the growth of crystals from the melt or solution (13). The adherence of the TiN film to the substrate was also considered to be promoted by the improved deposit properties.

Deposition mechanism of TiN on iron substrate.—The intermediate layer in Fig. 9a suggests a special growth mechanism for TiN at the initial stage of reaction. In fact, a coaxial growth layer of TiN can be observed in Fig. 4c, which was obtained at a reaction time of 13 min and a deposition temperature of 950°C. The deposition of TiN is found to be initiated radially from the center of the substrate surface. It takes 30 min at 950°C and 10 min at 1000°C, until the covering of all the substrate surface with a TiN layer is completed.

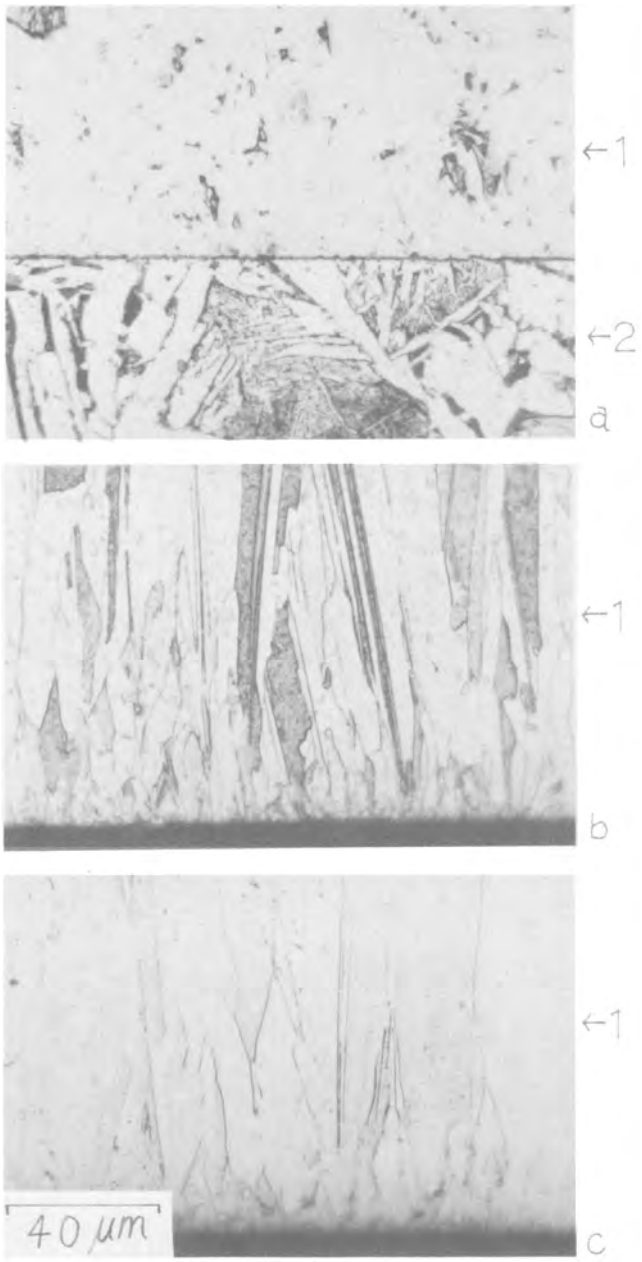

Fig. 9. Etching figures of cross section. (a) Etched by nital solution (b) Etched by hot aqua regia for 10 min, ultrasound applied. (c) Etched by hot aqua regia for 10 min, no ultrasound. 1, TiN film; 2, carbon steel substrate.

Figure 10 shows the variation of x-ray diffraction patterns with reaction time when the substrate temperature was 950°C. At a reaction time of 13 min, the strong α-Fe and weak isotropic TiN lines occur (14). Anisotropic TiN, which has a <220> preferred orientation, is apparent as the reaction time increases. Only the (220) line of TiN occurs after a reaction time of 60 min (see Fig. 7a). Figure 11 shows electron microprobe scans of the cross section, where a mixed region of Ti and Fe cannot be confirmed except at the boundary between Fe substrate and TiN film. Figures 7, 9a, 10, and 11 suggest that the reaction process is not in disagreement with the two-step process proposed by Münster and Ruppert (7). The initial displacement reaction

$$TiCl_4(g) + 2Fe(s) + \tfrac{1}{2}N_2(g) \rightarrow \text{isotropic-TiN}(s) + 2FeCl_2(s) \quad [1]$$

may not occur below 950°C, probably because of the substrate surface being covered with molten $FeCl_2$. After the initial stage the following deposition reaction might proceed

$$TiCl_4(g) + 2H_2(g) + \tfrac{1}{2}N_2(g) \rightarrow \text{anisotropic-TiN}(s) + 4HCl(g) \quad [2]$$

Technical Notes

The Analysis of Anodic Oxide Films on GaAs and GaP by Means of Radioactive Tracer Techniques

J. C. Verplanke and R. P. Tijburg

Philips Research Laboratories, Eindhoven, The Netherlands

In III-V compound device technology native oxide films are becoming of practical interest. The importance of the native oxide on GaP and GaAs has been demonstrated by Spitzer *et al.* (1) and Schwartz *et al.* (2). Hasegawa and co-workers (3) published some promising results with GaAs MOS capacitors made with anodic oxide films. Logan *et al.* (4) suggested the use of anodic oxidation for the removal of thin predetermined layers in diffusion studies.

There have already been several studies aimed at determining the composition of the anodic oxide films (5) using for example Rutherford backscattering, Auger electron spectroscopy, combined with ion beam sputtering, and the electron beam microprobe. We analyzed anodic oxide layers made on GaAs and GaP with radioactive tracer techniques. The layers measured were as grown, as well as annealed at temperatures between 200° and 600°C. As well as the average composition we also determined the composition of anodic oxide layers on GaAs as a function of thickness.

Experimental Techniques

The compounds were activated in a thermal neutron flux prior to the oxidation step. The flux was about 3×10^{11} neutrons cm^{-2} sec^{-1} for 2 hr. The main nuclear reactions taking place are (n, γ) reactions

Key words: gallium phosphide, gallium arsenide, oxidation, radioactive tracer analysis.

$^{69}Ga(n,\gamma)^{70}Ga$ ($T_{1/2}$ = 20 min; low gamma abundance)

$^{71}Ga(n,\gamma)^{72}Ga$ ($T_{1/2}$ = 14.1 hr; main gammas 630 and 834 keV)

$^{75}As(n,\gamma)^{76}As$ ($T_{1/2}$ = 26.4 hr; main gammas 559 and 657 keV)

$^{31}P(n,\gamma)^{32}P$ ($T_{1/2}$ = 14.3 days; only betas E_{max} = 1.7 MeV)

^{72}Ga and ^{76}As can be used to analyze the oxide on GaAs and ^{72}Ga and ^{32}P for that on GaP. The half-life of ^{70}Ga is too short to be useful for analysis purposes. After activation of the starting material the anodization step is performed. Then the oxide layer is stripped off in warm diluted (10%) phosphoric acid. The activities are measured in both the anodization bath and the etching bath. ^{72}Ga and ^{76}As (GaAs) are measured simultaneously with a Ge(Li) semiconductor detector and a 2048 channel analyzer. The ^{72}Ga activity of GaP is measured with a NaI (Tl) scintillation detector and a 400 channel analyzer and the ^{32}P activity, after the ^{72}Ga has decayed, by means of its Čerenkov radiation in an aqueous solution, using a liquid scintillation analyzer. The measured activities are converted to mass by means of a standard of GaAs or GaP which is irradiated simultaneously and after that dissolved in aqua regia + some HBr. An aliquot part is pipetted and measured. The masses found in both the anodization bath and the etching bath are added in order to

determine the total layer thickness that was removed during the anodization and subsequent etching step. By adding the mole fractions of the III element in the two solutions and the mole fractions of the V element in the two solutions one has a check that no important errors have been made. The analyzing method for each element involved has an inaccuracy of less than 5%.

Sample Preparation

All our experiments were performed on (100) oriented GaAs and GaP slices with an n-type dopant between $5 \cdot 10^{17}$ and $1 \cdot 10^{18}$ atoms cm^{-3}, and having bright, etched surfaces. The anodic oxide layers are grown in a mixture consisting of one volume part of a 3% citric acid solution, with the *p*H adjusted to 6.0 with ammonia, and two volume parts of ethylene glycol (6). The samples were held in an aluminum clamp, upon which an oxide layer is formed as well. During the anodization the applied voltage is increased slowly until the desired value is obtained. The sample is held for 2 min at the maximum desired voltage during which time the current decreases to nearly zero. The oxide layer is etched off in diluted (10%) hot (80°C) phosphoric acid. Several oxide layers on GaAs were etched stepwise to check whether there is a gradient of Ga or As in the layer. The composition of that stripping solution is 20 volume parts methanol and 1 volume part phosphoric acid. The etch rate of this solution is about 50 Å/min.

Annealing of anodically oxidized layers above 300°C gives a change in color of the layer. In order to know whether this color change has to be correlated with a change in composition we analyzed samples which had been heated in evacuated capsules at different temperatures. The capsules, with a diameter of 1 cm and a length of 50 cm, were placed in a furnace. The samples were placed at the highest temperature of the capsule and radioactive material could sublime to colder parts of the capsule without causing environmental contamination.

Because anodic oxide layers contain a certain amount of water (1) the slices were heated slowly to 200°C in air (heating rate 1°C/min) and held at that temperature for 16 hr before being heated in the capsule. This treatment did not change the Ga and As content of the layers.

After annealing the oxide layers were stripped off in phosphoric acid and the etching solutions were treated as described above.

Results

The layer thickness of GaAs consumed during anodic oxidation is about twice as large as that of GaP at the same voltage (15 and 7.2 Å/V, respectively). Our data on GaAs agree with those given by Hasegawa *et al.* (6). As a function of time the growth of the layer on GaAs is somewhat faster than the growth on GaP. After 2 min 96 and 90% of the ultimate thicknesses (*i.e.*, after 20 min) are reached, respectively.

During the anodic oxidation almost twice as much gallium is lost in the oxidation bath for GaP as for GaAs (40 and 25%, respectively): The phosphorus and arsenic losses are low, however, 1.5 and 5%, respectively. In the anodic oxide layer on GaAs the average As/Ga ratio is thus 1.3 and in the anodic oxide layer on GaP the average P/Ga ratio is 1.6. This last result agrees reasonably with the results of Poate *et al.* (5), measured with Rutherford backscattering, who gave a P/Ga = 1.5. Stepwise etching of the anodic oxide layer shows that the outermost surface of the layer is Ga rich despite an As-rich gross composition, see Table I and Fig. 1. In Fig. 1 the As/Ga ratio is plotted as a function of the distance from the original surface of the layer.

Annealing was, as already described, performed in an evacuated and sealed capsule. Annealing at 400° and 500°C gave some problems in dissolving the remaining oxide layer. Now a hot, 10% water/90% phosphoric acid mixture was used. However some brownish stains could not be removed from the slices.

During annealing at these temperatures a mirrorlike deposit developed in the cold end of the capsule. Only ^{76}As activity could be detected (As, As_2O_3) in this deposit.

In Table II the results of the annealing experiments are summarized. Annealing at 300°C gives a slight decrease of the As content of the oxide layer. At 400°C (15 min and 1 hr) the As disappears very rapidly from the oxide while further oxidation clearly takes place, since more As is evaporated than the original amount in the oxide layer. The ^{72}Ga activity was now used to determine the total oxidized layer thickness because

the vapor pressure of Ga_2O_3 at these temperatures is very low.

Discussion

The ratio As/Ga >1 observed for the oxide layer differs clearly from data presented earlier in the literature. Guenther *et al.* (7) observed with Auger sputter etching technique an As/Ga ratio <1 in almost the whole film. Chang *et al.* (8) presented very recently data on the composition of anodic oxide layers. A substantial part of the studied layers was Ga rich. Only a few hundred angstroms close to the GaAs interface was As rich. The fact that, in contrast to Ref. (7) and (8), we found our anodic oxides to be As rich cannot be due to a preferential solubility of gallium oxide in our stripping solution because we found that the sum of the amounts of arsenic present in the anodizing and the stripping bath is about equal to the sum of the amounts of gallium in both solutions. This is also true for the total amounts of gallium and phosphorus detected after oxidation and dissolution of the oxide of GaP in the two solutions. For GaAs and GaP the ratios of total As/Ga and total P/Ga found for each layer are 0.95 and 1.05, respectively. This indicates that possibly a slight systematic error is made.

We conclude that the reason why our anodic oxides have a different composition from those presented in Ref. (7) and (8) must be traced back to the fact that we anodized in a glycol-based bath, whereas the authors of Ref. (7) and (8) used aqueous electrolyte. Apparently a glycol-based anodizing bath shows preferential solubility for Ga oxide and an aqueous bath preferentially dissolves arsenic oxide. Indications that oxide compositions depend on the nature of the electrolyte have already been observed by other authors (6, 9).

The top of the anodic oxide layer shows a markedly different composition compared with the bulk of it. The observed As/Ga ratio, however, is not completely independent of the etching times used. Etching times of 1 min or less give an As/Ga ratio which is somewhat lower than that observed with longer etching times. See samples 17-1 and 17-2 in Table I and Fig. 1 in which the etching time is indicated for each measuring point. An etching time of half a minute gives an As/Ga ratio of <1 on the top of the layer but of about 1.25 in the middle of it.

This indicates that there is a difference in the kinetics of the dissolution of gallium oxide and arsenic oxide, but this difference is not sufficient to account for the deviating composition of the top layer.

The reproducibility of anodization is given in Ref. (6). The reproducibility of the etching can be seen in Fig. 1 where data of many measurements fit quite well on the curve; the reproducibility depends slightly on the quality of the materials used. Dislocation-rich material shows pitting after ten or more oxidations. On good material more oxidation steps are possible with conservation of a smooth surface. At voltages higher than 150V pitting of the surface will occur very fast.

Concluding we can say that it is not possible to speak of the composition and the profile of an anodic oxide layer on GaAs since both are strongly dependent on the anodization bath used.

Properties of Cadmium Stannate Thin Film Electrodes and Their Use in Photogalvanic Cells

Dale Hall

Exxon Research and Engineering Company, Solar Energy Conversion Unit, Linden, New Jersey 07036

Cadmium stannate has recently been prepared as sputtered thin films displaying high transparency to visible light and exceptionally low sheet resistance (1). In CdS-Cu_2S photovoltaic cells, Cd_2SnO_4 has been used as a transparent, conducting substrate to permit backwall illumination (2). With suitable postdeposition heat-treatment, Cd_2SnO_4 films have exhibited sheet resistances of about 1 Ω/□ and ~90% visible light transmission from 500 to 650 nm. For applications requiring the highest possible conductivity and transparency, Cd_2SnO_4 appears to offer significant advantages over materials such as indium/tin oxide or tin oxide doped with antimony.

These unusual properties suggest that cadmium stannate may be a useful optically transparent electrode for research and photoelectrochemical energy conversion. The thin layer iron-thionine photogalvanic cell is a specific photoelectrochemical system in which the above-described properties of Cd_2SnO_4 can be used to advantage. Recently, a multilayer iron-thionine cell was described (3) which employed indium/tin oxide cathodes. However, Cd_2SnO_4 offers both higher light transmission and conductivity than indium/tin oxide.

The present communication reports the electrochemical behavior of Cd_2SnO_4 in sulfuric acid electrolyte. Photogalvanic short-circuit currents and open-circuit

voltages from cells using Cd_2SnO_4 cathodes are compared to outputs from cells using other cathode materials. In addition, compound transparent electrodes have been prepared with Cd_2SnO_4 thin film underlays. Data are presented to show that SnO_2/Cd_2SnO_4 photogalvanic cell anodes produce higher power outputs than identically prepared SnO_2 anodes lacking the underlay. The selectivity exhibited by the SnO_2 anode in the iron-thionine cell (3) is maintained and the electrode resistance is greatly reduced.

Electrochemical Properties

Cadmium stannate is a large bandgap [E_g ~2.9V after postdeposition heat-treatment (1)] n-type semiconductor. Charge carriers are provided by oxygen vacancies and interstitial cadmium donors in the sputtered films. Charge carrier densities of approximately 10^{21} cm^{-3} have been reported, with conductivities on the order of 6×10^3 Ω^{-1} cm^{-1}.

The Cd_2SnO_4 electrodes used in the present study were 1 × 1½ in. films sputtered on Corning 7059 glass. The sheet resistances of these films were all approximately 3 Ω/□. The electrodes were used as received for photogalvanic cell measurements, and were cut to smaller size for capacitance and current *vs.* potential measurements.

Capacitance *vs.* potential curves were recorded in sulfuric acid electrolyte at several acid concentrations. Schottky-Mott plots of $1/C^2$ *vs.* E were linear, and the flatband potential in 0.01*M* H_2SO_4 was about +0.45V *vs.* SCE (samples varied). The dielectric constant is necessary to calculate charge carrier density from Schottky-Mott plots, but could not be found in the literature. Using $\epsilon = 5$ [low frequency limit of refractive index ~2 (4)], charge carrier densities of about 10^{21} cm^{-3} were obtained for most Cd_2SnO_4 samples, with some as high as 5×10^{21} cm^{-3}. These results agree with the above-reported values based on Hall effect measurements (1).

Cadmium stannate films were initially quite hydrophobic; continued exposure to electrolyte caused a noticeable increase in wettability. Similar behavior is observed (5) for SnO_2 thin film electrodes, and has been attributed to the formation of surface hydroxyl groups (6).

Slow potential sweeps in 0.05*M* H_2SO_4 initially showed an ideally polarizable region extending from approximately +1.5 to −0.3V *vs.* SCE (Fig. 1A). After continued contact with the electrolyte, a small irregular reduction wave appeared at about +0.4V *vs.* SCE (Fig. 1B). A slight increase in anodic current appeared on the reverse scan at about +0.5V.

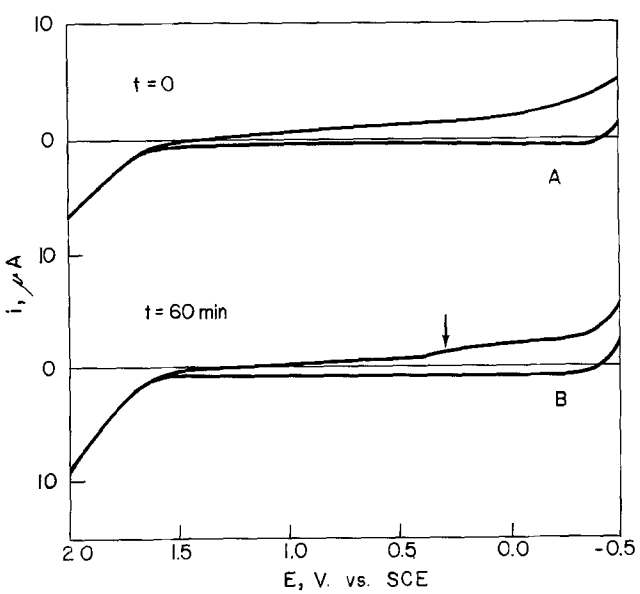

Fig. 1. Current *vs.* potential curve of Cd_2SnO_4 in 0.05*M* H_2SO_4. Electrode area = 0.35 cm^2, E_{FB} = +0.47V *vs.* SCE, n_D = 4.0 × 10^{21}, scan rate = 10 mV sec^{-1}.

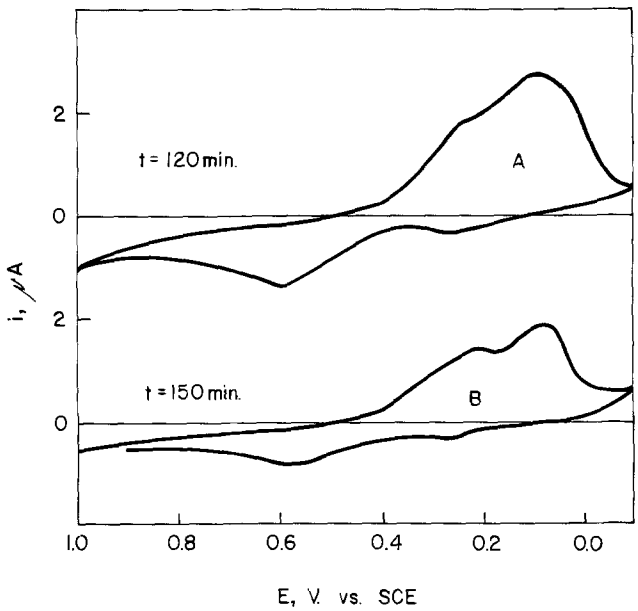

Fig. 2. Same conditions as Fig. 1, with scan rate = 2 mV sec^{-1}

A well-defined double reduction wave was observed after 2 hr of exposure to the electrolyte, with peak potentials at +0.25 and +0.1V *vs.* SCE (Fig. 2). A corresponding double oxidation wave was observed on the reverse scan. Prolonged cycling with the negative switching potential between +0.4V and the breakdown limit at −0.3V caused visible etching of the Cd_2SnO_4 film.

The cadmium, tin, and oxygen content of Cd_2SnO_4 films was examined by ESCA, both before and after exposure to sulfuric acid electrolyte. The ratio of both cadmium and oxygen content to tin content was substantially lower after use in the electrochemical cell.

The above behavior was verified with several Cd_2SnO_4 electrodes in H_2SO_4 concentrations ranging from 10^{-3} to 0.25*M*. However, one Cd_2SnO_4 sample showed an immediate and extensive reaction in 0.25*M* H_2SO_4 (Fig. 3). The symmetry of the anodic current peak and the first cathodic peak indicate that current flow is associated with surface electrolysis of the Cd_2SnO_4 film. This phenomenon has also been described elsewhere for other systems (7, 8).

The potential difference between the first cathodic peak and the anodic peak increased from 0.13V at a

Table I. Comparison of Cd_2SnO_4 and Pt cathodes

Anode	Cathode	V_{OC} (V)	I_{SC} (mA)
SnO_2(1)	Pt	0.147	0.40
	Cd_2SnO_4	0.128	0.30
SnO_2(2)	Pt	0.156	0.57
	Cd_2SnO_4	0.132	0.38

Cell area = 5.5 cm^2; photogalvanic solution and illumination described in Ref. (3).

sweep rate of 20 mV sec^{-1} to 0.20V at 100 mV sec^{-1}, indicating a slow electrochemical process. Rapid etching of the Cd_2SnO_4 film during the potential sweeps made further analysis impossible.

Cd_2SnO_4 as an Iron-Thionine Cell Cathode

Cd_2SnO_4 thin films were used as cathodes in iron-thionine photogalvanic cells. The usual cathode in single layer cells is an opaque sputtered platinum film. The multilayer cell, recently described (3), employed transparent films of indium/tin oxide (ITO). However, as pointed out above, Cd_2SnO_4 offers significant advantages over ITO.

Photogalvanic cell short-circuit current and open-circuit voltage measurements, comparing the performance of Cd_2SnO_4 and Pt cathodes, are shown in Table I. Cell solutions and measurement conditions were identical to those described previously (3). Some voltage and current loss was caused by the use of Cd_2SnO_4 cathodes. In spite of the lower resistance of Cd_2SnO_4, similar cells employing ITO cathodes gave comparable outputs. A partial explanation for this result is obtained from potential sweeps of the Fe^{+2}/Fe^{+3} and thionine/leucothionine (TH^+/TH_3^+) couples at Cd_2SnO_4. The expected similarity between Fe^{+2}/Fe^{+3} current-potential curves at platinum [or ITO (3)] and cadmium stannate electrodes was not observed (Fig. 4). The reduction of Fe^{+3}, which occurs at the photogalvanic cell cathode, is shifted to much more negative potentials at Cd_2SnO_4, and currents are considerably lower. The lack of Fe^{+2}/Fe^{+3} reactivity at Cd_2SnO_4, in spite of the high charge carrier density of Cd_2SnO_4 and the favorable relationship of flatband potential with the Fe^{+3}/Fe^{+2} redox potential, is the major cause of output losses in iron-thionine cells containing Cd_2SnO_4 cathodes.

A comparison of TH^+/TH_3^+ voltammetry at SnO_2 and Cd_2SnO_4 electrodes (Fig. 5) shows that the well-defined, closely spaced current peaks obtained at SnO_2 are replaced by a less reversible, partially rectifying current-potential characteristic at Cd_2SnO_4. The low reactivity of TH^+/TH_3^+ is desirable at the photogalvanic cell cathode; theoretical studies (9, 10) have shown that perfect selectivity, whether achieved by selectively permeable membranes or differential electrode reaction rates, provides optimum output in the totally illuminated cell. However, this desirable feature is more than offset by the lack of Fe^{+2}/Fe^{+3} reactivity at Cd_2SnO_4.

Cd_2SnO_4 Conductive Underlays

Electrochemical studies using resistive semiconductor thin films are often performed using conductive underlays to lower the over-all electrode resistance. Frequently, the underlay of an oxide semiconductor is the fully reduced metal, as in the combinations TiO_2/Ti (11, 12) and WO_3/W (13). Noble metal underlays have also been used [SnO_2/Pt (5) and WO_3/Au (13)]. Where transparency of the compound electrode is necessary, combinations such as TiO_2/SnO_2 (12) have been employed.

The properties of cadmium stannate appear to offer significant advantages over other transparent underlay materials, provided that those properties are not altered by overlay deposition. As part of this work, the use of Cd_2SnO_4 underlays with SnO_2 photogalvanic cell anodes was investigated. Two SnO_2 films were sputtered under identical conditions, one upon a glass

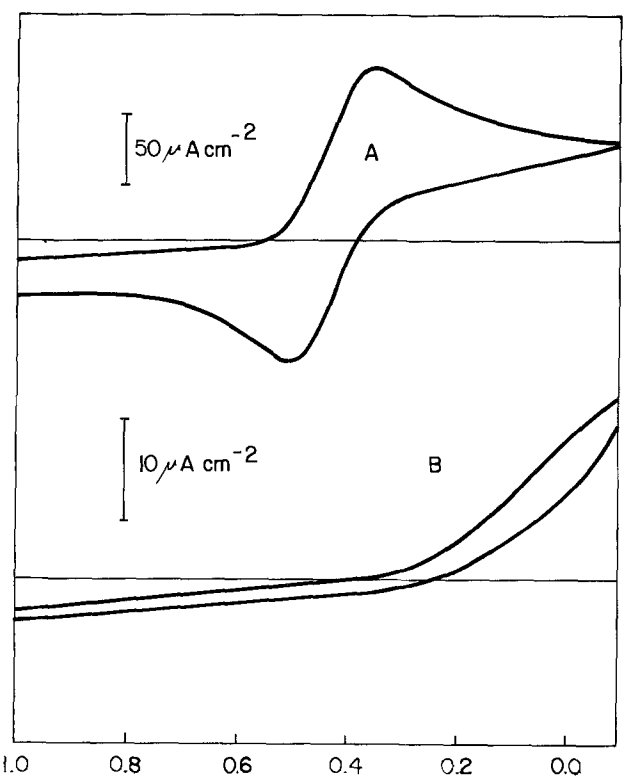

Fig. 4. Voltammetry of 1 mM Fe^{+2}/Fe^{+3} in 10^{-2}M H_2SO_4. Scan rate = 10 mV sec^{-1}; A, platinum thin film electrode; B, Cd_2SnO_4 electrode.

Table II. Effect of Cd_2SnO_4 underlay on SnO_2 anode performance

Anode	Condition	R_S (Ω/□)	V_{OC} (V)	I_{SC} (mA cm^{-2})
SnO_2	Initial	850	0.112	0.023
SnO_2/Cd_2SnO_4	Initial	5	0.135	0.072
SnO_2	Reduced	840	0.175	0.027
SnO_2/Cd_2SnO_4	Reduced	5	0.163	0.138

Cells contained Pt cathode; solution and illumination as in Table I. SnO_2 was sputtered at 400°C in 85% argon/15% hydrogen. Reduction was for 10 hr at 400°C under flowing hydrogen.

substrate and the other over a Cd_2SnO_4 film (Table II). SnO_2 deposition was performed at temperatures below those which affect the properties of the Cd_2SnO_4 film during postdeposition heat-treatment (1, 2). The underlay greatly reduced electrode resistance. In addition, photogalvanic power outputs were markedly higher using the SnO_2/Cd_2SnO_4 anode, with the major difference being the increased short-circuit current.

Reduction of the SnO_2 surfaces by hydrogen causes an increase in charge carrier density at the electrode surface due to greater oxygen deficiency. The slight change of sheet resistance upon reduction indicates that only a small fraction of film depth was affected. Outputs from both the SnO_2 and SnO_2/Cd_2SnO_4 electrodes were higher after reduction, with the greatest increase occurring in the short-circuit current for the compound electrode.

The usual SnO_2 photogalvanic cell anodes (3) are obtained commercially. Sheet resistances are typically 30-100 Ω/□. The relative improvement in cell output using Cd_2SnO_4 underlays with SnO_2 of this quality would almost certainly be less than reported here. However, for systems using semiconductor electrodes with substantially lower charge density than those used in the iron-thionine cell (10^{20}-10^{21} cm^{-3}) and where thin film, transparent electrodes are desirable, Cd_2SnO_4 appears to be an excellent choice as an underlay.

Summary

Cadmium stannate electrodes initially show a large ideally polarizable region similar to that of other large bandgap oxide semiconductors. Exposure to acid electrolyte eventually causes a reductive decomposition of the Cd_2SnO_4 film. Unfortunately, this reduction occurs in the potential region in which the iron-thionine cell cathode must function (3). Hence, although reasonable outputs are obtained from cells with Cd_2SnO_4 cathodes, the response slowly declines as the cathode is consumed. This suggests that electrode stabilization by the method of Murray and co-workers (14) may be useful in practical applications of cadmium stannate electrodes.

The lack of redox reactivity at Cd_2SnO_4 is not satisfactorily explained. Cadmium stannate appears to present the unusual case of a highly doped semiconductor at which redox couples react with difficulty, even when flatband and redox potentials are favorably aligned. This should prove an interesting topic for further research.

Cadmium stannate should prove valuable in studies at optically transparent electrodes when a highly conductive substrate is necessary, if the electrode material of interest can be deposited without damaging the Cd_2SnO_4 film. The resistance of SnO_2 thin film electrodes has been successfully reduced in this way. However, it is not known whether other electrodes requiring higher deposition temperatures (*e.g.*, commercially prepared SnO_2) can be overlaid successfully.

Acknowledgments

This research was performed under Grant No. SE/AER/72-03529 of the National Science Foundation's Research Applied to National Needs Program, awarded to Boston University. We are grateful to Dr. G. Haacke of the Chemical Research Division, American Cyanamid Company, for generously furnishing cadmium stannate electrodes, and to Mr. A. Candusso, Exxon Research and Engineering Company, for preparation of SnO_2 sputtered films.

Manuscript received Dec. 13, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by the Exxon Research and Engineering Company.

MnO_2 Cathodes for Seawater Cells

Charles P. Wales*

Naval Research Laboratory, Washington, D.C. 20375

ABSTRACT

Electrolytic MnO_2, carbon, and a binder were pressed onto conductive grids. Cells containing these cathodes and Al alloy A6 anodes gave an open-circuit potential of about 2.0V after adding seawater. Potential dropped rapidly in the early part of a discharge. During constant current discharges at the 15 day and 10 hr rates the average potential of these cells was 1.35 and 1.16V, respectively, with MnO_2 giving 80 and 65% of its theoretical capacity. A cell can be discharged over a period of months since the self-discharge rate of MnO_2 was low in seawater.

The AgCl-Mg seawater battery has probably been the most widely used type of seawater battery, even though it does have several disadvantages. Silver chloride is an expensive material and its use involves loss of the silver, except when recovery from the sea and salvage are feasible. Since the self-discharge or corrosion rate of Mg is large in seawater, it is not practical to use AgCl-Mg batteries over extended periods of time. Output voltage and useful capacity are lowered as Mg becomes passivated by insoluble precipitates which form on the surface of the Mg. If the cells are designed with openings so that motion of the seawater can wash the precipitates away from the Mg, then stray electrical currents can flow between the cells, resulting in another source of self-discharge.

One substitute for the AgCl cathode is CuCl (1) but this hydrolyzes readily and, therefore, is practical only when discharges are completed within a few hours after filling the cells. Successful seawater batteries have been made using $PbCl_2$ cathodes and Mg anodes (2, 3) as well as cathodes containing a mixture of $PbCl_2$ and CuCl (4). Even though the potential of $PbCl_2$ is lower than that of CuCl, $PbCl_2$ is more practical for many purposes because it does not hydrolyze readily.

Manganese dioxide is an attractive cathode material in several ways, having a high potential and being insoluble and readily available at low cost. It is likely that putting MnO_2 into the oceans would be environmentally acceptable because seawater already contains dissolved manganese. Since MnO_2 has a high ohmic resistance, the MnO_2 must be formed into electrodes of reasonably low resistance before MnO_2 can be used successfully.

A seawater cell using MnO_2 cathodes and Mg anodes has been proposed at least twice over the past thirty years (5, 6). Probable reasons why this cell has not been produced include difficulty in making suitable MnO_2 electrodes, and the choice of Mg as the anode. Experience with Mg in seawater cells indicates that Mg performs best at high rates of discharge, while it is well known that MnO_2 in Leclanché cells performs best at much lower rates of discharge, although MnO_2 has good high rate characteristics in alkaline MnO_2 cells. One would not expect MnO_2 to give a particularly good high rate performance in seawater, since the salts in seawater have a total concentration of only about 0.6 normal, and thus seawater should have a much higher electrical resistance than the electrolyte used in other cells.

Key words: seawater battery, water-activated cell, manganese dioxide, discharge capacity, voltage.

Experimental

Rectangular flat plates were the most practical shape of cathode to use in the experimental cells. In order to obtain good MnO_2 electrodes three conditions had to be met: the MnO_2 needed to be in reasonably good electrical contact with the conducting grid that was in the electrode, the active material mix had to have sufficient strength to remain on the grid during discharge, and the mix had to be porous so that it could be penetrated readily by seawater.

A number of ways were investigated for achieving these conditions. The cathodes all contained electrolytic MnO_2 (Tekkosha Company Limited, content about 91% MnO_2) and a conductive grid 36 × 36 mm with an 11 mm wide lead extending 44 mm up from one corner. The grids were cut from expanded Ag, Cu, and 304 stainless steel (all size 3/0, Exmet Company), from Pt gauze, from woven carbon fiber having a polyacrylonitrile base (made by Fiberite using Thornel 300), and from multilayered sheets of graphite foil (Grafoil of Union Carbide Corporation). Metal grids often had the lower half of their leads coated with silicone rubber for protection. Corrosion of grid metal tended to be worse near the seawater-air interface, which was about 12 mm above the 36 mm square part of the grid. Good conductivity within the active material mix was obtained by adding either UCET acetylene black or 615P graphite (both Union Carbide Corporation).

Several bonding methods were tried. The preferred way of binding the active material together was a modification of the polymer bonding method given by Weininger and Secor (7). The binder was Neoprene AD-20 (du Pont) dissolved in toluene. This neoprene is a chloroprene polymer intended for use in adhesive cements. Merely pasting a mix of MnO_2, carbon, and neoprene solution onto a grid was not satisfactory. If the carbon was in the form of graphite the electrode made by pasting was fairly strong but had rather high

resistance. Acetylene black gave lower resistance but the active material cracked as the toluene evaporated and electrodes were weak. Electrodes were much improved by making a mixture too dry for pasting and then pressing this onto the grid. Electrodes were air dried at room temperature after pressing. Cathodes made this way had a lower resistance, smaller volume, and greater strength than the pasted cathodes. Resistance between two points on the surface of a cathode decreased over the first 10-25 days. The amounts of neoprene and toluene used depended on the form of conductive carbon and the amount of pressure.

Six parts by weight electrolytic MnO_2 were mixed with one part acetylene black. Sufficient 10% neoprene solution was added so that the neoprene weight in the mix was usually 35% (but a few times 40-50%) as much as the acetylene black weight. This mix was pressed onto a conductive grid at 1.5 kg mm^{-2}. The MnO_2:acetylene black ratio was not varied. Therefore the value of 6:1 may not be the best proportion to use. After air drying for at least one week the electrodes were weighed and the amount of MnO_2 present was calculated. The electrodes contained about 5g of electrolytic (91%) MnO_2, which means between 4.5 and 4.6g MnO_2. The average thickness of the active material after pressing and drying was 2.85 mm, with approximately half on each side of the grid. Total electrode thickness was in the range 2.8-3.8 mm, depending on grid thickness.

Another method for making MnO_2 cathodes used an aqueous dispersion of finely divided Teflon as the binder. To a mixture of 7 parts by weight electrolytic MnO_2 and 3 parts graphite was added 2.0 parts Teflon 30B (du Pont) diluted with 0.85 parts water. This mix was pressed onto the grid at 7 kg mm^{-2} and dried at 80°-120°C. It was necessary to use higher pressures than when using neoprene and to use graphite instead of acetylene black. Only a few electrodes were made with Teflon since this method was more difficult and resulted in cells not quite as good as those obtained with the neoprene binder.

Since the MnO_2 performed best at medium to low discharge rates, the chosen anode should also be able to discharge slowly. Alloys of aluminum with zinc have been shown to give good results at medium to low discharge rates (8), suggesting that various aluminum alloys might be suitable. Two alloys of aluminum were tried. One alloy contained 5.2 weight percent (w/o) zinc. The other was a proprietary alloy called A6, developed at Olin and now owned by Conalco. Pryor, Keir, and Sperry reported the beneficial effects of alloying high purity Al with a small amount of Sn, with the alloy usually containing one or more additional elements (9-11). The results of spectrochemical analysis indicated that alloy A6 was relatively high purity Al containing on the order of 0.1% Sn, 1% Mg, and 0.1% Ga. Anodes were usually 36 × 36 mm with a lead 7 or 11 mm wide extending 44 mm up from one corner, although some anodes of A6 alloy were 40.5 × 40.5 mm. The lower part of the leads and the top 1-2 mm of the square portion of the anodes were given a protective coating of silicone rubber. The A6 aluminum alloy was 0.18 mm thick, while the Al-Zn alloy was 1.58 mm thick.

A cell contained one MnO_2 cathode in a loosely covered beaker, two anodes of aluminum alloy placed about 30 mm apart with one on each side of the cathode, a porous inert separator between each electrode, and a reference electrode of Ag/AgCl. A cell was activated by adding 150 ml simulated seawater (Sea-Salt of Lake Products Company with *p*H adjusted to 8.2). Cells had a large excess of anode active material so discharges were always limited by capacity of the MnO_2 cathodes. Cells were discharged at room temperature (19°-24°C) using constant current. Unless stated otherwise discharges began 1 hr after adding seawater.

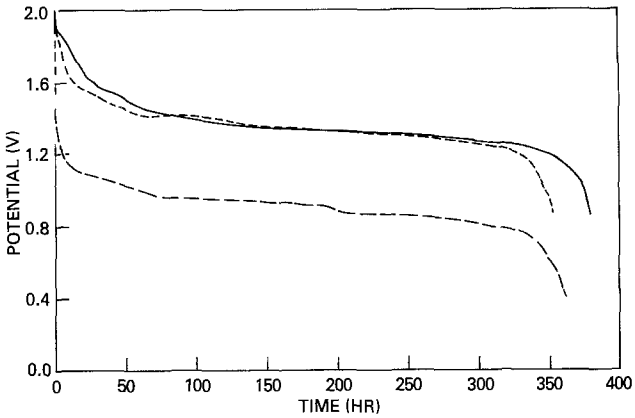

Fig. 1. Solid line, cell potentials when MnO_2 on woven carbon fiber grid was discharged in seawater at 3 mA vs. anode of Al alloy A6; line of short dashes, same except MnO_2 on Ag grid; line of long dashes, MnO_2 on Ag grid discharged vs. Al-Zn alloy.

Results and Discussion

Potentials for discharges of three cells are shown in Fig. 1. The difference in discharge lengths was not significant, representing random variation among the electrodes. Cells that contained A6 aluminum alloy gave a considerably higher potential than cells with Al-Zn alloy. The difference typically was about 0.47V for long discharges such as those in Fig. 1. Cells using the Al-Zn anodes had a continuously decreasing potential during the early part of a discharge, while potentials of cells using A6 anodes increased during the first few minutes of a discharge. Changes in cell potentials can be taken to represent changes in the MnO_2 cathode during the entire discharge when using Al-Zn anodes, and during all except the first 5% of a discharge using A6 anodes.

Reference electrode measurements indicated that anode potentials were relatively constant except at the beginning of a discharge. Potentials of the A6 anodes became increasingly negative during the first few seconds of a discharge, reaching a negative peak 3-10 min after a discharge began. These changes are indicated by the upper two cell potentials given in Fig. 1 rising to 2.0V after starting at 1.84 and 1.65V. Following this, A6 anode potential approached its normal value and became relatively constant. Potentials of the Al-Zn anodes were much more constant, usually varying less than 0.02V.

When the MnO_2 electrodes contained Ag grids the cell potential declined more rapidly during the first part of a discharge than when MnO_2 electrodes contained carbon grids (Fig. 1). The difference was caused by AgCl that formed on the Ag as a result of attack by seawater. Calculations indicated that the equilibrium potential for Ag/AgCl is $E_H = 0.245V$, assuming a chloride activity of 0.38 in seawater. Various potentials have been reported for MnO_2 depending on its source, previous treatment, and the cations in solution. Measured equilibrium potentials for MnO_2 usually fall between 0.55 and 0.63V on the hydrogen scale at *p*H 8.2 (12-14). The initial cathode potentials observed in the present work often exceeded these MnO_2 values. As a result of the MnO_2 potential being above the Ag/AgCl potential, AgCl can form on the Ag grid during a stand or in the early part of a discharge, until cathode potential drops to the Ag/AgCl value.

Figure 2 shows the way discharge potential and capacity were affected by rate of discharge. The cathodes were made with the usual 6:1:0.35 mix of MnO_2, acetylene black, and neoprene, pressed on carbon fiber grids. The discharge currents of 3, 12, and 48 mA amounted to 0.663, 2.63, and 10.5 mA g^{-1} of MnO_2. Since potential of A6 Al only changed about 0.01V when current was varied over this range, the displacements in the discharge potentials shown in Fig. 2 rep-

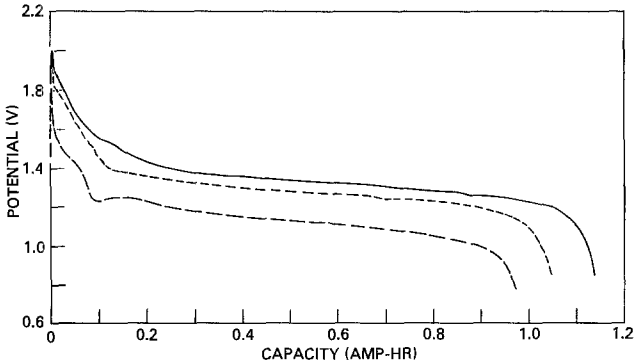

Fig. 2. Potentials when cells containing anodes of Al alloy A6 and MnO_2 cathodes with carbon fiber grids were discharged in seawater. Discharges were at 3 mA (solid line), 12 mA (line of short dashes), and 48 mA (line of long dashes).

resent the effect of discharge rate on the MnO_2 cathode. If the cells had been discharged through a fixed resistance load instead of using a controlled constant current, then the discharge potentials would have been more flat because of current falling as voltage decreased.

The effect of discharge rate on cell potential is shown in Fig. 3 with discharge length on a log scale. Cathodes made with the woven carbon fiber grids showed lower potentials, particularly at the higher rates of discharge. This potential difference was the result of resistance of the carbon fiber grid being about 2Ω, while resistance of the Ag grid was near zero. The lower curve in Fig. 2 would have been about 0.1V higher if Ag grids had been used.

According to information available the carbon fibers had been coated with an epoxy silane finish in order to improve handling characteristics before weaving. This finish was removed from one piece of the carbon fiber by soaking in acetone to dissolve most of the finish and then heating at about 315°C to burn off any residual coating. Two electrodes made using this uncoated carbon fiber gave lower potentials than the original coated material, indicating that resistance had increased.

The ampere-hour efficiency for constant current discharges of MnO_2 in seawater is given in Fig. 4 with time on a log scale. There was no significant difference between efficiency obtained from electrodes made with expanded Ag grids and those with carbon fiber grids. The straight line was fitted by the method of least squares using the combined data.

The MnO_2 electrodes in seawater did not exhibit nearly as rapid a drop in efficiency with increasing current as did Leclanché cells. Calculations based on data given by Huber [see p. 146 and 170 of Ref. (14)],

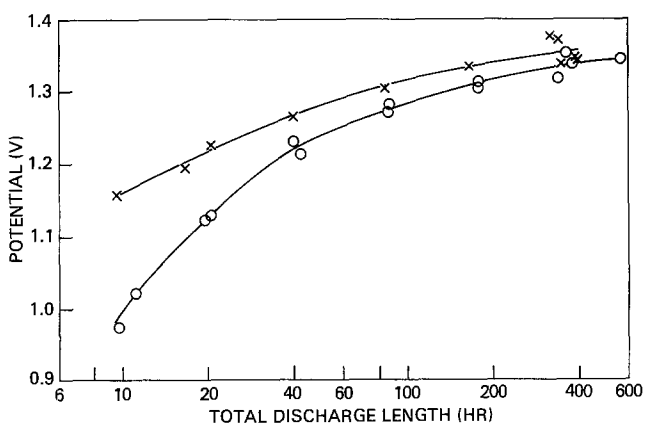

Fig. 3. Cell potentials when discharges of MnO_2 cathodes were 50% completed. Potentials are given vs. Al alloy A6. ○ cathodes contained carbon fiber grids; × cathodes contained Ag grids.

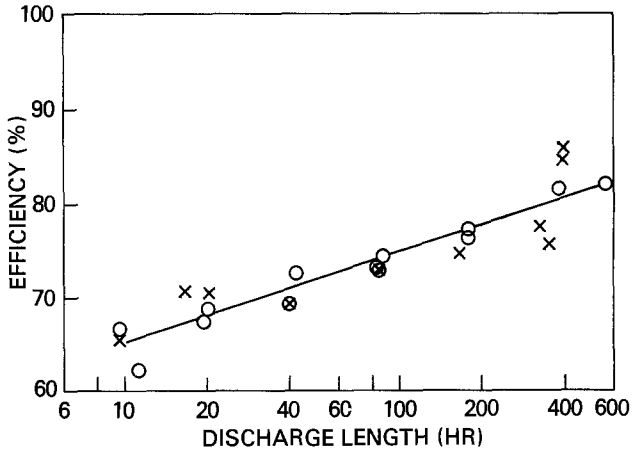

Fig. 4. Ampere-hour efficiency for discharge of MnO_2 in seawater based on the weight of MnO_2 present in the cathodes. ○ carbon fiber grids; × Ag grids.

indicated that size D or R20 dry cells gave about 30-45% efficiency when discharged in 10 hr (constant load of about 4.5-6Ω) while MnO_2 in seawater gave 62-67% (Fig. 4). On the other hand, Leclanché cells gave about 84-90% efficiency when discharged in 15 days (load of 70-80Ω) but the seawater cells gave 76-85%.

Stands in seawater.—Some cells were allowed to stand in seawater for 30 to 90 days before being put on discharge. The different behavior of the two Al alloys during a stand can be seen by comparing the upper and middle lines of Fig. 5. Potential of the A6 alloy soon became unsteady during a stand in seawater, while the Al-Zn alloy gave a relatively steady potential, only changing a few millivolts. Since the Al-Zn anodes gave an almost constant potential, the middle line in Fig. 5 indicates the way that potential of the MnO_2 cathode containing carbon fiber grids declined at a gradually decreasing rate during a stand in seawater.

When MnO_2 cathodes containing Ag grids were put in seawater their potential had an abrupt drop after about half a day (lower line in Fig. 5). After one day in seawater the potential of MnO_2 electrodes containing Ag grids was within a few millivolts of the potential of the Ag/AgCl reference electrode, indicating that the Ag grids had become covered with AgCl.

Figure 6 gives the discharge potentials for the three cells whose 30 day stands were shown in Fig. 5. When the cell with anodes of A6 alloy was put on discharge the anodic potential initially became about 0.8V less negative, which caused cell potential to fall to 1.12V (solid line in Fig. 6). After about 30 sec the anodic potential began to improve. Cell potential reflected the

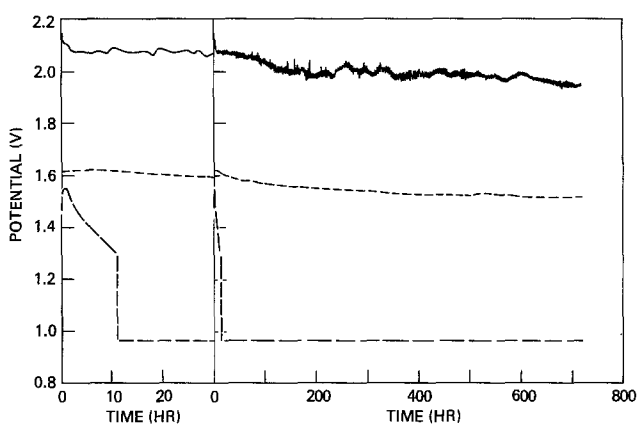

Fig. 5. Potentials during 340 day stands in seawater at room temperature. Time scale is expanded at the left. Solid line, MnO_2 on carbon fiber grid vs. A6 Al; line of short dashes, MnO_2 on carbon fiber grid vs. Al-Zn; line of long dashes; MnO_2 on Ag grid vs. Al-Zn.

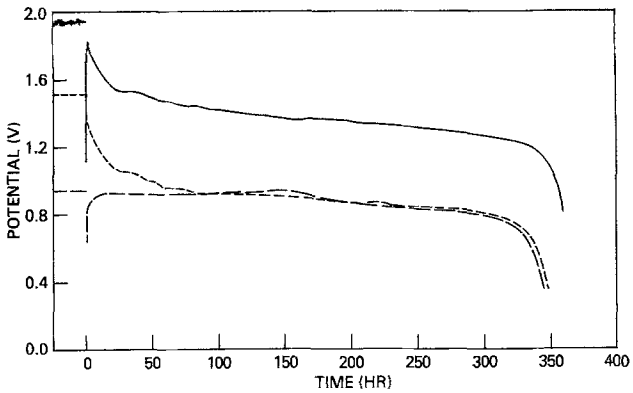

Fig. 6. Potentials during the last day of 30 day stand and during the subsequent discharge at 3 mA. See Fig. 5 for description of cells. Cathodes contained about 5g electrolytic (91%) MnO_2.

change, reaching a maximum of 1.84V after 24 min as A6 anode potential became 0.75V more negative. In this initial 24 min of discharge after a 30 day stand the MnO_2 cathodes that contained carbon fiber grids showed a potential decrease of only 0.05V from the open-circuit value. The MnO_2 potential dropped steadily during the early part of the discharge, falling 0.42V during the first day. After the first hour of discharge all changes in cell potentials shown in Fig. 6 can be considered to indicate changes in the MnO_2 potential since the anodes had relatively small potential changes beyond this point.

After a 30 day stand in seawater a cell with Al-Zn anodes had a much smaller potential change when put on discharge than did cells with anodes of the A6 alloy. Potential of the Al-Zn anodes initially became about 0.1V less negative than the stand value and then recovered 0.05V in the first 30 min of discharge and another 0.05V in the next 4 or 5 days, giving the stand potential for the rest of the discharge. The variation between the two anode alloys, as indicated by the difference in behavior of their potentials during the stand and also at the beginning of the discharge, may have resulted from the A6 alloy developing a coating that had a higher ohmic resistance. The fluctuations in stand potentials suggest continual cracking of the coating on the A6 alloy, followed by formation of a new coating.

The sharp initial drop in potential observed when the cell containing MnO_2 on the Ag grid was put on discharge after a 30 day stand (line of long dashes, Fig. 6) was attributed to resistance of the AgCl film that had formed on this grid. Potential subsequently rose in the early part of the discharge as the AgCl was reduced to Ag and resistance at the grid decreased. After these low rate discharges were 20-25% complete there was little difference between the potential of cathodes with Ag grids and those with carbon fiber.

Figure 6 can be compared with Fig. 1 to see the effect that a 30 day stand has on discharges. Both figures include one cell with a carbon fiber grid and A6 alloy anodes as well as one cell with MnO_2 on Ag and with Al-Zn anodes. Cell potentials were lower in the early part of a discharge following a stand, but these differences gradually decreased. After a discharge was about 25% complete potentials were about the same whether or not a cell had been standing 30 days in seawater.

There was no significant difference among the values obtained for the utilization of MnO_2 when using grids of woven carbon fiber, graphite foil, expanded Ag, or Pt gauze. For five cells given 30 day stands (two with carbon fiber grids and one cell containing each of the other three grid materials) the discharge efficiency for MnO_2 was in the range 73-78%, average 75%. The same discharge current gave an efficiency of 76-86% when discharges began after 1 hr in seawater (Fig. 4, hours 330-400) averaging 81%. Thus, after a 30 day stand the MnO_2 cathodes still gave about 93% of the capacity normally obtained. An efficiency of 73% was obtained when one cell with MnO_2 on Ag stood 90 days in seawater before discharge, suggesting that the loss after 90 days was not much greater than after 30 days. Discharge potentials after the 90 day stand with the Ag grid were much like those shown in Fig. 6, except that potential remained in the range 0.80-0.81V for the first 3 hr of discharge before rising to 0.9V, probably because of the larger amount of AgCl present.

Conductive grids.—Grid corrosion becomes a problem when most metals are held at the potential of MnO_2 in an electrolyte. Platinum was an excellent grid material, undergoing no corrosion after a 30 day stand in seawater followed by a discharge at the 15 day rate. But Pt is impractical considering its cost.

Type 304 stainless steel showed no attack after the bare metal had been standing in seawater for a week, but corroded very rapidly when used as a grid for a MnO_2 electrode. Potential dropped rapidly when seawater was added, and after 10 min of standing in seawater the potential was fluctuating in the range 1.08-1.16V in a cell with Al-Zn anodes. The stainless steel grid broke apart after the electrode had stood 20 days in seawater.

The corrosion rate of copper in seawater was low enough that copper could be used as the grid material if a discharge was completed within one or two days after adding seawater. The initial discharge potentials of MnO_2 cathodes containing Cu grids were not significantly different from those containing Ag grids, but potentials soon became lower because of the formation of resistive corrosion products. For example, when the MnO_2 was discharged at the 11 day rate the potential using a Cu grid was 0.08V lower after one day than the potential using Ag, and 0.15-0.20V lower from four days to the end of the discharge. Another disadvantage to using Cu grids was that potentials became unsteady after standing 14 hr or after discharging two days. Corrosion of Cu was faster during stands because the Cu was at a higher potential. After a 60 day stand in seawater the resistance of a Cu grid had become sufficiently high that cell potential fell to zero when a discharge was attempted at the 15 day rate.

Silver grids corroded more slowly than copper and could be used where cells were to be in seawater for several months, although initial discharge potentials of MnO_2 cathodes with Ag grids were lower than those obtained with carbon grids (Fig. 1, 6). Perhaps Ag or a more inert metal such as Pt or Rh could be plated on Cu in order to avoid the high cost of grids made from silver or a more noble metal, while retaining the advantage that a conductive metal has over a nonmetal such as carbon in giving higher discharge potentials (Fig. 3).

Successful MnO_2 cathodes were made using two forms of thin carbon as the conductive grid. Neither woven carbon fiber nor graphite foil underwent any noticeable attack after 30 days standing in seawater followed by discharges lasting 14-15 additional days. Reference electrode measurements indicated that after a 30 day stand in seawater the MnO_2 cathodes began discharging at a potential only 0.01-0.02V below the final stand potential. Such a small potential drop indicated that there was no formation of a highly resistive film during the stand, in contrast to the results when grids of Cu or Ag were used under similar conditions. Since MnO_2 has a low self-discharge rate in seawater, and carbon grids were apparently unattacked, it is believed that a MnO_2 cathode containing a carbon grid could be discharged continuously or intermittently and give good service over a period of one or more years.

One cathode was made by electrodepositing MnO_2 onto sheet graphite under conditions described by Storey *et al.* (15). Following the electrodeposition the cathode was washed in water and dried at room temperature. The deposit was somewhat irregular, having an average thickness of 1.2 mm. After 1 hr in seawater

this cathode gave an open-circuit potential of 2.00V in a cell with the Al-Zn alloy or 1.029V *vs.* the Ag/AgCl reference. This was about 0.35V higher than the potential obtained from the other carbon grids, perhaps indicating oxygen adsorbed on the graphite. A discharge at the 5 day rate gave a continuously decreasing potential and only 11% efficiency. Reduction of the MnO_2 apparently took place primarily next to the graphite. Then the remaining MnO_2 lost contact with the graphite, as indicated by the tendency for the MnO_2 to fall off of the graphite during the discharge. Ferrell and Vosburgh reported a similar loss of contact when using MnO_2 electrodeposited on graphite rods and reported that a layer of MnO_2 about 5×10^{-6}m thick was the maximum thickness that could be discharged completely in 2M ammonium salt solution (16).

Anodes.—Although the experimental work was designed for studying the cathodes, some information on the anodes was obtained at the same time. The efficiency with which the anodes were consumed during discharges in seawater is given in Fig. 7. Since the discharge conditions were not identical for the two alloys some caution should be used in interpreting Fig. 7. The values for the Al-Zn alloy were taken from earlier work (8) in which anodes were discharged until potential changes indicated that a discharge had ended. The results for alloy A6 come from the present work, with discharge length determined by the MnO_2 cathode. The two A6 anodes in a cell had a total theoretical capacity of 2.4 or 3.0 times the theoretical capacity of the MnO_2 cathode, depending on the particular anode size used. Therefore, the maximum discharge length of the anodes can be roughly estimated to be 2.4-3 times the discharge length measured for the cathodes. However, this does not take into account the differences between efficiency of the cathode and the anode, nor the likelihood that pieces of Al would become separated from the anode in the last half of the discharge and shorten the discharge, as was noted in the earlier work where the 5.2% Al-Zn alloy only gave 50-60% of the capacity theoretically possible (8).

The change in efficiency with discharge length (Fig. 7) indicated that a larger proportion of the A6 anodes was consumed during slow discharges. About 30% of the exposed metal in the A6 anodes having the smaller dimensions had been consumed during a discharge at the 10 hr rate and 53% at the 15 day rate, while 23 and 41% of the larger A6 anodes had been consumed at the same rates. The condition of these anodes when a discharge was ended depended on the discharge rate. During discharges at what was the 10 hr rate for cathodes many small holes 0.3-1.5 mm diam appeared in the A6 anodes. As discharge rate lengthened the holes tended to be larger but fewer in number. For example, at the 40 hr rate most of the holes were 2-4 mm diam, while at the 180 hr rate the holes were 5-11 mm in their largest dimension but only 1-3 holes were present. As the number of holes had decreased, the amount of material removed from the sides and bottom had increased. The appearance of the Al-Zn alloy after a discharge has already been described (8).

Both Al alloys gave potentials that were relatively flat during most of a discharge, so the potential when an anode was 50% discharged represented its average potential quite well (Fig. 8). The values reported here for the A6 alloy were the potentials given as the discharges of the cathodes came to an end. These potentials only differed an average of 4 mV from the anodic potentials when discharged half this much, with some potentials having risen and some fallen.

Potential of the A6 alloy changed only about 0.02V over the current density range from 0.1 to 4 mA cm^{-2}, while potential of the Al-Zn alloy changed by 0.17V over the same range (Fig. 8). Because of these potential changes a cell using the A6 alloy gave a potential that was 0.47V larger than a cell using the Al-Zn alloy at the lower current density cited and 0.61V at the higher current density. The A6 alloy was clearly the preferred alloy of the two at the higher discharge rates because of its higher cell potential and efficiency under these conditions. For very long discharges the extensive corrosion of the A6 alloy can be a problem, because it causes unsteady potentials on open circuit (Fig. 5) or when current is very low, and low initial potentials when a discharge is begun after corrosion has taken place, although it still has the advantage of soon giving a higher discharge potential.

Conclusions

The MnO_2 cathodes performed quite well in seawater, giving less of a capacity decrease with increasing discharge current than did Leclanché cells, and having a low capacity loss while standing after activation. About 93% of normal capacity was obtained following a 30 day stand in seawater. A 90 day stand before beginning a discharge gave little additional loss, indicating that the cell can be used over a period of many months.

Carbon was a good grid material when cathodes were to undergo stands or low rate discharges since carbon was not attacked by seawater when held at the MnO_2 potential. During rapid discharges the highest potentials were obtained when using conductive grids of low resistance such as Ag, but Ag cathodes gave lower potentials in the early part of a discharge because of AgCl formation. The average cathode potential was about 0.1 or 0.2V below the Ag/AgCl equilibrium potential when MnO_2 was discharged at the 7 day or 20 hr rates, respectively, so formation of AgCl was not a problem during most of a discharge. The corrosion

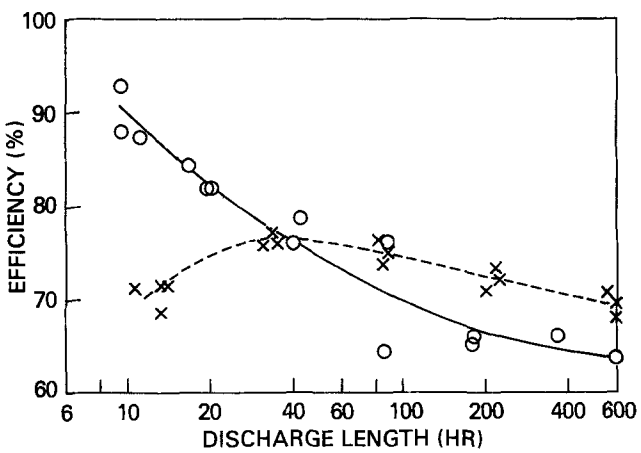

Fig. 7. Efficiency with which Al alloys were converted into current, based on weight loss during discharge. ○ Al-Sn-Mg-Ga alloy A6; × Al alloyed with 5.2% Zn.

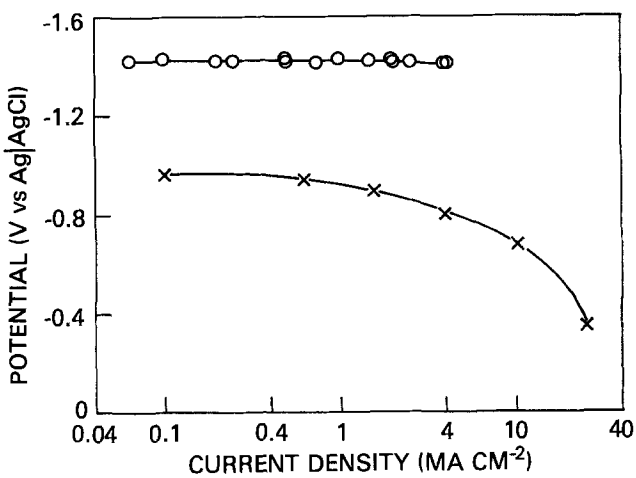

Fig. 8. Potentials when Al anodes were 50% discharged. ○ Al-Sn-Mg-Ga alloy; × Al-Zn alloy.

rate of Cu grids was low enough that they could be used in cathodes if a discharge was completed within one or two days after adding seawater.

The cathodes gave good results when coupled with anodes made from Al alloys. Of the two alloys used, the A6 Al (Al-Sn-Mg-Ga) was preferred over the Al-Zn because it gave higher cell potentials. Cells containing MnO_2 cathodes and A6 anodes gave an open-circuit potential of about 2.0V after adding seawater. Potential dropped rapidly in the early part of a discharge. Most of a discharge took place between 1.4 and 1.1V. Discharges lasting 15 days gave an average potential of 1.35V and those lasting 10 hr gave 1.16V when using grids of low resistance.

Acknowledgments

I wish to thank Dr. J. L. Weininger for providing information concerning neoprene as a binder in electrodes. The electrolytic MnO_2, acetylene black, and graphite were supplied by Union Carbide Corporation with the kindness of Dr. R. J. Brodd. Thanks are also due to E. I. du Pont de Nemours & Company for the samples of neoprene and aqueous Teflon dispersion, and to Conalco, Incorporated for providing some A6 aluminum alloy. Mr. S. H. Cress performed the spectrochemical analysis.

Manuscript received Nov. 16, 1976; revised manuscript received Dec. 27, 1976. This was Paper 65 presented at the Las Vegas, Nevada, Meeting of the Society, October 17-22, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by the Naval Research Laboratory.

The Anodic Oxidation of Tungsten in Aqueous Base

G. Stephen Kelsey

Department of Chemistry, University of Missouri-Columbia, Columbia, Missouri 65201

ABSTRACT

The kinetics of the anodic oxidation of tungsten metal in basic aqueous solution has been investigated using galvanostatic polarization. Anodic Tafel slopes were constant over all concentrations of hydroxide at 0.136 V/decade. Cathodic Tafel slopes ranged from 0.069 to 0.197 V/decade, increasing with hydroxide ion activity. Anodic exchange current density, obtained by extrapolation, averaged $5 \pm 3 \times 10^{-8}$ A/cm^2. Single ion activities, estimated by Harned's rule, in sodium hydroxide solutions buffered with sodium nitrate to constant ionic strength, yielded rate data indicating first-order dependence on hydroxide ion activity over a concentration range of 0.02-6.00M OH^-. A mechanism commensurate with the observed behavior is proposed involving oxidation to intermediate tungsten oxides, followed by nonelectrochemical dissolution to form the soluble tungstate anion. A brief discussion of the data for the hydrogen evolution reaction is also presented, in the light of recent studies on tungsten covered by oxide layers.

In recent years much work has appeared in the area of metal/metal ion electrode behavior in aqueous solutions (1-21). Within this broad area, investigations have focused on the kinetics of the anodic oxidation/cathodic reduction mechanisms (1-9), on the initial oxidation state of the anodic oxidation product [coulometric n value (10-12)], or on the application of the anodic generation of the metal ion to coulometric analysis (13-21). Development of a theoretical basis for activation-controlled electrode kinetics (22, 23) has enabled the oxidation/reduction mechanisms of several metals to be elucidated (5-9). The comparison of experimental results with theoretical calculations has been most successful in the case of solutions where the metal/metal ion couple is reversible and the parameters of exchange current density, i_o, and reversible potential, E_R, have their true meaning. In the case of metals which do not have reversible couples, or which form oxidation products which cannot be electrodeposited on the parent metal (such as Cr/CrO_4^{2-}, *e.g.*), the interpretation of potentiodynamic or galvanostatic data is less obvious.

The anodic behavior of metals, viz., dissolution, must be at least reproducible in order to utilize the anodic oxidation of pure metals for the purpose of titrant generation (20, 21) or for the coulometric preparation of standard solutions of low concentration. Because the stability of tungstate ion is greatest in basic medium,

Key words: Tafel, dissolution, tungstate, galvanostatic polarization.

conditions for precise current efficiency for its generation were sought in sodium hydroxide solutions.

Previous studies of the hydrogen evolution reaction (HER) on tungsten (24, 25,) while contradictory in part, lend most support for an oxide surface reduction of solvent. Results for the HER in this work are confined to Tafel data, which were collected to help complete the anodic part of the study.

Work by Johnson and Wu (26) (and references cited therein) indicated that Tafel slopes for anodic dissolution in basic solution have been observed over a significant range of values. The lack of agreement concerning the anodic reaction prompted the kinetic study.

Experimental

Apparatus.—All electrochemical measurements were obtained using a PAR 173 potentiostat/galvanostat (Princeton Applied Research Corporation, Princeton, New Jersey) equipped with a Model 179 digital coulometer. Electrochemical cells employed were Metrohm EA 880 Universal titration vessels of 20 ml initial volume, and jacketed for temperature control. Tungsten electrodes used in the study consisted of ¼ in. diameter rod, fixed in a demountable holder, suitable for purposes of weighing prior to and following polarization. Platinum foil counterelectrodes of about 1.5 cm^2 area were used inside isolation tubes inserted in the cell cap. A saturated calomel electrode (SCE) of the high impedance type was used as a reference electrode with a salt bridge in connection with a PAR Model 178 electrometer probe. This, in turn, was connected to the potentiostat and completed the three-electrode cell circuit. Solution temperature was thermostatted to 25.00° ± 0.05°C.

Tungsten metal was obtained as 99.95% pure ¼ in. diameter rod from A. D. Mackay, Inc., New York. Electrolytes were all reagent grade chemicals. Solutions were prepared from distilled deionized water and were purged with prepurified nitrogen prior to all experiments.

Anodic and cathodic current-potential (i-E) data were obtained under galvanostatic conditions, *i.e.*, as $E = f(i)$. Currents from $\pm 1 \times 10^{-5}$ to $\pm 5 \times 10^{-1}$A were applied to the working/counterelectrode pair and the potential of the tungsten electrode against SCE was recorded after it stabilized (a period not exceeding 30 sec, except for the first several measurements). These data points were then used to construct E *vs.* log i, Tafel plots for subsequent study. Current densities were calculated from the applied current and the geometric area of the immersed portion of the electrode, without regard for surface roughness. The technique used to obtain current-potential data (*vide supra*) was such as to minimize area changes during an experiment except at very high applied currents, where the real surface area exceeds the geometric one due to corrosion.

Electrode pretreatment was as follows: Tungsten rods were clamped in a chuck and rotated by an electric motor, while wet-sanded with 320 grit SiC paper, followed by 400 grit, and finally wet polished with 600 grit SiC paper; pretreatment was completed by thorough rinsing with distilled deionized water (27). The final sanding and rinsing were followed by careful wiping with tissue to remove any residual SiC fines or powdered metal. After this last step was repeated, the electrode was examined under magnification to insure that no pits or other irregularities were evident, and was oven-dried at 110°C for 5 min before weighing.

The electrolyte solutions.—Eleven solutions were prepared for the study, whose compositions are described in Table I. All solutions were prepared with a total molar ionic strength of 6.00 where ionic strength is given by

$$I(M) = \tfrac{1}{2} \sum_i M_i z_i^2 \qquad [1]$$

Table I. Composition, concentration, and ionic strength data for the applied solutions

XI	0.10	0.00	5.90	0.125	0.000	4.56	7.57

The concentrations of the various components are also reported in molality, calculated from the measured densities of the solutions at 25°C. Because of the high ionic strength of these solutions, activity coefficient data for the electrolytes were obtained graphically by interpolation (the case for sodium hydroxide) or extrapolations of mean molal activity coefficient data from tables by Parsons (28) and Robinson and Stokes (29). Because of the lack of data for sodium tungstate, the data for sodium chromate solutions of like molality were substituted. The assumption that the activity coefficients of these two compounds (and later, their osmotic coefficients) behave in a closely similar manner is an uncertainty in the derived activities. However, both chromate and tungstate salts are two-to-one electrolytes which undergo a base hydrolysis reaction in pure water and possess similar solubilities.

The estimation of activity coefficients for the three electrolytes was based on Harned's rule, expressed in Eq. [2], for a general three-component solution

$$\log \gamma_2 = \log \gamma_{2(0)} - \alpha_{23} M_3 - \alpha_{24} M_4 \qquad [2]$$

$$\alpha_{23} = (\Phi_3 + \Phi_2)/2.303M \qquad [3]$$

Values for α pertain to the total molality of the mixture and, for a multielectrolyte solution with a common ion, are given by Eq. [3]; again, Φ, the osmotic coefficients, are values at the total solution molality. The activity coefficients and calculated mean ionic activities are given in Table II. Because of the success of Harned's rule at high ionic strength compared to other methods of estimating single ion activities (30), it was chosen for use in the present work. Listed in Table II are the activities for water, which were obtained by extrapolation of a_{H_2O} *vs.* M data from Robinson and Stokes (29); the last column is the $-\log a_{H^+}$, which was calculated from Eq. [4]

$$K_w = \gamma_{H^+} M_{H^+} \gamma_{OH^-} M_{OH^-} / a_{H_2O} \qquad [4]$$

The value for K_w at 25°C was obtained from Hurlen (5).

The variation in the activity of hydroxide ion among solutions of equal hydroxide molarity is the probable cause of scatter in certain correlations among solutions I through V (*vide supra*), but the use of least squares analysis revealed correlation coefficients usually exceeding 0.99.

There was no attempt made to compensate for liquid junction potentials between saturated KCl and the electrolyte solutions. The Henderson equation (31) indicates that for the present solutions the junction potential could easily reach about 70 mV. More importantly, regardless of its magnitude, the liquid junction potential is a sensitive function of solution composition and probably varied quite a bit over the range of sodium hydroxide concentration (0.02-6.00M).

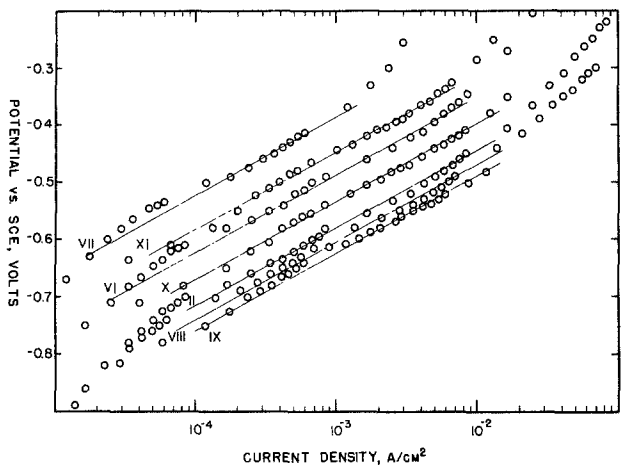

Fig. 1. Tafel diagram for the anodic dissolution of tungsten

magnitude (solutions II, VI-XI). In general, the linear portion extends for two decades of current density, nominally 5×10^{-5} to 5×10^{-3} A/cm². The solid lines are drawn with a slope of 4.606 *RT*/**F**. Slight dislocations were observed with changes in current ranges, but these discontinuities were attributed to an artifact of the potential display circuitry of the Model 173 since they appeared in both anodic and cathodic Tafel plots at regular intervals. A small uncertainty, about 2-5 mV, is due to the graduation of the voltage meter, from which potential readings were taken.

The direct dependence of anodic current (rate) on hydroxide concentration is evident from Fig. 1. A graph of log *i* *vs.* log a_{OH^-} is given in Fig. 2; data points are taken at two potentials in the linear portion of the Tafel diagrams. The solid lines in the figure represent a slope of +1, indicative of a first-order rate dependence on hydroxide ion activity. The least squares slope calculations were +1.09 and +0.91 for potentials of −0.50 and −0.60V *vs.* SCE, respectively, which illustrates, perhaps indirectly, the degree of success of Harned's rule in estimating activities in high ionic strength solutions. Graphs analogous to Fig. 2 for the other components of the solutions revealed no correlation between observed rate (current density) and activity.

The anodic Tafel plots for solutions I-IV (constant sodium hydroxide molarity), with varying amounts of sodium tungstate in them, were, within experimental error, superimposable. There seems to be no dependence on tungstate ion activity for the anodic reaction.

Coulometric experiments carried out both potentiostatically and galvanostatically revealed data consistent with those of Johnson (26) and are the subject of a separate communication. The six electron stoichiometry of Eq. [5] was observed in all solutions

$$W + 8\,OH^- \rightarrow WO_4^{2-} + 6e^- + 4H_2O \qquad [5]$$

Hydrogen evolution reaction.—The reduction of tungstate ion was not observed in any of the solutions containing the ion, and so the hydrogen evolution reaction appears to be the only one occurring during cathodic polarization. No weight changes were detected for even extended polarizations under potentiostatic conditions. Data for solutions I-V are depicted in Fig. 3. The solid lines represent a Tafel slope of 4.606 *RT*/**F**. Figure 4 represents the Tafel behavior of solutions II, VI-XI, where the hydroxide ion dependence of the reduction potential is evident.

Discussion

An exact quantitative understanding of the reversible potential and exchange current density of this system is hampered by the uncertainty of the liquid junction potential between the saturated calomel electrode and the electrolyte solutions. However, in the light of this uncertainty, the following observations are made.

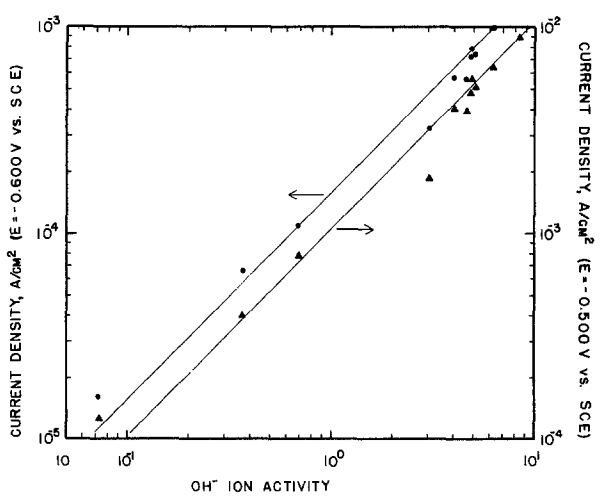

Fig. 2. Log anodic current density as a function of log hydroxide ion activity at constant potential.

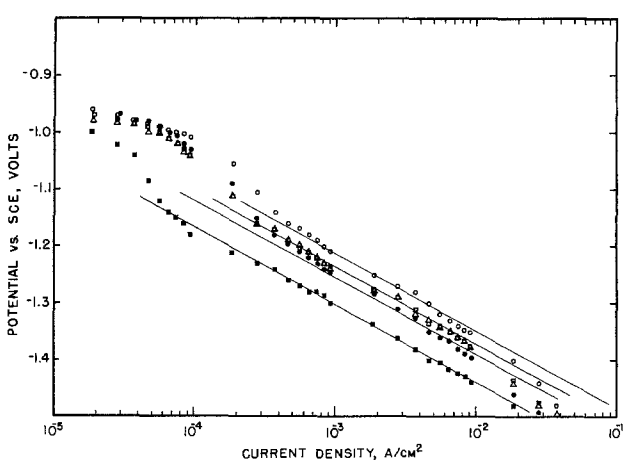

Fig. 3. Tafel diagram for the cathodic hydrogen evolution reaction in solutions I-V. ○, Solution I; □, solution II; △, solution III; ●, solution IV; ■, solution V.

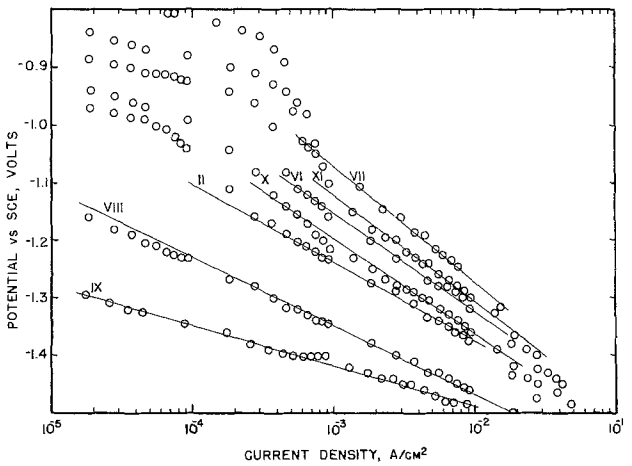

Fig. 4. Tafel diagram for the cathodic hydrogen evolution reaction in solutions II, VI-XI.

Extrapolation of the linear anodic and cathodic Tafel lines to intersection was done mathematically using the least squares values for those slopes. Values obtained in this way for the reversible potential, E_R, because of the irreversible nature of the redox system, do not have their usual meaning. In this instance the potential is more properly a corrosion potential, E_{corr}, and the exchange current density, i_o, a corrosion current density, i_{corr}. Table III contains E_{corr} and i_{corr} values, as well as open-circuit "rest" potentials obtained prior to current application in polarization experiments. Unlike earlier findings (26) the present results seem to indicate that the reaction taking place at rest involves a 2:1 ratio of OH^- to electrons. The slope of the E_{rest} *vs.* log a_{OH^-} plot in Fig. 5 is -0.123 ± 0.015 V/decade but also has sufficient scatter to cast doubt on the relationship. In the author's mind, the question of the rest potential requires a separate study to resolve the discrepancy.

The stoichiometric reaction for the oxidation of tungsten in basic solution as given by Eq. [5] masks what is doubtless a very complex mechanism. The determination of kinetic parameters involves the knowledge of the dependence of the rate-determining step on various species in solution. This unit reaction (rds) is repeated a number of times (the stoichiometric factor, ν) to produce Eq. [5]. Unfortunately, the calculation of ν is based on reversibility, requiring both anodic and cathodic Tafel slopes (22, 23). Some help, however, is gotten from a consideration of the product of the transfer coefficient, α, and the number of electrons involved in the rds as given by [6]. In work with chromium, Heumann (3) and Schwabe (4) chose values of n which yielded 0.5 for α, viz.

$$b_a = 2.303\,RT/\alpha n\mathbf{F} \qquad [6]$$

$n = 3$ and $n = 2$, respectively. From the anodic Tafel slope in the present work a transfer coefficient of 0.5

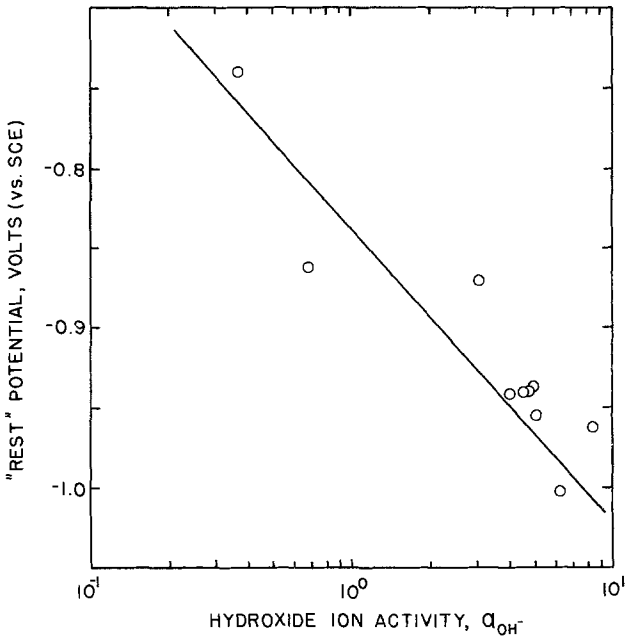

Fig. 5. Tungsten electrode rest potential as a function of log hydroxide ion activity.

yields a value of 1 for n, the number of electrons given up by tungsten in one rate-controlling event.

The sole reactant rate dependence observed gotten from Eq. [7]

$$(\partial\Delta\Phi/\partial \log a_{OH^-})_{i,T,a_{i\neq j}} = 2.303\,q'\,\nu RT/\beta n\mathbf{F} \qquad [7]$$

was for hydroxide ion, where $\Delta\Phi$ is the anodic potential at a constant current; q' is the order of the observed rate with respect to hydroxide ion ($q' = 1$, as in Fig. 2); $n = 1$; β, a symmetry factor, is taken as 0.5. The fit of these parameters to the experimental data is represented in Fig. 6. The least squares calculated slopes for the two current densities averaged 0.112 V/decade. From the measured slope, Eq. [7] was solved for ν, the number of times the rds occurs in the course of the over-all stoichiometry. A value of 1 was obtained. The deviation from the expected slope of 0.120V is actually not excessive since the activities of all the other ionic

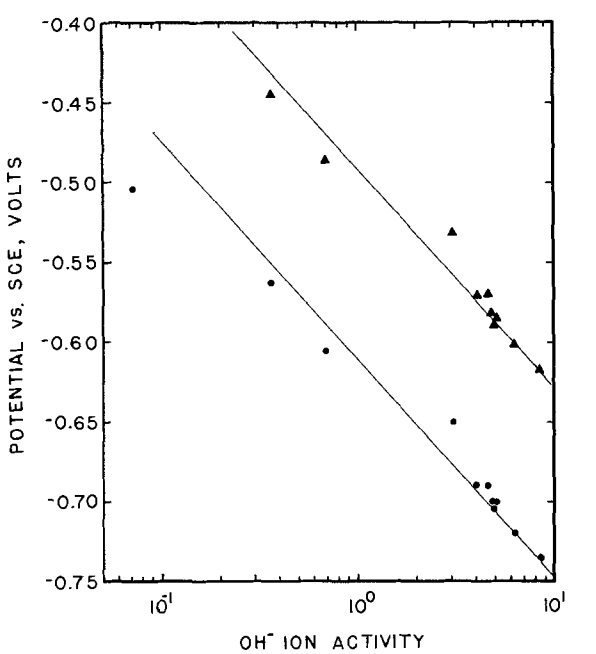

Fig. 6. Anode potential as a function of log hydroxide ion activity at constant current. ▲, Current density of 10 mA/cm²; ●, current density of 1 mA/cm².

constituents of the solutions and the activity of the water itself are not perfectly constant. The agreement with 4.606 $RT/\mathbf{F}$ is adequate, however, to corroborate the first-order dependence on hydroxide ion.

The proposed mechanism which fits the observed data is given below in six steps, four of them electrochemical

$$W_{(s)} + 2\,OH^- \rightarrow WO^+{}_{(s)} + 3e^- + H_2O \quad [9]$$

$$WO^+{}_{(s)} + 2\,OH^- \rightarrow WO_{2(s)} + e^- + H_2O \quad [10]$$

$$WO_{2(s)} + OH^- \xrightarrow{\text{rds}} WO_3H_{(s)} + e^- \quad [11a]$$

$$WO_3H_{(s)} + OH^- \xrightarrow{\text{fast}} WO_{3(s)} + e^- + H_2O \quad [11b]$$

$$WO_{3(s)} + OH^- \rightarrow HWO_4^-{}_{(aq)} \quad [12]$$

$$HWO_4^-{}_{(aq)} + OH^-{}_{(aq)} \rightleftharpoons WO_4^{2-}{}_{(aq)} + H_2O \quad [13]$$

The mediation of anodic and cathodic kinetics on tungsten by oxide formation has been suggested by other investigators (25, 26) and this metal is not unique in Group VI in this respect (32, 33). In the present work evidence of oxide behavior was found in cathodic polarizations (*vide infra*). Indeed, the electrode pretreatment procedure employed also favors air oxidation of the surface and thus one or both of the steps preceding the rds may have taken place before polarization. While parts of the final dissolution reactions are common to Johnson's work (26), the electrochemical kinetic data here indicate a rds which is first order in hydroxide ion and at the same time involving a one-electron oxidation. Equation [11a] clearly fulfills these observed requirements as does [11b]. Since the oxidation potentials for the W(IV) → W(V) and W(V) → W(VI) steps are so similar, it is difficult to choose one over the other on that basis. The oxides WO_2 and WO_3 crystallize in the same manner; both have tetragonal and rhombic space groups. In fact, the coordination of tungsten in both oxides is octahedral and magnetic susceptibility data (34) indicate that the substoichiometric oxides between WO_2 and WO_3 are perhaps best represented by a surplus of free electrons in the conduction band from defects or vacancies in the WO_3 structure. Thought of in these terms, no monomeric representation of the W(V) intermediate could correctly describe it. The fact that Hull (33) observed soluble Mo(V) species at the ring electrode indicates that it is possible to remove a W(V) complex from the lattice. However, with a following one-electron oxidation to WO_3, [11b], this possibility is less likely. The choice of [11a] as rds is also consistent with the low overpotential region wherein the Tafel relationship was observed. Besides avoiding the necessity of invoking some complex dimeric species formation (26) the new kinetic data account for the observed first-order hydroxide ion dependence and apparent one-electron charge transfer in the rds.

The reactions subsequent to [11] are chemical dissolution steps with the final [13] equilibrium attained in the bulk solution. In the concentration polarization region (high overpotentials beyond Tafel linearity), where hydroxide ion is used up as fast as it arrives, the oxides become insoluble (low pH) and current flow is limited. In the present work, the concentration of hydroxide was high enough that the double layer region never became acidic enough for passivation to occur.

The sum of reactions [11a] through [13] gives a relation which fits the observed rest potential relationship of Fig. 5 and is given in Eq. [14]

$$WO_{2(s)} + 4\,OH^- \rightarrow WO_4^{2-}{}_{(aq)} + 2e^- + 2H_2O \quad [14]$$

It describes a potential derived from the irreversible dissolution of the oxide film in the presence of base, with the 2:1 hydroxide to electron ratio. It certainly represents a mixed potential since the deposition of tungsten from tungstate ion was never observed in the course of the present work.

The cathodic polarization plots reveal the expected cathodic shift with increasing hydroxide ion activity. The Tafel lines in Fig. 3, however, do not verify the expected anodic shift V > I > II > III > IV, based on increasing OH^- activity. A factor which was not accounted for in these five solutions, though, is the hydrolysis of tungstate [15] which might help explain the observed order I > II ~ III > IV > V

$$WO_4^{2-} + H_2O \rightleftharpoons HWO_4^- + OH^- \quad [15]$$

Because several of the lines are only separated by 50 mV or less, the observed dependence can only be described as qualitative.

Figure 4 reveals that in all solutions except VIII and IX, a dislocation occurred at low current densities. This behavior has been observed by other investigators (1, 5, 34) and has been attributed to the influence of the potential of zero charge (pzc) of the metal (35). The author is unaware of data for this medium for tungsten, so that no firm conclusion here is possible. The inflection occurs at −1.00 to −1.05V *vs.* SCE in all solutions for which data were taken in that potential region.

Data from two constant current densities, 1 and 10 mA/cm², were used, together with values for E_R(cath) gotten by least squares extrapolation to the potential for the HER in each solution, to obtain overpotentials, η; $\eta = E - E_R$. Figure 7 depicts η *vs.* log a_{H^+} at the two current densities. The slopes of −0.074 and −0.118V were gotten by regression analysis. The potential data used in computing the former slope covered a range of potentials from −1.1 to −1.4V *vs.* SCE, while the latter slope was gotten from potentials of −1.3 to −1.5V *vs.* SCE. If the pzc for tungsten is responsible for the inflection at *ca.* −1.05V *vs.* SCE, then the slope difference in Fig. 7 would be attributable to the fact that the electrode potential in the former case is within 300 mV of the pzc (23), and lies between −2.303 and −4.606 $RT/\mathbf{F}$.

Finally, the observed range of cathodic Tafel slopes in Fig. 4 (−0.197V/decade at 0.02M NaOH to −0.069V/decade at 6.00M NaOH) are in qualitative agreement with Ammar's (25) dual-barrier model of reduction of solvent at a thin oxide film.

Summary

The electrochemical oxidation of tungsten metal in basic solution has been found to proceed smoothly to tungstate ion over a large range of current densities and hydroxide ion activities. Formation of the oxide film, known to exist on the metal, and allowed to occur in the present study, has been incorporated into the assigned mechanism. In addition, the data for the

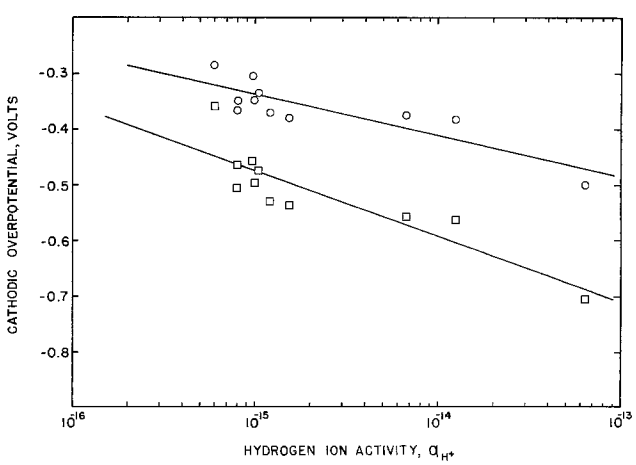

Fig. 7. Cathodic overpotential as a function of log hydrogen ion activity.

HER have also been reconciled with the oxide barrier model.

An average value for the corrosion current density of $10^{-5.5}$ A/cm^2 was obtained. The open-circuit rest potential can be described by an anodic exchange reaction involving WO_2 oxidation to tungstate ion and a cathodic solvent reduction reaction. Finally, the behavior of tungsten appears to closely resemble that of molybdenum in basic solution, with intermediate oxide species implicated in its redox chemistry.

Manuscript submitted Nov. 8, 1976; revised manuscript received Jan. 24, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Anodic Corrosion of Zinc Alloys in Seawater

Jeff Perkins, W. H. Luebke, K. J. Graham, and J. M. Todd

Materials Science and Chemistry Group, Naval Postgraduate School, Monterey, California 93940

ABSTRACT

Zinc alloys are widely used as sacrificial anodes in cathodic protection systems. In order to better understand the corrosion performance of these alloys the structure and morphology of corrosion products have been studied under laboratory conditions as a function of time, potential, current density, temperature, and velocity. Polarization curves have been determined and scanning electron microscopy, energy-dispersive x-ray microanalysis, and x-ray diffraction have been utilized to identify and characterize surface corrosion. Nucleation and growth processes for the primary anodic electrocrystallization product, ZnO, have been determined. A dissolution-precipitation mechanism is postulated, which describes the development of network arrays of zinc oxide platelets. The relationship of anodic corrosion to microstructural features of the bulk alloy is also described, including the role of grain boundaries and second-phase particles. Conditions leading to formation of passivating thick films are discussed.

The typical corrosion product structure formed on a sacrificial anode zinc material when coupled with mild steel in still seawater for 100 hr is shown in Fig. 1. X-ray diffraction of the as-corroded surface reveals that the primary compound seen here is zinc oxide (ZnO) (1). Morphologically, the corrosion product consists of an array of discrete single crystal plates of zinc oxide. These plates are about 30 μm average diameter, with a hexagonal plate shape, and there are about 10^6 plates per square centimeter zinc surface area (1, 2). The plates are obviously forming by a dissolution-precipitation mechanism (3, 4), developing a three-dimensional network array that is porous on the microscale. This porosity is a desirable feature since it allows free access of the electrolyte to the base anode surface and allows the sacrificial anode to corrode. This point emphasizes the impetus for the present studies, namely, decreased efficiency of sacrificial anodes due to passivation.

Key words: cathodic protection, morphology, passivity, velocity effects.

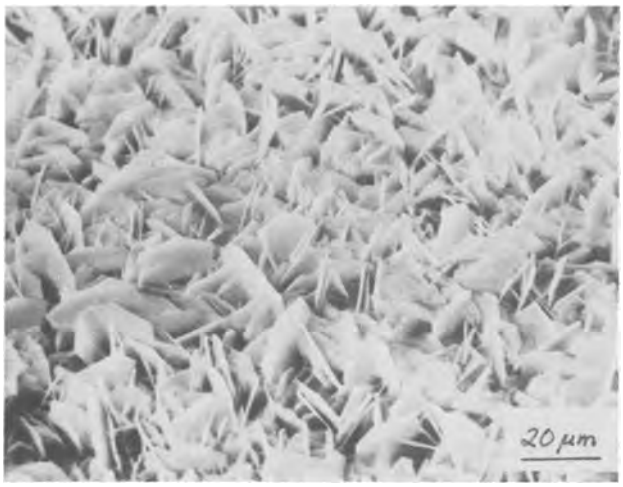

Fig. 1. Typical corrosion product structure formed on sacrificial zinc anode when coupled with steel in seawater for 100 hr. The discrete plates are ZnO crystals.

Zinc alloys have long been used as sacrificial galvanic anodes for cathodic protection. A common problem associated with this usage has been the development of apparent anode passivity and, therefore, loss of current-providing capability. This phenomenon is, of course, attributed to the development of dense, adherent corrosion product structures, unlike that seen in Fig. 1. Due to this passivation problem, extensive research was conducted in the 1950's and 1960's, leading to present specifications for ships' hull zincs (5). These specifications place impurity limitations on the zinc compositions, largely as a result of various empirical corrosion-rate studies (6-9). In order to develop better understanding of compositional influences on the corrosion performance of zinc-based materials, studies were initiated at the Naval Postgraduate School several years ago (1-4). These studies were intended to develop a fundamental understanding of composition specifications. The present studies have emphasized microscopic aspects of corrosion product formation and the influence of base metal microstructural features such as the distribution of alloying elements in the microstructure. Surface microanalytical beam techniques such as scanning electron microscopy and energy dispersive x-ray spectroscopy have been utilized extensively.

This paper summarizes several aspects of zinc anodic corrosion product formation, including (*i*) nucleation and growth sequence under stationary conditions, (*ii*) effects of base metal microstructure on the form and distribution of corrosion products, (*iii*) velocity effects, and (*iv*) current density effects. From these observations we have isolated conditions under which passivating thick films are favored.

Experimental

In previous work (1-4), when "natural" unbiased zinc-steel couples were used, they had an effective surface area ratio of about 1:50 (zinc to steel), which approximates the area ratio typical for ship hull protection. For this situation the anodic current density is about 1.5 mA/cm^2. This value is a useful reference point for comparison with imposed galvanostatic exposures reported here. Note that this current density is derived for static (no-flow) conditions at room temperature for natural couples in aerated synthetic seawater at short exposure times.

The experimental apparatus for dynamic galvanostatic experiments consisted of a cylindrical tank, rotating-disk assembly, galvanostatic power source, digital voltmeter, and frequency counter. The exposure tank was Plexiglass, 46 cm diam filled to a level of approximately 29 cm to hold 48 liters of synthetic seawater. A system of plastic baffle strips was installed within the tank volume and along its interior and bottom to keep the electrolyte as stationary as possible during traveling-electrode experiments. The tank bottom was also fitted with an embedded, 35.5 cm diam aeration canal which allowed compressed air to be bubbled through the liquid from an array of 12 air holes spaced 30° apart to ensure that the electrolyte was saturated with oxygen. The bubbling also provided a vertical circulation pattern to eliminate potential concentrations of corrosion products in the solution during tests.

The rotating-disk assembly (Fig. 2) consisted of a 30.5 cm diam, 1.27 cm thick Plexiglas disk suspended 20 cm below the electrolyte surface by a 2.54 cm diam Plexiglas shaft. The shaft was connected via a pulley arrangement to an electric motor, with variations in pulley size allowing disk speed to be varied. A single zinc sample was located in the disk underside in a small rectangular slot near the disk perimeter, 14.5 cm from the disk center. The slot was carefully machined to accommodate the 1.1 × 1.1 × 0.5 cm specimens with close tolerances, so that once in place they were flush with the disk surface and clearance between the sides of the zinc sample and the Plexiglas slot was minimized. The sample was held in place with a plastic setscrew threaded into a tapped hole in the back of each sample, as seen in Fig. 3.

The anodic zinc current was controlled using an impressed galvanostatic current system. Electrical contact was accomplished by using a brass ring in the inner wall of the setscrew hole in the disk. As the speci-

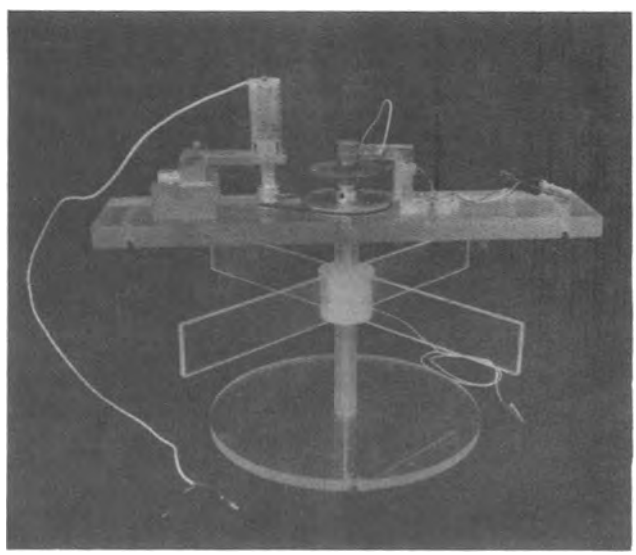

Fig. 2. Rotating-disk assembly

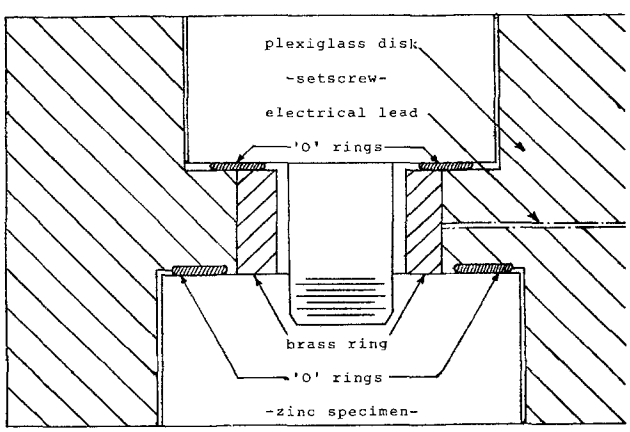

Fig. 3. Schematic detail drawing of specimen arrangement in rotating disk.

men was secured into the slot it was forced against the brass ring to complete the circuit. Two rubber "O" rings were used to isolate the brass/zinc connection from the electrolyte; one under the setscrew head and one around the outer perimeter of the brass/zinc interface. Current was delivered by a wire running into the hollow drive shaft through a watertight route along the disk radius. At the top of the shaft were fitted the drive mechanism and counting apparatus. A copper pickup brush positioned against a brass pickup ring on the shaft allowed current control to the zinc anode at velocity. The cathode was a 3.8 cm diam platinum disk positioned on top of the tank bottom baffles at the center of the tank approximately 3.2 cm below the plastic disk. As with the zinc electrode, construction was such as to ensure that the platinum disk was the only cathode in the tank during experimentation. Current output to the zinc specimen was governed by voltage selection across precision resistors in series with the load; maximum current available was 0.75A (7.50V with a 10Ω resistor). The dynamic response of this configuration was on the order of 15 μsec and over-all regulation was 0.1% of full scale of the selected range. It was possible to control specimen current to ± 2 μA regardless of anode velocity.

Zinc samples used in experimentation were machined from a standard 48.5 kg zinc alloy slab obtained from Mare Island U.S. Navy Shipyard, Vallejo, California. This was nominally a MIL-specification (5) material intended for cathodic protection use as a ship hull anode. Chemical analysis confirmed the alloy as conforming to Military Specification A-18001H, being approximately 99.99% zinc with trace amounts of lead, iron, cadmium, aluminum, copper, and silicon (5). Prior to exposure, the surface of each specimen underwent a standard preparation sequence, being sanded to a 600 grit finish, rinsed with tap water and alcohol, then dried with a jet of freon gas. Unless otherwise noted, the initial surface of samples is this uniformly sanded 600 grit finish; however, some samples were prepolished and etched to make base metal microstructural correlations. All experiments were performed with synthetic seawater electrolyte prepared using the formula and procedure developed by Kester *et al.* (10). Before each experiment the solution was tested and, if necessary, adjusted for *p*H and conductivity to meet the specifications (*p*H of 8.0-8.4 and resistivity between 22 and 24 Ω-cm): usually only small additions of distilled water, to compensate for evaporation losses, were needed to bring the seawater quality within the desired limits. Of course, the synthetic seawater electrolyte used in these experiments presents conditions which differ from natural seawater in terms of organic constituents, metallic ions, and temperature fluctuations. All of these factors can be imagined to affect the microscopic aspects of zinc corrosion, which are the subject of this paper. For example, organic impurities can participate in adsorption/desorption phenomena, noble metallic impurities may participate in local displacement reactions with zinc, and temperature affects the solubility of corrosion product compounds. However, these kinds of effects are not considered substantial in view of previous work where natural and synthetic seawater exposures were compared and microscopic corrosion observations were essentially identical (1).

Once a specimen was fastened into the rotating-disk slot, but before being lowered into the electrolyte, checks were made to ensure that the corrosion current delivered would be that actually prescribed by the experimental plan and procedures were employed to avoid current surges during circuit completion. For tests involving a stationary anode, the desired value of impressed current was applied within 10 sec of immersion. Under rotating conditions the time elapsed was approximately 20 sec because the necessary assembly rpm could not be achieved instantaneously; no current was applied until anode velocity was stable. A detailed analysis of relative velocity distribution of the electrolyte has not been attempted. In all rotating-disk mechanisms, such as used here, there is an inherent radial flow over the disk surface as well as the tangential velocity component. Mathematical solutions exist which can provide the net velocity vector under these general conditions, but the computational efforts required were considered to exceed the utility of the solutions in this case. For convenience, relative anode velocities are expressed here simply as disk rpm, and for reference corresponding approximate tangential relative velocities in cm/sec and knots are given where of interest. For example, a disk rpm of 60 rpm corresponds to a relative tangential velocity component of about 100 cm/sec or about 2 knots.

Once each corroded specimen was removed from the tank, but prior to being loosened from the disk slot setscrews, its surface was immediately rinsed by immersion in distilled water. This procedure has been shown to induce no disturbance to the corrosion product structure, while thoroughly washing away electrolyte salts. Specimens were subsequently removed from the slot, rinsed again, and allowed to dry naturally in air. After corrosion exposure, the surface of each sample was studied using a Cambridge S4-10 scanning electron microscope (SEM) equipped with a Princeton Gamma-Tech PGT-1000 energy-dispersive x-ray spectrometer.

Results and Discussion

Nucleation and growth sequence.—For natural zinc-steel couples in still seawater, an incubation time of about 7.5 min is observed prior to the formation of initial corrosion product crystals by a dissolution-precipitation mechanism (4). The nucleation and growth sequence of the network array is shown in Fig. 4. In controlled galvanostatic anodic exposures in still sea-

Fig. 4. Nucleation and growth sequence of network array of ZnO platelets on zinc in natural galvanic couple with steel in still seawater; (a) 10 min, (b) 12 min, (c) 20 min, (d) 25 min, and (e) 30 min.

water an $i \times t$ product of about 15 mA min/cm^2 is obtained, for current densities in the range 0.775-7.75 mA/cm^2. This correlates with measurements indicating that the typical current density experienced in natural galvanic couples at short terms is on the order of 1.5 mA/cm^2. Quantitative microscopic determinations of the time variation of average plate diameter in the array shows that an approximately parabolic function is followed.

Effects of base metal microstructure.— The microstructure of zinc samples employed in these studies is shown in Fig. 5. This shows a noncorroded polished and etched surface, which is not the surface condition generally employed in corrosion experiments, although some prepolished and etched samples were corroded to make better base metal microstructural correlations. The microstructure reveals grain boundaries, twin boundaries, and a distribution of apparently less conductive inclusions. Base metal grain boundaries and twin boundaries have virtually no effect on the nucleation and growth of individual ZnO platelets, as seen in Fig. 6 for a prepolished and etched sample. A narrow region free of dissolution pits is observed adjacent to the grain boundaries, perhaps indicating that the grain boundaries act as dislocation sinks in these alloys, but this heterogeneity in dissolution has no apparent effect on corrosion product formation, which is oblivious of the presence of these boundaries. On the other hand, impurity-based inclusions have a distinct effect on the distribution of dissolution and corrosion product formation. Inclusions which are microcathodic with respect to the zinc matrix cause accentuated zinc dissolution and corrosion product formation around their periphery, leading to locally denser arrays (see Fig. 7). These microstructural observations were made on prepolished and etched surfaces exposed for relatively brief periods in natural couples with mild steel under static conditions.

In controlled galvanostatic exposures at low current densities (less than natural galvanic values of about 1.5 mA/cm^2), for both static and moderate flow conditions, "ribbonlike" bands of corrosion product define interfaces between microscopic anodic and cathodic areas on the sample surface, as seen in Fig. 8a. These structures appear in the early stages of corrosion exposure, prior to the precipitation of individual ZnO platelets (*i.e.*, at $i \times t$ products less than 15 mA min/cm^2). They are firmly bonded to the base metal surface and consist of dense wall formations of zinc oxide (Fig. 8b). These walls typically encircle areas of higher dissolution (Fig. 8c), *i.e.*, locally microanodic regions. The encircled regions often, but not always, show the

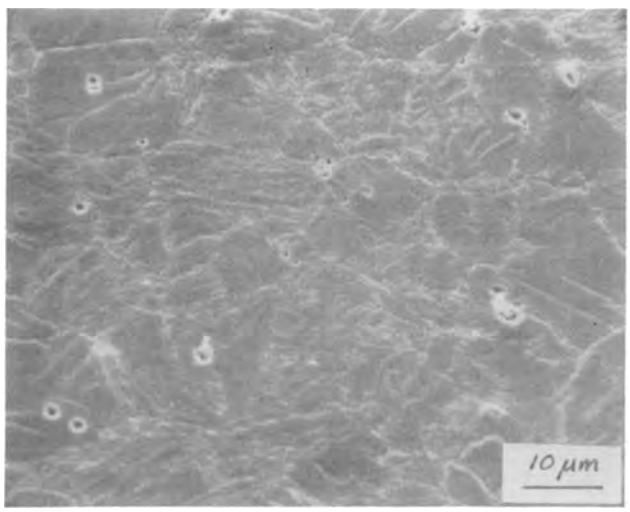

Fig. 5. Base metal microstructure of zinc samples employed in these studies. Note that this does not represent the typical surface condition employed, but was used in certain cases to make base metal microstructure; corrosion product correlations.

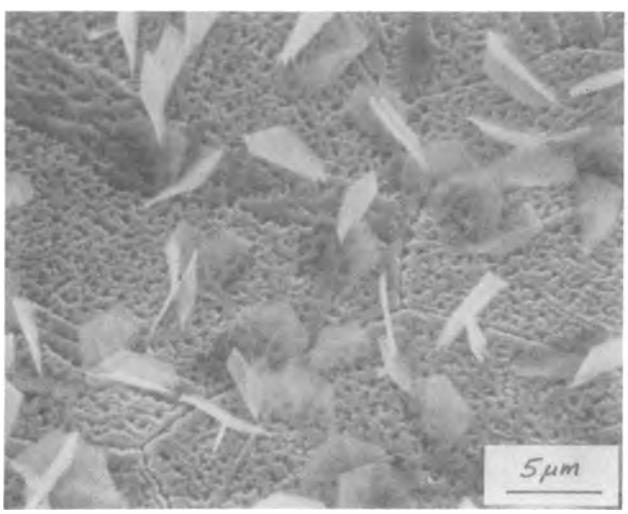

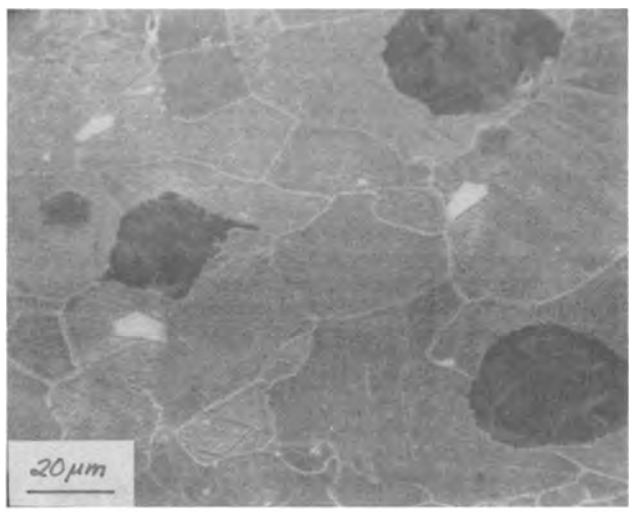

Fig. 6. Corrosion product on prepolished and etched surface shows that base metal grain boundaries and twin boundaries have virtually no effect on corrosion product distribution or orientation on specimen surface. Note dissolution pit-free region adjacent to grain boundaries.

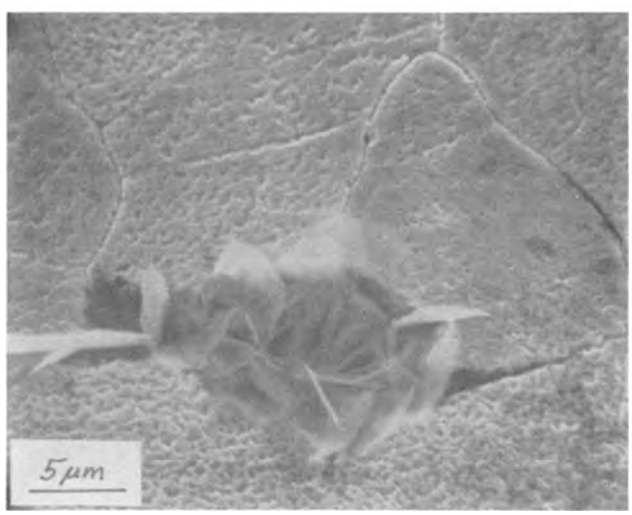

Fig. 7. Effect of base metal inclusions which are microcathodic relative to the matrix (a) accentuated zinc dissolution around such inclusions (b) pronounced corrosion product outgrowth over a grain-boundary situated particle.

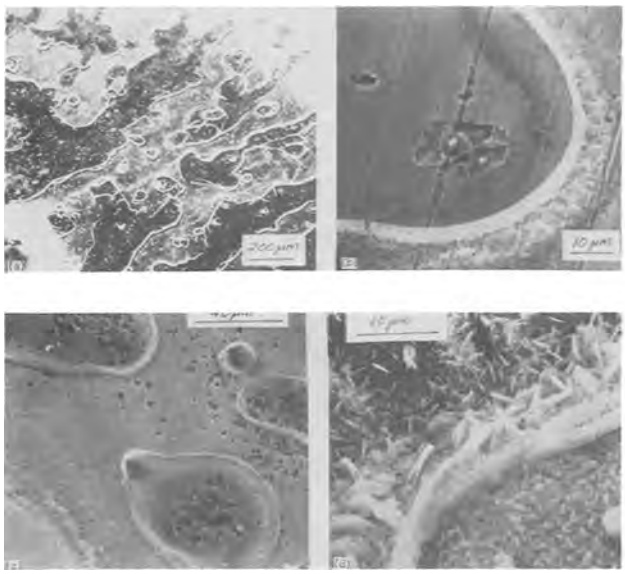

Fig. 8. Ribbonlike walls of corrosion product define interfaces between microscopic anodic and cathodic regions on the specimen surface at low galvanic current density (a) 5 min exposure at 0.775 mA/cm^2 current density and 25 cm/sec relative velocity; (b) 2 min exposure at 0.0775 mA/cm^2, stationary; (c) 2 min exposure at 0.155 mA/cm^2, stationary; (d) 40 min exposure at 1.55 mA/cm^2, 100 cm/sec.

presence of microcathodic inclusions at their centers (Fig. 8d).

Growth of these ribbonlike structures seems to continue until the walls have a given height and thickness, and they are eventually overgrown by a general network of ZnO platelets. The initial individual ZnO platelets form just to the inside of the walls encircling the dissolution pits (Fig. 8d). and in the early stages platelet nucleation is abruptly less pronounced outside the ribbon-encircled regions.

Velocity effects.—At a given current density, increased relative anode velocity leads to an increase in the number of dissolution sites per unit surface area, as seen in Fig. 9. Streaks originate from small local areas which have undergone a large amount of dissolution relative to the surrounding surface. Figure 9d shows one dissolution site at higher magnification. Increases in relative velocity increase the number of dissolution sites and associated streaks, and there is a decrease in the size of individual sites and the width of streaks.

Fluid dynamics has an important role in these changes in distribution of dissolution sites. This can be explained by considering the interaction between the hydrodynamic boundary layer and the electrochemical double layer (11). The hydrodynamic boundary layer constitutes a necessary transition layer in a fluid when there is relative motion between an object and that fluid. The fluid just next to the solid surface adheres to it without relative motion or slippage. Moving away from the surface, the relative fluid velocity changes until, at the extreme of the boundary layer, the free-stream condition of the bulk electrolyte is obtained. The electrochemical double layer refers to the distribution of ions which arises due to dissolution of the anode surface. With each added increment of relative velocity the velocity gradient in the hydrodynamic boundary layer is greater, and shear stresses at the specimen surface increase. Considering the observed increase in dissolution sites with increasing velocity, it may be inferred that increasingly irregular removal of metal ions to the hydrodynamic boundary layer occurs, leading to variable ionic concentration from place to place along the surface. Note that the role of physically microcathodic microstructural features is

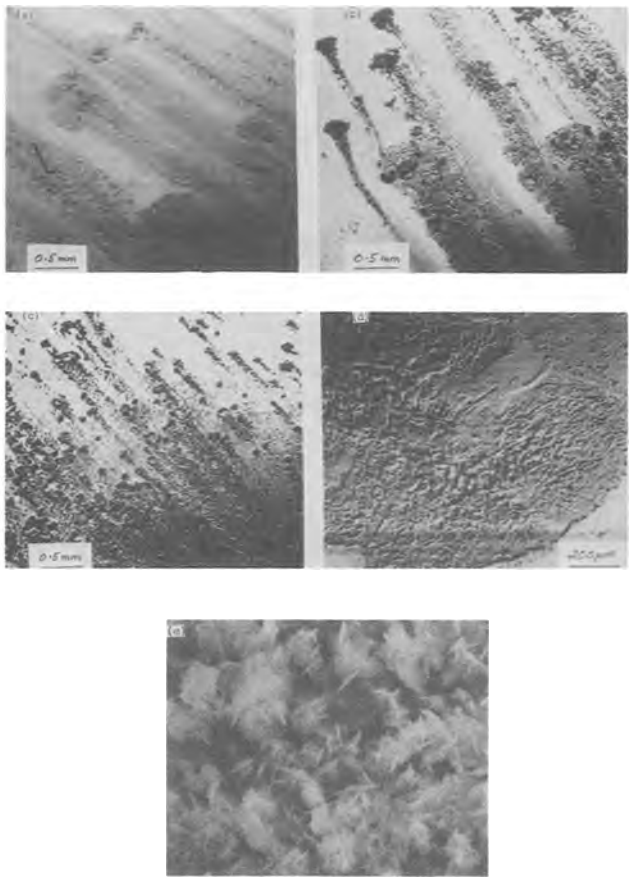

Fig. 9. Effect of relative anode electrolyte velocity on dissolution; all exposures 40 min at 1.55 mA/cm^2: (a) 50 cm/sec; (b) 125 cm/sec; (c) 150 cm/sec; (d) detail of dissolution site at 50 cm/sec; (e) high magnification view of platelet precipitation within dissolution site.

apparently reduced under dynamic conditions, as they do not seem to be preferred sites. To check the hypothesis that dissolution sites in dynamic situations are essentially independent of minor variations in surface character of the metal, artificial pits and scratches were cut into the specimen surface prior to corrosion; dissolution streaks were observed to pass over these features. They were not used as preferred nucleation sites for dissolution, whereas grinding scratches typically serve as preferred nucleation sites in static exposures. Therefore, the distribution of dissolution sites in dynamic exposures is considered to represent instabilities in the hydrodynamic boundary layer, rather than a base metal microstructural effect.

With respect to the precipitation step, the formation of ZnO platelets depends on the degree of metallic ion supersaturation in the electrolyte layer immediately above the anodic area on the surface. Figure 9e, which is a high magnification view of the dissolution site shown in Fig. 9d, shows a fine-scale platelet network, illustrating that supersaturation is still achieved and precipitation occurs under hydrodynamic conditions.

Farmer and Webb have considered the dependence of anodic zinc corrosion on electrolyte velocity with the aid of diffusion theory (12). They point out that development of a passivating film is dependent on attaining a certain critical concentration of zinc ions immediately at the electrode surface rather than in the electrolyte above it, so that passivation depends on the difference between the rate of ion formation and the subsequent rate of ion removal by the electrolyte. Ion transport from the surface can be described by reference to a hypothetical "diffusion layer" of electrolyte adjacent to the anode surface. A thick diffusion layer, such as would be expected to exist under more stagnant conditions, would inhibit ion removal and favor

passivating film growth, since ionic diffusion is relatively slow. Under laminar conditions (low relative anode velocity) the diffusion layer thickness can be assigned a value, δ, which is related to the hydrodynamic boundary layer thickness, δ_o, as: $\delta = \delta_o/Pr^{1/3}$, where Pr is the Prandtl number associated with ionic diffusion. For the particular electrolyte environment under consideration in these studies $Pr \approx 10^3$, so that $\delta \approx 0.1\delta_o$. The hydrodynamic boundary layer thickness in lamellar flow over a flat surface is inversely proportional to the square root of the relative free-stream velocity, so that both it and the diffusion layer decrease in thickness as the velocity increases. Therefore, the critical ionic diffusion path and the passivation tendency will decrease with relative velocity. Note that because of the inverse square root relationship passivation time will decrease and become less sensitive to velocity as velocity increases.

For flow conditions produced at higher relative velocities (>150 cm/sec in these studies) for current densities of natural galvanic values, the typical open network arrays of ZnO platelets are not favored, and instead, a thin compact film forms over an underlying fine-scale network array (Fig. 10). This film is quite fragile, however, and because of a cyclic film formation-cracking sequence, permanent anodic passivation does not occur under these conditions. Figure 10b reveals the sublayer present under a spalled area of the compact film. The boundary layer formed at this disk speed is probably turbulent. Turbulent boundary layers, of course, exhibit marked differences from laminar ones, with regions of intense fluid particle mixing and high shear stress on the surface. Rapid and uniform dispersion of zinc ions is inevitable under these conditions; in a sense this represents the limiting case for the observed increase in dissolution sites with boundary layer instability. It may be that because of the lack of supersaturation three-dimensional nucleation of ZnO platelets cannot occur, so that a two-dimensional lateral-growth mechanism gives rise to the more compact corrosion film. Therefore, it is likely that the observed undergrowth network was formed subsequent to formation of the compact film. As mentioned earlier, a tendency for this film to crack and spall was evident, indicating poor adhesion. It is likely that due to this cracking and loss of contact between the compact film and base metal surface, the platelet network is able to nucleate and grow under the film, where velocity effects would not be felt and supersaturation could easily be obtained. In fact, as the platelet network grows it may contribute to the tendency for the compact film to spall.

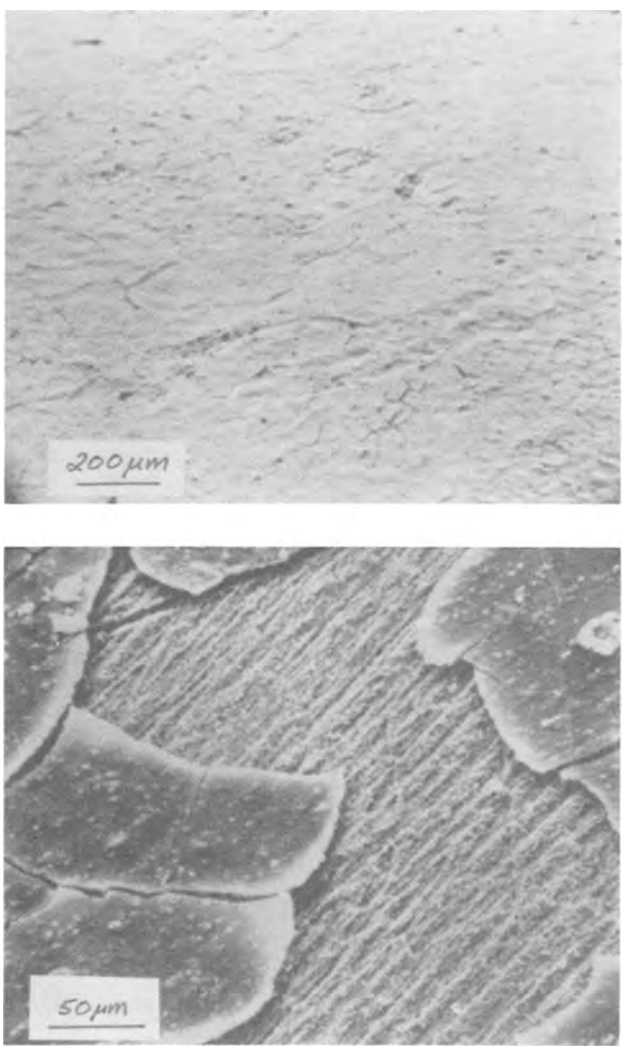

Fig. 10. (a) Fragile compact film formed under turbulent flow conditions; (b) fine network sublayer formed below compact film.

It should be noted that all the velocity effects discussed in this section refer to specimens galvanostatically corroded at a current density of 1.5 mA/cm^2, a value close to the experimentally determined approximate "natural galvanic" value. Later discussion of high current density effects will also include some consideration of the interaction between velocity and dissolution/precipitation processes.

Current density effects.—In galvanostatic exposures at zero relative anode velocity, increased current density yields more dissolution sites per unit surface area, thus leading to faster and more uniform corrosion product formation. This is illustrated in the series of photomicrographs in Fig. 11 for a given exposure time of 4 hr at zero velocity. The current densities in this series of exposures represent 1, 2, 3, and 5 times the typical natural galvanic values. Note that the exposures represent $i \times t$ products that also increase in this ratio. However, it is variation in the scale of the corrosion product network which is most notable. Keeping in mind magnification differences for the series of photomicrographs in Fig. 13, one can easily discern that the network structure nearest the base metal surface is finer for higher current densities, and that after this network is complete a secondary network is formed which commences at earlier times for higher current densities and attains a larger scale of size for a given time. Figure 12 schematically presents a model for the effect of current density on corrosion product structure.

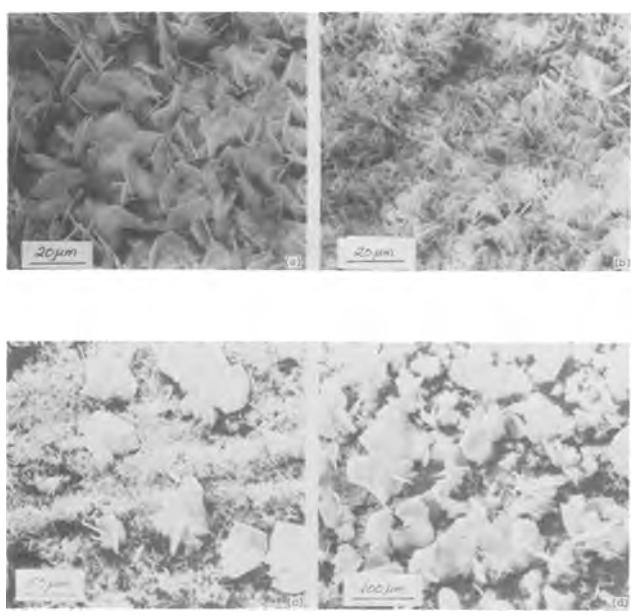

Fig. 11. Effect of current density for static exposures of 4 hr duration (a) 1.55 mA/cm^2; (b) 3.10 mA/cm^2; (c) 4.65 mA/cm^2; (d) 7.75 mA/cm^2.

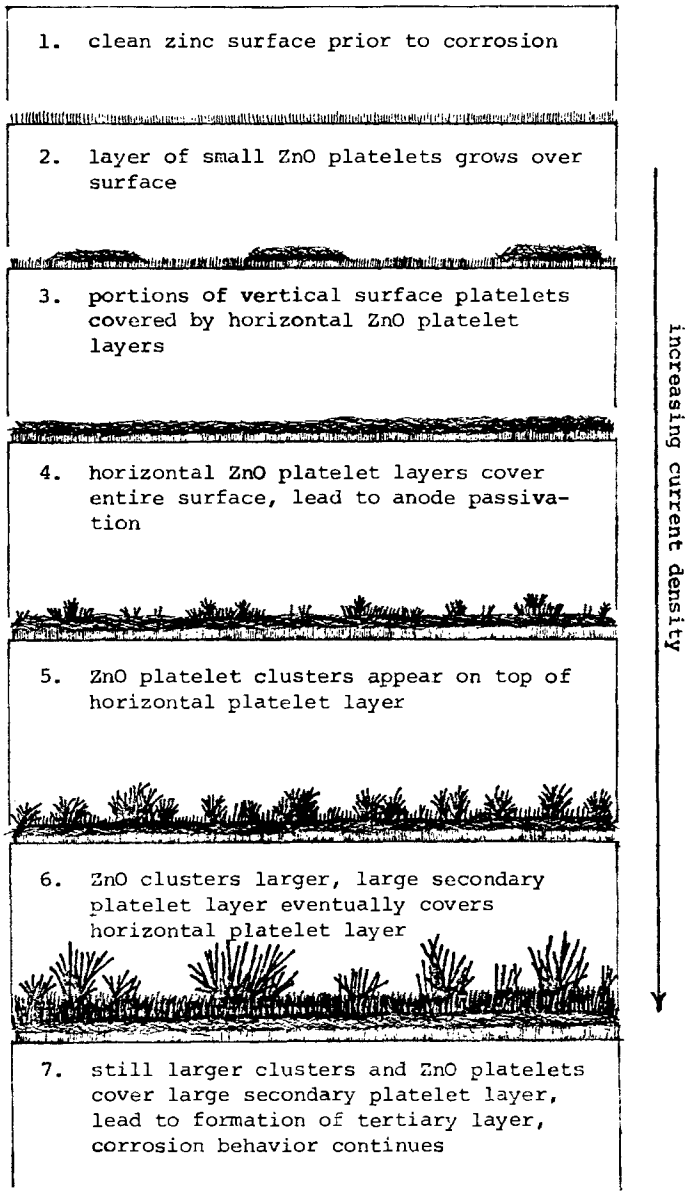

Fig. 12. Schematic model for the effect of current density on the development of corrosion product structure under static conditions.

Note that high impressed current density conditions do not lead to passivation in stationary exposures. The entire corrosion product structure consists of platelet networks with the outer networks increasing in scale, but with the entire structure microscopically porous and therefore nonpassivating. It is also noticed that as current density is increased velocity effects tend to be less evident. For example, at very high current densities (20 times natural galvanic values) high velocities had virtually no effect on the development of corrosion product structures. This is illustrated in Fig. 13, where the sequence of corrosion product formation with increasing time (at 31 mA/cm^2 and 200 cm/sec) is typical of what is observed under static conditions at lower current densities, *i.e.*, a sequence showing ribbons/dissolution pits (Fig. 13a-13c) and ZnO platelet network overgrowth (Fig. 13d). It was surprising that these fragile-appearing platelets sustain the turbulent high velocity conditions with virtually no damage. However, sections of the structure eventually do spall away, revealing the underlying ribbon structures still adhering to the base metal surface (Fig. 13e).

Conditions favoring passivating thick films.—From these studies the particular conditions favoring passivating corrosion product formation have become evident, as well as those conditions which tend to discourage passivation. The toughest, most compact films are favored by low current density, long-time exposures under static (no-flow) conditions. The film formed under these conditions consists of a layer of zinc oxide platelets compacted parallel to the anode surface over an underlying platelet network. It was shown in previous studies that the initiation of compact parallel structures is favored in the vicinity of microcathodic inclusions which modify the local field lines. The present studies show that even in the absence of such sites to trigger such formations parallel overgrowth layers will always tend to form in low current density, long-time, stationary exposures. On the other hand, high impressed current densities and turbulent flow conditions, as might be expected, tend to prevent passivation. Higher impressed fields preclude the formation of surface-parallel layers, while high velocities tend to impart mechanical stresses which crack and spall corrosion product layers, particularly as their thickness increases.

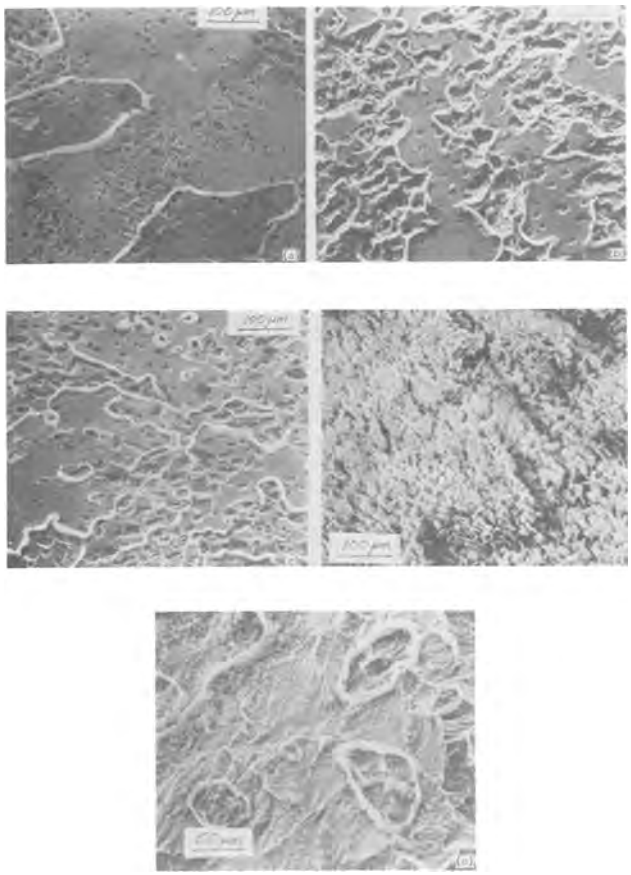

Fig. 13. High current density (31 mA/cm^2), high velocity (200 cm/sec) exposures indicates decreased velocity effect at high current density. Development of ribbon structures (a) 2 min; (b) 5 min; (c) 10 min; (d) 60 min (overgrowth of ZnO platelet network); (e) base metal surface exposed under spalled area of corrosion product formed at 60 min. Note underlying ribbon structures.

Conclusions

1. The typical structure of the corrosion product on zinc anodes in seawater consists of a three-dimensional network array of discrete single crystal ZnO (zinc oxide) plates.

2. Under galvanostatic conditions in still seawater, individual ZnO platelets initially precipitate after a current density time product of about 15 mA min/cm^2 is obtained. High current density conditions (above typical galvanic values) are not passivating in a stationary environment. These conditions promote growth of layers of primary and secondary platelet networks, with the outer layer much larger in scale.

3. Base metal microstructural inclusions which are microcathodic with respect to the zinc matrix cause ac-

centuated zinc dissolution and corrosion product formation around their periphery. The increased activity at these locations leads to locally denser corrosion product formations.

4. In galvanostatic exposures at zero relative anode velocity, increased current density yields more dissolution sites per unit surface area, thus giving faster and more uniform corrosion product formation. Turbulent flow conditions at relatively high velocities and at current densities typical of natural galvanic couples tend to disfavor the open network array typical of natural couples in still seawater, instead favoring a thin compact film over an underlying network of fine platelets. However, a cyclic film formation-cracking process prevents anode passivation under these conditions. High current density conditions (above typical galvanic values) are not passivating in a stationary environment. These conditions promote growth of layers of primary and secondary platelet networks, with the outer layer much larger in scale.

5. Compact, passivating thick films are favored by low current density, long-time exposures under no-flow conditions. The coherent film consists of ZnO platelets compacted parallel to the anode surface.

X-Ray Photoelectron and Auger Spectroscopic Study of the Underpotential Deposition of Ag and Cu on Pt Electrodes

J. S. Hammond[1] and N. Winograd*

Department of Chemistry, Purdue University, West Lafayette, Indiana 47907

ABSTRACT

The underpotential deposition of monolayer quantities of Ag and Cu has been studied using XPS and Auger spectroscopy. XPS chemical shifts of −0.65 and −0.95 eV *vs.* the bulk metal have been observed although no distinction was noted between the various underpotential states present in the cyclic voltammogram. The shifts were identical to vapor-deposited submonolayer films of Ag and Cu on Pt in the low coverage ($\theta \sim 0.1$) limit. A gradual shift with coverage to the bulk metal value for the vapor-deposited films and a constant shift with coverage for the underpotential deposit indicated that islanding was present only in the evaporated films. Measurement of the Cu and Ag Auger spectra gave results independent of the surface work function when compared to the XPS spectra. Interpretation of this Auger parameter is, however, at present ambiguous.

The faradaic deposition of monolayer quantities of metal cations on foreign metal substrate electrodes at potentials more anodic than the reversible thermodynamic Nernstian potential has been recognized for many years (1, 2). This underpotential deposition (UPD) phenomenon has been studied using a variety of techniques. For example, the underpotential deposition of Ag on Pt electrodes has been characterized using radioisotopic techniques (2-5), electrochemical techniques such as linear sweep voltammetry with stationary (6) and rotating ring-disk electrodes (7, 8), and specular reflection spectroscopy (9). The underpotential deposition of Cu^{2+} on Pt electrodes has also been extensively studied using linear sweep voltammetry (10), constant current coulometry (11), rotating ring-disk electrodes (12-15), and a combination of constant current coulometry and radioisotopic techniques (16, 17).

The coulometric results for Ag UPD (8) and Cu UPD (12-16) on Pt electrodes have shown that the metal ion is deposited in a zero-valent state with strong metallic bond interactions between the metallic adatoms and substrate electrode. Schultze (11), however, has concluded that copper atoms adsorbed at underpotential obey a Temkin isotherm. An electrosorption valency of $\gamma = 0.83$ was also reported where $2(1 - \gamma)$ represents the residual positive charge on the adsorbed copper atoms. The optical results of McIntyre and Kolb have also shown that the optical constants of the Ag underpotential deposit differ markedly from those of bulk silver metal (9). Further spectroscopic studies are, therefore, needed to elucidate the metallic nature of these underpotential-deposited films.

X-ray photoelectron spectroscopy (XPS or ESCA) has been established as a viable spectroscopic technique for the study of electrode surface states (18-20). The technique is well suited for analyzing the structure of the underpotential-deposited species due to its detec-

[1] Present address: Ford Motor Company, Scientific Research Laboratory, Dearborn, Michigan 48124.
* Electrochemical Society Active Member.

tion limit of 1% of a surface monolayer and its sensitivity to the electronic environment of the analyzed atom (21). A major disadvantage of the approach, however, is that the measurements must be carried out in the ultrahigh vacuum of the electron spectrometer. In this paper, we present the results of XPS analysis of underpotential-deposited Cu and Ag layers on Pt substrate electrodes. In addition, the results for *in situ* vapor phase deposition of Cu and Ag atoms on clean Pt foils are presented. The binding energies of core photoelectrons and Auger electrons show the spectral equivalence between electrochemical and vapor phase deposition of submonolayer quantities of copper and silver on platinum substrates. The observed binding energy chemical shifts conclusively reveal the metallic nature of the electrochemical UPD species.

Experimental

A potentiostat utilizing conventional operational amplifier circuitry is used to prepare the electrode samples. Electrolytes were prepared using reagent grade sulfuric and perchloric acids and water which is deionized, then doubly distilled. The electrode is a platinum plug 0.095 cm^2 in diameter press-fit into a Teflon holder 1.07 by 1.27 by 0.14 cm thick. This Teflon holder allows the electrode to be mounted onto the HP 5950A ESCA sample introduction probe and onto electrochemical cells. Due to the significant charging of photoelectron lines originating from insulating surfaces in an HP 5950A ESCA, any contamination originating from manual manipulation of the Teflon holder during transfer of the electrode from the cell to the sample probe is not observed in the XPS spectrum. Potentiostatic preparation of the electrodes was accomplished in a miniature cell of ~250 μliter internal volume (20). The typical electrolyte volume is 100-150 μliter minimizing the total dissolved contamination that could possibly adsorb on the electrode surface. If the total contaminant level is 10^{-6}M concentration in a 150 μliter electrolyte solution and all of this contaminant adsorbs on a 0.095 cm^2 geometrical surface area platinum electrode, assuming a one molecule contaminant to one platinum surface atom adsorption geometry, less than 0.7 monolayers of that contamination would appear in a subsequent XPS surface analysis. A tungsten pseudo-reference electrode is used to maintain potentiostatic control. All potentials are reported with respect to a saturated calomel reference electrode (SCE), as supplemental electrochemical experiments were carried out with the same electrolyte-working electrode combination in an electrochemical cell equipped with a SCE. Under potentiostatic control electrolyte is injected into the cell and removed using aspiration. The attenuation of the electrochemical current due to aspiration of the electrolyte from the cell occurs within the response time of the Hewlett-Packard 7035B X-Y recorder.

All experiments were completed at ambient laboratory temperature (20°-22°C). The electrodes were electrochemically cleaned by rigorous constant potential anodization at $> +2.0$V *vs.* SCE for 5-10 min. The solution was then aspirated under potentiostatic control, the potential adjusted to +1.2V, the electrolyte injected into the cell, and the electrode cycled using linear sweep voltammetry between +1.2 and 0.0V. This process was repeated until the electrode reproduced a clean *i vs. V* trace.

The XPS spectra were recorded on a Hewlett-Packard 5950A ESCA spectrometer using monochromated Al Kα x-rays. The use of monochromated x-ray flux decreases the total x-ray exposure by approximately two orders of magnitude and thereby minimizes x-ray decomposition. Platinum electrode samples were prepared in a Vacuum/Atmospheres HE 43-6 inert atmosphere box (Hawthorne, California) which encloses the ESCA sample introduction probe. A nitrogen atmosphere with a contamination level of <100 ppm was used. Details of the contamination levels observed on electrode surfaces after transfer have been reported (20). All binding energies are referenced to Au $4f_{7/2}$ at 83.8 eV. Other details concerning the ESCA sample handling system have been previously described (22).

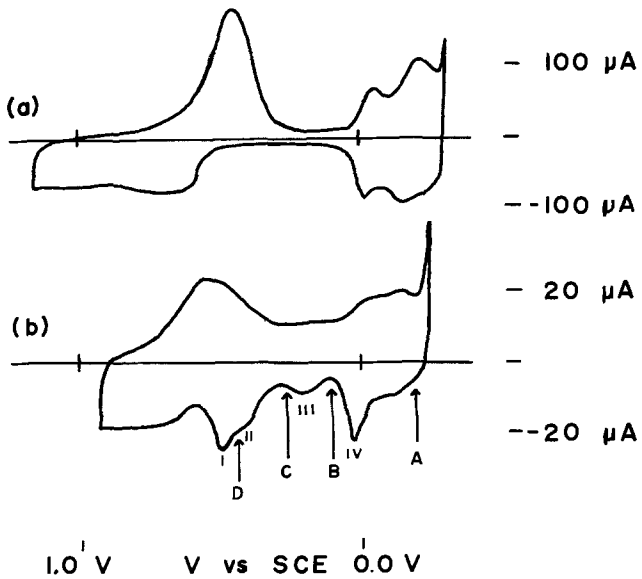

Fig. 1. Cyclic voltammograms for Cu-Pt UPD systems: (a) platinum electrode, 0.100M H_2SO_4 electrolyte, 100 mV/sec scan rate; (b) platinum electrode, 0.100M H_2SO_4 + 5 × 10^{-4} $CuSO_4$ electrolyte, 20 mV/sec scan rate. See text for explanation of I-IV and A-D designations.

Results and Discussion

The cyclic voltammograms for a Pt electrode in 0.10M H_2SO_4 and for a Pt electrode in 0.10M H_2SO_4 + 5 × 10^{-4}M $CuSO_4$ are shown in Fig. 1a and 1b, respectively. The cyclic voltammograms of the solution containing Cu(II) ions reveal four oxidation current peaks (labeled I-IV) not present in the 0.100M H_2SO_4 electrolyte. The potential associated with each peak and the potential separation between each peak and the potential for bulk anodic oxidation of copper is listed in Table I. The assignment of peak IV to the stripping of bulk copper metal can be confirmed by interrupting the potential scan at a working electrode potential of −0.25V *vs.* SCE for varying lengths of time and only the current associated with peak IV will increase during the subsequent anodic potential scan. The peak structures I, II, and III will retain their relative intensities and maximum current potential values with increasing cathodic deposition of copper(II). The assignment of peak structures I-III as the underpotential oxidation of copper on platinum agrees with previously published results (12-15).

To study the three peak structures associated with the Cu underpotential oxidation on Pt, the anodic potential scan was interrupted at the potentials designated A through D on Fig. 1b. The deposition of Cu at potential A (−0.23V *vs.* SCE) was continued for 60 sec before the solution was aspirated from the cell and the electrode removed for XPS analysis. After the anodic potential scan was interrupted at either potentials B, C, or D, the current associated with the oxidation of underpotential-deposited Cu decayed rapidly to

Table I. Peak current potentials for copper oxidation from platinum electrodes

Peak	Potential *vs.* SCE, V	Peak separation from bulk Cu oxidation
I	+0.50	+0.47
II	+0.41	+0.38
III	+0.21	+0.18
IV	+0.03	0.00

an insignificant value. If the positive potential scan was then reinitiated, the oxidative stripping peaks at potentials more positive than the interruption potential were still observed. This demonstrates the validity of interrupting the potential scan at a desired potential in order to investigate with XPS the more anodic features of the voltammogram.

The active electrochemical surface area of the platinum electrode electrochemically precleaned in 0.100M H_2SO_4 was measured by integrating the faradaic charge flow associated with hydrogen adsorption. Assuming one hydrogen atom per surface platinum atom, the electrode surface area was found to be 1.0-1.2 cm^2. By comparing the O adsorption current at +0.75V *vs.* SCE for Pt electrodes in 0.1M H_2SO_4 with and without 5×10^{-4}M Cu(II), the electrode surface area during UPD of Cu(II) was measured as 1.09 cm^2. Coulometric integration of peaks I, II, and III (Fig. 1b) averaged 271 μC or 46% of a monolayer using a value of 540 $\mu C/cm^2$ (15). The roughness factor (electrochemical surface area/geometrical surface area) of 11.3 indicates that our electrochemical cleaning produces a highly dispersed Pt surface layer in which the deposition of Cu becomes sterically hindered relative to the coulometrically measured hydrogen absorption sites. Assuming this coulometric value of 271 μC to equal one monolayer of copper UPD (12), coulometric measurement of the bulk deposition of copper for one minute at −0.17V *vs.* SCE produced a bulk deposit corresponding to a 5.8 average atomic layers of Cu. Assuming a covalent radius of 1.4Å, this bulk Cu deposit corresponds to an average thickness of 8.1Å. Coulometric measurement of peaks I and II indicates that peak III represents 10% of the total UPD Cu or an averaged thickness of approximately 0.1Å (see Table II).

The UPD Cu deposit is next transferred directly to the high vacuum environment of the XPS spectrometer. The measured binding energies of the UPD species are reported in Table II. These energies are in excellent agreement with those reported earlier (23).

The average calculated thickness of the copper adatoms on the surface of the platinum electrode can be determined from XPS spectra from the relationship

$$\frac{I_o}{I_s} = \frac{I_o^\infty}{I_s^\infty} \frac{\{1 - \exp[-d/(\lambda_o \sin\theta)]\}}{\{\exp[-d/(\lambda_o \sin\theta)]\}} \quad [1]$$

where I_o and I_s are the XPS intensities of the overlayer (o) and substrates (s), I_o^∞ and I_s^∞ are the photoelectron intensities of bulk samples of overlayer (o) and substrate (s) under an x-ray flux, d is the effective thickness of the overlayer in angstroms, and λ_o is the attenuation depth due to inelastic scattering of a particular observed photoemission core level. The sin θ term is due to the geometry of the sample and electron lens aperture. The ratio of I_o^∞/I_s^∞ for Cu $2p_{3/2}$/Pt $4f_{7/2}$ was determined empirically to be 3.07 for Cu and Pt foils which were cleaned *in situ* using Ar^+ bombardment. The attenuation depths are based on a λ $4f_{7/2}$ of Pt photoelectrons of 20Å (24) and a λ $2p_{3/2}$ of Cu photoelectrons of 12.5Å as calculated from the relationship

$$\lambda \propto \sqrt{h\nu - BE} \quad [2]$$

where $h\nu$ is the Al K_α photon energy and BE is the binding energy of the observed photoelectrons.

The calculated average thicknesses for Cu UPD on Pt electrodes at aspiration potentials A-D (Fig. 1b) are shown in Table II. The 10% decrease in the coulometric measurement of Cu UPD between aspiration potentials B-C is also reflected in the 10% average thickness decrease resulting from XPS intensity ratio measurements. However, a high degree of confidence should not be placed in the absolute calculated thickness values as significant error is to be expected from the simplicity of the homogeneous two-layer model and the exclusion of the photoelectron attenuation effects of the overlaying contamination and residual electrolyte layer (20).

The XPS binding energy shifts of the Cu $2p_{3/2}$ electrons relative to Cu $2p_{3/2}$ binding energy of bulk clean copper metal are reported in Table II for the Cu UPD electrode samples. Within the experimental uncertainty of ±0.1 eV for measuring the peak position of the Cu $2p_{3/2}$ photoelectrons, a −0.95 eV shift is observed for aspiration potentials B, C, and D. This indicates that the Cu $2p_{3/2}$ binding energy shift is not sensitive to the parameters that determine the electrochemical UPD peak structure and that the XPS core level shift is constant for coverages of Cu atoms up to an average coverage of one atomic layer. The Cu $2p_{3/2}$ binding energy shift of −0.50 eV for aspiration potential A indicates that although the electrochemical anodic stripping peaks indicate 4.8 layers of bulk Cu deposited over the UPD Cu, the XPS binding energy of these Cu atoms is still not indicative of bulk Cu metal. Further discussions of this multilayered Cu binding energy shift will be presented later. No shift of the Pt substrate photoelectron binding energies are observed.

To further characterize the Cu UPD electrodes, the $L_3M_{4,5}M_{4,5}$ Auger electrons of the Cu overlayers were measured. The Cu $L_3M_{4,5}M_{4,5}$ spectrum for bulk metallic Cu has a multipeak structure based on the multiplet splitting of the final states in the Auger electron process (25). For this reason only the binding energy equivalent of the kinetic energy of the most intense multiplet state will be used to assign the Auger binding energy. A binding energy shift of the Cu UPD Auger electrons relative to bulk Cu was not detected within the experimental uncertainty of determining the peak position (±0.2 eV).

To enhance the chemical significance of the spectral binding energy shifts for the Cu UPD electrodes, XPS data were obtained for anhydrous $CuSO_4$ CuO, and

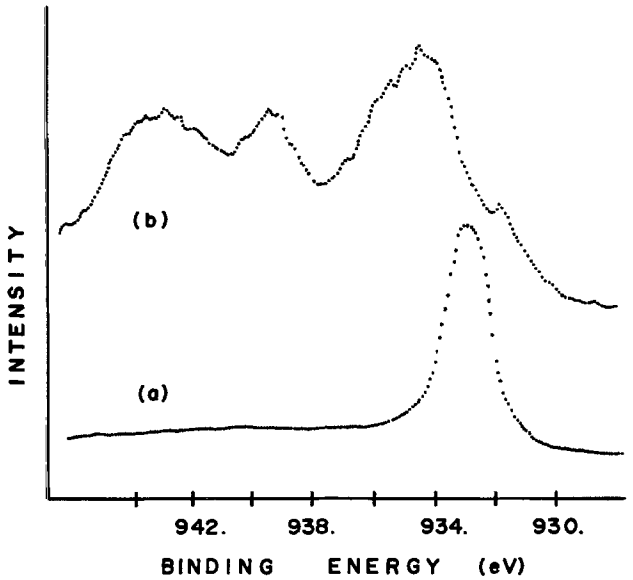

Fig. 2. Cu $2p_{2/3}$ spectra of Cu and $CuSO_4$: (a) clean Cu foil; (b) anhydrous $CuSO_4$.

Cu_2O. Figure 2, a and b, respectively, shows the Cu $2p_{3/2}$ spectra of Au^+ cleaned Cu foil and anhydrous $CuSO_4$. As noted in Table II, a +1.6 eV chemical shift is observed in the $CuSO_4$ Cu $2p_{3/2}$ binding energy relative to the clean bulk metal. A very intense Cu $2p_{3/2}$ shake-up satellite structure is also observed in $CuSO_4$ (Fig. 2b) with the satellite peaks having a binding energy separation of 4.9 and 8.5 eV from the parent peak. The satellite structure accounts for ~50% of the total Cu $2p_{3/2}$ intensity. Schön has also reported a +0.8 eV shift for the Cu $2p_{3/2}$ binding energy of CuO relative to bulk copper metal and strong satellite transitions to higher binding energy of the main parent peak (26). The appearance of strong satellite structure for Cu^{2+} species has been shown to be characteristic for a Cu d^9 compound (27). From the lack of any shake-up satellite structure and a −0.95 eV binding energy shift relative to bulk metal for the Cu UPD electrodes, the observed Cu photoelectron intensity cannot be associated with any Cu(II) species on the surface of the electrode. This eliminates any absorbed $CuSO_4$ or oxidized CuO (originating from oxidation of the electrode surface during the electrode transfer process) from being present during XPS analysis. The possibility of any Cu_2O on the surface of the electrode can be neglected due to the significant +1.9 eV binding energy shift of Cu_2O $L_3M_{4,5}M_{4,5}$ Auger electrons relative to bulk metal (see Table II). With the elimination of copper oxide or copper sulfate species as being present on the electrode surface, the binding energy chemical shift of the Cu UPD electrodes must be interpreted on the basis of a metallic structure.

In addition to the Cu adatom layer, significant quantities of residual electrolyte remain on the surface of the Pt electrode. By comparing the Cu $2p_{3/2}$/S $2p_{3/2}$ intensity ratios of pure anhydrous $CuSO_4$ with intensity ratios from the Cu UPD electrodes, and by comparing the S $2p_{3/2}$ binding energies, sufficient $SO_4^=$ is present to form a $CuSO_4$ stoichiometry (see Table II). From the separation between Cu $2p_{3/2}$ to Cu $L_3M_{4,5}M_{4,5}$ binding energies and the separation between Cu $2p_{3/2}$ to S $2p_{3/2}$ binding energies (see Table II), we can again rule out $CuSO_4$ compounds existing in the surface layer. The $SO_4^=$ or HSO_4^- is present as adsorbed electrolyte on the metallic electrode. Sulfate or bisulfate adsorption has been previously observed with XPS for Pt electrodes exposed only to sulfuric acid electrolytes (20). A similar experiment was performed by exposing unpolarized clean Pt electrode to a solution of 5×10^{-4}M $CuSO_4$ plus 0.10M H_2SO_4 for 4 min. After aspiration of the electrolyte from the electrode surface, the XPS spectral analysis of the electrode surface revealed a significant $SO_4^=$ intensity, agreeing with the previous results (20), but Cu $2p_{3/2}$ photoelectrons were not observed. This result further confirms our assignment of the XPS copper intensity recorded from Cu UPD electrodes as resulting from potentiostatic control of the electrode surface and not from extraneous deposition occurring during electrode transfer.

To complement the XPS analysis of UPD Cu on platinum electrodes, *in situ* vapor deposition of Cu on clean Pt permits the analysis of the interaction between Cu adatoms and the Pt substrate without the possible complicating influence of the residual electrolyte. The average calculated thicknesses of the Cu overlayer for several evaporations are listed in Table III. The thicknesses were calculated using Eq. [1]. The Cu $2p_{3/2}$ and Cu $L_3M_{4,5}M_{4,5}$ binding energy shifts relative to clean bulk Cu binding energy values are also listed in Table III. As with the Cu UPD electrodes, no shift of the Pt binding energies is observed due to the vapor deposition of copper adatoms. At very low coverages of copper adatoms, the Cu $2p_{3/2}$ binding energy shift matches the Cu UPD binding energy shift. As the amount of evaporated Cu is increased, however, its binding energy gradually approaches that of bulk metal at average calculated thicknesses well below monolayer coverage. In the UPD experiments, the binding energy is essentially constant with coverage until monolayer deposition is reached. We believe this discrepancy is related to the difference in the structure of the two deposited layers. In the UPD experiments, only copper ions which reduce to form a copper-platinum metallic bond can deposit at an UPD potential. This insures the formation of a complete two-dimensional monolayer of Cu adatoms before bulk Cu deposition can commence. This interpretation is consistent with the notion that Cu(o) displaces one monolayer of H in forming a uniform monolayer deposit (28). Without the electrochemical constraint on initial uniform growth, vapor phase deposition can produce a significant number of copper clusters or islands. These clusters or islands should have electronic structure approaching that of bulk Cu (29) while the XPS intensity ratios will reflect a submonolayer average thickness. The spectral convolution of these different copper geometrical groupings produced by vapor phase deposition will therefore cause a gradual increase in the Cu $2p_{3/2}$ peak binding energy with increasing calculated thickness of the vapor-deposited species.

The spectral convolution of different copper geometrical groupings can also explain the −0.5 eV Cu $2p_{3/2}$ binding energy shift for aspiration potential A (see Table II). Even though the XPS calculated average thickness of Cu is 12.6Å, a uniformly smooth nine-layer Cu adatom structure cannot be assumed. By analogy with the vapor phase deposition experiments, it seems likely that bulk electrochemical deposition of Cu proceeds through an islanding mechanism such that the aspiration potential A electrode has both thick clusters of bulk Cu and thin layers of UPD like Cu.

[d] Intensity ratios based on total integrated peak intensities.

The −0.5 eV binding energy shift is a convolution of these states.

The intensity ratios of Cu $2p_{3/2}$ to O 1s for the vapor-deposited Cu on Pt samples are listed in Table III as well as the Cu $2p_{3/2}$ to O 1s intensity ratio for Cu_2O. For all samples except one, less than one in three Cu atoms could be associated in a Cu_2O stoichiometry, even if all oxygen atoms were associated with copper atoms. The C 1s intensity was much lower than the O 1s intensity and, therefore, the binding energy shift of the Cu $2p_{3/2}$ photoelectrons must be a result of Cu-Pt interaction and not a result of copper atom interactions with other elements in the surface layer matrix. We believe that the similarity of the low coverage vapor deposition and UPD binding energy shifts is due to the same Cu-Pt interactions and that the effect of residual electrolyte on the Cu adatom is not reflected in the XPS spectrum.

We have also studied the UPD of Ag on Pt using XPS to observe specific differences between UPD and bulk silver deposition. As noted previously (8), the anodic stripping of UPD Ag occurs concurrently with the oxidation of the Pt substrate electrode. Without the use of a ring-disk type of electrode system, accurate coulometry to separate the two oxidation processes is very difficult. Therefore, the results presented in this paper will rest on the previously presented coulometric results (8) which show that the first monolayer of UPD Ag in 0.2M H_2SO_4 oxidizes over a broad potential range from 0.65 to 1.0V *vs.* SCE. The potential for maximum oxidation current of the UPD Ag occurs at approximately 0.74V *vs.* SCE. The cyclic voltammogram for a Pt electrode in 0.18M H_2SO_4 + 2×10^{-5}M Ag(I) was interrupted in the anodic scan at 0.60V *vs.* SCE by aspiration of the electrolyte. The electrode was then transferred to the XPS spectrometer. The average calculated thickness of Ag present as an UPD layer was obtained using Eq. [1] (see Table IV) Ftn[a]). The Ag present from XPS analysis corresponds to one-half to two-thirds of a monolayer. This is reasonable considering the low Ag(I) concentration and the 100 mV/sec scan speed used in the experiment.

To demonstrate that potentiostatic control of the electrode surface is maintained during aspiration of the electrolyte, electrolyte was aspirated from the microcell at a potential of +1.03V. From previous work (8) no Ag UPD adatoms should be present on the Pt surface at this oxidation potential. No trace of Ag was present in the XPS analysis with a detection limit of approximately 1% of a monolayer of Ag. In addition to cyclic voltammetry aspiration experiments, the cyclic voltammetric sweep of the Pt electrode was also interrupted in the Ag UPD region without simultaneous removal of the electrolyte from the surface of the electrode. Clean, unpolarized Pt electrodes were also exposed to the electrolyte for 4 min, the electrolyte was then aspirated and the electrodes transferred to the XPS spectrometer. The results of these experiments are listed in Table IV Ftn.[b] and [c], respectively.

The Ag $3d_{5/2}$ UPD binding energy shifts relative to clean bulk metal value of 368.2 eV average −0.65 ± 0.1 eV, a result in excellent agreement with those reported earlier (23). The Ag $M_5N_{4,5}N_{4,5}$ binding energy shifts relative to the clean bulk metal value of 1134.75 eV average 0.0 ± 0.15 eV. As with the Cu UPD electrodes, no binding energy shift of the substrate Pt photoelectrons was observed due to Ag UPD. To demonstrate that these binding energy shifts are truly representative of an Ag-Pt UPD surface state and not due to interactions with the residual electrolyte, data from samples of Ag_2SO_4, Ag_2O, and AgO are also listed in Table IV. A negative binding energy chemical shift is observed for the Ag $3d_{5/2}$ photoelectrons for these three compounds but a significant positive binding energy shift is observed for the Ag $M_5N_{4,5}N_{4,5}$ Auger electron for these same compounds. The binding energy difference between the Ag $M_5N_{4,5}N_{4,5}$ Auger electrons and Ag $3d_{5/2}$ photoelectrons indicates that the Ag UPD species is not an adsorbed Ag_2SO_4 or silver-oxide-like species. However, XPS analysis of the Ag UPD electrode surfaces reveals the presence of $SO_4^=$ or HSO_4^- ions due to the S $2p_{3/2}$ binding energy of ~168.4 eV. The intensity ratios of Ag $3d_{5/2}$ to S $2p_{3/2}$ are much lower for the electrode surfaces than for a pure sample of Ag_2SO_4. This discrepancy between the Ag $3d_{5/2}$ to S $2p_{3/2}$ binding energy separation values for the electrode samples *vs.* Ag_2SO_4 samples indicates, however, that the $SO_4^=$ or HSO_4^- is bound in the surface layer as residual electrolyte and is not interacting with the Ag atoms in an Ag_2SO_4-like compound. As was pointed out for the Cu UPD electrodes, XPS analysis of Pt electrodes exposed to H_2SO_4 electrolyte will always include a substantial $SO_4^=$ or HSO_4^- photoelectron intensity [see also Ref. (20)]. Ag atoms with an UPD-like Ag $3d_{5/2}$ and Ag $M_5N_{4,5}N_{4,5}$ binding energy shift were also observed after exposure of unpolarized electrodes to the electrolyte solution. This contrasts the absence of any XPS Ag intensity after aspiration at +1.03V *vs.* SCE and points out the validity of our aspiration technique for removing the electrolyte from the electrode surface under potentiostatic control. If electrolyte remained on the electrode surface without potentiostatic control after aspiration at +1.03V *vs.* SCE, Ag should be present in the XPS analysis.

Following a pathway analogous to the Cu experiments, we studied the *in situ* vapor deposition of silver on clean platinum. The average calculated thicknesses, based on Eq. [1], of the Ag overlayer for several evaporations are listed in Table V. The Ag $3d_{5/2}$ binding energy shifts relative to clean bulk Ag binding

energy values are also listed in Table V. As with the silver UPD electrodes, no shift of the Pt substrate photoelectron binding energies is observed due to the vapor deposition of silver adatoms. It is noteworthy that the sample with an average calculated thickness of 6.85Å still has a −0.20 eV binding energy shift relative to bulk Ag. The tendency toward clustering exhibited in Cu vapor phase deposition could be responsible for islands of bulk silver with patches of UPD-like silver being convoluted into the Ag $3d_{5/2}$ spectrum. The intensity ratios of Ag $3d_{5/2}$ to O 1s for the evaporated silver on platinum samples do not rule out the possibility of oxide or oxygen silver atom interaction, but previous experimental data do not support the formation of such an oxide layer (22).

Comparison of the UPD species to the samples prepared by vapor deposition defines the metallic rather than ionic nature of the overlayer. The lack of movement of the peak position with surface coverage for the electrode samples also yields indirect evidence for a uniform deposit *vs.* aggregate formation in the vapor deposition experiments. The next question of interest is to elucidate the electronic properties of the adatom layer by careful examination of the observed chemical shift of the UPD species *vs.* the bulk species. It is this important question on which we now focus our attention.

The most successful progress to date in characterizing the bonding of metal adatoms on foreign metal substrates has been made by studying alkali metal adsorption on several transition metal surfaces. At low coverages, the alkali metal adatom forms a dipole with the metal surface and significant charge transfer occurs from the adatom to the substrate. The changes in the macroscopic work function and the alkali adatom energy loss spectra as a function of coverage both indicate positive charge localization on the adatom (31).

For transition metal adatoms on foreign transition metal substrates, the interpretation appears to be somewhat different. The adsorption of Hg on W(110) (32), Ni(100) (33), and Cu(111) (34) as well as solid phase Hg (35) has recently been studied by electron spectroscopy. The ultraviolet photoelectron spectra for Hg vapor adsorbed on Ni(100) reveal that there is no change in the work function between the atomically clean Ni(100) surface and the Ni surface saturated with adsorbed Hg (33). The work function remains 5.03 eV, representative of pure Ni(100), in contrast to the work function of bulk Hg of 4.49 eV (35). This differs dramatically with the results from alkali metal adsorption where the work function at monolayer coverage of alkali adatoms approaches the bulk work function of the alkali metal (31, 36). For these Hg adsorption systems, the electronic density of states of the substrate continue to define the density of the surface electrons and hence the work function stays constant.

The binding energy shifts in XPS core level spectra generally correlate with the charge density of the observed atom. However, to provide an interpretation of changes in charge density, the core level binding energy must be referenced to the vacuum level (37). For solid conducting samples, however, the experimental binding energies are referenced to the sample Fermi level, E_B^F, with the vacuum level binding energy, E_B^V, equal to E_B^F plus the bulk work function ϕ. For chemisorption studies, the relationship between E_B^F and E_B^V for the adsorbate layer has not yet been clearly defined. Several approaches have been suggested, the most recent of which is by Hagstrum who points out that the ionization energy of a surface orbital can best be approximated by the Fermi level referenced binding energy of that orbital plus the work function of the saturated uniformly covered surface (33). This relationship only holds, however, in the absence of significant adsorbate-adsorbate interactions at the full coverage limit.

One possible approach for dealing with this problem is through the use of the Auger parameter (38). The kinetic energy for a jkk Auger transition can be approximated

$$E^V(jkk) = E_B^V(j) - 2E_B^V(k) - F + 2E_R + R_e \quad [3]$$

where $E^V(jkk)$ is the vacuum level referenced kinetic energy of the jkk transition, $E_B^V(j)$ and $E_B^V(k)$ are the vacuum level referenced one electron binding energies of the j and k orbitals, F is the hole-hole interaction term due to the double ionization of the final state, $2E_R$ is the intra-atomic "static" relaxation contribution to the second $E_B^V(k)$ binding energy due to the previous creation of a k hole state, and R_e is the extra-atomic relaxation (39). The binding energy equivalent to the $E^V(jkk)$ kinetic energy is $E_B^V(jkk)$ where

$$E_B^V(jkk) = h\nu - E^V(jkk) \quad [4]$$

The Auger parameter α is then defined as

$$\alpha = E_B^V(j) - E_B^V(jkk) \quad [5a]$$

$$= E_B^F(j) - E_B^F(jkk) \quad [5b]$$

$$= 2E_B^F(j) - 2E_B^F(k) - F + 2E_R + R_e - h\nu \quad [5c]$$

The Auger parameter is, in fact, independent of the sample work function and either E_B^F or E_B^V values can be used. The difference in the Auger parameter $\Delta\alpha$ can then be defined as

$$\Delta\alpha = \alpha_{metal} - \alpha_{UPD} \quad [6]$$

where α_{metal} is the Auger parameter for the bulk metal of the UPD species and α_{UPD} is the Auger parameter for the UPD adsorbate species (38). For the Ag UPD system, $\Delta\alpha$ is +0.65 eV and for the Cu UPD system $\Delta\alpha$ is +0.95 eV.

The experimental $\Delta\alpha$ term should now be compared to the individual terms of Eq. [5c]

$$\Delta\alpha = \Delta(2E_B^F(j) - 2E_B^F(k) - F + 2E_R + R_e) \quad [7]$$

The F and $2E_R$ terms are considered atomic properties and should not vary from the bulk to UPD samples (39). From the ground-state sphere model, the relaxation contribution, ΔR_e, should be the major contribution to the $\Delta\alpha$ parameter (38). The experimental $\Delta\alpha$ values of +0.65 and +0.95 for Ag and Cu UPD therefore suggest an increase in extra-atomic relaxation for the Ag and Cu adatoms relative to bulk Ag and Cu metals, respectively.

One present theory for extra-atomic relaxation in metals is based on the formation of a semilocalized exciton (40). Coincident with core hole photoionization, the first unoccupied orbital in the photoionized atom drops below the Fermi level and is filled with an electron from the conduction band. For metal adatom adsorption on foreign metal substrates, this semilocalized exciton model predicts that the extra-atomic relaxation should be matrix independent. Therefore, either the semilocalized exciton model is inappropriate for the UPD binding energy shifts or relaxation effects are not responsible for the $\Delta\alpha$ shifts.

If we now assume that the ΔE_R term is negligible, the positive $\Delta\alpha$ values must be interpreted as shifts in the $E_B^F(k)$ terms. For Ag UPD, the $\Delta 2E_B^F(k)$ value is −0.65 eV and for Cu UPD, the $\Delta 2E_B^F(k)$ is −0.95 eV.

The ground-state sphere model assumes that the orbital separation, $E(j) - E(k)$, stays constant. One would therefore predict a $\Delta 2E_B^F(k)$ value for Ag UPD of -1.30 eV and -1.90 eV for Cu UPD. Assuming no change in relaxation, the k orbitals for Ag and Cu UPD adatoms would now appear at higher binding energies relative to the core j orbitals. It is noteworthy that a similar decrease in the core to valence level orbitals separation is observed from gaseous Hg to solid Hg (35). The relative higher binding energy of the valence level can be directly correlated with the cohesive energy of the solid Hg (35). It is tempting to use the same interpretation for the UPD spectra. The electrochemical oxidation of the UPD species at more positive potentials than bulk metal anodic stripping indicates that the cohesive energy of the UPD adatom-substrate system is higher than the bulk-deposited metal. The Auger parameter is then measuring this increase in cohesive energy.

The increase in cohesive energy as measured by $\Delta\alpha$ may now provide a comparison with the empirical correlation of Gerisher *et al.* (41, 42). The underpotential shift, ΔUp, the potential difference between bulk metal oxidation and underpotential adatom oxidation, is found to be proportional to the difference in the bulk work functions, $\Delta\phi$, of the adsorbate and substrate metals such that

$$\Delta\text{Up} = 0.5\ \Delta\phi \qquad [8]$$

where ΔUp and $\Delta\phi$ are in units of volts and electron volts, respectively. The $\Delta\phi$ may be compared with experimental increase in cohesive energy of the UPD samples. However, the experimental uncertainty in our measurements and the lack of experimental $E_B^F(k)$ values indicate that our interpretation at this time is not unambiguous and that further quantitative correlation between $\Delta\alpha$ and $\Delta\phi$ values would be highly speculative.

It is difficult to define the $E_B^F(j)$ values for the UPD adatom species. The alkali adatom adsorption experiments suggest the use of the bulk adatom metal work function. This assumption leads to a negative chemical shift for the Ag $3d_{5/2}$ photoelectrons which seems physically unreasonble. The use of the bulk Pt work function, as suggested by the Hg adsorption experiments (32-34), leads to the assignment of some partial charge on the Ag adatoms. This is more reasonable from the standpoint of increased cohesive energy influencing the initial state orbital energies. Further experimental and theoretical advances are needed to more fully elucidate this point.

Conclusion

The ESCA results indicate that in the absence of an applied electrochemical potential, binding energy shifts are observed in the core photoelectron spectra which are distinctive of the UPD adatom surface states. The binding energy shift is insensitive to the parameters responsible for the multiple UPD anodic stripping peaks and remains constant with coverage. The vapor deposition at low coverages models the UPD deposition and demonstrates the metallic nature of the UPD surface layer. The interpretation of the binding energy shifts is not without ambiguity, but is consistent with an increase in cohesive energy of the UPD surface layer. The $\Delta\alpha$ parameter permits the analysis of the binding energy shifts without requiring the determination of the sample work functions. Further study of the valence level binding energies for the UPD adatoms should be completed, however, before the interpretation of $\Delta\alpha$ values can have meaning.

Iron Oxide Semiconductor Electrodes in Photoassisted Electrolysis of Water

Lun-Shu Ray Yeh* and Norman Hackerman†

Department of Chemistry, Rice University, Houston, Texas 77001

ABSTRACT

The preparation of polycrystalline n-type iron oxide electrodes by heating of iron samples in air is reported. The behavior of these electrodes in aqueous solutions of different *p*H values in the presence and absence of illumination is shown. The photocurrent response of these electrodes to all wavelengths in the visible region is seen. Photoassisted electrolysis of water occurs at these wavelengths resulting in the evolution of oxygen bubbles at the iron oxide electrodes with no noticeable corrosion problems in *p*H 4.0 acetate buffer to 5.5M KOH solutions

Recently there has been much interest in utilization of semiconductor electrodes for electrochemical studies (1-4) and for solar energy conversion by the photoassisted electrolysis of water (5-8). An electron transfer between electrode and electrolyte occurs only if either the conduction band or the valence band in the semiconductor overlap with the occupied or unoccupied states in the electrolyte. Therefore, large bandgap semiconductor electrodes have been particularly interesting in electrochemical reactions because they offer the possibilities for studies of the energy parameters of fundamental charge transfer processes. Large bandgap electrodes, such as TiO_2 (3, 5, 6, 8) (bandgap: 3.2 eV), ZnO (4, 9) (bandgap: 3.1 eV), and SnO_2 (10-12) (bandgap: 3.8 eV) have been studied considerably. On the other hand, small bandgap semiconductor electrodes are particularly useful to decompose water by utilizing solar energy.

By illuminating an n-type semiconductor with light energy greater than the bandgap of the semiconductor, holes are generated in the valence band by exciting electrons to the conduction band. These holes move to the surface of the electrode under anodic polarization where they can transfer to the electrolyte. Therefore, a suitable semiconductor electrode can be used to oxidize water to oxygen or oxidize one chemical species to the other by utilizing solar energy. In utilizing solar energy, one would like to use as much energy as possible from the sunlight. This requires a small bandgap semiconductor. Unfortunately, small bandgap semiconductors such as Si (13) (bandgap: 1.1 eV) and CdS (14) (bandgap: 2.4 eV) decompose under anodic polarization or illumination. In fact, a nondestructive or nondecomposing semiconductor is hard to obtain. Only TiO_2 (5, 6, 8), SnO_2 (11, 15), and $SrTiO_3$ (8) electrodes with bandgaps greater than 3.0 eV are known to be capable of oxygen generation from water without electrode material destruction. It is also known that only about 3% of the total solar spectra (wavelengths shorter than 400 nm) is useful for these large bandgap electrodes (7) and the rest is wasted. Therefore, in order to utilize solar energy efficiently it is important to develop a practically useful material which is nondestructive and is capable of using the greater part of the incident solar photons.

Iron oxide film semiconductor electrode has been prepared by chemical vapor deposition by Hardee and Bard (16) to observe a photocurrent response up to 550 nm. Although wavelengths greater than 550 nm, the greater part of the solar incident photons, are inefficient, the electrode does offer some advantages because of its relative stability in high *p*H solutions. We report here a simple way of electrode preparation by heating the iron samples in natural gas flame resulting in an unexpected small bandgap n-type semiconductor with an extraordinary stability in both acidic and basic solutions.

Experimental

Several iron and steel samples were used to prepare the polycrystalline semiconductor electrodes. These included zone-refined iron (generously donated by Batelle Memorial Institute), magnetic iron (obtained from Armco Steel Company, 99.9%), and cold-rolled steel (99%). The samples were cut into about 1 × 1 cm square by 2 mm thick and polished with emery paper. All samples were then cleaned in distilled water and degreased in methanol prior to use. The samples were then placed in the flame of a Fisher burner for about 15 min. The samples became red hot during this treatment and upon removal from the flame a uniform, smooth, dark gray oxide appearance was seen on the samples. An iron wire was attached to the substrate under the oxide layer by removing the oxide layer using a file around a small hole which was drilled before the substrate was heated. The iron wire was fastened on the bare metal around the hole to provide the electrical contact. The oxide layer was fairly thick and different in color than the bare metal. Silicon adhesive, from Dow Corning Company, Midland, Michigan, was used to coat the iron wire and the bare metal on the substrate. Only iron oxide, as the electrode, was exposed to the solution.

All solutions were prepared with triply distilled water, with the first distillation from potassium permanganate in deionized water, and all chemicals were reagent grade. A simple three-compartment cell containing a Luggin probe for reference electrode, platinum foil counterelectrode, and iron oxide working electrode was used for electrochemical measurements. A saturated calomel electrode (SCE) was used as the reference electrode.

The potentiostat and ramp generator used were constructed in this laboratory using Teledyne-Philbrick operational amplifiers and the design was similar to that already published (17). Data were recorded on a Moseley Autograf (Model 2DR-2) or a Hewlett-Packard (Model 7044A) X-Y recorder. For photoexcitation experiments, a 500W General Electric quartzline lamp with very little focusing was used. A 0.25m Jarrell-Ash monochromator, Model 82-410, was used to obtain the photocurrent-wavelength curves. The action spectrum was also obtained by irradiating the electrode through a circular graded interference filter (Barr and Stroud, Limited. A 5 mW spectra-Physics Stabilite™ helium-neon laser (Model 120) and exciter (Model 256) with monochromatic light output at 632.8 nm was also used for the photoexcitation experiments.

Results and Discussion

The current (i) *vs.* voltage (E) curves of iron oxide electrodes, prepared from zone-refined iron, in various solutions are shown in Fig. 1. Under the illumination there is a large rise in anodic current commencing at about +0.3V *vs.* SCE in pH 4.0 solution, at +0.15V in pH 8.4 solution, at −0.2V in pH 12.0 solution, and at −0.5V in 5.5M KOH solution. The dark current in this potential region is essentially zero. Oxygen gas evolution appears promptly with the rise of the anodic current and is quite noticeable on the electrode surface, implying that the reaction is photoassisted oxidation of water to oxygen gas. Oxygen gas evolution occurs in the dark on the iron oxide electrode at about 0.9V more positive than when the electrodes are under illumination. The oxidation in dark at high positive potentials is probably due to the result of tunneling electrons into the conduction band of the semiconductor after the band bending (18). The potential for the onset of the photocurrent shifts to more negative potentials with increasing pH values. This shift is shown in Fig. 1 with about 60 mV shift per unit pH change. The photocurrent onset potentials varied somewhat for different electrodes. Some electrodes with photocurrent onset potential occurred at about +0.5V in pH 8.4 solution, and the nonphotoassisted oxidation current at large positive potentials added to the photoassisted current to mask the appearance of photocurrent plateau. These curves are not shown here. The variation of the photocurrent onset potential from one electrode to the other (0.1-0.2V variation for most electrodes) remains unexplained in this study. Iron oxide electrodes prepared from magnetic iron or cold-rolled steel also showed similar current-voltage curves as shown in Fig. 1 with somewhat smaller current response compared to that from zone-refined iron.

The photocurrent of a semiconductor electrode depends primarily upon the intensity of the incident light providing that the incident light has an energy equal to or higher than the bandgap of the semiconductor electrode. No attempt was made to increase the focusing or the intensity of the light source. An experiment was conducted in a solution containing borate buffer (pH 8.4) with 25 mM equal molar mixture of $K_4Fe(CN)_6/K_3Fe(CN)_6$ and the result is shown in Fig. 2. In the dark the reduction current of $Fe(CN)_6^{-3}$ becomes noticeable at −0.1V and increases rapidly as the potential becomes more negative. A small oxidation current is also seen in the potential range where no oxidation current can be observed when the $K_4Fe(CN)_6/K_3Fe(CN)_6$ couple is absent. The oxidation current was also seen for Fe^{+2} at a highly doped n-type ZnO semiconductor electrode, and this was interpreted as due to the tunneling effects (19). Under illumination of the unfocused sunlight the oxidation current increases appreciably as shown in Fig. 2. This indicates that the semiconductor electrode is capable of using the sunlight in photoassisted oxidation.

The iron oxide electrodes appeared stable in all solutions from a pH of 4.0 acetate buffer to 5.5M KOH. Continuous potential scans in the range shown in Fig. 1 produced no noticeable changes in current-voltage curves or in the surface appearance of the electrode in these solutions. Also no aging effect was found in a period of 2 months. There was no detectable current change after holding the electrode for 1 hr at +1.0V in a pH of 4.0 (acetate buffer), at +0.8V in pH of 8.4 (borate buffer), at +0.6V in pH of 12.0 (phosphate buffer), or at +0.3V in 5.5M KOH solution. Under these conditions the electrode was covered with gas bubbles and gas bubbles were continuously evolved.

The photocurrent response *vs.* wavelength of the incident light is shown in Fig. 3a for iron oxide electrode prepared from zone-refined iron, Fig. 3b for that from

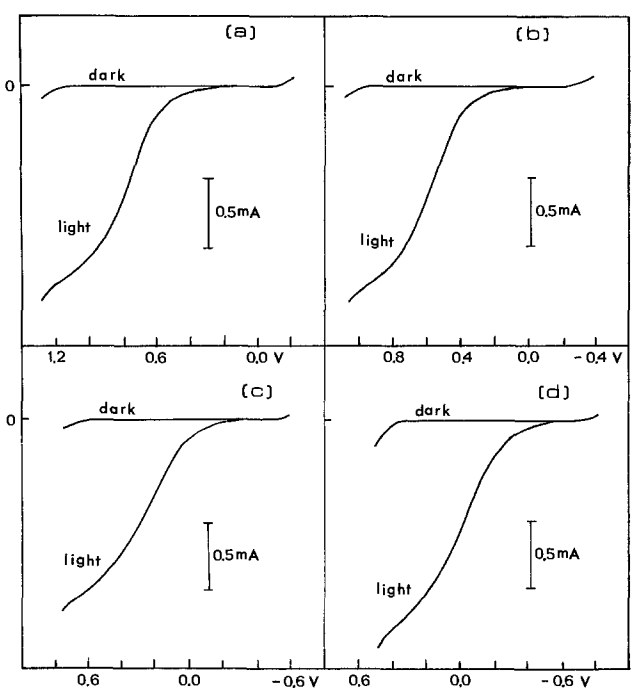

Fig. 1. Current *vs.* potential (*vs.* SCE) curves for iron oxide electrode prepared from zone refined iron with the electrode area of 1 cm^2 in 0.2M $NaNO_3$ solutions buffered to pH (a) 4.0, acetate, (b) 8.4, borate, and (c) 12.0, phosphate. Curve (d) is for 5.5M KOH.

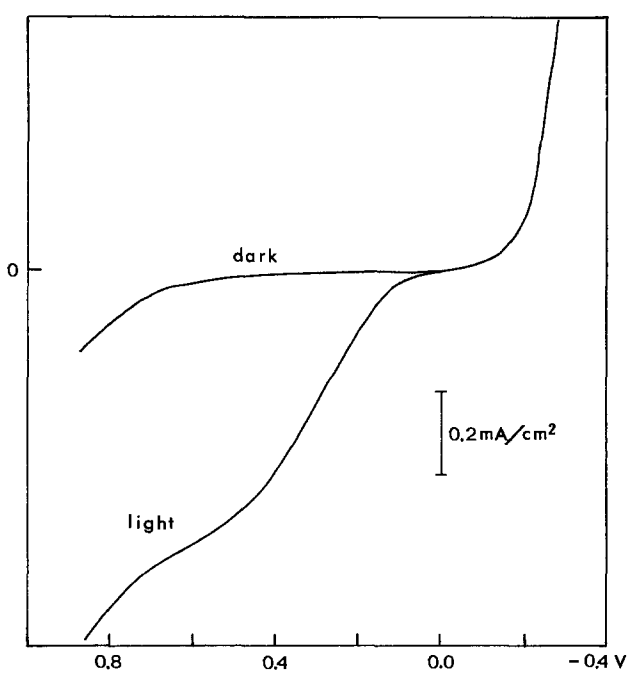

Fig. 2. Current *vs.* potential (*vs.* SCE) for iron oxide electrode prepared from zone refined iron with the electrode area of 1 cm^2 in pH 8.4 borate buffer (0.3*N*) solution containing 25 mmole equal molar mixture of $K_4Fe(CN)_6/K_3Fe(CN)_6$.

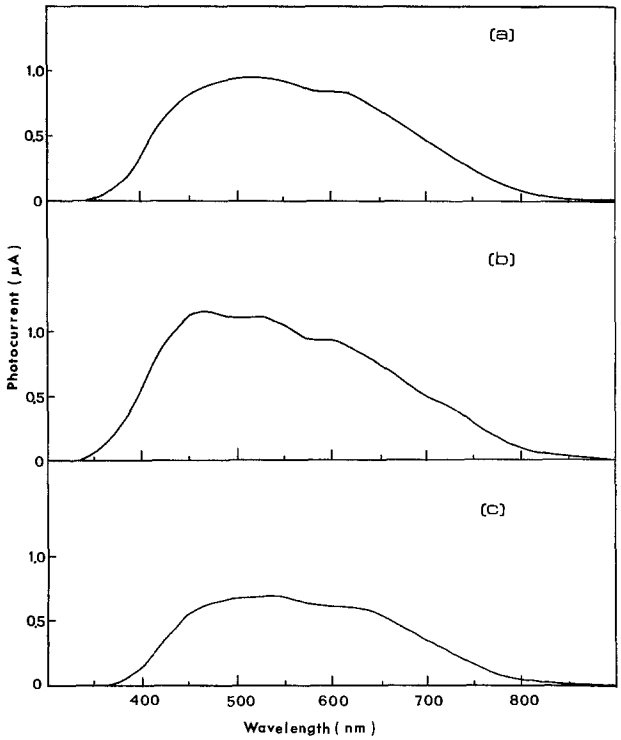

Fig. 3. Photocurrent *vs.* wavelength at a potential $E = +0.80V$ *vs.* SCE in 0.2M $NaNO_3$ solutions buffered to pH 8.4 (borate). Electrodes prepared from (a) zone refined iron, 10 nm band pass slits used for the monochromator, (b) magnetic iron, and (c) cold-rolled steel.

magnetic iron, and Fig. 3c for that from cold-rolled steel. The spectral response was recorded at $E = +0.8V$ in pH of 8.4 solutions. The incident light was not focused for these experiments and 10 nm band pass slits were used for the monochromator in Fig. 3a; no slits were used for Fig. 3b and 3c. The spectral response of all these iron oxide electrodes was essentially identical in shape and wavelength region. The coverage of all wavelengths in the visible region of these electrodes was rather unexpected, since the bandgap of Fe_2O_3 was reported to be 2.2 eV (20). This indicated that the photocurrent would decay to zero at 550 nm. Hardee and Bard (16) also observed this result for an iron oxide electrode prepared from iron acetylacetonate ($Fe(C_5H_7O_2)_3$) by chemical vapor deposition. Instead of showing no photocurrent response at 550 nm, the greater part of the incident sunlight, our electrodes showed maximal response there. The photocurrent response covered the whole visible region and extended to 850 nm. This corresponds to a semiconductor electrode with energy bandgap of 1.4 eV. Similar results were shown from different electrodes prepared here, and with excellent agreement. The extraordinarily small bandgap does provide the advantage of using the whole region of the sunlight spectra.

The photocurrent response was also performed using a 5 mW helium-neon laser with wavelength output at 632.8 nm. The result is shown in Fig. 4a to provide other evidence of the photoassisted oxidation using the low energy photons. It is interesting to point out that an anodic transient current appeared when the very weak intensity monochromatic light was turned on. These sharp anodic transients decayed fairly fast to a steady photocurrent with intensities being about a half of the peak value. When the monochromatic light was turned off a cathodic transient current with the peak about a half of the anodic transient peak was observed. However, the transients disappeared by increasing the light intensity to polychromatic light as shown in Fig. 4b. The transient response was also observed by Memming *et al.* (21) at a TiO_2 electrode when the potential was held on the rising portion of the *i-E* curve. In

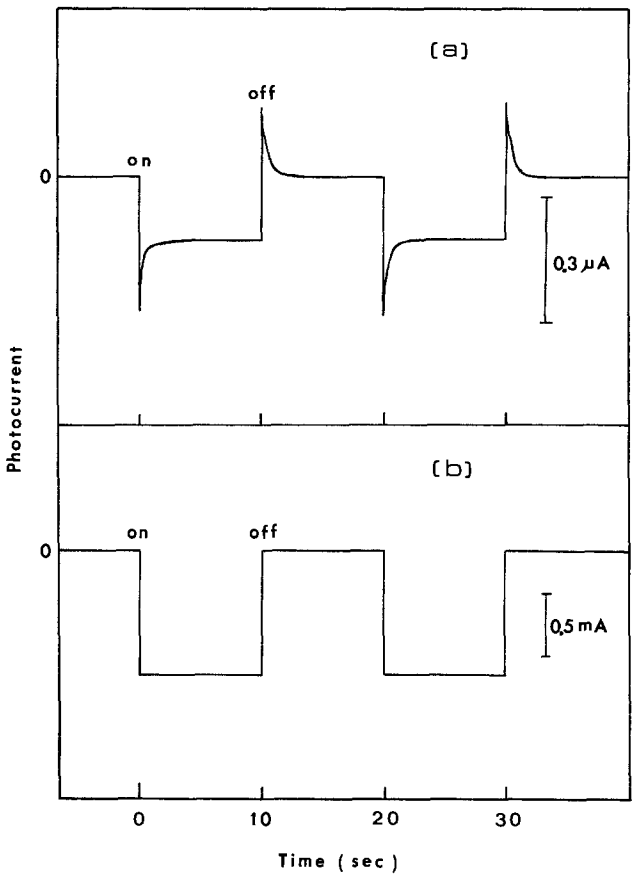

Fig. 4. Photocurrent transient (*i-t*) curves for iron oxide electrode prepared from zone refined iron in 0.2M $NaNO_3$ solutions buffered to pH 8.4 (borate) at a potential $E = +0.80V$ (*vs.* SCE) with photoexcitation source of (a) 5 mW laser monochromatic light at 632.8 nm, (b) white light.

the higher potential range at a well-defined current plateau, those transient peaks disappeared at TiO_2. Due to the lack of a well-defined current plateau at the iron oxide electrode, the whole curve is similar to the rising portion of the *i-E* curve of a conventional electrode. Therefore, the photoassisted electro-oxidation products and the intermediate species are thermodynamically reducible at these potentials. A cathodic current component is then observed by this back-reaction. Increase of the light intensity causes the transient peaks to disappear. This indicates a rather low and constant back-reaction which is undetectable at the recorder sensitivity used for the high intensity illumination. A similar light intensity effect was also observed recently by Bard and Hardee (22).

The photocurrent for the iron oxide electrode begins at 850 nm. This indicates coverage of the whole visible region in the sun spectra. Iron oxide powder was removed from an electrode and mixed with a large quantity of KBr to make a transparent pellet. An absorbance *vs.* wavelength curve, taken with a Cary 17 spectrophotometer, showed a steep rise in absorption at 850 nm with continuous rise in shorter wavelengths in the visible region. This agrees with the photocurrent experiments.

The iron oxide electrode in this study does offer advantages over large bandgap semiconductor electrodes because of its response to the whole visible region. It also offers advantages over small bandgap semiconductor electrodes because of its high stability. These advantages make it possible to be used in photoassisted electrolysis of water and in an electrochemical solar cell.

Study of the Critical Activation Time in the Continuous Activation of Electrode Surfaces

M. Farooque and T. Z. Fahidy

Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

ABSTRACT

A method to determine the time required for the reactivation of an electrode surface exposed to oxide poisoning is illustrated in the instance of methanol oxidation in a multipolar rotating wiper-blade electrode system. The critical time can be computed by means of a mathematical model correlating electrode potential, bulk electrolyte concentration, anodization time, and experimentally determined parameters.

It has been suggested in recent research (1) on multipolar rotating wiper-blade electrodes that CH_3OH, HCHO, HCOOH, and possibly other species (such as H_2 and N_2H_4) could be continuously oxidized at a high rate on a platinum electrode. The oxide layer formed on the platinum surface, responsible for poisoning the oxidation process, is removed when the electrode passes under the wiper blade where open-circuit conditions exist. This removal is due to a chemical reaction with methanol and it ensures a higher oxidation rate than normally observed. One of the most important parameters in such oxidations is the time required for any arbitrary portion of the electrode to spend under a wiper blade at open-circuit conditions in order to become free of the "oxide" poison. This time, called the critical time, depends, for a given electrochemical system, on the potential of oxidation, the amount of oxide on the surface (which, in turn, is a function of the anodization time), and the concentration of the oxidizable species. One design criterion for a cell of this kind would be to minimize this time period, T, during which the electrode remains under the wiper blade under open-circuit conditions to ensure complete removal of the oxide layer.

In this study, a mathematical model has been developed to compute this critical time for the continuous removal of oxide poisons in the electro-oxidation of organic materials, in general, by using the methanol system as an experimental test case. Such a model could be useful in the design of continuously activated electro-oxidation processes and helpful in establishing the mechanism whereby the (O) species is removed from the electrode surface in the presence of the oxidizable species.

Key words: oxide layers, methanol oxidation, kinetics of oxide removal, electrode coverage.

Experimental

The apparatus has been previously described (1-3) in detail and its application to continuous electrode activation has been treated in the instance of the Kolbe reaction, oxygen evolution, and impurity stripping (4, 5). Experiments were performed to measure the effect of anodization time, anodization potential, and methanol concentration on the time required to free the wiped electrode of the "oxide" poison, which in this particular case was taken to correspond to the time required for the electrode potential to fall below 0.45V (NHE) after open-circuiting. This particular value is the midpoint of the 0.4-0.5V potential range which has been demonstrated (16-18) to correspond to complete oxide removal from a platinum surface.

The electrolyte was freed of oxygen by bubbling pure N_2 through it at a rate of 4.6 cm^3/sec, and in each experiment the electrode surface was prepared to the same initial state. The methanol concentrations employed were 0.9501, 0.1064, 0.0142, and 0.00683 mole/dm^3 in a 0.1 mole/dm^3 H_2SO_4 supporting electrolyte solution. The anodization potentials applied were 1.5, 1.4, 1.3, 1.2, 1.1, and 1.0V (NHE). The time of anodization was controlled by an electronic timer circuit and

was varied between zero and 1 hr. The experiments were chosen via factorial design (6) providing for two sets of replica needed in the estimation of experimental error, and conventional variance analysis was used to compute the experimental error variance and to establish the goodness of fit of the proposed model. The results of 152 experiments, replica included, are summarized in Fig. 2-5 which illustrate typical variations of the oxide-removal time. Figure 1 shows a typical oxide removal rate behavior. Note that after the anodization step there is no current flow in the circuit, hence no further oxygen adsorption. The oxide removal is due to a chemical reaction whose rate is potential independent.

Mathematical Formulation of the Critical-Time Model

Various models of growth mechanisms of thin anodic oxide films have been described in the literature and summarized in a recent review by Damjanovic and Ward (7). In the case of Pt, recent developments [*e.g.*, (8)] indicate that the oxide film is an oxide phase above approximately 1V (NHE) oxidation potential, but below this potential the film consists of reversibly chemisorbed oxygen. While the rate of oxide growth on Pt has been characterized by different mathematical "rate laws," the equation suggested by Genshaw (9) was chosen as the starting point to describe the growth rate of the conducting oxide layer formed during anodization. Genshaw's formulation yields

$$\frac{dL}{dt} = a \exp\left(-\frac{\Delta G_o^{\neq}}{RT}\right) \qquad [1]$$

where a is a proportionality constant, $\Delta G_o^{\neq}$ is the standard free energy of activation of the oxide growth, and L is the thickness of the oxide layer at time instant t of anodization. If it is assumed that the free energy of activation increases linearly with the oxide layer thickness, *i.e.*

$$\Delta G^{\neq} = \Delta G_o^{\neq} + bL \qquad [2]$$

then the appropriate form of Eq. [1] may be written as

$$\frac{dL}{dt} = a \exp\left(-\frac{\Delta G\#}{RT}\right) \qquad [3]$$

Hence, upon integration under potentiostatic conditions, one obtains that

$$L = \frac{RT}{b} \ln\left[1 + \frac{RT_a}{b} t\epsilon^{-\Delta G_o^{\neq}/RT}\right] \qquad [4]$$

by virtue of the ($t = 0$; $L = 0$) initial condition. Since the process is linked to electric discharge, its free energy must be potential dependent, which is approximated by the linear relationship

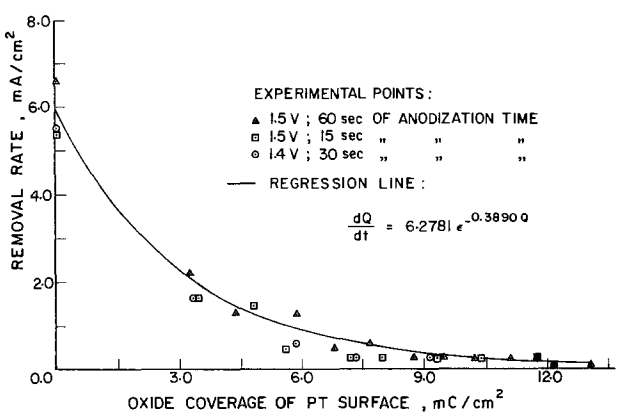

Fig. 1. Oxide removal rate as a function of oxide coverage of the electrode and anodization potential. CH_3OH: 0.035 mole/dm³, H_2SO_4: 0.1 mole/dm³; $T = 23°C$.

$$\Delta G^{\neq} = \Delta G_o - k\mathbf{F}V \qquad [5]$$

where k is a proportionality constant, $\mathbf{F}$ is the Faraday constant, and V is the electrode potential.

Let Q and Q_{ml} be the charge associated with the oxide on the surface and the monolayer, respectively, A_o the electrode area, and L_{ml} the thickness of the monolayer. Then, if q is the charge density of the oxide, one can write for θ_{ox}, the electrode coverage by oxide, the following equivalent relationships

$$\theta_{ox} = \frac{Q}{Q_{ml}} = \frac{A_o L q}{A_o L_{ml} q} = \frac{L}{L_{ml}} \qquad [6]$$

It then follows that in view of the potential effect on $\Delta G\#$ shown in Eq. [5]

$$\theta_{ox} = \frac{RT}{bL_{ml}} \ln\left[1 + \frac{RT_a}{b} t\epsilon^{-\Delta G_o/RT} \epsilon^{\frac{k\mathbf{F}}{RT}V}\right] \qquad [6]$$

which, in terms of the lumped parameters A, B, and K may be simplified to

$$\theta_{ox} = A \ln\left[1 + Bt\epsilon^{KV}\right] \qquad [7]$$

where $A \equiv \frac{RT}{bL_{ml}}$, $B \equiv \frac{RT_a}{b}\epsilon^{-\Delta G_o/RT}$, and $K \equiv \frac{k\mathbf{F}}{RT}$.

While in an earlier work (1) the rate-determining process in open-circuit oxide removal was reasoned to be the chemical reaction between Pt-O and adsorbed methanol to yield CO_2 and water, an equally plausible and more amenable assumption is that the rate of adsorption of CH_3OH on smooth Pt is the rate-controlling step. We can then characterize this process by the Roginskii-Zeldovich equation (10)

$$r_a = k_a c\epsilon^{-\alpha f\theta_{meth}} \qquad [8]$$

where r_a is the rate of adsorption, c is the methanol concentration, f is the inhomogeneity factor of the electrode surface, θ_{meth} is the coverage of this electrode surface by methanol, and $0 < \alpha < 1$. According to Beskorovainaya *et al.* (11), r_a is proportional to $c^{1.1\text{-}1.2}$ and this finding suggests a more general rate expression of the form

$$r_a = k_a' c^N \exp - [\alpha f\theta_{ox} + \alpha_{meth} f_{meth}\theta_{meth}] \qquad [9]$$

Equations [8] and [9] are isomorphic to relationships recommended in the pertinent literature (11, 19, 20); in the latter, N is an experimental constant. Since adsorbed methanol is removed from the continuously activated wiped electrode to a much larger extent than the oxide layer, it is reasonable to assume that $\theta_{ox} >> \theta_{meth}$; an alternative view would be that methanol adsorption being the rate-determining step, θ_{meth} is always smaller than θ_{ox} and varies little. It then follows that Eq. [9] may be simplified to the form

$$r_a = k_a c^N \epsilon^{-\alpha f\theta_{ox}} \qquad [10]$$

where k_a is the combination of k_a' and the essentially invariant exponential term containing θ_{meth}. Then, the rate of oxide removal may be expressed as

$$\frac{d\theta_{ox}}{dt} = -r_a = -k_a c^N \epsilon^{-\alpha f\theta_{ox}} \qquad [11a]$$

or, alternatively as

$$\frac{dQ}{dt} = -k_a Q_{ml} c^N \epsilon^{-\frac{\alpha f}{Q_{ml}}Q} \qquad [11b]$$

In Fig. 1, typical experimental observations of the oxide removal rate are shown, together with the solid line which corresponds to the statistical regression line

$$\frac{dQ}{dt} = m\epsilon^{-nQ} \qquad \begin{matrix} m = 6.2781 \\ n = 0.3890 \end{matrix} \qquad [12]$$

for c = 0.035 mole/dm³ at 23°C, in good qualitative agreement with Eq. [11b]. To obtain experimental values of Q and dQ/dt, the oxide layer was produced on the anode surface by applying a suitable potential for a given period of time, then the circuit was opened and the oxide was allowed to react with the electrolyte for a certain length of time. The remaining surface oxide was removed galvanostatically at a current density of 10 mA/cm². The charge required to lower the potential of the electrode to 0.45V was taken as equivalent to the amount of oxide present. The rate of oxide removal was obtained from the experimental Q-t plot via appropriate graphical differentiation.

Integrating Eq. [11] between the limits ($t = 0$; $\theta_{ox} = \theta_{ox}^{o}$), ($t = T$; $\theta_{ox} = 0$), and substituting Eq. [7], the expression for critical time is finally obtained as

$$T(t,V,c) = \frac{(Bt\epsilon^{KV} + 1)^{\alpha fA} - 1}{k_a \alpha f c^N} \qquad [13]$$

In Fig. 2-5 the experimentally observed oxide removal times are compared to Eq. [13]. Statistical analysis based on 152 experiments yields the least squares minimal regression line

$$T = 0.02357C^{-0.83613}[(4.78 \cdot 10^{-12} t\epsilon^{30.505V} + 1)^{0.21347} - 1] \qquad [14]$$

for the oxidation of methanol, with an error variance of 0.5227.

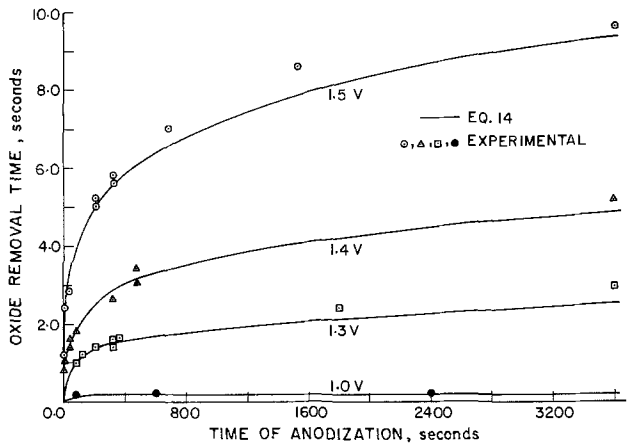

Fig. 2. Oxide removal time at open-circuit conditions as a function of anodization time and potential. CH_3OH: 0.9501 mole/dm³, H_2SO_4: 0.1 mole/dm³; T = 24°C.

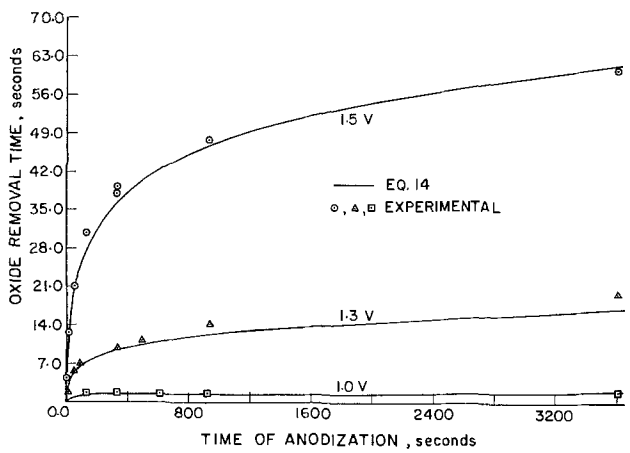

Fig. 3. Oxide removal time at open-circuit conditions as a function of anodization time and potential. CH_3OH: 0.1064 mole/dm³, H_2SO_4: 0.1 mole/dm³; T = 24°C.

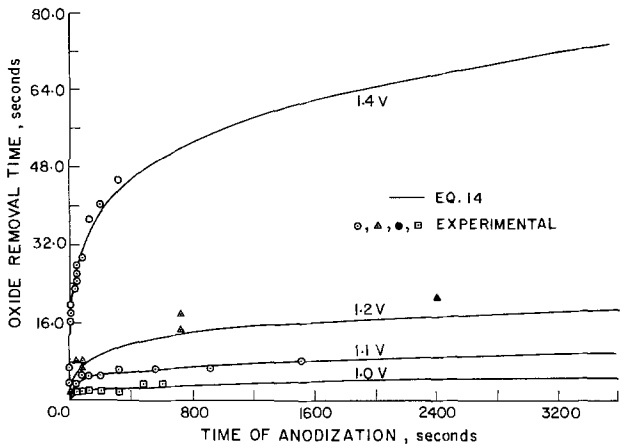

Fig. 4. Oxide removal time at open-circuit conditions as a function of anodization time and potential. CH_3OH: 0.0412 mole/dm³, H_2SO_4: 0.1 mole/dm³; T = 24°C.

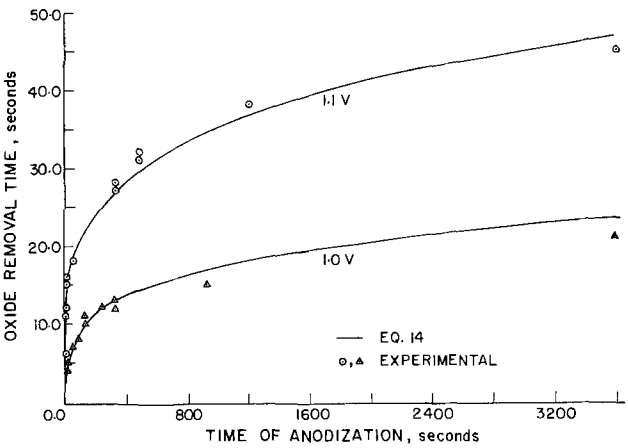

Fig. 5. Oxide removal time at open-circuit conditions as a function of anodization time and potential. CH_3OH: 0.0068 mole/dm³, H_2SO_4: 0.1 mole/dm³; T = 24°C.

Discussion

The good agreement between experimentally determined values of the oxide removal times and Eq. [13] (in 92 cases the magnitude of the relative error is less than 10% and only in 8 cases larger than 20%) indicates that the rate-determining step in the open-circuit removal of oxide from a Pt surface in the instance of methanol oxidation is the rate of methanol adsorption on the surface, followed by a chemical reaction. This finding agrees with Gromyko's report (12) about the rate-controlling behavior of CH_3OH adsorption on its electrochemical oxidation at potentials higher than 0.8V (NHE) in a different experimental apparatus.

It is instructive to compare Eq. [4] to certain relationships reported earlier in the literature for the oxide layer thickness. Using the Elovich-type expression relating the current associated with oxide growth to potential and electrode coverage, the so-called "direct logarithmic law of growth"

$$L(t) = L_0 + L_1 \log (t/t_0); \quad V = \text{const.} \qquad [15]$$

has been derived. There is some experimental evidence that Eq. [15] is obeyed on Pt anodes [*e.g.*, (13, 15)], although at the initial stage of oxide growth the layer thickness-time relationship does not follow Eq [15] [*e.g.*, (14)]. It is believed that Eq. [15] holds when either the oxide formation is the only anode reaction, or when oxide formation is a much less important process occurring in parallel with a predominant process, say, oxygen evolution. Although methanol oxidation, for example, is neither case, the degenerate forms of Eq. [4] and [15] at short times of oxide formation indicate

an essentially linear growth (*i.e.*, constant growth rate) regardless of the relative importance of the oxide formation in the over-all anodic process

$$L(t) \cong \left[\left(\frac{RT}{b}\right)^2 a\epsilon^{-\Delta G_0^{\neq}/RT}\right]t \qquad [4']$$

$$L(t) \cong [(L_0 - L_1) - L_1 \log t_0] + L_1 t \qquad [15']$$

Another interesting point would be the variation of the critical time with pertinent process parameters under galvanostatic conditions in view of the well-documented difference in the growth rate *vs.* time re-relationship with respect to potentiostatic conditions [*e.g.*, (7)], in the instance of Pt anodes. Since galvanostatic conditions are less inviting than potentiostatic conditions for a rotating wiper-blade electrode, such an investigation would be beyond the scope of our current research. The hereby presented analysis of critical time would most likely prove useful in improved design of wiper-blade electrode systems both for mechanism studies and practical oxidations at the continuously activated electrode surface, by choosing appropriate rotation rates and wiper-blade widths for a given electrode metal and specific electrochemical reactions.

Corrosion Suppression on Rutile Anodes by High Energy Redox Reactions

L. A. Harris, D. R. Cross,[1] and M. E. Gerstner

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Rutile photoanodes are known to corrode slightly in 0.5*M* H_2SO_4. Experiments with different electrolytes show that corrosion does not occur in 9*M* H_2SO_4 or in 0.5*M* H_2SO_4 with 1*M* cobaltous ion added, though in each case water is decomposed into hydrogen and oxygen. The addition of cobaltous perchlorate to perchloric acid fails to inhibit corrosion. It is postulated that, where corrosion is suppressed, high energy intermediates are formed by single electron-transfer reactions at the electrode, and that these intermediates go on to split water in the aqueous electrolyte independently of the electrodes.

Photoelectrochemical cells, having one or both electrodes of semiconducting material are being studied as possible devices to generate electricity or to promote useful chemical reactions using the photon energy in sunlight (1-7). One of the key problems in these cells, particularly in those for decomposing water into hydrogen and oxygen, is corrosion of the semiconductor electrode (7-10).

[1] Present address: Chemistry Department, Western Maryland College, Westminster, Maryland 21157. Contributions by Dr. Cross were made during his tenure at CRD under the NSF Faculty Research Participant Program.

Key words: photoelectrochemistry, titanium dioxide, semiconductor electrodes.

It has been shown by a number of workers that introduction into the electrolyte of species that can be oxidized and reduced (redox couples) by simple electron-transfer reactions decreases electrode corrosion (11-15). In the cases reported so far, the standard redox potentials of the couples used are smaller than the potential required to decompose water (1.23V) so that it is no longer possible to split water and the cell may be used only to generate electricity at a potential determined by the redox couple, or to promote even lower energy reactions. In this report we show that higher energy redox couples can suppress the corrosion

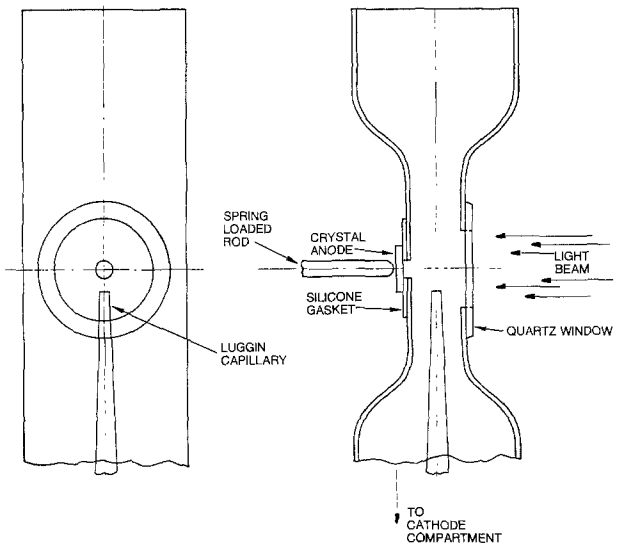

Fig. 1. The anode portion of the electrolytic test cell. The Luggin capillary leads to a saturated calomel reference electrode.

of rutile (TiO_2) and still allow the decomposition of water to taken place.

This work was done with n-TiO_2 because it is one of the few semiconducting materials with the conduction band edge located so that photogenerated holes have sufficient energy to oxidize the reduced member of redox species involved (16). It is recognized, of course, that corrosion of TiO_2 is no problem if it is used in basic electrolytes (2). But TiO_2 does corrode in 0.5*M* H_2SO_4 at a rate that can be monitored (7), so it provides a useful vehicle for this kind of study, which may have implications for the suppression of corrosion of smaller bandgap materials.

Experimental Methods

These tests were done following procedures similar to those described previously (7). The anode material was single crystal rutile cut to expose the (001) face and reduced in hydrogen at 650°C for 30 min. After reduction the surface was repolished to remove any thermal etching and to provide a high gloss surface on which corrosion would be evident. Samples were reused, without further heat-treatment, after repolishing between tests.

The cell in which the samples were tested had an anode compartment arranged as shown in Fig. 1. The rutile crystal was held against the gasketed window of the cell by a spring-loaded metal rod contacting the back of the crystal, where ohmic contact was assured by applying a paste of Ga-Ag alloy. This arrangement allowed for easy installation of the crystal and accurate weighings of the crystal before and after test. (The Ga-Ag contact is easily removed without affecting the crystal by immersing it in HCl.) The window also provided a well-defined active area (⅛ cm^2) in which the effects of corrosion contrasted with the polished surrounding area. In use, the recessed position of the anode sometimes caused bubbles to be trapped in the window. It also prevented the free convection of electrolyte past the electrode surface, making diffusion limitations more obvious than they might otherwise have been. Though the electrolyte was not stirred the volume in the vicinity of the anode surface could be flushed occasionally by a jet of solution from a dropper. No membranes or other diffusion barriers were used between the anode and cathode compartments of the cell.

The circuit used was the same as that described previously (7) except that a coulometer (VariTech Company Model VT 1176B) was inserted to record the total anodic charge passed through the rutile electrode. Illumination was provided by light from a 75W high pressure xenon lamp focused with a quartz lens to an intense but nonuniform spot of light with an intensity of about 1-1.5 W/cm^2 (10-15 times solar intensity) over the exposed sample area of 0.125 cm^2.

The samples were aged by applying enough anodic voltage (typically 1-1.5V SCE) to maintain the cell current at its saturation value. Gas evolution at the semiconductor anode and at the platinum-black cathode was observed in a qualitative fashion, but no attempt was made to measure quantitatively the amount of gas released in each case. Even though currents, charges, and weight losses were measured as accurately as possible, it would be a mistake to view most of the results as more than qualitative in nature, since quantitatively reproducible behavior of TiO_2 is difficult to achieve.

Results

The general behavior of the rutile anodes with the various electrolytes was similar to that described in the earlier paper (7) and is not described in detail here. The volt-ampere curves under full-spectrum illumination showed the same kind of changes due to aging as previously observed in 0.5*M* H_2SO_4.

The observations of principal interest for this work are summarized in Table I and are explained in more detail for each of the electrolytes in the remainder of this section.

Electrolyte 1: 0.5M H_2SO_4.—This electrolyte is the one used in our previous study in which corrosion and other aging effects were demonstrated (7). The gases liberated at the anode and cathode have previously been identified as oxygen and hydrogen, respectively. A useful indicator of hydrogen generation is polarization of the cathode to the potential expected for a hydrogen electrode at the electrolyte *p*H.

In some earlier tests using TiO_2 reduced at different temperatures average weight losses between 2 and 6 μg/C were measured after charges of 50-150C passed through the cells. If we assume that two oxygen atoms are removed with each Ti atom, these limits correspond respectively to about 410 and 140 electrons for each Ti atom removed.

After passage of 4 or 5C through the sample the corrosion is obvious to the eye; the exposed area being a velvety black in contrast to the glossy surface of the unexposed part of the crystal. The structure of the corroded surface is difficult to discern with the optical

Table I. Summary of TiO_2 electrode and cell behavior with various electrolytes

Electrolyte	1 0.5*M* H_2SO_4	2 0.5*M* H_2SO_4, 1.0*M* $CoSO_4$	3 0.5*M* H_2SO_4, 1.0*M* $Co(ClO_4)_2$	4 0.5*M* H_2SO_4, 0.58*M* K_2SO_4	5 9.0*M* H_2SO_4	6 1.0*M* $HClO_4$	7 1.0*M* $HClO_4$, 1.0*M* $Co(ClO_4)_2$

* Sequential tests on same electrode with same illumination.

microscope, but the scanning electron microscope (SEM) reveals the square tapered pits characteristic of this etching process and shown in Fig. 2a. It has already been shown that the semiconductor must be illuminated and carry a photocurrent for this etching and other effects to occur (7). To verify that simple chemical dissolution was not involved, a similar TiO_2 crystal was kept immersed in this acid for 186 hr with no detectable change in surface appearance or weight.

During photoelectrochemical aging, bubbles tended to accumulate in the anode aperture where they blocked the current. These had to be removed occasionally by flushing with a dropper, but otherwise stirring the electrolyte appeared to have little effect. After the passage of several coulombs the rate of bubble formation at the anode visibly decreased, though it remained relatively constant at the cathode. Over the same interval the saturation current increased to a peak value from which it slowly declined. The peak saturation current could not be restored by flushing the anode surface, but it was restored briefly by reversing the cell current for a minute or so and then returning to the anodic polarity. The increased current was transient, however, and in a few minutes declined to its former value. This behavior is indicated in Table I as an increase for "ΔI_s after cathodic run."

Electrolyte 2: 0.5M H_2SO_4, 1.0M $CoSO_4$.—The addition of $CoSO_4$ to the electrolyte produces a dark wine-red color characteristic of the Co^{2+} ion. Although light transmission through the solution is markedly reduced in the visible portion of the spectrum, the absorption at the shorter wavelengths needed to excite bandgap transitions in TiO_2 is not very different from that of electrolyte 1. Figure 3 shows the light transmission for 1 cm of electrolyte 2 relative to that of electrolyte 1. The total effective light reaching the sample through the cobalt-containing electrolyte, estimated by weighting the transmission values with the spectral intensity of the xenon lamp for wavelengths less than 410 nm is approximately 72% of that passing through electrolyte 1. This estimate neglects spectral variations of sample quantum efficiency. Table I shows that the saturation current with electrolyte 2 is reduced to about 63% of its former value. With both electrolytes 1 and 2, the saturation current was observed to be proportional to light intensity, which was varied by inserting calibrated neutral density filters in the optical path.

After passage of almost 50C there was no visible evidence of corrosion and no detectable weight change of the TiO_2 electrode. A slight discoloration due to a surface film on the exposed area was visible, but this did not affect the surface sheen, and no surface structure was found in the SEM.

The behavior during aging with this electrolyte differed from the first case in several respects. Though bubbles, verified by gas chromatography to be O_2, formed in the vicinity of the anode, they did not tend to adhere to the anode or block the cell current. The rate of bubble formation at the anode decreased in the same fashion as in the first case while the cathode bubbling and saturation current remained comparatively constant. After several hours, bubbles began to appear on the cell walls decreasing in density with distance from the anode.

Even when clear of bubbles, the anode had to be flushed periodically to maintain the saturation current

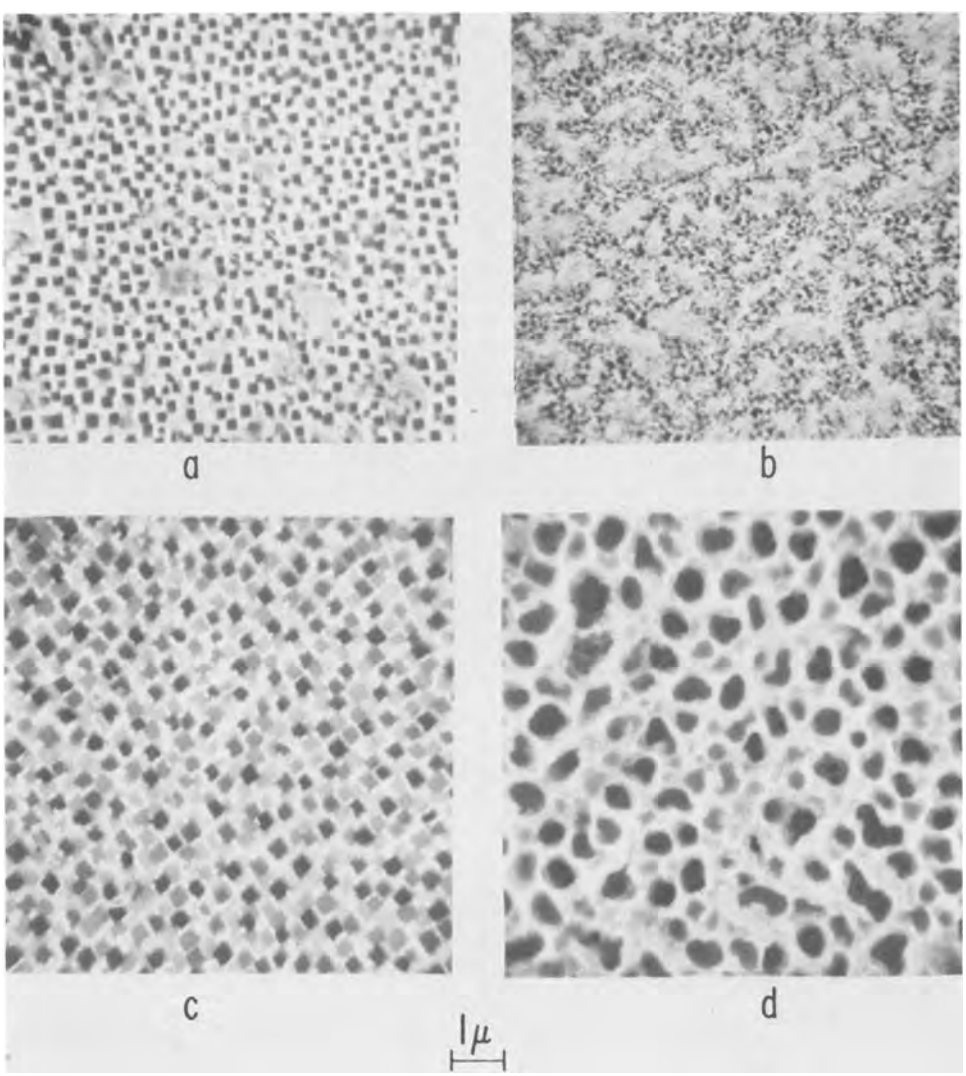

Fig. 2. Scanning electron micrographs of rutile anodes corroded in: (a) 0.5M H_2SO_4 by passage of 16C; (b) 0.5M H_2SO_4, 0.58M K_2SO_4, 45C; (c) 1.0M $HClO_4$, 45C; (d) 1.0M $HClO_4$, 1.0M $Co(ClO_4)_2$, 20C.

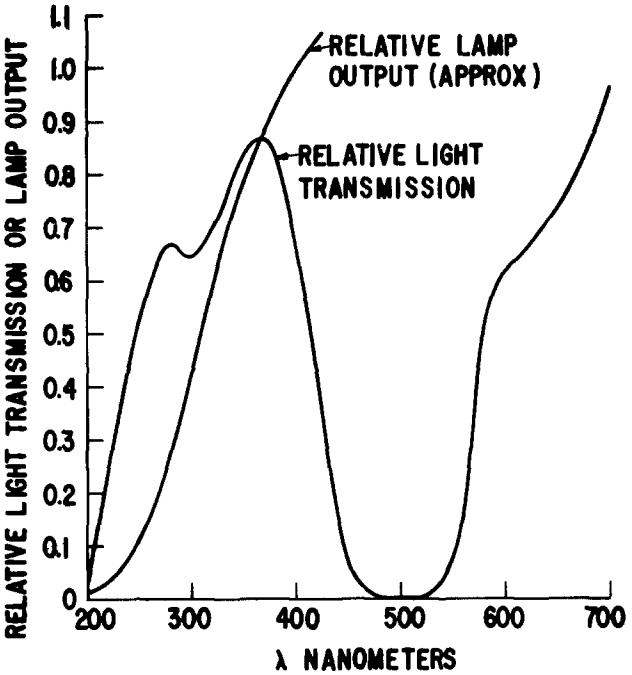

Fig. 3. Transmission of light through 1 cm of electrolyte 2 (with cobalt) relative to that through 1 cm of 0.5M H_2SO_4. Approximate spectral intensity (relative to that at 400 nm) of xenon lamp source is also shown.

level which tended to decrease, perhaps 10-30%, in a few minutes after flushing. The "flushed" value of current, however, could be increased even further by a brief cathodic run, as described for electrolyte 1.

Electrolyte 3: 0.5M H_2SO_4, 1.0M $Co(ClO_4)_2$.—Substitution of the perchlorate anion for the sulfate anion of the cobalt salt made no significant difference in cell behavior. No evidence of corrosion was found after passage of 20C. The saturation current, bubble formation, and response to flushing or reverse current were all essentially the same as for electrolyte 2.

Electrolyte 4: 0.5M H_2SO_4, 0.58M K_2SO_4.—Here the $CoSO_4$ of electrolyte 2 was replaced by as much K_2SO_4 as could be dissolved in the acid solution. This change increased the concentration of SO_4^{2-} and raised the pH from about 0.45 to 1.65.

In general this electrolyte behaved much like electrolyte 1, producing a steady flow of bubbles at the cathode and a decreasing flow at the anode. Except for clearing the aperture of bubbles flushing the anode region had little effect on the saturation current, which also matched that of electrolyte 1. The effect of a cathodic current flow, though still evident, was not so marked as in previous cases. As with electrolyte 2, bubbles eventually formed on the cell walls at an appreciable distance from the anode.

The sample lost weight at a rate comparable to that in electrolyte 1, but the SEM revealed the development of the square etch pits on a much finer scale, as shown in Fig. 2b.

Electrolyte 5: 9.0M H_2SO_4.—This strong acid did not corrode the rutile anode at all. Bubbles formed only slowly at the anode and occasionally had to be cleared away, but flushing the surface otherwise had no effect, nor did reversing the current direction in the cell. Evolution of gas at the cathode was steady and copious, consistent with the higher level of saturation current obtained.

Electrolyte 6: 1.0M $HClO_4$.—Replacing the sulfate ion of electrolyte 1 by the perchlorate ion produced little change in cell behavior. The currents were comparable, the anode had to be flushed to maintain the current, and reversing the current temporarily increased the anodic current level. As with 0.5M H_2SO_4 the sample corroded, but at a reduced weight loss per unit of charge. The corrosion pattern shown in Fig. 2c, had the characteristic square pits seen with other samples.

This electrolyte differed from the others by a somewhat reduced rate of bubble formation at the cathode.

Electrolyte 7: 1.0M $HClO_4$, 1.0M $Co(ClO_4)_2$.—Addition of $Co(ClO_4)_2$ to the perchloric acid did not prevent corrosion. Indeed the rate of corrosion, though low, was somewhat higher than with perchloric acid alone, but the pattern of corrosion was altered as Fig. 2d shows. The presence of cobalt did reduce the saturation current to a value consistent with the other cobalt-containing electrolytes. Gas was released at both electrodes.

Attempts were made to repeat some of these experiments with $MnSO_4$ substituted for $CoSO_4$, and with $CoSO_4$ dissolved in water (pH = 3.5). They could not be carried to completion because in both cases the cell currents were only transient. Initial anodic current flow soon decreased, apparently because some nonconducting species formed to block the anode. In the case of Mn, this blocking layer was visible as a brown deposit, tentatively identified as MnO_2.

Discussion

The rates of corrosion of TiO_2, in any of the electrolytes allowing this to take place, are very low since at the very least 100 electrons must transfer from the electrolyte to valence-band holes to remove one Ti atom. This fact suggests that the electrode material takes little part in the chain of chemical reactions that ultimately result in the decomposition of water. (In contrast, ZnO, which has a band structure similar to that of TiO_2, corrodes very efficiently. We observed that in a nondissolving solution of $ZnSO_4$ an illuminated ZnO anode lost one Zn atom for every two electrons transferred.)

Since each O_2 molecule requires 4 electron transfers there must be a series of intermediate activated species if the reaction is to proceed at any reasonable rate. These activated intermediates can involve chemical bonding with the electrode surface making it more susceptible to corrosion (8-10); or they can exist entirely in the electrolyte phase with the final step of O_2 formation taking place independently of the surface. In the latter case the semiconductor anode serves the purpose of oxidizing a species in the electrolyte by simple electron transfer.

The photogenerated holes in the valence band at the surface of TiO_2 are very powerful oxidizing agents having a reduction potential about 3V above that of the hydrogen electrode (16). They are thus sufficiently energetic to oxidize many species normally considered to be extremely stable in their reduced state. These high energy oxidized species can act as the intermediate in the electrolyte phase and ultimately lead to the liberation of oxygen from water, away from the electrode.

We suggest the following system of reactions as being consistent with the observed behavior of the seven different electrolytes described in the previous section. In sulfuric acid, the first reaction is

$$SO_4^{2-} + p^+ \rightarrow SO_4^- \quad [1]$$

where p^+ represents a positive hole in the valence band of the illuminated semiconductor anode. If the SO_4^- ions do not react with the material of the anode, they pair up to form the peroxydisulfate ion $S_2O_8^{2-}$

$$2SO_4^- \rightarrow S_2O_8^{2-} \quad [2]$$

The over-all reaction

$$2SO_4^{2-} + 2p^+ \rightarrow S_2O_8^{2-}$$

has a standard reduction potential of 2.01V (17), and it seems reasonable to ascribe to the first step (Eq. [1])

most of the energy to oxidize SO_4^{2-} ions. The independent, if brief, existence of the SO_4^- ion and its decay via reaction [2] have been demonstrated (18, 19).

Reaction [1] proceeds at a rate limited only by the number of photogenerated holes at the electrode surface. The negative charge on the SO_4^{2-} ion attracts it to the positive anode, and only a single electron transfers without the formation of intermediates so the reaction is unlikely to be limited by these kinetic factors. The SO_4^- so formed is an active species that can react with the electrode surface and lead to its corrosion, unless it is effectively scavenged by a competing reaction.

The principal competing reaction is the formation of $S_2O_8^{2-}$ (reaction [2]) which subsequently reacts with water independently of the electrode, and possibly assisted by the light passing the solution, by the following series of reactions (20-22)

$$S_2O_8^{2-} + H_2O \rightarrow SO_5^{2-} + SO_4^{2-} + 2H^+ \quad [3a]$$

$$SO_5^{2-} + H_2O \rightarrow SO_4^{2-} + H_2O_2 \quad [3b]$$

The peroxide can release O_2 by

$$SO_5^{2-} + H_2O_2 \rightarrow SO_4^{2-} + H_2O + O_2 \quad [3c]$$

or

$$S_2O_8^{2-} + H_2O_2 \rightarrow O_2 + 2HSO_4^- \quad [3d]$$

With high illumination levels one might expect more rapid pairing of SO_4^- ions and therefore less corrosion per unit charge transferred. In one isolated test at low light intensity the weight loss per unit charge was observed to exceed those measured at higher intensity.

In the more concentrated sulfuric acid (electrolyte 5) the concentration of SO_4^- ions is not increased because that is limited by light intensity. The reduced corrosion indicates a more effective scavenging reaction than [2]. Possible mechanisms for removal of SO_4^- from the electrode surface are simple charge exchange with other SO_4^{-2} ions

$$SO_4^- + SO_4^{2-} \rightarrow SO_4^{2-} + SO_4^- \quad [4]$$

or the formation of a triply charged peroxydisulfate ion

$$SO_4^- + SO_4^{2-} \rightarrow S_2O_8^{3-} \quad [5]$$

In either case the SO_4^- ion is prevented from reacting with the electrode and the series of reactions [3] can ultimately proceed in the volume of the cell.

When cobaltous ion is added to the electrolyte it provides another mechanism for scavenging the SO_4^- ion by the reaction

$$Co^{2+} + SO_4^- \rightarrow Co^{3+} + SO_4^{2-} \quad [6]$$

so long as $[Co^{2+}] >> [SO_4^-]$.

The Co^{3+} ion is known to release O_2 from H_2O by the over-all reaction

$$4Co^{3+} + 2H_2O \rightarrow 4Co^{2+} + 4H^+ + O_2 \quad [7]$$

which presumably involves the intermediate formation of aquated or sulfated dimeric cobalt complexes (23-27).

Direct oxidation of Co^{2+} at the electrode

$$Co^{2+} + p^+ \rightarrow Co^{3+} \quad [8]$$

is not responsible for suppressing corrosion since Co^{2+} fails to do so in the absence of the sulfate ion (electrolyte 7). The change in redox potential of the Co^{2+}/Co^{3+} couple from sulfate to perchlorate cannot be so great as to explain the difference in behavior. Nevertheless, the cobalt ion must play some part in the process since the corrosion pattern (Fig. 2d) is significantly altered. Reaction [8] seems less probable than reaction [6] because of the similar electric charge on the anode and the cobalt cation. The perchlorate ion, if oxidized at the anode surface, probably can exist only as an activated species bound to the electrode, the first step in corroding that surface.

As oxidized species tend to accumulate near the anode they limit the access of reduced species to that electrode. On flushing the anode region fresh electrolyte allows the current to increase. This diffusion limitation is assisted by the high current densities (20-30 mA/cm^2), the geometry of the cell, and the fact that reactions [3] and [7] are both relatively slow ones. It is known that reaction [7] is inhibited by the presence of H^+ ions (23), but the acid medium must be used, as insoluble $Co(OH)_2$ is formed at higher *p*H.

It is the slowness of these reactions that allows the oxidized species to diffuse out into the cell, eventually releasing oxygen in the electrolyte itself. This behavior is illustrated in electrolyte 2 by the failure of bubbles to block the anode and in electrolytes 2, 3, and 4 by the appearance of bubbles on the cell walls. It is also consistent with the observed decrease of bubble formation at the anode, as a greater proportion of the oxygen is released in the large volume of the cell where it is not so evident.

The additional increase of saturated anodic photocurrent after a brief cathodic run indicates the presence of a species bound to the electrode surface, one not readily removed by flushing the electrolyte over it. The presence of such species is confirmed by large transient sorption and desorption peaks in the voltammogram as polarity is changed. This subject has not been studied in detail and additional work is required to establish the identity of the sorbed species.

Conclusions

As noted early in this paper corrosion of TiO_2 is not a serious problem because this material can always be used in alkaline electrolytes without corroding. The qualitative observations reported here, however, do provide some insight into the nature of the electrode-electrolyte interactions that lead eventually to release of O_2 and to electrode corrosion. Hopefully some of these insights will find application to other, smaller bandgap electrode and electrolyte combinations.

To suppress corrosion and retain the ability to split water into its components a series of reaction intermediates should exist in the electrolyte so that the electrode is involved only in the first electron transfer step. The result of an electron (or hole) transfer across the interface should be the formation of a species (*e.g.*, SO_4^-) that can exist independently of the electrode long enough to react with another entity, either a different species (*e.g.*, Co^{2+} or SO_4^{2-}) or another of its own kind (*e.g.*, SO_4^-). The eventual outcome of this chain of electrolyte reactions should be the evolution of O_2 at a location removed from the electrode.

The detailed series of reactions proposed in this paper is of course a hypothetical one chosen to be consistent with known chemical reactions and the various observations reported here. Although the validity of this hypothesis will have to be determined by other more quantitative studies, the present work clearly establishes that corrosion can be suppressed by high energy redox systems which can decompose water in their turn. It appears that avoidance of a multi-electron transfer and the formation of intermediate electrode-radical species at the electrode surface provides a kinetic advantage of greater importance in suppressing corrosion than the reaction potential, provided, of course, that thermodynamic conditions are met.

ABSTRACT

Pulse and continuous wave NMR measurements are reported for protons in hydrous melts of calcium nitrate at temperatures between −4° and 120°C. At temperatures near 50°C mean Arrhenius coefficients, ΔH_{T_1} (kcal/mole), are 7.9, 7.3, and 4.8, respectively, for melts containing 2.8, 4.0, and 8.0 moles of water per mole of calcium nitrate, compared to 4.6 kcal/mole for pure water. Temperature dependence of T_1 and T_2 in $Ca(NO_3)_2$-2.8 H_2O between −4° and 120°C are non-Arrhenius and can be represented by a Fulcher-type equation with a "zero mobility temperature" (T_0) of 225°K, close to the value of T_0 for solute diffusion, electrical conductance, and viscosity. Resolution of the relaxation rates into correlation times for intramolecular (rotational) and intermolecular (translational) diffusional motion is discussed in terms of the Bloembergen-Purcell-Pound and more recent models for dipolar relaxation.

Hydrous melts are highly concentrated aqueous electrolytes which may be characterized as molten salts containing water in amounts insufficient to form hydration shells about the ions and an intervening hydrogen-bonded solvent structure. They include the hydrate melts, which are fused stoichiometric hydrates such as $Ca(NO_3)_2 \cdot 4H_2O$ and $CaCl_2 \cdot 6H_2O$, as well as melts of nonstoichiometric composition of both higher and lower water content. Thermodynamic, transport, and theoretical investigations of hydrous melts have demonstrated the usefulness of molten salt models in understanding the behavior of concentrated electrolytes in the region where the structure is predominantly an ionic distribution perturbed by water molecules, rather than a hydrogen-bonded structure perturbed by ionic charges (1). A basic understanding of such electrolytes is important not only for theoretical reasons but also because the properties of these melts lend themselves to application in a number of developing technologies, including geothermal systems, some geothermal brines being very concentrated electrolytes; thermal energy storage with Glauber's salt or sodium thiosulfate; high temperature fuel cells (water is an anode product and a proposed cathode gas additive in molten carbonate fuel cells); interactions of water with magmas; improved water electrolyzers for hydrogen production; and thermochemical cycles for hydrogen production, in which steam-molten salt reactions may be invoked (2).

Transport studies of hydrous melts have been concerned largely with bulk properties such as the shear viscosity or electrical conductance (3). Diffusivities have been reported for dilute solute cations dissolved in hydrous melt solvents (4, 5), but little attention has been given to diffusivities or mobilities of water in hydrous melts. Proton chemical shifts have been reported for some hydrous melts (5) but these provide no information on transport properties. Nuclear spin relaxation measurements have been carried out on less concentrated aqueous electrolytes approaching the hydrous melt range (6) as well as on protons of nitric acid dissolved in molten nitrates (7) and of alkali metal ions in molten nitrates (8), but the application of this method to transport studies of hydrous melts has received little attention (9).

In this paper we report new measurements concerned with water transport properties in hydrous melts containing less than one water molecule per ion. We have determined spin-lattice and spin-spin

relaxation times of protons, using pulsed and continuous wave NMR measurements, as a function of water content and temperature. The temperature dependence and the dependence on water concentration are compared with those for other transport and thermodynamic properties of hydrous melts. We present preliminary results on the resolution of the observed relaxation rates in terms of correlation times for intramolecular (rotational) and intermolecular (translational) motion.

Experimental

Sample preparation.—Hydrous melt samples of $Ca(NO_3)_2$-R_{H_2O}, where the mole ratio of water, R_{H_2O} moles of water per mole salt, was between 2.8 and 16, were prepared in 5 mm NMR tubes. The melts were prepared from anhydrous salt which had been dehydrated in a desiccator containing $Mg(ClO_4)_2$ under vacuum (less than 50 μm) at ambient temperature for at least a week (10). The desired composition was prepared by the addition of a calculated amount of triply distilled water to a weighed amount of the anhydrous salt (*ca.* 10g) in a stoppered 25 or 50 ml Erlenmeyer flask. The saltwater mixture was then melted to a clear solution. The 5 mm NMR tubes were loaded with approximately 0.5 ml of the hydrous melt. Loading the tubes with the more concentrated hydrous melts, $R = 2.8$ or 4.0, required the melt, tube, and delivery tube to be heated. Prior to sealing, oxygen was removed by repeated evacuation of the samples frozen in a trichloroethylene-Dry Ice mixture (liquid nitrogen provided too great a thermal shock and led to breakage of the tubes).

Instrument.—NMR measurements were carried out with a Varian XL-100 NMR spectrometer with the Nicolet TT-100 Fourier transform accessory, with a magnetic field of 23.490 kG and a frequency of 100 MHz. Spectra were obtained at temperatures ranging from −20° to 120°C by using the variable temperature accessory for the XL-100. Spin-lattice relaxation times, T_1, were obtained from pulsed measurements with a 180°-τ-90° pulse sequence (11). Spin-spin relaxation times, T_2, were calculated from the width at half-height of continuous wave (CW) measurements (12). Precision of the reported values of T_1 and T_2 is ±10 and ±20%, respectively. Temperatures were determined from the separation of the hydrogen resonances, in ethylene glycol above 35°C, and in methanol below 35°C. It is estimated that the uncertainty in temperature is ±1°C.

Results

Relaxation times.—Values of the proton spin-latttice relaxation time, T_1, and of the spin-spin relaxation time, T_2, are listed in Table I for the melt of composition $R_{H_2O} = 2.8$ at temperatures between −4° and 120°C. Measurements at temperatures between 35° and 100°C were made also on melts of composition $R_{H_2O} =$ 4.0, 8.0, and 16.0.

* The concentrations of salt and water in moles/liter at 50°C are $C_{Ca(NO_3)_2}$ = 8.57 and C_{H_2O} = 24.00 (28).

The values of T_1 were obtained from the spectrometer's computer evaluation of the free induction decay of the signal amplitude in the 180°-τ-90° pulse sequence (11, 12). With decreasing temperature (or decreasing water content) the relaxation times decreased, and line broadening led to a decrease in sensitivity. In this region values of the spin-spin relaxation time, T_2, were calculated from the width at half-height of the continuous wave resonance peaks, a typical one being shown in Fig. 1. In this initial study, unfortunately, values of both T_1 and T_2 were not determined at the same temperatures. Nevertheless, as will be seen, the indications are that T_1 and T_2 approach equality in the high temperature (long relaxation time) region.

Composition variations.—Although the composition dependence of the relaxation times over a broad range of saltwater ratios will be dealt with in more detail in a subsequent paper, the general character of the composition dependence is similar to that reported previously for other transport properties and for thermodynamic properties (10). This may be seen in the plot in Fig. 2 of mean Arrhenius energies for spin-lattice relaxation in the temperature range 35°-100°C, obtained from best straight lines in this temperature interval where deviations from Arrhenius behavior are not pronounced. Also shown are the water concentration dependence of the diffusion coefficient (logarithmic) of dilute massive solute ions, Cd^{2+} (13); the enthalpy of vaporization of water from hydrous melts,

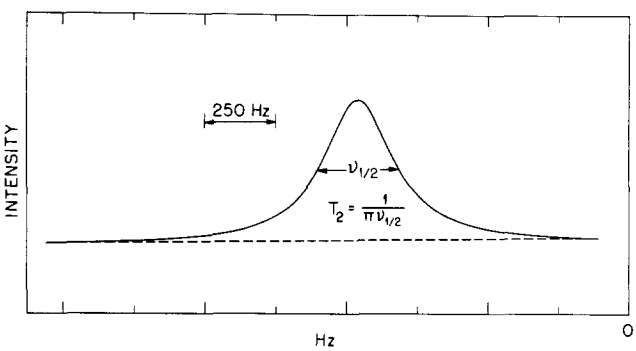

Fig. 1. Typical proton NMR CW spectrum in calcium nitrate-water mixtures, $Ca(NO_3)_2$-2.82H_2O at 287.5°K.

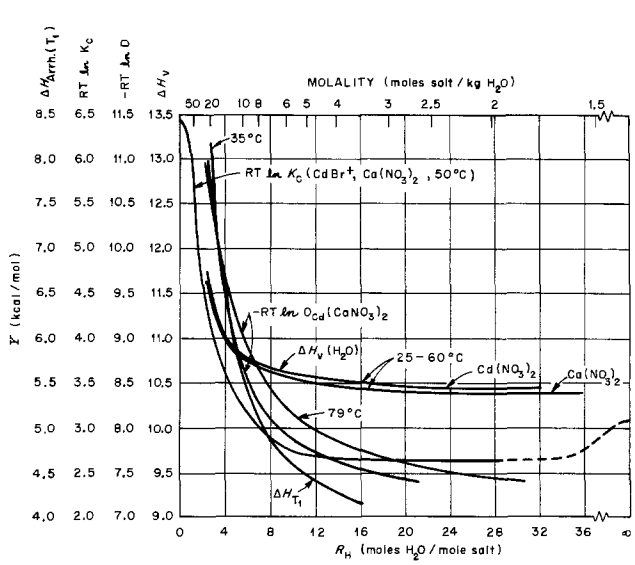

Fig. 2. Enthalpy of vaporization of water, solute association free energy, solute diffusion coefficient, and Arrhenius activation energy of the spin-lattice relaxation time (T_1) in hydrous melts of $Ca(NO_3)_2$ vs. water content.

and the free energy of association of dilute solute ions in hydrous melt solvents (10). Although a quantitative relation between the concentration dependences of the thermodynamic and transport properties may not yet be available, both reflect the change of behavior in the range of concentration between aqueous solution and molten salt. The transport properties, however, appear to show a greater variation with composition than the thermodynamic properties.

Temperature dependence.—Figure 3 shows the variation of T_1 with temperature in the melt $Ca(NO_3)_2 \cdot 4H_2O$ along with values of the fluidity (3), cadmium ion diffusivity (13), and equivalent conductance (14). The striking parallel between the behavior of the relaxation times and the macroscopic transport coefficients suggests that the same mechanism applies.

Although the Arrhenius equation can be fitted to the data over a limited range of temperature to provide mean activation energies for relaxation, measurements over an extended temperature range show marked deviations from Arrhenius behavior, as is the case for the macroscopic transport coefficients. A Fulcher-type equation (3, 13, 14) was therefore fitted to the combined spin-spin relaxation times and high temperature spin-lattice relaxation times for melts with $R_{H_2O} = 2.8$ at temperautres between −4° and 120°C, and is plotted as the solid line in Fig. 4

$$[T_1 \text{ (high temperature) and } T_2] = AT^{-1/2}e^{-\frac{k}{T - T_0}} \quad [1]$$

The parameter T_0 represents a hypothetical "zero-mobility temperature" (14). Because of the high degree of correlation of the parameter values, uncertainty about the location of the inflection, and experimental uncertainties, it was convenient to fix either k or T_0 for the T_1 data in comparing values among differing properties. The value $k = 649.5$ obtained for diffusion data in $Ca(NO_3)_2$-$4.09H_2O$ (15) leads to the values $A = 361.3 \pm 59$ and $T_0 = 224.9 \pm 0.9$ in Eq. [1] with a standard error of fit of 21.3%. This error may result in part from a slight mismatch in the joining of the high temperature T_1 data with the low temperature T_2 data as well as from the possible start of low temperature leveling off of the T_2 data, as indicated by the dashed line. The T_2 data point at the lowest temperature was excluded from the computer fit, as were the T_1 data at temperatures below 70°C.

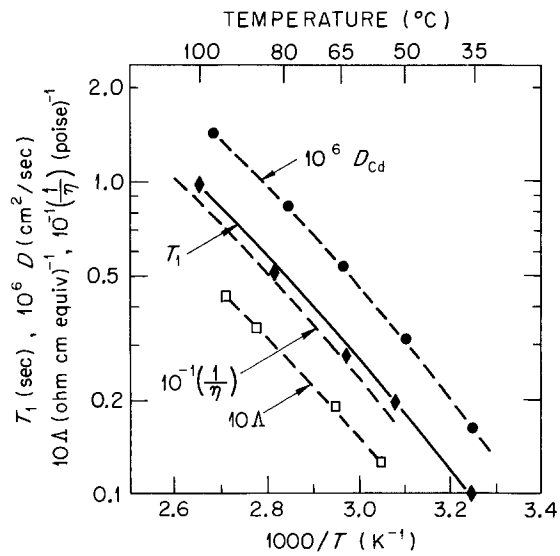

Fig. 3. Temperature dependence of proton spin-lattice relaxation time (T_1), diffusion coefficient (D) of dilute Cd^{2+}, equivalent conductance (Λ)*, and fluidity ($1/\eta$) in $Ca(NO_3)_2$-4.00 H_2O, 35°-100°C. [*$Ca(NO_3)_2$-$4.09H_2O$.]

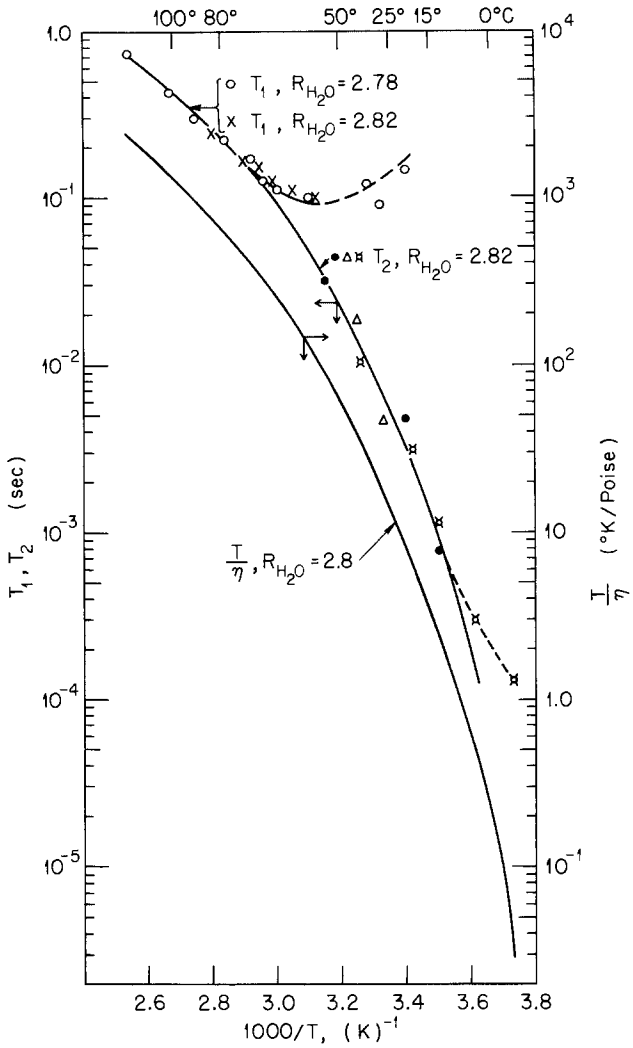

Fig. 4. Temperature dependence of proton spin relaxation times (T_1 and T_2) and of the temperature-viscosity ratio (T/η) in $Ca(NO_3)_2$-$2.8H_2O$.

Because of the experimental uncertainty in the lower temperature T_1 data, it is not certain whether the minimum and upturn indicated by the dashed line are real or an artifact, but both a minimum in T_1 and a leveling off of T_2 with increasing viscosity (decreasing temperature) would be expected from the elementary theory of nuclear magnetic relaxation via dipolar coupling, and has been observed for proton magnetic relaxation in glycerol (16). It may be seen also that the temperature dependence of the relaxation times is very close to that for the viscosities (3).

Discussion

A quantitative test of models with these preliminary results may be premature in view of some experimental uncertainty in the behavior for the shortest relaxation times and the absence of needed information on water diffusivity in the melts with water contents less than in $Ca(NO_3)_2 \cdot 4H_2O$ (9). Nevertheless, a number of qualitative conclusions may be drawn, and the application of some proposed models of relaxation may be instructive.

Grotthus mechanism.—First, the results (Fig. 3 and 4) demonstrate clearly parallel behavior of the proton relaxation times and the macroscopic transport properties. To the extent that the proton spin-lattice relaxation may be governed by the same mechanisms governing diffusion of more massive solute metal ions (such as Cd^{2+}) in the solution, our results suggest that the Grotthus chain mechanism for the anomalously high proton mobilities in aqueous solutions is not operative. This is not unreasonable since, as the water content of

a solution decreases, proton transfer could be expected to become less significant than water molecule diffusion as a mode of proton transport. Polarographic measurements of limiting currents for hydrogen reduction as compared to dilute solute metal ion reduction in concentrated lithium halide solutions are consistent with this (17). Also, experiments with hydrous melts "doped" with nitric acid (at concentrations of about 0.1M) showed little difference in the relaxation times. However, as pointed out by McCall and Douglass (18), the Grotthus mechanism applies to the mobility of excess protons over those "bound" in the water structure in dilute solutions. Since the measured relaxation time is an average for all the protons, bound and unbound, the number of excess protons may have been insufficient in our measurements to distinguish "excess" protons. Spin-echo measurements of proton diffusion coefficients in pure water are in essential agreement with tracer diffusion coefficients, but are lower than the "excess proton" diffusion coefficients calculated by application of the Nernst-Einstein equation to the limiting ionic conductance of hydrogen ions in solution. Similar behavior may occur in hydrous melts with the added complication that, in the absence of a hydrogen bonded structure, a larger concentration of excess protons may be required before a Grotthus mechanism can occur.

BPP.—A model of spin-lattice relaxation ("BPP") has been proposed by Bloembergen, Purcell, and Pound (16) for the dipole-dipole coupling mechanism for relaxation, based on a single correlation time, τ_c, proportional to the macroscopic transport properties such as the temperature reduced viscosity, η/T, or by the reciprocal diffusivity, $1/D$. This model, which is oversimplified (19) in that it assumes the Stokes-Einstein equation and neglects the possibility of a distribution of correlation times [which would correspond to a cooperative rather than to a single-event transport mechanism (20)], leads to the relation for the rotational or intramolecular part of the relaxation rate

$$(1/T_1)_{rot} = K_1 \left[\frac{\tau_c}{1 + 4\pi^2\nu^2\tau_c^2} + \frac{4\tau_c}{1 + 16\pi^2\nu^2\tau_c^2} \right] \quad [2]$$

where K_1 is a constant comprised of the nuclear spin, gyromagnetic ratio, and "molecular size" constant, ν is the radio frequency, and τ_c is the correlation time, $\tau_c \propto \eta/T \propto 1/D$. For nuclei of spin ½, like the proton in water, the dipole-dipole relaxation mechanism predominates over other modes of relaxation such as those arising from quadrupole or spin-rotational coupling, and paramagnetic impurities. In deoxygenated calcium nitrate hydrous melts, only nitrogen (besides the water protons and isotopes of H, Ca, and O) has a nuclear spin and is therefore capable of interacting with the proton nuclear spins. Equation [2], as well as a treatment of the translational or intermolecular contribution to the relaxation rate, predicts that a plot of the logarithm of the spin-lattice relaxation time *vs.* the logarithm of the correlation time (η/T, $1/D$) should have a negative slope of unity at short correlation times (high temperature, high fluidity) and a positive slope of unity at long correlation times (low temperature, low fluidity). Figures 5 and 6 are logarithmic plots of T_1 *vs.*, respectively, $1/D_{Cd}$ (in the absence of water diffusivity data, Cd^{2+} diffusivity is used for purposes of qualitative comparison) and η/T for $Ca(NO_3)_2$-$2.8H_2O$, with lines of unit slope drawn through the high temperature points. The rise at low temperatures is not well defined because of the loss of sensitivity in the measurements, but the minimum appears to occur at a relaxation time of about 0.1 sec. This is comparable with the relaxation time at the minimum in the classical measurements of proton relaxation time in glycerol by Bloembergen (when the difference of frequency is accounted for).

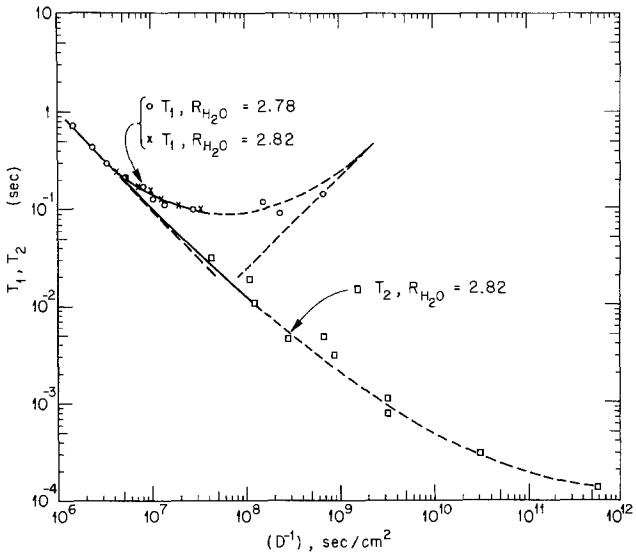

Fig. 5. Spin-lattice relaxation time (T_1) and spin-spin relaxation time (T_2) as a function of the reciprocal of the diffusion coefficient of dilute Cd^{2+} in $Ca(NO_3)_2$-$2.8H_2O$.

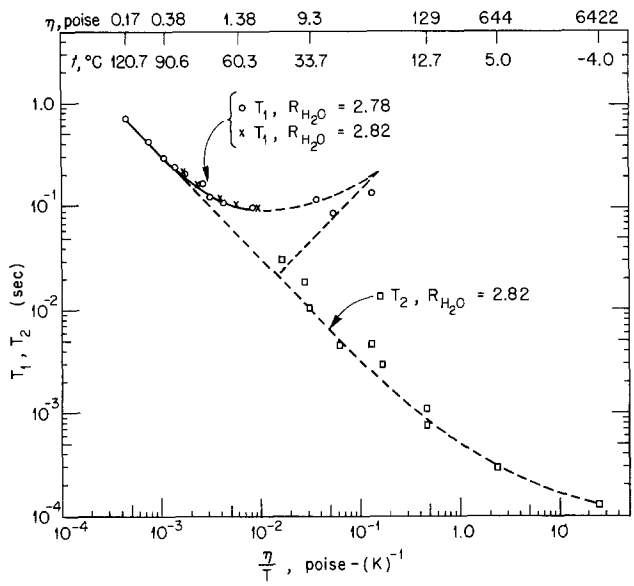

Fig. 6. Spin-lattice relaxation time (T_1) and spin-spin relaxation time (T_2) as a function of the viscosity temperature ratio (η/T) in $Ca(NO_3)_2$-$2.8H_2O$.

For the spin-spin relaxation time, the BPP model (16) leads to the equation

$$(1/T_2)_{rot} = \frac{1}{2}K_1 \left[3\tau_c + \frac{5\tau_c}{1 + 4\pi^2\nu^2\tau_c^2} + \frac{2\tau_c}{1 + 16\pi^2\nu^2\tau_c^2} \right] \quad [3]$$

which predicts a leveling off with increasing correlation times rather than a minimum. For short correlation times, T_1 and T_2 are predicted to be equal. According to BPP (16), the minimum in log T_1 occurs when $\omega_0\tau_c = 1/\sqrt{2}$, and the ratio of T_1/T_2 at this minimum is 1.6. The intersection of the T_2 slope (45°) with the T_2 plateau (0°) should occur at $\tau_c = T_2/\sqrt{2}$. If, as seems likely, there is distribution of correlation times resulting from the different molecular environments experienced by the nucleus during relaxation then the minimum value of T_1 will increase, with decreasing sharpness of the curve at the minimum point and an increased ratio of T_1/T_2. It would thus be desirable to extend the low temperature measurements in this sys-

tem to ascertain with greater accuracy the position of the minimum of T_1 and the leveling off of T_2.

Resolution of intramolecular and intermolecular motion.—Hertz (21) has discussed the interpretation of NMR relaxation measurements in terms of hydration numbers in ionic solutions. In hydrous melts such as $Ca(NO_3)_2$-2.8H_2O, where there is less than one water molecule per ion, the concept of hydration number loses significance. It is of interest however, to attempt to resolve the contributions to the measured relaxation rates of intramolecular (rotational) and intermolecular (rotational and translational motion). The BPP treatment (16) provides a starting point, although it must be recognized as only semiquantitative (22) in its use of macroscopic transport parameters, in the variety of intra- and intermolecular hydrogen distances used and in the lack of direct experimental evidence on the relative rates of the intra- and intermolecular relaxation processes (27). Modifications made by Torrey (22) (using the theory of the random walk) and others (23-26), have been discussed by Fiorito and Meister (27). Figure 7 is a plot of experimental T_1 and T_2 in $Ca(NO_3)_2$-2.8H_2O melts *vs.* several different estimates of the rotational correlation time, both from macroscopic data alone (curves III and V) and from the measured relaxation rates (curves I, II, and IV).

In curve I, T_1 is plotted against rotational correlation times, τ_{tot}, calculated from the rotational relaxation rate in the high temperature limit ($\omega\tau_{rot} << 1$) where ω is the angular frequency, $\nu/2\pi$, b is the intramolecular hydrogen-hydrogen distance, 1.52Å, γ is the gyromagnetic ratio of the proton, and $\hbar$ is Planck's constant divided by 2π

$$(1/T_1)_{rot} = \frac{3}{2}\frac{\gamma^4\hbar^2}{b^6}\tau_{rot} \qquad [4]$$

Values of $(1/T_1)_{rot}$ were obtained by subtracting the estimated intermolecular relaxation rate, $(1/T_1)_{inter}$, from the measured total relaxation rate $(1/T_1)$ (16), using the Kruger (25, 27) equations for the diffusive limit (which assumes a mean jump length much smaller than the distance of closest approach) and for the high temperature limiting case ($\omega\tau_{inter} << 1$)

$$\left(\frac{1}{T_1}\right)_{inter} = \frac{\pi\gamma^4\hbar^2N}{3dD} \qquad [5]$$

Here d is the water molecular diameter, taken as 2.76Å, and N is the spin concentration (protons per cubic centimeter). The low temperature limiting case ($\omega\tau_{inter} >> 1$) is shown in curve II with the intermolecular relaxation rate given by

$$\left(\frac{1}{T_1}\right)_{inter} = [6(5)^{1/2}/25]\frac{\pi\gamma^4\hbar^2N}{d^3}\left(\omega^{3/2}\left(\frac{d^2}{6D}\right)^{1/2}\right)^{-1} \qquad [6]$$

In the absence of water diffusivities in the melt $Ca(NO_3)_2$-2.8H_2O, D was taken as the diffusion coefficient of Cd^{2+} (13).

Curve III of Fig. 7 shows T_1 *vs.* macroscopic estimates of the rotational correlation times. The squares were calculated from the viscosity with Debye's equation for dielectric dispersion in polar liquids (16)

$$\tau_{rot} = \frac{1}{3}\tau_{Debye} = \frac{4}{3}\pi\eta a^3/kT \qquad [7]$$

assuming an H_2O molecular radius, a, of 1.38Å. The triangles correspond to estimates of the rotational correlation time

$$\tau_{rot} = a^2/6D_r \qquad [8]$$

D_r should be a rotational diffusion coefficient, but is here approximated by the Cd^{2+} diffusion coefficient (13). Correlation times were estimated also from the measured spin-spin relaxation time, T_2, with the condition of extreme narrowing, $(T_1)_{rot} = T_2$ and Eq. [4] to give the results shown on curve IV. The macroscopic τ_{rot} calculated using Eq. [7] and [8] were also plotted against T_2 as the triangles and squares on curve V.

Comparing curves I and II with III, and IV with V in Fig. 7, it is seen that the rotational correlation times calculated from the relaxation rates (Eq. [4]) are shorter than those estimated from macroscopic transport coefficients alone. Application of the BPP theory and its modifications to water at 30°C yields intramolecular correlation time estimates of 0.25×10^{-11} to 0.263×10^{-11} sec and intermolecular correlation times of 0.23×10^{-11} to 0.64×10^{-11} sec. Application to the spin-lattice relaxation times in the $Ca(NO_3)_2$-2.8H_2O melts at 121°C yields intramolecular correlation times in the range 0.318×10^{-11} to 0.802×10^{-11} sec and intermolecular correlation times of 3.62×10^{-11} to 18.4×10^{-11} sec. These preliminary results indicate that the intermolecular correlation times are greater than the intramolecular correlation times by a factor of approximately ten in $Ca(NO_3)_2$-2.8H_2O melts. Although the calculations are based on the application of macroscopic concepts of viscosity and diffusion to intermolecular motion on a molecular scale, and although correlation times for translation (motion over a distance of the order of a molecular diameter) and rotation (rotation through 180°) are not directly comparable, the order of magnitude increase of the ratio

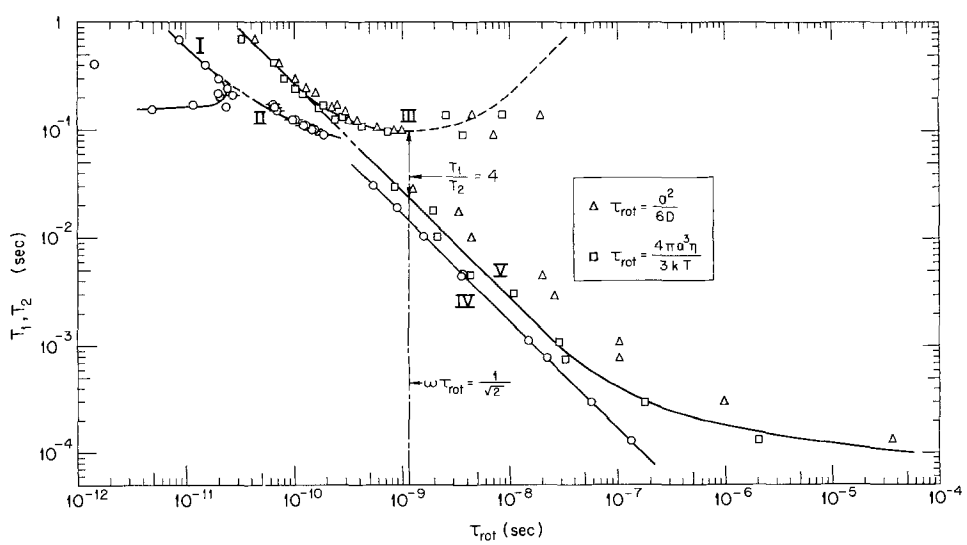

Fig. 7. Spin-lattice (T_1) and spin-spin (T_2) relaxation times as a function of correlation time (τ_{rot}) in calcium nitrate water mixtures $Ca(NO_3)_2$-2.8H_2O with τ_{rot} estimated from the relaxation rates (curves I, II, IV) and from macroscopic transport coefficients alone (curves III, V).

of intermolecular to intramolecular correlation time in the hydrous melts relative to water would appear to have at least qualitative significance. The greater freedom for rotation than from translation in melts of such high charge density suggests that the effect of electrostriction is analogous to the effect of high pressure on relaxation in liquids (28).

Conclusions

Spin-lattice and spin-spin relaxation times have been measured for hydrous melts $Ca(NO_3)_2$-R_{H_2O}, and show concentration and temperature dependences similar to those for the macroscopic transport properties. Estimates of rotational and translational correlation times, based on models for magnetic dipolar relaxation, suggest an order of magnitude greater degree of freedom for rotation than for translation in $Ca(NO_3)_2$-$2.8H_2O$ at 120°C ($\omega\tau << 1$). Low temperature results suggest that the region $\omega\tau \approx 1$ is accessible to measurement in hydrous melts, and our new techniques should provide higher precision. Additional relaxation measurements over a wide range of water contents, together with spin-echo measurements of water diffusivities, measurements with paramagnetic ions to provide shorter relaxation times, and with quadrupolar nuclei should prove useful in resolving intermolecular and intramolecular motions of water molecules in hydrous melts.

Acknowledgments

We would like to thank Professors D. H. Smith and R. Livingston for fruitful discussions of this manuscript, C. A. Angell and C. T. Moynihan for calling our attention to some valuable references, and especially R. Meister for making available a prepublication copy of Reference (9). This research was sponsored by the Energy Research and Development Administration under contract with Union Carbide Corporation.

Manuscript submitted Sept. 20, 1976; revised manuscript received Jan. 11, 1977. This was Paper 416 presented at the Washington, D. C., Meeting of the Society, May 2-7, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by Oak Ridge National Laboratory.

Corrosion of Lithium in Alkaline Solution

E. L. Littauer* and K. C. Tsai*

Lockheed Palo Alto Research Laboratories, Palo Alto, California 94304

ABSTRACT

The corrosion of Li was studied in 3-5M LiOH at 25°C and in 4.5M LiOH at 4°-60°C. The Arrhenius relationship is obeyed and the apparent activation energy for the Li corrosion reaction is found to be 15.5 kcal mole^{-1}. An empirical relationship is derived from which the corrosion rate v_f can be obtained at any molar LiOH. At 25°C v_f(kA m^{-2}) = 0.31(54.1 − 10[LiOH]). An equation is also given which allows calculation of the Li corrosion rate when the metal is anodically polarized. The kinetics of the H_2 evolution reaction (e.r.) on Li were determined, the transfer coefficient α has a value of 0.14. The rate-controlling process of the Li dissolution reaction is the highly polarized H_2 evolution at cathodic sites. Based on the α value obtained, the enthalpy of activation for the H_2 e.r. on Li at OCV is calculated to be 22.8 kcal mole^{-1}. It is proposed that the protective film on Li has a duplex structure with a thin oxide/hydroxide layer adjacent to the metal and an outer porous hydrated layer through which the reaction products and reactants can pass freely.

The rapid dissolution of Li in alkaline aqueous solutions can be utilized electrochemically to produce high rate battery systems (1). This is possible because the corrosion (parasitic) reaction in 3-5M LiOH can be virtually eliminated if the metal is anodically polarized by about 300 mV. It has been found that the rate of the Li dissolution reaction

$$Li + H_2O \rightarrow LiOH + \tfrac{1}{2} H_2 \qquad [1]$$

is essentially constant at constant temperature from OCV to the above-mentioned polarization level. Unlike conventional batteries, in Li-H_2O cells the current efficiency is governed by the ratio of two competing reactions, namely, the anodic dissolution reaction and the parasitic reaction (2, 3). The current efficiency increases with an increase in the anodic dissolution rate (*i.e.*, the current density), and it decreases at elevated temperatures where the corrosion reaction is stimulated. Since current efficiency is critical to cell performance, a fundamental understanding of the factors which influence the parasitic reaction is important.

No prior investigations of the corrosion of Li immersed in aqueous electrolytes have been reported. Papers on the electrochemistry of the system have been concerned with anodic passivation and mathematical modeling. This corrosion study of Li in flowing electrolyte under conditions identical to battery operation was undertaken to gain knowledge of three aspects of the Li-H_2O reaction.

(*i*) Information on the reaction at various LiOH concentrations and temperatures provides data for the determination of the reaction rate constant. This then allows calculation of corrosion rates in practical battery systems.

(*ii*) To characterize the processes which occur across the oxide/hydroxide film in a Li-H_2O cell, knowledge of the H_2O activity at the active Li surface is necessary. The assumption of the previous mathematical modeling paper (2) was that the exchange current density for the parasitic hydrogen evolution reaction is proportional to the 0.5 power of water activity at the active Li surface. This was equivalent to assuming that the transfer coefficient α is 0.5, which would be a reasonable figure in the absence of contrary experimental data. The experiments reported here have provided a precise value for α.

(*iii*) Diagnostic data from the anodic passivation studies (4, 5) led to the initial assumption on the nature of the complex film which forms on Li. Normal specimen preparation and microscopic examination of the film cannot be confidently used since reaction of occluded water with the metal on its removal from the test solution probably alters the structure. However, demonstrated correlations from this study with prior vapor phase investigations (6-8), which included visual and theoretical analyses of the film structure, would add confidence to predictions of film characteristics in the present situation.

Experimental

The test cell, support equipment, and procedures described previously for polarization studies of Li (4) were used for many reasons.

(*i*) The test cell is designed to insure uniform reaction across a lithium electrode of constant cross section. Even solution flow across the electrode surface is achieved because of the configuration of the ribbed steel screen flow-through matrix which acts as the counterelectrode in cell polarization experiments. This matrix is pressed against the Li surface. In alkaline aqueous solutions the Li surface is covered by a porous but protective oxide/hydroxide film.

(*ii*) Accurate potential measurements can be taken at the Li film/solution interface. The resistance of the film has been characterized and thus *IR* correction is straightforward.

(*iii*) The data obtained with this cell can be conveniently correlated with previous results.

(*iv*) Real-time corrosion rate measurements were obtained since the setup incorporated a precise hydrogen gas measuring system.

Briefly, the apparatus consisted of a circular 1.14 × 10^{-3} m^2 electrode area test cell incorporating a system to maintain constant the pressure of the ribbed screen matrix against the Li surface. In the present experiments the pressure was held at 3.5 × 10^4 Pa. Electrolyte temperature and concentration were controlled experimental variables. Solution flow rate was fixed at 0.3 m/sec. Hydrogen gas evolved during the reaction was separated from the electrolyte and measured with an American Meter Company Model 802 1 liter per revolution wet test meter. The instrument was modified with a Renco Corporation Model KT23A-500 optical encoder which, mounted on the wet test meter shaft, provided a digital signal output of 500 pulses per revolution. The encoder was mounted to eliminate the frictional drag component which would have amplified inaccuracies endemic to wet test meters at low flow rates. The encoder output was processed by an electronic digital to analog converter which provided instantaneous rate and total gas volume data. The gas rate was converted from volumetric flow rate (cubic centimeters

per second) to current (I) using the ideal gas law and Faraday's law.

Corrosion rate determinations were taken about 1 min after commencing electrolyte flow. By waiting this period of time, system stability was assured. Hydrogen evolution measurements were taken over a number of 20 sec periods. The experiments were performed in solutions of χM LiOH where $\chi = 3$, 3.5, 4, 4.5, and 5 ($\pm$ 0.05M) at 25° $\pm$ 0.1°C. The influence of temperature on the corrosion rate was determined at 4°, 15°, 25°, 35°, 45°, and 60°C in 4.5M LiOH. The corrosion potential in the same solution was determined at $T = 4°$, 15°, 25°, 35°, and 45°C. A Cd/Cd(OH)$_2$ reference ($E°_H = 0.81$) was used. This electrode has a temperature dependence of 0.14 mV/°C (9). At elevated temperatures, *i.e.*, above about 45°C, steady-state potential readings were not obtainable because of difficulties in maintaining isothermal conditions. At these high temperatures, a phenomenon referred to as thermal runaway occurs wherein the corrosion rate increases with time causing the electrode temperature to rise inconsistently. However, corrosion rate measurements could still be obtained reproducibly at up to 60°C by following a modified procedure. Here, before taking a hydrogen measurement, the anode was polarized by about 1V to temporarily suppress the parasitic reaction. On returning to OCV the electrode rapidly reverted to its active state. Its temperature remained essentially constant for about 20 sec during which time the hydrogen was monitored.

All experiments were run in triplicate. A regression analysis was performed on the data and the standard deviation was always less than 5%. Averaged values are therefore given in the figures.

Results

The corrosion rates of Li in 4.5M LiOH from 4°-60°C are shown in Fig. 1. The dramatic increase in rate above about 45°C is clearly evidenced. In this electrolyte, isothermal conditions could not be maintained for more than about half a minute, and on longer term exposure thermal runaway occurred.

The linear plot of logarithmic corrosion rate, ln v_f *vs.* $1/T$, in Fig. 2 shows that the Arrhenius relationship is obeyed for the aqueous corrosion of Li. Experiments performed in LiOH concentrations other than 4.5M (e.g., 4.0M) gave plots parallel to that shown. The apparent activation energy for the reaction $E_{act,r}$ calculated from the slope is 15.5 kcal mole^{-1}.

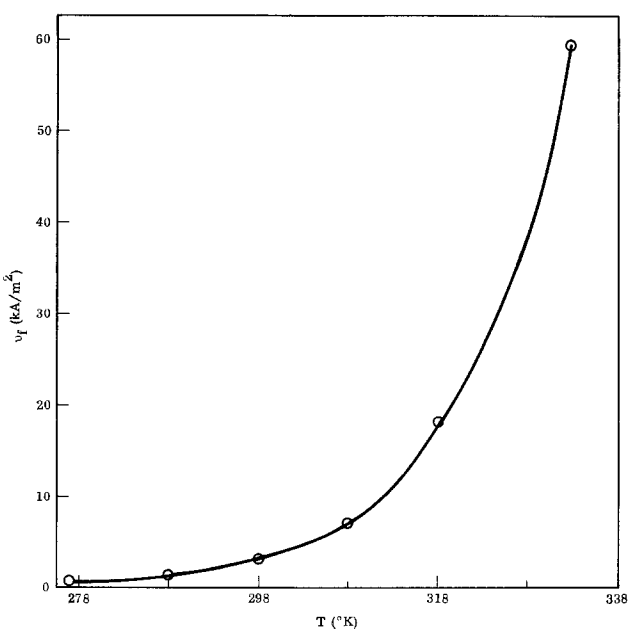

Fig. 1. Lithium corrosion rates at various temperatures in 4.5M LiOH.

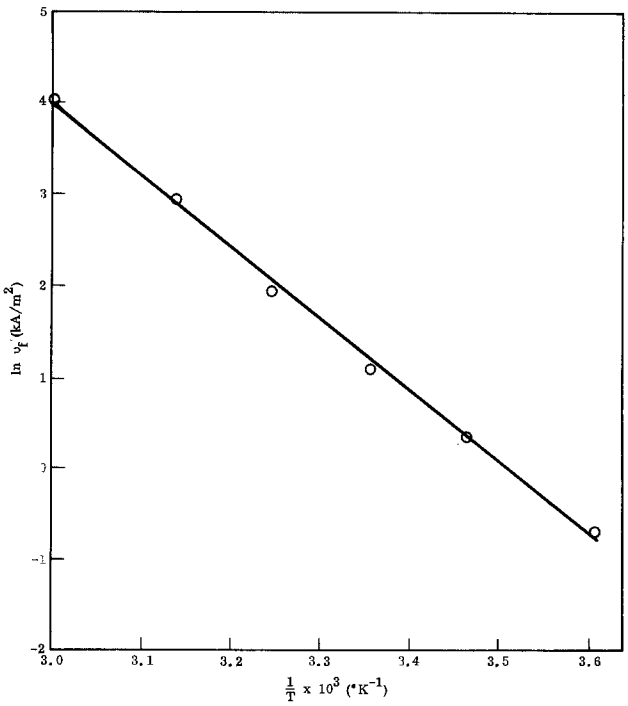

Fig. 2. Logarithmic corrosion rate (observed), ln v_f, vs. reciprocal temperature, $1/T$, (Arrhenius plot) in 4.5M LiOH.

Figure 3 indicates dependence of corrosion rate on concentration of LiOH at 25°C. This figure suggests that a linear rather than a logarithmic or parabolic relationship holds for the Li-H_2O reaction. Interestingly, extrapolation of the plot to $v_f = 0$ shows that Li would not corrode in 5.41M LiOH at 25°C. In actuality, the maximum solubility of LiOH in H_2O at that temperature is 5.3M.

Figure 4 indicates the temperature dependence of the corrosion potential, E_c, in 4.5M LiOH. The slope of the linear plot gives a value of 8 mV/°C. It was observed that the corrosion potentials under fixed experimental

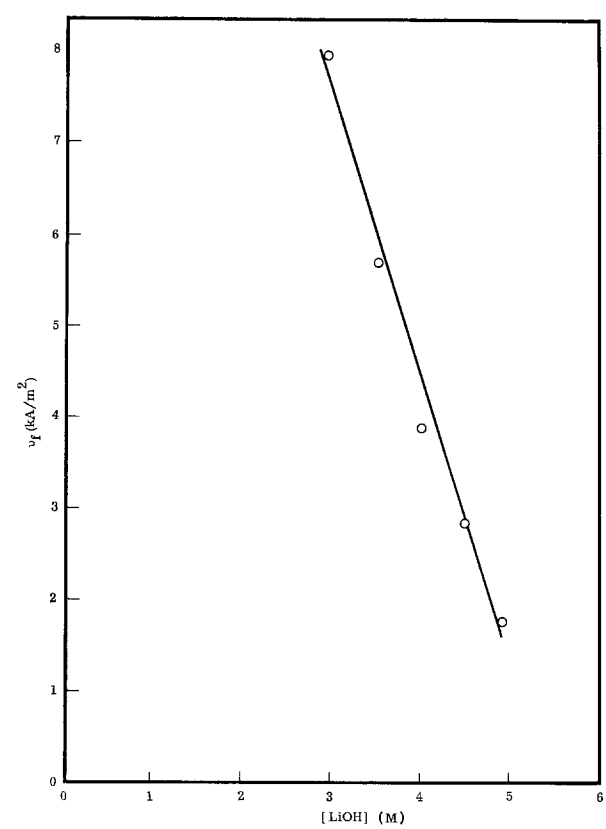

Fig. 3. Corrosion reaction rates vs. molar LiOH at 298°K

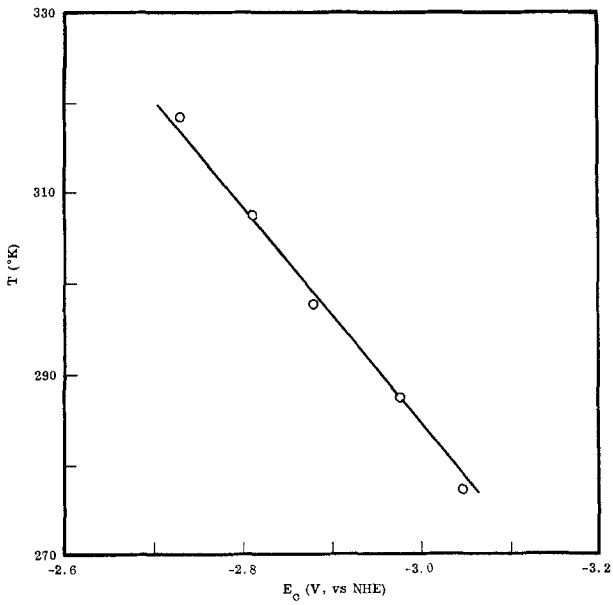

Fig. 4. Lithium corrosion potential, E_c, vs. temperature in 4.5M LiOH.

conditions were highly reproducible and remained fixed for the duration of the test, *i.e.*, >1 hr.

Discussion

Kinetics.—The chemical reaction between Li and H_2O, Eq. [1], is highly irreversible and therefore the forward reaction rate v_f may be related to the reaction rate constant k_f by

$$v_f = k_f[Li][H_2O] \quad [2]$$

It may be inferred from Fig. 2 that the Arrhenius equation is obeyed in this system. Hence

$$k_f = A \exp(-E_{act,r}/RT) \quad [3]$$

where A is the frequency factor and $E_{act,r}$ is the experimental activation energy. $E_{act,r}$ does not refer to constant absolute potential but comprises, as is discussed later, both the enthalpy of activation and a major contribution from the electric field involved (10).

Combining [2] and [3] gives the rate equation for the Li-H_2O reaction

$$v_f = A[Li][H_2O]\exp(-E_{act,r}/RT) \quad [4]$$

The rate-controlling step in the Li corrosion reaction is shown subsequently in this paper to be the reduction of H_2O at cathodic Li sites. It also represents the over-all rate of oxidation of Li in the aqueous solution.

The activity of Li at the metal surface may be assumed to be unity and pure water is 55.5 M/liter. In LiOH solution, however, the activity of H_2O is dependent on the LiOH concentration, *i.e.*

$$LiOH + nH_2O \rightleftarrows Li(H_2O)_l^+ + OH(H_2O)_m^- \quad [5]$$

where l and m represent the coordination numbers (CN) of the respective aquo complexes and $l + m = n$. Equation [4] can then be expressed

$$v_f = A(55.5 - (l + m)[LiOH])\exp(-E_{act,r}/RT) \quad [6]$$

Figure 3 plots the rates of the Li-H_2O reaction as a function of LiOH concentration and verifies the relationship given by [6]. Although the CN, m, for OH^- is unknown in LiOH solutions, the CN, l, for Li may be taken as 6 (11). Extrapolation of the plot of Fig. 3 to $v_f = 0$ gives m a value of 4. It should be pointed out that l and m represent the maximum coordination values for Li^+ and OH^- in aqueous solution. One might expect that with increasing solubility of LiOH at elevated temperatures, there would be a decrease in CN's. In practice, however, the maximum electrolyte concentration which is used in Li-H_2O cells is *ca.* 5M. Therefore this effect is unimportant here. Accordingly, $l + m$ may be set as approximately 10. Then, at 298°K, by inserting values for $E_{act,r}$ and R into [6], from the slope of the plot in Fig. 3

$$\frac{\partial v_f}{\partial[LiOH]} = -3.12 \text{ kA m}^{-2} \text{ mole}^{-1}$$

we have $A = 7.5 \times 10^{10}$ kA m^{-2} mole^{-2}. The frequency factor obtained here when put into [3] or alternately by combining [2] and [6], gives the rate constant for the Li-H_2O reaction

$$k_f = 0.31 \text{ kA m}^{-2} \text{ mole}^{-2}$$

By considering the volume fraction of LiOH solute, a modified empirical rate equation for the corrosion reaction may be obtained

$$v_f = \{a - 10[LiOH]\}\exp(b - E_{act,r}/RT) \quad [7]$$

where $a = 54.1$, *i.e.*, $10[LiOH]$ at $v_f = 0$ (extrapolated from Fig. 3) and $b = \ln A = 25.04$. This equation describes the observed linear dependency of the Li corrosion rate on LiOH conc. under conditions typical of Li/H_2O battery operation. It would appear reasonable to hypothesize that the water molecules which do not form aquocomplexes with Li^+ and OH^- play the primary role in the reaction. At elevated temperatures where isothermal conditions cannot be maintained in the system (see experimental) or in very dilute electrolytes where the corrosion rate is so high as to cause thermal runaway, this equation will not implicitly hold.

In actual practice, the rate of the Li-H_2O reaction is measured by the rate of hydrogen evolution. Reaction [1] may be regarded as a combination of two local cell reaction, *i.e.*

$$Li + OH^- \rightleftarrows LiOH_{(aq)} + e^- \quad [8]$$

$$e^- + H_2O \rightleftarrows OH^- + \tfrac{1}{2}H_2 \quad [9]$$

At OCV, [8] and [9] proceed at exactly the same forward reaction rate and the back-reaction rates are extremely small. The OCV (corrosion) potential E_c is a mixed potential representing the polarization of the Li dissolution sites and the H_2O reduction sites at the reacting surface. At 25°C in 4.5M LiOH, $E_c = -2.88$V *vs.* NHE which indicates that the H_2O reduction at the Li electrode is highly polarized. The reversible potential E_H for the H_2 e.r. in 4.5M LiOH ($pH = 14.3$) (4) = −0.84V. The electrochemical reduction of H_2O over Li may be assumed to be predominantly under activation control. The basis for this assumption is the report of prior work on the evolution of H_2 on various metals (Mg, Pb, Zn, etc.) in strongly alkaline solutions (12). The Tafel relationship is obeyed at least up to 10 kA m^{-2} and concentration polarization was found to be insignificant. Transfer coefficient, α, values reported for the H_2 e.r. on Mg, Pb, and Zn were 0.17, 0.25, and 0.32, respectively. It is assumed that the Mg and Zn electrodes, like Li, are covered with an oxide film and thus similarities would be expected in the kinetics. Then, following the model based on potential energy curves (13) the rate constant for the H_2 e.r. may be expressed

$$k_f = k \exp\left(-\frac{E - E_c}{RT/\alpha n\mathbf{F}}\right) \quad [10a]$$

and

$$k = k^\circ \exp\left(\frac{E_H^\circ - E_c}{RT/\alpha n\mathbf{F}}\right) \quad [10b]$$

where k° is the rate constant when $E = E_H^\circ$. The term $E_H^\circ - E_c$ represents the local cell potential for the Li oxidation and H_2O reduction couples. At OCV E and E_c are synonymous and [3] and [10b] will coincide. Then

$$RT \ln(A/k^\circ) = E_{act,r} + n\alpha\mathbf{F}(E_H^\circ - E_c) \quad [11]$$

and

$$\frac{\partial T}{\partial E_c} = \frac{n\alpha\mathbf{F}}{R \ln(A/k^\circ)}^{1} \quad [12]$$

The experimental data plotted in Fig. 4 of E_c *vs.* T depicts the relationship described by [11]. A straight line is observed. From the slope of this plot one could determine the H_2 e.r. rate constant k° if α were precisely known. This coefficient may be calculated as follows. By combining Eq. [2] and [10b] in the case where [Li] = 1, one obtains [13]

$$\ln v_f = \ln(k^\circ[H_2O]) + \frac{n\alpha\mathbf{F}}{RT}(E_H^\circ - E_c) \quad [13]$$

then, by plotting $\ln v_f$ *vs.* E_c/T, as in Fig. 5, the slope, 1.55×10^3, represents the term $n\alpha\mathbf{F}/R$. In the case of hydrogen evolution in alkaline solutions, $n = 1$, then α computes to 0.14. This value compares with those given above for the H_2 e.r. on Mg, Pb, and Zn.

This is perhaps a novel approach to the derivation of α. While confirmation of its magnitude from polarization curves would be desirable, in this system it is impossible to obtain discrete H_2 polarization plots because of the confounding influence of the concurrent Li dissolution reaction.

To obtain k°, we have from [11]

$$k^\circ = A \exp\left\{-\left(\frac{E_{act,r}}{RT} + \frac{E_H^\circ - E_c}{RT/n\alpha\mathbf{F}}\right)\right\} \quad [14]$$

and, at 298°K, k° computes to 5×10^{-6} kA m^{-2} mole^{-2}. With knowledge of k° and of the potential of the corroding electrode as a function of temperature, the lithium corrosion rate constant can be calculated independently from [10b] without directly measuring the H_2 evolution rate as a function of temperature.

A rate equation for the general case of H_2 evolution at a polarized electrode can be obtained where $i_{H_2} = v_f$. Combining [7] and [13] we have

$$i_{H_2} = k\{54.1 - 10[LiOH]\} \exp\left(\frac{-n\alpha\mathbf{F}(E - E_c)}{RT}\right) \quad [15]$$

and, for the special case at OCV where $E = E_c$, the corrosion current

$$i_{corr} = k(54.1 - 10[LiOH]) \quad [16]$$

Knowing the transfer coefficient also permits calculation of the enthalpy of activation for the H_2 e.r. on Li. Based on Fig. 1 and 4, Fig. 6 may be generated. A constant overvoltage has been arbitrarily taken at 25°C, *i.e.*, $\eta_{298°K} = E_H^\circ - E_c = 2.04$V. The observed corrosion rate, v_f, has been corrected to this overvoltage by $(v_f)_{\eta 298°K} = v_f \exp(\Delta E/b)$ with $b = RT/n\alpha\mathbf{F}$ and $\Delta E = E_{OBS} - E_{c(298°K)}$, where E_{OBS} is the corrosion potential at any given temperature and $E_{c(298°K)}$ is the corrosion potential at 25°C. From the slope of the plot in Fig. 6, the enthalpy of activation is

$$\Delta H^\dagger = -R\left[\frac{\partial \ln(v_f)_{\eta 298°K}}{\partial 1/T}\right]$$

and this computes to 22.8 kcal mole^{-1}.

The interconnection between the H_2 evolution and the Li dissolution reactions at OCV and also when anodically polarized is illustrated in Fig. 7. Here, the H_2 activation polarization curve, represented by curve A, has been calculated using [15]. 4.1M LiOH was selected as the solution of interest since data exist for the anodic polarization of Li in that electrolyte. The anodic curve which has been published previously in Fig. 1 of Ref. (5) is corrected here for IR and appears

[1] Actually, $k^\circ = A \exp(-E_{act,r}/RT) \cdot \exp(-n\alpha\mathbf{F}\, E_H^\circ/RT)$, but $\partial E_H^\circ/\partial T$ is effectively zero over the temperature range of concern to this study.

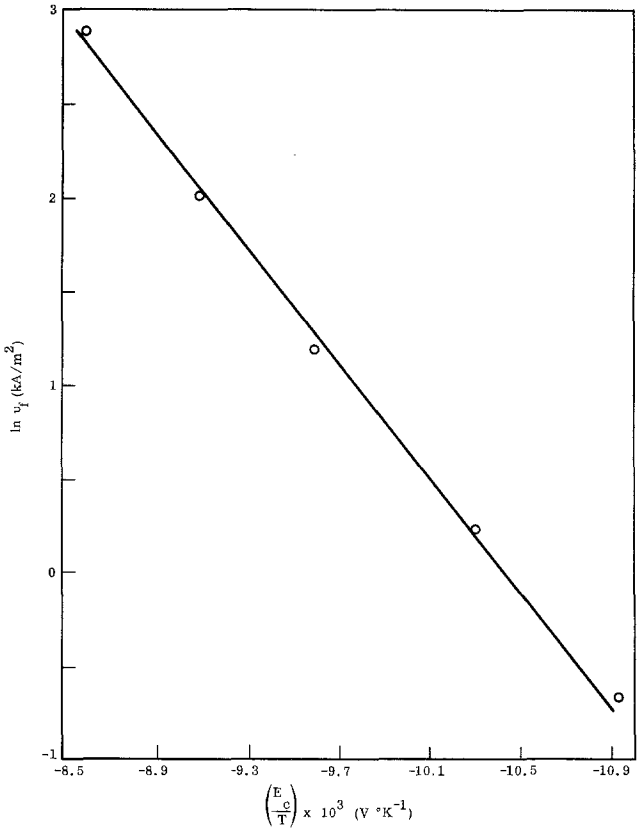

Fig. 5. Logarithmic corrosion rate, ln v_f, *vs.* E_c/T

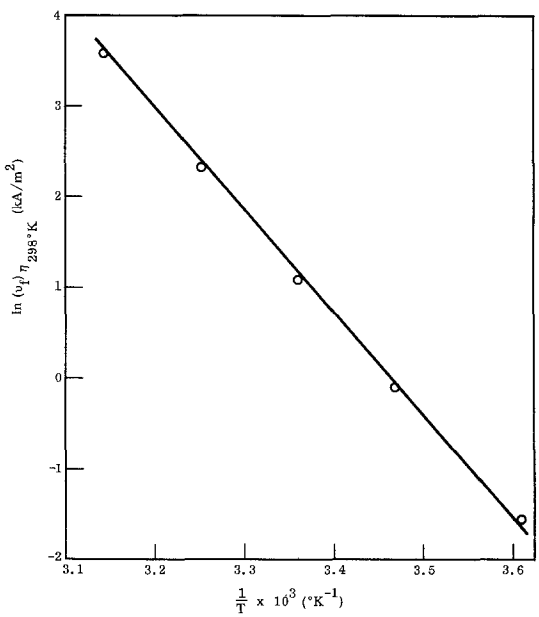

Fig. 6. Logarithmic corrosion rate (calculated) at constant overvoltage $\ln(v_f)_{\eta\ 298°K}$, *vs.* reciprocal temperature, $1/T$, in 4.5M LiOH.

as curve B. Then, by subtracting curve B from A, curve C is derived which represents the H_2-free polarization curve for Li in the solution of interest.

The E_H° for the Li dissolution reaction [1] in 4.1M LiOH ($a_{Li^+} \approx 2$) is −3.03V, while the observed OCV potential of the Li electrode E_{OBS} in that solution is −2.76V. To speculate at this time on the kinetics of the Li dissolution reaction over the narrow span $E_{Li}^\circ - E_{OBS}$ would be unwise because (*i*) no information is available on the transfer coefficient, and (*ii*) it has not been established that the Tafel relationship is obeyed for this highly energetic irreversible reaction. However, for present purposes, it is sufficient to consider the situation from −2.76V anodic as depicted in

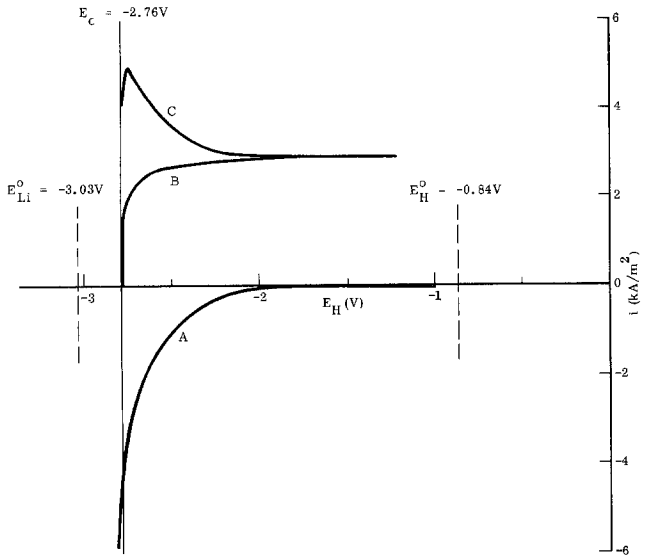

Fig. 7. Composite figure showing hydrogen evolution polarization plot on Li (curve A), actual mixed potential polarization plot for Li (curve B), and generated anodic dissolution plot of Li (curve C) in 4.1M LiOH at 298°K.

Fig. 7. Two interesting aspects are illuminated. First and most important, from the point of view of the Li/H_2O cell, is the fact that the rate-controlling process in the corrosion of Li is the polarization at the H_2 evolution reaction sites. In other words, the corrosion is under cathodic control. The activation energy for the rate-controlling step of the Li corrosion reaction as calculated above therefore clearly represents the energy for the H_2 e.r. This leads to the assumption that electrolyte additives which polarize the H_2 e.r. could significantly inhibit the corrosion reaction. The second aspect is the H_2-free polarization curve C. The configuration of this curve is quite unlike that generally observed for the anodic dissolution of metals in aqueous electrolytes. Here, the highest dissolution rate occurs in the vicinity of OCV. At about −2.2V a situation resembling a limiting current takes effect. This then defines the maximum usable current which can be drawn from the system under specific conditions of molar LiOH, solution flow rate, and temperature.

Film properties.—In the past, the high reactivity of Li with H_2O has discouraged studies of the metal immersed in aqueous solution. Experiments in saturated LiCl at low temperatures have been reported (15) but no attempt was made to examine the properties of the film. There is however information available on the reaction of Li with H_2O vapor. Irvine and Lund (6) studied the reaction at a partial pressure of H_2O vapor up to 12.6 mm Hg, and Deal and Svec (7) at 22-100 mm Hg. There is consensus that when exposed to H_2O vapor, Li becomes covered initially with a thin coherent glassy black film shown by x-ray to be LiOH. The formation of this thin film (its thickness has not been reported) follows a logarithmic rate law. Therefore it is assumed that it is protective of the underlying metal. After some hours exposure to moisture, a white layer of $LiOH \cdot H_2O$ grows over the outer surface, and the reaction rate then obeys a linear rate law. This observation at first suggests that the LiOH layer becomes permeated by cracks or pores so that the H_2O can have access to the metal. However, Evans (16) has pointed out that a linear rate law will hold during oxidation if lattice diffusion is the controlling process as long as the diffusion distance is constant. Irvine and Lund took a modified approach to this model. They proposed a duplex film where the layer adjacent to the metal remains protective and of constant thickness and, as reaction proceeds, the outer portion becomes hydrated to form the porous $LiOH \cdot H_2O$. This outer layer would then be freely permeated by H_2O and OH^-. The $LiOH \cdot H_2O$ represents the final reaction product. Eventually all the Li is converted to this form via the intermediate black film.

The reaction of Li in H_2O vapor has also been studied at elevated temperatures (8). Again, LiOH was identified as the product which forms directly adjacent to the metal with $LiOH \cdot H_2O$ as an outer layer.

Although Li immersed in aqueous LiOH poses a different situation because the reaction product can dissolve freely into the solution, certain similarities have been noted. In place of the thin shiny black film, a fairly thick dull gray covering is observed. Also, as reported in the vapor studies, a loosely adherent product which has been identified as $LiOH \cdot H_2O$ overlays some areas. This material which dissolves into the electrolyte could be considered the final reaction product. However, in contradistinction to the vapor case, it does not seem to play an important role in the reaction of the metal with aqueous solution.

Certain important differences exist between Li exposed to H_2O vapor and Li immersed in LiOH solutions. Unlike the black film, the gray film cannot be analyzed *in situ*. Although x-ray analysis shows it to be a mixture of anhydrous and hydrous LiOH, it cannot be stated categorically that morphological adjustments are absent after specimen removal from the solution or in the drying process. However, the film does not appear to change color or undergo any other alterations. More importantly, one may postulate that a duplex film exists in both systems, but in the present case the protective film directly adjacent to the metal probably comprises a very thin layer of an oxide possibly intermixed with adjacent LiOH. In a previous study of anodic passivation (4), thermodynamic considerations were given to support the proposition that Li_2O can exist at least transiently within pores in the LiOH film. Also Vermilyea (17) suggests that unstable higher oxidation states may form on metals undergoing anodic oxidation. The corrosion rate of Li in aqueous solution is so high that a situation very similar to anodic oxidation exists.

The basis for proposing the duplex film rests on the following observations. It has previously been shown that in the active polarization region, *i.e.*, from OCV to *ca.* 300 mV anodic, a linear i-η relationship is obtained (4, 5). Activation polarization for the Li dissolution reaction is negligible, and therefore the observed polarization is predominantly *IR* across the film. Recent work in these laboratories has shown that over the same polarization range, with fixed temperature and flow rate, the film thickness remains essentially constant. This thickness is in the range 6-9 $\times$ 10^{-2} cm and its value is dependent on molar LiOH (18). To support the high OCV corrosion current densities reported in this paper, in 3.5M LiOH i_{corr} = 5.92 kA m^{-2} (projected) and in 4.5M LiOH i_{corr} = 2.82 kA m^{-2} (projected), requires that the film must be permeated with electrolyte. Knowing the conductivity of the LiOH solutions, it can be calculated that approximately 5% of the projected area will comprise electrolyte. One may hypothesize that the flooded pores or fissures in the film terminate at bare Li sites, but because of the high reactivity of Li it seems logical to assume that a protective layer exists at the pore extremities. Since the actual current density within the pores must be about 20 times greater than the values given above, it follows that the protective layer must have excellent electronic or ionic conductivity. This layer (the inner portion of the duplex film) sustains such high flux rates with minimum polarization that in all likelihood it is only a few molecular layers thick. The proposed model therefore resembles that suggested by Irvine *et al.* except for differences of film thickness and perhaps morphology. The main difference is the composition of the "inner" protective layer.

In summary, a duplex film model is proposed. It comprises an outer porous layer permeated with electrolyte which provides a medium for the mass trans-

port of ions and/or gas from and to active sites. This overlays a thin inner conducting layer adjacent to the metal. The model which is based on corrosion experiments described in this paper and prior anodic polarization studies seems at the present to satisfactorily describe the system. Exact morphological and structural information about the protective film cannot be obtained by direct inspection because fine changes probably occur on removal of the specimen from solution.

Further, even if improved techniques could be developed, the film is too thick for sensitive inspection by, say, Auger or ESCA spectroscopy. Fortunately, fairly simple electrochemical experimentation gives extremely reproducible results and diagnostic techniques now being used on the system (18) may in the future provide additional insight.

Conclusions

The corrosion of Li in LiOH solutions has been considered from the point of view of the kinetics of the over-all dissolution reaction, the electrochemistry of the concurrent Li dissolution and H_2 reduction reactions, and the features of the protective film on the metal. A rate expression for the Li-H_2O reaction has been obtained, and the temperature dependence of the rate constant can be described by the Arrhenius equation. The apparent activation energy and the enthalpy of activation for the H_2 e.r. on Li are reported for the first time. It has been shown that the polarization of the H_2 evolution at the Li surface is the rate-limiting process rather than the Li dissolution reaction. The kinetic parameter, α, for the H_2 e.r. was found to compare with published values of it on metals such as Mg and Zn. Equations have been derived which permit calculation of (*i*) the OCV corrosion rate of Li in LiOH solution, and (*ii*) the corrosion rate when the metal is anodically polarized. These equations assist in the determination of optimized control points for the Li/H_2O electrochemical cell. An unusual feature of the electrochemistry of the system is revealed when the H_2-free anodic polarization curve is plotted. This curve has a configuration quite different to that normally observed for metals undergoing anodic dissolution. The effect which is reported here, but is not diagnosed in detail at this time, may perhaps be described as anodic polarization on a deenergized electrode. To account for the chemical and electrochemical characteristics of the system, a duplex film model is proposed. It comprises an "inner" presumably thin coherent layer of oxides and an outer porous layer of admixed LiOH and LiOH·H_2O. This model in conjunction with the kinetics of the H_2 e.r. helps to explain the coexistence of Li and H_2O in aqueous LiOH solution without violent reaction.

Correlations Between ^{1}HNMR Spectroscopy and Transport Properties in Molten Pyridinium Salts

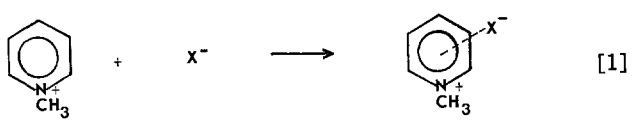
David S. Newman,* Richard T. Tillack, David P. Morgan, and Wai-Ching Wan

Department of Chemistry, Bowling Green State University, Bowling Green, Ohio 43403

ABSTRACT

The equivalent conductance, viscosity, and ^{1}HNMR spectra of several molten pyridinium salts were measured as a function of temperature. The spectra of N-methylpyridinium chloride, bromide, and iodide were measured relative to an external standard of dimethylsulfone. The spectra of 4-methylpyridinium chloride and bromide were measured relative to an internal standard of hexamethyldisiloxane. No changes in chemical shifts or line widths as a function of temperature were observed, but there were significant changes in chemical shifts with change of halide ion. From correlations between these data and energies of activation for conductance and viscosity we conclude that N-methylpyridinium chloride, bromide, and iodide are most likely completely dissociated into pyridinium and halide ions, but that complex species are present in 4-methylpyridinium chloride and bromide melts.

The molten organic salts studied in this investigation were N-methylpyridinium chloride (I), N-methylpyridinium bromide (II), N-methylpyridinium iodide (III), 4-methylpyridinium chloride (IV), and 4-methylpyridinium bromide (V). They are shown in Fig. 1. These pyridinium salts are technologically and theoretically important for a variety of reasons, but especially because they are low melting, relatively stable, and can be studied by ^{1}HNMR techniques (1, 2).



Many investigators have debated the propriety of using organic melts as general models for the molten state because of the possible presence of complex ions. In their discussion of molten alkyl ammonium salts, Janz, Reeves, and Ward (3) suggest that the rather striking similarity between the energy of activation for viscosity, E_η, and the energy of activation for equivalent conductance, E_Λ, arose from one of two causes. Either a complex was forming in the melts whose lifetime was relatively long compared with the time it took for both the electrical and mechanical stresses to relax, or steric factors, such as size, shape, and ionic orientation, made it very difficult for the ions to move past each other. The authors favored the latter explanation.

It should be kept in mind that E_η is considerably larger than E_Λ for molten alkali metal halides and many other molten inorganic halides (4). Viscosity involves the cooperative movement of both anion and cation and its energy of activation is largely determined by the ion with the greater radius. Conductance is largely due to the mobility of the smaller species and therefore requires less energy.

Lind, Abdel-Rehim, and Rudich studied another series of alkyl ammonium salts having particularly symmetrical cations and anions (Pr_4NBF_4 and Pr_4NPF_6 among others) and observed quite similar values for E_η and E_Λ in each of their melts (E_η always being slightly larger than E_Λ) (5). These authors suggested the hydrocarbon chains block or clog interstices of the melts, and cause a great deal of interionic friction. The conductance in these melts is affected to a greater extent than the viscosity because there is a transfer of neighboring ions in opposite directions during conduction while viscosity arises largely from the macroscopic movement of one layer of liquid past another with momentum transfer occurring via phonons. In other words, the alkyl chains prevent anions from passing cations, but affect the phonons to a much lesser extent.

The pyridinium salts we have chosen for study are also low melting organic compounds, but without long hydrocarbon chains. They do contain several sets of protons whose magnetic environments are vulnerable to the forces of interaction in the melts and can serve as spectroscopic probes of the molten state. We selected salts with cations and anions differing in size to foster differences between E_η and E_Λ, if they exist, and account for these differences by direct observation of changes in chemical shift of appropriate protons. On the other hand, if E_η and E_Λ were nearly equal in the pyridinium salts despite the ion size differences and the absence of hydrocarbon chains, this could be construed as a more general property of molten organic salts.

If a complex species were to form between the methylpyridinium ion and the halide ion it could do so in one of two ways. A dissociated cation and anion can combine to form an ion pair, as described by Eq. [1], or the species bonded to the nitrogen can dissociate and combine with the halide producing an R^+X^- ion pair plus a neutral picoline or pyridine as described by Eq. [2]

In either case, the magnetic environment around at least one set of protons will change as a result of com-

Key words: molten pyridinium salts, conductance, viscosity, ^{1}HNMR.

plex formation and produce a temperature-sensitive ^{1}HNMR spectrum provided the energy barrier between dissociated ions and ion pairs is great enough.

Most authors divide the time scale for proton exchange into three regions. At relatively low temperatures a slow exchange region exists in which two distinct spectra, characteristic of each isolated species, are obtained. As the temperature is raised an intermediate exchange region occurs in which the peaks coalesce, broaden, and possibly change their positions making it comparatively easy to make a rough approximation of the rate constant. Finally, a fast exchange region occurs in which the coalesced peak (or peaks) narrow until a limiting single line width is reached.

In the intermediate exchange region the rate constant is given by the equation

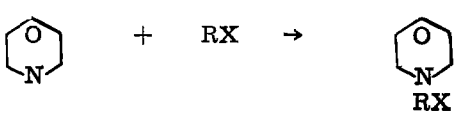
$$k_A = \tau_A^{-1} = \sqrt{2}\pi\Delta\nu_0 \qquad [3]$$

where τ_A^{-1} is the reciprocal of the mean lifetime of the proton or protons in magnetic environment A and $\Delta\nu_0$ is the separation (chemical shift in hertz) before coalescence (9). In the fast exchange region τ_A^{-1} is given by Eq. [4]

$$\tau_A^{-1} = 4\pi n_A n_B (\Delta\nu_0)^2 (W^E - W^\circ)^{-1} \qquad [4]$$

where n_A and n_B are the concentrations of species with magnetic environments of type A and B, respectively, W° is the limiting single line width, while W^E is the line width at temperature T (10).

Since k_A (or τ_A^{-1}) is related to the enthalpy of activation by the equation



$$k_A = \left(\frac{kT}{h}\right) \exp\left(\frac{-\Delta H^\ddagger}{RT} + \frac{\Delta S^\ddagger}{R}\right) \qquad [5]$$

a measurable line width or peak position change would be expected over a 50° temperature interval if $\Delta H^\ddagger$ is 40 kJ/mole or greater and $\Delta S^\ddagger$ is not too large (11-13).

From previous data and the fact that the melt is at a relatively high temperature, we assumed our melts were in the fast exchange region and the principal experimental results, if complex species were present, would be a change of line width as temperature rose provided the lifetime, τ, of each species was long enough.

Experimental Details

Preparation of the salts.—All of the salts were synthesized in essentially the same way using a technique first described by Rozdhestvenskii and Brode (6) and modified by Newman *et al.* (1). The syntheses can all be summarized by Eq. [6]

[6]

The purity of each salt was ascertained by C, H, N analyses, infrared spectrum, and melting point.

Density measurements.—The density of each molten salt was measured as a function of temperature using a modified Lipkin bicapillary arm pycnometer. A detailed description of the density measurements appear elsewhere (7), but because the densities of salts II, III, and V are needed for the discussions that follow they are given, as a function of temperature, in Table I. The density of salt III has not been reported elsewhere.

Table I. Density as a function of temperature
$\rho(g/cm^3) = a + bT(°K)$

Salt	a	$-(b \times 10^3)$	Temperature range, °K
II	1.723	0.6528	398-468
III	1.943	0.688	390-460
V	1.703	0.7004	430-518

Viscosity measurements.—Viscosity was measured as a function of temperature using a modified Ostwald viscometer. This kind of viscometer was found to be very simple to use and precise enough for our purposes.

Dry solid salt was introduced into a large reservoir attached to one arm of the viscometer. The filled viscometer was then immersed in a constant temperature bath (± 0.10°) of Dow Corning 710 oil and the salt was allowed to melt. Viscosity readings were made at 5° intervals after allowing the bath to equilibrate for 15 min at each temperature. A minimum of two series of viscosity measurements were made with each salt.

Conductivity measurements.—The specific conductance, κ, of each salt was measured as a function of temperature using an Industrial Instruments bridge at a frequency of 1000 Hz. The salts were contained in a Pyrex capillary cell similar to the one described by Janz (8) and modified by Newman *et al.* (1). The cell constants ranged from 150 to 1500 cm^{-1} depending on the diameter of the capillary. A minimum of two series of conductance measurements was made on each of the molten salts. Conductivity readings were taken at 10° intervals over a temperature range bounded at one end by the temperature at which the melt froze (often below the normal melting point) and at the other by a temperature just below the boiling or decomposition point of the salt. The system was allowed to equilibrate at each temperature for 15 min.

^{1}HNMR spectra.—The ^{1}HNMR spectra were obtained using the variable temperature probe of a Varian A60 A NMR machine. Two techniques were used. The first employed hexamethyldisiloxane as an internal standard contained in a sealed 5 mm NMR sample tube and the second, more satisfactory technique, used dimethylsulfone as an external standard. For the external standard experiments concentric NMR tubes with circular cross-sectional area were used to contain both the external standard and sample. The capillary containing the dimethylsulfone had an ID of 1 mm and was inserted into the standard 5 mm NMR tube, surrounded by salt, in such a way that its axis was held parallel to the axis of the outer tube. This arrangement minimized errors due to differences in bulk magnetic susceptibility between sample and standard. The NMR machine maintained a temperature constant to within ± 1° during a ^{1}HNMR spectral measurement.

Results

The ^{1}HNMR spectrum of the salt III cation is shown in Fig. 2. The α, β, γ, and methyl peaks are so marked. The sweep time is 500 sec, the sweep width is 1000 sec^{-1}, and the external reference is $CH_3—\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}—CH_3$.

The chemical shifts, δ, and the difference in chemical shifts, Δ, of various sets of protons in salts I, II, and III relative to the external standard, are listed in Table II. Neither the line widths nor the chemical shifts of

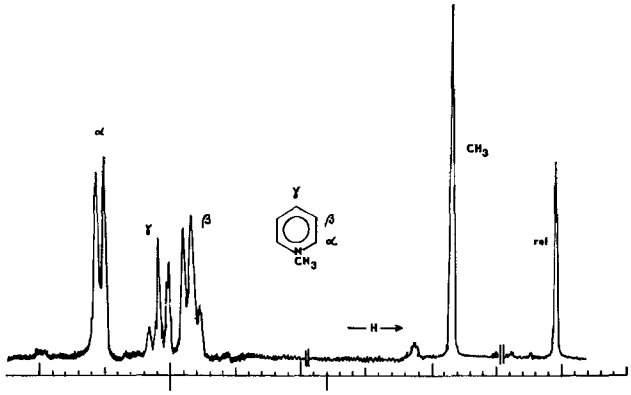


Fig. 2. The ^{1}HNMR spectrum of molten N-methylpyridinium iodide.

Table II. Chemical shift, δ, relative to the external standard $(CH_3)_2SO_2$, ppm

Salt	CH_3-N	α*	γ	β	$\Delta_{\alpha-\beta}$
III I^-	2.2	6.80	6.41	6.00	0.80
II Br^-	2.2	6.81	6.28	5.86	0.95
I Cl^-	1.5	6.2	5.6	5.1	1.1

* Measured from the large upfield peak of the doublet.

these protons were observed to change as a function of temperature so spectra at only one temperature are reported.

Table III lists δ and Δ values for the remaining two salts relative to the internal standard hexamethyl disiloxane, while the ^{1}HNMR spectrum of the 4-methylpyridinium ion is shown in Fig. 3.

The equivalent conductances of salts I-V can be described by the equation

$$\ln \Lambda = P + q/T°K \quad [7]$$

The constants, P and q, and the temperature range over which each molten salt was studied are given in Table IV.

The viscosities of salts II and III, described by the equation

$$\ln \eta = r + s/T°K \quad [8]$$

r and s together with the temperature range over which the conductance was measured are listed in Table V.

Discussion

The ^{1}HNMR spectra of salts I, II, III show a definite downfield shift in δ (*vs.* $CH_3\overset{O}{\underset{O}{S}}-CH_3$) as a function of halide ion size. Since the cation is the same in all three salts the changes in δ must be due to intermolecular interactions rather than intramolecular changes. The downfield shift (deshielding) increases as the anion radius increases which means the principal interactions are steric and not electrostatic. If they were electrostatic the downfield shift would increase in the order $Cl^- > Br^- > I^-$. Because of the strict packing requirements, we think the I^- ions passing by the methylpyridinium ions perturb the ring protons and distort the ring current by compressing the molecular orbitals. The Br^- ion is smaller than the I^- and therefore distorts the ring current and ring protons slightly less than the I^-, but considerably more than the Cl^-. The requirements for packing the Cl^- and the methylpyridinium ions in melt I are the least stringent, resulting in relatively little cation distortion. This would certainly account nicely for all of the chloride peaks being shifted upfield relative to the corresponding peaks in the bromide and iodide melts. This conjecture is strengthened by comparing the chemical shifts of the α, β, and γ peaks of salt II with the corresponding peaks of the salt dissolved in DMSO where the ionic interactions are considerably more feeble (1, 14). All of the peaks of the dissolved salt are further upfield than the corresponding peaks in the melt relative to an internal standard of TMS. The different Δ values in these melts are much more difficult to account for in detail. A plausible explanation is that in III each cation is being perturbed by at least two I^- ions, probably acting in concert. This means that the CH_3 and α protons on the nitrogen end of the molecule, where presumably the charge is located, as well as the β and γ protons on the opposite end of the molecule, are all slightly distorted by interionic interactions at any instant of time. In the chloride melt, the principal perturbation occurs at or in vicinity of the positive charge, causing a slight relative deshielding of the CH_3 and α protons, but leaving the β and γ protons relatively unperturbed. This explanation accounts for the fact that $\Delta_{\alpha\text{-}CH_3}$ is the same in all three salts, but $\Delta_{\alpha-\beta}$, $\Delta_{\alpha-\gamma}$, and $\Delta_{\beta-\gamma}$ are all larger in the chloride melt than the iodide melt. The Br^- probably perturbs both ends of the molecule simultaneously, but there is more free space at the end of the molecule opposite to the charge than in the iodide melt. Since the ions are less crowded than in III, weaker interactions occur and the values for $\Delta_{\alpha-\beta}$ and $\Delta_{\alpha-\gamma}$ will be less than in the chloride melt, but greater than in the iodide melt.

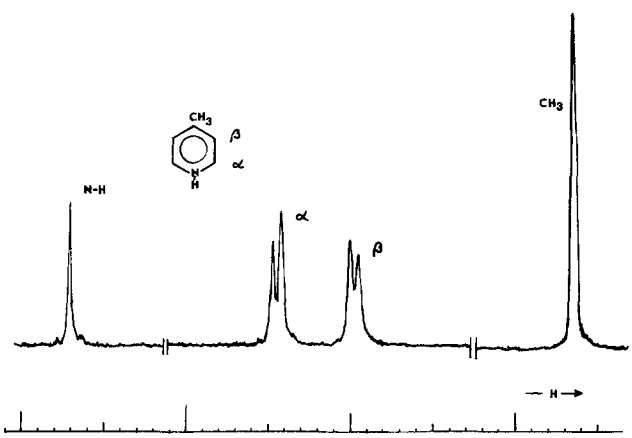

Fig. 3. The ^{1}HNMR spectrum of molten 4-methylpyridinium bromide.

Table III. Chemical shift, δ, relative to the internal standard, $(CH_3)_3SiOSi(CH_3)_3$, ppm

Salt	α	β	CH_3	H	$\Delta_{H-\alpha}$	$\Delta_{\alpha-\beta}$
V Br^-	8.98	8.03	2.61	15.30	6.32	0.96
IV Cl^-	8.16	7.16	1.66	15.36	7.20	1.0

Table IV. Equivalent conductance data
$\ln \Lambda = P + q/T$

Salt	P	$-(q \times 10^{-3})$	Temperature range, °K
I	8.818	2.747	418-463
II	8.309	2.60	433-474
III	9.47	3.15	396-450
V	7.79	2.45	435-475

Table V. Viscosity data (poise)
$-\ln m = r + s/T$

Salt	r	s	Temperature range, °K
II	9.35	-2.85×10^3	435-475
III	6.16	-3.24×10^3	400-450

The most interesting feature of the ^{1}HNMR spectra of the two 4-methylpyridinium salts is the large difference in $\Delta_{H+\alpha}$ between the Cl^- and the Br^- melts. This is especially intriguing when it is noted that the $\Delta_{\alpha-\beta}$ values are identical. We shall return to this point later.

The ^{1}HNMR spectra from all salts showed no reproducible temperature dependent chemical shift or line broadening greater than 0.03 ppm over a temperature range of at least 50°, with the possible exception of the H-N peak in salt V which narrowed approximately 0.03 ppm.

The lack of a temperature sensitive line width or δ is significant because it implies that complexes whose energy barriers are greater than approximately 40 kJ/mole cannot be present in the melt. This minimum value for the energy barrier is estimated from Eq. [5] and the fact that an A60 ^{1}HNMR machine can read 0.03 ppm at a 500 sec^{-1} sweep width. Values for $\Delta G^{\ddagger}$ ($\approx \Delta H^{\ddagger}$) are introduced into Eq. [5] and $k_A = \tau_A^{-1}$ is solved for. If τ_A is greater than 10^{-7} sec, a narrowing of

Table VI. Energies of activation

Salt	E_η (kJ)/mole	E_Λ (kJ)/mole	E_κ (kJ)/mole
N-methpyrBr	23.5	21.5	17.6
4-methpyrBr	—	20.4	17.6
N-methpyrI	26.0	25.8	24.7
N-methpyrCl	—	23.0	23.0

the band at half-height should be visible over the temperature range 400°-450°K. This idea can be seen more clearly by observing Eq. [4] which requires $W^E - W^\circ$ to approach zero as τ_A^{-1} approaches infinity.

The energies of activation for the various transport properties studied are summarized in Table VI.

A comparison of E_η with E_Λ in melt III shows that E_η is just slightly greater than E_Λ. A similar relationship between energies of activation is observed in melt II. This is the sort of behavior observed by previous workers for the alkylammonium salts and strongly suggests that it may be a general property of molten organic salts. There are no long chains to block interstices in the pyridinium melts and the Br^- and N-methylpyridinium cation differ in size, nevertheless, strong interactions and a high degree of cooperative movement are occurring.

The most striking result of our transport studies is seen by comparing Λ for 4-methylpyridinium bromide with Λ for N-methylpyridinium bromide over similar temperature ranges. It is immediately obvious that the N-methyl salt is the better conductor. At 430°K there is a 16.1% difference while at 470°K there is an 18.4% difference. We think this difference is due to the presence of complex species in melt V that are absent in melt II.

We think the chemical shift difference between salts IV and V also arises principally from complex ion formation. This conjecture is strengthened by noting that the α, β, and CH_3 peaks are upfield relative to the α, β, and CH_3 peaks of the Br^- melt, but, the $N\text{-}H^+$ peak is downfield. Moreover, Bloom and Reinsborough (15) gave strong evidence, from ultrasonic absorption studies, that molten pyridinium chloride is associated. It is reasonable to assume 4-methylpyridinium chloride behaves analogously. We think that if complexation is occurring in melt IV it is also occurring in melt V, but the complexes are more labile. The density of this salt is slightly less than the density of the N-methylbromide salt at corresponding temperatures. The only plausible explanation for the large difference in Λ that is consistent with our ^{1}HNMR data is that fewer species are present to carry the current because of complex formation between the bromide ion and either the proton or the methylpyridinium ion.

In order to further refine our model of the pyridinium melt we define a complex ion as any species in which the individual particles carry out identical translational movements while diffusing. The difference in the activation energies for equivalent conductance and specific conductance is

$$E_\Lambda - E_\kappa = \alpha RT^2 \qquad [9]$$

where α is the expansivity of the melt. To a rough approximation the energy of activation, E_κ, is equal to the energy a species must acquire to pass over an energy barrier from one site to another during translational motion in an electric field. If one assumes the Nernst-Einstein equation to hold at least approximately, this same energy is required for diffusion. Based on these ideas we make the assumption that if ΔH°_{+-}, the thermodynamic enthalpy of complex formation, is less than the enthalpy of activation for this species to diffuse, the complex will fly apart upon absorption of this amount of energy rather than pass over the barrier. The energy of activation then determines the minimum energy a complex can have and still move through the melt as a single entity. We found that in the iodide melt $E_\kappa = 25$ kJ/mole while in the bromide melt $E_\kappa = 17.5$ kJ/mole. We can therefore say, with confidence, that it is highly unlikely for complex species with ΔH°_{+-} less than 25 kJ/mole or greater than 40 kJ/mole to be present in the iodide melt. It is also very unlikely for complex species with ΔH°_{+-} less that 17.5 kJ/mole or greater than 40 kJ/mole to be present in the bromide or chloride melts. The 40 kJ/mole maximum arises from the assumption that to remain intact for approximately 10^3 diffusional jumps, or 10^{-7} sec, $\Delta H^\circ_{+-} \geqq \Delta H^\ddagger = 40$ kJ/mole. Stating it differently, no complex species are present whose lifetimes are less than approximately 10^{-10} sec in the bromide melt, 10^{-9} sec in the iodide melt, or greater than approximately 10^{-7} sec in any melt.

In salts IV and V, where there is a labile proton, it is very possible for a complex to exist that is stable enough to lower the conductivity relative to the corresponding N-methyl salt, but have a lifetime that is short compared with ^{1}HNMR resolution times. Therefore, the existence of H^+X^- ion pairs or $R\ldots H^+\ldots X^-$ ion pairs in the 4-methyl chloride and 4-methyl bromide melts is not excluded by our data.

In salts I, II, and III we think ion pairs or complex species probably do not exist. This conjecture arises from the narrow energy range allowable, the lack of a temperature sensitive peak width, the observed change in δ with change in halide ion, the near equivalence of E_η and E_Λ for both bromide and chloride melts, and the large difference in equivalent conductance between 4-methyl and N-methylpyridinium bromide.

Experimental Errors

We estimate that both the specific conductance and density data are accurate to ±1%. This figure includes errors due to impurities in the salts, decomposition products, difficulties in reading the salt level in the pycnometer, etc. This means the equivalent conductances are accurate to ±2%. We estimate the measured viscosity to be accurate to ±3% because a viscometer reading and a density reading are required. The error in the ^{1}HNMR data is difficult to ascertain. Our machine can be maintained at a constant temperature of ±1° at the elevated temperatures, but the change in noise level, variation in samples spin rate, etc. that arise near the top of the useful temperature range of the variable temperature probe of an A60 A NMR machine are uncertain. We therefore hesitate to rely on any chemical shift differences less than 0.03 ppm.

Summary and Conclusion

The equivalent conductance, viscosity, and ^{1}HNMR spectra of several fused pyridinium salts were investigated with the intention of correlating transport properties with spectral properties. From these correlations we were able to say with some assurance that 1-methylpyridinium iodide and bromide are completely dissociated, but that 4-methylpyridinium chloride and bromide probably contain complex ions. In addition, we have shown that ^{1}HNMR spectroscopy is a useful tool in elucidating the properties of molten organic salts. Finally, it seems that approximate equality of E_η and E_Λ may indeed be a property of molten organic salts.

Technical Notes

Continuous Electrochemical Preparation of Chlorotrifluoroethylene

S. Wawzonek*

Department of Chemistry, The University of Iowa, Iowa City, Iowa 52242

and Stephen Willging

Loras College, Dubuque, Iowa 52001

The monomer chlorotrifluoroethylene is prepared commercially in a batch process by treating 1,1,2-trichloro-1,2,2-trifluoroethane (Freon 113) with zinc dust. The present work finds that the chemical method can be replaced by a continuous electrochemical process with over-all energy saving in the production of zinc at a cathode and with the formation of a more useful by-product, chlorine, at the anode. The cell used was similar to that described for the production of dichloroethylene from 1,1,2,2-tetrachloroethane (1). A copper wire was used as the cathode and a carbon rod was employed as the anode. The electrolyte was an aqueous solution of zinc and sodium chlorides. Deposition of the zinc on the copper cathode was followed by a reaction with Freon 113 and formation of chlorotrifluoroethylene

$$CF_2ClCFCl_2 + Zn \rightarrow CF_2{=}CFCl + ZnCl_2$$

This reaction is slow at the boiling point of Freon 113 (47.7°C) and the deposition of the zinc was therefore done intermittently; when the majority of the zinc had disappeared from the cathode, electrolysis was resumed.

The yield of the product (44%) was determined by converting the olefin to the dibromo compound which is higher boiling (92.9°C) than the olefin (−23°C). The value reported is actually a minimal one since some of the olefin is polymerized in this reaction.

Attempts were made to increase the rate of the dehalogenation of Freon 113 by forming zinc amalgam electrochemically instead of the metal. The rate proved to be very low since none of the olefin was actually isolated.

The direct electrochemical reduction of Freon 113 to chlorotrifluoroethylene was also studied. Such a reaction is reported to occur in potassium acetate solution and forms the olefin in a 74% yield (2). Using conditions which would be more suitable for the continuous formation of chlorotrifluoroethylene, the electrochemical reduction of Freon 113 was studied at a mercury cathode in 0.2*N* ammonium chloride-60% methanol. Freon 113 in this medium shows a polarographic wave at −1.34V *vs.* (Hg pool). The yield of olefin obtained under these conditions was only 5%.

* Electrochemical Society Active Member.

Key words: dehalogenation, Freon 113, zinc.

Experimental

The cell used for the zinc dehalogenation consisted of a 300 ml Berzelius beaker fitted with a rubber stopper which contained openings for a condenser, anode, cathode, and a glass tube capped with a serum cap for the introduction of Freon 113. The cathode consisted of 75 cm of 10 gauge copper wire wound as a flat spiral and placed slightly above the bottom of the beaker. The anode was a hollow carbon rod 1.5 cm in diameter sealed at the bottom with a carbon rod and perforated above the level of the electrolyte to allow the chlorine to evolve. The anode compartment consisted of a porous cup (75 × 30 mm) sealed with a rubber stopper containing the anode. The condenser was cooled with ice water and connected to two traps cooled with ice and salt and Dry Ice and isopropyl alcohol, respectively. The electrolyte consisted of an aqueous solution of 10% zinc chloride and 5% sodium chloride. The cell was maintained at the boiling point of Freon 113 with a steam bath. Freon 113 (5 ml) was injected into the cell through the serum cap. Using a voltage of 5V a current of 1.55-1.7A was obtained. After 1.5 hr the electrolysis was terminated. The zinc formed disappeared in 1.5 hr and the electrolysis of the zinc was resumed for another 2 hr. This zinc was again dissolved in a period of 1.5 hr. More Freon 113 (15 ml) was added and the intermittent electrolysis was repeated in 2 hr intervals for the next 10 hr. At the end of this time the ice salt trap contained 3 ml of Freon 113 and the Dry Ice-isopropyl alcohol trap contained 15 ml of a liquid which was converted to the dibromo compound (17.3g) in the following manner. The trap was slowly allowed to come to room temperature and the resulting vapors were passed through bromine cooled in an ice bath and then through a Dry Ice-isopropyl alcohol trap. The liquid condensed in the latter was recycled through the bromine. Excess bromine was removed by washing with a sodium bisulfite solution and the organic layer was separated, dried with anhydrous calcium chloride, and distilled. The resulting 1-chloro-1,2-dibromo-1,2,2-trifluoroethane boiled at 90°-92°C. The mass spectrum was in agreement with this formulation.

The cell for the direct reduction of Freon 113 consisted of a 1000 ml beaker which was modified in the following manner. The top was ground so that a glass cover with a similar ground surface could be used to give a gas-tight container. The glass cover contained four openings for the carbon anode, stirrer, chlorine outlet, and a condenser. A glass tube (12 mm in diameter) was connected through a glass frit to the lower part of the beaker and was used for the reference electrode (0.2*N* KCl-HgCl-Hg). The mercury pool cathode had an area of 78.6 cm^2. Contact was made through a wire sealed into the bottom of the beaker. Provisions for collecting product were similar to that given earlier.

In a typical run 50 ml of 0.2*N* ammonium chloride-60% methanol was used in the anode compartment. The catholyte consisted of 500 ml of 0.2*N* ammonium chloride-60% methanol and 15 ml of Freon 113. Electrolysis was carried out at 1.45V and gave an initial current of 0.4A. The current increased to 0.7A after 8 hr and then slowly decreased to 0.2A after 23 hr. Work-up of the material in the Dry Ice-isopropyl alcohol trap as above gave 2.1g of the dibromo compound (5%) and 3g of Freon 113.

Electrochemical Doping of TiO_2 and Fe_2O_3

D. Haneman and F. Steenbeeke

School of Physics, The University of New South Wales, Kensington, New South Wales, Australia 2033

We report electrochemical doping of TiO_2 and Fe_2O_3 with positive results for the former. The materials are of interest as electrodes in photoelectrochemical methods of solar energy conversion (1). The current work was undertaken in an effort to improve the surface region properties without using heat-treatment or ion bombardment which introduce unwanted side effects.

The doping method involves the semiconductor and a platinum strip (at 1 cm distance) as the two electrodes, the ions in solution being driven into the lattice by the applied field. Nickel and copper ions and various current densities, solution concentrations, and voltages were used, as shown in Table I. The success of the method was tested by attempting to detect the presence of the foreign atoms in the surface region of the semiconductor.

The single crystal specimen, of area approximately 1 cm^2, was pressed against a protective outer (Teflon) ring, leaving only a central disk region exposed to plating. In the case of TiO_2 a definite optical contrast was observable between the plated and protected regions. The whole specimen face was then polished away but the central disk remained detectably darker until a finite measured amount of crystal had been removed.

It was established that the persistence of the dark patch was due to alteration of the bulk, and not due to material remanent in surface valleys. When various fine paints were applied to the surface, the patch disappeared after 2 sec polishing, whereas 5 to 10 times this length of treatment was needed to remove the doped patch.

The thickness of crystal removed was measured by a weight loss method. The surface was carefully polished on a glass surface with either 1000 grade silicon carbide, or 1F compound using a uniform mechanical action and constant time periods. It was weighed periodically on a delicate balance. Reproducibility was checked by several repetitions of the treatment. The absolute thickness removed, calculated from the area,

Key words: semiconductor surfaces, solar energy, titanium oxide.

Table I. Penetration of impurities into TiO_2 during electrochemical deposition

Thickness in microns removed by polishing after which patch is		Ion used	Cell voltage (V) range	Cell current (mA) range	Time (sec) range
still visible	gone				
Several samples					30-60
range 0.3-0.6	0.4-0.7	Cu	1.8-2.1	0.55-1.0	30-60
0.4-0.7	0.5-0.8	Ni	2.3-2.7	0.5-1.0	15-30

density, and weight loss, was also checked by micrometer measurements after sufficient material was removed to make the latter measurement meaningful, and consistency was found (0.023 mm *vs.* 0.02 ± 0.005 mm by micrometer). Approximately 1 μm was removed per 30 sec of polishing.

The depths of penetration measured from disappearance of optical contrast are shown in Table I. Due to the spread in depth values, a dependence on voltage, current, time of deposition, or combinations of these parameters was not established. Over-all, the depths for Cu and Ni, for currents of 0.5-1.0 mA, voltages of around 2V, and times of about 1/2 min were close to 1/2 μm.

The concentration of dopant material in the TiO_2 lattice was estimated from the optical contrast. Considerable darkening is known to occur with approximately 0.5% doping and it is barely detectable at 10^{-2}%. Therefore our rough estimate is that the maximum initial concentration was in the region of 0.1%. Due to the diffusion profile, the concentration in the first few atomic layers is probably much higher.

The above method using optical contrast of the doped region was less effective in the case of Fe_2O_3 since it is not transparent to most of the visible spectrum, having a bandgap of about 2.2 eV. Hence the method of x-ray photoemission spectroscopy (XPS) was used.

The XPS instrument was a Varian IEE spectrometer which utilizes cylindrical samples. Hence four pieces of single crystal Fe_2O_3 were prepared which fitted together roughly to form a hollow cylinder around the central shaft of the specimen holder. The metal portions above and below the specimen were covered with Teflon and the assembly immersed in the nickel plating solution and rotated slowly with respect to the 1 cm^2 flat Pt electrode at a distance of 1 cm. In this way the specimen pieces were uniformly coated. Drying was achieved by several stages of pumping followed by air exposure, in a vacuum chamber.

The XPS spectra, which are sensitive to about the first five atomic layers, showed strong Ni peaks after the doping. However, a light rub with a paper tissue was sufficient to render the peaks completely unobservable. Hence penetration of even the first few atomic layers was less than the detection sensitivity of the instrument which we estimate in the present case as about 1% of one layer. This corresponds to a volume concentration of about 0.1%. Therefore we cannot rule out the possibility of lattice penetration but it was less than 1% of one layer in the first five layers. The indication is thus that this is less than for TiO_2 which might be expected since the latter, of tetragonal structure, has channels of about 0.15 nm diameter orthogonal to the (0001) face used (c-direction). A number of interstitial impurities show enhanced diffusion in the c-direction compared to the a-direction (3, 4). In the case of Fe_2O_3, of rhombohedral structure, such channels are not present.

The actual field at the TiO_2 surface during plating is difficult to ascertain precisely. Taking into account the resistivity and estimated surface barrier thickness of about 5 μm (5), one can calculate a field of about 2000 $V\text{-}cm^{-1}$ which is quite low. However penetration of at least 0.5 μm was achieved which is the main result of this work.

It was found that the photogalvanic current response of the TiO_2 as a function of wavelength was not affected by the doping, suggesting that impurities were in interstitial rather than substitutional positions, consistent with penetration into lattice channels. Although the method was therefore not effective in improving TiO_2 for solar energy use, it may nevertheless be useful for other materials.

Acknowledgments

The electrochemical doping method was suggested to one of us (D.H.) by Professor M. Calvin. The Fe_2O_3 samples were prepared by I. Bedwell. This work was supported by the Australian Research Grants Committee.

Photochemical Studies on a Substituted Naphthalene-2,1,Diazooxide

The Formation and Identification of a Ketene from a Wolff Rearrangement

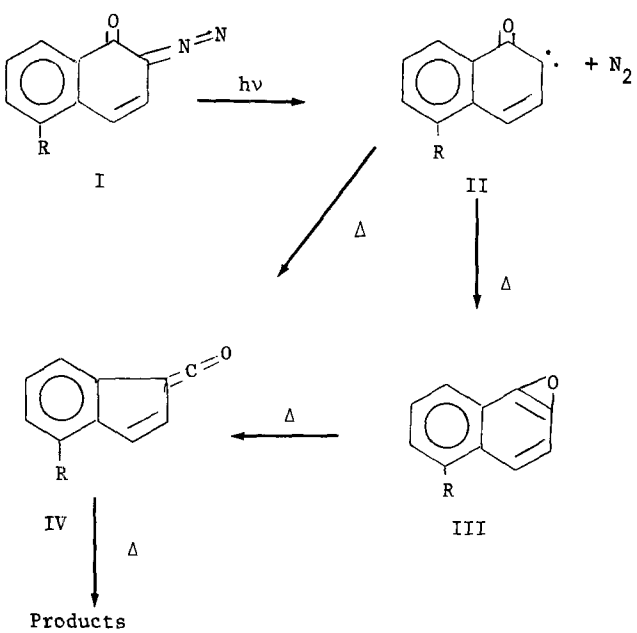
Jacob Pacansky and Duane Johnson[1]

IBM Research Laboratory, San Jose, California 95193

The use of naphthalene-2,1-diazooxides as photoresists has been reviewed by Dinaburg (1) and more recently by De Forest (2). According to these reviews, diazo compounds have been known for a long period of time but detailed studies on light decomposition of these compounds have been carried out only recently. Süs (3) was one of the first (1944) to describe the conversion of a naphthalene-2,1-diazooxide to an indene carboxylic acid by exposure to light. However, in this proposed mechanism as well as subsequent ones, intermediates were not identified. The present studies do describe the trapping of a ketene from a photoactive compound (PAC).

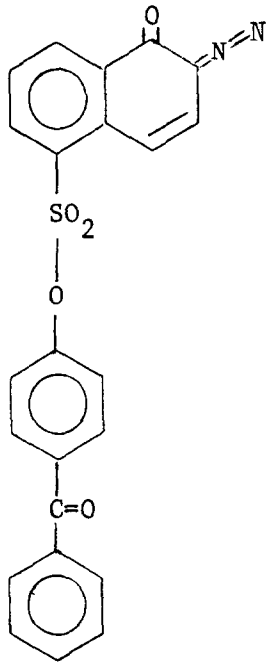
[1] Deceased.

Key words: photoresist, diazo, photochemistry, Wolff rearrangement, ketene.



Mechanistic studies of the complex over-all processes observed when a substance is irradiated with ultraviolet light often overlook the fundamental distinction between a purely photochemical process and a complex process comprising photochemical and thermal components. It is frequently

simple photochemical process $M \xrightarrow{h\nu} M^* \longrightarrow P$



complex photothermal process $M \xrightarrow{h\nu} M^* \longrightarrow In \xrightarrow{\Delta} P$

assumed that an electronic excited state (M*) decays directly to observed product (*P*) without consideration of the possibility that a *meta*-stable ground state intermediate (*In*) may intervene. The intrusion of an intermediate can lead to serious errors in interpretation and to inordinate complexity in what is called photochemistry. Results suggest that the number of primary photochemical processes of complex molecules is rather small and that the bewildering array of products encountered in structurally similar substrates is due to a confusing overlay of thermal transformations of the initial photochemical products. The substituted naphthalene-2,1-diazooxides (**I**) are an excellent example of the confusion which has occurred.

The naphthalene-2,1-diazooxides are postulated to photodecompose by the following mechanism

Upon photochemical extrusion of N_2 from **I**, the carbene **II** is formed. The thermal transformation of **II** through the as-yet-unknown oxirene **III** or directly to the ketene **IV** is known as the Wolff rearrangement (4, 5). That this rearrangement has a very low barrier of activation was established in photochemical matrix isolation experiments on diazoketones where, in spite of the very low temperatures (below 10°K) at which the studies were performed, the rate of formation of a ketene could not be impeded (6). The success for observation of the reactive ketene intermediate, however, is not as hopeless. It may be spectroscopically identified at relatively higher temperatures (77°K), trapped, and its thermal reactions followed by warming to ambient temperatures. In light of the above discussion, we present low temperature photochemical experiments which, for the first time, show unequivocal spectroscopic and chemical evidence for a reactive ketene intermediate involved in the photolysis of the substituted naphthalene-2,1-diazooxide (4-benzoylphenyl, 6-diazo-5-oxo-5,6-dihydronaphthalene-1-sulfonate) shown below and hereafter referred to as **V**

V

A neat film of **V** was cast from a dioxane solution onto a suitable infrared transparent substrate such as CsI. The infrared spectrum of **V** at 77°K is shown in Fig. 1. The pertinent features in this spectrum are the vibrational bands due to the diazo group (the doublet at 2162 and 2118 cm^{-1}) and the carbonyl stretching frequency of the naphthoquinone at 1625 cm^{-1}.

Irradiation of **V** with u.v. light emitted from a high pressure mercury lamp and filtered to allow only light with $\lambda > 3700$Å produced total decomposition of **V** in 15 min. The infrared spectrum of **V** after photolysis at 77°K is shown in Fig. 2. It can be seen that the characteristic special features of the naphthalene-2,1-diazooxide structure (2162, 2118, and 1625 cm^{-1}) have disappeared and that many new bands appear. These are listed in Table I. In Fig. 3 are shown the results of a kinetic plot (band intensity *vs.* time) for the 1625 cm^{-1} of the starting material and the 500 cm^{-1} band of the photoproduct. (All of the bands of the starting material and photoproduct exhibit similar behavior. These two bands are picked only to be representative.) The kinetic plots clearly show that the new bands correlate with the disappearance of **V** and thus, under these conditions, the new bands appear to be due to a primary photo product.

Assignments of the new bands to a ketene structure were made on the following basis: First, ketenes characteristically have very intense absorptions at 2135 cm^{-1}. The parent ketene (7) (CH_2CO) has an intense

absorption at 2151 cm^{-1} (the CO stretch) and less intense absorptions at 1120 cm^{-1} (C=C stretch) and 588,528 cm^{-1} (C=C=O bending). The bands at 2135 and 2100 cm^{-1} are assigned to the C=O stretch of the ketene. Those at 1040, 570, and 500 cm^{-1} can only be tentatively assigned to the C=C stretch and C=C=O bending vibrations. Second, and more important, is the chemical evidence obtained from trapping experiments. Methanol was added to the PAC. After irradiation at 77°K had completely converted **V** to ketene, the temperature was allowed to rise. Synchronously the ketene and methanol disappeared with the appearance of a carbonyl band at 1720 cm^{-1} characteristic of the methyl ester,[2] the expected adduct of the trapping experiment. These results are summarized below[3]

In like manner the ketene was trapped with m-cresol. In this experiment a band appeared at 1750 cm^{-1} which could be assigned to the phenyl ester.

The ketene was further characterized by allowing a reaction with water vapor at room temperature to proceed. Compound **V** was converted to a ketene at 77°K

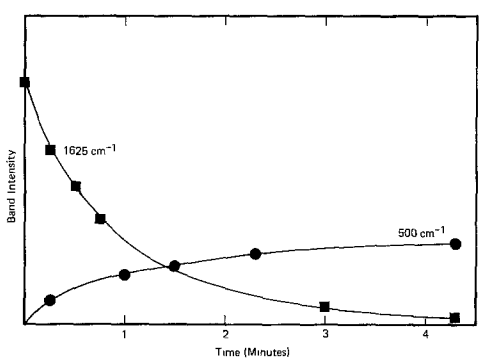

Fig. 3. Plot of band intensity of significant bands as a function of irradiation time. Substituted naphthalene-2,1-diazooxide band is 1625 cm^{-1} (■). The ketene band is 500 cm^{-1} (●).

and after allowing the temperature to rise to room temperature water vapor was introduced into the cryostat. The ketene rapidly reacted with the water vapor. The infrared spectra recorded before and after the reaction are shown in Fig. 4. At this point it should be added that the ketene at room temperature, in the absence of water vapor, is remarkably stable and will exist for hours in vacuum.

The photochemical apparatus was fitted with u.v. filters to determine the photostability of the ketene. Conversion of **V** to a ketene did not occur until a Corning No. 3-73 filter was used (0% T at 4000Å). After 20 min of irradiation, **V** was completely transformed to a ketene (T = 77°K). Irradiation with a set of filters in the high pressure mercury lamp which progressively decreased the wavelength of the light to 2900Å did not induce any phototransformations of the ketene. In fact, no changes occurred when the ketene was exposed to

[2] The methyl ester of 3-indene carboxylic acid was synthesized. The infrared spectrum of the neat liquid has a carbonyl band at 1725 cm^{-1}.

[3] Note that the methyl ester of 3-indene carboxylic acid is shown and not that of 1-indene carboxylic acid. The 3-indene acid has been misidentified as the 1-indene acid for over 60 years. This error has led to considerable confusion in unraveling the photo and thermal decomposition mechanisms of resists. To our knowledge the first study to point out this problem was the elegant work of P. Yates and E. W. Robb, *J. Am. Chem. Soc.*, 79, 5760 (1957).

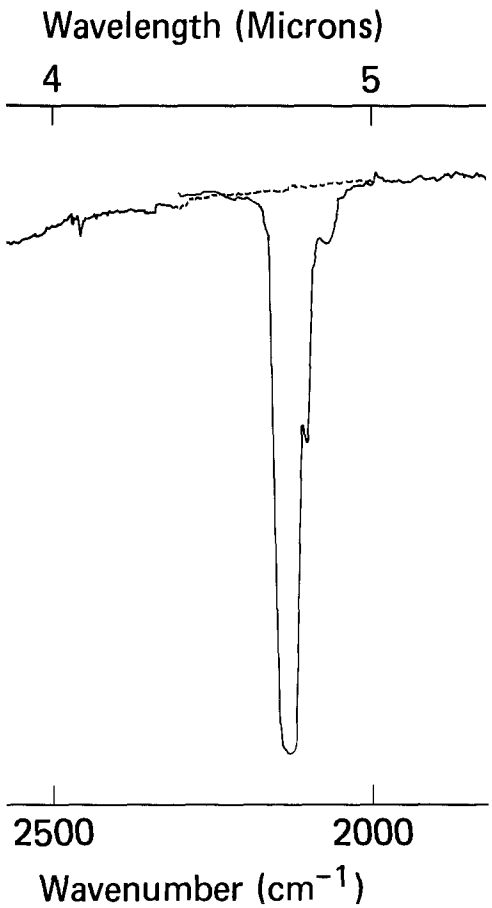

Fig. 4. The infrared spectra of irradiated V before reaction with water vapor (——) and after reaction with water vapor (– – – –).

the unfiltered high pressure mercury lamp for several hours.

In summary, the formation and identification of a ketene intermediate from a PAC used in photoresist solutions has been accomplished. The PAC was irradiated at $\lambda > 3700$Å, 77°K, and under a vacuum of 2×10^{-6} Torr. The ketene was found to be stable at ambient temperatures while still under vacuum. Infrared peak assignments have been made and a ketene trapped using methanol and m-cresol.

Acknowledgment

The substituted naphthalene-2,1-diazooxide was supplied by Nicholas Clecak. His contribution is gratefully appreciated.

Brief Communication

Comments Regarding Electronic Conductivity in Solid Electrolytes

John H. Kennedy*

Department of Chemistry, University of California, Santa Barbara, California 93106

The use of solid electrolyte materials in practical devices usually requires that they exhibit little or no electronic conductivity. It is simple to express conductivity as the sum of the ionic and electronic components

$$\sigma_{tot} = \sigma_i + \sigma_e \quad [1]$$

or in terms of transference numbers

$$t_i = \frac{\sigma_i}{\sigma_{tot}}, \quad t_e = \frac{\sigma_e}{\sigma_{tot}} \quad [2]$$

Investigators may make statements that $t_i > 0.999\ldots$ or that $t_e < 10^{-n}$ to indicate that the solid electrolyte will be useful in applications. Before proceeding to the point of this paper I would like to point out the obvious that in most applications the real question is the amount of charge transferred ionically with external electronic transfer (Q_i) *vs.* the amount of charge transferred by internal electronic conductivity (Q_e)

$$Q_{tot} = Q_i + Q_e \quad [3]$$

with faradaic efficiency being

$$\eta_F = \frac{Q_i}{Q_{tot}} \quad [4]$$

It is sometimes implied that t_i is related to η_F but in actual fact η_F will depend on the rate at which charge is drawn from the device. In the extreme, if a battery is not used, it will eventually completely self-discharge through even the smallest electronic path with a faradaic efficiency of 0%.

Returning to the initial expression for σ_{tot} I have noted that investigators may use a bridge method for

* Electrochemical Society Active Member.

Key words: electronic conductivity, electronic decomposition potential.

σ_{tot} and a Wagner blocking method for σ_e which is really σ^0_e. I would like to consider the difference between σ_e and σ^0_e and show that σ^0_e for hole conductivity, σ^0_+, has a different meaning in the typical galvanic cell than σ^0_e for electron carrier conductivity, σ^0_-.

Electronic conductivity is sensitive to environment, and the beauty of the Wagner technique is that it defines the conditions for which the electronic conductivity value applies. For example, in the cell Ag/AgBr/M where M is an inert blocking electrode, the value for σ^0_- refers to the electronic conductivity which would be observed in the cell Ag/AgBr/Ag. This conductivity cannot be measured directly because when a voltage is applied to the latter cell a predominantly ionic current flows. The important point to be realized is that for any electrode environment more positive than Ag the concentration of electron carriers will be lower, and σ_e will be less than σ^0_-. Electrodes more negative than Ag cannot be used since they would reduce Ag^+. Therefore, in all electrochemical cells using AgBr electrolyte the electronic transference number will be less than that calculated using σ^0_-. In other words, we are quoting the worst (highest) possible value for the electronic contribution.

However, the situation is reversed when the electrolyte is a hole conductor. Now σ^0_+ represents the conductivity in the cell M/MX/M but as the electrode potential increases the concentration of hole carriers and σ_e increase exponentially. In other words, σ^0_+ represents the minimum electronic conductivity via holes while σ^0_- represents the maximum conductivity via electron carriers.

I have found the following numerical examples instructive in appreciating this difference. Let us suppose we have an electrolyte in which σ^0_+ is $2 \times 10^{-7}\ \Omega^{-1}\ cm^{-1}$ and compare it with an electrolyte in which σ^0_- is $2 \times 10^{-7}\ \Omega^{-1}\ cm^{-1}$. For calculation purposes let us assume in both cases that $\sigma_i = 0.1\ \Omega^{-1}\ cm^{-1}$ and that the cell has an open-circuit potential of 1.0V. The expressions for the partial ionic and electronic currents [see Ref. (1) for derivation and discussion of the electronic conductivity equations], assuming no polarizations other than ohmic, are

$$I_i = \frac{V_{o.c.} - V}{l/A}\sigma_i \qquad [5]$$

$$I_+ = \frac{RT\,\sigma^0_+}{l/A\,\mathbf{F}}[\exp(V\mathbf{F}/RT) - 1]$$

$$\cong \frac{RT\,\sigma^0_+}{l/A\,\mathbf{F}}\exp(V\mathbf{F}/RT) \quad \text{when} \quad V > 0.2\text{V at } 300°\text{K} \qquad [6]$$

$$I_+ = \frac{RT\,\sigma^0_-}{l/A\,\mathbf{F}}[1 - \exp(-V\mathbf{F}/RT)]$$

$$\cong \frac{RT\,\sigma^0_-}{l/A\,\mathbf{F}} \quad \text{when} \quad V > 0.2\text{V at } 300°\text{K} \qquad [7]$$

$$I_i/I_+ = \frac{(V_{o.c.} - V)\mathbf{F}}{RT\exp(V\mathbf{F}/RT)}\left(\frac{\sigma_i}{\sigma^0_+}\right) \qquad [8]$$

$$I_i/I_- = \frac{(V_{o.c.} - V)\mathbf{F}}{RT}\left(\frac{\sigma_i}{\sigma^0_-}\right) \qquad [9]$$

where V is the voltage difference between the two electrodes. From these expressions the ratio of ionic current to electronic current can be calculated for any cell voltage and temperature. The ionic transference number (fraction of current carried ionically) increases as the cell voltage decreases but voltage efficiency decreases. In general, cells are not operated at voltages lower than the maximum powerpoint ($V_{o.c.}/2$) assuming no other polarization losses. Thus, for our example with $V = 0.5$, $T = 300°$K

$$I_i/I_+ = 0.038$$

$$I_i/I_- = 9.7 \times 10^6$$

That is, if the electrolyte is a hole conductor the current passing through the cell would be about 96% electronic. In this case, the electromigration of the holes when external current is flowing would also need to be included. On the other hand if the electrolyte is an electron carrier conductor the current would be < 1 ppm electronic. Based on the ratio σ_i/σ_e (5×10^5 in the example) one would predict the electronic current to always be smaller than the ionic current.

In a recent paper Bonino and Lazzari (2) determined the hole conductivity of nominally stoichiometric KCu_4I_5 to be $2 \times 10^{-7}\ \Omega^{-1}\ cm^{-1}$ at 281.5°C and the total conductivity to be about $0.1\ \Omega^{-1}\ cm^{-1}$, the same values as in the example above. They concluded that the electronic conductivity contribution was negligible when the electrolyte was equilibrated with copper. This statement is strictly true but could be misleading since the electronic current will not be negligible in a galvanic cell in which the cathode side is equilibrated at some positive potential compared to copper. From the equations and data given above the ratio I_i/I_+ will be 150 at 555°K (282°C) so that nearly 1% of the current would be electronic at 0.5V.

I propose that in addition to quoting σ^0_+ for hole conductors which allows calculations to be carried out, an "electronic decomposition potential" be quoted. The current-potential curve is similar in nature to an electrochemical decomposition curve, and an extrapolation back to zero current would be a helpful potential to quote. Figure 3 in Ref. (2) would indicate an electronic decomposition potential of about 0.4V. This means that the use of any cathode material more positive than 0.4V would lead to high electronic conductivity and, therefore, high self-discharge.

Another example is PbF_2 which was studied by Kennedy *et al.* (3). Data given in Fig. 8 of Ref. (3) showed that the electronic decomposition potential was 1.5-1.6V (the quoted value will vary somewhat depending on the current scale used). In agreement with that value Miles (4) found that thermodynamic potentials were achieved for cathodes of CuF_2 (0.70V) and AgF (1.30V) but the highest potential observed with PbF_4 cathodes was 1.6V instead of the thermodynamic value of 2.56V.

In conclusion, it is important to realize that a cathode material will act like the blocking electrode in a Wagner study at an applied voltage equal to the cathode potential. If an electrolyte exhibits significant hole conductivity at potentials greater than some value then all cathode materials with potentials greater than that value will self-discharge. The use of an electronic decomposition potential would alert investigators to the electrolyte's limitations much the same as the ionic domain does for oxide electrolytes (5).

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 123, No. 2, 8, 9, 10, and 12; February, August, September, October, and December 1976.

Electrochemical Semipermeability and the Electrode Microsystem in Solid Oxide Electrolyte Cells

J. Fouletier, P. Fabry, and M. Kleitz (pp. 204-213, Vol. 123, No. 2)

H.-H. Möbius and R. Hartung:[1] In Table II of this interesting article, published values of the oxygen semipermeability flux π^* and other parameters are compared. In some cases the values differ by nearly a factor of 10^4 and here one expects great measurement discrepancies. But the reasons for the differences are found in the value units used by the authors and in discrepancies of calculations. In early papers about semipermeability of solid oxide electrolytes,[2,3] results were given in cm^3O_2 (0°C, 1 atm) cm/cm^2 sec, that is cm^2 sec^{-1} (Table 1,[2] misprinted cm^2/sec^{-1}). Later we, like other authors, used for values of semipermeability the unit mole O_2 cm/cm^2 sec, that is mole cm^{-1} sec^{-1}. For a comparison it is valid: mole cm^{-1} sec^{-1} = cm^2 $sec^{-1}/2.2414 \times 10^4$ cm^3 $mole^{-1}$. The value for 1200°C from our experiments amounts to 1.6×10^{-6} cm^2 sec^{-1} (the value attributed to us in the paper of Ullmann[3] is incorrect) and after conversion 7.1×10^{-11} mole O_2 cm^{-1} sec^{-1} (the value of Ullmann 1.8×10^{-10} mole O_2 cm^{-1} sec^{-1}). The article under discussion also contains a discrepancy between the flux J defined in Eq. [17] for holes and the flux J connected in Eq. [23] with the oxygen semipermeability flux π^* of Table II without the factor 4; therefore one can expect that some values in Table II refer to mole holes ($\pi^*_h = 4\pi^*_{O_2}$).

The great deviations of equilibrium observed from Fouletier *et al.* with their original method between 1250° and 1450°C indictae a relatively high polarizability of the electrodes. The combination of the results in Fig. 7, 8, 9, 12, and 13 shows that the used platinum layer reference electrode at $p_{O_2} \approx 10^{-3}$ atm already has a polarization resistance $r_P \approx \Delta E_{ref}/JF$ of the order of 10^3 Ω-cm^2. At the same oxygen partial pressure but more than 400° lower (at 800°C) on unobjectionable operating platinum layer electrodes we measured much lower polarization resistances on the order of 10 up to the maximal 10^3 Ω-cm^2. At this point, one has to take into consideration that r_P falls exponentially with growing temperature.

Errors of potentiometric oxygen analysis with solid oxide electrolyte cells and with air at the reference electrode (because of semipermeability and therefore deviations from equilibrium) from our experience are negligible at temperatures near 800°C and oxygen partial pressure $> 10^{-6}$ atm. The polarizability of the electrodes, as well as the oxygen semipermeability, is important for errors. The polarizability of the electrodes is not only dependent on the kind of materials used, temperature, and oxygen partial pressure, but also on the conditions of preparation in thermal, electrical, and chemical treatments of the electrodes.

Evaluation of Electrochemical Information Transfer System

I. Effect of Electric Fields on Living Organisms

A. A. Marino, T. J. Berger, B. P. Austin, R. O. Becker, and F. X. Hart (pp. 1199-1200, Vol. 123, No. 8)

G. E. Kaufman and M. W. Miller:[4] There are several problems with the authors' interpretation of their results as indicating that biological alterations were produced in rats by chronic exposure to a 60 Hz, 150 V/cm electric field.

For example, the authors appear to consider the slightly lower levels of serum corticoids (with no indication of statistical significance) in the exposed rats in experiments 1-3 as an indication of the general adaptation syndrome as described by Selye. However, a lower than normal level of serum corticoids would be consistent with general adaptation syndrome only if the animals were in the exhaustion phase, a possibility which is ruled out by the results of experiment 4. Also, the authors refer to "a statistically significant elevation in albumin percentage and a statistically significant decrease in gamma globulin percentage." Clearly there is no basis for determining that these differences are statistically significant since only one experimental and one control serum pool were collected in each experiment. The listed standard deviations represent only variability between replicate measurements and not variability among the individual animals comprising each pool.

Thus the only results which could conceivably be taken as indicating a statistically significant difference between exposed and control rats are the final body weights in experiments 1 and 4. However, in this regard some additional information about the reported experiments may be of interest. First, there was already a statistically significant difference in weight between the exposed and control groups in experiment 1 prior to the commencement of exposure (exposed group starting weight 60.50 ± 3.03; control group 63.58 ± 3.12; $t = 2.828$ with 31 d.f., $P < 0.01$).[5] No starting weights were available for experiment 4. Second, the exposed rats were kept one to a cage throughout the exposure period while the controls were kept three to a cage in larger cages.[6] Thus, the exposed and control conditions differed by more than the single agent being examined.

In summary, if there are any biological effects produced by exposure to a 60 Hz, 150 V/cm electric field, such effects are not apparent from the results reported by A. A. Marino *et al.*

A. A. Marino,[7] T. J. Berger,[7] B. P. Austin,[7] R. O. Becker,[7] and F. X. Hart:[8] We appreciate the interest that Kaufman and Miller have shown in our work, and we respond as follows to the four points that they have raised.

1. The average decrease in the serum corticoids of the rats which were exposed to the electric field for 1 month was about 31%. Such a decrease is entirely con-

sistent with the initial stages of the general adaptation syndrome.[9]

2. We thought it was apparent that the differences which we described were those between the control and experimental groups, and not differences among animals within each group. In any event, application of the electric field produced the same alteration in the distribution of serum proteins in three consecutive experiments, thereby establishing the electric field as the causitive factor.

3. There were no differences in the initial weights between the experimental and control groups in any experiment. Kaufman and Miller have performed their calculation employing weights of the experimental and control animals which were recorded on different days.

4. Other work has demonstrated that the biological effects which we observed could not possibly be attributed to any aspect of the manner in which the animals were housed.[10,11]

Investigation of Adsorbed Hydrogen on Platinum Electrode by Means of Dynamic Impedance Measurement

T. Ohsaka, Y. Sawada, T. Yoshida, and K. Nihei
(pp. 1339-1345, Vol. 123, No. 9)

R. Durand:[12] 1. The authors do not make enough distinction between two different models: the classical one of Llopis *et al.*[13]-Senda and Delahay[14] which, in the case of a single intermediate species, corresponds to their Fig. 4(c), and the model of Delahay *et al.*,[15] which does not suppose *a priori* separation of double layer charging. This last notion follows from the fact that the electrode "charge" generally depends on Γ with E constant, and it must be associated to the notion of thermodynamic charges brought by Frumkin at the same period[16] and spread out later on. In the case of one or two intermediate species, the works of Grafov *et al.*[17,18] and Barker[19] lead to equivalent circuits requiring transformers or coupling capacitors.

2. The lack of measurements beyond 2000 Hz in the paper under discussion can involve severe uncertainties for the calculations of R_E, C_D, and r: on one hand it is hardly acceptable to assume for C_D, in the "hydrogen region," a constant value obtained by extrapolation of measurements at 0.70 V_{HE}, whereas C_D strongly depends, for a well-defined pretreatment, on the value of Γ;[20-22] on the other hand, values of r per unit projected area seem to be too high for a semiactivated electrode.

3. The authors do not indicate how the experimental difficulties inherent to the use of solid electrodes were tackled: it should be necessary to investigate the influence, for instance, of the current distribution (poor in the case of a disk), of any possible electrolyte penetration between the electrode and its holder (not described), and of the surface roughness of the electrode (possibly increased by voltage scanning pretreatment) on the results, before explaining them by questionable Warburg impedance and second step (at 0.15 V_{HE}).

T. Ohsaka,[23] **Y. Sawada,**[23] **T. Yoshida,**[23] **and K. Nihei:**[24] 1. A few applications of the idea of coupling between the faradaic and nonfaradaic components have been investigated. Sluyters has treated the most convenient model using simplified procedure. Moreover, on solid electrodes it is difficult to reasonably modulate each parameter in analysis. We failed to explain our results, using Sluyters' complex plane method with coupling idea.[25] However, the results fitted well with the equivalent circuit of Fig. 4(c) in the paper under discussion. We analyzed the experimental results using the classical procedure (potential independence of C_D) combined with the equivalent circuit approach.

2. The frequency dispersion of C_p strongly depends on the value of reaction resistance r as shown in Fig. 1, assuming the equivalent circuit (a) in Fig. 4 or 9 in the paper under discussion (the results agreed with the circuit behavior especially in the high frequency range). We plotted the Bagotzky data[21] as C_p *vs.* R_p^{-1} (the relationship is similar to that found in Fig. 7 in the paper under discussion). From the linear portion [which means the assumption of equivalent circuit (a)], we estimated the value of r to be *ca.* 0.02 Ω-cm^2. This value of r gives a frequency dispersion similar to that given by Bagotzky *et al.*[21] In the case of $r = 0.58$ Ω-cm^2 which corresponds to our data in 1*N* sulfuric acid, the frequency dispersion ceases at $f > 1$ kHz. Therefore, we concluded that the dispersion of C_p may be caused largely by the difference of r which is due to the activated condition of the electrode and that the high frequency limits of 2 kHz are considered to be enough in our experiments (*cf.*, Ftn.[1] in the paper under discussion: we regret the mistake in the footnote: the sixth line should read $r = 0.58$ and $f > 1$ kHz). The reciprocal value of 0.58 Ω-cm^2 ($r^{-1} = 1.72$) is not too high a value compared to the value of r^{-1} reported by Frumkin,[26] *i.e.*, the value of r^{-1} ($r = 0.29$) in 1*N* sulfuric acid agrees approximately with our data, but not with Bagotzky's data ($r^{-1} = 50$) which is higher in magnitude. Though the double layer capacity C_D depends on Γ of adsorbed hydrogen as shown by Shuldiner[20] and Petrii,[22] C_D was determined at 0.7V in the double layer region for convenience. The assumption of the constancy of C_D does not affect so much the conditions of $C_A >> C_D$, *i.e.*, the theoretical representation of equivalent circuit (a) becomes semicircular in the complex representation and the intercepts of C_p axis show C_D and ($C_D + C_A$). In the conditions of $C_A >> C_D$, however, the representation is scarcely influenced with the change of C_D.

3. Since the change of the electrode area influenced the reproducibility and stability of the admittance data, we determined the optimum area earlier; probably this behavior is connected to the current distribution. We confirmed that there is no electrolyte penetration between electrode and its holder, from the a *vs.* i plots (where a = area of the electrode and i = current density). It is well known that the surface roughness of an electrode increases with voltage scanning (used as pretreatment). The reproducibility of surface roughness was taken care of in the present experiment by checking the shape of the i-E curves (both the general shape and magnitude of adsorbed hydrogen peak were taken into account). The scanning was always from the double layer to hydrogen

region, reversal of scanning was done at 0.05V. With this technique, we can get good reproducibility in our case. This is also indicated by the roughness factor which we determined to be in the range 1.7-2.5.

The Comparative Crevice Corrosion Resistance of Co-Cr Base Surgical Implant Alloys

T. M. Devine and J. Wulff (pp. 1433-1437, Vol. 123, No. 10)

P. Süry:[27] In their article (see also Ftn. [28-30]) Devine and Wulff describe the relative corrosion behavior of several surgical implant alloys in chloride-containing media at human body temperature. Special attention is paid to the relative crevice corrosion susceptibility, since this phenomenon seems to frequently initiate implant damage.

On the basis of *in vitro* electrochemical (potential time variation and polarization characteristics) and simple immersion tests on specimens with and without artificial crevice in aqueous solutions of NaCl and $FeCl_3$ + HCl, the authors have concluded that MP35N,[31] a wrought, high strength CoNiCrMoTi alloy, is less resistant to crevice corrosion in the human body than cast, cast and solutionized, and wrought CoCrMo alloy HS 21,[32] or an experimental Co base alloy with 20% Cr and 10% Mo without nickel.

We are unable to confirm these results. In a series of reports[33-36] it has been shown that MP35N exhibits strong resistance to the local breakdown of the passive oxide in general and in cases where crevice formation is to be expected. According to our findings this resistance is minimally equal to or exceeds that of cast CoCrMo. The beneficial (and theoretically expected) effect of solutionizing heat-treatment of CoCrMo reported by Devine and Wulff has also been found by us, but an improvement over wrought MP35N through heat-treatment could not be definitely deduced from *in vitro* measurements. These have so far included the following methods: "breakthrough potentials" from potentiodynamic polarization curves[33] in oxygenated and deoxygenated NaCl solutions, differential aeration cell models in Ringer's solution,[34-35] galvanostatic determination of pit repassivation potentials in Ringer's solution,[34] polarization resistance in deaerated hydrochloric acid at 50°C,[34] cyclic voltametric polarization curves with high voltage sweep rates in Ringer's and HCl solution,[34-36] immersion tests in $FeCl_3$ and $FeCl_3$ + HCl solutions with creviced and noncreviced samples,[34] potentiodynamic polarization curves in the active to passive transition region in HCl solution[35,36] potentiostatic current-time curves of creviced anchorage shafts in Ringer's solution,[35,36] and potentiostatic etching in hydrochloric acid.[35,36]

The decision to replace cast CoCrMo as a material for anchorage shafts by forged MP35N has been taken for the latter; in addition to a nondetectable loss in corrosion resistance in our experiments, it presents greatly enhanced mechanical strength and toughness, thus minimizing the risk of fatigue and corrosion fatigue. This material change was facilitated by the fact that the outstanding resistance to crevice and pitting corrosion of MP35N in polluted seawater had already been established in a four-year immersion test.[37]

In the meantime, at least two other reports have been published independently, qualifying MP35N as an implant material with high resistance to depassivation[38] and crevice corrosion[39] in saline solutions at 37°C.

In his first paper on the subject, Devine[28] pointed out that the pitting resistance of MP35N was superior to that of cast CoCrMo, while the inverse was true of crevice corrosion. From the theoretical point of view and on the basis of published data, there is no reason why this inversion should be real. It has been concluded that increasing amounts of Ni in the Co base alloy impair the resistance to crevice corrosion. With the exception of one report,[40] this effect has, to our knowledge, never been described in the literature, and there is no theoretical explanation for it.

In the course of further electrochemical studies concerning active-passive transitions of highly passive iron and cobalt base alloys in chloride media, we have come to the conclusion that it is very difficult to distinguish the different materials with the aid of only a limited number of parallel measurements. This is due to a considerable scatter of electrochemical results on such systems which, in turn, is most probably due to uncontrolled surface states and irregularities in electrode mounting procedures. The surface finish and the impurity level of the final implant should, therefore, be of great importance with respect to the actual behavior in the human body.

The weightiest evidence for the optimum combination of mechanical and corrosion properties of MP35N as a shaft material is, furthermore, the fact that our Company will soon deliver the 100,000th prosthesis based on MP35N, and that we have never heard of any crevice corrosion problem since 1972, *i.e.*, the year of the first implantation of joint endoprostheses made of MP35N.

To sum up, the results of Devine and Wulff have neither been confirmed by *in vivo* implant practice, nor verified by our own or other independent *in vitro* measurements.

T. M. Devine[41] and J. Wulff:[42] Before responding to the specific questions raised by Mr. Süry, we should first like to summarize in general terms our opinion of alloys currently employed as femoral stems in hip-joint prostheses. We do not doubt that the wrought alloy MP35N, because of its superior resistance to fatigue cracking, is more suitable for use as femoral

stems of hip-joint prostheses than the cast HS21 type alloys previously used by Sulzer Brothers. We also do not doubt that wrought MP35N is superior to wrought Cr-Ni-Mo austenitic stainless steels for this purpose because of its vastly greater resistance to general and pit corrosion as well as corrosion fatigue. However, as discussed below, our data and that of others clearly show that the crevice corrosion resistance of wrought HS21 is significantly greater than that of cast HS21 which, in turn, is slightly greater than that of MP35N.

In regard to the passivation characteristics of MP35N, we agree with Mr. Süry that MP35N is similar to HS21 (*i.e.*, Co-Cr-Mo). In fact, our results as given in the paper under discussion show the passive corrosion current densities and pitting potentials of MP35N, HS25, as cast HS21, as cast and solutionized HS21, and wrought HS21 to be quite close to one another in solutions of 0.9% NaCl and 10% HCl + 1% $FeCl_3$. However, we feel that such tests as well as all the electrochemical tests cited by Mr. Süry and performed by him and his colleagues[33-36] do not evaluate the crevice corrosion resistance of an alloy. Pitting potential measurements in aqueous NaCl, for example, merely indicate the potential at which pits initiate and grow in a given solution for a given potential scan rate. Such pitting potentials are a function of the presence of pit initiation sites such as soluble inclusions, *e.g.*, sulfides.[43] Crevice corrosion is not dependent on the presence of such microscopic initiation sites since the crevice site has already been determined as the surface area containing the stagnant electrolyte. Thus, although ultrahigh purity stainless steels are immune to pitting during anodic polarization in 0.1M HCl at slow potential scan rates (60 mV/hr), they are susceptible to crevice corrosion.[44] For these reasons, we feel that electrochemical polarization tests on specimens fitted with a crevice, such as our Teflon-crevice specimens or Lizlovs'[45] glass bead crevices, are more meaningful tests of an alloy's resistance to crevice corrosion.

The results of constant potential polarization tests reported by us on creviced samples of cast HS21 and MP35N in 0.9% NaCl are completely consistent with the measurements of Rostoker and Pretzel[39] referred to by Mr. Süry. Rostoker and Pretzel[39] found MP35N and cast Co-Cr-Mo to have equivalent crevice corrosion resistance in 1% NaCl. Neither alloy underwent crevice corrosion when immersed in 1% NaCl for 100 days. Our results also showed MP35N and cast Co-Cr-Mo (HS21) to have equivalent crevice corrosion resistance in 0.9% NaCl. Both materials resisted crevice corrosion at applied potentials less than 300 mV *vs.* Ag-AgCl, but both were susceptible to crevice attack at applied potentials greater than 300 mV. In similar tests, we found MP35N to crevice corrode at lower applied potentials than cast HS21 in 10% HCl + 1% $FeCl_3$, implying that the latter is more crevice corrosion resistant than MP35N in 10% HCl + 1% $FeCl_3$. In agreement with this finding are the data reported by the Latrobe Electric Steel Company,[46] the American fabricators of MP35N, which show that MP35N is less resistant to crevice corrosion in 10% HCl + 1% $FeCl_3$ than other Co-Ni-20Cr-10Mo alloys with lower nickel contents. We were unable to crevice corrode wrought HS21 at any applied potential in either 0.9% NaCl or 10% HCl + 1% $FeCl_3$. At this point we must emphasize the distinction between cast HS21 and wrought HS21. As-cast, HS21 is highly chemically inhomogeneous.[47] Even after 24 hr at 1200°C, microprobe measurements have indicated that complete homogenization has not taken place. It does not surprise us to hear of, and in fact we ourselves have examined, castings of HS21 which, because of their casting defects and chemical inhomogeneities are of inferior corrosion resistance. As such, we feel that the wrought versions of HS21, being highly homogeneous,[47] represent a truer indication of the corrosion resistance of the HS21 composition. As additional proof of this point, Hodge and Lee[48] have recently shown that the strength and corrosion resistance of cast HS21 is much improved by hot isostatic pressing and heat-treatment which help to minimize microporosity and alloy segregation. Finally, we would like to point out that the excellent *in vivo* results achieved to date on MP35N are quite consistent with our *in vitro* results which indicate MP35N to possess excellent crevice corrosion resistance, albeit inferior to that of HS21. However, this four-year *in vivo* data presented by Mr. Süry cannot be considered as proof of the immunity of MP35N to crevice corrosion in body fluids especially since it has long been known that crevice corrosion is not a major problem in this application but is far more serious in other multipiece weight-bearing implants of the kind described by Scales.[49] Additionally, times much longer than four years are required to establish the immunity of an alloy to *in vivo* crevice corrosion.

In summary, the results of our electrochemical crevice corrosion tests are indeed consistent with the literature cited by Mr. Süry, and our ranking of the crevice corrosion resistances of all the alloys examined is in agreement with the *in vivo* results known to date as summarized in Table III of our paper. Where we disagree most certainly with Mr. Süry is that wrought HS21 is superior to cast HS21 and MP35N. In this regard, Hodge and Lee have also found that homogenization treatments improve the corrosion resistance of cast HS21. The literature Mr. Süry cites does not deal with wrought HS21 other than Smith's patent[40] of MP35N which, as Mr. Süry has mentioned, agrees with our data.

Streaming Potential Measurements of Biosurfaces

R. A. Van Wagenen, J. D. Andrade, and J. B. Hibbs, Jr.
(pp. 1438-1444, Vol. 123, No. 10)

J. J. Bikerman:[50] The Helmholtz equation for the streaming potential $E = P\epsilon\zeta/4\pi\eta K$ (P being the pressure difference, ϵ and η the dielectric constant and the viscosity of the liquid, K its electric conductivity, and ζ the electrokinetic potential) is valid only as long as the solid phase is a perfect insulator. Do the fibroblast cells used by the authors belong to this class?

Moreover, do these cells swell in the solutions used? If they do, then the above equation should be altered to $E = P\epsilon\zeta/4\pi\eta K \cdot S_1/S_2$, S_1 being the cross section (of the capillary) available to laminar flow of the liquid and S_2 the cross section available to ions.[51,52]

The authors laudably studied the effect of the capillary length and some other factors on the experimental value of E. Unfortunately, to obtain significant results, S_1, S_2, and the electric conductivity of the cells should also be known.

R. A. Van Wagenen,[53] **J. D. Andrade,**[53] **and J. B. Hibbs, Jr.:**[54] 1. It is reasonable to assume that fibroblast cells have the same general membrane structure as those commonly utilized for microelectrophoresis. The

transmembrane resistance is undoubtedly very high in these fibroblasts as in most cells. More important is the existence of a pronounced ionic conductance both along the plane of the cell membrane and throughout the hydrated surface of the glass substrate utilized for the fibroblast culture. The specific conductance in this region is comparable to that of bulk streaming electrolyte, but its contribution to the total conductance should be negligible at the ionic strength used in this research simply because the volume of the surface region (including cells) is so minute compared to the total volume of the capillary manifesting bulk electrolyte conductance, *i.e.*, less than 1%.

2. The medium was not isotonic, but this should not affect cell swelling since the fibroblasts were thoroughly prefixed in buffered, isotonic glutaraldehyde. The ratio S_1/S_2 should be essentially unity for capillaries of 600 μm internal diameter containing cells less than 1 μm in thickness. Also, the flow throughout the system was laminar on the basis of Reynolds number calculations determined by flow rate.

Ionic Conductivity of Some Lithium Silicates and Aluminosilicates

I. D. Raistrick, C. Ho, and R. A. Huggins
(pp. 1469-1476, Vol. 123, No. 10)

A. D. Franklin and K. F. Young:[55] Raistrick *et al.* fit their low temperature, high frequency data with an equation for the admittance which reads

$$Y^* = R_B^{-1} + j\omega C_\infty + A_B\omega^{+\beta} + jB_B\omega^{+\beta} \qquad [1]$$

This equation can be derived from an equivalent circuit for a polycrystalline ionic conductor given by Bauerle,[56] with some modification. This equivalent circuit is shown in Fig. 1, as the part labelled "low temperature high frequency" to the left of the vertical dotted line. The geometric capacitance is represented by C', while R' represents the summed internal resistance of the crystal grains, and Z^*_{gb} represents the impedance contributed by the grain boundaries. Presumably these boundaries are quite variable in their structure, composition, and properties, and Z^*_{gb} must, in general, be represented with a distribution of relaxation times. If we choose a Cole-Cole[57] distribution, which while purely empirical has been found to describe a wide variety of dielectric materials, then

$$Z^*_{gb} = \frac{\Delta Z}{1 + (j\omega\tau)^\beta} \qquad [2]$$

Under the condition that the grains are very conductive, that is, R' is vanishingly small, the admittance of this part of the circuit becomes

$$Y^* = 1/\Delta Z + j\omega C' + (1/\Delta Z)\,[(\omega\tau)^\beta \cos(\beta\pi/2) + j(\omega\tau)^\beta \sin(\beta\pi/2)] \qquad [3]$$

which is equivalent to Eq. [1] with the identifications

$$R_B = \Delta Z \qquad [4a]$$

$$A_B = (\tau^\beta/\Delta Z)\cos(\beta\pi/2) \qquad [4b]$$

$$B_B = (\tau^\beta/\Delta Z)\sin(\beta\pi/2);$$

$$C_\infty = C' \qquad [4c]$$

This equivalent circuit exhibits all of the properties discussed by Raistrick *et al.* In addition, it relates A_B, B_B, and β through

$$B_B/A_B = \tan(\beta\pi/2) \qquad [5]$$

Values of 2 arctan $(B_B/A_B)/\pi$ calculated using the data of Raistrick *et al.* for Li_2SiO_3 given in their Tables I and II are compared with their β in Table I below. The correspondence is reasonably good, although there appears to be a small but systematic difference between the two estimates of β. This discrepancy may have the following origin. In writing the Cole-Cole equation, we have applied the same exponent to j and to $(\omega\tau)$. However, this does not appear to be necessary, and Eq. [2] could be written more generally still as

$$Z^*_{gb} = \frac{\Delta Z}{1 + j^\gamma(\omega\tau)^\beta} \qquad [6]$$

The exponent γ determines how far the center of the circular arc is depressed below the real axis in the complex plane while β determines the frequency dependence. In Table I $2\arctan(B_B/A_B)/\pi$ is an estimate of γ which appears to differ a bit from the β derived by Raistrick *et al.* from the frequency dependence.

The expression for the impedance corresponding to Eq. [3] is

$$Z^* = \frac{\Delta Z}{1 + (j\omega\tau)^\beta + j\omega C'\Delta Z} \qquad [7]$$

In the complex plane this would produce a distorted arc, one that approaches the real axis at very high frequencies at an angle of $\pi/2$ and with a zero intercept, and at very low frequencies at an angle of $(\beta\pi/2)$ and with an intercept of ΔZ. A careful examination of Fig. 4 in the paper under discussion suggests just this type of asymmetry.

Turning to the high temperature, low frequency data reported by Raistrick *et al.*, we interpret their additional series element Y^*_I somewhat differently and it is illustrated to the right of the dotted line in Fig. 1. They observe that B-G (admittance) plots as a function of temperature are portions of circles that pass through the origin and have centers that lie below the real axis. As the temperature is increased the center of the circle rises until it lies upon the real axis. We suggest that this behavior can be represented with a distribution of relaxation times, but in the admittance rather than the impedance. If we again choose a modified empirical Cole-Cole[57] distribution as in Eq. [6], then the sample electrode admittance and impedance are

$$Y^* = \frac{R_B^{-1}}{1 + j^{-\epsilon}(\omega\tau)^{-\alpha}} \qquad [8]$$

$$Z^* = R_B + R_B\,[\cos(\epsilon\pi/2) - j\sin(\epsilon\pi/2)]\,(\omega\tau)^{-\alpha} \qquad [9]$$

As ϵ is allowed to go from ½ to 1, a transition from Warburg-like[58] behavior (as for a diffusion-controlled

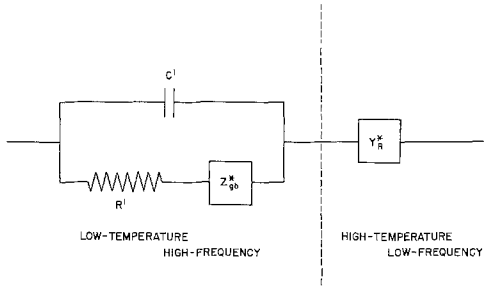

Fig. 1. Equivalent circuit for lithium silicates and aluminosilicates

Table I. Test of Eq. [5] for Li_2SiO

T, °C	$2\arctan(B_B/A_B)/\pi$	β
224	0.83	0.74
255	0.71	0.67
325	0.69	0.65
431.5	0.78	0.71
499	0.45	0.71

process) to that of a simple capacitor occurs. During this process the center of the arc in the Y^* complex plane rises toward the real axis, and the angle subtended by the Z^* line and the real axis in the Z^* complex plane increases toward $\pi/2$. This appears to match the behavior described by Raistrick *et al.*

Raistrick *et al.* represent their high temperature, low frequency sample electrode response with Z^*_I in series with the bulk resistance R_B, as

$$R_B + Z^*_I = R_B + A_I\omega^{-\alpha} - jB_I\omega^{-\alpha} \quad [10]$$

and the slope of the line in the complex impedance plane as

$$\psi_Z = B_I/A_I \quad [11]$$

which is equivalent to Eq. [9] where

$$A_I = R_B\tau^{-\alpha}\cos(\epsilon\pi/2) \quad [12a]$$

$$B_I = R_B\tau^{-\alpha}\sin(\epsilon\pi/2) \quad [12b]$$

$$\psi_Z = B_I/A_I = \tan(\epsilon\pi/2) \quad [12c]$$

Table II below shows that the estimates of ϵ from Eq. [12c] differ considerably from values of α from the frequency dependence, as given by Raistrick *et al.* Since ϵ and α are the exponents on j and $(\omega\tau)$, respectively, then it appears that they must definitely be distinguished from one another, as γ and β are in Eq. [6].

The equivalent circuit of Fig. 1, with Cole-Cole equations (modified as in Eq. [6] and [8]), describing Z^* and Y^*, is therefore an alternative to the one presented by Raistrick *et al.* This equivalent circuit fits the data equally well, and has the advantage of a more direct correspondence with expected physical processes.

I. D. Raistrick, C. Ho, and R. A. Huggins:[59] *Low-temperature-high frequency response.*—Consider the original expression for the bulk complex admittance

$$Y^*_B = A_B\omega^\beta + jB_B\omega^\beta \quad [1]$$

It may be shown by integration of either the real or the imaginary part of this expression, using the Kramers-Kronig relationship, that

$$B_B/A_B = \tan(\beta\pi/2) \quad [2]$$

and hence Eq. [1] may be rewritten as

$$Y^*_B = (jA_B'\omega)^\beta \quad [3]$$

with the identities

$$A_B = A_B'\cos(\beta\pi/2) \quad [4a]$$

$$B_B = A_B'\sin(\beta\pi/2) \quad [4b]$$

Now, taking Eq. [3] and adding a parallel resistance ΔZ to this expression gives

$$Y_B' = \Delta Z^{-1} + (jA_B'\omega)^\beta \quad [5]$$

and a corresponding impedance of

$$Z_B' = (Y_B')^{-1} = \frac{\Delta Z}{1 + \Delta Z(jA_B'\omega)^\beta} \quad [6]$$

[59] Center for Materials Research, Stanford University, Stanford, California 94305.

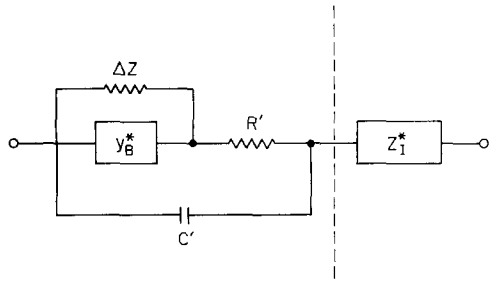

Fig. 2. Franklin and Young's equivalent circuit redrawn after separation of real and complex components of Z^*_{gb}.

This corresponds exactly to Franklin and Young's Eq. [2] with the identification

$$\tau = A_B'\Delta Z^{1/\beta} \quad [7]$$

Thus we may rewrite Franklin and Young's circuit, to the left of the dotted line, as shown below (Fig. 2). This formulation has the advantage that Z^*_{gb} has been divided into a frequency-independent (purely real) resistance, ΔZ, and a frequency-dependent (complex) admittance Y^*_B, which is identical to that proposed in our original paper.

If we then neglect R' at all frequencies, the Franklin and Young circuit is identical in all respects to our original circuit, Fig. 7a, with the identities given by Franklin and Young in their Eq. [4a]-[4c], with the additional relations given above (Eq. [4a], [4b], and [7]). The neglect of R', however, is open to question. Two points are of interest. As ω increases, Y^*_B will shunt ΔZ until R' ultimately becomes important. In the complex impedance plane the general response of the Franklin and Young circuit will be two arcs. The high frequency arc will be semicircular, the low frequency arc will have its center depressed below the real axis if $\beta < 1$. If the time constants associated with the two arcs are similar, and/or if $R' << \Delta Z$ then the Franklin and Young response will be similar to that shown in Fig. 4 of the paper under discussion. It seems, however, that the introduction of unseen circuit elements, which are then neglected, *i.e.*, R', is an unnecessary complication.

A more serious problem posed by Franklin and Young is that ΔZ is equated with an intergranular resistance rather than any kind of bulk resistance, *i.e.*, it is never possible to measure bulk conductivities in a polycrystalline material, if $R' << \Delta Z$. All that one can do is measure intergranular effects.

At the time the original paper was written, no single crystal data were available on these materials. Recently, however, measurements have been made on single crystals of β-eucryptite (β-$LiAlSiO_4$) by von Alpen *et al.*[60] $LiAlSiO_4$ is an anisotropic Li^+ conductor with the higher conductivity parallel to the crystallographic c-axis. The conductivity values perpendicular and parallel to the c-axis, lie below and above the data reported by Raistrick *et al.* and, further, the activation enthalpy perpendicular to the c-axis was identical to that which we obtained. Although certainly not definitive, this comparison suggests that we were in fact measuring a bulk conductivity rather than an intergranular effect. Further experiments on samples with a wide range of controlled concentrations of grain boundaries will be necessary to fully resolve this problem.

The modification suggested by Franklin and Young in their Eq. [6], although fitting the experimental data rather better than the original form of the admittance we used, is open to the objection that it does not conform to the general laws governing linear processes.

Expanding Franklin and Young's Eq. [6] and removing ΔZ as discussed above gives

[60] U. von Alpen, E. Schonherr, H. Schulz, and G. H. Talat, *Electrochim. Acta*, To be published.

$$Y = C\beta\omega^{\beta}\{\cos(\gamma\pi/2) + j\sin(\gamma\pi/2)\} \quad [8]$$

where

$$C = \tau/\Delta Z^{1/\beta}$$

Using the Kramers-Kronig relation

$$B(\omega) = 2\omega/\pi\int_0^{\infty}\frac{G(\nu)}{\nu^2 - \omega^2}d\nu \quad [9]$$

where B and G are the imaginary and real parts of Y, we can show, given

$$G(\omega) = (C\omega)^{\beta}\cos(\gamma\pi/2)$$

that

$$B(\omega) = (C\omega)^{\beta}\cos(\gamma\pi/2)\tan(\beta\pi/2)$$

which is not equal to

$$(C\omega)^{\beta}\sin(\gamma\pi/2)$$

unless

$$\beta = \gamma$$

In other words, the circuit element implied by Eq. [6] of Franklin and Young's discussion is nonlinear and cannot be used to describe a distribution of relaxation times.

High temperature-low frequency response.—Equations [8] and [9] of Franklin and Young are open to the same objection as their Eq. [6] discussed immediately above.

If, however, we allow ϵ to equal α, then Eq. [8] reduces to the same interface impedance formulation as was used in the paper under discussion, in series with a resistance R_B (or ΔZ).

The apparent discrepancy noted in Table II of Franklin and Young's discussion, however, remains unexplained. More careful experiments on single crystal β-PbF_2[61] have indicated rather different behavior. In this later work, much better agreement between α and the expression $2\arctan(B_I/A_I)\pi$ was obtained. Further, α appeared to be almost independent of temperature whereas B_I and A_I both appeared to follow an Arrhenius-like temperature dependence $A_I = A_I^{\circ}\exp(-\Delta H/RT)$.

As a consequence of the relationship between A_I and B_I deduced from the Kramers-Kronig relations, A_I and B_I must have the same temperature dependence if α is independent of temperature. This was confirmed experimentally. α took different values depending on the nature of the electrode preparation, and could be as low as ~0.3. This behavior cannot be explained by a simple Warburg mechanism as suggested by Franklin and Young.

Summary.—The principal points we should like to make are as follows:

First, the Franklin and Young impedance function is directly derivable from our original admittance functions, and their equivalent circuit is exactly equivalent to ours if the series resistance in their circuit is neglected, as they have done. The introduction, and subsequent neglect, of additional components which make no observable contribution to the frequency dispersion seems an unnecessary complication.

Second, Franklin and Young did this in order to arrive at an impedance function of a form analogous to the empirical relations first used by Cole and Cole to describe the complex dielectric constant. They also chose to interpret this function in terms of a distribution of relaxation times. In the paper we made a point of deliberately avoiding this interpretation. Although the complex bulk admittance appears to be associated with grain boundary effects (it was absent in the single crystal PbF_2 samples,[61] even though a complex interface impedance of the same form was still present) there appears to be no direct experimental evidence that a distribution of relaxation times is responsible, except in a formal sense.

Third, we feel that the modification of the impedance function suggested by Franklin and Young is open to the serious objection that it implies a nonlinear process.

We should like to thank Drs. Franklin and Young for their interest in our paper. The questions of interpretation raised by their comments are worthy of careful investigation in the future.

On the Differential Thermal Analysis of the Platinum-Oxygen System

J. P. Hoare, R. F. Paluch, and S. G. Meibuhr
(pp. 1821-1824, Vol. 123, No. 12)

K. Kinoshita:[62] In the paper under discussion, Dr. Hoare and co-workers reported on the application of differential thermal analysis (DTA) to identify two absorbed states of oxygen on oxidized Pt. The DTA curves for preanodized and HNO_3 treated Pt beads deserve further comment in view of the recent data obtained by the present author on the DTA of commercial PtO_2 in an inert atmosphere.[63]

Hoare and co-workers reported that two exothermic peaks were produced in the DTA scan by the desorption of oxygen species on Pt. DTA studies on PtO_2 (commercial product of Engelhard Industries, 115Å crystallite size) in flowing He by this author showed that PtO_2 decomposed to metallic Pt with an endothermic reaction at about 500°C when the sample was heated at 10°C/min. After cooling to room temperature, a second DTA curve was run and no endothermic peak was observed. Apparently, complete decomposition of PtO_2 to Pt was achieved in one heat cycle to 700°C. Weight loss measurements and x-ray diffraction analysis of the decomposition product suggested that the decomposition reaction is given by

$$PtO_2 \rightarrow Pt + O_2$$

There is evidence in the literature suggesting that the oxidation of finely divided Pt in air is an exothermic reaction.[64] For the reaction

$$Pt\ (solid) + \tfrac{1}{2}\ O_2\ (gas) \rightarrow Pt - O\ (solid)$$

the measured enthalpy at 40°C for a Pt coverage of 0.5 is −58 kcal/mole O_2,[65] which means the desorption of oxygen from Pt-O is an endothermic reaction.

The exothermic peaks in the DTA curves (Fig. 1-3 in the paper under discussion) ascribed to the desorption of oxygen from oxidized Pt beads are difficult to reconcile with the DTA results obtained on commercial PtO_2 [63] and the other results cited from the published literature.[64,65] One explanation is that the PtO_2 and Pt-O species present on the oxidized Pt beads possess thermal properties different from those found in commercial PtO_2 or Pt-O produced by the adsorption of O_2 on clean Pt.

The authors report that "the DTA curve does not return to the base line (intercept on the ΔT ordinate) between the peaks and that a long tail exists at the high temperature end of the curve." Since the specific heat capacities of the Pt sample and the Al_2O_3 reference material are not the same, this behavior in the DTA base line is generally observed. The base line would be zero only if the reference and sample parameters are identical, if heat leakage from both sample and reference thermocouples are identical, and if the sample was not undergoing a phase change or a chemical reaction.[66]

Examination of the DTA curves (Fig. 1-3) suggests another interpretation to explain the thermal analysis

data. Assume that the over-all shape of the DTA curve, that is, an increase in ΔT followed by a decrease in ΔT as the sample temperature increases, represents the base line characteristics. The desorption of oxygen from Pt would then produce a DTA peak which would be observed superimposed on the changing base line. If this was the case, the minimum in ΔT evident at 200°-300°C in Fig. 1-3 would be associated with the desorption of oxygen from Pt and the oxidized Pt beads would then exhibit an endothermic desorption of oxygen similar to the anticipated result based on other reports.[63-65] Furthermore, only one species of adsorbed oxygen is required to explain the endotherm rather than the two species postulated by Hoare and coworkers. Norton[67] reported evidence for the presence of two adsorbed states of oxygen on Pt, one oxygen species desorbing below 300°K and the other above 600°K. The latter oxygen species may very well be similar to the oxygen species desorbed from the oxidized Pt bead. On the other hand, two oxygen species would not be expected in the DTA curves (Fig. 1-3) since one oxygen species desorbs below 300°K and the DTA scan starts at 0°C.

There are several methods of detecting base line shifts in a DTA instrument. A DTA scan of Al_2O_3 in both the sample and reference Pt dishes should yield a ΔT of zero throughout the temperature range of the experiment. If a base line deviation exists with identical material in both the reference and sample dishes, a variety of reasons may be responsible: thermocouple placement, difference in heat leakage rates from sample and reference dishes, for example. Alternatively, oxidized Pt beads in both the reference and sample dishes should yield a base line with ΔT of zero. Finally, a DTA scan of an oxidized Pt bead in the sample dish and an untreated Pt bead in the reference dish would yield information on the presence of adsorbed oxygen species produced by the oxidation of Pt.

J. P. Hoare, R. F. Paluch, and S. G. Meibuhr:[68] We wish to thank Dr. Kinoshita for calling to our attention some interesting aspects of this DTA work and for confirming that PtO_2 is unstable. Let us point out again that the DTA peaks do not correspond to adsorbed PtO_2 because any PtO_2 formed during anodization decomposed on the Pt surface before the DTA curve could be run. Also, let us note that Booth *et al.*[64] concluded that the heat liberated during exposure of finely divided Pt or Pd to oxygen arose from the recrystallization of the Pt- or Pd-black since no oxides were detected.

According to Smith,[69] Pt is an endothermic occluder of hydrogen so that the DTA curve of the Pt-H_2 system should show an exothermic peak in agreement with Fig. 3F in the paper under discussion. Consequently, the data in our paper indicate that Pt is also an endothermic occluder of oxygen since exothermic peaks have been observed in Fig. 1-3. As stated in our paper, the peaks correspond to the adsorption of oxygen on two types of surface sites. Many other investigators have detected at least two kinds of surface adsorption sites on Pt.

Although bulk PtO_2 exhibits one endothermic peak on the DTA curve,[63] this is expected since it is the decomposition of a nonconducting compound which is certainly not the same species present on an anodized Pt sample. We plan to make some measurements on bulk PtO_2.

With regard to base line shifts, we did run DTA scans with Al_2O_3 in both pans and observed nearly flat lines. What shifts were present were always in the positive direction; we never observed a negative shift. If one superimposes an endothermic peak on a base line with a positive shift, there is no way one could observe the two humps in the curves of Fig. 1-3. Surely Fig. 3 cannot be explained by a shift in base line. Because of base line shifts, accurate measurements of the area under a given peak cannot be made, however.

We agree that using a Pt sample as a reference may give us some interesting data and we plan to carry out experiments of this type.

High Temperature Corrosion of Chromium and Chromium (III) Oxide in Chlorine and Chlorine-Oxygen Mixtures

K. Reinhold and K. Hauffe*

Institute for Physical Chemistry, University of Göttingen, D-3400 Göttingen, Germany

ABSTRACT

The chlorination kinetics of Cr between 650° and 800°C is characterized by a time-constant weight loss of the specimen caused by volatilization of $CrCl_3$ and $CrCl_4$. At low Cl_2 pressures also a scale is formed consisting of $CrCl_2$ and $CrCl_3$. The rate-determining step is the diffusion of volatile products across the laminar boundary layer. Cr_2O_3 pellets show time-constant weight loss in Cl_2 and Cl_2-O_2 mixtures. In the mixtures, the rate constant of the corrosion of Cr_2O_3 is about a hundred times smaller compared to the chlorination of Cr in the absence of O_2. It increases with the fourth root of the O_2 pressure and linearly with the Cl_2 pressure indicating that CrO_2Cl_2 seems to be the only reaction product. In a mixture of Cl_2 and O_2, the corrosion of Cr is inhibited due to formation of an outer Cr_2O_3 layer and of CrO_2Cl_2 as the only volatile product. Since Cr_2O_3 can be volatilized as described above, preoxidized samples of Cr exhibit no long-time corrosion resistance in Cl_2.

There is some interest in chemical engineering to find suitable construction material for reactions in which chlorine is involved at high temperatures. Among metals only nickel has some importance because of the comparatively low vapor pressure of $NiCl_2$. At 700°C, however, a considerable metal consumption already takes place. In a previous work Hauffe and Hinrichs (1) studied the chlorination behavior of Ni and NiO. They found time-constant weight loss of the samples due to the formation of volatile $NiCl_2$. The rate constant was proportional to the square root of the flow rate. When Ni was chlorinated, the rate constant first increased linearly with the Cl_2 pressure but became independent of the Cl_2 pressure after a critical value was reached. The authors' attempt to improve the corrosion resistance of Ni against Cl_2 by adding small amounts of O_2 to the atmosphere was not successful. While oxygen did not affect the reaction at low O_2 pressures it even caused an ignitionlike reaction above a critical pressure. This behavior may be attributed to the small difference in thermodynamic stability of $NiCl_2$ and NiO. Later on, Halfdanarson and Hauffe (2) gave a more detailed discussion of the mechanism of Ni chlorination. They were able to elucidate the rate-determining step of the reaction to be diffusion of either Cl_2 toward the sample surface or $NiCl_2$ away from it across the laminar boundary layer. They also studied the chlorination kinetics of Ni-Cr alloys. No difference was found between the rate constants of Ni and Ni-Cr alloy chlorination because of the small difference between the vapor pressure of $NiCl_2$ and $CrCl_3$ or $CrCl_4$. Preoxidized samples of Ni-Cr alloys, however, showed better resistance against chlorination than those of Ni.

In the system Cr-Cl-O, Cr_2O_3 has a much higher thermodynamic stability than the other possible products. For example the free energy of formation from the elements at 700°C is $\Delta G°_{CrCl_2(s)} = 65.7$ (3), $\Delta G°_{CrCl_3(s)} = 78.2$ (3), and $\Delta G°_{Cr_2O_3(s)} = 103.7$ (3) kcal for 1 g-atom Cr. Therefore, the aim of this investigation was the elaboration of the conditions under which inhibition by Cr_2O_3 formation takes place. This study seemed to be much more promising, since it is supported by the observation (4, 5) that the nitriding of Cr in air is inhibited by Cr_2O_3 formation. In addition, the corrosion resistance of numerous alloy systems has been considerably improved by small amounts of Cr. In the system Cr-Cl-O, however, the existence of oxyhalogenides has to be taken into consideration. It must be assumed that the extent of inhibition depends on the reactivity of Cr_2O_3 in Cl_2-O_2 mixtures. Therefore, the volatilization of Cr_2O_3 in Cl_2 and Cl_2-O_2 mixtures was investigated. Little previous work has been done. According to Moissan (6), Cr_2O_3 gives $CrCl_3$ with dry Cl_2 and CrO_2Cl_2 with wet Cl_2 at 440°C. Wasmuht (7) has found that the weight loss of Cr_2O_3 after 1 hr of chlorination at 800°C is 6.6% (no data about flow rate and chlorine pressure). If carbon is present, the reaction between Cr_2O_3 and Cl_2 starts at lower temperatures giving $CrCl_3$ (8). Recent thermodynamic investigation by Sano and Belton (9) indicates that CrO_2Cl_2 is the only reaction product in Cl_2-O_2 mixtures.

First, the chlorination kinetics of Cr had to be investigated since only little previous work was available. According to Sargent (10) the reaction between Cr and dry Cl_2 starts measurably at 300°C giving $CrCl_3$. Above 350°C, $CrCl_3$ begins to dissociate into $CrCl_2$ and Cl_2 (11). The vapor pressure equilibrium over solid $CrCl_3$ and $CrCl_2$ was thoroughly studied by Doerner (12). On the basis of these experiments he was the first to ascertain the existence of $CrCl_4$.

Experimental

Apparatus.—The weight change of the samples during corrosion was continuously followed by a quartz spiral balance. In order to avoid depletion of the reactive gases at the surface of the sample, the measure-

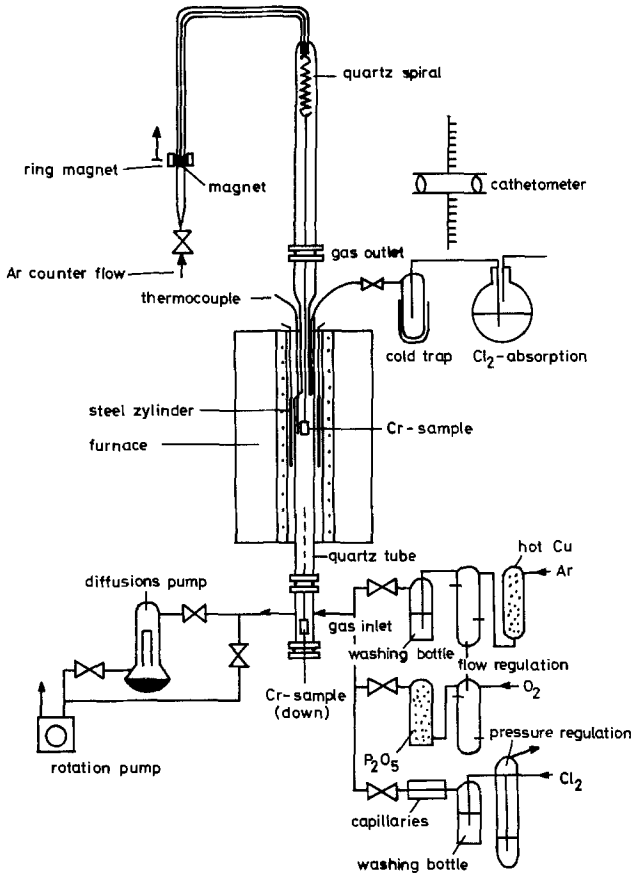

Fig. 1. Corrosion apparatus (schematic)

ments were carried out in a flow system. Argon was used as carrier gas to which oxygen and chlorine were added in suitable amounts. Thus a constant gas composition and a continuous removal of volatile products were achieved. The main part of the corrosion apparatus (Fig. 1) was the quartz reaction tube (1). The temperature in the reaction zone could be maintained to about ± 1°C. Since the upper cooling zone of the quartz tube was tapered, convective flow was avoided. A weak Ar counterflow was introduced at the top of the quartz tube to prevent precipitation of volatile products on the quartz fiber suspended from the quartz spiral balance. The dilatation of the spiral was followed by observation of a marker on the quartz fiber by means of a cathetometer. The movement of the marker could be read to ± 0.01 mm. Since the sensitivity of the spiral balance was 43 mg/cm, the accuracy of the weight determination was ± 0.05 mg.

Argon, oxygen, and chlorine of purity 99.997, 99.995, and 99.9 volume percent, respectively, were supplied by Messer-Griesheim. Small amounts of oxygen in the argon were removed by hot active copper (13), water in chlorine and oxygen was absorbed by H_2SO_4 and P_2O_5, respectively.

In order to clean the reaction chamber and dry the samples before each measurement, the apparatus could be evacuated to about 10^{-3} Torr.

Sample preparation.—Because of the brittleness of Cr no foils can be manufactured. A cylindrical ingot of 99.997% Cr, prepared by thermal decomposition of CrI_3, was supplied by General Electric, New York. This ingot was divided into smaller pieces by means of a diamond saw. From these pieces rectangular, 0.6-0.8 mm thick specimens were prepared by spark erosion. After wet grinding on 400 silicon carbide paper, the samples were polished with finest 6/0 abrasive paper and degreased in petroleum. The geometrical surface of the coupons varied from 2 to 4 cm^2 and was determined by means of a slide gauge with an accuracy of 1%. Cr_2O_3 pellets 1.5 mm thick with a diameter of 13 mm were pressed from Cr_2O_3 powder of 99.9% purity, supplied by Riedel de Haen. Before the volatilization experiments, all the samples were annealed in air at 1000°C for 24 hr.

Measuring procedure.—After the sample was suspended from the quartz fiber, its position was below the lower cooling zone of the furnace. After evacuation, argon was introduced until the pressure reached 1 atm. Now the flow rate of argon as carrier gas was regulated and adequate portions of the reactive gases added. Finally, the sample was lifted up to the reaction zone as soon as a constant gas composition was achieved (after 15 min generally). Now the dilatation of the balance was followed in suitable time intervals and thus the course of corrosion recorded. Because of initial vibrations of the spiral, caused by lifting the sample up to the reaction zone, the first reading was possible 1 min after the start. Since this time is required for the samples to reach reaction temperature, the rate of corrosion was neglected in the first minute.

Results

Chlorination of chromium, kinetics.—In the temperature and chlorine pressure region used the chlorination of Cr is characterized by a weight loss of the specimen proportional to the reaction time. Figure 2 shows a typical straight line the slope of which gives the rate constant $k = -d(\Delta m/A)/dt$, where A = geometrical surface of the sample. The rate constant does not change as long as the geometrical surface of the sample remains constant. The weight loss is caused by volatilization of the reaction products.

At low chlorine pressures also a thick scale is formed. As illustrated in Fig. 3, the mass of the scale increases linearly with time. The scale mass was determined by weighing the sample before and after scale removal. Since the inner layer of the scale is hygroscopic, the scale can be removed easily and quantitatively.

The plot in Fig. 4 gives the chlorine pressure dependence of the rate constant between 10 and 200 Torr at 700°C. Initially the rate constant is proportional to the square root of the chlorine pressure. Above the inflection point, however, (about 40 Torr) the rate con-

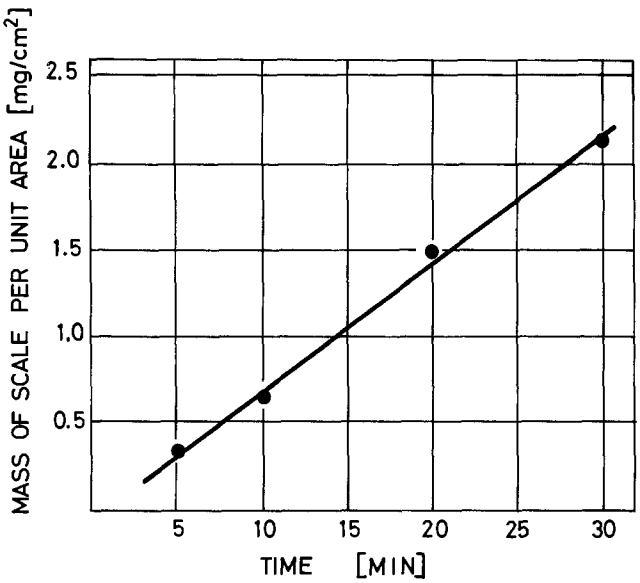

Fig. 3. Dependence of scale mass on reaction time during Cr chlorination at $T = 700°C$, $p_{Cl_2} = 20$ Torr, and $v = 1.5$ cm/sec.

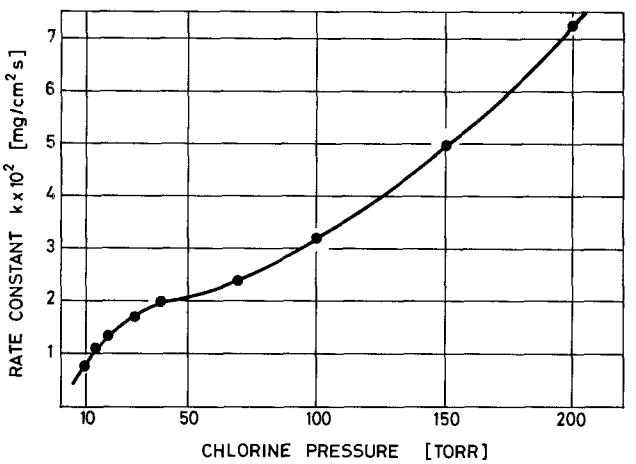

Fig. 4. Dependence of rate constant of Cr chlorination on chlorine pressure at $T = 700°C$ and $v = 1.5$ cm/sec.

stant is proportional to the second power of the chlorine pressure. For a given reaction time, the scale becomes thinner with increasing chlorine pressure. The temperature dependence of the rate constant is shown in Fig. 5. As can be seen from this plot, k initially increases exponentially. Above 750°C, however, the increase becomes smaller, caused by chlorine depletion. Above 815°C, the melting point of $CrCl_2$, the reaction could not be continuously followed anymore. As described below, the inner layer of the scale was found to be $CrCl_2$.

The flow rate is given by the equation

$$v_{(T)} = \frac{N_o}{q \cdot 60} \cdot \frac{T}{T_o} \text{ cm/sec}$$

where N_o = total gas flow at room temperature T_o in cubic centimeters per minute, q = cross section of the quartz tube in the reaction zone, and T = reaction temperature in Kelvin. This is a mean flow rate with regard to the cross section of the quartz tube. Since a parabolic flow rate profile is formed in the tube, the flow rate in the center of the tube, where the sample is located, is about two times the mean flow rate. As can be seen from Fig. 6, the rate constant follows the square root of the mean flow rate: $k \sim \sqrt{v}$.

Sample and product analysis.—The chlorination operates like a pickling procedure. After scale removal

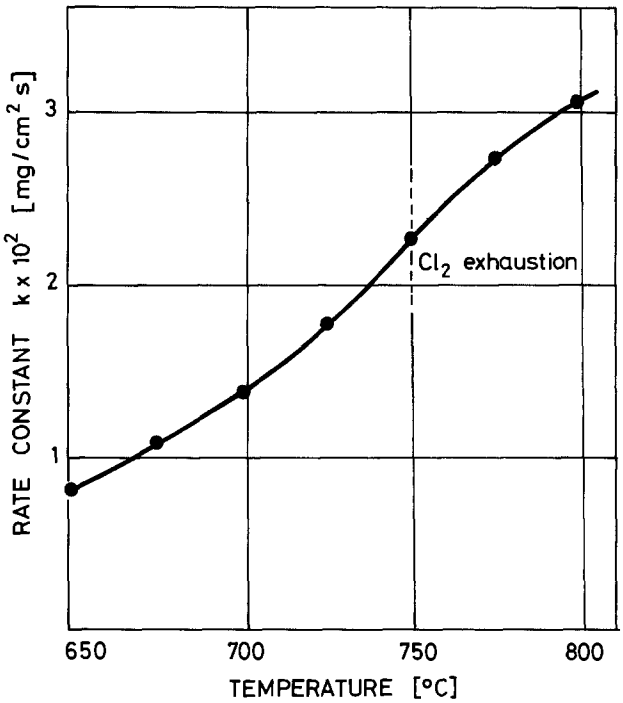

Fig. 5. Dependence of rate constant of Cr chlorination on temperature at $p_{Cl_2} = 20$ Torr, $v = 0.46 \times T/298$ cm/sec.

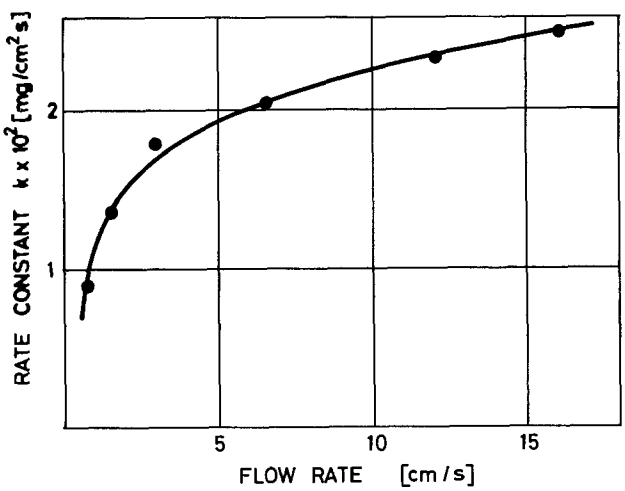

Fig. 6. Dependence of rate constant of Cr chlorination on flow rate at $T = 700°C$, $p_{Cl_2} = 20$ Torr.

the grain structure of the metal becomes visible (mean grain size = 4.8 mm²). The thickness of the metal after corrosion has decreased more markedly in the lower than in the upper part of the sample. The thickness d of the remaining metal sheet for a given reaction time t is about proportional to the square root of the distance x from the lower edge of the sample: $d \sim \sqrt{x}$.

Because of their volatility, reaction products are found not only in the scale but also as sublimates on the walls of the outlet tube. At low chlorine pressures a violet sublimate is found identified as $CrCl_3$ by chemical and x-ray analysis. At higher chlorine pressures, a dark brown precipitation is found in the cooler parts of the gas outlet. This compound decomposed rapidly in wet air under chlorine formation. We assume this product to be $CrCl_4$, since v. Wartenberg (14) who first tried to synthetize $CrCl_4$, obtained a compound of same properties.

Because of its hygroscopicity, porosity, and bad mechanical adherence, the scale was difficult to analyze. As could be concluded from qualitative and quantitative chemical analysis, the scale consists of two layers: a very thin, hygroscopic inner $CrCl_2$ phase and

a thick, porous outer layer of both $CrCl_2$ and $CrCl_3$. For microscopic investigation, the samples had to be impregnated by a transparent lacquer and embedded in epoxy resin. As was found by microscopic investigation, the thickness of the outer phase of the scale increases linearly with time. Since the thin inner $CrCl_2$ phase does not contribute to the scale mass, this result is coincident with the previous observation that the scale mass is linear with the reaction time.

Volatilization of Cr_2O_3.—The weight loss of Cr_2O_3 pellets in chlorine is linear with the reaction time. Plot a in Fig. 7 shows the chlorine pressure dependence of the rate constant between 10 and 70 Torr. The rate constants are very much smaller compared to those of Cr chlorination. Plot b in Fig. 7 shows the chlorine pressure dependence of the rate constant between 10 and 70 Torr in Cl_2-O_2 mixtures. Both in chlorine and in Cl_2-O_2 mixtures, the rate constant increases linearly with the chlorine pressure. In Fig. 8, the oxygen pressure dependence of the rate constant is represented for three temperatures. It is exactly a linear function of the fourth root of the oxygen pressure in Cl_2-O_2 mixtures. The rate constants obtained in Cl_2-O_2 mixtures are higher than in pure chlorine, but about a factor of 100 lower than the rate constants of Cr chlorination. Analogous to Cr chlorination the rate constant was found to be proportional to the square root of the flow rate.

Simultaneous attack of Cl_2 and O_2 on Cr.—Figures 9 and 10 represent the corrosion rate of Cr in several Cl_2-O_2 mixtures at 700°C. There are three typical oxygen pressure regions:

1. Between $p_{O_2} = 0$ and $p_{O_2} = 2$ Torr, a considerable initial weight loss is found. The inflection points of curves b and c are caused by precipitation of volatile chlorides as Cr_2O_3 on the quartz fiber. That could not be avoided in this oxygen pressure region. Therefore, no good reproducibility was obtained.

2. Between $p_{O_2} = 2$ and $p_{O_2} = 20$ Torr, a mass gain of the specimen was observed. After a definite reaction time (dependent on oxygen pressure) the sample mass becomes constant.

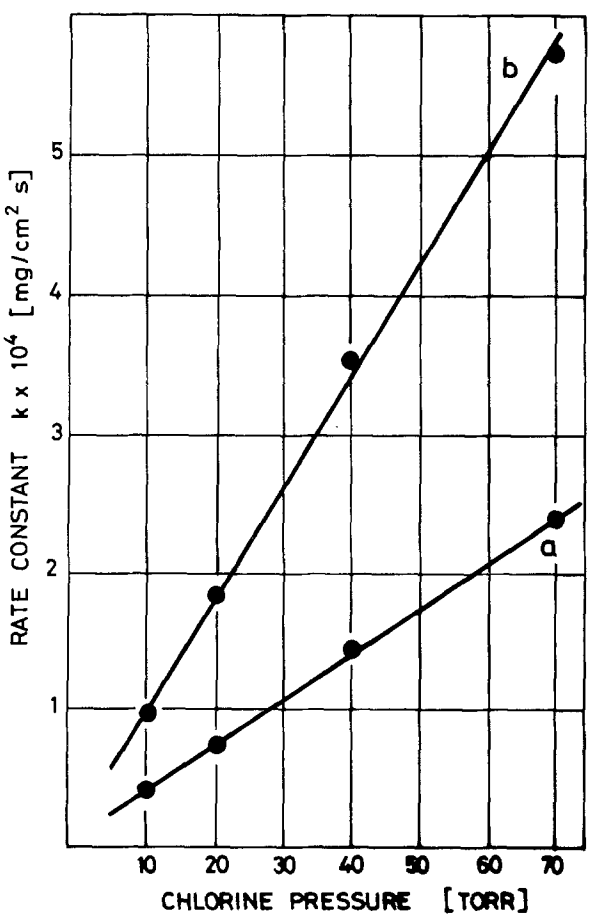

Fig. 7. Dependence of rate constant of Cr_2O_3 volatilization on chlorine pressure at $T = 700°C$, $v = 1.5$ cm/sec. Curve a, no oxygen present; curve b, $p_{O_2} = 20$ Torr.

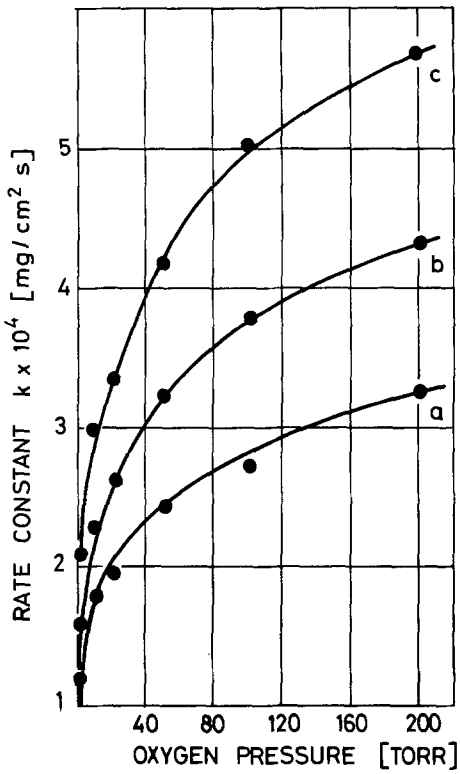

Fig. 8. Dependence of rate constant of Cr_2O_3 volatilization on oxygen pressure at $p_{Cl_2} = 20$ Torr and $v = 1.5$ cm/sec. Curve a, $T = 700°C$; curve b, $T = 750°C$; curve c, $T = 800°C$.

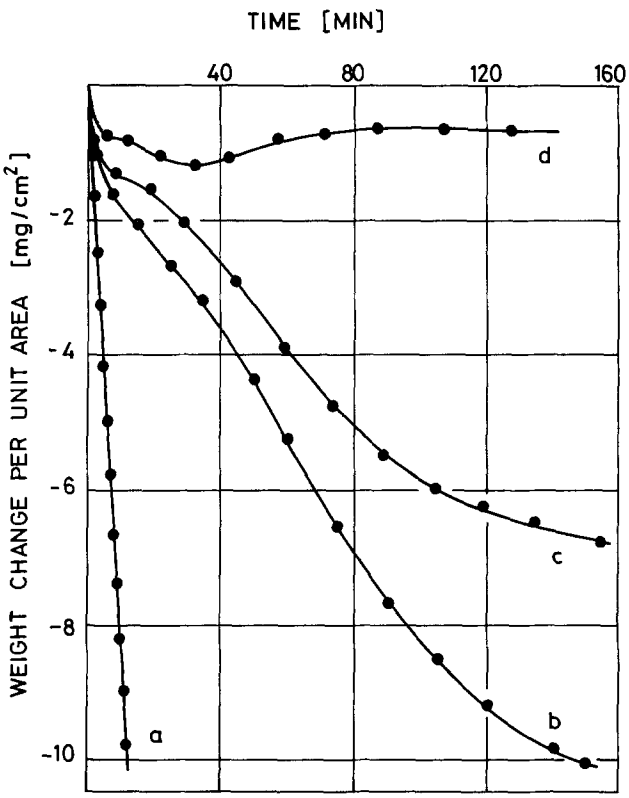

Fig. 9. Corrosion rate of Cr in Cl_2-O_2 mixtures at $T = 700°C$, $p_{Cl_2} = 20$ Torr, and $v = 1.5$ cm/sec. Curve a, no oxygen present; curve b, $p_{O_2} = 0.5$ Torr; curve c, $p_{O_2} = 1$ Torr; curve d, $p_{O_2} = 2$ Torr.

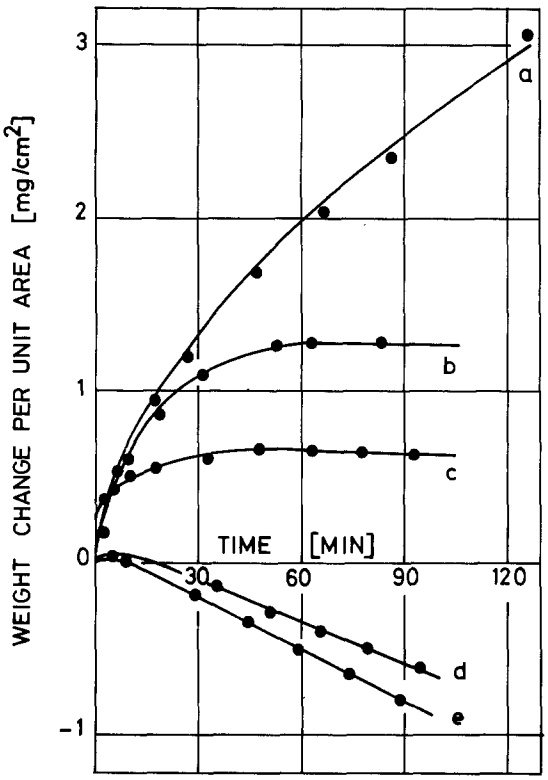

Fig. 10. Corrosion rate of Cr in O_2-Cl_2 mixtures at $T = 700°C$, $p_{Cl_2} = 20$ Torr, and $v = 1.5$ cm/sec. Curve a, $p_{O_2} = 3.5$ Torr; curve b, $p_{O_2} = 10$ Torr; curve c, $p_{O_2} = 20$ Torr; curve d, $p_{O_2} = 50$ Torr; curve e, $p_{O_2} = 100$ Torr.

3. Above $p_{O_2} = 20$ Torr, a time-constant weight loss is found again. The rate constants are $k = 1.1 \times 10^{-4}$ mg/cm² sec for $p_{O_2} = 50$ Torr and $k = 1.6 \times 10^{-4}$ mg/cm² sec for $p_{O_2} = 100$ Torr.

The influence of the oxygen pressure on scale mass and Cr consumption is shown in Fig. 11. At low oxygen pressures, there is still a high portion of volatile products after 1 hr of corrosion. With increasing oxygen pressure, the consumption of Cr decreases rapidly while the scale mass passes a maximum.

Up to $p_{O_2} = 20$ Torr the scale mass is comparable to that found for Cr chlorination. Above $p_{O_2} = 20$ Torr, however, both scale mass and Cr consumption become

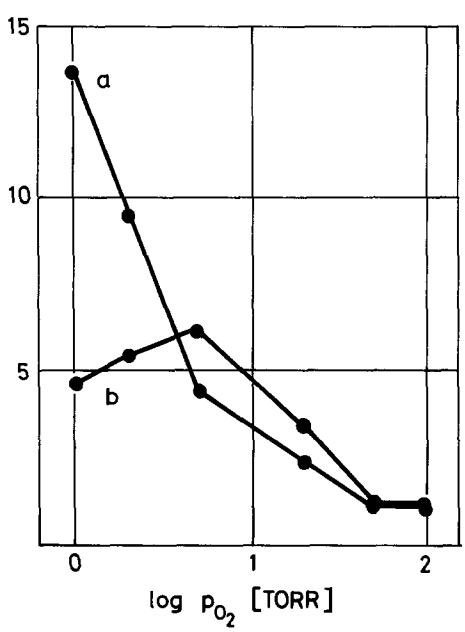

Fig. 11. Dependence of Cr consumption (curve a) and scale mass (curve b) on oxygen pressure at $T = 700°C$, $p_{Cl_2} = 20$ Torr, $v = 1.5$ cm/sec, and $t = 60$ min.

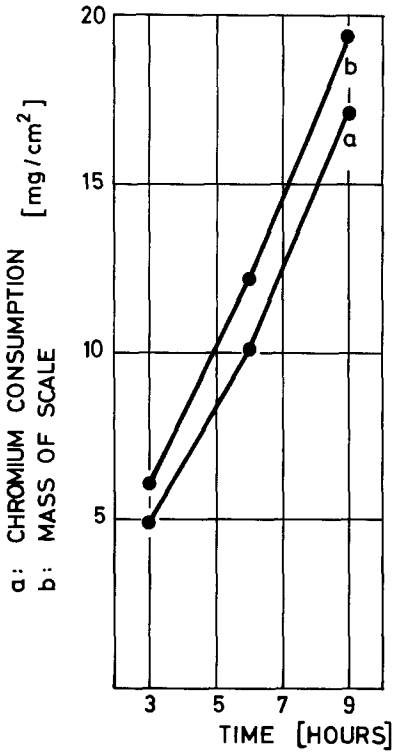

Fig. 12. Dependence of Cr consumption (curve a) and scale mass (curve b) on reaction time at $T = 700°C$, $p_{Cl_2} = 20$ Torr, $p_{O_2} = 20$ Torr, and $v = 1.5$ cm/sec.

small. As can be seen from Fig. 9 and 10, the mass of the samples attains a constant value under certain conditions. This cannot be attributed to a standstill of reaction, since Cr_2O_3 is volatilized in Cl_2-O_2 mixtures as described above. Therefore, the dependence of scale mass and Cr consumption on reaction time has been investigated. The result is given in Fig. 12. Both scale mass and Cr consumption linearly increase with the reaction time. After the sample mass has become constant, the weight gain due to formation of solid products must be equal to the weight loss caused by formation of volatile products.

Scale analysis.—Generally, the sample surfaces were completely covered by green layers. These layers were identified as Cr_2O_3 by x-ray analysis. Microscopic investigation of the samples after embedding in epoxy resin revealed a very porous and voluminous scale structure (Fig. 13). Up to $p_{O_2} = 20$ Torr the profile of the scale is as follows: $Cr/CrCl_2/CrCl_3/Cr_2O_3$. With increasing oxygen pressures, the chloride layers become thinner for a given reaction time. At $p_{O_2} = 100$ Torr, no $CrCl_3$ is detectable (Fig. 14).

Chlorination of preoxidized Cr.—The samples were preoxidized at 700°C and $p_{O_2} = 760$ Torr. After 3 hr of oxidation, a weight gain of 7×10^{-2} mg/cm² was found corresponding to an oxide layer thickness of 4200Å.

The weight loss of a preoxidized sample in chlorine at 700°C and $p_{Cl_2} = 20$ Torr is shown in Fig. 15. As can be seen from this picture, the weight loss is proportional to the second power of the reaction time: $-\Delta m/A \sim t^2$.

Discussion

By the following experimental results we may assume that transfer processes toward and away from the sample control most of the reactions described above:

1. Linear scale growth during Cr chlorination does not affect the rate constant.

2. The thickness d of the sample after scale removal is proportional to the square root of the distance x from the leading edge.

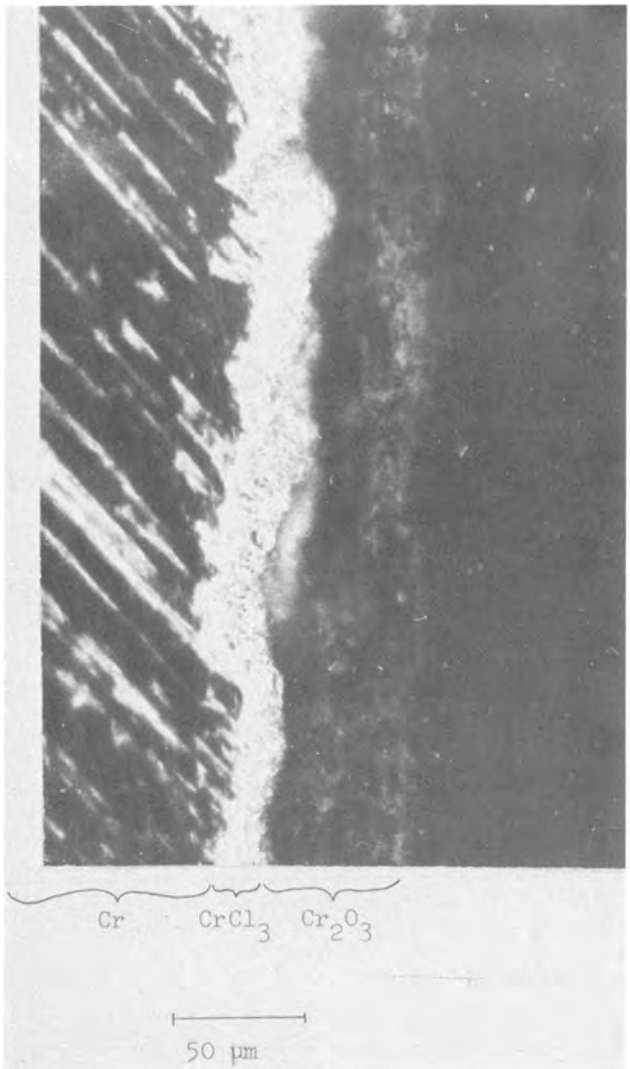

Fig. 13. Microphoto of sample profile after corrosion in a Cl_2-O_2 mixture at $T = 700°C$, $v = 1.5$ cm/sec, $p_{Cl_2} = 20$ Torr, $p_{O_2} = 10$ Torr, and $t = 60$ min.

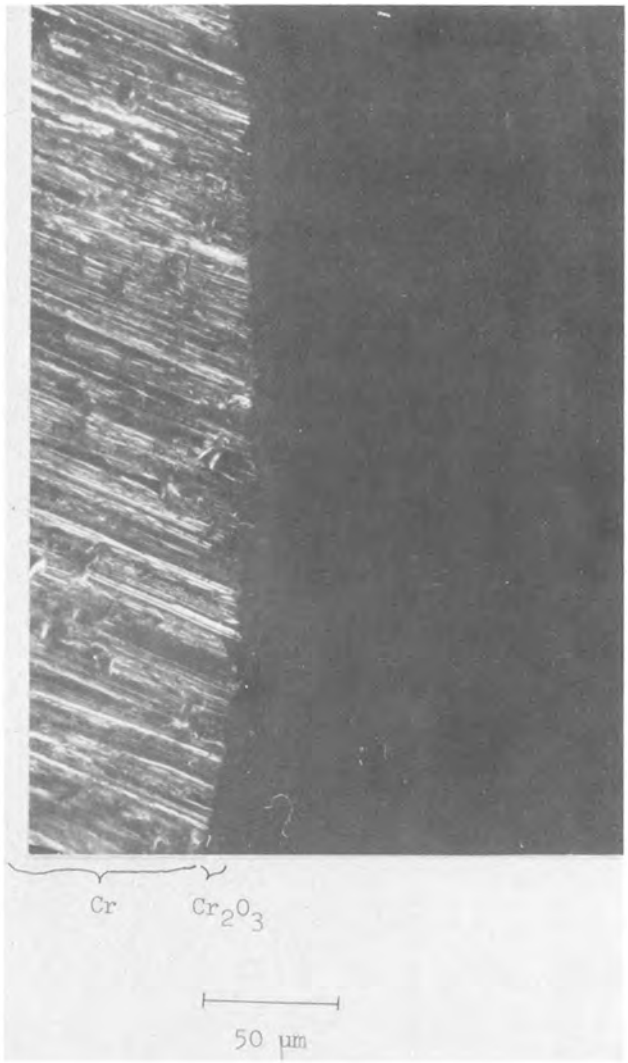

Fig. 14. Microphoto of sample profile after corrosion in a Cl_2-O_2 mixture at $T = 700°C$, $v = 1.5$ cm/sec, $p_{Cl_2} = 20$ Torr, $p_{O_2} = 100$ Torr, and $t = 60$ min.

3. The rate constants of Cr chlorination and Cr_2O_3 volatilization are proportional to the square root of the flow rate.

A Reynolds number between 1 and 10 has been calculated for the temperature and flow rate region used. Therefore, a laminar flow in the reaction tube and a laminar boundary layer at the surface of the sample are assumed. In order to simplify the solution of the Navier-Stokes equations the thickness of the boundary layer is believed to be small compared to the distance from the lower edge of the sample. In addition, the influence of mass transfer on the flow rate is neglected so that the flow equation can be solved independently of the diffusion equation.

According to Bennett, and Myers (16) the thickness of the laminar boundary layer at a flat plate is given by the equation

$$\delta = 5\sqrt{\frac{\nu x}{v_\infty}} \qquad [1]$$

where ν = kinematic viscosity, v_∞ = two times the mean flow rate, and x = distance from the lower edge of the sample. The mass transfer toward and away from the sample surface is given by the following equation (16)

$$j_A = 0.33\ (c_{A_\infty} - C_{A_0})\ \frac{D_{AB}^{2/3}}{\nu^{1/6}}\sqrt{\frac{v_\infty}{x}} \qquad [2]$$

where c_{A_∞} = concentration of A in great distance, c_{A_0} = concentration of A at the surface, and D_{AB} = diffusion coefficient of A in A + B.

The reaction between Cr and Cl_2 consists of the following steps: (*i*) transfer of chlorine toward the sample surface across the laminar boundary layer, (*ii*) diffusion of reactants across the scale, (*iii*) formation of solid products, (*iv*) formation of volatile products, and (*v*) transfer of volatile products away from the sample surface across the laminar boundary layer.

The following equilibria have to be considered: the scale formation

$$Cr(s) + Cl_2(g) = CrCl_2(s) \qquad [3]$$

$$CrCl_2(s) + \tfrac{1}{2}\,Cl_2(g) = CrCl_3(s) \qquad [4]$$

and the volatilization process

$$CrCl_3(s) = CrCl_3(g) \qquad [5]$$

$$2CrCl_3(s) + Cl_2(g) = 2CrCl_4(g) \qquad [6]$$

According to Doerner (12) the dissociation pressure of $CrCl_3$ (equilibrium [4]) is very small compared to the chlorine pressures employed in our experiments. Therefore, the scale exclusively consists of $CrCl_3$ at the interface scale/gas. From recent investigations by Oppermann (15), the data of equilibria [5] and [6] have been calculated, as shown in Tables I and II. As can be seen from these tables, the weight loss of the Cr specimen is caused mainly by the volatilization of $CrCl_4$ up

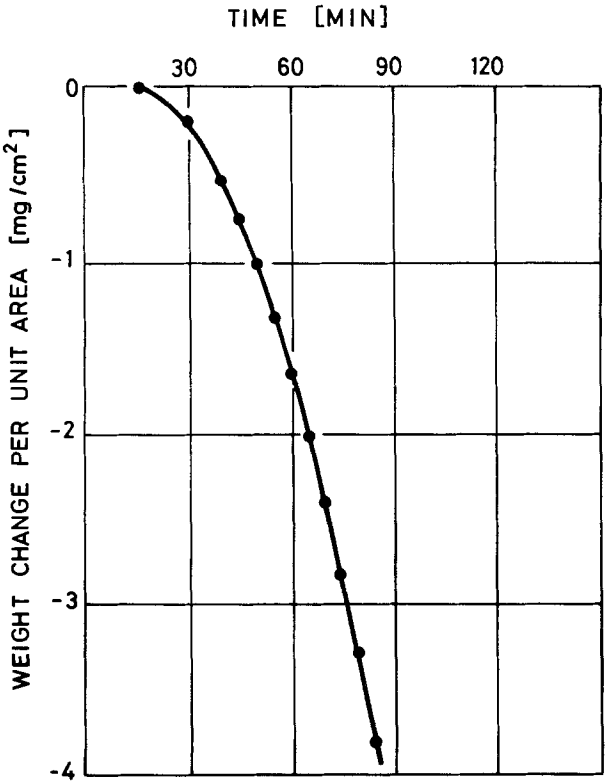

Fig. 15. Chlorination rate of a preoxidized Cr sample at T = 700°C, p_{Cl_2} = 20 Torr, and v = 1.5 cm/sec.

to 700°C. Above this temperature, however, the vapor pressure of $CrCl_3$ can be neglected no longer.

For the chlorine transfer toward the sample surface, we obtain from Eq. [2] with $c_{Cl_2 0} = 0$ and $c_{Cl_2 \infty} = p_{Cl_2}/RT$

$$j_{Cl_2} = 0.33 \cdot \frac{p_{Cl_2} D_{AB}^{2/3}}{RT\nu^{1/6}} \sqrt{\frac{v_\infty}{x}} \qquad [7]$$

The transfer of $CrCl_3$ and $CrCl_4$ away from the sample surface with $c_{CrCl_3 \infty} = 0$, $c_{CrCl_3 0} = p_{CrCl_3}/RT$, $c_{CrCl_4 \infty} = 0$, and $c_{CrCl_4 0} = p_{CrCl_4}/RT$ can be written as follows

$$j_{CrCl_3} = -0.33 \frac{p_{CrCl_3} D_{AB}^{2/3}}{RT\nu^{1/6}} \sqrt{\frac{v_\infty}{x}} \qquad [8]$$

$$j_{CrCl_4} = -0.33 \frac{p_{CrCl_4} D_{AB}^{2/3}}{RT\nu^{1/6}} \sqrt{\frac{v_\infty}{x}} \qquad [9]$$

Assuming the diffusion coefficients of $CrCl_3$ and $CrCl_4$ to be almost equal, the total mass transfer away from the chlorinated sample can be described by the sum of [8] and [9]

$$j = j_{CrCl_3} + j_{CrCl_4} = -0.33 \frac{(p_{CrCl_3} + p_{CrCl_4}) D_{AB}^{2/3}}{RT\nu^{1/6}} \sqrt{\frac{v_\infty}{x}} \qquad [10]$$

Table I. Vapor pressure of $CrCl_3$ according to Oppermann (15)

T(°C)	650	700	750	800
p_{CrCl_3} (Torr)	$2.7 \cdot 10^{-1}$	1.17	4.42	14.77

Table II. K_p for equilibrium [6] and p_{CrCl_4} for p_{Cl_2} = 20 Torr according to Oppermann (15)

T(°C)	650	700	750	800
K_p [6] (Torr)	$7.24 \cdot 10^{-1}$	3.38	13.58	47.89
p_{CrCl_4} (Torr)	3.8	8.22	16.48	30.95

The rate constant k (milligrams per square centimeter second) is correlated with the mass transfer j (mole per square centimeter second) by the following equation

$$k = -d(\Delta m/A)/dt = -j \cdot M_{Cr} \cdot 10^3 \qquad [11]$$

where M_{Cr} = atomic weight of Cr. Therefore

$$k = \frac{0.33 \cdot 10^3 M_{Cr} D_{AB}^{2/3}}{RT\nu^{1/6}} (p_{CrCl_3} + p_{CrCl_4}) \sqrt{\frac{v_\infty}{x}} \qquad [12]$$

Up to 700°C, the vapor pressure of $CrCl_3$ can be neglected (see Tables I and II). With $p_{CrCl_4} = K_{p[6]} p_{Cl_2}$ (equilibrium [6]), we obtain

$$k = \frac{0.33 \cdot 10^3 M_{Cr} D_{AB}^{2/3} K_{p[6]}^{1/2}}{RT\nu^{1/6}} \sqrt{\frac{p_{Cl_2} \cdot v_\infty}{x}} \qquad [13a]$$

or, for a given temperature

$$k = \text{constant} \cdot \sqrt{\frac{p_{Cl_2} \cdot v_\infty}{x}} \qquad [13b]$$

By this equation, the thickness profile of the metal after corrosion and the dependence of the rate constant on flow rate and chlorine pressure up to p_{Cl_2} = 40 Torr is described in accordance with the experimental results at 700°C.

By increase of the chlorine pressure, equilibrium [6] is shifted in favor of formation of more $CrCl_4$ and the thickness of the scale decreases for a given reaction time. The increase of the rate constant above the inflection point, as illustrated in Fig. 4, is not yet completely understood. For thermodynamic reasons, a direct chlorination according to

$$Cr(s) + 2Cl_2(g) = CrCl_4(g) \qquad [14]$$

should give a very much stronger increase of the rate constant than was observed. On the other hand, the rate constant is still found to be proportional to the square root of the flow rate also at high chlorine pressures.

The volatilization of Cr_2O_3 in Cl_2/O_2 mixtures between 700° and 800°C cannot be attributed to the vapor pressure of Cr_2O_3 or to formation of CrO_3. As was shown by mass spectrometry (17), the total dissociative vapor pressure over Cr_2O_3 which consists of Cr, CrO, CrO_2, O_2, and O, amounts to about 5×10^{-4} Torr at 1566°C. At 1325°C, the vapor pressure is already below 10^{-6} Torr (4). During oxidation of Cr above 1000°C, deviations from the parabolic rate law of oxidation occur. By numerous thermodynamic and kinetic investigations (4, 17-22), these deviations could be explained by oxidative volatilization of Cr_2O_3 according to

$$Cr_2O_3(s) + 3/2\ O_2(g) = 2CrO_3(g) \qquad [15]$$

From the temperature dependence of the equilibrium constant of Eq. [15], which was given by Kim and Belton (18), extrapolation to 700°C gives a CrO_3 pressure of 3×10^{-8} Torr at 76 Torr oxygen pressure. The apparent vapor pressure in the simultaneous presence of 20 Torr Cl_2, however, amounts to 1.1×10^{-1} Torr (9). Therefore, formation of CrO_3 can be neglected under these conditions. It must be concluded from our experimental results in accord with Sano and Belton (9) that CrO_2Cl_2 is the exclusive reaction product in Cl_2-O_2 mixtures. The rate constant is directly proportional to the chlorine pressure and a linear function of the fourth root of the oxygen pressure, according to

$$\tfrac{1}{2}\ Cr_2O_3(s) + Cl_2(g) + \tfrac{1}{4}\ O_2(g) = CrO_2Cl_2(g) \qquad [16]$$

The equilibrium pressure of CrO_2Cl_2 is given by

$$p_{CrO_2Cl_2} = K_{p[16]}^{1/2} p_{Cl_2} p_{O_2}^{1/4} \qquad [17]$$

Since the rate constant depends on the flow rate, diffusion of CrO_2Cl_2 across the laminar boundary layer must be assumed to be the rate-determining step of the

reaction. Taking into account that Cr_2O_3 disks, suspended so that the circular surfaces were parallel to the direction of the gas flow, have been used, Eq. [2] must be rewritten as follows

$$j_A = \text{constant}\ (c_{A_\infty} - c_{A_0}) v_\infty^{1/2} \quad [18]$$

with $c_{A_\infty} = c_{CrO_2Cl_2} = 0$, $c_{A_0} = c_{CrO_2Cl_{2_0}} = p_{CrO_2Cl_2}/RT$ and Eq. [17] we obtain

$$j_{CrO_2Cl_2} = -\text{constant} \cdot \frac{K_{p[16]}^{1/2} p_{Cl_2} p_{O_2}^{1/4} v_\infty^{1/2}}{RT} \quad [19]$$

With

$$j_{CrO_2Cl_2} = -2k/10^3 M_{Cr_2O_3} \quad [20]$$

where $M_{Cr_2O_3}$ = molecular weight of Cr_2O_3, tht rate constant k is given by the expression

$$k = \text{constant} \frac{M_{Cr_2O_3}}{2RT} 10^3 K_{p[16]}^{1/2} p_{Cl_2} p_{O_2}^{1/4} v_\infty^{1/2} \quad [21]$$

or, if all constants for a given temperature are combined

$$k = \text{constant} \cdot p_{Cl_2} p_{O_2}^{1/4} \cdot v_\infty^{1/2}$$

The volatilization of Cr_2O_3 by chlorine may be attributed to two parallel reactions

$$Cr_2O_3(s) + 3Cl_2(g) = 2CrCl_3(g) + 3/2\ O_2(g) \quad [22]$$

and

$$\tfrac{1}{2}\ Cr_2O_3(s) + Cl_2(g) + \tfrac{1}{4}\ O_2(g) = CrO_2Cl_2(g) \quad [16]$$

On the basis of the scale analysis, the corrosion characteristics (Fig. 9-10) and the volatilization experiments with Cr_2O_3 described above, the following reactions must be assumed to take place during corrosion of Cr in Cl_2-O_2 mixtures

solid products

$$Cr(s) + Cl_2(g) = CrCl_2(s) \quad [3]$$

$$CrCl_2(s) + \tfrac{1}{2}\ Cl_2(g) = CrCl_3(s) \quad [4]$$

$$2CrCl_3(s) + 3/2\ O_2(g) = Cr_2O_3(s) + 3Cl_2(g) \quad [23]$$

volatile products

$$CrCl_3(s) = CrCl_3(g) \quad [5]$$

$$2CrCl_3(s) + Cl_2(g) = 2CrCl_4(g) \quad [6]$$

$$\tfrac{1}{2}\ Cr_2O_3(s) + Cl_2(g) + \tfrac{1}{4}\ O_2(g) = CrO_2Cl_2(g) \quad [16]$$

At low oxygen pressures reactions [5] and [6] predominate and the initial weight loss of the specimen is high. Gradually, the surface is covered by Cr_2O_3 according to reaction [23] and the extent of reaction [5] and [6] decreases.

At higher oxygen pressures, from the beginning of the reaction, weight gain of the samples is observed. The tendency of the curves in Fig. 9 and 10 leads to the assumption of a maximum weight gain at a special oxygen pressure. This pressure must be high enough to prevent reaction [5] and [6] but low enough to allow formation of solid $CrCl_3$ and to keep reaction [16] small.

Figure 12 shows that the scale mass linearly increases with reaction time even after the sample mass has become constant. The scale mass which predominantly consists of Cr_2O_3 at $p_{O_2} = 20$ Torr, is very much higher than found for Cr oxidation. Gulbransen and Andrew (23), for example, found 1.4×10^{-2} mg/cm^2 weight gain after an oxidation time of 6 hr at 700°C and $p_{O_2} = 76$ Torr. As can be seen from Fig. 12, scale mass after 9 hr amounts to about 20 mg/cm^2. Therefore, a porous scale structure has to be assumed. This assumption is supported by the microscopic profile analysis shown in Fig. 13. The result for $p_{O_2} = 20$ Torr (Fig. 12) and $p_{O_2} = 10$ Torr (Fig. 13) can certainly be generalized for lower oxygen pressures, since a porous oxide structure must be assumed as long as the oxide grows on inner chloride layers. It even may be generalized for higher oxygen pressures since strong CrO_2Cl_2 formation enlarges oxide surface roughness.

Above $p_{O_2} = 20$ Torr, the corrosion is determined by reaction [16]. At $p_{O_2} = 50$ Torr and $p_{O_2} = 100$ Torr, the samples lose weight after a small initial weight gain (curves d and e in Fig. 10). The rate constants are 1.2×10^{-4} and 1.6×10^{-4} mg/cm^2 sec, respectively. Under the same conditions, the rate constants of Cr_2O_3 pellet volatilization are 1.7×10^{-4} and 1.9×10^{-4} mg/cm^2 sec, respectively (experimental values multiplied by a factor of 0.69, the portion of chromium in Cr_2O_3). The difference between the rate constant obtained for Cr_2O_3 pellet volatilization and those obtained for Cr corrosion in Cl_2-O_2 mixtures is small, indicating that the scale growth has become small above $p_{O_2} = 20$ Torr.

A real measure of inhibition found in the system Cr-Cl-O is the ratio of the consumption of Cr in Cl_2 to that in Cl_2-O_2 mixtures at constant chlorine activity. Since no difference in scale mass between Cr corrosion in chlorine and chlorine-oxygen mixtures has been found, inhibition must be mainly caused by a decreased formation of volatile products. Therefore, if the oxygen pressure is high enough to form CrO_2Cl_2 as the only volatile reaction product in Cl_2-O_2 mixtures, then the ratio of the ($CrCl_3$ + $CrCl_4$) equilibrium pressure to the CrO_2Cl_2 equilibrium pressure is a practical measure of inhibition in the system Cr-Cl-O.

The rate constant of Cr chlorination is given by the equation

$$k = \frac{0.33 \cdot 10^3 \cdot M_{Cr} \cdot D_{AB}^{2/3}}{RT\nu^{1/6}} (p_{CrCl_3} + p_{CrCl_4}) \sqrt{\frac{v_\infty}{x}} \quad [12]$$

The rate-determining step of CrO_2Cl_2 formation in the presence of oxide layers on chromium should be (analogous to Cr_2O_3 pellet volatilization) the diffusion of CrO_2Cl_2 across the laminar boundary layer

$$k' = \frac{0.33 \cdot 10^3 \cdot M_{Cr} \cdot D_{AB}^{2/3}}{RT\nu^{1/6}} p_{CrO_2Cl_2} \sqrt{\frac{v_\infty}{x}} \quad [24]$$

Under the assumption that the diffusion coefficients of the volatile molecules are almost equal, we obtain by division of the rate constant k by k'

$$k/k' = p_{CrCl_3} + p_{CrCl_4}/p_{CrO_2Cl_2} \quad [25]$$

If the corrosion is determined by reaction [16] (above $p_{O_2} = 20$ Torr), the ratio $p_{CrCl_3} + p_{CrCl_4}/p_{CrO_2Cl_2}$ can experimentally be confirmed by the ratio of the rate constants k/k'. At 700°C and $p_{Cl_2} = 20$ Torr, equilibrium pressures of $CrCl_3$ and $CrCl_4$ are 1.17 Torr (Table I) and 8.22 Torr (Table II), respectively. Using the equation

$$\log K_{p[16]} = -4750/T + 0.86 \quad [26]$$

given by Sano and Belton (9) for the temperature dependence of reaction [16], the equilibrium of CrO_2Cl_2 has been calculated to be 10^{-1} Torr at $p_{Cl_2} = 20$ Torr and $p_{O_2} = 50$ Torr. Thus

$$(p_{CrCl_3} + p_{CrCl_4})/p_{CrO_2Cl_2} = 93.9$$

In fair agreement with this ratio, it has been found experimentally for k/k'

$$k/k' = 1.37 \cdot 10^{-2}/1.2 \cdot 10^{-4} = 110$$

The weight loss of preoxidized samples of Cr cannot be explained by an exclusive volatilization of Cr_2O_3, since no straight line was obtained for the corrosion rate. From these results, we tentatively conclude that chlorine reaches the metal surface after a fast migration through the porous oxide layer enlarging the free surface for a $CrCl_3$ and $CrCl_4$ vaporization. This conclusion is supported by the presence of numerous holes

in the metal surface detected after scale removal. If we assume that

$$A' = kt \quad [27]$$

where A' = portion of the Cr_2O_3 free surface A of the sample, then we obtain with

$$-d\,(\Delta m/A)/dt = k'A' \quad [28]$$

the experimentally found relation

$$\Delta m/A = -k'' \cdot t^2 \quad [29]$$

An O^{18} Study of Field-Assisted Pore Formation in Compact Anodic Oxide Films on Aluminum

J. Siejka* and C. Ortega

Groupe de Physique des Solides de l'Ecole Normale Supérieure, Université Paris VII, 75005 Paris, France

ABSTRACT

The mechanism of field-assisted pore formation in 15% wt H_2SO_4 aqueous solutions was studied by O^{18} tracing techniques. Compact base layers were first formed in an O^{18} labeled solution and further oxidized in a nonlabeled solution, leading to field-assisted pore formation. The O^{18} content and depth distribution was measured in these duplex films. It was found that the initial number of O^{18} atoms per square centimeter is conserved to within 2% and that the major part of the oxygen of the initial base layer is located on the top of the duplex film with the same O^{18} isotopic concentration. This observation shows clearly that the pore formation does not take place through a simple oxide dissolution process whether chemical or field assisted. Pore formation consists of some kind of oxide decomposition involving only cation transfer into the solution. The values of the cationic and anionic currents are calculated. Possible mechanisms for ion movement are discussed.

In our previous work (1) we found that the small values (53-64%) of the current efficiency of porous film formation are associated neither with equivalent oxygen losses following the reaction

$$Al_2O_{3oxide} + 6H^+_{sol.} \rightarrow 2Al^{3+}_{sol.} + 3H_2O$$

nor with electronic losses (1, 2). Consequently, we proposed a mechanism of direct dissolution of aluminum cations into the solution. But these experiments were not sufficiently precise to establish whether or not pore formation, which results in a decrease of the current efficiency by 14% (1), is accompanied by corresponding oxygen losses as implied by the mechanisms proposed in the literature (2, 3, 4).

The answer to this question is the main purpose of this work. The base layer thickness remains constant during the porous layer formation in "steady-state" conditions. This implies that the "dissolution" rate of the oxide at the bottom of the pores, *i.e.*, the rate of the pore depth increase, is about 10^3-10^4 Å/min under the usual formation conditions (2, 4). This rate is 10^4-10^5 times higher than the chemical dissolution rate of the oxide (1). The theories explaining this effect by an increase of the local chemical attack of the oxide due to Joule's effect, for example (3, 5, 6), have been rejected and a theory of "field-assisted dissolution of the oxide" has been proposed (4, 7). According to Ref. (4), this mechanism consists of the hydrolysis of Al-O bonds;

* Electrochemical Society Active Member.

Key words: nuclear microanalysis, O^{18} tracing, aluminum, porous oxide, sulfuric acid, dissolution current, field-assisted dissolution, oxygen movement.

the OH^- and Al^{3+} ions thus formed would pass into the solution. This kind of mechanism is tacitly accepted in the literature [*e.g.*, see Diggle *et al.* (2)].

In this work we have studied the oxygen losses during the initiation of pore formation using nuclear microanalysis and O^{18} tracer techniques (1, 8). The base layers were formed in O^{18} enriched water solution of sulfuric acid and then reoxidized in a natural solution. Following the geometrical model of Keller *et al.* (6) and of Wood *et al.* (9, 10), the volume of the pores formed through the O^{18} enriched initial layer should correspond to 14% of the volume of the oxide. According to the mechanism of chemical attack or of the "field-assisted dissolution of the oxide," a loss of O^{18} equal at least to 14% of the initial value should be observed (3, 4, 6). No oxygen losses should be observed if the mechanism of field-assisted dissolution of aluminum suggested in our previous work holds during the pore formation. This idea was recently accepted in the literature (11, 12). The mechanism of oxygen movement during the pore formation was also studied by locating in the duplex films the O^{18} atoms previously fixed in the base layer.

A second purpose of this work is to elucidate the mechanism of sulfate anion incorporation. Isotopic exchange between the oxygen of the water and the oxygen of the SO_4 anions can be disregarded (13). Consequently, the use of solutions where only water was enriched in O^{18} allowed us to measure the quantities of oxygen fixed in the oxide coming from the water and from the sulfate anions. The measurements of sulfur incorporation enabled us to establish whether the oxygen coming from SO_4^{2-} in incorporated as SO_4^{2-} anions or whether it comes from their electrochemical decomposition. This last mechanism was suggested in many papers [*e.g.*, see Ref. (14)]. From these measurements we have calculated the average charge of the oxygen atoms fixed in the oxide using coulometric measurements and the measure of oxygen content. The nature of the cation movement during the porous film formation was deduced from "pore filling" experiments (15).

Experimental Technique

We used aluminum samples (11 mm × 22 mm × 0.6 mm) pure to 99.95 or 99.999%. The preparation of the samples and aqueous solutions of sulfuric acid (15% in weight) was described in our previous paper (1). We used two solutions; s_o16 and s_o18. The s_o16 solution was made with water of natural isotopic composition, *i.e.*, containing 0.204% O^{18}. The s_o18 solution contained normalized water (*i.e.*, containing hydrogen at near-natural isotopic composition) enriched[1] to ~40% O^{18}. All the experiments were carried out at constant voltage (V = 10V) and constant temperature (14°C ± 0.5°C). The samples were left in open circuit for 1 min before each oxidation. We have observed that this process improves the reproducibility of the layer thickness.

As before (1), we used the nuclear reactions O^{16} (d, p) O^{17} [1] and O^{18} (p, α) N^{15} induced by deuteron or proton beams from a 2 MeV Van de Graaff accelerator (8) to measure the number of oxygen 16 (N_{O16}) and oxygen 18 (N_{O18}) atoms/cm² of the oxide layer. N_{O18} and $N_O{}^{16}$ have been calculated as follows

$$N_{O18} = \frac{n^{18}}{\mathcal{N}_{ref.18}} \cdot \mathcal{N}^{18}$$

and

$$N_O{}^{16} = \frac{n^{16}}{\mathcal{N}_{ref.16}} \cdot \mathcal{N}^{16}$$

where $\mathcal{N}^{16}$, $\mathcal{N}^{18}$, and $\mathcal{N}_{ref.16}$, $\mathcal{N}_{ref.18}$ are the counts measured on the sample and on the oxygen references, respectively, and n^{16} and n^{18} represent the number of oxygen 16 and oxygen 18 atoms per square centimeter fixed in the O^{16} and O^{18} references [see Ref. (8) for details]. In our experimental conditions the counts are determined with a precision of 0.2% (statistical error), whereas the values of n^{16} and n^{18} are known to within ± 3%. The O^{18} concentration profiles were estimated from the analysis of the excitation curves of the O^{18} (p, α) N^{15} reaction in the vicinity of the resonance at 629 keV, according to the method described in Ref. (1, 8). The sulfur content of the oxides was measured by the use of MeV helium backscattering techniques (1, 8).

[1] Normalized O^{18} enriched water produced at the Weizmann Institute, Rehovot, Israel.

Results and Interpretation

Oxygen 18 content of duplex films obtained by the reoxidation in s_o16 of O^{18} enriched base layers.—First we measured the values of the current density I as a function of the time t during anodic oxidation at constant voltage (Fig. 1). The $I(t)$ relationship was found to be the same for the samples oxidized in s_o16 and s_o18 solutions. Under our experimental conditions (I_o = 25 mA/cm², T = 14°C) we found t_2 = 14 sec and $t_3 \simeq$ 35 sec (see Fig. 1). According to the literature (2), the beginning of the pore formation started at time $t_1 = \frac{1}{2}t_2$. Consequently, we formed the base layer during 7 sec in s_o18 and reoxidized it in s_o16 for either 53 sec or 1 min 53 sec so that the total oxidation times were equal to 1 and 2 min.

Reproducibility of the oxygen 18 content of the base layers.—We measured the values of N_{O18} on about thirty samples formed during the time t_1. The relative spread of N_{O18} values with respect to the average was at most equal to 5%; the spread on individual sample at various points was at most equal to 1.5%. The beam diameter of the Van de Graaff accelerator was equal to 2 mm and the sample area was 2.4 cm², so measurements were made at different points on the same sample. Subsequently, each sample was cut in two parts, one (a) being reoxidized in s_o16, the other one being used as a reference (b).

Reoxidation of the base layers.—The parts (a) of the samples were reoxidized in s_o16 solution for 53 sec or 1 min 53 sec; the parts (b) were left in the same solution for the same period of time. This process allowed us to subtract the effect of the purely chemical dissolution of the oxide. The measurements of N_{O16} and N_{O18} contents were carried out on both parts of the samples. If ΔN_{O16} is the difference between the O^{16} content of the duplex layer and of the base layer, the corresponding increase $\Delta_o N_{O18}$ of the O^{18} content is equal to $2 \times 10^{-3} \times \Delta N_{O16}$ (due to the natural O^{18} content of 0.204%).

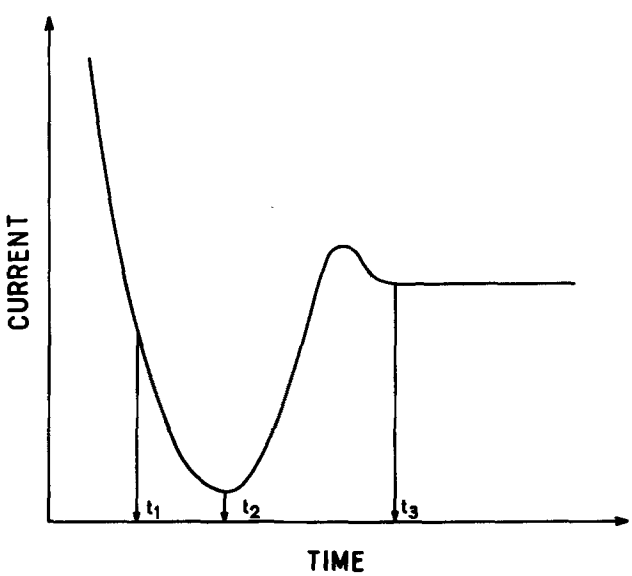

Fig. 1. Current density as a function of time during potentiostatic (V_{OX} = 10V porous film formation on aluminum; arbitrary units. Initiation of pore formation occurs at time $t_1 = \frac{1}{2}t_2$: for $t > t_3$ the oxidation takes place at steady-state conditions.

The variations of the O^{18} content due to possible oxygen losses were calculated by means of the formula

$$\Delta N_{O^{18}} = N_{O^{18}}(b) - (N_{O^{18}}(a) - \Delta_o N_{O^{18}})$$

$N_{O^{18}}(b)$ and $N_{O^{18}}(a)$ are the O^{18} contents of the barrier layers (b) and of the duplex films (a) obtained by reoxidation of (b) in s_o^{16}.

Relative oxygen 18 losses are defined, and may be written as

$$\frac{\Delta N_{O^{18}}}{N_{O^{18}}(b)} = \frac{\mathcal{N}^{18}(b) - \mathcal{N}^{18}(a)}{\mathcal{N}^{18}(b)} + 2 \times 10^{-3} \cdot \frac{n_{ref.16}\mathcal{N}_{ref.18}(\mathcal{N}^{16}(a) - \mathcal{N}^{16}(b))}{n_{ref.18} \times \mathcal{N}_{ref.16}\mathcal{N}^{18}(b)} \quad [1]$$

The first term depends only on the number of counts. The error of this term is hence of statistical origin only (0.2%). The second term depends on the number of counts and also on the absolute number of O^{16} and O^{18} atoms/cm² in the references. Thus, we find here two kinds of errors; statistical and systematic. We propose [according to Amsel (16)] the following procedure to calculate the error on the relative oxygen losses (Eq. [1]). First we calculate the standard deviation σ_{st} of all statistical terms present in Eq. [1] using the classical formula

$$\sigma_{st} = \sqrt{\sigma_1^2 + \sigma_2^2}$$

σ_1 and σ_2 being the standard deviations of statistical origin of the first and second term in Eq. [1]. The systematic error on the second term (due to the error on $q = n_{ref.16}/n_{ref.18}$ must then be expressed as a standard deviation. For this purpose we assume that the true value of q is uniformly distributed on the interval $q_o - \epsilon_{ref.}$, $q_o + \epsilon_{ref.}$, where q_o is the best estimate of q and $\epsilon_{ref.}$ the corresponding systematic error. It is readily shown that the standard deviation of q is then $\sigma q = \epsilon_{ref.}/\sqrt{3}$. In this case $\epsilon_{ref.}$ was estimated to be approximately 0.03. The over-all error in the related oxygen losses may then be estimated by inserting the above value of σq in the usual formula for calculating standard deviations.

In Table 1 we report as an example the results relating to two series of experiments in which the O^{18} concentration in the water and the sulfuric acid concentration were slightly different. As the results show, the changes of oxygen 18 contents during the reoxidation, due to possible oxygen losses, are statistically equal to zero with a maximum deviation of 2%, *i.e.*, equal to the spread of the base layer thicknesses. It must be noted that these results are related to the losses of oxygen coming from the water. The possible losses of oxygen coming from the sulfate ions will be analyzed later and will be shown to have little influence on the conclusions of these experiments.

The O^{18} distribution in the duplex films.—We estimated the O^{18} concentration profile in the duplex films by means of excitation curves as mentioned above. Figure 2 shows the typical results registered for various conditions. The fact that the various excitation curves are nearly identical indicates that most of the O^{18} atoms originally in the base layer are kept at the top of the duplex films. Moreover, a slight decrease of the maximum and a widening of the excitation curves obtained on the duplex layers is observed. Many identical experiments have been carried out and this effect was always found. This result indicates that as pores form during reoxidation the O^{18} displaced by the pores ends up in a part of the oxide just below the O^{18} en-

riched layer. This is in agreement with the model of the growth of porous oxides on aluminum proposed in our previous paper (1) in which the oxide is formed at the oxide/metal interface by the migration of oxygen coming from the solution and from the part of the oxide located at the bottom of the pore. To explain the inversion during growth of the order of oxygen atoms in the base layer we suggested (1) that a substructure is present in the base layer, in agreement with others (17, 18).

Current efficiency of porous layer formation.—The values of the current efficiency depend on the average charge associated with each oxygen atom fixed in the oxide. This charge is equal to -2 for oxygen coming from the electrochemical decomposition of the sulfate anion or water and -0.5 in case of SO_4^{2-} incorporation. In order to establish in which form the incorporation of oxygen coming from the sulfate anions occurs, we have measured both the sulfur and the oxygen contents. The measurements of sulfur were carried out using the backscattering method (1) and typical results are shown in Fig. 3. As in the preceding case (1), the measurement reproducibility is rather bad, with the error on these measurements estimated to be equal to ~30%. Assuming all the sulfur is incorporated in the form SO_4^{2-} the percentage of oxygen incorporated in the form of sulfates lies between 15 and 30% [(23 ± 8)%, Table II].

In a second series of experiments we calculated the percentage α of oxygen coming from the sulfate anions and incorporated in films during growth in the transitory region (from 0 to 35 sec) and during growth at steady-state condition (from 35 sec). Films were formed in s_0^{18} and α was calculated as follows

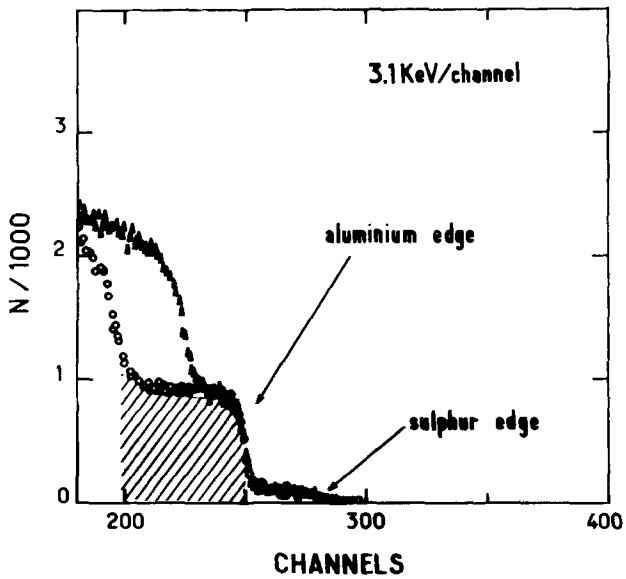

Fig. 3. Backscattering amplitude spectra for $^4He^+$ ions at 1600 keV obtained on duplex films (see Fig. 2); reoxidation during 53 sec (▲) or 1 min 53 sec (o). Shaded region represents aluminum in the oxide.

$$\alpha = \frac{C_{H2O} - C_{ox}}{C_{H2O} - C_{SO4}} \times 100\% \qquad [2]$$

where C_{H2O} and C_{SO4} represent the O^{18} concentrations of the water and the SO_4 anions (0.204%), respectively. C_{ox} represents the O^{18} concentration of the oxygen coming from the solution and fixed in films formed in the transitory region or at steady-state conditions. The O^{18} concentration of the water was deduced precisely from the measurement of the isotopic composition of an anodic oxide film of tantalum formed in this water containing a nonoxygenated salt (KCN). By using this technique [see Ref. (19)] we found an O^{18} concentration of the water equal to (42 ± 2)%. In the case of films formed in the transitory region C_{ox} was calculated by the formula

$$C_{ox} = \frac{N_{O18}(t)}{N_{O18}(t) + N_{O16}(t) - N_{O16}(i)} \qquad [3]$$

Where $N_{O18}(t)$ and $N_{O16}(t)$ represent the numbers of O^{18} and O^{16} atoms/cm^2 found on aluminum after oxidation in transitory region; $N_{O16}(i)$ represents the number of O^{16} atoms/cm^2 of the natural oxide before oxidation [$(20 \pm 5)10^{15}$ oxygen atoms/cm^2]. The number of O^{18} atoms/cm^2 of the natural oxide was neglected. In the case of films formed at steady-state conditions α was given by the formula

$$C_{ox} = \frac{N_{O18} - N_{O18}(t)}{N_{O16} - N_{O16}(t) + N_{O18} - N_{O18}(t)}$$

Where N_{O18} and N_{O16} represent the number of O^{18} and O^{16} atoms/cm^2, respectively, found on aluminum after oxidation. C_{ox} and α values are presented in Table II. From these results we can reasonably assume that α values are the same for films formed in the transitory region and at steady-state conditions. The average α from oxygen measurement is smaller than that deduced from sulfur measurement. Taking into consideration the high dispersion of sulfur measurements we cannot exclude some decomposition of SO_4^{2-}. However α values deduced from experiments with radioactive sulfur (20) were found to be equal to 10-15%. These results are in good agreement with that deduced from oxygen measurement. Consequently, we shall assume in what follows that the incorporation of sulfur occurs as SO_4^{2-}. The value of the average charge of oxygen incorporated in the oxide calculated by the formula

Table II. t_{ox} is the time of oxidation at constant voltage V = 10V. Oxides formed at steady-state conditions are oxides formed from 35 sec to 1 or 2 min

$\eta = \alpha(-0.5) + (1 - \alpha)(-2)$ where −0.5 and −2 represent the average charge of oxygen incorporated as SO_4^{2-} and O^{2-}, respectively, was found to be equal to −1.80.

The measurements of the current efficiency of the porous layer formation were only performed in steady-state conditions [see Ref. (1) for details]. The values of the current efficiencies are shown in Table II. These are the same for the oxidation in s_o^{16} and s_o^{18} and do not differ from the literature data (21). The use of the value −1.80 ± 0.05 for average oxygen charge in the oxide [instead of −1.65 ± 0.1, Ref. (1)] introduces an increase of ~10% of the current efficiency with regard to the value found in Ref. (1) (see Table II).

Components of the current during the porous oxide formation in steady-state conditions.—Let us call I_{ox} the current used to form the new oxide. In our experimental conditions we found $I_{ox} = 60\% \cdot I_{tot}$ (Table II). This current may only be due to the movement of oxygenated anions (O^{2-}, SO_4^{2-}) coming from the solution. Hence the total current due to losses (I_{dis}) is equal to $40\% \cdot I_{tot}$. In the absence of oxygen losses, the pore formation process implies a movement of aluminum cations toward the solution (I_{dec}^{c}) and a movement of equivalent quantities of oxygenated anions (O^{2-}, SO_4^{2-}) towards the oxide-metal interface (I_{dec}^{o}). In steady-state conditions $I_{dec}^{c} = I_{dec}^{o}$. These currents can be calculated by the following expression (assuming there is no loss of SO_4^{2-})

$$\frac{I_{dec}^{c}}{I_{dec}^{c} + I_{ox}} = 0.14$$

where 0.14 is the ratio of the pore volume to the total volume of the oxide. We find

$$I_{dec}^{c} = 10\% \cdot I_{tot}$$

$$I_{Al} = I_{dis} - I_{dec}^{c} = 30\% \cdot I_{tot}$$

The current I_{Al} represents the current of direct dissolution of Al cations in the solution without formation of any oxide [see Ref. (1)]. The current carried by Al^{3+} cations at the oxide-solution interface is hence equal to $I_{Al} + I_{dec}^{c} = 40\% \cdot I_{tot}$. The current carried by the oxygenated anions is equal to $I_{ox} = 60\% \cdot I_{tot}$, at the oxide-solution interface, whereas inside the oxide, it is equal to $I_{ox} + I_{dec}^{o} = 70\% \cdot I_{tot}$ (Fig. 4).

Calculation of the oxygen distribution in the duplex layers.—We shall now calculate the oxygen 18 distribution in the duplex layers obtained by the reoxidation of the O^{18} enriched base layers of thickness "l" in s_o^{16} when the total thickness increases from "l" to "$4l$" (Fig. 5). We shall take as an example the O^{18} enriched base layer 5b (Table I). Let us call $(2l)^{th}$, $(3l)^{th}$, and $(4l)^{th}$, respectively, the new base layers obtained by increasing the total thickness from l to $4l$. In order to explain the SO_4^{2-} incorporation during the pore formation we have to assume that the SO_4^{2-} anions participate in the oxide growth like the O^{2-} anions. This means that I_{ox} is carried by O^{2-} and SO_4^{2-}, but taking into consideration that some SO_4^{2-} losses during the pore depth increase cannot be excluded, we shall analyze two limiting situations: (*i*) no SO_4^{2-} losses occur during the pore formation, *i.e.*, I_{dec}^{o} is carried out by SO_4^{2-} and O^{2-} anions; (*ii*) the SO_4^{2-} anions already fixed in place where the pores are formed (14% of the SO_4^{2-} content of the base layer) pass into the solution during the pore formation. In this case I_{dec}^{o} is carried out only by O^{2-} anions.

(*i*) The O^{18} concentration of the new "$2l$"th layer, *i.e.*, the new base layer, depends on the relative contribution of oxygenated anions coming from the solution (O_s), from the decomposition of the oxide at the bottom of the pores (O_p), and from their respective O^{18} concentrations. The value of (O_p) expressed as the ratio $O_p/O_p + O_s$ is equal to the volume of the pores (14% of the volume of the base layer). The O^{18} concentration of O_p depends on the part taken by the oxy-

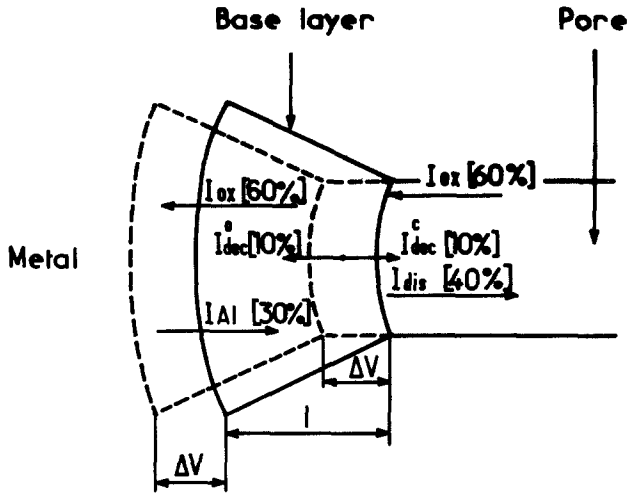

Fig. 4. Components of the current expressed as a percentage of the total ionic current flowing through the oxide during anodic oxidation at steady-state conditions; see text for definitions. l and ΔV thicknesses of the base layer and of decomposed oxide, respectively.

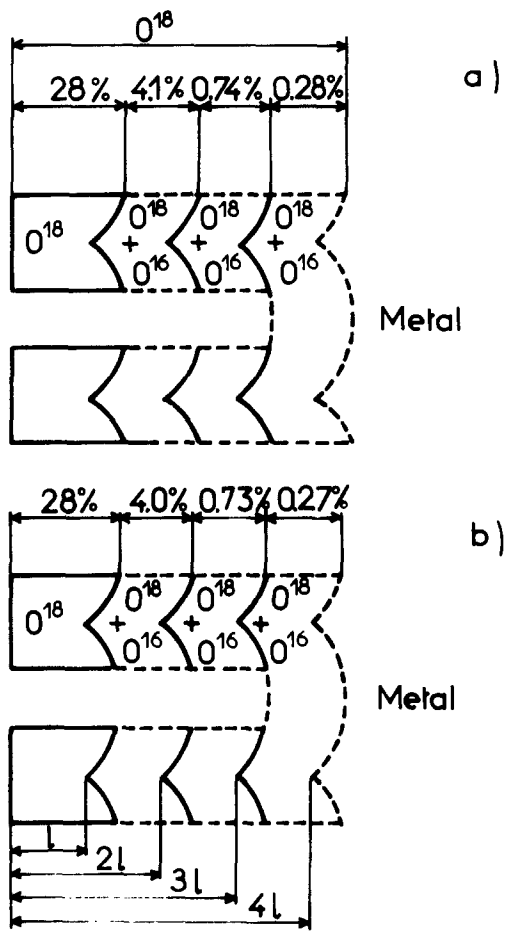

Fig. 5 Distribution of the oxygen 18 in the duplex films obtained by the reoxidation in s_0^{16} solution of O^{18} enriched base layer; "l" corresponds to the thickness of the base layer. (a) assuming that $I_{dec}°$ is carried out by SO_4^{2-} and O^{2-} anions; (b) assuming that $I_{dec}°$ is carried out only by O^{2-} anions.

gen of the natural oxide during oxide growth; either the oxygen of the natural oxide participates in the growth in the same manner as the oxygen coming from the solution or it remains at the oxide-metal interface. In the first case, assuming that the two kinds of oxygen are homogeneously distributed in the base layer, the O^{18} concentration of O_p in the base layer is equal to 28%. The O^{18} concentration of the $(2l)^{th}$, $(3l)^{th}$, and $(4l)^{th}$ layer is calculated as follows (Fig. 5a)

$$0.14 \times 28\% + 0.86 \times 0.2\% = 4.1\% \ (2l)^{th}$$

$$0.14 \times 4.1\% + 0.86 \times 0.2\% = 0.74\% \ (3l)^{th}$$

$$0.14 \times 0.74\% + 0.86 \times 0.2\% = 0.28\% \ (4l)^{th}$$

(0.2% is the natural O^{18} concentration)

If the natural oxide remains at the oxide-metal interface (taking into consideration that the number of oxygen atoms per square centimeter of the natural oxide is equal to 20×10^{15}) the O^{18} concentration of O_p is equal to 29.0/29 + 73 − 20 = 35% instead of 28%. The O^{18} concentration of the $(2l)^{th}$, $3l)^{th}$, $(4l)^{th}$ layer is equal to 5.1%, 0.88%, and 0.29%, respectively.

(*ii*) In this case the O^{16} loss is equal to $0.14 \times 14\%$ where 0.14 is the fraction of oxygen coming from SO_4^{2-}. The value of O_p is hence equal to $(1 - 0.14) \times 14\% = 12\%$. As above, the O^{18} concentration of O_p depends on the part taken by the oxygen of the natural oxide during oxide growth. If the oxygen of the natural oxide participates in the growth, O^{18} concentration of O_p is equal to the O^{18} concentration of the water (42%) diluted by the presence of 20×10^{15} oxygen atoms/cm^2 of the natural oxide.

It has been calculated as follows. Sample 5b contains 29.0×10^{15} O^{18} atoms/cm^2 and 73×10^{15} O^{16} atoms/cm^2. Subtracting 20×10^{15} oxygen atoms/cm^2 (natural oxide) we find that 82×10^{15} oxygen atoms/cm^2 come from the solution. The number of oxygen atoms per square centimeter coming from the enriched water is hence equal to

$$(1 - \alpha) \times 82 \times 10^{15} = 86\% \times 82 \times 10^{15} = 70.5 \times 10^{15}$$

It follows that the O^{18} concentration of O_p is equal to

$$(O_p) = \frac{29.0}{70.5 + 20} = 32\%$$

The O^{18} concentration of the $(2l)^{th}$ layer is equal to

$$0.12 \times 32\% + 0.88 \times 0.2\% = 4.0\% \ (2l)^{th}$$

Now we can calculate the O^{18} concentration of O_p in the $(2l)^{th}$ layer by the formula

$$4.0\% = 0.86 \times (O_p) + 0.14 \times 0.2\%$$

We obtain $(O_p) = 4.6\%$ and the O^{18} concentration of the $(3l)^{th}$ layer is equal to

$$0.12 \times 4.6\% + 0.88 \times 0.2\% = 0.73\% \ (3l)^{th}$$

From 0.73%, we deduce as above the O^{18} concentration of O_p in the $(3l)^{th}$ layer

$$(O_p) = \frac{0.73\% - 0.14 \times 0.2\%}{0.86} = 0.82\%$$

and the O^{18} concentration of the $(4l)^{th}$ layer

$$0.12 \times 0.82\% + 0.88 \times 0.2\% = 0.27\% \ (4l)^{th}$$

(see Fig. 5b)

If the natural oxide remains at the metal-oxide interface, the O^{18} concentration of O_p is equal to the O^{18} concentration of the water (42%). The O^{18} concentration of the $(2l)^{th}$, $(3l)^{th}$, and $(4l)^{th}$ layers is equal to 5.2%, 0.9%, and 0.3%, respectively. One can see that the O^{18} concentration of the duplex films is practically independent of possible losses of SO_4^{2-} incorporated anions.

The O^{18} concentration of the new oxide found at the oxide-metal interface is practically equal to the natural concentration when the total thickness is greater than $3l$. In our experimental conditions the thickness of the base layer l was equal to about 100Å^2; the total thickness of the enriched layer of the duplex film is hence equal to ~300Å. The O^{18} profiles calculated according

to the components of current (Fig. 5) are in good agreement with the form of the maximum of the excitation curves obtained on the duplex layers (Fig. 2).

Pore-filling process.—We formed a thin porous layer in s_o^{18} (t_{ox} = 35 sec) and then reoxidized it in an ammonium borate solution of natural isotopic composition to 100V (I = 1 mA/cm^2). During reoxidation the slope of the curve V(t) decreased to V $\simeq$ 60V. This well-known effect was interpreted in the literature (15) as the end of the pore-filling process. The excitation curves of O^{18} (p, α)N^{15} reactions near the resonance at 629 keV have shown that the O^{18} enriched oxide layer is completely covered by the O^{16} layer when the potential of reoxidation is greater than 60V. This implies that a part of the oxide is grown by cation movement, in agreement with Dekker and Middlehoeck (15).

Discussion

In this work we have shown that the formation of porous oxide layers on aluminum in 15 weight percent (w/o) H_2SO_4 may be explained by assuming the existence of three kinds of ionic currents I_{ox}, I_{Al}, and I_{dec} which can be expressed as percentages of the total current. The current I_{ox} is due to the movement of oxygenated anions which are transferred from the solution to the oxide-solution interface and then move through the base layer to the metal-oxide interface where the new oxide is formed. The value of this current is numerically equal to the current efficiency of porous layer formation. The current I_{Al} is due to the movement of aluminum cations going through the base layer and passing directly into the solution; the current I_{dec} is due to the movement of ions generated by the field-assisted decomposition of the oxide. I_{dec} is transported by the cations (I_{dec}^c) to the solution and by the anions (I_{dec}^o) to the metal-oxide interface. I_{dis} is the total interfacial transfer current of the cations passing into solution; $I_{dis} = I_{Al} + I_{dec}^c$ (Fig. 4). In what follows we shall discuss the mechanism of atomic movements which may account for these various kinds of currents.

The current of direct discharge of aluminum ions in the solution (I_{Al}).—The oxide-metal interface is a source of point defects for the oxide which may induce the migration of cations in the oxide by interstitial or interstitialcy mechanism or as lattice defects $(AlO)^+$ as was proposed by Dignam (22). Cation migration by vacancy motion can also occur, the injection of vacancies taking place at the oxide-solution interface by the transfer (dissolution) of the lattice cations into the solution. Let us call mechanism *A*, cation movement by interstitial or interstitialcy mechanism or as $(AlO)^+$; mechanism *B*; cation movement by vacancy motion. We do not take into account the possibility of formation of interstitial cations and vacancies in the volume of the oxide for thermodynamic reasons (22). In what follows we are going to discuss the likelihood of mechanisms *A* and *B* on the basis of our results and of the experimental data of Dekker and Middlehoeck (15) who have measured the fractional transport number of cations during the porous film formation and the pore-filling process. From measurements of the current efficiency of porous layer formation (in oxalic acid) these authors inferred that the ratio tm_1 of the interfacial transfer current of the cations passing into solution to the total current is equal to 0.33. On the other hand, they found that the fractional transport number of cations tm_2 is equal to 0.24 during the pore-filling process, *i.e.*, during the reoxidation of the porous layers in a solution of ammonium borate in glycol. The volume of the pores was found in this case to be equal to 0.12 of the total volume of the film. According to mechanism *B*, pore filling should occur without cation movement in the oxide, *i.e.*, with cation transport number equal to zero ($tm_2 = 0$), which is in contradiction with our results and those of Dekker and Middlehoeck.

Moreover, mechanism *A* is in full agreement with the experimental results of Dekker and Middlehoeck. Applying model *A* to their results (Fig. 4), using $tm_1 = 0.33$ and for volume of the pores 0.12, we can calculate the values of the various current components. It follows that

$$I_{dis} = 0.33 \cdot I_{tot} \text{ and } I_{ox} = 0.67 \cdot I_{tot}$$

From $\dfrac{I_{dec}}{I_{dec} + I_{ox}} = 0.12$ one finds that $I_{dec} = 0.09 \cdot I_{tot}$

From $I_{Al} = I_{dis} - I_{dec}$ one finds that $I_{Al} = 0.24 \cdot I_{tot}$

Thus, I_{Al} is equal to the value of tm_2 reported by these authors which suggests that mechanism *A* is valid. Moreover the current I_{Al}, which was a dissolution current during porous film formation, keeps the same value during the pore-filling process, being responsible for the oxide growth at the oxide-solution interface.

Cation movement by the lattice defects $(AlO)^+$ seems incompatible with the absence of oxygen losses, except if we assume that dissociation of the defects $(AlO)^+$ occurs before the aluminum is transferred into the solution. Moreover these defects exist only in a glass structure (22), which probably is not the case for porous aluminum oxides (23). For these reasons, we assume in what follows that cation movement occurs by interstitial or interstitialcy mechanism.

Oxygen movement (I_{ox}).—The inversion of the oxygen order in the base layer can be explained either by the migration of oxygen ions by interstitial mechanism or by migration of oxygen vacancies in "easy paths" of the oxides (1). As in the case of cationic movement, we do not take into account the possibility of the formation of interstitial oxygen anions and vacancies (Frenkel or Schottky defects) in the volume of the oxide for thermodynamic reasons (22). The two most likely kinds of oxygen migration are characterized by two different mechanisms of oxygen transfer at the oxide-solution interface, *i.e.*, injection into interstitial positions or vacancy filling. The activation energy of oxygen transfer from the solution into the oxide is much higher in the case of transfer in an interstitial position than for vacancy filling (25). Moreover, since porous oxide growth occurs only by anion migration, the most probable explanation of the observed SO_4^{2-} incorporation is the presence of oxygen vacancies at the oxide-solution interface. For these reasons, we may conclude that porous oxide growth occurs probably by migration of oxygen vacancies through "easy paths." This mechanism was also proposed by us to explain the mechanism of anodic oxidation of Zr (24). Note that such an assumption was not necessary to explain the cations movement which probably occurs by interstitial or interstitialcy mechanism.

The distance between two neighboring oxygen atoms in the molecule Al_2O_3 is the same as in the anion SO_4. This steric concordance could explain the large incorporation observed (2). However, the mechanism of movement of the adsorbed SO_4^{2-} anions through the base layer is not clear. The same difficulty of interpretation was found when studying anion impurity incorporations during the anodic oxidation of Zr, where cation movement is absent (2, 26). The latter results seem to indicate that movement of oxygen by a vacancy mechanism can introduce some anion impurity movements.

Field-assisted dissolution of the oxide (I_{dec}).—The value of I_{dec} is proportional to the rate of decomposition of the oxide at the bottom of the pores. It increases with temperature and acid concentration (2, 3). As Fig. 4 shows, the oxygen ions coming from the oxide decomposition migrate towards the oxide/metal interface and the cations pass into the solution. This effect involves the presence of a region at the oxide-solution

interface where the oxygen and aluminum ions are weakly bound, and hence more mobile than in the volume of the oxide.

Two models can be proposed to explain the presence of this region. The first model (*i*) assumes the presence of a high concentration of oxygen vacancies at the oxide-solution interface. This could be obtained by the adsorption of sulfate anions which inhibits oxygen transfer from the solution to the oxide. Then the presence of oxygen vacancies favors cation transfer into the solution. Following this model, the "field-assisted dissolution" of the oxide is a process whose rate is determined by the equilibrium between cation transfer into the solution and the reaction between oxygen and the vacancies at the oxide-solution interface. In Fig. 6 we show the diagram of the reactions which occur according to this model.

The second model (*ii*) considers that the protonization of the Al-O bonds at the surface of the oxide induces the formation of mobile $(OH^-)_s$ groups and favors cation transfer into the solution. $(OH^-)_s$ is transformed to O^{2-} and migrates by vacancy motion towards the oxide/metal interface ensuring the formation of the new oxide (Fig. 7). This is a variant of the mechanism already imagined by Hoar and Mott (27). These two mechanisms differ from one another in the mode of oxygen migration through the oxide: interstitial (Hoar and Mott); vacancy motion through "easy paths" (this work).

The density of mobile oxygen species $(OH^-)_s$ reached during porous growth depends on the chemical action of the solution and decreases with the electric field. These two models may operate simultaneously; taking into consideration that proton adsorption and diffusion in the oxide are thermally activated, the model (*i*) probably prevails at low temperature and model (*ii*) at high temperature.

Kinetics of Plasma Anodization of Aluminum

M. Propp, L. Young,* D. L. Pulfrey, and G. Olive*

Department of Electrical Engineering, The University of British Columbia, Vancouver, British Columbia, Canada V6T 1W5

ABSTRACT

The anodization of evaporated aluminum films in a d-c oxygen plasma has been studied using *in situ* automated ellipsometry to determine film thickness D. The aim was to investigate whether plasma anodization is analogous to solution anodization in that film growth occurs due to an ionic current produced by a high field in the oxide. Films were grown at constant total anodic current I_A, only a small part of which corresponded to film growth. The ionic current density J_i corresponding to growth was calculated from dD/dt using Faraday's law. Plots of the sample potential V (with respect to the discharge-sustaining anode) *vs.* thickness D were linear at each constant total current. The slopes dV/dD were taken as a measure of the electric field E in the oxide. The electronic current density J_e through the oxide could be represented by $J_e = J_e^o \exp CE^{1/2}$ where J_e^o varied between runs. Imposition of a chosen constant electronic current thus set the field in the oxide at a particular value in the oxide independent of thickness. By analogy with solution anodization the constant field would be expected to produce a constant ionic current. In fact, the data indicated an ionic current density J_i which decreased with increasing thickness, $J_i = (1/D)\ \alpha \exp BE$. Only if data were chosen for a narrow range of thickness was the expected relation $J_i = J_i^o \exp \beta E$ applicable, where J_i^o is constant, as found in previous work on tantalum, niobium, and aluminum. This result would be consistent with an unexpected model in which film growth involved the diffusion of some species whose surface concentration is set by the field or the electronic current. A trend of behavior with some points of similarity has previously been reported for silicon anodization in microwave-induced discharges.

In plasma anodization, a metal or semiconductor is positively biased in an oxygen plasma. This causes an oxide film to grow (1-13). It has been concluded by several authors that the process is, in principle, analogous to the process of anodic film growth in aqueous solutions. In other words, it has been believed that the applied voltage causes an electric field to be established across the oxide which draws metal or oxygen ions or both through the oxide by high field conduction. If the analogy is correct one expects (14, 15) to find a relation between the field E in the oxide and the ionic current J_i of the form $J_i = J_i^o \exp -(W - f(E)/kT)$ where W is the zero-field activation energy and $f(E)$ is αE or $\alpha E - \beta E^2$ or $\gamma E^{1/2}$. It is much more difficult to establish such relations for plasma anodizaion than it is for solution anodization. This is because the variability of plasma conditions, the problems of measuring the potential drop across the oxide, the low current efficiency, and possibly the effect of the exposure of the film to the plasma make it difficult to obtain reproducible and unscattered data. Furthermore, an oxide grows on open circuit, as first shown by Miles and Smith (3), and recently studied by Vrba and Woods (16). Conversely, the film may be simultaneously subject to erosion by sputtering (8).

Since the (supposed) ionic current density can only be determined using Faraday's laws from observed values of dD/dt (or equivalents) some *in situ* method of determining film thickness (or mass) is more or less essential for kinetic studies. Ellipsometry is suitable for this purpose (8, 9, 17, 18).

* Electrochemical Society Active Member.

The expected dependence of log J_i on E has been reported for tantalum and niobium upon anodization in a high frequency discharge (19, 20). For anodization in a d-c glow discharge results for tantalum, niobium (17, 18), and aluminum (9) gave linear relations of log J_i with E, but with values for the parameters which were outside the ranges found for anodization in various aqueous solutions. For silicon, the situation is considerably different. In the case of anodization in an rf plasma, the field has been reported to increase with thickness (21, 22), whereas, in a microwave frequency plasma growth has been attributed to diffusion, and not drift, processes (23, 24).

It will be appreciated from the foregoing that plasma anodization is a relatively complex process with the anodic film growth being affected by both the nature of the substrate and the nature and properties of the plasma. There is still very little information available on the kinetics of the film growth and it was the purpose of this work to obtain further data on the plasma anodization of aluminum in a d-c glow discharge.

Experimental Procedures

The plasma cell is shown diagrammatically in Fig. 1. It is a development of that used in our earlier work (17) and was the cell used for the work in Ref. (18). It consists of a fused silica tube with stainless steel end caps sealed with O-rings. A sorption pump and ion pump gave an ultimate vacuum (without baking) of 4×10^{-7} Torr. The specimen consisted of a silicon substrate coated on one side with a film of aluminum evaporated on to a cold substrate from high purity aluminum wire on a tungsten heater in a conventional

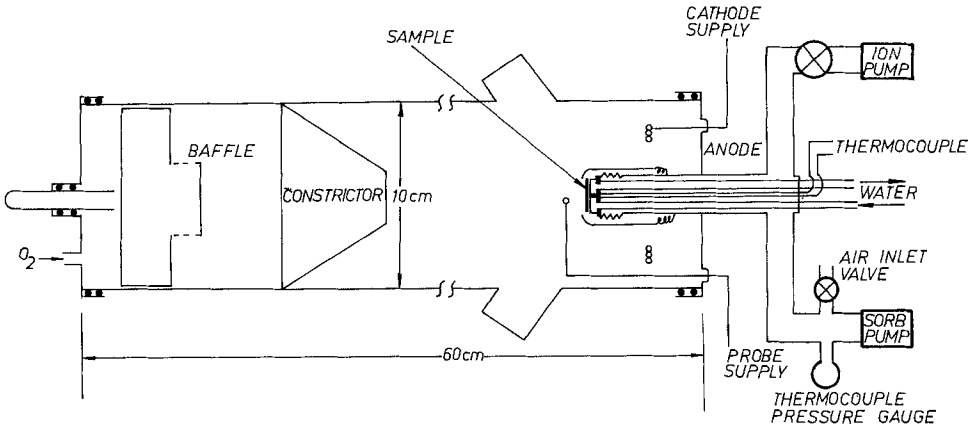

Fig. 1. The plasma anodization cell.

vacuum system. Silicon slices were used as substrates since they provided a cheap highly polished surface giving films flat enough for optical measurement. The specimen was aligned using screw adjustments, and the specimen holder was attached to the end cap with bellows. The cell and pumping system were mounted on an adjustable metal plate resting on a trolley which rode on metal rails rigidly attached to the metal frame supporting the ellipsometer. The samples were mounted in the sample holder, using silver paint on the back and a spring attachment, with a mica plate defining the area exposed to the plasma. Electrical connection was made using silver paint (not exposed to the plasma). The cell and movable ellipsometer arm were adjusted so that the light beams met the windows at normal incidence. The angle of incidence was thus set by the fixed windows and was 69.29°. The difference in zone 1 and 3 readings taken before and after insertion in the system was attributed to the window error. Changes in Δ of about 1.5° were observed with negligible change in ψ.

The pressure during runs was maintained at 100 mTorr by manual adjustment of a valve preceding the sorption pump, with high purity oxygen being supplied through a fixed valve. Water from a thermostatted bath was circulated through the sample holder. The sample temperature was assumed to be given by a Chromel-Alumel thermocouple in contact with the sample holder. The bath temperature was adjusted to maintain a constant sample temperature of 40°C. The discharge current was set at 20 mA using a variable high voltage supply with fixed series resistance. Constant currents were applied to the sample using the circuit shown in Fig. 2, while recording the specimen-discharge anode and probe-discharge anode voltages on a chart recorder. It was found that noise was reduced by using a 3-turn Al ring cathode rather than the previously used bucket cathode and constrictor arrangement. These two components were, however, left in the system, see Fig. 1. The specimen was situated in the negative glow region of the plasma. The ellipsometer is controlled by a PDP8E computer and has been described in previous papers (25, 26). It was used to track alternately in zones 1 and 3 so that readings could be averaged.

Results

Data were taken on five samples. The first three served to work out procedures and the results presented below were obtained with the last two samples.

Figure 3 shows tracings of chart recorder plots of sample voltage with respect to the discharge anode *vs.* time. On changing from a lower to a higher constant current (0.4 mA to 0.8 mA with an area of about 1 cm^2 for the cases shown) there was usually some overshoot followed by a steady constant rate of increase of voltage. The form of the transient was somewhat variable, as indicated in Fig. 3, with a tendency for the amount of overshoot to decrease with increasing thickness. These transients cannot be directly compared with the transients in solution anodization (27), because, in the plasma case, the current is mostly electronic rather than ionic, the field in the oxide sets itself at the value given by the imposed electronic current, and the observed transient is probably in electronic conductance not in ionic conductance.

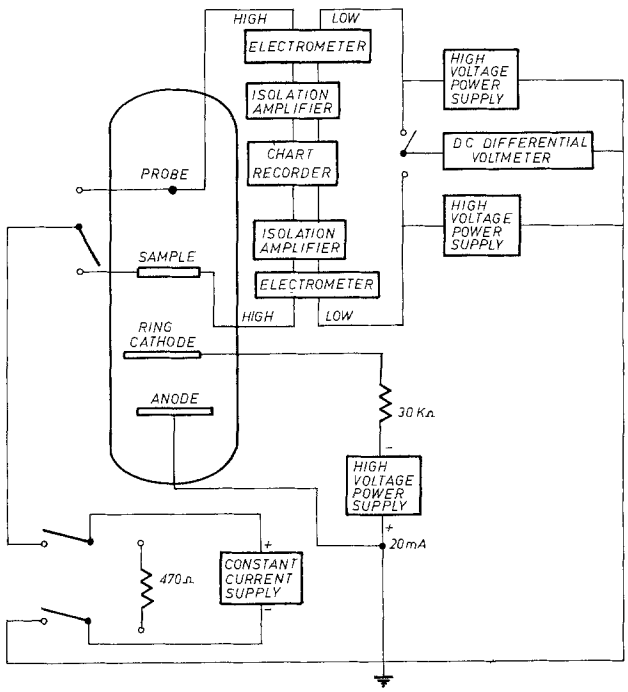

Fig. 2. The electrical circuit

Figure 4 shows plots of the ellipsometric variables ψ and Δ in $R_p/R_s = \tan \psi \exp i\Delta$ where R_p/R_s are the complex reflectivities of the oxide-coated metal in p and s light. The data shown fit a curve for a uniform film of refractive index 1.62 growing on a substrate of index 1.20 − i 6.74 up to a certain thickness beyond which one of the specimens started to diverge from the curve. Locker and Skolnick (8) found that the index of their films changed from 1.65 to 1.75 due to exposure to the plasma and possibly some effect of this kind occurred here. The films were assumed to be of uniform index through their thickness. To obtain the thickness, theoretical curves (Fig. 4b) were plotted for the fitted oxide index and for two indexes bracketing the fitted value. Contours were drawn corresponding to constant thickness. Film thicknesses were estimated from these contours and from Δ, ψ computer printouts for 0.2 nm increments in thickness.

Figure 5 shows some typical plots of thickness *vs.* time. For the times of formation involved these were linear or, particularly for thinner films, became so after some period of anodization at constant current. The slopes were calculated and converted into ionic

current density, using $J_i = (\rho 6\mathbf{F}/MW)dD/dt$ where ρ = film density [assumed (28) to be 3.1 g/cm^3], $\mathbf{F}$ = the Faraday, and MW is the molecular weight of Al_2O_3. The formations at each constant total current had to be continued for 60-70 min in order to obtain sufficient growth (*e.g.*, 1-15 nm) to give a reasonably accurate estimate of the ionic current density.

Figure 6 shows plots of voltage *vs.* thickness for the complete sequence of formations on two specimens.

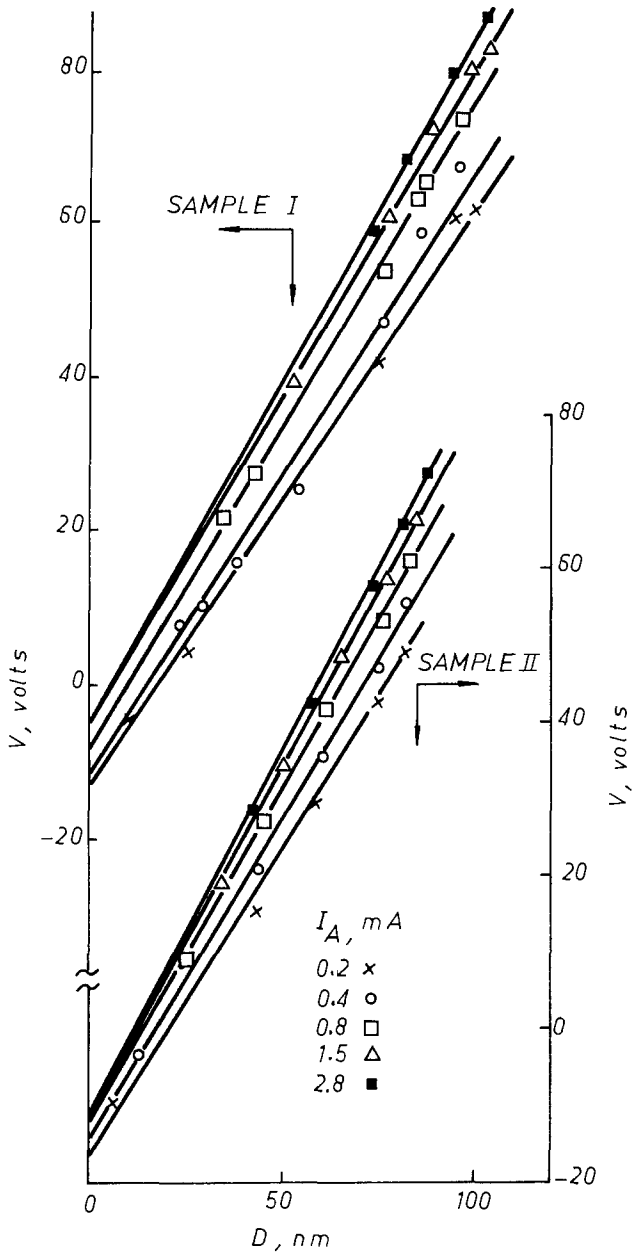

Fig. 6. Variation of V with oxide thickness

The points for each selected total current can reasonably be concluded to lie on straight lines, indicating a constant field independent of thickness at each current. The slope of the lines was taken as giving the field E in the oxide. The lines do not extrapolate to the same voltage at zero thickness. This is to be expected since the current drawn by the specimen perturbs the distribution of plasma potential (as was observed by the change in probe potential).

The dependence of E on the electronic current is explored in Fig. 7 and 8 where plots of $\log_{10}J_e$ *vs.* E and $\log_{10}J_e$ *vs.* $E^{1/2}$ are shown. Both plots gave straight lines but the Schottky plot gives more similar slopes for the two specimens. The shift in intercept between the two plots for the two specimens may be due to a difference in the distribution of plasma in the two runs. If the slope $d \log J/dE^{1/2}$ is identified as $e\sqrt{e/\pi\epsilon_0\epsilon_r}/kT$ the value of ϵ_r is found to be 8.5. The permittivity of the films at 1 kHz was measured at about 10.

Figure 9 shows a plot of $\log_{10}J_i$ *vs.* E. The fields are the average fields as derived from Fig. 6 and the result is a scatter diagram. However, from the film thicknesses shown against each point, a strong correlation is shown with thickness, the ionic current

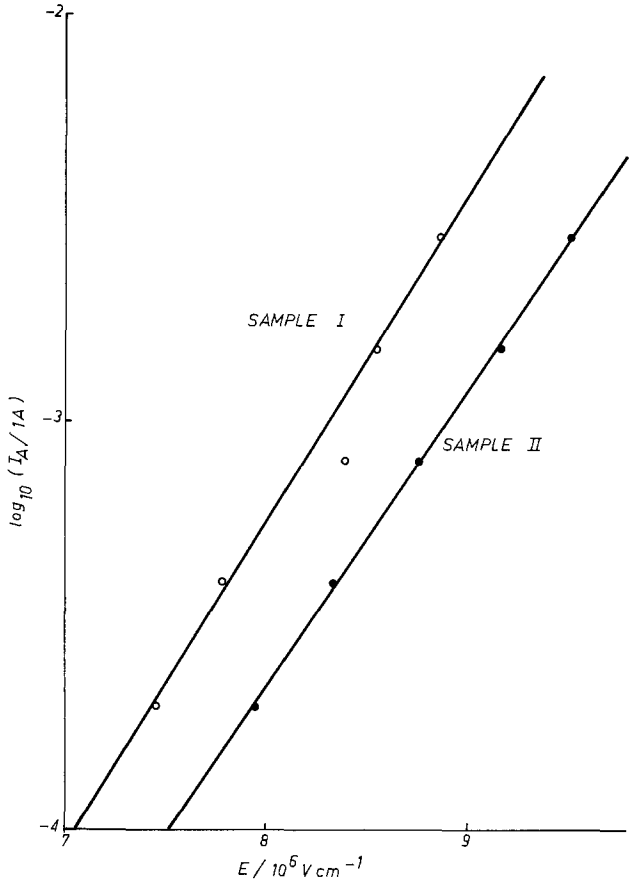

Fig. 7. Log_{10} I_A *vs.* E, with oxide field strength calculated from the slopes shown in Fig. 6.

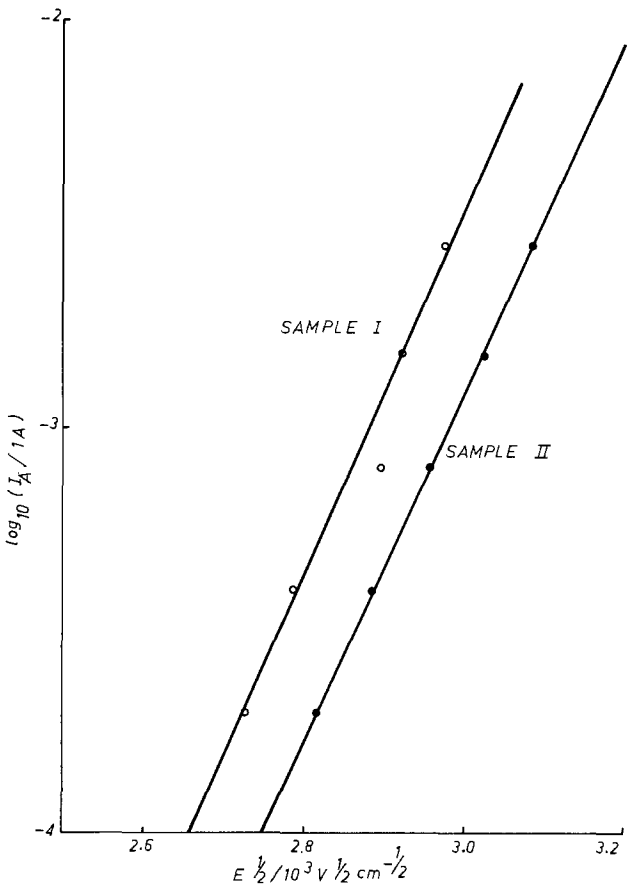

Fig. 8. Log_{10} I_A *vs.* $E^{1/2}$

tending to decrease with increasing thickness. Pursuing this correlation further, Fig. 10 shows plots of

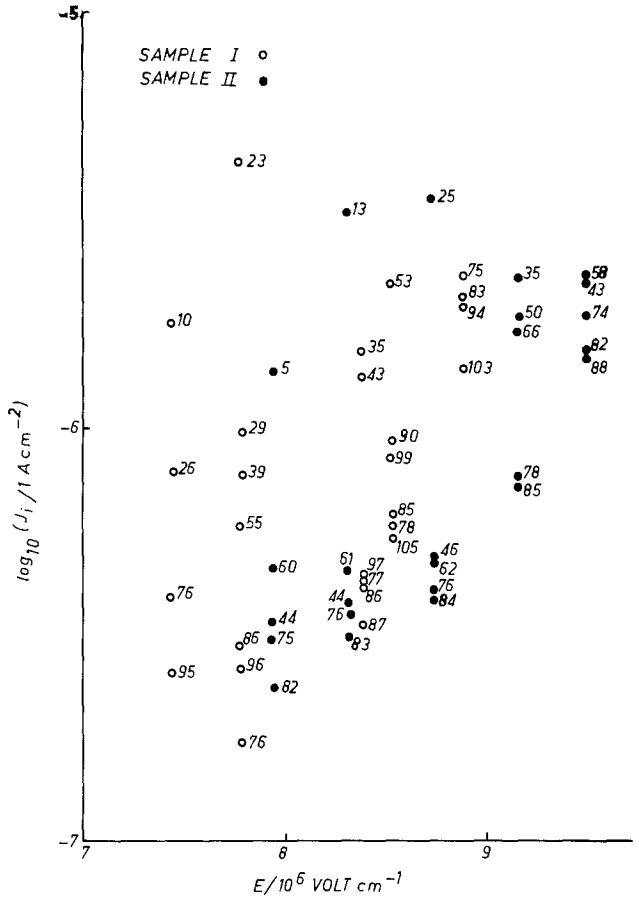

Fig. 9. Log_{10} J_i *vs.* E, with film thicknesses indicated in nanometers.

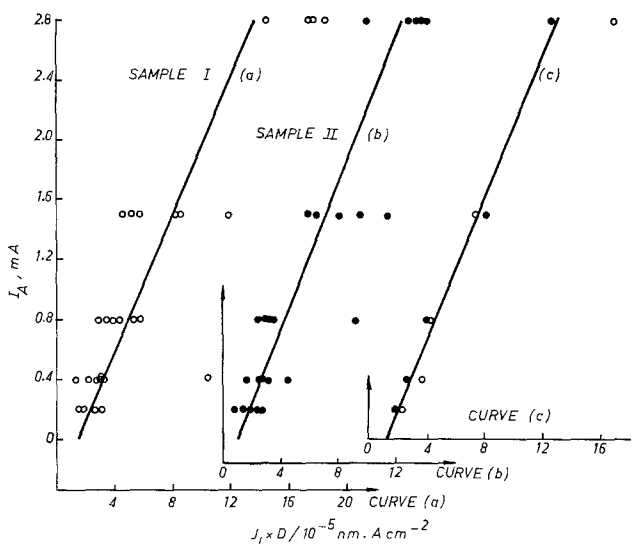

Fig. 10. Variation of ($J_i \times D$) with I_A. Curve (c) shows the average values of ($J_i \times D$) for each sample at each particular I_A.

total current *vs.* the product of thickness and ionic current. The data indicate a relation of the form $J_iD = mI_A + \gamma$ where m and γ are constants. Figure 11 shows the variation of $I_A/(J_iD - \gamma)$ where γ is the intercept in Fig. 10, over the range in D covered by the data. Further illustration of the dependence of the ionic current on thickness is given by Fig. 12 where the data for J_i *vs.* D can be compared with the curve constructed from the straight line drawn through the experimental points in Fig. 10.

Finally in Fig. 13, plots of $\log_{10}J_iD$ *vs.* E are given. Mean values of J_iD for a given total current are plotted in Fig. 14. Two lines are obtained with similar slope but different intercept, a situation similar to that for the electronic current (Fig. 7).

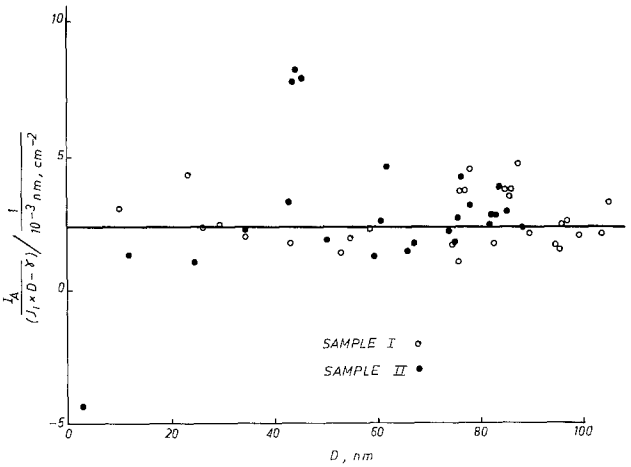

Fig. 11. Plot to examine the thickness dependence of $I_A/(J_i \times D - \gamma)$ where γ is the zero total current intercept from Fig. 10.

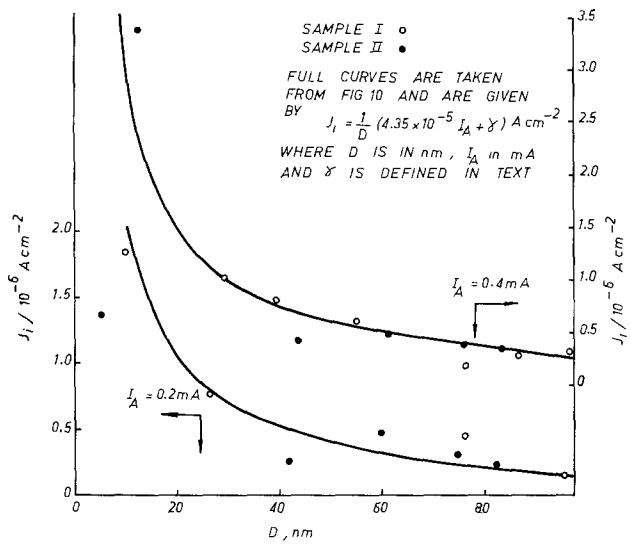

Fig. 12. Variation of ionic current density with oxide thickness, with the full curves computed from Fig. 10.

Discussion

The empirical expression $J_iD = mI_A + \gamma$ to which the data were fitted is of the form which would be given by the diffusion of a species whose concentration at the oxide/plasma interface was enhanced by the drawing of electronic current from the plasma. The relation suggests that this concentration was either linearly dependent on the electronic current or controlled by the oxide field which was determined by this electronic current. The question is whether such a model is correct or even reasonable. It is not without precedent. Previous work by Ligenza (23) and by Kraitchman (24) on the plasma anodization of silicon has indicated a diffusion process (parabolic growth law) enhanced by the plasma and applied voltage. Ligenza suggested that a mobile oxygen species was injected into the outer surface of the oxide from the plasma. The details of the observed kinetics were complex (for example, the dependence on voltage) and not fully explained by the model. In the present case, it is difficult to envisage what neutral species would be mobile in Al_2O_3 (as opposed to SiO_2) and one would expect drift to dominate over diffusion for a charged species at such high fields. Space charge effects may provide an alternative to the diffusion model. As discussed in early work on anodic oxidation (29) and recently treated numerically by Fromhold (30), space charge effects would require, in the case of transport of one ionic type without charge compensation, an increasing field with

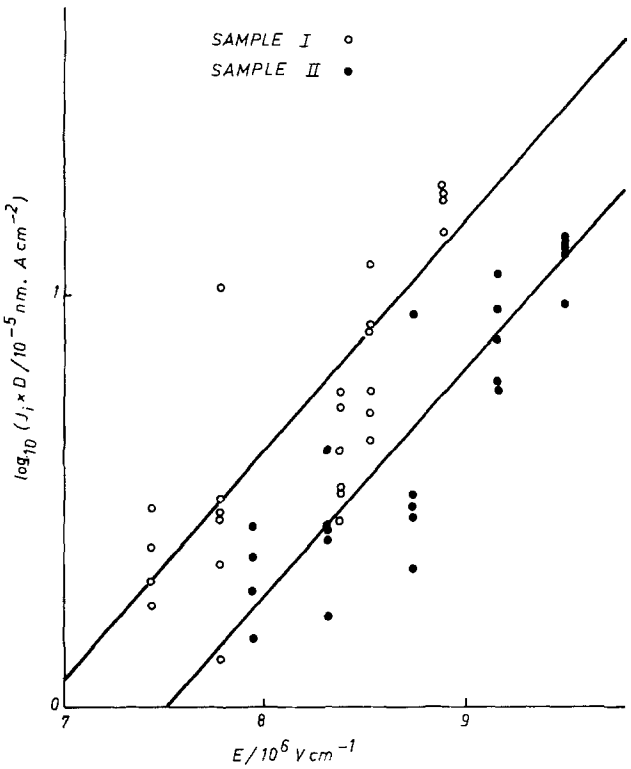

Fig. 13. Log_{10} ($J_i \times D$) vs. E for each formation but with the oxide field strength calculated from the slopes shown in Fig. 6.

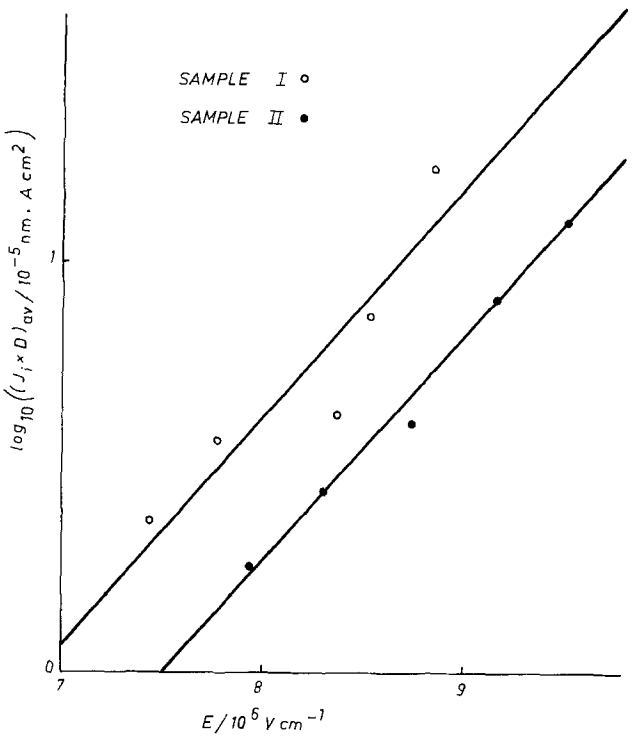

Fig. 14. Log_{10} $(J_i \times D)_{avg}$ vs. E, where the values of ($J_i \times D$) are the average values at each particular oxide field strength.

increasing thickness for high field transport at a constant ionic current. Conversely this would produce an ionic current decreasing with increasing thickness at constant average field, *i.e.*, the direction observed in the present work. In previous work on the plasma anodization of silicon in an rf plasma (21), space charge effects giving a tendency of this kind were indeed postulated. A difficulty is, then, why the electronic current should stay constant at constant average field.

Another possibility is that the mobile ions are somehow generated by the electronic current. Such an effect has been considered in connection with the stimulation of growth of anodic oxide films by u.v. radiation (31), and by Fritsche (32) in connection with the solution anodization of silicon, which occurs, like plasma anodization, at very low current efficiency. To fit the present growth law one might postulate the formation of some mobile oxygen species from absorbed oxygen at a rate proportional to electronic current.

Returning to the theory that a mobile species (or some precursor) is shot into the oxide from the plasma, work involving the application of rf + d-c voltages did not easily fit the idea that the supply of negative ions from the plasma was rate limiting (18). Arguments (2) that some plasma species (such as O_2^-) are rate limiting have often been based on reports that plasma anodization is faster in one part than another of the glow discharge. The problem is that the significance of such observations is not obvious and one must consider carefully what is being kept constant. Thus data at constant oxide field might be expected to be more significant than data at constant total current. The field to produce a given total current probably depends on the supply of electrons from the plasma. No sign of a saturation of ionic current with increasing total current has been observed.

As regards previous indications that the process of plasma anodization obeys the conventional law ($J_i \propto \exp BE$), it should be noted that, if data are taken over a range of thickness such that $1/D$ does not vary much (*i.e.*, if the thinner films are excluded), then such a law would tend to be found, particularly in view of the scatter typically shown by experimental data on plasma anodization. Perhaps the presence of this scatter, as contrasted to the extreme reproducibility of solution anodization data (where films may be made with 0.1% reproducibility of thickness) should be taken as further indication of difference in mechanism.

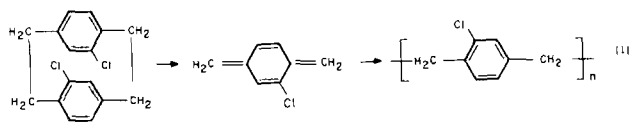
Characterization of Vapor-Deposited Paraxylylene Coatings

T. E. Baker,* S. L. Bagdasarian, G. L. Fix, and J. S. Judge*

Raytheon Company, Equipment Division Laboratories, Sudbury, Massachusetts 01776

ABSTRACT

Vapor deposition and polymerization of dichloro-diparaxylylene produces a parylene polymer film whose uniqueness as a superior conformal coating can be attributed to a combination of excellent properties and high throwing power. Additional advantages for low outgassing environments have been suggested for films whose composition and structure are critically controlled. Variations in vaporization temperature, pyrolysis temperature, material charge, deposition load, and charge/load ratio were made and the resultant films analyzed. Mechanical, spectroscopic, thermal, and chromatographic analysis of these films have elucidated the dependence of their oligomeric content and structure on deposition conditions.



Parylene is the generic name for members of a well-known polymer series (1). Many studies have been performed on the physical and chemical properties of polymeric paraxylylene films, particularly the unchlorinated material (2-4). These films have found application as conformal coatings for electronic assemblies and have been formally approved for military applications (5). Parylene, unlike most plastics, is not sold as a polymer but is produced by vapor-phase polymerization and deposition using a special vacuum application system (6). It cannot be applied easily from solvent solutions since it is insoluble in most common solvents (7).

The process for the vapor deposition of dichloro-diparaxylylene, known as parylene C,[1] has been commercially available for several years. The existing process had been optimized to produce a conformal coating capable of protecting electronic assemblies from adverse environments. In the present application, parylene C films were needed that had an additional requirement of a minimum outgassing product under a specified thermal/vacuum environment. While low outgassing films were desired it was also necessary that the basic material integrity and inherent properties of parylene be preserved (8). To achieve this goal it would be necessary to critically control the composition and structure of these films.

Experimental

Parylene is deposited in a vacuum system from the vapor phase at a pressure around 0.1 Torr. Therefore, parylene vapor approaches the object to be coated from all directions and since deposition is not line of sight all sides of an object are coated uniformly by impinging gas molecules. This characteristic in itself is one of the primary reasons for the increasing usage of parylene within the electronics industry. A diagram of the basic process apparatus is illustrated in Fig. 1.

The process for producing parylene C films starts with the dichloro-di-p-xylylene crystalline solid dimer which is vaporized and pyrolyzed in vacuum to produce the monomeric chloro-p-xylylene. Upon entering the deposition chamber it simultaneously adsorbs and polymerizes on substrate surfaces. The formation reaction is shown schematically in Eq. [1]

The parylene C dimer was obtained from Union Carbide and an analysis report accompanied each shipment. In our investigation films were produced using a

[1] Tradename, Union Carbide Corporation.

Union Carbide Model No. 10C coater and deviations from the standard vaporization and pyrolysis temperatures were made. Variations in material charge, deposition load and charge/load ratio were also initially made, however, the bulk of this work was performed under constant charge/load conditions. Changes in vaporization/pyrolysis temperatures also produced changes in other dependent variables such as chamber pressure and rate of deposition.

Variations from nominal ranged from −20° to +35C° for vaporization temperature and −50° to +50°C for pyrolysis temperature.[2] This exercise was essential in determining what effects, if any, these temperature variations had on film characteristics, particularly outgassing properties, since earlier work and characteristics of other free radical processes suggest a dependence (9).

The quantitative analysis of dimer content in the resultant polymeric material has been performed previously by infrared spectroscopy (10). The infrared method has a lower detection limit of approximately 1.3% of unconverted parylene dimer in the film. The quantitative analysis of dimer content of the polymer film was performed in our laboratory by means of liquid chromatography. The polymer film was first extracted with tetrahydrofuran in a Soxhlet type extraction apparatus to remove the unconverted dimer and any additional soluble oligomers. The film weight loss was then used to calculate the percent of extractable material. This soluble fraction was analyzed by reverse phase liquid-liquid chromatography. The intensity of the major isomer peak was then compared to the intensity of the same peak in the chromatogram of a standard solution of dimer. The resultant detection limit for the determination of dimer content in a 0.5g sample of polymer by this method is approximately 0.05%.

The refractive index and the thickness of each deposited run was obtained over the 1.8-2.6 μm wavelength range utilizing a variable angle specular reflectance accessory to a Beckman ACTA MVII NIR/-VIS-UV spectrophotometer. A silicon wafer accompanied other test coupons in the deposition chamber for each run. The coated wafers were mounted on the reflectance accessory and scanned over the predescribed wavelength range and an interference pattern was generated at two incident angles, 30° and 45°.

The weight loss of the film when exposed to heat and vacuum was determined by heating the film for 2 hr at 200°C at a pressure of less than 500 μm on a Cahn Model RG electrobalance.

Results

The resultant films from variations in vaporization and pyrolysis temperatures were analyzed for relationships among percentage dimer content, percentage extractables, and vacuum weight loss. Figures 2 and 3 graphically illustrate those relationships. Applying the least squares technique to the data, it is clearly seen that monotonic relationships exist between these three measured properties. There is nearly a one to one correlation between vacuum weight loss and percent extractables: there always being slightly more soluble material than volatile material. The dimer content of the film is, on the average, about one-third of the total extracted material. The other two-thirds is apparently other oligomers. Figure 4 is an overlay of reverse phase chromatograms of dimer and extractables illustrating the predominance of dimer in the extractables as noted by the major peak.

In addition to the dimer content determination, it was originally anticipated that the same procedure could be utilized for determining the anthracene content of a polymer sample. Anthracene is utilized as a fluorescent inspection agent and is codeposited with the polymer from a dimer charge containing 0.25

[2] The nominal temperatures will vary slightly depending upon deposition equipment. For our equipment, the nominal vaporization temperature was 165°C and the nominal pyrolysis temperature was 690°C.

weight percent (w/o) anthracene. Typically, therefore, the soluble fraction of a 0.5g sample should contain 1.25 mg of anthracene if it were incorporated into the film at its concentration in the dimer charge. Using 254 nm u.v. radiation, the detection limit for anthracene

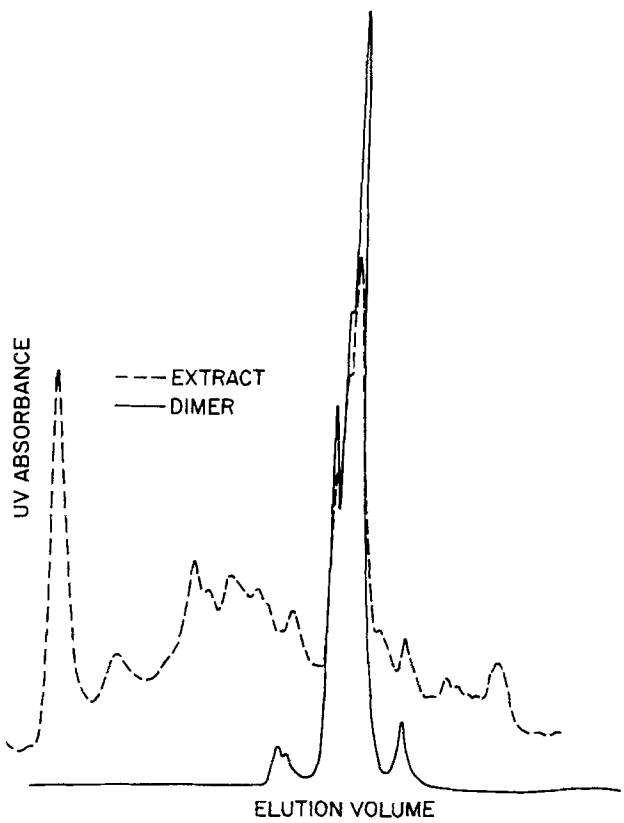

Fig. 4. Reverse phase chromatograms of dimer and extract

in the liquid chromatographic spectra of the solvent extract is such that 1/60$_{0}$0 of this amount would be detected. Surprisingly, no film extract was found to contain any detectable anthracene. This suggests that the anthracene which is incorporated into the polymer film during the CVD process is chemically combined with the matrix. Examination of the relative concentration of the three dichloro isomers present in both the dimer and polymer extracts (see Fig. 4) reveals an increase in the polymer of the dimer isomers originally present in the smallest amounts. This indicates that the reaction rates for the various isomers differ and that conditions must be optimized to assure conversion of all three isomers. Consideration of the parallel planar configuration of the parylene dimer dictates four configurational isomers with respect to the chlorine substitution. Steric hinderances probably forbid one of these configurations and, indeed, our analysis of the dimer material by reverse phase liquid-liquid chromatography reveals the predominance of three major constituents, undoubtedly the three isomers. Assuming the molar extinction coefficients of the isomers and the other impurities are equal, the three isomers typically account for 92% of the starting material. These results agree quite favorably with the 92.7% dimer reported by Union Carbide for the various lots of material used in this investigation (based on gas chromatography). The additional 8% of dimer material is reported as "other chlorinated homologs" which implies additional chlorine substitution. However, examination of the molecular weight distribution of the dimer by gel permeation liquid chromatography reveals the material to be composed of 99.2% of the di-chloro isomers.

Undoubtedly the "chlorinated homolog" content can best be attributed to noncyclic dimer formed through hydrogen abstraction having molecular weights close to that of the di-chloro isomers. Stereochemical considerations predict three noncyclic isomers and the results of reverse phase liquid chromatography analysis show three distinct minor peaks which can account for the 8% "chlorinated homolog" impurity fraction.

Somewhat surprising were the results of the electrical data obtained on the films. It was determined that the basic electrical parameters of dielectric strength, dissipation factor, and dielectric breakdown voltage did not vary significantly regardless of the process conditions. This was unexpected in that the excellent electrical properties obtained with parylene C under normal process conditions were still observed even though higher dimer and weight loss constituents were present in some films. Table I reflects the relatively high dielectric breakdown voltage strength of parylene C films produced under a wide range of process variations. Similarly, dielectric constant and dissipation factor are essentially constant despite processing variations. Examination of the data in Table II indicates that the yield stress and tensile modulus also remained relatively constant suggesting that there are no adverse effects on the mechanical properties over the variation of the deposition conditions.

Table III summarizes the effect of the various process conditions on the permeability of the film to water. It is apparent that no pronounced dependence is observed.

Selected films were also studied for degree of crystallinity. Diffraction patterns were obtained using graphite-filtered copper radiation. The unannealed samples produced similar patterns with one broad peak between 14° and 15° and probably an extended "amorphous bump" from the peak, slowly decaying out to 30°-35°. Annealing produces changes in the observed patterns. The peaks are all much sharper and the slightly elevated amorphous bump disappears. The intensities increase markedly which indicates considerable enhancement of the degree of crystallinity by annealing. Table IV summarizes the intensity changes. It is apparent that initial crystallinity is relatively independent of the deposition parameters, however, crystallinity is increased upon annealing. An examination of the data on refractive index where values ranged from 1.58 to 1.80 produced no meaningful correlations with other basic material properties which were measured.

Figures 5 and 6 graphically represent the relationships between the weight percentage extractables and the variations in vaporization and pyrolysis temperatures. It is clearly evident that at the normal vaporization temperature, the weight percent extractables increases dramatically as the pyrolysis temperature is lowered even slightly. Conversely, as pyrolysis temperature is increased, the reaction tends to yield a more complete conversion of dimer to monomer prior to ultimate polymerization, and thus lower oligomeric content is found. Lowering the pyrolysis temperature or increasing the vaporization temperature tends to increase the tetrahydrofuran-extractable portion of the films. An increase in the vaporization temperature must be accompanied by a concomitant increase in pyrolysis temperature to produce minimum extractables in the resultant polymer film.

An examination of basic mechanical characteristics was made for comparison to other similar materials. A

typical stress/strain curve for parylene C is shown in Fig. 7 (assuming constant volume or Poisson's ratio = 0.5). Parylene, like similar organic films, has a characteristic load/deflection curve (11).

The effect of aging on the yield stress and tensile modulus of parylene was also investigated. A number of samples from one deposition run were aged at 71°C in air for various times to determine if this accelerated aging had any effect on the yield stress or modulus. Contrary to previous work on parylene N, no aging effects were noted in the parylene C under these conditions (9). Since these results show that parylene is not greatly affected by aging for periods of over 10 days at temperatures up to 71°C, it may be inferred that parylene C is a relatively stable nonsensitive material. Also, no significant differences were observed in mechanical properties for films produced under the various deposition conditions.

Summary

The minimization of vacuum weight loss products in parylene C films can be achieved by critical control of the vaporization and pyrolysis temperatures. Electrical, mechanical, and physical properties of the film are essentially unchanged with minor variations in the deposition conditions which do change the films oligomeric content. Furthermore, no increase of degradation products was found in the resultant film as a consequence of increasing the pyrolysis temperature 20°C.

A more sensitive method of parylene film dimer content analysis has been developed based on liquid chromatographic analysis of solvent extracted oligomers. This analysis has demonstrated that anthracene codeposited as a fluorescent agent is chemically bound to the polymer backbone. It also suggests that the reactivities of various isomers in the starting dimer may influence the dimer content of the resultant films.

Sensitivity of Intensifying Screens to Scattered Radiation in Radiography: Physical Measurements

J. W. Castle

Eastman Kodak Company, Research Laboratories, Rochester, New York 14650

ABSTRACT

The x-ray absorption of rare earth (gadolinium-lanthanum) and medium speed calcium tungstate screens was measured in regions of high and low radiographic density of a chest phantom. The ratio of absorptions for the two regions was higher for the rare earth screens. This confirms by direct measurement that the higher observed radiographic contrast for the rare earth screens when compared to calcium tungstate screens is caused by the change in absorption of the screen phosphors with change in transmitted beam quality. The net effect in rare earth screens of this type is a reduction in the recording of scattered radiation with an increase in the percentage of information-containing (primary) radiation. The degree of this effect is a function of the amount of scattered radiation in the transmitted beam incident on the cassette.

It was suggested by Buchanan (1) that a higher radiographic contrast should be observed for x-ray intensifying screens of rare earth phosphors as compared with calcium tungstate if scattered radiation is present in the beam incident on the cassette. However, with only primary radiation the opposite effect would be expected. No difference in contrast was reported. Higher contrast for the rare earth screens was observed by Huff and Shaffer (2) for radiographs of a phantom with scattered radiation at 75-95 kVp and at 95 kVp with a grid.

In an attempt to explain this effect, screen absorption measurements were made at 60-100 kVp using 12.5 cm of plastic as the absorber. These showed the ratio of scatter/primary absorption in the screen material to be lower for rare earth screens (an 80/20 blend of the oxysulfides of gadolinium and lanthanum) than for calcium tungstate screens (3). This ratio is an indication of the relative sensitivity of a screen to scattered radiation as compared with primary. A lower ratio denotes a reduction in the recording of scattered radiation and will increase the radiographic contrast, as is evident from various other scatter reduction techniques used in radiography.

A reason for this difference in contrast is indicated in Fig. 1 which shows the absorption curves for gadolinium-lanthanum and calcium tungstate phosphors as calculated from mass energy absorption coefficients (4). Typical primary and scattered radiation spectra are included for an 85 kVp x-ray beam after passing through 12.5 cm of plastic. It can be seen that the shift of the scattered beam to lower energies results in only a minor absorption difference for the rare earth phosphors, because of the K-absorption discontinuities at 38.9 and 50.2 keV, but for calcium tungstate the shift is to a region of higher absorption.

Although the explanation for the reduction in the recording of scattered radiation seems valid, it has not been proven by measurements of a radiographic object that the ratio of total x-ray absorption by the screens in regions of high and low transmission of the radiographic object would differ for the two screens, or that the rare earth screen would have the greater difference. In fact, by the above reasoning the calcium tungstate would be expected to show higher contrast for the primary beam alone, because low density areas of the radiograph are exposed by more heavily filtered, hence harder x-rays than the higher density areas. Thus, the more rapid change in screen absorption with x-ray energy for the calcium tungstate would produce higher radiographic contrast than would be produced with the rare earth screens. However, differences in the scatter/primary beam energy ratio for the two regions could change the total beam quality as recorded by the screen/film combination and so may reverse the overall radiographic effect.

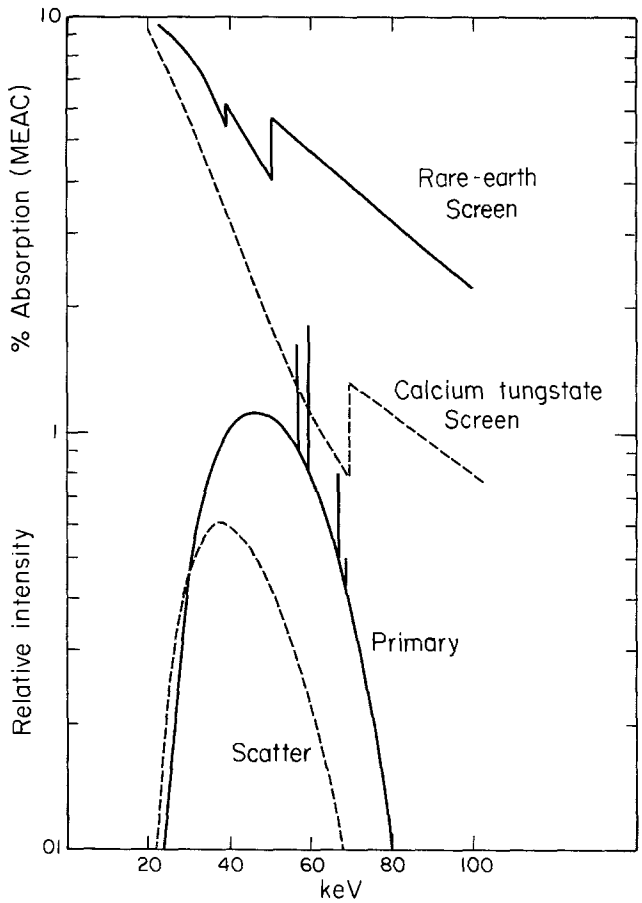

Fig. 1. Absorption curves for a rare earth screen and a medium speed calcium tungstate screen calculated from mass energy absorption coefficients. The rare earth screen is an 80/20 blend of the oxysulfides of gadolinium and lanthanum. Also shown are typical primary and scatter transmission spectra through 12.5 cm of plastic.

To obtain such data, the spectra of the primary and the scattered beams transmitted by a region of high (lung area) and low (heart area) transmission to x-rays for a chest phantom (5) were measured with an x-ray spectrometer (Fig. 2). The spectrometer has an intrinsic germanium detector feeding through a pile-up rejector/lifetime corrector, amplifier, and into a multichannel analyzer. The geometry of the detector with

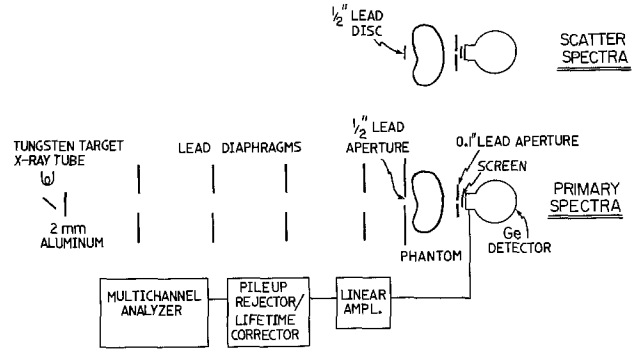

Fig. 2. Diagram of method used for measuring primary and scattered spectra through a chest phantom using a x-ray spectrometer.

its aperture is such that radiation up to 40° off axis may be recorded. Because of this the total amount of scattered radiation from an object that would be incident on a cassette is not detected. The measured spectra (Fig. 3) indicate the change in beam quality of the scattered radiation although not the total intensity. The spectra so obtained are shown in Fig. 3. From these spectra can be calculated the relative energy in the x-ray beams. The results of these calculations are shown in Table I. Although the primary beams are seen to differ in intensity by a ratio of 6.18, the total beams differ by only 3.10 for the two regions. This is because the scattered component of the total beam is nearly constant and is thus a much larger portion of the total beam through the area of the heart than through the lung.

In order to determine the energy absorbed by the screens for the different beam qualities, the screen absorption associated with the spectra for the two regions of the phantom were then measured by placing a piece of the screen over the detector and again measuring the transmission spectra. From the ratio of the energies in the transmitted beam with and without a screen, the absorption of the screens could be calculated. Table II shows the measured absorptions of the two screen pairs. For both lung and heart areas, the rare earth screens show a lower scatter/primary ratio indicating less relative sensitivity to the scattered radiation. This agrees with previously reported data in which 12.5 cm of plastic was used as the absorbing medium (3).

By combining the data of Tables I and II, we can determine the relative energies absorbed by the screens for the different conditions. The calculated energies absorbed by the two screens are shown in Table III. The absorbed energy, which is approximately proportional to the light emitted by a given phosphor, is a measure of the photographic exposure produced by a

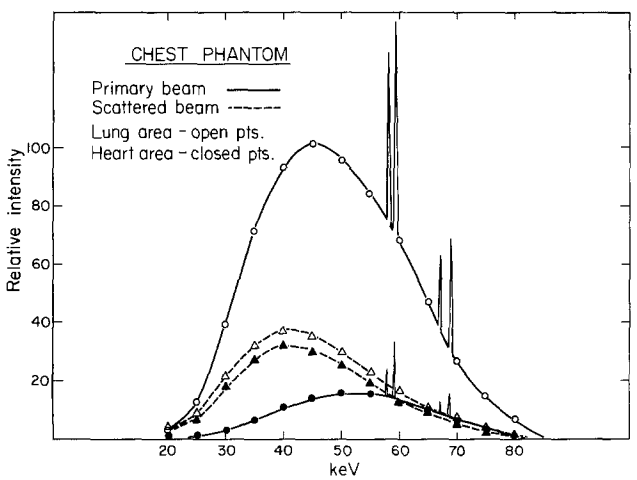

Fig. 3. Transmission spectra measured through the lung and heart area of a chest phantom at 85 kVp with 3 mm aluminum inherent filtration.

Table I. Relative measured energy of transmitted beam

	Lung area	Heart area	Ratio
Primary (P)	835	135	6.18

	Scatter (S)	28	1.17	30	1.58
	Total (T)	24		25	

Table III. Relative beam energy absorbed by screens

Screen		Lung area	P/T	Heart area	P/T	Ratio (contrast)
Rare earth (Gd/La)	Primary (P)	515		85		6.06
	Scatter (S)	150	0.77	130	0.40	1.15
	Total (T)	665		215		3.09
Medium speed $CaWO_4$	Primary (P)	190		25		7.60
	Scatter (S)	70	0.73	65	0.28	1.07
	Total (T)	260		90		2.88

screen when irradiated with beams of different qualities. It is seen that, while the calcium tungstate has a higher ratio of absorbed energies for the primary beam through the two areas, the ratio (or contrast of the radiograph) for the total beam is higher for the rare earth screens (3.09-2.88).

Although the data confirm that for these conditions the rare earth screen would be expected to show higher contrast, this contrast difference is only a visible indication of a more fundamental difference between the two phosphors in the region of 70-120 kVp. This fundamental difference is the higher ratio of primary to total radiation absorbed in any area of a radiograph. Because of this ratio, the radiographic exposure will have a higher percentage of information-containing (primary) radiation absorbed by the rare-earth screen. This ratio is shown in the P/T columns in Table III.

To emphasize this, it is of interest to arbitrarily reduce the measured scatter from Table III by 40 and 60% (in the range of scatter reduction in some magnification techniques) and 90% (use of a grid). However, if a grid is used the primary is also reduced. For the column showing 90% scatter reduction, the primary has been reduced by 30% (6). The resulting contrast and P/T were calculated as in Table III. The results are given in Table IV. It is seen that at higher than 50% scatter reduction the contrast for the calcium tungstate screen is higher, but the rare earth screen continues to show a higher P/T ratio indicating that the rare earth screen is still recording a higher percentage of the primary radiation.

These data confirm by absorption measurements that the observed higher radiographic contrast of a rare earth screen as compared with calcium tungstate

Table IV. Effect of scatter reduction

Contrast	Screen	Percent scatter reduction 0	40	60	90
	Gd_2O_2S/La_2O_2S	3.09	3.71	4.20	5.40
	$CaWO_4$	2.88	3.62	4.27	6.25
P/T (lung)	Gd_2O_2S/La_2O_2S	0.77	0.85	0.90	0.95
	$CaWO_4$	0.73	0.82	0.87	0.93
P/T (heart)	Gd_2O_2S/La_2O_2S	0.40	0.52	0.62	0.80
	$CaWO_4$	0.28	0.39	0.49	0.68

screen is the result of change in beam quality in different areas of a radiographic object. An important corollary is the higher percentage of information-containing primary radiation absorbed by the rare earth screens.

Low Pressure Silicon Epitaxy

M. Ogirima, H. Saida, M. Suzuki, and M. Maki

Hitachi, Limited, Central Research Laboratory, Kokubunji, Tokyo, Japan

ABSTRACT

In a reduced pressure epitaxial system using SiH_4, growth parameters and autodoping from a heavily doped substrate were investigated as a function of pressure. It was found that the activation energies of epitaxial growth are about 43 and 11 kcal/mole for 80 and 760 Torr, respectively. Both vertical and lateral autodoping are remarkably reduced by epitaxial growth under low pressure. A simple one-dimensional gas diffusion model is proposed to explain the autodoping behavior in low pressure epitaxy.

The suppression of autodoping has been one of the most serious problems in epitaxial growth techniques. There are many factors which control autodoping in an epitaxial layer on a substrate with heavily doped buried layers. Autodoping from a substrate with buried layers is phenomenologically classified into two types. One is vertical autodoping and the other is lateral autodoping. The former is autodoping in an epitaxial layer on a buried layer and the latter is that on a substrate around buried layers. Vertical autodoping contains outdiffusion of impurities from buried layers in addition to autodoping from a vapor phase. Up to now, several techniques have been proposed to suppress autodoping. They are, (*i*) low temperature epitaxy, (*ii*) epitaxy using a silicon source without halogen atom, such as silane, (*iii*) two-step epitaxy, and (*iv*) low pressure epitaxy.

In comparison with high temperature epitaxy using silicon tetrachloride, low temperature epitaxy using silane has little effect on reducing lateral autodoping. Lateral autodoping has its maximum value at the interface between a substrate and an epitaxial layer. For this reason, the two-step epitaxial growth technique (1) is not an effective solution for reducing lateral autodoping.

Deines and Spiro (2) suggested the possibility of reducing autodoping by low pressure epitaxy. We therefore tried to reduce autodoping in an epitaxial layer by low pressure epitaxy and investigated the pressure dependence of autodoping in the silicon epitaxial deposition process. This paper describes some experimental results and discusses growth parameters and autodoping mechanisms of low pressure epitaxy.

Experimental

Epitaxial layers were grown in a standard horizontal reactor. Figure 1 shows the growth apparatus for low pressure epitaxy. Palladium-diffused high purity hydrogen and silane (4% in H_2) were injected into the reaction tube and reacted gas was exhausted forcibly by a mechanical oil-sealed rotary pump from the outlet of the reaction tube. Oil mist was trapped by a liquid nitrogen trap. The pressure was measured by a diaphragm-type vacuum gauge, and was controlled by varying exhaust resistance.

Key words: autodoping, growth rate, *C-V* measurements, buried layers, impurity profile.

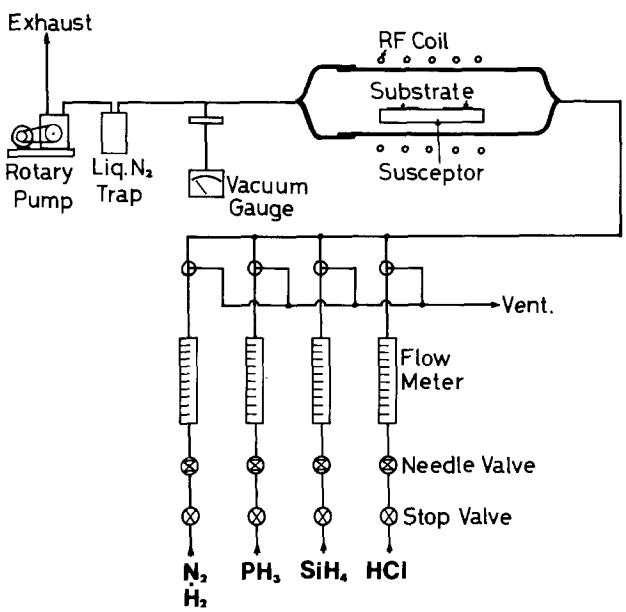

Fig. 1. Growth apparatus for low pressure silicon epitaxy

Epitaxial growth was carried out using a silicon carbide coated and RF inductively heated graphite susceptor. The inner diameter of the reaction tube was 75 mm and the susceptor could accommodate three wafers 2.5 in. in diameter. Growth temperature was always 1050°C when not indicated. After epitaxial growth, planar diodes of 300 μm in diameter were fabricated in epitaxial layers by boron diffusion. The carrier concentration was measured by the capacitance and voltage method and impurity profiles near the interface of the epitaxial layer and the substrate were obtained.

The structure of the samples for measurements of autodoping is illustrated in Fig. 2. The metallurgical in-

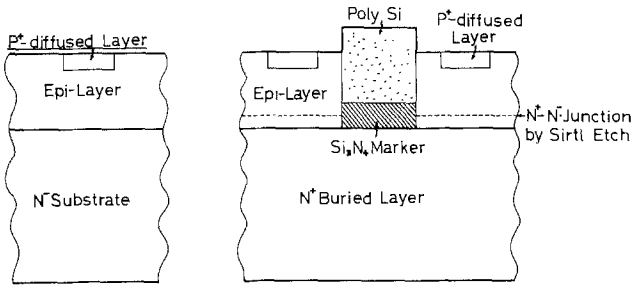

Fig. 2. Section of the samples for C-V measurements: (a, left) for lateral autodoping measurements, (b, right) for vertical autodoping measurements.

terface between an epitaxial layer and a substrate was delineated by a silicon nitride marker. After beveling a sample, n^+-n^- junction in an epitaxial layer was delineated by Sirtl etch and the shift of the junction (vertical autodoping) during the epitaxial process was measured by an optical microscope. Lateral autodoping was measured on a n^- substrate.

Results and Discussion

Growth rate.—The growth rate and uniformity of the epitaxial layer thickness are extremely dependent on the pressure in a reaction tube. Figure 3 shows the relation between growth rate and the mole ratio of SiH_4/H_2 carrier gas, which indicates that the growth rate decreases almost in proportion to the pressure. This result is reasonable because the partial pressure of silane decreases in proportion to the total pressure and is consistent with the results obtained by Henderson *et al.* (3). Figure 4 shows the temperature dependence of growth rate. For 760 and 150 Torr, an Arrhenius plot of the relation between growth rate and temperature gives an activation energy E_A of about 11 kcal/mole, but for 80 Torr, E_A is about 43 kcal/mole. This experimental fact suggests that there is a change in the reaction mechanism of silane from 150 to 80 Torr. The value 11 kcal/mole is nearly equal to that of the previous work (10 kcal/mole) by Farrow *et al.* (4), and this result indicates that surface reaction of silane is prevailing at 760 and 150 Torr. In this case, growth rate is controlled by diffusion process above 1000°C, and is almost independent of epitaxial growth temperature. On the other hand, at 80 Torr, the value of the activation energy, 43 kcal/mole, suggests that the growth rate is controlled by homogeneous nucleation in a vapor phase.

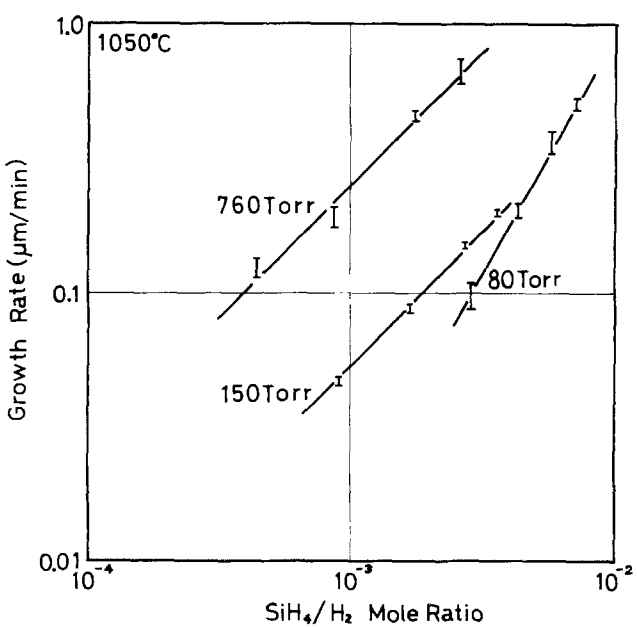

Fig. 3. Relation between growth rate and SiH_4/H_2 mole ratio

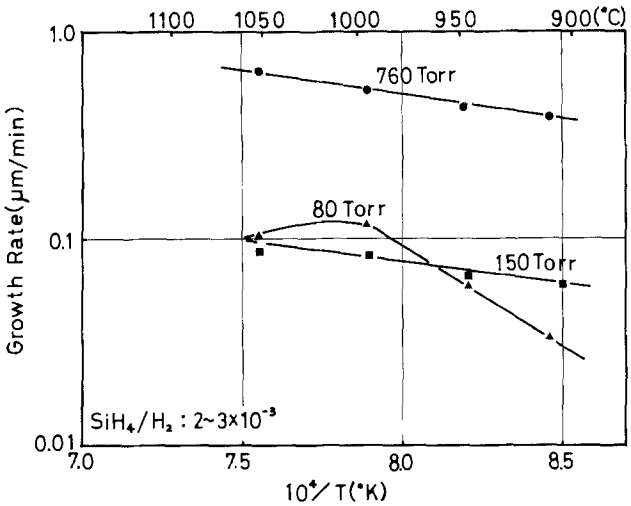

Fig. 4. Arrhenius plots of growth rate vs. growth temperature

Doping behavior is illustrated in Fig. 5 which shows that the transfer ratio (=0.56) at 80 Torr is the same as that at 760 Torr.

Autodoping.—An example of the impurity profiles near the interface is shown in Fig. 6. Parameter x is the distance of the measured diodes from the edge of the n^+ buried layer. The maximum carrier concentration is obtained at the interface between an epitaxial layer and a substrate. It is evident that the maximum impurity concentration decreases with the increase of the lateral distance x.

Photographs in Fig. 7 show the shift of the junction between the epitaxial layer and the n^+ buried layer during epitaxial growth. When epitaxial layers are grown at atmospheric pressure using silicon tetrachloride or silane, the shift of the junction, Δd, is about 0.1 or 0.2 μm at 1050°C, but, on the other hand when they

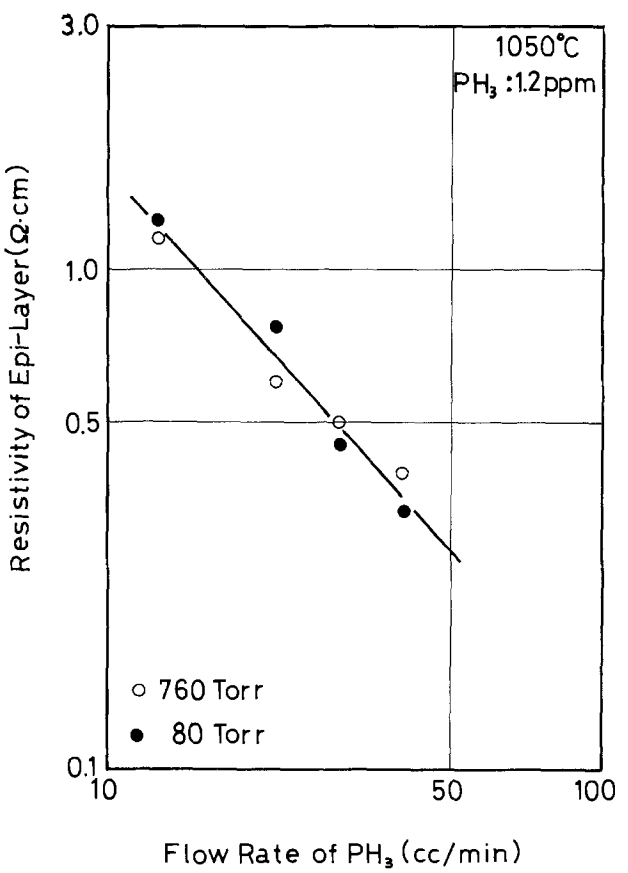

Fig. 5. Doping behavior in low pressure and atmospheric pressure epitaxy.

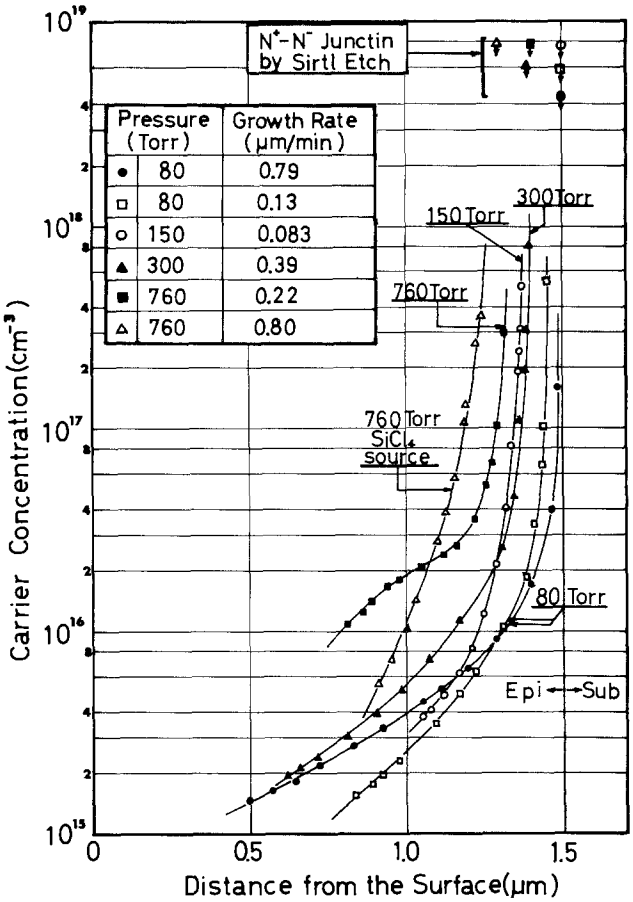

Fig. 8. Carrier concentration profiles in the epitaxial layers on n^+ burried layer.

are grown at low pressure, for example, at 150 or 80 Torr, the shift Δd is nearly equal to zero. These results are confirmed by Fig. 8. This figure illustrates the carrier concentration distribution in epitaxial layers on n^+ buried layers. The vertical line at 1.5 μm is the metallurgical interface between the epitaxial layer and the substrate. The marks at the top of the figure indicate the junction obtained from the photographs in Fig. 7. In low pressure epitaxial layers, the shift of the junction is nearly equal to zero, whereas at 760 Torr, it is about 0.2 (SiH_4 source, 1050°C) or 0.3 μm ($SiCl_4$ source, 1150°C). The shift of the junction during epitaxial growth is due mainly to two mechanisms: vertical autodoping from a vapor phase and out-diffusion in a solid from the substrate, as mentioned before. The shift of the junction by out-diffusion is calculated

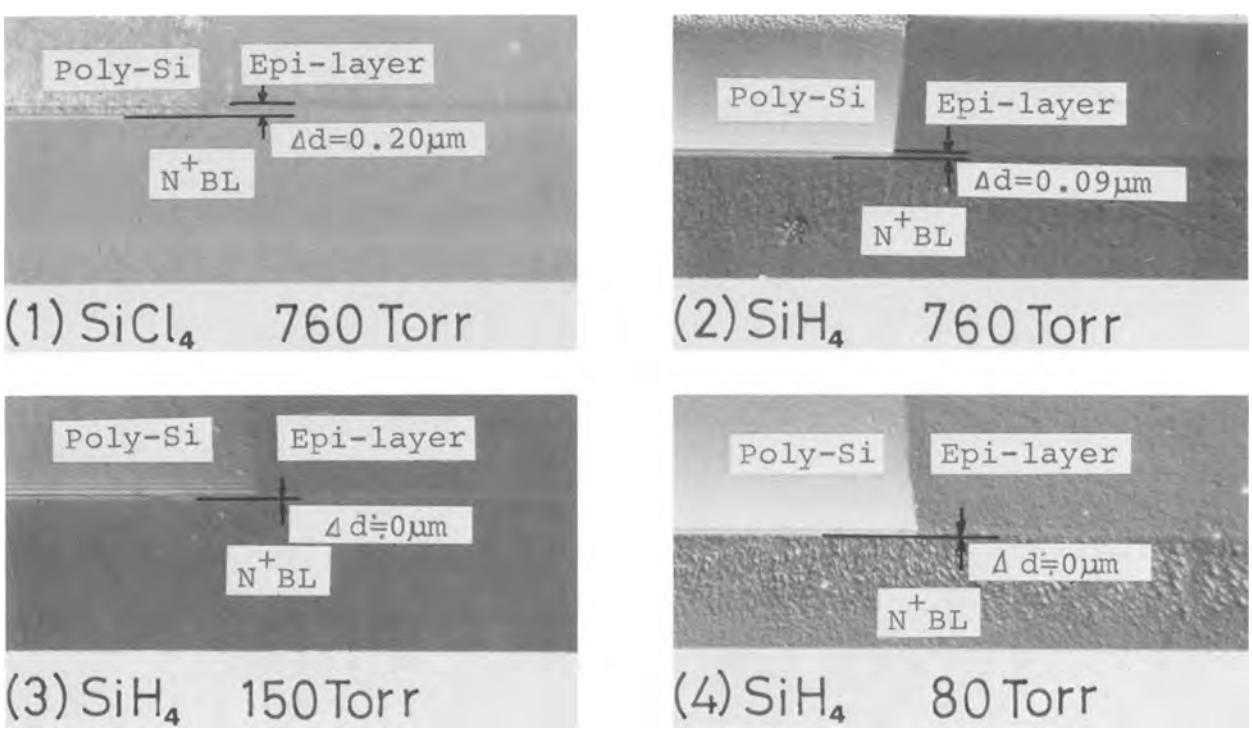

Fig. 7. Shift of the n^+-n^- junction during epitaxial growth (1050°C, 5 min)

to be about 0.025 μm when the epitaxial growth is carried out at 1050°C for 5 min. This value is comparable to the measurement error of an optical microscopic observation. Therefore, it can be concluded that in the case of low pressure epitaxy (<1050°C, <150 Torr) the decrease in vertical autodoping is due mainly to the decrease in incorporation of gaseous arsenic atoms sublimated from the n^+ buried layers.

Figure 9 shows the wafer for measuring lateral autodoping. In the central zone of the n^- substrate (20-30 Ω-·cm), there is an n^+ buried layer, 15 mm square, doped with arsenic to a concentration of 6×10^{19} cm^{-3}. In order to investigate the influence of the gas flow on lateral autodoping, the carrier concentration at the interface between the substrate and the epitaxial layer was measured as the function of the distance from the edge of the n^+ buried layer. The measurements were carried out for up-, down-, left-, and right-stream positions of the n^+ buried layer.

Figure 10 shows lateral autodoping as a function of the distance from the edge of the n^+ buried layer. Lateral autodoping is expressed by the maximum carrier concentration at the interface of an epitaxial layer and a n^- substrate. From these figures we can conclude the following three points.

1. Below 150 Torr, the dependence of lateral autodoping on the distance from the edge of the n^+ buried layer has the same tendency for down-, up-, and right (left)-stream positions.

2. Above 300 Torr, lateral autodoping is much greater in the downstream position than in the upstream position, and an epitaxial layer located in both sides of the n^+ buried layer has a middle value of the epitaxial layers located in the upstream position and in the downstream position. The curve for upstream position of atmospheric pressure epitaxy is not shown in Fig. 10a because the concentration is too high to be measured by the capacitance methods, but the concentration near the edge of the n^+ buried layer is estimated to be about 3×10^{17} cm^{-3}. It must be noted that lateral autodoping in an epitaxial layer in the upstream position for atmospheric pressure falls steeply as the distance increases, and is lower than that for 80 Torr at a point about 6 mm from the edge of the n^+ buried layer.

3. Generally speaking, lateral autodoping decreases monotonously as the pressure decreases.

The relationship between the pressure in the reaction tube and the carrier concentration at the edge of the n^+ buried layer is illustrated in Fig. 11. This figure indicates that lateral autodoping is in proportion to the nth power of the pressure p. In this case, n is about one, which suggests lateral autodoping is in proportion to the partial pressure of arsenic on the surface of the n^+ buried layer by thermal out-diffusion which is hardly affected by the pressure in the reaction tube. Then it is estimated that the partial pressure controls the equilibrium concentration of arsenic on the surface of a n^+ buried layer. As mentioned before, the transfer ratio of dopants in silicon epitaxy is independent of the pressure, and for this reason lateral autodoping is in proportion to the concentration of arsenic vapor on the n^+ buried layer. As a result, lateral autodoping is lower by about one order of magnitude in the epitaxial layer grown at 80 Torr than that at 760 Torr.

Figure 12 shows the n-channel in the p^- substrate caused by oxidizing the epitaxial layer, which demonstrates the effect of low pressure epitaxy. The distribution coefficient of arsenic in an Si/SiO_2 system is about 10 (5), the autodoped arsenic atoms in the epitaxial layer accumulate at the interface between silicon dioxide and silicon. Therefore, we can evaluate

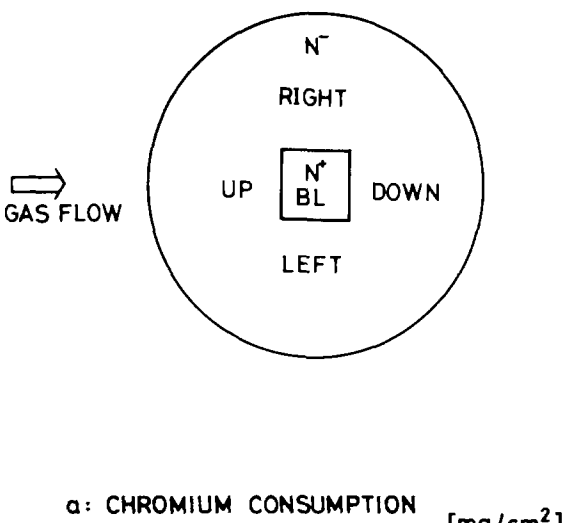

Fig. 9. Wafer for measurements of lateral autodoping

the amount of autodoped impurities by measuring the channel conductance. As indicated in Fig. 12 the channel conductance of the epitaxial layer under an atmospheric pressure is about 5 times larger than that of low pressure epitaxial layer.

The Mechanism of Autodoping

From Fig. 10, it can be recognized that the influence of the gas flow is apparently weaker for low pressure epitaxy. For the epitaxy at an atmospheric pressure, the gas flow decreases lateral autodoping of the epitaxial layer in the upstream position and increases that in the downstream position. This fact is seen in the report by Pogge *et al.* (6). On the contrary, in the case of low-pressure epitaxy, lateral autodoping is apparently not affected by the gas flow, and is controlled only by the diffusion of arsenic atoms in the gas phase. From the direct observation of gas flow patterns in a horizontal epitaxial reactor, it is found that the gas flow pattern becomes more lamellar as the pressure decreases (7, 8). For low pressure epitaxy, we postulate that arsenic atoms diffuse laterally along the substrate surface in a stagnant layer and are hardly affected by the gas flow.

Figure 13 illustrates the schematic figure of the lateral autodoping mechanism. Let us suppose a one-dimensional diffusion model. The concentration of gaseous arsenic at a distance x from the edge of the n^+ buried layer can be denoted by C (x). Then the diffusion of arsenic in a steady state is expressed by the following differential equation

$$D\frac{d^2C}{dx^2} - v_x\frac{dC}{dx} - kC = 0 \qquad [1]$$

where v_x is the velocity of the gas flow, k is a constant, and D is a diffusion constant of arsenic in hydrogen. Using the boundary conditions

$$(x = 0,\ C = C_0) \text{ and } (x \Rightarrow \infty,\ C \Rightarrow 0)$$

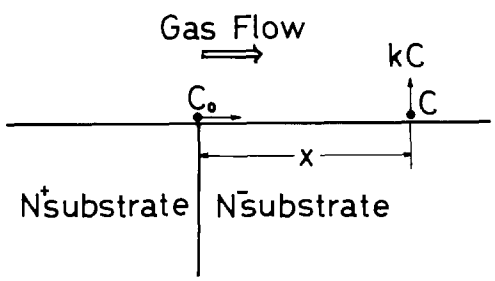

Fig. 13. One-dimensional diffusion model of lateral autodoping

the solution of Eq. [1] is in the following formulas

$$\left.\begin{aligned}&\text{(down stream)}\\ &C = C_0\exp\left(-\frac{v_x + \sqrt{v_x^2 + 4kD}}{2D}x\right)\\ &\text{(up stream)}\\ &C = C_0\exp\left(\frac{v_x - \sqrt{v_x^2 + 4kD}}{2D}x\right)\end{aligned}\right\} \qquad [2]$$

In the case of low pressure epitaxy, it is supposed that the influence of the gas flow can be neglected compared with the diffusion of arsenic atoms, that is, $v_x/D = 0$ and, formulas [2] are modified and reduce to the equation

$$C = C_0\exp\left(-\sqrt{\frac{k}{D}}x\right) \qquad [3]$$

When the transfer ratio of arsenic is m which is independent of pressure, lateral autodoping N is related to x in the formula

$$N = mC = mC_0\exp\left(-\sqrt{\frac{k}{D}}x\right) \qquad [4]$$

The natural logarithm of N varies linearly with the distance x from the n^+ buried layer, and the behavior indicated in Fig. 10 can be explained qualitatively by this one-dimensional diffusion model. Since the temperature gradient above a susceptor at 80 Torr is larger than that at 760 Torr, the buoyancy is greater at a low pressure. In addition, as arsenic atoms are much heavier than hydrogen atoms, arsenic atoms sublimated from the substrate diffuse along the wafer surface. A stagnant layer is therefore formed in low pressure epitaxy, but the thickness of the stagnant layer will be much thinner than that calculated from the experimental results by Eversteyn *et al.* (9).

Summary

Silicon epitaxial layers were grown on heavily doped (As) substrates in a reduced pressure system. Lateral and vertical autodoping was measured by the capacitance and voltage method. The following results were obtained for low pressure epitaxy.

1. Growth rate decreases with decrease of the pressure in a reaction tube.
2. The activation energy is 11 kcal/mole for the epitaxy in 760 Torr and 43 kcal/mole in 80 Torr.
3. The interface between n^+ and n^- substrate hardly moves during epitaxial growth at 1050°C for 5 min.
4. Lateral autodoping near the edge of the n^+ buried layer is in proportion to the pressure.
5. Below 150 Torr, there is little difference in lateral autodoping between the up- and downstream position of the n^+ buried layer.
6. A simple one-dimenstional diffusion model was proposed in order to explain the above results.

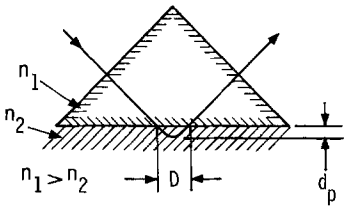
ABSTRACT

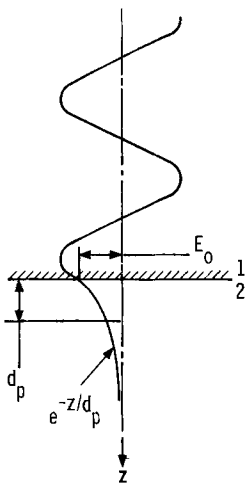
The effects of the ammonia-to-silane ratio, R, during deposition, and of postdeposition heating on chemically bound H in 1000Å silicon-nitride films have been investigated using multiple internal reflection (MIR) spectroscopy. The films were deposited at 700°C with R equal to 10:1, 100:1, and 1000:1 in an Ar carrier gas. Vibrational modes for N-H and Si-H bonded centers show that H is incorporated into the films. The sum of the NH and SiH band intensities (total bound H) increased with R. The SiH band intensity, however, was largest in the 100:1 film. The increase in bound H with R is attributed to an increase in reactive H from NH_3 decomposition in the presence of incompletely bonded Si and N. The decrease in SiH centers when R is increased from 100:1 to 1000:1 is attributed to more complete Si-N bonding. Annealing behavior at 800°C suggests an initial transfer of H from N-H to Si-H bonds in 10:1 and 100:1 films consistent with the presence of incompletely bonded Si. Bonding of implanted H in Si_3N_4 was demonstrated by isotopic substitution of D for H, and a calibration to determine H concentrations from MIR measurements was obtained. Bond energy-limited H loss is suggested to explain an observed mass-independent annealing for implantation-produced NH and ND centers.

Thin film CVD Si_3N_4 is a technologically important material for nonvolatile MNOS (metal/Si_3N_4/SiO_2/Si) memory elements in integrated circuits. Many workers have reported on the electrical characteristics of CVD Si_3N_4, and the electrical properties are known to depend on the flow ratio, R, of NH_3 relative to SiH_4 during deposition (1). Less is known, however, about the structural or chemical compositional changes that accompany changes in R between 10:1 and 1000:1 which represent ratios of primary interest for memory-quality Si_3N_4. It is also important to know the effects of postdeposition heating on the properties of Si_3N_4 because, depending on the particular schedule for integrated circuit fabrication, the nitride may be subjected to postdeposition temperatures which are higher than that for deposition.

As a step toward an understanding of the dependence of chemical composition on the deposition parameters and on postdeposition processing, we have investigated the effects of R and of postdeposition heating upon chemically bound H in CVD Si_3N_4 films. We show that chemically bound H in thin film Si_3N_4 is readily observed by multiple internal reflection (MIR) spectroscopy, and we have used ion implantation to obtain a calibration for the concentration of H. Isotopic substitution of implanted D for H has been used to verify chemical bonding of the implanted species, and to explore the mechanism for H loss from the films caused by heating.



Key words: CVD silicon nitride, internal reflection spectroscopy, hydrogen bonding, nonvolatile memory.



Experimental Details

Si_3N_4 films were deposited on one side of high resistivity Si MIR plates 50 × 20 × 2 mm³ with 45° end faces, and also on 1.5 in. diameter 3 Ω-cm n-type (100) Si wafers. The chemical vapor depositions were carried out at 700°C in a cold-wall horizontal reactor with an rf induction-heated graphite susceptor. The NH_3 was supplied by Air Products with a purity of 99.999+%. The ultrahigh purity (UHP) argon carrier gas and the semiconductor grade SiH_4 at 1% dilution in UHP argon were supplied by Matheson Gas Products. The SiH_4 flow rate and the total flow rates were maintained constant at 5 and 9505 cm³/min, respectively, for depositions with R equal to 10:1, 100:1, and 1000:1. The deposition rate was ~150 Å/min for all films. Thermal annealing of the films was performed with ±5°C temperature control in flowing nitrogen gas.

Index of refraction data were taken at 5461Å on a Gaertner L119 ellipsometer. A complex index of 4.050-0.028i for the Si substrate, with no corrections for a possible 10-15Å native oxide on the Si substrates, was used in determining the index of the Si_3N_4 film from Δ (change in phase) and ψ (arc-tangent of the amplitude ratio factor for polarization normal to and in the plane of incidence) measurements (2). Electrical contact was made to the nitride on the Si wafer by vapor depositing Al dots of 1 mm² through a shadow mask and then sintering at 450°C. The wafers were diced into small chips which were scrubbed onto headers

MULTIPLE INTERNAL REFLECTIONS

Fig. 1. Illustration of the internal reflection technique for obtaining absorption data on thin films.

where the Al dot was wire bonded to a header post. Current measurements at a constant field were made as a function of temperature between 200° and 500°K. The temperature was increased stepwise and allowed to stabilize before each current measurement.

The MIR technique, developed by Harrick (3) and illustrated in Fig. 1, makes it possible to use infrared absorption to measure the vibrational modes for H bound to N and Si in Si_3N_4 with film thicknesses representative of those used in MNOS memory elements. Since the penetration depths, d_p, given according to Eq. [1] of Fig. 1 are significantly greater than the film thickness, the effective thickness is ~3 times the actual thickness, d, according to Eq. [2] and [3] of Fig. 1. The geometry and dimensions of the plate used in the present investigation give 12 internal reflections at the film-covered surface. In addition to the advantage of increased sensitivity compared to conventional infrared absorption, there are no interference effects in MIR. The MIR measurements for the present study were made at room temperature in a nitrogen-purged Perkin Elmer Model 221 spectrophotometer (CaF_2 prism) using a fixed angle MIR accessory in the sample beam.

Hydrogen and deuterium implantations were performed in a vac-ion pumped line of a 300 keV Accelerator Incorporated machine. Ions of 20 keV H_2^+ or D_2^+ were extracted from rf ionized sources selected and scanned across the sample through a beam-defining aperture. Secondary electrons were electrically suppressed, and the ion fluence was obtained by integrating the ion current passing through the aperture. Atomic ion energies of ≤5 keV are needed to locate H or D within the nitride film, whereas the practical lower limit for operation of the accelerator is ~20 keV. Therefore, 20 keV molecular species, which dissociate into 10 keV atomic species on encountering a solid surface were accelerated for the implantation. Implantations were made through 1000Å of Al evaporated onto the Si_3N_4 in order to reduce the energy of the atomic species to 3-4 keV before passing into the Si_3N_4.

Experimental Results and Discussion

Electrical characterization.—Electrical characteristics for Si_3N_4 films deposited for this study of chemically bound H are shown in Fig. 2 to illustrate the large R dependence of the conductance. Current densities, I, at an electric field, E, of 2.86×10^6 V/cm (metal electrode positive) for films deposited with ratios of 10:1, 100:1, and 1000:1 at 700°C are plotted as a function of reciprocal temperature. Near room temperature the current density decreases four orders of magnitude with each order of magnitude increase in R. Thermally activated transport is apparent for all films, particularly at room temperature and above. The slopes of ln

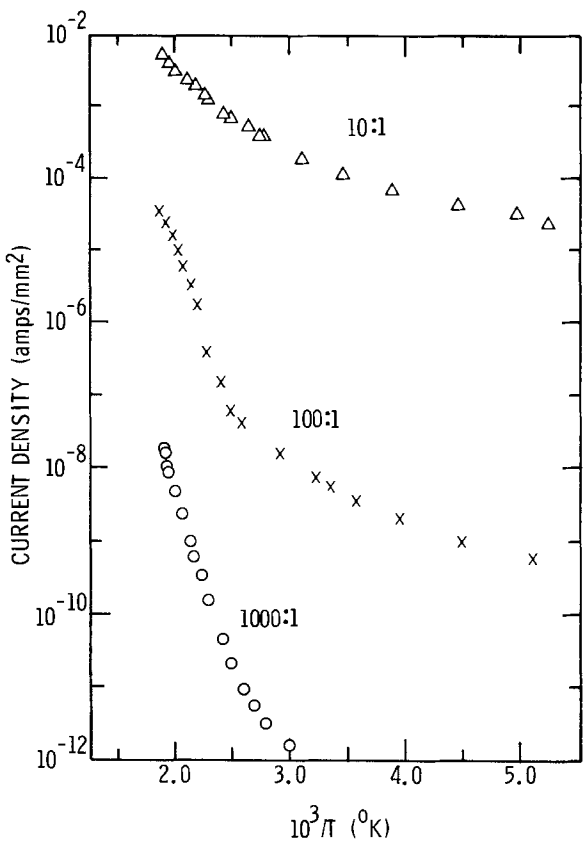

Fig. 2. Current density vs. reciprocal temperature at a constant field of 2.86×10^6 V/cm (metal electrode positive) on nitride films deposited with 10:1, 100:1, and 1000:1 NH_3/SiH_4 ratios.

current *vs.* reciprocal temperature for the 100:1 and 1000:1 films are approximately 1 eV in the region above room temperature, which implies a trap depth of ~1.5 eV when including the dielectric permittivity according to the Poole-Frenkel mechanism (4). Likewise, the smaller slope of ~0.3 eV for the 10:1 film gives an activation energy of ~0.8 eV. Shallow levels near 0.8 eV have been previously observed and attributed to Si islands (5). A 1.5 eV level has also been reported previously (5), but the centers responsible for the 1.5 eV level have not been identified.

Chemically bound hydrogen in as-deposited films.— Plotted in Fig. 3 are the optical densities measured by the MIR technique between 4000 and 2000 cm^{-1} (wave numbers) for 1000Å silicon nitride films deposited with ratios of 10:1, 100:1, and 1000:1 at 700°C. The traces are displaced relative to each other for clarity. The results show vibrational modes associated with Si-H (2160 cm^{-1}) and N-H (3335 cm^{-1}) bonding for all films (6), but the intensities of the absorption bands are dependent on R. Although searched for, there was no evidence of a band near 4160 cm^{-1} which would indicate H_2 in the films (7).

Optical densities for the peaks of the NH and SiH bands as a function of R are plotted in Fig. 4. The NH band increases with increasing R; whereas, the SiH band has a maximum intensity in the 100:1 film. Since the SiH_4 flow rate is held constant for all R, increased concentrations of NH_3 decomposition products will be the primary effect of increasing R. An increase in R should, therefore, give more complete bonding of Si to N, and give a higher probability for H bonding on remaining dangling and distorted bonds. But both NH and SiH bands are observed to increase for R equal to 100:1 relative to 10:1. Consequently, we suggest that the amount of H bound to either Si or N is limited in these two films by H available in the gaseous atmosphere. In contrast, the SiH band in the 1000:1 film is smaller than in the 10:1 and 100:1 films. This decrease in the SiH band is attributed to more complete bonding of Si to N. Simultaneously, the increased NH_3 flow causes an increase in NH bonding in the film.

The refractive index for these films decreases with increasing R as shown in Fig. 4. A high refractive index for low R has been attributed to excess Si in the films (8). If the fractional increase in refractive index is assumed to be proportional to fractional Si-Si bonding, with the refractive index for 100% Si-Si bonding taken equal to 4.05, then there is an estimated 1.5% Si-Si bonding in the 100:1 film and 7% in the 10:1 film. Backscattering measurements reported by Gyulai *et al.* (9) indicated excess Si of this magnitude and higher in films with a refractive index of 2.2. The larger SiH bands in 10:1 and 100:1 films than in the 1000:1 film discussed above is in accord with excess Si in the lower R films.

Heating above deposition temperature.—The effects of heating above the deposition temperature on chemically trapped H are shown in Fig. 5 through 7 for films deposited with R equal to 1000:1, 100:1, and 10:1, respectively. For clarity, uncertainties in the optical density are shown for the SiH band only; similar error bars apply to the NH band.

Results from isothermal annealing at 800°, 850°, and 900°C on the NH and SiH bands in the 1000:1 film are shown in Fig. 5. The data are plotted as a function of $\sqrt{\text{time}}$ because it has long been known that Si_3N_4 is an effective barrier for H diffusion at 600°C and below (10), and $\sqrt{\text{time}}$ is a commonly observed dependence for diffusion-limited loss from a medium. There is an initial rapid decrease in both the SiH and NH bands at 800°C where 0.33 of the NH band and 0.66 of the SiH band anneal out in the first 100 min. There is a further slow decrease in the bands at 850°C where the SiH band becomes unresolvable, followed by rapid decrease in the NH band at 900°C.

Annealing results for the 100:1 film in Fig. 6 show some similarities to those for the 1000:1 film, but also show a marked difference in the annealing of the SiH band. The SiH band in the 100:1 film exhibits an initial tendency to increase at 800°C and it then remains

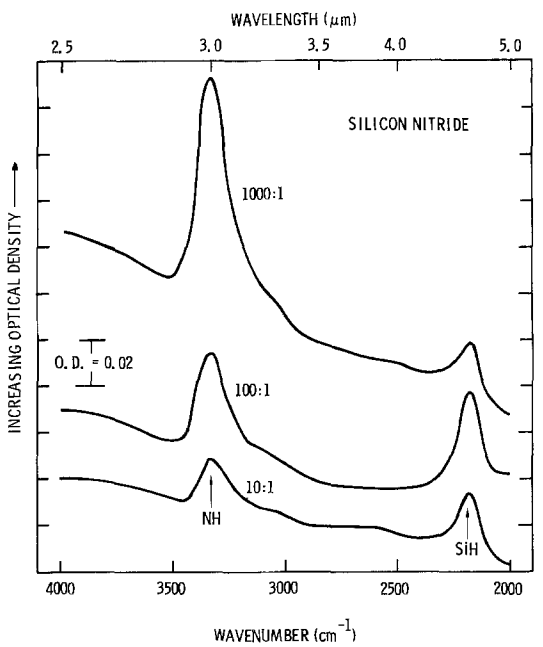

Fig. 3. Optical density vs. wave number showing NH and SiH absorption in 1000Å silicon nitride films deposited with NH_3/SiH_4 ratios of 10:1, 100:1, and 1000:1. Traces displaced relative to each other to provide clarity.

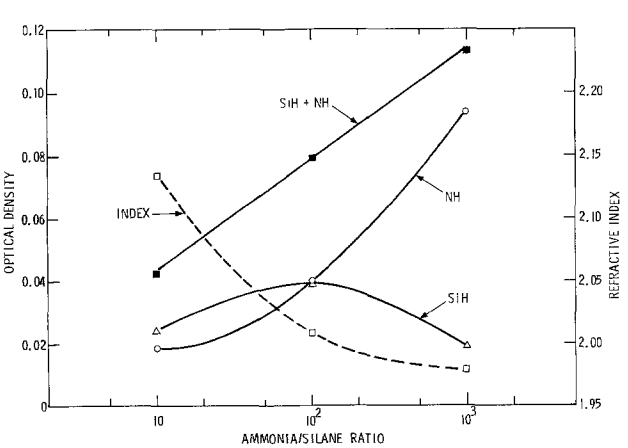

Fig. 4. Optical density for peaks of the NH and SiH bands and also refractive index as a function of NH_3/SiH_4 ratio.

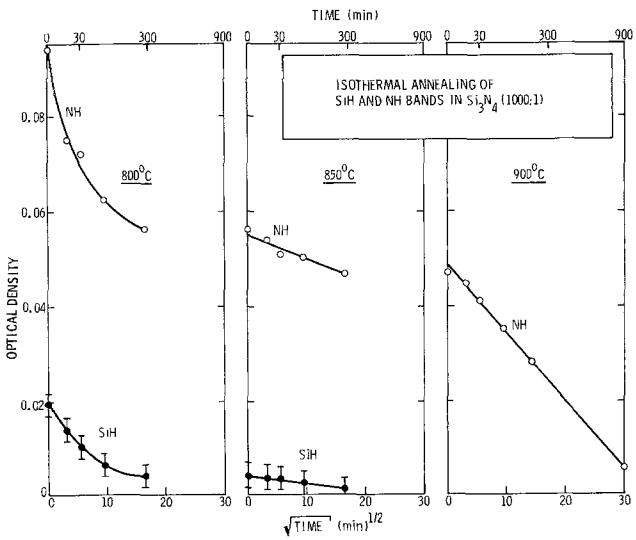

Fig. 5. Annealing behavior for the NH and SiH bands in the 1000:1 film.

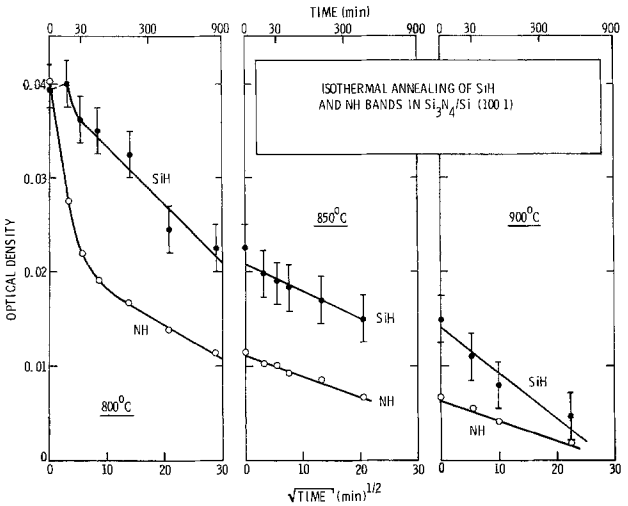

Fig. 6. Annealing behavior for the NH and SiH bands in the 100:1 film.

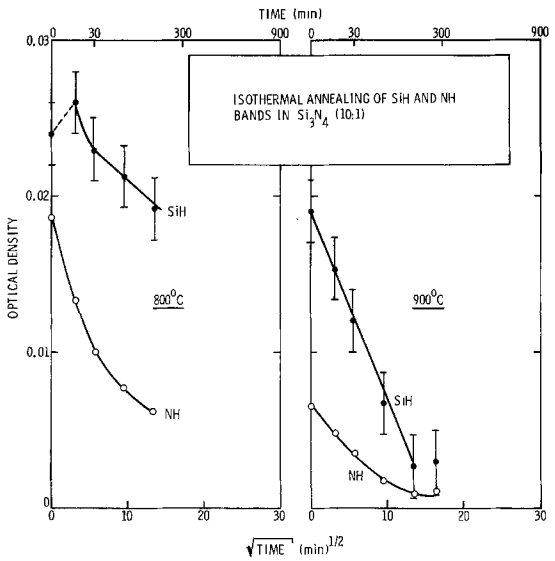

Fig. 7. Annealing behavior for the NH and SiH bands in the 10:1 film.

larger in magnitude than the NH band throughout the subsequent annealing. A more subtle difference occurs in the fractional anneal of the NH band which is 0.55 in the first 100 min in the 100:1 film compared to 0.33 of the NH band in the 1000:1 film. The *R*-dependent trend in the annealing behavior is continued in the 10:1 film as shown in Fig. 7. The 10:1 film again shows an initial increase in the SiH band intensity, and a large fractional decrease (0.60) in the NH band for the first 100 min at 800°C. These annealing results are additional evidence for incompletely bonded Si in the 10:1 and 100:1 films such that some transfer of H from N-H to Si-H bonds occurs initially at 800°C.

Bonding of implanted hydrogen and deuterium in films.—In order to obtain a calibration to determine the concentration of chemically bound H from an MIR measurement, 2×10^{16} H atoms/cm^2 were implanted through 1000Å of Al and into the 1000:1 film. Prior to implantation the film was heated at 975°C to reduce the NH band below the limit of detectability, and Al was vapor deposited on the Si_3N_4. After implantation the Al was removed and *IR* spectra were recorded as a function of annealing. The sequence for the same film was then repeated for 2×10^{16} D atoms/cm^2. Optical densities measured after implantation and heating for 10 min at the initial deposition temperature of 700°C are plotted in Fig. 8. The ratio of the frequencies 3330/2455 =

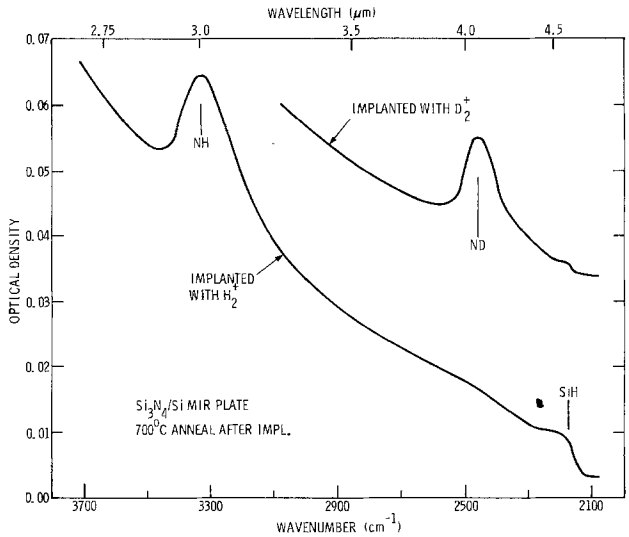

Fig. 8. NH and ND absorption bands produced by implantation of 2×10^{16} hydrogen or deuterium atoms followed by 10 min at 700°C

1.356 for the major bands observed after H and D implantation is approximately that expected for isotopic substitution of D for H in the NH molecule (7)

$$\nu_{NH}/\nu_{ND} = \sqrt{\mu_{ND}/\mu_{NH}} = 1.369$$

where μ_{NH} and μ_{ND} are the reduced masses for the atoms in the molecule according to

$$\frac{1}{\mu_{NH}} = \frac{1}{m_N} + \frac{1}{m_H}, \text{ and } \frac{1}{\mu_{ND}} = \frac{1}{m_N} + \frac{1}{m_D}$$

A similar small difference between the observed frequency shift and that expected for a free diatomic molecule was also observed for SiH and SiD band formation by ion implantation into Si (11). Consequently, the shift in vibrational frequency caused by isotopic substitution of D for H confirms chemical bonding of implanted H in Si_3N_4. The intensity of the SiH band after H implantation is ~0.2 that of the NH band. This intensity ratio is nearly equal to the ratio after deposition which suggests rebonding of implanted H at distorted or dangling bonds where H was initially bonded in the as-deposited film.

Having demontrated chemical bonding of implanted H, a calibration to relate the NH center concentration, C_{NH}, to the absorption coefficient, α, is obtained by assigning 80% of the implanted H to NH centers and 20% to SiH centers in the 1000:1 film. Since annealing of implantation-induced disorder is known to occur for temperatures $\lesssim$ 800°C (12), absorption data measured after 10 min at 800°C where the intensity of the NH band reached a maximum (see Fig. 9) was used in determining the proportionality factor between α and C_{NH}. Taking 12 internal reflections, and an effective thickness of 3*d*, the absorption cross section per NH center is

$$\sigma = \alpha/C_{NH} = \frac{\alpha d_T/d_T}{0.8(\phi)/d} = \frac{0.046/36d}{0.8(\phi)/d}$$

$$= 8 \times 10^{-20} \text{ cm}^2$$

where $d_T = 3 \cdot 12 \cdot d$ cm, $\phi = 2 \times 10^{16}$ cm^{-2} and $\alpha d_T = 0.046$. Note that *d* cancels in the above equation to make the determination of σ independent of the thickness. The cross section obtained here is in good accord with that per SiH center produced by H implantation into a thick (4500Å) oxynitride (13), and also with that per SiH center produced by H implantation into Si (11).

Annealing of implanted films.—Identification of the controlling mechanism for H loss is important since it will determine the depth distribution of chemically bound H, particularly in partially annealed films. For

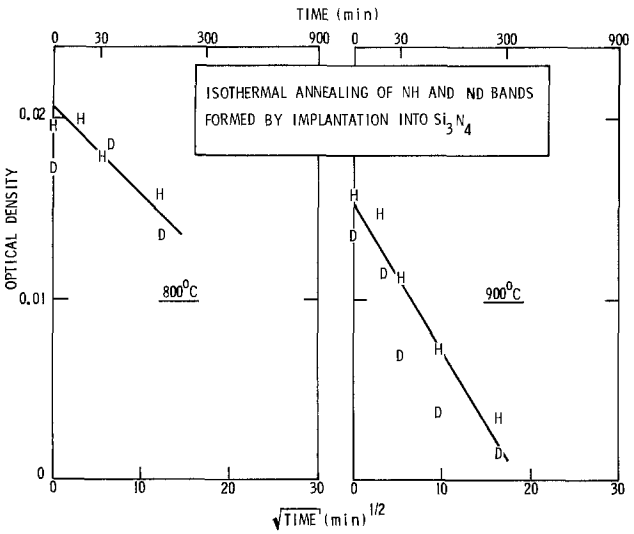

Fig. 9. Annealing behavior for implanted NH and ND bands at 800° and 900°C. H represents the NH band and D represents the ND band.

example, a diffusion-limited loss will leave a higher concentration in the center of the film than near the surfaces where H escapes, whereas bond energy-limited loss will maintain a flat profile.

Plotting the annealing results as a function of $\sqrt{\text{time}}$ (see Fig. 5 through 7 and 9) is a preliminary check for diffusion-limited behavior. However, $\sqrt{\text{time}}$ is not necessarily a valid representation of loss from a thin plane sheet (14). A comparison of NH and ND annealing is another approach for investigating the loss mechanism (15). Assuming random diffusion and no cooperative effect of the surrounding lattice, the diffusion coefficient, θ, is dependent on the jump frequency, and hence upon the isotopic mass, analogous to the vibrational frequency dependence, $\theta_H/\theta_D \approx \sqrt{m_D/m_H}$ (15). The close correspondence between the annealing of NH and ND bands shown in Fig. 9 does not support a diffusion-limited loss of H from Si_3N_4. Therefore, H loss is attributed to a bond energy-limited mechanism since the dissociation energy is only weakly dependent on the isotopic mass (16).

Summary and Conclusions

This study demonstrates that multiple internal reflection spectroscopy readily provides a measure of N-H and Si-H bonding in Si_3N_4 films which have thicknesses comparable of those for nonvolatile memory elements. Hydrogen, which is a decomposition product of the NH_3 and SiH_4 gases used for deposition, is observed in the films by way of the vibrational modes for N-H and Si-H bonded centers. Concentrations of NH and SiH centers are shown to depend on the NH_3/SiH_4 ratio, R, during deposition at 700°C.

The observed effects of R on N-H and Si-H bonding are attributed to a simultaneous increase in both H and N with increasing R. For depositions with $R \leq 100:1$ the results are interpreted to be representative of Si_3N_4 where the concentration of dangling and distorted Si and N bonds exceed the concentrations of observed NH and SiH centers such that both the NH and SiH centers increase with R. Refractive index measurements suggest that Si-Si bonds are also present in films for $R \leq 100:1$. Results for R equal to 1000:1 are interpreted to be representative of a film with nearly complete bonding of Si to N, hence small concentrations of Si-Si and Si-H bonding.

A loss of bound hydrogen from Si_3N_4, and R-dependent changes in the relative concentrations of NH and SiH centers occur on heating at temperatures between 800° and 900°C. The R-dependent changes are consistent with an excess of incompletely bonded Si in 10:1 and 100:1 film. Dissociation energy rather than diffusion is suggested as the limiting mechanism for H loss from Si_3N_4 because the loss during annealing is independent of isotopic mass for ion implantation-induced NH and ND centers. Ion implantation of hydrogen and deuterium demonstrated that these implanted species are bonded into Si_3N_4, and intensities for ion-induced absorption bands give a conversion factor to determine the concentration of chemically bound H from optical absorption measurements.

The electrical conductance of films deposited for this investigation also shows a strong dependence on R, but additional studies are required to separate H-bonding effects on film conductance from effects of Si-Si bonding.

The Dominant Recombination Centers in Electron-Irradiated Semiconductors Devices

A. O. Evwaraye and B. J. Baliga*

General Electric Corporate Research and Development, Schenectady, New York 12309

ABSTRACT

The defect states introduced by electron irradiation of silicon and the effects these defect levels have on low level minority carrier lifetimes have been studied by the capacitance transient spectroscopy and reverse recovery techniques. The E3 defect level (E_c — 0.41 eV) is the principal recombination center that controls lifetime following room temperature irradiation. As the E3 defect level anneals, however, a secondary defect level E4 emerges which then becomes the dominant recombination center. This defect level E4 is related to the electron-induced defects since it is not produced in unirradiated samples. The energy levels and capture cross sections of these electron-induced defects are reported.

In the past several years, considerable effort has been made to locate the principal recombination centers induced by either electron or gamma irradiation of silicon. The microscopic structures of these radiation-induced defects have been studied in detail with EPR by Watkins and Corbett (1-3). The dominant defect responsible for the control of minority carrier lifetime is, however, still a source of controversy in the literature. Table I summarizes the published results and the results of this work described below.

Wertheim (4, 5), using Hall effect, conductivity, and lifetime measurement techniques in his studies of electron-irradiated n-type silicon, reported a level at E_v + 0.27 eV to be the principal recombination center. He found the room temperature cross sections for this level to be 8×10^{-13} cm^2 and 9×10^{-15} cm^2 for holes and electrons, respectively. Galkin *et al.* (6), on the other hand, reported that the dominant recombination center is the level at E_c — 0.16 eV. This is presumably the A-center (oxygen-vacancy complex). They reported the room temperature cross sections for this defect level to be 4×10^{-14} cm^2 and 1.10×10^{-15} cm^2 for holes and electrons, respectively. Baicker, in his studies of electron-irradiated n-type silicon, further confused the issue (7). The results of measurements on three of his four samples agree with Galkin's conclusions, while the results on the fourth sample agree with Wertheim's measurements. Both Carter (8) and Bielle-Daspet (9) have independently reported that the principal recombination center is located at E_c — 0.17 eV. Berman *et al.* (10), investigating defects in silicon p$^+$-n junctions irradiated with gamma quanta, concluded that recombination occurs mainly at the A-centers. More recently, Rai-Choudhury *et al.* (11) concluded that the dominant center is located at E_v + 0.26 eV.

There has recently been an increased interest in the use of electron irradiation to control the recovery characteristics of power rectifiers and thyristors (12). Solar cell degradation in outer space due to radiation has also been correlated to the lifetime variation (13). Therefore, a precise determination of the principal recombination center in irradiated n-type silicon is a necessity.

In this study, the transient capacitance technique (14, 15) was used to monitor the defect concentrations as well as other changes in the spectrum as the samples were annealed. The deep level transient spectroscopy technique allows one to study each specific defect in the defect spectrum. The low level minority carrier lifetime, measured by the reverse recovery technique (16), was also monitored during the annealing process. This allowed correlation of the lifetime variation with a specific defect in the defect spectrum. Our results show that the dominant recombination center is the single negative charge state of the divacancy (17) located at E_c — 0.41 eV. During these measurements it was observed that upon annealing of this defect level the minority carrier lifetime does not recover to the preirradiation value. This is due to the emergence of a secondary defect level, E4, located at E_c — 0.35 eV, as the E3 defect level anneals out.

Table I. Summary of published results of the dominant recombination center in irradiated n-type silicon

Dominant recombination center	Measuring technique	Ref.
E_v + 0.27 eV	Hall effect	(5)
E_c — 0.16 eV	Hall effect and lifetime measurements	(6)
E_c — 0.16 eV E_v + 0.27 eV	Minority-carrier lifetime measurements	(7)
E_c — 0.17 eV	Hall effect measurements	(8)
E_c — 0.17 eV	Minority-carrier lifetime measurements	(9)
E_c — 0.17 eV	TSCAP	(10)
E_v + 0.26 eV	TSC	(11)
E_c — 0.41 eV (E3) E_c — 0.36 eV (E4)	DLTS and lifetime measurements	This work

Experimental Procedure and Results

The silicon diodes used in these studies (p$^+$nn$^+$) were fabricated from float-zone, dislocation-free, n-type silicon substrates normally used in the fabrication of commercial high voltage rectifiers and thyristors. The resistivity of the starting material was 25-35 Ω/cm. The boron-doped p$^+$ layer with a surface concentration of 10^{19} cm^{-3} and the phosphorus-doped n$^+$ layer with a surface concentration of 10^{21} cm^{-3} were obtained using conventional diffusion processing. No special care was taken to avoid the introduction of oxygen into the devices during the p$^+$ and n$^+$ diffusion cycles. These devices were then mounted on a cooling block and irradiated with 1.5 MeV electron beams to a flux of 2.8×10^{14} e/cm^2. The decrease in lifetime caused by the electron bombardment was measured by the reverse recovery technique (16). In this method, the storage time was measured for a step recovery of the diode with a forward-to-reverse current ratio of unity. These measurements were conducted over a wide range of current levels. The current level was decreased until the storage time became independent of current. The low level minority

* Electrochemical Society Active Member.
Key words: electron-induced defects, dominant recombination center, electron irradiation, gamma irradiation, defect levels.

carrier lifetime was then computed from this storage time using the relationship

$$\tau \simeq 4.38\,\tau_{sec} \qquad [1]$$

where τ is the minority carrier lifetime and τ_{sec} is the measured storage time. It must be noted that this relationship is valid only for diodes with base widths greater than twice the diffusion length. For the diodes used in this study lifetimes as high as 20 μsec could be measured without correcting for the base width. The data reported in this paper have been confined to lifetime values below this limit.

The defect spectrum was obtained by the technique of deep level transient spectroscopy (DLTS) (14, 15). Figure 1 shows the defect spectrum resulting from the 1.5 MeV irradiation. Three electron traps (E1, E2, and E3) and two hole traps (H1 and H2) were induced by radiation. The average value of the low level minority carrier lifetime immediately after room temperature irradiation was approximately 1 μsec.

The E1 defect level is the well-characterized A-center (O-V pair) located at E_c — 0.17 eV. The E2 and E3 defect levels located at E_c — 0.23 eV and at E_c — 0.41 eV, respectively, have been identified as the double negative ($[V \cdot V]^=$) and single negative ($[V \cdot V]^-$) charge state of the divacancy (17). The divacancy is known to introduce three energy levels in the bandgap (2, 18). Therefore, the presence of the divacancy would be detected by observing three activation energies with an identical introduction rate and the same annealing behavior. The microscopic structure of the H2 defect level is not known but it does not have the same introduction rate nor the same annealing behavior as E2 and E3 so that it cannot be the single positive charge state ($[V \cdot V]^+$) of the divacancy. There has been speculation that H2 is either an alternate charge state of the A-center or an interstitial related defect (19). The relationship between the A-center and H2 level is under investigation.

The H1 defect level is probably the single positive ($[V \cdot V]^+$) charge state of the divacancy. This identification is purely speculative since it was extremely difficult to follow the annealing behavior of H1 or its introduction rate because of the large concentration of H2, which tends to dominate the spectrum when minority carriers are introduced into the depletion region. If H2 is indeed a different charge state of the A-center, the use of Schottky diodes and ion-implanted junctions will reduce the concentration of both E1 and H2 defect levels. This is being tried at present.

The annealing of the samples was performed in a furnace that has been described in Ref. (17). The DLTS spectrum was recorded after each annealing step at a fixed temperature and the low level minority carrier lifetime was measured after each annealing step. From previous studies (17) it is known that the E2 and E3 levels do not significantly anneal below 280°C. So the annealing of the samples in this study was carried out at 300°, 350°, 370°, 380°, and 395°C.

Figure 2 shows the DLTS spectrum of a device after it has been annealed for 60 min at 300°C. The E3 defect level has annealed to 65% of its original value and the emergence of the E4 defect level is clearly visible. The low level minority carrier lifetime was found to increase from 1 μsec following irradiation to 1.40 μsec after 60 min of annealing at 300°C. It is seen from this figure that no other (besides E4) secondary defects appeared in the spectrum at this temperature.

Figure 3 shows the normalized DLTS signal for the E2, E3, and E4 defect levels as a function of the annealing time at 300°C. The variation of the inverse of the low level minority carrier lifetime as a function of annealing time is also shown. The accuracy of these measurements is better than ±5%. It is not surprising that the annealing of defect levels E2 and E3 follows the same simple exponential form that was previously reported (17). It is interesting to note that $1/\tau$ follows this same exponential form up to 130 min and thereafter remains essentially constant. The defect level H2 is not shown in this plot because

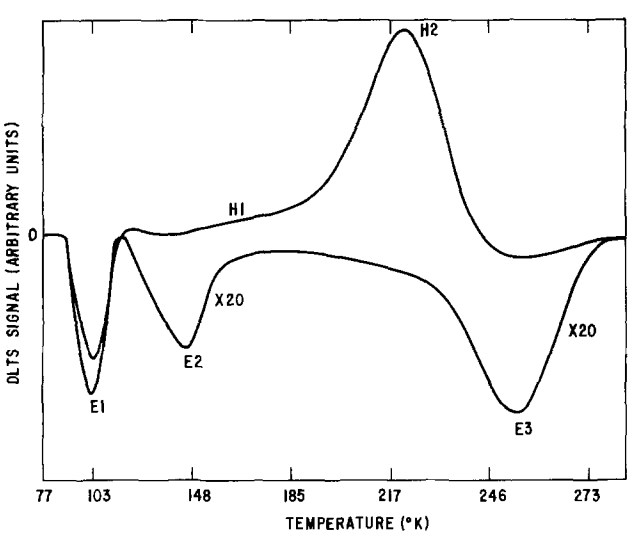

Fig. 1. DLTS spectrum of 1.5 MeV electron irradiation-induced defects in n-type silicon. E1-E3 are electron traps; H1 and H2 are hole traps.

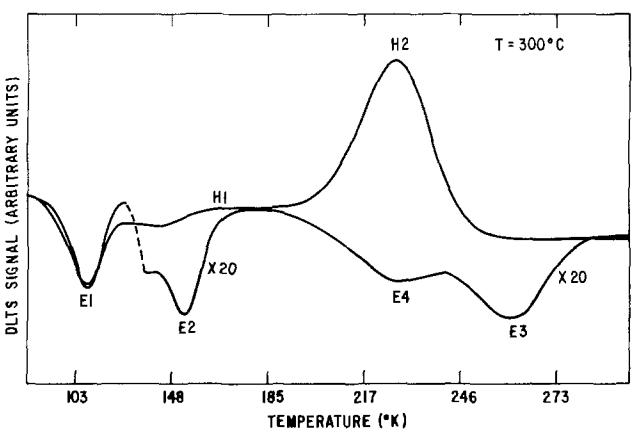

Fig. 2. DLTS spectrum of an electron-irradiated device that has been annealed at 300°C for 60 min. Note the emergence of a secondary defect E4.

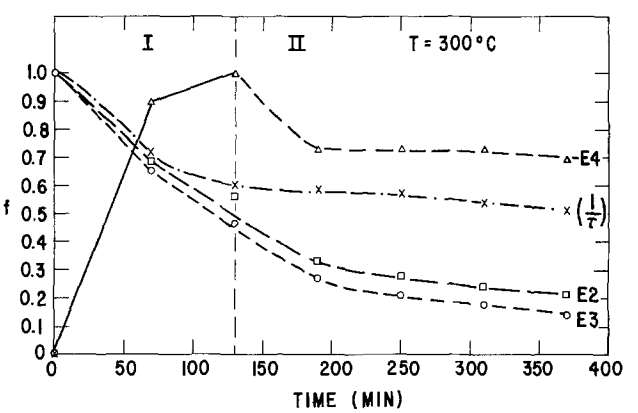

Fig. 3. The variation of the normalized concentrations of the defects E2, E3, and E4 as a function of annealing time at 300°C. Also shown is the variation of $1/\tau$ vs. annealing time. Note the two sections of the plot in which $1/\tau$ has two distinct behaviors.

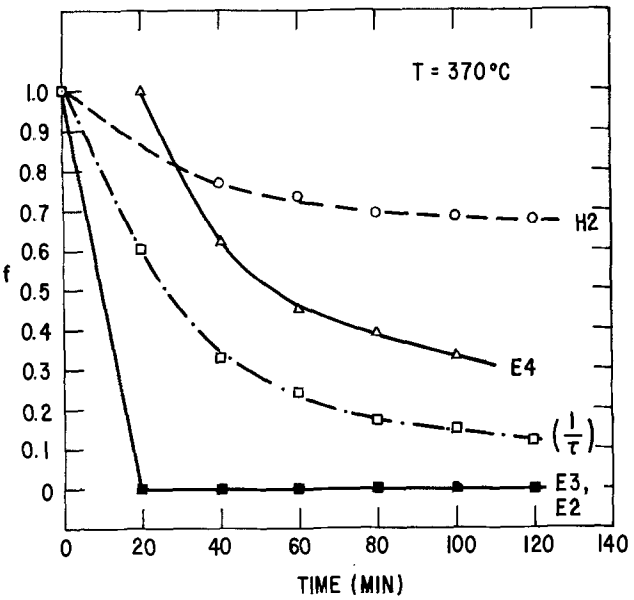

Fig. 4. The variation of the normalized concentrations of the defects E4 and H2 and the variation of the normalized $1/\tau$ as a function of annealing time at 370°C. Note that the defect levels E2 and E3 have completely annealed out after less than 20 min at this temperature.

this defect shows no measurable annealing at 300°C for these annealing times.

Figure 4 shows a plot analogous to the plot of Fig. 3 except that in Fig. 4 E3 and E2 have annealed out completely after 20 min at 370°C. It is seen from this figure that the defect level H2 is annealing but at a slower rate than E4. The variation of $1/\tau$ follows the same exponential form as the defect level E4. This suggests a relationship between the minority carrier lifetime and the defect level E4.

The electron capture cross section at E4 was determined by the usual technique of varying the majority carrier pulse duration. The electron capture cross section at E4 (σ_n^{E4}) is 4×10^{-16} cm^2, while σ_n^{E3} and σ_n^{E2} are 1.62×10^{-16} cm^2 and 0.6×10^{-16} cm^2, respectively (17).

The lifetime connected to the recombination centers produced by electron irradiation is usually expressed as

$$\frac{1}{\tau} = \frac{1}{\tau_o} + K\phi \qquad [2]$$

where τ_o is the preirradiation value of the lifetime due to the recombination centers initially present after fabrication, ϕ is the integrated electron flux, and K is the radiation damage coefficient. τ_o for most of the devices was 20 μsec and τ is about 1 μsec following room temperature irradiation to a flux of 2.8×10^{14} e/cm^2. These give a K value of 3.4×10^{-15} cm^2/e · μsec. It is realized that the radiation damage coefficient K is usually obtained from the plot of $1/\tau$ *vs.* Φ since K depends upon many variables such as the introduction rate of the recombination center (N_{TT}/Φ), the injection level, the location of the recombination center E_t, and the capture cross sections. However, the value of K obtained here agrees quite well with recent published values by Rai-Choudhury *et al.* (11). This seems to imply that in the two studies the same defect is controlling the minority carrier lifetime.

Discussion

The low level lifetime τ is given by

$$\tau = \tau_{po}\left[1 + \exp\left(\frac{E_t - E_F}{kT}\right)\right] + \tau_{no}\exp\left[\frac{2E_i - E_t - E_F}{kT}\right] \qquad [3]$$

where τ_{po} and τ_{no} are the minority carrier lifetimes in heavily doped n- and p-type silicon, respectively; E_t, E_F, and E_i are the positions of the trap level, Fermi level, and intrinsic level, respectively; k is Boltzmann's constant, and T is the absolute temperature. Substituting

$$\tau_{po} = \frac{1}{N_T <v>_p \sigma_p} \quad \text{and} \quad \tau_{no} = \frac{1}{N_T <v>_n \sigma_n} \qquad [4]$$

where N_T is the density of the recombination center, $<v>$ is the thermal velocity of the carriers, and σ the capture cross section, in Eq. [3] gives

$$\tau = \frac{1}{N_T}\frac{1}{<v>_p \sigma_p}\left[1 + \exp\left(\frac{E_t - E_F}{kT}\right)\right] + \frac{1}{<v>_n \sigma_n}\exp\left(\frac{2E_i - E_t - E_F}{kT}\right) = \frac{C}{N_T} \qquad [5]$$

where C is a constant at any fixed measurement temperature and is independent of the trap density. Thus, the low level lifetime is proportional to the reciprocal of the trap density during the annealing of a single recombination center.

From previous studies (17) and Fig. 3 we know that the annealing of the defect level E3 exhibits first-order kinetics and fits a simple exponential expression of the form

$$N_T(t) = N_T(o)e^{-t/R} \qquad [6]$$

where $1/R$ is the annealing rate of the defect. Since $1/\tau$ is proportional to N_T, then

$$1/\tau \propto e^{-t/R}$$

if N_T is the concentration of the recombination center responsible for controlling the minority lifetime.

The variation of $1/\tau$ at 300°C as a function of annealing time can be divided into two sections. The dividing line is at $t = 130$ min. In the first section $o \leq t \leq 130$ min, $1/\tau$ has the same exponential variation as E2 and E3. Since E2 is much more shallow ($E_c - 0.23$ eV) than E3 ($E_c - 0.41$ eV) and has a smaller capture cross section for electrons, it can be concluded that E3 is the dominant recombination center in Section I. It is instructive to note that in this section the defect level E4 is growing to its maximum concentration. In Section II of Fig. 3 ($130 \leq t \leq 400$ min), $1/\tau$ deviates markedly from its exponential behavior of Section I to a very little variation as a function of annealing time. At the same time the defect level E4 shows as much variation as $1/\tau$, which suggests that the defect level E3 is no longer the dominant recombination center and that E4 now controls the lifetime.

Figure 4 clearly demonstrates that the defect level E4 is the dominant recombination center after the E3 level has annealed out. Here the defect level E4 has the same exponential behavior as $1/\tau$. It is also seen from this figure that 68% of the original defect level H2 is unannealed after 120 min at 370°C, while E2 and E3 are completely annealed out after less than 20 min at this temperature. This allows the conclusion that H2 cannot be the single positive $[(V \cdot V)^+]$ charge state of the divacancy, and it not determining the lifetime.

The defect level E4 has an electron capture cross section comparable to σ_n^{E3}; it is probably as effective a recombination center as E3. It is important to point out that E4 is not formed in unirradiated devices that were annealed at these temperatures and is observed only in electron-irradiated devices, *i.e.*, the E4 defect is definitely related to the electron-induced defects.

The fact that we obtained approximately the same K value as Rai-Choudhury *et al.* (11) indicates that the same center is controlling minority lifetimes in both cases. Our results, however, do not support their

conclusion that the defect at $E_t = 0.26$ eV is the dominant recombination center. Further, our experimental results also disagree with the conclusions of Berman *et al.* and Galkin *et al.* that the A-center is the dominant recombination center. The A-center (O-V pair) is quite shallow ($E_c - 0.17$ eV) and for it to be the dominant recombination center the Fermi level would have to be above it so that it is always filled with electrons. This could conceivably happen in very heavily doped samples where the Fermi level is locked at the level due to the shallow dopants. In lightly doped samples such as the ones used in this study and those used by Berman and Galkin ($N_D \approx 10^{14}$ cm^{-3}) and like wafers used for device fabrication, the Fermi level is well below the A-center and it is usually empty. This requires that it capture electrons from the conduction band and holes from the valence band (which is 0.93 eV away). Unless the hole capture cross section is very large ($\approx 10^{-12}$ cm^2), which is highly unlikely, this center will act more like a trapping center for electrons than as a recombination center. Further, our annealing data show no correlation between the lifetime and the concentration of the A-center.

As pointed out earlier, these studies were done using 20-35 Ω/cm float-zone phosphorous-doped silicon irradiated with 1.5 MeV electrons. We have observed three electron traps E1 ($E_c - 0.17$ eV), E2 ($E_c - 0.21$ eV), and E3 ($E_c - 0.4$ eV) and two hole traps H1 ($E_v + 0.28$ eV) and H2 ($E_v + 0.42$ eV). Defect levels produced by electron irradiation of phosphorous-doped silicon with energy ranging from 0.7-10 MeV have been reported (3, 17, 19). It has been found that the same defect levels are produced over this energy range (0.7-10 MeV). In low resistivity phosphorous-doped silicon, an additional defect center due to phosphorous vacancy pairs is also observed (20, 21). However, at resistivity above 5 Ω/cm the divacancy dominates (*i.e.*, the concentration of the E-center is less than 10% of the divacancy). In the case of Czochralski-grown crystals, the same defect levels are observed with a higher concentration for the E1 ($E_c - 0.17$ eV) defect level. Since this level is much shallower than the E3 ($E_c - 0.41$ eV) defect level, we believe that the E3 defect level is also dominant in Czochralski-grown silicon. We conclude, therefore, that our results are applicable to a wide range of irradiation energy and phosphorous concentration.

Summary

We have studied the annealing behavior of the E2 and E3 defect levels as well as the variation in minority lifetimes at various temperatures; 300°, 350°, 370°, and 395°C. The dominant recombination center immediately after room temperature irradiation is the defect level E3 which has been identified as the single negative [$(V \cdot V)^-$] charge state of the divacancy. As E3 anneals out, however, a secondary defect E4 appears in the spectrum. This secondary defect then controls the minority lifetime in the n-type silicon. Our results clearly demonstrate that the dominant recombination center in high purity n-type silicon is neither the A-center (O-V pair) nor the defect level located at $E_v + 0.27$ eV, as has been assumed in the past.

Tapered Windows in SiO_2: The Effect of NH_4F:HF Dilution and Etching Temperature

G. I. Parisi,* S. E. Haszko, and G. A. Rozgonyi*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Etching of windows in thermally grown silicon dioxide to achieve an approximately 45° taper edge profile has been empirically optimized using NH_4F/HF compositions and etching bath temperatures. Steeper slopes or much shallower tapers are obtainable by suitable adjustments of these two experimental parameters. The mechanism by which tapering occurs may best be described as a controlled separation of the photoresist/oxide interface which relates the lateral etch rate to the bulk etch rate. Depending on etching conditions, each beveled window edge consists of two or three distinct regions which comprise the final shape of the sloping taper. The dissolution reaction in all instances was found to be activation controlled with an apparent activation energy of 9.9 kcal/mole. Curves of etch rates as a function of temperature and HF molarity are presented and a quantitative relationship for etch rate in terms of these two parameters is given.

It has recently been shown (1-5) that dilute solutions of HF in NH_4F will produce tapered steps at the edges of windows in both thermally grown and chemically deposited SiO_2. The occurrence of a tapered step, or ramp, in place of a sharp step, or cliff, depends on the relative etch rates of the bulk oxide and the rate, be it enhanced or suppressed, at the oxide/photoresist interface. Several schemes for artificially enhancing the etch rate of the top portion of a given oxide have been reported (6-8). However, since a simple dilution of HF with NH_4F was known to produce shallow tapers it was decided to empirically optimize the etching phenomena using only two variables, etching bath temperature and NH_4F:HF concentration. In this way only the etching bath would be adjusted and the oxide materials processing would remain unchanged.

The resulting taper desired was set at ~45° (a 1:1 ramp slope) with a bulk oxide etching rate of ~1000 Å/min. It was also anticipated that a systematic study of the etching results would provide some insight into the mechanisms controlling the variable etching rates in the thickness and interfacial directions.

Experimental Procedures

Experiments were performed on thermally grown oxides of nominally 10,000Å thickness that were formed in wet oxygen at 1050°C. Kodak 747 microneg photoresist was used to generate a pattern having windows ranging in size from 8 to 40 microns. Some work was also done with Waycoat IC-III photoresist. The etchant solutions used consisted of 49% HF diluted with varying amounts of 40% by weight aqueous solutions of NH_4F. The etchant compositions ranged from 6.7:1 to 30:1 and are expressed as the volume ratios of the NH_4F solution to the HF solution. Etching solution temperatures were varied between 25° and 55°C after stabilization in a controlled temperature water bath. The volume of etchant was deliberately made large (approximately 800 ml) in order to (*i*) insure accurate composition that might otherwise not be achieved when measuring small liquid volumes, (*ii*) maintain virtually constant concentration of reactant species throughout the etching process, and (*iii*) simulate a batch processing environment capable of handling up to 20 wafers simultaneously. Both scanning electron microscopy (SEM) and Nomarski interference contrast optical microscopy were used to examine the edge profiles.

Results and Discussion

Qualitative observations.—The dependence of slope on etching solution at the edges of oxide windows is illustrated by the two SEM photographs in Fig. 1. A typical steep slope in an approximately 10,000Å thick oxide etched in a 6.7:1 solution is shown in Fig. 1a, while a shallow taper is obtained if a 30:1 solution is used, see Fig. 1b. Note that there are two distinct regions to the slope along each oxide edge profile. In Fig. 1a the etching rate in the depth direction, γ_d, is initially much faster than the rate, γ_l, in the lateral direction. However, the lower part of the oxide etches about the same in each direction, *i.e.*, $\gamma_d = \gamma_l$. This re-

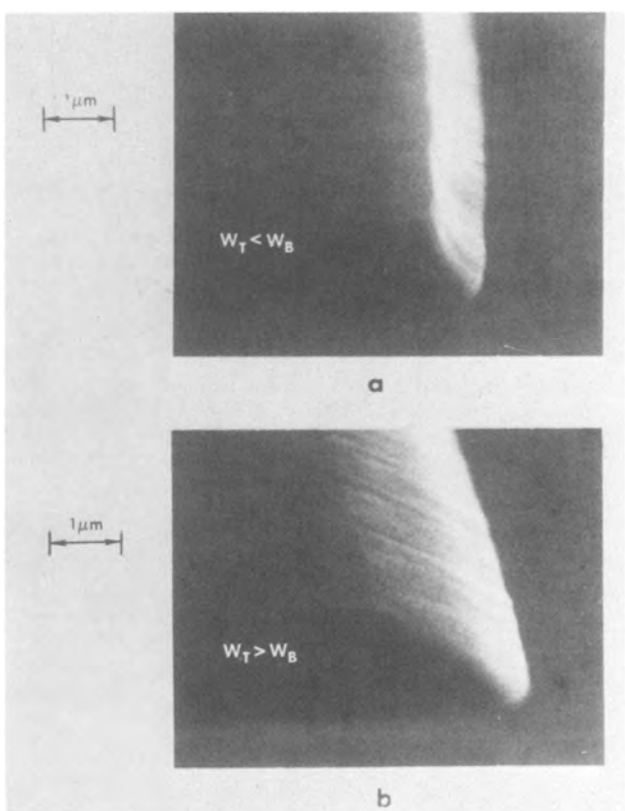

Fig. 1. Scanning electron micrographs of edge profiles etched in thermal SiO_2; magnification 14,000×. a. Steep taper slope etched with a 6.7/1 solution of NH_4F/HF at 25°C. b. Shallow taper slope etched with a 30/1 solution of NH_4F/HF at 25°C.

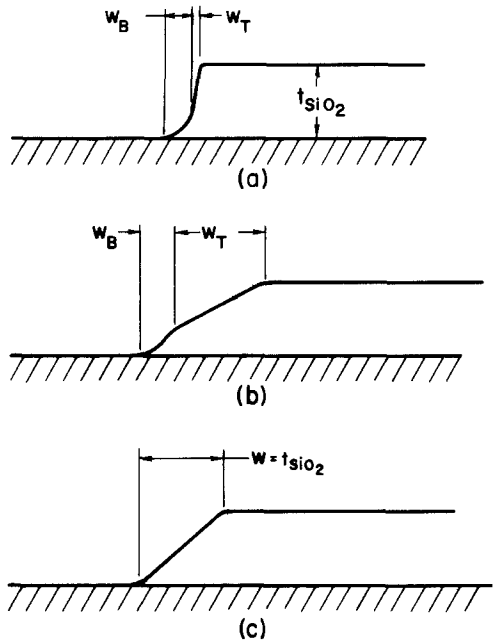

Fig. 2. Diagramatic representation of tapered oxide edges showing the different distinct regions of the profiles. a. Steep taper slope where $W_B > W_T$. b. Shallow taper slope where $W_B < W_T$. c. Ideal taper slope where $W_B = W_T = t_{SiO_2}$.

sults in a taper profile as depicted in Fig. 2a, which is very steep at the top and forms a quarter-circle at the bottom. The symbols W_T and W_B have been used for the projected width at the top and bottom of the profile since these widths are initially measured or estimated in an optical microscope. The 30:1 solution, for which $\gamma_l > \gamma_d$, see Fig. 1b, also has a final etching profile which approximates a quarter-circle as illustrated in Fig. 2b.

The differences observed for these two solutions in an optical microscope at 1000× are shown in Fig. 3. Note that the shallow taper, Fig. 3b, can be conveniently evaluated optically be measuring the number

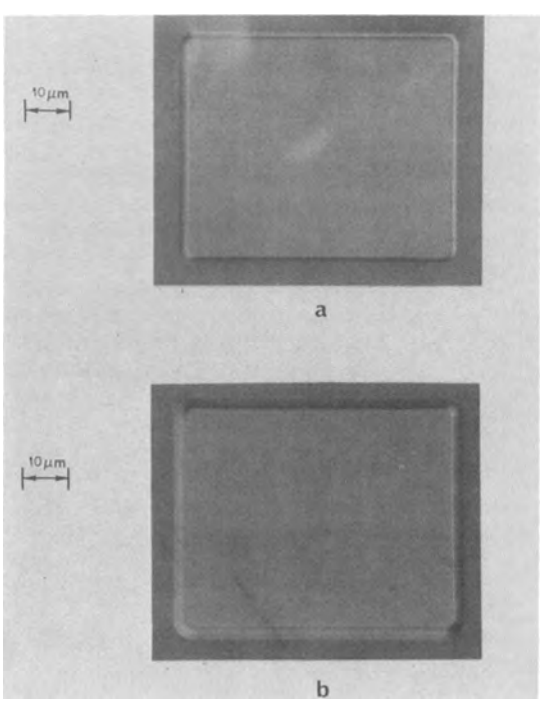

Fig. 3. Nomarski interference contrast optical micrographs of etched windows in thermal SiO_2; magnification 1000×. a. Steep taper slope showing no fringes. b. Shallow taper slope showing very discernible fringes.

and periodicity of the fringes. However, samples with taper angles greater than ~35°, *e.g.*, Fig. 1a and 3a must be examined in the SEM to obtain an unambiguous profile of the taper. Since $W_B > W_T$ for a 6.7:1 solution and $W_B < W_T$ for a 30:1 solution, dilutions intermediated to these two were investigated with the aim of obtaining a profile with $W \simeq t_{SiO_2}$ as shown in Fig. 2c.

Before extensive studies of the relative etching rates could be carried out, it was first necessary to establish that the photoresist material was not, in itself, grossly affecting the results, *e.g.*, by curling up or in some way separating from the top of the oxide surface. This was checked by examining the etched profiles of two samples (6.7:1 and 30:1) in the SEM before the photoresist was stripped. Figures 4a and 4b show that the photoresist is coherent with the oxide and behaves like a rigid cantilevered beam. However, if the undercutting is considerably more than the oxide thickness, *e.g.*, as with the 30:1 solution, see Fig. 4a, there is a tendency for the overhung part of the photoresist to lift. The photoresist undercutting was also found to be temperature independent as shown by the SEM photograph of Fig. 4b, which resulted from a 48°C etch in a 6.7:1 solution. Comparison of Fig. 4b with Fig. 1a shows that at the higher temperatures there is an increased tendency for the top of the oxide to etch faster and penetrate the photoresist/oxide interface. This indicates that the temperature dependence of γ_l is favorable for reducing the steep tapers at oxide edges.

A further proof that enhanced etching at the photoresist/oxide interface is the main factor in controlling edge tapers is illustrated by etching the oxide through a window in a Si_3N_4 mask which is known to bond very well to SiO_2 and would be expected to have a $\gamma_l < \gamma_d$. Figure 4c shows that there is very little undercutting of the nitride mask and that as a result the taper is very steep at the top of the oxide. A similar result can be obtained if the etching solution is inhibited

from attacking a photoresist/oxide interface by the use of a wetting agent prior to etching. The four SEM photographs in Fig. 5 show the tapers for two pairs of samples consisting of two different photoresists, Microneg 747, Fig. 5a and 5b, and Waycoat IC-III, Fig. 5c and 5d. A predip in a 0.2% solution of Synthrapol-N has been used for the samples shown in Fig. 5b and 5d. The gross difference in the slopes at the top of the oxides is attributed to the formation of a barrier between the interface and the etching solution. The inhibiting action of the wetting agent persists even if the samples are rinsed in deionized water following the predip and prior to etching. Oxide slopes similar to Fig. 5b and 5d continue to be obtained and are independent of the type of photoresist used. The precise role of the wetting agent is speculative. This observation, however, does suggest that a controlled separation of the photoresist/oxide interface occurs, viz., a controlled penetration of the etchant at the interface and not simply a random uncontrollable undercutting.

Figures 5a and 5c also illustrate the nature of the profile achieved when optimum etching conditions are achieved. The shape of these tapered steps, schematically shown in Fig. 6, is such that the middle region is a uniform ramp of width W_M, the bottom is arced, W_B, and concave upward, while the top, W_T, is curved and convex upward. The over-all width of the structure is approximately equal to the oxide thickness. The functional dependence of profile shape on etching solution and temperature is presented in the next section.

Quantitative rate data and profile analysis.—Etch rate in the depth direction, γ_d, as a function of HF concentration is shown in Fig. 7 for the several temperatures investigated. The compositions of the mixtures of 40% NH_4F and 49% HF have been converted to molarity of HF. Although the actual concentration of HF in these solutions is lower than that which is added, molarity has been used for preparative purposes. The corresponding equivalents are shown in Table I. The linearity of these curves suggests that the dissolution of SiO_2 in HF at any fixed temperature is a first-order reaction dependent on the concentration of HF. Since all four curves converge at the origin, the HF appears to be the sole reactive species during the etching. The other reactant is the SiO_2 which, being in the solid

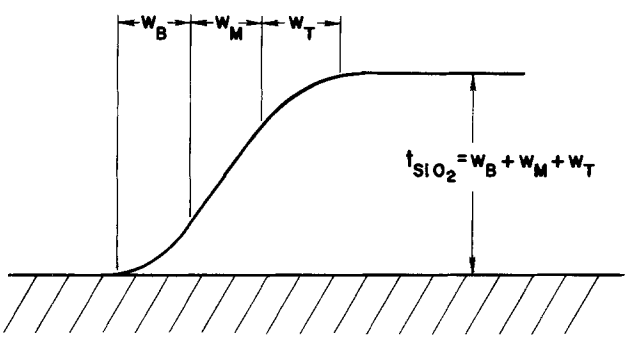

Fig. 6. Schematic representation of tapered profile for optimum etching conditions.

Table I.

NH_4F/HF	[HF] (moles/liter)
6.7/1*	3.8
10/1	2.6
15/1	1.8
30/1	0.9

* Commercially available buffered hydrofluoric acid (BHF) used throughout the industry is a mixture with a ratio of NH_4F:HF of 6.7:1.

phase, has a partial molar concentration of unity until such time that it is fully consumed. This dependence is, of course, a pseudolinear one that is valid within the composition range of etchants studied. It is known that etchant solutions of this type contain a large excess of F^- and hence HF_2^- which influence the reaction rate (11). From a processing consideration, however, the dependence on the HF concentration of the solutions as prepared, is followed and is useful as such.

The effect of increased temperature enhancing the etch rate is clearly evident from the steeper slopes at the higher temperatures. The dependence may be better visualized if these same etch rate data are replotted on semilogarithmic coordinates as a function of reciprocal absolute temperature. These curves are shown in Fig. 8 for the several etching solutions used. As expected, straight lines are observed, each with a negative slope typical of a single reaction mechanism. Since the slopes are all equal, the energy of activation is constant and independent of HF concentration. Clearly, the reaction mechanism is activation controlled for all of the etchant solutions investigated. These results are not completely in agreement with those reported by Lawrence (1) who proposed a diffusion-controlled mechanism for etchant solution with ratios of 20:1 or greater to explain the gradual tapered profiles obtained.

It is seen in Fig. 8 that the effect of HF concentration is to shift the position of the curves and is included in the frequency factor, A, of the rate equation

$$\text{Etch rate} = A \exp(-\Delta E/RT)$$

Using this rate equation the activation energy was calculated and found to be 9.9 kcal/mole.

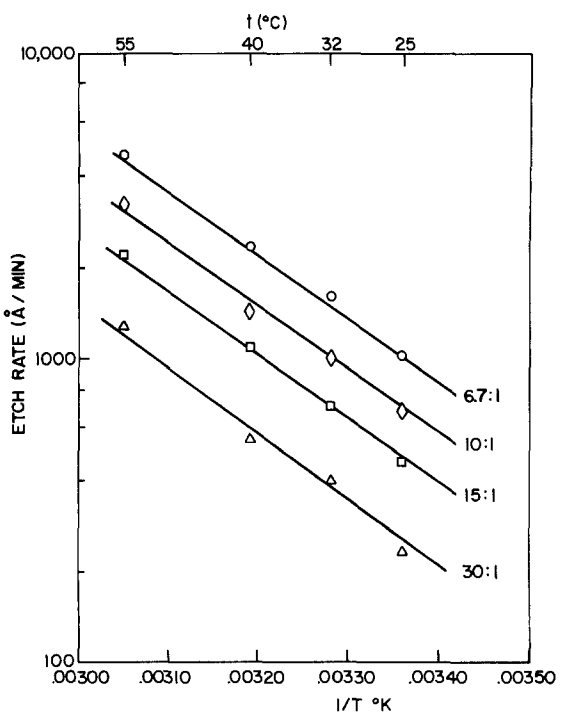

Fig. 8. Etch rate of thermal oxide as a function of temperature in several NH_4F/HF mixtures.

Both Judge (11) and Lawrence (1) have reported apparent activation energies that range from 6.7 to 11.0 and 9.2 to 11.2 kcal/mole, respectively, depending on the etchant solution composition. In both cases these authors found that the value of ΔE_{app} increases as the ratio of NH_4F to HF is increased. From these results Judge suggests several parallel reaction paths while Lawrence attributes a change in reaction type from activation controlled for low ΔE to diffusion controlled for high ΔE. Although it would appear that the relationships of ΔE with etchant composition from these two sets of data are in general agreement, an obvious discrepancy is noted for the absolute value of ΔE, if one uses a common reference point. Comparison of the value of ΔE_{app} for the commonly used buffered etch shows it to lie at the higher end of the range found by Judge (11.0 kcal/mole) whereas Lawrence's determination shows it to be at the lower end (9.2 kcal/mole). As pointed out previously, in our work, ΔE was found to lie about midway between these two values (9.9 kcal/mole) and independent of solution composition.

Finally, from our data, a simple rate equation can be formulated in which the preexponential term contains the concentration dependence. Plotting the intercepts of each of the curves of Fig. 8 as a function of HF concentration results in a straight line with slope equal to 4.50×10^9. This gives a rate equation of the following form

$$\gamma_d = 4.5 \times 10^9 \,[\text{HF}] \exp(-4980/T)$$

where γ_d = etch rate in angstroms per minute, [HF] = concentration of HF in moles per liter, and T = absolute temperature in degrees Kelvin. This expression is valid for the dissolution of thermal oxide within the range of parameter levels investigated, viz., etchant solutions between 6.7:1 and 30:1 and temperature range from 25° to 55°C. It may also hold for etchant mixtures and temperatures beyond the ranges indicated. Although the above relationship does not account for the equilibrium that exists in the etchant solutions, it is presented in the form shown for its usefulness as a processing guide.

Considering now the dependence of profile shape on temperature and etching solution, it is necessary to analyze the etching behavior in the lateral direction. Isotropic etching will, in fact, yield a quarter-circle edge profile (9). With continued etching (*i.e.*, overetching) and no photoresist lifting the quarter-circle edge profile both advances and its radius increases yielding a taper slope which becomes progressively steeper, as noted previously in Fig. 4c.

If, however, the penetration rate of etching solution at the photoresist-oxide interface, γ_l, exceeds the bulk etch rate, γ_d, of the oxide then a gradually sloping taper will be obtained that is dependent on the relative ratio of these two rates. It is this mechanism which prevails and manifests itself in giving beveled windows. The angle θ, that the taper forms with the original film surface is given by (10)

$$\sin\theta = \frac{\gamma_d}{\gamma_l}$$

For a penetration rate that is less than the bulk etch rate, ($\gamma_l < \gamma_d$) the latter, of course, is controlling and a quarter-circle with a 90° profile at the top is obtained.

A correlation of the etch or penetration rate in the lateral direction, γ_l ,as a function of temperature and HF concentration cannot be as precisely defined as the bulk etch rate, γ_d, because it is also dependent on the chemistry of the photoresist/oxide interface. Unfortunately, this interface is subject to some degree of variation due to the particular processing schedule used. Further, the undercutting is affected by the duration of etching which again is inextricably related to

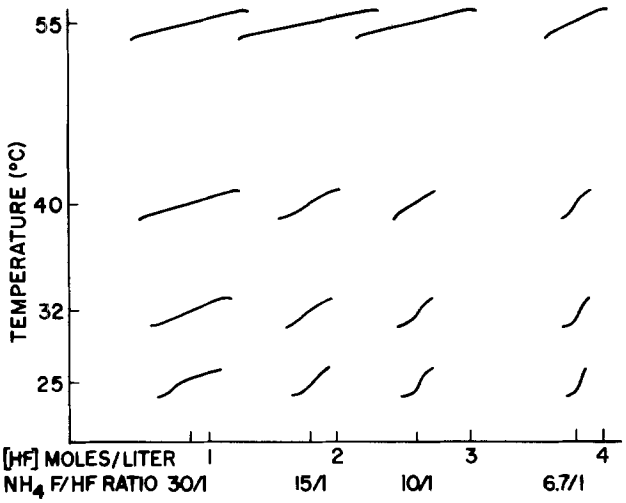

Fig. 9. Pictorial representation of normalized taper edge profiles for several temperatures and etchant compositions. Etchant composition is noted along the abscissa in both NH_4F/HF ratio and HF molarity.

temperature, etchant composition, and oxide thickness. Despite these several influencing factors, the penetration rate does, with minor exceptions, follow remarkably well the expected trend of increasing with higher temperature and higher HF molarity. A pictorial representation of the penetration rate as it relates to the profile shape is depicted in Fig. 9. Typical edge profiles for each of the temperatures and etchant compositions studied, have been taken from SEM photographs and normalized to facilitate comparison. It is important to realize that etch time has been omitted from Fig. 9 and it is merely an artifact of this representation which makes the higher penetration rates appear to have the least lateral penetration. The distinct regions to the slope along each oxide profile are clearly apparent, particularly in the lower and right portions of Fig. 9 where etching conditions are at or near room temperature and standard buffered HF concentration. The experimentally determined values of γ_I which correspond to the profiles are given in Table II. These numbers, however, are not sufficient to reveal the shape of the taper but can serve as a guide to the total penetration that occurs during etching.

For an ~45° side wall, (sin 45° = 0.707) γ_I should be equal to 1.41 γ_d. If γ_d is chosen at approximately 1000 Å/min, a good practical value for the bulk etch rate, then γ_I should be about 1400 Å/min. From either Fig. 7 or 8 and Fig. 9 it is seen that these conditions are satisfied, with some flexibility, using a 10:1 solution at 32°C.

Summary and Conclusions

The data presented in the previous section demonstrate that a wide range of options exists in applying the etchant NH_4F:HF to thermally grown SiO_2. Although we have optimized our procedures to achieve an ~45° taper with an etch rate of 1000 Å/min in a 10:1 NH_4F:HF etching bath, it is possible to obtain much shallower tapers by suitable adjustments of the temperature and NH_4F:HF ratio, as demonstrated in Fig. 9.

The advantages of the procedure are obvious when compared to the various oxide doping (7, 8), and ion implantation (6) techniques previously described, primarily because no adjustments or treatments of the SiO_2 layer need be made. In fact, introduction of the process into our device fabrication line required only the addition of a constant temperature bath. Reproducible results on large batches of wafers were obtained immediately.

Table II. Typical lateral penetration rates for thermal SiO_2 γ_I (Å/minute)

NH_4F/HF ratio	HF molarity	Temperature, °C 25	32	40	55
6.7/1	3.8	700	1600	2500	11,000
10/1	2.6	800	1300	2200	14,000
15/1	1.8	600	1200	2200	11,000
30/1	0.9	500	1200	2000	6,000

Although the etch rate *vs.* temperature or dilution curves presented in Fig. 7 and 8 are believed to be generally applicable to all steam oxides, the final shape of the etched window or step may be expected to vary depending on the type of photoresist used, or the condition of the exposed oxide/photoresist interface prior to etching. The latter problem is most evident if a wetting agent is employed as shown in Fig. 5. However, other treatments such as the influence of heating the oxide prior to photoresist application or the photoresist prior to etching, as well as the hydrophilic or hydrophobic nature of the oxide surface did not appreciably influence the taper profiles.

The mechanism by which tapering occurs may best be referred to as a controlled separation of the photoresist/oxide interface. It is completely dependent on the combined effects of the photoresist, etchant composition, temperature, and duration of etching in a reasonably uniform and controllable manner. The dissolution reaction per se we have found to be entirely activation controlled and in no case diffusion limited as suggested by Lawrence (1).

Anodic Oxide on GaAs: Quantitative Chemical Depth Profiles Obtained Using Auger Spectroscopy and Neutron Activation Analysis

C. C. Chang, B. Schwartz,* and S. P. Murarka*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The growth of oxides on GaAs, with the required properties for semiconductor applications, has obvious uses in passivation, masking, as a dielectric, etc. One promising method is anodization, and in order to assist in refining this technique, the chemistry and structure of 2500Å anodic oxides, before and after 250° and 650°C treatments in 1 atm nitrogen, have been investigated using neutron activation analysis and Auger spectroscopy combined with ion milling. The Auger data were normalized and corrected for Auger sensitivity and differential sputtering to provide profiles estimated to be quantitative within ±10%. All the oxide films investigated had compositions close to $x Ga_2O_3 + y As_2O_3$ except at the oxide-GaAs interface. Hydrogen was not detectable and was ignored. The as-anodized oxide displayed four distinct layers; these are in order, starting from the oxide surface: I, ~400Å, highly arsenic-deficient layer; II, ~1700Å, moderately arsenic-deficient layer; III, ~300Å, arsenic-rich transition layer; and IV, ~400Å, arsenic-rich interface to GaAs. The over-all As/Ga ratio in the oxide was 0.68. After 250°C anneal, only small changes in the depth profiles were observed. After 650°C anneal, most of the arsenic and some gallium were lost, and the arsenic excess near the oxide-GaAs interface was greatly reduced.

The ability to grow native oxides on GaAs has obvious implications for GaAs device technology. However, methods for growing oxides on GaAs with the necessary properties for semiconductor applications have not been perfected. One promising technique is anodization (1-3), and in order to understand the chemical and physical processes involved in the oxide growth, it is desirable to know the oxide chemistry and depth profile after anodization and after various heat-treatments. Therefore, chemical depth profiles from anodized and subsequently heat-treated GaAs have been obtained using Auger spectroscopy combined with argon ion milling. Neutron activation analysis was utilized for a quantitative calibration of the Auger data.

Experimental

Oxide films were grown on GaAs by anodization (3) in dilute aqueous solutions of H_3PO_4 at a pH of 2.5-3.5. Five samples were organic solvent degreased, bromine-methanol polished, and then anodized at 150V to grow 2500-3000Å oxides; the oxide thickness was determined by the voltage and dopant dependence of the oxide growth (3). The samples are listed in Table I, together with descriptions of the heat-treatments.

Chemical analyses were performed by measuring the surface composition using Auger electron spectroscopy (4, 5); the spectra were obtained with a cylindrical analyzer (Varian, 3 kV electrons). Depth profiles were obtained by measuring the surface composition while simultaneously milling the surface with an Ar ion gun (PHI, 1 kV argon ions).

The chemical compositions were calculated from the Auger data using the equation for the normalized Auger signal (5)

$$A_i = \alpha_i I_i / \Sigma_j \alpha_j I_j \qquad [1]$$

where $100A_i$ is the concentration of element i in atom percent (a/o), I is the Auger current determined from the peak-to-peak heights of $dEN(E)/dE$-type spectra and j runs over all elements detected. Hydrogen was not detectable and its possible presence was ignored. The small amounts of argon (several percent) implanted during ion milling were also ignored.

Table I. List of samples

Sample no.	Heat-treatment	Orientation	Doping	Oxide thickness (Å)
1	None	$(\bar{1}\bar{1}\bar{1})$	5×10^{16}/cm³, Zn	2500
2	None	$(\bar{1}\bar{1}\bar{1})$	5×10^{16}/cm³, Zn	2500
3	250°C, 2 hr, 1 atm N_2	$(\bar{1}\bar{1}\bar{1})$	5×10^{16}/cm³, Zn	2500
4	250°C, 2 hr, 1 atm N_2	(100)	9×10^{17}/cm³, Si	3000
5	250°C, 2 hr, 1 atm N_2 plus 650°C, 15 min, 1 atm N_2	$(\bar{1}\bar{1}\bar{1})$	5×10^{16}/cm³, Zn	2500

The inverse Auger sensitivity factors α_i for gallium and arsenic were determined from ion-mill-cleaned GaAs, as described elsewhere (5, 6). The α_0 for oxygen was determined from a single crystal of Ga_2O_3. This crystal was prepared by melting commercial Ga_2O_3 powder in an iridium crucible by rf heating and then cooling to room temperature; x-ray diffraction analysis showed this crystal (after pulverization) to be β-Ga_2O_3; no other material was detected. The Auger transition energies and the α_i are listed in Table II.

Table II. Auger transition energies, inverse sensitivity factors α_i, and preferential sputtering coefficients, s

Element	O	Ga	As
Energy (eV)	507	1067	1228
α_i (in GaAs)	—	3.7	5.7
α_i (in oxide)	1.4	2.2	3.3
s	1.0	1.0	1.6

The α's and s's apply under the following conditions: a-c modulation 2 5 V_{p-p}, incident electrons at 3 kV, 50 μA, analyzer resolution 0.8%.

The "preferential sputtering coefficient" s includes the effects of both the electron and ion beams. When the electron beam is turned off, the value of s changes, so that the contribution from the electron beam alone is not negligible and in fact may be larger than that from the ion beam alone (6).

Preferential sputtering effects[1] were next considered. The chemical composition of a cleaved surface of Ga_2O_3 was measured before and after ion milling and was found to be the same within ±3%, so that there was no detectable preferential sputtering; *i.e.*, the differential sputtering coefficient of oxygen, referenced to gallium, was $s(O/Ga) = 1$ for Ga_2O_3.

The differential sputtering coefficient[1] for arsenic in Ga-As-oxide, referenced to gallium $s(As/Ga)$, was determined by first measuring the As/Ga concentration ratio in the anodic oxide using neutron activation analysis. Sample no. 1, which was an as-anodized specimen, was irradiated for 1 hr in a thermal neutron flux of $\sim 3 \times 10^{13}/cm^2$ sec. After 24 hr, the oxide was dissolved in a known volume of 1:1 $HCl:H_2O$. A precise volume of this solution was then transferred to a 2 in. diameter filter paper since the lithium drifted germanium detector was calibrated for this geometry. Counting was performed as a function of time to determine the half-life of the detected radiation (isotopes Ga-72 and As-76), and the concentrations of gallium and arsenic were then calculated using known efficiencies. This procedure was repeated several times and the results are presented in Fig. 1. The amount of gallium was constant with time but the amount of arsenic decreased, possibly due to loss of arsenic as chlorides, since some arsenic chlorides are relatively volatile. Contributions from other radioisotopes causing this decrease in the amount of arsenic are highly unlikely because we have carefully monitored all five gamma-ray emissions designated to radioactive As-76 and results were identical. We used the As/Ga concentration ratio at the time of dissolution as the value in the oxide, which assumes no precipitation in the HCl solution, no concentration change in the 24 hr after irradiation, and no preferential absorption at container walls. The As/Ga concentration ratio was 0.68, indicating a large arsenic deficiency immediately after anodization. This sample had an area of 0.3 cm^2, and an estimate of the total number of Ga + As atoms from the oxide thickness, assuming a composition of $xGa_2O_3 + yAs_2O_3$, gave $1.4_4 \times 10^{17}$ atoms which compares well with the neutron activation analysis result of $1.5_3 \times 10^{17}$ atoms in Fig. 1.

Chemical depth profiles of sample no. 2 are displayed in Fig. 2-4 which illustrate the data reduction process. Figure 2 shows the Auger peak heights, Fig. 3 displays the normalized Auger signal, and Fig. 4 exhibits the final depth profile corrected for differential sputtering. The ternary differential sputtering problem in Ga-As-oxide was reduced to a binary problem by assuming that both the gallium and arsenic oxides sputtered off stoichiometrically, as was the case for Ga_2O_3 described above. The corrected gallium and arsenic concentrations, x and y, respectively (Fig. 4), were calculated from the initial uncorrected values x', y' (Fig. 3) using the renormalized equation

$$x = \frac{x'(x' + y')}{x' + sy'} \quad \text{for gallium} \qquad [2]$$

and

$$y = \frac{sy'(x' + y')}{x' + sy'} \quad \text{for arsenic} \qquad [3]$$

so that $y/x = sy'/x'$. s was then evaluated by dividing the As/Ga concentration ratio from neutron activation analysis $y/x = 0.68$, by the ratio of areas under the arsenic and gallium curves of Fig. 3, which was $y'/x' = 0.44$, giving $s(As/Ga) = 1.6$ in the oxide. This correction was then applied, assuming it to be independent of composition. This completes the evaluation of the preferential sputtering coefficients which are listed in Table II.

[1] Includes electron beam desorption during Auger analysis; the separate contributions from the electron and ion beams were not differentiated in this work.

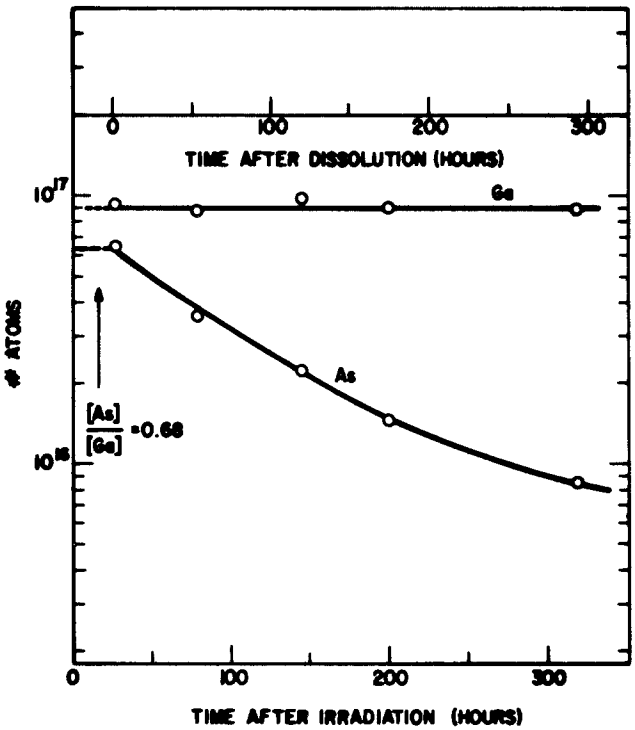

Fig. 1. Neutron activation analysis of the gallium and arsenic content of anodic oxide on GaAs. Note the gradual loss of arsenic with time after dissolution, sample no. 1.

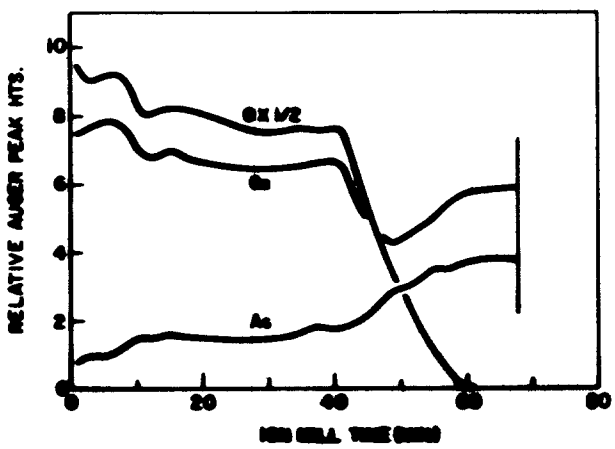

Fig. 2. Plot of Auger peak heights *vs.* ion-milling time. Reveals only the chemical constituents [*i.e.*, gallium (Ga), arsenic (As), oxygen (O)] and qualitative trends, sample no. 2, as anodized.

When measuring the As/Ga ratio in the oxide from Fig. 3, it is necessary to subtract the contribution from any GaAs that might be present, at the oxide-GaAs interface. This subtraction was accomplished by measuring the plasmon loss peak height, using the GaAs plasmon loss peak (7) about 16 eV below the main gallium Auger peak at 1067 eV. This plasmon loss peak is negligibly small in spectra from the oxide, as demonstrated in Fig. 5 where the Auger peak shapes near the gallium 1067 eV transition are displayed for spectra from the oxide (top), the oxide-GaAs interface (center), and GaAs (bottom). The plasmon loss peak is identified in Fig. 5 and the height of this peak, normalized to 50 a/o so as to be directly comparable with gallium and arsenic concentrations, is also indicated in Fig. 3 and 4 (dashed lines).

Equations [2] and [3] are valid at any given depth in the depth profile, but do not provide the correction

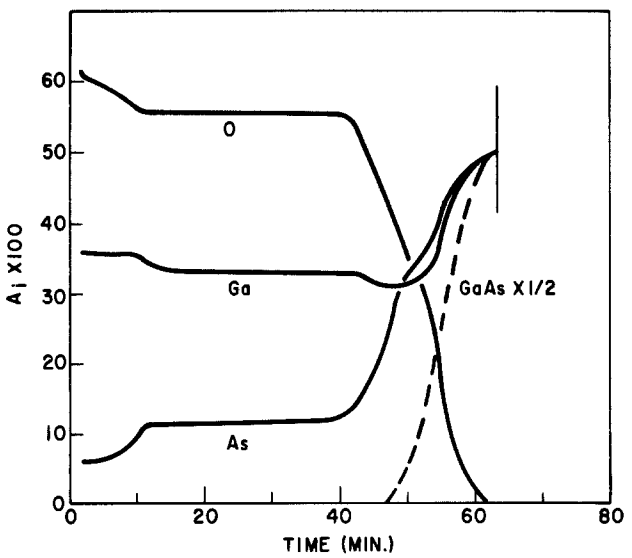

Fig. 3. Data of Fig. 2 after correction for Auger sensitivities and normalization. Amount of GaAs estimated from the plasmon loss peak height of the gallium Auger peak is also shown (dashed).

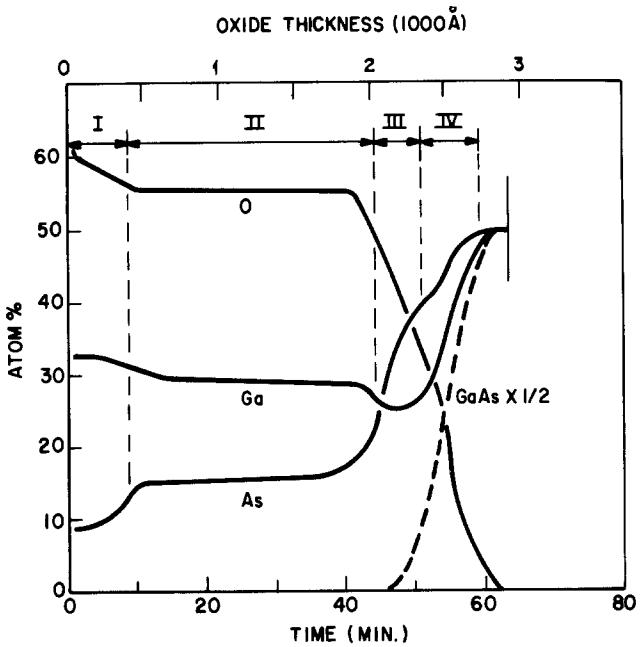

Fig. 4. Data of Fig. 3 after correction for differential sputtering. The oxide has four distinct regions. An approximate linear thickness scale is shown at the top, scaled to 2500Å at the point of 50% GaAs.

for the change in sputtering rate with change in composition. If we assume that the sputtering rate is linearly related to x, y, and s, *i.e.*, that the differential material sputtered, dm, is given by

$$dm \propto (x\rho_x + sy\rho_y)\,dt \qquad [4]$$

where ρ is the density and t is time, then our value of s(As/Ga) = 1.6 for the as-anodized oxide is too large (by ~7%). Clearly, Eq. [2] and [3] apply only to a differential depth, and for a more accurate analysis, the changes in sputtering rate with composition must be properly taken into account. A simple alternative for a more accurate determination of s is the use of an oxide whose composition is constant throughout its thickness; then the sputtering rate changes become negligible.

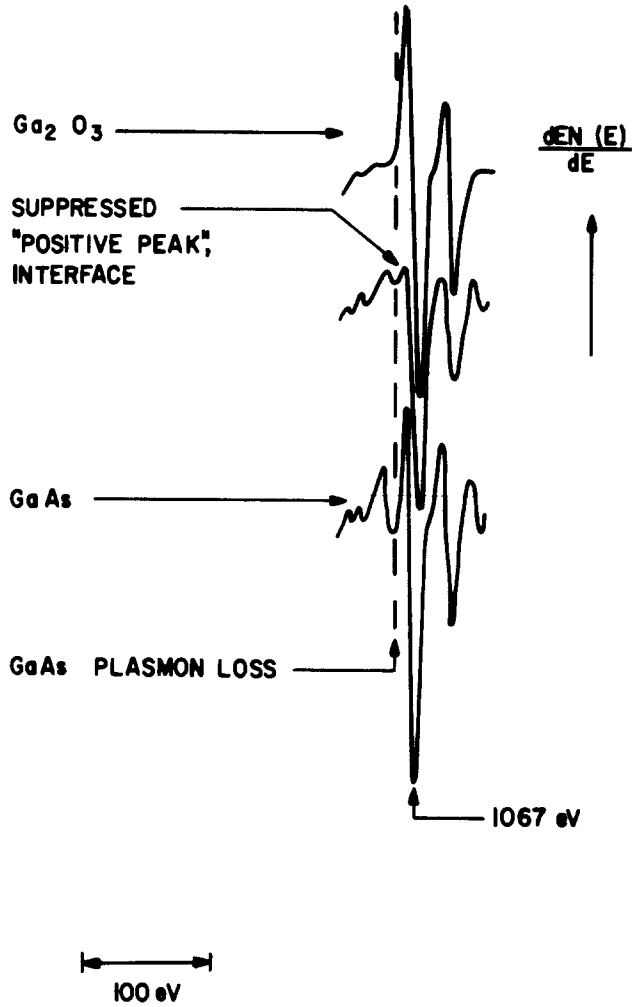

Fig. 5. The gallium Auger spectra near 1067 eV from: top, Ga_2O_3; center, region III of Fig. 4; and bottom, GaAs. The plasmon loss peak 16 eV below the main 1067 eV peak is indicated. The top two peaks have been displaced horizontally to coincide at 1067 eV.

Results

Some qualitative features of the chemical composition can be seen from a simple plot of the Auger peak heights (Fig. 2), but the quantitative information is not immediately obvious and there are several unexplained humps and dips. Many of the latter features disappear in the normalized data of Fig. 3, which is more quantitative, but without the differential sputtering correction. The curves of Fig. 4 are quantitative depth profiles which reveal the details of the arsenic deficiency in the oxide and the arsenic excess at the oxide/GaAs interface.

The as-anodized oxide of Fig. 4 has four distinct regions. The first, I, is an arsenic-deficient layer near the surface, ~400Å thick, with only ~10 a/o arsenic, an average Ga/As ratio of 2.9, and O/(Ga + As) ratio of 1.4. The second layer, II, is ~1700Å thick and has a nearly constant composition with depth; it is arsenic deficient, with a Ga/As ratio of 1.8 and an O/(Ga + As) ratio of 1.2[2]. The next two layers, III and IV, comprise the transition region from the oxide to GaAs. Region III is ~300Å thick, has a rapidly decreasing oxygen and a rapidly increasing arsenic gradient. and is arsenic rich. Region IV is the interface to GaAs; it is arsenic rich and is ~400Å thick.

The transition layers III and IV extend over a large thickness range in the depth profile; since the ideal depth resolution of the ion-mill Auger technique at ~2500Å is < 100Å for GaAs,[2] the measured total range

[2] The oxide/GaAs transition region for a ~2500Å plasma-grown (8) oxide on GaAs was <100Å when measured using the present technique.

of the transition layer of ~700Å reflects some physical property of the oxide and is not an artifact due to insufficient depth resolution. There are four possible interpretations of such a graded depth profile: (*i*) there is indeed a graded transition layer, (*ii*) the oxide thickness varies by ±300Å within the area irradiated by the incident electron beam used for Auger analysis, (*iii*) ion milling proceeds unevenly in these oxides, and (*iv*) the particular chemistry of this region causes it to ion mill unusually slowly. We speculate that (*i*) and (*ii*) are the most important factors with negligible contributions from (*iii*) and (*iv*) for the present samples.

The gallium Auger peak in region III showed a suppressed "positive peak," a feature not found anywhere else along the depth profile. This peculiar peak shape is shown in Fig. 5 and results from a superposition of the chemically shifted peak from gallium in the oxide and the unshifted peak from GaAs. To avoid large errors from this effect, the gallium concentrations were calculated by normalizing to the negative portion of the peak which is least sensitive to this perturbation. Even with this procedure, there is still an underestimate of the gallium peak height which may be non-negligible (>5%) in a small depth range approximately ±100Å near the boundary between regions III and IV in Fig. 4 (Fig. 6 and 7, also).

There is an excess of arsenic in regions III and IV; this is one of the most important definitive results of this work, and will be further discussed below. The plasmon loss peak associated with arsenic attained its maximum value (relative to the arsenic peak height) in region III so that in this layer a large fraction of the arsenic phases are separated from, and are much less oxidized than, the gallium phases. Because the plasmon loss peaks between an atom in a semiconductor and the same atom in a metal are generally not distinguishable at the energy resolution employed in this work, the present results are consistent with the interpretation, suggested by photoemission data (6), that the excess arsenic is in elemental form. This anomalous behavior of the arsenic peak is the reason why the gallium plasmon loss peak was selected for estimating the amount of GaAs. In regions I and II, the As peaks showed no measurable plasmon loss.

Quantitative depth profiles similar to Fig. 4 are plotted for sample no. 3, after 250°C treatment, in Fig. 6. There are small changes in composition, but the total arsenic content, the O/(Ga + As) ratio, and the regions I to IV, are only slightly changed. Regions III and IV have expanded to cover almost 1000Å. Results from sample no. 4 [same treatment as no. 3, but (100) instead of (111) orientation and higher conductivity] were similar to Fig. 6, except that the oxide was thicker, about 3000Å; this increased oxide thickness is due to the higher doping level (3).

Figure 7 displays quantitative depth profiles from sample no. 5 and shows that the oxide is ~800Å thinner after 650°C treatment, due to loss of much of the arsenic, some gallium, and the associated oxygen. Note that the thickness scale of the figure has been corrected for the decrease in arsenic, which caused the ion milling rate to decrease; the new milling rate was calculated using Eq. [4]. Now the oxide displays only three distinct regions, due to loss of the central arsenic-containing layer (region II). Whether an arsenic excess still remains at the oxide/GaAs interface is now not clear. In Fig. 4, 6, and 7, the oxygen concentrations are all close to 60 a/o, so that the oxide composition is approximately equal to $xGa_2O_3 + yAs_2O_3$.

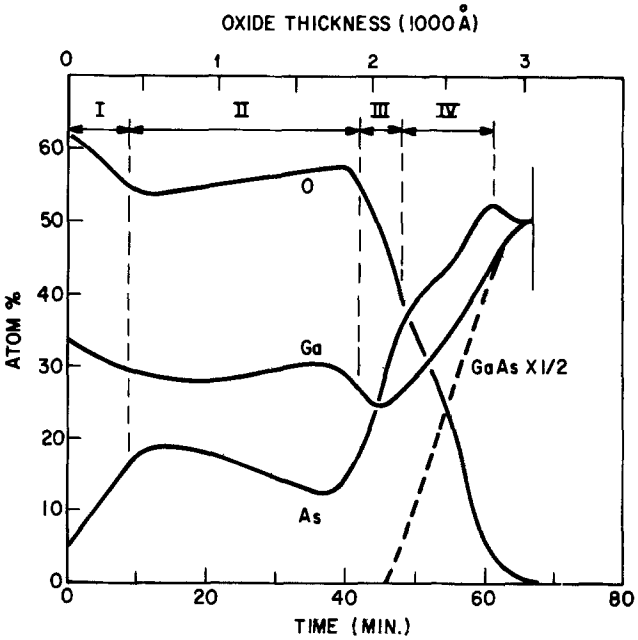

Fig. 6. Depth profile of 2500Å anodic oxide after 250°C anneal, sample no. 3.

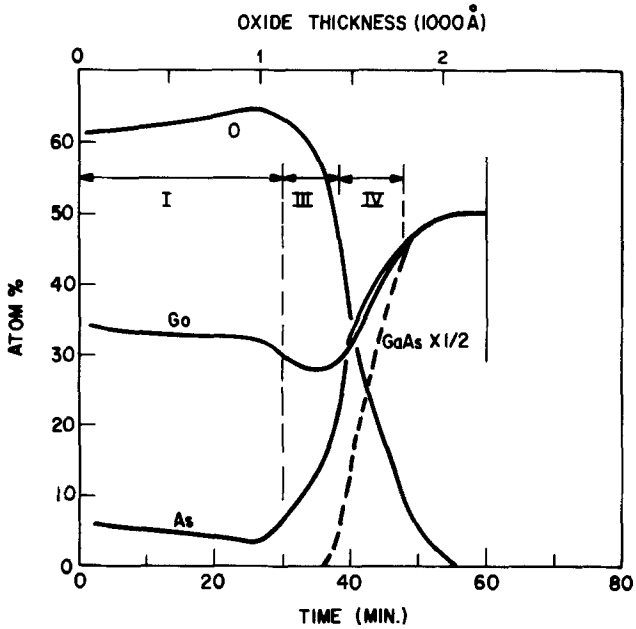

Fig. 7. Depth profile of anodic oxide after 650°C anneal; note the change in "thickness" scale due to change in composition, sample no. 5.

Discussion

The above results reveal that arsenic is preferentially lost during anodization. The arsenic deficiency near the oxide surface is probably due to preferential extraction of arsenic by the oxygen-containing species in the anodizing solution and subsequent dissolution of the molecular complex.

To explain the arsenic excess in regions III and IV, we propose that at the oxide/GaAs interface, Ga_2O_3 forms preferentially to As_2O_3 (*i.e.*, $\Delta F°$ of −238 kcal/mole for Ga_2O_3 compared to −136 kcal/mole for As_2O_3), and the arsenic is stranded as an elemental layer at the interface. The process of this and the above paragraph accounts for (*i*) the arsenic deficiency in regions I and II, (*ii*) the arsenic excess in regions III and IV, and (*iii*) the anomalously large plasmon loss peak from arsenic in region III.

Our observation of excess As at the oxide/GaAs interface is in agreement with previous ellipsometric

findings (10). The value of 0.68 for the over-all As/Ga ratio in the oxide is in fair agreement with the value of 0.77 measured using chemical analysis of an anodic oxide on GaAs formed using a different solution (11). Our depth profiles are consistent with results from ion-induced x-ray analysis (12), but the present results are much more accurate due to the higher depth resolution. Other workers (13, 14) have published Auger depth profiles of oxides on GaAs, but those results are analogous to our Fig. 2, so that the quantitative data reduction was incomplete without the three major corrections for Auger sensitivity, normalization, and differential sputtering that we incorporated into our analyses.

The most significant result of this work is the new information we obtained concerning the complex oxide-GaAs transition layer which includes regions III and IV. These transition regions are surprisingly thick and must contribute significantly to the properties of the oxide as a whole. These regions are important in determining the electronic properties of the oxide/GaAs interface, in diffusion problems, in device processing (*e.g.*, chemical etching), and for understanding the oxide growth process itself. Therefore, further experiments should be performed to (*i*) study in greater detail the oxide/GaAs interface chemistry, and (*ii*) study the interface structure by examining thin cross sections with transmission electron microscopy (15). In particular, the precise reason for the apparently diffuse oxide/GaAs interface must be elucidated. Finally, oxides on the more complex compound semiconductors, especially GaAlAs, should also be studied.

Conclusions

1. All the anodic oxides investigated in this work had compositions nearly equivalent to $xGa_2O_3 + yAs_2O_3$. The over-all As/Ga concentration ratio was 0.68 before and after 250°C treatment in 1 atm nitrogen.

2. The as-anodized oxide had four distinct layers: I, the first ~400Å at the surface, which is arsenic deficient with an average Ga/As concentration ratio of 2.9. The arsenic concentration in this layer decreased rapidly towards the oxide surface. II, a center region, ~1700Å thick with an average Ga/As ratio of 1.8 and O/(Ga + As) ratio of 1.22. III, the first transition region to GaAs where the oxygen concentration begins to decrease. This layer is arsenic rich and is ~300Å thick. IV, the interface layer to GaAs, ~400Å, which contains excess arsenic.

3. After 250°C anneal in 1 atm nitrogen, only small changes in composition were observed. After 650°C anneal, most of the arsenic, and some oxygen and gallium were lost, and the arsenic excess at the oxide/GaAs interface was greatly reduced.

The Anodic Behavior of Group Six Metals in Methanolic Solution

G. Stephen Kelsey

Department of Chemistry, University of Missouri-Columbia, Columbia, Missouri 65201

ABSTRACT

The anodic behavior of chromium, molybdenum, and tungsten in aqueous solution has been the subject of considerable research. With growing interest in nonaqueous electrochemistry, a number of protic and aprotic solvents suggest themselves as suitable media for generation of soluble species from metal electrodes. The behavior of the metals was characterized by determination of current-potential data and coulometric n value determination, where n is the number of electrons lost per metal atom during the electrochemical oxidation. Data for four electrolytes were gathered: the lithium salts of chloride, methoxide, nitrate, and perchlorate. Concerted formation of Cr(III) occurs only in chloride solution. Cr(VI) forms in perchlorate and nitrate solutions, and is reduced to Cr(III) by the solvent if the methanol is allowed to acidify during the course of the electrolysis. Chromium appears to react only with traces of water in methanolic methoxide solutions, with the formation of CrO_4^{2-} ion. Molybdenum and tungsten behave similarly, forming M(VI) in chloride and methoxide solutions with high efficiency. Their behavior in perchlorate and nitrate proceeds with n values between 4 and 6, with nitrate being more conducive to a constant value over a range of current densities of 5-330 mA/cm^2. The effect of trace water contamination in the solutions was also studied, with shifts in the i-E curves observed for all three metals.

The anodic behavior of transition metals in aqueous solution has been the subject of considerable study (1-28). Both mechanistic (2-15) and analytical (16-24) implications of the electrochemical generation of dissolved species exist for the early transition metals and many of the later ones (1, 3, 11-14, 24, 26) as well. The growing importance of nonaqueous electrochemistry, both for analysis and synthesis, led us to extend the study of Group VI metals into nonaqueous solvents. By way of bridging the gap, the protic solvent methanol was chosen for study of the anodic dissolution of chromium, molybdenum, and tungsten. Of particular importance is the question of apparent oxidation state of the products often referred to as "initial valency," n (25-28).

Experimental

Apparatus.—All electrochemical measurements were obtained with PAR 173 potentiostat/galvanostat (Princeton Applied Research Corporation, Princeton, New Jersey). Accumulated coulombs were recorded with a PAR 179 digital coulometer, used in conjunction with the 173. Current-potential curves were obtained with a PAR 175 universal programmer in the single sweep mode, which applied a 1 mV/sec voltage ramp to the potentiostat. Log current-potential curves were obtained with the PAR 376 logarithmic current converter. The former data were obtained as $i = f(E)$ potentiodynamic polarization; the latter were $\log i = f(E)$. Both data fields were recorded with an Omnigraphic Model 2000, X-Y plotter (Houston Instruments, Incorporated). Electrochemical cells used were Metrohm EA 880 universal titration vessels of appropriate volume, jacketed for temperature control.

Ultraviolet-visible spectra were recorded on a Cary-14 spectrophotometer or a Perkin-Elmer 124 double-beam recording spectrophotometer.

Reagents.—Chromium metal was polycrystalline in nature, irregular in morphology, and of CP purity. Molybdenum was obtained as 0.25 in. diameter rod, 99.95%, from A. D. Mackay, Incorporated, New York. Tungsten was also 0.25 in. diameter rod, 99.95% from the same supplier.

Key words: chromium, molybdenum, corrosion, tungsten, methanol.

Methanol was reagent grade, purified by fractional distillation from magnesium ribbon through a 1m adiabatic column packed with helices, and a second distillation from 3Å molecular sieves. Karl Fischer water determinations revealed a water concentration of from 50 to 150 μg/ml.

All other chemicals used were of analytical reagent quality and used without further purification, with the exception of lithium nitrate. The as-received $LiNO_3$ (G. Frederick Smith, Columbus, Ohio) gave rise to an active/passive peak in the log i-E plots for tungsten metal. Drying at 110°C under vacuum for 8 hr removed residual water and perhaps some volatile impurities. Polarizations conducted in solutions of the reagent thus treated, yielded no such peak.

Procedure.—So-called initial valency data were obtained by careful weighing of the metal electrode before and after the passage of a fixed number of coulombs, sufficient to cause a weight loss of *ca.* 0.10g. The value of the Faraday used in the calculation of n was 96,487 C/equiv. These experiments were performed under galvanostatic conditions.

The chromium electrode, because of its polycrystalline form could not be sanded conveniently; so electrode pretreatment was restricted to immersion in 6*M* HNO_3 for 1 min followed by copious rinsing with distilled deionized water and oven drying at 110°C for 5 min. Both the molybdenum and tungsten electrodes were rotated by an electric motor while sanded in turn with wet 320, 400, and 600 grit SiC paper. This was followed by rinsing and drying as for chromium.

Column chromatographic separation of Cr(III) species was achieved by taking a 10 ml aliquot of cell solution which had previously been quantitatively transferred to a 25 ml volumetric flask and loading it onto Dowex 50-WX2 resin, 200-400 mesh in the H^+ form. The 1 cm diameter × 20 cm long column was kept at 3°C. Bands were eluted with aqueous perchloric acid solutions ranging in concentration from 0.2 to 3M. Chromium assays were done using peroxide oxidation to Cr(VI) and subsequent spectrophotometric analysis as chromate (29).

Results and Discussion

Initial experiments focused on the effects of trace water. A thorough investigation of phenomena related

to water concentration, including analytical implications will be the subject of a separate communication. Trends in i-E behavior, including the limiting cases of anhydrous methanolic solution and totally aqueous solution are depicted for each metal in Fig. 1-3. The concentration of ammonium chloride chosen represents its solubility in methanol at room temperature. The water content for the dryest case was determined by volumetric Karl Fischer titration to be 50 ± 5 mM.

The seemingly anomalous behavior of chromium is complicated by the fact that different reactions occur in the two extremes. In dry methanolic chloride, Cr(III) is formed, whereas Cr(VI) is produced in aqueous solution. The behavior of molybdenum in chloride solution of essentially neutral pH is more predictable, in that a coulometric n value of 6 was observed in all three solutions (discussed later). The cathodic shift with increasing water content has been observed at platinum electrodes by others (30). For tungsten, the aqueous chloride solution is sufficiently acidic to render the electrode passive. An extrapolation of the straight-line portion of the i-E curves for molybdenum and tungsten to zero current, yields almost identical potentials (1.12 ± 0.05V). It is interesting to note that the thermodynamic oxidation potentials for the two metals in aqueous solution are also identical (31).

Because of the marked effect of water on the i-E behavior of the metals, solvent dehydration and handling were done carefully and special attempts were made to dry supporting electrolytes also. Typical water concentrations were 1-6 mM.

Chromium.—Log i-E data for the four electrolytes are given in Fig. 4-7. In general, chromium exhibits a more anodic potential at any given current density. This correlates well with potentials tabulated for aqueous solutions. The greatest difference (*ca.* +0.33V) occurs in the seemingly noncomplexing electrolytes, NO_3^- and ClO_4^-. In $LiOCH_3$ solution, which ought to

be the methanolic analog of aqueous 1M OH^- solution, chromium exhibits potentials only about 100 mV anodic of molybdenum and tungsten, whereas the standard potentials in aqueous base ($a_{OH} = 1$) reveal a 330 mV separation. Initial valency data in the OCH_3^- solutions will show that this anomaly can be explained on the basis of a Cr-H_2O or Cr-OH^- reaction in the basic methanol solution (see shift with [H_2O] in Fig. 1).

The initial valency data of Fig. 8 reveal 100% current efficiency for generation of Cr(III) in chloride solution, over a broad current density range, even in the concentration polarization region. The ultraviolet-

visible (UV-VIS) absorption spectrum of the resulting green solution was obtained and the salient features reported in Table I. The corresponding features of a $CrCl_3 \cdot 6H_2O$ solution in 1M LiCl, CH_3OH are given for comparison. The similarities lead to the conclusion that the observed electronic spectrum is characteristic of a d^3 configuration for chromium (32). Shifts in the positions of bands are probably due to the difference in donor strength between the two hexasolvo Cr(III) species, or the presence of more than one species in the cell solution. The spectral features of species separated chromatographically from the cell solutions are in Table II, also containing eluent composition and percentages of each species. The very mixed composition of the solution casts doubt on the likelihood of a concerted "clean" oxidation mechanism. On the other hand, the substantial amounts of both mono- and dichloro complexes does not rule out a diatomic intermediate chromium species in the mechanism, as postulated for iron oxidation in aqueous solution (5). The low recovery is due to the formation of green precipitates on the frits of the cathode isolation tubes and from a highly charged species which could not be eluted in a sufficiently small volume from the ion exchange column to be spectrally analyzed. The former species could easily be polymeric oxides precipitated by the basic solution in the cathode compartments of the cell.

These results in chloride are particularly interesting in that chromium passivates in aqueous chloride (acidic) solutions (10). In water, the availability of oxygen from the solvent promotes oxidation to chromate (dichromate in acidic solution), but only in the transpassive region, at about +1.1V *vs.* SCE (18). The same investigator also observed an active region at about −0.5V *vs.* SCE, where chromium(II) was produced in HCl solution. In the present methanolic solutions, with very low concentrations of water, the available oxygen can effectively only be gotten from solvent, and unlike water, the O—CH_3 bond would be considerably more difficult to break than an O—H bond. The stablest oxidation state for chloro complexes is +3 for chromium. and in that respect the present observations are consistent.

In nitrate and perchlorate solutions, the anodic behavior of chromium was characterized by high values for initial valency. An attempt was made to ascertain whether or not this might be explained on the basis of concommitant solvent oxidation. The n and i-E data were used to extract a current-potential curve for the chromium oxidation process and a separate one for the

competing reactions (33), where the sum of the current densities at each potential is equal to the observed (total) current density. One would have expected to observe essentially identical curves for the background reaction if the hypothesis were correct. However, these curves were quite different in the two electrolyte solutions, both with respect to shape and location along the potential axis. The background reaction in nitrate exhibited almost ohmic behavior and that in perchlorate exhibited a limiting current plateau. The overall oxidation in these two media is likely very complex, but some qualitative explanations are possible, based on observations made during the coulometric experiments.

he aqueous oxidation of chromium in basic solution is given in Eq. [1a]. By analogy, a simplistic methanolic stoichiometry can be written, as in Eq. [1b]

$$Cr + 4H_2O \rightarrow CrO_4^{2-} + 6e^- + 8H^+ \quad [1a]$$

$$M + 6CH_3OH \rightarrow M(OCH_3)_6 + 6e^- + 6H^+ \quad [1b]$$

Since the cathode was isolated from the anolyte during the electrolysis, the pH in the anode compartment will decrease with the passage of coulombs. As electrolysis proceeds and conditions in the cell acidify, the solvolytic reduction of Cr(VI) to Cr(III) is favored. This behavior is common for acidic Cr(VI) solutions with a variety of primary and secondary alcohols (34), wherein acid catalysis takes place. In the present case, when electrolysis began, a yellow color was imparted to the cell solution [Cr(VI)], which gradually changed to green [Cr(III)] as electrolysis proceeded, and which intensified after the cessation of current.

Additional evidence was obtained by running the same experiment in a flow cell, designed to supply fresh 1M $LiNO_3$, CH_3OH to the anode compartment at a rate of about 5 ml/min. In these experiments the anolyte was not permitted to acidify, and the resulting solutions were yellow. This color persisted after cessation of current and a spot test for Cr(VI) using a s-diphenylcarbazide was positive (35).

The electronic spectra of the green cell solutions (NO_3^- and ClO_4^- electrolytes) taken after the n experiments were qualitatively identical, the maxima and calculated average molar absorptivities given in Table III.

Table III. Absorption maxima and molar absorptivities for chromium cell solutions in 1M $LiClO_4$ and 1M $LiNO_3$, CH_3OH

	λ_{max}(nm)/ϵ(M^{-1} cm^{-1})		
$LiNO_3$	592/21.2	427/27.5	342(sh)/—
$LiClO_4$	590/18.6	425/24.9	345/—

Exhaustive electrolyses in perchlorate and nitrate solutions without isolation of the cathodes produced copious amounts of green precipitate, which seems to indicate that electrochemical reduction of Cr(VI) to Cr(III) occurred. The filtrates were yellow and also gave positive tests for Cr(VI). Comparison of the weight of recovered precipitate with electrode weight loss indicates that the precipitate could easily be Cr_2O_3 with a small amount of occluded solvent. Additional support for this oxide came from similar solubility characteristics observed.

A series of experiments in 1M $LiBF_4$, CH_3OH was performed in order to see if oxidation in the presence of an inert electrolyte which did not contain oxygen, would show significant differences. Unfortunately, the results of anodic polarization were green solutions of Cr(III), typical of a monohalo complex. Chromatographic separation of components of the solution showed at least three species, the results given in Table IV. Aside from a third band with high charge characteristics, some precipitate on the cathode compartment frits contributed to the low recovery. An interesting result is that the tetrafluoborate anion, commonly used in electrochemistry to increase the potential range in nonaqueous solvents, is not in this instance inert.

Generation of chromium in 1M $LiOCH_3$ was expected to parallel aqueous base behavior, wherein a high current efficiency for generation of Cr(VI) is observed (15). However, n data showed random scatter from 50 to 90 electrons per chromium oxidized over a current density domain of 10-190 mA/cm^2. The resulting solutions were yellow, with two absorption bands of about equal intensity at 375 and 275 nm, with respective molar absorptivities of 2200 and 1780 M^{-1} cm^{-1} (based on electrode weight loss measurements). A solution prepared from K_2CrO_4 dissolved in the electrolyte yielded an identical spectrum. Since the UV-VIS data seemed to indicate CrO_4^{2-} ion, it was thought that perhaps water contamination in the methanol might be responsible for the yellow colored solutions and very high n values. A series of galvanostatic experiments was made with various amounts of water spiked into the methanolic OCH_3^- solution. Figure 9 displays the n *vs.* water concentration relationship. It seems that the n data represent a coulometric consumption of the water present, or perhaps of hydroxide ion, depending on the position of the equilibrium in Eq. [2]. A detailed study of the water effects on these metals is underway

$$OCH_3^- + H_2O \rightleftharpoons OH^- + CH_3OH \quad [2]$$

Molybdenum.—This metal exhibits the widest variation in Tafel slope (Fig. 4-7) of the three metals, an

observation perhaps to be expected in light of molybdenum's rich redox chemistry. Polarization in chloride solutions produced yellow colored solutions, which faded to near-colorless on standing. The former possessed a shoulder at 360 ± 10 nm on a large band in the u.v. The colorless solution had a single peak at 225 nm and a shoulder at 300 nm. These latter values agree fairly well with aqueous molybdate solutions at low pH (36). The molar absorptivity at 225 nm was 6560 M^{-1} cm^{-1} ± 1%, which is the average of five samples run at different current densities. Acid-base titrations of aliquots of cell solution taken after polarization yielded a H^+:Mo ratio of 5.7 ± 0.2, which suggests the possibility of an over-all oxidation stoichiometry approaching Eq. [1b]. Some coulombs arise from side reactions, as indicated in Fig. 10; the potentials corresponding to current densities in excess of 50 mA/cm^2 are above +1.5V *vs.* SCE and so could easily be sufficient to oxidize chloride ion to chlorine, an observation in keeping with the yellow coloration.

Generations of molybdenum in lithium nitrate solution produced both a low *n* (5.14) and a low Tafel slope (0.150V). Addition of thiocyanate to cell solutions failed to yield the characteristic red Mo(V) thiocyanate complex until stannous chloride was added, indicating

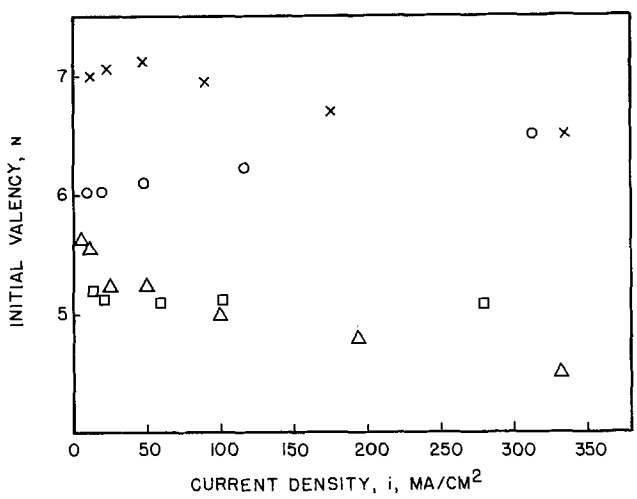

Fig. 10. Coulometric *n* as a function of current density for tungsten. ○, 1.0M LiCl, CH_3OH; △, 1.0M $LiClO_4$, CH_3OH; □, 1.0M $LiNO_3$, CH_3OH; ×, 1.0M $LiOCH_3$, CH_3OH.

that Mo(VI) was the species present in solution at the end of electrolysis. An anodic polarization in 0.5*M* KSCN, CH_3OH was made, and the yellow Mo(VI) isothiocyanate complex only was obtained (37). A similar run in 1*M* $LiNO_3$/0.1*M* KSCN, CH_3OH also gave negative results for the generation of a stable Mo(V) species, possibly because of a fast nonelectrochemical oxidation to Mo(VI) by NO_3^-. Subsequent addition of $SnCl_2$ immediately produced the intense red Mo(V) complex, which proved to be sensitive to air oxidation on standing. The suspected oxidation of Mo(V) to Mo(VI) by nitrate ion has been observed in aqueous solution with other metals (38, 39). Equation [3] is the reduction reaction in water

$$10H^+ + NO_3^- + 8e^- \rightarrow NH_4^+ + 3H_2O \qquad [3]$$

While the potential in methanolic solution would not be the same, the required acidity would be favored in the double layer where a reaction similar to [1b] would be taking place.

UV-VIS spectra of the colorless cell solutions were less satisfactory than those obtained in chloride solution, because of intense absorption by nitrate ion over most of the u.v., which prevented location of an absorption maximum. Three shoulders were observed, though, at 340, 365, and 352 nm.

Generation of Mo(VI) in lithium perchlorate occurred with high current efficiency (Fig. 10). Like nitrate, perchlorate is an oxidizing agent, and very likely responsible for the low initial valency observed at high current densities (40, 41). Equation [4] is the reduction reaction in aqueous solution

$$8e^- + 8H^+ + ClO_4^- \rightarrow Cl^- + 4H_2O \qquad [4]$$

Tests with thiocyanate for Mo(V) in the cell solutions proved negative. Acid-base titrations were complicated by decomposition of the indicator in this medium. The UV-VIS spectra were characteristic of chlorine dioxide (42). A large charge transfer band for molybdenum extended from about 460 nm to well into the u.v., with fairly well resolved shoulders at 475, 460, 445, 435, 420, 410, 400, 390, 380, 370, 360, and 350 ± 3 nm. The solution obtained from a lengthy generation was pumped under vacuum and the yellow ClO_2 trapped at liquid nitrogen temperatures. The liquid was then dissolved in pure methanol and the spectrum recorded. A maximum at 360 nm (ϵ = 1242 M^{-1} cm^{-1}) was observed. The stoichiometry of the molybdenum oxidation in this medium is very complicated and is currently under study.

The production of Mo(VI) in perchlorate and nitrate solutions is not surprising, if the analogous aqueous potential-pH diagrams have any validity (44). The absence of oxide films and passivity, however, is uncommon among data reported in nonaqueous solvents. Studies of molybdenum (14) and vanadium (45) in acetic acid solution revealed facile formation of oxide layers, with the development of intensely colored interference patterns (46). Aside from this rather unusual medium, the nonaqueous electrochemistry of molybdenum has not been heavily studied. Essential to the formation of the oxides of both of these metals is the presence of from 1 to 2*M* H_2O in the 0.02*M* $Na_2B_4O_7 \cdot 10\ H_2O$ acetic acid solution. While the present work provides oxygen in the electrolyte salts themselves (ClO_4^-, NO_3^-), every effort has been made to exclude other than trace quantities of water. Given lithium ion's affinity for water of hydration (47), it is conceivable that actual free water concentrations in these methanolic solutions could be less than the Karl Fischer titration values. This qualitative and quantitative difference, anhydrous solvent *vs.* 1*M* water, may be part of the explanation of the disparate behavior. The absence of sodium tetraborate from the present work must also represent a significant difference, in light of the fact that another valve metal, bismuth, also forms oxide layers in borate-containing aqueous solutions (48).

The oxidation products in the present work for perchlorate and nitrate solutions are soluble and if the mechanism proceeds through an oxide film as in aqueous solution (12), the rate of dissolution of the film must exceed the rate of its formation, at least under the galvanostatic conditions imposed here. And while the method of data acquisition has been shown to affect the observed overpotential parameters (49), the possibility of an ECE mechanism or another double layer oxidation step cannot be ruled out as an explanation for the low n values in these electrolytes.

Lithium methoxide proved conducive to Mo(VI) generation, analogous to the aqueous case, at all current densities. The high value of n at low current densities may be due to a slow reduction reaction occurring in the bulk solution. Evidence of this arose from observation of the yellow cell solution after electrolysis. Spectral scans were made from 600 to 300 nm immediately following electrolysis and at 15 min intervals thereafter. The charge transfer band shifted into the u.v. and a peak at 450 nm grew in. The latter band is characteristic for Mo(V) species (43), and it is possible that in strong base, methanol can be oxidized by the Mo(VI) species.

Another, though less likely explanation would be that indeed a Mo(VII) species was generated; such a permolybdate species was postulated to be stable in very basic aqueous solution at high potentials by Pourbaix (44), although such species are formed by treatment of Mo(VI) with peroxide.

Tungsten.—The behavior of this metal in methanolic chloride appears uncomplicated, and essentially represents oxidation to W(VI). Tafel linearity extends for one decade of current density (Fig. 11). Cell solutions lacked absorption characteristics in the visible spectrum and were without precipitates.

The E *vs.* log i curves in perchlorate and nitrate solutions exhibit Tafel slopes roughly parallel to those for chromium in the same media, and like chromium, were characterized by the formation of precipitates. In this instance they appeared as white dendrites on the anode itself, which proved to be freely soluble in aqueous base.

In one molar nitrate the average initial valency was 5.42 ± 0.12 and fairly constant, whereas in perchlorate solution it exhibited behavior similar to that of molybdenum, without the formation of chlorine dioxide. This range of n data would indicate that perhaps more than one oxidation mechanism is operative in ClO_4^- and NO_3^- solutions. The formation of insoluble oxidation products (probably oxides or mixed oxide esters) was observed at localized pitting sites rather than evenly over the anode surface, and could be responsible for the tendency toward lower apparent oxidation states at the higher current densities. These observations of apparent oxidation number in perchlorate and nitrate solutions are in keeping with aqueous behavior in other electrolytes for tungsten (13) and also for molybdenum (14). The rich aqueous oxide chemistry of tungsten, which includes substoichiometric oxides between WO_2 and WO_3 seems to be operative in methanolic solution also.

Lithium methoxide solution favors simple oxidation to W(VI), and the E *vs.* log i behavior is identical to that of molybdenum in this medium (Fig. 7). Evaporation of cell solutions under nitrogen produced a vitreous gel which, on exposure to air, turned to an amorphous white solid.

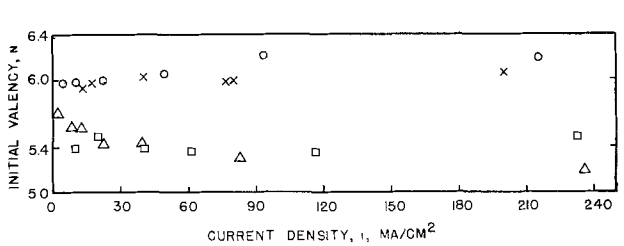

Fig. 11. Coulometric n as a function of current density for molybdenum. ○, 1.0M LiCl, CH_3OH; △, 1.0M $LiClO_4$, CH_3OH; □, 1.0M $LiNO_3$, CH_3OH; ×, 1.0M $LiOCH_3$, CH_3OH.

Summary

The anodic behavior of Group VI metals in methanolic solution has proven to be a rather dramatic function of supporting electrolyte. In parallel with established chemistry in aqueous solution, chromium shows a more recalcitrant oxidation than either molybdenum or tungsten. Only in chloride solution is oxidation to Cr(III) well behaved and 100% efficient. Oxidation to a nonintegral electrochemical valence seems to be the rule for molybdenum and tungsten in perchlorate and nitrate media, with accompanying formation of insoluble oxides.

The production of chlorine dioxide in perchlorate solutions during anodic polarization of molybdenum was noteworthy, in that previous observations were in acetonitrile at a noncorroding anode (50).

Tafel slopes for all the metals in all four electrolytes were well above 2.303 $RT/\mathbf{F}$, indicating a complex oxidation reaction.

Finally, the role of water in methanol was seen to be significant as measured in terms of shifts in the current-potential behavior along the potential axis.

The relatively straightforward aqueous electrochemistry of these metals is not retained in the protic solvent methanol; a rich redox chemistry has emerged which might have significant analytical and synthetic implications.

Acknowledgment

Much of the data for chromium and molybdenum was part of the thesis of the author and the remainder was supported by the Research Council of the University of Missouri-Columbia, under a Summer Research Fellowship.

Manuscript submitted Dec. 6, 1976; revised manuscript received Jan. 28, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

The Thermal Decomposition of $CaSO_3$ and Its Enthalpy of Formation

D. Cubicciotti,* A. Sanjurjo, and D. L. Hildenbrand

Stanford Research Institute, Menlo Park, California, 94025

ABSTRACT

The decomposition pressure of $CaSO_3$ was measured by the torsion-effusion method over the temperature range 723°-767°K. Mass spectrometric analysis showed the effusing vapor to be SO_2 and that the decomposition/vaporization process was $CaSO_3(s) = CaO(s) + SO_2(g)$, in agreement with vapor molecular weight determinations. The observed vaporization process was not the thermodynamically most favored one, which would have produced gaseous S_2. Observed pressures were found to be dependent on the area of the effusion orifice, and the results were extrapolated to zero orifice size to derive the following equation for the equilibrium pressures of SO_2

$$\log p(\text{atm}) = -\frac{(11{,}710 \pm 600)}{T} + (9.27 \pm 0.80)$$

The standard enthalpy of formation of $CaSO_3$ at 298°K was found to be -277.0 ± 1 kcal/mole.

The reactions of lime and limestone with gaseous SO_2 are of considerable interest for the control of sulfur pollution in combustion gases. The chemistry of the absorption of SO_2 by CaO or $CaCO_3$ at high temperatures is rather complex because the reaction is heterogeneous and also because several solid phases are involved. Calcium sulfite is presumably the first solid formed in the reaction. Surprisingly, its enthalpy of formation has not been measured although a number of estimated values have been reported. In the present work, we have studied the vacuum decomposition of $CaSO_3$ to SO_2 and CaO and evaluated the enthalpy of formation of $CaSO_3$.

The high temperature equilibrium chemistry of the Ca-S-O system has been discussed recently by Tarradellas and Bonnetain (1) and by Schwitzgebel and Lowell (2). Calcium sulfite is thermodynamically unstable over the temperature range of interest, and should disproportionate by a reaction that produces no gaseous products, namely

$$4CaSO_3(s) = 3CaSO_4(s) + CaS(s) \qquad [1]$$

for which $\Delta G°$ at 700°K is -214 kcal/mole. However, that reaction is kinetically limited, presumably because it involves drastic rearrangements of the atoms in the sulfite ion.

Apparently, $CaSO_3$ can exist in a state of metastable equilibrium. No measurable disproportionation occurs when it is heated to temperatures below 775°K for periods of many hours, even though the free energy change of reaction [1] is quite negative. Tarradellas and Bonnetain (1) found from x-ray diffraction studies that disproportionation did not occur below 825°K (we presume the time of heating in their work was at least an hour). Marier and Ingraham (3) found no weight changes or thermal effects below 925°K when $CaSO_3$ was heated in N_2. Pechkovskii (4) observed some formation of $CaSO_4$ in excess SO_2 at 810°K. Foerstel and Kubel (5) observed disproportionation at 857°K, but not at 775°K when samples were heated for 2 hr in a

* Electrochemical Society Active Member.

Key words: sulfur dioxide, calcium oxide, thermodynamics, torsion effusion, gas molecular weights.

current of N_2. Low *et al.* (6) studied the infrared spectra of surface layers of $CaSO_3$ on CaO heated in vacuum. They found changes in the spectrum occurred only at temperatures of 825°K and above in 3 hr time periods.

Marier and Ingraham (3) did find endotherm and weight losses beginning about 925°K in DTA measurements on $CaSO_3$, which imply that a gaseous product is formed. They suggest the reaction was

$$CaSO_3(s) = CaO(s) + SO_2(g) \quad [2]$$

Our results, below, show that reaction [2] was the reaction that occurred under the conditions of our experiments, and probably those of Marier and Ingraham (3). At 700°K, $\Delta G°$ for that reaction is 23.9 kcal/mole. A more thermodynamically favored way of forming a gaseous product involves the formation of sulfur by the reaction

$$6CaSO_3(s) = 4CaSO_4(s) + 2CaO(s) + S_2(g) \quad [3]$$

which has $\Delta G°$ at 700°K equal to 9.5 kcal/mole, and the pressure of S_2 should be of the order of 10^{-3} atm. If both reactions [2] and [3] occurred, the equilibrium ratio of S_2 to SO_2 should be of the order of 10^5 in this temperature range. Our results show the reaction [3] did not occur.

The pressure of SO_2 for the decomposition reaction [2] would be expected to attain values in the range of $3 \cdot 10^{-7}$ atm at 750°K. Pressures in that range were too small to be measured in the manometric system used by Marier and Ingraham (3), and they observed no decomposition pressure. The present study utilized torsion-effusion measurements, which are suited to pressures of that magnitude, and mass spectrometric analysis to identify the gaseous species.

Experimental Method

Preparation.—Commercially available samples of $CaSO_3$ were not acceptable because their x-ray diffraction patterns indicated the presence of $CaSO_4$, presumably formed by air oxidation.

Samples were prepared for this work by very slow addition of aqueous Na_2SO_3 solution to $CaBr_2$ solution in aqueous ethanol. The precipitate was filtered under an N_2 atmosphere and dried in a current of argon at 675°K for 4 hr. The product was handled in a dry N_2 atmosphere. The observed x-ray pattern agreed with that reported (7) for $CaSO_3$.

Effusion measurements.—In the torsion-effusion weight-loss method (8) used here, the pressure of gas escaping through an orifice is calculated from the torque exerted on a fiber; the weight-loss information allows the molecular weight of the effusing gas to be calculated. The apparatus used has been described in earlier publications (8, 9). The effusion cells used in the present study were fabricated from high purity alumina; each cell assembly was comprised of two vertically aligned sample chambers, 3 cm long and 1 cm in diameter, mounted on either side of the suspension axis.

The sample (350 mg in each leg of the cell) was loaded under an N_2 atmosphere and the cell was quickly attached to the apparatus and evacuated. The sample was heated slowly so that the pressure in the apparatus was always less than 10^{-8} atm. At temperatures up to about 600°K some H_2O was evolved, as determined from molecular weight measurements. From about 600° to 700°K, no measurable amounts of gas were evolved. Above about 700°K, gas was evolved with a molecular weight of 64 ± 8.

Measurements were made over the range 723°-767°K. The upper temperature was chosen to avoid the disproportionation of the sample which was anticipated from the literature. After the temperature and angular deflection were steady for 1 hr at each temperature, measurements were taken. The sample was studied over a period of days during which time less than 2% of the sample had decomposed. The sample was x-rayed at the end of the run.

Table I. Cell characteristics

Cell	Orifice diameter, mm	Lever arm, mm	Wall thickness, mm	$\Sigma(Ca)$,* cm^3
1	1.048	9.744	1.083	$8.708 \cdot 10^{-3}$
2	2.095	9.949	0.966	$4.752 \cdot 10^{-2}$

* C is the Clausing factor (13) and a the area of each orifice.

Two cells were used with different effusion orifice areas. The cell geometrical constants, determined from measurements with a traveling microscope, are given in Table I. The calibration constants of the cells were checked by measuring the vapor pressure of KCl; the results were within 5% of the data reported by Pugh and Barrow (10).

The pressure of the gas effusing from the cell was calculated from the expression

$$p = \frac{2k\theta}{\Sigma afq} \quad [4]$$

where k, the torsion constant of the suspending ribbon, had a value of 0.07814 dyne-cm/rad as determined from a torsion pendulum treatment, in close agreement with the supplier's specifications. The angular displacement, θ, was measured by observation of a fixed scale reflected in a mirror attached to the suspension system. Values of f, the orifice force factor, were taken from Schulz and Searcy (11). The moment arm is q and the area of the orifice is a.

The molecular weight of the effusing gas was calculated from the expression

$$M = 2\pi RT\{[\dot{w}(\Sigma afq)]/[2k\theta(\Sigma Ca)]\}^2$$

in which $\dot{w}$ is the rate of weight loss, T the temperature, and C is the orifice Clausing factor.

Results

The pressures obtained by the torsion-effusion method are given in Table II in the chronological order in which they were obtained. Determinations of the molecular weight required that the sample be maintained at constant temperature for long times; therefore, only a few such measurements were made. The resulting molecular weights were in the range 64 ± 8

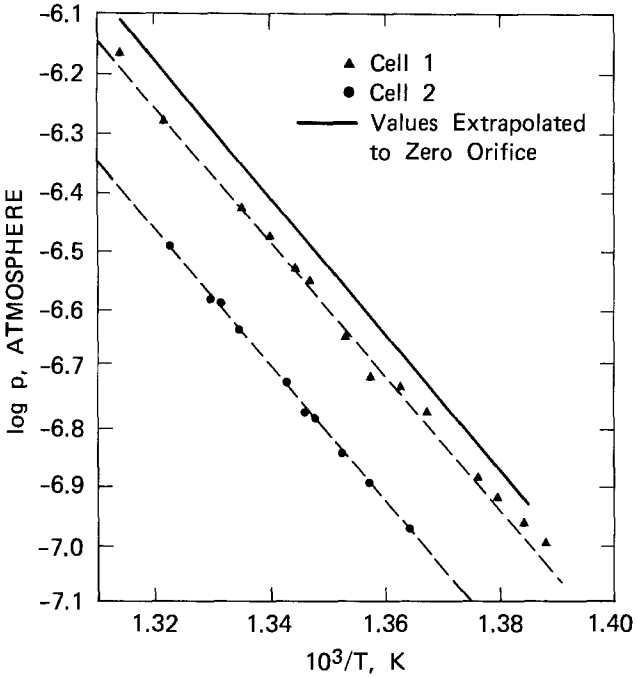

Fig. 1. Torsion effusion pressures for $CaSO_3$

and were interpreted to indicate that the effusing species was SO_2 or S_2.

The measured pressures are shown graphically in Fig. 1; higher pressures were observed with the smaller effusion orifices. Such results indicate that the rate of escape of gas from the cell was sufficiently large to perturb the rate of release of gas from the solid. That effect is not surprising in an incongruent vaporization process like the one under study. The values obtained in the two cells were analyzed by a least squares treatment, which resulted in the following equations for the apparent pressures in atmospheres

$$\text{cell 1:} \quad \log p = 8.76 - 11{,}380/T \qquad [6]$$

$$\text{cell 2:} \quad \log p = 8.71 - 11{,}500/T \qquad [7]$$

The Whitman-Motzfeldt treatment is normally applied to extrapolate effusion results to zero orifice size (9). That equation relates the measured pressure (p) to the orifice area (a), Clausing factor (C), and equilibrium pressure (p_{eq}) through a constant (β), as follows

$$\frac{p_{eq}}{p} = (1 + \beta aC) \qquad [8]$$

Thus a plot of the reciprocal of measured pressure *vs.* aC has $1/p_{eq}$ as an intercept and β/p_{eq} as a slope.

A correlation of the pressure data obtained with the two cells yielded a β value of 18 ± 1, independent of temperature. With this value of β, the equilibrium pressure (p_{eq}) was calculated for each measurement; the results are given in Table II. A least squares treatment of the equilibrium pressures for both cells gives

$$\log p_{eq}\ (\text{atm}) = -\frac{(11{,}710 \pm 600)}{T} + (9.27 \pm 0.80) \qquad [9]$$

Our initial interpretation of the results following the general tenor of the literature was that we were measuring the pressure of SO_2 generated according to reaction [2]. The molecular weight of effusing gas agreed with that of SO_2, and the enthalpy of formation derived for $CaSO_3$ was in agreement with estimated values. During our study we realized that the vaporization of $S_2(g)$ by reaction [3] was thermodynamically more favored than the vaporization of $SO_2(g)$. Thus, the partial pressure of S_2 should have been significantly greater than that of SO_2. Because the molecular weight of S_2 is the same as SO_2, the torsion weight-loss measurement of molecular weight could not distinguish between those species. Mass spectrometer studies were made to identify the gaseous species. Although the mass number of the ions produced from the two species (SO_2^+, S_2^+, or fragments) were not distinguishable in the mass spectrometer, the ions could be distinguished from their ionization efficiency curves. Thus, S_2 has an ionization potential of 9.4 eV while that of SO_2 is 12.4 eV. Therefore, measurable ion currents of parent S_2^+ would be observed at ionizing electron energies small enough so that no SO_2^+ would be formed.

A sample of $CaSO_3$ was heated in an alumina cell, with a 1.5 mm orifice, in the mass spectrometer. At 758°K, the m/e 64 signal exhibited a sharp shutter effect, indicative of an effusion cell origin, and had a threshold appearance potential of 12.6 ± 0.3 eV in agreement with that of SO_2^+. With higher sensitivity, there was no indication of S_2^+ at ionizing energies below 12.5 eV, nor were any other effusion cell species observed. A second set of observations made with a 0.3 mm diameter orifice yielded similar results. At about 900°K, well beyond the range of the torsion measurements, a small S_2^+ signal did appear below 12.5 eV, but the relative ion intensities indicated the ratio $p(SO_2)/p(S_2)$ to be greater than 20. Thus, the effusing gas was clearly identified as SO_2.

Discussion

In view of the mass spectrometer identification of SO_2 as the effusing gas, the pressures measured in the effusion studies should be interpreted according to reaction [2]. Thus, the pressures obtained from the extrapolation of the effusion pressures to zero orifice size will be taken as the equilibrium pressures for reaction [2].

The thermochemical information available for SO_2 and CaO at temperatures of interest is essentially complete and is reported in the JANAF Tables (13). For $CaSO_3$, the heat capacity up to room temperature has been measured, so the absolute entropy is known (2, 12). The heat capacity above room temperature has been estimated by extrapolation and comparison with other salts (2). The free energy function of $CaSO_3$, calculated from those values, is given in Table III.

Table III. Thermochemical data for $CaSO_3(s)$

T, °K	$C_p°$, cal/mol deg	$S°$, cal/mol deg	$-\left(\frac{G°_T - H°_{298}}{T}\right)$, cal/mol deg	$H°_T - H°_{298}$, kcal/mole	$\Delta Hf°_T$,* kcal/mole	$\Delta Gf°_T$,* kcal/mole	log K_p*
298	21.72	24.20	24.20	0.00	−277.0	−257.1	188.6
400	24.21	30.96	25.09	2.35	−277.5	−250.2	136.7
500	26.20	36.58	26.84	4.87	−277.7	−243.4	106.4
600	28.02	41.52	28.88	7.58	−277.6	−236.7	86.2
700	29.76	45.96	31.00	10.47	−277.3	−229.7	71.7
800	31.46	50.05	33.14	13.53	−290.3	−224.2	61.3
900	33.13	53.86	35.23	16.76	−289.6	−216.0	52.5
1000	34.78	57.43	37.27	20.16	−288.7	−207.8	45.4

* $\Delta Hf°_T$, $\Delta Gf°_T$, and log K_p refer to the equation for formation from the elements in their standard states as defined in the JANAF Tables.

The enthalpy change for reaction [2] at 298°K was calculated from each value of the equilibrium pressure, using the thermochemical data of Table III. The values are given in Table II. The enthalpy changes given are so-called third law values because the absolute entropies of all reactants were combined with the derived equilibrium pressures at the individual temperatures quoted. There is no drift of the enthalpies with temperature, within experimental error. The average values for each of the two cells were 54.3 ± 0.2 and 54.2 ± 0.2 kcal/mole, so that 54.3 ± 0.2 kcal/mole represents the enthalpy change at 298°K for the entire set of data.

The temperature coefficient of pressure can be used to determine a second-law value of the reaction enthalpy change. The result provides a check on the internal consistency of the data. The value calculated from Eq. [9] is 53.6 ± 2.7 kcal/mole and represents the enthalpy change for reaction [2] at 745°K. That result is converted to a 298°K value of 55.3 ± 2.7 kcal/mole by use of the heat capacity data in Schwitzgebel (2) and Table III. The result is less precise than the third law value primarily because of the short temperature range in which measurements could be made; however, the two values are in good agreement.

The standard enthalpy of formation of $CaSO_3(s)$ at 298°K was calculated from the third law value and enthalpies of formation (12) of CaO (−151.79 ± 0.2 kcal/mole) and $SO_2(g)$ (−70.95 ± 0.1 kcal/mole). The resulting value is −277.0 kcal/mole. We estimate an uncertainty of 1 kcal/mole. Table IV compares the experimental value of the enthalpy of formation of $CaSO_3$ to several estimates in the literature. The estimated values are within a few kilocalories of the experimental value obtained in the present work. A table of thermodynamic functions based on that value is given in Table III. Those functions are compatible with the JANAF Tables and can be used with them for equilibrium calculations.

Under the conditions of our experiments, the reaction that occurs, namely reaction [2], is not so thermodynamically favorable as at least two other reactions ([1] and [3]) that do not occur. That apparent anomaly must be due to kinetic effects so that under other experimental conditions one might expect different net reactions. For example, if $CaSO_3$ were heated in a closed container so that SO_2 could not escape, or if it were heated in excess SO_2 then the other reactions might begin to occur. A study of the kinetics and mechanisms of these reactions should prove fruitful.

Even without a knowledge of the detailed mechanism one might suspect that decomposition to SO_2 would be kinetically easier than the thermodynamically favored reactions.

Table IV. Estimates of enthalpy of formation of $CaSO_3(s)$ reported in the literature compared with present experimental value

Estimated $-\Delta H°_f$, 298°K (kcal/mole)	Reference
275.1 ± 2	Schwitzgebel *et al.* (14)

276.3 ± 1.5	Erdos (16)
275.9 ± 2.5	Lowell (2)
284.3†	Trautz and Pakeschwer (17)
277.5‡	Pechkovskii (4)
274.0	Tarradellas and Bonnetain (1)
Experimental value	
277.0 ± 1	This work

* Although Schwitzgebel *et al.* quote Maslov's value as experimental, it is really an estimate based on an extrapolation of hydrated salt values to anhydrous values.
† This value corresponds to $CaSO_4 \cdot 2H_2O$.
‡ Estimated from Pechkovskii calculations.

The formation of a molecule of SO_2 from $CaSO_3$ results from the rupture of one S—O bond, and the residual $O^=$ simply replaces the original $SO_3^=$. The formation of a molecule of S_2, on the other hand, involves rupture of six S—O bonds. Eventually, four of the oxygen atoms released become incorporated into the structure to form four $SO_4^=$ ions with a recovery of sufficient energy, including the S_2 bond energy, to make the process energetically more favorable.

The mechanism of reaction [1] is also expected to be complex. The formation of one $S^=$ ion requires rupture of three S—O bonds and redistribution of the oxygens to form three $SO_4^=$ ions. It is not surprising that the activation energies for those processes are significantly larger than that for SO_2 vaporization.

In first approximation, the β of Eq. [8] is related to the vaporization coefficient, α, and the decomposing surface area, A, by the expression $\beta = (\alpha A)^{-1}$. If A is taken to be the cross-sectional area of the cell, *i.e.*, the projected sample surface area, then $\alpha \cong 5 \times 10^{-2}$. Interestingly enough, this is close to the value $\alpha \cong 4.4 \times 10^{-2}$ found in effusion studies (13) of the decomposition process $MgSO_4(s) \rightarrow MgO(s) + SO_3(g)$, indicating that the kinetic barriers in the two processes are quite similar. Because the initial step in the decomposition processes of both $CaSO_3$ and $MgSO_4$ appears to be a rupture of an S—O bond, this similarity seems reasonable.

High Conductivity Cuprous Halide-Metal Halide Systems

Tsuneo Matsui[1] and J. Bruce Wagner, Jr.*,[1]

Materials Research Center and Department of Materials Science and Engineering, Northwestern University, Evanston, Illinois 60201

ABSTRACT

The a-c electrical conductivity has been measured for the systems, CuI + CdI_2, CuCl + $CdCl_2$, CuI + KI, CuI + RbI, and CuCl + RbCl and the results have been discussed in relation to phase diagrams. New highly conducting materials at room temperature have been surveyed for the system, RbCl + CuCl.

The solid electrolytes MAg_4I_5 (M = K, Rb, and NH_4) have recently been reported to have unusually high ionic conductivities (1-3). Because of the similar properties of the Ag^+ and Cu^+ ion together with the much lower cost of copper compared to silver, it is of considerable interest to synthesize copper electrolytes with high ionic conductivities analogous to those of the silver electrolytes. Copper ion high conducting materials have been recently reported (4-7). But all these materials contained organic compounds as additives. Thus some of these were somewhat unstable when used in galvanic cells (6).

In the present investigation, three methods were investigated for the preparation of new solid electrolytes with high copper ion conductivities at low temperatures. The first was the classical method of doping CuI by an aliovalent cation, in this case Cd (as CdI_2). The second was to make the different compounds by utilizing open structures. In the present study, the layered structure of $CdCl_2$ was used to make the new compound of Cu_4CdCl_6 (4 CuCl + $CdCl_2$). The third method was the preparation of a different compound by using monovalent alkali-metal halides in analogy to the highly conducting silver compounds (1-3). In the present study, KI and RbI were added to CuI, and RbCl was added to CuCl. The conducting characteristics of the compounds prepared by these three methods have been studied by using a-c conductivity measurements. The results are also discussed in relation to phase transitions.

Experimental

Materials.—The samples used in this study were polycrystalline pellets. The following materials were used: ultrapure, anhydrous CuI powder (99.9998%, Alfa Products, Ventron Corporation); ultrapure CdI_2 powder (99.998%, Alfa Products, Ventron Corporation); CuCl powder (99.999%, Semielements Incorporated); $CdCl_2$ powder (99.999%, Apache Chemicals Incorporated); KI powder (99.998%, Apache Chemicals Incorporated); and RbI and RbCl (99.9%, Apache Chemicals Incorporated). The samples were made by mixing the powders with the appropriate amounts of the halides, from which some of the water had been removed by heating at about 110°C in an evacuated Pyrex or Vycor tube before mixing.

A spark source mass spectrometric chemical analysis of $RbCu_4Cl_5$ after completion of the experiments is shown in Table I. The impurities total 0.067% by weight. The carbon most probably was introduced by the graphite electrodes used in the subsequent polarization study (23). Other impurities may have been present in the RbCl and RbI starting materials. The mixed powders were pressed at 75,000 psi in a 0.319 in. steel die at room temperature in air. The freshly prepared pellets were sintered in a sealed, evacuated quartz tube. In the case of the RbI + CuI and RbCl + CuCl systems, the halides were melted in the evacuated, sealed tubes at temperatures of 235° and 250°C, respectively (see Table I). After solidifying the material was ground, pressed, and annealed. The sizes of all the pellets were about 8 mm in diameter and 2 mm long. The detailed conditions of sample preparation and annealing conditions used in this study are presented in Table II.

* Analysis by Quad Group, Santa Barbara, California.
** Residual elements.
No determination for hydrogen was made.
Gold and tantalum are not reported since gold electrodes and tantalum slits are used.
Concentration of major matrix elements, Rb, Cu, and Cl are not listed.
Background lines interfere with the determination of beryllium, cesium, and germanium. Other elements not listed were not reported and have a detection limit of 1 ppma.

Conductivity measurements.—The electrical conductivity was measured by using a General Radio a-c bridge (1650A) at 1 kHz and also measured in the frequency range 1-20 kHz by audio oscillator Model 202D (Hewlett-Packard). There was no frequency dependence in this range except for the RbCl + CuCl system. All the measurements were carried out under flowing argon gas (about 0.3 cm/sec) purified by passing over heated copper turnings at about 400°C to remove trace oxygen gas and passing through a tube of silica gel to remove water vapor.

* Electrochemical Society Active Member.

Key words: cuprous halide, metal halide, high electrical conductivity.

Table II. Sample preparation

Compound	Sintering condition	Annealing condition	Density (g/cm^3)
Cu_4CdI_6	320°C for 15 hr and then 420°C for 105 hr	400°C for 2 hr	4.98
Cu_2CdI_4	320°C for 15 hr and then 420°C for 105 hr	400°C for 2 hr	4.85
Cu_4CdCl_6	400°C for 93 hr	370°C for 2 hr	3.48
Cu_2CdCl_4	400°C for 93 hr	370°C for 2 hr	3.55
KCu_4I_5	After first sintering at 310°C for 71 hr, the pellet was pulverized and pressed, and then sintered again at 300°C for 115 hr	300°C for 2 hr	4.12
$RbCu_2I_3$	After melting at 335°C for 14 hr, the samples were ground and then pressed.	255°C for 16 hr	4.68
$RbCu_4I_5$			4.89
$RbCu_3Cl_5$	After melting at 250°C for 16 hr, the samples were ground and then pressed.	145°C for 16 hr	3.39
$RbCu_4Cl_5$			3.69
CuCl	After first sintering at 390°C for 72 hr, the pellet was pulverized and pressed, and then sintered at 390°C for 96 hr.	370°C for 2 hr	3.69

To make the conductivity measurements, the sample was sandwiched between copper electrodes which were 99.999% pure copper rod obtained from the American Smelting and Refining Company. Electrical contact was ensured by applying a slight spring pressure. Prior to the measurements, the cells were given a second anneal (see Table II). The annealing conditions and the densities are also summarized in Table II. Before and after measurements, there was no change in densities.

A Marshall resistance furnace was used in a horizontal position. The temperatures were controlled to ± 1°C by Leeds and Northrup Electromax controller and the temperature was measured by Doric Digital voltmeter using a Chromel-Alumel thermocouple which was calibrated by the phase transitions (369° and 407°C) of CuI.

Results and Discussion

CuI + CdI_2 system.—The crystal structure of CdI_2 is hexagonal with a layered structure, which can be viewed as more or less perfect packing of large anions with the smaller cations situated in the interstices (8). Herrmann (9) has reported that CdI_2 is soluble in CuI in all concentrations.

In the present investigation, the electrical conductivities of Cu_2CdI_4 [33 mole percent (m/o) CdI_2] and Cu_4CdI_6 (20 m/o CdI_2) samples were measured, and the results are shown in Fig. 1 and summarized in Table III. In previous studies (10), HgI_2 was used to stabilize the high temperature α-CuI phase at lower temperatures, and stabilization was achieved by formation of the compound, Cu_2HgI_4. Compared with the results on Cu_2HgI_4, our results on Cu_2CdI_4 and Cu_4CdI_6 suggest that the α-phase was not stabilized enough at lower temperatures, although the temperature above which the α-phase is stable was lowered from 407° to 308°C. This may be due to the difference in the crystal structure between Cu_2HgI_4 and Cu_2CdI_4. The crystal structure of α-Cu_2HgI_4 is the same as that of α-AgI (11), but the structure of Cu_2CdI_4 is not that of the intermediate phase, Cu_2HgI_4, but almost the same as α-CuI. This may occur because Cu_2CdI_4 is a solid solution with 33 m/o CdI_2 (7).

The transition temperatures obtained by the electrical conductivity in the present study and from previous data (9) are shown in Fig. 2. Previous results obtained by thermal analysis (9) are not sufficiently detailed to allow clarification into two (α-β and β-γ) phase transitions. Both the α-β and β-γ transition temperatures decreased with increasing concentrations of CdI_2. On the other hand, the activation energies in α-phase increased, which suggests that the mobility of copper ions was decreased by cadmium ions at normal copper lattice sites (interaction between cadmium ions and copper ions).

The electrical conductivities of Cu_2CdI_4 and Cu_4CdI_6 are higher by about one order of magnitude than pure CuI (Fig. 1) at high temperatures (200°-300°C) which may be due to the contribution of copper vacancies produced by introduction of cadmium ions. At low temperatures, the conductivities of Cu_2CdI_4 and Cu_4CdI_6 are lower than pure CuI (12). This may be due to the association (or clustering) between copper vacancies and cadmium ions.

Table III. Transition temperatures and activation energies for cuprous iodide and cuprous iodide-metal iodide system

Materials	Transition temperatures (°C) α to β	β to γ	Previous* results (9)	Activation energies (eV)**
CuI	407 ± 2	369 ± 2	414 ± 8	0.15 ± 0.03
Cu_4CdI_6	360 ± 2	325 ± 2	340 ± 6	0.33 ± 0.01
Cu_2CdI_4	308 ± 2	276 ± 4	290 ± 4	0.40 ± 0.01
Cu_2HgI_4	67 (10)	—	—	0.59 ± 0.01

* These transition temperatures previously reported are not sufficiently detailed to allow clarification into α to β or β to γ transitions (9).
** These activation energies are for the high temperature α-phases.

CuCl + $CdCl_2$ system.—The crystal structure of $CdCl_2$ is almost the same layered structure as that of CdI_2, and only differs from the CdI_2 structure in having its anions in a cubic rather than hexagonal close-packing (8). Herrmann has also studied the phase diagram of the CuCl + $CdCl_2$ system (9). According to his result, Cu_4CdCl_6 can only exist as a compound in this system.

In the present study Cu_4CdCl_6, Cu_2CdCl_4 [strictly speaking Cu_2CdCl_4 consists of two coexisting phases

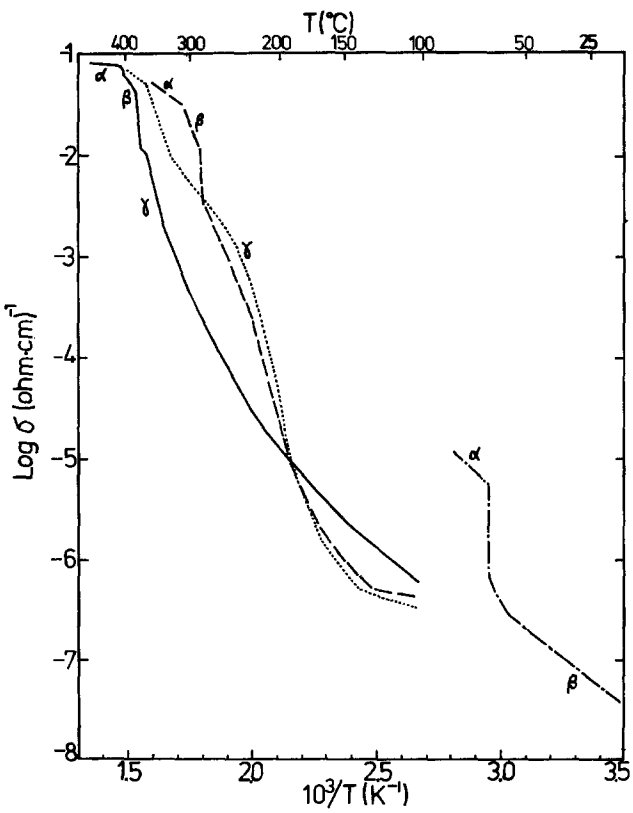

Fig. 1. The temperature dependence of the electrical conductivity of the CuI + CdI_2 system: —— pure CuI, ... Cu_4CdI_6 (20 m/o CdI_2), – – – – – Cu_2CdI_4 (33 m/o CdI_2), –·–·– Cu_2HgI_4 [Ref. (10)].

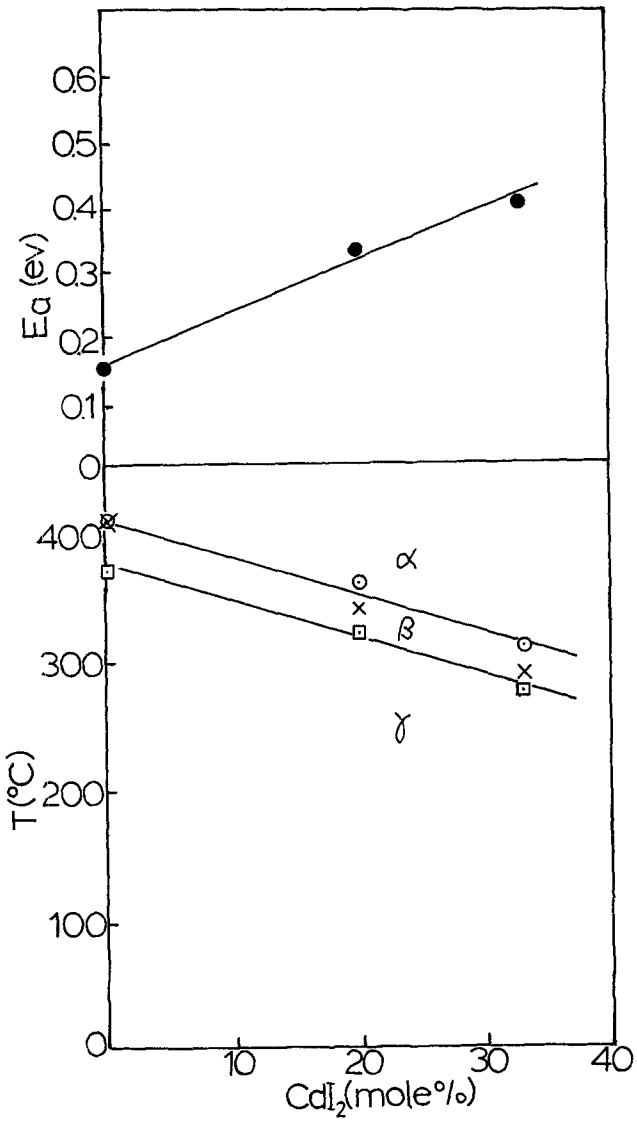

Fig. 2. Transition temperatures and activation energies vs. molar percentage of CdI_2: ● activation energy in the α-phase (this study), ⊙ transition temperatures of α-β transition (this study), ⊡ transition temperatures of β-γ transition (this study), X transition temperatures by thermal analysis (9).

of Cu_4CdCl_6 and $CdCl_2$ (9)], and pure CuCl samples were made. The conductivity results are shown in Fig. 3 and Table IV. At temperatures above 130°C, both Cu_4CdCl_6 and Cu_2CdCl_4 exhibited higher electrical conductivity than pure CuCl. This is due to the contribution of copper vacancies produced by introduction of cadmium ions. At lower temperatures there was no significant change which may be due to the precipitation of $CdCl_2$. The present data on polycrystalline CuCl are in good agreement with the data reported previously on single crystals (14, 15) and on polycrystals (16) at high temperatures (the intrinsic region). However, at low temperatures, our conductivities are higher than the previous data on single crystals (14, 17). This discrepancy may be attributed to grain boundaries or to impurities. The transition temperature of β to γ for Cu_4CdCl_6 (*i.e.*, the stable existence region of high temperature β-phase) was lowered from 407° to 330°C, and the transition temperatures obtained in the present study are in good agreement with previous data on Cu_4CdCl_6 obtained by thermal analysis (9). Both activation energies and transition temperatures of Cu_4CdCl_6 and Cu_2CdCl_4 were in good agreement with each other within experimental error. This is because Cu_2CdCl_4 does not exist as a single phase but exists as two phases of Cu_4CdCl_6 and $CdCl_2$ (9).

KI + CuI system.—The phase diagram of the KI + CuI system has been studied by Bradley and Greene

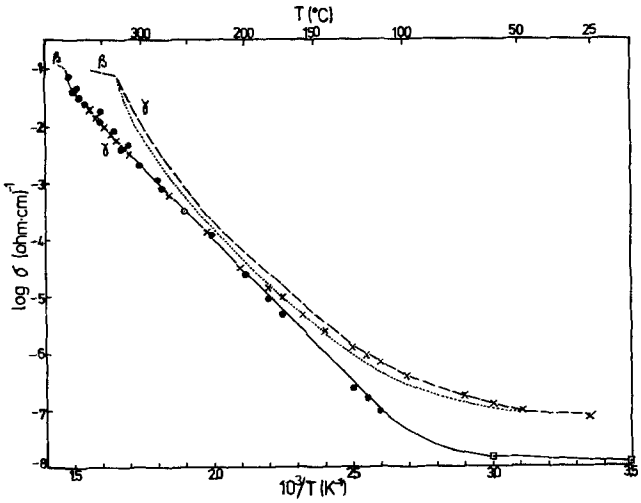

Fig. 3. The temperature dependence of the electrical conductivity of the CuCl + $CdCl_2$ system: ..... Cu_4CdCl_6 (this study), – – – – – Cu_2CdCl_4 (this study), x x x CuCl (this study), ⊙ Wagner and Wagner (16) CuCl, ⊡ Rivera et al. (17) CuCl, ● Hseuh and Christy (14) CuCl.

(2). According to their data, the KI + CuI system contains only one intermediate compound KCu_4I_5 which is stable between 257° and 332°C, the latter temperature being the incongruent melting point. However, they have not reported electrical conductivity data of KCu_4I_5. The present conductivity data are shown in Fig. 4. The temperature below which KCu_4I_5 decomposes to KI and CuI was 261° ± 2°C (see Fig. 4). This is in agreement with previous data [257°C by Bradley and Greene (2)], As seen from Fig. 4 the conductivity of KCu_4I_5 decreased abruptly by two orders of magnitude at 261°C. Above this transition, the electrical conductivity of KCu_4I_5 is about three orders of magnitude higher than that for pure CuI, although even after decomposition the conductivity of the two-phase mixture of KI and CuI was still higher than that of pure CuI. The small value of the activation energy for conduction in KCu_4I_5 suggests that the defect structure of KCu_4I_5 consists of highly disordered copper ions which, in turn, produce the high conductivity and is very similar to the MAg_4I_5 (M = K, Rb, and NH_4) compounds (1-3, 18).

CuI + RbI system.—In this system, two compounds, $RbCu_2I_3$ and Rb_2CuI_3, have been reported (2). The electrical conductivities of $RbCu_2I_3$ and $RbCu_4I_5$ (strictly speaking the latter is not a compound but consists of coexisting phases of $RbCu_2I_3$ and 2CuI) were measured between 25° and 250°C. The results are shown in Fig. 4. The electrical conductivity of $RbCu_2I_3$ was lower than pure CuI which may be due to the difference of crystal structure. The electrical conductivity of $RbCu_4I_5$ was also a little lower than pure CuI. The lower conductivity is due to the coexisting phase of CuI and the low conducting $RbCu_2I_3$, as is evident in the phase diagram (2).

CuCl + RbCl system.—In the present study the electrical conductivities of $Rb_2Cu_3Cl_5$ and $RbCu_4Cl_5$ (80

Table IV. Transition temperatures and activation energies for cuprous chloride and cuprous chloride-metal chloride system

Materials	Transition temperature (°C) β to γ	Previous results (9)	Activation energies* (eV)
CuCl	407 (13)	—	—
Cu_4CdCl_6	330 ± 2	350 ~ 310	0.26 ± 0.03
Cu_2CdCl_4	330 ± 2	319 ~ 309	0.22 ± 0.03

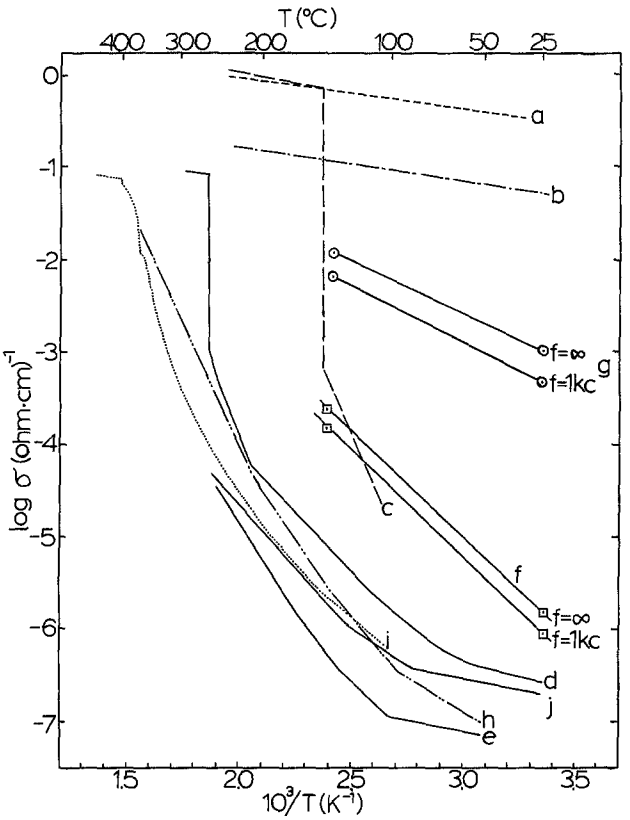

Fig. 4. The temperature dependence of the electrical conductivity of the cuprous halides and alkali halides system: (a) $RbAg_4I_5$ (18), (b) KAg_4I_5 (1), (c) AgI (22), (d) KCu_4I_5, (e) $RbCu_2I_3$, (f) $Rb_2Cu_3Cl_5$, (g) $RbCu_4Cl_5$, (h) CuCl, (i) CuI, (j) $RbCu_4I_5$.

m/o CuCl) were measured. The results are shown in Fig. 4. Sandonnini (19) has reported that the CuCl + RbCl system contains two intermediate compounds, Rb_2CuCl_3 and $Rb_2Cu_3Cl_5$, but he has not reported electrical conductivity data. These two compounds, especially the compound (80 m/o CuCl), have exceptionally high conductivity values even at room temperature. The electrical conductivity of these two samples exhibited a frequency dependence. None of the other samples exhibited such a frequency dependence. In Fig. 4, the conductivity values at 1 kHz and ∞ Hz are shown for the two samples, $Rb_2Cu_3Cl_5$ and $RbCu_4Cl_5$. Extrapolation to ∞ Hz was made to eliminate the faradaic impedance ΔR that may exist at the interface between electrode and electrolyte because the faradaic impedance is inversely proportional to the square root of frequency (20, 21). The sample containing 80 m/o CuCl [$RbCu_4Cl_5$] may be the new compound because of its high conductivity values compared to those of RbCl, CuCl, and $Rb_2Cu_3Cl_5$, and may exhibit predominantly ionic conduction just like $RbAg_4I_5$. Detailed results on the surveyed system, RbCl + CuCl will be reported in a subsequent paper (23).

The activation energies of cuprous halide and alkali-halide systems are summarized in Table V. As seen in this table, the higher the conductivity, the smaller the activation energy.

Summary

Electrical conductivity measurements on the systems CuI + CdI_2, CuCl + $CdCl_2$, CuI + KI, CuI + RbI, and CuCl + RbCl were carried out using the a-c method. The compounds KCu_4I_5, $Rb_2Cu_3Cl_5$, and $RbCu_4Cl_5$ (80 m/o CuCl) have been surveyed. These all exhibited high conductivity, especially $RbCu_4Cl_5$ which exhibited exceptionally high conductivity even at room temperature, for example, 8.25×10^{-4} Ω^{-1} cm^{-1} at 25°C and 1.14×10^{-2} Ω^{-1} cm^{-1} at 140°C. These conductivity values are higher than values reported for other copper-inorganic electrolytes and they are comparable to those previously reported for the copper-organic compounds (4-7).

Investigations on a High Conductivity Solid Electrolyte System, RbCl + CuCl

Tsuneo Matsui[1] and J. Bruce Wagner, Jr.*,[1]

Materials Research Center and Department of Materials Science and Engineering, Northwestern University, Evanston, Illinois 60201

ABSTRACT

Solid electrolytes with high copper ionic conductivity and low electronic hole conductviity have been found in the RbCl + CuCl system. The highest conductivity of $RbCu_3Cl_4$ [75 mole percent (m/o) CuCl] was 2.25×10^{-3} $(\Omega\text{-cm})^{-1}$ at 25°C. The conductivity has been measured as functions of temperature and of composition. X-ray patterns and thermal analyses indicate that the material is a new compound and not a mixture of the constituents.

Solid electrolytes exhibiting high conductivity such as Ag_3SI (1, 2), MAg_4I_5 (M = K, Rb, and NH_4) (3-5), KAg_4I_4CN (6), $Ag_{19}I_{15}P_2O_7$ (7), silver organic compounds (8-11), and β-Al_2O_3 (12) have been found and all these are silver ion or alkali ion conductors. Recently, Takahashi and his co-workers (13-15) and Sammells *et al.* (16) have found new copper ion solid electrolytes with high ionic conductivity. These copper compounds were copper-organic compounds, and some are unstable when used in galvanic cells (16).

The purpose of the present study is to prepare copper solid electrolytes without organic additives. In our preceding paper (17), many kinds of compounds in the cuprous halides and metal halides systems have been examined by a-c conductivity measurements, and the new compounds with high conductivity at room temperature have been found in the RbCl + CuCl system.

In the present study, the properties of the RbCl + CuCl system were investigated in more detail by the electrical conductivity measurements and x-ray techniques.

Experimental

Materials.—Ultrapure CuCl powder (99.999%, Semi-elements Incorporated) and RbCl (99.9%, Apache Chemicals Incorporated) were used. The compounds and intermediate compositions were prepared by mixing the powders with the appropriate amounts of two kinds of chlorides, from which some of the water had been removed by heating to about 110°C in an evacuated Vycor glass tube before mixing. The preparation and annealing condition of samples have been reported in the preceding paper (17).

Conductivity measurements.—The electrical conductivity was measured by using a General Radio a-c bridge (1650A) at 1 kHz and also measured in the frequency range 1-20 kHz by audio oscillator Model 202D (Hewlett-Packard). For the electronic conductivity measurements, a constant voltage supply (099034 Leeds and Northrup Company) with a voltage divider (Gertsch Products Incorporated, Model 1001) was used to apply the polarization potentials for the Cu/electrolyte/graphite cell. The polarization potential was measured by a Keithley 610B electrometer and the current in response to the applied polarization potential was measured by reading the voltage drop across a series resistor with a Doric Digital microvoltmeter. Before measurements the polarization cell was annealed at 145°C for 16 hr.

X-ray diffraction analysis.—The x-ray diffraction patterns were obtained at room temperature by using a Philips diffractometer with $KuC\alpha$ radiation through a Ni filter.

Differential thermal analysis.—A du Pont 990 digital thermal analysis instrument was used with the various heating rates (2°-10°C/min). As the reference material α-alumina powder was used, and the measurement was carried out under the nitrogen gas flow.

Results and Discussion

In the RbCl-CuCl system, two intermediate compounds, Rb_2CuCl_3 and $Rb_2Cu_3Cl_5$, have been reported by thermal analysis (18). The compounds $Rb_2Cu_3Cl_5$ (60 m/o CuCl) and $RbCu_3Cl_4$ (67.5, 75, 80, 85, 90 m/o CuCl) were studied in the present work.

Electrical conductivity measurements.—The values of electrical conductivity at 1 kHz and ∞ Hz are summarized in Table I. Extrapolation to ∞ Hz was made to eliminate the faradaic impedance ΔR, which is inversely proportional to the square root of frequency (19, 20)

$$\Delta R = K \cdot f^{-1/2}$$

where f is frequency and K a proportionality constant. The measured resistance Rm contains both the bulk electrolyte resistance R and any faradaic impedance effects that may exist at the interface between electrolyte and electrodes. Thus

$$Rm = R + \Delta R = R + Kf^{-1/2}$$

The error caused by ΔR was minimized by extrapolating the measured resistance to infinite frequency. The typical frequency dependences are shown in Fig. 1 and 2. As shown in Fig. 1, a linear extrapolation was possible to infinite frequency. This frequency dependence changed under the different annealing conditions (at 110°C for 16 hr and at 145°C for 16 hr). This

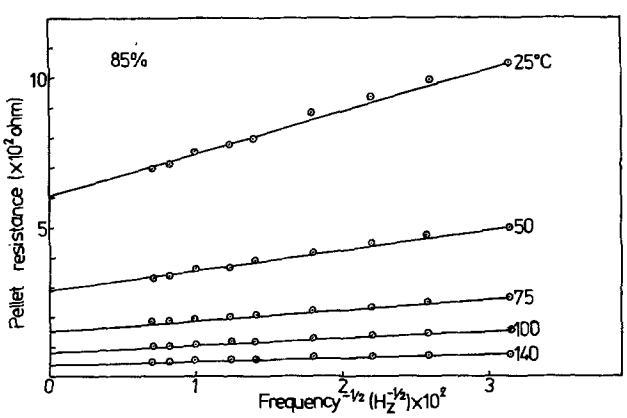

Fig. 1. Frequency dependence of the pellet resistance for the compound containing 85 m/o CuCl.

* Electrochemical Society Active Member.
[1] Present address: Center for Solid State Science, Arizona State University, Tempe, Arizona 85281.
Key words: copper electrolyte, high ionic conductivity, low electronic conductivity.

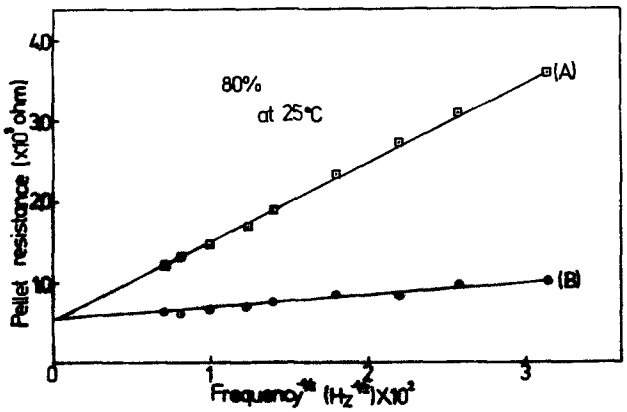

Fig. 2. Frequency dependence for the sample containing 80 m/o CuCl under the different annealing conditions: (A) annealed at 110°C for 16 hr, (B) annealed at 145°C for 16 hr.

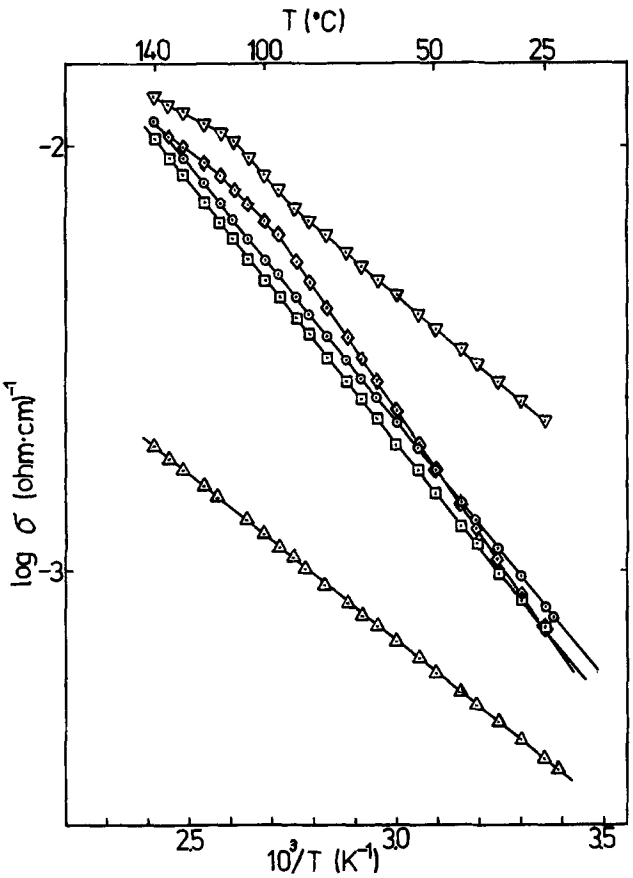

Fig. 3. Temperature dependence of the electrical conductivity for the compounds with various mole percent of CuCl at ∞ Hz: ◈ 67.5 m/o CuCl, ▽ 75.0, ⊙ 80.0, ▣ 85.0, ◬ 90.0.

behavior is probably due to the different contact conditions. However, the resistance at the infinite frequency was the same for each as is shown in Fig. 2. In this study we report the conductivities for samples annealed at 145°C for 16 hr. The temperature dependence of the electrical conductivity is shown in Fig. 3. For two samples ($RbCu_3Cl_4$ containing 75 m/o CuCl and 67.5 m/o CuCl), the changes of slope were observed at about 100° ~ 110°C. No heat change was observed near these temperatures by using the differential thermal analysis. This change in slope is unexplained at present.

The effect of composition (mole percent CuCl) upon the conductivity at room temperature (25°C) is shown in Fig. 4. The maximum value of 2.5×10^{-3} $(\Omega\text{-cm})^{-1}$ occurred at 75 m/o CuCl, which suggests the existence of a new compound whose stoichiometric composition is $RbCu_3Cl_4$. The conductivity values of the compounds from 67.5 m/o CuCl to 90 m/o CuCl were higher than that of $Rb_2Cu_3Cl_5$ by about three orders and were much higher than that of pure CuCl [polycrystalline CuCl (17) and single crystal CuCl (21)] by about four and five orders, respectively.

The activation energies of conductivity of these compounds are summarized in Table I. Note that the higher the conductivity, the smaller the activation energy.

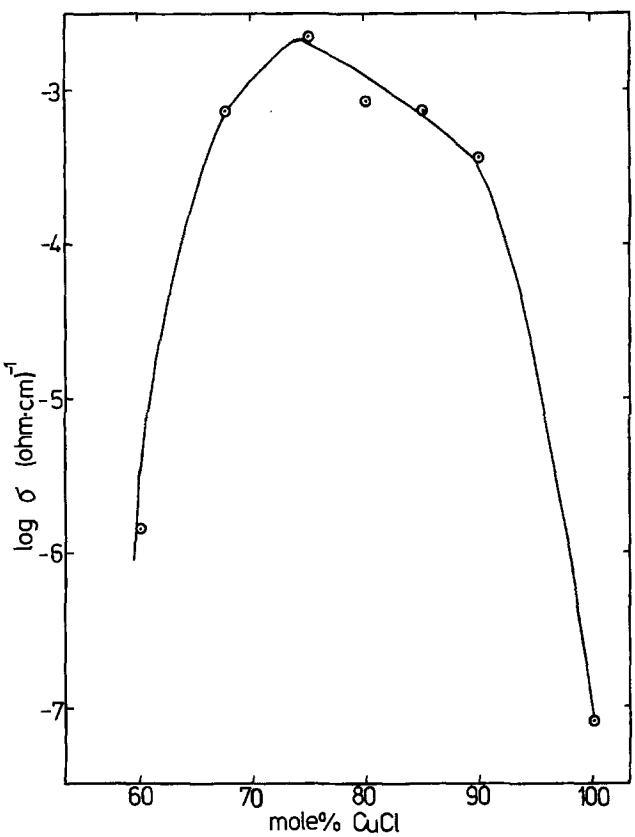

Fig. 4. Electrical conductivity extrapolated to ∞ Hz at 25°C vs. composition.

Table I. Conductivity results

Compound	m/o CuCl	Conductivity $(\Omega\text{-cm})^{-1}$ 25°C 1000 Hz (±3%)	25°C ∞ Hz (±10%)	140°C 1000 Hz (±3%)	140°C ∞ Hz (±10%)	Activation energy (eV)
$Rb_2Cu_3Cl_5$	60	8.41×10^{-7}	1.45×10^{-6}	1.41×10^{-4}	2.16×10^{-4}	0.49 ± 0.02 (25° ~ 145°C)
	67.5	3.63×10^{-4}	7.37×10^{-4}	8.42×10^{-3}	1.12×10^{-2}	0.32 ± 0.02 (25° ~ 95°C) / 0.18 ± 0.02 (115° ~ 140°C)
$RbCu_3Cl_4$	75	4.50×10^{-4}	2.25×10^{-3}	1.06×10^{-2}	1.31×10^{-2}	0.19 ± 0.02 (25° ~ 90°C) / 0.14 ± 0.02 (110° ~ 140°C)
	80	4.55×10^{-4}	3.25×10^{-4}	6.35×10^{-3}	1.14×10^{-2}	0.27 ± 0.02 (25° ~ 140°C)

CuCl*	100	8.05×10^{-8}		2.55×10^{-6}		1.00 ± 0.02 (230° ~ 370°C)

* There is no frequency dependence on pure CuCl.

Differential thermal analysis.—The melting temperature of $RbCu_3Cl_4$ (75 m/o CuCl) which exhibits the highest conductivity was measured by using DTA apparatus. An endothermic peak which is due to melting of the sample was observed for $RbCu_3Cl_4$ at 170° ± 10°C, and this melting temperature is different from the melting temperature of $Rb_2Cu_3Cl_5$ (about 150°C) reported previously (18). This also suggests the existence of a new and different compound, $RbCu_3Cl_4$.

Electronic conductivity measurements.—Preliminary electronic conductivity measurements were carried out by Wagner's polarization method (22). As was first suggested by Wagner (22) and by Hebb (23), the ionic part of the current for a two-component system can be suppressed by the use of one electrode that does not contain the constituents of the crystal. The other one may contain the constituent which is used to fix the electrochemical potentials of the electrolyte at that side of the cell, a reversible electrode. Thus, for cuprous halides, Wagner and Wagner (24) and recently Joshi and Wagner (25) have used a carbon anode and a copper cathode. However, for the ternary system, it is necessary to fix the electrochemical potential of two constituents of the electrolyte. For example, the polarization cell, $Ag|Ag_3SI|I_2 + C$, was used for Ag_3SI (26). For the RbCl + CuCl system, the polarization cell, $Cu|RbCu_3Cl_4|Cl_2 + C$, is suitable to determine the electronic conductivity. However, such a cell was difficult to construct because of the gaseous chlorine at room temperature. In the present study the cell Cu|sample (80 m/o CuCl)|graphite, was used under a very slow flow rate of argon gas (≃0.05 cm/sec). Since the activity of chlorine is not fixed in this cell, chlorine ion may migrate from the copper electrode toward the graphite electrode, which causes an ionic current in addition to the electronic current. Thus, in this cell, the chlorine evolution becomes important at higher applied voltages. As seen in Fig. 5, which shows the steady-state current as a function of polarization potential, the theoretical slope calculated by Wagner's theory could be fitted to the experimental results in the applied voltage region between 0.4 and 0.6V at all temperatures from 23° to 140°C. These experimental values were very reproducible with increasing and decreasing temperature. The reproducible data and the experimental slope which could be fitted to the theoretical slope suggested that even in this preliminary study the ionic contribution from chlorine evolution was very small compared to electronic current and also decomposition of the sample was negligibly small. Figure 5 also shows that the new compound containing 80 m/o CuCl exhibits a small electronic hole conductivity.[2] The temperature dependence of the electronic conductivity due to electron holes is shown in Fig. 6. Compared to the electrical conductivity, it is concluded that the new compound is an essentially ionic conductor.

X-ray diffraction analysis.—X-ray diffraction patterns were obtained at room temperature for all the samples containing 60-100 m/o of CuCl. The x-ray patterns of these compounds showed very different results from that of $RbAg_4I_5$ observed by Bradley and Greene (27). The comparison of d-values and intensities of some compounds in the RbCl + CuCl system and pure CuCl is presented in Table II.

[2] Electron hole conduction was inferred from the behavior of the electronic current as a function of applied voltage.

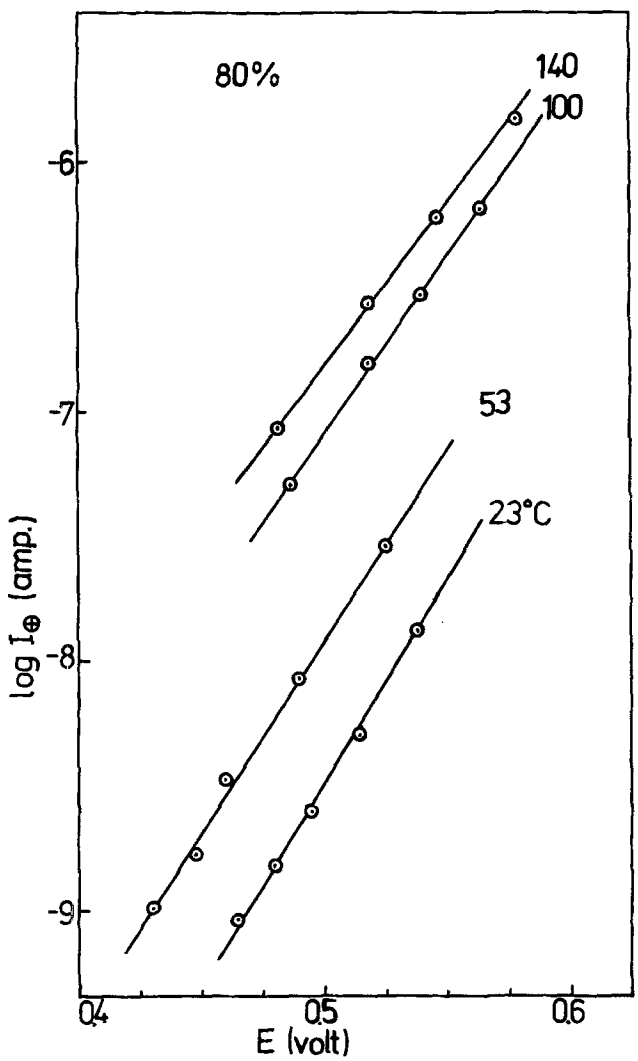

Fig. 5. Electronic hole conductivity vs. applied voltage (80 m/o CuCl).

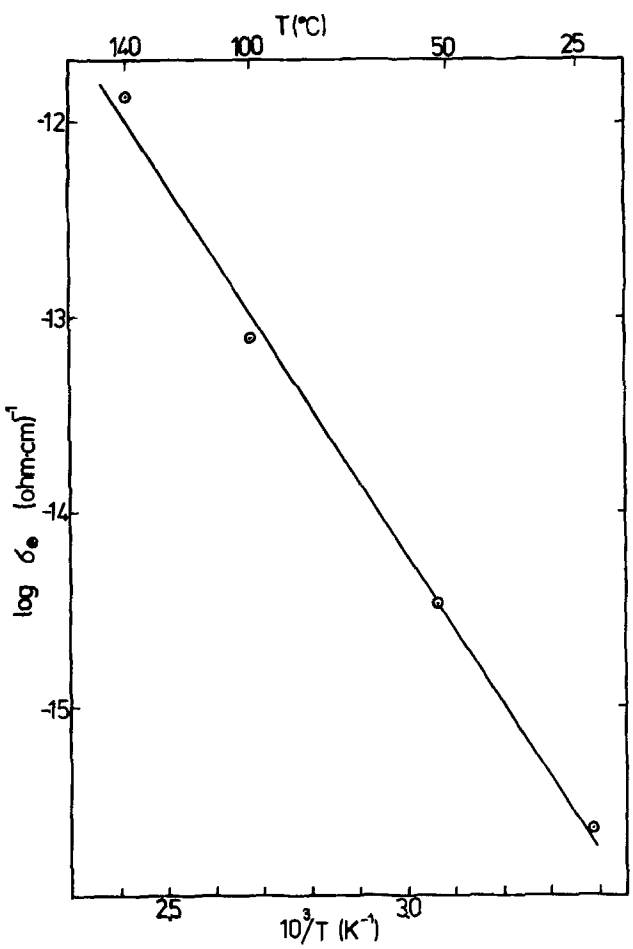

Fig. 6. Temperature dependence of the electronic hole conductivity for the sample (80 m/o CuCl).

After annealing the compound at 145°C for 16 hr, the intensity of x-ray patterns increased and also the electrical conductivity increased which is similar to the behavior reported for $RbAg_4I_5$ (8).

The sample containing 67.5 m/o CuCl showed almost the same diffraction lines as those of the compound (75 m/o CuCl) together with the lines characteristic of $Rb_2Cu_3Cl_5$. The samples containing 85 and 90 m/o CuCl also showed similar diffraction lines to those of the compounds (75 or 80 m/o CuCl), but some weak lines originated from the compounds (75 or 80 m/o CuCl) disappeared and the intensity of the lines characteristic of pure CuCl increased. Although some lines characteristic of both $Rb_2Cu_3Cl_5$ and CuCl are found, the occurrence of some extra lines suggests that the compound (75 or 80 m/o CuCl) is not simply a disordered or contaminated phase but rather a separate new compound. However, the presence of CuCl and $Rb_2Cu_3Cl_5$ cannot be ruled out, indicating that the phase was not optimized to equilibrium.

From the x-ray powder data alone, no conclusions could be reached about the structure of the new compound except that the number of reflections would not be consistent with a structure of high symmetry. Further comment on the stoichiometry must await the x-ray determination on the single crystal.

Summary

New electrolytes with high copper ionic conductivity and low electronic hole conductivity were found in $RbCu_3Cl_4$ compounds. The values of the conductivity are comparable to those of organic cuprous halides previously reported by Takahashi *et al.* (13-15).

ABSTRACT

Cadmium iodide crystals have been grown by the vapor phase technique. Under different thermal and supersaturation conditions, cadmium iodide crystals of the same morphological form and shape, but of different size and thickness, have been obtained. No spirals are observed on the crystals which grow with their basal planes normal to the wall of the growth tube, whereas, spirals have been observed on crystals grown on a glass substrate at high supersaturation. The observations indicate that a screw dislocation mechanism is not operative in the growth of CdI_2 crystals in the present case. The growth starts with a dendritic skeleton and then changes to flat platelets by the filling in process and by two dimensional nucleation. Formation of spirals on crystals grown on glass slides has been attributed to adsorbed impurities or debris and irregularities on the substrate surface. An x-ray study of the crystals has revealed that nearly all vapor-grown crystals show the most stable basic polytype (4H) of CdI_2. Observations indicate that conditions of growth play an important role in deciding the structure.

A large number of reports on growth and polytypism (1, 2) in CdI_2 crystals have appeared in the literature; however, except for a couple of attempts by melt (3) and vapor phase (4) techniques, these crystals have been grown from solution using the isothermal evaporation technique. The growth of these crystals has often been attributed to the spiral growth mechanism. This mechanism was first proposed by Frank (5) in 1949 to explain the growth of crystals at low supersaturation. Since then spirals have been observed in crystals of many compounds during evaporation, condensation, and solidification and lend support to the Burton Cabrera, and Frank (BCF) growth theory (6). This theory has also been able to explain many of the observed effects and growth features. Frank extended the dislocation growth theory to explain the formation of polytypes (7) in a direct and simple way. The existence of polytypism in CdI_2 was predicted by Forty (8) from an optical study of the growth features on the (0001) faces of the crystals. The prediction was borne out by the x-ray investigations of Mitchell (9), who discovered 29 polytypic modifications of the compound. By combining his x-ray diffraction results with the step height measurements of Forty (8), Mitchell (9) showed that a correlation exists between the spiral step height and the unit cell height, thus supporting Frank's theory. Initial observations of growth spirals on SiC crystals by Verma (10), Amelinckx (11), and others lend support to this theory but subsequent observations of step height on solution-grown cadmium iodide crystals by Trigunayat and Verma (12) and on vapor-grown crystals by Chadha and Trigunayat (13) did not agree with the theory.

Although a large number of other theories of polytypism have been put forth, none of them explain all the observed facts. There is scattered evidence in the existing literature which indicates that conditions of growth may have an influence on polytypism.

It was felt that for a better understanding of the phenomenon of polytypism, crystals should be grown under improved and steady-state (stabilized) conditions. In the present investigation good quality CdI_2 crystals have been grown by the vapor phase technique. Optical microscope, scanning electron microscope, and x-rays were used as tools for the study. Transmission electron microscope has also been used for studying dislocation structures, the results however will be described elsewhere.

Experimental

A quartz crucible containing cadmium iodide powder of 99.5% purity was kept in the maximum temperature region (390°-420°C) of a horizontal Kanthal resistance furnace. A cross-sectional view of the experimental arrangement together with the temperature profile is depicted in Fig. 1. The crucible was enclosed in a Pyrex tube of 3.5 cm diameter, in which a vacuum of 10^{-1}-10^{-3} mm of Hg can be maintained. Glass slides are kept in the region 150°-300°C, where most of the growth is found to take place. The charge temperature was gradually increased to the desired value (390°-

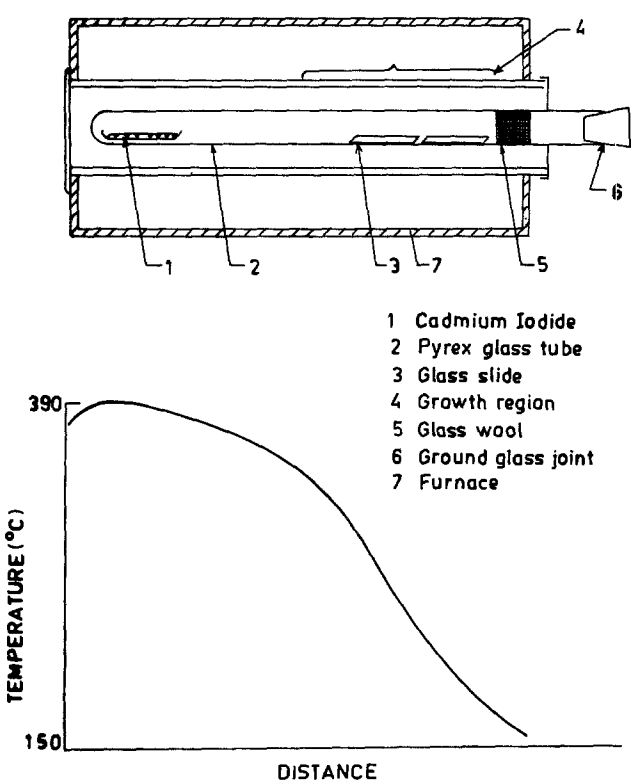

Fig. 1. Experimental arrangement for the growth of dendrites and platelets from vapor phase.

420°C) and was maintained at this value for 10-24 hr. On the completion of a growth run, the furnace was cooled to room temperature at the rate of ~ 20°C per hour. The crystals grown on slides and on the wall of the Pyrex tube were picked up and examined with a Carl Zeiss NU_2 Universal optical microscope using bright and dark field illumination and with the S4 10 Cambridge scanning electron microscope.

The as-grown crystals were also subjected to x-ray examination for structural determination. As the crystals are extremely soft, great care was exercised to ensure that they were not deformed while being taken out of the tube or during mounting on the x-ray goniometer.

Optically perfect crystals were mounted on glass fibers and were oscillated about the a-axis, the c-axis being horizontal. The range of oscillation was 15° and was adjusted to be between 55.5° and 70.5° with the incident x-ray beam. To set the a-axis of the crystal vertical, the method followed was that of Agrawal (14). After setting, the range of oscillation was taken from 33° to 48°. This range was particularly chosen to record a large number of (10.l) reflections required for the identification of polytypes. The crystals exhibiting a mixture of higher polytypes were oscillated about a*-axis in the range of oscillation between 53° and 68° for their polytypic identification (15).

The oscillation photographs of all the crystals were recorded with a camera of radius 3 cm and a collimator of aperture 0.5 mm. The size of focal spot was 1 mm^2. The photographs were taken with the Ni filtered CuKα radiation or with Cu white radiation.

Growth Observations and Mechanism

The growth of CdI_2 crystals has been examined in detail and the observations under different experimental conditions in various runs are summarized in Table I. It is evident from Table I that if the charge temperature is suitable to yield sufficient vapor, the growth of CdI_2 crystals can be classified under three groups.

1. Platelet crystals are formed at the lowest supersaturation (2-5). They invariably grow on the upper part of the growth tube with their basal faces normal to the axis of the tube.
2. Small hexagonal crystals, with their basal faces parallel to the axis of the tube, grow at intermediate supersaturation (20-100) on the glass slide substrate in the lowest part of the tube.
3. Dendrites and powderlike deposition are observed at high supersaturation (100-500).

It can be seen from Table I that the morphology of the crystals in a particular growth zone remained almost unchanged even when the charge temperature was changed from 390° to 420°C. This indicates that growth temperature is the main parameter in determining the basic morphology of the crystals. This observation is in agreement with the observation on ice (16) and ammonium chloride (17) crystals grown from the vapor phase.

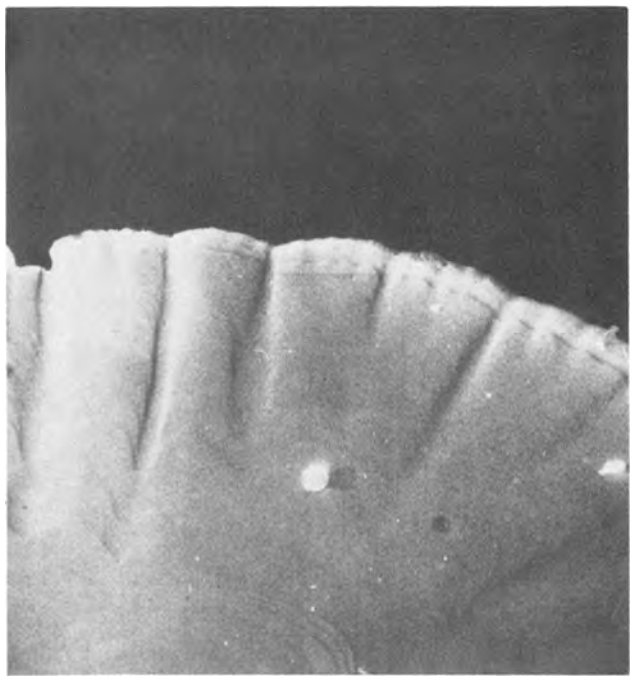

Fig. 2. SEM micrograph of a platelet which is smooth and flat in the central region and shows markings near the periphery.

The surface features of the as-grown crystals were examined in detail under high resolution optical microscopy and scanning electron microscopy.

Two principal observations were:

1. The platelets, growing with their basal faces normal to the tube axis, were smooth and flat in the central region and showed markings near the periphery (Fig. 2 and 3), and often had dendritic edges (Fig. 4). No spirals were observed on their surfaces in examination of hundreds of platelets.
2. The crystals growing in the lower part of the tube on the glass substrate often had spirals (Fig. 5 and 6) on their surfaces.

Thus the platelets growing at a lower supersaturation did not exhibit spirals while crystals from higher supersaturation areas commonly had spirals.

Burton, Cabrera, and Frank (6) have been responsible for the well-known model of spiral growth by means of the termination of a screw dislocation at the growing interface. The distinguishing features of this theory are:

1. Growth takes place under conditions of low supersaturation, less than 1%.
2. Adjacent or successive turns of the spirals should be separated by a distance of the order of $4\pi r_c$ where r_c is the radius of the critical two dimensional nucleus.
3. The step height of the spiral, at least according to the original BCF model should be monoatomic.

Table I.

Serial no	Charge temperature, °C	Period of growth, hr	Pressure of air in the tube, mm Hg	Morphology	Growth temperature, °C
1.	420	20-24	760	Platelets up to 1 cm diameter and 10 μm thick grow normal to the axis of the tube	320-390
				Small hexagonal crystals up to 4 × 4 mm on glass substrate	220-330
				Dendrites on the upper wall of the tube	190-250
				Powderlike deposition	165-200
2.	420	20-24	10^{-2}	No platelets or dendrites. Thick powder-like deposition	190-350
3.	390	20-24	760	Platelets up to 6 mm diameter and 5 μm thick grow normal to the axis of the tube	270-350
				Small hexagonal crystals up to 3 × 3 mm on glass substrate	210-290
				Dendrites on the upper wall of the tube	180-230
				Powderlike deposition	150-200
4.	390	20-24	10^{-2}	Large number of small hexagonal crystals	170-300
5.	350	20-24	760	Insufficient flux, negligible growth

Furthermore, the BCF model describes only the addition of layers to an already existing layer or substrate and can operate only after this initial layer has been formed. It accounts only for growth in a direction parallel to the screw axis and does not explain the lateral growth necessary for the formation of the platelets. In the past few years a number of reports challenging the role of the screw dislocation mechanism in crystal growth have also appeared in the literature (18-25).

The observed value of pitch ($\sim 10^2$-10^3Å as is evident in Fig. 5) and the spacing of adjacent segments ($\sim 10^3$-10^5Å, Fig. 6) of the spirals and the value of the growth supersaturation (20-100) for the crystals revealing spirals are in contrast with the prediction of the BCF theory. These features combined with the fact that no spiral is observed on platelets which grow at the lowest value of supersaturation (senal nos. 2-5) clearly indicate that the formation of CdI_2 platelets in the present case does not take place by the screw dislocation mechanism and that mere observation of spirals is not sufficient evidence to attribute the growth to this mechanism.

It is felt that the spirals on crystals grown on the substrates may be due to the presence of impurity debris and/or to the irregularities on the substrate surface. To estimate the role of the debris, a few runs were performed in which a semicylindrical glass tube of external diameter equal to the internal diameter of the tube was kept in the upper region of the growth tube; only a few of the crystals, grown on the semicylindrical tube, showed spirals, whereas the spirals were again commonly observed on the crystals grown on the substrate in the lower region. These observations imply that the debris falling under gravity in the lower regions may be responsible for the formation of spirals. Again the platelets that grow in the upper region with their faces normal to the tube axis should have the minimum share of the debris and indeed no spirals were observed on them.

The formation of CdI_2 platelets has been examined in detail. It has been observed that the initiation of the growth of the platelets is dendritic (Fig. 7); this is understandable as the growth conditions, supersaturation, and the details of the growth run (Table I) are favorable for dendritic growth (26-31). The main axis of the

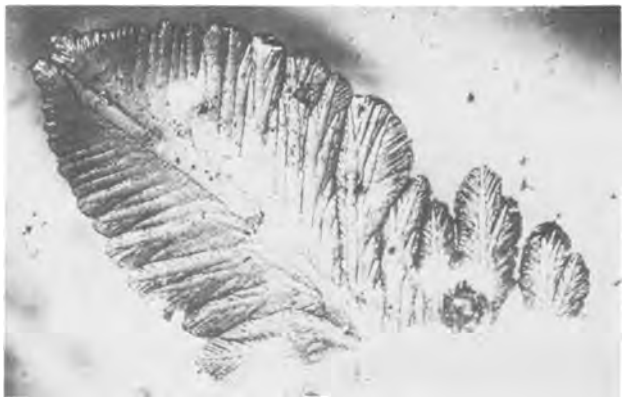

Fig. 7. View of the initial morphology of a crystal in the initial stages of growth (X220).

dendrites and its branches are found to be along $<11\bar{2}0>$, the closest packed directions.

As the growth proceeds further, more and more surface becomes available. Supersaturation is then expected to decrease and a quasi-equilibrium condition exists between growing crystals and the vapor; this results in the formation of sound crystals, *i.e.*, the dendrites grow in the fast growth direction and this stage is followed by a period during which the region between the dendritic arms is filled in (32-34). Such a transition from dendrites to platelets has been observed in a large number of crystals (Fig. 8). Figures 2, 3, and 4 show platelets which are flat and smooth in the central portion, but their edges are still dendritic; filled in portions of the dendritic arms are also evident. The growth of symmetrical crystals finally may proceed by the advance of layers, *i.e.*, layer growth is responsible for the growth of comparatively thick platelets.

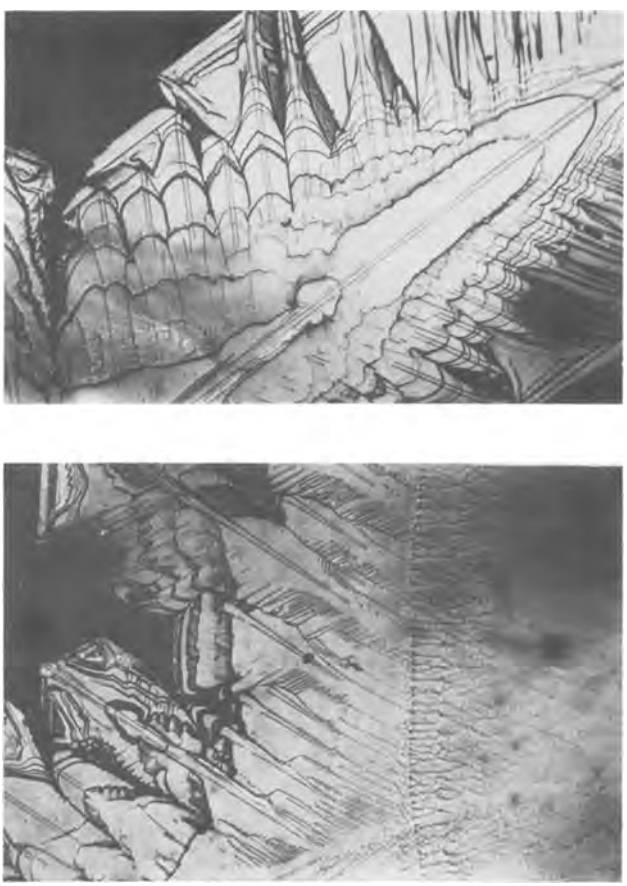

Fig. 8(a) and (b). Photographs showing dendrites changing to a platelet (X100).

X-ray Results and Discussion

Thirty-one platelets and dendrites were subjected to x-ray examination. Of these, 28 were found to be pure 4H on both the opposite basal surfaces. As the crystals sometimes displayed syntactic coalescence, diffraction spots from the two faces of a crystal were separately recorded. In two cases some unidentified polytype mixed with streaking was found on one face and the other face showed 4H. Only one crystal was found to exhibit a well-defined polytype 26H mixed with 4H (Fig. 9) on one face and a mixture of 4H, 12H and 12R on the other face (Fig. 10).

The cadmium iodide structure is made up of molecular sheets piled one on top of the other, each consisting of a layer of cadmium ions sandwiched between two layers of hexagonal close-packed iodine ions. Thus the structure of cadmium iodide permits adjacent iodine layers to slip easily with respect to one another parallel to the basal plane giving rise to stacking faults. As the faults do not involve any distortion of the nearest neighbor bonds, they have low surface energy. The effect of stacking faults is to destroy the regularity of the structure in the direction perpendicular to the layers introducing 1-D disorder in it, which gives rise to streaking on x-ray photographs. Only in a few cases streaking was observed in the vapor-grown crystals.

To explain the formation and growth of polytypic structures, Frank (6) suggested that they result from spiral growth around screw dislocations of the nonintegral Burgers vector created in certain basic structures. The absence of spirals in the present case on the

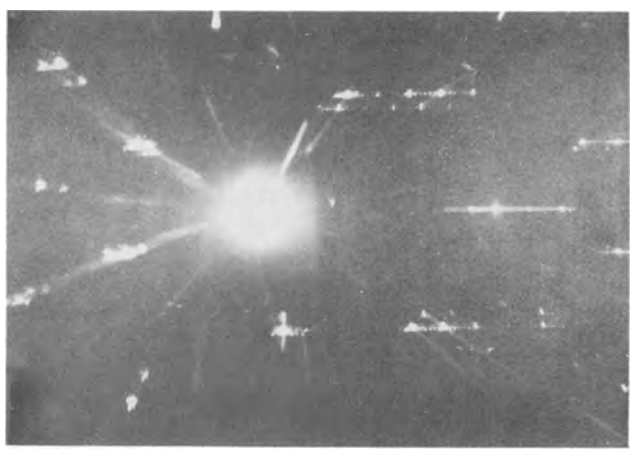

Fig. 9. a*-axis x-ray oscillation photograph of a CdI_2 crystal; the angle between incident beam and c-axis varies between 53° and 68°, Cu white radiation; camera radius 3 cm. The crystal is a mixture of polytypes 4H and 26H.

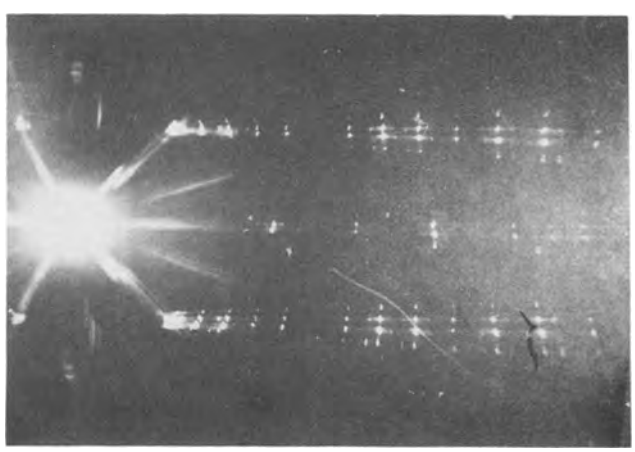

Fig. 10. a-axis oscillation photograph of the other face of the crystal in Fig. 8. The angle between the incident beam and the c-axis varies between 33° and 48°, $CuK\alpha$ radiation; camera radius 3 cm. The crystal is a mixture of polytypes 4H, 12H, and 12R.

face of nearly all platelet crystals and dendrites indicate that the polytypism and spirals are not necessarily correlated. Furthermore, the present observations on the growth of CdI_2 crystals from vapor phase have clearly demonstrated that the crystals do not grow by the screw dislocation mechanism and even the presence of spirals need not be always due to the operation of this mechanism. Thus, the formation of polytypes in the present vapor-grown CdI_2 crystals cannot be explained by Frank's theory of dislocations.

Polytypism seems to be a complicated phenomenon as the same conditions of temperature and pressure give rise to different polytypic modifications. The generally prevailing view is that the polytypes have nearly the same energy and the appearance of a particular kind of polytype is determined practically by chance. However, observations show that one particular polytype always dominates in one substance. The conditions of growth can be an important factor in determining the structure. The vapor growth under stabilized conditions indeed favors the most stable structure of the substance as is evident from the observations in the present case; whereas, the crystals of CdI_2 grown from solution (under rather undefined conditions) show a large number of polytypes (1). In solution growth the solute concentration and thus the supersaturation in different regions changes during crystallization. Variation in growth conditions may favor the nucleation of another structure; depending on conditions of growth, the crystal may develop any polytype structure. The stabilized conditions should favor the most stable polytype with least disorder, which indeed has been observed in the present case. Thus, it is evident that the growth kinetics play an important role in the formation of polytypes.

Reverse Bias Life Test Stability of Tantalum-Titanium Anodic Oxide Thin Film Capacitors

F. G. Peters and N. Schwartz*

Bell Laboratories, Murray Hill, New Jersey 07974

In a previous publication, the composition and some of the dielectric properties of tantalum-titanium anodic oxides were determined (1); this note describes some of the thin film capacitor (2) properties.

* Electrochemical Society Active Member.

It is well known that alloying of tantalum film with substitutional metals (3-5), nitrogen (6, 7), oxygen (7), or carbon (7) increases the cathodic breakdown voltage at room temperature, This increase results in near-symmetric d-c leakage characteristics compared

Table I. Time to failure of β-tantalum based TM type capacitors on anodic (9) or cathodic (10) bias at 85°C

Percent of capacitors failing	Time to failure, hr			
	+6V	−6V	+12V	−12V
2	5×10^3	1×10^3	5×10^2	5×10^1
30	5×10^7	9×10^3	8×10^6	9×10^2

to the well-known asymmetric characteristic (8). It is not clear, however, that this symmetry in room temperature d-c leakage reflects itself in increased reliability on reverse or cathodic bias.[1] This reliability is frequently evaluated at 85°C with either anodic (forward) or cathodic (reverse) bias applied. Table I indicates that, despite a high degree of conductivity symmetry near room temperature for the standard β-tantalum based TM[2] capacitor, the time to failure on anodic bias at 85°C is much larger than on cathodic bias.

In the present study, sputtered tantalum-titanium films with varying atom fractions were prepared as described earlier (1), fabricated into TM capacitors (2) by anodization to 230V in 0.01% citric acid and where the counterelectrode was evaporated Nichrome-gold film. Figure 1 shows the relative capacitance of these samples as a function of the atom fraction of titanium; the figure also gives comparable results where the alloying agent is either nitrogen (11), aluminum (12), or silicon (13). The addition of titanium to tantalum tends to maintain the capacitance density of the tantalum oxide better than either nitrogen, aluminum, or silicon. Figure 2 gives the dissipation factor at 1 kHz for the tantalum-titanium based capacitors; the dissipation factor increases with increasing titanium composition, although it is below 0.0035 for compositions below 5 atom percent (a/o) titanium.

Because of the known improvement of room temperature cathodic breakdown voltage with small additions of titanium (5), capacitors with titanium concentrations below 5 a/o were investigated with respect to cathodic life-test stability at 85°C. Fifty-six capacitors were prepared at each composition of 1.1, 1.5, 1.8, 2.5, and 3.4 a/o titanium in tantalum and fabricated into 0.1 cm^2 capacitors. The properties of these samples are relatively independent of composition, and they have been taken together as one group for the purpose of this note. The initial yield of the 280 capacitors prepared was above 93% based on a leakage criterion of 10 A/farad for a standard d-c leakage test at +50V. All of the capacitors were placed in an 85°C oven and one-half of the samples were tested at −6V for 6200 hr. At the end of this test, the other half of the samples were tested at −12V. The criterion for failure was a blown 180 mA fuse in series with the capacitor. The yield of capacitors remaining on test as a function of time is shown in Fig. 3, with a comparison to the performance (10) of standard β-tantalum based capacitors with slight nitrogen additions (14).

Figure 3 indicates that there were 2 out of 125 failures in the first 50 hr at the −6V test, and there were no other failures to the end of the test. Since these are developmental prototype samples, these initial few failures are not necessarily typical of the eventual performance of these capacitors. The failure rate at −6V is thus less than 1.6% in 6400 hr, compared to 2% in 1000 hr for standard capacitors (Table I), or 15% in 6400 hr (Fig. 3). At −12V, the tantalum-titanium based capacitors demonstrate a 30% failure rate in 4600 hr compared to the same failure rate for standard samples in only 900 hr. These results indicate that the tantalum-titanium based capacitors have a failure rate on cathodic bias at 85°C which is less than one-fifth that of the standard capacitors.

[1] The terms "anodic" and "cathodic" refer to the tantalum-based thin film electrode, equivalent to the terminology for the polarity of this electrode during the electrolytic formation at the oxide.

[2] TM is equivalent to T(tantalum-tantalum-oxide)/M(metal) capacitor structure.

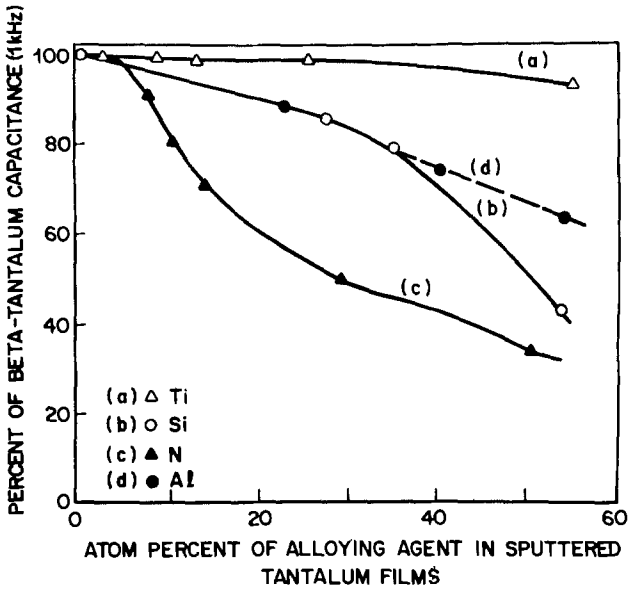

Fig. 1. Normalized capacitance at 1 kHz as a function of atom percent of alloying agent in sputtered tantalum film: Ti (this work), Si (13), Al (12), N (11).

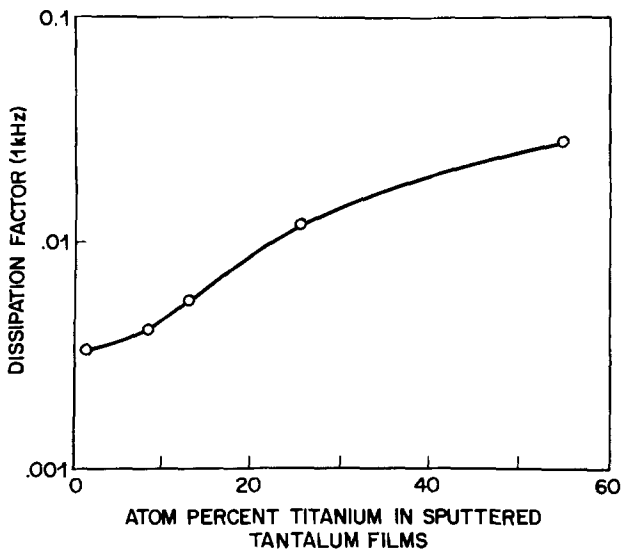

Fig. 2. Dissipation factor at 1 kHz as a function of the atom percent of titanium in sputtered tantalum films.

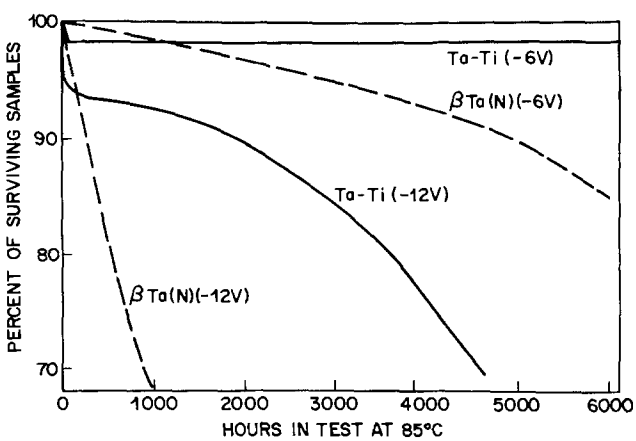

Fig. 3. Life-test stability of tantalum-titanium based capacitors at 85°C and either −6 or −12V. There were initially 125 samples on the −6V test and 121 samples on the −12V test. There were only minimal changes in capacitance and dissipation factor at the end of the −6V test, being respectively −0.15% and −0.05%.

The asymmetric room temperature d-c conductivity of the standard capacitors has been ascribed to heterogeneous conduction sites with an unknown structure (4). It has been proposed (4) that the addition of the alloying agent prevents the formation of these sites. If this model has any validity, the removal of these discrete sites has not been sufficient to improve the cathodic life-test stability so that it is equivalent to that on anodic bias (Table I). The stability of the tantalum-titanium based samples is more than adequate, however, for the cathodic bias that these components are exposed to in circuit applications.

Acknowledgments

We wish to thank W. F. McNamara for the life-test measurements.

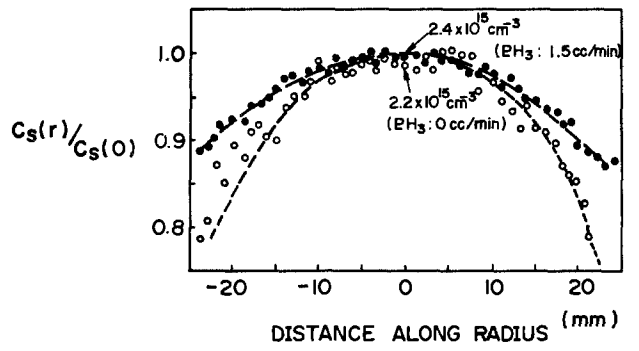
A Method to Improve the Radial Impurity Distribution in Czochralski Silicon Crystals

Katsuro Sugawara* and Hiroo Tochikubo

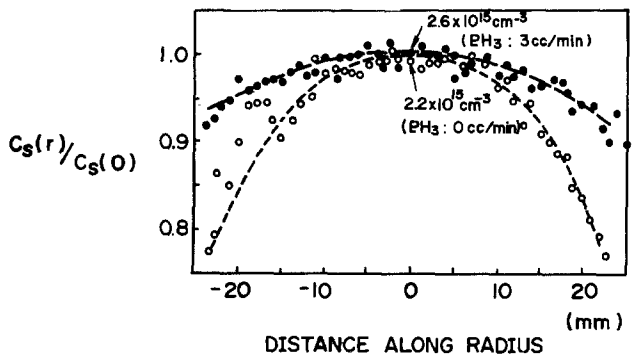
Hitachi, Limited, Semiconductor and Integrated Circuits Division, Kodaira, Tokyo, Japan

The impurity distribution in Czochralski crystals should be investigated both macroscopically and microscopically. Macroscopically, the impurity distribution should be investigated both along the growth direction and along the radius, and microscopically within the growth striae (1-3). The distribution along the growth direction has been normally obtained by the "normal freezing" (4), but the radial distribution has not been quantitatively analyzed. The analyses of the radial distribution are classified as follows: (*i*) variation of the impurity distribution by appearance of (111) facets (2, 5-10), (*ii*) the distribution experimentally correlated by the growth parameters (11-12), and (*iii*) analysis of liquid flow by fluid dynamics (13-14). Recently, a novel method for obtaining uniform impurity distribution has attracted attention, using neutron activation. Float-zoned crystals of ultrahigh purity are doped by the ^{30}Si (n, γ) ^{31}P reaction (15-16). These crystals, however, are limited to high resistivities doped with phosphorus and are much more expensive than the conventionally grown crystals.



In this note, radial impurity distribution of Czochralski grown silicon crystals which are phosphorus doped from the gas phase through free melt surface in addition to the usual doping in the melt is compared with the distribution in conventionally melt-doped crystals.

The crystal growing furnace used to pull the silicon single crystals was resistance heated. A polycrystalline silicon rod of approximately 1000g in weight was charged in a high purity quartz crucible with an ID of 100 mm. After melting the polycrystalline rod, a seed crystal with (100) orientation was dipped into the melt and the single crystal of about 50 mm in diameter was pulled. The melt was doped with phosphorus to obtain a crystal of 2-3 Ω-cm resistivity; the impurity concentration ranged from 1.5×10^{15} to 2.3×10^{15} atoms/cm^3. The ambient gas was argon; the flow rate was 10 liters/min in the 300 mm diameter chamber. To investigate the effect of the phosphorus doping from the gas phase, phosphine was added to the argon. At first, the silicon single crystal was pulled up to 3 cm in length without the phosphine doping, the growth was stopped, the phosphine was added for 30 min, and then the pulling was carried out again up to 6 cm in length. This procedure was used to avoid donor formation (17) during cooling of the grown crystal by reducing the interval of heat-treatment at 450°C. The standard growth condition was a pull rate of 1.4 mm/min, and the rotation speed of the seed and that of the crucible 15 and 5 rpm (in reverse direction), respectively. The grown single crystal was cut normal to the growth axis into 5 mm thick sections at the middle of which the interface without and with the phosphine doping was located, lapped, and the resistivity measured by the four-probe method (18) at every 1 mm along the radius. Then, the impurity concentration was calibrated by using Irvin's chart (19) which shows the correlation between the resistivity and the impurity concentration of silicon. Correction of the resistivity at the edge of the silicon block along the radius was neglected, due to an error of less than 2% except for the outer 1 mm (20); the measurement of the resistivity was done by the probe with 0.25 mm spacing.



The radial impurity distribution, $C_s(r)/C_s(0)$, normalized by the value of the center, $C_s(0)$, was plotted in Fig. 1; open and closed circles show the impurity concentration without and with the phosphine doping, respectively. In the figure, the broken and solid lines represent the measured value without and with the phosphine doping. Figures 1(a), (b), (c), and (d) are the result of the phosphine doping at flow rates of 1.5,

3, 5, and 30 cm^3/min, respectively, in addition to the usual doping into the melt, together with that without the gas phase doping. The impurity distribution along the radius was generally convex and the concentration at the edge of the crystals was smaller by 20, 12, 6, 5, and 4% for the above-mentioned five cases (the phosphine flow rates of 0, 1.5, 3, 5, and 30 cm^3/min, respectively) than the corresponding concentration at the center.

Results of the computational calculation and comparison between measured and calculated values will be published in the near future.

Properties of Pretilted Liquid Crystal Structures

K. Fahrenschon and M. F. Schiekel

AEG-Telefunken, Serienprodukte AG, Ulm, West Germany

This paper describes the variable control of colors in a transmissive arrangement based on the deformation of aligned nematic liquid crystal (NLC) layers between polarizers in an electrical field (DAP effect). Several authors have found different field effects which originate from different configurations of the zero-field optic axis and from use of NLC with either negative or positive values of the dielectric anisotropy $\Delta\epsilon = \epsilon_{11} - \epsilon_{\perp}$ (1-4).

We have studied a pretilted structure where the directors of NLC are well aligned within parallel planes (Fig. 1) (5). It should be mentioned that with these pretilted structures materials with either sign of the dielectric anisotropy could be used as well as materials whose dielectric anisotropy changes from positive to negative when the driving frequency changes. In this paper, however, we limit our subject to materials with a negative dielectric anisotropy, but similar results can be achieved with other materials.

In the case of the DAP effect and also with asymmetrical pretilted cells using negative anisotropic materials, an increase of the optical phase retardation is achieved with increasing cell voltage. Besides the usual measurements of the phase retardation as a function of the voltage across the cell, we also used the conoscopic observation for examining the electro-optic behavior of the LC cell. Because the reproducible and uniform generation of colors in transmissive systems is based on a uniform and well-defined deformation of the liquid crystal layer, the conoscopic method offers a quick check for the optical properties. We used a conoscopic projection method, which results in very wide angles of visual field of ±40°. Figure 2 shows the conoscopic picture of a LC cell under zero-field condition without inclination ($\bar{\theta}_0 \sim 0°$), *i.e.*, homeotropic orientation. The good zero-field orientation of this uniaxial crystal layer is marked by the sharp cross of the isogyres. Just above the threshold voltage, numerous disclinations arise, as indicated by a less-pronounced conoscopic figure. Figure 3 shows the zero-field condition of a pretilted cell with a mean pretilt angle $\bar{\theta}_0$ of about 8°, relating to an angle of incident light in air of about 12°, Note that the isogyre cross, though moving far out of the optical axis of the conoscopic system, remains sharp and that the isochromates show bright, well-defined, birefringent colors.

Figure 4 shows the state with an increased cell voltage. The isochromates in the center of the field are nearly exact straight lines. That means that within one plane, the observed color of the LC cell is independent of the angle of view. By using a stop within the projection system, which has a rectangular cross section with its longer edge perpendicular to this plane, no angular dependency arises.

The possible color range for asymmetric pretilted NLC cells is shown in the well-known charts of birefringent colors. A cell, with a mean deformation angle $\bar{\theta}_0 \sim 10°$, determined by conoscopic measurements, corresponds to an initial phase retardation of about 80 nm, which is equivalent to a dark gray instead of a black optic field.

The cells are made of 2 sheets of soda-lime glass, covered with tin-oxide or tin-indium-oxide electrodes, as usual. One electrode was then coated with a dielectric film of either silicon oxide or magnesium fluoride

with a thickness of approximately 100Å. An electron beam evaporation was used, where the distance between source and target was made large enough to keep the range of deviation from the mean evaporation angle small (6). The beam angle was varied between

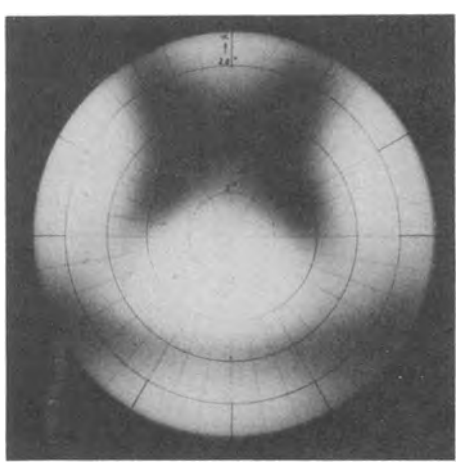

Fig. 3. Conoscopic figure of a pretilted LC cell: $\bar{\theta}_0 = 8°$, $U = 0$.

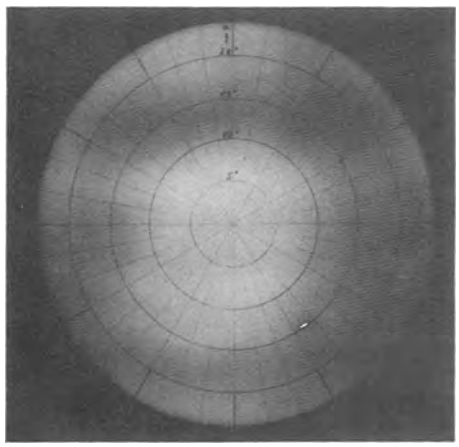

Fig. 4. Conoscopic figure of a pretilted LC cell: $\theta_0 = 8°$, $U = 5V$.

60° and 85° from the normal to the surface. The opposite electrode of the cell remained uncoated or was coated under different evaporation angles.

The LC cells used in our experiments were conventional sandwich-type cells with a thickness of the LC layer of approximately 10 μm. The glass plates with the above-mentioned electrode preparation were fitted together and sealed with glass-frit. We used two different NLC materials: N5 [an azoxy-compound made by Merck (7)] or KS 701 [a schiff-base and carbonester mixture made by Riedel de Haen (8)]. Special surfactants (9), for instance lecithines or acid "T" (Merck), were added to the bulk material in quantities < 0.5%. The additives cause the NLC directors to align perpendicular with one electrode and under a divergent angle at the opposite electrode. Thus, an asymmetric pretilted liquid crystal structure was achieved. It is obvious that the directors of the pretilted structure should always be oriented in parallel planes which are defined with respect to the plane of evaporation of the dielectric layer.

Figure 5 shows the angular transmission characteristic of a pretilted cell, measured with a He-Ne laser

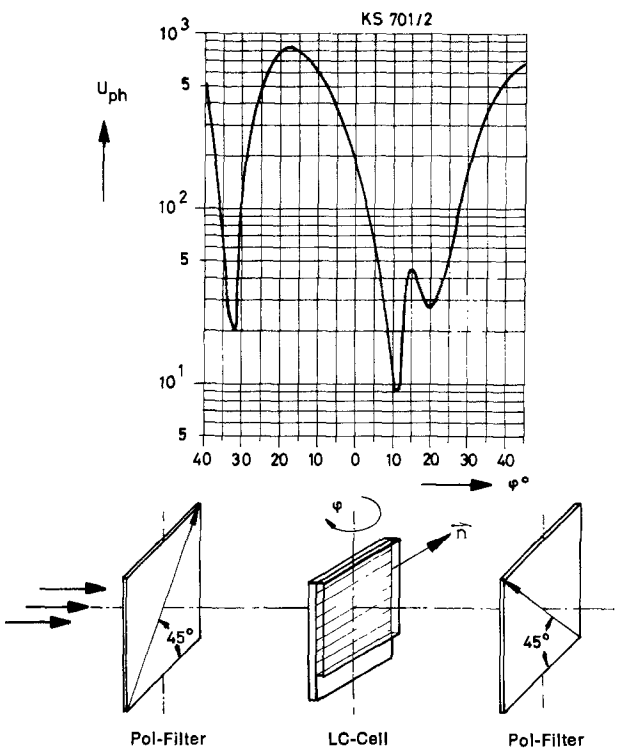

Fig. 5. Angular dependence of pretilted liquid crystals: $\vec{n}$ = projection of evaporation direction on cell surface.

($\lambda = 632.8$ nm). In Fig. 5a minimum is found, at an angle ϕ of 12°, if the axis of the cell rotation during the measurement is orthogonal to the trace of the inclined directors. Taking into account the different refractive indexes of air and the NLC, the mean pretilt angle $\overline{\theta_0}$ of the directors is calculated to be 7.5° from the normal. By conoscopic observation, an angle of approximately 8° was found, showing good agreement of both methods.

Figure 6 shows the transmission characteristic T of a NLC cell between crossed polarizers as a function of the cell voltage U. One is a homeotropic cell with $\overline{\theta_0} = 0°$ and one is an asymmetric pretilted cell with a relative large mean pretilt angle of 16°, corresponding to an initial phase retardation of 133 nm. The threshold voltage, which is about 3.8V for KS 701 in a homeotropic cell, disappeared completely with the mean pretilt of 16°. The difference in the quality of both interference curves is remarkable. For the pretilted cells, the maxima are nearly identical with the theoretical predicted values, while in the case of perpendicular orientation on both electrodes the amplitudes are much smaller due to ambiguities (or disclinations).

The dynamic behavior of a NLC cell is usually characterized by three values: delay time, turn-on time, and turn-off time. The delay time is only existing in a homeotropic layer. In a pretilted layer, only one direction is possible for a further tilt, therefore the deformation starts without any delay. The disappearance of the delay time in pretilted LC layers corresponds with the disappearance of the threshold voltage (5).

Figure 7 shows the quadratic dependence of the reciprocal turn-on time $1/t_\delta$ on the normalized cell

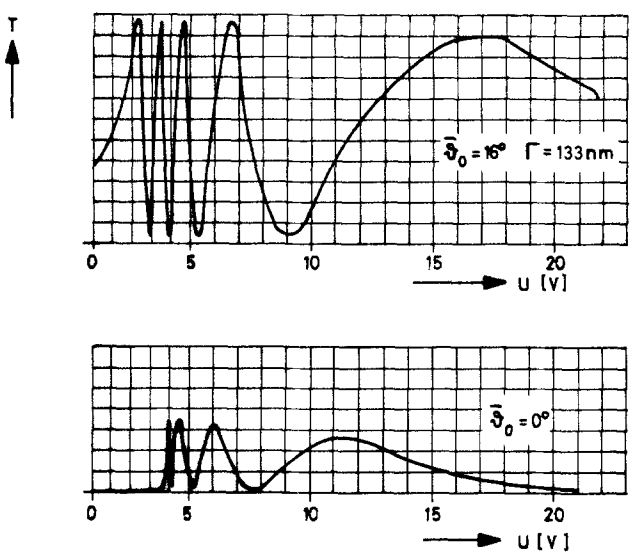

Fig. 6. Interference curves of pretilted and homeotropic cells

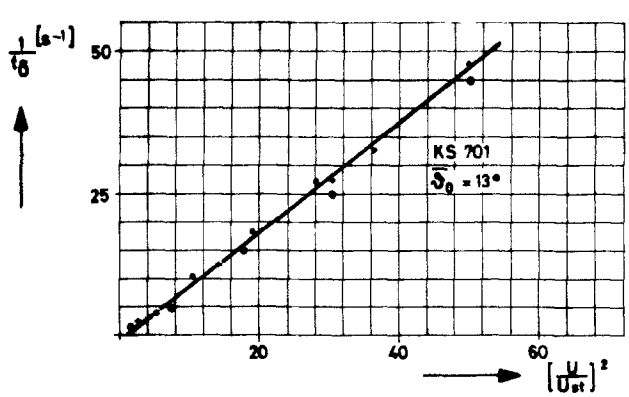

Fig. 7. Turn-on time of pretilted LC cells: t_δ = time for achieving optical retardation δ, $t \to \infty$, $U \to U_{stat}$.

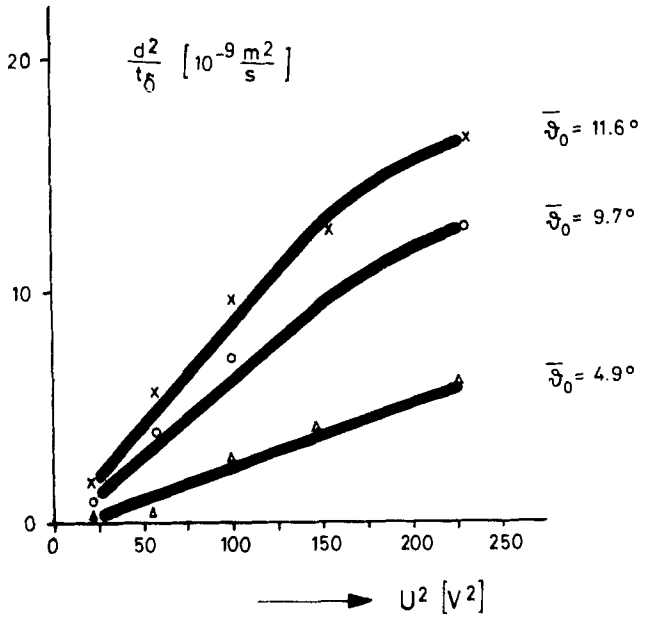

Fig. 8. Turn-on time of pretilted liquid crystal: t_δ = time for achieving optical retardation at a cell voltage U.

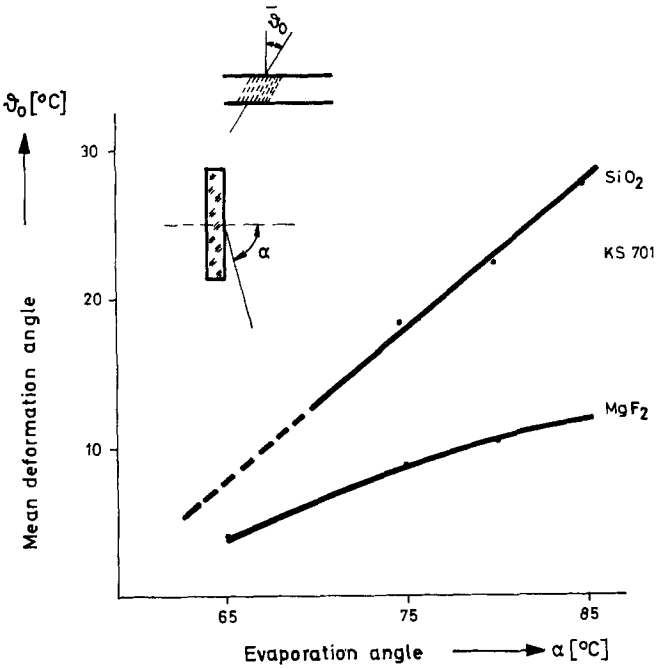

Fig. 9. Mean deformation angle of pretilted LC cells vs. evaporation angle α.

voltage U/U_{stat}. t_δ is the time during the turn-on period when a certain deformation state, characterized by a phase retardation δ, is reached. This deformation state can be achieved as equilibrium for the voltage $U = U_{stat}$ when t goes to infinity, so that the curve for $1/t_\delta = 0$ passes through $U/U_{stat} = 1$.

Figure 8 shows the dependence of the normalized reciprocal response time d^2/t_δ from the cell voltage for different values of the pretilt. With increasing mean pretilt angles $\bar{\theta}_0$ the turn-on time becomes smaller as expected. For practical applications it has a big advantage that with asymmetric pretilted cells high multiplexing ratios $Z = 100{:}1$ can be achieved, because of the large dependency of colors from the cell voltage.

The mean pretilt angle can be chosen arbitrarily by proper choice of the evaporation material and evaporation angles.

Figure 9 shows the dependency of $\bar{\theta}_0$ from the evaporation angle α in an asymmetric pretilted cell for silicon dioxide and for magnesium fluoride, using the mixture KS 701 as the liquid crystal. NLC cells with asymmetric pretilted structures are well suited as switchable color filters or as light valves for electrical and together with photoconductors for optical addressing.

Cathodoluminescent Properties of Yttrium Terbium Aluminum Borate $Y_{1-x}Tb_xAl_3B_4O_{12}$ Phosphors

T. Takahashi* and O. Yamada

RCA Research Laboratories, Incorporated, Machida City, Tokyo, Japan

Rare earth aluminum borates, $RAl_3B_4O_{12}$, where R is yttrium or rare earth from Nd to Yb, are isostructural with huntite, $CaMg_3(CO_3)_4$ (1). The luminescent properties of the $YAl_3B_4O_{12}$ host lattice for various activators such as Eu, Cr, Tb, Ce, and Bi were investigated earlier (2-6). For a 5% Tb-doped $YAl_3B_4O_{12}$ phosphor,

* Electrochemical Society Active Member.
Key words: yttrium aluminum borate, Tb activation, coactivators.

a moderately high radiant efficiency of 5% for CR excitation was reported (4). However, no further attempt was made at that time to improve its CL properties. Because of persistent interest in good rare earth activated green emitting phosphors, it was thought worthwhile to reinvestigate this phosphor. In particular, the system $Y_{1-x}Tb_xAl_3B_4O_{12}$ is well suited to study the effect of a so-called concentration quenching on CL properties. We investigated the effects of various phosphor parameters such as preparation technique, Tb concentration, and impurities on CL properties of the phosphors. The results are discussed in this paper.

Experimental

Sample preparation.—Stoichiometric amounts of Y_2O_3, Tb_4O_7, and Al_2O_3 and 50% excess of stoichiometric amount of B_2O_3 or H_3BO_3 plus codopant in the oxide form, if desired, were mixed and ground thoroughly in a mechanically driven mortar and pestle. The mixture was placed in a Pt crucible and heated in air to 1100°C at a heating rate of 15 ~ 30°C/hr. After heating for 2 hr at 1100°C, a loosely sintered sample was immediately removed from the Pt crucible and ground by hand. It was then poured in a glass beaker half-filled with cold 1:1 HCl. After immersing in 1:1 HCl for 2 hr, the remaining powder was washed with deionized water by decantation and dried. The dried powder was mechanically reground and refired in air at 1100°C for 2 hr in a Pt crucible. The phase of powder samples was confirmed by x-ray diffraction. The Fe content of the samples was analyzed semiquantitatively by optical emission spectroscopy.

Cathodoluminescent measurements.—Sample powders were packed in shallow stainless steel dishes and were excited in a demountable cathode-ray apparatus. Most of the measurements were made at 10 kV beam voltage and about 1 $\mu A/cm^2$ beam current. Emission spectra of the phosphors were measured with a Nikon p250 grating monochrometer using HMT R376 photomultiplier as a detector. The wavelength-dependent sensitivity of the system was later corrected with a standard tungsten lamp, if necessary. The apparatus of a similar design fitted with a spectrophotometer system which gives emission spectra automatically corrected for the characteristics of the system was used in some cases. The description of the latter apparatus can be found elsewhere (7).

Results

Preparation technique and raw materials.—The preparation techniques of $Y_{1-x}Tb_xAl_3B_4O_{12}$ phosphors were checked by both x-ray diffraction and CR emission intensity. It was found that a large excess amount of B_2O_3 or H_3BO_3 (50 ~ 100% in excess of stoichiometry) was necessary to form a huntite structure single phase sample. The sample fired with 50% excess B_2O_3 became pure white after a single firing, indicating complete reduction of Tb^{4+} ions to Tb^{3+} ions, whereas the sample fired from a stoichiometric or a 1 ~ 5% excess B_2O_3 added mixture was slightly colored and also contained a small amount of an unidentified impurity phase. The leaching in cold 1:1 HCl after the first firing turned out to be quite effective to improve Tb^{3+} emission intensity under CR excitation. As much as 50% improvement over unleached samples could be achieved by this process. Such a pronounced improvement is thought to be brought about by the dissolution of B_2O_3 coating, probably in the form of glass, on $Y_{1-x}Tb_xAl_3B_4O_{12}$ particles in 1:1 HCl.

It was found that impurity Fe mainly from Al_2O_3 and B_2O_3 raw materials had a damaging effect on Tb^{3+} emission. When CP grade Al_2O_3 and/or B_2O_3 were used as raw materials, the Fe content in the phosphor was as much as 200 ppm. The use of electrolytically oxidized Al_2O_3 (99.99%) and Merck "suprapur" grade B_2O_3 or H_3BO_3 lowered the Fe content to 50 ppm or below. Approximately 15% improvement in emission intensity was attained by the use of the high purity raw materials (99.99%+).

Concentration quenching of Tb^{3+} emission.—The emission of $Y_{1-x}Tb_xAl_3B_4O_{12}$ phosphors ($x \geqq 0.05$) was due to transitions from $^5D_4$ level to the ^7F levels of Tb^{3+} ion, as was reported earlier (4). Unless otherwise stated, the effect of various parameters on CL properties was compared via the intensity of the strongest Tb^{3+} emission peak at 543 ± 1 nm due to the $^5D_4 \rightarrow {}^7F_5$ transition.

The Tb^{3+} emission intensity increases with Tb concentration up to $x = 0.3$ in $Y_{1-x}Tb_xAl_3B_4O_{12}$, but concentration quenching sets in thereafter as can be seen in Fig. 1. The tendency was unaffected by the Fe impurity level in the phosphors. In Fig. 1, the open circles are for high purity samples (Fe $\lesssim$ 50 ppm) and the closed circles are for high Fe content samples (Fe > 100 ppm) prepared from CP grade Al_2O_3 and B_2O_3.

In some Tb compounds, the quenching of Tb^{3+} emission under u.v. excitation has been successfully interpreted by the formation of Tb^{3+} ion complexes (8). The general relationship for the concentration of Tb^{3+} ions with n neighbors C_n is given by

$$C_n = [Z!/n!(Z-n)!]x^{n+1}(1-x)^{Z-n}$$

where x is the fraction of the site available to the Tb^{3+} ions and Z is the maximum number of Tb^{3+} ions in neighboring sites. In the garnet series $(Y_{1-x}Tb_x)_3Al_5O_{12}$, the quenching sets in at $x = 0.35$ where $C_0 + C_1$ takes its maximum. Such a result can be expected when single ($n = 0$) and paired ($n = 1$) Tb^{3+} ions emit with equal intensity, but more complex aggregates ($n \geqq 2$) do not.

In the $Y_{1-x}Tb_xAl_3B_4O_{12}$ system, each Y or Tb atom has six nearest Y or Tb atoms ($Z = 6$) (9), so that the maximum in $C_0 + C_1$ takes place at $x = 0.24$. Hence, even in the $Y_{1-x}Tb_xAl_3B_4O_{12}$ system under CR excitation, the formation of Tb^{3+} ion complexes with $n \geqq 2$ seems to cause the quenching.

Effect of coactivators on Tb^{3+} emisison.— A number of elements such as Bi, Sb, and Ce are known to act as sensitizers for Tb^{3+} emission under u.v. excitation (10). We also confirmed that such sensitization took place. As much as two orders of magnitude enhancement in emission intensity under 254 nm u.v. excitation was observed with a small addition of these elements (up to a few percent). However, no such sensitizing

* Data obtained at 10 kV and about 1 $\mu A/cm^2$.

effect was observed for Tb^{3+} emission intensity under CR excitation. Figure 2 shows such a result for Bi and Sb coactivation. As can be seen, a quenching effect exists even at a very low concentration and this becomes more pronounced with increasing concentration. The quenching effect was even more marked when a small amount of other rare earth atom was added as shown in Fig. 3. In these cases, the energy lost due to quenching of Tb^{3+} emission seems to be dissipated nonradiatively. Although a small emission peak characteristic of the rare earth coactivator such as Tm, Eu, and Dy was sometimes detected, its intensity was not strong enough to compensate for the intensity loss in Tb^{3+} emission.

The quenching of Tb^{3+} emission in calcium metaphosphate glasses due to the energy transfer from Tb to a second rare earth ion under u.v. excitation has been systematically studied (11). It was found that the degree of quenching was proportional to a so-called

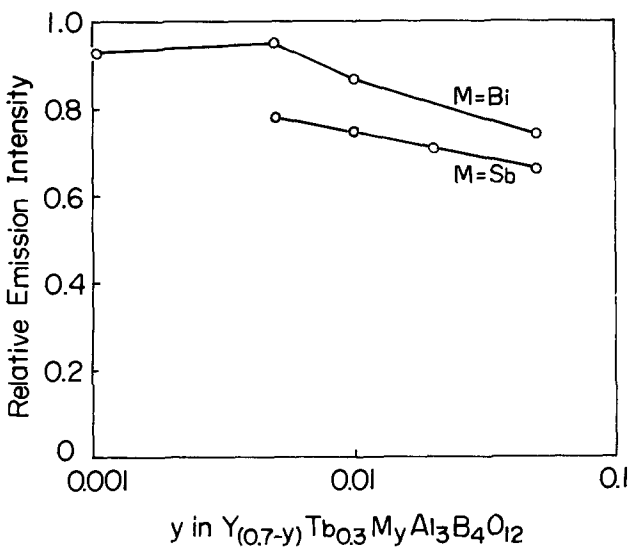

Fig. 2. Relative intensity of Tb^{3+} emission *vs.* coactivator concentration in $Y_{0.7-y}Tb_{0.3}M_yAl_3B_4O_{12}$; M = Bi or Sb.

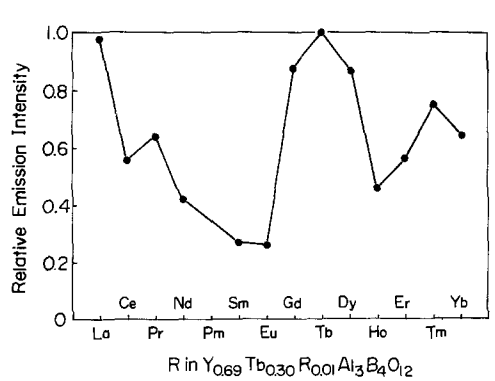

Fig. 3. Relative intensity of Tb^{3+} emission in $Y_{0.69}Tb_{0.30}R_{0.01}Al_3B_4O_{12}$.

overlap integral, $S = \int_0^\infty I(E)\sigma(E)dE$, where $I(E)$ is the emission spectrum of Tb^{3+} ion and $\sigma(E)$ is the absorption spectrum of the second rare earth ion. However, in the present case, no such systematic behavior was found to exist, indicating that the energy transfer under CR excitation is predominantly nonresonant, *i.e.*, from a higher-lying level of Tb^{3+} to a lower level of a second rare earth that is not matched in energy (8).

The case of Sm coactivation was considerably different from others and the energy transfer from Tb to Sm seems to take place quite effectively. Enhanced emission peaks of Sm^{3+} at 590 ~ 610 nm and at 640 ~ 645 nm gave rise to a yellow orange emission color. Such enhancement of Sm^{3+} emission was also observed in the series $Na_{0.5}Tb_{0.5-x}Sm_xWO_4$ only when the Sm concentration was low (12). The enhancement was believed to take place when the energy was transferred from an excited Tb to a Sm atom, rather than to a Sm-Sm or a Sm-Tb pair.

In summary, the best CL efficiency was realized in the $Y_{0.7}Tb_{0.3}Al_3B_4O_{12}$ phosphor without any coactivator. Figure 4 shows the relative peak output of the $Y_{0.5}Tb_{0.5}Al_3B_4O_{12}$ phosphor with respect to a standard Zn_2SiO_4:Mn(Pl) phosphor as a function of electron beam current density at 5 kV. As expected for rare earth activated phosphors in general, the relative efficiency gets better under the high current density operation. In Table I, the emission data are summarized for the $Y_{0.7}Tb_{0.3}Al_3B_4O_{12}$ phosphor together with the data for Zn_2SiO_4:Mn(Pl) and ZnCdS:Cu,Al(Z910). The latter is a green phosphor now in use in RCA color TV screens. It must be concluded that the $Y_{0.7}Tb_{0.3}Al_3B_4O_{12}$ phosphor is only moderately efficient as a phosphor for CRT screens.

Acknowledgments

The authors wish to thank J. Gerber and F. S. Stofko, Jr., for carrying out some of the CL measurements and H. H. Whitaker for the analysis of Fe content in the phosphors. They also wish to thank F. Okamoto and T. Oka for their technical assistance during the course

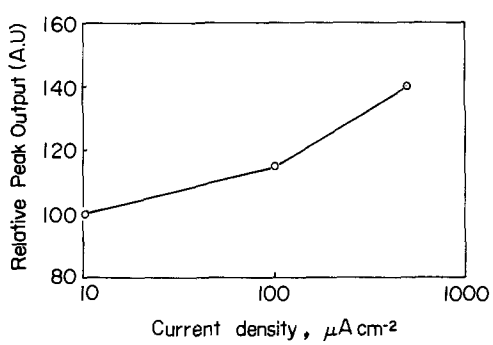

Fig. 4. Relative peak output of the $Y_{0.5}Tb_{0.5}Al_3B_4O_{12}$ phosphor with respect to Zn_2SiO_4:Mn as a function of electron beam current density. Peak output of Zn_2SiO_4:Mn at 523 ± 1 nm is taken to be 100 at each beam current density. Accelerating voltage = 5 kV.

Brief Communications

Control of Al_2O_3 Position in Anodic GaAs Native Oxide

B. Bayraktaroglu, S. J. Hannah, and H. L. Hartnagel

Department of Electrical and Electronic Engineering, University of Newcastle upon Tyne, Newcastle upon Tyne, NE1 7RU, England

It is shown that by careful control of kinetic growth parameters, it is possible to anodically position a thin Al_2O_3 layer in a native GaAs-oxide film either near the oxide-semiconductor interface or on the surface of the GaAs oxide. The ability to produce composite oxide structures promises several interesting advantages, such as: (*i*) stabilization of GaAs native oxide against many chemicals by placing the Al_2O_3 on the surface of the film, (*ii*) when Al_2O_3 is placed near the semiconductor surface, such a layer will be advantageous for optimum electrical characteristics due to the large bandgap of Al_2O_3 (~8 eV), and (*iii*) possible application to optical waveguides with a variation in refractive indexes of oxide layers.

Due to the difference in the threshold fields required for the activation of different anions and cations, it is possible to influence the growth mechanism of anodic oxide films, and therefore shift the effective oxide formation region anywhere from the metal-oxide interface to the oxide-electrolyte interface. For anodic Al_2O_3 films it is known (1) that the threshold field required for the activation of cations is larger than that for anions. Our findings suggest that a similar system also exists for anodic GaAs native oxides with the threshold field for cation activation again being larger than for anion activation. It is therefore possible to use a sufficiently low field so that OH^- drifts across any oxide formed to create further oxidation at the semiconductor-oxide interface, or to use a high field so that the cations become mobile which exhibit with their larger mobility a primary ion flow to the oxide surface where further oxidation occurs.

Composite oxides on GaAs have been produced by first evaporating a known thickness of Al on a polished and etched GaAs surface and then anodizing the whole structure with constant current in an electrolyte first suggested by Hasegawa and Hartnagel (2). Since the average field across the oxide during the growth is dependent on the current density, the control of growth kinetics was achieved by keeping the electrolyte temperature constant and varying the current density. The first oxide to form is always Al_2O_3 and then, depending on the current density used, GaAs native oxide can be made to form either underneath or on top of the Al_2O_3 by further anodization. Mixed oxides were previously reported under different anodic conditions without establishing or making use of the kinetic details presented here (3, 4).

If low current densities are used, *i.e.*, ~20 $\mu A/cm^2$, after the Al_2O_3 is formed, there are only anions moving across the oxide to the GaAs-Al_2O_3 interface, whereas the field at this current density is insufficient to produce mobile Ga and As ions. The oxide growth then forms GaAs native oxide underneath Al_2O_3. However, at high current densities (>2 mA/cm^2), Al_2O_3 is formed by transporting metal ions to the oxide-electrolyte interface and after all the Al is converted into Al_2O_3 the field is high enough to create Ga and As interstitial ions which are consequently transported through the Al_2O_3 layer to the oxide-electrolyte interface and hence GaAs native oxide forms on the Al_2O_3, as indicated by etch tests described below.

Although it was possible to produce thick layers of Al_2O_3 on GaAs native oxide, there is a limit to the thickness of Al_2O_3 on the GaAs surface. For Al_2O_3 thicker than ~500Å, the Al_2O_3 acts as an effective diffusion barrier for Ga and As interstitial ions and even at intermediate current densities, *i.e*, ~0.1 mA/cm^2, GaAs native oxide then still forms underneath Al_2O_3. But at higher current densities cations tend to punch through the Al_2O_3 creating locally damaged areas.

A chemical test was applied to the composite oxides using tartaric acid, which is an etchant of GaAs native oxide but not of Al_2O_3, in order to establish which oxide is on the top. When Al_2O_3 is underneath GaAs native oxide, an etching of some of the composite oxide was observed. The thickness of the oxide left behind was measured with a Dektak profile plotter.

Measured values were compared with the expected thickness of Al_2O_3 and it was concluded that the oxide left behind is, except for small traces of GaAs oxide, only Al_2O_3. For the structures grown with Al_2O_3 on top of the native oxide, no etching was observed for the same etch conditions. These results imply that in the first case practically all the Ga and As ions move across, whereas in the latter case only OH^- ions move across Al_2O_3 in the opposite direction.

It is possible to determine at which interface the Al_2O_3 layer is formed from the overpotential *vs.* time (v-t) graphs plotted during anodization. After all the Al is converted into Al_2O_3, the overpotential exhibits a temporary steep increase for the high current density case, whereas a constant potential is maintained over a short period for the low current density case. The first case corresponds to the growth of GaAs native oxide at the electrolyte interface, and the second one at the semiconductor interface.

Since most other valve metals have anodic behavior very similar to Al, it is expected that Al_2O_3 may be replaced by some other oxide systems promising wider ranges of possibilities.

Mask Preparation for Small Dimension Ion Milling by Two Step Lift-Off Process

O. Wada, S. Yamamoto, K. Kobayashi, A. Taguchi, and Y. Toyama

Fujitsu Laboratories Limited, Nakahara-ku, Kawasaki, Japan

The requirement for fabricating structures with dimensions smaller than a few microns has increased in recent years the need for improvements in the packing density and the operating speed of integrated circuits. The ion milling technique (1) combined with the scanning electron beam lithography (2) is very useful for this purpose because of the high resolution and the sharp edge profile of the exposed resist patterns and the small undercutting of the etched structure. In such a process, one has to prepare a mask which is resistant to the ion beam using the patterns delineated in the electron beam resist layer.

The purpose of this communication is to describe an improvement in the mask preparation in conjunction with the formation of small holes or grooves in the substrate.

In the practical fabrication processes for realizing small structures, the following subjects should be taken into consideration: (*i*) The patterns in the resist layer have to have good edge resolutions, therefore it is more useful to use the positive acting resist such as polymethylmethacrylate (PMMA) resist rather than the negative acting resist (3). (*ii*) The coverage of the exposed area in the resist layer should be minimized, because the exposure time is proportional to the area to be exposed with the scanning-type exposure system (4). (*iii*) The mask material for the ion milling should have an etching rate small enough to protect the substrate, and usually it is not easy to obtain a high yield of small structures by using the resist layer itself as an etching mask.

In the case of forming small islands, all of the conditions stated above are satisfied with the use of the so-called lift-off method (3) in which the etch-resistant metal layer is delineated using the resist pattern as a deposition mask. On the other hand, however, it is difficult to make small holes in the substrate because the exposure time for positive acting resist should be extremely long if the usual lift-off method is applied. In order to save the exposure time and simultaneously maintain the high resolution, we have introduced an improved method in which the metal patterns are delineated through a two step lift-off process. In the present method, a double metal layer structure is first patterned by the usual lift-off method with positive acting resist and the resultant structure is then used as a stencil in the subsequent lift-off process.

Key words: ion milling, two step lift-off, microfabrication.

The sequence of the processes is in the following:

1. The PMMA resist is coated on the substrate and the area under which the substrate has to be etched is exposed by the scanning electron beam system and then developed.
2. An Al layer and subsequently a Ti (first) layer are evaporated on the substrate and the resist layer is removed together with the upper Ti/Al layer by the usual lift-off method.
3. The lateral dimension of the lower Al layer is reduced using the side-etch effect of a chemical solution, in order to make an overhang structure in the double metal layer.
4. A Ti (final) layer is evaporated on the substrate and then the substrate is dipped into the Al etchant again. This results in the removal of only the Ti/Ti/Al layer and leaves behind the desired pattern in the final Ti layer.
5. The exposed area of the substrate is etched by the argon ion milling technique using the residual Ti layer as a mask.

Figure 1(a) shows the schematic illustration of the cross section of the substrate before the unwanted Ti/Ti/Al layer is removed. Prior to the evaporation of the final Ti layer, the Al layer was etched in the lateral direction by immersing in an Al etchant (3:1 H_3PO_4:-C_2H_5OH) for 60 sec. The thickness of the starting resist layer should be chosen from the required thickness of the final mask metal layer, where the thickness of the stencil Al layer should exceed the final Ti thickness, since the Al etchant has to penetrate through the gap of Ti layers. Figure 1(b) shows an example of the scan-

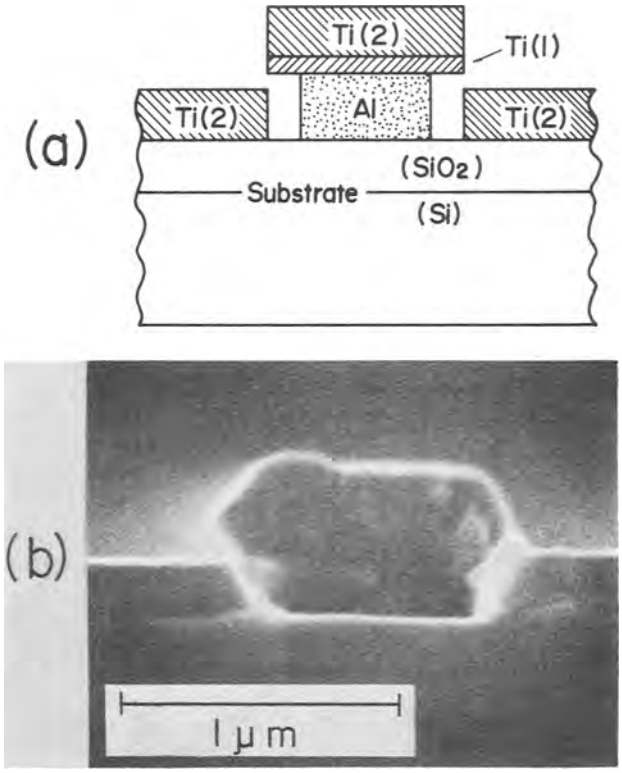

Fig. 1. (a) Schematic illustration and (b) scanning electron micrograph showing the second lift-off process. The lower Ti/Al stencil is first formed by the usual lift-off method and the chemical etching technique.

ning electron micrograph indicating the structure corresponding to Fig. 1(a). The pattern width is 1 μm, and the thicknesses of the Al, the first Ti, and the final Ti are 0.25, 0.15, and 0.18 μm, respectively. The starting resist thickness was 0.48 μm in this case. In our experiments, the removal of the unwanted Ti/Ti/Al layer was achieved in a reasonable etching time for the pattern width up to 5 μm. By increasing the starting resist layer thickness to 0.7 μm, a final Ti layer as thick as 0.48 μm was obtained. Figure 2 shows the structure revealed after the ion milling of the substrate SiO_2 to 0.5 μm depth using this 0.48 μm thick Ti mask. Because of the small etching rate of Ti layer compared with the SiO_2 layer (etching rate ratio $\simeq$0.6), deep holes and grooves with sharp edge profiles were realized.

As described above, the present method can realize a high resolution in the preparation of small holes or grooves in the substrate which are used for processes such as metallization and ion implantation. The present method together with the usual one step lift-off method are considered to be applied as complementary processes in forming structures (holes or islands) with dimensions smaller than a few microns, especially in the submicron range. Adding to the fine structure, the present method has the advantage that the final metal layer can be deposited at an elevated temperature. This is advantageous for improving the adhesion to the substrate. This feature cannot be expected for the usual lift-off method using the resist as a mask, because of the low glass-transition temperature of the resist, and therefore, the present method can also find a wide usage for patterning of high melting point metal layers.

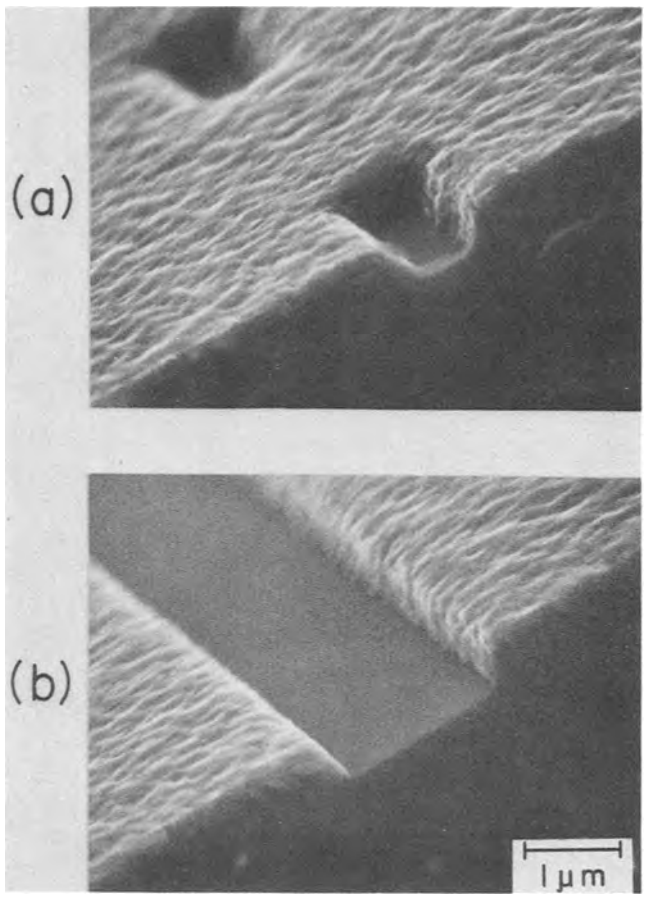

Fig. 2. Scanning electron micrographs showing (a) square holes and (b) a narrow groove both of which have been formed in the SiO_2 layer by argon ion milling technique using the patterned Ti layer as a mask.

Acknowledgment

The authors are grateful to T. Inagaki and his coworkers for exposing PMMA. They also thank S. Furuya and T. Fukuda for experimental help and T. Misugi, Y. Fukukawa, and H. Takanashi for encouragement.

A Chemical Polish for the Cadmium and Sulfur Faces of Cadmium Sulfide

A. A. Pritchard and Sigurd Wagner

Bell Laboratories, Holmdel, New Jersey 07733

In this note we report that chemical polishing with KCl buffered aqueous solutions of HCl leads to high quality finish on both the cadmium, or A, or (0001) and the sulfur, or B, or $(000\bar{1})$ surfaces of cadmium sulfide. The polishing solution is an aqueous hydrochloric acid-potassium chloride buffer with optimum *p*H values of 2.5 for the cadmium face and 1.0 for the sulfur face.

Satisfactory cadmium and sulfur surfaces have always been difficult to achieve. Three polishing procedures have been published. Warekois and co-workers (1) used a solution of $K_2Cr_2O_7$ in H_2SO_4 at 90°C to obtain a high polish, with dislocation etch pits, on the sulfur face. Sullivan and Bracht (2) chemically polished cadmium, sulfur, and prismatic faces by feeding a 30 volume percent (v/o) aqueous solution of conc HCl onto a rotating Pellon cloth. Pickhardt and Smith (3) chemo-mechanically polished cadmium faces on a Politex-Pix poromeric pad with a solution of 90 ml conc HNO_3, 300 ml precipitated silica suspension, and 10g $AlCl_3$ per 1000 ml H_2O; on sulfur faces no satisfactory finish was obtained. In an unpublished study, Polito (4) produced smooth sulfur (but not cadmium) faces with the Sullivan and Bracht technique, and smooth cadmium (but not sulfur) faces with Syton HT, a colloidal aqueous suspension of silica. The surface quality was characterized by standard incident light microscopy.

Each procedure appears to work well on only one of the two faces. In addition, the criteria for a satisfactory finish have become more stringent because the demands on surface quality have risen. Warekois *et al.* desired a visually smooth surface. Rozgonyi and Polito (5) sputtered epitaxial ZnO films on CdS for structural, electrical, and optical characterization. The CdS phonon spectrometer recently developed by Shah *et al.* (6) requires highly polished platelets. Pickhardt and Smith (3, 7) discuss the extreme surface finish of substrates needed in molecular beam epitaxy for waveguide structures.

Another explanation for the differences in polishing behavior observed in these studies may be found in the variable quality of CdS crystals. We have, for instance, observed that an acidic Syton polish can result in perfectly smooth sulfur faces in some batches while failing in others.

We now describe a procedure which reproducibly produces flat and highly polished cadmium and sulfur faces. Surfaces were inspected with a Nomarski-type incident light interference microscope at magnifications up to 1000× and with a Nomarski-type polarization interferometer ($\lambda = 546$ nm) at 125× and 290× magnification. The most satisfactory results have been obtained with batches of three CdS wafers of about 1 cm^2 area each. After string-saw cutting about 1 mm thick (0001) plates, they were etched for 2 min in 1:1 conc HCl and water in an ultrasonic bath to remove damaged surface layers and to differentiate cadmium and sulfur faces. The Cd face turns shiny while the S face remains mat (2). The first two polishing steps are carried out with Hyprez lubricant (Engis Equipment Company, Morton Grove, Illinois) on 3 μm emery paper and on 3 μm alumina paper (Ultralap, Pfizer Corporation), respectively; both papers, manufactured with self-adhesive backs, were attached to flat glass plates. The two following steps use the alumina abrasives, 0.3 μm Linde A and 0.05 μm Linde B, on Pellon cloths which also were attached to glass plates. The cloths are prepared by rubbing in the abrasive and a paraffin binder with a sapphire disk to obtain a flat surface. Before polishing, more abrasive is spread and tallow-base shaving cream is added as a lubricant. It is important to produce a smooth surface before the chemical polish is applied. Any crosshatch pattern arising from prepolishing must be removed at this point by repeating the polishing sequence with all three alumina abrasives.

Key words: crystal polishing, cadmium sulfide, buffer.

The chemical polish is an aqueous HCl/KCl buffer with *p*H = 2.5 (0.50 ml conc HCl, 13.7g KCl, 1000 ml dist H_2O) for the cadmium face; and *p*H = 1.0 (16.0 ml conc HCl, 13.3g KCl, 1000 ml dist H_2O) for the sulfur face. The solution is dripped at a rate of about 3 ml/min onto a Politex-Pix pad mounted on a motor driven (58 rpm) stainless steel plate 6 in. in diameter. To rotate the block, it is placed in a stainless steel dressing ring held by rollers near the edge of the poromeric pad. Brass weights are added to provide a pressure of 0.25-0.40 kg/cm^2 of CdS surface. Typical polishing times to reach a featureless finish are 2-4 hr.

The photoluminescence of CdS excited with a 457.9 nm argon laser beam provides a sensitive measure of the surface quality. With the absorption length for the exciting light being of the order of 0.1 μm (8), the luminescence spectrum reflects the perfection of a shallow surface layer. On vapor grown crystals or on cleaved faces the I_1 peak is narrow and intense, and the lowest background intensity between the I_1 and I_2 lines is 100-200 times smaller than that of I_1. The luminescence spectrum presented in Fig. 1 is typical of A and B faces polished with HCl/KCl buffers. This spectrum is comparable to spectra obtained on cleaved or vapor grown faces and demonstrates a damage-free finish.

Extended defects, which can be observed by focusing through the CdS crystal, always led to surface irregularities. We have also found that some crystals, especially when well conducting (~1 Ω-cm), contain entire layers of defective material. These layers seem to be (0001) oriented. When they surface it is not possible to obtain a perfect finish. One then needs to return

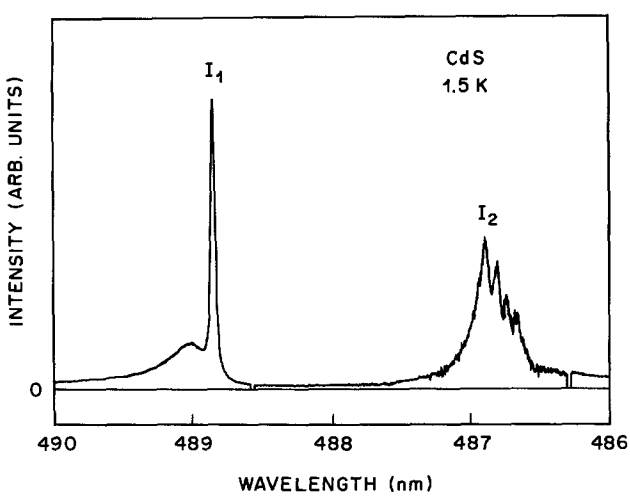

Fig. 1. I_1 and I_2 lines of the 1.5°K luminescence spectrum of polished CdS excited with 457.9 nm Ar laser light. The narrow I_1 peak and high I_1 to background (between I_1 and I_2) ratio are typical for A and B faces polished with HCl/KCl buffers.

to the alumina abrasives, remove 0.05-0.1 mm of the crystal, relap, and then repolish with the KCl/HCl buffer.

Acknowledgments

We would like to acknowledge helpful discussions with Dr. A. H. Dayem and Dr. B. I. Miller. We also thank Dr. J. Shah for providing and commenting on the luminescence spectrum.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 123, No. 3 and 6; March and June 1976.

A High Speed X-Ray Topographic Camera for Semiconductor Wafer Evaluation

D. L. Parker and W. A. Porter (pp. 407-409, Vol. 123, No. 3)

C. A. Wallace:[1] The experiments reported by Parker and Porter bear a close similarity to the work of Wallace, Ward, and Eastlake.[2,3] However, the vacuum chuck described does not allow the technique to be used in the transmission mode. Wallace *et al.* have developed an instrument which can be used in both the transmission (Laue) and the reflection (Bragg) modes. The crystal is mounted by an atmospheric mechanism to a plate which is subject to continuously adjustable opposed couples in a bending mechanism. In the transmission mode the direct beam is eliminated by a set of Soller slits aligned with the diffracted beam and oscillated laterally to diffuse the shadows of the diaphragms. The topograph can be viewed directly with a TV camera as an aid to alignment and for inspection of the crystals at coarse resolution.

Evolution and Current Status of Aluminum Metallization

A. J. Learn (pp. 894-906, Vol. 123, No. 6)

P. S. McLeod:[4] Table I of this article omits a rapidly developing area of sputtering commonly called planar magnetron sputtering.[5] We estimate the cost per wafer for metallization by planar magnetron sputtering to be between \$0.05 and \$0.06 for 1 μm thickness films from a five 9's pure aluminum target. This is comparable to costs for flash evaporation. We have measured static rates of deposition as high as 1.6 μm/min at 5 kW power input into a 3 1/2 $\times$ 8 1/4 in. source. This is greater than rates cited in Table II of the article and comparable to rates run at the same power from a 2 in. diameter electron beam source without a crucible liner and beam sweep. With good vacuum technique, we have made aluminum coatings with Q_0 of less than 8×10^{-3} V/PFD, and voltage shifts in C-V plots of a few hundred millivolts before annealing are typical if the sputtering voltage is kept below 500V. After annealing, evidence of damage in all cases we have seen can be eliminated by annealing for 5-10 min at 400°-450°C.

A. J. Learn:[6] Development in the area of sputtering, and plasma-related processing in general, is indeed showing rapid advancement. While magnetron sputtering is not listed in Table I of the subject article, it is, of course, referenced in the discussion of items in that table and in the concluding paragraph of the article. At the time of the paper, the published information on magnetron sputtering, was insufficient to allow full assessment of that technique as regards meeting requirements for metallization on silicon devices. This has been remedied to a large extent for general magnetron sputtering by the publications of Wilson and Terry[7] and Hoffman.[8] Similar information for planar magnetron sputtering is still lacking, although one suspects that such data are abundant, as evidenced by the unpublished results quoted above. The comparison of deposition rate for planar magnetron sputtering and other deposition methods is not entirely meaningful since the deposition geometries are typically quite different. It is noteworthy that the deposition rate for magnetron sputtering into conventional spherical rotary planetary fixturing remains relatively low at < 0.1 μm/min.[8,9] In a practical sense, presumably the throughput of silicon wafers of a given size forms a better basis for comparison. Planar magnetron sputtering is found[10] to compare favorably with other methods in this respect.

Alkali Peroxydisulfates for Water-Activated Reserve Batteries

J. R. Dafler*,[1]

ESB Incorporated, Technology Center, Yardley, Pennsylvania 19067

ABSTRACT

Peroxydisulfates (persulfates) possess very high specific free energy changes for oxidation in aqueous systems. The alkali persulfates are very soluble and yield, in 40% aqueous systems, cell voltages, at the 4 hr rate, that exceed 2V. Persulfates are stable and can be dry-stored for long periods with little loss of oxidizing power. Used in conjunction with Mg alloy (AZ-61) anodes, persulfate cells can be activated with most common aqueous media. The $Na_2S_2O_8$/AZ-61 cell has fast start-up capability and a flat discharge characteristic at all reasonable rates of discharge. Comparisons to other battery systems at equivalent currents and rates are presented. The persulfate cell is seen as a potentially useful reserve battery for either high or low rates.

Water-activated batteries were rapidly developed during the 1940's when there was specific need for long shelf-life, higher power, reserve systems. The impetus for development came from military applications (1, 2). An early result of the intensive work done to develop such new energy sources was the silver chloride-magnesium reserve battery, which became commercially available in 1943 (3, 4). After 1946, applications for the AgCl/Mg battery grew rapidly and this system, despite its relatively high cost, became widely adopted. It has been used for weather ballons, air-sea rescue equipment, and sonobuoys, the latter application having accounted for a major fraction of production.

The cuprous chloride-magnesium reserve battery (Cu_2Cl_2/Mg) first became commercially available in 1949 (5, 6). Like the AgCl/Mg battery, it is a long shelf-life, water or seawater activated unit. It is not suitable for the same kinds of use as the AgCl/Mg battery, having lower rate capability and, generally, lower energy density.

The high cost of silver and the lower rate capabilities of Cu_2Cl_2 have led to considerable effort to find other systems suitable to replace the AgCl/Mg system. A number of water-activated systems appeared in the 1970's and deserve mention.

Aluminum/air battery.—The Furukawa Battery Company, Limited, of Tokyo introduced an aluminum/air battery in 1969 (7). It consisted of a series of closed cells containing KOH pellets and utilized a 2.54 mm thick aluminum anode and a 3.38 mm thick, porous carbon, air breathing cathode. The battery was a five-cell device activated with water poured into one cell, which then filled all five subunits through overflow connections. Sold as a low rate (0.3A) battery, this system did not fulfill its advertised energy density goals. Moreover, though sealed in water-vapor resistant PET-plastic film bags, the KOH deteriorated after 5-6 months of storage.

Cuprous fluoride/magnesium.—This cell system, Cu_2F_2/Mg (AZ-31) is a retained electrolyte cell of reasonably high power density (8). It was not, in the configurations tested here, a water-activated battery, but carried, in conjunction with its cathode/anode pouch, a plastic container filled with a strong solution of $NaClO_4$. Activation was accomplished by puncturing the electrolyte reservoir. Activation was then rapid. As with most retained electrolyte systems, this was not an "any attitude" battery such as the AgCl/Mg and Cu_2Cl_2/Mg batteries.

Lead chloride/magnesium.—Commercial samples of this system appeared in 1970-1971 as typically pasted positives in conjunction with AZ-61 anodes. The pasted positives contained $PbCl_2$ and basic Pb(OH)Cl, on an antimonial SLI grid. The system was attractive and easy to use. It yielded energy densities, in our testing, of ~66 W-hr/kg.

Coleman (9) reviewed the $PbCl_2$/Mg technology in 1971 and reported similar energy densities using Cu-mesh supports rather than typical SLI grids. Recent advances in electrode manufacture (10, 11) have made this an exceptionally attractive system, presently yielding energy densities high enough to replace AgCl/Mg in many of its applications.

Alkali peroxydisulfates.—A water-activated system designed to employ the alkali peroxydisulfates (persulfates) as a depolarizer would necessarily need to be, as in the case of the CuF_2/Mg cell, a contained electrolyte system.

The high solubilities of alkali persulfates [$(NH_4)_2S_2O_8$, 47.7 g/100 ml solution; $K_2S_2O_8$, 1.72 g/100 ml solution; and $Na_2S_2O_8$, 49.9 g/100 ml solution] can provide a reserve battery system with electrolyte of high ionic strength immediately after water activation, so that conductivity of electrolyte is never a problem. The ionic strength of persulfate depolarized batteries increases rapidly during discharge, due to the following reactions

$$Mg \rightleftarrows Mg^{++} + 2e^- \quad [1]$$

$$S_2O_8^{=} + 2e^- \rightleftarrows 2SO_4^{=} \quad [2]$$

An operating $S_2O_8^{=}$/Mg battery would be of low internal resistance, and prior to activation, should have

* Electrochemical Society Active Member.

Key words: magnesium electrodes, persulfates, water-activated batteries.

an excellent shelf-life. Alkali persulfates do not deteriorate if kept dry. They can be expected to lose ~1% of their active oxygen in one year of dry storage.

Codd (12), in 1932, reported on a $(NH_4)_2S_2O_8$ depolarized primary battery, but little seems to have come of it until 1952, when Blake (13) reported on the use of $K_2S_2O_8$ to improve the performance of AgCl/Mg water-activated batteries. Most of the experiments described were carried out using a Burgess AgCl/Mg battery (ICC40), adding $K_2S_2O_8$ or $Na_2S_2O_8$. There was improved performance (14) but this system offers no great advantage in price because the cathode material was either silver foil or silver-carbon pastes. Blake suggests that some undefined synergism makes the persulfate additive-AgCl/Mg battery perform better than either system's separate performance indicates.

Recently, primary cells with persulfate depolarizers have attracted some limited attention. Wijnen and Boter produced a flat primary system capable of driving an electric shaver (15). A semiwet system employing a feltlike absorber, saturated with alkali persulfates, this cell required clamping action to realize full current capabilities.

In 1970, Cohen *et al.* obtained some very general patents on primary cells using peroxygen chemicals as additives and as depolarizers (16). They explored the use of peroxyphosphates acting as corrosion inhibitors for the anodes used, which were either Zn or Mg and their alloys. Their embodiments, however, were cells of exceptionally low rate and capacity, even after "pro-rating' them for the quantities used.

Alkali persulfate chemistry.—Alkali persulfates, produced in enormous quantities in the United States, are widely used in the chemical and related industries. Persulfate ion is a powerful oxidant as can be seen by its standard reduction potential

$$S_2O_8^{=} + 2e^- = 2SO_4^{=} - 2.0V \qquad [3]$$

Solutions of the persulfates are intrinsically unstable, decomposing to dilute sulfuric acid and oxygen in neutral or alkaline solutions. In acidic media, the hydrolysis yields Caro's acid (H_2SO_5) and H_2O_2. The hydrolyses are

$$S_2O_8^{=} + H_2O = 2HSO_4^- + \tfrac{1}{2}\,O_2 \qquad [4]$$

in neutral media, and

$$S_2O_8^{=} + H_2O = H_2SO_5 + SO_4^{=} \qquad [5]$$

$$H_2SO_5 + H_2O = H_2O_2 + H_2SO_4 \qquad [6]$$

in acid media.

Kolthoff and Miller (17) have postulated a thermal decomposition mechanism, and report a first-order reaction rate with hydrogen ion catalyzing the decomposition. The rate is given by

$$d(S_2O_8^{=})/dt = -[k_1(S_2O_8^{=}) + k_2(H^+)(S_2O_8^{=})] \qquad [7]$$

The mechanism proposed is a chain mechanism, the uncatalyzed and catalyzed reactions being independent. The uncatalyzed chain involves the formation of labile species SO_4^- as the rate-determining step, while the formation of $HS_2O_8^-$ determines the rate of the catalyzed reaction.

Solutions of persulfates tend to become more acidic on standing, due to formation of HSO_4^-. On standing, the *p*H falls and the acid catalyzed decomposition becomes significant.

Early battery work on the alkali persulfates yielded low rate units because an effective electrode for persulfate reduction was not found. Silver, silver compounds, and silver-carbon pastes were reasonably effective but are not appropriate. The need was for a cheap, high surface area material that provided a high density of sites for decomposition. The material must also have a sufficient electrical conductivity to act as a proper electrode.

After a large number of experiments, a material was found, *i.e.*, a graphite fabric made by treating polymeric fiber cloth at high temperatures. The material has good conductivity (18), is robust, and has enough surface area to support large currents.

Experimental Procedures

Commercial samples of the alkali persulfates were used as test active material. These were supplied by the FMC Company of Princeton, New Jersey. All other chemicals used were reagent grade materials. Magnesium anode materials were supplied in the form of standard alloys such as AZ-21, AZ-31, and AZ-61. These were purchased from the Dow Chemical Company.

A standard, single cell test unit was adopted. It consisted of a small polystyrene case with plastic spacers used to adjust total cell volume. The cell finally adopted for test purposes had a volume of 22 cm^3 and used a 20 cm^3 volume of electrolyte. The separator was styrene bonded, nonwoven fiberglass mat, and electrolyte volume was defined by two negative sized pieces of corrugated, perforated PVC. The test unit exposed 39 cm^2 of Mg alloy, and 60 cm^2 of graphite cloth.

Discharges of test cells were conducted at constant currents, and ranged from 30 mA to 1.0A.

Inhibition of excess Mg alloy corrosion was done by first activating the surface with dilute HNO_3, then dipping in acidic solutions of $K_2Cr_2O_7$. Other techniques appear to be widely used (19, 20) but since they begin with a $K_2Cr_2O_7$ treatment, the simple dip treatment was used for most of the work reported here.

Treatment of data.—All discharge data was abstracted from continuous strip-chart collections, and subjected to point-by-point integration to yield point-by-point evaluation of the cell average voltage $\bar{E}$. Reference electrode discharges were followed continuously using infinite resistance linear amplifiers to prevent polarization of references. Utilization, U_T, of active material is referred to the two-electron reduction of $S_2O_8^{=}$, as indicated in Eq. [3].

A number of comparisons to other systems are presented. These are usually plotted as a dimensionless voltage [the cell terminal voltage, V, divided by the open-circuit voltage (OCV), E_{oc}] *vs.* a dimensionless capacity (the capacity, C, extracted at V, volts, divided by the total abstracted capacity, C_T).

Results and Discussion

Persulfate cell.—Sodium persulfate was quickly adopted as the material of choice. The more limited solubility of $K_2S_2O_8$ precluded use at high concentrations and $(NH_4)_2S_2O_8$ testing generally led to excessive generation of heat; high current drains often produced boiling in concentrated cells. This was due, presumably, to enhanced acid decomposition according to Eq. [7].

In a similar manner, AZ-61 was made the choice for anode. It consistently gave the highest OCV and better over-all discharge performance. AZ-61 has different corrosion characteristics than does AZ-21 or AZ-31 and, for this reason, its sludging characteristics appear superior. Robinson (21) pointed out that the higher aluminum alloys, such as AZ-61 or AZ-63, appeared to sludge and polarize less than other alloys. The films of $Mg(OH)_2$ formed are sloughed off via energetic aluminum corrosion or kept thin by hydrogen evolution and the stirring produced. Carson, Fischer, and Siewek (22) also found that, of the common alloys, AZ-61 was superior for water-activated systems. They found the sludges from AZ-21 and AZ-31 to be fluffy and slow settling, making those materials inferior to AZ-61. In this system, the *p*H is low enough to partially solubilize the $Mg(OH)_2$ formed and lower the effect of the hydroxide layer.

Table I. Summary of persulfate cell testing 22 cm³ cell at room temperature (25°C)

i_D (mA)	Concentration (g/100 ml solution)	U_T (%)	$\bar{E}$ (V)	t_D (hr)
100	10	68	1.70	3.00
	15	68	1.65	4.62
	20	68	1.98	6.10
	25	64	1.92	7.25
250	15	64	1.57	1.73
	20	65	1.74	2.35
	25	64	1.71	2.88
	30	58	1.84	3.12
	40	59	1.94	4.27

An extended series of simple experiments using increasing concentrations (g/100 ml solution) were done at two discharge currents, i_D. Electrolytes were made up as fully developed solutions and discarded daily. The data for these preliminary cell tests, using the standard cell described above, are summarized in Table I.

These tests were conducted at room temperature without inhibitor. The voltage column, $\bar{E}$, is a point-by-point integrated value preferable to the use of mid-voltage, with cells discharged to 0.5V end point.

Having achieved consistent data at reasonable discharge rates, the possible use of added, supporting electrolyte was investigated. To this end, 3% of NaCl was added to test electrolytes to simulate seawater activation. The data from these tests are summarized in Table II.

The use of 3% NaCl in conjunction with the $Na_2S_2O_8$ has led, in almost every case, to increases in performance figures for the cells (in watt hours). The increases are greater for lower concentrations of $Na_2S_2O_8$ cells than for high, and in the case of 40% solutions, the test unit without NaCl had higher operating voltages, if slightly poorer utilization and discharge time. This suggests that the value of the presence of NaCl is added initial conductivity, and the values derived from this decrease as the total concentration of electrolyte rises in the test series.

Inhibitor tests.—During discharge of a typical 40% $Na_2S_2O_8$ cell, a considerable quantity of sludge, presumably hydrated MgO is formed. There appears to be enough gassing, however, to keep the AZ-61 anode active. Control of gassing, therefore, had to be balanced with the need to keep the Mg/electrolyte interface well stirred.

The use of inhibitor as a premixed additive in the electrolyte was tried. $K_2Cr_2O_7$ or other chromate treatments appear the most recommended (19, 20) and $K_2Cr_2O_7$ was added to electrolyte solutions and tested. It was found that additions of 0.5 g/100 ml solution would effectively deactivate the cell, reducing utilization approximately to 6%. Reduction of additive inhibitor by an order of magnitude brought utilization in 20% cells up to ~73%.

A series of dip-treatment inhibitor tests were then made and these results summarized in Table III. Comparison indicated that cell voltages remained higher if the dip inhibition was used rather than the additive technique.

Table II. Summary of persulfate cell testing 22 cm³ cell at room temperature (25°C), 3% NaCl

i_D (mA)	Concentration (g/100 ml solution)	U_T (%)	$\bar{E}$ (V)	t_D (hr)	ΔW-hr* (%)
100	10	71	1.82	3.25	16.0
	15	71	1.63	4.78	2.21
	20	70	1.98	6.33	3.77
	25	67	1.95	7.50	5.06
250	10	66	1.52	1.18	
	15	68	1.66	1.82	11.2
	20	69	1.81	2.48	9.8
	25	67	1.74	2.98	5.29
	30	64	1.86	3.44	11.4
	40	60	1.87	4.28	−3.38

* ΔW-hr: percent change in watt hours, for this regime, compared to NaCl-free cells.

Table III. Summary of $K_2Cr_2O_7$ dip-inhibitor tests, i_D = 250 mA, 25°C, with and without 3% NaCl

	Concentration (g/100 ml solution)	U_T (%)	$\bar{E}$ (V)	t_D (hr)
Without NaCl	20	68	1.72	2.44
	30	69	1.81	3.72
	40	72	1.95	5.19
With NaCl	20	72	1.82	2.59
	30	69	1.85	3.72
	40	67	1.85	4.89

The inhibition treatment is effective both in suppressing gassing of Mg and in increasing the values of performance parameters. In the case of 40% units, the inhibitor treatment is seen to be quite beneficial, although the addition of NaCl and inhibitor apparently yields poorer performance than inhibitor alone. At levels of 20 and 30%, the use of inhibitor and NaCl led to increases in both utilization and average voltage.

Limited testing of longer dip treatments of the alloy negatives, and of alternate treatments was also done. Five minute dip treatments did not lead to notable increases in performance.

The long term efficacy of the $K_2Cr_2O_7$ inhibition technique was measured by discharging standard 20% cells at 30 mA. That data is shown in Fig. 1 and gives quite clear indication of the usefulness of this form of inhibitor application.

Gassing experiments, done using a modified Amlie-Ruetschi gas collecting technique (21), on electrode-sized AZ-61 pieces permitted the calculation of loss of capacity during activated, open-circuit stand. For 40% $Na_2S_2O_8$ cells with NaCl, uninhibited cells lost 0.15 A-hr/hr, and inhibited cells lost 0.077 A-hr/hr.

Work to inhibit excess gassing has led to considerable improvement of cell performance at all concentrations investigated. For low concentrations, the inhibitor + NaCl addition has led to substantial increases in U_T, E, and t_D. Added NaCl has not been beneficial for the highest percentages of $Na_2S_2O_8$.

Polarization effects.—A group of typical, standard cells were discharged in a 25°C thermostat and electrode voltages measured *vs.* SCE.

The discharges were conducted at i_D = 250 mA in inhibited anode cells with 3% NaCl added. The electrodes exhibit typical activation polarization behavior but the anode (AZ-61) does not exhibit either iR or concentration polarization. This is, of course, not unexpected. The anode reaction does not depend on the $Na_2S_2O_8$ concentration, but only on the AZ-61/H_2O interface (22, 23).

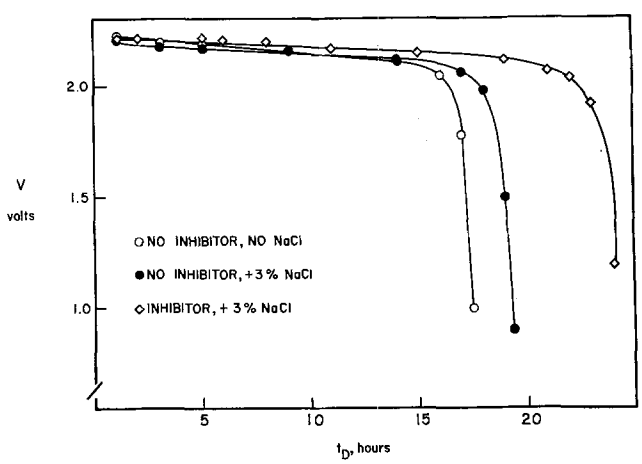

Fig. 1. Inhibitor efficiency. The dip inhibition technique was tested by using a low rate discharge over a long term. As indicated, 20% $Na_2S_2O_8$ cells were tested at discharge currents of 0.030A.

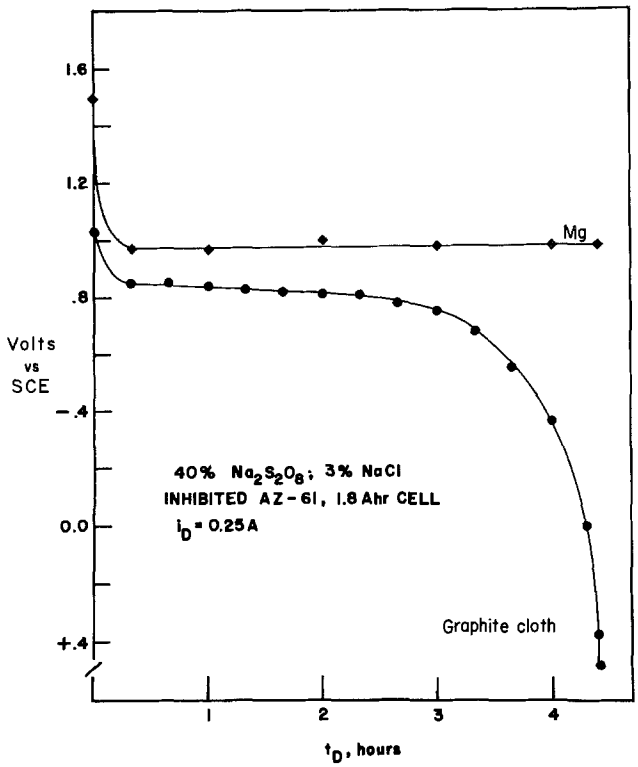

Fig. 2. Polarization of a standard 1.8 A-hr cell. A 1.8 A-hr cell was discharged at 0.25A in a 25°C thermostat. Data synthesized from six individual experiments.

The graphite cloth electrode displays typical polarization behavior, exhibiting a small activation polarization, and as the $Na_2S_2O_8$ is utilized, a very extensive, increasing, diffusion polarization. The data from a large population of experiments were synthesized and are shown in Fig. 2.

A similar series of experiments were done in a system such that the effective concentration of persulfate remained constant ($d[S_2O_8^=] = 0$). It was a well-stirred system and, as expected, there was no apparent activation polarization at the Mg electrode, with a very slight effect at the graphite cloth electrode. The iR polarization was extensive for the graphite cloth, but

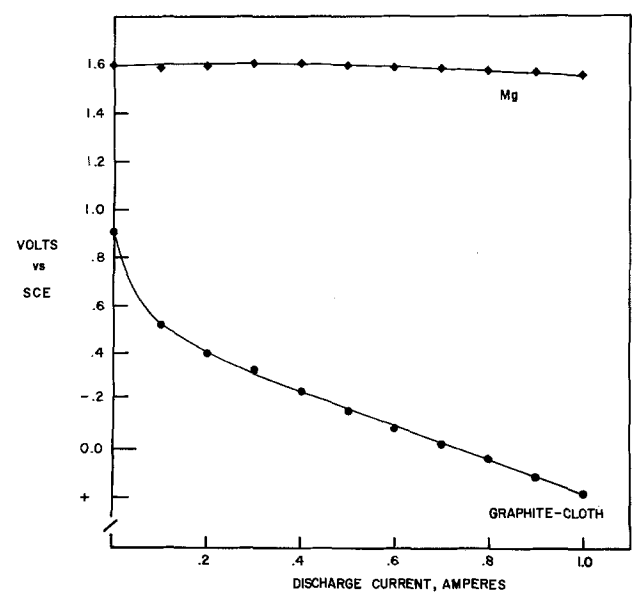

Fig. 3. Polarization effects. The elements typical of a 1.8 A-hr cell were subjected to increased polarization in an environment such that $d(S_2O_8^=) = 0$. The temperature was controlled to 25° ± 0.5°C, and the areas are: AZ-61 = 39 cm^2; graphite cloth = 60 cm^2.

the current used was not large enough to produce diffusion polarization at either electrode. The polarization data from these experiments are synthesized and displayed as Fig. 3.

The persulfate cell is a cathode-limited unit whose chemical makeup resists the onset of diffusion polarization effects. As utilization of $Na_2S_2O_8$ proceeds, the resistivity of the electrolyte drops by a factor of 4 or 5 and the ionic strength increases due to the reactions shown in Eq. [1] and [2]. A set of model solutions that represented the electrolyte at increased stages of utilization were used to collect the data shown in Fig. 4,

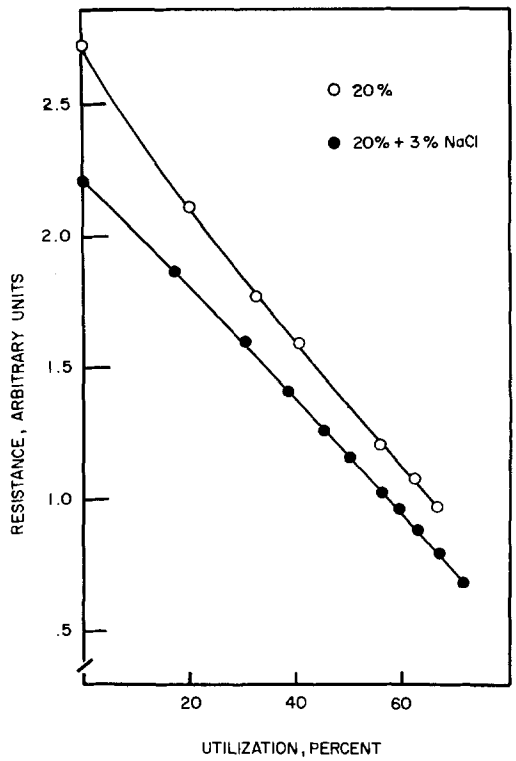

Fig. 4. Decreasing resistivity of working cells. The resistivity of the cell medium was tested by modeling the cell discharge processes as a function of U_T.

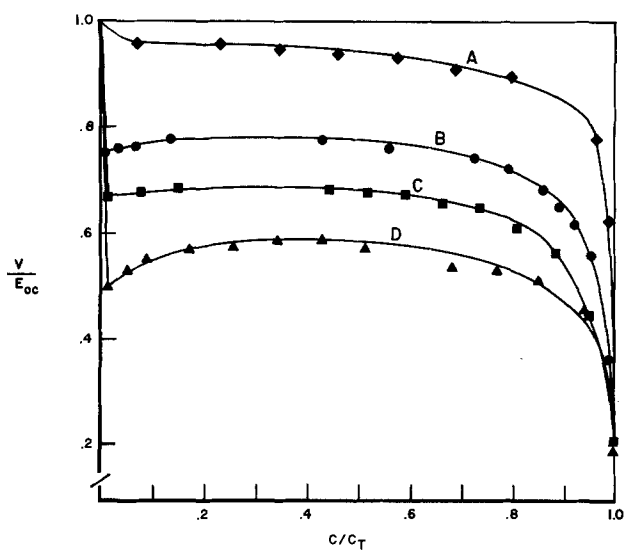

Fig. 5. Performance characteristics of persulfate cells. This dimensionless plot indicates the relative performance characteristics of 1.8 A-hr persulfate cells at increasing discharge currents. Curve A, i_D = 0.030A, $\overline{E}$ = 2.11V, C = 1.49 A-hr; curve B, i_D = 0.25A, $\overline{E}$ = 1.93V, C = 1.24 A-hr; curve C, i_D = 0.50A, $\overline{E}$ = 1.69V, C = 1.13 A-hr; curve D, i_D = 1.00A, $\overline{E}$ = 1.31V, C = 0.77 A-hr.

where the resistivity is presented as a function of utilization. At 60% utilization, the electrolyte has only 40% the resistivity of the undischarged cell.

Comparison with other systems.—The $Na_2S_2O_8$/AZ-61 cell appears to be capable of both high rate and low rate discharge. It produces a flat discharge characteristic at rates that vary from the 40 to the 1.2 hr rate. It has certain intrinsic problems because it is a "contained-electrolyte" unit and is not really suitable for intermittent service. Its over-all performance can be seen in Fig. 5, a dimensionless plot based on useful delivered capacity. Curve A, the 40 hr rate, delivers almost all its energy at voltages above 90% of OCV (2.54V). The 2 hr rate discharge, curve C, delivers its energy at ~70% of OCV. All the discharges demonstrate an attractive flat characteristic, whatever the rate.

We have compared the performance of typical 40% $Na_2S_2O_8$ cells, which have a theoretical capacity of 1.8 A-hr, to 2.0 A-hr AgCl/AZ-61 cells. The two systems were compared at i_D's of 0.25 and 0.50A. The comparisons are shown in Fig. 6, where $\overline{E}$ is plotted against time, the discharges done at room temperature. The

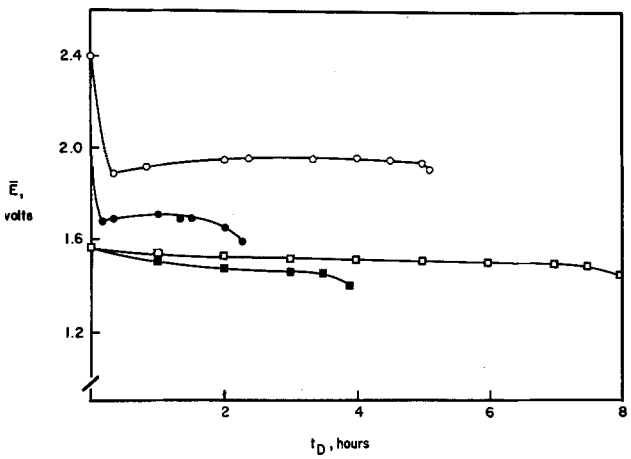

Fig. 6. Persulfate cells compared to AgCl/AZ-61. The open and filled circles represent 1.8 A-hr persulfate cells discharged at 0.25 and 0.50A, respectively. The open and closed squares represent AgCl/AZ-61 cells (2.0 A-hr) discharged at 0.25 and 0.50A, respectively.

AgCl/AZ-61 cells were discharged in 2 liter containers of artificial seawater which was stirred constantly. As the discharge curves indicate, the AgCl/AZ-61 system gives better over-all performance at lower average voltage. In the case of the $Na_2S_2O_8$/AZ-61 system, the average voltages are much higher, achieving almost 2.0V for the lower rate discharge.

A more interesting set of comparisons was made with other small systems discharged at the same current, plotted on dimensionless voltage/capacity axes, and shown as Fig. 7. All these cells have small volumes, in the neighborhood of 25 to ~ 54 cm^3. The $Na_2S_2O_8$ system is superior to all, save the Ni/Zn C-cell, which is rated almost twice the capacity. The $Na_2S_2O_8$ cell is clearly superior to both the Leclanché and alkaline MnO_2 cells though clearly operating at a much higher rate.

A final comparison was made to other systems, but at approximately the same rates, in this case, the 40 hr rate (C/40). An alkaline Ni/Zn cell and a Pb/acid battery were discharged at 0.75 and 2.0A, respectively, to achieve rate parity. An alkaline-MnO_2 cell was discharged at i_D = 0.25A, while a standard 1.8 A-hr $Na_2S_2O_8$/AZ-61 cell was discharged at 0.030A. The dimensionless variables are plotted in Fig. 8 and indicate the energy delivering capabilities of the experimental system compared to systems in current use.

ABSTRACT

The electrochemical reduction and reoxidation of Cr_2O_5, Cr_3O_8, thermally decomposed CrO_3, and a commercially available "CrO_3-graphite" preparation are compared in organic Li^+ electrolytes. All these cathode materials reveal an average discharge voltage of approximately 3V *vs.* a lithium anode and a maximum charge transfer exceeding one electron per Cr atom. The basic general discharge reaction is shown to be the reduction of higher chromium oxides Cr_nO_m with $1.5 < m/n < 3$. CrO_3 itself does not represent a suitable cathode material. From structural considerations it is concluded that the electrode processes are likely to be topotactic reactions of chromium oxides, yielding ternary phases $Li_xCr_nO_m$ which can be reoxidized with high coulombic efficiency.

Trioxides of Group VIa metals, particularly MoO_3 (1-6) and WO_3 (7, 8), have received considerable attention because of their potential application as cathode materials in primary and secondary organic electrolyte lithium cells. The mechanism of the MoO_3– (6, 9) and WO_3– (10) discharge reaction has been confirmed to be the reversible formation of ternary nonstoichiometric molybdenum and tungsten bronzes $A_x^{x+}[MoO_3]^{x-}$ and $A_x^{x+}[WO_3]^{x-}$, where A^+ is an alkali cation; x_{max} was found to be approximately 1.5 for Li_xMoO_3 (3, 6) and 0.5 for Li_xWO_3 (8).

Very little is known about the reduction of corresponding chromium oxides which, by virtue of their low molecular weight, should be the most interesting materials of Group VIa metal oxides. CrO_3 was repeatedly claimed to be a suitable cathode material for organic electrolyte batteries (11-13), however, this oxide is rather soluble in organic donor solvents, forming Lewis acid-base complexes CrO_3-solvent. As a substitute for free CrO_3, CrO_3 intercalated in graphite was proposed for rechargeable batteries with a solid β-alumina or organic electrolyte (13-15). It was assumed (14) that unoccupied d-orbitals of CrO_3 accept electrons from the filled p-orbitals of the sp^2 carbon atoms, thus lowering the Fermi level of graphite. Consequently, nonstoichiometric phases such as $A_x^{x+}[C_8CrO_3]^{x-}$, formed by electrochemical intercalation of an alkali metal A into C_8CrO_3 should be more stable, *i.e.*, show a more positive potential than the corresponding binary alkali metal graphites $A_x^{x+}C_8^{x-}$ (14). Indeed, a cell comprising a cathode prepared by heating (16) CrO_3 and graphite, a β-alumina solid electrolyte, and a Na anode shows an emf of 3.9V (14) and may be discharged at more than 3V, whereas the potentials of binary alkali metal graphites AC_8 are $< +$ 1V *vs.* free A (17).

From x-ray data it was however concluded in a recent publication that heating of CrO_3 and graphite does not yield a CrO_3-graphite intercalation compound but results in a mixture of unreacted graphite and the oxide Cr_3O_8 as the main thermal decomposition product of CrO_3 (18). The product formed under these conditions offers a method for the selective oxidation of primary alcohols to the corresponding aldehydes and is commercially available ("Seloxcette," Alfa products). A genuine intercalation of CrO_3 into graphite can be achieved by refluxing graphite in a solution of CrO_3 in glacial acetic acid (19) and the resulting prod-

Key words: lithium anodes, nonaqueous electrolytes, ternary phases, topotactic redox reactions.

uct is claimed to be an ionic compound, containing one CrO_4^{2-} for every three CrO_3 molecules (18). In order to elucidate the reactions of free and intercalated chromium oxides, the discharge and reoxidation behavior of CrO_3, thermally decomposed CrO_3, Cr_3O_8, Cr_2O_5, CrO_2, Seloxcette, and CrO_3-graphite prepared in acetic acid was compared in different organic electrolytes.

The most striking result of the present investigation was the observation that free CrO_3 and CrO_3-graphite prepared by the acetic acid method are practically inert *vs.* electrochemical reduction in organic Li^+ electrolytes, whereas Cr_3O_8, Cr_2O_5, thermally decomposed CrO_3, and Seloxcette behave very similarly and can be discharged at approximately + 3V *vs.* Li/Li^+. This corroborates that the reduction of chromium oxides is the essential discharge reaction in every case. Carbon present in the chromium oxide electrodes acts only as an inert electronically conducting support and can be replaced, *e.g.*, by Cu powder. The reduction of Cr_2O_5, Cr_3O_8, and Seloxcette yields more than one electron per Cr atom and can be reversed with high coulombic efficiency. The discharge mechanism of Seloxcette was assumed in an earlier publication to be the formation of a ternary phase, such as $LiCr_3O_8$ (20). The results presented here confirm this concept in principle, however, the maximum lithium content of these ternary phases and therewith the energy density of Cr_3O_8 and Cr_2O_5 cathodes were found to be much higher than was expected.

Experimental

The oxides Cr_2O_5 and Cr_3O_8 were prepared from CrO_3 (analytical grade) according to the literature (21, 22). Thin layer electrodes (approximately 10 mg cathode mixture per square centimeter geometric surface) were prepared by pressing a mixture of finely divided chromium oxide and graphite powder into Pt gauze at 5000 kg · cm^{-2}. Seloxcette, CrO_3-graphite prepared by the wet method, and CrO_2 were used without additional electronically conducting support. For the long-term galvanostatic experiments weighed pressed powder electrodes were sandwiched between porous glass to avoid losses caused by crumbling off. All measurements were carried out in a cell of the double-H type fitted with an inlet for inert gas. The working electrode was faced by two Pt counterelectrodes, separated by glass diaphragms. Instrumentation and purification of solvents and solutes have been described in former reports (23, 24).

Results and Discussion

Figure 1 shows the galvanostatic reduction and reoxidation of Seloxcette (Anal.: C = 39.5%; O = 26.0%; Cr = 34.3%, corresponding to a formal Cr/O ratio $CrO_{2.46}$) in $LiClO_4$/DME (1.2-dimethoxyethane). A cyclic voltammogram (CV) of Seloxcette in the same electrolyte (Fig. 2) demonstrates that the rate of reoxidation is slow as compared to that of the reduction. The anodic range is limited by solvent decomposition. The low coulombic efficiency of the reoxidation as calculated from the CV is not caused by irreversible side reactions but is rather due to a kinetically hindered recharging. This is evidenced by a typical reoxidation efficiency of 75-80% in low rate galvanostatic experiments (Fig. 1); values close to 100% may be found indeed for reoxidation at extremely low current density or after an incomplete discharge.

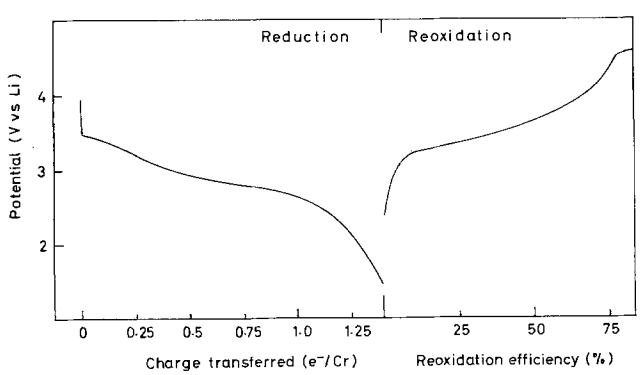

Fig. 1. Galvanostatic reduction/reoxidation of a sandwiched Seloxcette pressed powder electrode in saturated $LiClO_4$/DME; $i \approx 200$ $\mu A \cdot cm^{-2}$.

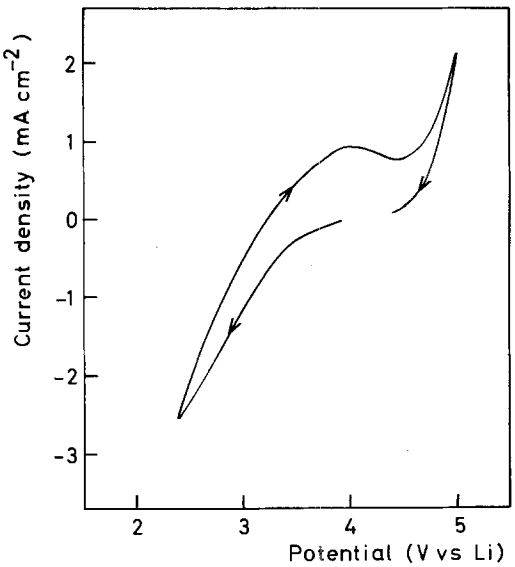

Fig. 2. Cyclic voltammogram of a Seloxcette pressed powder electrode in saturated $LiClO_4$/DME; V = 300 mV · min^{-1}.

In the range $100 < i < 1000$ $\mu A \cdot cm^{-2}$ the discharge utilization of Seloxcette depends only slightly on the current density: in 1M $LiClO_4$/DMSO (dimethylsulfoxide) a factor 2 increase of current density caused a decrease in the utilization of only about 5%. Therefore, the maximum theoretical utilization is likely to be close to 1.3 electrons per Cr atom. The current density applied cannot be lowered beyond a certain limit since the ratio discharge/background current is decreasing rapidly at low current density values.

The charge transfer observed of about 1.3 electrons per Cr atom does not correlate with the potential formation of Li_2O and Cr_2O_3 as final products, which should yield approximately 2 electrons per Cr atom. Apart from this the reversibility of the reduction may hardly be explained in terms of a rearrangement of higher chromium oxides from the insoluble insulators Li_2O and Cr_2O_3. Attempts to oxidize Cr_2O_3 in pressed powder electrodes containing Li_2O and graphite failed and there was no evidence for Cr_2O_3 formation in x-ray powder diagrams of discharged Seloxcette. A hypothetical discharge mechanism involving the reduction of CrO_3 to Cr_2O_3 was rejected earlier by thermodynamical considerations since this reaction should produce an emf of only 2V (18). The emf of Seloxcette *vs.* Li/Li^+ is +3.9V (14) and the corresponding emf data of CrO_2, Cr_2O_5, and Cr_3O_8. *e.g.*, in $LiClO_4$/DME, were found to be close to this value, however, a significant current flow does not occur above +3.6V. Supposedly an emf of +3.9V does not arise from a "bulk" reaction of the oxide crystallites but from surface products such as adsorbed oxygen. The line broadening, exhibited by the x-ray powder diagrams of the preparations used, indicates a rather small particle size and thus a high surface area of the oxides.

The maximum utilization of Cr_2O_5 and Cr_3O_8 pressed powder electrodes containing 35 weight percent (w/o) graphite powder (in $LiClO_4$/DME and $LiClO_4$/DMSO, conditions corresponding to those given in Fig. 1 and 3) was found to be close to 1.2 respective to 1.4 electrons per Cr atom. The shape of the Cr_3O_8 discharge characteristic nearly coincides with that of Seloxcette and

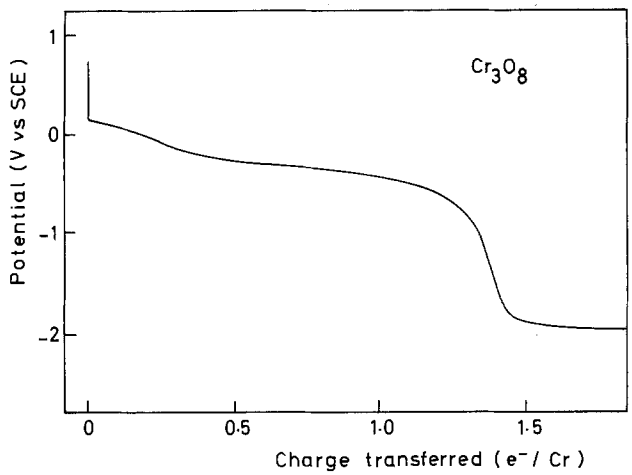

Fig. 3. Galvanostatic reduction of a sandwiched Cr_3O_8 pressed powder electrode containing 35 w/o graphite in 1M $LiClO_4$/DMSO; $i \approx 200\ \mu A \cdot cm^{-2}$, Li|1M $LiClO_4$/DMSO|SCE = −3.35V.

shows one voltage plateau at about +3V *vs.* Li/Li^+ (Fig. 3). This voltage plateau is slightly lower in the case of Cr_2O_5. An easy way to get a material which is characterized by the discharge behavior of higher chromium oxides is thermal decomposition of CrO_3. A mixture of chromium oxides with the main components according to the powder diagram being Cr_2O_5 and Cr_3O_8 (Anal.: $CrO_{2.45}$) was obtained at 300°C (18 hr, 1 Torr). Pressed powder electrodes from this material, containing graphite, Ni, or Cu powder as electronically conducting support, revealed a discharge behavior fairly similar to that of Seloxcette.

The reduction of CrO_2 also gives rise to a voltage plateau at approximately +3V *vs.* Li/Li^+ but the utilization does not exceed 0.5 electrons per Cr atom.

Preliminary experiments with CrO_3-graphite prepared by the wet method (19) (Anal.: ratio C/Cr = 15.0) gave no indication of its reduction at useful potentials. A most surprising kinetic stability toward electrochemical reduction was also observed for CrO_3 which is practically inert at a Pt electrode in $LiClO_4$/DME. Moreover, CrO_3 is not a suitable cathode material because of its high solubility in organic donor solvents.

The discharge characteristics of Seloxcette samples were not significantly affected by the type of solvent or anion of the solute, but depended strongly on the kind of cation (Fig. 4). The performance is best in Li^+ electrolytes, lower in Na^+ electrolytes; solutions of salts with cations of large ionic radii, *e.g.*, K^+, are unsuitable for the reduction of chromium oxides. Decreasing discharge voltages with increasing cation radius cannot be understood as poorer thermodynamic stability of the Na^+ and K^+ compounds as compared

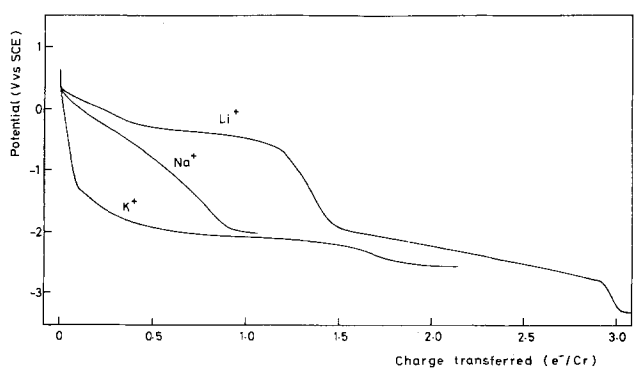

Fig. 4. Galvanostatic reduction of sandwiched Seloxcette pressed powder electrodes in 1M $LiClO_4$/DMSO, 1M $NaClO_4$/DMSO, 1M $KClO_4$/DMSO; $i \approx 200\ \mu A \cdot cm^{-2}$.

to the Li^+ compound. They are rather to be considered as increasing polarization which can be demonstrated by current interruption in the course of the galvanostatic reduction of Seloxcette. At 0.5 e^-/Cr, *e.g.*, the potential rise after current interruption is about 0.2V in the case of Li^+ but exceeds 1V in the case of K^+.

Since this potential rise is very slow and since the specific conductivities of 0.5 $LiClO_4$/DMSO and 0.5 $KClO_4$/DMSO are similar, the polarization is assumed to be caused by hindered transport in the solid phase. This behavior is similar to that observed for the reduction of the layered oxide MoO_3 (6) and is typical for a discharge mechanism involving the penetration of unsolvated alkali cations into the crystal lattice of the cathode material as the rate-determining step. On the other hand, the topotactic uptake of solvated cations [*e.g.*, intercalation of alkali cations from DMSO electrolytes into MoS_2 (23) or graphite (24)] or reactions which proceed via dissolved species (*e.g.*, the reduction of sulfur in DMSO electrolytes) in general show only little dependence of the electron acceptor utilization on cation radius. Although an interpretation of the cation dependence in terms of different solubilities of cathode material or its discharge products in different electrolytes cannot be definitely excluded, the simultaneous presence of cation dependence, efficient reversibility of the reaction, and an "odd" number of electrons transferred per Cr atom in Cr_2O_5 and Cr_3O_8 agree well with the assumption of nonstoichiometric ternary phases such as $Li_xCr_2O_5$ and $Li_xCr_3O_8$ being formed on cathodic reduction

$$xLi^+ + xe^- + Cr_nO_m \rightleftharpoons Li_xCr_nO_m \qquad [1]$$

This discharge mechanism is analogous to that of MoO_3 and WO_3 which yield ternary molybdenum and tungsten bronzes Li_xMoO_3 and Li_xWO_3.

It is obvious that structural considerations will be the crucial point for an explanation of the reaction mechanism of these electrode materials. A series of binary chromium oxides is known in the range of oxidation number +3 to +6 (21); those which are defined at least by their powder patterns are listed in Table I. The existence of additional phases has been claimed, but there is still much controversy on this point as well as on the question whether nonstoichiometric chromium oxides with notable phase ranges occur. For only four of the oxides listed in Table I, a three-dimensional structural analysis has been reported: CrO_3 which is built of infinite chains formed by the linking up of CrO_4 tetrahedra and Cr_5O_{12}, CrO_2, and Cr_2O_3 built up by three-dimensional frameworks containing either CrO_4 tetrahedra and CrO_6 octahedra or octahedra only. The structures of Cr_2O_5 and Cr_3O_8 are unknown so far. Ternary alkali chromium oxides with known structures are listed in Table II. In the series ACr_3O_8 (25) these crystallize

Table I. Binary chromium oxides

Formula	Average oxidation number (Cr)	Structure
CrO_3	+6	Chain type
Cr_3O_8	+5.4	—
Cr_2O_5	+5	—
Cr_5O_{12}	+4.8	3-dimensional framework
CrO_2	+4	Rutile type
Cr_2O_3	+3	Corundum type

Table II. Ternary phases $A_xCr_nO_m$

Formula	Structure
$Li_3Cr_3O_8$	3-dimensional framework
$NaCr_3O_8$	2-dimensional framework
KCr_3O_8	2-dimensional framework
$RbCr_3O_8$	2-dimensional framework
$CsCr_3O_8$	2-dimensional framework
$K_2Cr_8O_{16}$	Hollandite type

(depending on the type of cation) either in layer or in framework structures were built up by chromium-oxygen tetrahedra and octahedra, whereas $K_2Cr_8O_{16}$ (26) crystallized in the channel-type structure of hollandite.

It is thus apparent that a large variety of building principles is found among the binary and ternary chromium oxides. If one recalls that the maximum ratio Li/Cr taken up by the electrode materials discussed above exceeds unity, some restrictions can yet be taken into consideration as to the potential structure of the oxides investigated, if the reaction proceeds by a topotactic mechanism. As pointed out in an earlier study (6) a solid matrix with a system of interconnected and easily accessible lattice sites for guest ions is, from the viewpoint of structure, a premise in this case. For three-dimensional frameworks a relative low ratio Li/Cr should be expected; this is established by the reaction of CrO_2. Although some of the three-dimensional structures such as the hollandite type found also for $K_2Cr_8O_{16}$ have large open channels, which potentially could accommodate considerable amounts of small ions like Li^+, these phases seem not to be very stable. The lattice, *e.g.*, of those manganese oxide hydrates which crystallize in the hollandite or psilomelane structure, are known to break down easily on reduction. Rather high Li^+/metal ratios were, however, found for solids with two-dimensional or one-dimensional matrix units, *e.g.*, in the case of chain-type chalcogenides $NbSe_3$ and TiS_3 with Li/Nb respective to Li/Ti = 3 (27).

It is concluded, therefore, that the higher chromium oxides studied in this investigation are more likely to have layers or chains as structural elements, although a very open channel or zeolithe-type framework cannot definitely be excluded at this point. Detailed structural data of the oxides and Li phases under consideration have to be awaited for a final picture of the reaction mechanism.

Extended discharge of Seloxcette reveals a second voltage plateau at approximately +1V *vs.* Li/Li^+ (Fig. 4) but the length of this plateau is poorly reproducible. At approximately +1V *vs.* Li/Li^+ the intercalation of alkali cations into the graphite component of the electrode is a competing process. However, the total charge transfer of the second plateau exceeds the theoretical transfer calculated from the known stoichiometries of solvated alkali metal graphite phases (24, 28). It is more likely that irreversible processes such as solvent decomposition or further reduction of the ternary phases contribute to the electrode reaction in this discharge range.

Conclusions

The insoluble chromium oxides Cr_3O_8 and Cr_2O_5, a mixture of which can be prepared by heating of CrO_3, are suitable cathode materials for low rate secondary organic electrolyte batteries. The calculated theoretical energy density of the Li/Cr_3O_8 couple (corresponding to Eq. [1]) is 1080 W-hr · kg^{-1} (360 A-hr · kg^{-1}) based on the experimental values $x = 1.4$ and average cell voltage = 3V. The corresponding values for the Li/MoO_3 couple ($x = 1.5$, average cell voltage = 2.5V) are substantially lower with only 650 W-hr · kg^{-1} (260 A-hr · kg^{-1}). From electron transfer data, reversibility behavior and structural considerations it is concluded that the electrode processes are likely to be topotactic reactions of chromium oxides with two-dimensional or one-dimensional structural units.

Evidence for the Existence of Stable $CO_2^=$ Ion and Response Time of Gas Electrodes in Molten Alkali Carbonates

Alina Borucka*

Borucka Research Company, Livingston, New Jersey 07039

ABSTRACT

Experimental evidence is presented confirming the existence of a previously unknown $CO_2^=$ ion formed by the combination of CO gas and $O^=$ ion at the $CO/CO_2/Au$ electrode in molten ternary eutectic, $Li/Na/K/CO_3$. The new ion is kinetically active and its oxidation to CO_2 product is responsible for the second of two anodic processes displayed by the CO/CO_2 electrode in this melt at a half-wave potential of about +300 mV (standard CO/CO_2 reference). $CO_2^=$ has a limited solubility in the molten electrolyte and, apparently when $p_{CO}/p_{CO_2} \geq 0.25$, it decomposes to CO and $O^=$ relatively quickly: within 10 sec in the example studied. Perturbations of the standard CO/CO_2 and 1:2 O_2/CO_2 electrode equilibria by addition of solid Li_2O to the melt show that: (*a*) the response of both these electrodes to local concentration changes in the melt is very fast (0.1 sec or faster), (*b*) the carbonate dissociation equilibrium is slow, and (c) the correct forms of the Nernst equations governing the departures of the potentials of these electrodes from equilibrium are, respectively

$$E_{CO/CO_2} = E^\circ_{CO/CO_2} + \frac{RT}{2F} \ln [p_{CO_2}^2/p_{CO}]$$

$$E_{O_2/CO_2} = E^\circ_{O_2/CO_2} + \frac{RT}{2F} \ln K_p + \frac{RT}{2F} \ln [p_{O_2}^{1/2}/[O^=]]$$

Background

Previous work (1) on the kinetic behavior of the CO/CO_2 electrode in molten ternary eutectic of Li-Na-K carbonates [43.5-31.5-25.0 mole percent m/o)][1] in the temperature range of 700°-800°C led to the firm conclusion that the first oxidation wave observed was due to the reaction $CO + CO_3^= \rightarrow 2CO_2 + 2e^-$, and a tentative conclusion that the second oxidation process (see Fig. 1 and Table I) could be due to the existence of a previously unknown ionic species, $CO_2^=$, formed and oxidized as follows

$$CO + O^= \rightleftarrows CO_2^= \quad [1]$$

$$CO_2^= \rightarrow CO_2 + 2e^- \quad \text{(over-all)} \quad [2]$$

The kinetic results obtained indicated also that $CO_2^=$ has a limited solubility, as indicated by the constant value of the second limiting current when p_{CO}/p_{CO_2} ratio is equal or greater than 0.25. This was taken to indicate a saturation limit with respect to the $CO_2^=$ ion in the melt though not necessarily by way of precipitation, which in any event could not be observed under the conditions of the experiments. The tentative conclusions concerning the $CO_2^=$ ion needed further confirmation but to this date no further work on this subject has been reported.

While the thermodynamic studies of the gas electrodes in molten carbonates have been extensively reported and reviewed (5), the reliable kinetic investigations are very few and these are primarily devoted to the O_2/CO_2 reduction (6-9). The most neglected area of the kinetic and mechanistic studies in molten carbonates is still that of the anodic processes involving H_2/CO_2 and CO/CO_2 electrodes, both being of direct practical importance to the molten carbonate fuel cell and some new antipollution processes.

So far, no reliable study of any kind has been presented on the H_2/CO_2 electrode, which in these melts represents a more complex $H_2/CO/H_2O/CO_2$ system. The CO/CO_2 electrode has been evaluated fully only with respect to its thermodynamic properties (1, 6, 10) and its near-equilibrium kinetics (7), as summarized in Ref. (5). Both the prior and the present work referred to here were conducted on pure gold sheet electrodes of 1 cm^2 area, fully submerged in the electrolyte. Under unstirred conditions the CO/CO_2 gas mixture was above the melt while the stirring conditions corresponded to bubbling the gas mixture into the melt in an accurately reproducible manner (1, 5).

Present Work

The present publication reports additional experimental evidence for the existence of the $CO_2^=$ ion as the CO-carrying species (involved in the second oxidation process) and provides a basis for a more accurate kinetic and mechanistic analysis of the anodic oxidation of carbon monoxide in molten alkali carbonates.

Table I is included here because it has not been published before [other than in Ref. (1)] and because it shows the complete range of the results obtained, relating to Fig. 1 and 2 shown below.

Based on these (steady-state polarization data) (1), Fig. 1 illustrates the general character of the $CO/CO_2/CO_3^=$ system and the range of stability of the molten carbonate electrolyte under 1 atm of pure CO_2 at 800°C. The potential scale is referred to the standard CO/CO_2 electrode (p_{CO} = 0.382 atm and p_{CO_2} = 0.618 atm) and E°_B represents the limiting Boudouard potential, both previously established (1, 10). The value of E°_B shown in Fig. 1 indicates the limit to the cathodic polarization that can be applied at 800°C before carbon deposition occurs due to the Boudouard equilibrium

$$2CO \overset{K_B}{\rightleftarrows} CO_2 + C_{(solid)} \quad [3]$$

* Electrochemical Society Active Member.

Key words: $CO_2^=$ ion, molten carbonates, CO/CO_2 electrode.

[1] This eutectic composition was published by Janz and Lorenz (2) and used both in the prior and this work. While an earlier publication by Volkova (3) indicated somewhat different composition, the one quoted here was adopted because of the availability of other property data for this salt mixture [see Ref. (4)].

** Values of i^I impossible to estimate, approximately zero.

The equilibrium stability of the carbonate melt is governed by its dissociation

$$CO_3^= \overset{K_p}{\rightleftarrows} O^= + CO_2 \qquad [4]$$

which defines its oxide ion content at any given partial pressure of CO_2 gas above the melt. Without accurate control of the CO_2 component either at or above the equilibrium partial pressure, the composition of the carbonate changes with time, and gradually tends toward pure oxide. This feature can be observed in Fig. 1 by comparing the polarization curves obtained with pure argon and pure CO_2 above the melt. Under kinetic conditions with pure CO_2, the anodic stability of the ternary eutectic at 800°C extends to +800 mV before $CO_3^=$ is oxidized with evolution of oxygen while its cathodic stability, according to the reduction curve with pure argon (very low CO_2 and very high $O^=$) extends even well beyond the Boudouard potential of −204 mV.

The steady-state polarization curves for different CO/CO_2 electrodes (1) shown in Fig. 1 display two distinct oxidation stages. The lower limiting current is due to the diffusion of CO gas to the electrode surface and, as expected, shows direct proportionality to the partial pressure of CO, p_{CO}, and independence of p_{CO_2}. The upper limiting current is more complex and shows a direct proportionality to the p_{CO}/p_{CO_2} ratio.

As shown in Fig. 2, this relationship is linear up to $p_{CO}/p_{CO_2} \simeq 0.25$, above which the current remains substantially constant (its small increase with increase in p_{CO_2} being probably not significant).

The possibility of formation of the oxalate ion and its subsequent oxidation

$$CO + CO_3^= \rightleftarrows C_2O_4^= \rightarrow 2CO_2 + 2e^- \qquad [5]$$

was dismissed since this, in view of the large excess of $CO_3^=$, would require the current to be proportional to p_{CO} and independent of p_{CO_2}.

The second limiting current was interpreted as being due to the oxidation of a carrier ion $CO_2^=$ formed by the reaction [1] quoted above. While the analysis of the half-wave potentials supported the existence of the proposed ionic species, the available diagnostic criteria were not regarded as fully conclusive and the work (1) was therefore not published in open literature.

Further evidence, reported here, supports the existence of the $CO_2^=$ ion and is in agreement with a full mechanistic analysis of the oxidation of carbon monoxide in molten carbonates which will be reported separately (11).

This evidence was obtained by simple experiments consisting of: (*a*) monitoring the change in the equilibrium potential of the standard $CO/CO_2/Au$ and the 1:2 $O_2/CO_2/Au$ electrodes resulting from the addition of Li_2O solid to the molten ternary eutectic at 800°C, and (*b*) testing the response time of the 1:2 $O_2/CO_2/Au$ electrode to the sudden interruption and restoration of gas flow to the electrode.

The response time of gas electrodes in molten alkali carbonates has not been previously studied in a direct way. Equilibration studies reported for O_2/CO_2 and CO/CO_2 electrodes range from 1 to 24 hr but in view of the high exchange currents (of the order of 10^{-4} A/cm²) reported for both these electrodes (7), this seems likely to reflect the periods necessary to purge the "dead space" of the apparatus involved and the saturation time of the melt rather than the response

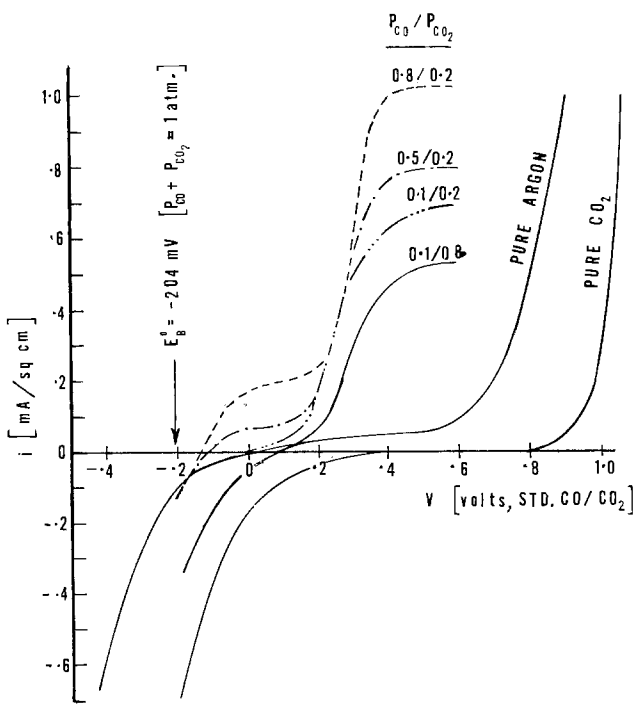

Fig. 1. General polarization characteristics for Au electrode in stirred $Li/Na/K/CO_3$ eutectic at 800°C and different gas atmospheres (p_{CO} and p_{CO_2} expressed in atmosphere units).

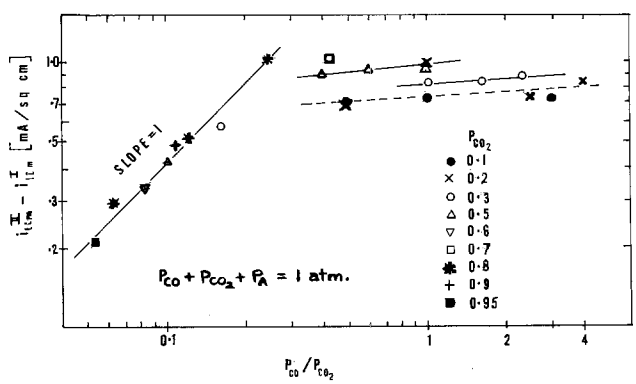

Fig. 2. Reaction order plot for $CO/CO_2/Au$ electrodes; stirred conditions, 800°C (p_{CO} and p_{CO_2} expressed in atmosphere units).

time of these electrodes in reaching their correct Nernst potentials, *i.e.*, registering the local changes in concentrations of the reacting species in the melt. The question of the response time of these electrodes is of basic and practical importance: for better understanding of the carbonate electrochemistry and for the correct use of these electrodes as accurate indicators of the local concentration changes in the melt (as demonstrated by the present study).

Experimental

The apparatus and the experimental procedure including that for outgassing and fully drying the melt and test gases were exactly the same as reported previously (6). The new tests involved only one special feature, namely, a gas- and vacuum-tight glass chamber through which accurately weighed samples of Li_2O solid (in form of pills) could be introduced into the carbonate melt. Typically, 80 mg pills of Li_2O were formed in a pill-press, subjected to drying, evacuation and equilibration with the test gas mixture before they were dropped into 200g of the melt via a 1 cm ID alumina tube serving as a guide. Both the reference and the test electrodes were of pure gold (as before) and supplied with the same gas mixture, either standard CO/CO_2 or 1:2 O_2/CO_2 to secure the lowest potential difference in the course of the experiments. Potential changes resulting from the addition of Li_2O were recorded by a Hewlett-Packard X-Y plotter Model 7035A.

Results and Discussion

In addition to the evidence for the existence of $CO_2^=$ ion shown in Fig. 1 and 2, Fig. 3 provides an additional confirmation. This shows the rate of dissolution of the Li_2O added to the melt and its effect on the equilibrium potential of the standard CO/CO_2/Au and 1:2 O_2/CO_2/Au test electrodes.

Comparison of the two sets of results in Fig. 3 shows the following interesting facts. Dissolution of Li_2O and its effect is very rapid in both cases, but its rate of reaction (as indicated by the recovery of the equilibrium potential) is much faster in the CO/CO_2 system. In this case, the effect of the added pill totally disappears in 1 min while in the case of the O_2/CO_2 electrode it disappears only after about 15 min. Additionally, Fig. 3 shows that the effect of added Li_2O on the equilibrium potential of the CO/CO_2 electrode is opposite to that shown by the O_2/CO_2 electrode and opposite to that which can be directly expected from the Nernst equation involved.

To accept the first of the above findings as meaningful, a separate test was made to establish how fast is the response of the "slower" 1:2 O_2/CO_2/Au electrode under our experimental conditions. To do so, the decay and recovery of the equilibrium potential was recorded resulting from turning the gas mixture flow to the electrode off and then on. This was done separately for the test electrode located in the bulk of the melt and then for the reference electrode enclosed in its own small separate compartment [see Ref. (10)]. The results in Fig. 4 show that both the electrodes are extremely sensitive to the local changes in concentration as affected by the supply of the gas mixture even under unstirred conditions. When the gas flow is stopped, both the electrodes drift immediately and at a rate of about 10 mV/sec. When the gas flow is again turned on, both the electrodes recover instantly to within about 20 mV of their initial equilibrium potentials. These responses may seem surprising at first but they reflect: (*a*) very fast reaction rate at the electrode (at 750°C, 1:2 O_2/CO_2 electrode has exchange current density of the order of 10^{-4} A/cm^2) (7); (*b*) very fast dissolution rate for the O_2/CO_2 gas mixture in the melt (as shown in Fig. 4 by the instantaneous recovery); and (*c*) relatively slow gas diffusion rate within the dead space of the apparatus (as shown by the potential drift of 10 mV/sec on closing the gas supply).

Additionally, the results of Fig. 4 show that the very much slower recovery of the O_2/CO_2 electrode shown in Fig. 3 is definitely not due to its inherent sluggishness.

The reasons for the changes of the equilibrium potentials of the two electrodes shown in Fig. 3 can be examined as follows. According to the dissociation equilibrium of the melt, Eq. [4] above, at any temperature T (°K)

$$O^= = \frac{K_p[CO_3^=]}{p_{CO_2}} \qquad [6]$$

which shows that for a small degree of dissociation of the $CO_3^=$ ion, a local increase in $O^=$ is effectively equivalent to a decrease in p_{CO_2} provided that the equilibrium is fast.

Because of Eq. [6], the Nernst equations for the two electrodes discussed

$$E_{CO/CO_2} = E^\circ_{CO/CO_2} + \frac{RT}{2F}\ln\left[\frac{p_{CO_2}}{p_{CO}[CO_3^=]}\right] \qquad [7a]$$

and

$$E_{O_2/CO_2} = E^\circ_{O_2/CO_2} + \frac{RT}{2F}\ln\left[\frac{p_{O_2}^{1/2}\cdot p_{CO_2}}{[CO_3^=]}\right] \qquad [8a]$$

can also be written as

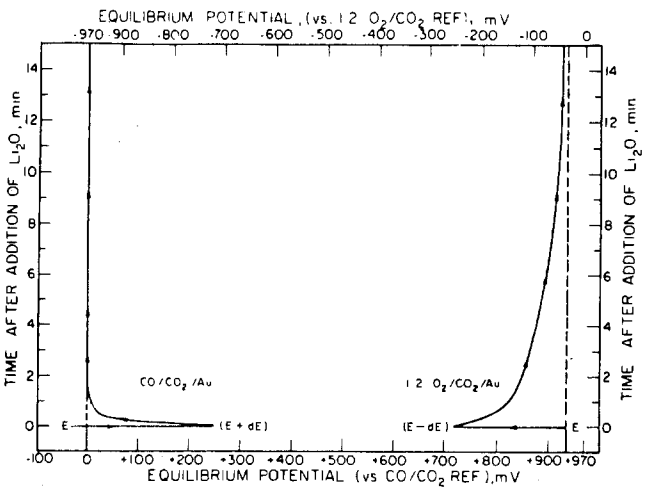

Fig. 3. Effect of added Li_2O (80 mg) on equilibrium potentials of CO/CO_2/Au and O_2/CO_2/Au electrodes (800°C; electrolyte unstirred).

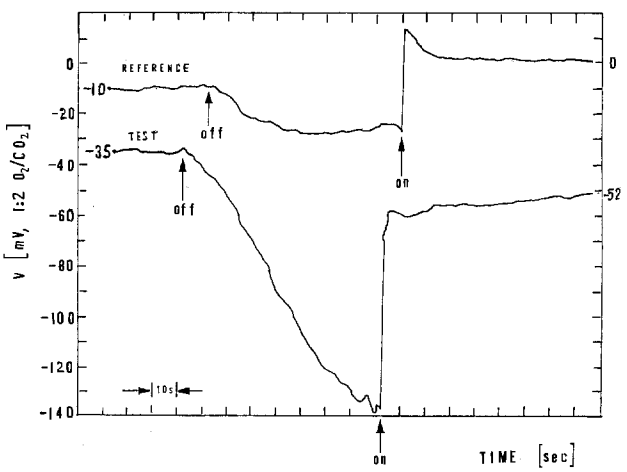

Fig. 4. Decay and recovery of equilibrium potential of 1:2 O_2/CO_2/Au electrode with gas flow off and on (750°C, unstirred electrolyte).

$$E_{CO/CO_2} = E^\circ_{CO/CO_2} + \frac{RT}{F}\ln K_p + \frac{RT}{2F}\ln\left[\frac{[CO_3^=]}{p_{CO}[O^=]^2}\right] \quad [7b]$$

and

$$E_{O_2/CO_2} = E^\circ_{O_2/CO_2} + \frac{RT}{2F}\ln K_p + \frac{RT}{2F}\ln[p_{O_2}^{1/2}/[O^=]] \quad [8b]$$

(the activity of $CO_3^=$ ion being substantially unity under conditions studied).

While at equilibrium no distinction can be made between Eq. [7a] and [7b] nor between [8a] and [8b], it is worth considering which of these truly reflect the electrode potentials under perturbed conditions such as those shown in Fig. 3.

Considering the O_2/CO_2 electrode first, we see from both the Eq. [8a] and [8b] that a sudden addition of $O^=$ ion to the melt must shift the equilibrium potential to a more negative value: $(E_{O_2/CO_2} - \Delta E)$ as it does. However, the fact that the observed shift is instantaneous while the recovery is slow suggests that Eq. [8b] more truly reflects the immediate effect of added $O^=$ and indicates that its recombination with CO_2 to form more $CO_3^=$ is rather slow. Equation [8b] therefore and not Eq. [8a] is the more correct form of the Nernst equation for the O_2/CO_2 electrode in molten carbonates.

Similarly, considering the two forms of the Nernst equation: [7a] and [7b] for the CO/CO_2 electrode and the fact that the added Li_2O causes an instantaneous positive shift of the equilibrium potential one may conclude that Eq. [7b] does not truly apply under dynamic conditions since $O^=$ shows no immediate negative effect on the equilibrium potential. Any dominating interaction between the added $O^=$ and CO_2 must also be ruled out for the same reason. Such interaction would also lead to a negative and not a positive shift in E_{CO/CO_2}.

In fact, the observed positive positive shift in E_{CO/CO_2} can presently be explained only by a very rapid interaction of the added $O^=$ with the dissolved CO and the formation of the $CO_2^=$ ion as discussed above. Formation of this ion according to reaction [1] above would cause a temporary local shortage of CO and thus shift the potential in the positive direction as observed in Fig. 3. The subsequent recovery of E_{CO/CO_2} which is relatively fast (only 1 min) is probably due to the breakdown of the new species to CO and $O^=$ which would assist in the fast recovery to the original more negative potential.

If the above, short-lived effect of added Li_2O is due to the formation of $CO_2^=$, then the following questions require answers: (*i*) In what range of potentials, if any, does it participate in the anodic or cathodic reactions of the CO/CO_2 electrode? (*ii*) Is this range of potentials the same as that indicated for the second oxidation wave in Fig. 1?

The answers to both these questions and additional evidence for the existence of the new species are shown by the results of Fig. 5. These results demonstrate dramatically how the steady-state currents of the standard CO/CO_2 electrode, potentiostated at various selected potentials, are instantly affected by the addition of a constant-weight (80 mg) pill of Li_2O.

Since the equilibrium of the CO/CO_2 electrode is governed by the reaction

$$CO + CO_3^= \rightleftarrows 2CO_2 + 2e^-$$

then, from Fig. 5, we can only conclude that the additional cathodic current observed (after addition of the pill) is due to the reduction of CO_2 being enhanced by the local shortage of CO at the electrode. The area of each cathodic peak shown in Fig. 5 is,

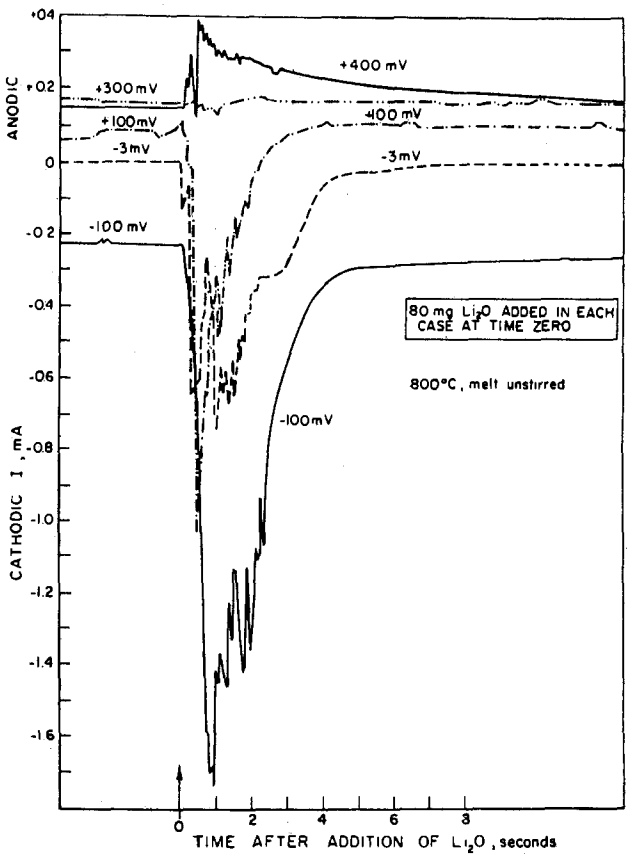

Fig. 5. Effect of added Li_2O on steady-state current of standard CO/CO_2 electrode potentiostated at different potentials (vs. standard CO/CO_2 reference).

therefore, a measure of the amount of CO_2 reduced in that period of time during which the electrode is "short" of free CO. Even at +100 mV, the steady-state current changes immediately from an anodic to a relatively cathodic value which then, in about 4 sec, returns to the original anodic level.

As the electrode is potentiostated at progressively more positive potentials, the surge of the cathodic current on addition of the same quantity of Li_2O becomes progressively smaller. The surge totally disappears at +300 mV and becomes anodic at +400 mV and higher. Evidently, at +300 mV any cathodic effect of the added Li_2O is balanced equally by the anodic oxidation of the $CO_2^=$ formed so that the net anodic current (of about 0.15 mA) remains unchanged. The fact that +300 mV is the normal half-wave potential for the second oxidation process of the CO/CO_2 electrode as shown in Fig. 1 proves that, there also, the species reacting at +300 mV must be $CO_2^=$.

With regard to the stability of the $CO_2^=$ ion, the results of Fig. 1 and 5 suggest that the species is stable but only to the extent of its limited solubility in the melt under given p_{CO}/p_{CO_2} atmosphere. Excess of it, displayed best by the curve at +400 mV, is unstable and apparently decomposes within about 10 sec.

The quantities of electricity involved at each level of potential and the effect of agitation of the electrolyte are shown in Table II. Table II shows that the rapid surge of current in each case represents no more than a few millicoulombs of total electricity and, therefore, on 1 cm^2 surface, only a few "monolayer" quantities of the reactant. ${}^uQ$ is higher than ${}^sQ$ in stirred electrolyte. This supports well the proposition that it is the cathodic reduction of CO_2 which is mainly involved, because of the shortage of CO. (With stirring, CO is more rapidly transported to the electrode and, therefore, the CO_2 current dies

Table II. Quantity of electricity and the effect of melt agitation involved in decay of current caused by addition of 80 mg of Li_2O to 200g of melt at 800°C: standard CO/CO_2 electrode potentiostated at different potentials

Constant potential, mV (*vs.* standard CO/CO_2)	Quantity of electricity, C ^sQ (stirred)	^uQ (unstirred)
−100	$\sim 1.1 \times 10^{-3}$	3.03×10^{-3}
−3	0.85×10^{-3}	1.45×10^{-3}
+100	$\sim 0.711 \times 10^{-3}$	0.894×10^{-3}
+300	~0	~0
+400	$\sim 0.133 \times 10^{-3}$	0.88×10^{-3}
+500	—	1.011×10^{-3}
+600	—	2.093×10^{-3}

out more quickly, as does also the anodic current due to $CO_2^=$.)

Since the recovery of the O_2/CO_2 electrode from the effect of added Li_2O is much slower than that of the CO/CO_2 electrode, taking about 15 min, it was of interest to check what if any effect the additive has on the cathodic reduction of oxygen. Figure 6 shows clearly that apart from the displacement of the equilibrium potential (in agreement with that shown in Fig. 3), no major kinetic effect is detected over the time interval from 2.6 to 10 min after addition of the oxide. This is in agreement with the interpretation offered above, and suggests further that the over-all oxygen reduction reaction

$$\tfrac{1}{2}O_2 + 2e^- \rightarrow O^= \qquad [9]$$

which governs the potential of the O_2/CO_2 electrode as shown above (see Eq. [8b]) does not, in fact, control its current. If it did, addition of Li_2O to the melt would reduce the cathodic current very drastically.

The results of Fig. 6 give, therefore, a broad support to the mechanism of oxygen reduction proposed by Appleby and Nicholson (8, 9) in which $O^=$ does not play any direct part. According to these authors, in the presence of oxygen, at a given partial pressure of CO_2 above the melt, fixed concentrations of peroxide, $O_2^=$, and superoxide, O_2^-, are established and these species are then, in turn, reduced in the two-step cathodic process observed.

However, since $O^=$ has clearly a major effect on the equilibrium potential of the O_2/CO_2 electrode as demonstrated by Fig. 3 yet has no apparent effect on oxygen reduction kinetics at higher overpotentials, it seems likely that its activity is restricted to the close vicinity of the equilibrium only which is neither well shown in Fig. 6 nor discussed in full detail by Appleby and Nicholson (8, 9).

The results shown in Fig. 3-6 and their analysis presented in this study demonstrate that very important diagnostic information can be gained even from very simple experiments by utilizing suitable additives to perturb the system studied.

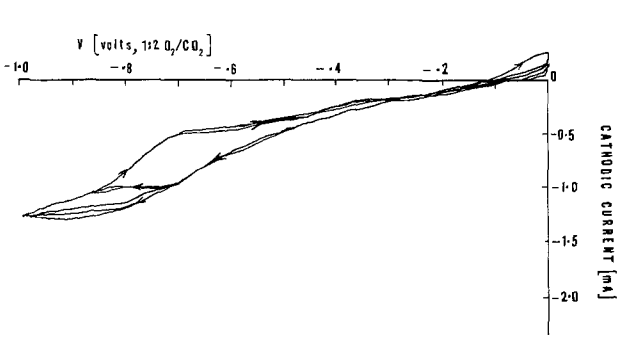

Fig. 6. Potential scans for 1:2 O_2/CO_2/Au electrode before and after addition of one 80 mg pill of Li_2O; 750°C, unstirred electrolyte, scan rate of 2500 mV/min (one scan before addition, six scans between 2.6 min and 10 min after oxide addition).

Conclusions

1. Experimental data and analysis presented confirm earlier kinetic evidence for the existence of previously unknown $CO_2^=$ ion which is formed by interaction of CO gas with $O^=$ ion in molten alkali carbonates.

2. This ion is responsible for the second of the two anodic processes displayed by the CO/CO_2 at half-wave potential of about +300 mV *vs.* standard CO/CO_2 electrode and causes a rapid positive shift in the equilibrium potential of this electrode upon addition of solid Li_2O to the carbonate melt.

3. $CO_2^=$ has a limited solubility in the melt studied and any excess of it decomposes to CO and $O^=$ relatively quickly.

4. Both CO/CO_2 and O_2/CO_2 electrodes at 800°C are extremely sensitive to local changes of concentration, whether these are caused by changes in the gas mixtures supplied or by addition of an active ionic species such as $O^=$ directly to the melt. Their response time is of the order of 0.1 sec or less.

5. In relation to the fast electrode equilibria of the standard CO/CO_2 and the 1:2 O_2/CO_2 electrodes at 800°C, the dissociation equilibrium of the ternary eutectic melt, $Li/Na/K/CO_3$ is very slow.

6. For the CO/CO_2 and the O_2/CO_2 electrodes in molten carbonates, Eq. [7a] and [8b] above are, respectively, the true Nernst equations since they reflect perturbation from equilibrium more accurately than Eq. [7b] and [8a]. (The above two sets of Nernst equations were previously regarded as equivalent since under equilibrium conditions they are not distinguishable.)

7. Contrary to the past understanding, $O^=$ ion does not play any major role in the cathodic reduction of oxygen in molten carbonates away from equilibrium in spite of its evident role in determining the potential of the O_2/CO_2 electrode at equilibrium.

Acknowledgments

Figures 3-6 presented in this paper were obtained in the course of work conducted by the author at the Institute of Gas Technology, Chicago, Illinois, as a part of the TARGET fuel cell program sponsored by Pratt & Whitney Aircraft Division of United Aircraft Corporation and published here with their kind permission. The excellent help of Mr. A. K. Robinson in preparation of this publication and helpful discussions with him and Dr. A. J. Appleby are gratefully acknowledged.

Effects of Oxygen on the Mechanism of Cadmium Dissolution in Sulfate Solutions

T. N. Andersen,[1] M. H. Ghandehari,[2] E. Feng, and H. Eyring

Department of Chemistry, University of Utah, Salt Lake City, Utah 84112

ABSTRACT

The dissolution rate of cadmium was measured in various nitrogen- and oxygen-saturated acidic sulfate solutions under potentiostatic conditions. At a given potential, the dissolution rate was found to be greater in O_2- than in N_2-saturated solutions. A dissolution mechanism is proposed which explains this phenomena as well as results from tests in which potential, solution agitation, and solution composition were varied. According to this mechanism Cd^+ ions are formed as intermediates and are then oxidized to the product Cd^{+2} ions by a chemical path involving O_2 as well as by the conventional electrochemical path.

Uniform corrosion of a metal in solution is most frequently explained in terms of the electrochemical polarization curves for the independent processes, *i.e.*, metal oxidation and H^+ or O_2 reduction [*e.g.*, see Ref. (1-4)]. The polarization curves for the part reactions are added to yield that for the over-all system. This type of treatment is useful in explaining corrosion, passivation, and protection phenomena. It also has been recommended as a means for accelerated corrosion testing [*e.g.*, Ref. (2, 5)]. In the latter application the Tafel curves for one or both half-reactions (assuming one predominant cathodic and one predominant anodic reaction) are obtained by suppressing the opposite reaction. The Tafel curve is then extrapolated to the measured corrosion (mixed) potential or the two Tafel curves are extrapolated to the point of overlap to yield the corrosion current. The above superposition procedures are a means of replacing lengthy weight-loss or assay-dependent tests with one rapid electrochemical test. In order for this superposition approach to function it is necessary that the rate and kinetics of each partial reaction be independent of the other partial reaction(s) at a given potential. This independence of partial processes has been shown for several combinations of reductant (metals or hydrogen) and oxidant (5-9), and consequently would appear to be quite general. However, independence of the partial processes is not a necessary criteria for charge and mass balance across the electrode-solution interface, as suggested in some previous work (10, 12). Also an experimental attempt to obtain the corrosion rate of copper in oxygenated acid sulfate solutions by extrapolating the anodic copper polarization curve gave a corrosion rate which was erroneously low (11).[3] In the latter work (11) studies were made to determine why the partial processes were not independent when coupled, and a mechanism was proposed to explain the results.

The present study was made to investigate other systems for which the partial processes are not independent, as part of an evaluation of the superposition means of accelerated corrosion testing. Cadmium in acidic sulfate solutions was the metal chosen for study because previous work (13) suggests it dissolves as Cd^{+2} ions via a Cd^{+1} intermediate; such an intermediate offers a vehicle for interactions between the part reactions. Both H^+ ions and O_2 were studied as oxidants.

[1] Present address: Kennecott Research Center, Salt Lake City, Utah.

[2] Present address: Fansteel Research Center, Salt Lake City, Utah.

Key words: corrosion, intermediate reactions.

[3] Reference (11) attributed this failure to the mixed potential concept, but in fact should have distinguished between the law of mixed potentials ($i_{net}(E) = \sum_j i_j(E)$), which is applicable, and the superposition approach which is not applicable in this case. Donahue (12) emphasized this distinction.

Experimental

Cadmium electrodes were held at various potentials in N_2- and O_2-saturated sulfate solutions; the Cd dissolution rate and the electric current were determined for comparison in each case. All tests were made with pieces of high purity Cd sheet, 1 × 1 cm, which were covered on one side and on the edges with silicone rubber (Dow-Corning Silastic). The tests were run in a tightly covered Pyrex cell which contained 200-250 ml of H_2SO_4 acid solution of various strengths or of H_2SO_4-Na_2SO_4 mixtures. The reference electrode was a saturated calomel half-cell located in a side compartment of the main cell; it contacted the test electrode through a Luggin tube and capillary placed within a few tenths of a millimeter of the Cd surface. All potentials are reported with respect to the SCE. The counterelectrode for polarization measurements consisted of a Pt electrode, placed in a porous cup within the cell to prevent mixing of anodic and cathodic products. The solution was stirred at a constant, moderate rate with a magnetic stirrer in all cases except for those tests in which agitation was varied. The above rate is referred to throughout the remainder of this paper as "standard stirring." Oxygen or high purity N_2 was purged through the solution at approximately the same rate during each experiment. All tests were performed at 25°C.

Before each test the Cd electrode was pretreated with dilute HNO_3, then H_2O, and finally acetone to give a shiny, reproducible surface. After drying the test electrode was inserted in the cell, the open-circuit potential was measured, and polarization tests were begun. The electrode was potentiostated at various potentials near and to the positive side of the open-circuit potential, and the electric current was recorded during the entire test. Potentials were made with an electrometer voltmeter which was calibrated with a potentiometer.

Each potential was maintained at times up to 1 hr. The electrolyte was sampled several times during this test period and the Cd^{+2}-ion concentration was measured by atomic absorption to yield the rate of metal dissolution. A given electrode surface was polarized at various potentials before being withdrawn from the solution to ensure that parametric tests of potential dependence did not suffer from surface changes. Effort was concentrated near the open-circuit potential so that results would be relevant to open-circuit corrosion and so that the ohmic resistance between the Luggin capillary and test electrode would be kept negligibly small by keeping the external current moderately small. Steady-state polarization curves were obtained over a much larger range, however, to aid in establishing mechanisms.

At the end of each series of tests on a given electrode, the solution was tested for H_2O_2 concentration using the titanium sulfate colorimetric method (14).

Results and Discussion

Experimental Results

Cadmium ions (Cd^{+2}) and H_2O are the products of the reaction in oxygenated solutions. The concentrations of H_2O_2 after potentiostatic tests and even after 10 hr of open-circuit corrosion were below the detection limit of 4×10^{-5}M H_2O_2.

The Cd dissolution was linear with time (*e.g.*, Fig. 1) and the electric current was likewise nearly constant throughout each test. The dissolution data were converted to current densities on the basis that each Cd atom loses two electrons upon dissolution. The resultant dissolution current densities in N_2- and O_2-saturated solutions [$i(Cd, N_2)$ and $i(Cd, O_2)$, respectively] are shown as a function of potential in Fig. 2 and 3. Open-circuit potentials are shown also for reference purposes.

It is observed (Fig. 2) that the rate is greater in O_2- than in N_2-saturated solution at each potential for a given solution. Repeat tests with different electrodes (shown by the various points at each potential) show that this difference is statistically significant. This result is parallel to that found for Cu in dilute H_2SO_4 (11) but is unexpected in light of various other mixed potential systems (5-9). Other trends from Fig. 2 and 3 are: (*i*) Increased stirring increases the Cd dissolution current in both O_2- and N_2-saturated solutions; the effect in O_2 is shown in Fig. 3. (*ii*) The rate of dissolution of Cd is greater in M H_2SO_4 than in either 0.1M or 3M H_2SO_4. In 0.1M H_2SO_4 + 0.9M Na_2SO_4, $i(Cd, O_2)$ and $i(Cd, N_2)$ are approximately the same as in M H_2SO_4; these curves are not shown in the figures. (*iii*) The values of $i(Cd, N_2)$ and $i(Cd, O_2)$ increase with an increase in potential.

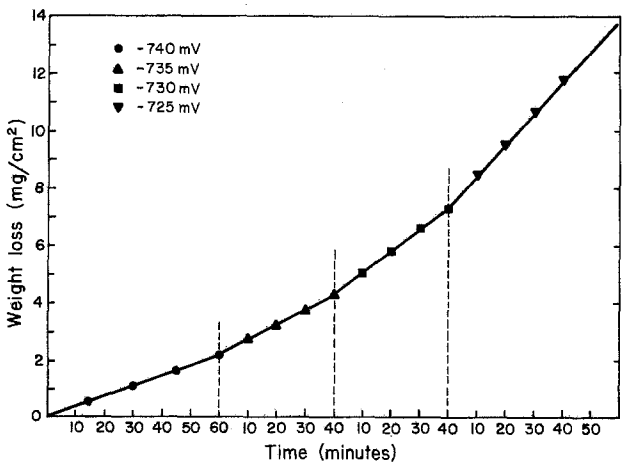

Fig. 1. Cd dissolution in O_2-saturated M H_2SO_4 at various potentials. Solution stirred at standard rate. T = 25°C.

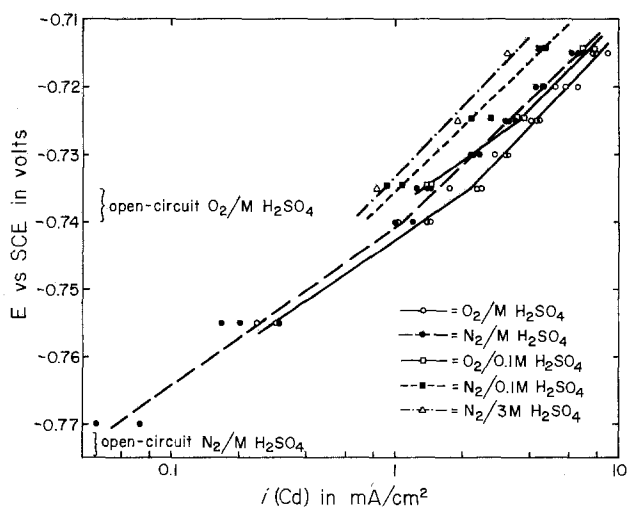

Fig. 2. Rate of Cd dissolution, i(Cd), in various O_2- and N_2-saturated solutions as a function of potential.

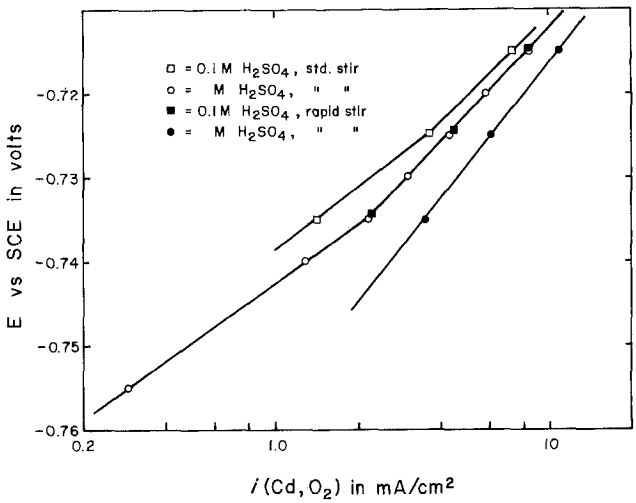

Fig. 3. Rate of Cd dissolution in O_2-saturated H_2SO_4 solutions of different strength and with varied stirring.

Further tests to expose the kinetics of the Cd dissolution consisted of determining the steady-state polarization curves for Cd dissolution in N_2-saturated solution, for H^+-ion reduction in N_2-saturated M H_2SO_4, and for O_2 reduction in O_2-saturated solutions. These curves, which are shown in Fig. 4, were determined over a much greater potential range than the dissolution rate data in Fig. 2 and 3, the purpose being to determine the kinetics of each pertinent step in the potential range of Fig. 2 and 3.

The anodic curve for Cd dissolution shows a Tafel slope over the range tested of $dE/d \log i$ = 30-35 mV. This curve shifted to higher current densities with faster stirring, which indicates that Cd dissolution is controlled both by charge transfer and mass transfer. The reduction curve in N_2-saturated solution gives a well-defined Tafel line for H_2 evolution at potentials more negative than approximately −930 mV. The shape of the curve at more positive potentials indicates the presence of a depolarizer impurity at low concentrations. Irreproducibility in the curve at the most positive potentials is further evidence that O_2 is the impurity. Oxygen reduction gives a curved E *vs.* log i plot which goes to the limiting diffusion current, $i_{l_{O_2}}$, at approximately 2.2 mA/cm², and then on to the hy-

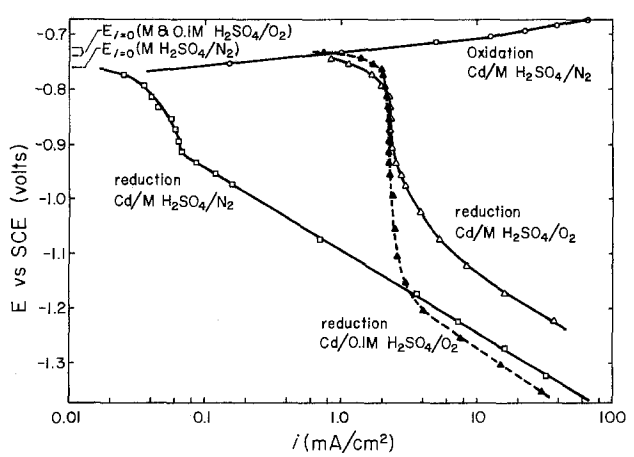

Fig. 4. Steady-state polarization curves for the reduction or oxidation at the Cd electrode in various H_2SO_4 solutions. Stirring at standard rate. T = 25°C.

drogen evolution Tafel line. At the "faster-than-standard" stirring rate $i^l_{O_2}$ was approximately 2.6 mA/cm^2.

Model to Explain Results

In N_2-saturated solution the rate of Cd dissolution accounts quantitatively for the anodic electric current. At open circuit, the measured Cd dissolution rate of approximately 0.05 mA/cm^2 appears to be balanced by H^+ ion and impurity reduction; *i.e.*, the inflection in the reduction curve in N_2/H_2SO_4 (Fig. 4) corresponds to this general current.

At or positive of the open-circuit potential in O_2-saturated solution, H^+-ion reduction is negligible, as can be seen from Fig. 4. With this fact in mind we propose the following mechanism to explain the data in Fig. 2-4

$$Cd \leftrightarrows Cd_{ad}^+ + e^- \quad [1]$$

$$Cd_{ad}^+ \leftrightarrows Cd^{+2} + e^- \quad [2]$$

$$Cd_{ad}^+ + \tfrac{1}{4}\,O_2 + H^+ \rightarrow \tfrac{1}{2}\,H_2O + Cd^{+2} \quad [3]$$

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O \quad [4]$$

Steps [1] and [2] are assumed to be the steps for the electrochemical dissolution in N_2/H_2SO_4 [in agreement with other recent studies (13)] and step [4] is the expected reduction reaction. In addition step [3] is added because of the need for a step in which some metal dissolution occurs via a nonelectrochemical pathway, to explain the fact that $[i(Cd, O_2) > i(Cd, N_2)]_E$. Reactions [3] and [4] are irreversible whereas the reverse, as well as the forward, reactions of [1] and [2] must be considered to explain the experimental results. Monovalent Cd^+ ions are never observed in sulfate solutions (as the present faradaic dissolution results in N_2/H_2SO_4 reattest) and therefore exist only in the adsorbed state.

In N_2-saturated solution reactions [3] and [4] are negligible such that the steady-state rate of Cd dissolution is given by

$$i(Cd, N_2) \simeq i(N_2) = i_1 + i_2 = 2i_2 \quad [5]$$

When O_2 is present, reactions [3] and [4] also must be considered, which results in a steady-state electric current, $i(O_2)$, of

$$i(O_2) = i_1 + i_2 - i_4 \quad [6]$$

and a Cd dissolution rate, $R(Cd, O_2)$ (in moles/sec · cm^2), of

$$R(Cd, O_2) = R_3 + i_2/\mathbf{F} \quad [7]$$

Here R_3 is the rate of step [3] in moles Cd/sec · cm^2. Each time i_1 occurs, the resultant Cd_{ad}^+ ion is removed by step [2] or [3]. Therefore

$$i_1/\mathbf{F} = i_2/\mathbf{F} + R_3 \quad [8]$$

from which Eq. [6] becomes

$$i(O_2) = 2i_2 + \mathbf{F}R_3 - i_4 \quad [9]$$

as

$$i(Cd, O_2) = 2i_2 + 2\mathbf{F}R_3 \quad [10]$$

In addition to the above expressions one may write an equation for the balance of O_2 diffusing to the surface and the utilization of it in steps [3] and [4]; *i.e.*

$$\frac{D_{O_2}}{\delta}(a_{O_2,s} - a_{O_2,e}) = \frac{i_4}{4\mathbf{F}} + \frac{R_3}{4} \quad [11a]$$

or

$$i^l_{O_2} - \frac{4\mathbf{F}D_{O_2}a_{O_2,e}}{\delta} = i_4 + \mathbf{F}R_3 \quad [11b]$$

The subscripts s and e refer to the solution and electrode surface, respectively. Likewise a balance exists between the production of Cd^{+2} ions and diffusion of them away from the surface; this is given by

$$\frac{D_{Cd^{+2}}}{\delta}(a_{Cd^{+2},e} - a_{Cd^{+2},s}) = R_3 + \frac{i_2}{\mathbf{F}} \quad [12]$$

The parametric tests of Fig. 2 and 3 can only be rationalized and the proposed model tested (further than explaining why $[i(Cd, O_2) > i(Cd, N_2)]_E$ by assuming a specific dependence of the individual current steps on the various parameters. The present tests and information in the literature are sufficient to approximate these closely enough for the present purpose.

The fact that $i(Cd, N_2)$ depends on stirring indicates that i_1 is not rate controlling. Therefore we assume that i_2 is rate controlling and i_1 is in quasi equilibrium. Accordingly

$$i_1 = i_1^+ - i_1^- = \mathbf{F}k_1^+ \exp(\alpha_1\mathbf{F}E/RT) - \mathbf{F}k_1^- a_{Cd^+,e} \exp[-(1-\alpha_1)\mathbf{F}E/RT]\,[4] \quad [13]$$

and $i_1^+, i_1^- >> i_1$
or

$$a_{Cd^+,e} = \frac{k_1^+}{k_1^-}\exp(\mathbf{F}E/RT) \quad [14]$$

$$i_2 = i_2^+ - i_2^- = \mathbf{F}k_2^+ a_{Cd^+,e} \exp(\alpha_2\mathbf{F}E/RT) - \mathbf{F}k_2^- a_{Cd^{+2},e} \exp[-(1-\alpha_2)\mathbf{F}E/RT]\,[4] \quad [15]$$

We assume the simplest form possible for R_3, *i.e.*, that it is first order with respect to both $a_{Cd^+,e}$ and $a_{O_2,e}$. Therefore

$$R_3 = a_{Cd^+,e}a_{O_2,e}k_3 \quad [16]$$

The kinetics of Eq. [4] is known for reduction on metals in general and is of the form

$$i_4 = 4\mathbf{F}k_4 a_{O_2,e} \exp(-\alpha_4\mathbf{F}E/RT)\,[4] \quad [17]$$

Expressions [11]-[17] are sufficient to eliminate the unknown activities at the electrode surface, *i.e.*, $a_{Cd^{+2},e}$, $a_{Cd^+,e}$, and $a_{O_2,e}$, and to solve for i_2, R_3, and i_4. These are as follows

$$i_2 = \frac{(D_{Cd^{+2}}/\delta)\mathbf{F}\left(\frac{k_1^+}{k_1^-}\right)k_2^+ \exp[(1+\alpha_2)\mathbf{F}E/RT]}{\frac{D_{Cd^{+2}}}{\delta} + k_2^- \exp[-(1-\alpha_2)\mathbf{F}E/RT]} - \frac{(D_{Cd^{+2}}/\delta)\mathbf{F}k_2^- a_{Cd^{+2},s} \exp[-(1-\alpha_2)\mathbf{F}E/RT]}{\{(D_{Cd^{+2}}/\delta) + k_2^- \exp[-(1-\alpha_2)\mathbf{F}E/RT]\}}$$

$$- \frac{k_2^- i^l_{O_2} \exp[-(1-\alpha_2)\mathbf{F}E/RT]}{\left(\frac{D_{Cd^{+2}}}{\delta} + k_2^- \exp[-(1-\alpha_2)\mathbf{F}E/RT\right)\left(\frac{4D_{O_2}k_1^-}{\delta k_1 k_3^+}\exp[-\mathbf{F}E/RT] + \frac{4k_4k_1^-}{k_1k_3^+}\exp[-(1+\alpha_4)\mathbf{F}E/RT] + 1\right)} \quad [18]$$

Since the rate of Cd dissolution is expressed in Fig. 2 and 3 in terms of the equivalent current density (with two electrons per Cd atom), Eq. [7] may be rewritten

[4] The potential-independent portion of the rate constants in Eq. [13]-[15], [17] (*i.e.*, the k's) are defined such that the measured potential, E, may be used in the exponents. Therefore the k's include a constant which is a function of the standard electrode rates at the potential of the reference electrode.

$$\mathbf{F}R_3 = \frac{i^l_{O_2}}{\frac{4D_{O_2}k_1^-}{\delta k_1 k_3^+}\exp(-\mathbf{F}E/RT) + \frac{4k_4k_1^-}{k_1k_3^+}\exp[-(1+\alpha_4)\mathbf{F}E/RT] + 1} \quad [19]$$

$$i_4 = \frac{i^l_{O_2}}{1 + \frac{D_{O_2}}{k_4\delta}\exp(\alpha_4\mathbf{F}E/RT) + \frac{k_1k_3^+}{4k_1k_4^-}\exp[(\alpha_4+1)\mathbf{F}E/kT]} \quad [20]$$

The model is best tested in terms of the measured parameters, the rate of metal dissolution (i(Cd)) and the measured current density, i. The rate of Cd weight loss obtained from Eq. [10], [18], and [19] is

$$i(\mathrm{Cd}) = 2i_2 + 2\mathbf{F}R_3$$
$$= \frac{2(D_{Cd^{+2}}/\delta)\mathbf{F}(k_1^+/k_1^-)k_2^+\exp[(1+\alpha_2)\mathbf{F}E/RT]}{(D_{Cd^{+2}}/\delta) + k_2^-\exp[-(1-\alpha_2)\mathbf{F}E/RT]} - \frac{(D_{Cd^{+2}}/\delta)\mathbf{F}k_2^- a_{Cd^{+2},s}\exp[-(1-\alpha_2)\mathbf{F}E/RT]}{D_{Cd^{+2}}/\delta + k_2^-\exp[-(1-\alpha_2)\mathbf{F}E/RT]}$$
$$+ \frac{2i^l_{O_2}D_{Cd^{+2}}/\delta}{\left(\frac{D_{Cd^{+2}}}{\delta} + k_2^-\exp[-(1-\alpha_2)\mathbf{F}E/RT]\right)\left(\frac{4D_{O_2}k_1^-}{k_3\delta k_1^+}\exp(-\mathbf{F}E/RT) + \frac{4k_4k_1^-}{k_3k_1^+}\exp[-(1+\alpha_4)\mathbf{F}E/RT] + 1\right)} \quad [21]$$

In N_2-saturated solution the last term in [21] is omitted such that i(Cd) = i(Cd, N_2). Experimentally i(Cd, N_2) showed well-defined Tafel behavior with $b \simeq$ 30 mV (cf. Fig. 4). Also i(Cd, N_2) depended strongly on stirring (to approximately the same extent as the O_2 limiting current). Finally i(Cd, N_2) did not change over several orders of magnitude of $C_{Cd^{+2},s}$ (from 0 to $\sim 10^{-3}$M). These facts indicate that the second term in [21] is negligible and that $D_{Cd^{+2}}/\delta << k_2^-[\exp -(1-\alpha_2)\mathbf{F}E/RT]$ in the denominator of the first term. Thus under the present conditions i(Cd, N_2) is given by

$$i(\mathrm{Cd}, N_2) \simeq 2\mathbf{F}\frac{D_{Cd^{+2}}}{\delta}\frac{k_1^+}{k_1^-}\frac{k_2^+}{k_2^-}\exp(2\mathbf{F}E/RT) \quad [22a]$$

That this reaction is diffusion controlled was also concluded earlier (7) from studies of stirring effects on Cd dissolution.

The effect of electrolyte composition on i(Cd, N_2)$_E$ (*i.e.*, the fact that i(Cd, N_2) is greater for M H_2SO_4 than for 0.1 or 3M) appears to be due principally to electrolyte effects on the diffusion coefficient, $D_{Cd^{+2}}$, on δ, and on $k_1^+k_2^+/(k_1^-k_2^-)$. Inasmuch as $(k_1^+/k_1^-)(k_2^+/k_2^-)$ is just the equilibrium constant between metallic Cd and Cd^{+2}, ions immediately outside the metal surface (*i.e.*, inside the diffusion layer), Eq. [22a] may be rewritten as follows

$$i(\mathrm{Cd}, N_2) = 2\mathbf{F}(D_{Cd^{+2}}/\delta)(a_{Cd^{+2},e}/a_{Cd})\exp(2\mathbf{F}E/RT) \quad [22b]$$

The origin of the electrolyte effects on i(Cd, N_2) was further identified by measuring the cathodic limiting diffusion currents for Cd^{+2}-ion deposition onto Cd. These limiting currents were measured several times for deposition of Cd from 0.1, 1, and 3M H_2SO_4 which contained 2 mM $CdSO_4$. The electrode arrangement and solution agitation were identical to those in the anodic experiments, *i.e.*, Fig. 2. The resulting limiting currents were statistically equivalent (within the limit of the ± 6% reproducibility) for the three solutions. We interpret these results from the following expression

$$i^l_{Cd^{+2}} = \frac{2\mathbf{F}D_{Cd^{+2}}a_{Cd^{+2}}}{\delta} = \frac{2\mathbf{F}D_{Cd^{+2}}C_{Cd^{+2}}\gamma_{Cd^{+2}}}{\delta} \quad [23]$$

where C and γ are the concentration and activity coefficient. Since the H_2SO_4 concentration is much greater than the Cd^{+2}-ion concentration, $\gamma_{Cd^{+2}}$, $D_{Cd^{+2}}$, and δ would be determined principally by $C_{H_2SO_4}$ (rather than by small changes in $C_{Cd^{+2}}$). Because $i^l_{Cd^{+2}}$ is independent of $C_{H_2SO_4}$ at a fixed concentration of Cd^{+2} ions, it follows that $D_{Cd^{+2}}\gamma_{Cd^{+2}}/\delta$ is a constant independent of $C_{H_2SO_4}$. If this conclusion is applied to the anodic dissolution current of Eq. [22b], one concludes that i(Cd, N_2) varies with $C_{H_2SO_4}$ at constant E because $C_{Cd^{+2},e}$ varies with $C_{H_2SO_4}$. Therefore the competition between the liquid phase and the metal for the Cd^{+2} ions would appear to determine the concentration of Cd^{+2} ions ready to diffuse, $C_{Cd^{+2},e}$, in Eq. [22b].

In O_2-saturated solution both the first and last terms in Eq. [21] must be taken into account to explain the results. The last term is positive which justifies the observation that i(Cd, O_2)$_E$ > i(Cd, N_2)$_E$. The data show that the first term in Eq. [21] is the larger of the two terms, *i.e.*, (Cd, O_2)/i(Cd, N_2) in M H_2SO_4 (see Fig. 2) ranges from 1.6 at −735 mV to 1.3 at −715 mV. Therefore, the Tafel slope for i(Cd, O_2) is basically the same as for i(Cd, N_2), *i.e.*, 30 mV or 2.3 $RT/2\mathbf{F}$. After Eq. [22a] is substituted for the first two terms in Eq. [21], the ratio of Cd dissolution in O_2- to that in N_2-saturated solution is given by

$$\frac{i(\mathrm{Cd}, O_2)}{i(\mathrm{Cd}, N_2)} = 1 + \frac{i^l_{O_2}}{\frac{\mathbf{F}k_1^+}{k_1^-}k_2^+\exp[(1+\alpha_2)\mathbf{F}E/RT]\cdot B} \quad [24]$$

where

$$B = \frac{4D_{O_2}k_1^-}{\delta k_3k_1^+}\exp(-\mathbf{F}E/RT) + \frac{4k_4k_1^-}{k_3k_1^+}\exp[-(1+\alpha_4)\mathbf{F}E/RT] + 1 \quad [25]$$

As E becomes more positive, the denominator of Eq. [24] increases, so the over-all second term decreases. This is in qualitative agreement with the observed ratio, i(Cd, O_2)/i(Cd, N_2).

The value of i(Cd, O_2) increases with stirring (cf. Fig. 3), as both terms in Eq. [21] qualitatively predict.

Table I. Average rate of O_2 utilization in potentiostatic tests

Solution	E (mV)	$[i(\mathrm{Cd},O_2) - i(O_2)]_{avg}$ Standard stirring (mA/cm²)		$[i(\mathrm{Cd},O_2) - i(O_2)]_{avg}$ Rapid stirring (mA/cm²)
1M H_2SO_4	−755	1.4		
	−745	2.6		2.6
	−730	2.1		
	−725	2.2		2.5
	−720	2.3		
	−715	2.2		2.3
0.1M H_2SO_4	−735	2.2		2.8
	−715	2.6		2.7
		2.2	$i^l_{O_2}$	2.6

Table II. Open-circuit corrosion rates, i_{corr}, under various conditions

H_2SO_4	Gas	Rate of stirring	i_{corr} (mA/cm²)	Corrosion potential E_{corr} (mV)
M	O_2	Standard	1.76, 1.45, 1.75, 1.49 (1.61)*	−740
M	N_2	Standard	0.0143, 0.086, 0.084, 0.0172, 0.0465, 0.072, (0.053)	−770 to −780
M	Air	Standard	0.31, 0.49, 0.67, 0.37 (0.46)	−745 to −753
0.1M	O_2	Standard	1.63, 1.81, 1.75 (1.73)	−733
M	O_2	More rapid than standard	2.30, 2.33, 2.63 (2.42)	−740

* The average value for tests at a given set of conditions is shown in parentheses.

The increase in $i(Cd, O_2)$ with ionic strength is basically the same as for $i(Cd, N_2)$; this was discussed previously.

From the preceding paragraphs it is observed that the theoretical metal dissolution rates, $i(Cd, N_2)$ and $i(Cd, O_2)$, are qualitatively consistent with the observed dissolution rates (trends) with regard to all tested variables, *i.e.*, potential, O_2 concentration, stirring rate, and salt strength. The theory may also be tested with the measured electric current $i(O_2)$. Rather than do this directly, we note that

$$i(Cd, O_2) - i(O_2) = \mathbf{F}R_3 + i_4 \qquad [26]$$

However this is $4\mathbf{F}\cdot$ (total rate of O_2 utilization in moles cm^{-2} sec^{-1}) as shown by Eq. [11]. The experimental value for Eq. [26] is shown in Table I.

The data show that within experimental deviation, O_2 is used at a rate approximately equal to its limiting diffusion current at all conditions of stirring, solution composition, and potential with the possible exception of the potentials more negative than −735 (*i.e.*, at −755). This indicates that the second term in Eq. [11b] is much smaller than the first. It also means that the term $(4D_{O_2}k_1^-/(\delta k_1^+ k_3))\exp(-\mathbf{F}E/RT)$ in the denominator of $\mathbf{F}R_3$ (Eq. [19]) is insignificant, as is the pair of terms $1 + (D_{O_2}/(k_4\delta))\exp(\alpha_{10}\mathbf{F}E/RT)$ in the denominator of i (Eq. [20]). The O_2 utilization rate thus reduces to

$$\mathbf{F}R_3 + i_4 = i^l_{O_2}\left[\frac{1}{1+\frac{1}{a}} + \frac{1}{a}\right]$$

$$= i^l_{O_2}\left(\frac{a^2+a+1}{a+1}\right) = i^l_{O_2} \qquad [27]$$

where

$$a = \frac{4k_4k_1^- e^{-\alpha_4\mathbf{F}E/RT}}{k_1k_3^+ e^{\mathbf{F}E/RT}} \qquad [28]$$

In order for Eq. [27] to be valid, $(a + 1) >> a^2$ or, if $(a + 1) > 10a^2$ then $-0.27 < a < 0.37$. But a is just the ratio of the rates $i_4/\mathbf{F}R_3$ (cf. Eq. [16] and [17]). The applicable solution is $a < 0.37$, so the chemical step [3] utilizes a greater fraction of the O_2 than does step [4].

Application to Open-Circuit Corrosion

The open-circuit corrosion potential for Cd in the oxygenated H_2SO_4 solutions studied is approximately −740 mV. Table I shows that the O_2 utilization rate at this potential is slightly less than the limiting diffusion current for O_2, $i^l_{O_2}$. Correspondingly, the corrosion rate (see Table II) is somewhat less than $i^l_{O_2}$ (1.6 mA/cm² compared to 2.2 mA/cm² at the standard-stirring rate). Nevertheless the kinetics are substantially controlled by O_2 diffusion, so the effects of experimental parameters on the open-circuit corrosion rate should parallel those for O_2 diffusion. The corrosion data in Table II show that this prediction is borne out; *i.e.*, the corrosion rate is strongly dependent on stirring, approximately first order with respect to O_2 partial pressure, and nearly independent of the solution composition. The corrosion potential, E_c, is not the value obtained by equating $i^l_{O_2}$ and $i(Cd, N_2)$, given as −725 mV by Fig. 4. Rather E_c is more negative because of the additional "chemical" dissolution step (Eq. [3]). If the current from this step were added to the anodic electrochemical curve in Fig. 4, the resultant anodic curve would equal $i^l_{O_2}$ very near the corrosion potential.

Galvanic Cell Studies on Ionic Carbide and Nitride Solutions in Molten Salts

A. Bonomi,* M. Hadate, and C. Gentaz

Battelle, Geneva Research Center, 1227 Carouge-Geneva, Switzerland

ABSTRACT

The free energy (Gibbs) of formation of Li_2C_2, CaC_2, and Li_3N and their activities in molten salt solutions at temperatures between 823° and 973°K have been determined by using the following galvanic cells

Fe, Li-Ca (alloy) | LiCl-$CaCl_2$ eut. CaC_2 | C (s), Fe [I]

and

Fe, Li (c) | LiCl-LiF eut. Li_3N | N_2 (g,1 atm), Fe [II]

The nitrogen electrode used in cell (II) has been proved to have a Nernstian behavior by studying the dependence of emf on the partial pressure of nitrogen. The activity coefficients of CaC_2 and Li_3N in molten salts have been found to decrease with increasing concentration.

Galvanic cells using CaC_2 solutions in molten salts as electrolyte have been studied by previous authors (1-3) with unsatisfactory results as regards the possibility of determining accurately the carbon activity in iron electrodes. The reason for this lack of accuracy has been ascribed to the existence of electronic conductivity in the melt (3, 4) as a consequence of the presence of calcium resulting from the establishment of the following equilibrium

$$CaC_2 \text{ (melt)} \rightleftarrows Ca \text{ (melt)} + 2C \text{ (s)} \qquad [1]$$

Most of the previous authors (1, 3) have used pure synthetic CaC_2 prepared from the elements at a temperature near 1000°C and the physicochemical behavior of molten salt solutions prepared with the pure synthetic CaC_2 seems to be quite different from that obtained with technical grade carbide. In fact, anodic voltametric curves (5) and chronopotentiometric studies (6) carried out in solutions prepared with synthetic CaC_2 show, respectively, two waves and two transition times, the first attributed to the oxidation of calcium and the second to the oxidation of carbide ion. In the case of solutions prepared with the technical grade CaC_2, the voltametric curves show only one wave corresponding to the oxidation of carbide ion (7). Furthermore the decarburization of carbon-rich austenite samples has been reported when a low carbon steel crucible was used as electrolyte container (3) but only the carburization reaction has been observed in technical grade CaC_2 solutions even in presence of low carbon steel crucibles (7, 8).

This different behavior may be explained by assuming that the synthetic CaC_2 has a higher calcium content than the technical material and this difference in Ca content is conserved in the molten solution because equilibrium [1] is characterized by a very slow kinetic in one or both directions. Actually, the presence of calcium in synthetic CaC_2 solutions has been detected previously (9), but the analytical results show, in most cases, a much higher calcium content than the calculated values for the case of an ideal solution. Therefore, these results do not allow a conclusive opinion about the actual attainment of equilibrium [1] in molten salt solutions of CaC_2.

These preliminary considerations lead us to suppose that electrolytes based on the technical grade CaC_2 solution do not show a significant electronic conductivity. Consequently, they could be used to realize suitable galvanic cells for the activity and free energy measurements of ionic carbides in molten salt solutions. Analogously, an electrolyte based on Li_3N solution in molten salts and a nitrogen electrode have been developed in order to realize suitable galvanic cells for studying the thermodynamics of ionic nitrides in molten salt solutions.

Key words: galvanic cells, calcium carbide solution, lithium nitride solution, carbon electrode, nitrogen electrode, calcium carbide, lithium nitride, free energy of formation.

Experiments

Two types of galvanic cells have been realized

Fe, Li-Ca (alloy) | LiCl-$CaCl_2$ eut. CaC_2 | C (s), Fe [I]

and

Fe, Li (c) | LiCl-LiF eut. Li_3N | N_2 (g, 1 atm), Fe [II]

the first one, corresponding to a formation cell of carbides, has been operated between 873° and 973°K, and the second one, corresponding to a formation cell of nitrides, has been operated between 823° and 973°K.

The experimental apparatus was constituted by an Inconel cell under argon (cell [I]) or nitrogen (cell [II]) atmosphere and heated by a thermoregulated furnace as described in a previous work (10). About 300g of electrolyte [30 mole percent (m/o) of $CaCl_2$ for LiCl-$CaCl_2$ eutectic, melting point 496°C or 29 m/o LiF for LiCl-LiF eutectic, melting point 485°C] was contained in an iron crucible and dehydrated by heating slowly under vacuum from room temperature to the melting point during 5 hr.

Calcium carbide or lithium nitride was added to the molten electrolyte using an iron basket that remained one night in the melt for the complete dissolution. Analytical grade $CaCl_2$ and LiCl supplied by Merck and LiF of 99.5% purity supplied by Ozark were used for the preparation of the eutectic mixtures. Technical grade CaC_2 of 80% purity, the rest being essentially CaO, and Li_3N of 94% purity supplied by Alfa Inorganics were dissolved in the electrolyte. The concentration of CaC_2 was determined by the gas volumetric analysis of the acetylene evolved by hydrolysis of bath samples as described in a previous work (11). The nitride content was determined on bath samples by the Kjeldahl method.

Using an iron crucible as anode, the pure Li or Li-Ca alloy electrode was realized by imposing a cathodic impulse to an iron microelectrode of 0.2-0.3 cm^2. The thin layer (10-100 μm) of metal deposited dissolves slowly after the pulse within a time of 5-80 min, allowing an easy recording of the emf of galvanic cells. The voltages were recorded *vs.* time using a W + W Recorder 100 and independently accurately measured on a digital voltmeter Fluke 800 A.

Table I. Solubility data for CaC_2 in molten LiCl-$CaCl_2$

Temperature (°C)	600	650	680	700
Solubility, w/o CaC_2	2.5	2.6	2.7	3.0

As it was not possible to determine directly the composition of the Li-Ca alloy produced, we have assumed a concentration of 52 atomic percent (a/o) of Ca on the basis of results reported in a previous paper (12) concerning the compositions of Li-Ca alloys obtained at the cathode by electrolysis of LiCl-$CaCl_2$ melts with different compositions.

The carbon electrode was made by a thin layer of anodic deposit of carbon on an iron pin of about 2 mm diameter and dipped about 5 mm into the bath. The nitrogen electrode was made by bubbling the gas through an iron frit or a nozzle with a 0.6 mm diameter hole. Different N_2-argon mixtures have been prepared in order to equilibrate the electrode at different nitrogen partial pressures.

Data on the solubility of CaC_2 in molten LiCl-$CaCl_2$ eutectic are not available in the literature. We have obtained the conditions of saturation adding a slight excess of CaC_2 and controlling its content at the different working temperatures. Solubility data determined in this work for CaC_2 in molten LiCl-$CaCl_2$ eutectic are given in Table I. Solubility of Li_3N in LiCl-LiF eutectic has been measured by Glemser and co-workers (13) and our chemical analysis of bath samples has confirmed the values reported by these authors.

Results

The potential decay observed after the cathodic pulse presents two plateau voltages in the case of Li-Ca electrodes and one plateau voltage in the case of Li electrodes. An example of potential decay recording obtained for the Li-Ca electrode is reported in Fig. 1.

The persistence of the plateaus has been found directly proportional to the charge used for the pulse, and decreased with the temperature. In Fig. 2, we have reported as example the time of persistence of the first plateau obtained with the carbide cell as a function of the charge used at different temperatures. The linear behavior observed confirms that the dissolution of Li or Li-Ca layers on the iron microelectrodes are the cause of the plateau voltages observed. The voltage measured at the beginning of the plateau is a function of temperature and of the CaC_2 or Li_3N content in the melt, and its reproducibility was found quite good in

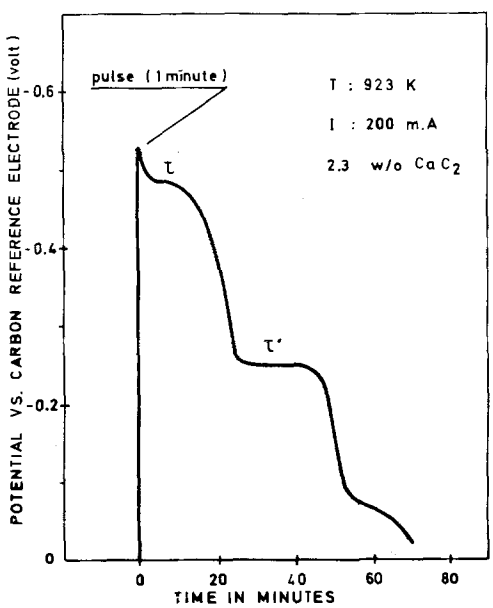

Fig. 1. Potential vs. carbon reference electrode as a function of time after 1 min of cathodic pulse.

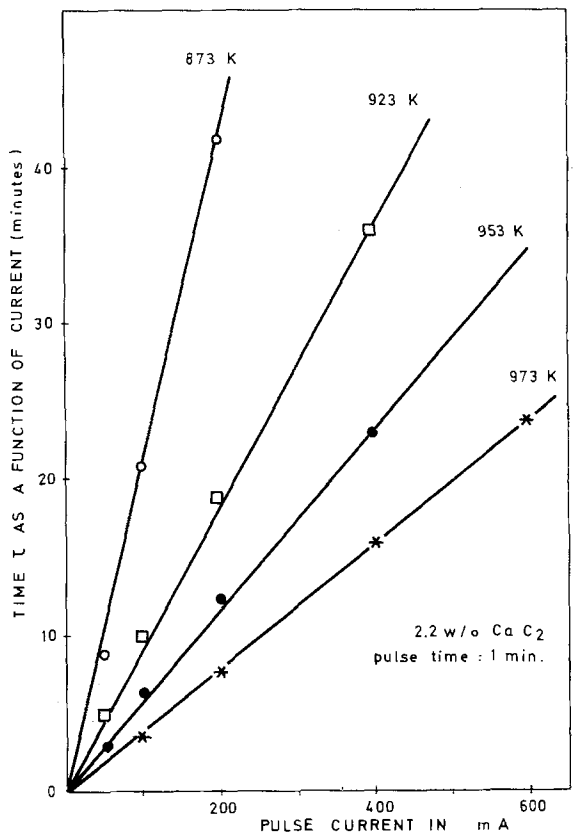

Fig. 2. Time τ as a function of pulse current at different temperatures.

the case of the nitride cell at temperatures between 823° and 973°K and for the first plateau observed with the carbide cell at temperatures between 873° and 923°K. On the other hand, a less reproducible behavior was observed in the case of the second plateau characteristic of the carbide cell and only a few values of the voltage plateau have been considered acceptable in this case.

Considering a possible composition of the Li-Ca alloy of 52 a/o Ca, from the Li-Ca phase diagram (12) at 873° and 923°K, the metal layer deposited should be formed by a two-phase system constituted by solid calcium and a liquid Li-Ca alloy. The cell voltage recorded at the beginning of the first plateau hence could be attributed to the existence of cell [I] where the negative electrode is actually constituted by the two-phase system reported above with the following cell reaction

$$Ca\ (s) + 2C\ (s) \rightarrow CaC_2\ (melt) \qquad [2]$$

As calcium is known to be much more soluble than lithium in molten salts (14), a selective depletion of Ca from the two-phase system is expected and this depletion may be the reason for the formation of the second plateau observed with the carbide cell.

After the complete depletion of Ca, we have in fact the formation of another galvanic cell [I']

$$Fe, Li\ (c) \mid LiCl\text{-}CaCl_2\ eut.\ CaC_2 \mid C\ (s), Fe \qquad [I']$$

with the following cell reaction

$$2Li\ (c) + 2C\ (s) \rightarrow Li_2C_2\ (melt) \qquad [3]$$

In the case of the nitride cell, the formation of the plateau corresponds to the existence of cell [II] with the following cell reaction

$$3Li\ (c) + \tfrac{1}{2} N_2\ (g, 1\ atm) \rightarrow Li_3N\ (melt) \qquad [4]$$

In Fig. 3 and 4 we have reported, respectively, the emf of cell [I] and of cell [II] as a function of tem-

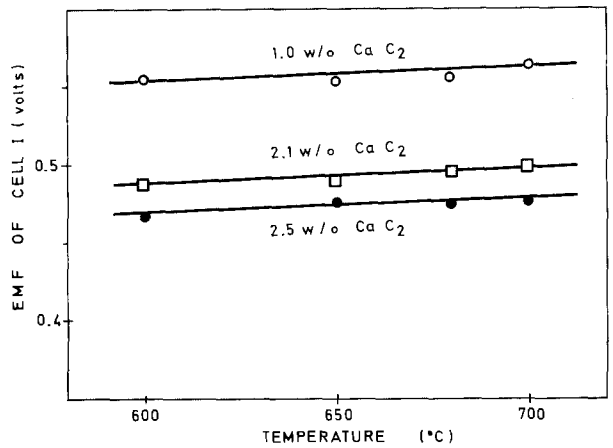

Fig. 3. EMF of cell [I] as a function of temperature at different calcium carbide concentrations.

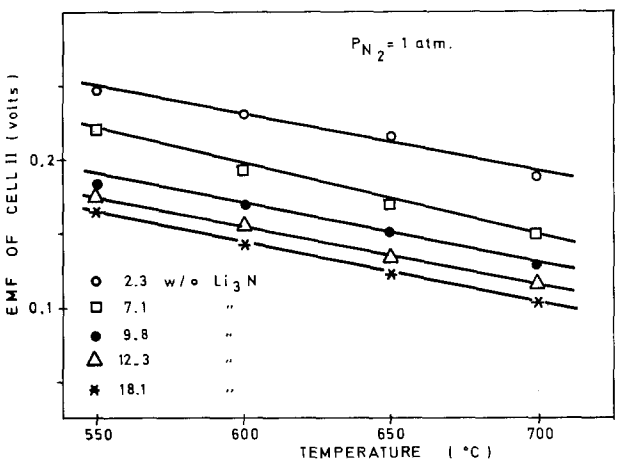

Fig. 4. EMF of cell [II] as a function of temperature at different lithium nitride concentrations.

perature at different concentrations, respectively, of CaC_2 and Li_3N.

In order to verify the thermodynamical behavior of the nitrogen electrode of cell [II], we have studied the dependence of the plateau voltage on the nitrogen partial pressure. In Fig. 5, we have reported the values of emf recorded as a function of N_2 partial pressure for two Li_3N concentrations in the melt. Then, one could remark the Nernstian behavior, being the experimental slope only 0.2 mV higher than the theoretical value calculated for a cell reaction of the type

$$3Li\ (c) + \tfrac{1}{2}\ N_2\ (g, p_x) + Li_3N\ (melt) \qquad [5]$$

Therefore, we have a good support for the possibility that our iron/nitrogen electrode could behave as a reversible nitrogen electrode with the corresponding electrode reaction

$$N^{3-}\ (melt) \leftrightarrows \tfrac{1}{2}\ N_2\ (g) + 3e^- \qquad [6]$$

in a molten electrolyte dissolving ionic nitrides.

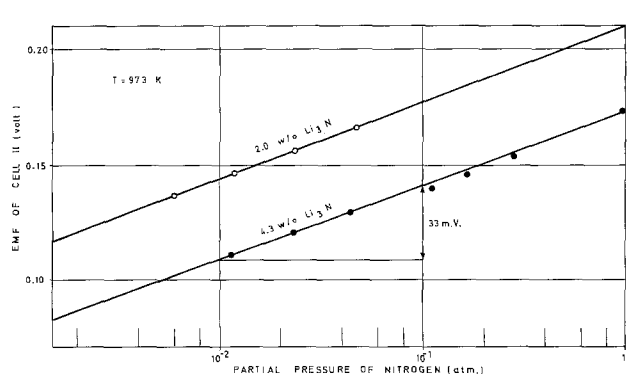

Fig. 5. EMF of cell [II] as a function of the partial pressure of nitrogen.

Discussion

As molten salt electrolytes containing CaC_2 are known to be partial electronic conductors (3, 8), the expression for the cell voltage should include a correction term involving the electron transport number (18). This partial electronic conductivity could be in addition to a simple dissolution process at the origin of the gradual depletion of Ca from the Ca-Li electrode observed in this work. However, for different reasons explained previously and concerning the behavior of technical grade CaC_2 solutions, we have considered this term reasonably small. Another source of possible partial electronic conductivity could be the metal dissolved in the melt originated by cathodic pulses on the microelectrode. In order to maintain negligible the increment of concentration of this metal and in consequence of the partial electronic conductivity we have used a great amount of electrolyte. These considerations are also valid for electrolytes containing Li_3N. Hence the same precautions have been taken experimentally and also in this case we have neglected the correction term involving the electron transport number in the expression of the cell voltage.

Galvanic cell [I].—In order to evaluate our emf data and determine the behavior of the activity coefficient of CaC_2 dissolved in molten salts, we have reported the plateau voltages of cell [I] and [I'] in Fig. 6 and 7 as a function of the logarithm of the ratio between the concentration C of CaC_2 and the value of saturation C_s at 873° and 923°K. In these figures, we have also shown for cell [I] a solid line, that indicates the emf behavior assuming the activity coefficient of CaC_2 remains constant and equal to the value existing in a saturated solution. In the same figures we have indicated the values of $E°_{CaC_2}$ and $E°_{Li_2C_2}$ calculated on the basis of the free energy of formation of the two carbides available in the literature. So we can observe the values of emf of cell [I] measured in a saturated solution of CaC_2 slightly higher (in absolute value) than those calculated from literature data and this difference in terms of free energy corresponds to about 2 kcal/mole. Nevertheless, as these data are reported with an error of ±3 kcal/mole, we consider that our experimental values are in fairly good agreement with the literature.

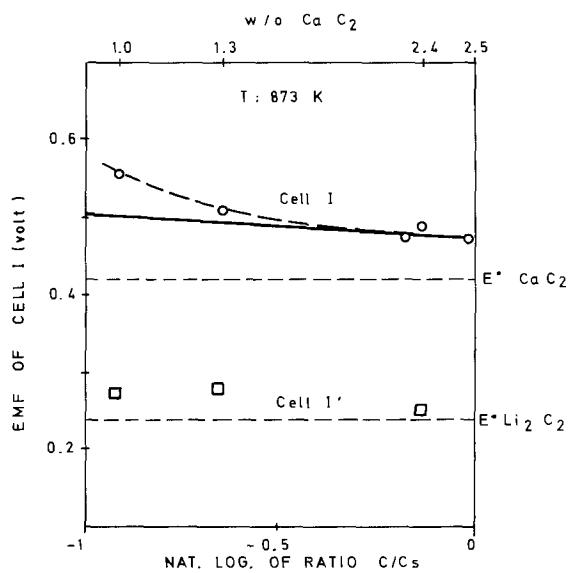

Fig. 6. EMF of cell [I] as a function of ratio C/C_s

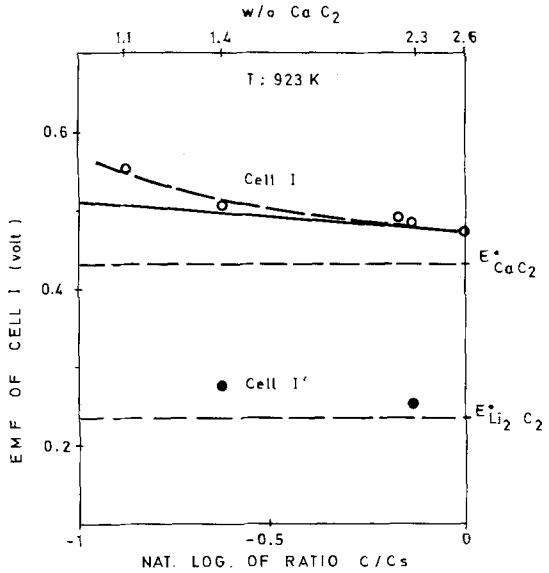

Fig. 7. EMF of cell [I] as a function of ratio C/C_S

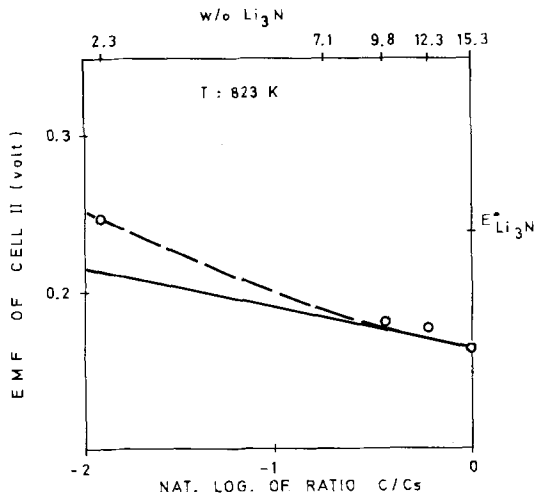

Fig. 8. EMF of cell [II] as a function of ratio C/C_S

With regard to the emf values of cell [I] reported in Fig. 6 and 7 for CaC_2 concentrations lower than the saturation, one could remark that these values are above the solid line of reference at the constant activity coefficient. This fact indicates that the activity coefficient of CaC_2 decreases slowly with the concentration.

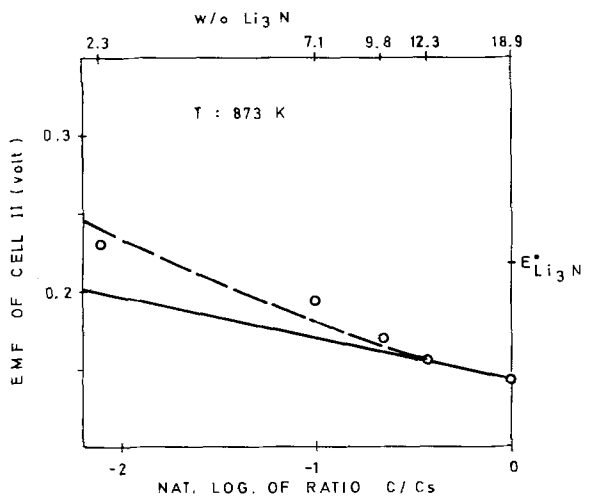

Fig. 9. EMF of cell [II] as a function of ratio C/C_S

Considering now the emf values of cell [I'] of formation of Li_2C_2, they are, as we can see in Fig. 6 and 7, in fairly good agreement with the values calculated from the literature data. However, the lack of knowledge of the solubility of Li_2C_2 in LiCl-$CaCl_2$ eutectic hinders an accurate interpretation of these data.

Galvanic cell [II].—As in the case of cell [I] we have reported the emf data of cell [II] measured at four temperatures between 823° and 973°K in Fig. 8-11

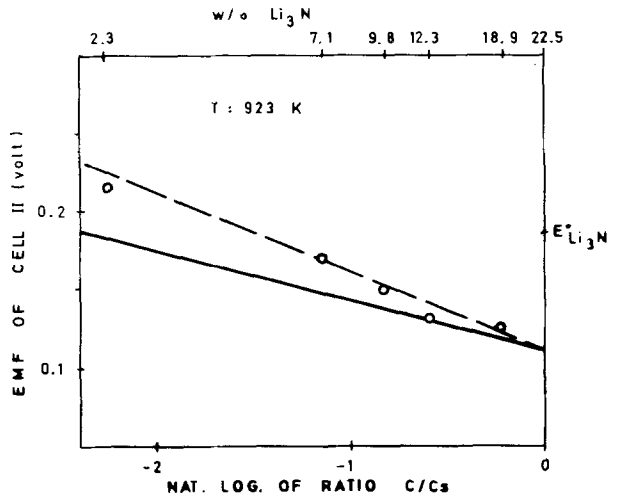

Fig. 10. EMF of cell [II] as a function of ratio C/C_S

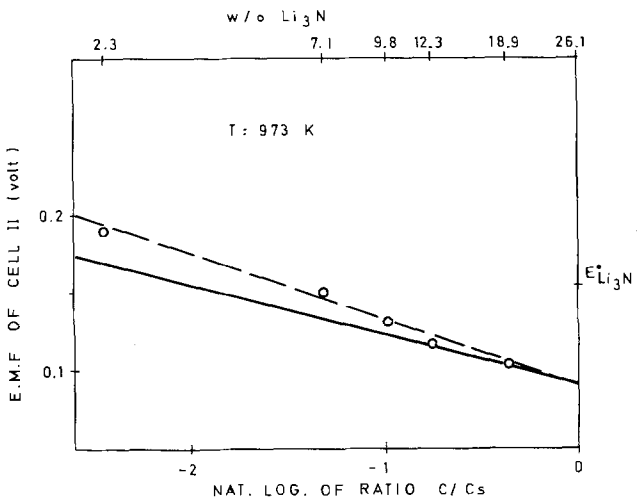

Fig. 11. EMF of cell [II] as a function of ratio C/C_S

as a function of the logarithm of the ratio of concentration C of Li_3N and the saturation value C_S. As in the analogous diagrams of Fig. 6 and 7, we have shown as a solid line the behavior of the emf for the case of an activity coefficient of Li_3N which remains unchanged and equal to the value existing in a saturated solution.

The free energy of formation of Li_3N calculated on the basis of measurements in saturated solutions are reported in Fig. 12 and compared with the values of the literature (15) and some recent data based on thermal decomposition measurements of solid Li_3N (16). Our values are about 4-5 kcal/mole lower (in absolute value) than the old literature data but in good accord with the more recent values (16). On the basis of our data, we can calculate the following free energy function valid between 823° and 973°K

$$\Delta G_{Li_3N}\ (\text{cal/mole}) = -40{,}652 + 35.2T$$

It must be remarked that our values of free energy for Li_3N are subject to uncertainty due to the fact that solid Li_3N reacts with LiCl to form a new phase $Li_9N_2Cl_3$ (17) that could be the actual compound that

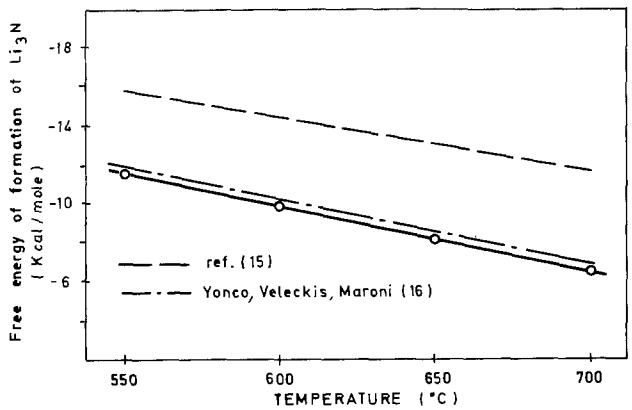

Fig. 12. Free energy ΔG of formation of Li_3N as a function of temperature.

saturates the melts used. As the reaction of formation of this phase

$$2Li_3N + 3LiCl \rightarrow Li_9N_2Cl_3$$

has probably a quite small free energy, we expect that the error affecting our data is small.

With regard to the emf of cell [II] measured for unsaturated solutions of Li_3N, one could observe in Fig. 8-11 that the values are higher than the solid line of reference at the constant activity coefficient. As in the case of CaC_2 solutions, this fact indicates that the activity coefficient of Li_3N decreases with the concentration.

Conclusion

Our results show that it is possible to realize galvanic cells giving useful results upon the free energy and the activity of ionic carbides and nitrides in molten salts, and that it is possible to realize a nitrogen electrode with a thermodynamical reversible behavior in a molten electrolyte dissolving ionic nitrides.

Magnetic Field Effects on Electrochemical Reactions Occurring at Metal/Flowing-Electrolyte Interfaces

Eugene J. Kelly*

Oak Ridge National Laboratory, Chemistry Division, Oak Ridge, Tennessee 37830

ABSTRACT

A study was made to determine whether a magnetic field, such as that associated with a thermonuclear reactor, might adversely affect the corrosion behavior of metallic surfaces in contact with a flowing electrolyte. In metal/flowing-electrolyte systems, electrochemical reactions dependent on the metal/electrolyte interfacial potential difference are affected by an applied magnetic field as a consequence of the Lorentz forces acting on the charged components of the flowing electrolyte. A theoretical analysis of the magnetic field effect was developed, and its validity established by experiments involving the Ti/H_2SO_4 (H_2-saturated) system. Quantitative agreement between theoretical and experimental results was obtained for the electrochemical behavior of Ti in 1*N* H_2SO_4 (mean flow velocity: 0-650 cm/sec) over the available range of magnetic flux density (0-2.1 Tesla). Although the experimental work employed discrete Ti electrodes set in the wall of nonconducting Pyrex glass pipe, the theory was extended to include metallic pipes, *i.e.*, the "conducting-wall" case, for which case the "wall-shorting" effect was shown to be negligible. In addition to the adverse effect of a magnetic field on the "uniform" corrosion behavior of metals, the imposition of a magnetic field can also result in enhanced susceptibility to stress corrosion cracking, localized (pitting or crevice) corrosion, oxidation and reduction of solution species, and electrochemical decomposition of the electrolyte. The aforementioned processes, to name a few, are all potential dependent and, consequently, subject to the magnetic field effect.

The primary purpose of this investigation was to determine what effects a magnetic field has on electrochemical reactions occurring at metallic surfaces in contact with a flowing electrolyte. Although the study was motivated by a concern that the intense magnetic field (10-12 Tesla) associated with a Tokamak-type thermonuclear reactor might adversely affect the corrosion behavior of pipes used to transport an aqueous or molten-salt heat-exchange medium, the results are applicable to magnetoelectrochemical systems in general.

A magnetic field may affect the rates of both activation (charge-transfer) and mass-transport-controlled processes. Consider an electrochemical reaction occurring at a metal/solution interface, for example, a simple reduction reaction occurring under conditions such that the reverse reaction can be ignored

$$M^{+z} + e^- \rightarrow M^{+(z-1)} \qquad [1]$$

If the Nernst diffusion layer concept (1) is applied, the steady-state current density ($\bar{i}$) corresponding to the reduction reaction is given by Eq. [2]

$$\bar{i} = \mathbf{F}\bar{k}(D/\delta)C/[\bar{k} + (D/\delta)] \qquad [2]$$

where D and C represent the diffusion coefficient and bulk concentration of M^{+z}, respectively, δ is the Nernst diffusion layer thickness, $\bar{k}$ is the electrochemical rate constant for the charge-transfer step, and $\mathbf{F}$ is the Faraday constant. For pure mass-transport control, $\bar{k} >> (D/\delta)$, Eq. [2] reduces to Eq. [3]

$$\bar{i} = \mathbf{F}(D/\delta)C \qquad [3]$$

For pure activation control, $(D/\delta) >> \bar{k}$, Eq. [2] reduces to Eq. [4]

$$\bar{i} = \mathbf{F}kC\exp(-\alpha\lambda\mathbf{F}\Delta_{M\phi S}/RT) \qquad [4]$$

where $\bar{k} = k\exp(-\alpha\lambda\mathbf{F}\Delta_{M\phi S}/RT)$, α is the symmetry factor ($\alpha = 1/2$), λ is the charge-transfer number (in this case, $\lambda = 1$), $\Delta_{M\phi S}$ is the potential difference between the metal phase and a point just inside the electrolyte phase (the preelectrode plane or outer Helmholtz plane), and the other symbols have their conventional significance. A magnetic field can alter the hydrodynamic state within the electrolyte phase, thereby altering the value of δ and, consequently, altering the rate of a mass-transport-controlled reaction (Eq. [3]). Quantification of the effect of a magnetic field on mass-transport-controlled reactions remains a problem in classical magnetohydrodynamics and has been the subject of several recent studies (2, 3). On the other hand, the effect of a magnetic field on activation-controlled processes has not been previously quantified, and it is this phenomenon which is examined in the present report. In brief, the interfacial potential difference, $\Delta_{M\phi S}$, at a metal/flowing-electrolyte interface is altered by the presence of a magnetic field and, consequently, the rate of the charge-transfer reaction is changed (Eq. [4]). In addition to affecting the rates of activation-controlled reactions, a magnetic field may introduce mechanistic changes into the electrochemical system. For example, a metal undergoing active-state dissolution may become passive in the presence of a magnetic field. Susceptibility to localized (pitting or crevice) corrosion or stress corrosion cracking may be enhanced (or diminished). Indeed, under severe conditions, electrolytic decomposition of the electrolyte may be induced. In brief, any electrochemical process dependent on $\Delta_{M\phi S}$ may be affected by an applied magnetic field.

The electrochemical system chosen for this study, titanium in H_2-saturated 1*N* H_2SO_4, has been studied extensively in the absence of a magnetic field (4, 5), and is one in which the interfacial reactions, the oxidation of titanium to form Ti(III) ions in solution and the hydrogen evolution reaction, are both under activation control. Moreover, titanium is "nonmagnetic," *i.e.*, the magnetic permeability of titanium may be equated to that of free space.

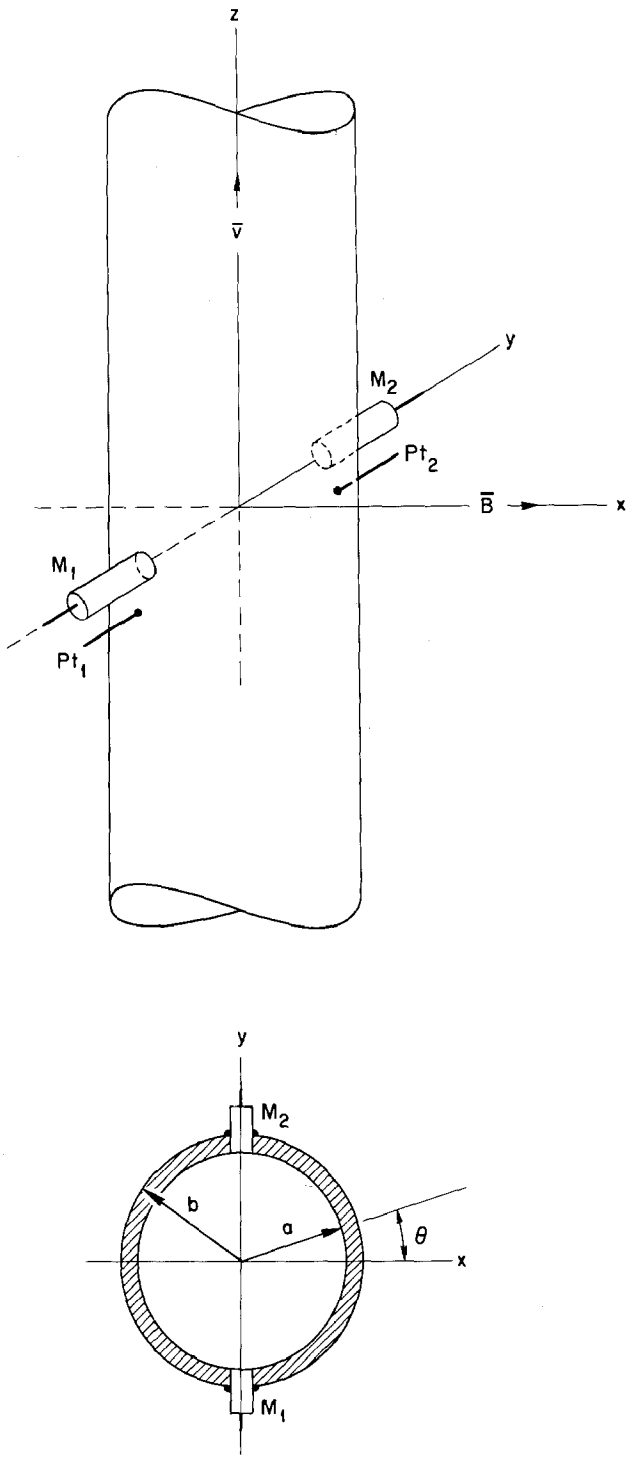

Fig. 1. Schematic drawing of the electrochemical cell segment of the forced-convection loop.

Experimental

A schematic drawing of the electrochemical cell, *i.e.*, that segment of the forced-convection loop located between the pole pieces of an electromagnet, is shown in Fig. 1. The inner and outer radii (a and b in the schematic) of the Pyrex glass pipe were 0.953 and 1.27 cm, respectively. The axis of the cylindrical cell coincided with the z axis, and the magnetic field was aligned parallel to the x axis. The fluid flow and the magnetic field were directed in the positive z and positive x directions, respectively. A pair of identical cylindrical titanium electrodes (M_1 and M_2 in Fig. 1) were located opposite one another, their common axis coinciding with the y axis. The titanium electrodes (diameter = 0.397 cm) were mounted through the wall of the pipe, and the surfaces in contact with the electrode were polished to conform to the inner surface of the pipe. Thermally collapsible polypropylene tubing was used to mask the cylindrical surfaces of the electrodes. An epoxy cement (Araldite) was used to seal the covered electrodes into slightly oversized holes in the wall. A pair of identical platinum electrodes (diameter = 0.159 cm), similarly mounted but displaced 1.27 cm along the z axis, completed the electrochemical cell.

The electrolyte (1*N* H_2SO_4) was circulated through the reservoir, pump, control valves, electrochemical cell, and back to the reservoir. The flow velocity through the cell could be varied over the range, 0-650 cm/sec. Neither the magnetic-drive centrifugal pump (March Manufacturing Company, Model TE-7R-MD), nor the polypropylene valves contained metallic parts in contact with the electrolyte. In the entire closed loop, the only metallic surfaces in contact with the electrolyte were the cell electrodes. The reservoir was made of Pyrex glass and contained 50 liters of solution. The remainder of the loop contained an additional 3 liters of solution. The temperature of the circulating electrolyte was maintained at 30.0° ± 0.1°C. In order to prevent the temperature from rising above 30°C, refrigerated water (7°C and H_2 saturated) was circulated through Teflon coils within the reservoir. Precise temperature control was then obtained with a quartz immersion heater and mercury thermoregulator located within the reservoir. A continuous stream of H_2 was maintained through the electrolyte in the reservoir. The hydrogen source was a Matheson generator which produces ultrapure gas via diffusion of electrolytically generated hydrogen through a palladium membrane.

The titanium electrodes employed in this study were made from zone-refined, polycrystalline titanium (Materials Research Corporation). The electrolyte was prepared from reagent grade H_2SO_4 and triply distilled water.

The electromagnet (Varian Associates, Twelve-Inch Electromagnet System, Model V-4012-3B with regulated power supply, Model V-2100-B) was equipped with tapered pole pieces (13.2 cm diameter at the air gap), and had a gap width of 3.2 cm. The magnetic flux density between the pole faces was variable over the range 0-2.1 Tesla (0-21 kG), and homogeneous to within 1%. Magnetic flux densities were measured with a Hall-effect gaussmeter (F. W. Bell, Incorporated, Model 610 Gaussmeter, Model STG1-0404 transverse Hall probe).

Electrochemical measurements were made with a Wenking potentiostat (Model 61 RH) used in conjunction with a Wenking electronic potentiometer (Model PPT-67) and a Hewlett-Packard/Moseley recorder (Model 7100B, Model 17501A plug-ins). A Tektronix oscilloscope (Type 533, Type D plug-in) equipped with a Polaroid camera was used for recording fast (microsecond region) potentiostatic current/time transients. The platinum electrodes (Fig. 1) served as reference (Pt/H_2) and counter electrodes.

Theory

For the configuration presented in Fig. 1 and described in the preceding section, it may be shown that, as a consequence of the Lorentz forces acting on the charged components of the electrolyte phase, a potential difference ($\Delta\phi_{MAG}$) is induced in the electrolyte phase between the two titanium (M_1 and M_2) electrodes (or between the two platinum electrodes). The magnetically induced potential difference is described by Eq. [5]

$$\Delta\phi_{MAG} = 2Ba v_m \qquad [5]$$

where a is the inner radius of the pipe, v_m is the average flow velocity [$v_m = (1/\pi a^2) \int_0^a 2\pi r v dr$], and B is the applied magnetic flux density. In the derivation of Eq. [5] (see discussion section), it will be

shown that the equation is valid for axisymmetric flow (laminar or turbulent) whether the pipe is nonconducting (Pyrex glass) or conducting (metallic). From the practical viewpoint, of course, it is the conducting-wall case which is of greatest interest. For the present, one may accept the validity of Eq. [5], and examine the electrochemical consequences of the induced potential difference.

Three potential-distance profiles for the cell shown in Fig. 1 are presented in Fig. 2. The subscripts, M and S, refer to the metal and electrolyte phases, respectively, and the subscripts, 1 and 2, designate the electrodes M_1 and M_2 located as shown in Fig. 1 or, in the case of the electrolyte phase, points just inside the electrolyte phase adjacent to M_1 and M_2. The three profiles (indicated by the subscripts a, b, and c) correspond to the following conditions: (a) Heavy line; $\Delta\phi_{MAG} = 0$ (no magnetic field present); M_1 and M_2 both at open circuit, *i.e.*, the net faradaic current at either electrode is zero. (b) Medium line; $\Delta\phi_{MAG} = 2Bav_m$ (magnetic field applied); M_1 and M_2 at open circuit. (c) Light line; $\Delta\phi_{MAG} = 2Bav_m$; M_1 and M_2 externally short-circuited to form an analogue of a metallic pipe.

The potential difference (V) between electrodes M_1 and M_2 is defined by Eq. [6]

$$V = (\phi_M)_2 - (\phi_M)_1 \quad [6]$$

and may be expressed in the expanded form

$$V = [(\phi_M)_2 - (\phi_S)_2] + [(\phi_S)_2 - (\phi_S)_1] + [(\phi_S)_1 - (\phi_M)_1] \quad [7]$$

or, for the sake of compactness

$$V = (\Delta_M\phi_S)_2 + (\Delta_2\phi_1)_S - (\Delta_M\phi_S)_1 \quad [8]$$

The change (η) in a metal/solution interfacial potential difference which accompanies a finite net faradaic current density ($\bar{i}$) at the interface is defined by Eq. [9]

$$\eta = \Delta_M\phi_S - \Delta_M\phi_S^\circ \quad [9]$$

where $\Delta_M\phi_S^\circ$ is the interfacial potential difference

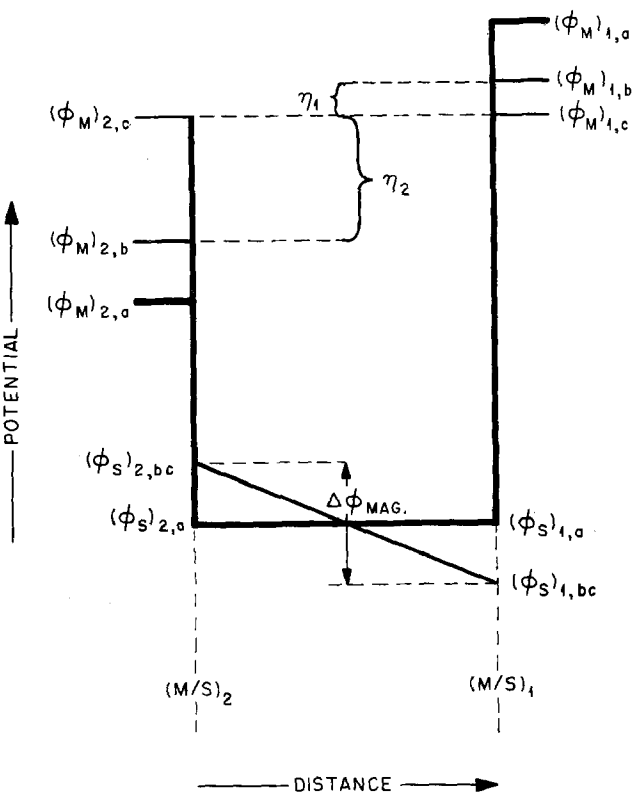

Fig. 2. Potential-distance profiles for the cell shown in Fig. See text for conditions corresponding to cases (a), (b), and (c).

when $\bar{i} = 0$. Conventional potentiostatic or galvanostatic measurements, conducted in the absence of a magnetic field, are used to determine the current densities $\bar{i}_1$ and $\bar{i}_2$, at electrodes M_1 and M_2 as function of η_1 and η_2, respectively, *i.e.*, to evaluate the functions

$$\bar{i}_1 = f(\eta_1) \quad \text{and} \quad \bar{i}_2 = g(\eta_2) \quad [10]$$

If $\Delta_M\phi_S$ from Eq. [9] is substituted into Eq. [8], one obtains Eq. [11]

$$V = \eta_2 - \eta_1 + (\Delta_2\phi_1)_S + V^\circ \quad [11]$$

where $V^\circ = [(\Delta_M\phi_S^\circ)_2 - (\Delta_M\phi_S^\circ)_1]$. For case (a) above, both electrodes are at open circuit and, consequently, $\eta_1 = \eta_2 = 0$ and no *IR* drop exists in the electrolyte phase. Therefore, with $\Delta\phi_{MAG} = 0$, it follows that $(\Delta_2\phi_1)_S = 0$ [heavy horizontal line in the electrolyte phase between the interfaces, $(M/S)_2$ and $(M/S)_1$], and Eq. [11] reduces to $V = V^\circ = (\phi_M)_{2,a} - (\phi_M)_{1,a}$. If the two electrodes are identical, then $V^\circ = 0$. In constructing Fig. 2, this assumption was not invoked, *i.e.*, $(\phi_M)_{2,a}$ and $(\phi_M)_{1,a}$ are shown to be quite different.

For case (b) above, a magnetic field is applied and, therefore, $\Delta\phi_{MAG} = 2Bav_m$. However, open-circuit conditions still apply and, consequently, the interfacial potential differences must remain the same as in case (a) ($\eta_1 = \eta_2 = 0$). This is illustrated in Fig. 2 where, for example, one observes that $(\phi_S)_{2,a}$ increases to $(\phi_S)_{2,b}$ and, in order to maintain a constant interfacial potential difference at $(M/S)_2$, $(\phi_M)_{2,a}$ increases identically to $(\phi_M)_{2,b}$. With $\Delta_2\phi_1 = \Delta\phi_{MAG}$, Eq. [11] reduces to Eq. [12]

$$V = V^\circ + \Delta\phi_{MAG} \quad [12]$$

which, in view of Eq. [5], becomes

$$V = V^\circ + 2Bav_m \quad [13]$$

Equation [13], an equation which enables one to calculate average flow velocities from open-circuit potential measurements and known values of B and a, serves as the basis for electromagnetic flow measurements (6). Moreover, according to Eq. [12], one may determine $\Delta\phi_{MAG}$ directly from potential measurements for those cases where insufficient data are available to calculate $\Delta\phi_{MAG}$ via Eq. [5], or where $\Delta\phi_{MAG}$ deviates from the value indicated by Eq. [5]. Experimental verification of Eq. [13] for the system under study is presented in the results section.

For case (c), with the magnetic field applied, electrodes M_1 and M_2 are externally short-circuited and, therefore, assuming the *IR*-drop in the highly conductive metallic phases is negligible, $(\phi_M)_{2,c}$ and $(\phi_M)_{1,c}$ must be equal. The common potential must lie somewhere between $(\phi_M)_{2,b}$ and $(\phi_M)_{1,b}$ and, consequently, it is clear from Fig. 2 that, for the system as shown, $(\phi_M)_2$ must increase from $(\phi_M)_{2,b}$ to $(\phi_M)_{2,c}$ while $(\phi_M)_1$ must decrease from $(\phi_M)_{1,b}$ to $(\phi_M)_{1,c}$, *i.e.*, η_2 becomes positive and η_1 negative. These changes in interfacial potential differences require finite faradaic currents to flow at both electrodes (Eq. [10]), *i.e.*, one electrode (M_2 for the system as illustrated in Fig. 2) must become anodically polarized (η_2 positive) while the other electrode becomes cathodically polarized (η_1 negative). Suppose, however, that M_1 and M_2 were identical electrodes, *i.e.*, $(\phi_M)_{1,a} = (\phi_M)_{2,a}$. Then, for the same $\Delta\phi_{MAG}$ shown in Fig. 2, $(\phi_M)_{2,b}$ would be greater than $(\phi_M)_{1,b}$ and, upon short-circuiting the electrodes, $(\phi_M)_2$ would necessarily decrease to the common potential while $(\phi_M)_1$ would increase to the same potential, *i.e.*, M_2 would become cathodically polarized (η_2 negative) and M_1 anodically polarized (η_1 positive). In general, if the open-circuit value of V is positive, then upon short-circuiting M_1 and M_2, electrons in the external circuit flow from M_1 to M_2, *i.e.*, M_1 becomes

the anode (net oxidation) and M_2 the cathode (net reduction). It should be noted that a reversal in the sign of the vector cross product, $\mathbf{v} \times \mathbf{B}$, resulting from a change in either the direction of the magnetic field or the fluid flow would be accompanied by a change in the sign of $\Delta\phi_{MAG}$, *i.e.*, in Fig. 2, $(\phi_S)_2 - (\phi_S)_1$ would be negative rather than positive.

The preceding discussion of the potential-distance profiles shown in Fig. 2 provides a qualitative understanding of what occurs when electrodes M_1 and M_2 are externally short-circuited in the presence of a magnetic field. A quantitative analysis of the problem follows. When M_1 and M_2 are short-circuited, the net faradaic currents at the two electrodes must be equal in magnitude and opposite in sign, *i.e.*

$$A_1\bar{i}_1 = -A_2\bar{i}_2 \qquad [14]$$

where A_1 and A_2 are the surface areas of the electrodes. According to Eq. [11], with $V = 0$ (Eq. [6], short-circuited condition) and $V^\circ = 0$ (electrodes assumed to be identical)

$$\eta_2 - \eta_1 = -\Delta\phi_{MAG} \qquad [15]$$

In writing Eq. [15], $(\Delta_2\phi_1)_S$ has been equated to $\Delta\phi_{MAG}$.[1] Equations [10], [14], and [15] are sufficient for the quantitative evaluation of the magnetic field effect on the electrochemical system. In order to illustrate the procedure, suppose the oxidation and reduction reactions occurring at the electrodes, for example, the anodic oxidation of the metal to form metallic ions in solution and the cathodic reduction of protons to form H_2, are both under activation control (as in the case of the Ti/H_2SO_4 system), and, furthermore, let it be assumed that the partial current densities corresponding to the anodic ($\bar{i}_a$) and cathodic ($\bar{i}_c$) reactions are given by Eq. [16] and [17], respectively

$$\bar{i}_a = k_a \exp(\beta_a \Delta_M\phi_S) \qquad [16]$$

and

$$\bar{i}_c = k_c \exp(-\beta_c \Delta_M\phi_S) \qquad [17]$$

where k represents a rate constant, and β represents a Tafel constant, *i.e.*, $\beta_a = (\partial \ln \bar{i}_a/\partial\Delta_M\phi_S)$. The net faradaic current density ($\bar{i}$) at the electrode is given by Eq. [18]

$$\bar{i} = \bar{i}_a - \bar{i}_c \qquad [18]$$

which, in view of Eq. [9], [16], and [17], may be rewritten in the form

$$\bar{i} = \bar{i}^\circ[\exp(\beta_a\eta) - \exp(-\beta_c\eta)] \qquad [19]$$

where $\bar{i}^\circ = \bar{i}_a^\circ = \bar{i}_c^\circ$ for $\Delta_M\phi_S = \Delta_M\phi_S^\circ$. If values of $\bar{i}_1$ and $\bar{i}_2$ from Eq. [19] are inserted into Eq. [14], a second relationship (in addition to Eq. [15]) is established between η_1 and η_2

$$A_1\bar{i}_1^\circ[\exp(\beta_{a1}\eta_1) - \exp(-\beta_{c1}\eta_1)] = -A_2\bar{i}_2^\circ[\exp(\beta_{a2}\eta_2) - \exp(-\beta_{c2}\eta_2)] \qquad [20]$$

Since $\Delta\phi_{MAG}$ is known (Eq. [5] or [12]), Eq. [15] and [20] enable one to calculate η_1 and η_2. Having determined η_1 and η_2, one may evaluate $\bar{i}_1$ and $\bar{i}_2$ by means of Eq. [19]. For illustrative purposes, suppose the two electrodes are identical, *i.e.*, $\beta_{a1} = \beta_{a2}$, $\beta_{c1} = \beta_{c2}$, and $\bar{i}_1^\circ = \bar{i}_2^\circ$. For the "small polarization" case *i.e.*, $\exp(\pm\beta\eta) \approx 1 \pm \beta\eta$, and assuming $A_1 = A_2$, Eq. [15] and [20] lead to the particularly simple result, $\eta_1 = -\eta_2 = \Delta\phi_{MAG}/2$. In actual practice, the various simplifying assumptions made above are unnecessary. In particular, a quantitative analysis requires only that the i/η polarization curves in the absence of a magnetic field be experimentally established, not that the explicit mathematical relationship between $\bar{i}$ and η be determined. The polarization curves, together with $\Delta\phi_{MAG}$ and Eq. [14] and [15], suffice to quantitatively evaluate the effect of the applied magnetic field on the electrochemical system.

In order to determine the electrochemical polarization behavior of a particular metal/electrolyte system, one employs a conventional three-electrode cell (test, reference, and counter electrodes), and measures the faradaic current at the test electrode as a function of the potential (E) of the test electrode relative to an arbitrary reference electrode (Pt/H_2, SCE, etc.). Any magnetically induced potential difference in the electrolyte phase between the test and reference electrodes ($\Delta\phi_{MAG}$) is included in E, *i.e.*

$$E = \eta + \Delta\phi_{MAG} + E^\circ \qquad [21]$$

where E°, the open-circuit potential of the test electrode when $\Delta\phi_{MAG} = 0$, depends on the specific reference electrode used, and where the IR drop in the electrolyte phase between the test and reference electrodes attributable to the faradaic current has been corrected for or, as in the present work, is negligible ($<<1$ mV). According to Eq. [21] and [10], the faradaic current density, $\bar{i} = f(\eta)$, is a function not only of E, but also of $\Delta\phi_{MAG}$. One may quantify the effect of a magnetic field on the polarization curve ($\bar{i}$ *vs.* E) by substituting η from Eq. [21] into the appropriate $\bar{i}/\eta$ equation, for example, into Eq. [19]. Again, it is not necessary to determine the explicit mathematical relationship between $\bar{i}$ and E (or $\bar{i}$ and η) in order to quantitatively evaluate the effect of a magnetic field on the polarization data. One may obtain the $\bar{i}/\eta$ polarization curve in the absence of a magnetic field by measuring $\bar{i}$ as a function of E and evaluating η in accordance with Eq. [21], *i.e.*, $\eta = E - E^\circ$. Then, if E is potentiostatically maintained at E° and $\bar{i}$ measured as a function of $\Delta\phi_{MAG}$, the identical $\bar{i}/\eta$ polarization curve must be obtained when η is again evaluated in accordance with Eq. [21], *i.e.*, $\eta = -\Delta\phi_{MAG}$. This conclusion is verified in the results section. Finally, if E_1 and E_2 refer to electrodes M_1 and M_2, respectively, in Fig. 1, then with $\eta_1 = E_1 - E_1^\circ$ and $\eta_2 = E_2 - E_2^\circ$, Eq. [15] may be rewritten in the form

$$E_2 - E_1 = -\Delta\phi_{MAG} \qquad [22]$$

In view of Eq. [22], the polarization curves, $\bar{i}_1 = f(E_1)$ and $\bar{i}_2 = g(E_2)$, measured in the absence of the magnetic field, together with $\Delta\phi_{MAG}$ and Eq. [14], enable one to quantitatively evaluate the magnetic field effect for case (c) described above.

Results

According to Eq. [13], at a constant flow velocity, the open-circuit potential difference between electrodes M_1 and M_2 (or between Pt_1 and Pt_2) in Fig. 1 should be a linear function of the magnetic flux density. A test of Eq. [13], using the two Pt electrodes, is shown in Fig. 3. Since the two electrodes are identical, $V^\circ = 0$, the straight line passes through the origin. The slope of the straight line, $(\partial V/\partial B) = 2av_m$, corresponds to an average flow velocity of 653 cm/sec. The same flow velocity measured with two Ti electrodes in positions M_1 and M_2 was 648 cm/sec, whereas, that obtained using either M_1(Ti) and Pt_2 or M_2(Ti) and Pt_1 was 650 cm/sec. Deviations in the average flow velocity over a period of 6 hr did not exceed ±0.3%.

The effect of a magnetic field on the electrochemical polarization behavior of a metal/flowing-electrolyte

[1] In the derivation of $\Delta\phi_{MAG}$ (Eq. [5]) presented in the discussion section, it will be shown that, for a metallic pipe (conducting-wall case), $(\Delta_2\phi_1)_S = \Delta\phi_{MAG}$. In the results section it will be shown that for the glass cell described above, and for the system under investigation, the IR drop in the electrolyte phase attributable to the faradaic current is entirely negligible.

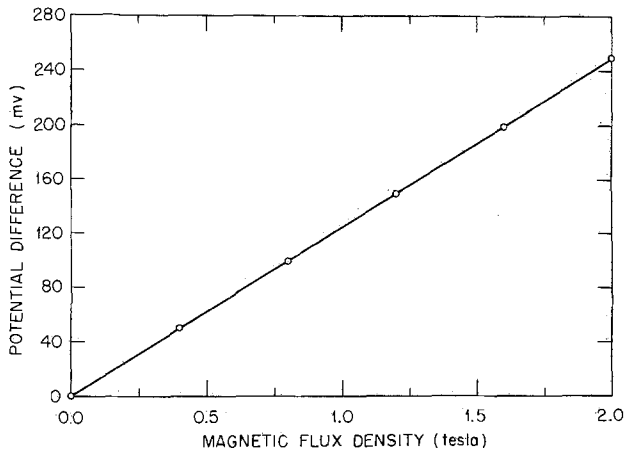

Fig. 3. Test of Eq. [13] Open-circuit potential difference between the two Pt or Ti electrodes (Fig. 1) as a function of the magnetic flux density at a constant flow velocity (v_m = 650 cm/sec).

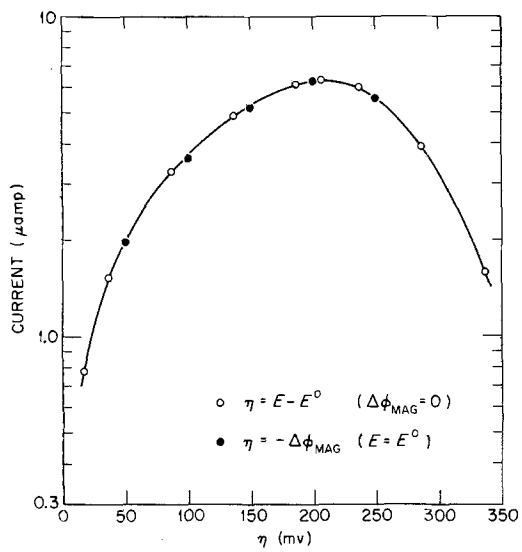

Fig. 4. Effect of magnetic field on the electrochemical polarization behavior of Ti. Test of Eq. [21]. Anodic current measured as a function of E with $\Delta\phi_{MAG} = 0$ (open circles), and as a function of the magnetic flux density at constant E and v_m, i.e., as a function of $\Delta\phi_{MAG}$ (solid circles).

system is illustrated by the results shown in Fig. 4. In the determination of the polarization curves, the titanium and platinum electrodes opposite the titanium test electrode served as the counter and reference electrodes, respectively. The anodic polarization curve for titanium, measured in the absence of a magnetic field (open circles), is independent of flow velocity, and virtually identical with results reported earlier (4, 5). As the potential of titanium is made increasingly positive relative to the open-circuit (corrosion) potential ($E°$ = −735 mV *vs.* SCE), the anodic current corresponding to the oxidation of Ti to Ti(III) ions in solution increases to a maximum at η = 205 mV (E_{MAX} = −530 mV *vs.* SCE), and then decreases as the metal is transformed from the active to the passive state. In this experiment, i was measured as a function of E, and η was calculated in accordance with Eq. 21, *i.e.*, $\eta = E - E°$. The anodic polarization curve was also determined by potentiostatically maintaining the potential of the test electrode at its open-circuit value (*i.e.*, $E = E°$), and measuring i as a function of the magnetic flux density at a constant flow velocity of approximately 650 cm/sec. Again, η was calculated in accordance with Eq. [21], *i.e.*, $\eta = -\Delta\phi_M = -2aBv_m$, and the resultant polarization curve, $i = f(\eta)$, is shown by the solid circles in Fig. 4. In agreement with the theory discussed in connection with Eq. [21], the polarization curves determined by the two methods are coincident. The potentiostat method was used to determine the resistance of the electrolyte phase between the test and reference electrodes (4). The potential of the test electrode was suddenly (<1 μsec) changed from an initial value (E_1) to a second constant value (E_2), and the resulting current-time transient was displayed on an oscilloscope and recorded on film. From an extrapolation of the current-time curve in the microsecond time region (10-100 μsec) to t = 0, the value of $(i_2)_{t=0}$, the current at E_2 for t = 0, was determined, and the electrolyte resistance (R_S) calculated by means of Eq. [23]

$$R_S = (E_2 - E_1)/[(i_2)_{t=0} - i_1] \qquad [23]$$

The solution resistance was only 8.25 ± 0.7% Ω and, consequently, even at the maximum faradaic current (6.3×10^{-6}A in Fig. 4), the IR drop in the electrolyte phase amounted to only 0.05 mV, a negligible ohmic correction. Within indicated limits of reproducibility, the solution resistance was found to be independent of the magnetic flux density (0-2.1 Tesla) over the entire range of flow velocities employed in this study.

The anodic polarization curve for the titanium electrode located in position M_1 (see Fig. 1), and the cathodic polarization curve for the titanium electrode located in position M_2, both determined in the absence of a magnetic field ($\Delta\phi_{MAG}$ = 0), are shown in Fig. 5. When the two electrodes are externally short-circuited, and a magnetic field applied to the flowing electrolyte (see Fig. 1 for the directions of v and B), the titanium electrode in position M_1 becomes anodically polarized while the electrode in position M_2 becomes cathodically polarized, the faradaic current being equal in magnitude but opposite in sign at the two electrodes. According to Eq. [22], the magnitude of the magnetically induced faradaic current may be determined by simply locating on Fig. 5 that current for which $E_2 - E_1 = -\Delta\phi_{MAG} = -2Bav_m$. Thus, the magnetic field effect may be

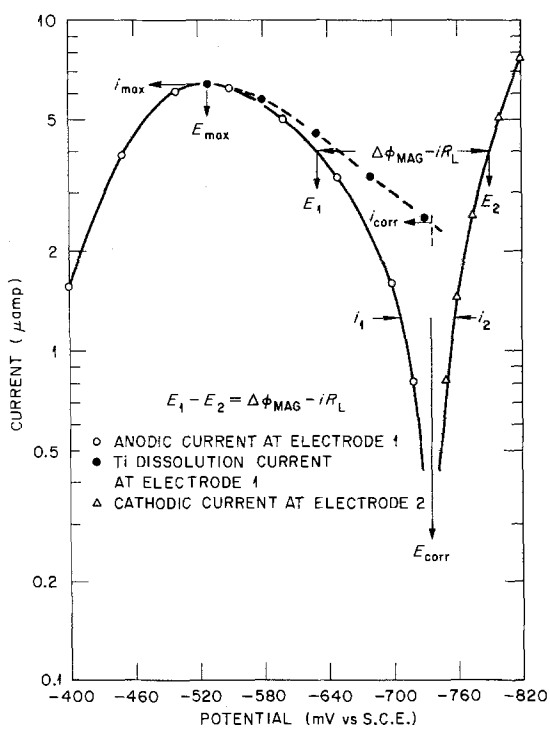

Fig. 5. Anodic and cathodic polarization curves for the two Ti electrodes, M_1 and M_2, respectively, shown in Fig. 1. Curves measured in the absence of a magnetic field ($\Delta\phi_{MAG}$ = 0). See Eq. [24].

quantitatively evaluated by a simple graphical procedure. In order to prove experimentally the validity of the theory, the two electrodes were connected through an external precision resistor (R_L), and the faradaic current determined by measuring the potential difference (IR_L) across the load resistor. Of course, Eq. [22] must be corrected to account for the potential difference appearing across the load resistor, *i.e.*

$$E_1 - E_2 = \Delta\phi_{MAG} - IR_L \qquad [24]$$

a correction indicated in Fig. 5. In Fig. 6, the net faradaic current is shown as a function of R_L at constant $\Delta\phi_{MAG}$, *i.e.*, at constant v_m and B. The open circles show the current determined by application of Eq. [24] to the net polarization curves (solid lines) shown in Fig. 5, while the solid circles show the current determined by measuring the potential difference across R_L. The results are in excellent agreement.

The currents shown by the solid curves in Fig. 5 are net currents. The partial anodic polarization curve corresponding to just the titanium dissolution reaction, *i.e.*, the net anodic polarization curve corrected for the hydrogen evolution reaction, is shown by the dashed line in Fig. 5, and was determined by measuring the concentration of Ti(III) ions in solution as a function of time at constant potential for the various potential values shown by the solid circles (5). Once E_1 and E_2 have been determined by applying Eq. [24] to the net polarization curves in Fig. 5, the actual dissolution rates at E_1 and E_2, along with the rates of the hydrogen evolution reaction, may be evaluated by means of the dashed (partial) curve. The open-circuit corrosion rate (i_{corr}) in the absence of a magnetic field is shown in Fig. 5 for comparative purposes. At E_{MAX}, the contribution of the hydrogen evolution reaction to the net anodic current is negligible (<2%), *i.e.*, the net and partial anodic currents are virtually identical. Then, a comparison of the maximum current (i_{MAX}) to i_{corr} shows that the maximum enhancement of the dissolution rate of titanium in this system is limited to a factor, (i_{MAX}/i_{corr}) = 2.5. Further increases in $\Delta\phi_{MAG}$ are accompanied by a decrease in the net current as a result of the transformation of the anode from the active to the passive state at potentials more positive than E_{MAX}.

Figure 7 shows the results of an experiment in which R_L was maintained constant at a mere 200Ω, and the current was measured as a function of the magnetic flux density at a constant flow rate. Again, the currents determined by direct measurement (solid circles), *i.e.*, by measuring the potential difference across R_L, and those determined by the application of Eq. [24] to the polarization curves shown in Fig. 5, are in excellent agreement.

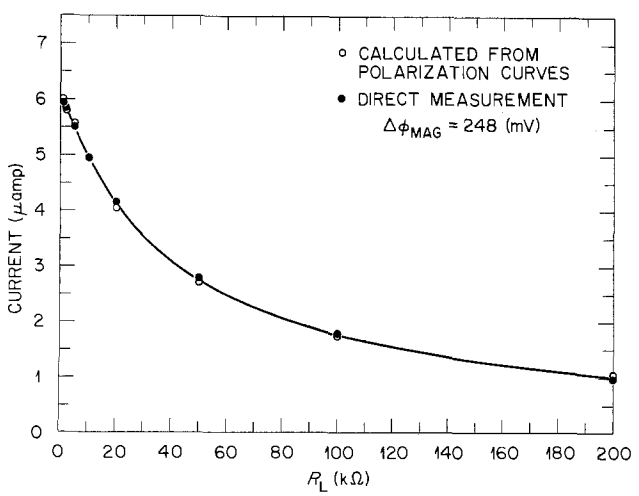

Fig. 6. Faradaic current at the Ti electrodes, M_1 and M_2 in Fig. 1, when connected through an external resistance (R_L), as a function of R_L at constant $\Delta\phi_{MAG}$. Application of Eq. [24], using the curves shown in Fig. 5.

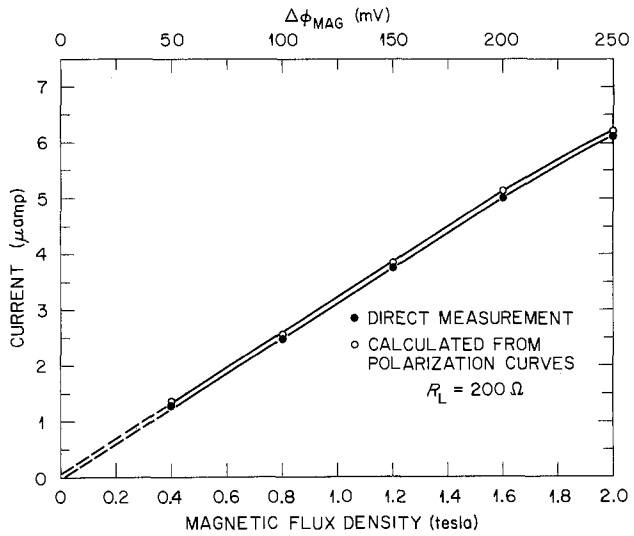

Fig. 7. Faradaic current at the Ti electrodes, M_1 and M_2 in Fig. 1, when connected through an external resistance of 200Ω, as a function of the magnetic flux density at constant v_m, *i.e.*, as a function of $\Delta\phi_{MAG}$. Test of Eq. [24].

Discussion

The experimental results presented in the preceding section establish the validity of the theoretical analysis of the effect of a magnetic field on electrochemical reactions occurring at a metal/flowing-electrolyte interface. However, the experiments necessarily involved the use of discrete electrodes set in the nonconducting wall of a Pyrex glass pipe (see Fig. 1), *i.e.*, in order to establish that the results of the short-circuit (metallic pipe analogue) experiments shown in Fig. 6 and 7 were in agreement with theoretical expectations, it was necessary to determine the anodic and cathodic polarization curves shown in Fig. 5, and the electrochemical polarization measurements, in turn, required the use of discrete electrodes in a nonconducting wall. In the following discussion, it will be shown that the analysis is equally valid for metallic pipes and, in the course of extending the theory to include the conducting-wall case, the origin and limitations of Eq. [5] will be examined. In brief, the conducting-wall case is distinguished by the wall-shorting effect, an effect which is a function of the specific conductivities of the metal and electrolyte phases, the electrochemical polarization resistance, and the inner and outer radii of the pipe. Using appropriate values of the aforementioned parameters, one finds that the wall-shorting effect is negligible for the systems of interest and consequently, the results obtained for the nonconducting-wall case apply quantitatively to metallic pipes.

The form of Ohm's law appropriate to the electrolyte phase in MHD systems is given by Eq. [25]

$$\mathbf{j}_S = \sigma(\mathbf{E} + \mathbf{v} \times \mathbf{B}) \qquad [25]$$

where, at a point in the electrolyte phase, j_S represents the current density, E is the electric field intensity, B is the magnetic flux density, v is the fluid velocity, and σ is the specific conductivity of the electrolyte. Equation [25] may be derived by expressing j_S in terms of the "drift velocities" of the ionic components of the electrolyte, and taking into account the fact that the drift velocities are proportional to the Lorentz electromagnetic forces acting on the ions and are negligibly small (drift velocities under a potential gradient of 1 V/cm, *i.e.*, conven-

tional ionic mobilities, are typically on the order of $\sim 5 \times 10^{-4}$ cm^2 sec^{-1} V^{-1}) compared to the fluid velocities of interest in this work (7). The equation is more frequently derived, however, by noting that in the coordinate system which moves with the fluid (indicated by prime marks), $\mathbf{j}_S' = \sigma\mathbf{E}'$. If the Maxwell-Lorentz transformations to the laboratory frame of reference are applied, then $\mathbf{j}_S'$ and $\mathbf{E}'$ become $\mathbf{j}_S$ and $(\mathbf{E} + \mathbf{v} \times \mathbf{B})$, respectively, and, consequently, one obtains Eq. [25] directly (8). In addition to Ohm's law, the analysis requires the use of the basic Maxwell equations

$$\nabla \times \mathbf{E} = -(\partial\mathbf{B}/\partial t) = 0 \qquad [26a]$$

$$\mathbf{E} = -\nabla\phi \qquad [26b]$$

$$\nabla \times \mathbf{B} = \mu\mathbf{j} + \mu(\partial\mathbf{D}/\partial t) = \mu\mathbf{j} \qquad [27a]$$

$$\nabla \cdot \mathbf{j} = 0 \qquad [27b]$$

where $\mathbf{D}$ is the electric displacement vector, and μ is the magnetic permeability of the medium. For the steady-state case, $(\partial\mathbf{B}/\partial t) = 0$ and $(\partial\mathbf{D}/\partial t) = 0$, Eq. [26b] and [27b] follow directly from Eq. [26a] and [27a], respectively, recalling in the latter case that div.(curl) $= 0$. For the electrolyte phase, Eq. [25], [26b], and [27b] may be combined to obtain Eq. [28]

$$\nabla^2\phi_S = \nabla \cdot (\mathbf{v} \times \mathbf{B}) \qquad [28]$$

For the geometry illustrated in Fig. 1, and transforming to the polar coordinate system shown therein, Eq. [28] may be written in the form

$$(\partial^2\phi_S/\partial r^2) + (1/r)(\partial\phi_S/\partial r) + (1/r^2)(\partial^2\phi_S/\partial\theta^2) = B(dv/dr)\sin\theta \qquad [29]$$

In writing Eq. [28] in this form, use was made of the vector identity, $\nabla \cdot (\mathbf{v} \times \mathbf{B}) = \mathbf{B} \cdot (\nabla \times \mathbf{v}) - \mathbf{v} \cdot (\nabla \times \mathbf{B})$, and the fact that $\mathbf{v} \cdot (\nabla \times \mathbf{B}) = \mathbf{v} \cdot (\mu\mathbf{j}_S) = 0$. The solution of Eq. [29] is given by Eq. [30]

$$\phi_S = \psi \sin\theta + \phi_S^0 \qquad [30]$$

where ψ is a function of r only (9). If one substitutes ϕ_S and its partial derivatives with respect to r and θ into Eq. [29], and integrates from $r = 0$ to $r = a$ (see Fig. 1), then, noting that $v = 0$ at $r = a$, one obtains the result

$$a^2\psi'_{r=a} - a\psi_{r=a} = -Ba^2v_m \qquad [31]$$

where $\psi'_{r=a}$ refers to $(d\psi/dr)$ evaluated at $r = a$, and where v_m, the average flow velocity of the fluid, was defined in the theory section. According to Eq. [25], since $v = 0$ at $r = a$, the component of $\mathbf{j}_S$ normal to the wall at $r = a$, *i.e.*, $(\mathbf{j}_S \cdot \mathbf{r}_u)_{r=a}$ is given by the expression

$$(\mathbf{j}_S \cdot \mathbf{r}_u)_{r=a} = -\sigma(\partial\phi_S/\partial r)_{r=a} = -\sigma\psi'_{r=a}\sin\theta \qquad [32]$$

where $\mathbf{r}_u$ is a unit vector normal to the wall. For a glass pipe, the nonconducting wall case $(\mathbf{j}_S \cdot \mathbf{r}_u)_{r=a} = 0$, and, therefore, $\psi'_{r=a} = 0$, *i.e.*, Eq. [31] reduces to Eq. [33]

$$\psi_{r=a} = Bav_m \qquad [33]$$

Substitution of $\psi_{r=a}$ from Eq. [33] into Eq. [30] gives the result

$$(\phi_S)_{r=a} = Bav_m \sin\theta + \phi_S^\circ \qquad [34]$$

As shown in Fig. 1, $\sin\theta$ is equal to 1 and -1 at M_2 and M_1, respectively, and therefore, according to Eq. [34], $(\phi_S)_2 - (\phi_S)_1$, *i.e.*, $\Delta\phi_{MAG}$, is given by Eq. [5]

$$\Delta\phi_{MAG} = 2Bav_m \qquad [5]$$

In order to extend the analysis to metallic pipes (conducting-wall case), it is necessary to consider a few additional equations relating to the metal phase and boundary conditions. The appropriate form of Ohm's law for the metal phase (wall at rest) is

$$\mathbf{j}_M = -\kappa\nabla\phi_M \qquad [35]$$

where κ is the specific conductivity of the metal. With $\nabla \cdot \mathbf{j}_M = 0$ (Eq. [27b]), the potential in the metallic phase is described by the Laplace equation

$$\nabla^2\phi_m = 0 \qquad [36]$$

The component of $\mathbf{j}_M$ normal to the wall at $r = b$, $(\mathbf{j}_M \cdot \mathbf{r}_u)_{r=b}$, is equal to zero, *i.e.*

$$(\mathbf{j}_M \cdot \mathbf{r}_u)_{r=b} = -\kappa(\partial\phi_M/\partial r)_{r=b} = 0 \qquad [37]$$

With this boundary condition, the solution of Eq. [36] may be written in the form

$$\phi_M = C_1[(r/b^2) + (1/r)]\sin\theta + \phi_M^\circ \qquad [38]$$

where C_1 is a constant determined by the boundary conditions at $r = a$ (9). At $r = a$, the boundary condition is $(\mathbf{j}_S \cdot \mathbf{r}_u) = (\mathbf{j}_M \cdot \mathbf{r}_u) = -i$, *i.e.*

$$\sigma(\partial\phi_S/\partial r)_{r=a} = \kappa(\partial\phi_M/\partial r)_{r=a} = \bar{i} \qquad [39]$$

For the purpose of this analysis, the linearized form of $\bar{i}$ given by Eq. [19] is used, *i.e.*, with $\exp(\pm\beta\eta) = (1 \pm \beta\eta)$, $\bar{i}$ becomes

$$\bar{i} = (1/\tau)(\Delta_M\phi_S - \Delta_M\phi_S^\circ) \qquad [40]$$

where τ, the electrochemical polarization resistance, is equal to $[i^\circ(\beta_a + \beta_c)]^{-1}$. Using Eq. [30], [31], and [38], together with the boundary conditions represented by Eq. [39] and [40], one may solve for ϕ_S at $r = a$

$$\phi_S = [(Bav_m \sin\theta)/(1 + Z)] + \phi_S^\circ \qquad [41]$$

where the dimensionless Z is given by Eq. [42]

$$Z = [(\kappa/\sigma)(b^2 - a^2)]/[(\tau\kappa/a)(b^2 - a^2) + (a^2 + b^2)] \qquad [42]$$

According to Eq. [41], the potential difference in the electrolyte phase between the points (a, θ) and $(a, -\theta)$ is given by Eq. [43]

$$(\Delta_{\theta\phi-\theta})_S = [2Bav_m/(1 + Z)]\sin\theta \qquad [43]$$

For the particular case of $\Delta\phi_{MAG}$, defined as $(\phi_S)_2 - (\phi_S)_1$, $\sin\theta = 1$ and, consequently, Eq. [43] reduces to the result

$$\Delta\phi_{MAG} = 2Bav_m/(1 + Z) \qquad [44]$$

where Eq. [44] is to be compared with Eq. [5]. The wall-shorting effect represented by the coefficient $1/(1 + Z)$ in Eq. [43] is negligible, *i.e.*, $(1 + Z) \approx 1$, for systems of interest. This may be seen by evaluating Z in accordance with Eq. [42], using the following data: $\kappa = 1.75 \times 10^6\ \Omega^{-1}$ m^{-1}, $\sigma = 22.5\ \Omega^{-1}$ m^{-1}, $\tau = 0.3\ \Omega$ m^2, $a = 9.53 \times 10^{-3}$m, and $b = 1.27 \times 10^{-2}$m. The calculated value of Z is 1.41×10^{-3} and, consequently, Eq. [43] reduces to Eq. [5]. If $\tau = \infty$, as in the case of a glass pipe, $Z = 0$ and, again, one obtains Eq. [5].

The interfacial potential difference $(\Delta_M\phi_S)$ corresponding to any value of θ is given by Eq. [45]

$$\Delta_M\phi_S = \Delta_M\phi_S^\circ - [Z\tau\sigma Bv_m/(1 + Z)]\sin\theta \qquad [45]$$

Substitution of $\Delta_M\phi_S$ from Eq. [45] into Eq. [40] gives the net faradaic current density at a point on the inner circumference of the pipe for any value of θ, *i.e.*

$$\bar{i} = -[Z\sigma Bv_m/(1 + Z)]\sin\theta \qquad [46]$$

Equation [46] shows that $\bar{i}$ varies from 0 at $\theta = 0$

to the maximum cathodic ($\theta = 90°$) and anodic ($\theta = 270°$) values at positions corresponding to M_2 and M_1, respectively, in Fig. 1. According to Eq. [9] and [40], $\bar{i}$ may be written in the form $\bar{i} = (1/\tau)\eta$, and, as was shown in the theory section, for the "small polarization" case involving short-circuited identical electrodes in positions M_1 and M_2, $\eta_1 = -\eta_2 = \Delta\phi_{MAG}/2$, *i.e.*

$$\bar{i}_1 = -\bar{i}_2 = (1/2\tau)\Delta\phi_{MAG} \qquad [47]$$

With $(1 + Z) \approx 1$, Z is virtually equal to $(a/\sigma\tau)$ and, therefore, for positions M_1 and M_2, Eq. [46] also reduces to Eq. [47]. If the values, $\Delta\phi_{MAG} = 250$ mV and $\tau = 0.3\ \Omega\ m^2$, are substituted into Eq. [47], the calculated value of $\bar{i}$ is 5.2×10^{-6} A/cm^2. The observed value is 6.2×10^{-6} A/cm^2 (see Fig. 7). The difference between the observed and calculated values of $\bar{i}$ is to be attributed to the deviation from the linearized relationship between $\bar{i}$ and $\Delta_M\phi_S$ (Eq. [40]) at high values of $|\eta|$. The assumption of a linear relationship between $\bar{i}$ and $\Delta_M\phi_S$ facilitated the analysis while not materially affecting its purpose, namely, to extend the theory to include metallic pipes and to demonstrate that the wall-shorting effect is negligible. It should be apparent that the magnetic field effect on electrochemical systems described by Eq. [19], with large values of β_a and β_c, can be very much larger than that observed in the present study of the Ti/H_2SO_4 system.

Conclusion

The results of this investigation clearly demonstrate the adverse effect of an applied magnetic field on the corrosion behavior of metals in contact with a flowing electrolyte. In the case of the Ti/H_2SO_4 system, the maximum increase in the active-state dissolution rate of the metal was limited to a factor of 2.5, a limit resulting from the passivation characteristics of titanium in 1*N* H_2SO_4. Depending on the specific metal/electrolyte system, one might expect dissolution enhancement factors many times greater than that observed in this work, all other factors remaining constant (geometry, flow velocity, magnetic flux density, etc.). Moreover, it should be emphasized that in addition to the adverse effect of a magnetic field on the "uniform" corrosion behavior of metals, the imposition of a magnetic field can also lead to enhanced susceptibility to stress corrosion cracking, localized (pitting or crevice) corrosion, oxidation and reduction of solution species, etc., and, in the limit, to electrochemical decomposition of the electrolyte. The aforementioned phenomena, to name a few, are all potential-dependent electrochemical processes and, as such, are subject to the magnetic field effect. In order to illustrate the unusual corrosion situations that could arise as a result of the magnetic field effect, consider a metal/flowing-electrolyte system which, in the absence of an applied magnetic field, exhibited an open-circuit corrosion potential corresponding to the near passive potential region, *i.e.*, to a potential somewhat positive to the active-passive transition potential region. Upon imposition of the magnetic field, one-half of the pipe would become anodically polarized as its interfacial potential difference moved in the positive (noble) direction, while the other half would become cathodically polarized. The anodically polarized section might be polarized to the transpassive potential region, and the cathodically polarized section to the active-passive transition potential region, both potential regions of enhanced susceptibility to stress corrosion cracking. Further polarization could result in activation of the once passive cathodically polarized section. The anodically polarized section, depending on the specific metal/electrolyte system, could encounter a pitting potential or a potential region of enhanced crevice corrosion. In considering the various possibilities, it should be noted that $\Delta\phi_{MAG}$ is directly proportional to the magnetic flux density and, consequently, in contrast to the relatively small value observed in the work ($\Delta\phi_{MAG} = 0.25$V at $B = 2.0$ Tesla), $\Delta\phi_{MAG}$ would attain a value of 1.5V at $B = 12$ Tesla, all other factors remaining constant. The magnetic field effect described in this paper poses potentially serious corrosion and other electrochemical problems for metal/flowing-electrolyte systems, and must be considered carefully when evaluating such systems for applications involving magnetic fields.

Acknowledgment

The author is especially indebted to Mr. A. A. Palko for his collaboration in assembling the forced-convection loop and the refrigeration system used in this program. ABSTRACT

Adherent films of polymers on different metal surfaces are formed by the electroinitiated polymerization of acrylonitrile alone and of mixtures of acrylonitrile and acrylic acid in 0.05*N* H_2SO_4 aqueous solution. Five different metals—aluminum, nickel, copper, stainless steel and steel—are used as the cathodes for purposes of the coatings while platinum plate is the anode in each case. The electrolysis is carried out under a constant voltage. After the electrolytic runs, the coatings are scraped off the metals for infrared analysis to establish the functional groups. Furthermore, the scanning electron microscope (SEM) is used to examine the structure of the film surfaces. The effects of variable monomer concentrations and polymerization voltages on thickness and appearance of the film are also investigated. Corrosion tests are performed to compare the corrosion resistance of coated and uncoated metals in various corrosive solutions, through both the weight-loss and the electrochemical methods. It is observed that good and uniform coatings always reduce the corrosion rate of the metals (*e.g.*, coated nickel and copper). However, porous coatings are seen to accelerate the corrosion rate of the support metals (coated aluminum, for example). Also, it is observed that the monomer concentration and voltage for the electroinitiated polymerization process have some influence on the corrosion resistance of coated metals. All of these phenomena are explained through the surface structure and thickness of the coatings,

Electrocoating is a relatively new technique that was industrially initiated during the 1960's (1). In electrocoating, the object is dipped into a tank of paint and a current is passed through the system whereby the paint material is attracted to the article and is then plated out on its surface. The essential point to be noted in electrocoating is that an already formed polymer (paint) is deposited on a metal surface by employing electrophoretic processes.

Electroinitiated polymerization of monomers onto metal surface is quite different from electrodeposition. Polymerization initiated by electrolysis has been reported by some investigators (2-5). However, all these early works have been carried out with the objective of achieving polymerization within the cell solution. In the research reported here, polymerization is initiated by electrolysis as reported above but with the modified objective of depositing these polymers onto different metals to form protective films and thus resist corrosion, enabling practical use of these metals or objects. The formation of adherent films of polymer on metal electrodes by electroinitiated polymerization of monomers has been reported in earlier work from our laboratories (6, 7).

Corrosion is the destructive attack of a metal by chemical or electrochemical reaction with its environment. Reduction or practical elimination of corrosion is possible by anything that interferes with these reactions. Protective coatings such as paint can bring about this. However, the manual or mechanical application of paint or protective coating has its inherent disadvantages and gives rise to additional problems. In electroinitiated polymerization, since it is directly formed from the monomer, the film will be more economical and more uniform than other organic coatings which are obtained through electrodepositing polymers on metal surface.

Key words: comonomers, corrosion, micrographs, constant voltage, static cell.

Experimental

Materials.—Acrylonitrile (AN), a pure Aldrich product, is washed with 5% NaOH and then with 5% H_3PO_4 and dried under anhydrous Na_2SO_4 or $CaSO_4$ for several days, then stored in a refrigerator for use. Acrylic acid (AA) and N,N-dimethyl formamide (DMF) (pure Aldrich products), $NaNO_3$ (Baker) and concentrated H_2SO_4 (Mallinckrodt analytical grade) are used without further treatment.

Preparation of metal surface for coating.—An adequate preparation of the metal surface is very important for adhesive bonding. As a first step all ink markings and other foreign matter are removed from the metals by washing with soap, water and acetone, and then degreased with trichloroethylene. Different cleaning steps for different metals are then followed, as recommended in the literature (8).

Electrolytic cell and polymerization runs.—In order to obtain a coating on both sides of the metal cathode, the electrolytic cell used is a three-compartment cell separated by two sintered glass disks (7, 17, 23). The central compartment of about 500 ml capacity is used as the cathode region while the two outer compartments of about 250 ml capacity each, one on each side of the cathode, are used as the anode regions with two platinum plates as the anodes. The dimensions of anode and cathode plates are about 4 × ½ × 0.03 in. The use of the monomer is restricted to the cathode area since the coating is desired only on the cathode metal surface. The volumes of cathodic and anodic solutions are 400 ml in each compartment for all runs.

The electrical potential is applied by means of a variable direct current power supply unit (Hewlett-Packard, 6348 B). The current and voltage drop

through the cell are recorded as a function of time on a two-channel chart recorder (Hewlett-Packard, 7128 A) in series with the circuit and connected with a 10Ω shunt resistor. All electrolysis runs are carried out at room temperature. Nitrogen gas is bubbled through the solution 15 min prior to and during the process. At the end of a run, the coated metal is dipped into distilled water several times, then dried in a vacuum oven at about 40°C for 4 hr.

Infrared analysis of coatings.—The polymer coating is scraped off the metal and mixed with KBr to form a thin and transparent pellet under pressure. The instrument used is a Perkin Elmer Infrared Spectrophotometer Model 700 which automatically measures and records the transmittance of the above pellet as a function of frequency in the range of 4000-600 cm^{-1}.

Elemental analysis of coatings.—The elemental analysis of the polymer coating is carried out with a Perkin-Elmer Model 240 Elemental Analyzer.

Observation of coating surface under scanning electron microscope.—The SEM instrument used is the ETEC Auto Scan model. A small piece of coated metal is cut and a sputter coating of gold is deposited on the above specimen, in vacuum, prior to examination under the SEM.

Weight loss method for determining corrosion rates.—The test method described here is according to the steps suggested by the "Technical Practices Committees, National Association of Corrosion Engineers, NACE Standard TM-01-69" (18). The use of corrosion rates implies that all weight loss is due to general corrosion and not due to localized corrosion, such as pitting or intergranular corrosion. Assuming that localized or internal corrosion is not present, the corrosion rate expressed as mils penetration per year (mpy) is calculated by the equation

$$\text{Corrosion rate (mpy)} = \frac{\text{wt loss} \times 534}{(\text{area})\ (\text{time})\ (\text{metal density})}$$

where weight loss is in milligrams, area is square inches of metal surface immersed, and time is hours exposed.

Electrochemical method for determining corrosion rates.—Corrosion rate can be determined electrochemically by a number of methods (19) that result in a corrosion current density which is converted to corrosion rate through Faraday's law

$$\text{Corrosion rate (mpy)} = 0.1288\ I \times \frac{\text{equiv. wt}}{\rho}$$

where I = current density, $\mu A/cm^2$
ρ = specimen density, g/cm^3
equiv. wt = specimen equivalent weight, g

Corrosion currents are hence measured as a means of representing corrosion rates. The setup used here is according to ASTM designation G5-69 (20).

Results and Discussion

Current density-time relationship.—The deposition of a polymer (or copolymer) film onto a metal surface by electroinitiated polymerization can be followed on current *vs.* time curves. These curves are obtained by recording the current density through the electrolytic cell at any instant, for the duration of the experiment, on a two-channel recorder.

Some typical curves, when nickel and copper are used as cathodes and with AN in DMF solution containing $NaNO_3$ as electrolyte, are shown in Fig. 1a. It is observed that the current starts to drop off rather sharply and rapidly the moment the circuit is connected, indicating that the polymerization commences immediately and the polymer begins to deposit on the metal surface; this deposit increases the

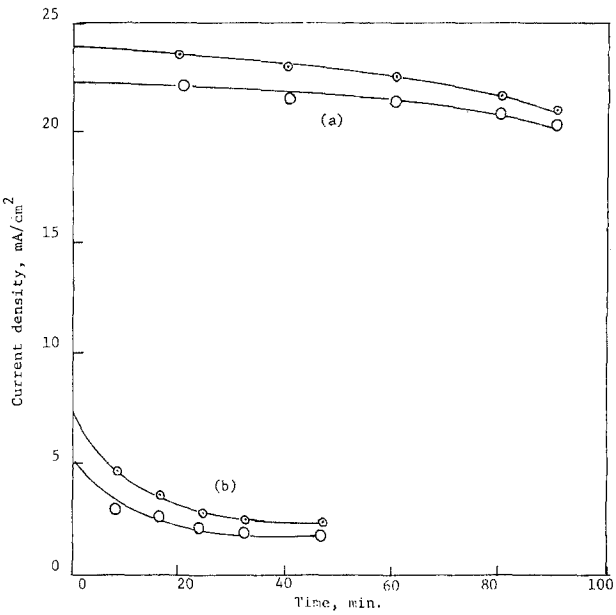

Fig. 1. Typical current density *vs.* electrolysis time curves. (a) Single monomer AN in DMF solution, (b) comonomers AN-AA in aqueous solution, (⊙) nickel electrode, (○) copper electrode.

resistance of the electrode, hence current flowing through the cell decreases gradually. However, in Fig. 1b, in which comonomer AN-AA is polymerized in 0.05*N* H_2SO_4 aqueous solution instead of in DMF solution, the current is almost constant initially, then drops off slowly and smoothly about 20 min later (depending on the metal electrode). This could be explained on the basis that the poly (AN-CO-AA) is swollen in the aqueous system, leading to greater mobility of the charge through the polymer coating. It is also observed that the curve for the thicker coating (Fig. 1a) drops off more sharply than the curve for the thinner coating (Fig. 1b), as is to be expected.

Infrared analysis of coatings.—Infrared spectroscopy is employed to prove the formation of a polymer film on each of the five different metals. For a sample of the poly (AN-CO-AA), there is an O—H band at about 3500-3400 cm^{-1} (frequency) suggesting condensed water vapor in the sample. Also, there are peaks of C—H band at about 2950 cm^{-1}, C≡N band at about 2300 cm^{-1}, C=O band at about 1700 cm^{-1}, CH_2 band at about 1450 cm^{-1}; all these prove the coatings to be the copolymer. Since the coating on aluminum includes the presence of a large amount of metal oxide, the C≡N band in the spectrum of aluminum coating is very weak. The presence of metal oxide is further confirmed through elemental analysis and SEM photographs.

The typical infrared spectrum of polyacrylonitrile film on steel when compared to the spectrum of copolymer film on steel, shows that the only difference between the two is the peak around frequency 1700 cm^{-1} which represents the C=O band; there is no C=O group in the pure PAN.

Elemental analysis of coatings.—The elemental analysis of the copolymer coating scraped off aluminum shows that the total composition of nitrogen, carbon, and hydrogen atoms is only about 11% and the color of the residue after elemental analysis is black, due to the metal oxide also being removed with the coating. However, the presence of this oxide on the metal gives rise to strongly adhering but porous coatings. In the analysis of pure polyacrylonitrile, the experimental values of nitrogen, carbon, and hydrogen composition are 24.9%, 67.1%, 5.8%, while the theoretical values should be 26.4% 67.9%, and 5.6%. The decrease in nitrogen composition may be due to condensation of water vapor and the presence of some metal oxide

Table I. Elemental analysis of poly (AN-CO-AA)[a] and polyacrylonitrile coatings on different metals

Material	Metal	% N	% C	% H	% O[b]
Poly (AN-CO-AA)	Al	2.04	7.17	1.77	—[c]
	Ni	18.47	60.83	5.96	14.74
	S-steel	20.23	59.26	8.10	12.41
PAN alone	S-steel	24.89	67.09	5.83	—

[a] Monomer mixture: 80% AN and 20% AA by volume; 30 ml monomer in 400 ml of aqueous solution, containing 0.05*N* H_2SO_4 electrolyte.
[b] The composition of oxygen is obtained by difference.
[c] Because the copolymer sample scraped off aluminum left black residue after combustion in the elemental analysis, we are unable to make the above assumption [(b)] for oxygen composition.

Table II. Comparison of coatings of polyacrylonitrile on various metal surfaces—DMF solvent

Monomer concentration	Cathode metal	Electrolyte concentration	Current density (mA/cm²) I_o	Current density (mA/cm²) I_f	Electrolysis time (min)	Thickness of coating (mg/in.²)
30 ml AN in 400 ml of DMF solution	Al	1.5g $NaNO_3$ in 400 ml of DMF solution	6.35	5.64	45	39.2
	Ni		7.52	2.41	45	54.8
	Cu		5.70	2.24	45	41.0

	Steel		8.83	3.10	30	28.4

Polymerization voltage is maintained constant at 20V for all runs.

in the tested sample. A summary of results is given in Table I.

Examination of coating surfaces under scanning electron microscope.—The photomicrographs of copolymer coatings obtained on five different metal surfaces are shown in Fig. 2a-e. The electrolyte for these is a 30 ml monomer mixture (80% AN and 20% AA) in 400 ml of 0.05*N* sulfuric acid solution; the polymerization voltage is 13V for 90 min. Next, keeping voltage, electrolysis time, electrolyte concentration, and cathode metal the same as before, the monomer mixture is replaced by monomer AN; the appearance of the film structure in this case is shown in Fig. 3a-e. It is observed that the coatings on the nickel and copper are more uniform than the coatings on the other metals. This may be due to the higher hydrogen overvoltage of copper (9) (high hydrogen overvoltage indicating hydrogen is more difficult to evolve along the metal electrode). The coating on the aluminum surface is quite rough, porous, and nonuniform although it is thicker than the other coatings. The coatings on the stainless steel and steel are not so uniform as the coatings on the nickel and copper. Also, there are some globules formed on these coatings.

SEM pictures of copolymer coatings on nickel and copper, under various polymerization voltages, are shown in Fig. 4a-d and Fig. 5a-d, respectively. It is is found that dense and uniform coatings can be obtained if the polymerization voltage is about 11-15V.

SEM pictures of copolymer coatings on nickel and copper, due to varying monomer concentrations, shown in Fig. 6a-e and Fig. 7a-e, indicate that if the monomer concentration is very low, the metal surface is not totally covered by the coating.

Influence of solvent and electrolyte on the coatings obtained through electroinitiated polymerization.—According to Funt (10) and Friedlander (11), polymers are formed on the cathode by electroinitiated polymerization in solution of AN in DMF saturated with sodium nitrate. Based on these, five different cathodes are first investigated: aluminum, nickel, copper, stainless steel, and steel, from the point of view of uniformity of the surface and thickness of the coatings. It is found that the coatings are dark yellow, uneven, nonuniform, poorly adhesive and easily dissolved in the water; however, the coatings are quite thick. A summary of these results is given in Table II. The coating thickness is based on the weight difference of the coated metal before and after polymerization, divided by the coated area and reported as milligrams per square inch. I_o and I_f are the initial and final current densities through the cell during the electrolysis process.

In order to overcome the disadvantages observed in the above coatings, the polymerization of AN and of mixtures of AN and AA in aqueous solution are tried. Although they are thin, the coatings are found to be uniform, adhesive and insoluble in the water. A summary of these results is given in Table III.

Lewis and Forrestal (12) point out that there is a polar force between nitrile C≡N and the metals, but that this force is not strong enough for the polymer to metal adhesion. Gadgieva (13) points out that in water or in humid air an oxide film on the metal surface is more easily wetted by a more polar liquid, such as water, than by a less polar hydrocarbon phase, for example, paint. The hydrogen evolved in the aqueous solution (in DMF solution there was no hydrogen evolved) will also increase the difficulties of coating. Thus, the polymer coating obtained from sulfuric acid solution is very thin, while the polymer coating obtained from DMF solutions, though thick, is more easily wetted and separated by the moisture or water.

Influence of voltage on coatings obtained through electroinitiated polymerization.—Experimental studies (2, 10, 14) show a direct proportionality between current density and polymer yield in electroinitiated polymerization. But in our work, the decrease in polymer film thickness and the increase in film defects such as pores, blisters, etc., above some voltage values require explanation. Table IV and Fig. 4 and 5 (SEM pictures) show the optimum voltage to be between 11-15V. The current density is about 20 mA/cm².

The initiation scheme for acrylonitrile in sulfuric acid solution may be free radical (14)

$$H^+ + e^- \rightarrow H\cdot$$

then

$$H + M \rightarrow M\cdot$$

or

$$H\cdot + H\cdot \rightarrow H_2$$

Table III. Comparison of coatings of poly (AN-CO-AA) and PAN on various metal surfaces

Monomer concentration	Polymer	Cathode metal	Current density (mA/cm²) I_o	Current density (mA/cm²) I_f	Electrolysis time (min)	Appearance of coating	Thickness of coating (mg/in.²)

Electrolysis time for each run, 90 min.

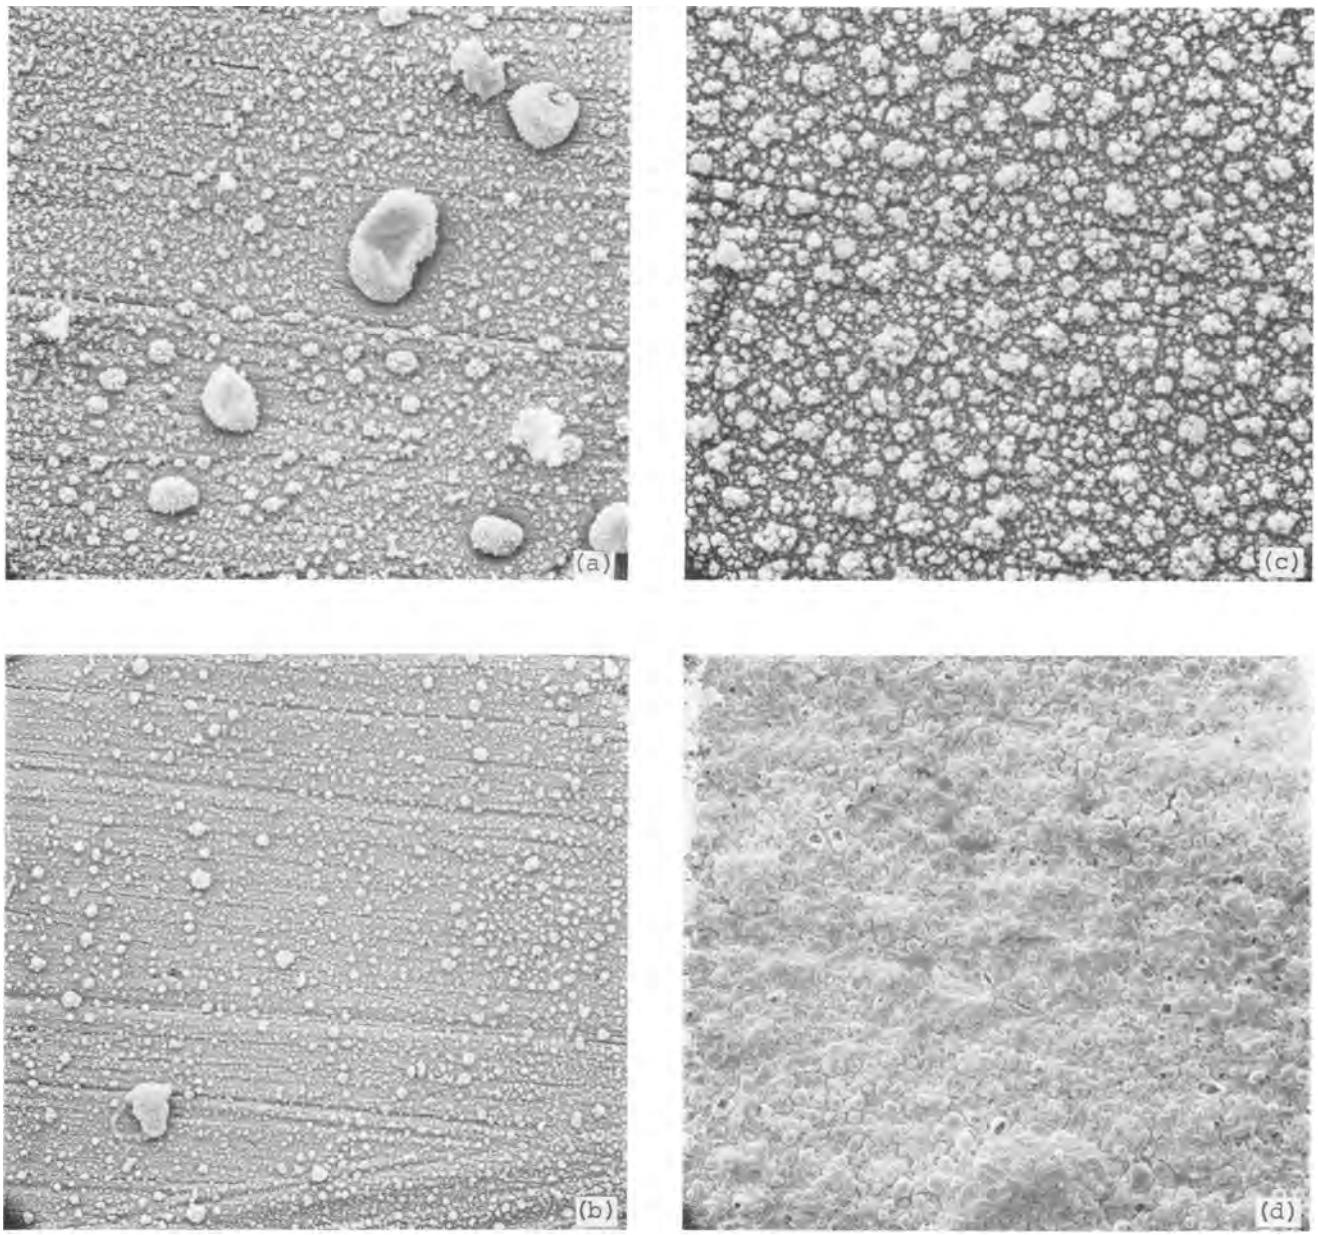

Fig. 5. Surface structure, under the scanning electron microscope at 1000X, of coatings of poly (AN-CO-AA) on copper surface obtained at various polymerization voltages, (a) At 8V, (b) at 11V, (c) at 15V, (d) at 20V.

According to this mechanism, much hydrogen is evolved along the electrodes (as has been observed during the experiments). This increases the difficulty of coating the metal. In fact, the ease of polymer deposition by electroinitiated polymerization is strongly dependent upon the hydrogen overvoltage (16) of the metal (9). If the applied voltage is too high, there is too much hydrogen evolved and water is also easily electrolyzed to form oxygen—a free radical inhibitor. In their work on electroinitiated polymerization of vinylic monomers in a polar system, Albeck, Konigsbuch, and Relis (15) point out that the decrease in polymer yield, occurring after a certain voltage value is exceeded, should be the result of the production of a free-radical suppressor by the electrolysis process.

If the voltage is too low, the current density is low, too. This will reduce the initiation rate of polymerization. It is seen that there is no polymer coating formed on the nickel surface if the voltage is less than 2V because the low voltage is actually used solely for the electrolysis of water.

Influence of monomer concentration on the coatings obtained through electroinitiated polymerization.—If the voltage, electrolyte concentration, and electrolysis time are kept constant and the monomer concentration changed, the coating thickness increases with the increase in monomer concentration. This is easily understood because initiation and propagation rates for polymerization increase as monomer concentration increases. Due to the solubility limit of acrylonitrile in water (about 7.5%), higher monomer ratios result in two-phase systems and in the nonuniformity of the coatings formed. A summary of these results is given in Table V for nickel and copper.

Comparison between corrosion rates for coated and uncoated metals, using weight loss method.—Test solutions which moderately corrode the metal specimens are used in the corrosion tests. These are 0.85% phosphoric acid, 0.27% and 0.9% ammonium hydroxide, 0.43% nitric acid, 3.55% hydrochloric acid, 5.25% and 3.15% acetic acid solution (all are weight percentage concentration) (21).

From Table VI, it is observed that the coatings on nickel and copper can prevent corrosion, based on the corrosion ratio being always greater than 1. In the case of aluminum, the coating seems to accelerate corrosion and the corrosion ratio is seen to be less than 1. From the infrared and elemental analyses and the SEM pictures, the aluminum coating is seen to be porous, rough, and nonuniform. So, the corrosion rate

* The coating where applicable is poly (AN-CO-AA). Concentration of monomers: 24 ml AN and 6 ml AA, in 400 ml, 0.05N H_2SO_4 aqueous solution. Polymerization voltage: 13V.
** The coating where applicable is polyacrylonitrile which is obtained with 30 ml AN in 400 ml, 0.05N H_2SO_4 aqueous solution. Polymerization voltage: 13V.
Area: 1.03-2.89 in.².
Time: 23-25 hr.

of coated aluminum is increased. The coatings on nickel and copper are uniform (from the SEM pictures) and are also quite thick, especially on the nickel surface; hence, the reduced corrosion rates for nickel and copper.

Asahara, Seno, and Tsuchiya (22), in their experiments on formation of polymer film onto aluminum electrode by electrolysis of vinyl compounds, found copolymer coatings of AN-MMA, AN-MA, AN-EA, and AN-ST, etc. will cause higher hydrogen overvoltage than polyacrylonitrile alone. This accounts for the film thickness of the copolymer being thicker than of the pure polymer. In our work, it is similarly observed that the thickness of poly (AN-CO-AA) is higher than that for the pure polyacrylonitrile.. So, the corrosion rates for the copolymer coatings are less than those for PAN.

From Table IV and Fig. 4-5, it can be seen that if the polymerization voltage is changed, the thickness and surface structure of the polymer film are also changed. Also from this table, it is seen that the coating obtained at 13V is more uniform than those obtained at the other voltages. Thus, the corrosion rate of the coating corresponding to that voltage is always the smallest. Also, a thick and uniform coating on the nickel surface occurs at 8V. So, the corrosion rate for nickel with the polyacrylonitrile coating obtained at 8V is the smallest. The corrosion data are shown in Table VII.

From Table V and Fig. 6-7, it can be seen that if the monomer concentration is changed, the thickness and structure of the polymer film is also changed. As shown in Table VIII, the smallest corrosion rate occurs for the higher monomer concentration because thick and uniform coatings are obtained at the higher monomer concentrations. Also, if the monomer concentration is too low and the coating is too thin to cover the entire metal surface, the corrosion ratio is very close to 1, *i.e.*, the corrosion rates of coated and uncoated metals are almost equal.

Comparison between corrosion rates for coated and uncoated metals, using electrochemical method.—The electrochemical method is employed to cross check the corrosion rates obtained by the weight loss method. It is observed that the two methods differ within the acceptable range of less than 30% (Tables IX and X). Comparison of Tables VI and IX shows the large difference between the two testing methods occurs for nickel in 0.43% nitric acid solution and for steel in 3.15% acetic acid solution. Because it always takes a whole day for testing by the weight loss method, the nitric acid solution appears to wet the inside metal surface and loosen the bonding between polymer film and metal. The coating on the coated nickel after the corrosion test in nitric acid solution appears to swell and is easily scraped off the metal. But it takes only half an hour for testing by the electrochemical method and all coatings on the metals are found to be still strongly adhering to the surfaces after electrochemical corrosion tests.

It should be recognized that although the test corrosion media for both the methods could be considered to be moderately severe for the organic coatings developed, the amount of information developed is valuable, especially on the adherence, porosity, and uniformity of the coatings.

Conclusions

For the specimens prepared by electroinitiated polymerization, bonding between the metal and the polymer may be assumed to be through an electrostatic force between the positive metal ion in the metal oxide and the negative functional group of the polymers. The coating thickness and uniformity vary not only with the solvents, electrolytes, and electrodes, but

they are also functions of polymerization voltage and monomer concentration. It is also observed that the resistance of the coated metals to corrosion is also a function of the above variables. Since a metal oxide is present on aluminum, the coating is found to be porous, nonuniform, and having poor corrosion resistance but strongly adhesive. The optimum polymerization voltage and monomer concentration from the point of view of good corrosion resistance are found to be around 11-15V and at 45 ml monomer in 400 ml aqueous solution. Also it is found that monomer mixtures of acrylonitrile and acrylic acid are more suitable to form good corrosion resistant coatings than the monomer acrylonitrile alone.

Evaluation of Corrosion Rates from Nonlinear Polarization Data

Rodney L. LeRoy*

Noranda Research Centre, Pointe Claire, Quebec, Canada H9R 1G5

ABSTRACT

Evaluation of corrosion rates from polarization measurements in the vicinity of the corrosion potential (the linear polarization method) depends on a knowledge of the Tafel slopes for the anodic dissolution reaction and for the corresponding cathodic process. A method is presented for derivation of these parameters from the polarization data. One calculation, based on the extent to which the polarization curve is symmetrical about the corrosion potential, yields a reliable value for the difference between the inverses of the two Tafel slopes. A second calculation computes the separate values of the parameters from this difference and measurements of the degree of nonlinearity in either the anodic or cathodic direction. This approach is presented in the form of a simple algorithm which gives Tafel constants of sufficient accuracy to make possible reliable calculation of the corrosion current from the polarization data.

Since its proposal by Stern and his co-workers (1-4), the linear polarization method has come into widespread use for determination of corrosion rates. It is common, for example, in corrosion laboratories for measurement of very low corrosion rates where conventional techniques such as weight-loss and gas-evolution measurements are insufficiently sensitive (5). Even for rapidly corroding samples, the experimental simplicity of this method and the short times required for obtaining accurate estimates of corrosion rates make it invaluable (6-8), provided that correction is made when necessary for effects of ohmic resistance (9). Several commercial corrosion rate meters are based on the linear polarization method (10), and with suitable corrections these can give good estimates of corrosion rates if the anodic and cathodic Tafel slopes are known (11).

In view of this generally recognized utility, it is surprising that the accuracy of corrosion rate measurements using the linear polarization technique has been limited by an incomplete theoretical formulation. This is true even in the simplest (and most common) case where the corrosion potential is sufficiently displaced from the reversible potentials of the anodic and cathodic reactions that competing processes can be ignored (12, 13). The principal failings relate to the assumption of linearity and to the requirement that the Tafel slopes for the anodic and cathodic processes be known in order to allow computation of the corrosion current. Recently, several authors have made contributions to the understanding of these limitations and to devising methods of overcoming them (14-22).

In the classical linear polarization method, the current density i which flows when a corroding sample is polarized to a potential ϵ from the corrosion potential is given by the linear expression

* Electrochemical Society Active Member.

Key words: Tafel slope estimation, corrosion currents, zinc corrosion, iron corrosion.

$$i = i_{corr} (\log_e 10) \left(\frac{1}{\beta_a} + \frac{1}{\beta_c}\right) \epsilon \qquad [1]$$

where i_{corr} is the corrosion current, and β_a and β_c are, respectively, the Tafel slopes of the anodic and cathodic processes. This equation is simply a linear approximation, valid for small ϵ, of the general expression for the net current which flows when competing activation-controlled anodic and cathodic reactions are taking place

$$i = i_{corr} (10^{\epsilon/\beta_a} - 10^{-\epsilon/\beta_c}) \qquad [2]$$

As was originally emphasized by Stern (4), and has been since highlighted by several other authors (15, 16), the linear approximation of Eq. [1] can rigorously be applied only to the tangent of the polarization curves at $\epsilon = 0$. Polarization data frequently exhibit significant curvature in the potential range used for these measurements, within 10-20 mV of the corrosion potential (17-22). Thus a corrosion current calculated using Eq. [1] from the best straight line which is drawn through "linear polarization" data can introduce significant errors. The magnitude of these errors and their dependence on the Tafel parameters β_a and β_c were estimated in an earlier paper (19).

It is possible to compute the corrosion current from such polarization data, however, without introducing any theoretical error, using the expression (22)

$$i_{corr} = \frac{\sum_{j=1}^{n} [i_j (10^{\epsilon_j/\beta_a} - 10^{-\epsilon_j/\beta_c})]}{\sum_{j=1}^{n} [(10^{\epsilon_j/\beta_a} - 10^{-\epsilon_j/\beta_c})^2]} \qquad [3]$$

where the anodic and cathodic Tafel constants β_a and β_c are assumed to be known. Although somewhat formidable in appearance, Eq. [3] is readily evaluated from the point-by-point polarization data using a hand calculator. The resulting corrosion current is quite insensitive to errors in the assignment of the Tafel parameters (22) although serious inaccuracy can result if approximate estimates of these parameter values are not available.

Mansfeld (20, 23), has proposed a curve-fitting procedure for determination of the anodic and cathodic Tafel slopes from nonlinearity in the vicinity of the corrosion potential. This involves computation of the polarization resistance from the tangent to the polarization curve at $\epsilon = 0$, plotting of modified polarization data ($\log_e 10 \times$ (polarization resistance) $\times i$) *vs.* the polarization ϵ, and subsequent comparison with theoretical curves calculated for various values of β_a and β_c. He also proposed (20) an elegant least squares fitting technique which requires the use of a computer. The latter of these approaches is more attractive, as it allows estimation of the corrosion current without the errors which result from drawing a tangent to the experimental data at the corrosion potential.

The purpose of this paper is to present a simple and accurate alternative approach to the estimation of Tafel parameters from the nonlinearity of polarization data. The resulting estimates, when used in Eq. [3], allow accurate evaluation of the corrosion current.

Symmetry of the Polarization Curve

An accurate relationship between the anodic and cathodic Tafel slopes can be derived from the symmetry of the polarization data about the corrosion potential. The currents which flow when a corroding sample is polarized ϵ mV in the anodic ($i_{\epsilon+}$) and cathodic ($i_{\epsilon-}$) directions are recorded and their ratio is calculated. This experimental ratio is compared with the theoretical quantity computed from Eq. [2]

$$\begin{aligned} i_{\epsilon+}/i_{\epsilon-} &= (10^{\epsilon/\beta_a} - 10^{-\epsilon/\beta_c}) / (10^{-\epsilon/\beta_a} - 10^{\epsilon/\beta_c}) \\ &= \frac{10^{\epsilon/\beta_a} (1 - 10^{-(\epsilon/\beta_a + \epsilon/\beta_c)})}{-10^{\epsilon/\beta_c} (1 - 10^{-(\epsilon/\beta_a + \epsilon/\beta_c)})} \\ &= -10^{(\epsilon/\beta_a - \epsilon/\beta_c)} \end{aligned} \qquad [4]$$

This result is conveniently rewritten in terms of the difference D of the inverse Tafel slopes

$$D = \left(\frac{1}{\beta_a} - \frac{1}{\beta_c}\right) = \frac{1}{\epsilon} \log_{10}(-i_{\epsilon+}/i_{\epsilon-}) \qquad [5]$$

Equation [5] was first derived by Reeve and Bech-Nielsen (14) and an analogous result was used by Barnartt (24).

The difference D will seldom be less than -0.035 mV^{-1} or greater than $+0.035$ mV^{-1}. The lower of these limits corresponds to a passivated surface for which the anodic Tafel slope β_a = infinity while the cathodic Tafel slope is $\beta_c = 30$ mV ($2.3\ RT/2\mathbf{F}$). The upper limit corresponds to $\beta_a = 30$ mV and β_c = infinity, for example for a diffusion-limited cathodic reaction.

The difference of the inverse Tafel slopes D is plotted in Fig. 1 as a function of the ratio $-i_{\epsilon+}/i_{\epsilon-}$. Curves are plotted for polarization values 5, 10, 15, and 20 mV from the corrosion potential. Equation [5] would, of course, be valid for much higher polarizations. However, in deriving corrosion currents it is normally desirable to restrict attention to data obtained with 10-15 mV of the corrosion potential in order to minimize possible interference effects due to competing reactions, or to modification in the mechanism of the corrosion process or its corresponding cathodic reaction.

In some instances Eq. [5] and Fig. 1 alone will suffice for definition of the Tafel parameters β_a and β_c, and for subsequent calculation of the corrosion current from Eq. [3]. An example is the analysis of the data for the corrosion of zinc in 3% sodium sulfate solution which is presented in Fig. 2. These measurements were made in a well-stirred polarization cell which was thermostated at 30°C. Potentials were measured with respect to a mercury/mercury sulfate reference electrode which was contacted to the electrolyte through a Luggin probe. The potential was scanned at a rate of 0.1 mV/sec using a Princeton Applied Research potentiostat Model 173, controlled by a Model 175 programmer. Current values obtained at plus and minus 5, 10, 15, and 20 mV are recorded in Table I, along with the corresponding calculated values of D.

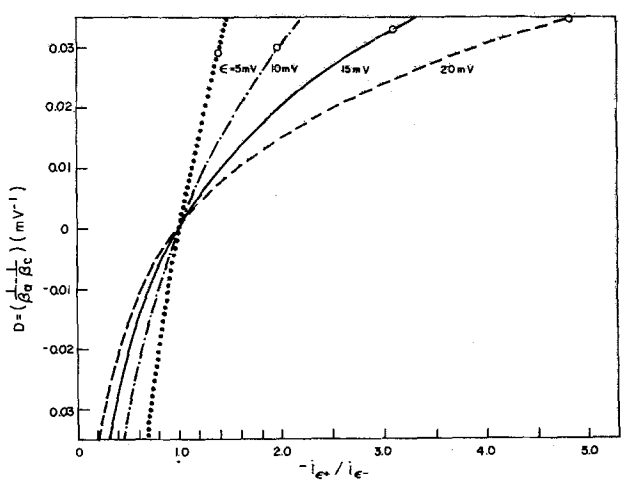

Fig. 1. Relationship between the difference D of the inverse anodic and cathodic Tafel slopes and the ratio of the net currents i which flow when a corroding sample is polarized by ϵ mV in the anodic and cathodic directions. Curves are plotted from Eq. [5] for four values of the polarization, 5, 10, 15 and 20 mV. Points indicate data obtained for zinc corroding in 3% sodium sulfate (Table I).

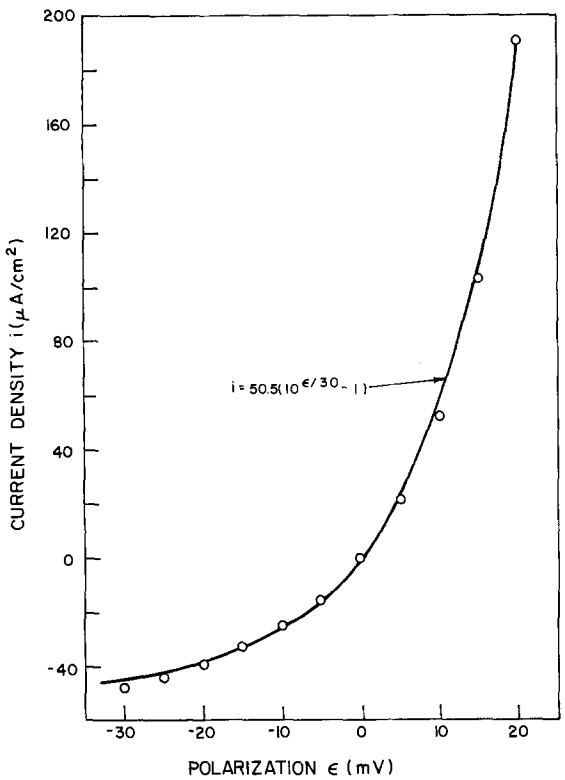

Fig. 2. Polarization data for zinc corroding in 3% sodium sulfate solution at 30°C. The solid curve is drawn from Eq. [2], for an anodic Tafel slope of $\beta_a = 30$ mV, a cathodic slope of $\beta_c =$ infinity, and a corrosion current of 50.5 μA/cm².

These values of D are indicated as data points in Fig. 1. They increase slightly with increasing polarization, but their mean value of 0.0312 mV^{-1} is a good estimate, within the required degree of accuracy (22).

Maximum Values of β_a and β_c

When the ratio of the anodic and cathodic current densities for a given polarization ϵ (the quantity $-i_{\epsilon+}/i_{\epsilon-}$ in Eq. [4] and [5]) is greater than unity, the value of the cathodic Tafel slope β_c is greater than the anodic slope, β_a. In this case, for a particular value of D there will be an upper limit on possible values of β_a, corresponding to a cathodic Tafel slope β_c of infinity. Such maximum values of β_a are plotted in Fig. 3 as a function of $-i_{\epsilon+}/i_{\epsilon-}$ for polarization values of 5, 10, and 15 mV.

For corrosion situations in which the cathodic Tafel slope is very large, Fig. 3 provides sufficient information for assignment of the Tafel slopes and for accurate calculation of the corrosion current. The data for zinc in 3% sodium sulfate solution (Fig. 2) are an example of this. The two points indicated in Fig. 3 represent maximum possible values of the anodic Tafel slope from the zinc corrosion data, for $\epsilon = 5$ and $\epsilon = 10$ mV. Both values fall close to $\beta_a = 30$ mV. The smallest value of the anodic Tafel slope normally encountered for activation controlled processes is 30 mV, corresponding to 2.3 $RT/2F$. Thus these data indicate that the anodic Tafel slope for this zinc corrosion reaction had approximately this value, 30 mV, while the corresponding cathodic Tafel slope was infinite. These assignments are consistent with the anodic dissolution parameters determined for zinc dissolution over a much wider current density range (25) and with diffusion-limited reduction of oxygen being the cathodic process.

Table I. Calculation of $D = (1/\beta_a - 1/\beta_b)$ for zinc corroding in 3% sodium sulfate solution

ϵ (mV)	$i_{\epsilon+}$ (μA/cm²)	$i_{\epsilon-}$ (μA/cm²)	$-i_{\epsilon+}/i_{\epsilon-}$	$D = (1/\beta_a - 1/\beta_c)$ (mV^{-1})
5	21.2	−15.2	1.39	0.0289
10	50.2	−25.3	1.98	0.0298
15	102.6	−32.8	3.13	0.0330
20	191.0	−39.0	4.90	0.0345
			Mean value =	0.0312

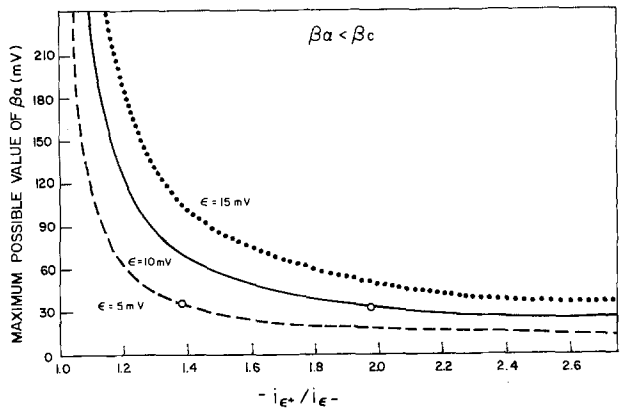

Fig. 3. Maximum possible values of the anodic Tafel slope β_a, as a function of the ratios of the net currents which flow on polarizations of $\pm\epsilon$ from the corrosion potential. The curves correspond to $\beta_c =$ infinity in Eq. [5].

Using these assigned values of the Tafel parameters ($\beta_a = 30$ mV and $\beta_c =$ infinity), the corrosion rate of zinc in the 3% sodium sulfate electrolyte was calculated directly from the polarization data using Eq. [3]. This calculation is detailed in Table II. The quantities in the numerator and denominator of Eq. [3] were calculated for each data point, and the appropriate summations were performed. The resulting value of the corrosion current was 50.5 μA/cm². Corresponding calculated current values derived from Eq. [2] are recorded in Table II, and plotted as a solid line in Fig. 2. The good agreement of the calculated curve with the experimental data suggests that "more accurate" estimation of the Tafel parameters, for example by a computer-fitting procedure, would not offer improved precision in the estimate of the corrosion current.

If the value of D calculated from Eq. [5] is negative, the value of the anodic Tafel slope β_a is greater than that of the cathodic Tafel slope, β_c. In this case a maximum possible value of the parameter β_c can be derived, corresponding to $\beta_a =$ infinity (a passive electrode). Figure 4 displays these maximum possible values for polarizations of 5, 10, and 15 mV.

Separate Estimation of β_a and β_c

The example of zinc corrosion described above was an exceptional case, in that an analysis of the symmetry of the polarization curve about the corrosion potential provided sufficient information to allow accurate computation of the corrosion current. In general, the anodic and cathodic Tafel slopes will be non-infinite, and an alternate method of calculation is required. The method used is based on the extent to which the polarization data deviates from linearity, in either the anodic or cathodic direction.

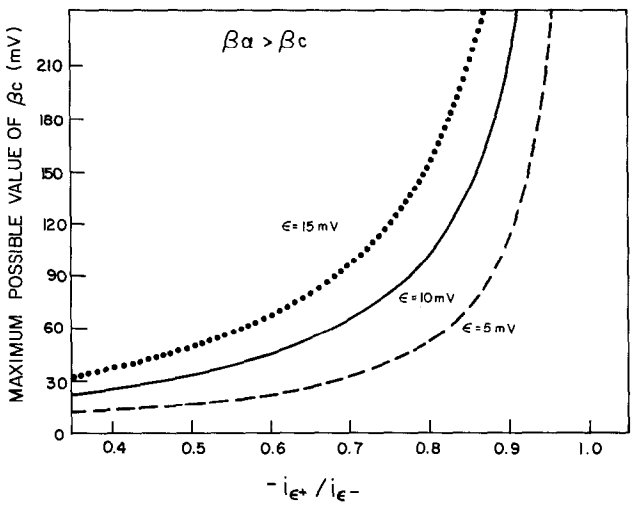

Fig. 4. Maximum possible values of the cathodic Tafel slope β_c as a function of the ratio of the currents i which flow on polarizations of $\pm\epsilon$ from the corrosion potential. The curves correspond to an anodic Tafel slope of β_a = infinity in Eq. [5].

Values of the net current which flows for polarizations of ϵ and 2ϵ from the corrosion potential are recorded, and their ratio is calculated. If the polarization data were linear, the value of this ratio would be two. In the more general case, described by Eq. [2], the value of this ratio is

$$R = \frac{10^{2\epsilon/\beta_a} - 10^{-2\epsilon/\beta_c}}{10^{\epsilon/\beta_a} - 10^{-\epsilon/\beta_c}} \qquad [6]$$

or

$$R = 10^{\epsilon/\beta_a} + 10^{-\epsilon/\beta_c} \qquad [7]$$

Using the difference D computed from the symmetry of the polarization data about the corrosion potential, the anodic Tafel slope β_a can be eliminated between Eq. [5] and [7], with the result

$$R = 10^{\epsilon D}\, 10^{\epsilon/\beta_c} + 10^{-\epsilon/\beta_c} \qquad [8]$$

Solution of this quadratic equation in $10^{\epsilon/\beta_c}$ gives the required result for the cathodic Tafel slope β_c

$$\beta_c = \epsilon/\log_{10} \frac{(R \pm (R^2 - 4 \cdot 10^{\epsilon D})^{1/2})}{2 \cdot 10^{\epsilon D}} \qquad [9]$$

The positive root is taken in Eq. [9] when the polarization from the corrosion potential, ϵ, is positive, while the negative root must be taken when the polarization is negative. The corresponding anodic Tafel slope β_a is calculated directly from the quantity D

$$\beta_a = \left(\frac{1}{\beta_c} + D\right)^{-1} \qquad [10]$$

The two Tafel parameters then allow computation of the corrosion current from Eq. [3].

Computation of values of the cathodic Tafel slope β_c from Eq. [9] and the experimental quantities R and D is facilitated by the use of Fig. 5-7, in which β_c is plotted as a function of the difference between the inverse Tafel slopes D, for different realistic values of the ratio R. Figures are drawn for lower polarization values ϵ of 5, 7.5, and 10 mV. Each of the figures has an "inaccessible region" where values of β_c would require a negative or imaginary value β_a.

Figures 5-7 are constructed for positive values of the lower polarization value ϵ. However, because of the symmetry of Eq. [2] and [5] in β_a and β_c, these figures can also be used to derive the value of the anodic Tafel slope when the polarization values ϵ and 2ϵ are negative. In this case the abscissa must be read as the negative of the difference D, $(\beta_c^{-1} - \beta_a^{-1})$.

The accuracy and utility of this method are illustrated using experimental data obtained by Mansfeld (20) for the corrosion of iron in 1*N* sulfuric acid. Comparison is made with Mansfeld's analysis of this data using both a curve-fitting procedure and a computer analysis (20, 23). The data used were obtained after the iron sample had been exposed in the sulfuric acid medium for 290 min [Fig. 3(b) of Ref. (20)].

Mansfeld's polarization data (20) are plotted in Fig. 8, and the net currents measured at polarizations of ± 5, 10, and 20 mV are recorded in Table III. Values of the difference of the inverse Tafel slopes D were calculated at each of these polarizations from Eq. [5], as described above. The resulting values were averaged to give $D = 0.0079\ \text{mV}^{-1}$.

Evaluation of the separate values of the Tafel parameters is indicated in the lower section of Table III. Calculations were carried out using the data at $\epsilon = 5$ and $\epsilon = 10$ mV, and the data at $\epsilon = 10$ and $\epsilon = 20$ mV. For example, the ratio of the positive currents measured at polarizations of 5 and 10 mV from the corrosion potential was 2.102. Substitution of this value and the mean value of $D = 0.0079\ \text{mV}^{-1}$ into Eq. [9] yielded a cathodic Tafel slope of 256 mV. The corresponding value of β_a, calculated from Eq. [10], was 85 mV. Rather than using Eq. [9], the value of β_c could have been taken with adequate accuracy from Fig. 5. This is indicated by the circle on this figure. At a value of $D = 0.0079\ \text{mV}^{-1}$, the contour for $R = 2.1$ corresponds to a value of β_c somewhat greater than 180 mV. The uncertainty in the cathodic Tafel slope β_c taken from Fig. 5 is a useful indication of the extent to which the polarization data is insensitive to the precise value of this parameter. Values of the corrosion current calculated subsequently from Eq. [3] have been shown to be correspondingly insensitive to precise assignment of such high values of the Tafel parameters (22).

The ratio of the currents flowing at negative polarizations of 5 and 10 mV from the corrosion potential was 1.962. The value of β_c calculated from this R value and the mean value of D was 62 mV, while the corresponding value of β_a (Eq. [10]) was 42 mV. These values could alternately have been derived from Fig. 5. In this case a value of β_a must be read from the graph at D = minus $0.0079\ \text{mV}^{-1}$, at a height intermediate between the contours for $R = 1.9$ and $R = 2.0$. This point is indicated by a triangle in the figure. The corresponding value of β_c was calculated using the appropriate modification of Eq. [10].

Similar evaluations of the anodic and cathodic Tafel slopes from the data at $\epsilon = 20$ and $\epsilon = 10$ mV are indicated on Fig. 7, and in Table III. The four sets of parameters determined obviously vary over a wide range. For example, the anodic Tafel slope β_a is as low as 42 mV and as high as 85 mV. However, when corrosion currents were calculated from Eq. [3] for each of the pairs of parameters, the reproduction of the polarization data was satisfactory. The data were not of sufficient accuracy to allow distinction among the different sets of Tafel parameters calculated from Eq. [9] and [10].

The parameters of the polarization curves (Eq. [2]) are summarized in Table IV, in comparison with the values derived by Mansfeld (20). The average values of the anodic and cathodic Tafel slopes and the cor-

Fig. 5-7. Relationships between the cathodic Tafel slope β_c and the difference between the inverse anodic and cathodic Tafel slopes. Contours are drawn for realistic values of the ratio of the net currents which flow on polarizations of ϵ and 2ϵ from the corrosion potential. The points are examples for the values of R and D calculated from the data of Tables III (Fig. 5 and 7) and V (Fig. 6). Figures 5-7 can also be used when the polarization ϵ is negative. In this case the ordinate is the anodic Tafel slope, while the abscissa must be read as the negative of D. The triangles are examples of such a determination for the data of Tables III and V.

rosion currents calculated in Table III agree closely with the values derived by the least squares computer fitting procedure. However, the corrosion currents calculated from particular results of Table III differ substantially, ranging from 3.14 to 8.74 mA. The curves corresponding to these extreme values are plotted in Fig. 8. It is apparent that in spite of the differences in the parameter values, both curves reproduce the data within its accuracy. If independent estimates of the Tafel parameters β_a and β_c are not available, the data do not allow more precise estimation of the corrosion current to be made.

The derivation of Tafel parameters which is outlined in Eq. [6]-[10] is similar to the three-point method proposed by Barnartt (24, 26). However, as applied here, these results offer a measure of the sensitivity of the resulting parameters to uncertainty in the experimental data. Furthermore, the resulting best estimates of β_a and β_c are used to calculate the best least

squares estimate of the corrosion current from the complete experimental data, using Eq. [3].

An Algorithm for Estimation of Tafel Parameters from Nonlinear Polarization Data

The method derived in the preceding sections can be summarized as an algorithm for calculation of Tafel parameters from polarization data near the corrosion potential. The data recorded by Mansfeld (20) for corrosion of iron in 1*N* sulfuric acid after 10 min exposure are used as an example. These data are recorded in Fig. 9, and estimation of β_a and β_c values from them is summarized in Table V.

Values of the net currents flowing at polarizations of plus and minus 7.5 and 15 mV are recorded. Corresponding values of the difference D were determined from Eq. [5] at each polarization value, and their average ($D = 0.0219$ mV^{-1}) was calculated. Values of the ratio R were then calculated for the positive and negative polarizations, and the corresponding values of β_c and β_a were estimated from Fig. 6 or Eq. [9], and Eq. [10]. In the general case, the average of the resulting estimates for each of the Tafel parameters would be calculated, and the corresponding value of the corrosion current would be calculated from the polarization data using Eq. [3].

In the example considered in Table V, no real value of the cathodic slope β_c could be calculated from Eq. [9] and the experimental ratio $R = 2.315$. This indicates that the data were not consistent with the general predicted form of Eq. [2], either because of experimental error, or because the influence of some other reaction was being felt at $\epsilon = 15$ mV. Nevertheless, Tafel parameters of adequate accuracy for corrosion rate estimation could be obtained by consideration of Fig. 6. This indicates that the imaginary value of β_c determined from Eq. [9] reflected inaccuracy in the calculated value of the difference D (Table V). β_c could be taken to be infinity, with $\beta_a = 46$ mV being estimated from this value and Eq. [5]. In this example the Tafel slopes determined from the negative currents were used, $\beta_a = 76$ and $\beta_c = 28$ mV. The corresponding value of the corrosion current calculated from the data points and Eq. [3] was 0.54 mA. The predicted polarization curve (Eq. [2]) for these parameter values is compared in Fig. 9 with the curve predicted using Mansfeld's computer-fitted parameters; $\beta_a = 37$ mV, $\beta_c = 136$ mV, and $i_{corr} = 0.81$ mA. It is clear from the figure that both sets of parameters represent the data equally well within its accuracy, and improved precision in the estimate of the corrosion current is not possible without the use of additional data bearing on the Tafel parameters.

Table IV. Comparison of polarization parameters derived from the degree of nonlinearity (Eq. [9] and [10]) with parameters determined by curve fitting, for iron in 1*N* H_2SO_4 (20)

Source of data	β_a (mV)	β_c (mV)	i_{corr} (mA)
Table III, data at $\epsilon = +5$ and $\epsilon = +10$ mV	85	256	8.74
Table III, data at $\epsilon = -5$ and $\epsilon = -10$ mV	42	62	3.14
Table III, average of 4 determinations of β_c, and corresponding β_a (Eq. [10])	62	121	5.49
Mansfeld (20), curve fitting	55	105	4.86
Mansfeld (20), computer fit	64 ± 13	128 ± 43	5.76 ± 1.50

Conclusions

1. A method is presented for deriving the difference between the inverse Tafel slopes of the anodic and cathodic processes occurring on a corroding metal, based on the degree to which the polarization data is symmetric about the corrosion potential. In some cases,

Table V. Estimation of β_a and β_c values from polarization data*

ϵ (mV)	$i_{\epsilon+}$ (mA)	$i_{\epsilon-}$ (mA)	$i_{\epsilon+}/i_{\epsilon-}$	$D = (1/\beta_a - 1/\beta_c)$ (mV^{-1})
7.5	0.633	−0.416	−1.522	0.0243
15	1.440	−0.734	−1.962	0.0195
R	2.315	1.799	Averages	$D = 0.0219$ mV^{-1}
β_c (mV)	**	76	$\beta_a = 76$ mV	
β_a (mV)	**	28	$\beta_c = 28$ mV	

* Data is for corrosion of iron after 10 min exposure in 1*N* H_2SO_4 (20).
** No real solution for β_c exists for the experimental values of R and D. Values of $\beta_a = 46$ mV, $\beta_c = \infty$ could be used (Fig. 6).

when one of the two Tafel parameters is very large, this information alone suffices to completely define the corrosion current.

2. A measure of the nonlinearity of the polarization data, in either the anodic or cathodic direction, is used to calculate the separate values of the two Tafel slopes.

3. The two basic results are combined into a simple algorithm in which anodic and cathodic Tafel parameters are calculated from four current measurements around the corrosion potential. When used in a previously derived expression for the corrosion current, these parameter values allow the best possible estimate of the corrosion current to be made.

Electrolytic Deposition of Thin Metal Films on Semiconductor Substrates

P. Bindra, H. Gerischer,* and D. M. Kolb

Fritz-Haber-Institut der Max-Planck-Gesellschaft, 1000 Berlin 33 (Dahlem), West Germany

ABSTRACT

Electrolytic deposition of metals on semiconductor electrodes was studied by a potentiostatic pulse method. Experimental data for the deposition of Pb, Ag, and Pd on ZnO, CdS, n-GaP, n-GaAs, and SnO_2 are analyzed to obtain information regarding the mechanism of deposition and the structure of the deposits. The results suggest that the actual overpotential required for the deposition of a metal depends on the relative position of the redox potential of the metal with respect to the flatband potential of the semiconductor while the nucleation behavior of the metal is influenced by the difference in work functions of the depositing metal and the substrate.

Semiconductor substrates covered with thin metal films are of considerable scientific interest in view of their wide-spread technical application. Metal films in the thickness range of a monolayer to a few monolayers are frequently used for surface studies on semiconductors (1) and in catalysis (2), and their use is gaining increasing importance in Schottky barrier devices (3, 4) and optical energy conversion devices (5).

The deposition of metal films on semiconductor substrates can be achieved either from the vapor phase or by electrolytic deposition in a solution containing ions of the metal. Deposition from the vapor phase occurs very far from equilibrium conditions for the condensate and requires expensive and elaborate equipment. Electrolytic deposition, on the other hand, may be achieved by suitably polarizing the substrate in a solution of the metal ions in a simple electrochemical cell. Whichever method is used, the first step for phase change is the process of nucleation and the nucleation behavior is a function of supersaturation (overpotential in electrolytic deposition) and interfacial energies. The formation of a monolayer of the metal, on the other hand, requires stronger interaction between metal atom and the substrate than between the metal atoms themselves, as has been shown by studies of underpotential deposition of metals on metal substrates (6).

In this publication we present results of a study of the electrolytic deposition of metals on semiconductor electrodes by a potentiostatic pulse method. Experimental data for the deposition of Pb, Ag, and Pd on ZnO, CdS, n-GaP, n-GaAs, and SnO_2 are analyzed to obtain information regarding the mechanism of deposition and the structure of the deposits. It should be emphasized that no attempt is made to analyze the deposition mechanism in any particular system rigorously, as not enough information regarding the exact surface structures of the substrates is available. The aim in this publication is simply to show which

factors determine the polarization behavior and the morphology of the metal deposits in electrolytic deposition of metals on semiconductor substrates.

Experimental

The electrochemical cell used was a standard laboratory type. In order to avoid contamination of the solution in the vicinity of the working electrode the cell was designed with separate compartments for the counter and the reference electrodes. The counter-electrode was a Pt foil and the reference electrode a silver wire (Ag^+/Ag) for silver deposition, or a saturated calomel electrode (SCE) for the deposition of Pb and Pd. The working electrodes were all semiconductor single crystals except for SnO_2 which was a polycrystalline film evaporated on a glass substrate. After ohmic contact was made, the crystals were embedded in Teflon cylinders using high chemical resistance Scotch Cast and polished to a mirror finish on a polishing wheel using successively finer grades of diamond paste as the abrasive. Surface damage of the crystals was then removed by subjecting the electrode surface to free chemical etching. The etchants used were 2M HNO_3 for ZnO and CdS and a solution of Br_2 in CH_3OH for n-GaP and n-GaAs. Finally, the electrodes were etched electrochemically by anodic polarization in the solutions in which the metal deposition experiments were carried out.

The solutions used were prepared with triply distilled water and Analar grade salts. The base electrolyte in each case was 1M KNO_3. Lead and silver ion solutions were made from $Pb(NO_3)_2$ and $AgNO_3$, respectively. Palladium ion solution was made by boiling PdO in concentrated nitric acid until all the salt had dissolved. The concentration of the metal ions used in the deposition experiments was 10^{-3}M in each case.

The experimental method used was the potentiostatic step method. Potential control of the working electrode was achieved using a potentiostat (PAR 173) in conjunction with a waveform generator (PAR 175 universal programmer) which was capable of providing both potentiostatic pulses and linear potential sweep profiles. The current-potential curves and the current-time transients obtained were recorded on a X-Y-t recorder.

The potential range in which metal deposition on a particular semiconductor electrode occurred was determined by obtaining current-potential curves. The capacity-potential curves for the Mott-Schottky plots were obtained by superimposing a 30 mV a-c signal of 800 Hz on the linear potential sweep.

Results

Current-time transients.—In the potentiostatic pulse method the potential of the working electrode is stepped from a potential anodic to the deposition potential for the metal to a potential range where deposition of the metal occurs. As a result, current-time transients are obtained which were compared with theoretically calculated expressions (7, 8) to ascertain the nucleation behavior and the growth mechanism for the deposition reaction.

Electrolytic deposition of metals is a highly complex process. Metal ions exist in solution as cations or complex anions and the deposition of the metal is a function of mass transfer, the charge transfer rate and its mechanism, nucleation, and crystal growth. In the case of semiconductor electrodes there is the added complication of the space charge layer inside the semiconductor which will influence the current distribution between surface parts already covered by the deposit and those which are still uncovered. Theoretical current-time curves for deposition reactions controlled by several combinations of these stages have been calculated (7, 8). When deposition of a metal is controlled by processes of nucleation and crystal growth (which is often the case on metal substrates) then rising transients of the form $i \sim t^n$ are predicted where n is a constant depending on the geometry and type of nucleation (7). Peaks in the current-time transients are predicted when two-dimensional layer growth of the metal takes place or when three-dimensional growth leading to passivation occurs (9). The falling parts of the transients are usually due to mass transport limitations.

Deposition on zinc oxide.—Lead.—The current-potential curve obtained by the application of a linear potential sweep profile for the deposition of Pb on ZnO showed that the deposition occurs at *ca.* −465 mV *vs.* SCE. The reversible potential measured for bulk lead in the same solution gave the value −460 mV/SCE. Therefore, the overpotential required for the deposition of Pb on ZnO is *ca.* −5 mV.

Current-time transients obtained for metal deposition by the potentiostatic pulse method are shown in Fig. 1. These curves have the characteristic shape often observed for the deposition of metals on metal substrates. The analysis of the rising part of the transients at higher overvoltages suggests nucleation of three-dimensional growth centers (9). At longer times the experimental curves show a falling current which is due to the onset of diffusion control.

Silver.—The deposition of Ag on ZnO requires rather high overpotentials, in the range −280 to −340 mV. The magnitude of the overpotential is explained in the discussion section in terms of the difference between the flatband potential of the semiconductor and the redox potential of the metal. Current-time transients for this deposition reaction are shown in Fig. 2. It is observed that the currents rise approximately linearly with time, the slight curvature at higher deposition potentials being due to the onset of diffusion. Clearly, these curves measure nucleation only and tell us nothing about crystal growth (10). Electron micrographs of the electrode surface showed instantaneous nucleation of three-dimensional growth centers.

Palladium.—The value of the overpotential required for the deposition of Pd on ZnO is quite high, over 400 mV. It is higher than the overpotential at which Pd deposition on palladium metal substrate occurs.

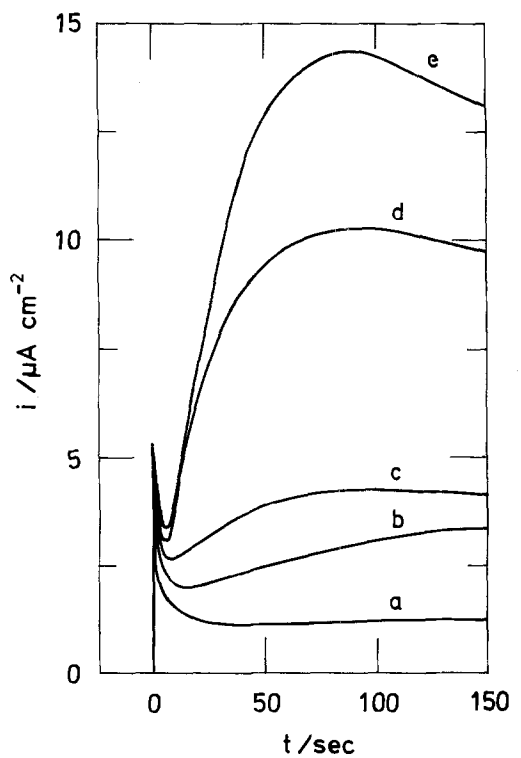

Fig. 1. Current-time transients for lead deposition on ZnO. Potentials stepped from +500 mV *vs.* SCE to (a) −520 mV, (b) −535 mV, (c) −545 mV, (d) −560 mV, (e) −565 mV.

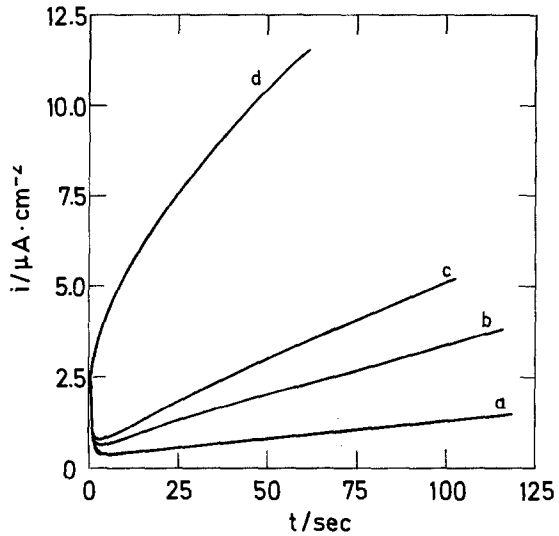

Fig. 2. Current-time transients for silver deposition on ZnO. Potentials stepped from +500 mV *vs.* Ag^+/Ag to (a) −280 mV, (b) −300 mV, (c) −320 mV, (d) −340 mV.

The acidic character ($pH = 1$) of the solution from which Pd is deposited on ZnO affects the deposition reaction in that the electrode surface undergoes chemical etching at the same time as the metal deposition occurs, thus giving rise to distorted current-time transients. The rising part of the current-time transients, shown in Fig. 3, suggests growth via progressive nucleation of three-dimensional growth centers. This growth mechanism was verified by microscopic examination of the electrode surface using a scanning electron microscope (Fig. 4). This micrograph shows nuclei of all ages (progressive nucleation) growing at the sides and the bottom of an etch pit.

Deposition on cadmium sulfide.—Lead.—The overpotential at which the deposition of Pb on CdS begins was shown by the voltammograms to be *ca.* −15 mV. Current-time transients for this deposition reaction show a slowly decaying current initially, but at longer times the current begins to rise again as processes of nucleation and crystal growth become rate determining. It is found that the deposition process is rather slow in the dark, but is strongly influenced by light with $\hbar\omega > 2.5$ eV (11).

Silver.—The transient response to the application of potential steps for the deposition of Ag on a CdS electrode is shown in Fig. 5. The reference electrode used in this case was a silver wire (Ag^+/Ag) and therefore the potentials given in Fig. 5 are the actual overpotentials. An interesting feature of this deposition reaction is seen in Fig. 5a where the deposition

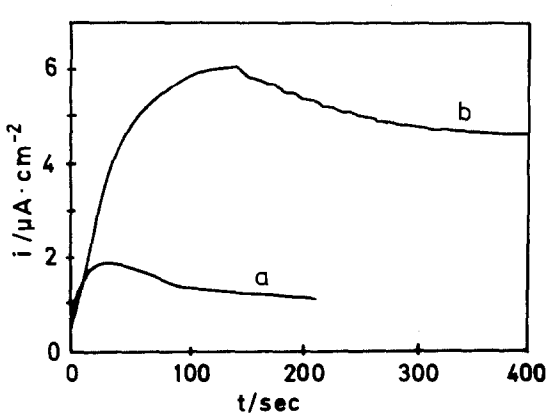

Fig. 3. Current-time transients for Pd deposition on ZnO. Potentials stepped from +1.0V *vs.* SCE to (a) +230 mV, (b) +220 mV.

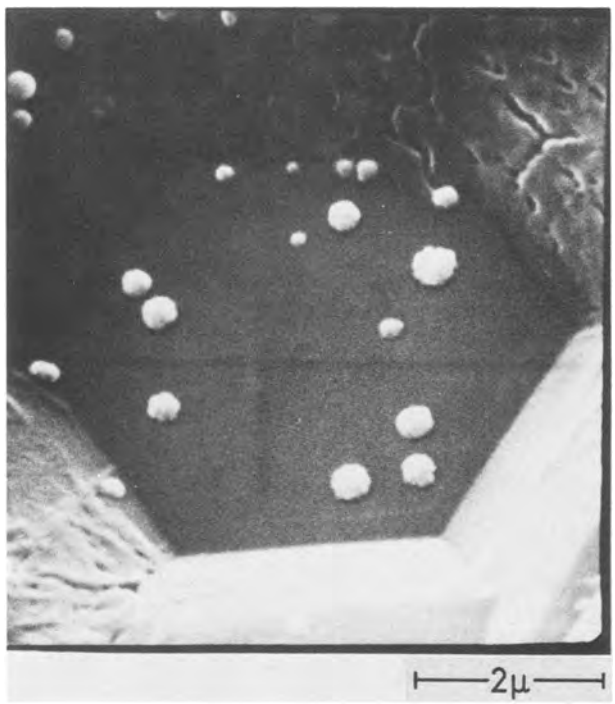

Fig. 4. Scanning electron micrograph of palladium deposited on ZnO.

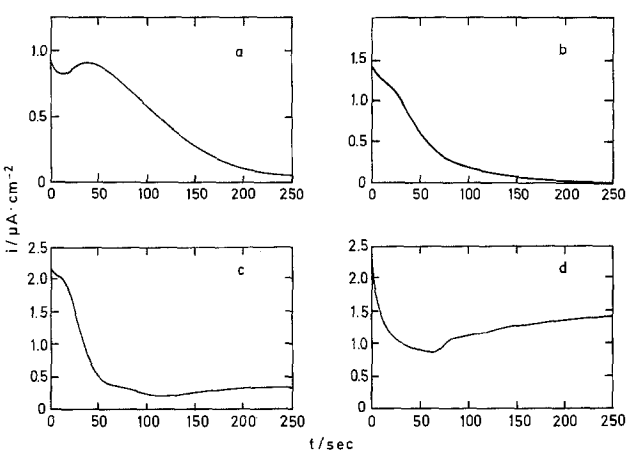

Fig. 5. Current-time transients for silver deposition on CdS. Potentials stepped from +500 mV *vs.* Ag^+/Ag to (a) +25 mV, (b) 0 mV, (c) −50 mV, (d) −100 mV.

of the metal occurs at potentials anodic to the thermodynamic reversible potential, *i.e.*, it appears as though there is underpotential deposition of Ag on CdS substrate. It is also of interest to note that the current-time transients at all overpotentials show an unsymmetrical peak of approximately constant area in the beginning. Integration of the peak shows that the charge passed is close to that required for the formation of a two-dimensional monolayer. It is very likely (7), therefore, that such a monolayer of Ag is formed on CdS when the potential is stepped to a region close to the equilibrium potential of silver.

Palladium.—The overpotential at which the deposition of Pd on CdS takes place is *ca.* −310 mV. This value still differs from the overpotentials at which Pd deposition on metal substrates occurs. Analysis of the current-time transients, shown in Fig. 6, indicates the growth of instantaneously nucleated three-dimensional nuclei.

Deposition on n-gallium phosphide.—Lead.—The current-potential curve obtained for the deposition of Pb on n-GaP showed that the deposition occurs at an overpotential of −590 mV. The current-time tran-

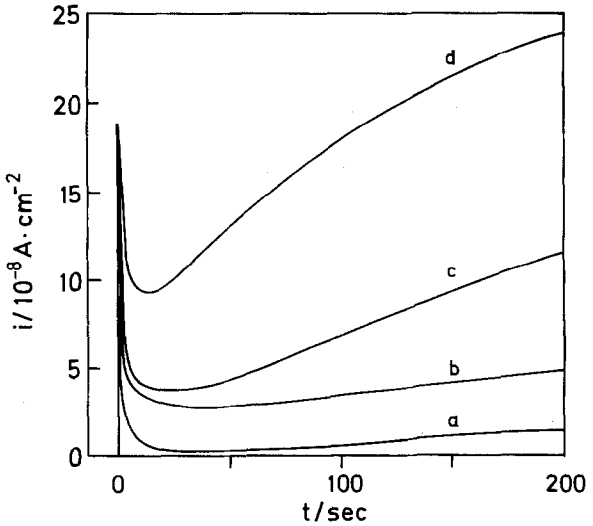

Fig. 6. Current-time transients for palladium deposition on CdS. Potentials stepped from +1.0V *vs.* SCE to (a) +337 mV, (b) +300 mV, (c) +285 mV, (d) +270 mV.

sients showed only a current decreasing with time. No characteristic features could be discerned and so the transients could not be analyzed without doing further supplementary experiments.

Silver.—The overpotential at which deposition of Ag on n-GaP occurs is *ca.* −700 mV. This is a very large overpotential in comparison with the overpotentials at which Ag deposition on metal substrates occurs. The experimental current-time transients obtained for this deposition reaction are shown in Fig. 7. The analysis of these curves shows that metal deposition occurs via instantaneous nucleation of (hemi)spherical growth centers and their subsequent three-dimensional growth controlled by transport processes (12). At short times the current increases due to the increasing area of contact between the substrate and the growing nuclei.

Palladium.—The deposition of Pd on n-GaP occurs at overpotentials greater than −800 mV. These overpotentials are much larger than the overpotential required for the deposition of Pd on metal substrates. Analysis of the current-time transients for the deposition of Pd on n-GaP at these overpotentials indicates progressive nucleation of three-dimensional growth centers. Transients at even higher overpotentials, however, indicate layer growth of the metal.

Deposition on n-gallium arsenide.—Lead.—The overpotential at which deposition of Pb on n-GaAs occurs was shown by current-potential curves to be *ca.* −160 mV. However, no additional information could be obtained from current-time transients, which had no characteristic features.

Silver and palladium.—Experiments, done with n-GaAs in solutions containing Ag^+ and Pd^{2+}, showed that deposition of these two metals also took place by simply dipping the electrode into the solution. Here, we obviously have a case of currentless deposition via hole injection by the metal ions. The analysis of current-time transients, as well as electron micrographs of these deposits, revealed layered structure. A possible explanation for the layer growth being favored in the case of hole injection into the semiconductor is given in the next section. A more extensive study on currentless metal deposition onto semiconductor electrodes will be presented later.

Deposition on tin dioxide.—Lead. —The deposition of Pb on SnO_2 starts at a low overpotential of only −2 mV. This is also the magnitude of the overpotential at which Pb deposition on metal substrates takes place. Current-time transients for the deposition reaction are shown in Fig. 8. It is observed that the form of the transients does not change over quite a large overpotential range. A peak in the transients at all overpotentials suggests a layer growth of the metal.

Silver.—The overpotential required for the deposition of Ag on SnO_2 is −35 mV. This value is similar to the overpotential at which Ag deposition on carbon (10) occurs. Potentiostatic current-time transients for the deposition of Ag on SnO_2 are similar to those for the deposition of Ag on ZnO and show that the current increases linearly with time until planar diffusion becomes rate determining. The theoretical transient for such a growth law predicts instantaneous nucleation, but, the potential dependence of the current suggests (13) that this is the case of nucleation at

the same site, *i.e.*, on top of existing nuclei. This is confirmed by the electron micrograph, Fig. 9, which shows the formation of three-dimensional single crystals of the metal.

Palladium.—Deposition of Pd on SnO_2 takes place at overpotentials below −300 mV. These values compare well with the overpotentials at which Pd deposition on metal substrates occurs. Current-time transients are shown in Fig. 10 and their analysis (Fig. 10b) indicates that Pd deposition takes place through progressive nucleation of three-dimensional growth centers whose subsequent growth is controlled by mass transfer in solution.

Discussion

The central question in the study of metal deposition on semiconductor electrodes is the extent to which the nature of the substrate influences the metal deposition reaction. The results of this investigation are discussed from two aspects: (*i*) the large overpotentials required for the deposition of some metals on semiconductor electrodes, and, (*ii*) the effect of the metal-semiconductor junction barrier on the nucleation behavior of the metal.

Metal deposition overpotential on semiconductor substrates.—The apparent overpotentials required for the deposition of Pb, Ag, and Pd on different semiconductors are summarized in Table I. It is observed that much larger overpotentials are usually required for the deposition of noble metals on semiconductors than is the case when deposition on metal substrates

occurs. This difference can be associated with the difference in the distributions of electronic charge at the semiconductor-electrolyte interface and the metal-electrolyte interface. A metal electrode immersed in the solution of an electrolyte develops a double layer at the metal-electrolyte interface. When a potential step is applied to such an electrode system all the charge appears at the surface and most of the potential drop occurs in the compact Helmholtz layer for solutions of high ionic strength. Electrons are always available in the surface of a metal in large enough concentrations to interact with the metal ions in solu-

tions, first for the formation of discharged atoms and then of the nuclei of the metal. Hence, for metal deposition on metal substrates only small overpotentials of a few millivolts are required to overcome the nucleation energy barrier before deposition of the metal occurs.

In the case of a semiconductor electrode the picture is totally different. As long as the semiconductor is not very highly doped, excess charge on the semiconductor electrode is distributed over an extended space charge layer. As a result the potential drop in the Helmholtz double layer can only be changed very little by the applied potential. However, due to the low density of mobile charge carriers (electrons of the conduction band in the n-type semiconductors, used in these experiments) the concentration of electronic charge carriers varies markedly with the electrode potential. Since electrons are needed for the metal ion discharge, there will be a critical concentration of electrons necessary to cause enough interaction with metal ions in solution to start nucleation of a metal deposit. The possibility of metal deposition and the overpotential required will therefore depend on the concentration of electrons in the surface of a particular semiconductor available at the equilibrium potential of the metal to be deposited. One can calculate the surface concentration of electrons for a semiconductor electrode as a function of the electrode potential V, if the flatband potential V_{fb} of the semiconductor is known. Denoting the bulk electron concentration with n_o, the approximate surface concentration of electrons, n_s, is given by

$$n_s \approx n_o \exp\left[-e_o\,(V - V_{fb})/kT\right]$$

Using this expression, we obtain a rough estimate of the surface electron concentration in the semiconductor at the equilibrium potential, V_o, of the metal and at the potential, V_D, where electrolytic deposition begins. These data are also presented in Table I for the systems studied.

The flatband potentials of the semiconductor electrodes at two different pH values are given in Table I. These values, except for SnO_2 were deduced from Mott-Schottky plots and are in good agreement with values reported by others (14). The values for SnO_2 were obtained from literature (15). In Fig. 11 the energy levels of the various semiconductors in solutions of pH = 5 and 1 are shown on the potential scale together with the equilibrium potentials of the metals deposited. These redox potentials were measured in the same cell in which deposition studies were carried out and their values agree reasonably well with literature values for metal ion concentrations of 10^{-3}M.

Inspection of Fig. 11 reveals immediately why in some cases such large overpotentials are required for metal deposition. Whenever the equilibrium potential of the metal is well below the conduction bandedge of the semiconductor, the concentration of electrons at the electrode surface is much too low to facilitate metal ion discharge. Comparing the calculated n_s values at the potentials V_o and V_D (Table I), the various systems may be separated into three groups: (*i*) the metallike substrate. When the redox potential of the metal is close to or above the conduction bandedge an accumulation layer is formed. Then enough electrons are available at V_o to allow deposition without appreciable overpotentials. This is certainly the case for the deposition of Pb on SnO_2 and ZnO, and most likely also for the deposition of Ag on SnO_2 and Pb on CdS. In these cases the overpotential is determined by the nucleation barrier of the metal and not by the semiconductor properties. This is also true for Pd on SnO_2 where the observed large overpotental is characteristic of Pd. As is seen in Table I, n_s at V_D for Pd is several orders of magnitude larger than the critical value; therefore no restrictions from the semiconductor are expected. (*ii*) Semiconductor

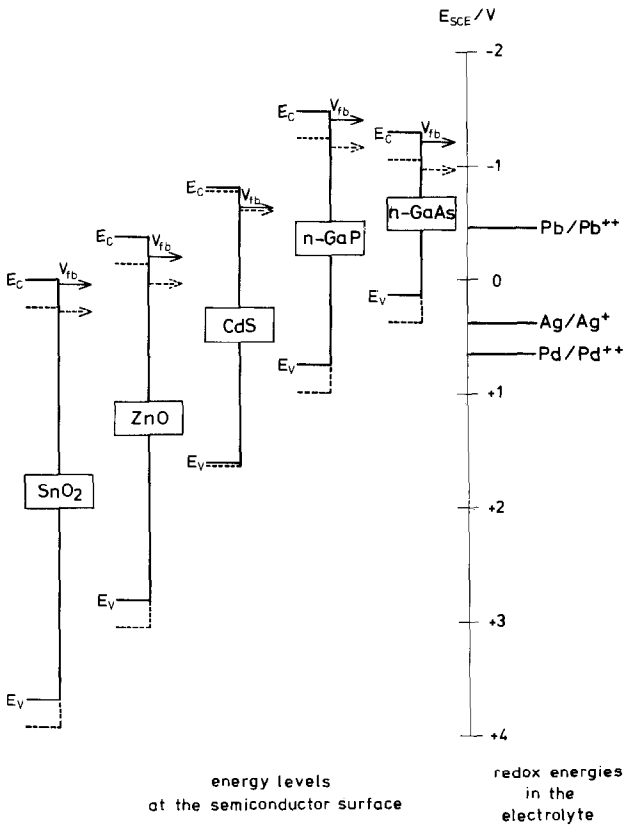

Fig. 11. Energy level diagram for the semiconductor/electrolyte interface. The flatband potentials V_{fb} of the various semiconductors are given for solutions of pH = 5 (——) and pH = 1 (– – –). The equilibrium potentials of the metals are shown on the right.

restriction due to low n_s. For Pb on n-GaAs and n-GaP, and Ag and Pd on ZnO the electron concentration at the equilibrium potential is too low to facilitate deposition. Therefore the potential has to be raised until a critical concentration of about 10^{10} electrons per cm^3 is available at the surface for all cases, before the deposition reaction can start. (*iii*) Chemical interaction with the substrate. For Ag and Pd on CdS, n-GaP, and n-GaAs the n_s values even at the deposition potentials are much too low to explain these overpotentials. Obviously in these cases a strong chemical interaction between semiconductor substrate and metal deposit helps deposition despite the low level of free electrons. This is most easily explained for Ag and Pd on n-GaAs, where currentless deposition by hole injection is possible (see Fig. 11) and indeed observed. To a much lesser extent the currentless deposition also occurs when n-GaP is brought into contact with solutions containing Ag^+ and Pd^{2+} ions. Since the hole in the semiconductor surface, describing a dangling bond, and the metal adatom are two rather reactive species, they will interact strongly with each other and form a stable bond. In the case of Ag and Pd on CdS the interaction between the metal atoms and S^{--} may lead to a polar bond, favoring the discharge of the metal ion. For Ag on CdS there is still the added complication of an exchange reaction occurring between the Cd ions in the lattice and Ag^+ in solution, forming a surface of presumably Ag_2S. This is analogous to the formation of a film of Cu_2S on a CdS crystal, when the latter is brought into contact with cuprous ions (17, 18). An investigation of this reaction has just been completed in this laboratory (19). A general consequence of the strong interaction between substrate and metal-adatom is the formation of a monolayer (6), which may manifest itself in the shape of the current-transients, in electron micrographs or in the occurrence of an underpotential deposition as in the case of Ag on CdS.

Effect of the metal-semiconductor junction barrier on the growth mechanism.—It is known from the thermodynamics of heterogeneous nucleation (20) that nucleation and growth behavior during metal deposition on a metal substrate is a function of the surface energies of the nucleate and the substrate. The experimental data obtained in this investigation, on the other hand, show that for semiconductor substrates it is the difference in work functions of the depositing metal and the substrate which mainly determines the growth behavior.

Deposition of metals on all substrates begins with the nucleation of minute clusters of the new phase formed at energetically favorable sites on the substrate. In the case of semiconductor electrodes, even small clusters consisting of only a few metal atoms in contact with the semiconductor constitute localized Schottky barriers. These contacts are in parallel to the semiconductor-electrolyte contact and thus modify the space-charge layer, which leads to a new distribution of charge at the surface as shown in Fig. 12. For a metal with a high work function the depletion layer at the contacts is extended due to charge accumulation in the deposit (see Fig. 12a), resulting in the formation of an additional barrier at the semiconductor-metal interface. Charge transfer on top of the existing metal nuclei is then more restricted by the availability of electrons so that a metal ion approaching the electrode surface would thus find it more favorable to deposit on the exposed parts of the electrode surface. That is, this system encourages progressive nucleation and therefore rapid coverage of the electrode by a layerlike growth of the metal. This is confirmed by the experimental data for the deposition of Pd on the n-type semiconductor electrodes investigated.

For a metal with a low work function (*e.g.*, Pb and Ag, see Table I) the picture is reversed. The depletion layer width at the metal-semiconductor contacts decreases so that the availability of electrons in these regions increases and the distribution of charge at the nucleus-electrolyte interface tends somewhat toward the distribution in the Helmholtz layer at a normal metal-electrolyte interface. The metal nuclei then become preferential sites for further phase change and prevent any further nucleation on the substrate. Such a system therefore encourages instantaneous nucleation. Experimental data for the deposition of Pb and Ag on the semiconductor substrates show that the metal deposition indeed occurs via instantaneous nucleation of the growth centers.

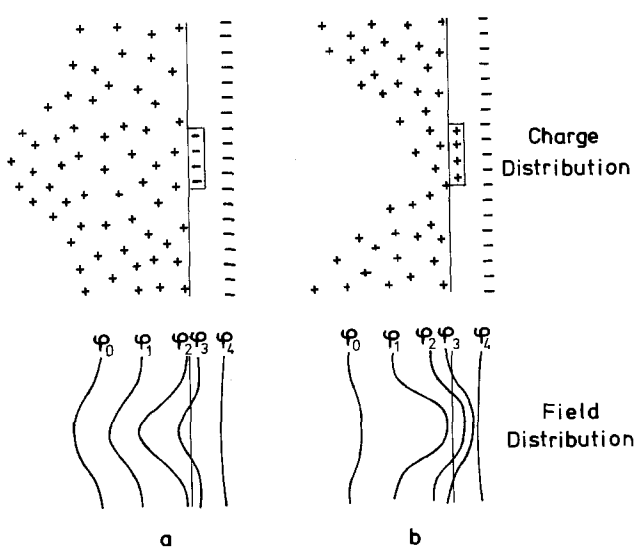

Fig. 12. Charge and field distributions in the space-charge layer of a semiconductor in contact with the nuclei of a metal with (a) high and (b) low work function.

In summary we have shown the dependency of the overpotential on the relative position of the redox potential of the metal with respect to the flatband potential of the semiconductor and the role played by the metal work function in influencing the nucleation behavior during deposition. Deviations from these observations are due to chemical interaction between the metal and the substrate and these interactions are the subject of a separate investigation in this laboratory.

Manuscript submitted Dec. 21, 1976; revised manuscript received Feb. 28, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

Solar Conversion Efficiency of Pressure Sintered Cadmium Selenide Liquid Junction Cells

B. Miller,* A. Heller,* M. Robbins, S. Menezes,
K. C. Chang, and J. Thomson, Jr.

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Pressure sintered electrodes of cadmium selenide subsequently doped with cadmium vapor have shown solar energy conversion efficiencies approaching ¾ of those of single crystal specimens in sunlight experiments. The cell CdSe/1F Na_2S-1F S-1F NaOH/C has operated at 5.1% conversion efficiency under AM2 conditions with polycrystalline electrodes. The relatively small sacrifice of efficiency from single crystal values of 7.5 ± 0.5% suggests the possibility of substantial cost advantage. The temperature and pressure conditions, cadmium doping procedure, material characterization, and the voltammetric behavior of the cell are discussed.

A major advantage of semiconductor liquid junction solar cells (1) with direct gap materials is their compatibility with polycrystalline electrodes (2-10). Since light is absorbed and holes are transferred to a solution redox couple at the same interface, high efficiency and little effect of grain boundaries are anticipated if the crystallite size is at least comparable to the light absorption depth. This dimension is of the order of 1μ for direct bandgap semiconductors (*i.e.*, those excited in transitions not involving transfer of momentum to phonons). These semiconductors include the cadmium chalcogenides, GaAs, and InP.

Since the preparation of single crystals is probably the most expensive step in producing photovoltaic cells, considerable economic advantage is expected from utilization of polycrystalline materials with efficiencies close to those of the single crystal in liquid junction based cells. Pressure sintering of semiconductor crystallites (initially prepared by conventional chemistry) is one excellent possibility for such a material. The technique can be automated, and disks or sheets of the polycrystalline material, convenient for solar energy converting electrolytic cells, can be formed.

In this work, cadmium selenide powder has been pressure sintered under controlled temperatures and pressures and doped with cadmium by heating the composite in the presence of the metal at controlled temperature. The n-type product resulting has been compared for performance relative to that of doped single crystal electrodes in the cell (11) CdSe/1F Na_2S-1F S-1F NaOH/C at typical solar irradiance levels, both in controlled laboratory and outdoor tests. Studies of CdSe photoelectrodes have been made previously (12-16).

Experimental

CdSe powder (99.999%, −325 mesh) from Alfa-Ventron was pressure sintered at temperatures in the range 925°-1100°C, usually near 10,000 psi for 2 hr. The resulting disks of about 3 mm thickness and 2.5 cm diameter were sliced in half, then annealed over Cd metal in evacuated quartz tubes at temperatures of 500°-700°C for 16-160 hr. Indium and silver epoxy electrical contacts to the sliced pellets and crystals were used. The electrode configuration, cells, and electronics were similar to those cited earlier (11, 17). The CdSe crystals were obtained from Cleveland Crystals, Incorporated as doped 1 cm^2 × 1 mm slices with resistivities in the range 1-10 Ω-cm and as a pure boule which was cut and Cd doped in the manner described for the pressed composites, but at 800°C.

The data compiled in Table I were obtained for a stationary CdSe electrode in a magnetically stirred cell with large area carbon counterelectrode. The comparable data in Table II were taken at rotating CdSe disk electrodes under three-electrode potentiostatic control where the zero cell voltage condition was that given by a carbon rod reference electrode. Thus the current-potential traces did not include any contribution from the polarization of a second carbon electrode used as a counterelectrode and were minimally affected by cell *iR* drop. We note that the latter two factors could be made very small in a suitable cell, as was the case for the one employed for Table I, in which negligible polarization of the working (large) carbon cathode relative to a carbon reference electrode was confirmed. The data of the two tables are thus equivalent in their estimate of cell efficiencies for solar conversion in spite of the operational differences. We note a higher level of efficiency for our cells [see also Ref. (11)] relative to the cell cited by Ellis, Kaiser, and Wrighton (12) where the values decline severely with light intensity as solar levels of irradiance are approached.

Polycrystalline CdSe was also formed by anodizing N5 Cd metal in 1M K_2Se-1M KOH, made by bubbling H_2Se (Matheson) in aqueous KOH. Anodization at 4 mA/cm^2 was continued for 16 hr. The electrodes were then etched in glacial acetic acid for 1 min. The anodic procedure for preparing CdSe is similar to that given by us for *in situ* formation of sulfide semiconductors (17).

All experiments were performed under argon or nitrogen atmospheres. Prior to use, all electrodes except the anodic film were etched in 3:1 or 4:1 HCl-HNO_3. All exposed electrode areas were approximately 0.3 cm^2.

The data in Table I were obtained with sunlight at approximately AM2 irradiances. Table II data were

obtained with a 100W tungsten-halogen source, with and without a Schott KG-2 filter. This filter brings the spectrum of the source much closer to that of sunlight.

Results and Discussion

The current-voltage characteristic of a pressure sintered electrode in the CdSe/1F Na_2S-1F S-1F NaOH/C cell configuration used to obtain the data in Table I is shown in Fig. 1. The photocurrent spectrum of the etched polycrystalline CdSe does not differ substantially from that of the etched single crystal (11), and is as expected for a 1.7 eV bandgap. The over-all AM2 efficiencies, determined from Fig. 1 type curves and thermopile measurements, for single crystal, pressure sintered polycrystalline, and anodized polycrystalline electrode cells are collected in Table I, along with other pertinent data. The solar energy conversion efficiency of the cell with the pressure sintered CdSe reaches 5.1%, or 68% of the value obtained with the single crystal electrode. The lower efficiency of the anodically formed CdSe is due primarily to the limited thickness achieved by anodization under present conditions. The CdSe layer is too thin to absorb a large fraction of the incident light. No correction has been made for Fresnel reflection and solution absorbance loss: The efficiencies measured are true external conversion efficiencies and would be higher if corrected to actual photon flux reaching the electrode.

The relative efficiencies of two single crystal and four pressure sintered CdSe electrode cells are shown in Table II. The values of efficiency are normalized with respect to the crystal electrode in Table I whose origin is identical to that of crystal I in Table II. The electrodes of Table II were run under identical conditions, by fixing the lamp current and the geometry. The average short-circuit current corresponding to the unit normalized value is about 25 mA/cm², or approaching 2 AM2 solar intensities. A number of runs representing both the filter and nonfilter conditions have been averaged to obtain Table II entries. Relative results were not affected by the filter.

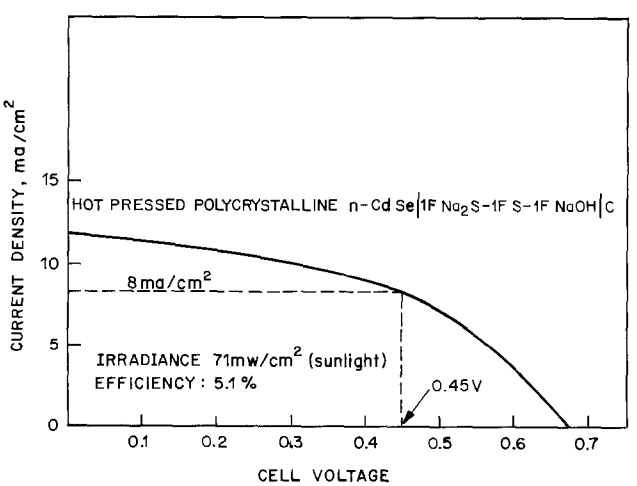

Fig. 1. Current-voltage curve for the cell n-CdSe (pressure sintered)/1F Na_2S-1F S-1F NaOH/C under sunlight.

Separate experiments in which a polycrystalline electrode was run for periods sufficient to dissolve nearly 1g of CdSe by photocorrosion showed no measurable weight loss, as also found for single crystal CdSe (12). The stability of cell currents is dependent both on average current level (light intensity) and sulfide-polysulfide concentration. Higher currents require higher concentrations to stabilize cell efficiency with time. For example, when run under tungsten illumination at short circuit initially producing a current density of 12.5 mA/cm² (~AM2 equivalence), a polycrystalline electrode dropped to 10.8 mA/cm² in 24 hr in 2F S/2F NaOH saturated with Na_2S (nearly 2F) and all the way to 0.4 mA/cm² in a 1F S/1F Na_2S/1F NaOH solution in the same time (the initial efficiencies in both solutions of the freshly etched electrodes were virtually the same). This important parameter will be discussed in detail in a future publication.

Numerous experiments have shown that the major determinant of relative performance is the etching pretreatment (11). The fill factor is sensitive to etching times, age, and preparation of the etchant. The relative efficiencies are unchanged when the fresh electrodes are etched for identical periods in identical etchants. Variation of the etching procedure changes the fill factor primarily. The fill factor entries in Table I represent the best average fill factors for the conditions used.

The flux of absorbed photons in the experiments of Table II exceeded the flux under AM2 sunlight conditions since the average short-circuit current for crystal 1 was ~25 mA/cm². The theoretical limit for 1.7 eV bandgap is 17.5 mA/cm² at AM2 sunlight (18).

The significant result is that pressure sintered specimens in Table II achieved between 48 and 70% of the solar conversion efficiency of the better of the two crystals. The second crystal, which was Cd vapor doped like the sinters, had only 77% of the efficiency of the reference crystal, and the pressed electrodes reached 90% of this level.

Sintering pressure and temperature are less critical than the doping level, which is currently being optimized. This is probably due to the large (10-20μ) grain size produced at all temperatures. (Grain sizes were measured after sintering in the plane parallel to the electrode surface.)

The doping of the samples in Table II was not ideally uniform, and there was variation in the data with the thickness of the layer removed from the surface first by mechanical abrasion, then by etching of the slices. This fact does not alter the key conclusions about the performance of the pressure sintered materials, but rather emphasizes the ease of producing polycrystalline materials with substantial conversion efficiencies.

The fact that, in these cells, the efficiencies of polycrystalline semiconductors approach those of single crystals is explained by the characteristics of the direct bandgap semiconductor-liquid junctions. These satisfy four requisites for efficient photovoltaic energy conversion with polycrystalline materials. These

requirements are that (*i*) the grain size should be sufficiently large to absorb practically all the light in the top layer of grains exposed to the electrolyte, (*ii*) the space charge layer thickness should be equal to or larger than the light absorption depth to assure rapid carrier separation (19), (*iii*) the light losses through the solution path to the semiconductor junction should be low, and (*iv*) the traps due to lattice mismatch or dislocations at or near the absorbing junction causing recombination of carriers should be minimized.

The first requirement says that L, the absorption length defined by the light absorption expression

$$I = I_0 \exp(-\alpha L)$$

must be less than the grain size. Since α for the direct gap CdSe is 10^4-10^5 cm^{-1}, grain sizes of a few microns are adequate. The 10μ grains produced by the described sintering easily satisfy this requirement. Absorption of light beyond the first layer of grains may not add to the photocurrents because of efficient trapping of the minority carriers at the grain boundary. The grain size criterion is probably also met in polycrystalline TiO_2 films in the photoelectrolysis of water (4).

In the second requirement, the thickness of the space charge layer, δ, must also be on the order of L to assure prompt separation of the carriers and thus reduce the probability of their recombination. δ is given by the equation (20, 21)

$$\delta = \left(\frac{2\epsilon\epsilon_0 \Delta\psi_{sc}}{qN_D} \right)^{1/2}$$

where ϵ is the static dielectric constant of the semiconductor [9.4 for CdSe (22)], ϵ_0 the permittivity of vacuum, $\Delta\psi_{sc}$ the voltage drop across the space charge layer (~0.7V in these cells), q the charge on the electron, and N_D the donor concentration. The latter is controlled by the time and temperature of exposure to Cd vapor in the annealing process.

For requirement (*iii*), liquid junction cells may be in a favorable position relative to p-n junction or Schottky barrier solid-state cells where light must pass through a semiconductor or metal, respectively. Many possible redox electrolytes are transparent over substantial parts of the relevant spectrum, although polysulfide solutions absorb strongly below 470 nm.

Requirement (*iv*) is inherently achieved in solid-liquid junctions where the liquid conforms to the solid. In contrast, faces of grains of two polycrystalline solids (such as two different materials of a heterojunction or even grains in a homojunction) are not easily so aligned as to match lattices. Furthermore, differences in thermal expansion coefficients at such interfaces can create stresses that result in dislocations and generate local recombination traps. Such problems do not exist at liquid-solid interfaces, and, if the grains are (operationally) single crystals, surface defects at the upper layer can be removed by etching.

Conclusion

Polycrystalline materials, as exemplified by pressure sintered CdSe, can be operated in regenerative electrolytic solar cells at substantial fractions of the respectable energy conversion efficiency of single crystal electrodes. Further optimization and control of these efficiencies appear possible and are being sought. It is anticipated that the demonstrated characteristics of these polycrystalline electrodes can be carried over to even more economic methods of manufacture. Although the problems of long term chemical stability of such liquid junction solar cells remain, a most important theoretical advantage of these systems has been further documented in this work, namely, that polycrystalline materials are not substantially inferior to single crystals.

Analysis of Impedance and Admittance Data for Solids and Liquids

J. Ross Macdonald* and J. A. Garber[1]

Department of Physics and Astronomy, University of North Carolina, Chapel Hill, North Carolina 27514

ABSTRACT

Some problems of analyzing small-signal impedance data on solids or liquids are discussed. A method of using ordinary nonlinear least squares fitting procedures with minor modification to fit at the same time real and imaginary functions of the same set of unknown parameters to complex data is described in detail. This method of complex least squares fitting, which has several advantages over previous approaches, is illustrated by fitting equivalent circuit impedances to some polycrystalline β-alumina impedance data and to synthetic impedance and admittance data calculated from a theoretical model of the response of homogeneous material with completely blocking electrodes. When different physical processes yield response in overlapping frequency regions so that the different processes lead to some melding of effects in an impedance plane representation, interpretation of equivalent circuit parameters becomes difficult even when the degree of fit of the model to the data is excellent. In particular, low frequency extrapolation in the impedance plane to obtain an estimate of bulk resistance, R_x, in an overlapping completely blocking situation can yield estimates of R_x with very large errors. A method is described of avoiding such errors for both conventional and complex least squares estimation. In essence, one must find and fit the unique equivalent circuit whose elements remain related by invariant formulas to underlying microscopic parameters of the material/electrode system no matter what the degree of phenomena overlap.

Small-signal a-c impedance measurements are gaining in popularity as a technique for characterizing liquid and solid electrolytes and other materials. Analysis of small-signal data can almost always yield estimates of bulk conductivity of new materials free from the electrode polarization effects which plague steady-state d-c measurements. Under favorable conditions, detailed analysis of impedance data for homogeneous materials in terms of an appropriate model of the electrode/material system can also yield accurate estimates of microscopic parameters: mobilities, dielectric constant, electrode reaction rate constants, etc., which characterize interface and bulk behavior of the system (1-3). Even for polycrystalline materials, such as the usual form of the superionic conductor β-alumina, proper analysis may lead to valuable information about electrode reactions and intergrain and intragrain properties.

In order to carry out a meaningful analysis of impedance or admittance data, one must compare them with an analytic expression for the measured quantity, a function of frequency which generally depends on several frequency-independent parameters. Optimum characterization of the system requires that one be able to relate the gross parameters of the analytical fitting model to the microscopic parameters of interest. Sometimes, however, in the absence of a sufficiently detailed model one must be satisfied, at least for a while, with estimates of the gross parameter values, since they, and the form of the impedance expression, at least provide a concise means of representing the data. The dependence of the gross parameters, determined from several data sets, on experimental variables such as temperature may then lead to valuable insights.

It is conventional, and very desirable when possible, to approximate the analytical model of the system by an equivalent electrical circuit, preferably one which offers a useful compromise between simplicity and accuracy. It is desirable, for instance, that the equivalent circuit include as few frequency-dependent elements, such as Warburg (diffusion) impedances (1, 3), as possible. Although the basic analysis method described and illustrated herein does not require equivalent circuit representation, but only an analytical expression of the model, equivalent circuits can often clarify model behavior by clearly identifying separate phenomena which may be significant in quite different frequency ranges. Thus, most of the subsequent analysis herein will employ equivalent circuit representation. Figure 1 is a diagram which illustrates some of the important elements in the characterization process.

Once one has obtained impedance-frequency data, there are three reasonable things one can do. One can plot the impedance, Z, and/or admittance, Y, as a parametric function of frequency in the complex plane (*e.g.*, Re(Z) along the abscissa and $-\mathrm{Im}(Z)$ along the ordinate axis); one can analyze the data to obtain gross and possibly even microscopic parameters; and one can convert the data to a complex effective dielectric constant, $\epsilon^*_{\mathrm{eff}}$, and consider its frequency dependence, loss tangent, and high and low frequency limiting values. The first two approaches are often desirable; the third may not be. Whenever a system involves inhomogeneities and phase boundaries (*e.g.*, homogeneous material and electrodes or polycrystalline material with

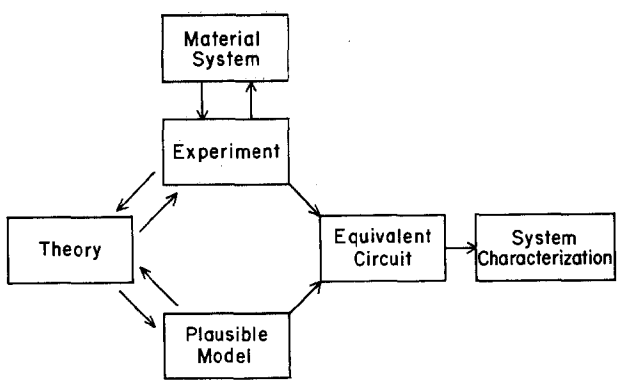

Fig. 1. Block diagram of possible system characterization elements and interactions.

[1] Present address: Department of Geosciences, North Carolina State University, Raleigh, North Carolina 27607.

Key words: complex least squares, data analysis, solid electrolyte, impedance.

or without electrodes), there is a good possibility that these inhomogeneities and phase boundaries may contribute appreciably to the small-signal electrical response of the system. The derivation of an effective dielectric constant for the whole system is then undesirable since dielectric constant is properly defined in terms of an average over a possibly small but macroscopic region of a homogeneous material. Thus, the derivation of a complex dielectric constant and construction of the corresponding Cole-Cole (4) plot is appropriate for a dipolar dielectric with no mobile charge and thus no electrode space-charge or reaction effects, but both are inappropriate when mobile charge is present and electrode and/or grain boundary processes may be important. In this latter case, however, it has been found that plotting the analog of the Cole-Cole diagram, the impedance and/or possibly the admittance, in the complex plane is almost always instructive and useful (1, 3, 5, 6).

Perhaps the most subtle and difficult aspect of impedance data analysis is the development of an adequate analytical model. Some aspects of the general problem of discriminating between several models (*i.e.*, picking the most appropriate one) have been discussed elsewhere (7). One possible model (to be denoted model A) which may be appropriate for the small-signal response over a considerable range of conditions is based on the exact solution of the appropriate transport, continuity, and boundary-condition equations for instrinsic-extrinsic conduction and possible electrode reactions and adsorption (2, 8). It is particularly pertinent for conduction by ions and/or vacancies and interstitials. Some of its predictions for a simple situation are used later in this work to illustrate the analysis method described herein and to demonstrate some pitfalls in interpretation.

The present paper deals primarily with data analysis when an analytical model is available, rather than with the much more difficult problem of finding the best model. Given the model (expressed, say, as an equivalent circuit), how can one best find meaningful estimates of its parameters? One approach, recently employed by de Levie and Vukadin (9), involves a sequence of extrapolations and subtractions. As these authors point out, however, the extrapolation-subtraction method inevitably tends to accumulate (estimation) errors in the last-determined parameters, and it yields no estimates of parameter or fitting uncertainties. It would, therefore, be valuable to have a method that avoids these weaknesses. Such a method is described and illustrated below.

Complex Least Squares

When an analytic expression of a model is available, whether expressed in equivalent circuit form or not, it seems natural to consider least squares fitting of the impedance or admittance data to the impedance or admittance of the selected model in order to obtain estimates of the model parameter values. Several good nonlinear least squares (NLS) computer programs are availabe which allow fitting of real data to the model $y = f(x)$, with or without weighting of Y_i measured values. Some generalized NLS programs also allow weighting of X_i data values as well (10, 11). Impedance data and analytic expressions are of the form $Z(\omega) = \mathrm{Re}[Z] + i\mathrm{Im}(Z) \equiv u(\omega) + iv(\omega)$. Clearly, $u(\omega)$ and $v(\omega)$ will be different functions of ω but will generally both involve some or all of the same parameters. When complex data have been fitted by least squares in the past, the real $u(\omega)$ and $v(\omega)$ functions have usually been fitted separately using $\mathrm{Re}(Z)$ and $\mathrm{Im}(Z)$ data, respectively. The result of the two independent fittings is then two separate sets of different parameter value estimates.

Although the above type of fitting may be useful, it is not a simultaneous (consistent) least squares fitting of all the data, yielding one set of parameter estimates determined by all the available data taken together. Therefore, it is desirable to fit the real and imaginary parts of measured impedance to the analytical form of a model or circuit simultaneously. The only published approach of this kind known to the authors is that of Sheppard, Jordan, and Grant (12, 13). We have found, however, that the readily available generalized NLS fitting programs of Powell and Macdonald (10) and Britt and Luecke (11) may be modified very simply to allow fitting of complex data to complex functions. These modified programs seem preferable to the approach outlined by Sheppard (13).

To do complex least squares fitting with the above programs it is unnecessary to use the full theoretical analysis of Britt and Luecke, which involves an arbitrary number of different variables, any of which can be weighted, and which has not been embodied in an actual computer program in complete generality. For typical impedance or admittance data, the measured real and imaginary parts are generally uncertain, and the individual data values may need weighting to obtain the most significant statistical parameter estimates. But the frequency, f or ω, is generally measured so accurately that its uncertainties are negligible. It can then be identified with the x variable, assumed known exactly, in $y = f(x)$ real NLS fitting. Now fitting of complex data, $Z(\omega)$, can be simply reduced, as follows, to real fitting of the usual $y_i = f(x) = f(\omega_i, A_j)$ model form. Here $i = 1, 2, \ldots, n$ designates the n complex (double-valued) data points and the n real frequencies, and $j = 1, 2, \ldots, m$ denotes the m real parameters, A_j. Let us define y_k as a composite variable with $k = 1, 2, \ldots, 2n$. For $k = 1$ to n, let $Y_k \equiv \mathrm{Re}[Z(\omega_k)]$, and for $k = n + 1$ to $2n$, let $Y_k \equiv \mathrm{Im}[Z(\omega_{k-n})]$, where $\mathrm{Re}[Z]$ and $\mathrm{Im}[Z]$ are the real and imaginary measured values of Z. Now, define the analytic fitting model for impedance as $Z_m(\omega_i, A_j) \equiv u(\omega_i, A_j) + iv(\omega_i, A_j)$. The actual analytical separation of the complex Z_m function into real and imaginary parts is unnecessary; only numerical separation by the computer is needed. Thus, we let $u \equiv \mathrm{Re}(Z_m)$ and $v \equiv \mathrm{Im}(Z_m)$ be either analytical or numerical real and imaginary parts of Z_m, and let $y_k \equiv u(\omega_k, A_j)$ for $k = 1$ to n, and $y_k \equiv v(\omega_{k-n}, A_j)$ for $k = n + 1$ to $2n$. Fitting of complex data then just involves the ordinary, real NLS fitting of the real, composite Y_k data ($k = 1$ to $2n$) to the real, composite y_k model (here made up sequentially of the real and imaginary parts of the original complex model). Notice that, unlike ordinary real NLS, one is using different fitting models for the two major parts of the data. This leads to no difficulty in fitting. Since the sum of squares which is minimized by the procedure, is for unity weighting

$$S = \sum_{k=1}^{2n} [Y_k - y_k]^2 = \sum_{i=1}^{n} [(\Delta \mathrm{R}_i)^2 + (\Delta \mathrm{I}_i)^2]$$

where $\Delta \mathrm{R}_i$ and $\Delta \mathrm{I}_i$ are the real and imaginary fitting residuals, it is evident that we are minimizing the sum of squares of the $s_i = [(\Delta \mathrm{R}_i)^2 + (\Delta \mathrm{I}_i)^2]^{1/2}$, themselves the distances in the complex plane between a theoretical point and a measured data point, just as desired. Further, as we shall illustrate later, weighting of the $(Y_k - y_k)^2$ squared residuals may be introduced in the usual way. It is also worth noting that the NLS programs of Ref. (10) and (11) require no analytical expressions for function derivatives, a substantial blessing when the model expression is complicated.

The above kind of fitting yields parameter value estimates, estimates of their uncertainties, and an estimate of the standard deviation of fit, s_f. If the data determine some parameter values less precisely than others, this is immediately obvious. Further, s_f may be used to discriminate between various different possible models or equivalent circuits. We suggest that in the past the absence of such a s_f estimate has led to a proliferation of apparently different equivalent cir-

cuits not justified by the data themselves. Proper procedure should generally involve choosing that circuit or model which is best justified microscopically and which yields a minimum or at least acceptably small s_f.

Experimental Data: Fitting and Discussion

As an example of complex least squares fitting, we shall analyze the data (private communication) of Hooper, McGeehin, and Hughes (14) on polycrystalline β-alumina with silver electrodes. The 38°C data consist of twelve admittance values spanning the range from 1 kHz to 2 MHz. The corresponding impedance plane plot is shown in Fig. 2. Hooper *et al.* analyzed their data by the extrapolation method using a model equivalent to the three-time-constant Voigt circuit

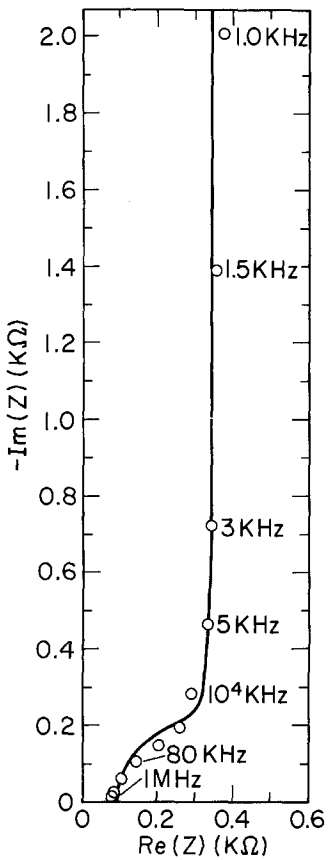

Fig. 2. Impedance plane plot of data (14) for polycrystalline β-alumina at 38°C. Experimental points, least squares line.

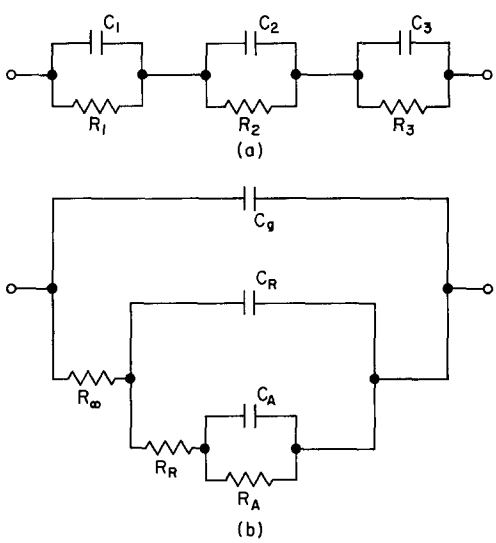

Fig. 3. Possible equivalent circuits for homogeneous and polycrystalline material/electrode systems.

(5, 6) of Fig. 3a with $C_1 = 0$ and $R_2 = \infty$. Before considering a model for least squares fitting and specific fitting results, it is useful to discuss the circuits of Fig. 3 briefly.

First, it has been shown using the exact model A results that the Fig. 3a circuit, which involves no Warburg elements, is appropriate for a homogeneous material when either the positive or the negative mobile species has a much higher mobility than the other, and pertinent time constants are separated from each other by factors of a hundred or more (2, 6). In this loosely coupled case, one can then identify R_1 and C_1 with, respectively, R_∞, the unperturbed bulk resistance of the material, and C_g, its geometric capacitance, which is, per unit area, $\epsilon/4\pi l$. Here ϵ is the bulk dielectric constant and l the electrode separation. In addition, R_2 and C_2 may be identified with the electrode reaction resistance R_R and capacitance C_R, and R_3 and C_3 with an adsorption resistance R_A and capacitance C_A. It is assumed that the reaction and adsorption processes, if present, involve the high mobility species with the one of opposite charge completely blocked at the electrodes. The reaction capacitance C_R is often found to be very nearly the double layer capacitance, C_{dl}, of two diffuse space charge layers in series, one from each electrode for identical plane parallel electrodes. Some of the possibilities following from the above are summarized in rows A-D of Table I. Note that complete blocking can occur with either R_2 or R_3 open circuited. Recent work (2) has demonstrated that for the same high mobility-ratio situation discussed above, the circuit of Fig. 3b applies exceptionally well for any ratios of the time constants, *i.e.*, for strong as well as weak coupling of the phenomena. It is therefore preferable to that of Fig. 3a for homogeneous material. Note that for loose coupling both circuits lead to three distinct, joined semicircles when impedance is plotted in the complex plane (1, 6). When a resistance is infinite, the corresponding semicircle has infinite radius.

Rows E and F apply to situations involving polycrystalline material between plane, parallel electrodes. It is assumed that the circuit of Fig. 3a is still formally applicable for such material. The bulk properties of all individual grains or crystallites contribute directly to give the over-all effective R_∞ and C_g. Because of differing grain sizes and orientations, one often finds, when measurements can be extended to sufficiently high frequencies, that the bulk semicircle in the complex impedance plane is displaced downward so that its center lies below the real axis. The R_R, C_R subcircuit, if present, may again be identified with electrode reaction/double layer effects, averaged over crystallites near the electrodes. One frequently finds nearly complete blocking again, as in system E. Farrington (15) has pointed out that adsorbed H_2O or H_2 may be expected to reduce the range over which complete blocking behavior occurs in Na-β-alumina with platinum electrodes. Finally, R_{GB} and C_{GB} are the over-all grain boundary resistance and capacitance associated with the contacts between all individual grains. As usual, one expects $R_\infty \propto l^1$, $C_g \propto l^{-1}$, and R_R and C_R independent of l, as expected for interface-related quantities. Experiment often suggests that $R_{GB} \propto l^1$ and

Table I. Identification of the R_i, C_i elements of a 6-element Voigt circuit for various systems with loose coupling. Rows A-D apply for homogeneous material and E and F for polycrystalline material.

System	Subcircuit 1		Subcircuit 2		Subcircuit 3	
	R_1	C_1	R_2	C_2	R_3	C_3
A	R_∞	C_g	∞	C_{dl}	—	—
B	R_∞	C_g	R_R	$C_R \cong C_{dl}$	—	—
C	R_∞	C_g	R_R	$C_R \cong C_{dl}$	∞	C_A
D	R_∞	C_g	R_R	$C_R \cong C_{dl}$	R_A	C_A
E	R_∞	C_g	∞	C_R	R_{GB}	C_{GB}
F	R_∞	C_g	R_R	C_R	R_{GB}	C_{GB}

$C_{GB} \propto l^{-1}$, showing these elements to exhibit bulk dependence, as one might perhaps expect for a large number of crystallites arranged in a series-parallel connection with series connections dominating. Here again, one would expect that the grain-boundary semicircle in the impedance plane would be displaced downward more often than not because of the distributed nature of the causes leading to the over-all behavior. Of course, when a semicircle is displaced, it cannot be represented adequately by means of frequency-independent elements such as the R_{GB} and C_{GB} of rows E and F. A more complicated contribution to the total impedance expression must then be employed [*e.g.*, see Ref. (6)], but again one whose parameters can best be estimated by complex least squares fitting.

Some preliminary computer modeling of the electrical properties of grains in series has been carried out by Armstrong, Dickinson, and Willis (16). It involves blocking electrodes, does not show downward displacement of semicircles, and the results appear to be representable by the circuit of row E. Further discussion of grain boundary and intragrain effects in polycrystalline β-alumina has been presented by Powers and Mitoff (17) and by Will (18). Powers and Mitoff give an equivalent circuit which agrees with that of row F except with C_g neglected and (implicitly) with little or no electrode blocking effects, so that $R_R \simeq 0$. Although specific adsorption at an electrode has not been incorporated in the circuits for systems E and F, it may sometimes be of importance and may even be the dominant process leading to nearly complete blocking behavior. Displaced semicircles and nonideal blocking and Warburg-like behavior have been recently reported for polycrystalline lithium silicates and aluminosilicates (19).

The analysis of displaced semicircles and nonideal Warburg-like data behavior in Ref. (19) employs an admittance or impedance function which can be represented by an equivalent circuit with frequency-dependent elements. Unfortunately, this particular approach, which corresponds closely to that of Jonscher in the dielectric area (20), was long ago shown to involve an impedance function associated with a physically nonrealizable system (21). The particular impedance functions used in Ref. (19) and (20) may, nevertheless, be useful empirical fitting functions if not pushed beyond their limits. On the other hand, other, somewhat empirical impedance functions have been proposed (6) which are associated with physically realizable systems, involve frequency-dependent circuit elements, and may be used to represent displaced semicircles and nonideal Warburg behavior. Although they may be formally interpreted in terms of distributions of relaxation times, they are not derived from a detailed microscopic theory of system response and, like all such semiempirical approaches, do not allow direct interpretation of impedance function parameters in terms of specific material parameters such as mobilities, reaction rates, etc. Until a theory which directly leads to nonideal behavior becomes available, circuit element characterization can only be adequately carried out for experiments which yield semicircles with little or no displacement and diffusional response close to ideal, finite-length Warburg behavior (2, 3, 6).

In β-alumina one expects to find many mobile Na^+ ions moving against a background of essentially immobile negative charges. Thus the circuits of Fig. 3 are possibly applicable for single crystal material and, with the interpretations given in rows E and F of Table I, are worth considering for polycrystalline material as well. The data of Hooper *et al.* do not extend to high enough frequencies to allow an estimate to be made of $C_1 \cong C_g$. It may be taken in the least squares fitting as fixed, indifferently, at 0 or at the value calculated from known values of area, ϵ, and l. As mentioned, Hooper *et al.* (implicitly) took $C_1 = 0$, $R_2 = \infty$, and identified R_1 and R_∞ (but including a tortuosity factor), C_2 with C_{dl}, and R_3 and C_3 with R_{GB} and C_{GB}, essentially row E of Table I with $C_1 = 0$. Since the R_{GB}, C_{GB} semicircle in Fig. 2 is not completely distinct from the C_R rise at low frequencies, it is not clear that the processes are well enough separated that the Fig. 3a circuit should necessarily be used in preference to one like Fig. 3b in interpreting the data (see later discussion). Thus, it is of interest to try fitting the data in impedance form to both the Fig. 3a circuit and that of Fig. 3b. In the latter case, since element identification is uncertain for polycrystalline data (especially where no experiments with different l's have been carried out), we shall beg the question by letting $C_g \to 0$, $R_\infty \to R_1$, $C_R \to C_2$, $R_R \to R_2$, $C_A \to C_3$, and $R_A \to R_3 \to \infty$.

The Fig. 3 impedance expressions for fitting are then

$$Z(\omega) = R_1 + (i\omega C_2)^{-1} + [R_3/(1 + i\omega R_3 C_3)] \quad [1]$$

for Fig. 3a, and

$$Z(\omega) = R_1 + \frac{1 + i\omega R_2 C_3}{(i\omega)[C_3 + C_2(1 + i\omega R_2 C_3)]} \quad [2]$$

for Fig. 3b. Fitting results yield $s_f = 15.98\Omega$ for both fits, carried out with the fixed values $C_1 = 0$ and with $R_2 = \infty$ for the first and $R_3 = \infty$ for the second. For Fig. 3a, one finds $R_1 = (96.5 \pm 7.1)\Omega$, $C_2 = (0.07734 \pm 0.00048)\mu f$, $R_3 = (248.4 \pm 9.3)\Omega$, and $C_3 = (0.0208 \pm 0.0020)\mu f$. Results for the Fig. 3b circuit were $R_1 = (96.5 \pm 7.1)\Omega$, $R_2 = (400.2 \pm 9.3)\Omega$, $C_2 = (0.0164 \pm 0.0020)\mu f$, and $C_3 = (0.06093 \pm 0.00048)\mu f$. If some of the fitting conclusions discussed in the next section apply to the present situation where different processes are not well separated in frequency, the Fig. 3b circuit element values may be more meaningful than the Fig. 3a ones. We shall not, however, pursue this subject further here.

The solid line in Fig. 2 has been drawn from the results of these fittings. It is because both circuits can, with proper element choices, represent the same impedance at all frequencies, as discussed in the next section, that fittings with them yield the same residuals and s_f values. The R_1 element, which is certainly the bulk resistance with crystallite-orientation tortuosity effects included, as stated by Hooper *et al.*, leads to a 38°C effective conductivity of about 0.00072 Ω^{-1} cm^{-1} using (private communication) $A \cong 0.44$ cm^2 and $l \cong 0.3$ cm.

While it seems reasonable to identify the R_3 and C_3 elements of Fig. 3a with R_{GB} and C_{GB}, it is clear that C_2 cannot be an ordinary diffuse double layer capacitance. Here $C_2 \simeq 0.176$ μf/cm^2 on a unit electrode area basis, a value very much smaller than would be expected if diffuse double layer theory applied to this very high Na^+ concentration situation. But diffuse layer theory ignores the finite size of charge carriers and discreteness of charge effects. Because of these effects there is a limit to how large the interfacial capacitance (without adsorption) can be (2, 22, 23), although the limit is much larger than the above value of C_2. While it is clear that C_2 is associated with the blocking character of the material/electrode interface, it is not clear from the present results whether it is an ordinary interface capacitance or is associated with pure specific adsorption (*i.e.*, $R_A \simeq \infty$ in Fig. 3b).

It will be noted that the low frequency points in Fig. 2 do not fall exactly on a vertical line. There are several sources which may lead to such a result, among which are surface roughness (16), specific adsorption (24), recombination (25), and large (but not too large) differences between the mobilities of mobile positive and negative species (1). Although a better fit of the data could be achieved were some of these effects included, possibly with the R_{GB}, C_{GB} circuit also replaced by one with a distribution of time constants (6), we are here more interested in demonstrating a fitting method and discussing the interpretation of the results than in trying to find the best model for the phenomena. In the next section, we consider in further detail

some simple fitting models for homogeneous materials and interpretation of fitting results when synthetic data are employed.

Theoretical "Data:" Fitting and Discussion

Theoretical model.—Some useful conclusions about fitting approaches and parameter interpretation can be developed by consideration and fitting of "data" derived theoretically from a known model. For present purposes it will be sufficient to use the model A already mentioned in its simplest form: an intrinsic situation where positive and negative charges have equal valences, z_e, and mobilities, μ_e; both are completely blocked at the electrodes; and there is no adsorption. Then R_x (per unit area) becomes $l/(ez_e\mu_e c_i)$, where c_i is the common equilibrium value of the positive and negative charge concentrations, and the Debye length L_D reduces to $[\epsilon kT/8\pi c_i(ez_e)^2]^{1/2}$. It will be convenient to deal with normalized quantities. Let $\tau_D \equiv R_x C_g$, the dielectric relaxation time, $\Omega \equiv \omega\tau_D$, a normalized frequency, and $M \equiv l/2L_D$. Further, normalize impedances and resistances with R_x and capacitances with C_g. Such normalization will be denoted by a subscript "N". In most experimental situations of interest for small-signal impedance measurements, $\Omega \lesssim 1$ and $M >> 1$.

For the situation defined above, the normalized total impedance of the system turns out to be (1)

$$Z_{TN} = \frac{1 + i\Omega\gamma_1}{i\Omega(1 + i\Omega)\gamma_1} = (1 + i\Omega)^{-1} - [i\Omega(1 + i\Omega)\gamma_1]^{-1}$$

$$\equiv R_{SN} + (i\Omega C_{SN})^{-1} \qquad [3]$$

where $\gamma_1 \equiv M(1 + i\Omega)^{1/2}\mathrm{ctnh}[M(1 + i\Omega)^{1/2}]$. The presence of $(1 + i\Omega)^{1/2}$ and the ctnh function are indications of the distributed nature of the system, consonant with the fact that all real systems are distributed. Their presence also means that no equivalent circuit made up only of frequency-independent circuit elements can represent the impedance of the system exactly. We shall, however, investigate the adequacy of such frequency-independent circuit approximations. Note that in normalized form, the model depends only on the single parameter M. Let us use a subscript zero to denote the limit $\Omega \to 0$. Then one finds (8) that $R_{SNO} = 1 + \{[r - 2 + \{(M)\mathrm{csch}(M)\}^2]/2(r - 1)^2\}$ and $C_{SNO} = r - 1$, where $\gamma_{10} \equiv r \equiv (M)\mathrm{ctnh}(M)$. For $M >> 1$, $R_{SNO} \cong 1 + (2M)^{-1} \simeq 1$. The total low frequency-limiting normalized parallel capacitance is $C_{PNO} = C_{SNO} + C_{gN} = r$. This result reduces to just the ordinary specific diffuse double layer capacitance for two double layers in series, one near each of the two identical electrodes, $C_{PO} = \epsilon/8\pi L_D$, for $M >> 1$.

Circuits and curves.—For the present system, the circuits of Fig. 3a and 3b reduce, respectively, to essentially those of Fig. 4a and 4c. We shall investigate the applicability of these circuits and the identity of their elements by NLS fitting of exact "data" calculated from the Eq. [3] model to the approximate models represented by these equivalent circuits. Although the Fig. 4a circuit has been widely employed for liquid, and to some extent, solid electrolyte situations, it will prove less directly applicable than that of Fig. 4c for the present homogeneous-material situation. Circuits 4a and 4c are degenerate forms of more complex equivalent circuits known as Voigt and Maxwell circuits, respectively (5, 6). The equality signs in Fig. 4 indicate that these circuits may be made to exhibit exactly the same impedance at all frequencies provided element values are chosen appropriately, as shown in the figure. Thus for example, the circuit of Fig. 4b will have the same impedance as that of 4a if the 4b element values are related, as shown, to those in 4a through the quantity μ, which involves a ratio of 4a capacitance values.

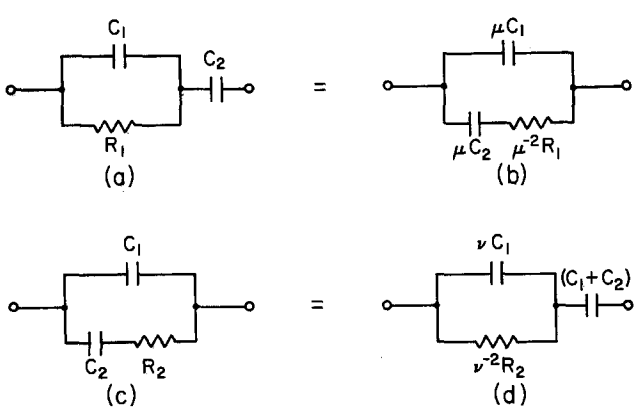

Fig. 4. Lumped-constant equivalent circuits with equal impedances when circuit (a) values are used to form $\mu \equiv C_2/(C_1 + C_2)$ and circuit (c) values are employed to form $\nu \equiv (C_1 + C_2)/C_2$.

Before considering detailed NLS fitting results, it is of interest to examine impedance and admittance plane plots following from Eq. [3]. Thus Fig. 5 and 6 show complex impedance and admittance plane plots of Z_{TN} and $Y_{TN} \equiv Z_{TN}^{-1}$ as parametric functions of Ω for several M values. As is conventional, we have actually plotted $Z_{TN}^* = \mathrm{Re}[Z_{TN}] - i\mathrm{Im}[Z_{TN}]$ in the (normalized) impedance plane. The (0,0; 1,1; 0,M) designation on the figures specifies completely blocking electrodes, equal valence numbers and mobilities, and no extrinsic conduction character. For $M >> 10^2$, Fig. 5 shows that there is present a semicircle, which is associated (in unnormalized form) with the bulk parameters C_g and R_x, and a well-distinguished vertical line, associated with the double layer capacitance. When $M \lesssim 10$, however, the bulk semicircle and the diffuse layer line begin to meld together since the frequency ranges where they occur approach each other more and more as M decreases. Qualitatively similar behavior occurs for the admittance plane results, but the semicircle there involves R_x and the double layer capacitance, and the vertical line is associated with C_g.

Were we to use NLS fitting of exact "data" derived from Eq. [3] to the Eq. [3] model itself, one would of course obtain a fit whose accuracy would be limited only by computer round-off error, and would also ob-

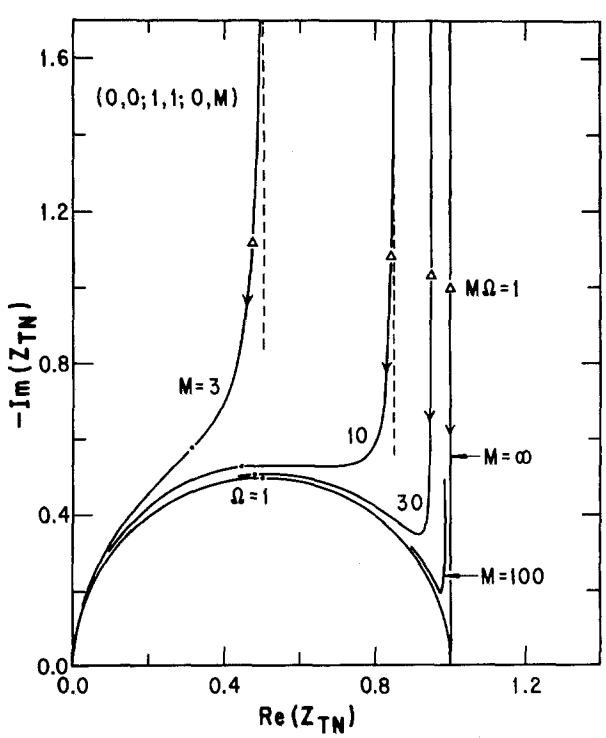

Fig. 5. Complex impedance plane plot of normalized impedance for the (0,0; 1,1; 0,M) situation.

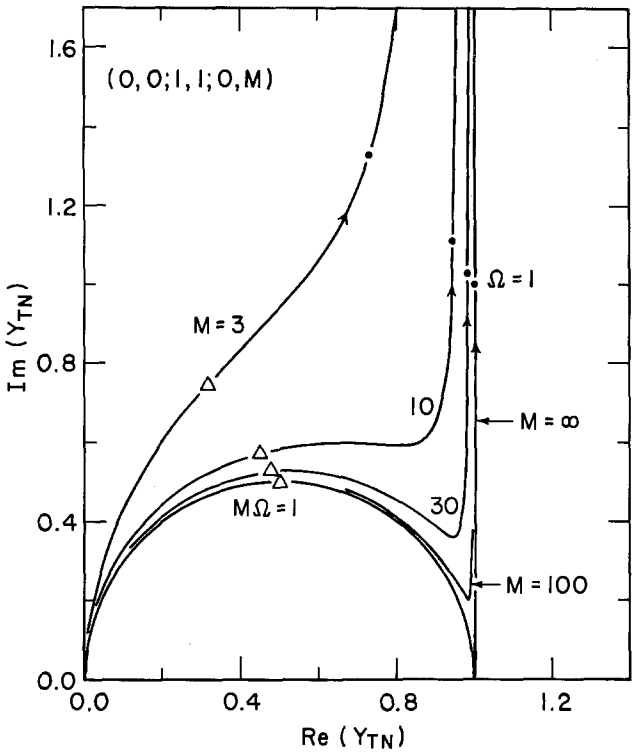

Fig. 6. Complex admittance plane plot of normalized admittance for the (0,0; 1,1; 0,M) situation.

tain a similarly accurate estimate of the single parameter M. In many experimental situations, however, one either does not have a good analytic model for fitting or finds that the appropriate analytic model is too complicated for direct least squares fitting (*i.e.*, model A in full generality). Thus one often finds an equivalent circuit approach to be useful.

Conventional analysis.—Although there is only one parameter, M, in the Z_{TN} of Eq. [3], there are three things which we want to determine from $Z_{TN}(\Omega)$ as accurately as possible. These are the normalized geometric capacitance and bulk resistance, both unity with present normalization, and M or r. If they can be well determined, we are assured that a similar procedure applied to unnormalized $Z_T(\omega)$ data will yield good values of C_g, R_∞, and C_{PO}. Since there are three distinct circuit elements in the circuits of Fig. 4a and 4c, one might expect that these elements could be related rather simply to C_g, R_∞, and C_{PO}, which are themselves expressed in terms of microscopic parameters. Consider first the usual extrapolation method applied to curves like those in Fig. 5 and 6. There is clearly no problem in obtaining estimates of C_g, R_∞, and a frequency-independent double layer capacitance, say C_{dl}, from results such as those in Fig. 5 or 6 when $M >> 10^2$. Then R_∞ (here $R_{\infty N} = 1$) may be obtained directly from the real-axis intercept of the vertical line in Fig. 5, C_{dl} from the capacitative reactance of a point on the line, and C_g from a point on the semicircle. Similarly, in Fig. 6, G_∞ (or $G_{\infty N} = 1$ here) occurs at the real axis intercept of the vertical line, C_g may be derived from the reactance on the line, and C_{dl} from a point on the admittance-plane semicircle.

Unfortunately, the situation is not so clear for relatively small M. Some authors have nevertheless used the extrapolation to the real axis of the asymptote of a curve such as that for $M = 3$ or 10 in Fig. 5 to obtain an estimate for R_∞. An extrapolation of this kind appears, for example, in Ref. (19). As Fig. 5 shows, such extrapolation can yield an R_∞ estimate incorrect by a factor of two or more for the present situation. In Fig. 6, on the other hand, all curves approach the $\mathrm{Re}(Y_{TN}) = 1$ line asymptotically, but this is by no means clear from that portion of the $M = 3$ curve shown, which might correspond to as much of an experimental curve as could be measured conveniently in a specific instance.

The determination of R_∞ from the real axis intercept of a vertical line associated with completely blocking electrode behavior corresponds to estimating R_∞ from low frequency experimental data since the impedance-plane vertical line occurs at the lowest frequencies of measurement. Alternatively, unlike such low frequency extrapolation, the determination of G_∞ from the real axis intercept of a vertical straight line in the admittance plane corresponds to high frequency extrapolation, and is in keeping with the $\omega \to \infty$ subscript of G_∞, the only conductance one expects to remain significant at sufficiently high frequencies. Similarly, C_{dl} is estimated by a low frequency extrapolation of Z_T data and C_g by a high frequency extrapolation of Y_T data. Although it is indeed much more common in liquid electrolyte work to obtain an R_∞ estimate from high rather than from low frequency extrapolation, Raistrick, Ho, and Huggins (19) have pointed out that for solid electrolytes practical frequency-range limitations often require R_∞ estimation by low frequency extrapolation (as in Fig. 5) for results obtained at low temperatures. We shall shortly demonstrate how such an estimate, which may differ appreciably from the true R_∞, may be transformed to obtain a much more appropriate estimate of R_∞.

Comparison of the shapes of the Fig. 2 curve for β-alumina and that for $M = 3$ of Fig. 5 shows considerable likeness. Since we have already seen that an extrapolation of the Fig. 5 $M = 3$ vertical asymptote to the real axis yields $R_{\infty N} \approx 0.5$ instead of the correct unity value, it is reasonable to conclude that in the case of Fig. 2, which also displays overlapping of phenomena, similar extrapolation may again lead to considerable error. Whenever this error cannot be reduced by high frequency extrapolation (because such data are lacking), it turns out, nevertheless, that it can be reduced by proper interpretation. But, as we shall see, NLS fitting of an appropriate model will always yield the most significant estimates of parameter values.

NLS analysis.—The theoretical "exact data," calculated with double precision on an IBM 370-155 computer from Eq. [3] for $M = 10^4$, 30, and 3, consisted of 25 complex Z_{TN} or Y_{TN} values and 25 Ω values. The Ω values were uniformly distributed in log Ω and covered $10^{-5} \leq \Omega \leq 10$ for $M = 10^4$ and $10^{-2} \leq \Omega \leq 10$ for $M = 30$ and 3. The data were fitted to the models of circuits of Fig. 4a and 4c

$$Z_{TN} = [R_{1N}/(1 + i\Omega R_{1N}C_{1N})] + (i\Omega C_{2N})^{-1} \quad [4]$$

and

$$Z_{TN} = [i\Omega\{C_{1N} + C_{2N}(1 + i\Omega R_{2N}C_{2N})^{-1}\}]^{-1} \quad [5]$$

respectively, with double-precision arithmetic using the present complex NLS method.

Results of fitting exact Z_{TN} "data" to the Eq. [5] model for Z_{TN} are shown in the first line of Table II for each M value. The second line presents the results of fitting exact $Y_{TN} \equiv Z_{TN}^{-1}$ "data" to the Y_{TN} following from Eq. [5]. If we identify C_{1N} as an estimator of $C_{gN} = 1$, R_{2N} as the R_{SNO} defined earlier, and C_{2N} as C_{SNO}, then the expected values of these quantities are as shown in the third line for each M choice. It is evident that these identifications are reasonable.

The $\pm$ quantities shown in the table are estimated relative standard deviations of the parameters. Had the circuit model been exactly appropriate for the data, the relative standard deviations would have arisen only from round-off error and would have been of the order of 10^{-12} or less in the present calculations. The larger values apparent here are a measure of the inexactness of the circuits employed. The larger M, clearly the better the lumped-constant approximations are to the actual distributed system. If one judged from the overall estimated standard deviation of the fit, s_f, one might

Table II. Fitting of unweighted (0,0; 1,1; 0,M) "data" to the circuit of Fig. 4c. For each M value: first line Z_{TN} fitting; second line $Y_{TN} \equiv Z_{TN}^{-1}$ fitting; third line expected value

10^4	6.6×10^{-7}	$1.000009\ (1 \pm 7.1 \times 10^{-7})$	$1.0000498\ (1 \pm 1.5 \times 10^{-7})$	$9.999000 \times 10^3\ (1 \pm 5.5 \times 10^{-8})$
	6.0×10^{-6}	$1.000002\ (1 \pm 4.9 \times 10^{-7})$	$1.0000457\ (1 \pm 1.3 \times 10^{-6})$	$9.999000 \times 10^3\ (1 \pm 6.6 \times 10^{-6})$
	—	1	1.00005	9999
30	2.9×10^{-4}	$1.00295\ (1 \pm 2.2 \times 10^{-4})$	$1.01669\ (1 \pm 8.0 \times 10^{-5})$	$28.9965\ (1 \pm 5.9 \times 10^{-5})$
	2.3×10^{-3}	$1.00076\ (1 \pm 1.5 \times 10^{-4})$	$1.01396\ (1 \pm 5.3 \times 10^{-4})$	$28.9759\ (1 \pm 1.8 \times 10^{-3})$
	—	1	1.0166468	29
3	7.2×10^{-4}	$1.0128\ (1 \pm 7.2 \times 10^{-4})$	$1.1500\ (1 \pm 8.1 \times 10^{-4})$	$2.0021\ (1 \pm 3.6 \times 10^{-4})$
	9.1×10^{-3}	$1.0050\ (1 \pm 6.2 \times 10^{-4})$	$1.1136\ (1 \pm 3.4 \times 10^{-3})$	$1.9818\ (1 \pm 7.9 \times 10^{-3})$
	—	1	1.13603776	2.0149094698

conclude that even for M as small as 3, the lumped-constant approximation would be adequate except for the most accurate data. One must, however, consider the estimated values of the parameters themselves and must treat all standard deviations shown here with caution. Since differences between the exact result of Eq. [3] and the present circuit models are systematic rather than random in nature, the least squares fitting residuals will generally show systematic behavior and will not be randomly distributed. The standard deviations will then generally be poor approximations (usually too small) although their trends here are certainly significant.

The results of Table II show that the circuit of Fig. 4c is indeed a good approximate model for the present system. It is also evident, in accordance with the conclusions of conventional analysis discussed above, that C_{1N} is best estimated from Y_{TN} fitting and R_{2N} and C_{2N} from Z_{TN} fitting. Although the differences here are associated with systematic errors, it is likely that the same conclusions will apply to experimental data dominated by random rather than systematic errors.

For $M \gtrsim 30$, the Table II results show that the parameter estimates are highly accurate. Even the $M = 3$ results are likely to be generally adequate. But how would one proceed to obtain estimates of M, C_g, and R_∞ if these quantities were unknown and one were analyzing experimental, unnormalized data? Let us consider the worst case here, $M = 3$, and deal with the present results as actually derived from unnormalized data, *i.e.*, that for which true M, C_g, and R_∞ values are 3, 1, and 1, respectively, in appropriate units. Assume further that only the $Z_{TN} \rightarrow Z_T$ fitting results are available. Then an estimate of r is $1 + (C_2/C_1) = 1 + (2.0021/1.0128) \cong 2.9768$ and the corresponding M estimate is 2.9609, in error by about 1%. The $C_1 = 1.0128$ estimate of C_g is also about 1% in error. The above values of r and M now allow one to calculate R_{SNO}, yielding 1.13708 (instead of the correct 1.13604). Then an estimate of R_∞ is $R_\infty \cong R_2/R_{SNO} = 1.15/1.13708 \cong 1.011$, again in error by about 1%. Thus, even in the extreme high overlap case of $M = 3$, we are able to use the circuit Fig. 4c model to obtain desired parameters to about 1%.

Now what happens if exact Z_{TN} "data" is fitted to the circuit Fig. 4a model, Eq. [4]? Some results are shown in Table III. Notice that the s_f values are exactly the same as the corresponding Z_{TN} results in Table II, showing that both circuits can fit the "data" to the same degree. But it is evident that C_{1N} here is an appreciably poorer estimate of $C_{gN} = 1$ than the C_{1N} of Table II and that R_{1N}, particularly for small M, is a very poor estimate of either R_{SNO} or $R_{\infty N} = 1$. On the other hand, C_{2N} is evidently a better estimate of $C_{PNO} = r$ here than is the C_{2N} of Table II of $r - 1$. Finally, it is gratifying to note that when the parameter estimates of Table III, associated with the Fig. 4a circuit, are transformed (by the relations shown in Fig. 4) to parameter values pertaining to the Fig. 4c circuit, one obtains exactly (within round off) the values shown in Table II for all M choices.

These results and conclusions suggest that best estimates of M, C_g, and R_∞ might be obtained using a C_1 estimate obtained from admittance data fitting of the Fig. 4c circuit, a R_2 estimate from impedance fitting of the Fig. 4c circuit, and a C_2 estimate either from impedance fitting of the Fig. 4a circuit or by transformation of the Fig. 4c impedance fitting results to yield a Fig. 4a C_2 estimate. For most purposes, however, Z_{TN} fitting to the Fig. 4c circuit should be sufficient.

In the present synthetic data situation, we know for the Fig. 4c circuit that C_{1N}, which represents $C_{gN} = 1$, should be unity. Table IV presents some results obtained when C_{1N} is constrained to remain unity during NLS fitting. The first three lines in the table, for unweighted (*i.e.*, unity, weighted) residuals, show that fixing C_{1N} has increased s_f values and most of the parameter relative standard deviations but has generally improved the R_{2N} and C_{2N} estimates appreciably. Moral: use *a priori* information when available.

In some cases, it may be desirable to carry out NLS fitting with weightings different from unity. Consider

Table III. Fitting of unweighted (0,0; 1,1; 0,M) Z_{TN} "data" to the circuit of Fig. 4a

M	Standard deviation of fit, s_f	C_{1N}	R_{1N}	C_{2N}

10^4	1	1.4×10^{-6}	$1.0000498\ (1 \pm 3.1 \times 10^{-7})$	$9.999000 \times 10^3\ (1 \pm 1.2 \times 10^{-7})$
30	1	6.2×10^{-4}	$1.0165\ (1 \pm 1.6 \times 10^{-4})$	$28.998\ (1 \pm 1.3 \times 10^{-4})$
3	1	2.0×10^{-3}	$1.135\ (1 \pm 9.8 \times 10^{-4})$	$2.01485\ (1 \pm 5.9 \times 10^{-5})$
	$\lvert x \rvert$	1.0×10^{-2}	$1.130\ (1 \pm 2.9 \times 10^{-3})$	$2.015\ (1 \pm 3.6 \times 10^{-3})$
	$\lvert x \rvert^{-1}$	1.2×10^{-3}	$1.141\ (1 \pm 9.6 \times 10^{-4})$	$2.01490\ (1 \pm 1.5 \times 10^{-6})$
	$\lvert x \rvert^{-2}$	9.0×10^{-4}	$1.1488\ (1 \pm 9.6 \times 10^{-5})$	$2.0149093\ (1 \pm 6.9 \times 10^{-8})$
	$\lvert x \rvert^{-4}$	7.7×10^{-4}	$1.149005\ (1 \pm 2.4 \times 10^{-7})$	$2.014909468\ (1 \pm 1.4 \times 10^{-10})$

a datum value x, say the real or imaginary part of an impedance. Let σ_x be the estimated uncertainty of a given x value. Then the appropriate weighting of the squared residual corresponding to this value of x becomes $w_x = \sigma_x^{-2}$. One might know, for example, that small values of x are more uncertain than large values because of limitations in resolution of measuring techniques, etc. Then, one might take, as a first approximation, $\sigma_x = a|x|^{-1}$, where a is a constant. Then $w_x = a^{-2}x^2$, and residuals associated with larger x values are thus more heavily weighted than those associated with smaller x. The last four lines of Table IV show nonunity weighting results for $M = 3$. One notices that $|x|$ weighting is worse than unity weighting and that as weighting progressively emphasizes larger values, R_{2N} estimates degrade and C_{2N} ones improve. This trend is not surprising since at low Ω values the contribution of C_{2N} dominates the expression for Z_{TN} in the present completely blocking situation. Although such extreme weighting as $\sigma_x = |x|^{-4}$ will be inappropriate for actual experimental data, it has here allowed us to estimate C_{SNO} correct to eight or nine decimal places. For experimental situations $|x|^{-1/2}$, or possibly $|x|^{-1}$, weighting may sometimes be useful.

As we have mentioned earlier, it is often impossible or inconvenient to carry out impedance measurements to sufficiently high frequencies to cover most of the bulk-effect semicircle. Here we have indeed done so by extending the data to $\Omega = 10$ ($\omega_{max} = 10/\tau_D$). Separate fittings with $\Omega_{max} < 10$ have shown, in fact, that for the present system, parameter estimates are improved if, say, $\Omega_{max} = 0.1$ rather than 1 or 10. The choice $\Omega_{max} = 0.1$ is a high enough (normalized) frequency that C_{1N} may still be reliably estimated, but it extends less far into the region where the distributed nature of the system (not represented by our equivalent circuits), appearing through $(1 + i\Omega)^{1/2}$, is more important.

In concluding this section, we suggest that in completely blocking situations the complex NLS fitting of impedance data, extending up to perhaps $\omega_{max} \sim (10\tau_D)^{-1}$, to the circuit of Fig. 4c is most appropriate for general purpose work. Further, several weightings different from unity should be tried for the above fitting in order to find the weighting(s) which yield(s) minimum estimated standard deviations of the several parameters of interest. Even in nonblocking situations, such weighting investigation should often prove useful.

Effect of length and concentration variation.—The use of normalized quantities, as in Eq. [3] and Fig. 5 and 6, is helpful in allowing one to subsume many possible dependencies in one. Real data are initially unnormalized, however, and it is therefore of interest to examine how unnormalized impedance/admittance-plane curves corresponding to the normalized curves of Fig. 5 and 6 depend on variation of such parameters as electrode separation length and equilibrium charge concentration.

Let us consider two values of length, l_1 and l_2, and two of concentration, c_{i1} and c_{i2}. Then one readily finds from the equations and definitions above that for l and c_i variation alone, $M_2/M_1 = (l_2/l_1)(c_{i2}/c_{i1})^{1/2}$, and $R_{\infty 2}/R_{\infty 1} = (l_2/l_1)(c_{i1}/c_{i2})$. Further, $\tau_{D2}/\tau_{D1} = (l_2/l_1)^0(c_{i1}/c_{i2})$. Since $Z_T \equiv R_\infty Z_{TN}$ and $Y_T \equiv G_\infty Y_{TN}$, it is clear that R_∞ and G_∞ determine the scales of the unnormalized Z_T and Y_T curves, respectively, following from Z_{TN} and Y_{TN}, Thus, unnormalized curve size may be readily obtained from normalized results when R_∞ or G_∞ is known. But complex plane curves are parametric in frequency. Therefore, it is desirable to investigate how frequency points move their position along unnormalized curves as such quantities as l and c_i change. Figures 5 and 6 show two points with normalized frequency $\Omega = 1$ and $M\Omega = 1$. Their positions do not change much until M is considerably less than 100. But suppose we ask how the ω's involved in $\Omega \equiv \omega\tau_D$ must change as l and c_i change when we restrict attention to the same two points $\Omega = 1$ and $M\Omega = 1$ of Fig. 5 and 6. One easily obtains for $\Omega = 1$ the relation $\omega_2/\omega_1 = (l_1/l_2)^0(c_{i2}/c_{i1})$, and for $M\Omega = 1$ the result $\omega_2/\omega_1 = (l_1/l_2)(c_{i2}/c_{i1})^{1/2}$.

Table V. Effects of l and c_i variation on pertinent quantities

Variation					$\Omega = 1$	$M\Omega = 1$
M_2/M_1	l_2/l_1	c_{i2}/c_{i1}	$R_{\infty 2}/R_{\infty 1}$	$G_{\infty 2}/G_{\infty 1}$	ω_2/ω_1	ω_2/ω_1
10	10	1	10	0.1	1	0.1
	1	10^2	10^{-2}	10^2	10^2	10
	$10^{1/2}$	10	$10^{-1/2}$	$10^{1/2}$	10	1
1	0.1	10^2	10^{-3}	10^3	10^2	10^2
	10	10^{-2}	10^3	10^{-3}	10^{-2}	10^{-2}

The above relations have been employed to calculate the specific results of Table V. It shows the effects of various l and c_i variations which produce $M_2/M_1 = 10$ and 1. We see, for example, that a 10 times increase in l with no change in c_i yields unnormalized impedance plane curves 10 times larger than the normalized ones. No change occurs in the ω corresponding to $\Omega = 1$, but that corresponding to $M\Omega = 1$ occurs at one-tenth the frequency found for the original length. The ω frequency scale is thus not shifted uniformly by a change of length. On the other hand, when l and c_i change in such a way that M remains the same, the results of the bottom two lines in the table show that the frequency scale is then uniformly expanded or contracted.

The Kinetics of the Magnesium Electrode in Thionyl Chloride Solutions

E. Peled* and H. Straze

Institute of Chemistry, Tel Aviv University, Ramat Aviv, Tel Aviv, Israel

ABSTRACT

The electrochemical behavior of the magnesium electrode in thionyl chloride (TC) solutions was studied. It was found that this electrode is covered by a passivating layer which consists of some insoluble magnesium salt, probably $MgCl_2$. The properties of this layer determine the chemical and electrochemical behavior of the electrode in TC solutions. Magnesium was deposited on a nickel cathode from TC solutions containing $Mg(FeCl_4)_2$. Magnesium deposition begins after the nickel cathode is covered by a passivating layer (consisting of reduction products of TC) in which $t_{Mg^{2+}} \sim 1$. It was concluded that the rds for the deposition-dissolution process of the magnesium electrode in TC solutions is not the electron-transfer reaction, but is instead the migration of the Mg^{2+} ions through a passivating layer which covers the electrode.

There has been no report in the literature of kinetics of the deposition-dissolution process for solid magnesium metal in nonaqueous solutions. However, many papers have been published in the last fifteen years on the kinetics of alkali metals in these media. The reason for this is that magnesium is a much more difficult metal to electrodeposit than are the alkali metals. Most of the attempts to electrodeposit magnesium from nonaqueous solutions have been unsuccessful (1).

The only system in which the electrodeposition of magnesium is feasible is that of Grignard reagents with the addition of boranes in ether solutions (2).

The electrode kinetics of the alkali metals in propylene carbonate, dimethyl sulfoxide, and dimethyl sulfide is reviewed in Ref. (3-6). Most of the investigations deal with the electrochemical behavior of the lithium electrode. It was found (3-6) that: (*i*) lithium metal is chemically stable in these solutions, (*ii*) film formation on the electrode has been detected, (*iii*) trace amounts of water induce film formation, and (*iv*) the reaction $Li^+ + e(M) \rightleftarrows Li$ has a high exchange current density (1-10 mA cm^{-2}).

The rate-determining step (rds) of the deposition-dissolution process for solid alkali metals was assumed to be the electron-transfer reaction: $M^+ + e(M) \rightleftarrows M^\circ$ with a transfer coefficient (α) of 0.5-0.8 (3-6). Dey (7) indicated that in propylene carbonate solutions the lithium electrode is covered by a passive film (probably Li_2CO_3) which is formed by the reaction between lithium and propylene carbonate. He concluded that this film should be a purely ionic conductor with the Li^+ being the sole conducting species ($t_{Li^+} = 1$) (7). The same conclusion was drawn (8) for lithium electrode in thionyl chloride solutions.

In this paper the electrochemical behavior of solid magnesium electrode in thionyl chloride solution was studied. It was found that the rds of the deposition-dissolution process for magnesium metal in thionyl chloride (TC) solution is not the electron-transfer reaction but is the migration of the magnesium ions through a passivating layer which covers the electrode.

Experimental

The cell and the electrodes are shown in Fig. 1. The three electrodes were made from magnesium ribbon BDH 99.9%, 0.4 mm thick and 3 mm wide. The working and reference electrodes were parallel to each other and about 5 mm apart. They had an area of 1.4-2.5 cm^2. Each electrode was connected by a stainless steel connector to a tungsten rod sealed in the glass cap. The cell was sealed by a Viton O-ring. Connection to the vacuum line was made through a Jobling "Rotaflo" valve. The magnesium electrodes were

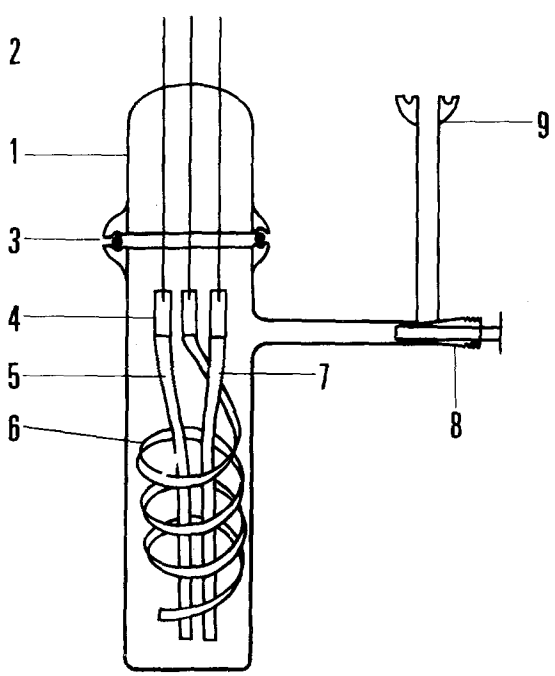

Fig. 1. The electrochemical cell. 1, Cell cap; 2, tungsten wires; 3, Viton O-ring; 4, stainless steel connectors; 5, working electrode; 6, counterelectrode; 7, reference electrode; 8, "Rotaflo" valve; 9, connection to vacuum line.

cleaned by degreasing in AR acetone, dipping in 1:4 HCl (AR Frutarom) for 15 sec, rinsing in distilled water, washing with AR acetone and drying on the vacuum line at pressure less than 10^{-4} mm Hg.

The thionyl chloride (Merck Zur Synthesis) was distilled and the first 10% and the last 20% were discarded. The middle fraction was vacuum distilled. At the end of this process a light yellow liquid was obtained.

For the preparation of $Mg(FeCl_4)_2$ solutions, weighed amounts of $FeCl_3$ (Merck Zur Synthesis) and $MgCl_2$ (Roc/Ric 98%) were transferred to a flask with a "Rotaflo" valve inside an argon-filled glove box. The flask was then attached to the vacuum line and distilled TC was transferred to it under vacuum. The salts were stirred with TC for 24 hr, and the TC was distilled. A calculated amount (for the preparation of 0.5M $Mg(FeCl_4)_2$) of twice distilled TC was transferred to this flask. The amount of $MgCl_2$ which was first introduced to the flask was always in excess (*i.e.*, for one mole of $FeCl_3$ about 0.7 mole of $MgCl_2$ was added). The exact concentrations of $FeCl_3$ and $MgCl_2$ were determined by atomic absorption spectrophotometry (Perkin Elmer, Model 403). It was found that the concentrations of $FeCl_3$ and $MgCl_2$ were 1 ± 0.1M and 0.5 ± 0.05M, respectively, in all experiments.

For the preparation of $Mg(AlCl_4)_2$ solutions the magnesium chloride was first dried in the same way as described above. Aluminum chloride (Fluka Puriss) was sublimed twice and transferred to the flask which contained the dry magnesium chloride. After this step a calculated amount of distilled TC was transferred to this flask. The magnesium chloride was always in excess (for 1 mole of $AlCl_3$ about 0.7 mole of $MgCl_2$ was employed). The solution was stirred for 48 hr to ensure complete dissolution of the magnesium chloride ($AlCl_3$ dissolved quickly in TC). It was found that the concentration of $AlCl_3$ and $MgCl_2$ were 1 ± 0.1M and 0.5 ± 0.05M, respectively, in all experiments.

All kinetic measurements were performed galvanostatically with an Elron CHG-1 galvanostat (rise time about 4 μsec). The *IR* drop was determined from the extrapolation to zero time of the fast initial jump in potential (Fig. 2).

The differential capacitance of the magnesium solution interface was calculated from the initial slope of the potential/time transient (Fig. 2) with the use of the equation

$$C = i \Big/ \left(\frac{dV}{dt}\right)_{t \to 0} \qquad [1]$$

These transients were recorded on a Tektronix Type 564 storage oscilloscope. Longer transients were recorded on a Yokogawa Type 3077 x-t recorder. Potential and current measurements were made with a Data Precision Model 245 Digital Multimeter. Electrolysis experiments were made galvanostatically with the galvanostat mentioned above.

Results

Reference electrode.—A magnesium ribbon dipped in the solution was used in all experiments as an indicator reference electrode. Thus, all the potentials measured during the current pulses or polarization experiments gave directly the overpotential values.

To ensure the suitability of magnesium as a reference electrode, several dozen such electrodes, in groups of three, were immersed in a saturated solution of $MgCl_2$ which contained about 1M $AlCl_3$ or $FeCl_3$. The potential difference between pairs of electrodes was recorded as a function of time. In the case of $AlCl_3$ solutions this potential difference was less than 2 mV (after a few minutes of stabilization) for a period of up to ten days. In the case of $FeCl_3$ solutions, the potential difference was unstable for the first hour, but later reached a stable value of less than 3 mV for the same lengths of time. However, in this system a bias potential of up to 25 mV was recorded in some cases for no apparent reason. This bias potential might conceivably result from impurities, particularly from penetration of traces of water into the cell. A polarizing current density of up to 500 μA cm^{-2} did not form a permanent bias potential. However, polarization with current densities of a few mA cm^{-2} sometimes caused a permanent bias potential of a few hundredths of a volt. In the case of $AlCl_3$ solutions this bias potential later disappeared.

Corrosion of magnesium in TC solutions.—The magnesium electrode corroded in 1M $AlCl_3$ TC solution forming a white film on the surface of the metal. Magnesium ribbons (0.4 mm thick) completely dissolved in the above solution within one month of storage at room temperature.

The corrosion rate in $Mg(AlCl_4)_2$ is much lower but still may be seen to take place. During the first ten minutes of the immersion of the magnesium ribbon in the system it loses its bright appearance and a black film is formed on the surface of the metal. This film then turns gray-black in color and after about 20 hr the ribbon regains its metallic appearance. After about four days of storage at room temperature a white precipitate appears at the bottom of the cell, while the light yellow color of the solution remains unchanged. After storing magnesium ribbons in this solution at 70°C for six days, they were found to be heavily corroded and a considerable amount of precipitate was found at the bottom of the cell.

The solubility of $FeCl_3$ was found to be 10^{-2}M in TC at room temperature. The color of this solution is light brown. On the addition of an excess of $MgCl_2$ it is possible to prepare 1M $FeCl_3$ TC solution which is saturated with $MgCl_2$. This solution is dark brown in color.

Magnesium ribbons kept their metallic appearance in $Mg(FeCl_4)_2$ solutions and no corrosion was detected even after one month of storage at room temperature. To ensure the chemical stability of magnesium in this solution, an acceleration corrosion test was performed at 70°C. It was found that even after storing magnesium ribbon in the above solution for a week no corrosion was apparent and the metallic appearance still remained. A magnesium ribbon which was weighed before and after six days of this treatment was found to have lost 0.3 mg cm^{-2}.

Kinetic measurements.—Two systems were studied: (*i*) $Mg(FeCl_4)_2$ and (*ii*) $Mg(AlCl_4)_2$. Several anodic (or cathodic) current pulses of 50-100 msec duration each, were applied to the magnesium working electrode at different times of immersion in the electrolyte. The shapes of the galvanostatic transients were the same in both systems. It was found that at low overpotentials

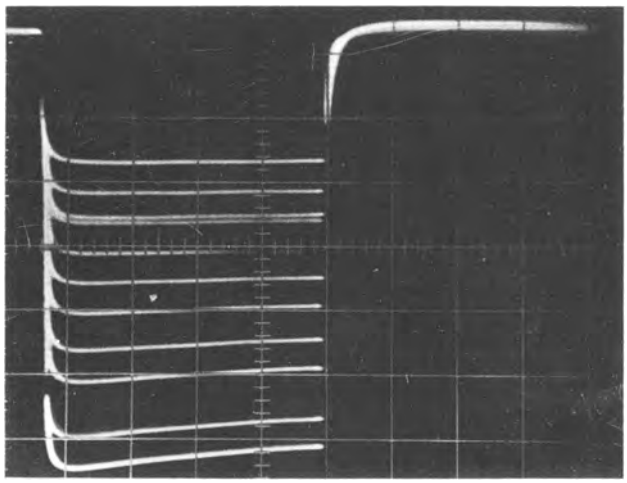

Fig. 3. Galvanostatic transients on Mg electrode in $Mg(AlCl_4)_2$ system at high anodic currents. Electrode area 2.4 cm^2. Scale: 10 mV/div, 10 msec/div, currents (μA): 206, 256, 307, 357, 408, 459, 519, 574, 662, 711.

the anodic and cathodic transients had the same shape. However, when the initial anodic overpotential was greater than about 30 mV, the potential transient had a small maximum (Fig. 3). This maximum increased in size with increasing polarizing current density. When similar polarizing cathodic current pulses were applied to the electrode, the potential did not reach a steady-state value, but increased continuously with time. The slope of the transient increased with current density. In cathodic steady-state experiments, an overpotential of 10V was obtained at a current density of 1 mA cm^{-2}.

From the data obtained in the low overpotential experiments micropolarization curves were drawn. The *IR* drop was negligible except in the cases of freshly dipped electrodes. For these electrodes, the overpotential was corrected for the *IR* drop. Typical micropolarization curves are shown in Fig. 4 and 5. The reaction resistance was calculated for both the cathodic and anodic branches. In all experiments the anodic reaction resistance ($R_{r,a}$) was 5-15% lower than the cathodic reaction resistance ($R_{r,c}$).

It was found, for both systems, that R_r increased with time of immersion of the magnesium electrode. The experimental results are summarized in Fig. 6 and 7.

In addition to the determination of R_r, the differential capacitance of the magnesium/solution interface was measured as a function of immersion time of the electrode. Identical values of capacitance were obtained from anodic and cathodic pulses. It was found that in the first day of immersion in the $Mg(AlCl_4)_2$ system the capacitance fluctuated between 1.5-4 μF cm^{-2} but later it decreased to 1 μF cm^{-2} or less. In the $Mg(FeCl_4)_2$ system the capacitance was always less than 1 μF cm^{-2}. These values of electrode capacitance are much lower than those measured in aqueous or nonaqueous solutions (9). Thus it was concluded that the electrode was covered by some passivating layer. The minimum thickness of this layer (d_{min}) was calculated from the equation (10)

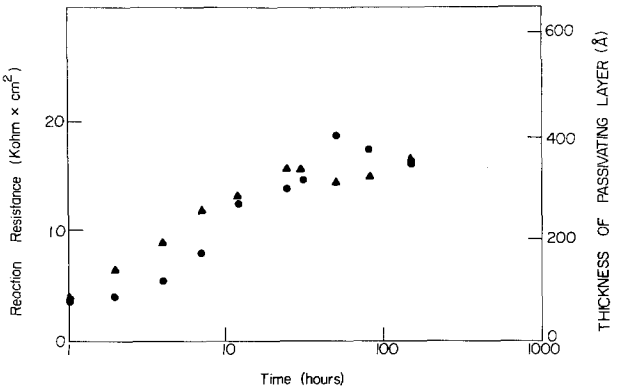

Fig. 7. The variation of $R_{r,a}$ and d_{min} with time of storage at room temperature in $Mg(FeCl_4)_2$ system. Electrode area 2.4 cm^2, ●, d_{min}; ▲, $R_{r,a}$.

$$d_{min} = \frac{\epsilon A}{C\pi\, 3.6 \times 10^{12}} \qquad [2]$$

where A = electrode area, C = differential capacitance, ϵ = dielectric constant of the passivating layers (assumed here to be 5). It was assumed that the roughness factor of the magnesium electrode was 1. The effect of immersion time on the thickness of the passivating layers is shown in Fig. 6 and 7.

A few galvanostatic experiments at various current densities were carried out in which the pulses lasted for several seconds. The micropolarization curves which were drawn from the data obtained in these experiments were similar to those obtained in the galvanostatic pulse experiments. In these cases too, $R_{r,a}$ was about 10% smaller than $R_{r,c}$. The values of R_r which were measured in steady-state experiments were 10-20% higher than those measured (for the same immersion time) by means of galvanostatic pulse techniques.

Electrodeposition of magnesium on nickel wire.—Some preliminary work was done in connection with the electrodeposition of magnesium on nickel wire in the $Mg(FeCl_4)_2$ system. The open-circuit potential (o.c.p.) difference between the nickel wire and the magnesium electrode was about 1.8V. When a C.D. of 100 $\mu A\ cm^{-2}$ was applied to the nickel working electrode, its potential (measured against a magnesium reference electrode) decreased with the electrolysis time from the o.c.p. of +1.8V to negative values. On turning off the current, the nickel potential fell immediately to a small positive value of about several hundredths of a volt, and remained there for a long time. Later, it slowly rose to 1.8V. A typical voltammogram describing this kind of experiment is shown in Fig. 8. The stabilization of the o.c.p. at about 30 mV following electrolysis indicates that magnesium metal electrodeposited on the nickel cathode. Unfortunately, this coating slowly corroded in the solution, and the nickel o.c.p. rose to its initial value.

Discussion

Solubilities and corrosion.—The halides of the alkali and alkaline-earth metals (which are donors for chloride ion) have low solubilities in TC (11). However, many Lewis acids such as $AlCl_3$, $SbCl_5$, and BCl_3 are very soluble in it (11). The solubilities of the alkali and alkaline-earth halides can be markedly increased by the addition of some Lewis acid to the TC solution. The reason for this is the formation of a large complex anion like $SbCl_6^-$, $AlCl_4^-$ or BCl_4^- (11). In this work it was found that the Mg:Al or Mg:Fe mole ratio in TC solution is about 1:2. This indicates the formation of Mg^{2+} and $AlCl_4^-$ ions in system (*i*), or Mg^{2+} and $FeCl_4^-$ ions in system (*ii*) as expected (11). However, it was found that $FeCl_3$ itself is practically insoluble in TC and we have no explanation for this.

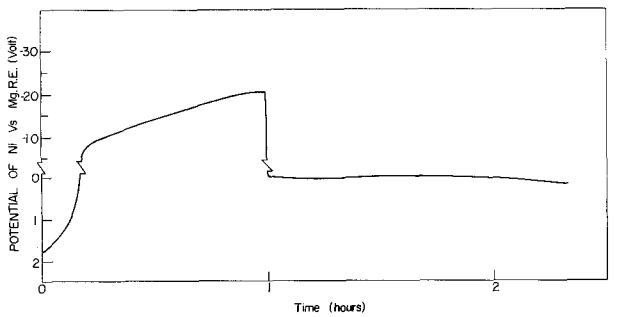

Fig. 8. Electrolysis experiment in $Mg(FeCl_4)_2$ system. Nickel cathode 1.0 cm^2, current 150 μA.

A metal will corrode if its surface has two kinds of sites: a cathodic area, where the electrons are transferred to the solution and an anodic area, where the metal ions are transferred to the solution. The rate of metallic corrosion depends on the corrosion cell potential, and on the cathodic and anodic exchange current densities (13). In the present case the corrosion cell potential is about 2V (12a). The $R_{r,a}$ for a freshly immersed magnesium electrode in the $Mg(FeCl_4)_2$ system is about 2 $k\Omega\ cm^2$ (equivalent to i_o of about 4 $\mu A\ cm^{-2}$). Thus the process responsible for the inhibition of the corrosion of magnesium in this system (even at 70°C) is the cathodic one, *i.e.*, the reduction of the solvent. However, it is well known that this solvent can be reduced and moreover it can be used as a soluble cathode for lithium (14) or magnesium (12a) batteries. Thus it can be concluded that in the $Mg(FeCl_4)_2$ system the magnesium electrode is covered by a passivating layer which is a very poor electronic conductor but is capable of conducting magnesium ions. The fact that magnesium corroded in acid solutions (containing $AlCl_3$ only) even at room temperature indicates that the passivating layer is basic and thus can dissolve in the Lewis acid. The corrosion of magnesium in $Mg(AlCl_4)_2$ system is more difficult and will be discussed later.

The composition of the passivating layer is as yet not known. It most likely consists of insoluble corrosion products. Magnesium chloride should not be soluble in this system since the latter is saturated with it. Thermodynamic considerations indicate that MgO may be soluble in this system. The standard free energy for the reaction $MgO + SOCl_2 \rightarrow MgCl_2 + SO_2$ is about -35 kcal $mole^{-1}$. Thus it is more likely that this film consists of $MgCl_2$. In any case, both $MgCl_2$ and MgO are very good electronic insulators and thus would prevent the transfer of electrons from the metal to the solution. In the case of the lithium electrode in TC solution of $LiAlCl_4$ the passivating layer was analyzed by SEM (15). It was concluded that it consists of LiCl.

Electrolysis.—Upon electrolysis of the $Mg(FeCl_4)_2$ system, the potential of the nickel cathode goes slowly from 1.8V (*vs.* MgRE) to zero within a few minutes (Fig. 8) and does not immediately jump to negative values as is the case in simple electrodeposition experiments. These phenomena can be explained as follows. When a current is passed through the cathode, its surface is in direct contact with the solution and thus can transfer electrons to the solution. In the vicinity of the o.c.p. of +1.8V, TC can be reduced but not the magnesium ions. Thus the reduction products of TC begin to accumulate near the cathode. These products may be SO_2, Cl^-, and S (16). Of these SO_2 and S are soluble in the electrolyte (16). The chloride ion concentration will exceed the solubility-product limit for $MgCl_2$ and the latter will precipitate on the cathode. In time this precipitate will prevent (or at least partially inhibit) the transfer of electrons from the cathode to the solution. From this point on, the current from the electrode to the solution will be essentially an ionic current. The magnesium ions will migrate through the passivating layer to the electrode and will be reduced to mag-

nesium atoms at the interface electrode/passivating layer. In this way the electrodeposition of magnesium continues until the current is interrupted. For the first hour the o.c.p. of the coated nickel cathode was several hundredths of a volt positive to MgRE, then it increased until it returned to its initial value of 1.8V. To explain this corrosion phenomenon it is suggested that the passivating layer which covers the magnesium deposit is not a purely ionic conductor, but, (because of impurities) it conducts electrons as well. This electron leakage through the film may also reduce the faradaic efficiency of the deposition of magnesium on nickel.

From the above, the failure of iron to undergo electroless deposition on solid magnesium electrodes in the $Mg(FeCl_4)_2$ system may be explained. As mentioned before, electrons are not transferred to the solution through the passivating layer on solid magnesium, and thus the $FeCl_4^-$ anion cannot be reduced. In addition, because of its charge and size, the iron anion cannot migrate (or diffuse) through the passivating layer (the way Mg^{2+} does). Thus it is not possible for it to reach the magnesium/passivating layer interface in order to accept electrons directly from the metal. It was found (12) that antimony and tin show the same behavior, that is, they do not undergo electroless deposition on the magnesium electrode in TC solutions when they are present as $SbCl_5^-$ and $SnCl_6^{2-}$, respectively.

The passivating-layer model.—In order to account for the observation during the chemical corrosion and electrochemical measurements of magnesium in TC solutions, a simple model is proposed in Fig. 9. The magnesium metal is covered by a passivating layer which consists of some insoluble magnesium salt, probably $MgCl_2$. The properties of this passivating layer determine the chemical and electrochemical behavior of the magnesium electrode in the TC solutions. When chemical corrosion is very slow, as in the $Mg(FeCl_4)_2$ system or in the $LiAlCl_4$ system (12), the transference number of electrons (t_e) through this layer is practically zero, and all the current is carried by ions, that is $t_{ion} \sim 1$. The value of $t_{Mg^{2+}}$ in the passivating layer in TC solutions is not known but is assumed to be close to unity. The magnesium electrode has two interfaces, the interface Mg/passivating layer in which the reaction

$$(Mg^{2+})_{pl} + 2e(M) \rightleftarrows Mg^{\circ} \qquad [3]$$

takes place, and the interface passivating-layer/solution in which the following reaction takes place

$$(Mg^{2+}(SOCl_2)_n)_{sol} \rightleftharpoons (Mg^{2+})_{pl} + n(SOCl_2)_{sol} \qquad [4]$$

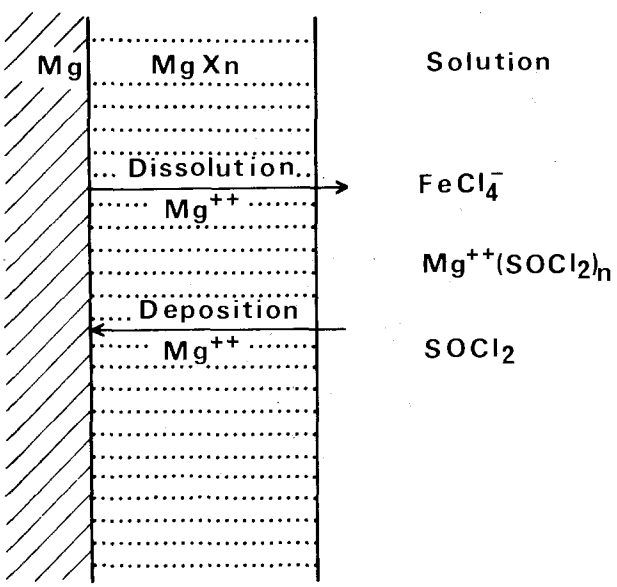

Fig. 9. Schematic model of the passivating layer on magnesium electrode in TC solutions.

The potential difference $\Delta\phi_{Mg/sol}$ contains these components

$$\Delta\phi_{Mg/sol} = \Delta\phi_{Mg/pl} + \Delta\phi_{pl} + \Delta\phi_{pl/sol} \qquad [5]$$

The first term is associated with the electron-transfer reactions, $\Delta\phi_{pl}$ is associated with the migration of magnesium cations through the passivating layer, and $\Delta\phi_{pl/sol}$ which is equivalent to the double-layer potential, is associated with the transfer of magnesium ions across the passivating-layer/solution interface.

In principle, any one of the processes associated with the three components of $\Delta\phi_{Mg/sol}$ may be the rate-determining step (rds) of the deposition-dissolution process of magnesium in TC solutions. The rds may depend on the thickness of the passivating layer, on its composition, or on the composition of the solution.

In studies of oxide films on valve metals (10) the thickness of the oxide is usually calculated from capacitance measurements. This kind of calculation is not accurate for several reasons: (*i*) The actual value of ϵ is not known. (*ii*) The passivating layer is not a single crystal. (*iii*) The roughness factor of the electrode is not precisely known and in this work is taken as unity. (*iv*) For an electrode covered by a porous passivating layer, this kind of determination of d may give values which are too small. In this work it was found that the reaction resistances which were measured in the milliseconds and in the seconds range gave similar values, and so it seems that the last quoted factor may not interfere with the determination of d_{min}.

It can be seen in Fig. 7, that in $Mg(FeCl_4)_2$ the reaction resistance of the magnesium electrode (both $R_{r,a}$ and $R_{r,c}$) and the thickness of the passivating layers (d_{min}) increase with time of immersion of the electrode. The electrical resistivity of the passivating layer (ρ_{pl}) was calculated by dividing the reaction resistance by the thickness of the passivating layer. It was found that this resistivity fluctuated between 4 and 9 $\times 10^{-9}$ Ω-cm during the time of immersion of the electrode in the solution. This indicates that the rds is the migration of the magnesium ion through the passivating layer. The rate of the electron-transfer reaction across the Mg/passivating-layer interface and the rate of transfer of Mg^{2+} ions across the passivating-layer/solution interface, should not depend significantly on the thickness of the passivating layer. It was found that $R_{r,a}$ is always smaller than $R_{r,c}$ (Fig. 4, 5). The reason for this may be as follows. Under cathodic polarization, Mg^{2+} ions must shed all its solvated $SOCl_2$ molecules before entering the passivating layer. This is a rather difficult process, the driving force for which is $\Delta\phi_{pl/sol}$ which is only a part of the total potential difference $\Delta\phi_{Mg/sol}$. In a simple aqueous electrodeposition experiment the partial discharge of the ion helps it (13); in the case at hand, partial discharge of the ion is not possible. Thus it seems that $R_{r,c}$ may include two components: the ohmic resistance to the migration of Mg^{2+} through the passivating layer and the reaction resistance for the transfer of Mg^{2+} across the passivating-layer/solution interface.

In accordance with the model the continuous increase of potential during high cathodic polarization may be ascribed to insufficient supply of Mg^{2+} ions from the solution to the passivating layer. Thus the concentration of the mobile magnesium ions in the passivating layer decreases, giving rise, in turn, to a decrease in the electrical conductivity of the layer and to an increase in the overpotential with electrolysis time (up to 10V). On anodic polarization at high current densities (C.D. > 0.5 mA cm^{-2}) the over-potential transient obtained shows a maximum (Fig. 3). This kind of transient has been observed in pulse-galvanostatic anodization experiments on valve metals in aqueous solutions (10). This phenomenon was explained (10) by an increase in the mobile-ion concentration in the oxide layer during the current pulse. It seems that this explanation applies to the present case as well.

The reason for the increase of d_{min} in this system may be a small leakage of electrons through the passivating layer. The electrons can reduce TC. At least one of the corrosion products of TC, the magnesium chloride, is not soluble in this system, and so will precipitate on the magnesium surface, giving rise to an increase in the thickness of the passivating layer. The electronic conductivity of this layer (t_e) may show the same sensitivity to impurities as does that of semiconductors. Thus in order to minimize t_e purified solutions must be used.

The magnesium electrode exhibits a more complicated behavior in $Mg(AlCl_4)_2$ system than in the previous one. The initial values of d_{min} are smaller by a factor of 2-3, while the initial R_r is 1/20 of its value in the previous system. In this system d_{min} did not increase during the first day of storage, while the reaction resistance increased by more than an order of magnitude. This process was associated with changes in the appearance of the electrode from metallic to black (fast) and then back to metallic. It is clear that during the first day of immersion the passivating layer changed. Three days later white precipitate was found at the bottom of the cell. The reason for this difference in behavior of the magnesium electrode in the two systems is not yet clear. It seems that in $Mg(AlCl_4)_2$ system t_e of the freshly found passivating layer is high, and as a result the metal corrodes. During this corrosion the passivating layer changes and a new layer with a smaller t_e is formed. This kind of behavior may result from some impurities which still stay in the solution after the present process of purification.

Summary

In the present work we found that in TC the magnesium electrode is always covered by a passivating layer. This layer cannot be completely removed and so no film-free surface can be obtained. However, it is possible to reduce the thickness of the film by anodic pulses. In the TC solutions the process of direct electron transfer from magnesium to the ions in the solution has a very low probability as the thickness of the passivating layer is higher than 20Å (after a stabilization period). The reaction resistance for the deposition-dissolution process of magnesium metal in TC solutions is mainly determined by the ionic conductivity of the passivating layer.

The model of the passivating layer proposed for the magnesium electrode in TC solutions may also be applied in the case of alkali metals in many nonaqueous systems especially those used for batteries. Under these conditions the alkali metal is usually covered with a passivating layer. When this layer is thick it is expected that the rds for the deposition-dissolution process will be the migration of metal ions through the passivating layer as was claimed by Dey (7) for lithium in propylene carbonate. However, for alkali-metal electrode covered by a thin passivating layer, the rds may be either the electron-transfer reaction

$$(M^+)_{pl} + e(M) \rightleftarrows M^\circ \qquad [6]$$

or the transfer of the alkali ions across the passivating layer/solution interface

$$(M^+ (solv)_n)_{sol} \rightleftharpoons (M^+)_{pl} + n(solv)_{sol} \qquad [7]$$

A direct transfer of electrons across the passivating layer should: (*i*) Cause a metal corrosion. (*ii*) Reduce the faradaic yield for the metal deposition as a result of simultaneous solvent reduction. Therefore it is an undesirable process in battery systems.

Electrochemical Nucleation in Hydrated Melts: Electroreduction of Thallium (I) from Calcium Nitrate Tetrahydrate

Narottam P. Bansal[1] and James A. Plambeck*

Department of Chemistry, The University of Alberta Edmonton, Alberta, Canada T6G 2G2

ABSTRACT

The electroreduction of thallium(I) on a mercury electrode from its solutions in molten calcium nitrate tetrahydrate has been studied using chronoamperometry, chronopotentiometry, and cyclic voltammetry. The early stages of metal deposition are controlled by a nucleation step as indicated by the maxima in current-time transients, potential overshoots in potential-time curves, and an anodic shift of the peak potential of the reduction process in subsequent cyclic voltammetric scans. A three step mechanism has been proposed. The first step, formation of nuclei of thallium metal on the electrode surface and the growth of these nuclei into full monolayer surface coverage, is in quantitative agreement with these results.

Moynihan and Angell (1) measured the diffusion coefficient of thallium(I) in $Ca(NO_3)_2 \cdot 4H_2O$ by chronopotentiometric reduction at a mercury pool electrode. Their work has been criticized by Lovering (2), who showed that Moynihan and Angell (1) did not collect their data under diffusion-controlled conditions. Lovering (2) reported polarographic half-wave potentials and diffusion coefficients for a large number of inorganic cations in different hydrated melts. In $Ca(NO_3)_2 \cdot 4H_2O$ he reported a polarographic maximum was observed for Tl(I) reduction at concentrations above millimolar; no further details were given. In the course of a study of Tl(I) reduction by a-c chronopotentiometry in this melt unusual phenomena were noted and a full study of this electroreduction by chronoamperometry, d-c chronopotentiometry, and cyclic voltammetry was therefore carried out. The results and interpretation of that study are described below.

Experimental

A double walled, water-jacketed Pyrex cell was used for the measurements. Hot water from a constant temperature bath was constantly circulated around the cell. The temperature control was better than ±0.1°C. The bath stirrer was turned off to avoid mechanical vibrations only during the measurements. An externally driven magnetic stirrer was used for better mixing in the viscous calcium nitrate tetrahydrate melt.

Calcium nitrate tetrahydrate (B.D.H., AnalaR) and thallium nitrate (Alfa Inorganics) were used without further purification. About 80g of the melt were used for each experiment. As the solubility of oxygen is negligible in this melt (1), no precautions were taken to exclude air from the system, save for tightly capping the cell to avoid loss of water. The density of the melt without solute (3) was used in calculating the molar concentrations, as the solute concentrations used were low. All measurements were carried out at 50°C.

The cell was in a three electrode configuration. The working electrode was a P.A.R. Model 9323 hanging mercury drop electrode (HMDE) which was set up using triply distilled mercury (Engelhard). A fresh mercury drop of constant known area (0.0176 cm^2) was taken for each observation unless otherwise stated. The auxiliary electrode was a platinum flag of large area. The reference electrode was silver nitrate (0.03M in the melt)/silver which was isolated in a fritted glass compartment of porosity 10-20μ.

The constant current source for the chronopotentiometric measurements was a 225V dry battery connected in series with two potentiometers (5 MΩ and 100 kΩ) which were used as adjustable resistors to regulate the current; the switching circuitry was conventional. The potential-time curves were photographed on ASA 3000 Polaroid film using a Hewlett-Packard oscilloscope and camera (Models 175A and 196B). The chronoamperometric current-time curves and cyclic voltammograms were obtained with a P.A.R. Model 173 potentiostat/galvanostat coupled to a P.A.R. Model 175 universal programmer. The current-time curves and the voltammograms at slow scan rates (<1 V/sec) were recorded with a X-Y recorder (Houston Instrument Type 2000). The cyclic voltammograms at higher scan rates were photographed from a Tektronix Model 535A oscilloscope using the same camera.

Results

Chronoamperometry.—Some of the results for the reduction of Tl(I) on mercury in this melt are shown

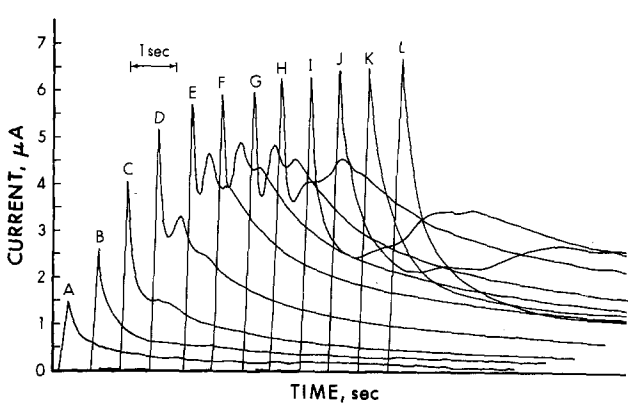

Fig. 1. Chronoamperometric curves for the Tl(I)/Tl(Hg) reduction in $Ca(NO_3)_2 \cdot 4H_2O$. Time scale arbitrarily displaced for each curve shown. Potential step (against Ag(I)/Ag reference) applied: A, −0.90V; B, −0.92V; C, −0.94V; D, −0.96V; E, −0.98V; F, −0.99V; G, −1.00V; H, −1.02V, I, −1.04V; J, −1.06V; K, −1.08V; L, −1.10V. Concentration of Tl(I) is 4.36 × 10^{-3}M. Area of HMDE, 0.0176 cm^2; temperature, 50°C. The initial potential was set at −0.2V before each run.

in Fig. 1, in which the curves clearly show maxima at potentials close to the potential of thallium(I) reduction, but are of normal shape both at potentials less cathodic than the reduction and in the region of diffusion control. The position and height of the maxima are functions of both the applied potential of the step and the concentration of Tl(I). No maxima are observed at any potential at low concentrations (below 0.459 mmole/liter); when the concentration is increased to 1.299 mmole/liter, broad maxima appear on curves whose potential step is between −0.96 and −1.02V. As the concentration is increased, the maxima become sharper, appear after shorter times, and appear at less negative potentials. When the concentration reaches 2.5 mmole/liter Tl(I) a second broad maximum appears at potentials of −0.96V; this is later than the first one which has now become sharp and appears at shorter times. When both maxima are present the shape of the curves changes as the step potential is made more cathodic; the sharpness of the second maximum increases and that of the first decreases until the two finally merge into one very broad maximum which becomes steadily less distinct. At potentials more cathodic than −1.08V the maximum can no longer be distinguished.

Polarograms can be constructed from the chronoamperometric current-time curves and are shown in Fig. 2. The presence of the maximum for all concentrations greater than 0.459 mmole/liter Tl(I) is obvious. The maximum does not affect the diffusion-limited plateau region of the polarographic curves, and the height of this plateau is directly proportional to Tl(I) concentration, as shown in Fig. 3. These composite polarograms show maxima at slightly lower concentrations than those reported by Lovering (2), whose concentration of 1.0 mmole/kg at 50°C in this melt is equivalent to 1.73 mmole/liter, while in our work a maximum is clearly apparent at 1.30 mmole/liter, which certainly confirms the maximum reported by this author.

Concentration of Tl(I) in $Ca(NO_3)_2 \cdot 4H_2O$: A, 4.36 × 10^{-3}M; B, 2.56 × 10^{-3}M; C, 1.3 × 10^{-3}M; D, 4.59 × 10^{-4}M; temperature, 50°C. Current was measured 10 sec after applying the potential step.

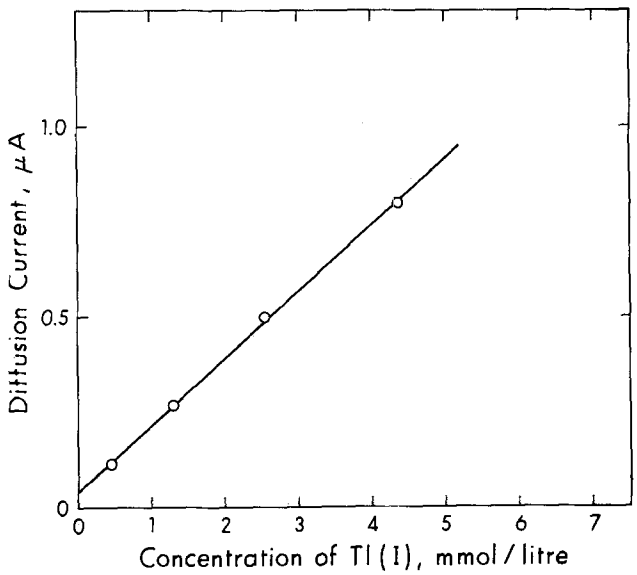

Fig. 3. Polarographic diffusion currents as a function of concentration of Tl(I) in $Ca(NO_3)_2 \cdot 4H_2O$; temperature, 50°C.

In chronoamperometry the current-time transient will follow the relationship $I = kt^{-1/2}$ when the potential is stepped to a value sufficiently cathodic of the reversible potential if semi-infinite linear diffusion controls the current. While our polarographic curves do indicate diffusion control at sufficiently cathodic potentials, the time transients are much longer than those used in cyclic voltammetric or chronopotentiometric studies and the effect of the geometry of the microelectrode may become more significant. This can be seen from the form of the equation for the current-time relationship for spherical diffusion-limited currents (4)

$$I = n\mathbf{F}AC^{\circ}D_0^{1/2}(1/\pi^{1/2}t^{1/2}) + n\mathbf{F}AC^{\circ}D_0/r_0 \qquad [1]$$

where r_0 is the radius of the spherical electrode and A, its area, is $4\pi r_0^2$. When the radius of the sphere is reasonably large, the spherical term normally will not be significant at short times. At longer times the contribution of this spherical term may become more significant. A plot of the data for thallium (I) reduction, shown in the form of a current-$t^{-1/2}$ plot in Fig. 4, indicates that our chronoamperometric data are, within experimental error, adequately described by semi-infinite linear diffusion when $t \leq 4$ sec and by spherical diffusion (dashed line) at longer times. The larger deviations at very short times are probably due to the effect of charging the double layer or to the response speed of our apparatus.

The linear portion of the I-$t^{-1/2}$ plot of Fig. 4 permits calculation of the diffusion coefficient of Tl(I) as 3.13 × 10^{-7} cm²/sec. This value, which is in good agreement with that of Lovering (2) (Table I), when inserted into Eq. [1] yields a value of 0.06 μA for the intercept rather than the 0.12 μA obtained by direct extrapolation. However, the uncertainty in the

extrapolation due to the effect of convection, which prevents acquisition of data at $t > 9$ sec even in this highly viscous melt, coupled with the observed deviation at very short times discussed above, is sufficiently large that the difference cannot be assumed to be significant.

Chronopotentiometry.—An investigation of the reduction of Tl(I) on mercury in this fused salt system by a-c chronopotentiometry was undertaken to establish the effect of markedly different diffusion coefficients of the oxidized and reduced forms of the Tl(I)/Tl(0) couple in the melt and in mercury, respectively. In the course of the investigation it was observed that transition times were sometimes unusually short and that an additional transition was sometimes present. Since the only significant advantage of a-c chronopotentiometry over d-c is better resolution of transitions, and its interpretation is otherwise less straightforward, the reduction was examined by d-c chronopotentiometry. It was found that the unusually short transitions (Fig. 5A) appeared at higher currents, while transitions were considerably longer at lower currents, although often distorted by a peak (Fig. 5B). The specific current density at which the comparatively abrupt changeover between the two types of behavior occurs is concentration dependent. The data shown in Fig. 5 are typical. It will be noted that the potential difference between the transitions is extremely small. At all concentrations the product $I_0\tau^{1/2}$ decreased with increasing current density I_0 up to the current density at which the unusually short transition appeared, which indicates that the process observed is not under normal diffusion control.

Chronopotentiometric current reversal gave values for the ratio of τ(reduction)/τ(oxidation) significantly greater than the value of 1/1 expected for a soluble product, but less than the value of 3/1 expected for soluble product.

Cyclic voltammetry.—A set of solutions of different concentrations were studied by cyclic voltammetry;

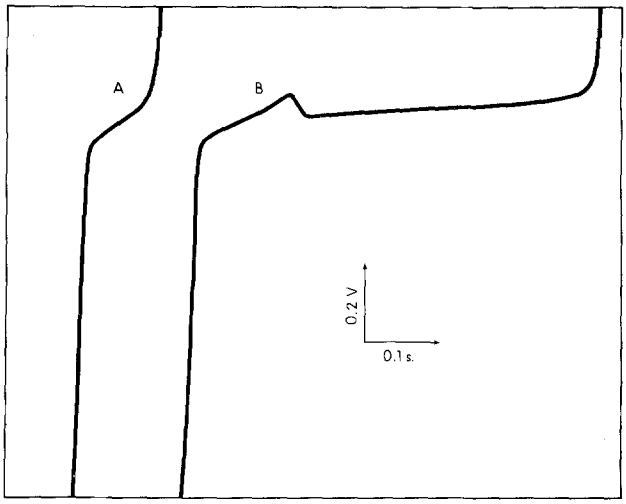

Fig. 5. Chronopotentiograms for the reduction of 10.24 × 10^{-3}M Tl(I) in $Ca(NO_3)_2 \cdot 4H_2O$ at 50°C. Area of HMDE, 0.0755 cm^2. Current applied: A, 80 μA; B, 70 μA.

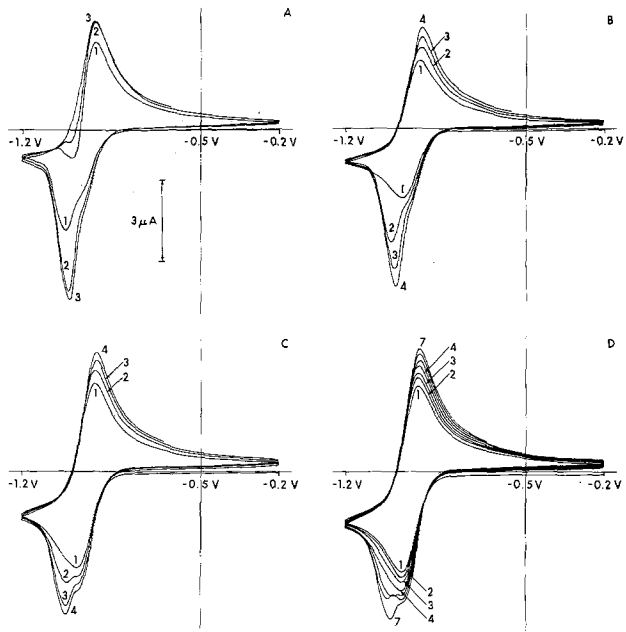

Fig. 6. Multicyclic voltammograms of 4.356 × 10^{-3}M Tl(I) in $Ca(NO_3)_2 \cdot 4H_2O$. Area of HMDE, 0.0176 cm^2. Voltage scan rate, ν: A, 50 mV sec^{-1}; B, 60 mV sec^{-1}; C, 100 mV sec^{-1}; D, 120 mV sec^{-1}. The current scale is same for all the four runs and is downward cathodic and upward anodic. Temperature 50°C.

sweep rate, ν, was varied between 0.02 V/sec and 50 V/sec. Typical cyclic voltammetric curves at several different scan rates are shown in Fig. 6, and the results are summarized in Table II. The cyclic voltammetric behavior observed depends upon both solution concentration of Tl(I) and sweep rate ν. For the two most dilute solutions, 0.459 mmole/liter and 1.299 mmole/liter, only a single cathodic peak and

a single anodic peak were present over the full range of sweep rate, even in multicycle runs. These peaks, *IC* and *IA*, persisted as concentrations were increased, but at higher concentrations the curves exhibited more complex behavior which is discussed later.

The peak current, *Ip*, of the cathodic peak *IC* is directly proportional to bulk concentration of Tl(I) as shown in Fig. 7 at all intermediate scan rates (0.10 V/sec $\leq \nu \leq$ 10.0 V/sec). At these scan rates the peak current for *IC* is also directly proportional to the square root of the scan rate as shown in Fig. 8. Further, the peak potentials of *IC* and its corresponding anodic peak *IA* were independent of the scan rate, and they retained the values of -0.975 ± 0.005V and -0.910 ± 0.010V against the 0.03M Ag(I)/Ag(0) reference electrode. The separation of the cathodic and anodic peaks was constant at 70 $\pm$ 5 mV up to at least 5 V/sec but increased at higher scan rates. The ratio of the anodic peak current to the cathodic peak current was within experimental error unity at the intermediate scan rates 0.10 V/sec $\leq \nu \leq$ 10.0 V/sec, but significant deviations from unity were observed both at slower and at faster scan rates. When $\nu \leq$ 0.2 V/sec the cathodic peak current was slightly less than the anodic peak current, while the reverse is true for $\nu >$ 0.2 V/sec. All of these results would indicate a simple reversible process, at least at intermediate scan rates.

More complex behavior was first observed at a Tl(I) concentration of 2.563 mmole/liter. The simple behavior of the more dilute solutions is observed

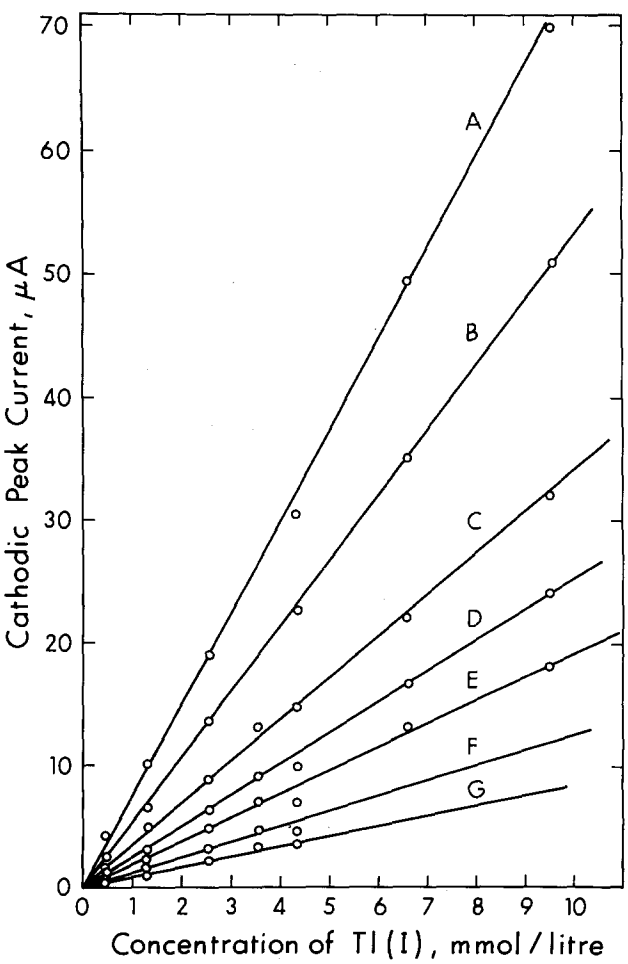

Fig. 7. Cathodic peak current *vs.* concentration of Tl(I) in $Ca(NO_3)_2 \cdot 4H_2O$ for various voltage scan rates, ν: A, 10.0 V sec^{-1}; B, 5.0 V sec^{-1}; C, 2.0 V sec^{-1}; D, 1.0 V sec^{-1}; E, 0.5 V sec^{-1}; F, 0.2 V sec^{-1}; G, 0.1 V sec^{-1}. Area of HMDE, 0.0176 cm^2, temperature 50°C.

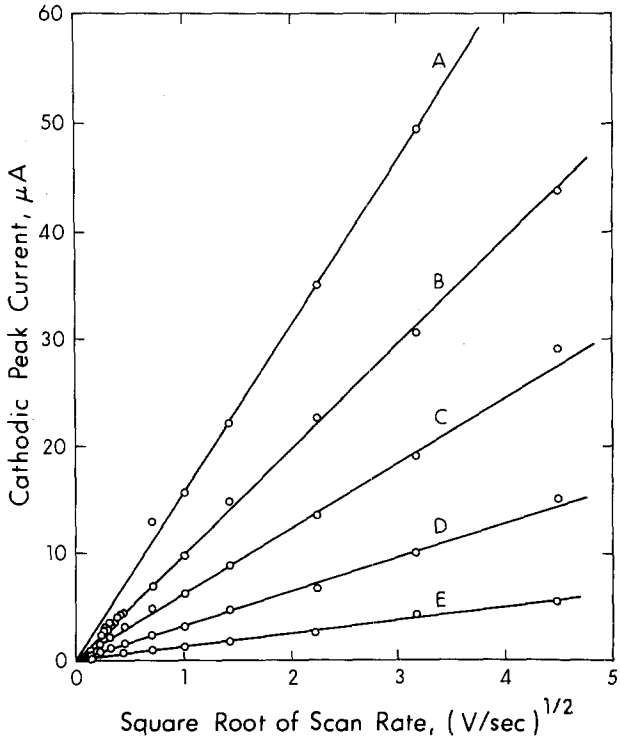

Fig. 8. Cathodic peak current *vs.* square root of voltage scan rate for the reduction of Tl(I) in $Ca(NO_3)_2 \cdot 4H_2O$ at 50°C. Area of HMDE, 0.0176 cm^2. Concentrations of Tl(I): A, 6.58 $\times$ 10^{-3}M; B, 4.36 $\times$ 10^{-3}M; C, 2.56 $\times$ 10^{-3}M; D, 1.30 $\times$ 10^{-3}M; E, 0.46 $\times$ 10^{-3}M.

at high and intermediate scan rates. However, at the slowest scan rate of 0.02 V/sec the first cycle was as expected but the second and subsequent cycles were not. In the second cycle a new cathodic peak *IIC* appeared at -0.995V and only a comparatively small shoulder appeared at the potential corresponding to cathodic peak *IC*. With additional cycles the positions of peaks *IIC* and *IC* shifted anodically and the relative magnitude of *IIC* increased while the *IC* shoulder disappeared. The height of the anodic peak *IA* increased significantly but its position did not shift with cycling.

As the concentration was further increased the complex behavior became more pronounced; the results at a Tl(I) concentration of 4.356 mmole/liter are given in Fig. 6 for several scan rates. At very low scan rates (Fig. 6A), where $\nu \leq$ 50 mV/sec, the prominent peak *IIC* appeared in the very first cycle, while at higher scan rates (Fig. 6B-6D) it appeared only in later cycles. As these typical data show, the effect of increasing scan rate is to cause the appearance of *IIC* at larger and longer numbers of cycles; this is true for all concentrations above 4.356 mmole/liter. As the concentration is increased further, the cathodic peak *IIC* becomes steadily more prominent and, at the same scan rate, appears in earlier cycles.

Determination of n.—Due to the presence of nucleation (see Discussion) during the reduction of Tl(I), no information on the number of electrons can be obtained from the slope of the polarograms or chronopotentiograms. The number of electrons can, however, be calculated when the current is controlled by diffusion. By relating the first-cycle cyclic voltammetric $Ip/\nu^{1/2}$ and chronoamperometric $It^{1/2}$, provided that the current-time curve is obtained at a potential corresponding to the diffusion plateau of the polarogram, one obtains (5, 6)

$$n^{1/2} = \frac{(Ip/\nu^{1/2})R^{1/2}T^{1/2}}{0.447\pi^{1/2}\mathbf{F}^{1/2}It^{1/2}}$$

At 50°C, this can be written as

$$n^{1/2} = 0.2106(Ip/\nu^{1/2})/It^{1/2}$$

The value of n calculated by this method, when the value of $It^{1/2}$ used was corrected for the sphericity of the diffusion field, comes out to be 0.84.

Diffusion coefficients.—The diffusion coefficients were calculated using the linear portion of the chronoamperometric I *vs.* $1/t^{1/2}$ plot obtained at plateau potentials and the mean $Ip\nu^{-1/2}/C^{\circ}$ value from the cyclic voltammetric results. The value of $n = 1$ was used in the calculations. Values of diffusion coefficients so obtained have been compared with those reported by other workers in the same melt in Table 1.

Hills *et al.* (7, 8) have reported that the presence of the nucleation process introduces discrepancies in D values. This is not reflected in our results. The values of D evaluated by the two techniques are in very good agreement not only with each other, but also with that reported by Lovering (2) using polarography. However, the value of the chronopotentiometric diffusion coefficient reported by Moynihan and Angell (1) is too high because these workers did not obtain their data under diffusion-controlled conditions (2).

In cyclic voltammetry the values of the diffusion coefficients obtained from two different runs on different days were 3.04×10^{-7} and 2.95×10^{-7} cm^2/sec, respectively. This shows the reproducibility of the results in this work.

Discussion

The unusual behavior of Tl(I) reduction in calcium nitrate tetrahydrate recorded above shows that this process is not the expected simple reversible reduction. It cannot be due simply to insolubility, since at 50°C thallium is soluble in mercury to the extent of 45 mole per cent (m/o) (9). One possible explanation would be adsorption phenomena. Lovering (10), in his study of the electroreduction of bromocadmium (II) complexes on mercury in this melt, interpreted curves showing polarographic maxima and multiple cyclic voltammetric peaks on the basis of adsorption; adsorption is well known in aqueous electrodeposition studies of many metal ions and has been demonstrated in anhydrous nitrate melts as well. The constancy of $Ip\nu^{-1/2}$ with scan rate argues against adsorption in the present case. Another possible explanation is electrocrystallization of a thallium compound on the surface of the mercury drop. This phenomenon is also known; the excellent study of Fleischmann, Pattison, and Thirsk (11) on the electrocrystallization of thin films of thallous chloride on thallium amalgam from aqueous solution shows chronoamperometric curves which are remarkably similar to those of the present work.

Yet a third possible explanation is a nucleation step. Hills, Schiffrin, and Thompson (7, 8) have shown that a nucleation step may be involved in the electrodeposition of metals from molten nitrates. This could result in large variations in the values of diffusion coefficients obtained by different workers using different techniques, perhaps as Lovering (2) and Moynihan and Angell (1) in the present case. Hills, Schiffrin, and Thompson (7, 8) studied the nucleation effects in the deposition of silver on platinum from molten $NaNO_3$-KNO_3 eutectic and also studied the aqueous electrodepositions of silver on platinum and on graphite and of mercury on graphite. These workers also have suggested that similar nucleation steps are unlikely to be observed in molten halides where predeposition reactions to form a monolayer, possibly from an adsorbed layer of metal ions, frequently occur (12). This limitation has not been substantiated. Mamantov and co-workers have observed a nucleation step in the electrodeposition of aluminum (13), zirconium (14), and iron (14) on solid microelectrodes in chloroaluminate melts. We note that initial potential overshoots very similar to those observed in the present work appear on chronopotentiograms observed during the reduction of the uranyl ion in molten NaCl-KCl (15) of Cr(II) (16) and the neptunyl ion (17) in molten LiCl-KCl, and of the chromate ion in molten LiCl-KCl in the presence of Zn(II) or Co(II) (18), all on solid electrodes, but these authors have not given an explanation of it other than overvoltage. Nucleation behavior is also known in aqueous solution, as in the electrodeposition of palladium on vitreous carbon electrodes (19).

Yet another possible explanation for these results could lie in a process which is indeed nucleation and in which the nucleation is followed not by film formation but by the formation of metal dendrites. Such phenomena have been observed by Calusaru and Kuta (20) when nitrate solutions of aqueous metal ions, including Tl(I), are reduced on the dropping mercury electrode. They state that there is a lower concentration threshold, about 18 mmole/liter for Tl(I), below which dendrite formation is not observed. This dendrite formation was favored by addition of nitrate and of gelatine. In the polarographic curves, the metal dendrite formation was observed at a potential characteristic of the metal in the diffusion-limited plateau region. This phenomenon has also been mentioned by Galus (21), who states in his review that it is sometimes observed that the deposition of aqueous metal ions on mercury electrodes gives metal which does not enter into the mercury phase; instead, it remains on the surface of the electrode in the form of a finely divided precipitate. The formation of such precipitates at the electrode surface does not appear to depend upon the normal solubility of the deposited metal since it has been observed (20, 21) both for metals that are sparingly soluble and for metals that are highly soluble in mercury.

We consider that the latter mechanism is in all probability that which prevails in the present case. Thus, the phenomena observed by us are due to the interaction of three processes. These are: (*i*) the formation of nuclei of thallium metal on the surface of the hanging mercury drop; (*ii*) the growth outward into the aqueous solution of these nuclei into dendrites of thallium; (*iii*) the dissolution of thallium on the surface into the hanging mercury drop, or the actual dissolution of the dendrite itself in the mercury drop.

The first of these steps, that of nucleation, has received considerable study in other systems. The usual effect of nucleation is the appearance of maxima in the chronoamperometric current-time curves (7, 8), as we have observed for Tl(I) reduction in this melt. These nucleation phenomena are observed in metal electrode oxidation (22-24) as well as in electrodeposition; maxima in chronopotentiometric curves (23) as well as in chronoamperometric curves (22, 24) have been reported, again in accordance with our observations. The second and third steps have been discussed qualitatively (20) but a quantitative treatment does not appear to be available. In view of the significant and thus far unpredictable change in the real area of the electrode which arises as a result of the interaction of the opposed rates of dendrite growth and dissolution, quantitative calculations appear possible only for the nucleation step. The observations are, however, in qualitative accord with these two phenomena as is discussed further below.

Quantitative study of the nucleation step can be carried out using the chronoamperometric curves given in Fig. 1. Integration of these curves from the point of origin to some arbitrarily selected time will give the total charge and enable calculation of surface coverage. In the present case integration was carried out using a planimeter. A straight line was constructed from the origin to the center of the first

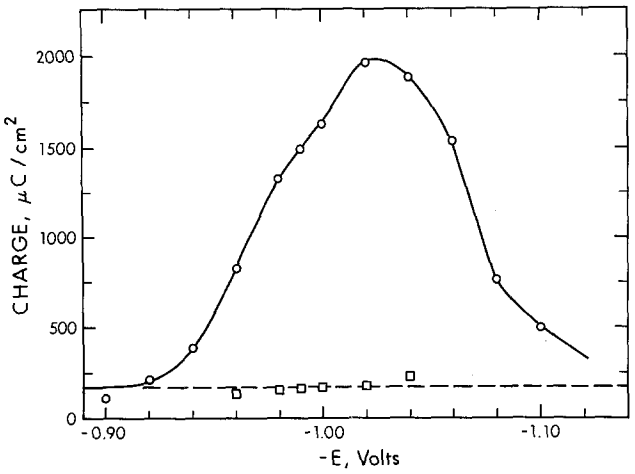

Fig. 9. Integrated area of chronoamperometric curves vs. applied potential of step. 0, Q_{total} in $\mu C/cm^2$ for charge of all processes to 14 sec from step application; □, Q_{nucl} in $\mu C/cm^2$ for charge of nucleation/nuclei growth step alone. Dashed horizontal line at 171.2 $\mu C/cm^2$ represents theoretical charge required to form monolayer of thallium metal. Area of electrode 0.0176 cm^2, HMDE.

minimum, since this is the point of initiation of nucleation (22), and the area integrated from this line to an arbitrary cutoff of 14 sec which is in all cases beyond the peak processes observed. In curves 1A, 1B, 1K, and 1L, which have no discernible minimum, the straight line was constructed through the shortest time point at which a minimum could occur, so that the areas calculated under these curves represent maximum possible values of the charge. The values of charge so calculated are shown in Fig. 9 and Table III.

It is instructive to compare these values with those which would be expected for monolayer coverage of the electrode. An expected value can be calculated from the density of metallic thallium, the atomic weight of thallium, the electronic charge, and the value of the Faraday constant; we obtain 171.2 $\mu C/cm^2$ for the charge so required. Since the maximum charge of 1.96 mC/cm^2 at −1.02V is far greater than this it is clear that the totality of the peak processes must involve far more than nucleation and must include multilayer or dendritic crystal growth. The peak processes are, however, separable into two peak processes in the chronoamperometric curves. Separation of the areas, and hence the charges, of these two processes is possible by separate integration of the area under the first peak from the initiation of nucleation, as described above, to the minimum between the two peaks, at which a perpendicular was dropped to the axis. The results of such integration are given in the last column of Table III; the values are in excellent agreement with the expected value of 171.2 $\mu C/cm^2$ for monolayer coverage and thus do reasonably correspond to a nucleation process. This argument is supported by an approximate integration of the chronoamperometric curves given in Fig. 1 of the work of Fleischmann, Pattison, and Thirsk (11), which gives values close to that of the expected monolayer for the formation of thallous chloride on thallium amalgam.

The same paper (11) also gives an expression, derived earlier by the senior authors, for the current-time behavior expected for the instantaneous formation of N_0 nucleation centers followed by their growth as

$$i = (2z\mathbf{F}\pi hMN_0k^2t/\rho) \exp(-\pi M^2N_0k^2t^2/\rho^2) \quad [2]$$

where z is the ionic charge, $\mathbf{F}$ the Faraday constant, h the height of the nucleation centers (in centimeters), M the molecular weight, ρ the density, k the rate constant for crystal growth (in moles cm^{-2} sec^{-1}). The logarithmic form of this equation yields a plot of log (i/t) against t^2 which should be linear; as shown in Fig. 10, linear behavior is indeed obtained from the first to the second minimum in the chronoamperometric curve. This is in excellent agreement with our explanation of dendritic or multilayer growth for the subsequent peak and nucleation growing to a monolayer at the first peak.

In this model, the slope of the line should be equal to $-2.303\ \pi M^2N_0k^2/\rho^2$. For the line of Fig. 10 the slope is $-1.592\ sec^{-2}$. From this slope, using the density and molecular weight of metallic thallium, a value of 7.40×10^{-4} $mole^2$ sec^{-2} cm^{-6} can be calculated for the product N_0k^2. While these curves do not permit the separation of N_0 from k, a maximum value of k would be the diffusion-controlled limit (11) of $\pi DC_0/5h$. For this system we already know D to be 3.0×10^{-7} cm^2 sec^{-1} and C_0 for this curve is 4.35×10^{-6} mole cm^{-3}. Estimation of h as the height of a single atom using the density of thallium, the atomic weight of thallium, and Avogadro's number yields 3.0×10^{-8} cm for h, so that the maximum value of k is then 2.68×10^{-5} $mole^2$ sec^{-1} cm^{-2} and the minimum value of N_0 is 1.03×10^6 nuclei/cm^2. This minimum value of N_0 is well below the 10.7×10^{14} atom/cm^2 of the monolayer which would give 171.2 $\mu C/cm^2$ charge coverage, as is reasonable since a single nucleus may be made up of a large number of thallium atoms.

Thus the over-all electrochemical reaction which is observed in this system by any technique consists

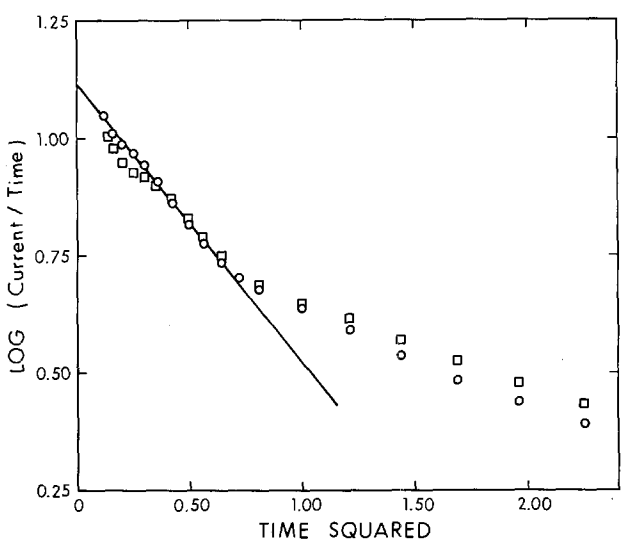

Fig. 10. Logarithmic form of Eq. [2] plotted for data of chronoamperometric curves F, 0; G, □. Values of i in μA, time in seconds.

of the three steps of nucleation, dendrite growth into solution, and dendrite dissolution in the hanging mercury drop. In the chronoamperometric curves, formation of the nuclei begins at the minimum of the current-time transient (22). As the current increases toward the maximum, perhaps the population, but at least the size of the surface nuclei, which may be visualized as monolayer islands of metallic thallium on the surface of the mercury electrode, increases. Beyond this maximum, crystal growth occurs on the surface until surface coverage is complete. The second maximum, which is observed at higher cathodic potentials and higher concentrations of Tl(I), corresponds to the formation of additional layers (11) or to initial dendritic growth.

The situation in the chronopotentiometric measurements is similar. The small overshoot occurring at the beginning of the chronopotentiometric transition (Fig. 5B) is probably the nucleation overpotential which must be achieved before bulk deposition can proceed (7, 8, 13, 14). Once nucleation has been achieved the charge transfer process is rapid and no longer requires this overpotential, so that the potential of the working electrode is seen to fall before the transient is completed with the sharp rise toward solvent reduction.

The shape of the chronopotentiometric transients was found to be a function both of current density and of bulk concentration of Tl(I). The initial potential overshoot (Fig. 5B) is observed at lower currents; as the current is increased, the overshoot disappears and the transition time becomes unexpectedly small (Fig. 5A). The abrupt disappearance of the nucleation overpotential at higher current densities may occur because at such higher current densities the transition time becomes smaller than the induction period required either to complete nucleation or to begin crystal growth. The supply of Tl(I) ions at the electrode surface is exhausted before nucleation is complete and hence the electrode potential does not fall back to the lower value characteristic of crystal growth. It is reasonable also that this change in current be small and the subsequent transition significantly longer because the dendritic growth will rapidly increase both the real area of the electrode and its outreach into solution, which will simultaneously reduce the real current density at the electrode and increase the supply of Tl(I) able to reach it to supply the current demanded.

It is further reasonable that the nucleation overpotential is smaller and the induction period for nucleation is larger when the bulk concentrations of Tl(I) are lower, because for nucleation to be completed and/or dendritic crystal growth to begin a certain minimum total amount of Tl(I) is required. Hence, in such solutions, only a single normal transition is observed.

In one experiment, the electrolysis was allowed to continue for some time after the transition time had been observed. The electrolysis current was then switched off, the solution was stirred, and allowed to stand a few minutes to ensure that uniform concentrations were achieved both in the bulk solution and in the mercury drop. A second chronopotentiometric transient was then recorded using the same mercury drop. This time the potential overshoot was very small. Since the mercury drop would still have been covered with thallium nuclei, although the dendrites may now be dissolved, nucleation should not occur and the surface layer should begin crystal growth at once. This appears to be consistent with our observation.

In the cyclic voltammetric results the appearance of the cathodic peak (*IIC*) depends upon two factors, concentration and the scan rate. It appears in earlier cycles when the concentration is high and scan rate is slow. The anodic shift of the peak potential of the reduction process in subsequent cycles has been taken (14) as the criterion for nucleation. The process of nucleation starts at the first cathodic peak (*IC*) and the population of nuclei at the electrode surface increases up to the second cathodic peak (*IIC*), when the electrode surface gets saturated; after that crystal growth takes place. The time required to complete the process of nucleation and to start crystal growth (peak *IIC*) should depend upon the concentration, the time elapsed after the nucleation has been initiated, and on the scan rate as has been experimentally observed. Thus, the cyclic voltammetric results agree well with the conclusions drawn from the other two methods, chronopotentiometry and chronoamperometry.

At the suggestion of a referee, we have attempted to compare the open-circuit potential of a HMDE upon which thallium was electrodeposited in a chronopotentiometric experiment with that of metallic thallium in the same melt. Upon cessation of the current the potential of the HMDE dropped immediately to a value identical to $E_{\tau/4}$ of the chronopotentiogram and remained constant at that potential for 5 min or more. This potential was -1.02 ± 0.01V against our Ag(I)/Ag(0) reference, while the stable potential of massive metallic thallium in the same melt was -1.20 ± 0.02V. Removal of all of the oxide from the surface of the metallic thallium was not possible, which may account for some of the observed difference, but since dissolution of thallium in mercury does occur in the third step of our proposed mechanism an exact correspondence in potential is unlikely unless the monolayer is permanently stable.

Acknowledgments

Thanks are due to Dr. G. M. Rao for his assistance during some of the experiments. This work was supported by the National Research Council of Canada through an Operating Grant.

Current Distribution in a Tubular Electrode under Laminar Flow: One Electrode Reaction

Richard Alkire* and Ali Asghar Mirarefi*

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

The reaction rate distribution along a tubular electrode was measured directly with a sectioned electrode during steady laminar flow of electrolyte through the electrode. The Fe(III)/Fe(II) redox reaction was studied at the limiting current, and the Cu(II) deposition reaction was studied at all fractions of the limiting current, The experimental conditions were systematically varied in order to determine the effect of counterelectrode placement, tube radius and length, reactant concentration, flow rate, and current density. Experimental polarization curves, limiting current, and current distribution data were compared with a theoretical model of the electrochemical system, and agreement was obtained over a wide range of parameter space. Theoretical calculations were carried out in order to make additional predictions of tubular electrode behavior at and below the limiting current.

During electrolysis, it is necessary that both chemicals and electrical energy arrive at the electrode surface in order that electrochemical reactions proceed. As a consequence, two limiting cases of current distribution phenomena arise. For example, the "limiting" current distribution may be determined without consideration of the potential field, while the "primary" and "secondary" current distributions are calculated without consideration of the mass transport of reactants to the electrode surface. In many practical situations, however, the current distribution does not conform to either simple limiting case of behavior. Interest therefore arises in analyzing the more general behavior of electrochemical systems where convective flow and electrical potential fields must be determined simultaneously. The investigation reported here (1) expands on previous work on tubular electrodes operating under steady laminar flow of electrolyte (2). In this paper, experimental and theoretical aspects were investigated in a system having a single electrochemical reaction. Next month, a similar study is described on multiple electrode reactions in a tubular electrode.

Previous Work

At limiting current conditions, the tubular electrode system is analogous to a classical problem of heat transfer through the wall of a tube held at constant temperature. Discussion of the theoretical and experimental aspects of the heat transfer problem and its mass transfer analog are commonly available for both laminar and turbulent flow situations (3). Experimental studies on tubular electrodes using the electrochemical limiting current technique have been carried out under laminar (11), turbulent (4, 5), and pulsatile forced flow (6) conditions. The role of natural convection on mass transfer in laminar flow in a straight tube has also received attention (7).

Below the limiting current condition, the reactant concentration at the tube surface varies with position and depends upon both the kinetics of the heterogeneous reaction at the wall and the potential field within the flowing electrolyte. When the potential field effect is neglected, the situation corresponds to a (nonelectrolytic) catalytic reactor problem. Chambré and Acrivos (8) developed a theoretical procedure for calculating the reactant concentration along a catalytic surface placed in a laminar flow field. Wissler and Schechter (9) used sets of orthogonal functions to evaluate the concentration profile for turbulent gas flow through a circular tube with chemical reaction at the wall. In a series of papers, Matsuda (10) analyzed a number of flow configurations and electrochemical reaction sequences including tubular electrodes with both heterogeneous and simultaneous homogeneous chemical reactions; the potential field distribution was neglected. Similarly, electroanalytical groups have investigated tubular electrodes in the presence of heterogeneous and homogeneous reactions, without consideration of the potential distribution (11, 12), *i.e.*, uncompensated resistance effects.

In order to take simultaneous account of the potential field and the concentration field, Asada *et al.* (13) developed a calculational procedure and applied it to free convection in a rectangular electrolysis cell. Newman and co-workers (14) developed and applied a related procedure to many systems having laminar forced convection. Cabán and Chapman (15) and, later, Varjian (16) showed that orthogonal collocation methods could also be used in the solution of such problems. In the tubular geometry, the only "complete" analysis (2) was carried out for laminar mass transfer in the entrance region with simultaneous consideration of a two-dimensional potential field distribution. The

* Electrochemical Society Active Member.
Key words: tubular electrode, sectioned electrode, mathematical model, copper deposition, ferric reduction, laminar flow.

work was subsequently applied to electrodeposition in circular through-holes in multilayer printed wiring boards (17, 18).

The investigation reported here (1) was intended to expand the experimental and theoretical literature on current distribution problems for currents below but at an appreciable fraction of the limiting current. An experimental system was used which enabled measurement of the local reaction rate distribution under controlled conditions (19). By systematic variation of the experimental parameters, data were obtained which were amenable to detailed comparison with theoretical calculations.

Apparatus

The experiment consisted of measuring the current distribution along a sectioned tubular electrode with steady laminar flow of electrolyte. Experiments were carried out with two different electrochemical systems: (*i*) deposition of copper from acid sulfate electrolyte, and (*ii*) reduction of ferric ions in sulfuric acid. Current distributions were measured at various fractions of the limiting current upon systematic variation of electrode geometry, flow rate, reactant concentration, and counterelectrode placement.

A diagram of the tubular electrode assembly is shown in Fig. 1. The cathode sections were fabricated by drilling out a copper rod and slicing off wafers. For studies with the Fe(III)/Fe(II) redox system, the electrode sections were platinized by a procedure described below. Electrode sections were insulated from one another with thin (0.25 mm) sheets of Teflon® having the same inner and outer radii as the copper wafers. Wafers and insulating sheets were compressed in the Plexiglas holder which had reference electrode compartments both upstream and downstream from the sectioned tubular electrode. Mercury/mercurous sulfate reference electrodes were used. The counterelectrode (not shown in Fig. 1) was placed either far upstream or far downstream from the tubular electrode, in side compartments.

The Plexiglas holder was placed in a 12 liter capacity gravity-flow system in which the hydrostatic head was kept constant by an overflow loop in the overhead reservoir. The flow rate through the cell was controlled with a needle valve and measured with precision rotameters (Gilmont No. 2-5). In order to assure fully developed laminar flow, the upstream section of the flow circuit was a smooth plastic tube in excess of 50 diameters in length.

Electrical connection to electrode sections was made through a slot in the Plexiglas holder. A potentiostatic power supply (Wenking 70TS-1 or 68TS-3) was used to control the cathode potential with respect to the reference electrode nearest the counterelectrode. Individual section currents were detected witth a multichannel zero-resistance operational amplifier device (built in-house) and displayed on a multipoint potentiostatic recorder (Leeds & Northrup Speedomax X). The total cell current was monitored with a potentiostatic strip-chart recorder (Sargent-Welch SRG). When polarization curves were measured, the potentiostat was driven at 1 mV/sec with a linear ramp generator (built in-house), and the output was displayed on an X-Y recorder (Houston 2000).

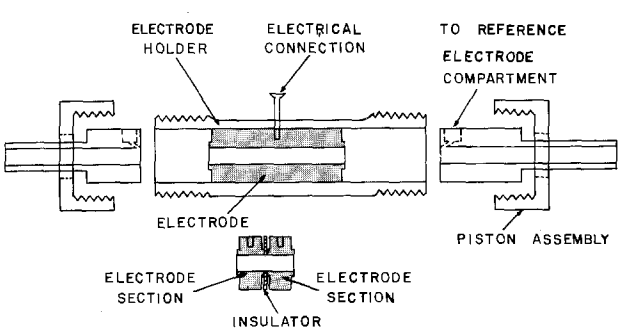

Fig. 1. Tubular electrode assembly

Experimental Procedures

Electrolytic solution was prepared from reagent grade chemicals and deionized water which had been distilled once in a tin-lined still, and which had a conductivity of 4×10^{-6} $(\Omega cm)^{-1}$. The solutions used in this study were $CuSO_4$ in 1.5M H_2SO_4 and $Fe_2(SO_4)_3$ + $FeSO_4$ in 1.5M H_2SO_4. No additives were used. The cupric concentration was measured either with a spectrophotometer (20) (Beckman Model B) or with an iodometric method (21). The ferric ion concentration was also determined by the iodometric method; the ferrous ion concentration was measured by titration with potassium permanganate (21). The conductivity of the solutions was measured with a bridge (Leeds & Northrup 4959) in a cell calibrated with 0.1 demal KCl at 26°C (29).

After assembly in the Plexiglas holder, the sectioned tubular electrode surface was polished down to 600 grade emery, then disassembled and rinsed in water. Electrode sections were scrubbed in trichloroethylene, soaked in hot phosphate/metasilicate solution, pickled in hot acidified ferric sulfate, etched in a dilute mixture of nitric and sulfuric acids, brightened in a concentrated mixture of nitric and sulfuric acids, and rinsed in distilled water. To plate platinum onto copper, the cleaned pieces were electropolished (Bath No. 200, Electro-Glo Company), gold plated (Orotemp 24, Technic Incorporated), and then platinum plated (No. 209, Engelhard). The cell was then assembled, placed in the flow circuit, and connected to the electrical circuit.

The flow rate was adjusted and the electrical circuit was energized to the desired applied potential. When steady state was reached (approximately ten residence times for low flow rates, less for higher flow rates) the applied potential, the potential difference between the upstream and downstream reference electrodes, the total current, and the section currents were measured. The applied potential was then increased and the procedure repeated until eventually the limiting current plateau was reached. The flow rate was then adjusted to another flow rate and the entire process was repeated.

Comparison of Experimental Data with Theoretical Calculations

Literature values used for the physical properties of the two chemical systems investigated are listed in Table I. In some cases, direct measurement of the properties was made; these, along with the experimental conditions for each current distribution measurement, are given in Table II. Experimental data from the copper system were compared directly with the theoretical model described in an earlier publication (2). Data for the redox system were compared with a modified version of that model (1) but, as mentioned below, only a limited number of redox experiments was carried out. Table III lists the dimensionless parameters which describe the tubular electrode model. The physical significance of these parameters has been discussed previously (2) and will be reviewed briefly in the discussion below.

Because the theoretical model is valid only in the mass transfer entrance region, or Lévêque region, the flow rate was constrained (23) to the criterion

Table III. Dimensionless system parameters

$$Z = \frac{z}{L} \qquad \gamma_O = \frac{R_o}{L}$$

$$\Phi = \frac{nF}{RT}\phi \qquad \bar{\beta} = \frac{2n\mathbf{F}L^2}{RTR_o\kappa}\langle j\rangle$$

$$J = \frac{j}{\langle j\rangle} \qquad J_N = \frac{j}{\langle j_{lim}\rangle}$$

$$\xi = \frac{2n\mathbf{F}L^2}{RTR_o\kappa} i_o \qquad N = \frac{n^2\mathbf{F}^2L^2c_{i\infty}}{-s_i\Gamma\left(\frac{4}{3}\right)RTR_o^2\kappa}\left(\frac{12QD_i^2}{\pi L}\right)^{1/3}$$

$$Q > \frac{\pi L D_i}{0.02} \qquad [1]$$

On the other hand, to conform to the requirement of laminar flow, one also has the condition

$$Q < 1050\pi R_o \qquad [2]$$

Electrodes were used only for which the aspect ratio (tube radius/length) was sufficiently small that the potential distribution within the electrolyte was essentially one dimensional. The criteria for establishing conditions of one-dimensional behavior will be discussed thoroughly in the Discussion of the Theoretical Model which follows.

Based on the simulation studies reported by Flanagan and Marcoux (22), it can be concluded that the experimental conditions studied here conform to the situation where axial diffusion is negligible, and where the velocity profile in the diffusion layer is linear.

Over-all current-potential data.—Polarization curves for both reaction systems exhibited limiting current plateaus, the plateau width being greater when the counterelectrode was upstream than when it was downstream. The average limiting current varied with flow velocity as given in Fig. 2. The dimensionless Nusselt and Graetz numbers used to correlate these data are defined as

$$\langle Nu\rangle = \frac{s_i I_{lim}}{n\mathbf{F}Dc_\infty L\pi}$$

$$Gz = \frac{Q}{DL}$$

The solid line in Fig. 2 corresponds to the solution of the convective diffusion (Lévêque) equation under limiting current conditions, that is (23)

$$\langle Nu\rangle = 1.6151\left(\frac{4}{\pi}Gz\right)^{1/3} \qquad [3]$$

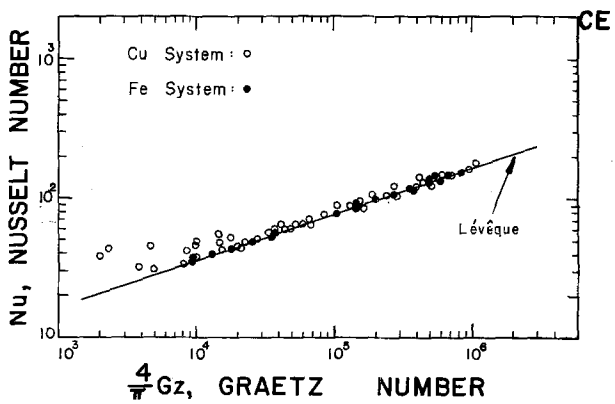

Fig. 2. Limiting current data for laminar tubular electrode

In the nomenclature given in Table III, Eq. [3] may also be written

$$\bar{\beta}_{lim} = -N \qquad [4]$$

from which it recognized [2] that the parameter N is the dimensionless limiting current density. Figure 2 indicates good agreement between data and theory at high flow rates. At lower flow rates, good agreement was found for the redox system and for dilute copper solutions (0.01M). Deviations from the theoretical correlation were observed for the more concentrated copper solutions (0.02M and above) and for tubes of large radius. These deviations have been attributed to natural convection effects superimposed on the forced flow (7); similar behavior has been observed by others (24, 25). The data in Fig. 2 have demonstrated that literature values of the system parameters can be used with the Lévêque equation to predict the average limiting current density.

Experiments below the limiting current were only carried out under those conditions for which the limiting current agreed with the Lévêque equation as judged from Fig. 2. It was found that the behavior of the redox system was not reproducible below the limiting current owing to significant variations from section to section in the rest potential of the platinum-plated electrodes. Although improvements could perhaps have been made in the plating procedures, the matter was not pursued. Rather, for comparison with theoretical calculations below the limiting current, only the copper deposition data were used.

Now let us turn to conditions far below the limiting current, under which mass transport effects play a negligible role in determining electrode behavior. Figure 3 contains current-potential data for seven electrode configurations which have been reduced to dimensionless form in accord with the definitions given

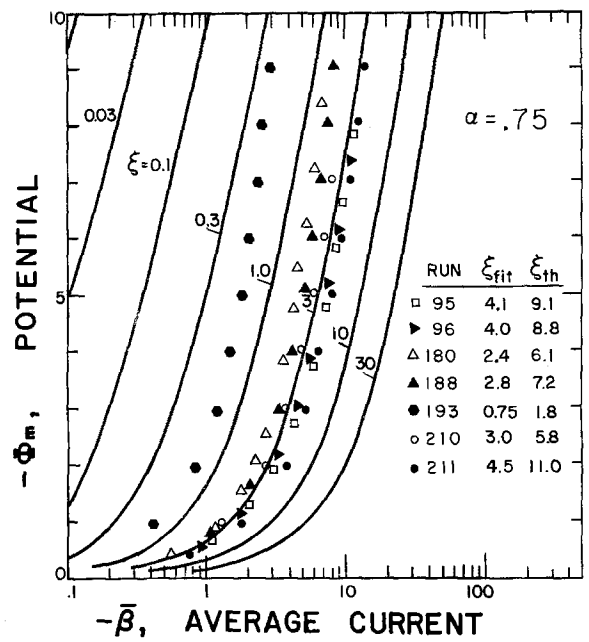

Fig. 3. Polarization data and theoretical calculations, far below limiting current (copper deposition system).

in Table III. In the absence of mass transport effects, the polarization curve should depend solely upon the dimensionless parameter

$$\xi = \frac{2nFL^2}{RTR_{o\kappa}} i_o$$

which is a dimensionless ratio of ohmic to charge-transfer resistances. The solid lines in Fig. 3 are theoretical polarization curves for various values of ξ, calculated with kinetic constants $\alpha = 0.75$, $\beta = 0.25$, and $i_o = 0.38$ mA/cm² (26). Comparison between theory and experiment is shown in the tabulated values of ξ given in Fig. 3. Based on comparison between data points and solid lines, the value of ξ which best "fits" the data is tabulated as ξ_{fit}; based on the system parameters for each run (see Tables I and II), the "theoretical" value of ξ which should characterize the data is tabulated as ξ_{th}. For the seven runs, the average value of ξ_{fit} was 43.4 ± 3.9% of ξ_{th}.

There are several reasons why the exchange current density in our flow system might be less than that measured under conditions of utmost purity (30) as cited in Ref. (26). Impurities in the flow system would be expected to reduce the exchange current density. Also, the acid concentration used here (1.5M) is greater than that used in (30) so that the i_o used here would be expected (31) to be lower. In addition, a recent examination of copper deposition kinetics in acid sulfate solutions (31) indicates that the parameters $i_o = 0.042$ mA/cm², $\alpha = 0.54$, and $\beta = 0.19$ would be consistent with the experimental conditions of the present study. Because of the consistency of the percentage difference between ξ_{fit} and ξ_{th}, it seems reasonable to conclude that the exchange current density which characterizes this experimental system is $i_o = 0.164 \pm 0.015$ mA/cm².

At intermediate fractions of the limiting current the shape of the polarization curve depends upon both ξ and N. Figure 4 gives theoretical and experimental results (polarization curves) at all fractions of the limiting current for several geometric ratios over a tenfold variation in flow velocity. The values of ξ used in calculating the lines in Fig. 4 correspond to ξ_{fit}, *i.e.*, those values which fit the data at low fractions of the limiting current. It is seen that the theory predicts correct trends upon variation of system parameters. In Fig. 4, the experimental potential is seen to be greater than the predicted value. As will be discussed below, the influence of reaction kinetics becomes minor above 60%

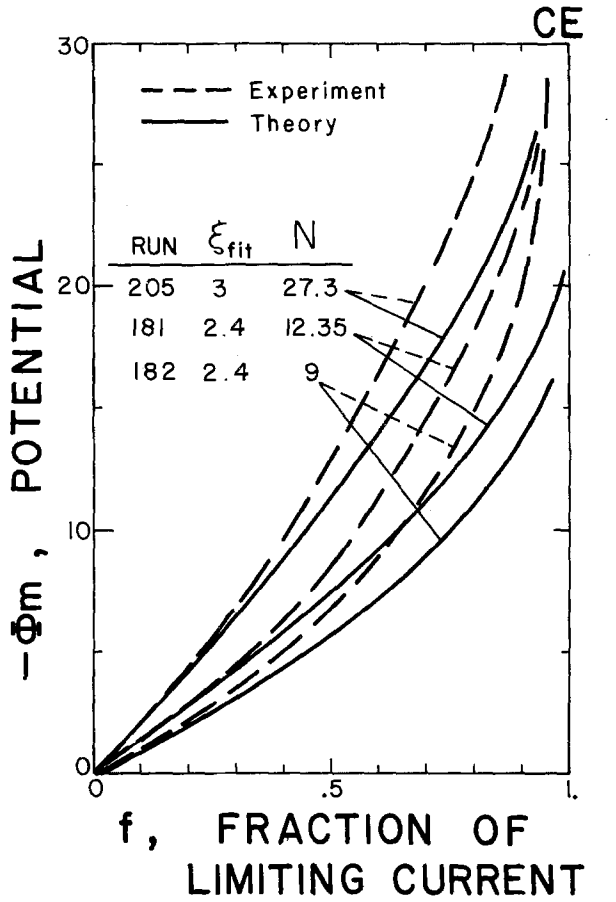

Fig. 4. Theoretical and experimental polarization curves (copper deposition system, counterelectrode downstream).

of the limiting current for the conditions given in Fig. 4; therefore the discrepancy cannot be wholly ascribed to inadequacies in the reaction rate equation. Since the mass transport measurements at the limiting current are in agreement with expectations, and since the geometry of the electrode is simple, it seems unlikely that the observed deviations could be attributed to errors in the convective diffusion or potential field aspects of the model. Whereas the source of the discrepancy remains unresolved and whereas it deserves closer attention, it seems also clear that the present model can be used to predict polarization behavior to within most engineering tolerances.

Current distribution data.—Data from current distribution measurements were reduced to dimensionless form by either

$$J = \frac{j^*}{\bar{\beta}} = \frac{j}{\langle j \rangle} \qquad [6]$$

or

$$J_N = \frac{j^*}{\bar{\beta}_{lim}} = \frac{\bar{\beta}}{-N} J = fJ \qquad [7]$$

which differ in that $\int_0^1 J \, dZ = 1$, while $\int_0^1 J_N \, dZ = f$ where f is the fraction of limiting current.

For currents far below the limiting current, the distribution should depend upon the parameter ξ such that the distribution becomes more nonuniform as ξ becomes large. Figure 5 shows typical data for three electrode lengths. The solid lines give theoretical results predicted with use of ξ_{fit} (*i.e.*, 17% of ξ_{th}), as was discussed with respect to Fig. 3. The good agreement between theory and data indicate that the model provides the correct linkage between polariation data and current distribution data. That is, once the parameter ξ_{fit} is determined from polarization curves, the model is able to predict accurately the secondary current distri-

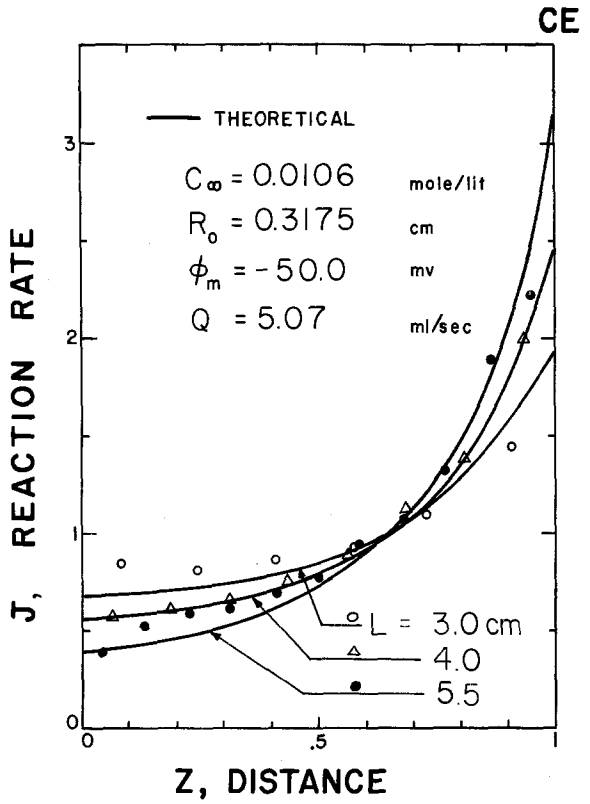

Fig. 5. Effect of electrode length on current distribution far below limiting current (copper deposition system, counterelectrode downstream).

bution. Experiments were performed with the counterelectrode either upstream or downstream; under otherwise identical conditions, the distributions were identical to within 5% and the most reactive electrode section was that nearest the counterelectrode. That is, mass transport effects did not appreciably influence the current distributions when the average current was less than about 25% of the average limiting current.

Current distributions were measured at appreciable fractions of the limiting current for the systems listed in Table II. Typical results are given in Fig. 6; experimental data are shown on the left side, and the corresponding theoretical calculations are given on the right side. Although the counterelectrode was downstream, the data at 35% of the limiting current indicate that the most reactive electrode section is the upstream section, farthest from the counterelectrode. Above 80% of the limiting current, the distribution is very similar to the limiting current distribution itself. The comparison shown in Fig. 6 indicates satisfying agreement over the entire range of f. These data indicate that once ξ_{fit} is chosen to fit polarization curves at low currents, then the model can be used to predict current distributions up to and including the limiting current.

At the limiting current, the current distribution data follow closely the distribution predicted by the Lévêque equation

$$J_{lim} = \frac{2}{3} Z^{-1/3} \qquad [8]$$

Discussion of the Theoretical Model

Since the experimental program indicated that the theoretical predictions were accurate over the range studied, it seemed worthwhile to pursue several purely theoretical aspects in order to compile salient features over a range of parameter space.

Let us first consider two aspects of behavior far below the limiting current. The first concerns the conditions under which the potential distribution within the tubular electrode can be reasonably approximated by a one-dimensional field. One basis for assessing the differences between the one- and the two-dimensional models is to compare the total currents predicted for a given applied potential, other parameters being held equivalent. Figure 7 shows the results of theoretical calculations well below the limiting current. The ordinate gives the ratio of currents predicted by the two models, and has the value of unity when the two models give identical predictions. It is seen that deviations always occur such that the two-dimensional current is less than the one-dimensional current. That is, the one-dimensional model does not account for the additional ohmic losses encountered by the radial component of current flow. Deviations from one-dimensional behavior set in for $\gamma_0 > 0.5$, that is, when the tube diameter exceeds its length. The extent of deviation becomes appreciable only over certain ranges of ξ. For small values of ξ, the applied potential is consumed primarily by charge-transfer overpotential so that geometric factors concerning the potential field are not essential. As ξ increases, deviations are observed to an extent depending upon the aspect ratio (γ_0) and owing to the nonlinear kinetics, the applied potential (Φ_m). For the experimental systems studied above, the one-dimensional model was accurate.

The second aspect of behavior far below limiting current concerns the conditions under which the current distribution in a tubular electrode is reasonably uniform. One measure of uniformity is the ratio of reaction rates at the two ends of the tube. If the distribution is uniform, then the ratio will be unity. Figure 8 gives a theoretical compilation of the reaction rate

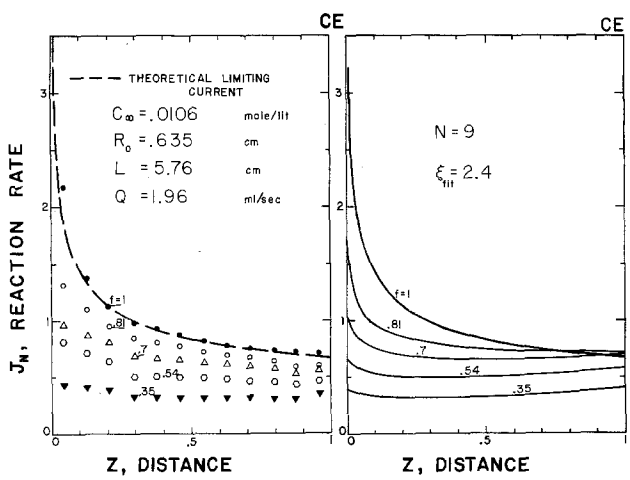

Fig. 6. Dependence of current distribution upon fraction of limiting current, experiment (left) and theory (right) (copper deposition system, counterelectrode downstream).

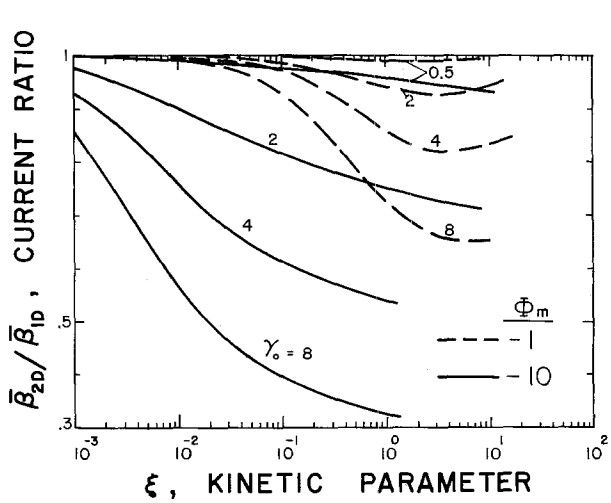

Fig. 7. Comparison between one- and two-dimensional potential field models far below limiting current.

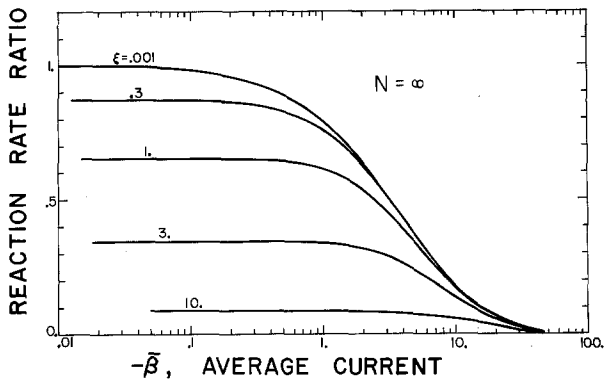

Fig. 8. Dependence of current distribution uniformness upon applied current and polarization parameter, far below limiting current.

ratio for various values of ξ and applied cathodic current $-\bar{\beta}$. It is seen that the secondary current distribution varies by less than 10% over the surface under the approximate conditions

$$\xi < 0.3 \qquad |\bar{\beta}| < 0.1 \qquad [9]$$

On the basis of discussion thus far, it would seem reasonable to suggest that Fig. 8 would apply for situations such that

$$N > 5\bar{\beta} \qquad [10]$$

At intermediate fractions of the limiting current, a more discerning criterion for evaluating the uniformity of the current distribution is

$$U = \int_0^1 |J - 1|\, dZ \qquad [11]$$

If the current distribution is uniform ($J = 1$), then $U = 0$. Figure 9 gives theoretical expectations for the current uniformity at all fractions of the limiting current for the case of a downstream counterelectrode. Far below the limiting current, it is seen that the uniformity depends upon ξ; under such conditions it is clear that the most reactive region of the electrode is the downstream end, near the counterelectrode. At the limiting current, on the other hand, the most reactive region is the upstream end where the diffusion layer is thinnest. At intermediate currents, the interaction between mass transfer and ohmic effects renders the current distribution more uniform than under either limiting condition of behavior. Were the counterelectrode upstream, no such minimum in current uniformity would be observed.

When the entire electrode operates at the limiting current, there is a characteristic potential difference between the ends of the tube which can be related to other system parameters. Knowledge of this relation is useful for designing tubular electrodes. The potential distribution when operating under limiting current is found by substituting the limiting current distribution

$$j^*_{\lim^*} = -\frac{2}{3} N Z^{-1/3}$$

into either

$$\Phi(Z) = \Phi_m - \int_Z^1 \int_0^\sigma j^*(\tau)\, d\tau d\sigma \quad \text{(downstream counterelectrode)}$$

or

$$\Phi(Z) = \Phi_m - \beta Z + \int_0^Z \int_0^\sigma j^*(\tau)\, d\tau d\sigma \quad \text{(upstream counterelectrode)}$$

and integrating. The potential difference across the

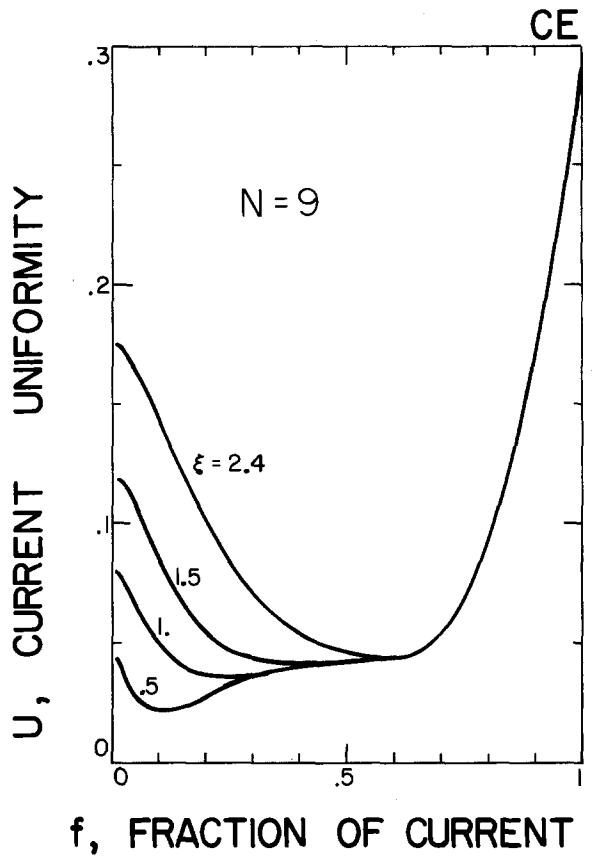

Fig. 9. Variation of current distribution uniformity upon fraction of limiting current and polarization parameter.

electrode is found to depend upon the position of the counterelectrode

$$\Delta\Phi_{\lim} = 0.4N \text{ (counterelectrode upstream)}$$
$$\Delta\Phi_{\lim} = 0.6N \text{ (counterelectrode downstream)} \qquad [12]$$

The potential drop across the tubular electrode is greater when the counterelectrode is downstream because the reaction occurs primarily on the upstream portions. This calculation illustrates why, under identical conditions of electrolysis, the limiting current plateau is wider when the counterelectrode is upstream than when it is downstream. In other words, for a given $\Delta\Phi_{\lim}$, placing the counterelectrode upstream enables the limiting current to be 50% higher. In view of the definitions of Φ and N, Eq. [12] corresponds to

$$L^5 = A \frac{1}{QD_i^2} \left[\frac{-s_i R_0^2 \kappa\, \Delta\Phi_{\lim}}{n\mathbf{F}c_{i_\infty}} \right]^3 \qquad [13]$$

where $A = 2.9128$ (counterelectrode upstream) and 0.8631 (counterelectrode downstream).

Conclusions

Because many electrochemical systems are designed to operate at appreciable fractions of the limiting current, it is often difficult to understand their behavior since competing effects tend to confound one's intuition. Continued emphasis on experimental confirmation of theoretical models therefore seems worthwhile if the advantage of using efficient models is to be practiced with confidence in engineering design work.

Whereas detailed predictions could be obtained for specific electrochemical systems, the following qualitative features seem to be characteristic of the tubular electrode geometry. For currents less than 20% of the limiting current, mass transport effects have little influence and the distribution of reaction is essentially uniform under the conditions of $\xi < 0.3$ and $\bar{\beta} < 0.1$. Above 25% of the limiting current, the current distri-

bution becomes essentially independent of the kinetics of the charge-transfer process. Appreciable mass transfer effects are encountered above 35% of the limiting current, although it is possible to maintain quite uniform current distributions by judicious placement of the counterelectrode(s). Above about 80% of the limiting current, the current distribution closely resembles the limiting current distribution and would, therefore, be influenced most by the hydrodynamic flow conditions.

The theoretical method used in this study is based on the condition that the diffusion layer is thin with respect to the tube radius; well-developed mass transfer situations cannot, therefore, be treated without additional complications.

Profile of the Refractive Index in the Cathodic Diffusion Layer of an Electrolyte Containing $CuSO_4$ and H_2SO_4

Yasuhiro Awakura, Mikio Okada, and Yoshio Kondo*

Department of Metallurgy, Kyoto University, Kyoto 606 Japan

ABSTRACT

The profile of the refractive index in the cathodic diffusion layer of a solution containing 1.85M H_2SO_4 and 0.05M $CuSO_4$ was measured by holographic interferometry. Measurement was carried out at various heights from the lower edge of the cathode and also at various cathodic current densities up to the limiting value. The theoretical expression for the difference of the refractive index between the cathode surface and the bulk electrolyte was derived assuming a uniform distribution of the local cathodic current density. Experimental results obtained at the current densities below one-half of the limiting value were in good agreement with the theoretical value. Measurement was also conducted with the solutions containing 1.85M H_2SO_4 and 0.01, 0.02, 0.03, 0.04, and 0.05M $CuSO_4$, respectively, at their cathodic limiting current densities. H_2SO_4 concentration at the cathode surface was estimated from the interferogram and $CuSO_4$ concentration at the cathode surface was presumed to be virtually zero at the limiting current. The estimated H_2SO_4 concentration was compared with the theoretical values, and it was found that they are in good agreement with each other.

During the electrodeposition of copper on a plane vertical cathode from an unstirred electrolyte, upward natural convective flow occurs along the cathode surface. This is caused by the lowered Cu^{2+} ion concentration in the cathodic diffusion layer. This natural convective flow affects the rate of electrodeposition of copper or the distribution of the cathodic current density in a vertical direction (1-3). Thus, many theoretical and experimental works have been made on the velocity profile of cathodic natural convection (4-6), on the concentration profile of solute in the cathodic diffusion layer (7-9), and on the distribution of current density on the cathode surface (10-12). Recently, two of the present authors studied the concentration profile of $CuSO_4$ in the cathodic diffusion layer during the electrolysis of aqueous $CuSO_4$ solution (13).

The industrial electrolytic refining and plating of copper are often conducted in the unstirred electrolyte containing $CuSO_4$ and H_2SO_4. Thus it is fairly important to study the concentration profiles of both components in the cathodic diffusion layer. As the first step toward the clarification of these concentration profiles, we have attempted in this paper to measure the profile of the refractive index of the solution in the cathodic diffusion layer by applying the technique of holographic interferometry, and the experimental results are compared with the theoretical values.

It is known that at the cathodic limiting current the concentration of $CuSO_4$ at the cathode surface is very close to zero (2, 14), thus the refractive index of the solution at the cathode surface is determined solely by the H_2SO_4 concentration. The concentration of H_2SO_4 at the cathode surface was estimated from the experimental results obtained at the cathodic limiting current, and the results were compared with the theoretical values.

Experimental

The profile of the refractive index in the cathodic diffusion layer was measured by holographic interferometry using the same electrodes and electrolytic cell which were described in a previous paper (13). Analytical reagent grade H_2SO_4, $CuSO_4$, and deionized water were used, and the mixed aqueous solutions of H_2SO_4 and $CuSO_4$ were prepared. The measurement was conducted at 23° ± 1°C.

First, the measurement was carried out below the limiting current. The experimental conditions are given in Table I. A solution of 1.85M H_2SO_4 and 0.05M $CuSO_4$ was used for the measurements at current densities up to the limiting value. From the current-potential curve shown in Fig. 1 it is seen that the average cathodic limiting current density of a solution of 1.85M H_2SO_4 and 0.05M $CuSO_4$ is 1.96 mA/cm². The applied cathodic current densities included 8 values up to the limiting current.

Next, the profile of the refractive index in the cathodic diffusion layer was measured at the limiting current densities with the solutions containing 1.85M H_2SO_4 and 0.01, 0.02, 0.03, 0.04, and 0.05M $CuSO_4$, respectively. The measurement was conducted at a height of 4 cm from the lower edge of the cathode. Holographic interferograms are illustrated in Fig. 2.

The profile of the refractive index of the solution was obtained from the measured interferograms as follows. The apparent profile of the refractive index in the diffusion layer, $n_f(y)$, is calculated from the holographic interferogram according to the conventional expression of

$$\frac{[{}^*n - n_f(y)]d}{\lambda'} = N \qquad [1]$$

When the incident beam is transmitted into the cathodic diffusion layer with a varied refractive index the beam is deflected toward the bulk electrolyte which has a higher refractive index. This optical distortion should be corrected. This correction involves the estimation of deflection of the incident beam, Δy, in the diffusion layer and the estimation of the position of a point at which the true refractive index of the solution is equal to the apparent refractive index at the exit point of the beam, $n_f(y_o)$. The correcting procedure described in the previous paper (13) was modified, and the following method was employed. One assumption in

Table I. Experimental conditions

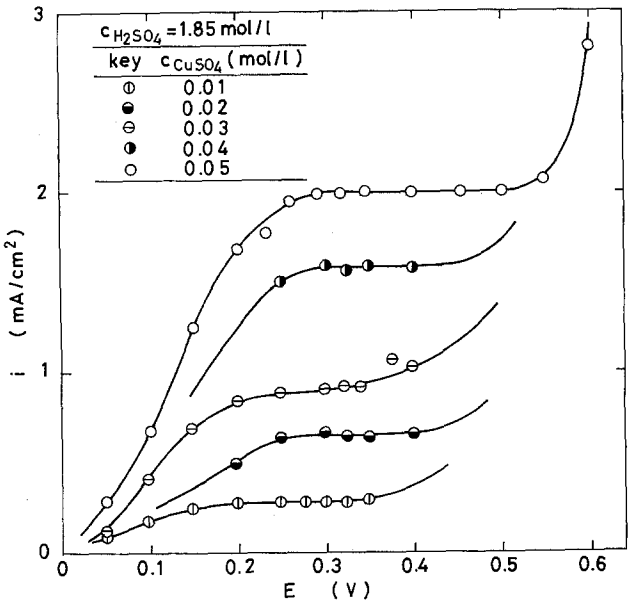

Fig. 1. Current-potential curve

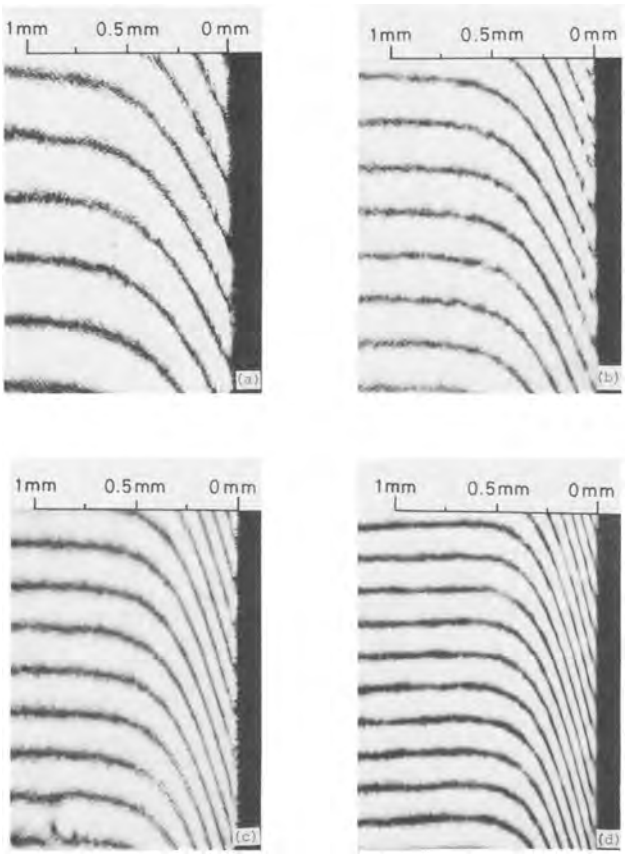

Fig. 2. Holographic interferograms of the cathodic diffusion layer at $x = 4$ cm with the solutions of (a) 0.02M $CuSO_4$-1.85M H_2SO_4, (b) 0.03M $CuSO_4$-1.85M H_2SO_4, (c) 0.04M $CuSO_4$-1.85M H_2SO_4, and (d) 0.05M $CuSO_4$-1.85M H_2SO_4 at their limiting current densities of 0.683, 0.910, 1.57, and 1.96 mA/cm², respectively.

this procedure is that the change of refractive index in the solution between the incident and exit points of the beam is approximated to be linear, as shown in Fig. 3. It is thought that the present procedure surpasses the previous one in that the employed assumption is simpler and clearer.

Under this assumption, the following expressions of the optical path length and the deflection of incident beam which passes through the solution near the

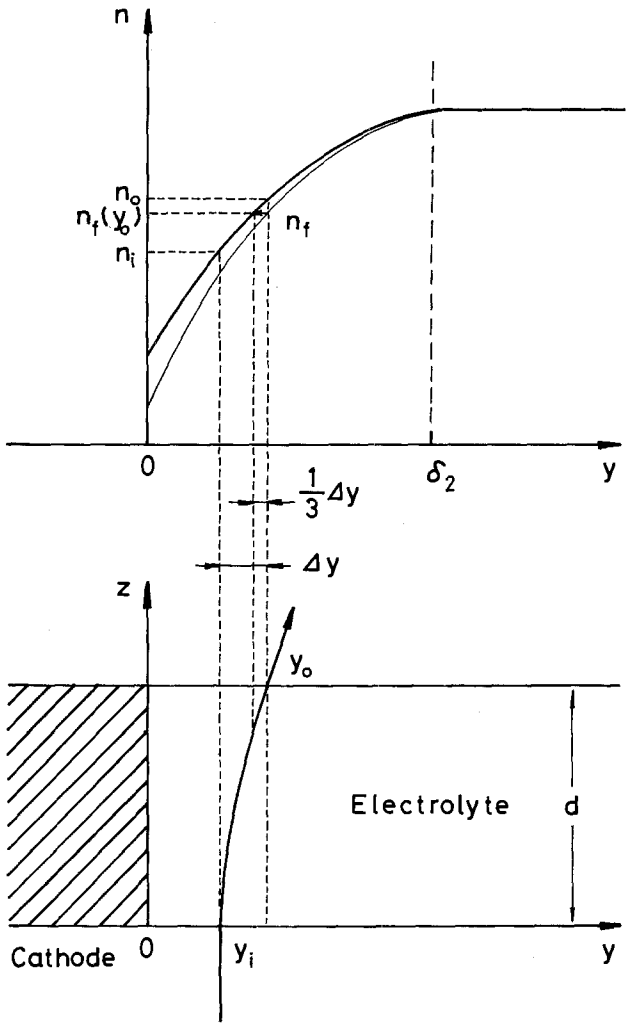

Fig. 3. Schematic illustrations of beam deflection and correction of the refractive index.

cathode surface are given by Müller (15). They are

$$p = \frac{n_i d}{2} + \frac{n_i^2}{4k} \sinh\left(\frac{2kd}{n_i}\right) \quad [2]$$

and

$$\Delta y = y_o - y_i = -\frac{n_i}{k} + \frac{n_i}{k} \cosh\left(\frac{kd}{n_i}\right) \quad [3]$$

respectively. The approximation of these equations yields

$$p = n_i d + \frac{1}{3!}\frac{2}{n_i} k^2 d^3 \quad [4]$$

$$\Delta y = \frac{kd^2}{2! n_i} \quad [5]$$

The apparent refractive index at the exit point of the beam, $n_f(y_o)$, calculated by Eq. [1] is equal to the ratio of optical path length and width of the cathode, p/d, and we have

$$n_f(y_o) = \frac{p}{d} = n_i + \frac{1}{3!}\frac{2}{n_i} k^2 d^2 \quad [6]$$

The deflection of the incident beam in the diffusion layer is about 50μ or less, and it is far less than the thickness of the diffusion layer which is about 500μ in our experiment (13). It is reasonable to assume that the change of refractive index is linear within the whole region of beam deflection, Δy. Thus we have

$$n = n_i + k(y - y_i) \quad [7]$$

By equating Eq. [6] and [7], we obtain the position of a point where the true refractive index, n, is equal to $n_f(y_o)$. It is

$$n_i + k(y - y_i) = n_i + \frac{1}{3!}\frac{2}{n_i}k^2d^2 \quad [8]$$

or

$$y - y_i = \frac{k}{3n_i}d^2 \quad [9]$$

By comparing $(y - y_i)$ with Δy of Eq. [5], we have

$$\frac{y - y_i}{\Delta y} = \frac{2}{3} \quad [10]$$

Then it can be said that $n_f(y_o)$ becomes equal to n at a point $(y_i + 2\Delta y/3)$ or $(y_o - \Delta y/3)$ under the assumption of a linear change of the refractive index between y_i and y_o.

Under the assumption of a linear change of the refractive index, Mizushina *et al.* (16) proposed the following calculating procedure of beam deflection within the diffusion layer from the apparent profile of the refractive index. When the direction of incident beam is at right angles to the inner wall of electrolytic cell, the beam trajectory within the diffusion layer is expressed by the following differential equation (17)

$$\left(\frac{dy}{dz}\right)^2 + 1 = \left(\frac{n(y)}{n(y_i)}\right)^2 \quad [11]$$

where $n(y_i)$ is the refractive index at the incident point of the beam. The integration of Eq. [11] under the boundary conditions of

$$\left.\begin{array}{ll} y = y_i & z = 0 \\ y = y_o & z = d \end{array}\right\} \quad [12]$$

yields

$$\int_o^d dz = \int_{y_i}^{y_o} \frac{n(y_i)}{\sqrt{[n(y)]^2 - [n(y_i)]^2}}\,dy \quad [13]$$

The left-hand side of this equation represents the width of the cathode, and the right-hand side can be integrated under the assumption of a linear change of the refractive index. Thus we have

$$d = \frac{n(y_i)}{\left(\frac{dn(y)}{dy}\right)_{y=y_i}} \cdot \ln\left[\frac{n(y_o) + \sqrt{[n(y_o)]^2 - [n(y_i)]^2}}{n(y_i)}\right] \quad [14]$$

The refractive indexes $n(y_i)$ and $n(y_o)$ are sufficiently close to each other, and the substitution of the approximate relationship of

$$n(y_o) + n(y_i) = 2n_f(y_o) \quad [15]$$

in Eq. [14] yields

$$\left[\frac{dn(y)}{dy}\right]_{y=y_i} = \left[\frac{n(y_o) - n(y_i) - \sqrt{2n_f(y_o)[n(y_o) - n(y_i)]}}{d}\right] \quad [16]$$

Furthermore, the deflection of the incident beam in the diffusion layer is expressed as

$$\Delta y = \frac{n(y_o) - n(y_i)}{\left(\frac{dn(y)}{dy}\right)_{y=y_i}} \quad [17]$$

From the definition of the optical path length of the incident beam in the diffusion layer, we have

$$p = \int_{y_i}^{y_o} n(y)\sqrt{1 + \left(\frac{dz}{dy}\right)^2}\,dy \quad [18]$$

Substitutions of Eq. [11] in Eq. [18] and the resultant equation in Eq. [6] yield

$$n_f(y_o) = \frac{1}{d}\int_{y_i}^{y_o} \frac{[n(y)]^2}{\sqrt{[n(y)]^2 - [n(y_i)]^2}}\,dy \quad [19]$$

Differentiation of this equation with y_o further yields

$$\frac{dn_f(y_o)}{dy_o} = \frac{1}{d}\sqrt{[n(y_o)]^2 - [n(y_i)]^2} \quad [20]$$

From Eq. [15], we have

$$n(y_o) - n(y_i) = \frac{\left[d \cdot \frac{dn_f(y_o)}{dy_o}\right]^2}{2 \cdot n_f(y_o)} \quad [21]$$

Then the deflection of the incident beam in the diffusion layer is calculated by using Eq. [16], [17], and [21], where the gradient of the apparent refractive index, $[dn_f(y_o)/dy_o]$, is obtained from the interferogram. In the calculation of $[dn_f(y_o)/dy_o]$, the measured $n_f(y_o)$ was expressed by the second-order equation of y_o by applying the least squares method. Then the correction of the profile of the refractive index is completed by transferring $n_f(y_o)$ to a position of $(y_o - \Delta y/3)$ in the direction toward the cathode surface.

Several examples of the corrected profile of the refractive index are demonstrated in Fig. 4. These profiles were obtained with a solution containing 1.85M H_2SO_4 and 0.05M $CuSO_4$ at a height of 4 cm from the lower edge of the cathode. The cathodic current density was varied between 0.236 and 1.96 mA/cm^2. The uncorrected profiles of the refractive index are also shown in the same figure. As seen in this figure, the refractive index at the cathode surface is lowered when the average cathodic current density is raised. It is also seen that the above-mentioned correction becomes more significant when the slope of the refractive index is steeper.

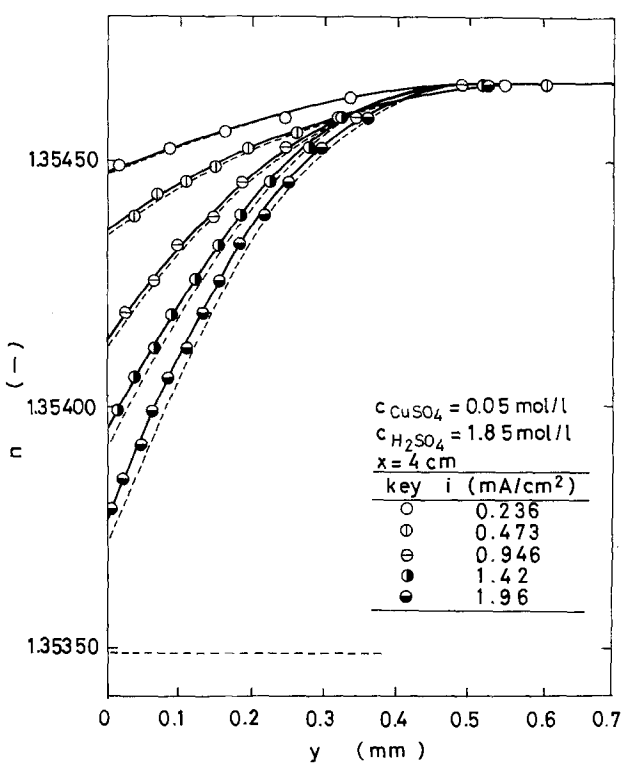

Fig. 4. Corrected profiles of the refractive index in the cathodic diffusion layer.

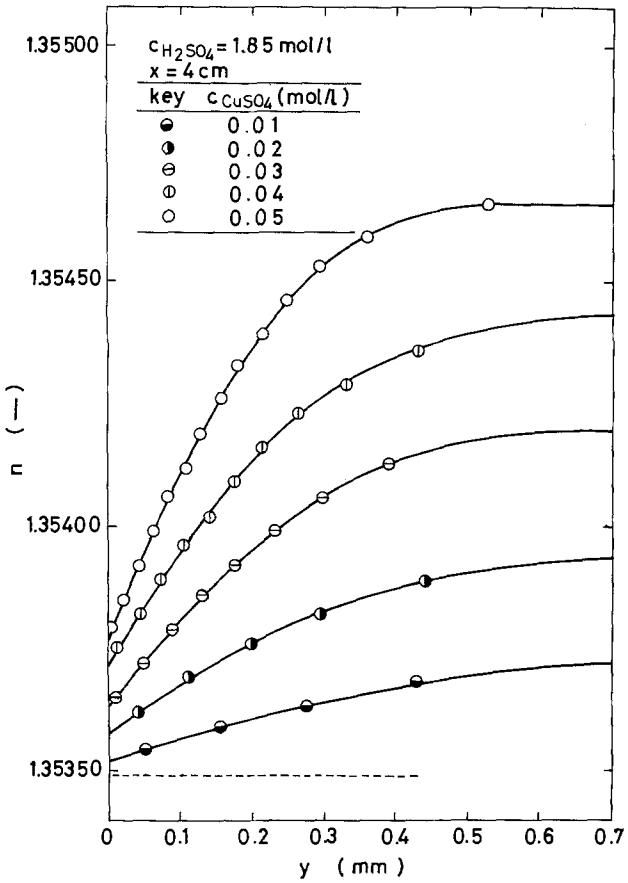

Fig. 5. Corrected profiles of the refractive index in the cathodic diffusion layer at the limiting current density.

Figure 5 demonstrates the corrected profile of the refractive index at the limiting current densities with solutions containing 1.85M H_2SO_4 and 0.01, 0.02, 0.03, 0.04, and 0.05M $CuSO_4$, respectively. As seen in this figure, the refractive index at the cathode surface decreases when the concentration of $CuSO_4$ in the bulk electrolyte is lower. The horizontal broken lines at 1.35349 in Fig. 4 and 5 represent the refractive index of aqueous 1.85M H_2SO_4 solution, respectively.

Discussion

The profile of the refractive index in the cathodic diffusion layer was measured with the solution containing 1.85M H_2SO_4 and 0.05M $CuSO_4$. In order to investigate the dependences of the difference of the refractive index between the cathode surface and the bulk electrolyte on the average cathodic current density and on the height from the lower edge of cathode, the theoretical expression was derived under the condition of uniform cathodic current density. The concentration difference of the Cu^{2+} ion, θ_1, between cathode surface and bulk electrolyte is expressed as follows (6, 13)

$$\theta_1 = \frac{\eta E}{\omega} \frac{(1 - {}^*t_1)}{z_1 F D_1} \cdot \left\{ \frac{\nu z_1 F D_1^2}{g\left(\alpha_1 - \frac{2}{3}\sigma^2\alpha_2\right)(1 - {}^*t_1)} \right\}^{1/5} \cdot i^{4/5} \cdot x^{1/5} \quad [22]$$

where

$$E = \left[\frac{\omega^2(\omega + 1)\lambda}{\eta^3 \phi} \right]^{1/5} \quad [23]$$

The symbol ϕ in Eq. [23] is

$$\phi = \frac{\lambda(\eta - 1)^{\omega+2}}{\eta^\omega(\omega + 1)(\omega + 2)} \left[\left(\frac{\eta}{\eta - 1} \right)^{\omega+2} - \frac{\lambda - 1}{\lambda e} - \frac{\omega + 2}{\lambda(\eta - 1)} - 1 \right] - \eta^{\lambda+1} B_{1/\eta}(\lambda + 1, \omega + 1) \quad [24]$$

where $B_a(b, c)$ is the incomplete beta function in the form of

$$B_a(b,c) = \int_o^a t^{b-1}(1 - t)^{c-1} dt \quad [25]$$

In addition, the concentration difference of H^+ ion, θ_2, between the cathode surface and the bulk electrolyte is related to θ_1 by taking account of the equations of mass transfer in the cathodic diffusion layer and electroneutrality in the solution as (2, 6)

$$\theta_2 = -\frac{2}{3}\sigma\theta_1 \quad [26]$$

where

$$\sigma = \frac{\delta_2}{\delta_1} \quad [27]$$

The notation σ in this equation represents the ratio of the thickness of cathodic diffusion layers of H^+ ion to Cu^{2+} ion. Its numerical value is slightly higher than unity (2). The negative sign in Eq. [26] represents the accumulation of H^+ ion in the cathodic diffusion layer which is caused by the migration of H^+ ion toward the cathode surface.

The refractive index of the solution depends not only on Cu^{2+} ion concentration but also on H^+ ion concentration. If the refractive index is expressed by a linear equation of

$$n = A + Bc_1 + Cc_2 \quad [28]$$

where c_1 and c_2 are the concentration of $CuSO_4$ and H_2SO_4, respectively, the difference of the refractive index between the cathode surface and the bulk electrolyte, Δn, is expressed from Eq. [26] and [28] as

$$\Delta = {}^*n - {}^\circ n = B\theta_1 + \frac{1}{2}C\theta_2 = \left(B - \frac{1}{3}\sigma C\right)\theta_1 \quad [29]$$

Substitution of Eq. [22] in Eq. [29] yields

$$\Delta n = \left(B - \frac{1}{3}\sigma C\right) \frac{\eta E}{\omega} \cdot \frac{(1 - {}^*t_1)}{z_1 F D_1} \cdot \left\{ \frac{\nu z_1 F D_1^2}{g\left(\alpha_1 - \frac{2}{3}\sigma^2\alpha_2\right)(1 - {}^*t_1)} \right\}^{1/5} \cdot i^{4/5} \cdot x^{1/5} \quad [30]$$

It is expected from this equation that Δn is proportional to $i^{4/5}$ and $x^{1/5}$, respectively.

The refractive index of mixed aqueous solutions of $CuSO_4$ and H_2SO_4 of various concentrations was measured at 23° ± 0.1°C. It was found that the change of the refractive index in these solutions is linear with the change of both $CuSO_4$ and H_2SO_4 concentrations in the regions from 0 to 0.27M $CuSO_4$ and from 0.8 to 2.0M H_2SO_4, respectively. The regression of the refractive index upon the concentrations of $CuSO_4$ and H_2SO_4 was calculated by the least squares method. It is as below

$$n = 1.3348 + 23.447c_1 + 10.075c_2 \quad [31]$$

The dependences of Δn on the average cathodic current density and on the height from the lower edge of the cathode shown in Eq. [30] were examined: the

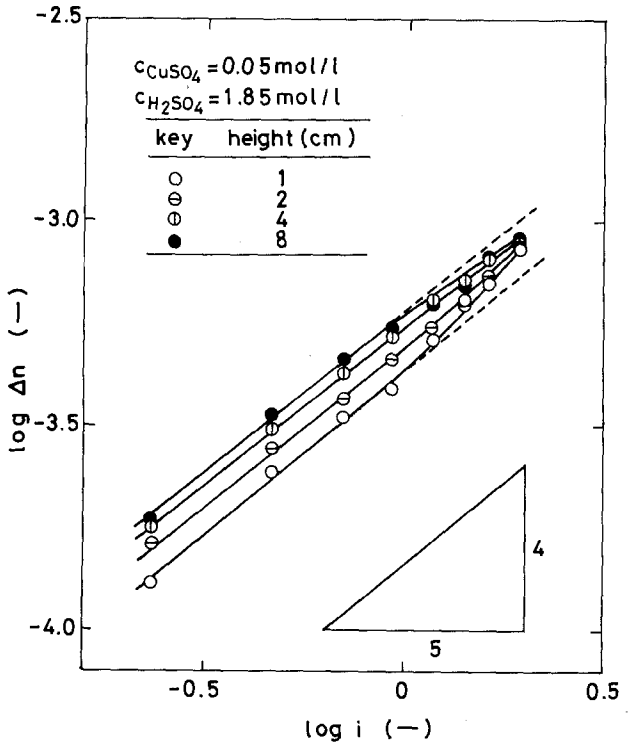

Fig. 6. Relationship between the refractive index difference and the average cathodic current density.

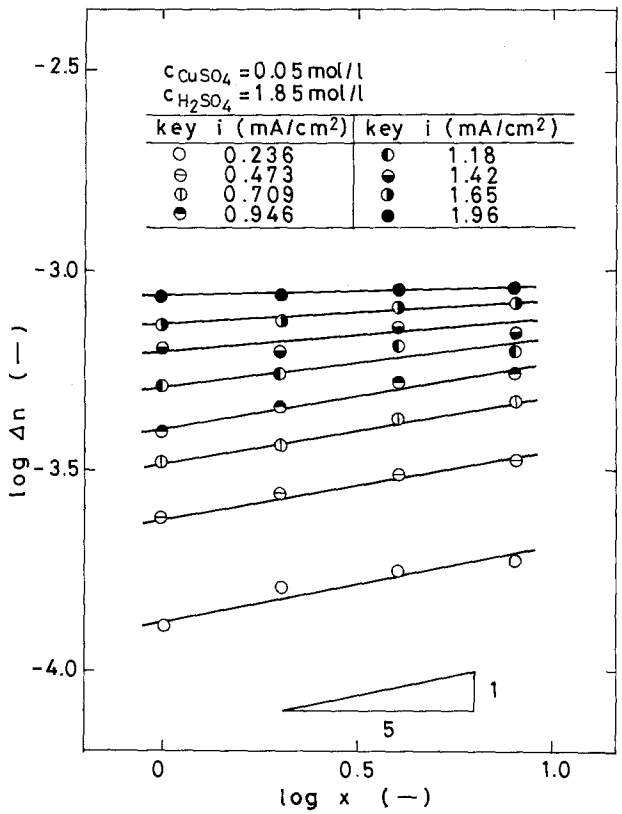

Fig. 7. Relationship between the refractive index difference and the height from lower edge of the cathode.

measured log Δn of the solution containing 1.85M H_2SO_4 and 0.05M $CuSO_4$ was plotted against the logarithmic average cathodic current density and demonstrated in Fig. 6. As seen in this figure, the slope of straight lines was obtained at 4/5, which is equal to the theoretical value of Eq. [30] when the cathodic current density is lower than the half-value of the limiting current density. Above this value of the current density, on the other hand, the Δn values start to converge into a fixed value at the limiting current density. Secondly, log Δn was plotted against log x and demonstrated in Fig. 7. By comparing the experimental slopes with the theoretical value of 1/5, it is clear that the experimental slopes are equal to 1/5 at the current densities which are less than a half of the limiting current density. They start to decrease when the average current density is raised above this half-value; it is virtually null at the cathodic limiting current density of 1.96 mA/cm².

Furthermore, the values of Δn were calculated by Eq. [30] and they were compared with the measured values. The following physical property constants and transport parameters were employed in the calculation

$D_1 = 5.74 \times 10^{-6}$ cm²/sec (19) *$t_1 = 0.0033$ (23-25)

$\nu = 1.148 \times 10^{-2}$ cm²/sec $\alpha_1 = 125$, $\alpha_2 = 26.8$ (12)

$\sigma = 1.36$ (6) $\omega = 2.3$ $\eta = 2.6$ and $E = 1.30$ (6)

Among these numerical values, ν was obtained by measuring the viscosity and density of the solution because no data were available in the literature. The results are summarized in Table II. It may be said from this table that the measured values are fairly well coincident with the calculated ones at the cathodic current denstities below 0.946 mA/cm², though the measured values are slightly lower than the calculated ones. It is also seen that the difference between the measured and calculated values becomes larger when current densities higher than 1.18 mA/cm² are applied. This difference is most significant at the height of 1 cm from the lower edge of the cathode. This may suggest that the local cathodic current density is not uniform in a vertical direction above the half-value of the limiting current density (10-12).

Following this, the difference of the refractive index between the cathode surface and the bulk electrolyte at the cathodic limiting current density was pursued; the solutions whose $CuSO_4$ concentration is varied between 0.01 and 0.05M and H_2SO_4 concentration is maintained at 1.85M were used. The logarithmic average limiting current density, log i_d, obtained with each of these solutions was plotted against the logarithmic $CuSO_4$ concentration, and it is demonstrated in Fig. 8. According to the theoretical calculations (2, 10), the

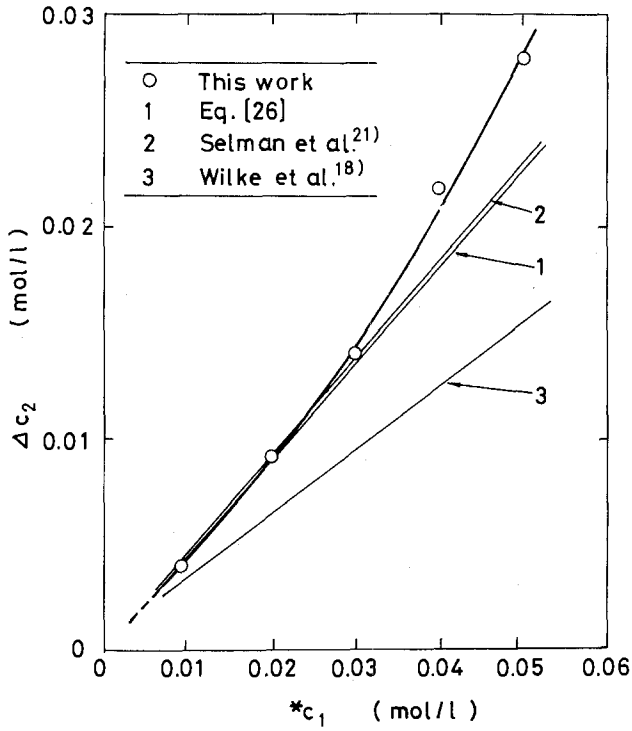

Fig. 9. Relationship between the concentration difference of H_2SO_4 (Δc_2) and the concentration of $CuSO_4$ in the bulk electrolyte ($*c_1$).

cathodic average limiting current density is proportional to the 5/4th power of $CuSO_4$ concentration in the bulk electrolyte. As seen in Fig. 8 this theoretical relationship is satisfied. For comparison, the experimental results obtained by Wilke *et al.* (10) were applied. That is, Wilke's results, where the plane vertical cathode of 3 in. height was used and the temperature was maintained at 23°C, were plotted in the same figure.

As mentioned before, $CuSO_4$ concentration at the cathode surface is regarded as zero at the cathodic limiting current density (2, 14), and the refractive index of the solution at the cathode surface shown in Fig. 5 represents the concentration of H_2SO_4. The concentration difference of H_2SO_4, $\Delta c_2 (= {}^\circ c_2 - {}^* c_2)$ between the cathode surface and the bulk electrolyte was calculated from Fig. 5, and they are plotted against the $CuSO_4$ concentration in the bulk electrolyte, respectively. It is demonstrated in Fig. 9. As seen in this figure, Δc_2 is lowered with the decrease of $CuSO_4$ concentration. This tendency is predicted in Eq. [26]. Furthermore, it is seen that the slope of Δc_2-curve decreases when the $CuSO_4$ concentration in the bulk electrolyte is lowered. This phenomenon may be explained as follows. The diffusivity of Cu^{2+} ion is lower in the solution of higher $CuSO_4$ concentrations (19, 20). When the $CuSO_4$ concentration in the bulk electrolyte becomes higher, the diffusion layer of Cu^{2+} ion, δ_1, becomes thinner (2), while the thickness of diffusion layer of H^+ ion, δ_2, is maintained to be virtually unvaried. As a result, the σ value in Eq. [27] increases, and the coefficient of $-(2/3)\sigma$ between Θ_2 and Θ_1 in Eq. [26] becomes higher when the $CuSO_4$ concentration is raised.

Brenner (7) measured the concentration of H_2SO_4 at the cathode surface by applying the freezing method during the electrodeposition of copper from a solution containing $CuSO_4$ and H_2SO_4. However, his experimental result cannot be directly compared with our experimental results because of the different electrolytic conditions. Our experimental results were compared with the following theoretical values: first, the concentration difference of H_2SO_4, Δc_2, was calculated from Eq. [26] in which Θ_2 was replaced by $2\Delta c_2$. At the cathodic limiting current density, Θ_1 is equal to the concentration of $CuSO_4$ in the bulk electrolyte, and the σ value of 1.36 was employed from our previous work (6). Selman and Newman (21), on the other hand, obtained the numerical solution for the differential equation of mass transfer at the limiting current density in the cathodic diffusion layer of a solution containing $CuSO_4$ and excessive H_2SO_4. They obtained the following expresion of Δc_2

$$\Delta c_2 = 0.46 * c_1 \qquad [32]$$

where $*c_1$ is $CuSO_4$ concentration in the bulk electrolyte. It was assumed in their calculation that the concentration of $CuSO_4$ is lower and H_2SO_4 is completely dissociated into $2H^+ + SO_4^{2-}$ ions. Furthermore, Wilke *et al.* (18) studied the mass transfer of Cu^{2+} ion in the cathodic diffusion layer by applying the technique of dimensional analysis, and they derived the following expression for the concentration difference of H_2SO_4

$$\Delta c_2 = \Delta c_1 \left[\frac{D_1'}{D_2'}\right]^{3/4} \cdot \frac{*t_2}{1 - *t_1} \qquad [33]$$

The numerical values (19, 22) of

$$D_1' = 5.74 \text{ to } 6.03 \times 10^{-6} \text{ (cm}^2\text{/sec)}$$

and

$$D_2' = 2.1 \times 10^{-5} \text{ (cm}^2\text{/sec)}$$

were employed, and the values of transference number, $*t_1$ and $*t_2$, were calculated from the mobility of each ion at the infinite dilution (23-25).

These calculated values of Δc_2 are also demonstrated in Fig. 9. It is seen that the calculated value from Eq. [33] is somewhat lower as compared with the former two calculated values and also that the measured values in the present work are in good agreement with the calculations by Eq. [26] and [32], both of which were derived from the assumption that $CuSO_4$ and H_2SO_4 in the solution are completely dissociated into $Cu^{2+} + SO_4^{2-}$ and $2H^+ + SO_4^{2-}$ ions, respectively.

Summary

It is important to pursue the concentration profiles of $CuSO_4$ and H_2SO_4 in the cathodic diffusion layer for the study of electrodeposition of copper from an unstirred aqueous solution containing H_2SO_4 and $CuSO_4$. As the first step toward this goal, the profile of the refractive index of the solution in the cathodic diffusion layer was measured by holographic interferometry at various heights from the lower edge of the cathode and at various cathodic current densities up to the limiting value.

The profile of apparent refractive index in the cathodic diffusion layer obained from the interferogram was corrected under the assumption of a linear variation of the refractive index within the region of beam deflection in the cathodic diffusion layer. The theoretical expression of the difference of the refractive index between the cathode surface and the bulk electrolyte was derived under the assumption of a uniform distribution of local current density on the cathode surface. In order to verify this theoretical relationship, the dependences of the measured log Δn on the logarithm of current density and on the logarithm of height from the lower edge of the cathode were examined. At cathodic current densities lower than the half-value of the limiting current density, these dependences were satisfied. It was also disclosed that Δn is virtually unchanged at the cathodic limiting current density along the vertical direction on the cathode surface. Both experimental and theoretical values of Δn are in good agreement with each other at the cathodic current densities less than a half of the cathodic limiting current density.

When the electrolysis takes place at the cathodic limiting current density the concentration of $CuSO_4$ at the cathode surface is regarded as virtually zero. Under this experimental condition, Δn was measured at a height of 4 cm from the lower edge of the cathode, with the solutions containing 1.85M H_2SO_4 and 0.01, 0.02, 0.03, 0.04, and 0.05M $CuSO_4$, respectively. From the above presumption that $^\circ c_1 = 0$ at the limiting current density, the concentration difference of H_2SO_4, Δc_2, is obtained from Δn. The Δc_2 value at the cathodic limiting current density decreases when $CuSO_4$ concentration in the bulk electrolyte is lowered. Furthermore, the slope of the curve of Δc_2 *vs.* $^* c_1$ decreases as $CuSO_4$ concentration in the bulk electrolyte is lowered. These experimental results were qualitatively explained from Eq. [26] and [27]. The measured Δc_2 values were compared with theoretical ones, and it was clarified that the measured Δc_2 values are in good coincidence with the calculated ones from Eq. [26] and [31].

LIST OF SYMBOLS

A	constant
B, C	constant (cm³/mole)
a, b, c	constant
c_1	concentration of $CuSO_4$ (mole/cm³)
c_2	concentration of H_2SO_4 (mole/cm³)
$^* c_1$	concentration of $CuSO_4$ in the bulk electrolyte (mole/cm³)
$^* c_2$	concentration of H_2SO_4 in the bulk electrolyte (mole/cm³)
$^\circ c_1$	concentration of $CuSO_4$ at the cathode surface (mole/cm³)
$^\circ c_2$	concentration of H_2SO_4 at the cathode surface (mole/cm³)
Δc_1	$= (^* c_1 - ^\circ c_1)$ (mole/cm³)
Δc_2	$= (^\circ c_2 - ^* c_1)$ (mole/cm³)
d	width of cathode (cm)
D_1	diffusivity of Cu^{2+} ion (cm²/sec)
D_1'	diffusivity of $CuSO_4$ (cm²/sec)
D_2'	diffusivity of H_2SO_4 (cm²/sec)
E	constant
$\mathbf{F}$	Faraday constant (= 96,500 C/g equiv.)
g	gravitational acceleration (= 980 cm/sec²)
i	current density (A/cm²)
k	gradient of the refractive index (1/cm)
n	refractive index of the solution
n_i	refractive index of the solution at the incident point of beam
$^* n$	refractive index of the solution in the bulk electrolyte
$^\circ n$	refractive index of the solution at the cathode surface
$n(y)$	refractive index of the solution at a distance y from the cathode surface
$n_f(y)$	apparent refractive index of the solution obtained from interferogram at a distance y
Δn	$= (^* n - ^\circ n)$
N	number of fringe shifts
p	optical path length along the beam trajectory (cm)
$^* t_1$	transference number of Cu^{2+} ion in the bulk electrolyte
$^* t_2$	transference number of H^+ ion in the bulk electrolyte
x	height from lower edge of the cathode (cm)
y	horizontal distance from the cathode surface (cm)
y_i	distance between the incident point of the beam and the cathode surface (cm)
y_o	distance between the exit point of the beam and the cathode surface (cm)
Δy	$= (y_o - y_i)$ (cm)
z	distance perpendicular to x- and y-directions (cm)
z_1	valency of Cu^{2+} ion (= 2 g equiv./mole)

Greek Letters

α_1	densification coefficient of $CuSO_4$, $1/\rho\ (\partial\rho/\partial c_1)$ (cm³/mole)
α_2	densification coefficient of H_2SO_4, $1/\rho(\partial\rho/\partial c_2)$ (cm³/mole)
δ_1	thickness of the diffusion layer of Cu^{2+} ion (cm)
δ_2	thickness of the diffusion layer of H^+ ion (cm)
$\epsilon, \eta, \lambda, \omega$	numerical parameter
Θ_1	concentration difference of Cu^{2+} ion between the bulk electrolyte and the cathode surface (mole/cm³)
Θ_2	concentration difference of H^+ ion between the bulk electrolyte and the cathode surface (mole/cm³)
λ'	wavelength (cm)
ν	kinematic viscosity (cm²/sec)
σ	$= \delta_2/\delta_1$

Technical Notes

Electrophoretic Mobilities in Battery Electrolytes

S. D. James*

Electrochemistry Branch, U.S. Naval Surface Weapons Center, White Oak, Silver Spring, Maryland 20910

and R. A. Neihof

U.S. Naval Research Laboratory, Washington, D.C. 20375

Surprisingly high electrophoretic mobilities were recently reported for particles of cadmium hydroxide, nickel (II) hydroxide, and silver (I) oxide in the concentrated KOH electrolytes of alkaline batteries (1). Mobilities were reported to range up to 17×10^{-4} cm^2 sec^{-1} V^{-1} in 11M KOH (43%, w/w). The validity of these data has been questioned (2) on the grounds that serious errors of both technique and calculation were involved. However, mobilities of this order could effect substantial transfer of active material through batteries. For example, in the silver-zinc torpedo battery, fields up to 0.3 V/cm exist in the electrolyte during a 6 min discharge. Suspended particles could thus, in this time, be driven a distance of 0.18 cm which is about seven times the interelectrode separation. Thus we deemed it advisable to undertake some brief experimental tests on particle mobilities in concentrated KOH. Our results support the contention (2) that the mobilities of Ref. (1) are in fact erroneous and indicate that they are too large, probably by at least two orders of magnitude.

Electrophoretic mobilities were measured directly by the microelectrophoresis method. The apparatus and technique have been described elsewhere (3). The method can detect a mobility as low as 0.1×10^{-4} cm^2 sec^{-1} V^{-1} and has yielded accurate data at quite high salt concentrations [*viz.* seawater of about 0.6 ionic strength (4)]. Measurements were made on two materials, silver (I) oxide and alumina at two KOH concentrations, 1M and 11.6M (45% w/w, a typical alkaline battery electrolyte). The silver oxide was precipitated from nitrate solution as in Ref. (1) and was a rather coarse, rapidly settling material. The alumina was a 99.99% pure, 0.05μ size powder of γ-alumina from Union Carbide, Crystal Products Division; it yielded relatively stable suspensions. The KOH contained carbonate at a level comparable with those of Ref. (1). All four measured mobilities were quite small. Only for alumina in 1M KOH did the particles move fast enough to yield a relatively accurate measurement. The alumina particles were negatively charged and an average of five determinations gave a mobility of $0.54 \pm 0.12 \times 10^{-4}$ cm^2 sec^{-1} V^{-1}. At 11.6M, the alumina had slowed down such that it was possible to say only that the particles were still negative with a mobility not exceeding 0.1×10^{-4} cm^2 sec^{-1} V^{-1}. The silver oxide particles were even slower. In 1M KOH, they appeared to be negative with a mobility no greater than 0.1×10^{-4} cm^2 sec^{-1} V^{-1}. In 11.6M KOH, the silver oxide particles had no detectable mobility. The very low mobilities found in this brief study are quite consonant with the electrokinetic literature. Although no prior data seem to exist for solutions as conductive as 1M KOH, mobilities have been reported up to the ionic strength of seawater and these diminish uniformly with increasing salt concentration (4, 5). Thus we can say that particle mobilities in the concentrated electrolytes of alkaline batteries are very unlikely to exceed 0.1×10^{-4} cm^2 sec^{-1} V^{-1} and are therefore of little or no significance in battery operation.

Cell Voltage Variation Caused by Break of Uniform Gap Distance Between the Electrodes of Mercury Cell for Brine Electrolysis

Nobuhiro Kawasaki[1] and Yasuaki Kurokami

Toyo Soda Manufacturing Company, Limited, Chlor-Alkali Section, Yokkaichi-shi, Miye-ken, Japan

The quantity of bus bar on a mercury cell for brine electrolysis increases with an increase in rated current capacity. When an anode sheet begins to get close to the mercury cathode, the electric current flowing through the bus bar, to which the anode is connected, begins to increase and the cell voltage to decrease. Therefore short circuit can be avoided if one of the two is observed all the time.

The problem is which should be observed or how they should be combined in order to prevent short circuit and prevent mechanical damage of the electrodes.

In this note, the authors are going to discuss the cell voltage and current density variations caused by a deviation from uniform gap distance between the electrodes.

In general, the cell voltage (V) can be shown within a limit range of current density (D) as follows

$$V = a + (b + cl)D \qquad [1]$$

where l is a gap distance between the electrodes, and a, b, and c are constant and determined by the operating conditions such as brine temperature, brine concentration, and amalgam concentration.

The top of Fig. 1 shows a scheme of a brine electrolysis cell having n pieces of bus bar with an anode sheet for each and uniform gap distance (l_0). One obtains the following equation as the current density dependence of cell voltage by substituting $l = l_0$ into Eq. [1]

$$V = a + (b + cl_0)D \qquad [2]$$

The total electric current in Fig. 1 is ni_0 providing i_0 for each bus bar. The cell voltage shown by V_0 becomes

$$V_0 = a + (b + cl_0)D_0 \qquad [3]$$

where D_0 is the current density corresponding to the electric current (i_0) of a bus bar.

When one of the anode sheets deviates from the uniform gap distance as the bottom of Fig. 2 shows, the cell voltage becomes

$$V = a + (b + cl_0)D' \qquad [4]$$

where D' is the current density corresponding to the electric current (i') of bus bars, and one can derive

$$D' = (nD_0 - D)/(n - 1) \qquad [5]$$

Substituting Eq. [5] into the Eq. [4], one obtains

$$V = \{a + nD_0(b + cl_0)/(n - 1)\} - D(b + cl_0)/(n - 1) \qquad [6]$$

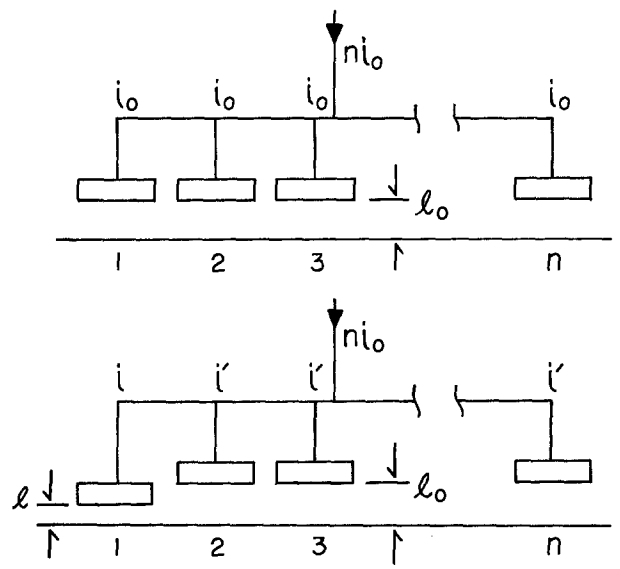

Fig. 1. Schematic brine electrolysis cells; uniform gap distance (top) and nonuniform gap distance (bottom).

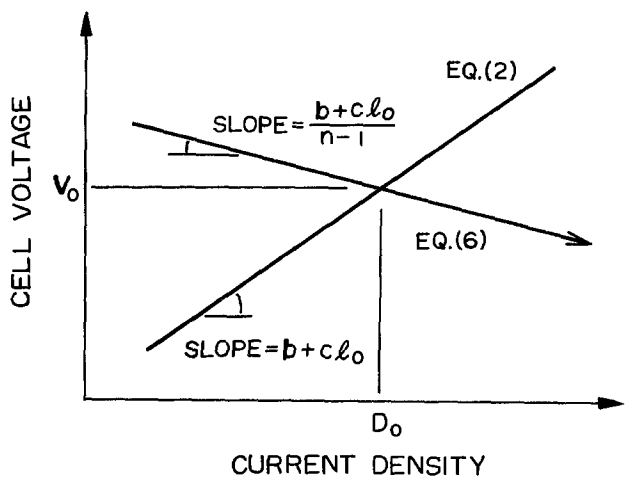

Fig. 2. Relationship between current density and cell voltage, Eq. [2] and [6] corresponding to the top and bottom of Fig. 1, respectively.

This equation is shown schematically in Fig. 2, where Eq. 2 is also shown for comparison. When one of the anode sheets breaks the uniform gap distance and gets close to the cathode, the cell voltage decreases and the current density increases in the direction shown by the arrow symbol with the slope of $(b + cl_0)/(n - 1)$. It should be noticed that the variation of cell voltage depends directly upon the quantity of bus bar.

[1] Present address: 2nd Production Division, Nanyo Plant, Toyo Soda Manufacturing Company, Limited, 4560 Tonda, Shin-nanyo-shi, Yamaguchi-ken, Japan.

Key words: cell voltage, gap distance, mercury cell, brine electrolysis.

In order to concretely understand the effect of quantity of bus bar on the cell voltage variation, the following explanation may be effective. The difference between V_0 of Eq. [3] and V of Eq. [6] is as follows

$$V_0 - V = (b + cl_0)(D - D_0)/(n - 1) \quad [7]$$

Assuming figures for both $(b + cl_0)$ and $(n - 1)$, *e.g.*, $(b + cl_0) = 0.013$ V/A · dm^2 at around 120 A/dm^2 of current density for the Olin metal anode (1) and $(n - 1) = 19$ for convenience, Eq. [6] becomes

$$V_0 - V = 0.00068\,(D - D_0) \quad [8]$$

In case the current density increases by 12 A/dm^2 corresponding to 10%, the cell voltage decreases by 0.008V. Generally the 10% increase of current density is predominant, and a certain countermeasure is taken to prevent a short circuit. On the other hand, a 0.008V variation of cell voltage is not easily detected, because this figure is within the cell voltage fluctuation due to the nonuniformity of the thicknesses of mercury cathode and iron bottom plate. Moreover, the cell voltages usually vary by more than 0.01V.

Twenty pieces of bus bar were used for the above explanation, and the cell voltage decrease was estimated to be 0.008V for a 10% increase in current density. For example, the cell voltage decrease is only 0.017V for 10 pieces of bus bar. From these examples using Eq. [7], it is apparent that the cell voltage variation caused by a deviation from uniform gap distance decreases reciprocally with an increase in the quantity of bus bar, which is related to the rated current capacity of a plant, and becomes less useful for protection of the anodes.

Electrochemical Patterning of Tin Oxide Films

B. Jayant Baliga*

General Electric Company, Corporate Research and Development Center, Schenectady, New York 12301

and Sorab K. Ghandhi*

Electrical and Systems Engineering Department, Rensselaer Polytechnic Institute, Troy New York 12181

Interest in tin oxide films has grown recently because of their potential application for solar cell structures. The high conductivity of doped tin oxide, coupled with a high transmission coefficient to light from wavelengths in the violet into the infrared, makes it well suited for transparent conductive antireflection coatings and for forming heterojunctions with silicon or gallium arsenide. An additional advantage of tin oxide for such applications is its durability under harsh ambients. For example, tin oxide is not attacked at room temperature by either concentrated acids such as nitric, sulfuric, hydrochloric, and hydrofluoric acids, or by concentrated bases such as ammonium, sodium, and potassium hydroxides. However, this property makes it a difficult material to etch for the purpose of making connection patterns or test cell structures. Sputter etching (1) has been used for patterning tin oxide films, but this technique is slow and requires the dedication of an expensive vacuum system for this purpose. The only alternative technique that has been reported in the literature is the HCl-zinc powder method (2). However, this technique is difficult to use for large area structures and results in extremely poor edge definition. This note describes an electrochemical technique developed to pattern tin oxide films with resolutions limited only by the photolithographic process.

Phosphorus-doped films used in this study were deposited on polished silicon and gallium arsenide substrates by the simultaneous oxidation of tetramethyltin and phosphine gas (3). Immediately after deposition, they were covered with a thin layer of SiO_2 (usually 2000Å) grown by the oxidation of silane in the same reactor. This silica layer was patterned by conventional photolithographic techniques and used as a mask for etching the tin oxide. On all substrates a corner was also etched to expose the SnO_2 layer for contacting during the electrochemical etching.

Etching was carried out in a bath of hydrochloric acid diluted in water with a platinum anode and the tin oxide as the cathode. In this system, nascent hydrogen is generated at the cathode by the passage of current, and probably reduces the SnO_2 to tin, which is continuously dissolved in the electrolyte as etching proceeds. Figure 1 shows the etch rate as a function of the current density at the tin oxide electrode. This etch rate was measured by visually determining the time required to etch through a 2000Å film of the oxide. Etching was carried out using electrolytes with 1 part of concentrated HCl (37%) in 1-10 parts of deionized water. Concentrated HCl was not used directly due to problems with fumes attacking the etch fixtures. As can be seen in Fig. 1, the etch rate was found to be independent of dilution between HCl:H_2O ratios of 1:3 and 1:10. Higher concentrations resulted in lower etch rates.

Ammonium hydroxide was also used successfully as an electrolyte. However, continuous etching is not possible in this system due to the formation of a tin coating on the SnO_2 film. This tin coating had to be periodically removed using hydrochloric acid. Consequently, the HCl-based system is more convenient to use in practice.

Electrochemical etching of tin oxide was also achieved on insulating glass substrates. Lower current densities were preferred for these applications in order to prevent the formation of isolated unetched

* Electrochemical Society Active Member.
Key words: tin oxide, patterning, etching.

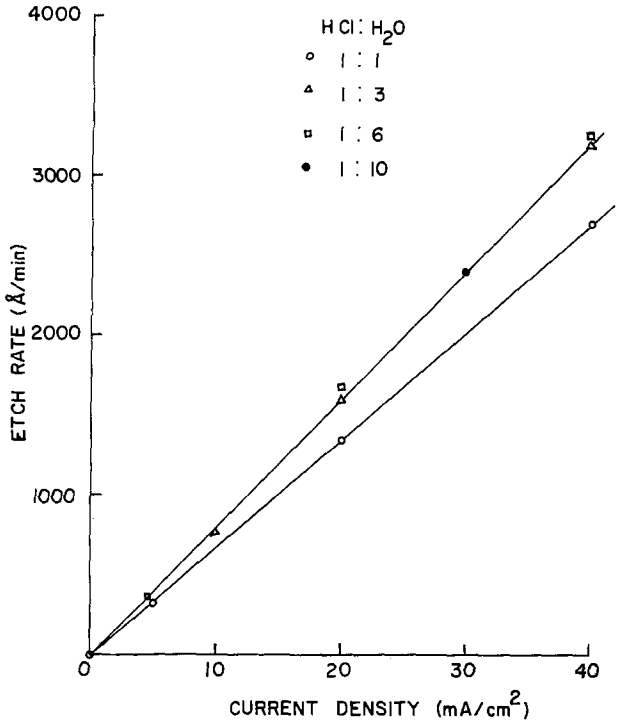

Fig. 1. Dependence of etch rate on current density and electrolyte concentration.

patches of tin oxide on the substrates. Such patches also appeared on conducting substrates at high current densities, but could be removed by prolonged etching.

In conclusion, tin oxide films can be patterned by electrochemical etching in a bath of dilute HCl, with resolutions that are typical of those obtained by photolithography. The etch rate is independent of the HCl concentration for the range of 1 part HCl (37%) diluted in 3-10 parts of water. Etching has been demonstrated to occur by the reduction of the tin oxide to tin by the generation of nascent hydrogen at the cathode (tin oxide), and its subsequent dissolution in the HCl.

Brief Communications

Anodic Sulfidation of Iron in Molten LiCl-KCl

C. A. Melendres,* C. C. Sy, and B. Tani

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

Electrochemical cells in molten salt electrolytes, utilizing light metal alloys as the negative electrode and iron sulfide (either FeS or FeS_2) as the positive, are being considered for application in load leveling in electric utility systems and for electric vehicle propulsion (1, 2). An understanding of the electrochemical characteristics of the iron sulfide electrode is of interest for the further engineering development of such cells. Initial investigations on compositional changes occurring during the charging and discharging of FeS_2 and FeS electrodes have been reported (3-5). In this communication, we report on preliminary results of studies on the electrochemical formation of sulfide films on iron during electrolysis in molten LiCl-KCl eutectic containing dissolved Li_2S. This formation was established by cyclic voltammetry and controlled potential electrolysis with identification of the products formed by x-ray analysis and optical and scanning electron microscopy.

* Electrochemical Society Active Member.
Key words: iron sulfide formation, molten salt electrolyte, cyclic voltammetry of iron, film formation on iron.

The voltammetric cell consisted of a 5.5 cm diam alumina crucible to contain the electrolyte and hold the working electrode compartment. The compartment contained the Li_2S solution and was also of alumina (1 cm diam) with a 0.25 mm hole at the bottom. The working electrode was either an iron rod (0.17-0.32 cm diam) or foil (0.25 mm thick) of 99.99% purity (Marz grade material from Materials Research Corporation, Orangeburg, New York). The reference and counter-electrodes were cast lithium-aluminum alloy [40 atomic percent (a/o) Li] whose composition was in the $\alpha + \beta$ region of the phase diagram (6) and whose potential at 450°C is about 292 mV anodic of Li/Li^+ in the eutectic electrolyte (7). Polarographic grade LiCl-KCl eutectic was obtained from Anderson Physics Laboratories (Champaign, Illinois). The Li_2S was purchased from Foote Mineral Company (Exton, Pennsylvania), ground, and then vacuum dried at room temperature for several days. Li_2S material, sintered above 600°C and having an average purity higher than 99%, was obtained from Eagle Picher Industries Incorporated and also used. Solutions of the desired composi-

tion were prepared by weighing. The experiments were conducted inside a glove box under high purity helium atmosphere. Temperature control of the furnace was within 1% of the temperature setting. A potentiostat/galvanostat (Princeton Applied Research Model 173) driven by a PAR Universal Programmer (Model 175) was used for cyclic voltammetry. Voltammograms were displayed by a Hewlett-Packard Model 7040A X-Y recorder.

Cyclic voltammograms of iron were obtained in 0.005, 0.01, and 0.02*M* solutions of Li_2S in LiCl-KCl eutectic at 450°C. For the 0.01*M* solution, additional runs were made at 375° and 525°C. Typical voltammograms are shown in Fig. 1. Two anodic waves (1a and 2a) are evident at 1.4 and 1.6V *vs.* LiAl. A minor peak (3a) appears at 1.1V. The cathodic peaks 1c and 2c appear to correspond to the reduction of 1a and 2a, respectively. Wave 2a increases linearly with Li_2S concentration and temperature at a given scan rate; 1a appears to merge with 2a as the temperature increases. The wave at 1.1V also becomes more prominent at higher Li_2S concentration but the peak current decreases with temperature instead.

The shape of the voltammograms is typical of that observed for the formation and reduction of surface films (8), *e.g.*, oxides in aqueous media. The effects of increasing the switching potential for the anodic scans are an increase in the maximum peak current for the respective cathodic waves and a shift of the potential at the current maximum to more cathodic values. The former is indicative of the increase in the quantity of surface material being formed during the anodic sweep, while the latter signifies the increasing difficulty of reducing thicker and thicker layers of the surface films.

Cyclic voltammograms taken at a constant scan rate in the anodic direction while varying that in the cathodic portion are shown in Fig. 2. Integration of the areas under the cathodic peaks for scan rates from 5 to 50 mV/sec shows the charge passed to be constant at about 31 mC/cm² and 14 mC/cm² for waves 1c and 2c, respectively, regardless of the scan rate. Similarly, for an anodic scan of 5 mV/sec for wave 3, the charge under the cathodic peaks was about 3.6 mC/cm². This result implies the existence of a roughly constant quantity of material coating the electrode surface produced during the preceding anodic scan. The films are calculated to be more than a monolayer thick. The shift in cathodic peak potentials and peak currents

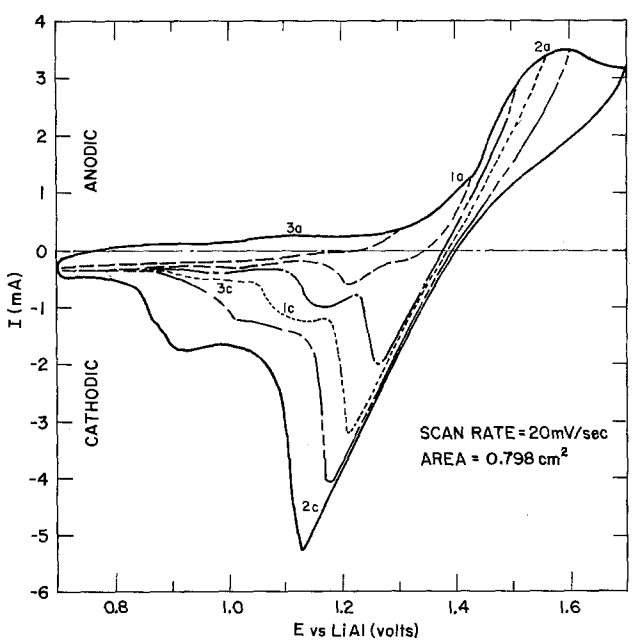

Fig. 1. Cyclic voltammograms of iron in 0.01M Li_2S solution at 450°C.

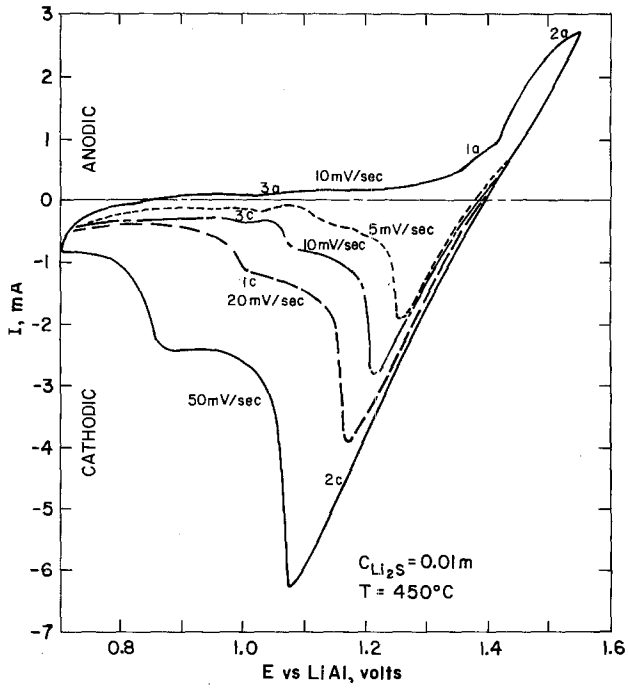

Fig. 2. Effect of scan rate on cathodic waves.

for the two waves is linear with the square root of scan rate; this is interpreted to mean that reduction of the surface films occurs under ohmic resistance control (9). The variation of peak current with the square root of scan rate for the main wave 2a is also linear. Assuming diffusion control of the process, a value of diffusion coefficient in the order of 1-4 $\times$ 10^{-6} cm²/sec at 450°C is obtained.

In order to determine the composition of the materials coating the electrode, electrolysis at various controlled potentials was undertaken at 450°C in 0.01 and 0.02*M* Li_2S solutions. Samples of the material found coating the electrode were taken and analyzed by x-ray diffraction. Results showed that FeS was present in samples anodized at potentials between 1.38 and 1.75V, while a sulfide phase of approximate composition $LiK_6Fe_{24}S_{26}Cl$ (henceforth referred to as J-phase) was found also when the potential was kept within 1.38-1.55V. Only LiCl-KCl was found at 1.2V, although the electrode appeared tarnished after the electrolysis. Examination of anodized electrodes under an optical microscope showed a coating which generally consists of a thin, grayish brown inner film and a rather thick, crystalline outer layer. This latter was identified by x-ray diffraction as either FeS, J-phase, or a mixture of both depending on the potential of anodization. Figure 3 shows an optical photomicrograph of the surface of an iron plate which has been anodized at 1.5V and subsequently washed by dipping momentarily in distilled water to remove the adhering LiCl-KCl salt layer. The black areas represent the outer layer whose composition in this particular case was determined as a mixture of FeS and J-phase by x-ray diffraction. The area of medium shade on the upper left corner corresponds to the inner film, while the light portions (bottom left) correspond to that of the iron substrate. Attempts to verify the composition of the inner film by x-ray diffraction have been unsuccessful so far; the film is very thin, making it difficult to obtain enough material, and it does not appear to be crystalline. However, elemental analysis of this inner film by an energy dispersive x-ray analyzer attached to a scanning electron microscope showed the presence of Fe and S. It is distinct from both the FeS outer layer (by the intensity ratio of Fe and S peaks) and also from the J-phase, which shows the presence of K in addition to Fe and S. Figure 4 shows the morphology of the outer layer as determined by scanning electron microscopy.

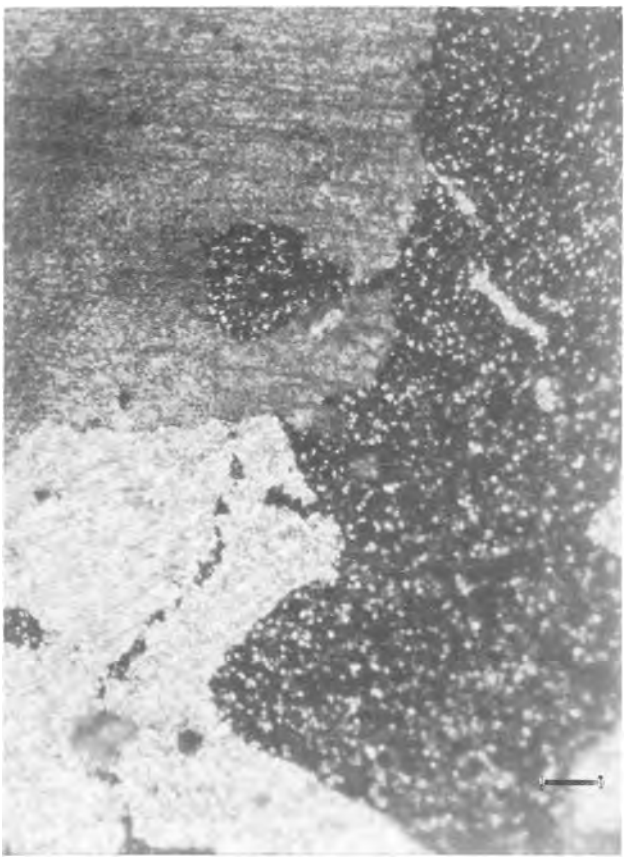

Fig. 3. Optical photomicrograph of iron electrode anodized at 1.5V (marker = 100 μm).

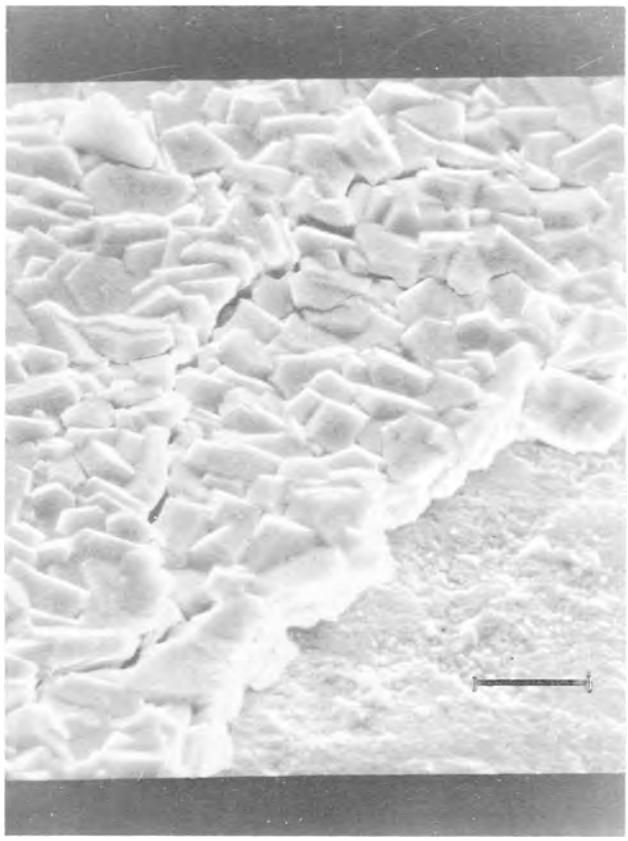

Fig. 4. Scanning electron microscope photograph of outer sulfide layer on iron electrode anodized at 1.5V (marker = 10 μm).

The hexagonal crystal habit of FeS as described in the literature (10) is not distinguishable from that of the J-phase by visual examination alone. Energy-dispersive x-ray analysis, however, shows the difference in elemental composition of the two. The cracks in the coating were inadvertently introduced during sample preparation. The coating does not seem to be very adherent, showing a tendency to peel off easily during the washing process to remove adhering electrolyte.

We consider briefly the possible reactions that could give rise to the coatings and sulfide phases. In the absence of detailed kinetic studies, any mechanistic proposal would be quite tentative. The foregoing results, nevertheless, suggest that wave 2a is due to the formation of FeS; the reaction rate at the current peak is presumably limited by diffusion of $S^=$ in the solution. The presence of wave 1a correlates well with the formation of J-phase material. The wave may be due to a change in properties of the coating because of the presence of this phase or to a distinct electrochemical reaction leading to J-phase formation. The complex composition of this phase suggests that it is probably formed by a chemical reaction following electron transfer to a precursor species. Reaction schemes that can account for the wave 1a are

Scheme (a)

$$Fe + Li_2S \rightarrow FeS + 2Li^+ + 2e^- \quad [1]$$

$$lFeS + mLi_2S + nK^+ + pCl^- \rightarrow \text{J-phase} \quad [2]$$

Scheme (b)

$$Fe + 2LiS^- \rightarrow Fe(LiS)_2 + 2e^- \quad [3]$$

or

$$Fe + 2Li_2S \rightarrow Fe(LiS)_2 + 2Li^+ + 2e^- \quad [4]$$

$$mFe(LiS)_2 + nK^+ + pCl^- \rightarrow \text{J-phase} \quad [5]$$

$$Fe(LiS)_2 + Fe \rightarrow 2FeS + 2Li^+ + 2e^- \quad [6]$$

where l, m, n, and p are integers.

For wave 2a, we propose the following

$$Fe + S^= \rightarrow FeS + 2e^- \quad [7]$$

$$J + 2Fe \rightarrow 26FeS + 4e^- \quad [8]$$

Scheme (a) suggests the possibility that FeS itself may be the precursor of the J-phase since it is found at potentials below the peak of the wave 1a. The role of Li_2S is suggested by the fact that the proportion of J-phase material formed during controlled potential electrolysis below 1.5V appears to increase with Li_2S concentration. Scheme (b) considers the possibility that another species which is directly discharged at the electrode is the precursor of the J-phase. The sulfidation reactions being proposed are analogous to the commonly observed anodic oxidation reactions of metals in aqueous alkaline solutions. The initial discharge product is thought here to be $Fe(LiS)_2$, a phase that has been found in cell studies (11). The J-phase presumably results from a chemical reaction of the $Fe(LiS)_2$ with KCl or from an inclusion of K^+ and Cl^- during formation of this stable phase. The potential dependence of the occurrence of the J-phase will be consistent with this scheme. Production of FeS from the solid phases $Fe(LiS)_2$ and J (Eq. [6] and [8]) is written in analogy with the dehydration reaction of metal hydroxide films (12). The cathodic waves would correspond to the reverse of the above reaction scheme. The nature of the reactions giving rise to waves 3a and 3c in the voltammogram has been difficult to ascertain. The peaks appear to be very symmetric and a doublet structure had been observed under high resolution. The closest separation between the anodic and cathodic portions was measured to be about 90 mV. These peaks may involve a minor species in solution which could be polysulfide; the thin inner film observed during microscopy may be due to this species or to the phase $Fe(LiS)_2$. Additional work is in progress; fur-

ther details of the present investigation also appear elsewhere (13).

Novel Semiconducting Electrodes for the Photosensitized Electrolysis of Water

J. Augustynski, J. Hinden, and Chs. Stalder

Laboratory of Electrochemistry and Applied Chemistry, University of Geneva, Geneva, Switzerland

The last months have seen a significant increase of interest in the utilization of semiconductor electrodes for the photoassisted electrolysis of water and in the implications of this process for solar energy conversion. As well as n-type TiO_2 (1) and SnO_2 (2), other semiconducting oxides; WO_3 (3), $SrTiO_3$ (4, 5), and Fe_2O_3 (6) have been recently proposed as possible anode materials for the photosensitized electrolysis of water. The best current-voltage characteristics have been hitherto obtained with the single crystal TiO_2 (7) and $SrTiO_3$ (4) photoanodes, although in some cases a similar behavior has been observed (8) for the polycrystalline TiO_2 electrodes. Here we report the preparation of novel semiconducting electrodes, based on polycrystalline titanium dioxide having exceptionally good current-voltage characteristics. These electrodes are formed by mixed oxide TiO_2-M_xO_y deposits on metallic titanium substrates, M being one of divalent or trivalent elements listed in Table I. The mixed oxide coatings were prepared by spraying a solution containing, for example, chlorides of both metals (elements) entering the film composition on Ti metal and heating at ~450°C in air to decompose the chlorides. Several layers, generally between 6 and 12, were deposited on each substrate. The electrodes were finally activated in argon at 600°-800°C during 30-60 min. The current-potential characteristics of the mixed oxide electrodes (area 0.9 cm^2) were measured in a two compartment cell using 1*N* sodium hydroxide solution.

Key words: semiconducting electrodes, oxide coatings, photoanodes.

Platinum foil served as the counterelectrode and a mercuric oxide electrode (HgO/Hg) was the reference electrode. All potentials are reported *vs.* normal hydrogen electrode (NHE). A 350W high pressure mercury arc lamp was used as a light source. Figure 1 shows a typical current-potential curve for a TiO_2-Al_2O_3 photoanode (electrode A, Table I) under illumination. Each point of this curve was measured after

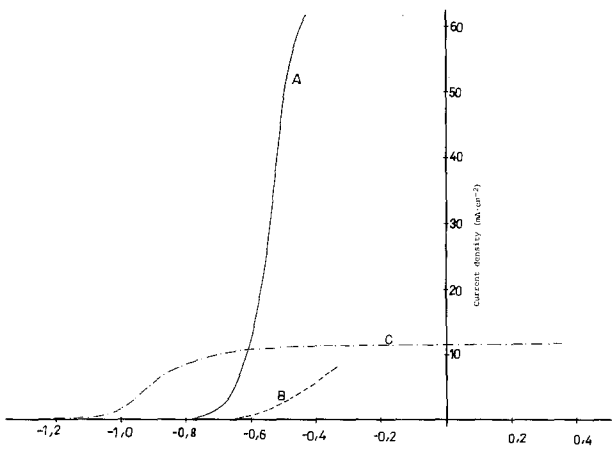

Fig. 1. Current-potential curve for a polycrystalline TiO_2-Al_2O_3 photoanode (A) illuminated by a 350W high pressure Hg lamp compared with single crystal TiO_2 (B) and $SrTiO_3$ (C) electrodes (from Ref. 7 and 4).

Table I. Some long time stability tests of mixed oxide photoanodes

	Electrode	Composition of the coating (w/o of metal)	Photoanode potential (mV vs. NHE) at 10 mA · cm^{-2}	at 20 mA · cm^{-2}	at 40 mA · cm^{-2}
A	TiO_2-Al_2O_3	94% Ti; 6% Al	−600 (−620 after 64 hr)	−570	−520 (−540 after 22 hr)
B	TiO_2-SrO	90% Ti; 10% Sr	−560	−510	−430
C	TiO_2-Ga_2O_3	94% Ti; 6% Ga	−490 (−500 after 16 hr)	−350	
D	TiO_2-Eu_2O_3	97% Ti; 3% Eu	−460	−300	
E	TiO_2-B_2O_3	94% Ti; 6% B	−530 (−500 after 15 hr)	−400 (−230 after 40 hr)	

polarization for at least 2 hr at a fixed current (controlled by a galvanostat). The current-potential characteristic of the TiO_2-Al_2O_3 photoanode is compared in Fig. 1 with those for the single crystal TiO_2 and $SrTiO_3$ electrodes (7, 4) determined under similar illumination conditions. If in the latter case the maximum anodic photocurrents observed are not higher than ~8 mA · cm^{-2} for TiO_2 and ~12 mA · cm^{-2} for $SrTiO_3$, the TiO_2-Al_2O_3 photoanode can sustain 60 mA · cm^{-2} without an excessive polarization, the potential remaining 0.85V less positive than the theoretical oxygen evolution potential in the dark. Another special feature of the TiO_2-Al_2O_3 electrode is a relatively small change in the potential with increasing anodic current as compared with the TiO_2 and $SrTiO_3$ single crystal electrodes. This difference in behavior might be attributed to the low resistivity of the mixed oxide coatings.

The good stability of the TiO_2-Al_2O_3 photoanode was confirmed by the results of long time tests given in Table I. No deterioration of the performance was observed after passage of about 6000 C · cm^{-2} corresponding to ~0.015 moles of oxygen evolved. Simultaneously there was no significant change in the weight of the electrode. As shown in Fig. 2, besides the TiO_2-Al_2O_3 electrode the best results have been obtained with a TiO_2-SrO coating. Up to ~30 mA · cm^{-2} the TiO_2-SrO electrode is nearly equivalent to the TiO_2-Al_2O_3 with respect to current-potential characteristic, but for higher current densities the TiO_2-SrO potential becomes distinctly more positive than that of TiO_2-Al_2O_3. In the case of the other two mixed oxide electrodes, TiO_2-Ga_2O_3 and TiO_2-Eu_2O_3, the current increase resulted in even larger polarization (Fig. 2), although their performances remain superior to the TiO_2 and $SrTiO_3$ single crystal electrodes. The thickness of the mixed oxide deposits being similar for all electrodes listed in Table I, the differences in their behavior must arise essentially from both unequal concentration and distribution of the oxygen vacancies in the TiO_2-M_xO_y system, resulting in the variations of conductivity. In this connection it should be stressed that the concentrations of divalent and trivalent elements in TiO_2-M_xO_y, given in Table I, are actually the mean values

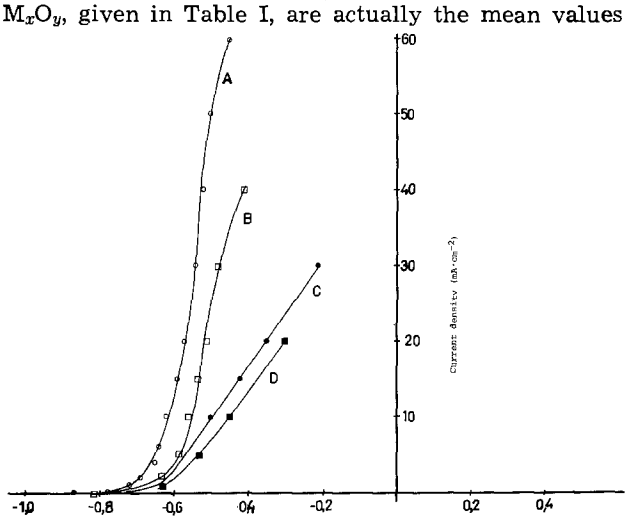

Fig. 2. Current-potential curves for different mixed oxide photoanodes: (A) TiO_2-Al_2O_3; (B) TiO_2-SrO; (C) TiO_2-Ga_2O_3; (D) TiO_2-Eu_2O_3 (the compositions of these mixed oxide coatings are given in Table I).

which can be quite different from the local concentrations through the thickness of the coating. For example, the Al^{3+} concentration in the surface region (15-20Å) of the TiO_2-Al_2O_3 electrode is much higher than the mean value of 6 weight percent (w/o), as established by the analysis performed using x-ray photoelectron spectroscopy. These changes in the concentration are certainly due to some preferential diffusion phenomena taking place during the heat-treatment of the electrodes in argon atmosphere.

One of the known features of TiO_2, having obvious implications for its utilization as photoanode, is the difficulty in making TiO_2 n-type with controlled conductivity. The latter is most likely the reason why the characteristics of the TiO_2 photoanode deteriorate during long time electrolysis despite an apparent chemical stability of this material under conditions of the oxidation of water. This deterioration which appears typically for the single crystal TiO_2 photoanodes (7) after the passage of about 1000 C · cm^{-2} was equally observed in some of our experiments carried out with no-doped, polycrystalline TiO_2 electrodes prepared in the similar way as the mixed oxide TiO_2-M_xO_y coatings. Therefore, the excellent long time characteristics of the TiO_2-Al_2O_3 photoanodes are related, in our opinion, to the fact that their initial high conductivity is not influenced by the passage of the anodic current. In other terms, the heat treatment of the mixed titanium-aluminum oxide coating deposited on Ti substrate leads to the formation of a stable TiO_{2-n}-Al_2O_3 defect structure resulting in an enhanced conductivity.

The spectral responses of the mixed oxide photoanodes listed in Table I were similar to that of the single crystal TiO_2 electrode (7), showing that the bandgap of TiO_2 is apparently not modified by the doping with Al^{3+}, Sr^{2+}, Ga^{3+}, Eu^{3+}, or B^{3+}. On the other hand, high quantum efficiencies are maintained for these electrodes up to very large current densities in contradistinction to the single crystal TiO_2 (9).

Electrical Properties of n-Type Polycrystalline Indium Phosphide Films

Tadashi Saitoh and Sunao Matsubara

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo, Japan

ABSTRACT

Electrical properties of n-type polycrystalline indium phosphide deposited on molydenum substrates are investigated as a function of deposition conditions. For undoped films, the electron concentration is found to be 10^{15}-10^{17} cm^{-3} and tends to increase with the increase in deposition temperature. The electron mobility and resistivity are almost constant irrespective of varying deposition conditions. On the other hand, the electrical properties of sulfur-doped films are found to be strong functions of deposition conditions and doping level. A grain boundary carrier trapping model is applied to explain the electronic transport properties of the polycrystalline films. The barrier height and the density of trapping states at grain boundaries are calculated.

Polycrystalline films of various semiconductors have been used in fabricating low cost solar cells (1-3). Consequently, the growth and structure of polycrystalline indium phosphide films have been investigated by the authors (4, 5). Understanding of the electronic transport properties of polycrystalline films are considered critical to the realization of solar cells with high conversion efficiencies.

In our present study, Hall measurement was performed to gain this clear understanding of the electrical properties of n-type polycrystalline indium phosphide as a function of deposition conditions. A model including carrier trapping centers at grain boundaries (6) was utilized to obtain the barrier height and the density of trapping states at grain boundaries.

Experimental

Polycrystalline films were prepared on 50 μm thick molybdenum sheets by chemical vapor deposition (4). The molybdenum sheets were cleaned in organic solvents and subsequently etched in a $1H_2SO_4$-$1HNO_3$-$3H_2O$ solution prior to indium phosphide deposition. This etchant makes molybdenum surfaces rough and acted effectively to secure a homogeneous nucleation in the initial stage of the deposition as well as to get pinhole-free films. The deposition was carried out at substrate temperatures between 450° and 650°C. Hydrogen sulfide was used as an n-type doping gas.

Electrical properties of both undoped and sulfur-doped films were measured by the van der Pauw method (7). Specimens for the measurement were prepared as follows: First, a polycrystalline film was attached upside down to a glass plate using an epoxy adhesive. Then, the molybdenum substrate was chemically etched off except four corners. The interface between the n-type polycrystalline indium phosphide and the molybdenum was found to have an ohmic contact. Consequently, the four molybdenum corners were used as electrodes.

Key words: Hall measurement, grain boundary, crystallite, barrier height, trapping density.

The Hall voltage was measured in both current polarities and averaged to calculate the electrical properties. The observed values of electron mobility, resistivity, and electron concentration were denoted as $\bar{\mu}$, $\bar{\rho}$, and $\bar{n}$, since the values relate to both crystallites and grain boundaries.

Resistivity vertical to the film surface was measured as follows: A eutectic AuGe alloy was evaporated on the film surface, annealed at 200°C in a hydrogen gas, and mesa-etched. Then, resistivity was calculated from the linear current-voltage relationship between the AuGe electrode and the Mo substrate.

Results

Undoped films.—The grain size of the polycrystalline films depended mainly on deposition temperature and growth time and not on PCl_3 concentration in a feed gas (4). So, the electrical properties were examined with respect to the former two conditions. The electrical properties of undoped films were compared to those of undoped epitaxial layers on Cr-doped single crystal substrates. The carrier concentration of polycrystalline films was appreciably lower than that of the epitaxial ones; whereas the electron mobility was lower and hence the resistivity higher by two orders of magnitude.

Resistivity of the polycrystalline films is almost constant irrespective of varying deposition temperature, as shown in Fig. 1. Also shown in the figure is the resistivity measured in a direction vertical to the film surface. The value is in the range of 1-10 $\Omega \cdot$ cm, being one order of magnitude lower than that measured parallel to the surface. The difference in the resistivities is considered to come from the difference in the orientation of the films (4).

On the other hand, electron concentration tends to increase with increasing deposition temperature and electron mobility decreases at around 600°C, as shown in Fig. 2 and 3, respectively. Since grain sizes increase at higher deposition temperatures, the grain boundary

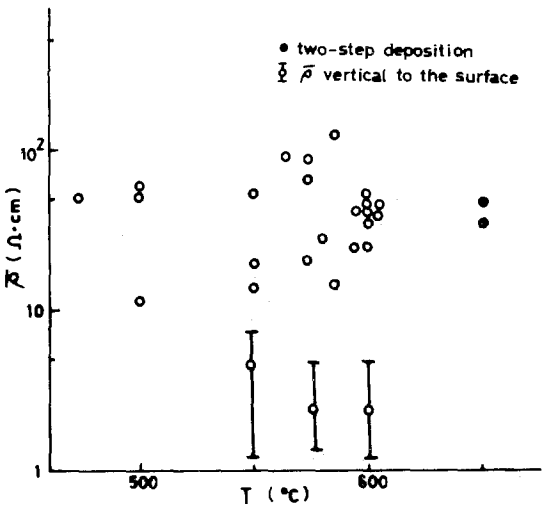

Fig. 1. Resistivity parallel and vertical to the surface vs. deposition temperature for undoped films.

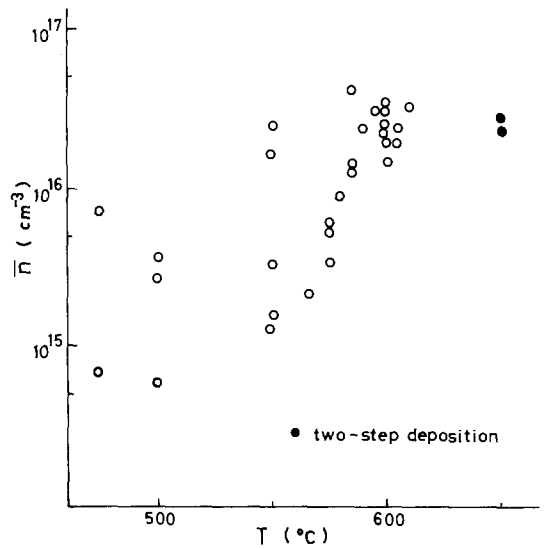

Fig. 2. Electron concentration vs. deposition temperature for undoped polycrystalline films.

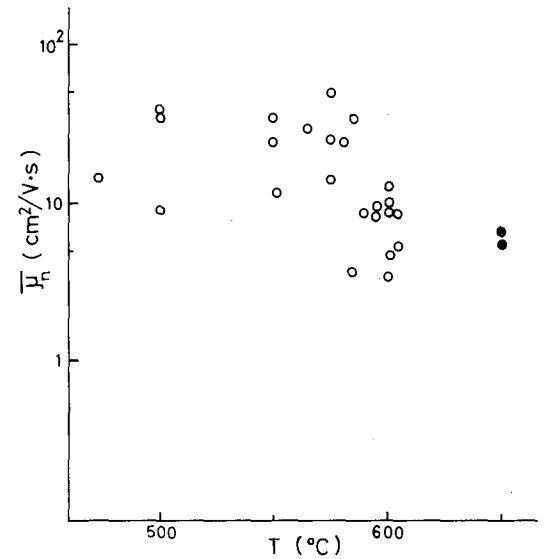

Fig. 3. Hall mobility vs. deposition temperature for undoped polycrystalline films.

area should decrease. It is assumed that a density of traps per grain boundary area remains constant. Thus, the higher the deposition temperature, the smaller the number of free carriers trapped at the grain boundary becomes causing an increase in the carrier concentration. When the deposition was carried out at more than 600°C, the deposited surface tended to become rough and have pinholes. This caused a decrease in the electron mobility of the films deposited at 600°C; probably due to the scattering of the carriers on the surfaces.

In the above figures data are also shown for two-step deposition in which a first layer was deposited at 600°C and then a second layer was deposited on it at 650°C. The observed values for the two-step deposition were similar to those of the films deposited at 600°C. This result suggests that the electrical properties of the second layers are determined mainly by those of the first layers. In other words, it indicates that each grain grows epitaxially on each of the substrates.

Furthermore, the variation of resistivity with thickness was examined. The observed values were found to be almost constant irrespective of thickness. Resistivity variation for an 18 μm thick film deposited at 575°C was also measured. It ranges from 1.2 to 4.9 $\Omega \cdot$ cm with the average value of 2.4 $\Omega \cdot$ cm.

Sulfur-doped films.—In the case of H_2S partial pressure of 6×10^{-7} atm, the carrier concentration increased with increasing deposition temperature; whereas the electron mobility increased and the resistivity decreased with the increase of deposition temperature, except around 600°C. The mobility decrease at around 600°C can be explained as the effect of free carrier scattering on the surfaces, as mentioned above.

A carrier concentration at a higher partial pressure of 3×10^{-6} atm was obtained to be about 1×10^{19} cm^{-3}, as shown in Fig. 4. It increased appreciably with deposition temperature. This suggests that saturation of the number of the carriers trapped at grain boundaries occurs. Resistivity decreased with deposition temperature, which is consistent with the increase in the grain size. In addition, electron mobility increases with deposition temperature as the value is calculated using the relationship $\bar{n}\bar{\rho}\bar{\mu} = q^{-1}$.

The variation of resistivity and electron concentration with H_2S partial pressure in the feed gas is shown in Fig. 5. It is notable that the resistivity drops rapidly at a partial pressure of 10^{-6} atm. On the other hand, the carrier concentration increased inversely. This tendency closely resembles that of polycrystalline silicon, in which the resistivity dropped drastically, about

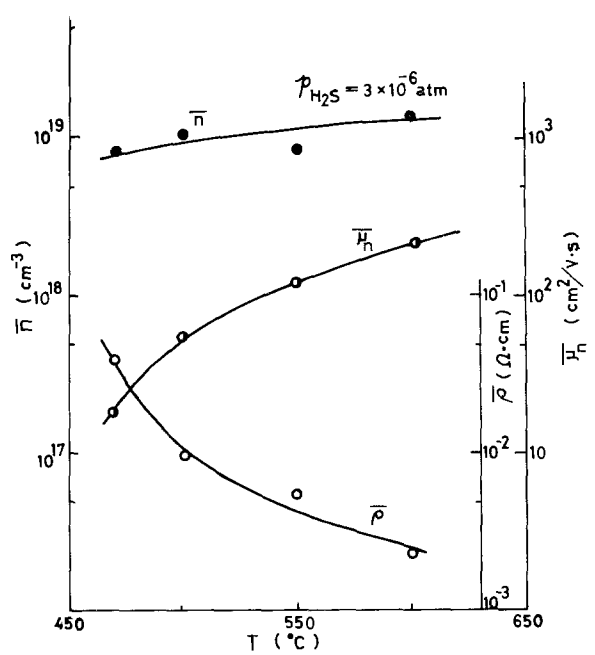

Fig. 4. Electron concentration, resistivity, and Hall mobility vs. deposition temperature for sulfur-doped films deposited at a hydrogen sulfide partial pressure of 3×10^{-6} atm.

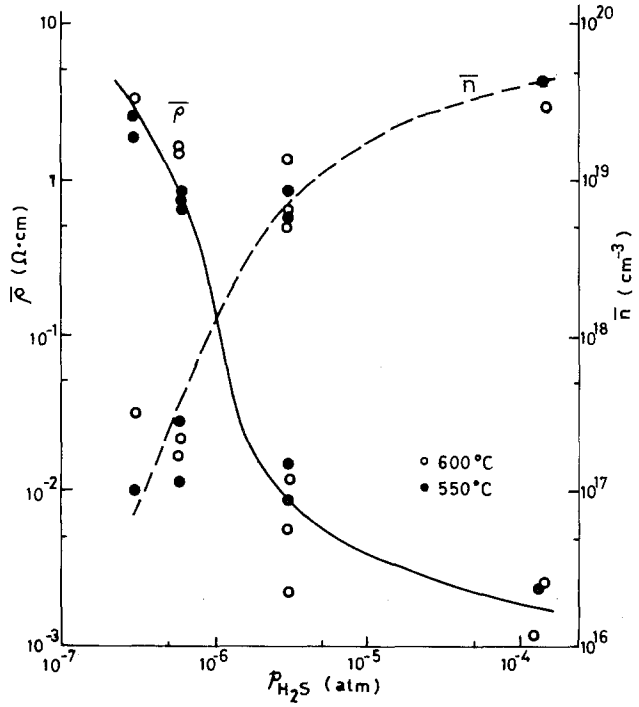

Fig. 5. Variation of resistivity and electron concentration with H_2S partial pressure in the gas phase for polycrystalline films.

five orders of magnitude (8, 9). This phenomenon can be understood as follows: As the carrier concentration decreased, the depletion-layer width around the grain boundary increased. When the depletion-layer width approached the grain size, the resistivity increased rapidly due to the trapping of almost all the carriers at the grain boundary. The smaller variation of resistivity for polycrystalline indium phosphide as compared to that of silicon is ascribed to the relatively high concentrations of residual impurities and to larger grain sizes.

The relationship between electron mobility and electron concentration for sulfur-doped films deposited at 550° and 600°C are shown as broken lines in Fig. 6. The electron mobility of polycrystalline films has a different tendency from that of the n-type single crystals shown as a solid line (10). The maximum value of the mobility is 200 cm^2/V · sec at a carrier concentration of 3×10^{19} cm^{-3}, about one-fifth that of single crystals. The lower values of the polycrystalline films deposited at 600°C than that of the films deposited at 550°C can be attributed to the scattering of the carriers at the nonuniform surfaces as already mentioned in Fig. 2.

Furthermore, the variation of the electrical properties for sulfur-doped films with thickness was measured and is shown in Fig. 7. Since the sample was attached upside down to the glass plate and etched gradually from the molybdenum side, the data at thinner thicknesses correspond to those near the as-deposited surface. As the grain size tends to increase when films become thick, the electrical properties nearer the front surface are less affected by the grain boundary. This tendency is compatible with the results shown in Fig. 7.

Barrier height at grain boundary.—In general, the electrical properties of polycrystalline films are discussed by dividing them into two regions, *i.e.*, a low resistivity region in crystallites and a high resistivity region around grain boundaries. In the case that doping level is relatively high and thus resistivity in the crystallites is sufficiently lower than that of the grain boundaries, the observed resistivity $\bar{\rho}$ is described by the following equation (6, 9, 11)

$$\bar{\rho} \propto \exp\left(\frac{\phi}{kT}\right) \qquad [1]$$

where ϕ is the barrier height.

A logarithmic plot of the resistivity *vs.* reciprocal temperature for undoped films is shown in Fig. 8. A linear relationship is obtained for samples deposited at various temperatures. Moreover, a logarithmic plot of electron mobility *vs.* reciprocal temperature was also found to vary linearly in an inverse manner. The barrier heights calculated from the figure are indicated in Table I. For films deposited at 600°C, barrier heights range from 0.2 to 0.3 eV. One barrier height for two-step deposition is almost equal to the above value. On the other hand, a smaller value of 0.081 eV is obtained for a film deposited at 500°C due to a relatively high concentration compared to other samples.

In the case of sulfur-doped polycrystalline films, a linear dependence is also obtained for a logarithmic plot of resistivity or electron mobility *vs.* reciprocal temperature. The barrier height calculated using the above equation is shown in Table I, indicating that the barrier height decreases inversely with the increase in electron concentration.

Discussion

In general, polycrystalline films have been considered to consist of single crystallites and grain boundaries including disordered atoms. There are some different models of electronic conduction around grain boundaries, *i.e.*, grain boundaries act as a sink for impurity atoms (12) or as a trap for free carriers (6, 9). The latter model is applied for elucidating the electronic conduction properties of polycrystalline indium phosphide.

In the model, the defects at grain boundaries are assumed to generate a density of traps Nt. Therefore, free carriers are trapped, and hence grain boundaries are surrounded by a depletion region.

From Poisson's equation, assuming that only part of crystallites is depleted, the potential variation throughout the polycrystalline films can be obtained. Since the barrier height ϕ is the difference between the potential at a center of the crystallite and that at an edge of the depletion region, it can be described as (6, 9)

$$\phi = \frac{q n_t^2}{8\epsilon n_1} \qquad [2]$$

where n_1 (cm^{-3}) is the carrier concentration in the crystallite, and ϵ is the permittivity. The parameter n_t (cm^{-2}) is the number of carriers trapped at the grain boundary and is given as

$$n_t = n_1 l_2 \qquad [3]$$

where l_2 is the depletion layer width.

Kamins introduced the following equation for the observed carrier concentration $\bar{n}$ under the assumption that the Hall coefficient is additive (6)

$$\bar{n} = \frac{n_1}{1 + (l_2/l_1)^2 \exp(\phi/kT)} \qquad [4]$$

Here, l_1 is the length of the low resistivity region.

Inserting Eq. [2] and [3] into Eq. [4], the following equation concerning n_1 is obtained

$$n_1^2 - \bar{n} n_1 - A\bar{n} = 0 \qquad [5]$$

where A is

$$A = \frac{8\epsilon\phi}{e l_1^2} \exp\left(\frac{\phi}{kT}\right) \qquad [6]$$

In the case of relatively high carrier concentrations, the length l_1 corresponds to the grain size. Then, A in Eq. [6] can be calculated using observed values of grain size and barrier height. Consequently, the carrier concentration in the crystallite n_1 can also be calculated from Eq. [5] and the number of carriers trapped at the grain boundary n_t from Eq. [2].

The electron concentration in the crystallites n_1 and the number of trapped carriers n_t for undoped films are also indicated in Table I. The concentration n_1 is higher than $\bar{n}$, indicating that the carrier trapping at the grain boundary is effective. The number of carriers trapped n_t tends to increase with the carrier concentration n_1 and to saturate at about 10^{12} cm^{-2}. In addition, the depletion-layer widths l_s were found to be 1000-2000Å from Eq. [3], being approximately one order of magnitude smaller than the grain size.

On the other hand, n_1 of sulfur-doped films is almost equal to the $\bar{n}$ value, as shown in Table I. The depletion-layer widths were calculated to be far smaller than 1000Å and inversely proportional to the carrier concentrations. The number of trapped carriers n_t tends to saturate with the increase in carrier concentration and to peak at 3.3×10^{12} cm^{-2}. This value is close to that of polycrystalline silicon films (9) and is considered to be near the density of trapping states, Nt, at the grain boundary.

Summary

Electrical properties of n-type polycrystalline films have been examined using the Hall measurements. For undoped films, the carrier concentration increased with increasing deposition temperature. On the other hand, electron mobility, being about two orders of magnitude smaller than that of single crystals, was almost constant irrespective of deposition temperature and

Table I. Barrier height, electron concentration in the crystallite, and number of carriers trapped at grain boundaries for polycrystalline indium phosphide films

	Deposition temperature (°C)	Average grain size (μm)	Observed electron concentrations (cm^{-3})	Barrier height (eV)	Carrier concentrations in the crystallites (cm^{-3})	Number of electrons trapped at grain boundaries (cm^{-2})
Undoped films	600-650*	7	1.9×10^{16}	0.23	6.7×10^{16}	9.1×10^{11}
	600	7	2.3×10^{16}	0.26	9.0×10^{16}	1.1×10^{12}
	600	7	3.2×10^{16}	0.23	9.2×10^{16}	1.1×10^{12}
	585	6	1.3×10^{16}	0.15	1.8×10^{16}	3.8×10^{11}
	500	2	6.2×10^{16}	0.081	6.4×10^{16}	5.3×10^{11}
Sulfur-doped films	550	4	1.0×10^{17}	0.083	1.0×10^{17}	6.7×10^{11}
	475	1	1.6×10^{18}	0.029	1.6×10^{18}	1.6×10^{12}
	550	4	2.8×10^{18}	0.019	2.8×10^{18}	1.7×10^{12}
	600	7	2.2×10^{18}	0.019	2.2×10^{18}	1.5×10^{12}
	600	7	3.0×10^{19}	0.007	3.0×10^{19}	3.3×10^{12}

* Two-step deposition.

growth time. The resistivity parallel to the surface did not depend on deposition conditions and was one order of magnitude larger than that measured vertically to the film surface.

For sulfur-doped films, the carrier concentration increased and the resistivity decreased with increasing deposition temperature. Especially, noteworthy was the fact that resistivity increased two orders of magnitude at the H_2S partial pressure of 10^{-6} atm in the feed gas. These results are considered to be caused by the grain boundary. Electron mobility increased with the partial pressure of H_2S gas up to 200 $cm^2/V \cdot sec$ at an electron concentration of about 10^{19} cm^{-3}.

A model in which grain boundaries act as free carrier traps was utilized to elucidate the electronic transport behavior. The barrier heights for undoped films were 0.2-0.3 eV and decreased inversely with the increase in electron concentration. The density of trapping states was determined as 3×10^{12} cm^{-2}.

The Corrosion Resistance of Worn Tin-Nickel and Gold-Coated Tin-Nickel Alloy Electrodeposits

M. Antler and M. H. Drozdowicz

ABSTRACT

The corrosion resistance of electrodeposited tin-nickel alloy is due to a thin passive film, believed to be mainly tin oxide with some tin and nickel hydroxides. Thin electrodeposited gold on tin-nickel also is corrosion resistant and is of interest as an electric contact material. Presumably, a similar protective film forms on the tin-nickel layer exposed at pores in the gold. These observations have been made with deposits of both single phase (SnNi) and multiphase mixtures of SnNi, Ni_3Sn_4, and Ni_3Sn_2. The protective film can be removed by mechanical wear but will spontaneously reform, taking approximately 1500 hr in air at room temperature to reach a limiting thickness. However, the resistance of tin-nickel to many corrodents is restored in less time, after only a few days of aging. Similar observations of the development of passivity were made with freshly plated tin-nickel deposits on copper, with aged deposits on copper that were chemically etched immediately before exposure, and with newly fractured edges of tin-nickel electroforms. If the substrate is exposed by wear-through or by brittle fracture of tin-nickel the corrosion resistance of the material is determined by the substrate, and may not be restored by aging.

Electrodeposited tin-nickel alloy has considerable technological importance because of its corrosion resistance. This material is equiatomic, having the weight percent (w/o) composition, 65 Sn-35 Ni. It does not appear (1) in the equilibrium diagram for the binary tin-nickel system, which suggests that it is thermodynamically unstable. However, practical experience has shown it to be kinetically stable, even at somewhat elevated temperatures, say to 250°C (2, 3). Tin-nickel is ordinarily deposited in a single phase having the NiAs structure (2), although sound deposits that are multiphase mixtures of SnNi and the thermodynamically stable compounds (Ni_3Sn_4 and Ni_3Sn_2) have been made (4).

[1] Present address: Centronics, Hudson, New Hampshire 03051.

Key words: contact resistance, mechanical wear, oxidation, passivation, porosity.

A necessary condition for corrosion resistance when it is plated on a corrodible substrate is that the tin-nickel layer be free of transverse porosity. Corrosion resistance is shown also by gold platings on tin-nickel even when the gold is porous, for a galvanic couple does not persist at the gold to tin-nickel interface in a surprisingly wide range of atmospheres. This was established in recent studies (4) of the effects of simulated environmental pollutants on gold-plated single phase and multiphase deposits. Thus, tin-nickel alloy is a desirable underplate for gold in some electric contact applications (5) for it could permit thin (less than 1 μm), less costly gold deposits to serve in chemically aggressive atmospheres where thicker gold (6) is otherwise required. Tin-nickel without a gold overplate cannot be used in most cases because of the presence on its surface of a tough, electrically insulating film. The inertness of tin-nickel is attributable to this film (7, 8).

In exploring the contact properties of gold-plated tin-nickel, it is necessary to consider the effect on its corrosion resistance when either the gold layer or both the gold and tin-nickel layers are damaged. This could occur, for example, when it is used as a printed circuit board edge contact plating due to mechanical wear from engagement with a separable connector or from scratching caused by careless handling. There is little information on the self-healing characteristics in air of the protective oxide on tin-nickel. Indeed, the corrosion resistance of freshly plated or oxide-free tin-nickel is unknown.

The objective of this investigation was to determine whether worn tin-nickel surfaces can be corroded in a variety of environments including some in which tin-nickel has previously (4) been found to be inert. In this earlier work, the samples were prepared and stored in air between one and three months prior to exposure. In the present study, similar samples were mechanically damaged before exposure by scribing with a pointed diamond. The reactivity of damaged surfaces of tin-nickel plated copper, with and without a gold overplate, was determined as a function of time between scribing and exposure. Ancillary determinations were made of the corrosion resistance of freshly plated tin-nickel and of tin-nickel surfaces obtained by fracturing electroforms. The kinetics of contact resistance increase of chemically etched tin-nickel were also examined.

A model for wear and corrosion with gold-plated tin-nickel on a corrodible substrate such as copper is given in Fig. 1 and 2. This model postulates that wear of gold-plated tin-nickel would not lead to high contact resistance if metal loss occurs within the gold layer or if some gold is worn away, exposing only a small area of the underplate. It is apparent also that for exposed tin-nickel to not corrode, a protective film must form on it spontaneously and quickly. Exposure of a reactive substrate through wearing away of both gold and tin-nickel, or cracking of the gold-plated tin-nickel layer [both single (9) and multiphase tin-nickel electrodeposits are brittle] could be deleterious in a chemically severe environment.

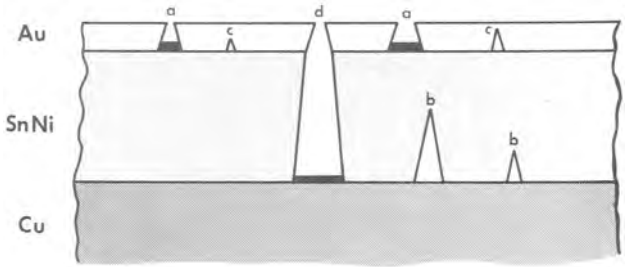

Fig. 1. Model of a plating of thin gold on tin-nickel alloy on a copper substrate: (a) designates random as-plated porosity in the gold to the underplate; (b) and (c) are internal pores in the tin-nickel and gold platings; (d) is the superposition of a pore in gold on one in tin-nickel to the substrate [adapted from Clarke and Chakrabarty (20)]. A film at the bottoms of the (a) pores inhibits corrosion of the plating. This film may be similar to that on bare tin-nickel electrodeposits. The film at the bottom of pore (d) is nonprotective. A desirable contact has few or no (d)-type pores. There is no (or little) oxide at the original interface between the gold and tin-nickel. (a)-type porosity is presumed to exist when the gold plating is thin.

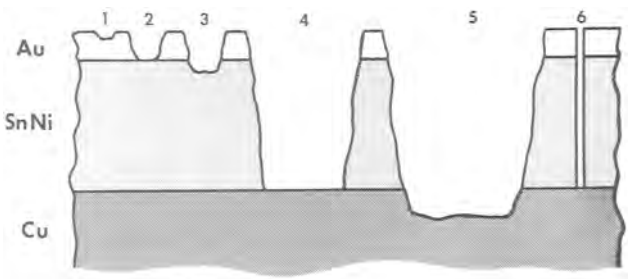

Fig. 2. Model of gold on tin-nickel plated contact after mechanical wear. Region 1 is loss of metal, localized to the gold layer; 2 is wear of gold to its interface with tin-nickel; 3 is loss of gold and tin-nickel localized to the tin-nickel layer; 4 is loss of gold and tin-nickel to its interface with copper; 5 is loss of gold, tin-nickel, and copper; and 6 is a crack through gold and tin-nickel which exposes the substrate. Condition 1 is acceptable; 2 and 3 are acceptable provided (a) that total area of material loss is small relative to the continuous gold surface in contact, (b) the sizes of individual 2 and 3 regions are small, and (c) a protective film quickly forms at the exposed surfaces of tin-nickel. Worn regions 4, 5 and cracks 6 in the plating which expose substrate would not be acceptable if they permit corrosion to occur at service conditions.

Experimental

Corrosion of Freshly Plated Tin-Nickel

Freshly plated tin-nickel can be hypothesized to be free of surface films, since it has been found to be solderable with tin-lead and mild fluxes, but this characteristic is lost if the sample is exposed in air for several hours prior to soldering (10).

The corrodibility of a tin-nickel deposit was determined by exposure for 1 hr to the vapors of concentrated (70%) HNO_3. This test is used to determine the porosity of gold on copper or nickel (11). A sample of 7 μm thick single phase (SnNi) tin-nickel plated from a fluoride bath (12) on polished copper was used, and exposure to HNO_3 commenced within 10 min of plating. This exposure produced a thin, discontinuous, light gray film on the surface. Elemental analysis of this film with an electron beam microprobe showed it to be free of copper, *i.e.*, the film was not caused by reaction with the substrate through pores in tin-nickel.

A comparison sample, plated with the first, was aged in air at 15% relative humidity (RH) for 8 days and then exposed to HNO_3 vapor in the same way. In this case, the surface on visual inspection was unattacked.

Corrosion of Fracture Surfaces of Tin-Nickel Electroforms

Additional experiments to determine whether tin-nickel alloy electrodeposits free of surface films can be corroded were made with electroformed material. Tin-nickel was plated 1.5 mm thick onto a copper tube, 4.8 mm in diameter and 33 mm long, from a fluoride bath (12). The copper was dissolved in nitric acid, leaving an intact hollow tin-nickel cylinder which then was broken into several pieces. After 3 months the pieces were cleaved again and exposed (11) within 1 min in closed vessels to the vapors of concentrated HNO_3 or to 10% SO_2 at 85% RH.

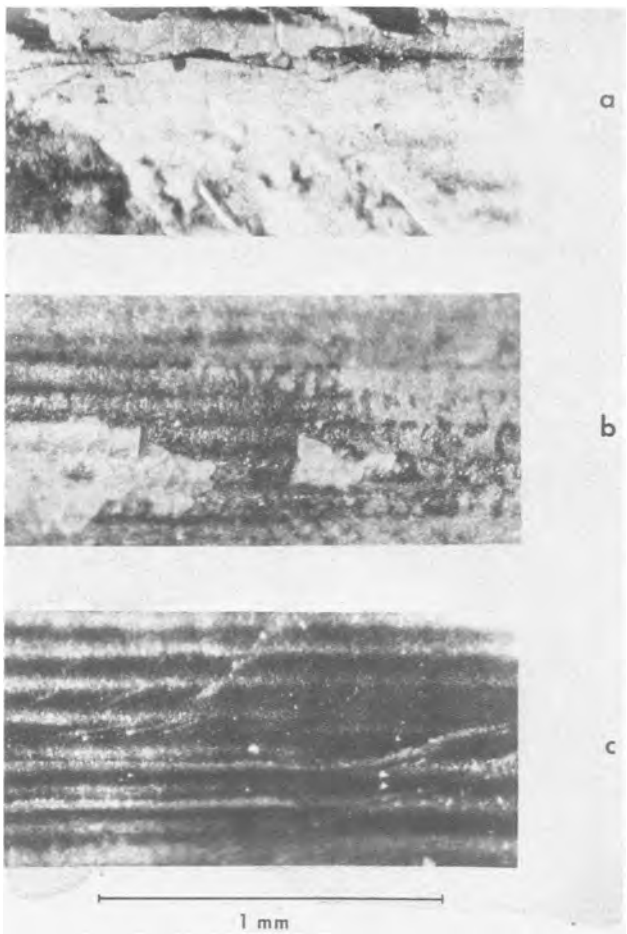

Fig. 3. Fracture surfaces of tin-nickel electroforms. (a) exposed to HNO_3 vapor for 1 hr immediately after fracture; (b) exposed to 10% SO_2 at 85% RH for 22 hr immediately after fracture; (c), same as (b), with 3 month delay between fracture and exposure. (a) and (b) are severely corroded, (c) is not corroded. Note layered structure of fractured surface. Original magnification, 70×.

It was found that the freshly fractured edges of tin-nickel were severely corroded, while the 3 month air-exposed fracture edges and the original tin-nickel electroformed surfaces were unaffected, as shown in Fig. 3. It was further established that there was visibly less corrosion on fracture edges that had been aged in air for 7 days compared to edges aged 1 day before exposure to the HNO_3 and SO_2 environments. Aging before exposure was in clean laboratory air at 25-60% RH. Additional experiments showed that 1 day air-aged fracture edges were moderately corroded when subsequently exposed at 88% RH for 27 days, while fractured samples aged for 1 week before exposure were unattacked. Other tin-nickel fracture edges aged 1 and 7 days were unchanged over flowers of sulfur for 1 week at 50°C and 85% RH. All observations were made at 70×.

It has been previously found (4) that air-aged electrodeposits of tin-nickel and porous gold plate on tin-nickel are unattacked by HNO_3 vapor, SO_2, and sulfur. Thus, both freshly fractured and freshly plated tin-nickel are corroded by some chemicals, but its usual corrosion resistance develops on aging in air. This conclusion is developed in greater detail in this paper.

Corrosion of Worn Tin-Nickel and Gold-Plated Tin-Nickel

Experimental.—Preparation of samples.—Electropolished OFHC[1] copper panels 3.8 cm square by 0.16 cm thick were plated with 12 μm of tin-nickel from a fluoride bath (12), and some of the specimens were overplated with 0.43 μm of gold from a cobalt-containing buffered acid $KAu(CN)_2$ solution. The tin-nickel samples were immersed in 18% HCl for 1 min prior to gold plating. This treatment, called "activation," common in commercial plating processes, is intended to assure good adhesion of the gold by removing any oxide that may be present on the tin-nickel surface. The cobalt content of the gold plate was 0.25 w/o. The tin content of the tin-nickel deposit was 65.2 w/o which is close to the theoretical value for the equiatomic alloy. X-ray diffraction analysis showed the tin-nickel to be single phase, having the expected NiAs structure (2). The porosity of the tin-nickel layer to the substrate was low, much less than 1 pore/cm² (except at the edges of the panels) as determined by exposure to HNO_3 vapor, SO_2, or electrography. The porosity of the gold overplating is unknown, but is presumed to be high because of its small thickness. Approximately one month elapsed between plating of the panels and the wear and electrography experiments.

Wear.—A wear machine was built which permits the sample to be moved with a weighted stylus pressed against it. The stylus was a 90° conical diamond having a rounded tip with a radius of 0.1 mm. Sliding velocity was 0.25 cm/sec. Four parallel tracks were made on each panel, 2.7-3.0 mm apart and 7 mm long, at loads of 20, 30, 50, and 100g for the tin-nickel plated samples, and at 30, 50, 100, and 200g for samples having a gold overplate.

A second set of wear tracks were made with samples lightly coated with a U.S.P. mineral white oil. This lubricant was chosen because of its purity and inertness. The appearance and reactivity to corrodents after removing the lubricant with warm reagent grade 1,1,1-trichloroethane was identical to wear without lubrication.

Additional sets of tracks were made on new areas of each sample after 23 and again after 6 more days. The panels were then aged another day before exposure to the environments numbered 1-5 in Table I and II.

Thus, the ages of wear tracks were 1, 7, and 30 days on exposure. In the cases of environments 6-7 in the tables, the ages of the tracks were 27, 33, and 57 days. Aging was conducted in clean laboratory air that varied from 25-60% RH. Individual panels with tin-nickel and gold on tin-nickel platings were prepared for exposure in each environment.

Corrosion studies.—Corrosion testing was done in both artificial and field environments, described in Table I and II. Exposure to HNO_3 vapor was over the concentrated acid in a desiccator (11). The 10% SO_2 test was over a mixture of $Na_2S_2O_3$, H_2SO_4, and water (11). The 88% RH test was made with a slurry of $BaCl_2$ in water which provided constant humidity. The sulfur test was made by suspending the samples over flowers of sulfur and a constant humidity solution using KNO_3. The chamber was held in an oven at 50°C for 1 week.

The out-of-doors exposure was in a louvered cabinet for 30 days during November-December 1975. The surfaces were observed to be sometimes wet during rapid temperature changes during this test. Factory exposures were in an electroplating plant and in a mechanical assembly area.

Electrographic testing.—In addition to the corrosion exposures, the samples were tested for porosity by a direct printing electrographic method (13). Dye transfer paper was soaked for 30 min in a solution of 20 g/liter of the disodium salt of dimethylglyoxime and 20 g/liter of NaCl. Applied pressure was approximately 50 kg/cm² (700 psi) and current was passed through the specimen and paper for 1 min at a constant voltage of 2.0V. The appearance of red in the electrograph indicates nickel, and green signifies copper. The prints were examined at 10×.

Copper was present in the wear tracks of coupons at the two higher loads, 50 and 100g for tin-nickel, and 100 and 200g for gold-plated tin-nickel. The green lines in the electrographs were continuous in tracks at the highest loads, and nearly continuous at the second highest loads. There was no red in the tracks. As shown later, the appearance of copper originated in minute cracks through the gold and tin-nickel layers produced by the wear experiment.

The electrograph of the large unworn regions of the tin-nickel plated panel was very faint pink. Thus, aged tin-nickel alloy is not significantly affected in electrographic testing by this procedure.

To determine whether the nonreactivity of electroplated tin-nickel was due to its protective surface film, a portion of a tin-nickel panel was lightly abraded with 600 grit metallographic paper and immediately electrographed. There was reaction, with the red coloration indicating nickel.

Confirmation of this result was obtained by electrographic testing a freshly plated tin-nickel deposit. A copper panel having 7 μm of tin-nickel was electrographed within 10 min of plating. A uniform bright red color appeared in the print except for a few, scattered, more deeply colored, small red spots. Thus, unaged tin-nickel is attacked in the electrographic test. a result consistent with the experiments using aged and freshly abraded samples if it is assumed that an air-formed protective film is responsible for the chemical inertness of tin-nickel.

Results of corrosion studies and discussion.—*Wear.*—Figure 4 shows wear tracks on tin-nickel and gold-plated tin-nickel panels. Deposit adhesion was excellent at both the tin-nickel to copper and the gold to tin-nickel interfaces.

Tin-nickel shows some plastic deformation in the wear tracks. At 50g there is slight cracking, and at 100g cracks appear at the sides of the track. From the electrographic study, the cracks in tin-nickel extend to

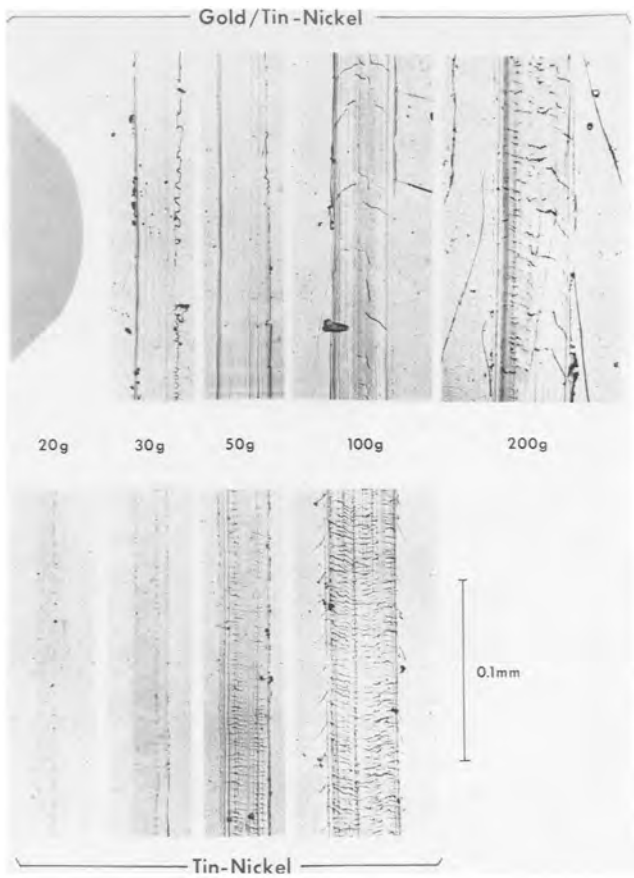

Fig. 4. Wear tracks in 12 μm thick tin-nickel electrodeposits on copper with and without a 0.43 μm thick gold overplate. Made with a diamond at loads from 20 to 200g. Shape and dimensions of conical diamond with a rounded end at top left (to scale). Direction of movement of samples, away from reader. Cracks in the platings are evident at 50 and 100g for tin-nickel and 100 and 200g for gold-plated tin-nickel. Original magnification, 460×.

the substrate. The orientation of the cracks is typical of brittle fracture wear (14) with a solid having a small tensile compared to its compressive strength.

There is no cracking at 30 and 50g with gold-plated tin-nickel, but at 100 and 200g cracks are plainly evident. The crack incidence at 100g is less with gold-plated tin-nickel compared to tin-nickel alone, but the individual cracks are larger. The electrographs show that the cracks at 100 and 200g extend to substrate copper, and that no copper is exposed in the tracks made at 30 and 50g.

Another feature of Fig. 4 concerns the removal of gold from the tin-nickel plating. Examination at 460× clearly reveals that gold has been worn from the wear tracks to an increasing degree with increasing load. This varies from none at 30g to about 25%, 70%, and 90% at 50, 100, and 200g.

The model of surface damage in Fig. 2 is therefore reasonable, except that there is no evidence from this work of significant tin-nickel removal by a smooth stylus at the loads used.

Reactivity to corrodents.—The reactivity of worn surfaces to various environments, summarized in Table I and II, is based on visual and microscopic examinations. Figures 5, 6, and 7 are typical observations.

Figure 5 is a worn tin-nickel plated panel after exposure to 10% SO_2. Corrosion is severe, especially at 50 and 100g where copper was exposed, except for tracks 11 and 12 in the photograph. With the latter, which were uncorroded, surface damage is confined to the tin-nickel layer and 30 days elapsed between wear and exposure.

Figure 6 illustrates worn gold-plated tin-nickel at 30g after SO_2 exposure. The beneficial effect of air

Fig. 5. Worn thick tin-nickel electrodeposit on copper after exposure to 10% SO_2 at 85% RH for 24 hr. Panel hung vertically. Upper row, unlubricated wear. Lower row, worn after coating with mineral oil. Lubricant removed after wear before each aging interval and before SO_2 exposure. Loads for tracks 1, 5, 9: 100g; 2, 6, 10: 50g; 3, 7, 11: 30g; 4, 8, 12: 20g. Groups of wear tracks were aged in air before SO_2 exposure as follows: 1-4, 1 day; 5-8, 7 days; 9-12, 30 days. All tracks display corrosion films except 11 and 12. Note that corrosion in tracks 3, 4, 7, and 8 is of SnNi, and in tracks 1, 2, 5, 6, 9, and 10 is of both substrate copper and tin-nickel. Original magnification, 2×.

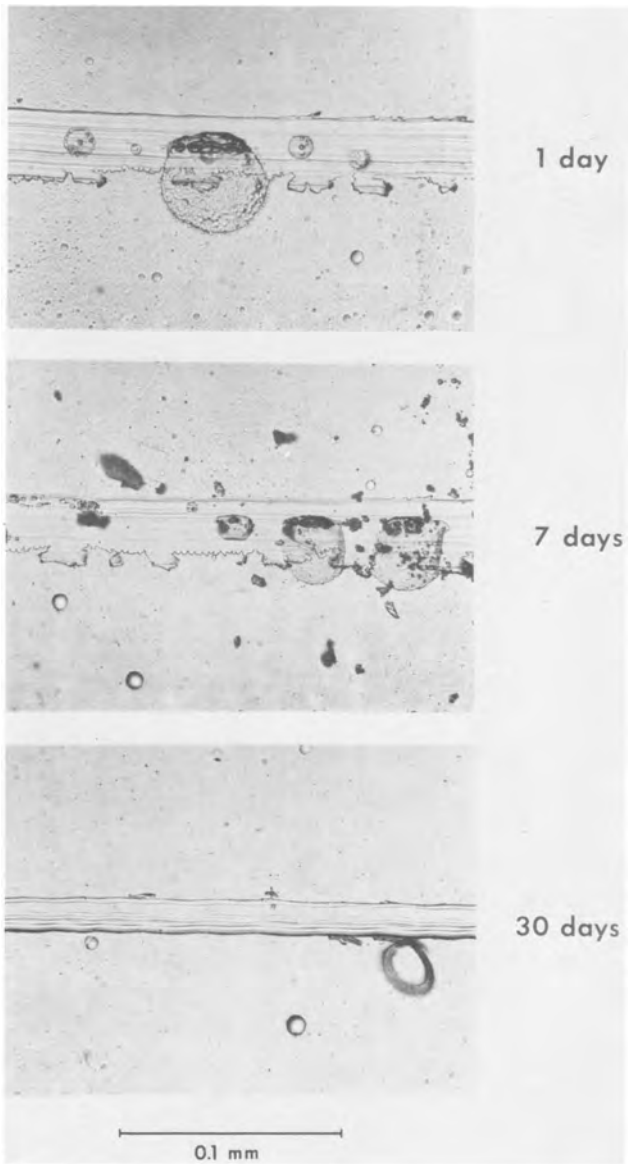

Fig. 6. Worn surface of thick tin-nickel electrodeposit plated with 0.43 μm of gold. Load: 30g. Exposed to 10% SO_2 at 85% RH for 24 hr. Aged in air before exposure for the lengths of time indicated. Original magnification, 460×.

aging before exposure is seen; there is no corrosion after 30 days, while corrosion occurs after 1 and 7 days. The volume of corrosion produced is greater in wear tracks made at 50g (Table II), because more tin-nickel was exposed than at 30g.

Figure 7 shows wear tracks made at 20g on the tin-nickel plated panel after exposure to HNO_3 vapor. There is corrosion in wear tracks after 1 and 7 days of aging prior to HNO_3 treatment. The extent of corrosion diminishes with aging, and after 30 days a film can no longer be detected on the surface. The severity of attack is less than with SO_2.

Many of the environments were corrosive to exposed copper in the wear tracks at the higher loads, as shown with SO_2 in Fig. 5. Copper does not possess the marked passivating tendency of tin-nickel.

Kinetics of Repair of Passive Film on Tin-Nickel from Contact Resistance Determinations

It is possible to determine the growth of an insulating film on a metal surface by monitoring the increase in contact resistance with time. A method for doing this has been described previously (15). Contact resistance at 100g was determined without wipe with a smooth hemispherically ended solid gold probe of 3.2

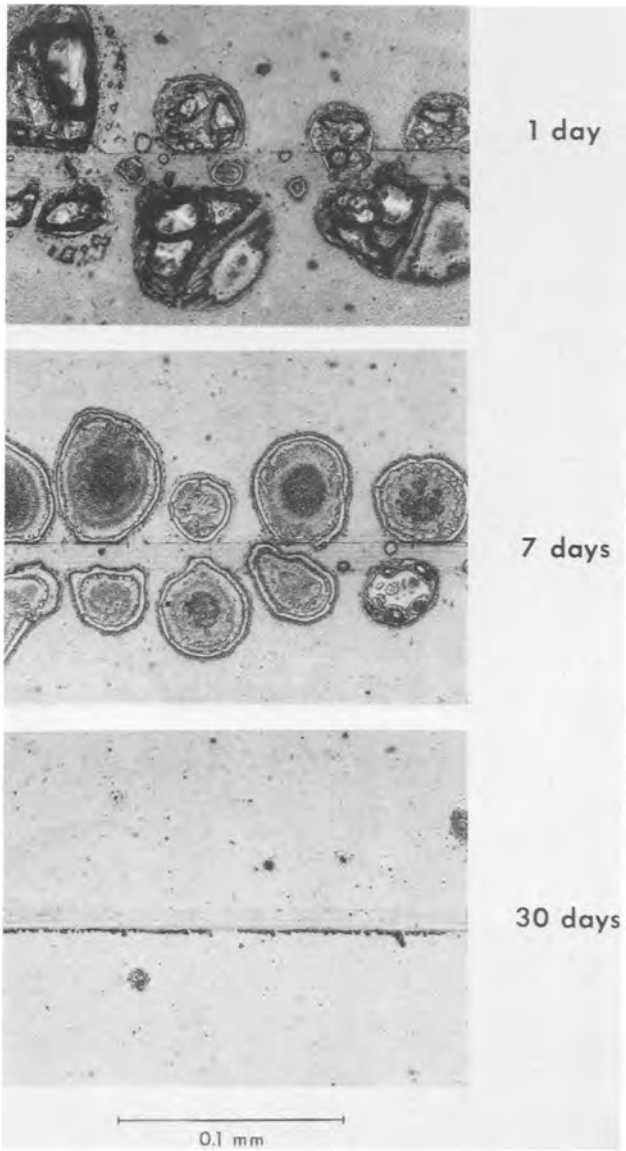

Fig. 7. Worn surface of thick tin-nickel electrodeposit after exposure to HNO_3 vapor for 1 hr. Load: 20g. Aged in air before exposure for the lengths of time indicated. Severity of corrosion diminishes with aging time. Original magnification, 460×.

mm diameter and an applied potential of 28 mV maximum. Since the contact resistance of a film-covered surface is strongly dependent on its roughness (16), a chemical method rather than mechanical wear was employed for film removal. A degreased tin-nickel plated panel was immersed in 18% HCl (1:1 mixture of water and concentrated HCl, sp gr = 1.18) for 1 min, during which there was gassing at the surface, thoroughly washed in distilled water, and dried in a stream of nitrogen. The surfaces were not visibly changed by etching. This procedure is used to activate tin-nickel prior to gold plating (see above).

The sample was probed at nine places from 0 to 200g with continuous measurement of contact resistance. Probing commenced within 6 min of etching, and was completed in 15 min. The median contact resistances at 50, 100, and 200g were 8.4, 5.4, and 3.3 mΩ. An auxiliary measurement of the contact resistance of a freshly plated tin-nickel sample, obtained within minutes of plating, showed it to be comparably low. Aging at 15-20% RH was continued to a total elapsed time of 1 hr from etching, and the median contact resistances rose to 14, 8.2, and 5.0 mΩ at the three loads. Aging continued in this environment for 1500 hr (*ca.* 63 days) with periodic probing.

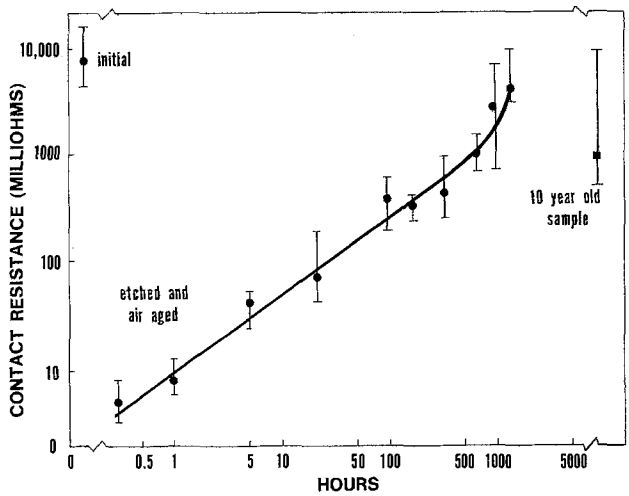

Fig. 8. ● Median contact resistance of smooth tin-nickel electrodeposit, 12 μm thick, on copper. Initial values are for electroplated sample before etching in 18% HCl. ■ Median contact resistance of 10 year old tin-nickel electrodeposit, 15 μm thick on brass. Probed at 100g with a hemispherically ended gold rod. Nine measurement at each time interval. The smallest and largest values are indicated at the ends of the vertical bars.

Figure 8 is a plot of contact resistance at 100g against time. The contact resistance of the freshly etched panel was in the range for clean metals, and increased steadily with time, approximating the value of the sample prior to etching in 1500 hr. The panel used for the contact resistance study was 3 months (*ca.* 2100 hr) old when etched.

Also shown is the contact resistance of a 10 year old sample of single phase tin-nickel 15 μm thick, plated on polished brass. Small differences in method of sample preparation probably account for its contact resistance being slightly lower than that of the 3 month old ("initial") sample of this study.

This trend of contact resistance is consistent with a mechanism of film growth which continues slowly, over a period of weeks, to some limiting value. The thickness has been estimated to be about 30Å by the electron spectroscopy for chemical analysis (ESCA) method combined with depth profiling and is believed to consist of tin oxide mixed with tin and nickel hydroxides (17). Adherent, compact films form a barrier between air and the metal, and grow at a diminishing rate with time, often following logarithmic kinetics near room temperature (18). The increase of contact resistance on aging parallels the increase in corrosion resistance of freshly plated tin-nickel, tin-nickel fracture surfaces, and tin-nickel whose passive surface oxide has been removed by mechanical wear, and occurs in the same time frame. Thus, development of full passivity to severe corrodents may take 30-60 days in air at room temperature (Table I), as long as it takes for contact resistance to reach a limiting value.

Conclusions

Tin-nickel and thin (porous) gold-plated tin-nickel electrodeposits on copper have earlier (4) been found to be corrosion resistant to a wide variety of synthetic polluted atmospheres. These findings apply to both the single phase SnNi material and to a multiphase mixture of SnNi, Ni_3Sn_4, and Ni_3Sn_2. The present work shows that this passivity is not an inherent characteristic of the material, but is due to a protective film on the tin-nickel surface which develops as the freshly plated deposit is aged in air. If this film is removed by wear or by chemical etching, it will spontaneously reform. A similar film forms on surfaces created by fracturing tin-nickel electrodeposits. In indoor environments, it may take approximately 1500 hr for the equilibrium film to be achieved. This film has the same

contact resistance characteristics as that on surfaces stored in the same environment much longer times.

The resistance to corrosion of tin-nickel and gold-plated tin-nickel increases with time of aging, but even in a few days after removing the passive film a large measure of the corrosion resistance of long aged tin-nickel is restored.

In this study wear was produced by scribing the samples with a sharply pointed diamond. This simulates the sliding action of an opposed contact of a hard material having sharp edges and possibly of loose foreign hard particles between the contacts which could contaminate the surface during handling. In conventional electrical contact applications with gold-plated tin-nickel, the mating member is a precious metal (usually gold or gold alloy) rounded contact generally having a much larger radius of curvature than the diamond. Adhesive wear with wiping contacts occurs in that case rather than the ploughing wear of these experiments. Contact lubricants can be used to reduce the severity of adhesive wear (19). The brittle fracture of tin-nickel observed in this work is not expected to occur at such conditions except at high loads with deformable substrates.

In testing for surface damage of gold-plated tin-nickel in sliding electric contact applications by exposure to corrosive gases such as HNO_3 vapor, evidence of wear-through of the gold layer to tin-nickel is dependent on the time between wear and exposure. That is, conventional "porosity tests" for wear, which are widely used for gold on corrodible substrates such as copper or nickel, can be misleading unless the self-healing characteristics of exposed tin-nickel surfaces are recognized.

Emission from Triplet State in Electrochemiluminescence of Pyrene at Low Temperatures

Takeshi Suminaga and Sohachiro Hayakawa

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo, Japan

ABSTRACT

The green emission from pyrene excimer has been observed usually in the electrochemiluminescence (ECL) of pyrene. The red emission, however, is observed additionally at low concentration. The ECL of pyrene at low concentration in dimethylformamide (DMF) is investigated at various temperatures between room temperature and −51°C. The red emission with a maximum about at 600 nm is observed predominantly at low temperature, and it has almost the same spectrum as the phosphorescence of pyrene. The current-potential curves and emission-potential curves are measured for these cases. The red ECL can be concluded to be the phosphorescence from the triplet state of pyrene and a probable mechanism is proposed for it.

The ECL of pyrene results mainly from the direct excimer formation via anion-cation annihilation (1-3). The ECL's of rubrene, perylene, and 9-10 diphenylanthracene are emitted from either the excited singlet state or excimer (4-5). Recently the possibility of the triplet-triplet annihilation was proposed (6) in the ECL's of the above-mentioned compounds. Nevertheless the emission from the excited triplet state to the ground state was hardly observed. Sano (7) reported that the red chemiluminescence in dimethylformamide was probably the phosphorescence of pyrene through comparison with the phosphorescence of pyrene in a rigid glass. Nakaharai (8) confirmed the

Key words: electrochemiluminescence, pyrene, triplet state.

prominence of red chemiluminescence having a maximum at 600 nm for solutions of lower concentration of pyrene. Though the emission was predicted to become stronger at lower temperatures (9), no work has been reported on the measurement of temperature effect for ECL of pyrene. The purpose of this work is to obtain some information on the mechanism of this red chemiluminescence of pyrene by measurements at low temperatures.

Experimental

Pyrene was recrystallized carefully from benzene solution. Tetra-n-butylammonium bromide (TBAB) to be used as a supporting electrolyte was recrystallized from ethyl-acetate solutions. The concentration of pyrene was 1 mM and that of TBAB was 10 mM in all experiments. The cell used for ECL measurement was made of Pyrex glass. A Pt disk (3 mm diam) was used as a working electrode and Ag wire was used as a reference electrode. The temperature of the cell was reduced by cooled N_2 gas through a Cu pipe which surrounded the cell. The temperature range for measurements was between room temperature and about −51°C and the solvent was frozen below −59°C. The emission intensity of ECL was measured with a Phillips 5-6 AVP photomultiplier through color filters, and the ECL spectrum was obtained by the use of OCLI rotational filters. The cyclic voltammograms and emission *vs.* potential curves were recorded on an X-Y recorder at various temperatures.

Results

The cyclic voltammogram of pyrene at low temperatures and the emission *vs.* potential curves from room temperature to −51°C are presented in Fig. 1. The former curves showed only slight changes as the temperature changed, and therefore only one curve is shown in the figure. As the temperature falls, the emission-potential curve separates into two parts, one of which is the emission at potentials below −2.8V (*vs.* Ag) (denoted by emission 1 hereafter) and the other of which appears at about 0V (emission 2).

As the temperature falls the emission 2 becomes stronger than that of 1, and the total emission intensity increases at first, reaches a maximum at about −30°C, and then decreases for lower temperatures. The dependence of the direction of the potential sweep is presented in Fig. 2.

No emission is observed in the case of anodic potential sweep. The emission can be observed only with the cathodic potential sweep and the emission intensity is independent of the anodic sweep before the cathodic sweep. Figure 3 shows the emission *vs.* potential curves in the case of a rectangular potential sweep. Figure 4 shows the ECL spectrum of pyrene at a low temperature. This is the spectrum of emission 1, and that of emission 2 cannot be observed.

But the shapes of emission *vs.* potential curves, measured through Toshiba glass filters VO-54 (cut off below 540 nm) and VR-60 (cut off below 600 nm), are almost the same and the intensity of the latter is about a half of the former.

This indicates that emission 2 has the same spectrum as that of the emission 1.

Discussion

The ECL of pyrene is considered mainly to result from the direct formation of excimer which gives a green emission spectrum with a maximum at about 480 nm. However, the red emission was observed at low concentration in this work and its spectrum has a maximum at about 600 nm. This emission may be concluded to be the phosphorescence from the triplet state of pyrene according to the following four reasons.

(*i*) In case the excited state is generated due to the anion-cation annihilation, the excited triplet state may be generated quite probably.

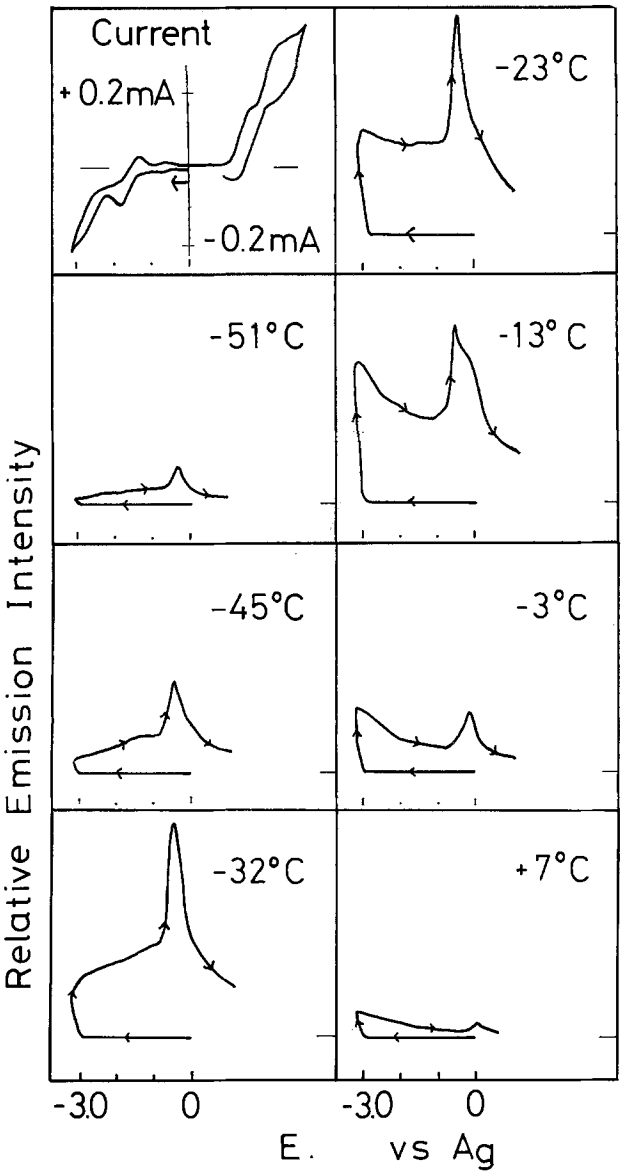

Fig. 1. Relation between the emission intensity and the applied triangular potential: pyrene 1 mM; TBAB 10 mM in DMF; scan rate 100 mV/sec.

(*ii*) The spectrum of red emission was found in the wavelength range from 570 to 660 nm with a maximum at about 600 nm which corresponded to the phosphorescence spectrum measured for pyrene in rigid glass by Hochstrasser (10).

(*iii*) No fluorescent material having a spectrum in the similar wavelength range (~600 nm) was observed after the electrolysis.

(*iv*) The strong emission observed in solutions with lower concentrations indicates that the triplet state of pyrene is not easily quenched at lower concentrations. It shows the case of pyrene to be somewhat like the case of rubrene in which both anion and cation radicals work as a quencher for the triplet state of rubrene.

Mechanism of emission.—The coexistence of anion and cation radicals of pyrene may be not necessary in the processes. Only existence of pyrene is necessary for the red emission because it can be observed only with the cathodic potential sweep.

Figure 3 shows that the relationship between the emission and the applied potential is independent of the electrolysis at −1.8V or +1.6V (in the region where anion or cation radicals of pyrene are produced) before the electrolysis at −3.0V. Then it is assumed that dianions of pyrene are produced at −3.0V. Two kinds

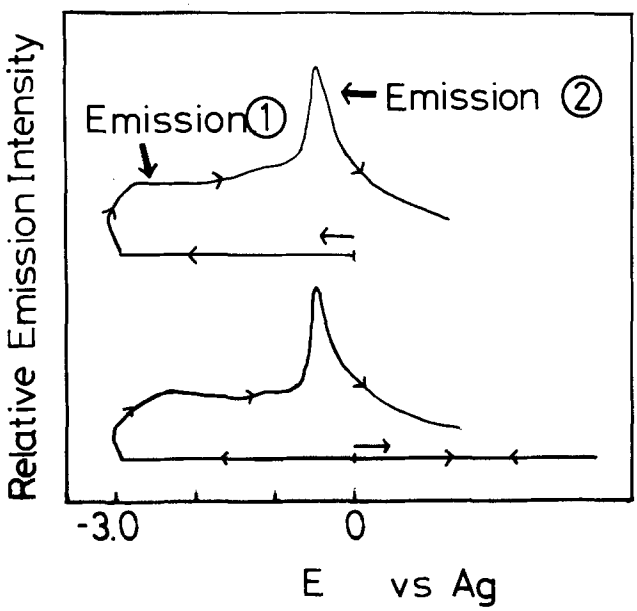

Fig. 2. Difference in the direction of potential sweep at −34°C; scan rate 100 mV/sec.

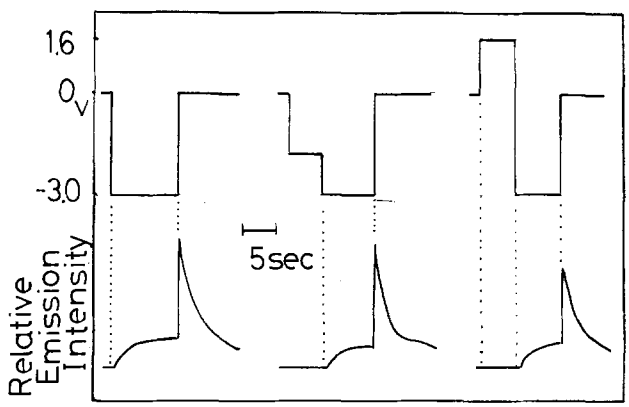

Fig. 3. Rectangular potential sweep electrolysis at −45°C

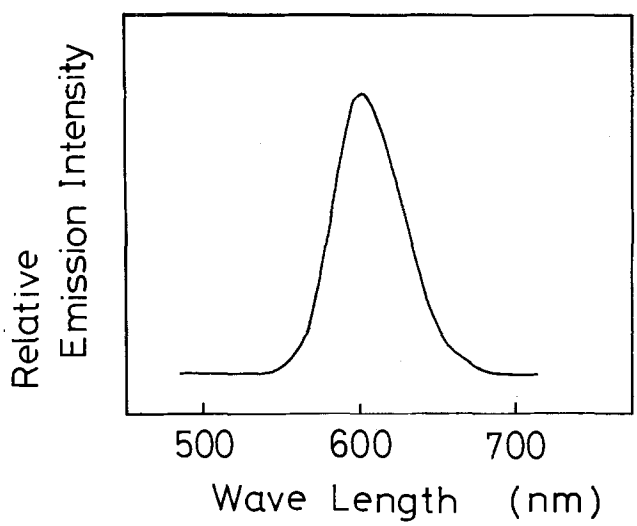

Fig. 4. ECL spectrum of pyrene in DMF at low temperature

of oxidants are proposed to exist because the cation radical of pyrene is apparently not useful as the oxidant for dianion of pyrene. One of them is produced depending on the potential and the other is not so. After the production of dianion of pyrene (P^{2-}) in the potential region near −3.0V, the following reaction occurs due to the first oxidant D

$$P + 2e^- \rightarrow P^{2-} \quad [1]$$

$$P^{2-} + 2D \xrightarrow{k_1} {}^3P^* + 2D^- \quad [2]$$

$$^3P^* \rightarrow P + h\nu \quad [3]$$

The emission in the reaction [3] is denoted by 1 in the figures. But in the region near 0V, another oxidant A reacts with the remaining P^{2-}. The reaction of [4] is estimated to be a rapid one with higher efficiency than the reaction [2]

$$P^{2-} + 2A \xrightarrow{k_2} {}^3P^* + 2A^- \quad [4]$$

$$^3P^* \rightarrow P + h\nu \quad [5]$$

The emission in the reaction [5] may correspond to emission 2 denoted in the figures.

Temperature effect.—As the temperature decreases, the peak of emission 2 becomes stronger than that of 1. This is explained in terms of increased viscosity and decreased rate constant k_1 in reaction [2]. The change of total emission intensity can be explained as follows. As the temperature becomes lower, the emission efficiency of $^3P^*$ increases but the rate constants k_1 and k_2 (reaction [4]) decrease. It, however, is acceptable that at first the former may give larger influence on the ECL than the latter but that next the latter may start to give larger influence than the former. Thus the total emission intensity may go through a maximum. Next the temperature effect of emission 2 will be considered on following reactions

$$P^{2-} + 2A \rightarrow {}^3P^* + 2A^-$$

$$^3P^* \xrightarrow{f_1} P + h\nu$$

$$^3P^* \xrightarrow{f_2\exp(-E/RT)} P \quad \text{(quenching process)}$$

$n(T)$ shows the concentration of $^3P^*$ at temperature T, the emission intensity $I(T)$ is given by

$$I(T) = \alpha n(T) \frac{f_1}{f_1 + f_2 \exp(-E/RT)}$$

$$I\infty = \alpha n\infty \quad \text{at large T}$$

$$\frac{I\infty}{I(T)} = \frac{n\infty}{n(T)} \left\{ 1 + \frac{f_2 \exp(-E/RT)}{f_1} \right\}$$

if $f_2 \exp(-E/RT) >> f_1$

$$\log I(T) = E/RT + \log n(T)/n\infty + \text{constant}$$

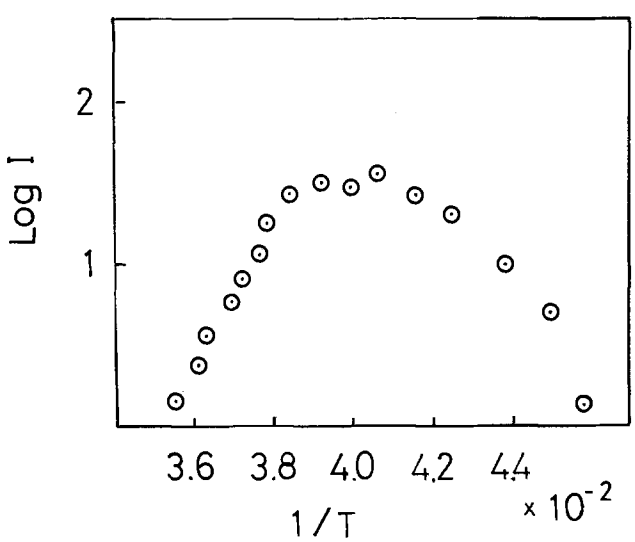

Fig. 5. Temperature effect of the emission 2

The effect of the second term of $1/T$ comes to be predominant at first and $I(T)$ increases as the temperature decreases. But that of the third logarithm term comes predominant in the lower temperature and $I(T)$ decreases through a maximum. The explanation may give temperature dependency like shown in Fig. 5.

Cerium and Terbium Luminescence in $ThOF_2$

A. M. J. H. Seuter and P. F. J. van den Boom

Philips Lighting Division, Eindhoven, The Netherlands

ABSTRACT

Under 254 nm excitation $ThOF_2$:Ce shows emission peaking at 313 nm with a quantum efficiency up to 70% at Ce contents of 20 a/o. On addition of Tb efficient Ce-Tb transfer is observed. The quantum efficiencies amount to 10% for Ce and 65% for Tb emission. The Ce-Tb energy transfer is discussed.

Efficient Ce and Tb luminescence has been reported in the compound CeF_3:Tb (1, 2). $ThOF_2$ crystallizes in the same hexagonal structure, the structure of tysonite (3). In this arrangement the cation has five equidistant anion neighbors and twelve cations as next nearest neighbors. In $ThOF_2$, the Th ions appear in two configurations. One has two oxygen and three fluorine neighbors, the other is surrounded by one oxygen and four fluorine ions. The present paper deals with the luminescence of Ce and Tb in $ThOF_2$.

Experimental

One mol analytical grade $Th(NO_3)_4 \cdot 5H_2O$ (Merck) and 7 mol NH_4HF (Riedel-de Haën) were fired at 650°C in an ambient atmosphere consisting of 98% nitrogen and 2% hydrogen. The procedure yielded white ThF_4 with hardly any $ThOF_2$ contamination.

The ThF_4 obtained was mixed with the amounts of ThO_2 (British Drug House), CeO_2, and Tb_4O_7 (Péchiney) required to obtain phosphors of compositions $Th_{1-x-y}Ce_xTb_yO_{1-x-y}F_{2+x+y}$. The mixtures were fired for 1 hr in an ambient of nitrogen and 1% hydrogen. The x-ray diagrams of the resulting white powders only showed the reflections of $ThOF_2$.

The optical experiments were performed as described previously (4).

Results and Discussion

Cerium activation.—Excitation, diffuse reflection, and emission spectra of $Th_{0.9}Ce_{0.1}O_{0.9}F_{2.1}$ at 300°K are shown in Fig. 1 and 2. The Ce emits with a band (48 nm) peaking at 313 nm. As long as charge compensation of Ce by F is maintained, the shape and position of the emission are hardly influenced at Ce contents between 1 and 40 atom percent (a/o). In contradistinction, a decrease in fluorine content yields both an excitation and emission shift to higher wavelengths (*e.g.*, $Th_{0.95}Ce_{0.05}OF_{1.90}$ peaks at 320 nm).

In comparison with phosphors such as LaF_3:Ce and CeF_3 (2), $ThOF_2$:Ce emits at lower energy. Apparently the influence of crystal fields on the Ce ion grows with increasing charge of the host lattice cations.

Key words: quantum efficiency, transfer mechanism, concentration quenching.

Usually Ce emission consists of a doublet due to the splitting of the ground state. In $ThOF_2$:Ce, however, only one emission band is observed, even at 77°K. Possibly the Ce ions occupy the two distinct cation sites in $ThOF_2$, thus obscuring observation of the emission-band splitting.

In Fig. 3 the quantum efficiency of $ThOF_2$:Ce is given as a function of the Ce concentration. The quantum efficiency first rises with increasing Ce concentration and is nearly constant above 20 a/o Ce. The lower quantum efficiencies at lower Ce concentrations are due to host lattice absorption. The constant value of the quantum efficiency at higher Ce concentration permits the conclusion that concentration quenching and energy transfer between Ce ions is not important. The latter conclusion is in agreement with the small overlap between emission and excitation bands.

Terbium activation sensitized by cerium.—Terbium can be excited directly into a broad band, due to a 4f-5d transition at the Tb ion (5). In $ThOF_2$ the position of this band is at high energy (>50 kK). For effective excitation at longer wavelength sensitization by Ce is required.

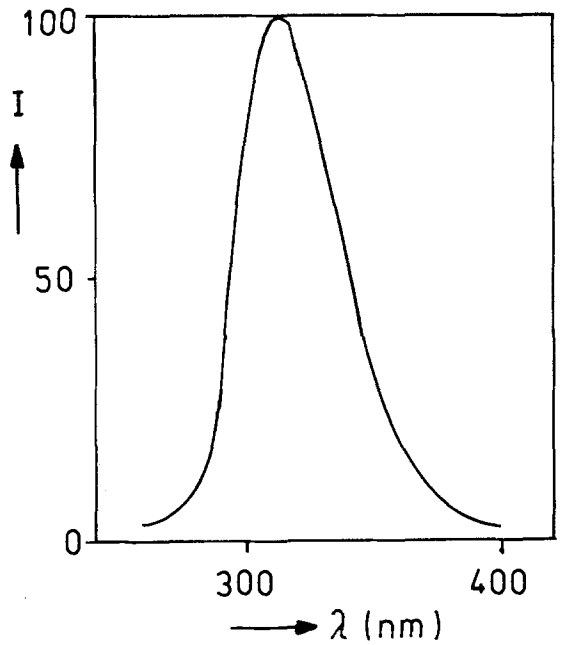

Fig. 2. Spectral energy distribution of the emission of $Th_{0.9}Ce_{0.1}O_{0.9}F_{2.1}$ under 254 nm excitation. I denotes the radiant power in arbitrary units.

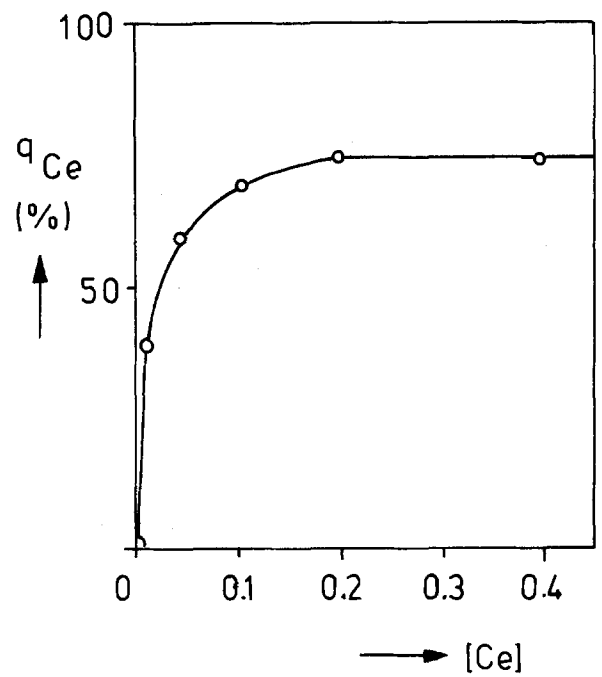

Fig. 3. Quantum efficiency of $ThOF_2$:Ce as a function of Ce concentrations.

Figures 4 and 5 show the terbium excitation spectrum and the emission spectrum of $Th_{0.7}Ce_{0.1}Tb_{0.2}O_{0.7}F_{2.3}$. There is a close similarity with the Ce excitation spectrum in $Th_{0.9}Ce_{0.1}O_{0.9}F_{2.1}$ (cf. Fig. 1), as must be expected in the case of energy transfer from Ce to Tb. The high energy part of the excitation spectrum is also observed in TbF_3 and must be ascribed to excitation in the broad band of Tb itself.

Table I gives the quantum efficiencies of Ce and Tb emission in $ThOF_2$ doped with 10 a/o Ce and various concentrations of Tb.

Mechanism of Ce-Tb transfer.—Because the Ce emission corresponds to an allowed electric dipole transition, we will only consider electric dipole-multipole interaction. To distinguish between the several possibilities (electric dipole-dipole, exchange, and electric dipole-quadrupole interaction) we will use arguments

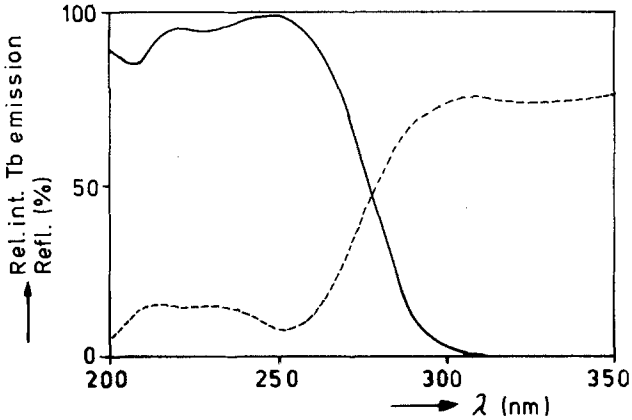

Fig. 4. Diffuse reflection (dashed) and excitation (solid) spectra of $Th_{0.7}Ce_{0.1}Tb_{0.2}O_{0.7}F_{2.3}$.

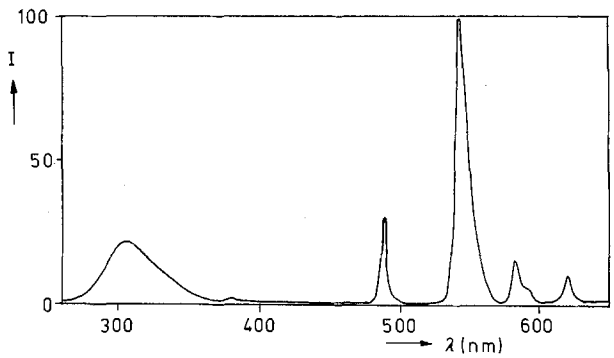

Fig. 5. Spectral energy distribution of the Ce and Tb emission in $Th_{0.7}Ce_{0.1}Tb_{0.2}O_{0.7}F_{2.3}$ under 254 nm excitation. I stands for the radiant power in arbitrary units.

similar to those considered by Verstegen *et al.* (6). Both Dy and Eu as activators in $ThOF_2$:Ce show less efficient energy transfer from Ce to the activator than Tb does. This is a strong indication that electric dipole-dipole and exchange interaction can be neglected. Therefore we assume that the energy transfer in $ThOF_2$:Ce,Tb results from an electric dipole-quadrupole interaction. Since these interactions are restricted to short distances, it may be expected that only nearest neighbor cations are involved in the energy transfer (7). Furthermore, the absence of concentration quenching in Ce-activated $ThOF_2$ led us to the conclusion that Ce-Ce transfer can be neglected. As a consequence, the energy from Ce to Tb is proportional to the fraction of Ce ions with at least one Tb ion as a nearest cation neighbor.

The fraction of Ce ions without Tb neighbors varies with the terbium concentration, (Tb), as $[1 - (Tb)]^{12}$, because every cation is surrounded by twelve cation neighbors at distances between 4.05 and 4.33Å. Hence, the fraction of Ce ions with at least one Tb ion as a nearest neighbor is $1 - [1 - (Tb)]^{12}$.

Assuming that the Tb emission varies proportionally with the fraction of Ce ions with at least one Tb ion neighbor, we obtain

$$q_{Tb} = q_{max}\,\alpha\{1 - [1 - (Tb)]^{12}\} \qquad [1]$$

where q_{Tb} stands for the quantum efficiency of the

Table I. Quantum efficiency of Ce and Tb emission (*viz.* q_{Ce} and q_{Tb})

x	q_{Ce} (%)	q_{Tb} (%)
0	70	—
0.05	39	30
0.10	27	49
0.20	12	64
0.30	8	61
0.40	9.5	60.5

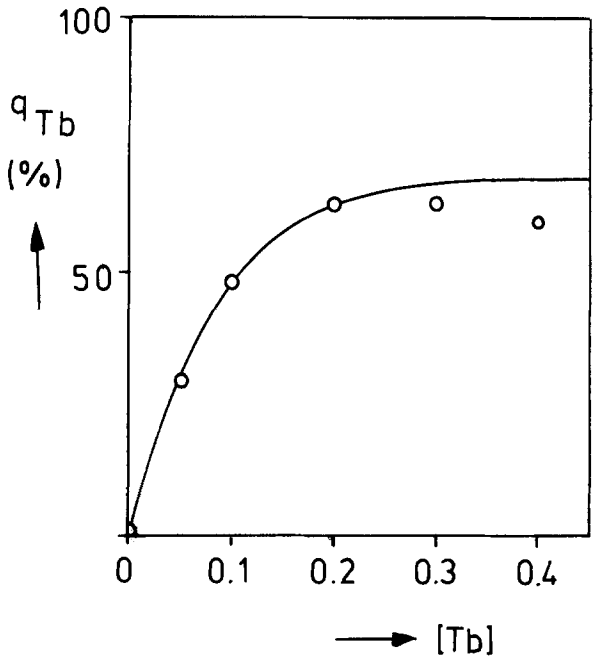

Fig. 6. Concentration dependence of the Tb quantum efficiency. The solid curve is obtained from Eq. [1]. The open data points refer to measurements.

Tb emission, q_{max} for the maximum quantum efficiency of the sum of Tb and Ce emission, and α for the probability of energy transfer from Ce to a Tb neighbor.

For a Tb concentration amounting to 0.2 the quantum efficiencies of Ce and Tb emission are 11 and 64% (cf. Table I). Hence we obtain for the probability factor

$$\alpha \approx 0.9$$

In Fig. 6 the quantum efficiency of the Tb emission, as calculated from Eq. [1], with $\alpha = 0.9$ and $q_{max} = 0.75$, is compared with the experimental results.

Sapphire Substrate Misorientation and SOS/MOS Transistor Performance

C. E. Weitzel* and R. T. Smith

RCA Corporation, RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Experimental data are presented which show that the crystalline perfection of silicon-on-sapphire epitaxial films as measured by x-ray diffractometry is dependent on both the magnitude and direction of misorientation of the {1$\bar{1}$02} sapphire substrate. Data obtained from SOS/MOS transistors indicate that devices fabricated in highly imperfect films have lower FET mobilities and exhibit leakage current asymmetry.

It has long been recognized that epitaxial {100} silicon films grown on {1$\bar{1}$02} sapphire substrates are subject to large stresses. This stress has been measured by various experiments to be on the order of 10^9-10^{10} dyne/cm^2 (1, 2). In all probability this stress results from both the difference in coefficient of linear expansion of the two materials (3) and the lattice mismatch between the {100} silicon and {1$\bar{1}$02} Al_2O_3 (4). The presence of this stress has a significant effect on the electrical properties of the SOS film. Carrier lifetimes in SOS films are much smaller than in bulk silicon wafers (5). The carrier mobility is somewhat smaller than that in bulk silicon and decreases the closer one gets to the silicon-substrate interface (6, 7). Moreover, a mobility anisotropy in SOS films (8) has been measured.

* Electrochemical Society Active Member.
Key words: x-ray diffractometry, θ:2θ half-width, FET mobility, leakage current.

A study of test transistor characteristics fabricated using the P+ polysilicon gate deep depletion process (9) indicated that there was considerable variation in device parameters for identically processed wafers. Assuming that the processing and epitaxial silicon growth were well enough controlled so as not to be the cause of such variations, a detailed study of the effect of substrate misorientation on SOS/MOS transistor parameters was begun. The initial results of this study are discussed in this report. The data to be presented show that the crystalline perfection of the silicon epitaxy, as measured by θ:2θ half-widths, is a function of the substrate misorientation. Moreover, there is a correlation between the crystalline perfection and SOS/MOS transistor parameters. Devices fabricated in highly imperfect epitaxial films have lower FET mobilities and exhibit source-drain leakage current asymmetry.

Experimental Techniques

The sapphire substrates used in this investigation were cut from EFG (Edge-Defined Film-Fed Growth) ribbon supplied by Tyco. The 1½ in. diam substrates were polished by Insaco, Incorporated. At the time these substrates were purchased state-of-the-art polishing techniques did not include a final Syton polish. Since a systematic investigation of substrate misorientation was planned, the misorientation of a large number of substrates was measured using x-ray Laue and diffractometry techniques.

Each wafer had a fiducial flat ground at 45° to an Al_2O_3 "a" axis lying in the plane of the wafer face. The projection of the Al_2O_3 "c" axis in the polished side of the wafer was determined relative to the ground fiducial flat by the back-reflection Laue method. Components of misorientation of the face of the wafers from the $\{1\bar{1}02\}$ were thus measured in orthogonal directions perpendicular and parallel to the projection of the c axis. The orthogonal components of misorientation were measured on a Siemens diffractometer equipped with a Siemens single crystal orienter, and using a Cu $K\alpha_1$ $\{1\bar{1}02\}$ reflection. Components of misorientation were read directly to an accuracy of ±0.02°.

From this pool of substrates groups of five substrates were selected to be processed together. In selecting the substrates for each group, care was taken to select substrates with widely varying misorientation so that any difference in transistor parameters would be obvious. Figure 1 shows the misorientation components of 25 of the substrates which were studied. The ordinate is the Al_2O_3 mirror plane and the abscissa is the a axis. A perfectly oriented wafer would be located at the origin of this graph. The solid circle gives the misorientation components of each wafer, and the arrow points in a direction perpendicular to the wafer flat. At the time the wafers were purchased, the orientation specification was 4.0° in any direction from $\{1\bar{1}02\}$. Only wafers No. 5 and 9 were outside of this specification. It is interesting to note that almost all of the substrates have an a axis component of misorientation greater than 1.0°. This is probably a result of the manner in which the ribbon was seeded.

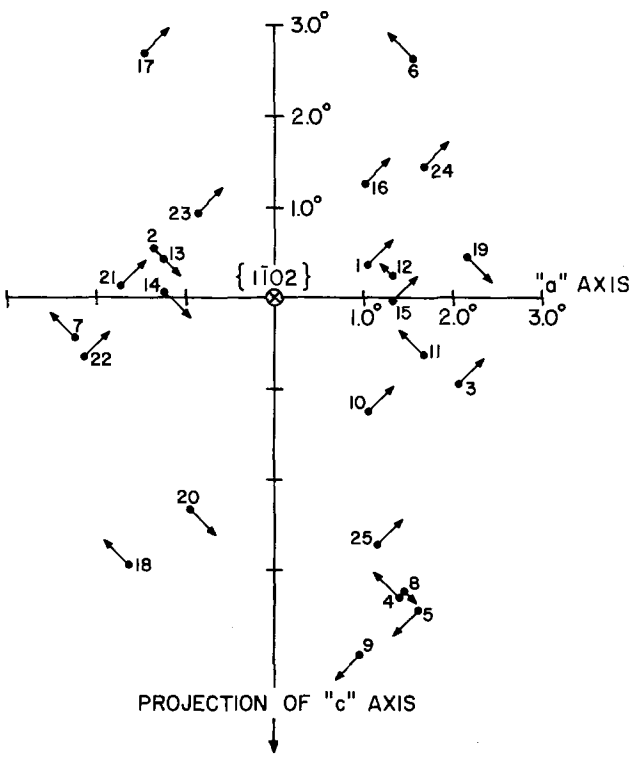

Fig. 1. Misorientation components of 25 EFG substrates. The arrow points in the direction perpendicular to the wafer flat.

Following characterization the substrates were fired in H_2 at 1200°C for 30 min. The epitaxial silicon films were grown on 5 substrates at a time in a 5 sided barrel reactor by the pyrolysis of SiH_4 at nominally 970°C. Nominally 0.6μ films were grown in 20 sec. Following epitaxial silicon growth, diffraction profiles were obtained from both the Al_2O_3 $\{2\bar{2}04\}$ and Si {400} in the rocking curve (ω scan) and θ:2θ modes. A Siemens ω drive diffractometer with Cu Kα radiation was used to record the peak profiles. The smallest entrance and receiving slits (0.125 mm; 0.05 mm) were used to minimize the instrumental broadening. Scanning speeds were ⅛°/min in the θ:2θ mode and ¼°/min in the ω mode. The crystal scanning-chart speed coupling gave a strip-chart recording sensitivity of 0.03125°/cm and 0.0625°/cm in the θ:2θ and ω modes, respectively. In the θ:2θ mode, one samples only from a set of parallel planes, and the broadening over instrumental may be caused by any crystalline defect causing nonuniformity in the d-spacing of these planes and/or small crystallite size effects. In the ω mode the detector is set at a fixed position centered within an angular range of 0.02° about the maximum diffracted intensity setting; hence any plane having a d-spacing characteristic of the angular setting of the detector may be sampled from as the crystal alone is rotated through its diffracting range. Broadening in this mode may be caused by relative misorientation of crystallites and/or sample curvature. Each sample was oriented such that its diffraction normal was in the plane of the diffractometer. This was accomplished by incrementally rotating the sample about its face normal and successively readjusting the crystal ω setting and detector 2θ setting to maximize the diffracted intensity. The correct setting is attained when ω reaches a maximum or minimum value.

Following characterization of the epitaxial silicon film, SOS/MOS transistors were fabricated using the P+ polysilicon gate deep depletion process (9). Briefly, the processing steps are; silicon island definition and etching, growth of 1200Å of channel oxide, polysilicon deposition, doping and etching, channel oxide self-aligned etch, doping of sources and drains from doped oxides, contacts, metallization, and overcoat. The process results in the fabrication of a n-channel deep depletion transistor and a p-channel enhancement mode transistor.

The FET mobility reported later in this report as the mobility for the wafer was arrived at by plotting the drain current *vs.* gate voltage with $V_D = 0.1V$. The test transistors were 12.56 mil wide with a source-drain spacing of 0.4 mil. With $V_D = 0.1V$, the device is operating in the so-called linear region of the MOS transistor characteristics. Theoretically, the drain current is related to the gate voltage by the equation

$$I_D = \frac{W}{L}\mu C_{ox}\left[(V_G - V_T)V_D - \frac{V_D^2}{2}\right] \qquad [1]$$

where I_D is the drain current, L the source-drain spacing, W the width of the transistor perpendicular to the direction of current flow, μ FET mobility, C_{ox} channel oxide capacitance, V_G gate voltage, V_T threshold voltage, and V_D drain voltage. The transconductance of the transistor is given by the slope of the I_D *vs.* V_G curve, or theoretically by

$$g_m = \frac{\delta I_D}{\delta V_G}\Bigg|_{V_D=\text{constant}} = \frac{W}{L}\mu C_{ox}V_D \qquad [2]$$

Using this equation and the experimentally determined slope, the FET mobility can be calculated. For all the data presented in this report, the transconductance was determined from the linear part of the curve where the g_m is maximum. For most devices this occurred in the 10-30 μA range, so the FET mobilities are for current

levels of about a μA/mil. The g_m decreases at large V_G because of increased surface scattering.

The threshold voltage and source-drain leakage current of test transistors across an entire wafer were measured using an automatic tester which is interfaced with a time-sharing computer system. The threshold voltage was measured by determining the voltage which when connected to the gate and drain caused 1 μA/mil to flow through the device. The leakage current was measured with the gate and source grounded with 10, 15, or 20V applied to the drain. The minimum measurable leakage current was 5 nA because of automatic tester noise.

Experimental Results

Substrate misorientation and silicon epitaxial perfection.—Of the four diffraction profiles obtained from each sample, the Si θ:2θ half-widths were found to have the greatest correlation to device performance. The Si ω scan half-widths paralleled those of the θ:2θ with some exceptions. It is thought that these exceptions are due to the dependence of the ω scan half-width on the direction of scan. Since each crystal was oriented so that it was scanned in the direction of misorientation and the orientation of each was different, a common scanning direction did not exist. Nonetheless, the θ:2θ half-widths remain a valid qualitative comparison of relative crystalline quality or perfection. In the following discussion we have chosen to compare device performance characteristics with the crystalline quality as obtained from θ:2θ scan half-widths.

Half-widths obtained from $\{22\bar{0}4\}$ θ:2θ scans of all the Al_2O_3 substrates were found to have a mean value of 0.0425° ± 0.0025°, while the {400} θ:2θ half-widths of Si deposited on these substrates ranged from 0.1170° to 0.2125°. The half-width of a {400} Cu $K\alpha_1$ reflection of bulk Si obtained with the same instrumental conditions was found to be 0.0500°. Thus it appears that the method was insensitive to any variations in the quality of the Al_2O_3 substrate, if present, while the θ:2θ half-widths of the epi Si were 2.34-4.25 times as large as those of bulk Si. Typical recorded diffraction profiles of the {400} Si reflection are shown in Fig. 2. Profiles of the least and most perfect SOS epitaxial layers are shown, Fig. 2c and 2b, respectively, and may be compared with the profile obtained from bulk Si, Fig. 2a. In the case of bulk Si, the $K\alpha_1$ and $K\alpha_2$ components are completely resolved, however, this is not true for the profiles of the SOS layers. There is enough resolution of the $K\alpha_1$ and $K\alpha_2$ components of the best layer to prevent asymmetric broadening of the $K\alpha_1$ component at half-maximum intensity. It can be seen that asymmetric broadening of the $K\alpha_1$ component of the worst layer does occur. Where asymmetric broadening was observed, only the low angle half of the $K\alpha_1$ component was measured and then doubled, thereby eliminating problems caused by asymmetrical broadening. Since the θ:2θ half-widths had the most relevance to device performance, these are plotted in Fig.

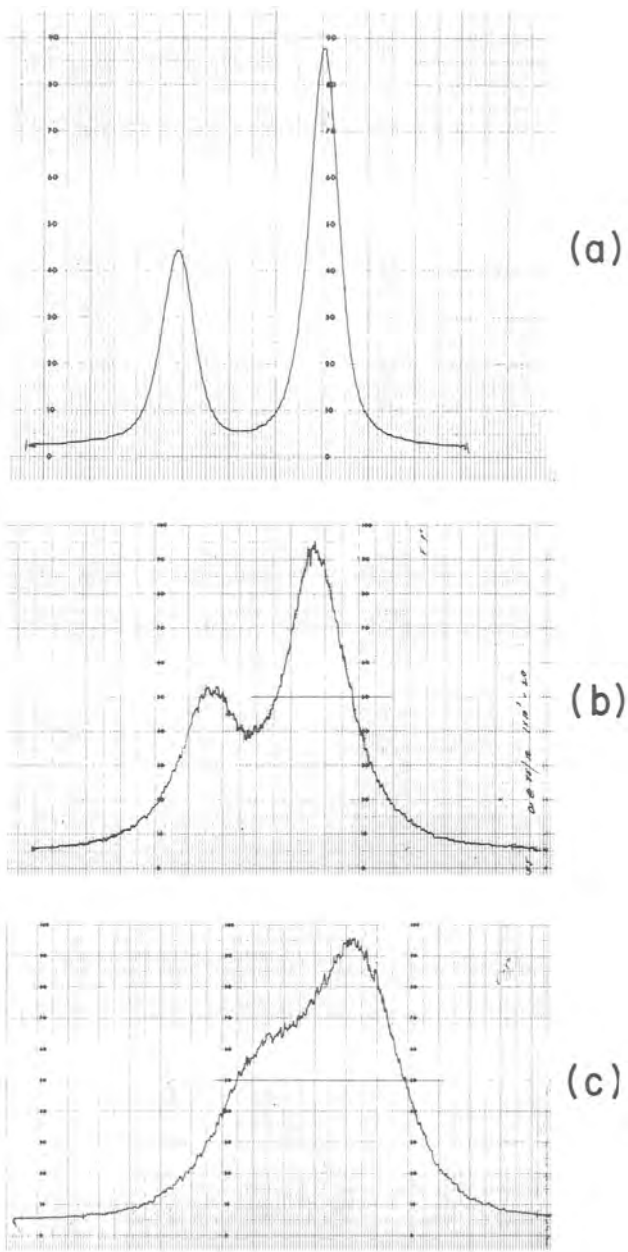

Fig. 2. Diffraction profiles of the {400} Si reflection for (a) bulk Si, (b) least imperfect SOS, and (c) highly imperfect SOS.

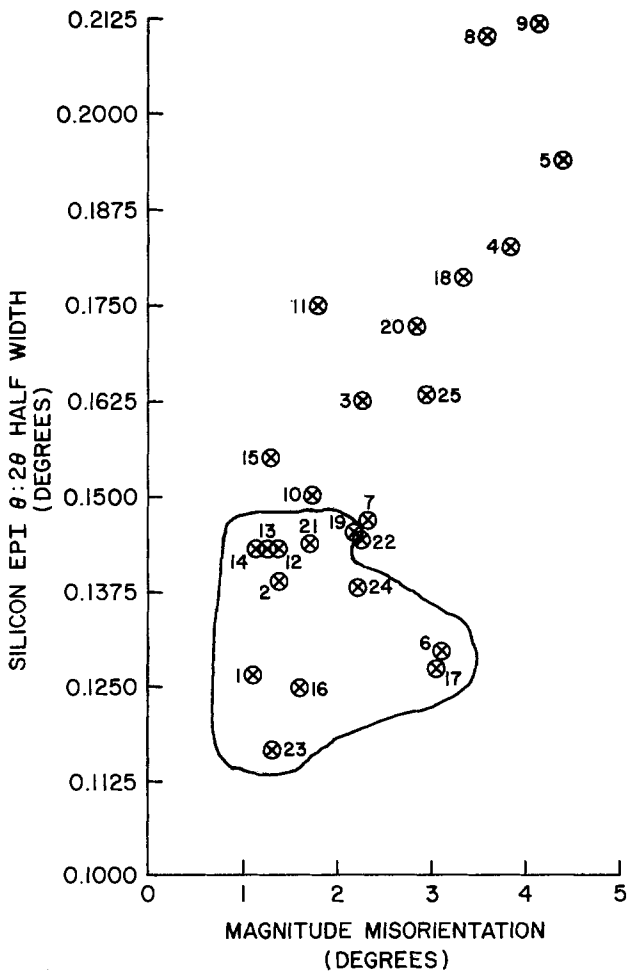

Fig. 3. θ:2θ half-width of silicon epitaxial film vs. the magnitude of misorientation of the substrate.

3 for the 25 wafers shown in Fig. 1. The $\theta:2\theta$ half-width (degrees) is plotted along the ordinate and the magnitude of misorientation (degrees) is plotted along the abscissa. The wafers are numbered the same in Fig. 1 and 3. The half-widths given for each sample are that of the $K\alpha_1$ components at half-maximum intensity corrected, when necessary, for broadening due to $K\alpha_1$-$K\alpha_2$ overlap.

After careful examination of the data presented in Fig. 1 and 3 one very interesting fact becomes obvious. Epitaxial silicon grown on wafers which are plotted in the top half plane of Fig. 1 has a lower $\theta:2\theta$ half-width than silicon grown on wafers plotted in the bottom half plane. By comparing the location of the numbered points in Fig. 1 with the data in Fig. 3, it can be seen that all of the data points in the top half plane of Fig. 1 are enclosed by the irregularly shaped solid line in Fig. 3. Therefore, with the exception of data point No. 22 every silicon film grown on a substrate misoriented in the top half plane of Fig. 1 is more perfect than every silicon film grown on a substrate misoriented in the bottom half plane. The data in Fig. 3 also show that as the magnitude of misorientation of substrates located in the bottom half plane increases so does the $\theta:2\theta$ half-width. This behavior is radically different from that of substrates located in the top half plane. For substrates removed farther and farther from the origin, half-widths do not increase. In fact, with the exception of data point No. 1, the five substrates with the smallest $\theta:2\theta$ half-width are located the farthest from the origin. These data indicate that the silicon epitaxial perfection is a function of a misorientation component which is parallel to the mirror plane. No correlation was found between the half-widths and the component of misorientation perpendicular to the mirror plane.

To examine this correlation more carefully, data from ten of these wafers are plotted, using a different format in Fig. 4. The $\theta:2\theta$ half-width is plotted on the abscissa and the component of misorientation which is parallel to the mirror plane is plotted on the ordinate. The data also show the wafers grouped together into 5 wafer lots for processing. The silicon epitaxial film was grown on these 5 wafers at the same time. The solid and dashed lines were drawn to connect data points in each lot. The data clearly show that as the component of substrate misorientation parallel to the mirror plane changes from large negative values to positive values, the $\theta:2\theta$ half-width decreases from over 0.18° to less than 0.14°. It is worth noting here that the half-width obtained from a bulk silicon wafer is typically 0.05° with the same x-ray diffraction parameters. Therefore, even the SOS films on substrates in the top half-plane have half-widths which are almost three times wider than typical bulk silicon. This larger half-width is an indication of the higher defect densities in SOS films than in bulk silicon. Some information on these defects is given by Abrahams and Buicchi (10).

Up to this point we have only established a correlation between substrate orientation and the $\theta:2\theta$ half-width of silicon-on sapphire epitaxial films thereon. If this were as far as the correlation went, this phenomenon would probably only be of scientific interest. As we shall see in the next section, however, this phenomenon significantly affects MOS transistor performance.

$\theta:2\theta$ half-width and FET mobility.—Since the $\theta:2\theta$ diffraction profile is a measure of the quality of the epitaxial film, one might intuitively feel that such a parameter would correlate with electrical parameters of the film which are also affected by film quality. This is indeed observed. The mobility of charge carriers is limited by scattering events. Therefore, the mobility of carriers in a more highly defected material would necessarily have to be smaller than in a more defect-free material.

This behavior is clearly illustrated in Fig. 5, where the FET mobility for n-channel deep depletion transistors and p-channel enhancement transistors is plotted against the $\theta:2\theta$ half-width of the silicon epitaxial film. The data show that the mobility in the accumulation layer of the n-channel device is reduced from 338 cm^2/V sec for a half-width of 0.130° to 155 cm^2/V sec for a half-width of 0.212°. The mobility in the inversion layer of the p-channel device decreases from 248 cm^2/V sec to 139 cm^2/V sec.

Threshold voltage data obtained from the automatic tester also agree with this correlation. Both n-channel and p-channel devices fabricated in highly defected epitaxial films had higher threshold voltages than devices fabricated in less imperfect SOS. Everything else being equal, devices fabricated in lower mobility material will need larger gate voltages to achieve a prespecified current level. It must be kept in mind,

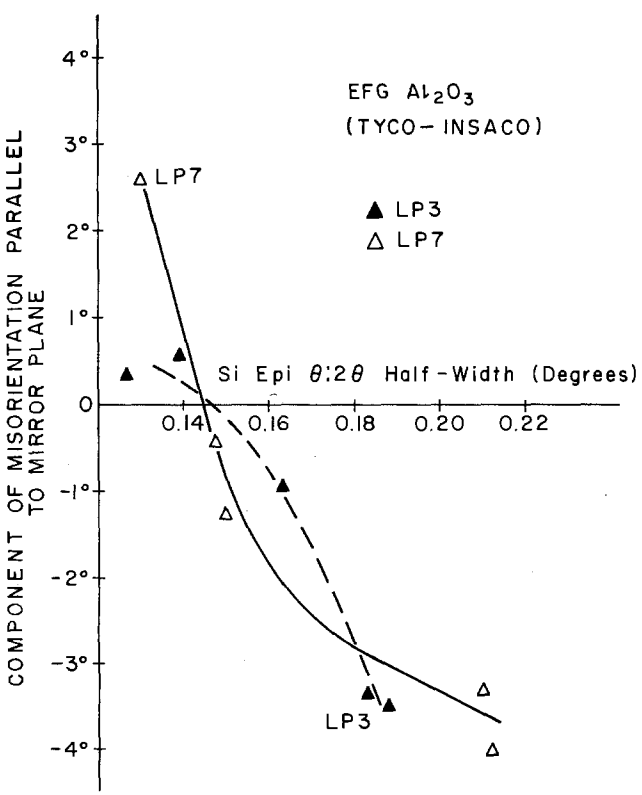

Fig. 4. Component of misorientation parallel to the mirror plane vs. $\theta:2\theta$ half-width of silicon epitaxial film.

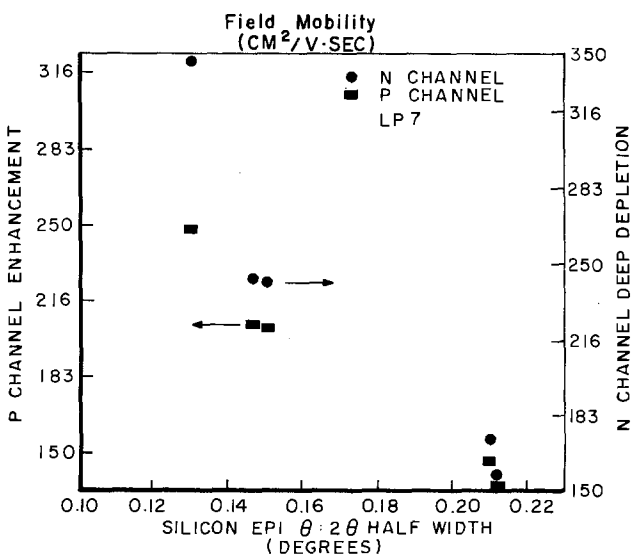

Fig. 5. FET mobility of n-channel deep depletion and p-channel enhancement transistors vs. $\theta:2\theta$ half-width of silicon epitaxial film.

however, that the threshold voltage is much more susceptable to processing variations than FET mobility. This is because the threshold voltage is strongly dependent on oxide charge and silicon film doping density. Nevertheless, the correlation between threshold voltage and substrate misorientation is observed.

Since the crystalline perfection correlates with misorientation direction and also with the FET mobility, the mobility must also correlate with misorientation direction. This is shown in Fig. 6 for processing lot LP3. In Fig. 6 the misorientation components for each substrate are plotted on a graph similar to Fig. 1. Next to each point is given the n-channel and p-channel FET mobility. Devices fabricated on substrates which are above the origin which in Fig. 3 have been shown to have lower defect concentrations have higher FET mobilities than devices fabricated on substrates which are located below the origin which have been shown to have higher defect concentrations.

A comparison of the respective device mobilities shown in Fig. 5 and 6 illustrate another phenomenon frequently observed with SOS/MOS transistors. Although the silicon epitaxial films for the two lots were grown under supposedly identical conditions and the processing of transistors was also done under identical conditions, the maximum FET mobilities are considerably different. In lot LP3 the maximum n-channel mobility is 407 cm^2/V sec, whereas the maximum p-channel mobility is 158 cm^2/V sec. On the other hand, in lot LP7 the maximum n-channel and p-channel mobility are 337 cm^2/V sec and 248 cm^2/V sec. Of course, the source of these variations could be process related, but it is also quite likely that these differences are caused by variation in the SOS film. These data have clearly shown that substrate orientation can have a significant effect on SOS film properties. However, there are probably many other unidentified parameters which also have a significant effect on the quality of silicon-on-sapphire films.

θ:2θ half-width and leakage current asymmetry.— Another anomalous phenomenon which the additional Si imperfection causes is source-drain leakage current asymmetry. Experimental data from test transistors fabricated in highly defective SOS films show that the leakage current from source to drain differs by orders of magnitude depending on which electrode is designated the source and drain. This is indeed anomalous behavior when one considers the symmetry of an MOS transistor. Figure 7 shows typical leakage current data from an n-channel deep depletion transistor fabricated in a highly imperfect SOS film. The leakage current is plotted on the ordinate using a log scale and the source-drain voltage is plotted on the abscissa also using a log scale. These data were taken from an SOS/MOS transistor 6.28 mil wide with a source-drain spacing of 0.4 mil. The gate electrode is grounded. In an MOS transistor biased in this way, the drain junction is reversed biased whereas the source junction is forward biased. The leakage current is primarily the result of the generation of carriers in the depletion region and also a result of junction breakdown. For source-drain voltages below about 2V, the leakage current through both junctions is the same. However, above this voltage the leakage current through the left-hand junction increases rapidly. 2V could, therefore, be called the threshold voltage for the change in current-voltage dependence. The threshold voltage for the right-hand junction, on the other hand, is about 8V. At $V_{SD} = 10V$ this 6V difference in threshold voltage results in over a three order of magnitude difference in leakage current through the two junctions of the same transistor. Defining the amount of junction asymmetry as the ratio of the larger current to the smaller current, the leakage current asymmetry at $V_{SD} = 10V$ is about 1750.

If this type of behavior was exhibited by only a few devices on a wafer and if on the average as many left-hand junctions as right-hand junctions had the lower threshold voltage, the cause of the asymmetry could be random defects. Data taken using the automatic tester, however, indicate that this is not the case. Data obtained from about 500 transistors of different

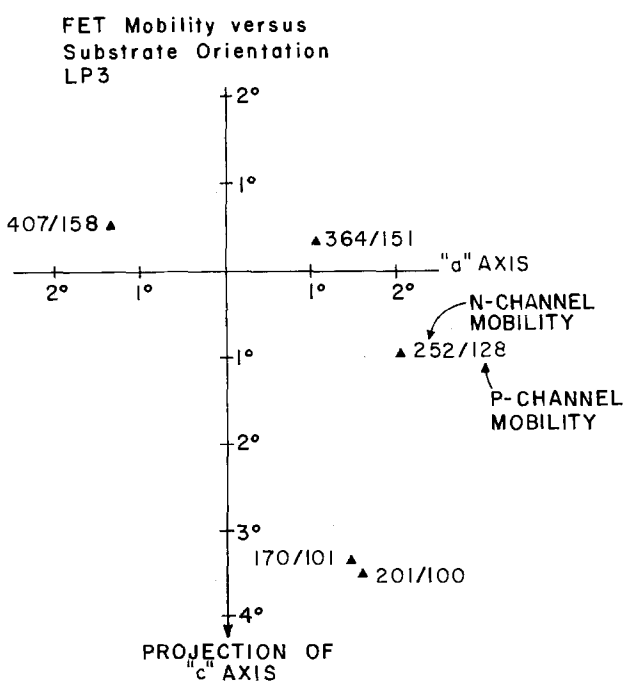

Fig. 6. FET mobility of n-channel deep depletion and p-channel enhancement transistors vs. components of substrate misorientation.

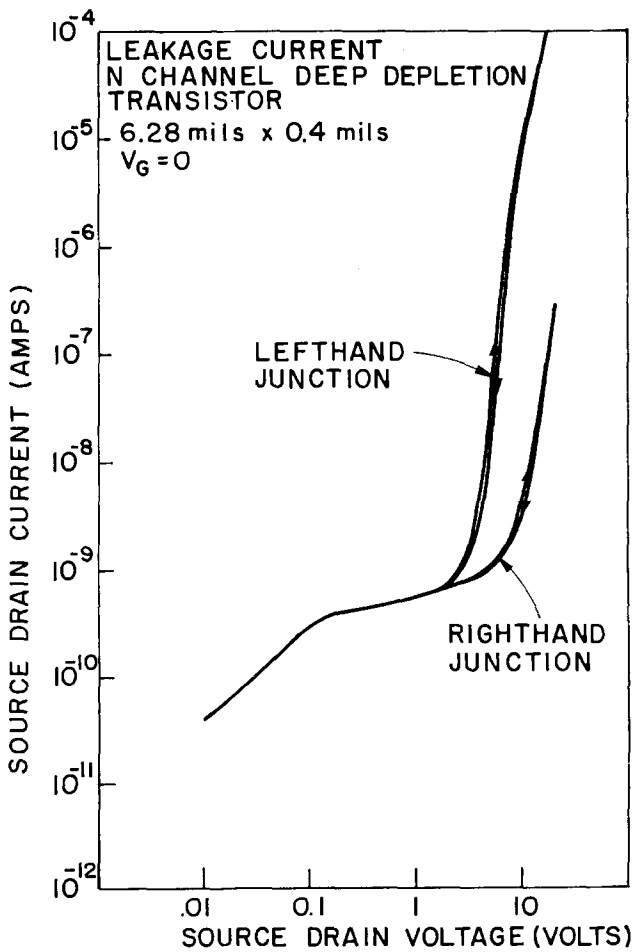

Fig. 7. Source-drain leakage current vs. source-drain voltage for both junctions of an SOS/MOS n-channel deep depletion transistor in highly imperfect SOS film.

sizes on a wafer indicate that over 95% of the devices have the same high leakage and low leakage junction. Moreover, this phenomenon has been observed on numerous wafers. It was also found that the junction which has the higher leakage current differs from wafer to wafer. A careful examination of data from devices fabricated in more and less perfect epitaxial SOS films from two 5 wafer processing lots indicated that the amount of leakage current asymmetry correlates with the $\theta:2\theta$ half-width. This correlation is shown by the data in Fig. 8. The $\theta:2\theta$ half-width is plotted along the abscissa and the junction asymmetry is plotted on the ordinate. The junction asymmetry was calculated by measuring the source-drain leakage current at 10, 15, and 20V of about 500 transistors on each wafer. The leakage current was measured through each transistor in both directions. The computer provided the geometric mean of the leakage current of all of the transistors at the three drain voltages of both possible device configurations. The asymmetry was calculated by dividing the geometric mean of the leakage current of one source-drain configuration by the geometric mean of the leakage current of the other source-drain configurations. These quotients for different size devices at different source-drain voltages were then averaged to give the junction asymmetry. The maximum asymmetry of 1000 was observed for n-channel deep depletion transistors on wafer D which also had the largest $\theta:2\theta$ half-width of 0.20°. P-channel devices on wafer D had a somewhat smaller asymmetry of 100. However, the functional dependence of asymmetry on $\theta:2\theta$ half-width was the same for p-channel transistors. As the $\theta:2\theta$ half-width decreases so does the junction asymmetry. Devices fabricated on wafers H, I, and J whose $\theta:2\theta$ half-widths are less than 0.14° exhibit essentially no asymmetry.

A large enough number of highly imperfect SOS wafers were examined to establish a correlation between the direction of the asymmetry and the direction of misorientation relative to the wafer flat. The graph in Fig. 9 shows the components of misorientation of highly imperfect SOS wafers from four proc-

essing lots. The magnitude of the asymmetry of devices on wafers A-G is shown in Fig. 8. The arrows in Fig. 9 point in a direction perpendicular to the wafer fiducial. When the wafers were processed, the SOS/MOS devices on all the wafers were laid out the same way relative to the wafer flat. The relationship between the wafer flat and the location of the source and drain of each transistor is shown by the insert in the lower left-hand corner of Fig. 9. The source-drain current of all the devices on all of the wafers is perpendicular to the wafer flat. This is equivalent to being parallel to the arrow which is perpendicular to the wafer flat. Thus, from a crystallographic standpoint the devices on wafers A and K are rotated by 180°. The data in Fig. 9 show that the low leakage junctions are also rotated by 180°. Moreover, this relationship between low and high leakage junctions and placement of the device junction relative to the wafer flat is consistent for all 10 wafers investigated. Wafers A, L, and F all have lower leakage junctions on the same side and opposite to that of wafers C, K, and M. The same is true of wafers D and E and wafers B and G. The data suggest that some property of the silicon epitaxial layer, possibly defects, is causing the asymmetry.

Discussion

Previous experimental results have clearly shown that the structural and electrical characteristics of silicon-on-sapphire films are dramatically different from bulk silicon (1-8). All of this anomalous behavior probably results from the difference in coefficient of linear expansion of the silicon and sapphire, and also the lattice mismatch between the {100} silicon and $\{1\bar{1}02\}$ Al_2O_3. The data presented in this report are the first evidence that the quality of the SOS film is also dependent on the orientation of the substrate. It should be emphasized that we are talking about small misorientation from the $\{1\bar{1}02\}$ axis. The current specification for Czochralski substrates is 2° in any direction from the $\{1\bar{1}02\}$ axis. The data show that silicon epitaxial films grown on substrates which are misoriented at opposite extremes of this specification along the mirror plane would have significantly different $\theta:2\theta$ half-widths. As a result SOS/MOS transistors fabricated in these films would have significantly different FET mobilities. More importantly SOS-integrated cir-

cuits fabricated on substrates misoriented at these two extremes would have different maximum operating frequencies. As a result, this observation of the dependence of film quality on substrate orientation is of practical importance. The data also imply that less variability between SOS films would be observed if the substrate orientation were specified about some point in the top half-plane of Fig. 1 rather than about the origin as is presently done. The location of this optimum point in the top half-plane of Fig. 1 is presently being sought. It should be kept in mind, however, that all of these observations were made using substrates grown by the EFG process. In addition, these substrates were not polished using a final Syton step. A study of state-of-the-art Czochralski substrates is presently underway. The results of this additional study are very important because they will indicate whether this phenomenon is dependent on the source of the sapphire or the polishing technique. If the study of Czochralski substrates yields the same results, we will be forced to conclude that this phenomenon is a result of the bonding interaction between the silicon and sapphire. This being the case, these observations are relevant to sapphire from all sources and maybe even to other insulating substrates.

Regardless of the outcome of additional experiments, however, these results clearly show the utility of the θ:2θ half-width measurement for characterizing the SOS film. Few techniques have been available for measuring film quality prior to device fabrication. The data presented here are the first direct correlation between preprocessing film quality and SOS/MOS device FET mobility. In terms of integrated circuit speed, FET mobility is a very important device parameter.

When one considers the symmetry of a MOS transistor, the asymmetry of leakage current through SOS/MOS transistors fabricated in highly defective epitaxial film is a unique effect. Before developing a model to explain this effect, it is necessary to understand the conduction mechanism of the leakage current in the high conductivity region. Since the leakage current of the left-hand junction in Fig. 7 is plotted on a pendence to another, in all probability the I-V characteristic is controlled by a mechanism which was not active below the threshold voltage. If the leakage current of the left-hand junction in Fig. 7 is plotted on a logarithm scale and the source-drain voltage is plotted as the square root of voltage $(V_{SD})^{1/2}$ the data points fall along a straight line. This fact is evidence that the conduction mechanism is Frenkel-Poole emission (11). For this conduction mechanism the current density J is related to the electric field E by the equation

$$J = J_o \exp\left(\frac{q}{kT}\sqrt{qE/\pi\epsilon}\right) \quad [3]$$

where J_o is the current density before the Frenkel-Poole conduction begins, q is the electronic charge, k is Boltzmann's constant, T is the absolute temperature, and ϵ is the permittivity of the material. Having identified a likely conduction mechanism, we can now speculate as to the cause of the junction asymmetry. Since at low fields the pre-Frenkel-Poole conduction current is symmetrical, the only parameter in Eq. [3] which could be asymmetrical is the electric field. Since the electric field which determines breakdown in thin film transistors is the field between the gate electrode and drain electrode, we must conclude that this field is different depending on which electrode is designated the source and drain. This could only occur if the diffusion profiles of the source and drain are different. A defect in the SOS film which propagates from the silicon-sapphire interface to the surface of the film could cause such asymmetrical diffusion profiles if it were inclined at some angle between 0° and 90° and if the density of defects in one direction exceeded the density in other directions. Such defects have actually been observed in SOS films (10). From a scientific standpoint this possible correlation between silicon film defects and MOS transistor leakage current asymmetry is very interesting. From a practical standpoint, however, devices should be fabricated in nearly perfect films to achieve maximum mobilities and as a result, no asymmetry will be observed, as shown by the data in Fig. 8.

Summary

Using x-ray diffraction techniques, a correlation between the quality of silicon-on-sapphire films and the misorientation of the {1$\bar{1}$02} substrates was found. The data clearly show that the θ:2θ half-widths of silicon films grown on substrates whose orientation differed by only a couple of degrees were significantly different. A correlation was also established between the θ:2θ half-width and SOS/MOS device performance. Devices fabricated in highly imperfect films had lower FET mobilities and exhibited source-drain leakage current asymmetry. It is proposed that the leakage current asymmetry results from the directional nature of defects in the SOS film. These observations establish x-ray line broadening studies as a valuable tool for characterizing preprocessed SOS films and also indicate that less variability in SOS film properties would result if the substrates were cut off axis in a specified direction.

Nondestructive, Reverse Decoration of Defects in IC Passivation Overcoats

Robert B. Comizzoli*

RCA Laboratories, Princeton, New Jersey 08540

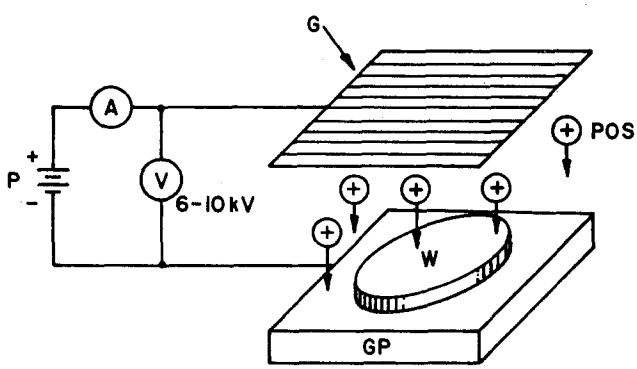
ABSTRACT

A new method for decoration and detection of defects in insulating films on semiconductor devices is described. The sample, which can be a wafer, chip, or opened packaged device, is first exposed to an atmospheric pressure, high voltage discharge (corona) of positive polarity. Then it is immersed in a suspension of carbon black in insulating liquid. Since the carbon black particles are negatively charged, they are attracted to and deposited on the positively charged insulating regions of the sample except at defects such as pinholes or cracks over metal. In this way a reverse decoration of defects is obtained which renders them clearly visible by microscopic observation. The sample can be cleaned and wafer probe testing shows that the procedure is not destructive. Various parameters of the process are discussed and the broad applicability of the process is indicated. The process is fast, simple, and sensitive.

The integrity of insulating passivation overcoats deposited on metallized integrated circuits (IC's) is important for device yield and reliability (1). Cracks and pinholes in the passivation overcoat can lead to various failure mechanisms (2-10). In this paper I report a new method for defect detection which is fast, simple, and nondestructive. The detection method has been principally applied to overmetal passivation layers of chemical vapor deposited (CVD) SiO_2 and phosphosilicate glass (PSG), but it is also applicable to primary insulating layers such as thermal oxide over silicon, and, indeed, to any thin insulator over a conductor.

Several techniques for the decoration of defects in insulating films on semiconductor devices have been reported. These methods, reviewed by Kern (11), include electrolytic metal decoration with copper anodes, electrophoretic decoration with copper colloidal particles from a copper anode, bubble formation by electrolysis, liquid crystal light scattering, and etching of underlying aluminum through the defects.

The bubble formation and liquid crystal techniques are "real time" methods in that the decoration exists only during the process implementation. The other methods, in contrast, result in a device or wafer which is permanently decorated and which can be examined after the decoration step. However, many of these latter techniques are destructive in that conductors are deposited which cannot be removed or device metal interconnects are removed by etching.



The decoration technique given in detail here was briefly described previously (12) and is one part of a larger study of new decoration methods for passivation overcoat layers (13-14). The reverse decoration technique is a two step process. In the first step, gaseous ions from an atmospheric pressure high voltage discharge (corona) are deposited on the insulating regions of the sample. Then the sample is immersed in a suspension of charged carbon black particles in an insulating liquid. The carbon black particles, of charge sign opposite to that of the ions on the insulator surfaces of the sample, are attracted to the insulator surface and deposited there, except at defects. Thus a uniform deposit of carbon is formed over the insulator surfaces except at defects such as cracks and pinholes. The defects and a halo region surrounding each defect are left bare, and their locations are easily observed microscopically. It is also possible to choose the sign of the corona ions to be the same as that of the carbon black. In this case a direct decoration (13-14) of defects is obtained which in most cases is less useful than the reverse decoration process described here. Some of the principles and methods are similar to those of electrophotography (15).

Corona-Charging Process

The first step for the reverse decoration process is the deposition of ions on the insulating regions of the sample as shown in Fig. 1.

Equipment.—The source of ions deposited on the sample is a plane array of 40 μm diam nickel alloy wires. This wire grid consists of seven parallel wires 1.8 cm apart held in an acrylic frame in a horizontal plane. The wires are commonly connected to a high voltage d-c power supply capable of $\pm$ 10,000V and 6 mA. It is recommended that only d-c power supplies with the step-up transformer operating at radio frequency and with current limitation of no more than 10 mA be used for operator safety. A grounded plate is placed 3 cm above the wires to provide greater current uniformity and to protect the wires from mechanical damage. The sample is placed on a grounded plate 2 cm below the wire array. The power

Fig. 1. Schematic of corona charging process

supply is operated from a foot switch. The process is carried out at relative humidity (RH) below 30% in a glove box in flowing nitrogen.

Parameter study of charging.—In order to understand the surface charge deposition process on device wafers, measurements of surface voltage of charged wafers were done as functions of sample geometry, passivating layer thickness, corona voltage, relative humidity, and corona wire-to-sample spacing. For these tests, IC wafers were not used because we wanted results to be independent of metallization patterns and bonding pad arrangements. To simulate an IC wafer, a square grid pattern was etched into thermal silicon dioxide on silicon, yielding a pattern of square islands of silicon dioxide surrounded by grid lines of bare silicon. Wafers with islands of different sizes and grid line widths were used.

Charging properties of wafers are studied by measuring the surface potential of the wafers after charging. This is done with an electrostatic voltmeter that uses a noncontacting probe with feedback to make absolute (independent of spacing) voltage measurements. The probe-to-wafer spacing is adjusted so that the geometry of the ground potential (bare silicon grid lines) and charged silicon dioxide islands is not resolved, to avoid lateral positioning errors. In this case, the probe detects an area average of the surface potential. In the following discussion the voltage values have been corrected to take into account the area ratios of charged insulator and ground potential silicon. Thus, the voltages plotted are those of the surface oxide of the square islands. All measurements were done in nitrogen ambient at RH = 25%.

The oxide surface voltage reaches a steady-state value within about 5 sec, when the corona charge is set just below sparking voltage. For lower voltages the time to steady state is greater. In the actual process used for decoration, the surface voltage reaches steady state in about 10 sec. The standard charging time used in the decoration process is set at 18 sec.

The magnitude of the oxide surface voltage at steady state depends mainly on the grid line geometry and is greater for higher ratios of oxide area to bare silicon area for a square geometry. This is shown in Fig. 2 where the oxide surface voltage, corrected for the area measurement effect, is plotted *vs.* the area of the oxide covered surface. There is little dependence on oxide thickness. This is shown in Fig. 3 for three oxide thicknesses of the same square geometry.

The observations indicate that the charging of a surface containing closely spaced insulator and conductor regions is limited mainly by the conducting areas. As the ions collect on the insulator they generate an electric field in the gas ambient which causes subsequent ions to move toward the ground potential regions before arriving at the insulator surface. Thus,

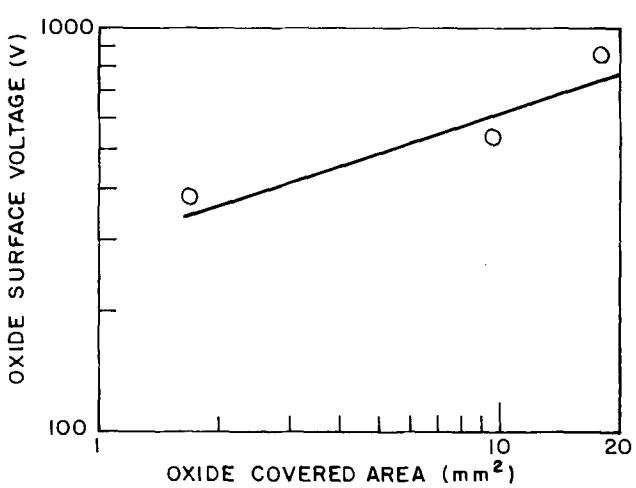

Fig. 2. Oxide surface voltage charged to saturation *vs.* area of oxide-covered surface. Oxide thickness is 10,000Å.

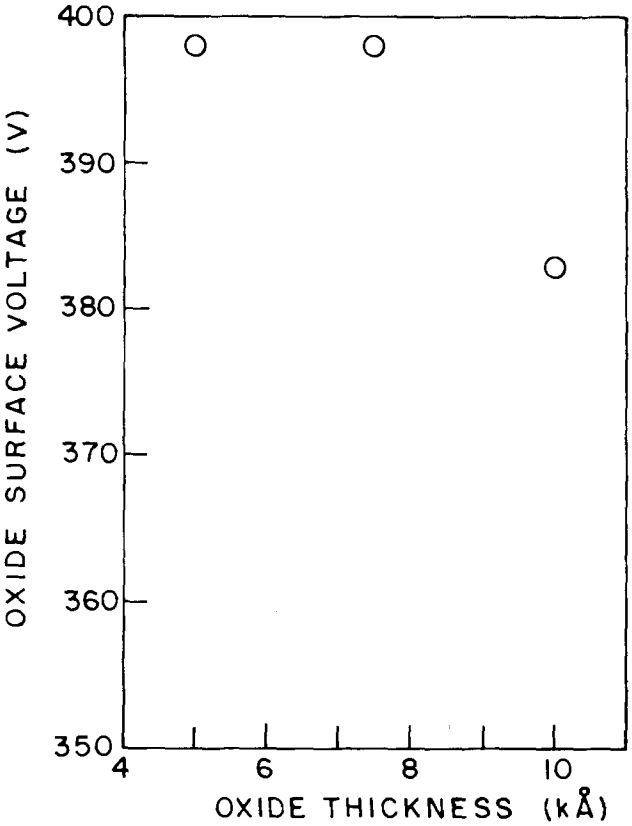

Fig. 3. Oxide surface voltage charged to saturation *vs.* oxide thickness for oxide-covered area of 1.7 mm².

for the geometries of interest, the oxide surface voltage is not determined by the oxide breakdown potential (except for very thin oxides or very large insulator areas).

Further support for the above is gained from the dependence of oxide steady-state voltage on corona voltage, shown in Fig. 4, and on corona wire-to-sample spacing, shown in Fig. 5. Based on the geometry-limited model of charging, the decrease in voltage for decreasing corona voltage or increasing spacing is related to deflection of incident ions from the charged oxide.

The ambient relative humidity must be controlled to prevent lateral current flow on the oxide surface.

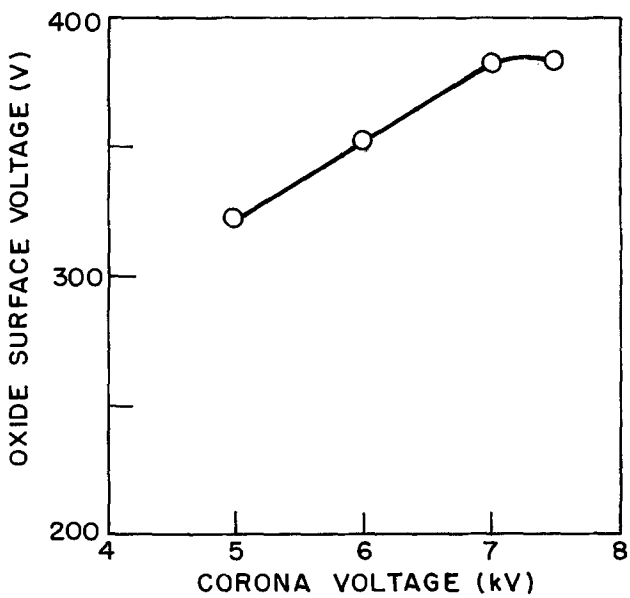

Fig. 4. Oxide surface voltage charged to saturation *vs.* voltage of corona wires for oxide 10,000Å thick and area of 1.7 mm².

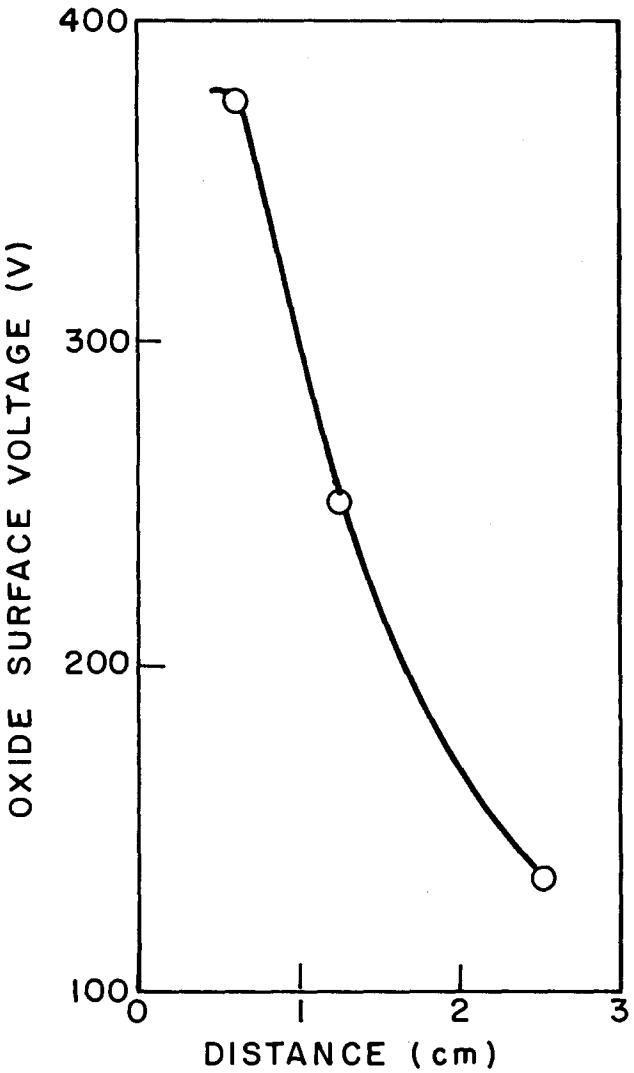

Fig. 5. Oxide surface voltage charged to saturation vs. distance from wafer to corona wires at 10 kV for oxide 10,000Å thick and area of 1.7 mm².

The oxide surface voltage decay rate after charging increases greatly above 30% RH for thermal silicon dioxide, CVD silicon dioxide, and CVD PSG, as shown in Fig. 6. The surface voltage will also decay rapidly if the bulk conductivity of the oxide is high due to the presence of moisture. Thus it is best to remove adsorbed or absorbed water before charging by heating at 200°C for 5 min in air. This has been made the first step in the standard process to ensure retention of surface charge on the sample.

The fact that the surface voltage of the sample insulator regions depends on the geometry of insulator and conductor regions is very important for the process implementation. Since the surface voltage depends on this geometry, it does not depend on the insulator thickness except for very thin insulators not used for passivation. Thus, the surface voltage is not set by insulator dielectric breakdown (except at latent or partial defects, as will be described later). If the surface voltage were set by dielectric breakdown the insulator regions over metal would have a lower voltage than those over the primary silicon oxide. In this case, a decoration conforming to the metal interconnects would result after charging and decoration. This is not normally desired for defect detection.

In the above discussion we have assumed that the sample is a chip or a wafer with the passivating layer etched open at the contact pads and at the grid lines. These etched-open regions furnish the closely spaced geometry of insulator-conductor required so that the surface voltage does not depend on whether the

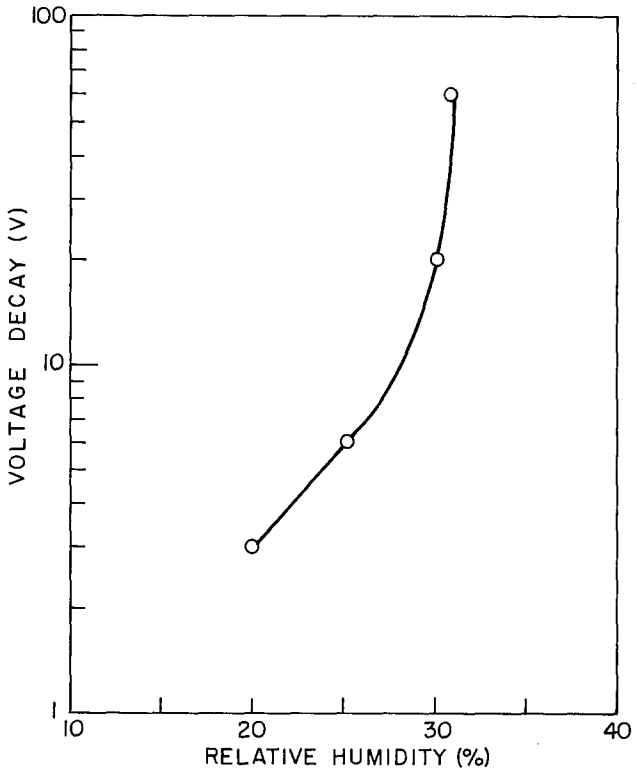

Fig. 6. Oxide surface voltage decay in first minute after charging vs. relative humidity.

passivating layer is over metal or over insulator. It is also possible to decorate wafers with a uniform insulator over metal (before the passivation layer is etched open). This can be done if a grounded conducting grid is placed over the wafer during the charging. A convenient grid consists of an aluminum sheet (0.8 mm thick) with 3.5 mm diam holes on 5.0 mm centers. This grid, placed over the wafer, furnishes the closely spaced insulator; conductor geometry required for the proper charging. When the grid is used, charge is deposited only at openings in the grid.

An important consequence of the charging properties is that the surface charge and potential around a defect decrease laterally as the defect is approached due to ion deflection during charging and to surface conduction. Thus, there is a smaller margin around a crack or pinhole of lower surface potential than around the potential in nondefect areas. This effect increases detectability since it magnifies the defects as far as charged particle deposition is concerned by providing a halo region free of carbon. The margin is of the order of 25 μm in lateral dimension.

For the process implementation it is necessary that the surface charge remain on the passivating layer for a time equal to the delay between charging and deposition plus the deposition time. This total time is about 20 sec, and it is required that the dielectric relaxation time of the passivation layer be about 20 sec or greater. Thus a bulk resistivity of about 10^{13} Ω cm or greater (at room temperature) is needed. By cooling the sample during charging and by the use of cooled particle suspensions it is possible to decorate defects on layers of lower resistivity.

Carbon Black Deposition

After the sample is charged it is immersed in a suspension of charged carbon black particles in an insulating liquid. The carbon black particles are of sign opposite to that of the surface charge and are thus deposited on the nondefect regions of the insulator, resulting in a reverse decoration, as shown in Fig. 7.

Suspension properties.—Various carbon black suspensions were tested which included commercially available electrophotographic toner concentrates and

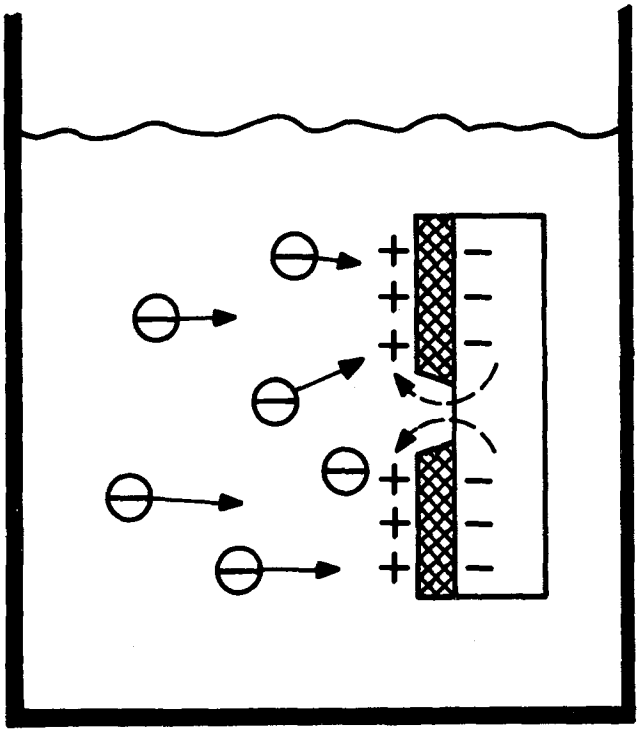

Fig. 7. Reverse decoration of defects after corona charging of insulator regions with ions of opposite sign to that of decorating particles in suspension. Dashed lines indicate forces on carbon particles at defect.

formulations prepared in our laboratory. Best results were obtained with a carbon black suspension (16) prepared in the following way. First a concentrate is made from: 17.0g Raven 1255 carbon black (Columbian Division, Cities Service Company); 100.0 ml toluene; 10.0 ml of 50g/50 ml toluene dilution of Lubrizol 894 (Lubrizol Corporation); and 10.0 ml of 50g/90 ml toluene dilution of AC Polyethylene-grade 430 (Allied Chemical). These ingredients are agitated for about 5 min with an ultrasonic probe at 100W power level to disperse the carbon black.

This concentrate is added at a proportion of 0.75 to 1.00 ml to 400 ml $C_2Cl_3F_3$ and stirred to produce the suspension. The concentrate and dilute suspension are stable for long periods (months). The carbon black in this suspension is negatively charged so that positive corona potentials are used for reverse decoration.

The materials used are readily available. The carbon black has an arithmetic mean particle diameter of 200Å and a nitrogen adsorption surface area of 130 m^2/g. The surface of the carbon black as supplied is acidic by addition of volatiles (17). Lubrizol 894 is an ashless dispersant additive for heavy-duty engine oils. Weight percent of nitrogen ranges from 1.65 to 1.95% (18). AC Polyethylene-grade 430 is a polyethylene-vinyl acetate copolymer (30% vinyl acetate). Its softening point is 60°C (19).

Measurements were conducted to characterize the electrical state of the carbon particles in the dilute suspension by depositing the carbon black on metal foils while recording the current, and then weighing the deposited carbon by difference. This was done as a function of applied voltage and time. The weight of carbon black deposited and the charge transported varied linearly with voltage and time. For electrode spacings of 1.7 cm on each side of a metal foil, an applied voltage of 100V for 4 min resulted in a deposition of 3.2×10^{-4}g carbon black per square centimeter. Tests such as these are convenient for monitoring the electrical properties of the suspension and ensuring reproducibility of these properties. Combined charge transport and weight measurements resulted in a charge per single carbon black particle of 5×10^{-2} electronic charge per particle, assuming all particles to be 200Å diam and singly dispersed. Since the minimum charge can be no less than 1 electronic charge per particle, the carbon black is not monodispersed but is aggregated at least by a factor of 20. Indeed, this aggregation is essential to obtaining dense black on the charged insulator surface since the surface charge after corona charging is only about 4×10^{11} electronic charges per square centimeter. This would result in somewhat less than monolayer coverage if the carbon were monodispersed with one electronic charge per particle. Actually, the layer deposited is many particles thick. Thick layers are an advantage since the optical density is saturated, and relatively large variations in thickness can be tolerated without affecting the percentage of light reflected.

The recommended ratio of 1 ml of the concentrate in 400 ml of $C_2Cl_3F_3$ results in a suspension containing 0.1g of carbon black; at least 10 IC wafers (75 mm diam) can be decorated with it.

Deposition Properties

The detection of cracks and pinholes is carried out quite conveniently by microscopic observation. An example is shown in Fig. 8. In this sample defects were deliberately induced by extreme heat-treatments not normally experienced in manufacturing or use. This was done with all samples shown here to generate high defect densities for purposes of illustration. Extensive comparison tests confirmed that every defect detected by etching (13,14) of the underlying aluminum through the defects was detected by the carbon black reverse decoration. This was done in two ways. Wafers and chips were decorated with carbon black, and photomicrographs were taken of crack and pinhole patterns. The carbon black was then removed and aluminum etching at 50°C for 5, 7, 10, and 15 min was done. The samples were again photomicrographed and the results compared. Hundreds of micrographs from many different sample types were compared and, in every case, all defects detected by etching were also clearly outlined by the carbon black. In the second method samples were decorated with carbon black and then aluminum etched with the carbon black in place. Again, the correlation was excellent. An example of the latter test is shown in Fig. 9, where the carbon black surrounds a pinhole defect in the passivation layer as confirmed by etching of the underlying aluminum.

Various carbon black suspensions have different voltage thresholds for deposition (20). The voltage threshold is that surface voltage on the insulator below which the carbon black will not deposit. For a given surface charge density, it is a function of the carbon black suspension and of the insulator properties. Since

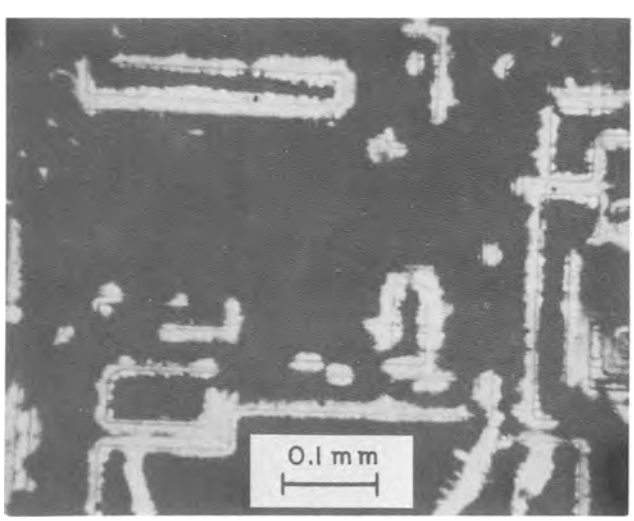

Fig. 8. Carbon black deposited on device to reverse decorate the defects. High contrast renders microscopic evaluation fast and sensitive.

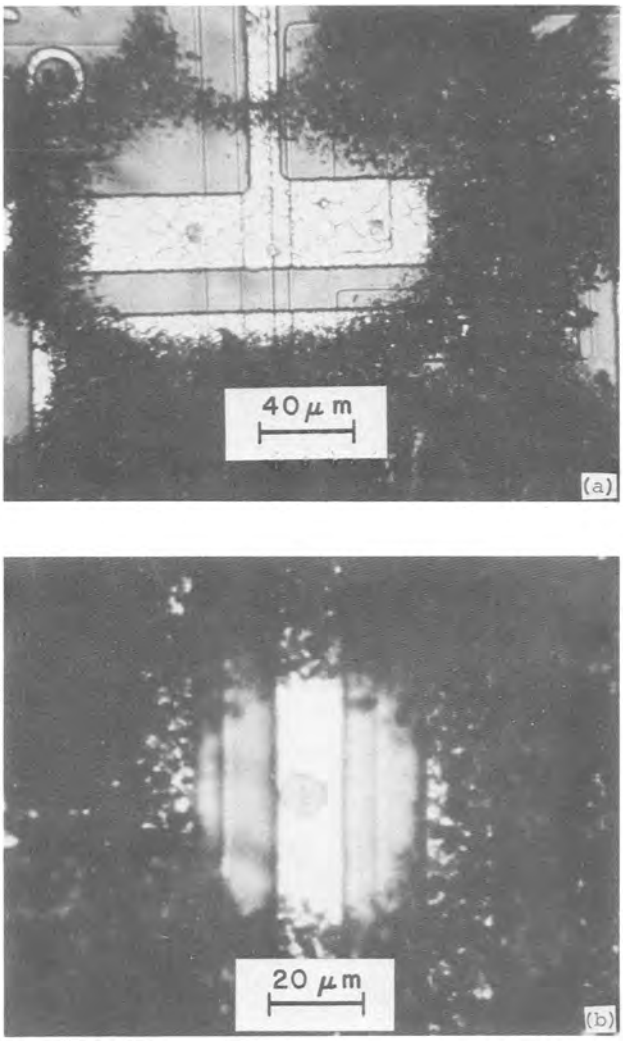

Fig. 9. Confirmation of defect detection by the reverse decoration method. Sample was aluminum etched at 50°C for 5 min without removing carbon black. Etched aluminum is seen as slightly darker circular area in the aluminum line.

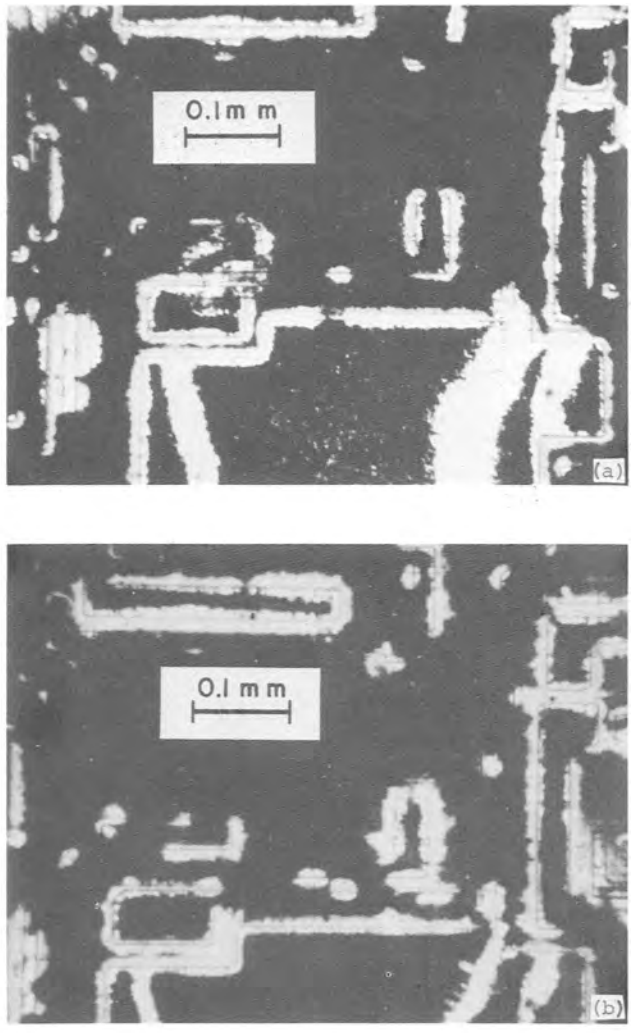

Fig. 10. Carbon black deposition with high threshold voltage in (a) compared to one with low threshold voltage in (b).

the surface voltage profile decreases to zero voltage radially around a pinhole, and laterally at a crack, a clear margin in which no carbon black is deposited is found around defects. The extent of this clear area or halo is a function of the threshold voltage for deposition and the surface conductivity. To avoid excessive width of clear areas a carbon black suspension formulated to have low threshold voltage was used, as described previously. This may be compared with a high threshold formulation in Fig. 10(a) and (b), where the differing margins are clearly evident.

As noted, the decrease in surface voltage near a defect leads to a clear margin around defects. Two effects contribute to the voltage decrease: (*i*) During charging ions are deflected to the defect area by the fringing fields; and (*ii*) finite surface conduction results in surface charge motion which modifies the charge distribution. At high corona potentials (10,000V) the ion deflection is a relatively small factor and, in this case, surface ion motion results in a nondeposited area which increases with time between charging and carbon deposition. For the lower voltage normally used (7000V) ion deflection effects are much greater, and in this case surface ion motion tends to shrink the nondeposited area for the first few seconds between charging and deposition. These effects are shown in Fig. 11(a), (b), and (c). In (a), deposited 4 sec after charging, there is a wide margin due to ion deflection during the charging. In (b), deposited 10 sec after charging, the margin has decreased due to surface ion motion. In (c), deposited 120 sec after charging, the margin has increased due to surface charge leaking off. Because of these effects a standard delay of 10 sec is used between the cessation of charging and the deposition of carbon black.

The width of clear, undeposited margin can be varied also by varying the temperature of the sample during charging and deposition. Using a thermoelectric cold plate, samples were cooled to −7°C during charging and then immersed in the carbon suspension held at −7°C. The defect margin was only about one third of that found for the same sample decorated at 23°C due to reduced surface conductivity.

Detection of partial pinholes is also possible with the reverse technique. Partial pinholes of 5000Å depth in 7000Å total thickness of thermally grown silicon oxide and 1.5 μm diam could be detected by heating the sample for 10 sec at 100°C between charging and deposition.

The reverse decoration process is very sensitive. Using this process, cracks induced by high temperatures were found in passivation glass at the edges of large aluminum areas on an IC. An example is shown in Fig. 12(a). The cracks shown by carbon black in Fig 12(a) were not seen before the heat-treatment. Thus they are not thin spots at the metal edge but are true cracks induced by heating. These cracks could not be detected by attempts to etch the underlying aluminum through the crack, nor were they detectable by scanning electron microscopy at 20,000X as shown in Fig. 12(b). Thus, carbon black reverse decoration can find defects not detectable by etching nor by SEM. When these samples were given a buffered hydrofluoric

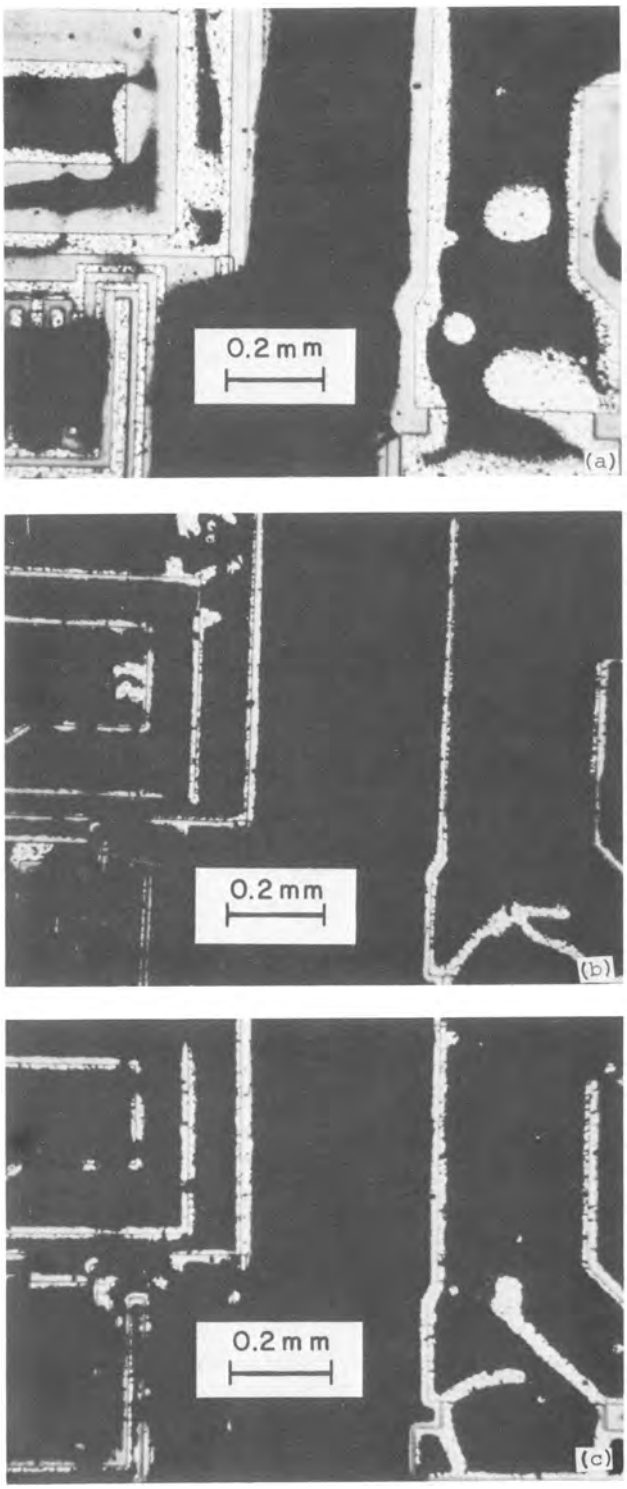

Fig. 11. Carbon black reverse decoration as function of time delay between charging and deposition. The time delays are (a) 4 sec, (b) 10 sec, (c) 120 sec.

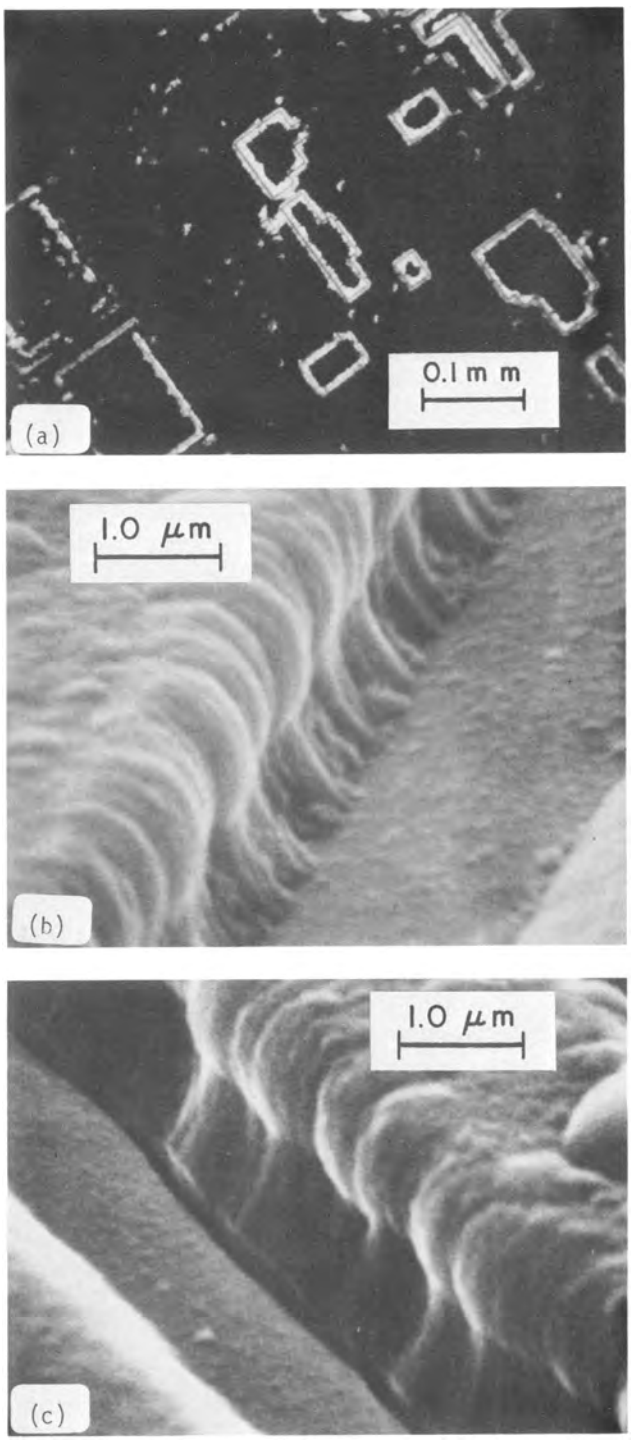

Fig. 12. Example of cracking at edges of large aluminum areas due to extreme heat-treatment. (a) Cracks outlined by carbon black; (b) SEM cannot detect cracks; (c) after 10 sec buffered hydrofluoric acid etching, the SEM does resolve the cracks.

acid etch for 10 sec, which widened the cracks to about 2000Å, it was possible to detect the cracks by aluminum etching and by SEM. The crack detected by SEM in Fig. 12(c) is at the lower edge of the passivation glass over the aluminum metal step. It should be noted that the cracking shown in Fig. 12(a) was exactly reproduced on every IC of an entire wafer. Many of these cracked regions were examined by SEM and no cracks could be detected until the sample was etched in buffered HF. After etching, the cracks as shown in Fig. 12(c) were visible at all edges of the aluminum areas as detected by the carbon black in Fig. 12(a).

Standard Process

The optimum procedure for sample decoration is summarized here: Dust and other particles should be removed from samples by blowing with clean air or by distilled water rinsing, followed by careful drying on a spinner or by rinsing in acetone and then in $C_2Cl_3F_3$.

It is required that the sample be grounded; thus, for wafers, it is sufficient to place the wafer on a grounded plate after ensuring that the reverse side is bare silicon. The normal native oxide is tolerable.

Chips are conveniently handled by fastening them to metal strips with conducting silver paste. Several can be processed at one time. For opened packaged devices,

the lead frame and wire bonds will normally act to connect the silicon to ground. If necessary, the ground connection can be made by painting conducting silver paste from the chip edge to some region of the package which can be grounded.

Samples should be baked at about 200°C for 5 min prior to corona charging. This is conveniently done on a hot plate for wafers and chips or in an oven for opened packaged devices.

The sample should be charged with positive corona for 18 sec with corona wires 2 cm from the sample at a wire potential of +7000V d-c. For wafers or wafer sections which do not have bond pads or grid lines etched open, a grounded grid must be placed over the sample during charging as described previously.

After a 10 sec delay wafers and chips are immersed for 12 sec and opened packaged devices for 6 sec in the carbon black suspension. The entire process is carried out in a glove box at RH $\lesssim$ 30%. The suspension is made from the concentrate described previously in the ratio of 1 ml concentrate to 400 ml $C_2Cl_3F_3$. After the sample is decorated and examined, the carbon black can be removed by ultrasonic agitation in toluene (13).

Nondestructiveness of Method

Several types of extensive tests were done to establish the nondestructive nature of the process. In one test, device wafers were aluminum etched to reveal pinholes. Then the wafers were exposed to the corona discharge at 10,000V d.c. for various times ranging up to 100 sec. After the corona discharge, aluminum etching revealed no new pinholes.

In a second test, a set of five device wafers was reverse decorated with carbon black, examined microscopically, and cleaned. This process was repeated five times. Only one wafer showed new defects (pinholes). These were found after the third carbon black deposition test. During cleaning, this wafer had been placed face down in the bottom of the ultrasonic tank, and it is believed that the mechanical contact caused these defects. Subsequent tests with the ultrasonic tank used in this manner did induce defects.

A third test involved automatic probe testing of CMOS wafers. These were chosen since it is known that CMOS devices are susceptible to static electrical damage. Two large (75 mm) CMOS device wafers were probed, and a map was made of good and bad devices. Then the wafers were charged, decorated, and cleaned. The wafers were probed again. One wafer showed a net loss of four devices out of about 130 good devices. The other wafer showed a net gain of five devices out of about 100 good devices. These variations are within the normal tolerance of repeated wafer probe testing.

In a fourth test, hermetically packaged CD 4007 devices were delidded and the threshold voltages and subthreshold leakage currents of the NMOS and PMOS devices were measured. The devices were then submitted to the decoration process and cleaned. Threshold voltages and leakage currents were measured again and no changes were found.

It is concluded that the process of corona charging and decoration is nondestructive. No life tests of decorated and cleaned devices were done, however. Thus, it may be possible to use decorated wafers for product, but an assessment of reliability by accelerated life testing is needed.

Feasibility Study of Automated Read-Out

A major advantage of the carbon black reverse decoration method is the high optical contrast available in reflected light microscopy. This permits a fairly simple form of automated quality assessment with a microscope-mounted photocell to measure the integrated light reflected from the defect areas. This technique is much simpler than the use of computer-implemented image analysis. The latter would provide a defect count, which the integrated reflected light method does not furnish. However, based on our feasibility study, it is believed that the simple method explored here could be used in a production facility to rank wafer quality and set a quality acceptance criterion.

A photocell microscope system was assembled to take direct readings of reflected light from decorated wafers. The arrangement used is shown schematically in Fig. 13. By placing a plano-convex lens of 57 mm focal length at the end of the camera tube, an image of the light source field stop was obtained about 6 cm from the end of the camera tube. This image, of uniform luminance, was placed on the photocell faceplate. The photocell employed an S-11 cathode and was operated at 100V. Light intensity was adjusted to give convenient current levels, and the over-all magnification was chosen so that a large portion of the circuit was visible, but bond pads and grid lines were excluded. Shielding prevented introduction of ambient light. Current readings were taken of each of 20 circuits of two wafers. For the "good" wafer, the lowest individual current was 2.9×10^{-9}A, the highest was 5.5×10^{-9}A, and the average was 3.5×10^{-9}A. For the "bad" wafer, the lowest current was 6.7×10^{-9}A, the highest was 1.5×10^{-8}A, and the average was 1.0×10^{-8}A. Pinhole counts on these wafers resulted in a difference of a factor of two in defect density. Thus, the photocell current measurement can easily detect a difference of a factor of two in pinhole density and is probably more sensitive than this.

Advantages of the Reverse Decoration-Carbon Black Method

In this section the relative advantages of the carbon black reverse decoration technique are summarized. In the discussion several unique advantages of the

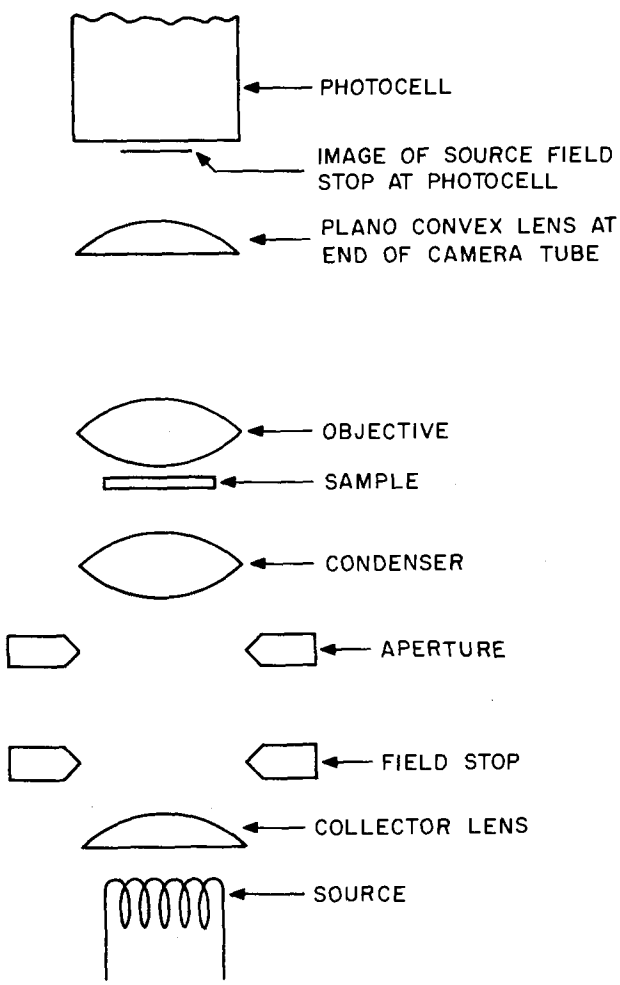

Fig. 13. Schematic of microscope use for obtaining image of source field stop at photocell for reflected light measurements.

corona-charging technique as used in the reverse decoration are pointed out. The use of the high voltage discharge, which initially appears to violate the normal rules for treatment of devices (particularly MOS type), is seen to be a definite advantage and to render the process actually nondestructive.

Speed.—In the standardized process the sample is charged for 18 sec, and after a 10 sec delay is immersed in the carbon black suspension for 6-12 sec. Thus the total decoration process time is, at most, about 40 sec. We do not include in this time the recommended 5 min, 200°C bake since this can be done in batch.

Simplicity.—The process is very simple and does not require precise positioning or delicate manipulations. The sample is placed on a platform for charging and then dipped into the carbon black suspension. The process thus shares the simplicity of chemical etching, with the added relaxation that the time of immersion in the liquid is constant for a wide range of samples, and does not depend on sample parameters.

Permanence of decoration.—Liquid crystal and bubble formation techniques (11) are real-time methods in that the decoration exists only during the process implementation. A photograph must be made for later examination. The carbon black decorated sample, however, has a permanent decoration and it may be set aside for future examination.

Nondestructive nature.—Tests by wafer probing showed no device loss after cleaning, as described previously. In methods which make use of voltages applied between electrodes and the sample in an electrolyte (11), as used in copper decoration, for example, there is the possibility of sample damage by high currents at dielectric weak spots. The corona-charging process in a dry ambient (RH $\lesssim$ 30%) is inherently nondestructive since corona potentials are well below sparking voltage and the corona has a very high impedance. Furthermore, any dielectric weak spot will discharge only the surface charge immediately surrounding it, and the stored energy is not great enough to cause any dielectric damage.

Avoidance of junction effects.—Decoration methods using electrolytes or other low resistivity liquids, such as alcohol or acetone, are limited by device junction effects. For example, a dielectric defect over a reverse-biased junction may not be detected or the deposition rate of decorating material may be slow. This effect can be overcome or moderated by illuminating the sample to induce photocurrents in reverse-biased junctions, but this may be difficult in some cases. For example, in the case of a large sample, as a wafer immersed in a decorating suspension of light-scattering particles, insufficient light may reach certain portions of the sample. On the other hand, the corona current impedance is so great that even reverse-biased junctions are sufficiently conducting that they do not interfere with charging effects.

High contrast.—The reverse decoration with carbon black provides a very high contrast when imaged in a microscope in reflection. This high contrast contributes to rapid evaluation of the relative quality of samples by the observer and, in addition, permits automated assessment by use of a photocell attachment to the microscope.

Ease of observation.—The reverse decoration process leaves the defect uncovered for easy examination by optical or electron microscopy. All other known processes result in direct decoration and the defect is covered or altered in some way.

Limitation.—The only fundamental limitation encountered thus far has been devices with regions of metal not connected to the semiconductor. This floating metal is brought to a high potential by the corona so that the metal is outlined with carbon black, but no defects can be detected over it. Thus, floating gates on some memory devices would not decorate properly if the device were examined at a stage of processing before the overlying metal is deposited. The other regions of the sample could be successfully decorated, however. After the device is completed and the second metal covers the floating gate, then it is possible, of course, to decorate the device in the standard manner.

Conclusion

A simple, nondestructive technique for detection of defects in insulating passivation layers on IC's has been described. It is useful for process research and control since it is very sensitive and results in a high contrast decorated sample. Because of the reverse nature of the decoration, the defect is left exposed for examination. Since the method is nondestructive, the carbon black can be removed and a process sequence can be evaluated at various stages with the same sample. The method holds promise as a production monitoring tool since it is nondestructive and since automated defect assessment is possible.

The principal application of this decoration process, thus far, has been that of detecting defects in and optimizing processing conditions of CVD SiO_2 and PSG passivation layers. In addition, defects in thermal SiO_2, including gate oxides, can be detected. Pinholes in photoresist and other polymer layers have been found using this method. Cracks and pinholes in protective glass coatings on steel plates also can be readily detected.

Acknowledgments

This work was one phase of a larger contract study of which Werner Kern was project scientist. For his advice and careful manuscript review I am very grateful. George L. Schnable made many important suggestions throughout this effort. Ruth Allen did most of the processing and experimental work, and C. Edward Tracy confirmed the carbon black defect detection by using etching techniques. A. Wayne Fisher, Leon Greenberg, Eugene Jordan, and Robert Vibronek supplied samples and I am grateful to them and to Gerald S. Lozier for useful discussions. Also, K. Schlesier assisted in some measurements.

The research contained in this report was partially supported by the Advanced Research Projects Agency, Order 2397, through the National Bureau of Standards Semiconductor Technology Program, Contract 5-35913, and RCA Laboratories, Princeton, New Jersey.

Manuscript submitted Dec. 2, 1976; revised manuscript received March 21, 1977. This was Paper 434 presented at the Washington, D.C., Meeting of the Society, May 2-7, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

Publication costs of this article were assisted by RCA Laboratories.

Morphology and Transport Rates of Mixed IV-VI Compounds in Micro-Gravity

H. Wiedemeier, H. Sadeek, F. C. Klaessig, M. Norek, and R. Santandrea

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

The positive effects of micro-gravity on crystal growth and basic properties of the vapor transport reaction were established by analyzing the results of three transport experiments of multicomponent systems performed during the Apollo-Soyuz mission. The systems employed were $GeSe_{0.99}Te_{0.01}$-GeI_4 (A), $GeS_{0.98}Se_{0.02}$-$GeCl_4$ (B), and GeS-$GeCl_4$-Ar (C). The crystallographic analysis is based on a direct comparison of space- and earth-grown (prototype) crystals, employing x-ray diffraction, microprobe, microscopic, and chemical etching techniques. The results demonstrate a considerable improvement of the space-grown crystals in terms of chemical and crystalline homogeneity, surface morphology, and bulk perfection relative to earth specimens. The confirmation of greater mass transport rates than predicted for diffusion-controlled transport in micro-gravity suggests the existence of "thermochemically" induced convective motion in chemical vapor transport systems. The morphological observations indicate, that the presence of different convective components yields turbulence which adversely affects crystal quality as observed on earth. The internal consistency and agreement between our ASTP and Skylab results obtained for several compounds, transport agents, and temperature gradients strongly support the validity of these observations.

Present models of chemical vapor transport (1) in closed ampuls predict that mass transfer via the gas phase is diffusion controlled at lower system pressures and occurs by convection at higher pressures. Crystal growth studies on MnS, MnSe (2), and on CdSe (3) indicate the effects of tube treatment, transport rate (2), and of transport mode (3) on crystal morphology. Systematic mass transport rate studies on the systems GeTe (4) and GeSe (5) demonstrated distinct changes in growth habit as a function of transport mode and a decrease in crystalline perfection with increasing convective contribution to the transport process. Analogous studies of other IV-VI and II-VI compounds in our laboratory reveal similar results. Based on the above observations it was predicted that crystals of improved quality could be grown in the absence of convective interference in a micro-gravity environment. The results of our transport studies on GeSe and GeTe performed on Skylab (6) demonstrate a considerable improvement in crystal morphology relative to corresponding ground specimens. In addition, the mass transport rates observed in space (6) are significantly greater than expected for a diffusion-controlled transport process.

In view of the unexpected mass flux results (6), an extension of these studies to modified systems and experimental conditions was desirable. The primary objectives of the present Apollo-Soyuz space experiments were to confirm the improved crystal morphology and the flux results observed previously (6), to extend these findings to mixed systems, and to further elucidate the cause of the higher transport rates (6).

Key words: chemical vapor transport, Ge-chalcogenides, micro-gravity.

For this purpose, three transport experiments on the systems $GeSe_{0.99}Te_{0.01}$-GeI_4 (A), $GeS_{0.98}Se_{0.02}$-$GeCl_4$ (B), and GeS-$GeCl_4$-Ar (C) were performed during the Apollo-Soyuz Test Program (ASTP). The definition of experimental conditions to meet the above objectives within the technical constraints on ASTP is based on extensive ground studies on these systems. The results of the latter studies in terms of mass flux *vs.* transport agent pressure are shown in Fig. 1. The pressures are for GeI_4 and $GeCl_4$ calculated at the mean temperature of the gradient assuming the ideal gas law. The flux curves reveal the diffusion-controlled transport regime at lower pressures (decreasing flux with increasing pressure) and convection-controlled transport at higher pressures (increase in flux with increasing pressure) (5). Further details are discussed below in connection with the flux results. The analysis of the space experiments is based on a direct comparison of crystal morphology and mass transport rates obtained on earth and in space.

Experimental Procedures

Apparatus.—The transport experiments on Apollo-Soyuz were performed in the multipurpose electric furnace which has been described previously (6). The three transport ampuls enclosed in separate metal cartridges were heated simultaneously in the reaction cavities of the furnace. The temperature gradient employed was 604° → 507°C with an isothermal region of about 1.5 cm length in the hot zone followed by a nearly linear gradient toward the cold end of the ampul. The same temperature gradient and profile were used in the prototype furnace for comparative ground-based studies.

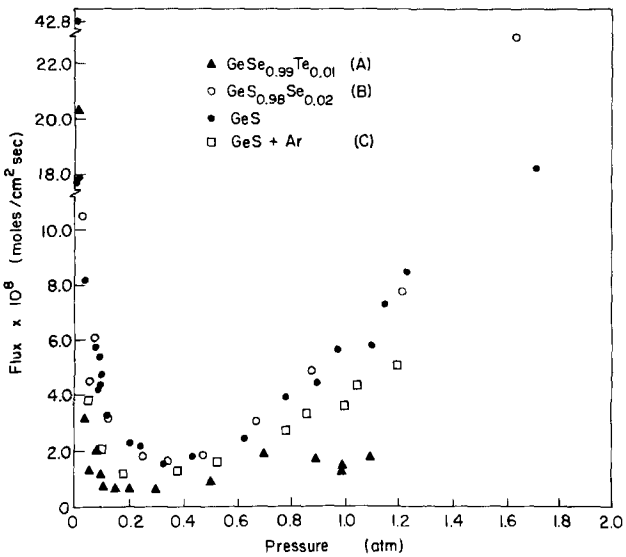

Fig. 1. Mass transport rates in terms of flux vs. pressure of transport agent for the temperature gradient 604° → 507°C determined under ground-based conditions. Transport agent for system A: GeI_4(g); for systems B, C, and GeS:$GeCl_4$(g).

Ampul and sample preparation.—The transport ampuls were made of fused silica tubing of 13.7 mm inner diameter and 150 mm in length. Close to the rounded end the ampuls contained two thin silica rods to prevent the source material from moving throughout the tube. The pretreatment, loading, and sealing procedures of the ampul have been discussed before (2). The polycrystalline starting materials were synthesized by repeated annealing at about 600°C of the appropriate stoichiometric mixtures of the binary compounds GeS, GeSe, and GeTe. The latter ones were prepared from high purity elements (99.999%) by annealing and subsequent sublimation of the products (5). Their crystallographic identity was established by x-ray diffraction techniques, and lattice parameters agreed with literature values for GeS (7), GeSe (8), and GeTe (9). Debye-Scherrer powder patterns of the two mixed compounds used in these experiments (systems A and B) confirmed the presence of a single phase with orthorhombic structure. High purity GeI_4 (99.999%) and $GeCl_4$ (99.999%) were used as transport agents. Ultrahigh purity argon was employed as an inert gas in system C. The ampul designated A in this experiment contained 1.50g of $GeSe_{0.99}Te_{0.01}$ and 123.5 mg GeI_4. Ampul B was loaded with 1.50g of $GeS_{0.98}Se_{0.02}$ and 59.1 mg of $GeCl_4$. The third ampul (C) contained 1.50g of GeS, 61.8 mg of $GeCl_4$, and 1.91 atm of Ar. The corresponding pressures of the transport agents computed for the mean temperature of the gradient in terms of GeI_4 and $GeCl_4$, respectively, and ideal conditions are 0.70 atm (A), 0.94 atm (B), and 0.96 atm (C). The argon pressure in ampul C is twice the partial pressure of $GeCl_4$, thus, yielding a total pressure of about three times the pressure employed for the closely related system B. Under the above pressure conditions, the mass transports on earth are affected by a low (A) and medium (B and C) convective contribution to the over-all transport process (Fig. 1). The ampuls of the comparative prototype (ground-based) experiments were identical with those used in space in terms of dimensions and content. The predominant chemical transport reactions of the solid solutions are analogous to those of the binary compounds (4) represented by

$$GeX(s) + GeY_4(g) = 2GeY_2(g) + \tfrac{1}{2}X_2(g) \quad [1]$$

where X = S, Se, and Te and Y = Cl and I, respectively.

Heating cycle.—The transport ampuls enclosed in hermetically sealed metal cartridges were inserted into the multipurpose furnace by the astronauts. After a heat-up period of about 2 hr the desired temperature gradient (604°C at the source and 507°C at the condensation region) was established. This gradient was maintained within ± 3°C for 16 hr, during which transport and crystal growth occurred. After termination of the experiment, cooling of the ampuls to ambient temperature took place in the furnace over a period of about 4 hr during which a helium quench of the metal cartridges was employed. The amount of transport during the heat-up and cool-down periods, which were identical for the earth and space experiments, was considered in the final flux calculations. In the returned ampuls the residual source material was firmly attached to the ampul wall of the source region. For further analysis the transport tubes were opened in a metal dry box which contained P_2O_5 as a desiccant and which was continuously flushed with purified nitrogen.

Results and Discussion

Structural and chemical homogeneity.—The crystallographic identification of crystals obtained in microgravity was established by means of Debye-Scherrer and Laue x-ray diffraction techniques, using a 114.59 mm diameter powder camera and standard Laue equipment. The lattice parameters of the space-grown crystals and the orientation of their native growth faces are in agreement with those of corresponding ground-based specimens. In view of the relative magnitude of chemical bonding and gravitational forces, the above results were entirely expected.

Laue transmission photographs of $GeSe_{0.99}Te_{0.01}$ (system A) ground and space crystals reveal considerable differences as shown in Fig. 2. The pronounced striations and multiplicity of individual diffraction spots in the Laue pattern of the ground-based crystal (Fig. 2a) indicate a high degree of strain and microstructural inhomogeneities. The x-ray pattern of the space crystal (Fig. 2b) shows the twofold symmetry of the predominant (001) oriented growth face. The considerably better defined diffraction spots indicate improved crystallographic perfection relative to the ground-based sample. Similarly striking differences in diffraction patterns are observed for the majority of randomly selected specimens of $GeS_{0.98}Se_{0.02}$ (system B) and GeS (system C) ground and space crystals.

In order to examine the chemical homogeneity of the solid solutions (systems A and B), the distribution of Te in GeSe (A) and of Se in GeS (B) was investigated using an electron microprobe analyzer (Model EPA 400S). For this purpose, cleaved faces of earth (prototype) and space-grown crystals and stoichiometric GeSe and GeTe as reference crystals were used. The relative concentration of Te (in GeSe) and of Se (in GeS) was measured along three directions approximately parallel to the a and b axes of the (001) ori-

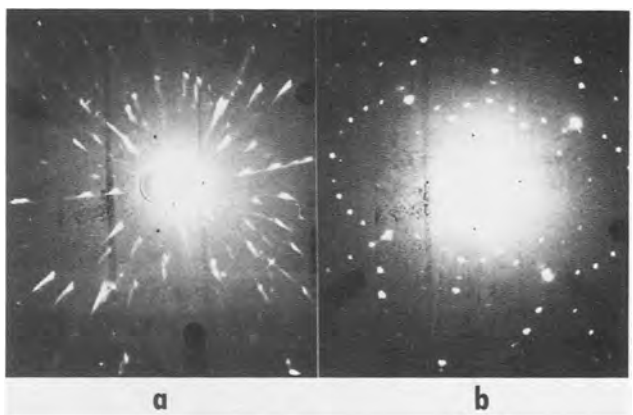

Fig. 2. Laue x-ray diffraction transmission photographs of (001) oriented $GeSe_{0.99}Te_{0.01}$ (system A) single crystal platelets: (a) ground-based (prototype), (b) space grown.

Table I. Distribution of Te (A) and Se (B) in ground-based and ASTP space-grown crystals

System	Concentration (atomic %) Average all data	Average parallel a axis	Average parallel b axis
$GeSe_{0.99}Te_{0.01}$ (ground-based, A)	1.83 ± 0.6	2.03 ± 0.5 1.71 ± 0.6 1.78 ± 0.4	1.59 ± 0.4 2.07 ± 0.3 1.81 ± 0.4
$GeSe_{0.99}Te_{0.01}$ (ASTP, A)	1.56 ± 0.1	1.59 ± 0.03 1.52 ± 0.08 1.56 ± 0.02	1.58 ± 0.04 1.57 ± 0.06 1.58 ± 0.02
$GeS_{0.98}Se_{0.02}$ (ground-based, B)	0.395 ± 0.092	0.371 ± 0.068 0.399 ± 0.061 0.399 ± 0.028	0.374 ± 0.034 0.402 ± 0.020 0.422 ± 0.015
$GeS_{0.98}Se_{0.09}$ (ASTP, B)	0.462 ± 0.048	0.470 ± 0.014 0.448 ± 0.020 0.470 ± 0.007	0.459 ± 0.046 0.471 ± 0.009 0.463 ± 0.007

ented crystal platelet. Along each direction intensity measurements were performed at several different locations. The results in columns 3 and 4 of Table I are average values for data points along a given direction. The error limits represent maximum deviations in atomic concentration of individual locations from the mean value for all points along the particular direction. The corresponding data for all points are listed in column 2. Based on the relative magnitude of the local variations in concentration, the distribution of Te in the solid solution of starting composition $GeSe_{0.99}Te_{0.01}$ is considerably more homogeneous in the space than in the ground-based crystals. Under present conditions, the uncertainty in the Te concentration of individual points is between 4 and 5% for the space and ground-based crystals. The corresponding improvement in the distribution of Se in the space crystals compared to the ground specimens for the compound of initial composition $GeS_{0.98}Se_{0.02}$ is less pronounced than for Te in system A. The uncertainty in Se concentration of individual points is about 5% for the ground and space crystals. For the space-grown materials of both systems, the local variations in the concentration of Te and Se, respectively, along different directions in the (001) plane are within the limits of uncertainty. The deviation of observed concentrations of Te and Se, respectively, in the transported crystals from the composition of the starting materials is due to slightly different transport properties of the binary compounds in the mixed systems. The inclusion of transport agent in the ground and space crystals appeared to be at the detection limits (about 10^{-2}%) of the instrument (6).

Optical microscopy of crystals.—Before a discussion of the microscopic examination of individual single crystals, a macroscopic view of the condensation pattern of the residual gas phase (primarily transport agent GeI_4) on the ampul walls of system A (Fig. 3) obtained during the cool-down period shows significant differences. The GeI_4 deposition in the ground (prototype) ampul (Fig. 3a) shows predominantly clustering and dendritic-type material with a distinct curvature of individual dendrites which have a length of up to about 8 mm. The transport agent in the space ampul (Fig. 3b) is condensed in form of well-developed, transparent single crystal platelets and a few needles. Based on the deposition patterns observed in space and on earth, the apparent presence of turbulent gas motion under ground conditions (Fig. 3a) during rapid cooling of the ampul is completely absent in micro-gravity environment.

Optical photomicrographs of representative $GeSe_{0.99}Te_{0.01}$ (system A) ground (prototype) and space crystals show qualitative differences in surface morphology (Fig. 4). The majority of prototype crystals (Fig. 4a) reveals ragged edges, twinning, and frequently stepped faces. The space crystals (Fig. 4b) have smoother surfaces and usually better defined edges. The average edge lengths of the ground specimens range from about 2-8 mm. The slightly smaller dimensions of the space

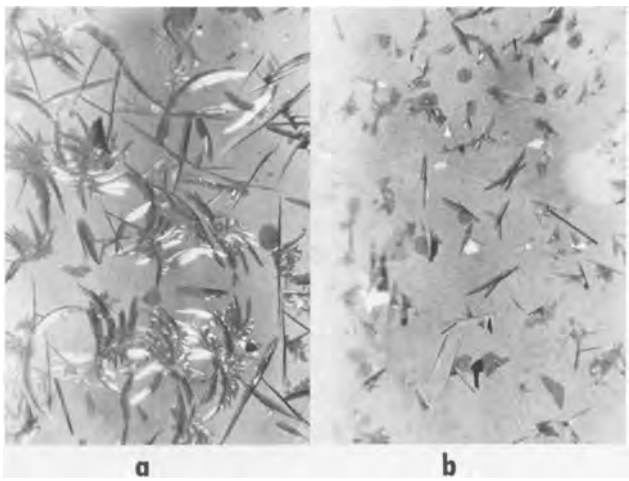

Fig. 3. Deposition pattern of transport agent GeI_4 (system A) on ampul walls: (a) obtained under ground-based (prototype) conditions, length of crystals 2-8 mm; (b) observed in micro-gravity, crystal sizes about 2-4 mm.

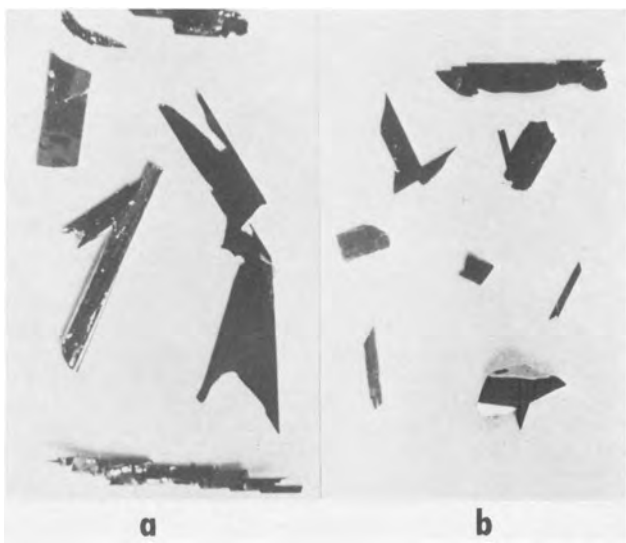

Fig. 4. Representative crystals of $GeSe_{0.99}Te_{0.01}$ (system A): (a) ground-based (prototype), (b) space grown. Edge lengths of ground (a) crystals 2-8 mm and of space (b) platelets 2-4 mm.

crystals are consistent with the lower transport rates in micro-gravity observed for this system (Table II).

Photomicrographs of typical $GeS_{0.98}Se_{0.02}$ (system B) ground (prototype) and space crystals in Fig. 5 reveal distinct morphological differences. The prototype crystals (Fig. 5a) show considerable aggregation, undefined edges, and very rough surfaces. The improved surface and edge morphology of the space crystals is evident from Fig. 5b. The average dimensions of the space material range from about 1-7 mm edge length. Since the transport rates for system B (Table II) are the same under ground and space conditions, the external morphological differences reflect the absence of grav-

Table II. Mass transport rates under ground-based (prototype) and micro-gravity conditions

System	Mass flux ((mol/cm² · sec) × 10^{-9}) Normal gravity	Micro-gravity	Extrapolated diff. mode
$GeSe_{0.99}Te_{0.01}$ (A)	7.9	4.2	1.4
$GeS_{0.98}Se_{0.02}$ (B)	22.1	22.1	6.5
GeS + Ar (C)	15.0	13.0	2.8

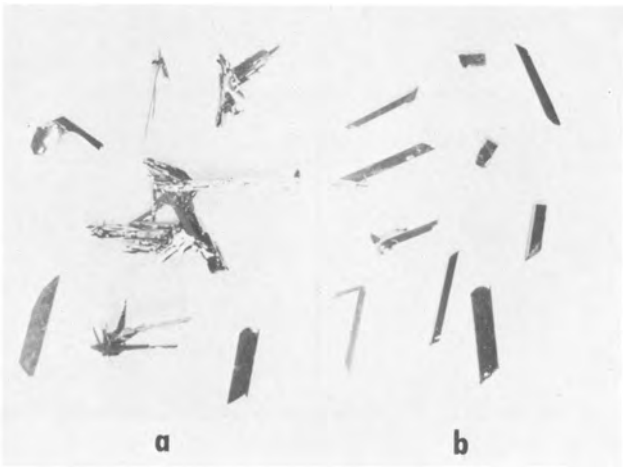

Fig. 5. Representative crystals of $GeS_{0.98}Se_{0.02}$ (system B): (a) ground-based (prototype), (b) space grown. Edge lengths of space crystals about 1-7 mm. Same magnification used for (a) and (b).

ity-driven convective interference with the transport and condensation process in micro-gravity environment. Similar differences in growth habits and surface morphology were observed for GeS crystals (system C).

Scanning electron microscopy.—Scanning electron photomicrographs (400×) of native faces and edges of $GeS_{0.98}Se_{0.02}$ (system B) ground (prototype) and space crystals in Fig. 6 reveal significant morphological differences. The surface of the ground crystal (Fig. 6a) shows extended channels and cavities penetrating into the bulk of the material. The smoother areas of the surface are nonplanar and separated by rounded edges. In addition polycrystalline deposits are visible. The surface perfection of the space crystal (Fig. 6b) is considerably improved relative to the ground specimen. The greater crystalline quality of the space material is attributed to significantly reduced convective interference and is not due to lower transport rates (Table II). Similar morphological differences between ground and space crystals were observed for the other systems. In particular, the majority of investigated ground specimens reveals nearly macroscopic imperfections for at least one edge extending into the bulk of the crystal; most space crystals have all edges well defined. These observations confirm similar results of the Skylab experiments (6).

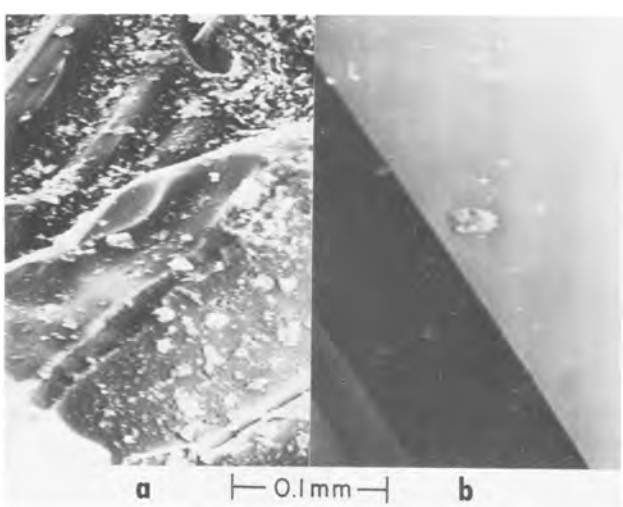

Fig. 6. Scanning electron photomicrographs (original magnification 400×) of native faces of $GeS_{0.98}Se_{0.02}$ (system B) crystals: (a) ground-based (prototype), and (b) micro-gravity grown. Crystal area shown in (a) corresponds to light face in (b) which is (001).

Chemical etching studies.—In order to determine differences in the degree of bulk crystalline perfection, freshly cleaved faces [parallel to the (001) plane] of ground and space crystals were investigated by chemical etching and optical microscopy. A warm (~60°C) solution containing 15% KOH applied for about 1 min gave reproducible results.

A representative optical photomicrograph (200×) of the cleaved (001) face of a $GeSe_{0.99}Te_{0.01}$ (system A) ground crystal (Fig. 7a) shows large cavities in the bulk of the material. Similar gross imperfections are observed on most ground specimens. Chemical etching of the same crystal area shows a high concentration of etch pits (Fig. 7b). It is interesting to note that the planar areas of the crystal which appear to be mirror smooth at this magnification (Fig. 7a) apparently have a higher etch pit density than the walls of the large cavity. The concentration of etch pits indicates a high degree of structural imperfections in the ground-based material which was observed for the majority of investigated crystals.

Application of the same cleaving and etching procedures to space-grown crystals of system A yields distinctly different results (Fig. 8). The photomicrograph (200×) of the cleaved crystal (Fig. 8a) reveals a greater structural quality than the corresponding ground specimen (Fig. 7a). This type of cleavage plane (Fig. 8a) was observed for the majority of space crystals. The photomicrograph (200×) of the cleaved and etched space crystal platelet (Fig. 8b) is nearly free

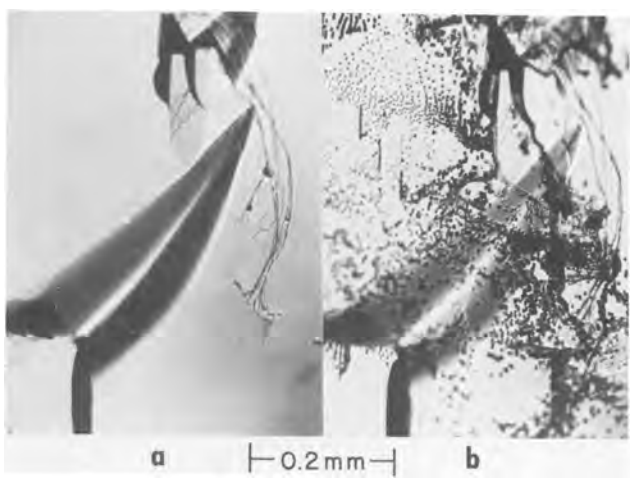

Fig. 7. Optical photomicrographs (original magnification 200×) of a cleaved and etched (001) face of a ground-based (prototype) $GeSe_{0.99}Te_{0.01}$ (system A) crystal platelet: (a) cleaved, (b) cleaved and etched.

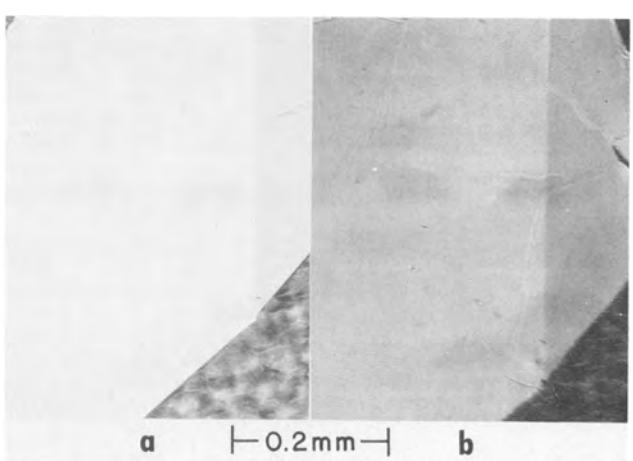

Fig. 8. Optical photomicrographs (original magnification 200×) of a cleaved and etched (001) face of a space-grown $GeSe_{0.99}Te_{0.01}$ (system A) crystal platelet: (a) cleaved, (b) cleaved and etched.

of etch pits indicating a high degree of structural microhomogeneity. The line pattern of the crystal face is due to cleavage, showing (001) planes of different depth with respect to the native surface.

Similar differences in etch patterns were observed for ground- and space-grown $GeS_{0.98}Se_{0.02}$ (system B) crystals shown in Fig. 9 and 10. For comparative purposes, the (001) cleavage plane (200×) of an above average quality ground crystal is shown in Fig. 9a. The majority of ground crystals (system B) contains cavities and elongated channels in the bulk of the material. Chemical etching of the cleaved (001) face (200×) yields large etch pits and lines (Fig. 9b) indicative of crystallographic imperfections. This is contrasted by optical photomicrographs (200×) of cleaved and etched (001) faces of average space crystals of this system (Fig. 10). The appearance of few isolated etch pits and large areas free of pits in the crystal plane (Fig. 10b) indicate the high degree of crystalline perfection of the space-grown material.

The above illustrated differences in cleavage and etch patterns are observed for the majority of investigated ground and space crystals for all systems. Considering the nonuniform distribution of etch pits in different planes of the ground specimens and their isolated appearance in the space samples, numerical values for the etch pit counts of individual crystals would not be too meaningful. The average density of etch pits is approximately one to two orders of magnitude lower in the space than in ground samples. The combined results of the morphological studies are consistent with those of x-ray diffraction techniques and show the considerably improved crystallographic perfection of crystals grown in the micro-gravity environment.

Mass transport rates.—The mass transport rates observed in micro-gravity and under corresponding prototype (ground-based) conditions are calculated from the mass of the transported crystals and the mass loss of the source material. The numerical results of the ASTP experiments are listed in Table II. The experimental uncertainties associated with the recovery of crystals were combined to yield minimum values for the mass fluxes observed in micro-gravity. Under these conditions the errors of the values listed in column 3 are estimated to be about + 30%. The computation of the transport rates expected for diffusion listed in column 4 is based on a graphical extrapolation of the diffusion-controlled region of the respective ground-based experimental flux curves shown in Fig. 1. For this purpose, flux *vs.* pressure data were plotted in logarithmic scales and the resulting straight line was extended to the flux corresponding to the pressure employed in the ASTP experiments. This is shown for system B and for GeS-$GeCl_4$ in Fig. 11. A similar plot was used for the A-system. In order to maximize the predicted flux values, the data selected for the extrapolation are close to the minimum of the diffusion branch of the individual flux curves (Fig. 1) with some convective contribution. The flux curves in Fig. 1 were established in our laboratory. Due to slight differences in temperature profiles between the laboratory and prototype furnace (the latter one was used for all direct comparisons), the flux values in Fig. 1 are greater than those obtained in the prototype furnace (column 2) for the corresponding systems and pressures. This and the above extrapolation procedures yield maximum values for the extrapolated fluxes with an estimated uncertainty of about −30%. The extrapolations are based on the assumption that mass transport in micro-gravity is exclusively by diffusion and that gravity- and nongravity-caused transport effects, *e.g.*, streaming, are included in the extrapolation of experimental flux data. The predicted flux value for system C was obtained analytically from the identical extrapolated values for system B and GeS (Fig. 11) and the argon pressure in system C, considering the different molecular weights of Ar and $GeCl_4$. The transport properties of system B and GeS (Fig. 1 and 11) and the transport agent ($GeCl_4$) pressures of systems B and C are close enough to allow a direct comparison of the effect of argon on the mass flux of these systems. The flux curve for GeS with $GeCl_4$ as a transport agent (Fig. 1) is shown for comparative purposes. The difference between this and the corresponding curve for system C is the presence

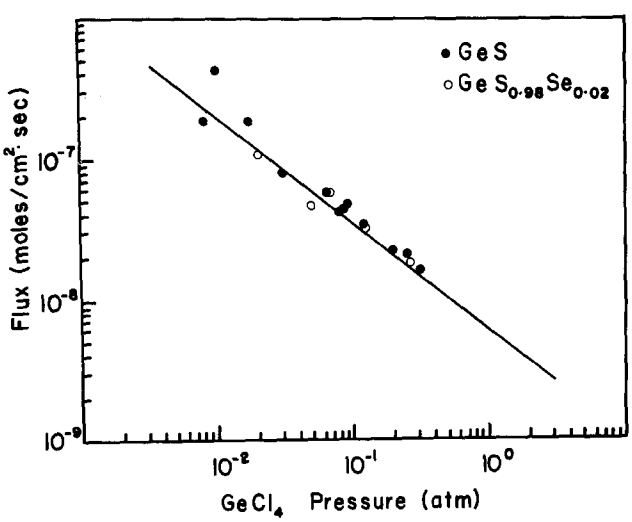

Fig. 11. Extrapolation of flux *vs.* pressure data of the diffusion-controlled region of the ground-based flux curves (Fig. 1) for systems B and GeS-$GeCl_4$.

of argon in the latter one. The argon pressure employed in the individual transport experiments of system C was approximately twice the pressure of transport agent ($GeCl_4$) given on the abscissa of the diagram. The observed reduction in transport rate upon the addition of argon to the GeS-$GeCl_4$ system was expected for the diffusion-controlled but unexpected for the convection-controlled regime of the ground-based flux curves.

The mass fluxes observed in micro-gravity (Table II) are about three to five times greater than predicted (extrapolated) for a diffusion-controlled transport process. For system A the transport rate in space is less than under prototype (ground) conditions. For system B the fluxes obtained on earth and in space are the same. These observations are consistent with the Skylab results (6) and confirm the trend in terms of the flux-pressure relationship observed in the previous space experiments (6). A comparison of the individual flux data of systems B and C obtained under prototype (ground) and space conditions leads to several important conclusions. Firstly, if vapor transport in space were exclusively by diffusion, then the mass fluxes of systems B and C in micro-gravity should be in the ratio of the diffusion coefficients. Estimated diffusion coefficients for these multicomponent systems (10) yield a minimized ratio of about 2.4 which agrees with the ratio of extrapolated fluxes but is greater than the observed ratio J_B/J_C in space. Although not conclusive by itself, the difference is consistent with other evidence and indicates that the effect of argon on the diffusion mode of system C is less important than on other properties which affect mass flux. Secondly, if the observed transport rates in space were caused by gravity fluctuations due to space craft operations, such fluctuations should affect the "diffusion mode" of systems B and C equally and the flux ratio J_B/J_C should again reflect a diffusion-type transport (11). Since that is not the case, gravity fluctuations could not be the only source of the observed higher space fluxes. Thirdly, estimates of the effects of gravity perturbations for the Skylab experiments (6) revealed that their contributions to the mass transport rates in space were negligible. This indicates that "G-jitter" is insignificant with respect to the transport rates observed in the ASTP experiments. Fourthly, a comparison of systems B and C demonstrates, that the effect of argon on the mass transport rates is the same within error limits under prototype (ground) and micro-gravity conditions. The observed decrease in flux upon addition of argon (in the "convection branch" for ground conditions) is in agreement with ground-based inert atmosphere studies indicated in Fig. 1. The combined experimental data strongly suggest that the addition of inert atmosphere affects those inherent properties of the transport systems which are the same on earth and in space and are gravity independent.

Before any further interpretation of these unconventional transport phenomena in micro-gravity, it is desirable to demonstrate independently the validity of the discrepancies between the mass fluxes observed in space and predicted (extrapolated) for a diffusion-type transport. This was accomplished by computing flux curves for diffusion-controlled vapor transport based on models proposed by Schäfer *et al.* (12), Lever (13), Mandel (14), and Faktor *et al.* (15). Computational procedures have been discussed previously (6). Emphasis was placed on the appropriate treatment of the so-called streaming effect (Stephan flow) and on the calculation of partial pressure gradients as a function of total pressure which are treated differently in the above models. The same procedures were applied to the transport systems and conditions of the ASTP and Skylab experiments. The calculations are based on reaction [1]. The required thermochemical data for the GeSe-GeI_4 system have been used previously (5). The heat of formation and absolute entropy of GeS(s) are from Ref. (16) and (17), respectively. For the heat capacity of GeS(s) the value for α-SnS(s) (18) was used. The corresponding enthalpies of formation and absolute entropies for $GeCl_4(g)$ and $GeCl_2(g)$ were derived from the heat and entropy of the reaction $Ge(s) + GeCl_4(g) = 2\,GeCl_2(g)$ (19) with the heat capacities for Ge(s) (20) and $GeCl_4(g)$ (21). The heat capacity for $GeCl_2(g)$ was estimated at 15 cal/deg · mole. The heat of formation (22), absolute entropy (22), and heat capacity (23) of $S_2(g)$ were used in these calculations. The contributions of GeTe in system A and of GeSe in system B to the pressures and mass transport rates of the major species are insignificant and have been neglected in these computations. The "theoretical" flux curves were fitted to the diffusion branch of the corresponding experimental ground-based curves [Fig. 1 for the present ASTP and accordingly for the Skylab (6) experiments] to obtain optimal agreement. This procedure yielded the numerical constants required for each model to compute the fluxes for the specific ASTP and Skylab conditions. The numerical results of these computations are listed in Table III together with the observed and extrapolated fluxes. A comparison of the data shows that the flux values obtained from the model computations agree within a factor of two with our extrapolated values. In no case are the transport rates predicted by the models greater than the observed fluxes, although, as pointed out above, the latter represent minimum values. Considering the uncertainties associated with thermodynamic calculations of partial pressures and transport effects, the agreement between the model calculations and experimental extrapolation procedures is reasonable. Because of these uncertainties our extrapolated data are considered the most reliable values for comparison. The combined data confirm that the discrepancies between predicted and observed fluxes in micro-gravity are real and that the latter cannot be explained on the basis of an exclusively diffusion-type process. This leads to the conclusion that the greater than predicted mass transport rates in the space environment are due to other nongravity-caused transport effects. The internal consistency and close agreement between the flux results of the present ASTP and earlier Skylab (6) experiments obtained for different chemical systems, eight pressures, two transport agents, and three temperature gradients strongly support the validity of the above conclusions.

The apparent failure to explain the observed transport phenomena in space on the basis of a diffusion process suggests the presence of convective gas flow in closed-tube vapor transport systems which measurably affects the mass flux in micro-gravity environment. The positive identification of the source of such convective motion requires a detailed analysis of available convection models and their application to transport conditions at normal and reduced gravity. This is beyond the scope of the present work and will be presented, together with additional ground-based experi-

Table III. Mass transport rates observed and predicted for micro-gravity conditions

ments, in a forthcoming publication. Present results of this analysis are briefly summarized below. Convective flow in a horizontal, closed-ampul vapor transport system was analyzed by Klosse and Ullersma (24). The end result of their treatment (24) is a dimensionless parameter K, which is the ratio of convective to diffusive mass transfer. This flux ratio K is expressed in terms of Grashof and Schmidt numbers and two other dimensionless quantities, which are solely functions of the aspect ratio of the ampul. Computations of Klosse and Ullersma's ratio K for conditions representative of our Skylab and ASTP experiments and normal gravity ($G = 980$ cm $\cdot$ sec^{-2}) show, that on earth convection is predominant at a total pressure of about 1 atm. The convective contribution to the over-all mass transport decreases with decreasing pressure and becomes negligible at pressures of about 0.1 atm. These results are in agreement with the shape of our experimental ground-based flux curves for the ASTP (Fig. 1) and Skylab (6) experiments. Analogous computations for these systems with the above model (24) for micro-gravity conditions (10^{-4}G or less) reveal that convective mass transport is negligible at all pressures applied in these experiments.

The above results are in qualitative agreement with independent estimates of thermogravitational flow obtained from a dimensional analysis (25). This involves the calculation of Rayleigh numbers for both ground and space conditions and the comparison of these values to the critical Rayleigh number. In addition, the aspect ratio and Prandtl number of the system are important parameters. For the purpose of these calculations system A of the Skylab 3 experiments (6) (Table III) was selected which showed the largest discrepancy between observed and predicted fluxes for micro-gravity. The pressure of $GeI_4(g)$ in Skylab 3A experiment (6) was 1.50 atm for the mean temperature of the gradient (470°C) and ideal gas conditions. The analysis (25) is based on a rectangular container with cross section 15 $\times$ 1.4 cm and on a residual gravity of about 10^{-4}G. In addition to the effect of constant residual gravity, the influence of gravity perturbations on the mass transport rate was studied. Although qualitative in nature, the results of the computer model analysis (25) show that the combined effects of steady 10^{-4}G convection and G-jitter (vibration) convection could not yield more than a 20% increase in mass transport rate over pure diffusion. This is negligible compared to the magnitude of the observed fluxes in micro-gravity.

In view of the combined results, we propose the following explanation for the unexpected transport phenomena in space. Present vapor transport models for diffusive and convective flow consider only the chemical reactions at the source and seed crystal. When these heterogeneous reactions are in a steady state and the partial pressure gradients are established, the gas phase is treated as an inert fluid migrating from the source to the condensation region. However, the vapor phase of a chemical transport system consists of reactive chemical species, and homogeneous chemical reactions in the gas phase should be considered. The energies associated with such reactions can cause localized temperature changes, which, in turn, will produce local density fluctuations superimposed on the density gradient due to the over-all temperature gradient. The instabilities caused by such temperature-density fluctuations could lead to "thermochemically" induced convective motion of the gas phase. Preliminary model calculations indicate that local temperature changes of several degrees can be expected if only minute amounts of gaseous species undergo chemcial reactions. In addition, changes in the number of moles of gaseous species as a result of homogeneous reactions could lead to pressure-volume changes and subsequent flow. Actual temperature oscillations in a closed ampul containing $TeCl_4$ in a vertical temperature gradient have been reported (26) earlier. At normal gravity, "thermochemical" convection may be overshadowed by gravity convection. In micro-gravity environment, the thermochemically driven component could have a significant contribution to mass transfer. The morphological differences between ground and space crystals indicate a more turbulent type of convection on earth and a laminar-type flow in space. This model would explain the unexpected transport phenomena observed in micro-gravity and any discrepancies between ground-based convection models (1, 24) and experimental flux data (27). A more detailed treatment of the above computations and proposed model will be presented separately.

Summary and Conclusions

The original objectives of these experiments were to investigate the effects of micro-gravity on the morphology of single crystals of mixed systems and to confirm the unusual mass transport rates observed earlier (6). The analysis of these experiments based on x-ray diffraction, microscopic, and etching techniques demonstrates a measurable improvement in structural and chemical homogeneity of the space-grown crystals relative to ground specimens. This is attributed to reduced convective turbulence and interference with the transport process. In addition to the confirmation of the greater mass transport rates in micro-gravity than predicted by present transport models, the analysis of the flux results points to the existence of thermochemically induced convection in reactive solid-gas phase systems. The morphological observations suggest that the interaction between different convective components causes turbulence and negative effects on crystal quality as observed on earth. The good agreement between the results of these and previous (6) vapor transport experiments performed in space supports the validity of the above conclusions.

Acknowledgments

This work was performed during the joint U.S.-U.S.S.R. Apollo-Soyuz Test Program (ASTP). The authors are pleased to express their sincere appreciation to the National Aeronautics and Space Administration for the opportunity to participate in the Apollo-Soyuz Test Program. We would like to thank the scientific and technical staff of the George C. Marshall Space Flight Center and the Astronauts of the ASTP Mission who made the performance of these experiments possible.

Ion-Implanted Gallium-Arsenide-Phosphide Surfaces

Thomas C. Arnoldussen* and Eugene Greenstein*

General Motors Corporation, Research Laboratories, Electronics Department, Warren, Michigan 48090

ABSTRACT

Study of thermal degradation of mechanical surface perfection and surface photoluminescence (PL) of $GaAs_{0.6}P_{0.4}$ samples, some of which received high dose room temperature Zn^+ or Ar^+ ion implants and others of which were unimplanted, strongly suggests that PL degradation and thermal etch pit formation have a common origin. Thermal etch pits are believed to nucleate at dislocations reaching the surface and these same dislocations act as sources of vacancy injection into the bulk, resulting in PL degradation. Ion implants rendering the surface amorphous are found to retard formation of thermal etch pits and to retard PL degradation during high temperature anneals. The model presented may explain the unusual dish-shaped p-n junction profiles observed when Zn^+ is implanted into n-type $GaAs_{0.6}P_{0.4}$ at room temperature and annealed.

Light emitting diodes fabricated by ion implantation of Zn into n-type GaAsP have been reported previously (1, 2). While we have also made such devices with efficiencies comparable to diffused diodes, the work reported here pertains not to diode behavior as such, but to the effects of room temperature, high dose ion implants on reducing surface degradation during high temperature annealing. The samples studied were $GaAs_{0.6}P_{0.4}$ grown on GaAs substrates. The constant composition region was ~80 μm thick and doped with 1.5×10^{17} cm^{-3} Te. The orientation of the surface was (100)[1].

The results we report suggest that dislocations reaching the $GaAs_{0.6}P_{0.4}$ surface act as vacancy generators during annealing and high dose room temperature ion implants reduce the surface dislocation density and vacancy generation rate during subsequent annealing. These results are in agreement with those recently reported by Okabayashi (3) in which anneal-induced photoluminescence degradation in $GaAs_{0.62}P_{0.38}$ was related to Ga vacancy formation. Our work not only corroborates this, but further delineates the anneal degradation mechanism by correlating photoluminescence degradation with heterogeneous thermal pit nucleation.

Mechanical Surface Effects

It is well known that materials such as GaAsP suffer dissociation and severe surface deterioration when annealed at high temperatures without adequate surface passivation. A pure, dense Si_3N_4 coating provides good protection, though at high enough temperatures some degradation can still occur. SiO_2, while not as good as Si_3N_4, can provide reasonable protection provided it is dense. Si_3N_4, SiO_2, and $(Si_3N_4)_{1-x}(SiO_2)_x$ films which are insufficiently dense provide diminished protection and at high anneal temperatures surface deterioration can occur.

In the first experiment reported here six chips were cut from a single wafer. Three of these were implanted with 8×10^{15} cm^{-2} Zn^+ ions at 50 keV, room temperature, and at 7° beam incidence. The remaining three were left unimplanted. All six chips were then coated with 700Å of $(Si_3N_4)_{1-x}(SiO_2)_x$ by reactively sputtering a Si target in a N_2 atmosphere after an incomplete pumpdown. This "contaminated nitride" provided some protection but allowed slow thermal degradation to occur during the high temperature anneal. The refractive index, ellipsometrically determined, of this coating was 1.8 compared to 2.0 for pure dense nitride.

One implanted sample and one unimplanted sample were annealed together at 850°C for 1 hr. A second implanted/unimplanted pair was annealed for 2 hr, and a third pair for 3 hr. In this way the unimplanted specimens, processed identically to their paired implanted chips, served as controls in order to separate the effects of the ion implantations. These anneal times were much longer than would normally be used in LED fabrication.

Extensive surface pitting occurred on the unimplanted samples, but a relatively small number of pits formed on the implanted chips during the anneals. Figures 1-3 show micrographs of these surfaces. Figure 4 shows an enlarged view of pits on 2 hr annealed samples. For both the implanted and unimplanted samples it appears that early nucleation of pits is followed by pit growth without continuing nucleation of new pits. These pit densities were about 5.7×10^4 cm^{-2} for unimplanted samples and 1.8×10^3 cm^{-2} for implanted samples. The pit density was thus over 30 times lower on the implanted samples.

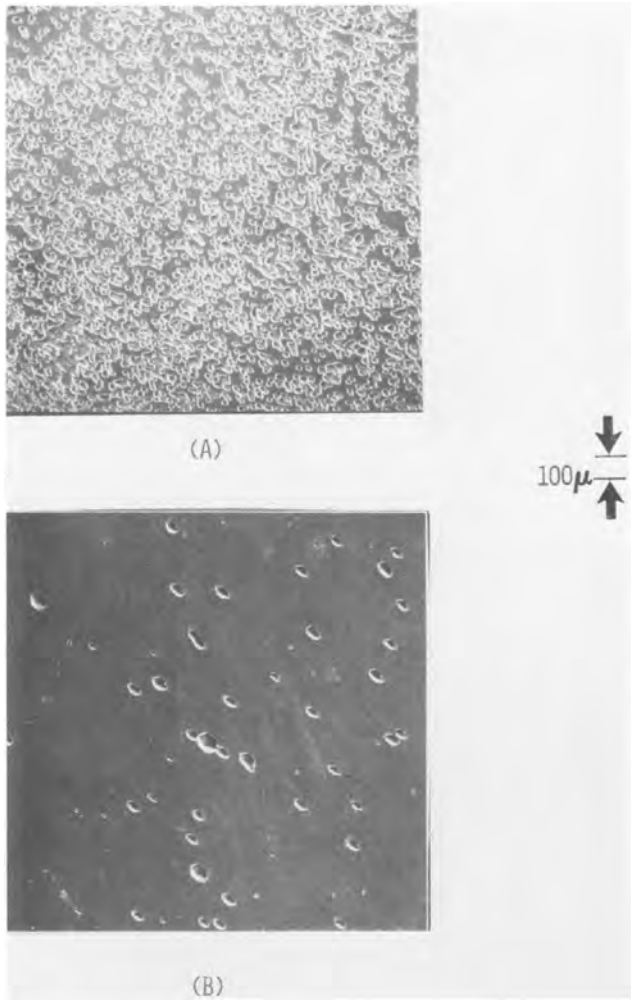

Fig. 2. Thermal etch pits seen at 30° incidence in (100) surface after 2 hr anneal at 850°C; (a) unimplanted, (b) implanted.

Photoluminescence effects.—Another set of six chips was cut from a similar wafer. Two of these were implanted with 8×10^{15} cm^{-2} Zn^+ ions, two were implanted with 8×10^{15} cm^{-2} Ar^+ ions, and the remaining two were left unimplanted. The implants were all performed at room temperature. All six samples were coated with 700Å Si_3N_4 reactively sputtered from a Si target in 4×10^{-3} Torr N_2 after an initial vacuum of $<1 \times 10^{-6}$ Torr had been achieved. Substrate temperature during sputtering was about 400°C. The Si_3N_4 sputtered under these conditions was pure and dense and had a refractive index of 2.0. The samples were then annealed at 900°C in sets for 15 and 30 min, as described in Table I. The Si_3N_4 coating was removed and no visible surface deterioration (thermal pitting) was observed, indicating the more adequate protection afforded by this pure, dense Si_3N_4.

Photoluminescence spectra were taken on each of these six samples plus a virgin sample using an argon laser (4900Å) for excitation. The optical absorption coefficient for this excitation is about 5×10^4 cm^{-1}. Figure 5 shows the magnitude of the PL photon intensity at the spectral peak for each of the samples normalized to that of virgin material (taken as unity).

Table I

Sample number	Implant	Anneal time
1a	none	
1b	Ar	15 min
1c	Zn	
2a	none	
2b	Ar	30 min
2c	Zn	

The Ar^+-implanted samples as well as the unimplanted samples [Fig. 5 (1a), (2a), (1b), and (2b)] showed a PL peak at 6620Å with a peak half-width of 140Å, compared with a virgin sample PL peak at 6600Å with a 140Å half-width. Both Zn^+-implanted samples [Fig. 5 (3a) and (3b)] showed a PL peak at 6700Å with a peak half-width 280Å. No subsidiary peaks (*e.g.*, from possible nitrogen doping) were observed for any sample.

The unimplanted samples showed a PL degradation by a factor of ~50. This is due primarily to the high anneal temperature used (900°C) and not to the quality of the coatings. Harris *et al.* (4) have reported annealing GaAs at 750°C using Si_3N_4 coatings with little PL degradation, despite having problems with Si_3N_4 adhering to the GaAs. We had no problem with nitride adherence, but the dissociation pressure (5) of GaAs (which we expect is comparable to $GaAs_{0.6}P_{0.4}$) is at least 100 times greater at 900°C, and atomic migration through the coatings is likewise enhanced.

The Ar^+ implants, which we expect are chemically and electronically inert, were found to diminish the high temperature anneal-induced PL degradation by a factor of 5-7.

The Zn^+ implants enhance the PL photon intensity by a factor of about 10 over the virgin sample. This increase is primarily a result of changing the dominant recombination mechanism from a donor-to-valence band mechanism to a conduction band-to-zinc acceptor band mechanism (6), as indicated by the PL peak shift to 6700Å and increase in peak half-width.
