A similar experiment in the $AlCl_3$-EPB melt at 23°C (Fig. 3) revealed different behavior for the aluminum electrode than in the previous case. Anodization begins almost immediately and a linear rise in current with increasing potential is evident to about 1.1V. At this point the current fell to a constant value, suggesting the formation of a partially insulating film of $AlCl_3$ (12). Attack of the Al_3Ni electrode was negligible until a potential of about 1.0V was attained. Thus, at potentials below 1.0V aluminum can be removed without significant attack on the Al_3Ni fibers. All electrolysis experiments demonstrating the selective removal of aluminum from the Al-Al_3Ni matrix in $AlCl_3$-EPB were carried out in a stirred melt in an attempt to limit the formation of the passivating film at the electrode. The results of these experiments are given below.

Photomicrographs of a portion of an Al-Al_3Ni rod prior to its electrolysis revealed no discernible exposed fibers (Fig. 4). Examination of the rod end surface at greater magnification (Fig. 5) showed Al_3Ni rods which protrude slightly from the Al-Al_3Ni matrix surface where the rod was saw cut. After electrolysis for 1 hr at a potential of 0.9V in an unstirred solution of $AlCl_3$-NaCl at 175°C, a photomicrograph (Fig. 6) revealed myriad-exposed Al_3Ni fibers. During electrolysis the current progressed from an initial value of 0.3 A/cm^2 to a final value of 0.02 A/cm^2. Similar results were obtained after 2 and 5 mA/cm^2 (Fig. 7) constant current electrolysis in the stirred $AlCl_3$-EPB melt at 23°C. During this experiment the potential did not exceed 0.5V.

There appeared to be no discernible difference in the appearance of Al_3Ni fibers exposed by electrolysis in the $AlCl_3$-NaCl melt and those produced in the $AlCl_3$-EPB melt. This was true in spite of the significant differences in the media used for anodizing the Al-Al_3Ni matrix. However, more extensive studies will be required before the extent of damage to the Al_3Ni fibers can be fully assessed. The fibers do appear to be suffi-

ciently intact to provide information about the quality of growth techniques used to produce them.

Conclusion

The selective electrolytic etching of aluminum from a two-phase Al-Al_3Ni matrix has been shown to be feasible in aluminum chloride containing molten salts. The molten salts chosen for this study, NaCl saturated $AlCl_3$-NaCl and 2:1M ratio $AlCl_3$-1-ethylpyridinium bromide represent wide extremes in conductivity and liquidus temperature available in aluminum chloride containing molten salts. It should be possible to employ almost any aluminum chloride containing molten salt whose properties lie within these extremes for the selective electrolytic etching of aluminum from an Al-Al_3Ni matrix providing the selectivity constraints are predetermined. In addition, the procedure demonstrated in this study appears promising for scale-up separation operations in which it is desired to produce free, intact, Al_3Ni filaments.

Acknowledgments

Financial assistance in this investigation was provided by the Rome Air Development Center (AFSC), Hanscom AFB, Massachusetts. We would like to thank Dr. J. Hutta and Dr. N. Klausutis of that organization for furnishing samples and for their helpful discussions of the work. We wish to express our appreciation to Dr. J. Clifford and Dr. R. Swedenburg of the Department of Physics, United States Air Force Academy, Colorado, for SEM photographs, and to Dr. J. Robinson and Dr. R. A. Osteryoung, Colorado State University for the gift of a glassy carbon electrode.

Sputter Deposition of a Metastable Equiatomic Tin-Nickel Alloy

J. A. Augis and J. E. Bennett

Bell Laboratories, Columbus, Ohio 43213

The equiatomic metastable tin-nickel alloy, "Sn-Ni", used for protective and decorative purposes and in electronic components, shows a remarkable resistance to most corrosive agents (1). It is a metastable single phase alloy which has been made only by electrodeposition (2, 3).

Thin film deposition (including electrodeposition) of metals and alloys often leads to phases which cannot be obtained by standard metallurgical techniques. Due to the different rates of nucleation and growth encountered in thin film deposition, it is possible to "quench-in" microstructures (4) which would evolve toward different equilibrium structures during typical metallurgical processing. Two important parameters ruling the microstructures and the kinetics of transformation during film deposition are the flux of impinging atoms and the temperature of the substrate.

While the impinging flux is more easily controlled during electrodeposition, the substrate temperature is more easily controlled during vacuum deposition. It seems reasonable then to expect that a metastable phase could also be produced by sputtering methods. The motivation behind sputtering tin-nickel is twofold: firstly, can certain undesirable properties of the electrodeposited alloy (*e.g.*, brittleness) be improved by the sputtering process; secondly, can the comparisons in physical properties of the two kinds of deposits (sputtered and plated) help to elucidate the nature of the metastable phase? This paper will simply confirm that a metastable tin-nickel alloy can be prepared by sputtering.

Experimental

The equiatomic "Sn-Ni" alloy was deposited using a MRC sputtering head mounted on a Veeco oil-diffusion pumping system. The sputtering gas was argon.

The deposition was made on a substrate of either molybdenum or copper placed on a platen assembly which could be either water cooled or heated and kept at a predetermined temperature. The temperature of the upper face of the substrate was monitored by a compensated thermocouple.

A target having a composition close to equiatomicity was needed. The mixture of equilibrium phases corresponding to the equiatomic composition (Ni_3Sn_4 and Ni_3Sn_2) is extremely brittle, and this precluded the manufacturing of a 5 in. thin disk by melting, forming, and homogenizing nickel and tin. Consequently, the target was prepared by electroplating 10 ml of the metastable phase from the bath previously described in Ref. (3) on a 254 μm thick layer of the 12.7 cm diam copper plate.

Sputter depositions were made under various conditions: the d-c voltage was kept at 3800V; the argon pressure was varied from 10 to 40 mTorr, corresponding to deposition rates ranging from 100 to 325 Å/min; and the substrate temperatures were fixed at values from 40° to 220°C.

Results

The metastable phase can be identified by x-ray diffraction and thermal analysis (3). The equilibrium system (5) corresponding to equiatomicity is a mixture of Ni_3Sn_4 and Ni_3Sn_2. The tin-rich phase Ni_3Sn_4 crystallizes in the monoclinic system; the phase Ni_3Sn_2 crystallizes in the hexagonal system and has the NiAs ($B8_2$) structure. The $B8_2$ structure was also assigned to the electroplated metastable phase by Rooksby (6). However, the x-ray diffraction patterns for two of the three phases are quite similar, suggesting analogous atomic arrangements. In particular, both "Sn-Ni" and Ni_3Sn_2 structures can be described by hexagonal cells with dimensions which are almost equal. The main difference between the two cells concerns the lattice spacings of the (110) and (102) planes. While in Ni_3Sn_2, the spacings are sufficiently different to give two resolvable diffraction peaks for this region of 2θ; the x-ray diffraction pattern shows only one peak for both the 110 and 102 reflections in the case of the electroplated metastable phase. Ni_3Sn_4 shows a somewhat different x-ray pattern in the same region of 2θ where 3 peaks can be resolved. Because only the x-ray pattern of Ni_3Sn_4 is sufficiently distinctive, we checked primarily for the presence of Ni_3Sn_4 diffraction lines in the sputtered deposit.

Table I shows the various sputtering conditions that were used, along with the nature of the film obtained. The compositions of the films were determined with energy-dispersive x-ray analysis (EDAX) using ingot Ni_3Sn_2, ingot Ni_3Sn_4, and electroplated "Sn-Ni" as standards. The latter sample had been previously analyzed by a wet chemistry method (3). It is generally observed during sputtering of alloys that the composition of the deposit is close to the composition of the target. Within the limits of the compositional analysis technique (EDAX), the sputtered films show Ni to Sn ratios comparable to that observed in typical electroplated films. In the two cases where copper substrates were used and sputtering was made at high temperatures (190° and 220°), the lower concentration of tin in the deposit is probably the result of its interdiffusion with the substrate. An evolved gas analysis (EGA) was run on a few samples. The plated samples evolved some water, oxygen, and chlorine. The sputtered samples showed mostly water and argon.

The next to last column of Table I indicates either the absence or the presence of x-ray lines characteristic of Ni_3Sn_4. The equilibrium equiatomic alloy should contain approximately 50% of the Ni_3Sn_4 phase. Only for the three cases where the substrate temperature was at 180°, 190°, or 220°C were any Ni_3Sn_4 x-ray lines observed. It was concluded that for all the runs where the substrate temperature was 100°C or below, a metastable deposit similar to the electroplated alloy was obtained.

Upon heating, the electroplated metastable phase reverts exothermically (3) to the equilibrium mixture presumably by the following reaction

$$6\ \text{"Sn-Ni"} \rightarrow Ni_3Sn_4 + Ni_3Sn_2 + \text{heat}$$

As in Ref. 3, a heat-treatment was given to some of the sputtered films. Substrates were etched away and the films (10 μm thick) were ground to a fine powder. Figure 1a shows the x-ray pattern obtained from unheated powder, and it is similar to the pattern of the as-plated "Sn-Ni" (ASTM x-ray diffraction file card 7-256). In Fig. 1b, which is the pattern given by the heat-treated powder (500°C, 1 hr), lines corresponding to Ni_3Sn_4 and Ni_3Sn_2 can be observed (ASTM

cards 4-0845 and 6-0141), showing that transformation to the equilibrium structures takes place during heat-treatment of the sputtered deposit also. These results were confirmed using the technique of differential thermal analysis (DTA) [see Ref. (3)]. Similar to the as-plated alloy, the sputtered material exhibits a broad exothermic peak. In Fig. 2, three DTA traces are shown. It is apparent that the exothermic peaks for the sputtered samples occur at a substantially higher temperature and are much larger than was observed for the plated sample. This indicates somewhat different kinetics of transformation, possibly linked to a different microstructure.

Discussion

From both the x-ray and thermal analyses results we can conclude that sputtering, just as electroplating, produces films of "Sn-Ni" having a different phase structure than equilibrium alloys of the same composition. Both types of films (plated and sputtered) are close to being equiatomic and, following heat-treatment, both have x-ray diffraction patterns corresponding to a mixture of the equilibrium phases Ni_3Sn_4 and Ni_3Sn_2. We have already mentioned in the preceding paragraph that the DTA results for the sputtered films indicate somewhat different kinetics of transformation. The x-ray data, besides showing strong similarities between the two types of films, also reveal some differences.

As explained in the results section, the main difference between the x-ray patterns of Ni_3Sn_2 and "Sn-Ni" is that the 110 and 102 reflections coalesce into a single broad peak in electroplated "Sn-Ni", while they are easily resolved in Ni_3Sn_2. The corresponding 2θ regions of the x-ray patterns for the sputtered samples were carefully examined. For the as-deposited sputtered films, which were believed to be the metastable phase, a small shoulder was always present on the lower 2θ side of the main peak when the sample was actually in film form. Sputtered and electroplated films often show strong preferred orientation. The main reflection which was enhanced by the preferred orientation in the as-sputtered films was found to be 110 using the Laue transmission pinhole technique, and the small shoulder corresponded to the 102 reflection. Effects of preferred orientations were minimized by using powder samples, and there is evidence of peak splitting (102, 110) in Fig. 1a. The x-ray spectra for powder smears of sputtered "SnNi", plated "SnNi", and Ni_3Sn_2 are shown in Fig. 3 with an extended 2θ scale. Note that for the sputtered sample in powder form the 102 peak is now more intense than the 110 peak which is the reverse of that observed for the film samples.

Table II shows the calculated d_{110} and d_{102} values for some of the films. Even when metastable character is attributed to the sputtered films, d_{102} is separated

from d_{110} by a Δd ranging from 0.02 to 0.033Å. It should be noted that with increasing substrate temperature, Δd tends toward the value observed for Ni_3Sn_2 of 0.041Å. The last four entries of Table II show the data on powder samples in which preferred orientation did not exist. The results for powders are also illustrated by Fig. 3. In this figure the x-ray traces for the 110 and 102 peaks (normalized to unit area) are shown for equilibrium Ni_3Sn_2, electroplated "Sn-Ni", and sputtered "Sn-Ni". The 102 peaks have been arbitrarily centered at the ASTM value for better illustration. In spite of a rather large broadening effect, two separate peaks can be resolved for the sputtered sample, while no such separation is observed for the plated sample. The extent of the peak broadening is also recorded in Table II as the corrected full width at half-maximum (FWHM). The correction was made by using the gaussian approximation and taking as instrument broadening the width observed for the equilibrium Ni_3Sn_2 sample. X-ray line broadening is known to be due to small grain size, internal microstresses, and/or lattice defects. While it is not possible in the present case to separate these three factors, the line breadth is still a semiquantitative measure of the lattice "irregularities." Results in Table II indicate that the amount of "irregularities" observed in the sputtered sample was comparable to that observed in the plated sample. It is also significant that the line breadth decreased with increasing substrate temperature, and increased with deposition rate. If the line breadth was due only to small crystallite size, the Scherrer formula (7) predicts crystallite main dimensions of roughly 100-150Å for the samples showing the most line broadening.

From these results we can reasonably conclude that both electroplating and sputtering deposit a seemingly homogeneous and equiatomic phase of tin-nickel, the lattice cell of which bears strong resemblance to the cell of the equilibrium phase Ni_3Sn_2. Both methods of deposition, due to the slow rates of growth and migration at low substrate temperature, lead to fine-grained and highly distorted structures. On the other hand, the NiAs-Ni_2In structure, in which both Ni_3Sn_2 and the metastable phase crystallize, is known to accommodate defects and a wide range of composition (8). It is possible then that the metastable "Sn-Ni" is not a new phase as thought by Clarke (9), but the result of a distorted Ni_3Sn_2 lattice as suggested originally by Rooksby (6). In this light, the differences exhibited by plating and sputtering can be attributed to differences in the levels of microstress and deformation produced in the two processes or minor differences in microstructure.

In the first approximation, the microstructure of thin films is primarily fixed by the substrate temperature, but the flux of impinging species in electroplating was almost two orders of magnitude greater than the rate observed in sputtering. Also, plating is a charged process while sputtering is neutral. These differences can lead to a greater "quenching" effect in plating than in sputtering. Also there is the possibility that the difference in impurity levels and impurity species stabilizes differently the plated and sputtered structures. As a consequence, plating may deposit a film with the Ni_3Sn_2 lattice having enough anisotropic deformation and microstresses to make d_{110} and d_{102} equal. Sputtering, however, may allow enough relaxation to produce a lattice in which deformation is not as severe, and thus d_{110} and d_{102} are different. This difference is not as much as in the equilibrium Ni_3Sn_2 compound.

Unfortunately, the dissimilarity in the DTA results, *i.e.*, the apparent shift in the transformation temperature and larger heat of reaction, do not lend themselves to a ready explanation. The DTA results in-

dicate that the sputtered films are stable to a higher temperature and release more energy upon decomposition. Both a thermal kinetic study and an electron microscope study are in progress to clarify these observations and ascertain the causes for these differences.

Conclusion

By using sputtering, we have been able to deposit a metastable equiatomic tin-nickel alloy which is in many ways similar to that which previously has been obtainable only by electrodeposition. Results show that the sputtered alloy has the same basic crystal structure and composition as the electroplated alloy and undergoes the same transformation to equilibrium compounds upon heating. The observed minor differences in x-ray results and stability of the two types of deposits are possibly linked to differences in microstructures and/or microstresses.

Acknowledgments

The authors extend their sincere appreciation to G. V. McIlhargie for his special expertise and effort in preparation of the electroplated sputtering target, T. M. Paskowski for his diligence in obtaining the DTA data, and P. K. Gallager who conducted the E.G.A. study.

Brief Communication

Passivation of Silicon p-n Junctions by Slightly Conductive Chalcogenide Films

E. T. J. M. Smeets, J. Dieleman, F. H. M. Sanders, and D. de Nobel

Philips Research Laboratories, Eindhoven, The Netherlands

Edge breakdown and excessive surface leakage are two well-known hazards of reverse-biased p-n junctions. As a result of numerous studies about the properties of thermal SiO_2 and its interface with silicon, the semiconductor technologist has learned how to avoid these hazards in most cases. Nevertheless, edge breakdown and excessive leakage remain a problem in devices with features that make them prone to these failures. Such features are, for instance, high internal fields, a shallow p-n junction (sharp edges), or a technology that precludes the use of high-temperature oxidation to passivate the critical region where the p-n junction intersects the surface.

The present contribution gives some results of an investigation aimed at exploring the merits of passivation by means of slightly conducting films directly applied to the silicon at a low temperature. With a proper conductivity such a film will cause a gradual voltage drop at the surface of the silicon and thus extend the depletion layer parallel to the surface, thereby reducing the curvature of the depletion layer at the edge of the p-n junction. It is shown that thin chalcogenide films can effectively suppress edge breakdown. Although this goes at the expense of some increase in reverse current because of the additional leakage path created by the chalcogenide film, it has nevertheless proved possible to keep reverse currents in the low nanoampere range and, what is also important, the currents were observed to stay in this range during operation.

Key words: passivation, chalcogenide films, p-n junctions.

The semiplanar mesa-type avalanche photodiode sketched in Fig. 1 was chosen as a vehicle for this study. This device is hard to passivate (1), and it shows all the awkward features mentioned above. The n^+ layer is a shallow ion-implanted layer (0.5 μm), and therefore the critical edges (A and A' in Fig. 1) are sharp and for this reason prone to edge breakdown. The device is designed for operation slightly below the intrinsic breakdown voltage of the active central part. $V_{BD}{}^{i} = 135$V, which is rather high. Moreover, the use of oxidation at high temperature and the use of a diffused guard ring is impracticable because of the risk of spoiling the critical doping profile at the interface between the p- and the π-layer, which was grown epitaxially in an earlier processing step. Attempts to passivate this device by thermal oxidation at or below 900°C or by applying oxide films with low temperature CVD or sputtering met with no success. Edge breakdown remained or the dark current was high and/or increased with time.

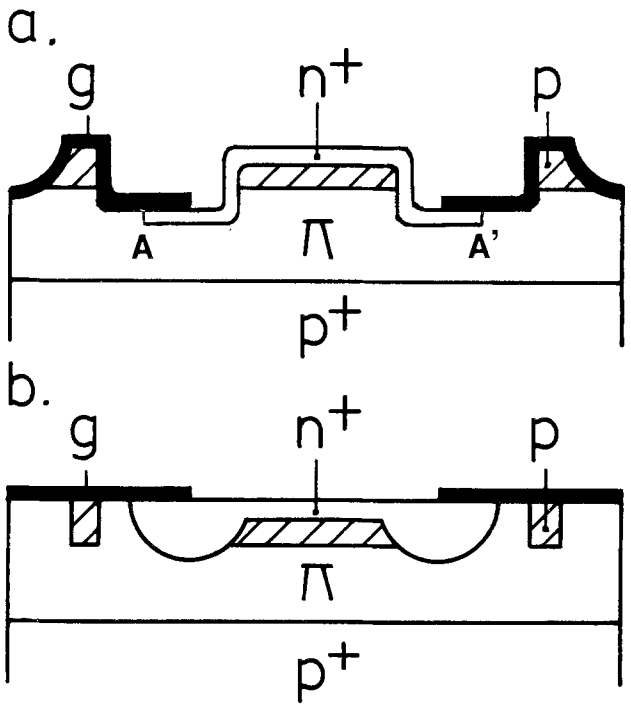

Fig. 1. Main Si APD structures: a. semiplanar mesa type; b. planar type. Both types have the $n^+pp^-p^+$ structure with the circular, active n^+p region surrounded by a concentric annular p-type channel stopper. The planar APD contains an additional n^+ guard ring at the edge of the active n^+p region. The film indicated by "g" is the chalcogenide film applied for edge breakdown suppression and/or passivation.

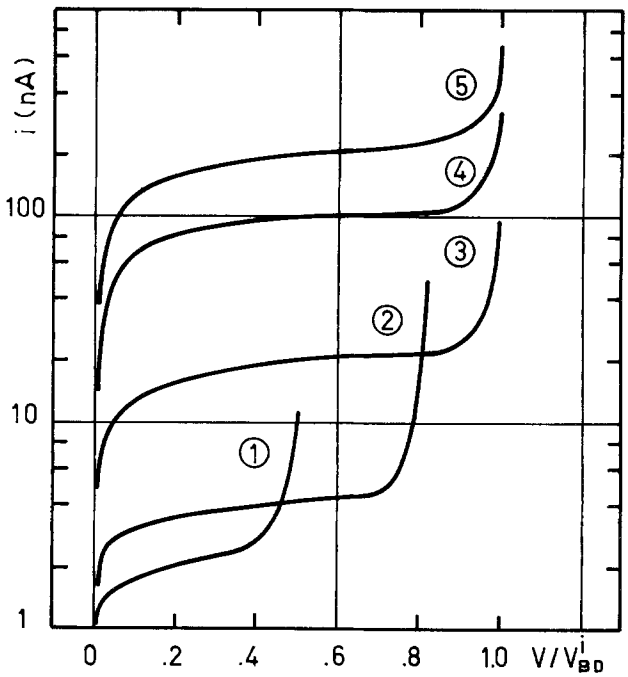

Fig. 2. I-V characteristics of the mesa-type APD for various conductivities of the chalcogenide film g. Curve 1 for a 0.1μ thick GaSe film; curve 2 for $GaSe_{1-x1}Te_{x1}$ with x_1 a few percent; curve 3 for $GaSe_{1-x2}Te_{x2}$ with $x_2 > x_1$ and just sufficient to suppress edge breakdown; curve 4 for a 0.5μ thick CdTe film heat-treated for 2 hr at 150°C in air; curve 5 for the as-deposited CdTe film.

Subsequently, chalcogenide films were examined, with particular emphasis on glassy films based on GaSe. These films are inert against corrosion in air and have high crystallization temperature of up to 450°C. Moreover, GaSe-based films, for instance, can be made over a large range of conductivities. The conductivity of these films increases with increasing substitution of Te for Se or of In for Ga (2, 3).

Figure 2 shows the reverse characteristics for such semiplanar mesa diodes (diameter n^+ region 400 μm) passivated with thin chalcogenide films. The conductivity of the films increases in the sequence 1-5. Curves 4 and 5 refer to diodes with a polycrystalline CdTe film, whereas curves 1, 2, and 3 give results for the glassy chalcogenide films.

The curves show that with increasing conductivity of the passivating film the breakdown voltage quickly rises up to the intrinsic breakdown voltage $V_{BD}{}^i$ (135V); apparently the passivation works satisfactorily. As expected, the reverse current increases with increasing conductivity of the film. This might suggest that the increased reverse current of the diodes is simply due to a resistive parallel leakage path. If this were the case, however, one would expect incomplete saturation of the reverse current with rising conductivity of the passivating film, which is not observed in Fig. 2. Apparently the assumption of simple parallel leakage is an oversimplification of the actual situation.

In Fig. 2 the switch towards intrinsic breakdown occurs somewhere between curves 2 and 3, *i.e.*, between diodes with leakage currents with, say, 4 and 20 nA. By proper adjustment of the Te content, films were deposited which gave diodes with intrinsic breakdown (135V) and a leakage current of only 5 nA at $V = 0.9\ V_{BD}{}^i$.

Another test was made on planar devices [see Fig. 1b and Ref. (1)], where, owing to the presence of a diffused guard ring, edge breakdown was no problem. Here films with even lower conductivities could be used satisfactorily. After stripping the oxide passivation of planar devices and deposition of a glassy GaSe film instead, good planar APD's (diam 450 μm) were obtained with stable dark currents as low as 2 nA at $V = 0.9\ V_{BD}{}^i$ ($V_{BD}{}^i = 250$V), *i.e.*, only about a factor of two higher than that of the original devices with standard high temperature thermal-oxide passivation. In summary, the present work shows that in cases where the well-established passivation with high temperature thermal oxide cannot be used, chalcogenide films of the kind described offer interesting possibilities.

Comparison of the Erosion of Vitreous Carbon and High Density Graphite in Molten Silicon

R. E. Chaney*

Motorola Incorporated, Semiconductor Group, Phoenix, Arizona 85008

Materials compatibilty problems have seriously affected the development of new silicon ribbon crystal growth technologies. One of the most notable problems has been the degradation of forming dies used for the edge-defined film-fed growth (EFG) process (1), the capillary action shaping technique (CAST) (2), and the inverted Stepanov technique (3). In an effort to understand the materials interaction phenomena, an investigation was undertaken to study the erosion processes of several materials in molten silicon (4, 5). In the previously reported work the materials studied were chosen because of possibly very low erosion, negligible contamination effects, and low porosity. Vitreous carbon[1] was selected as the most promising candidate of the various carbon products. However, many investigators use high density graphite for die fabrication. The purpose of this note is to compare the erosion characteristics of the two carbon products.

The experimental procedure was to immerse rods of the test materials in molten silicon. The rod was either withdrawn or immersed, in stages, to yield a sample with several segments which had been exposed to the melt for various lengths of time. At the top of each section, at the liquid-solid-ambient interface, a groove was produced by the combined effects of surface erosion and surface tension driven flow (6). That this effect is at least partially responsible for severe degradation of the edges of forming dies is a reasonable assumption. The radius change of the lower portion of the segment gives a measure of the surface erosion rate of the test material in silicon. The ambient was one atmosphere of helium while the temperature was maintained at the melting point plus 5°C.

Figure 1 graphically shows the surface erosion *vs.* exposure time for high density graphite.[2] Sample 1 gave very poor results. Several of the zones were so badly pitted that radius measurements were not possible. Sample 2 shows an offset from the axis indicating that the initial melt temperature was too close to the melting point, allowing a protective coating of silicon to be frozen onto the sample initially. Samples 3 and 4 gave reproducible results. All samples were polished prior to testing. The erosion rates for the surface of the rod and for the groove (near the liquid-solid-ambient interface) are tabulated in Table I for high density graphite and vitreous carbon. Fused silica is given as a reference.

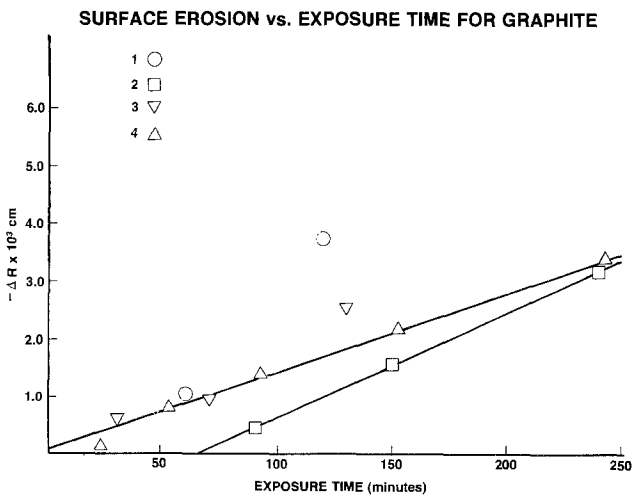

Fig. 1

The plot of groove depth *vs.* exposure time yields the erosion rate (groove) listed in Table I. Samples 1 and 3 were eroded severely, consequently the results were nonuseable. Samples 2 and 4 did yield a linear relationship similar to that for erosion of the rod surface.

Based only on the data in Table I it is not apparent that there is much difference in the behavior of the two carbon materials in molten silicon. However, investigation of cross sections of the interface between the test rods and the silicon adhering to the rod tip gives an insight into the erosion process. Results for vitreous carbon are given elsewhere (5). The nonporous material erodes by a simple dissolution mechanism involving the formation of a continuous and uniform SiC boundary layer. The presence and effects of this layer are discussed by Swartz *et al* (7).

Figure 2 shows the interface between the high density graphite and silicon. The boundary layer is thin but apparent. The broad light colored band, indicated by the arrow, between the interface and the bulk material is the region of penetration of the graphite by the melt after a 4 hr exposure. It consists of graphite, Si, and SiC in the pores of the bulk material. It is approximately 0.5 mm thick, and contrasts with the absence of penetration of vitreous carbon by the melt (5).

A closer view of the boundary layer is shown in Fig. 3. The layer is irregular and noncontinuous. The arrows indicate particles of SiC which appear to have been released from the layer and frozen into the melt at the termination of the experiment. During ribbon crystal growth such particles which are swept to the crystal growth interface cause twinning and polycrystalline ribbons (2, 3).

It is apparent that high density graphite undergoes erosion by a complex mechanism involving the formation and dissolution of a second phase compound (SiC) and intergranular corrosion.

From these results and those of previously reported work, it can be concluded that while the two carbon materials erode at approximately the same rate, the mechanism is more complex for high density graphite. Intergranular attack appears to result in SiC particles in the melt which affect the ribbon crystallinity and will produce irregular die surface geometry. Thus, forming dies fabricated from vitreous carbon, where

Table I. Erosion results

Sample	Erosion rate (surface)	Erosion rate (groove)

A Technique for Fabricating Oxide Passivated BARITT Diodes

B. M. Armstrong, R. A. Moore, H. S. Gamble, and J. Wakefield

Department of Electrical and Electronic Engineering,
The Queen's University of Belfast, Belfast, BT7 1NN, Northern Ireland

It is well known that oxide passivation as used in the "Planar" process greatly improves the reliability, life and yield of semiconductor devices. However, mesa diodes as used in microwave devices such as IMPATTs and BARITTs are not normally oxide passivated. It has been observed with such devices, particularly when Schottky barriers are employed, that degradation of the d.c. characteristic can occur leading to premature failure of the device.

This note reports on a fabrication technique for producing oxide passivated silicon BARITT mesa diodes. These may have either platinum silicide Schottky injecting contacts (M-N-P^+ BARITT) or diffused P^+ injecting contacts (P^+-N-P^+ BARITT). Particular features of this process are the method of production of the self-aligned contacts and the simple method of chip separation.

Experimental Procedure.-- Silicon nitride, because of its slow rate of oxidation (1) and resistance to silicon etch is ideally suited to the processes described below. Following an initial boron diffusion the wafers are coated with C.V.D. silicon nitride and silicon dioxide layers. These layers are then patterned with a scribe-line type network using standard photolithographic techniques, the silicon dioxide layer acting as a mask during etching of the nitride in hot orthophosphoric acid. The line network is then chemically etched into the silicon to a depth of about 10μm forming a matrix of squares which define the individual chips and aid device separation.

The remaining layers of silicon dioxide and nitride are re-patterned into an array of dots and 10μm tall mesas are formed by chemical etching. After removal of the masking oxide the wafers are thermally oxidised in water vapor at 1000°c for 20 minutes giving approximately 0.2μm of oxide on the mesa sides. The remaining nitride is easily removed in hot orthophosphoric acid leaving oxide passivated mesas with exposed silicon on

Keywords: transit-time devices, passivation, silicon nitride, Schottky barrier.

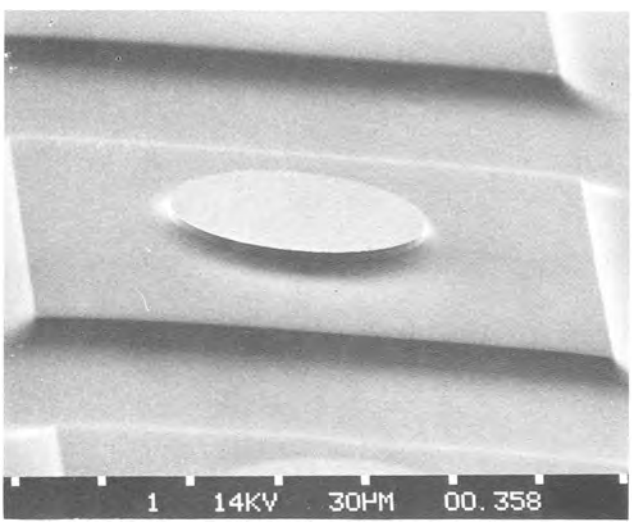

Fig. 1. Scanning electron micrograph of a mesa prior to thinning and separation X500.

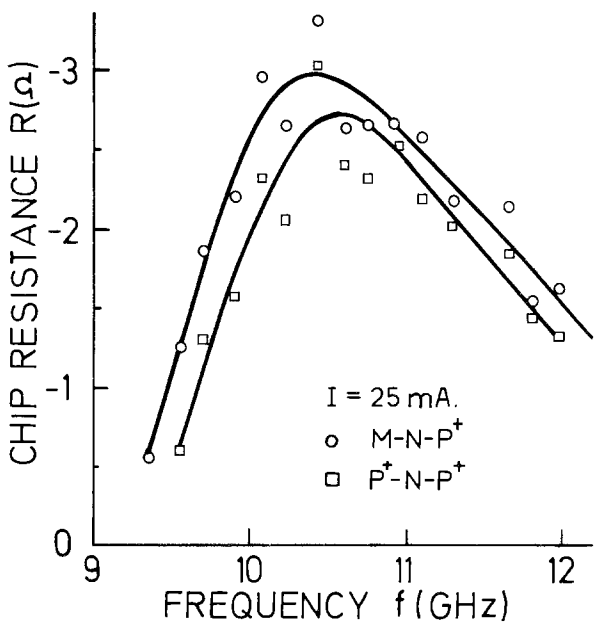

Fig. 2. Small signal chip resistance versus frequency.

top.

Platinum is sputtered over the whole wafer and annealed in nitrogen at 600°c to form platinum silicide on the mesa tops only. For bonding purposes the platinum is covered with evaporated layers of chromium and gold. The unalloyed platinum over the oxide is removed in an ultrasonic bath and this lifts off the chromium-gold leaving self-aligned contacts on the mesa tops. Fig. 1 shows a scanning electron micrograph of a typical mesa, with self-aligned contact, surrounded by etched channels.

The wafers are thinned from the back by mounting them face down on a float which is placed in a chemical bath (2). The process is stopped once the wafers have been thinned down to the scribe lines giving an overall device thickness of about 20μm. The individual chips remain fixed on the float and are coated with evaporated layers of chromium and gold. This chromium-gold layer is then copper plated to a reasonable thickness for handling. At this stage the copper plated chips are removed from the float as a unit and fine lines are scribed in the chromium-gold exposing the underlying copper which is then etched through in dilute nitric acid to produce isolated chips.

In the fabrication of M-N-P^+ BARITT diodes the initial diffusion is omitted and the platinum silicide layer becomes a rectifying Schottky barrier contact to the N-layer.

Results.-- Diodes manufactured using this technique exhibit excellent current-voltage characteristics. Schottky barrier and diffused BARITTs were fabricated from the same wafer to operate at approximately 10.5GHz. The N layer doping was $3 \times 10^{15} cm^{-3}$ and the respective active lengths were 4.4μm and 4.1μm giving punch-through voltages of 40.5V and 35.5V which are in good agreement with theoretical predictions.

The small signal r.f. impedance of these diodes was measured using a Hewlett Packard network analyser. Both types of diode, of area $1.8 \times 10^{-4} cm^2$, produced about 3 ohms of chip negative resistance at 10.5GHz as shown in Fig. 3. When operated in a triple slug-tuned coaxial circuit the P^+-N-P^+ diode produced a maximum power of 8mW and 0.82% efficiency while the M-N-P^+ diodes produced 13mW with 1% efficiency. These results were in good agreement with a computer analysis (3) assuming a diode series resistance of 0.5 ohms indicating that the oxide passivation does not appear to degrade the microwave performance of these diodes.

Conclusions.-- We have found with our oxide-passivated structures that failure due to metal contamination deposited on the mesa sides during top-cap welding is no longer a problem, and in general, oxide passivation reduces the loss of devices during handling and packaging. It has also been found that the technology outlined above produces high yields of good operating devices. Some devices have been operated for several months without a top-cap (i.e. exposed to the room atmosphere) and have shown no degradation, making them suitable for unpackaged insertion into microstrip. In conclusion these BARITT diodes have the advantages associated with semiconductor devices made by the "Planar" process.

Aspects of Molybdenum Chemistry in the Basic NaCl/$AlCl_3$ Melt at 175°C

J. Phillips[1] and R. A. Osteryoung*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523

ABSTRACT

A number of molybdenum chlorides and oxychlorides have been investigated in the sodium tetrachloroaluminate melt. The three- and five-oxidation states were stable in the melt, but the six-oxidation state, added as MoO_3, MoO_2Cl_2, and $MoOCl_4$, oxidized the melt and was itself reduced to Mo(V). The behavior of this Mo(V) was indistinguishable from that of Mo(V) added directly to the melt as the pentachloride. Mechanisms have been proposed to rationalize the electrochemical oxidation of Mo(III) and reduction of Mo(V), although in the latter case layer formation on the electrode surface prevented a dennitive characterization. A disproportionation mechanism is believed to be operative in the oxidation of Mo(III), and by cyclic voltammetry and rotating ring-disk techniques it has been possible to detect an intermediate Mo(IV) species.

Investigations involving molybdenum salts in fused salt media have been largely confined to the molten alkali halides (1-6). Popov (6) has defined the electrochemistry of MoO_3 in a LiCl/NaCl melt at 450°C in terms of the species MoO_2Cl_2, $Mo_2O_7^=$, and $MoO_4^=$. Reduction of these species results in a surface film of lower oxidation state molybdenum oxides. A study of the deposition of Mo from Mo(III) chloride at 600°C resulted in the postulation of a stable polymeric ion in equilibria with an electrochemically active monomer (3).

More limited investigations have been undertaken in alkali tetrachloroaluminate melts (7-8). Because of their low liquidus temperature, these melts provide excellent electrolytes for high energy battery and fuel cell systems. In this context, both $MoCl_5$ and MoO_3 have been investigated (9) and found to be eminently suitable as cathode materials in pelletized thermal batteries. In an investigation of both MoO_3 and K_3MoCl_6 in a ternary alkali tetrachloroaluminate melt, Marshall and Yntema (7) determined the deposition and decomposition potentials of a "black spongy deposit," and obtained values of 0.3 and 1.85V (*vs.* an Al reference electrode), respectively. This was assumed to be the deposition potential of molybdenum, the last reduction step being identical in the cases of MoO_3 and K_3MoCl_6. Senderoff (1) questioned the validity of these results, contending that air contamination of K_3MoCl_6 resulted in the production of higher valence oxygenated molybdenum compounds, which upon reduction deposit a mixture of molybdenum and molybdenum oxides. More recently, MoO_3 has found application as a cathode material in a nonaqueous secondary battery based on the solvent butyrolacetone (10-12).

The present investigation examines the electrochemical behavior of MoO_3, $MoCl_5$, MoO_2Cl_2, $MoOCl_4$, and K_3MoCl_6 in the sodium tetrachloroaluminate melt. The techniques employed included cyclic voltammetry, normal pulse voltammetry, and the rotating-disk electrode, as well as the newly developed rotating ring-disk electrode (13).

Molten NaCl:$AlCl_3$ (1:1) may be considered to consist of Na^+ and $AlCl_4^-$ ions. By a variation of the mole fractions of the component salts, it is possible to control the acidity of the melt. The dominant acid-base property is determined by the equilibrium (22) $2\,AlCl_4^- = Al_2Cl_7^- + Cl^-$, $K_M = 1.06 \times 10^{-7}$. The potential of an aluminum electrode immersed in the melt, *vs.* an aluminum electrode in a sodium chloride saturated reference compartment functions as a chloride ion indicator, and the pCl^- may be altered by anodizing or cathodizing this electrode.

Experimental

The cyclic voltammetric and rotating-disk studies were carried out using a potentiostat developed in these laboratories. Normal pulse voltammetry was achieved using a PAR 174 instrument. The independent control of the disk and ring potentials of the rotating ring-disk electrode (RRDE) was undertaken using a bipotentiostat based on the circuitry of Bruckenstein *et al.* (15). An ASR servocontrolled motor-tachometer (as supplied by the Pine Instrument Company) served to rotate the electrodes. Current voltage traces were recorded on a Housten Model 2000 X-Y recorder and a Techtronix storage oscilloscope.

The experimental work was carried out under a purified argon atmosphere in a Vacuum Atmospheres Company dry box equipped with a Model HE-493 Dri-Train for constant recirculation of the argon gas through a column of activated copper and molecular sieves. As an additional precaution, P_2O_5 was exposed to the dry box atmosphere. The criteria used to assess the purity of the atmosphere in the dry box was the duration of lifetime of a 25W light bulb filament run

[1] Present address: Department of Chemistry, Carleton University, Ottawa, Ontario, Canada.
Key words: sodium tetrachloroaluminate, fused salts, molybdenum.

from the line voltage (16). A five-day period was associated with an atmosphere of acceptable purity.

The basic sodium tetrachloroaluminate melt was prepared by the addition of aluminum chloride (Fluka A.G.) to a molar excess of sodium chloride (Fischer certified A.S.C. grade), and their subsequent fusion at 175°C. Purification of the melt was accomplished by preelectrolysis, using an aluminum rod anode (Johnson Matthey Specpure grade) and a coiled aluminum wire cathode (Alfa Inorganics m5N) (14). After 10 days of preelectrolysis at a current density of 1 mA cm^{-2}, the resultant melt was clear and colorless. Prior to use, the melt was filtered through a medium porosity glass-sintered frit in order to remove suspended aluminum particles.

The current-voltage curves were obtained with a Pyrex glass cell with a Teflon top. To allow free rotation of the rotating-disk electrodes, the hole for the RDE was made slightly larger than the diameter of the electrode. The cell was thus "open" to the dry box atmosphere.

Coulometry experiments were carried out in a glassy carbon crucible, also used as the working electrode.

Auxiliary and reference electrodes were isolated from the bulk melt by fine glass frits. Both electrodes consisted of aluminum wires. The reference electrode was allowed to equilibrate in the sodium chloride-saturated reference compartment for several hours before use. All working electrodes were G.C. 20 grade glassy carbon (as supplied by the Tokai Electrode Manufacturing Company Limited) sealed in Pyrex glass.

The u.v. spectra were recorded with a Carey Model 17 Spectrophotometer, using 1 cm pathlength Suprasil cells fitted with a ground glass joint. The sample compartment of the spectrophotometer was spacious enough to accommodate an aluminum block furnace (10 × 10 × 10 cm) which was heated by 4 Chromalox cartridge heaters.

Results

$MoCl_5$ in the sodium chloride-saturated melt.—Figure 1 illustrates the rotation speed dependence of the current voltage curve on a glassy carbon rotating-disk electrode (area 0.2 cm^2) for $MoCl_5$ in the melt. It is convenient to consider the cathodic going sweep in three distinct regions, *i.e.*: (*i*) a rotation speed-dependent wave at approximately 1.2V; (*ii*) a more cathodic wave at 0.5V; and (*iii*) a reduction peak prior to the potential associated with aluminum deposition. The anodic going sweep shows additional peaks at 340, 1600, and 1850 mV. At the rotating-disk electrode, these must be associated with the oxidation of material deposited on the electrode surface.

A coulometry experiment was carried out at successively more cathodic potentials, *i.e.*, 1.1, 0.5, and 0.1V. The number of electrons involved in each case was 1.95, 1.03, and 2.3, respectively, indicating that the three regions corresponded to the production of molybdenum three, two, and molybdenum species of low oxidation state, possibly molybdenum zero. The accuracy of the last coulometry experiment is of course limited by background currents close to aluminum deposition.

The reduction plateau at 1.0V was shown to be diffusion limited by its adherence to the Levich relationship. The data were derived from a steady-state determination. The slopes of the lines were proportional to the concentration of Mo(V) in solution, and a diffusion coefficient was calculated as 3.2×10^{-6} cm^2 sec^{-1}. An order plot, *i.e.*, log i *vs.* log $(i_d - i/w^{1/2})$ for the reduction [obtained from the rotation speed dependence of the current (17)], showed strict first-order kinetics with respect to Mo(V) throughout the potential and concentration range investigated. Tafel plots, corrected for first-order kinetics, were linear (Fig. 2) with a slope of 160 mV, which corresponded to an αn value of 0.6 at 175°C; α refers to the symmetry factor and n to the number of electrons in the rate-determining step.

Figure 3 illustrates the effect of the variation of the cathodic sweep limit upon the system. No oxidation wave in the voltage range 2.0-1.5V is associated with the diffusion-limited reaction at 1.0V: The products of this reaction wave would therefore appear soluble. Extending the sweep limit to encompass the second reduction wave results in a small oxidation current at 1600 mV. Further extension of the cathodic limit into the steeply rising current region results in the appearance of an oxidation wave at 1800 mV. These peaks are enhanced by increased cathodic limit or polarization

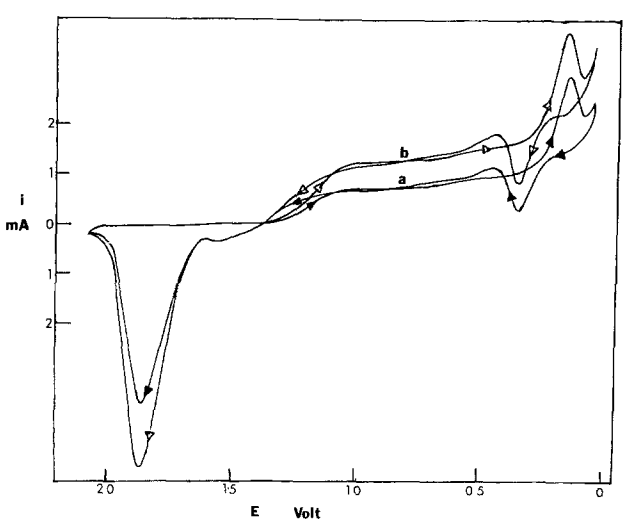

Fig. 1. Current voltage curves for $MoCl_5$ on a glassy carbon rotating disk in a basic tetrachloroaluminate melt. Curve a, 600 rpm; curve b, 2000 rpm; sweep rate, 18 mV sec^{-1}; concentration of $MoCl_5 = 4.5 \times 10^{-3}$M.

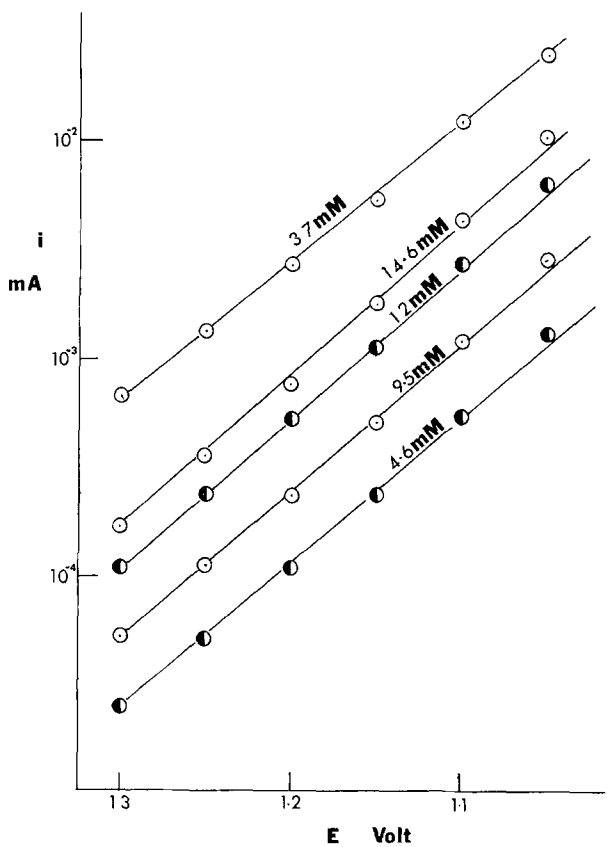

Fig. 2. Tafel plot for the first reduction wave for $MoCl_5$ at various concentrations, i, as plotted $i_{(observed)E} \times i_d/i_d - i(E)$.

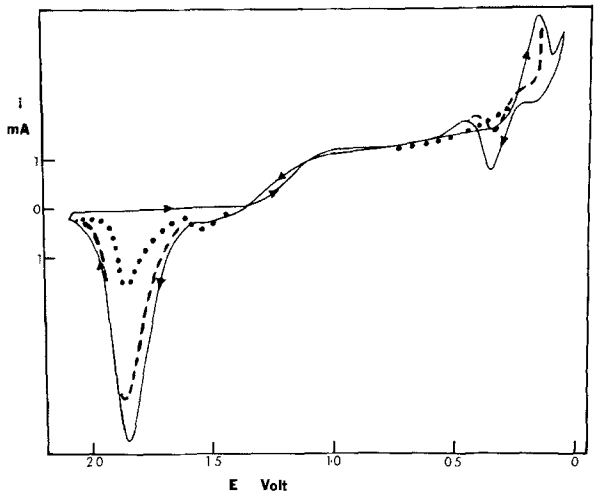

Fig. 3. Effect of varying the cathodic sweep limit upon the current-voltage curve for $MoCl_5$ in the basic melt. Rotation speed 2000 rpm; concentration 4.5 × 10^{-3}M. ------- Sweep reversed at 0.2V, . . . sweep reversed at 0.3V.

time at these cathodic potentials. From the rotation rate dependence, it is concluded that the peaks correspond to the oxidation of surface films, and are only rotation-speed dependent as a result of the deposition being influenced by rotation speed. Potential excursions beyond the reduction peak at approximately 0.1V results in an additional oxidation peak at 340 mV.

It can be seen (Fig. 4) by varying the anodic sweep limit that the reduction processes at more negative potentials involve surface species, which when not oxidized at more positive potentials, *i.e.*, 1.5-1.8V, increase in surface concentration by further reduction, hence the enhanced oxidation peaks at 340 and 1800 mV. The appearance of an additional anodic shoulder on the oxidation peak at 1800 mV subsequent to this more prolonged cathodic treatment suggests a progressive modification of the low oxidation state molybdenum surface species.

A significant feature of the current-voltage curves obtained with the rotating disk was the rotation speed dependence of the ratio of the heights of the two waves at 1.2 and 0.5V (see Table I). The coulometric experiment would indicate an expected value of 0.5; however, the decreasing values obtained as the rotation speed increased would be characteristic of a product of the first reduction undergoing a chemical reaction prior to the second reduction.

4000	0.30
6000	0.28

The rotating ring-disk electrode was utilized to detect solution products of the reduction and oxidation processes observed on the rotating-disk electrode. Adjusting the ring electrode potential to 1.9V, just cathodic of chlorine evolution, enabled the ring to oxidize Mo(III) reaching it from the disk. Figure 5 shows the ring response at this potential as the disk potential is swept. As the disk potential proceeds more cathodically, the ring oxidation current increases, and a current plateau is obtained at a disk potential of 800 mV.

The collection efficiency of the ring was calculated as 38%, and has been measured on known systems and found to be 40% (13). When the ring current is corrected by a factor of 2.5, the ring current does not correspond to 100% of the disk plateau current at 0.8V, but lies between 50 and 70% of that expected in the range of rotation speeds used. As the rotation speed of the electrode was increased to 6000 rpm, the proportion collected was 50% of that expected, and this percentage increased monotonically as the rotation speed was decreased. This rotation speed dependence of the collection efficiency implies the interference of chemical steps either during the transit time of a species between the disk and ring electrodes, or in the electrochemical oxidation process occurring at the ring. The former alternative would imply the generation of an electrochemically inactive species, as the product of the first reduction wave at 1.0V. This would then be expected to interconvert to a more electrochemically active species.

The second wave at 0.5V on the disk electrode is characterized by a decrease in the current response on the ring electrode. This indicates the further reduction of Mo(III) at the disk to an insoluble Mo(II) species. It is significant that this second reduction wave on the disk does not reduce all of the Mo(III) to an insoluble species, as indicated by the fact that the ring current is not reduced to zero. The depletion of the ring current when the disk is more negative than 0.5V is greatest at low rotation speeds (50% at 500 rpm), and

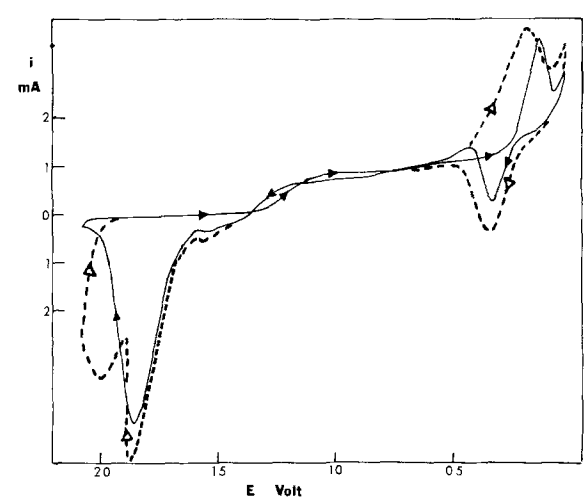

Fig. 4. Effect of varying the anodic sweep limit upon the current-voltage curve for $MoCl_5$ in the basic melt. – – – Sweep reversed at 0.5V. Rotation speed 1000 rpm; concentration 4.5 mM.

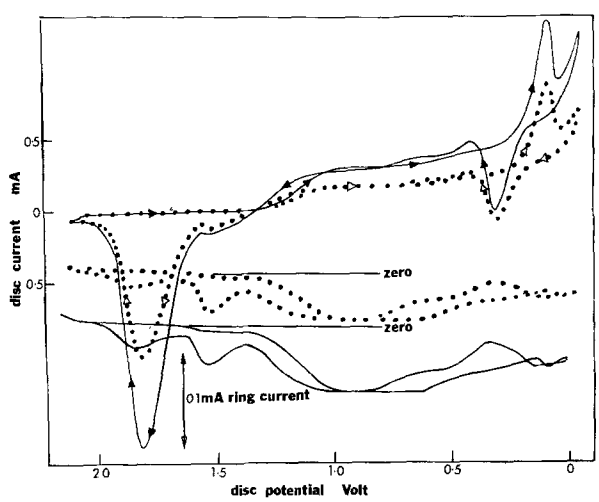

Fig. 5. Current-voltage curves obtained with the rotating ring-disk electrode. Concentration $MoCl_5$ 4.5 mM. Potential of ring electrode = 1.9V. Sweep rate on disk, 18 mV/sec; ——— rotation speed 2000 rpm; . . . rotation speed, 600 rpm.

is progressively lower as the rotation speed increases, *i.e.*, 40% at 1000 rpm and 30% at 3000 rpm. This reflects the existence of a chemical step occurring prior to the second electrochemical reduction at the disk electrode. A longer residence time (low rotation speeds) in the vicinity of the disk electrode allows the product of the first electrochemical reduction to undergo chemical change.

The potential region on the disk, corresponding to the more steeply rising current, is characterized on the ring by a further depletion of ring current. This is probably a result of the reduction of a small amount of soluble Mo(II) to a surface molybdenum species of low oxidation state. The prominent depletion of the ring current associated with the oxidation peak at 0.3V on the disk suggests that a reaction is occurring between the oxidized surface molybdenum species and the product of the first reduction wave on the disk, prior to its chemical reaction. As the disk electrode surface undergoes oxidation at 1.8V, the ring electrode detects two peaks corresponding to the liberation from the disk of oxidizable soluble species.

The surface electrochemistry involved here is certainly complex; however, the evidence of the ring-disk and disk electrodes indicates that the deposition of molybdenum species on the surface of the disk can be correlated somewhat to a chemical step subsequent to the first reduction wave.

The peak current at 0.1V on the disk electrode must be associated with a passivation phenomena. At higher Mo(V) concentrations (20 mM), the second reduction wave at 0.5V on the disk becomes peak-like, and upon potential reversal at 0.4V, the limiting currents for the Mo(V) reduction wave are significantly reduced, and exhibit a rotation speed dependence normally associated with a blocked electrode (18).

Upon adjusting the potential of the ring electrode to 800 mV [the diffusion-limited potential for Mo(V) reduction] the current response manifested two current values with and without the shielding effect of the disk electrode, *i.e.*, as the Mo(V) is reduced at the disk electrode, the amount reaching the ring decreases. A reduction peak was observed for the ring current as the disk was oxidized at 1800 mV. This indicated the retrieval of Mo(V). Normal pulse voltammetry was carried out upon $MoCl_5$ in the melt. The starting potential was 1600 mV, and a scan rate of 5 mV/sec was employed. Current-voltage curves resembling those obtained with the rotating-disk electrode resulted. The diffusion coefficient of the species was 3×10^{-6} cm^2 sec^{-1}, in good agreement with the RDE data. An αn value of 0.63 was obtained from a linear plot based on the analysis of Oldham and Parry (19). Again, a first-order dependence of the current upon the molybdenum concentration was indicated.

The reduction wave at 1.0V was further investigated by cyclic voltammetry at a stationary electrode. Figure 6 illustrates a typical voltammogram obtained at a sweep rate of 8 V/sec, where two reduction and one oxidation peak are observed. The more anodic reduction peak at 1600 mV was only observed after the first sweep and at lower sweep rates, *i.e.*, at less than 1 V/sec it could not be observed at all. The inability to observe this peak at low scan rates must be associated with the removal of the species involved by a chemical step.

The value of the quotient $i_p/\nu^{1/2}$ (between 0.2 and 8 V/sec) as a function of sweep rate for the reduction peak at 1.0V was constant, and substantiated the diffusion-limited nature of the reduction peak. An αn value of 0.53 is obtained from a plot of E_p *vs.* log ν, in good agreement with RDE work. The diffusion coefficient obtained from this data was 2.5×10^{-6} cm^2 sec^{-1}, a value slightly lower than the values obtained from the RDE and NPP. Figure 7 shows the ratio of the peak current for the reduction of Mo(V) at 1.0V to the peak current for the oxidation of Mo(III) as a function of

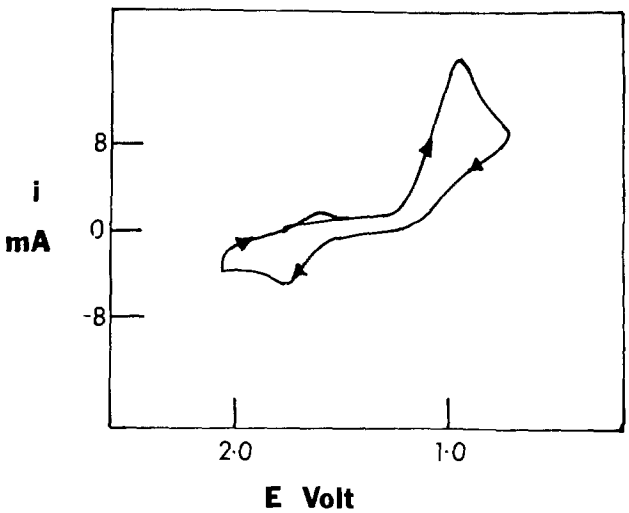

Fig. 6. Cyclic voltammogram for $MoCl_5$ in a basic melt over a limited voltage range. Concentration 37 mM; sweep rate 8V/sec; initial potential 1780 mV; initial scan cathodic.

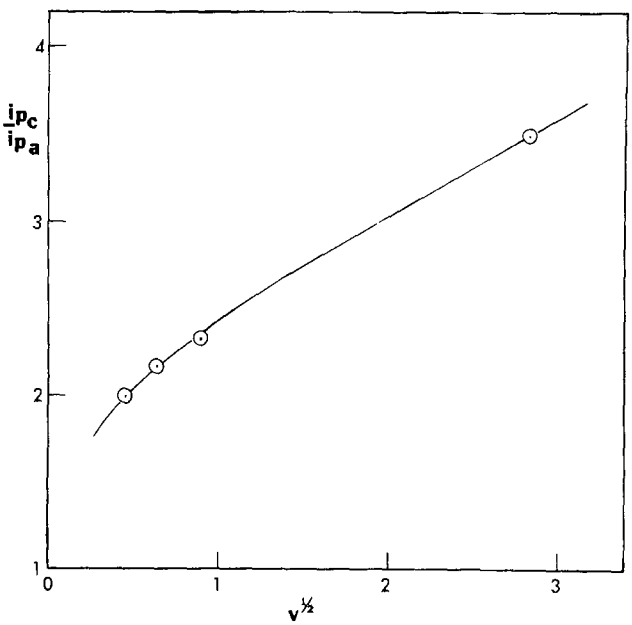

Fig. 7. The ratio of the peak current for Mo(V) reduction (at 1.0V) to the peak current for Mo(III) oxidation as a function of sweep rate.

sweep rate. At higher sweep rates, the value increases, supporting the conclusions arrived at with the RRDE.

The behavior of K_3MoCl_6 in the sodium chloride saturated melt.—This substance was introduced directly into the melt to yield an orange coloration. Some difficulty was encountered in dissolving the solid, particularly as the concentration rose above 3 mM.

The current-voltage curve obtained on the RRDE is illustrated in Fig. 8. On the disk electrode, the relief of the current-voltage is characterized by a double layer region in the midvoltage range. At anodic potentials lies a rotation speed-dependent limiting current which is superimposed upon the current, resulting from the reduction process occurring at cathodic potentials. An initial anodic going sweep from the rest potential at 1.0V reveals only the limiting current phenomena. The superimposed surface oxidation currents behave in an analogous manner to those of $MoCl_5$, in relation to the cathodic deposition potentials.

Coulometry on a K_3MoCl_6 solution indicated that the oxidation of Mo(III) at 1700 mV produced Mo(V). The

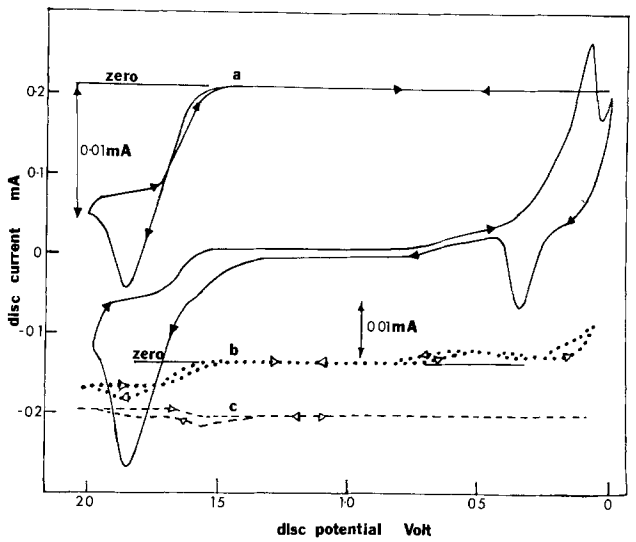

Fig. 8. Current voltage curves obtained on a rotating (2000 rpm) ring-disk electrode for K_3MoCl_6 in a basic melt. Concentration 3.2 mM; sweep rate 18 mV/sec; ring electrode potentials; curve a, 0.8V; curve b, 1.3V, curve c, 2.0V.

latter product could then be quantitatively reduced to Mo(III) again. Reduction of a Mo(III) solution at +0.1V gave a n value of 2.75. Holding the ring potential at 0.8V (Fig. 8) resulted in the detection of Mo(V). As the disk was scanned over the anodic potentials corresponding to the oxidation of Mo(III) to Mo(V), the current on the ring was 40% of that obtained on the disk, and was invariant with rotation speed. Figure 8 also shows the effect of holding the ring at 1300 mV and sweeping the voltage on the disk. This is the more cathodic potential of the reduction wave seen in Fig. 6. In this case, two processes are observed. As oxidation of Mo(III) occurs at anodic disk potential a ring reduction current is observed, which as a percentage of the disk plateau current, increases with rotation speed. Secondly, at cathodic potentials an oxidation current is observed which corresponds to the oxidation of any soluble Mo(II) species. The third ring response in this figure is obtained with a ring potential of 2.0V, where a shielding effect as well as the liberation of Mo(III) from the surface of the disk is shown.

An examination of the concentration dependence of the limiting current for Mo((III) oxidation at fixed rotation speed exhibited a positive deviation from linearity at higher concentrations. Investigations at higher concentrations encountered solubility problems. The rotation speed dependence of the limiting current is illustrated in Fig. 9. The relief of this series of curves is indicative of chemical reactions preceding charge transfer. At high rotation speeds, the reactive entity has been swept from the surface of the disk almost before the chemical reaction has occurred; hence the almost diffusion-limited behaviors.

Cyclic voltammograms illustrating the oxidation of Mo(III) are shown in Fig. 10. All scans were initially anodic going from the rest potential. At lower sweep rates, *i.e.*, less than 1 V/sec, the reduction peak at 1600 mV was not observed. In this range of sweep speeds, significant differences in the two peak heights were observed, with the peak height for the oxidation process being approximately two times that for the reduction process. The reduction peak at 1600 mV which appears at faster scan rates is identical with that observed in the case of Mo(V) solutions.

It is clear from the varying relative magnitudes of the two reduction peaks as a function of scan rate that one of two things occur. There could be an interconversion between two Mo(V) species, the more active, *i.e.*, that species which is reduced more anodically, being produced directly as a result of the Mo(III) oxi-

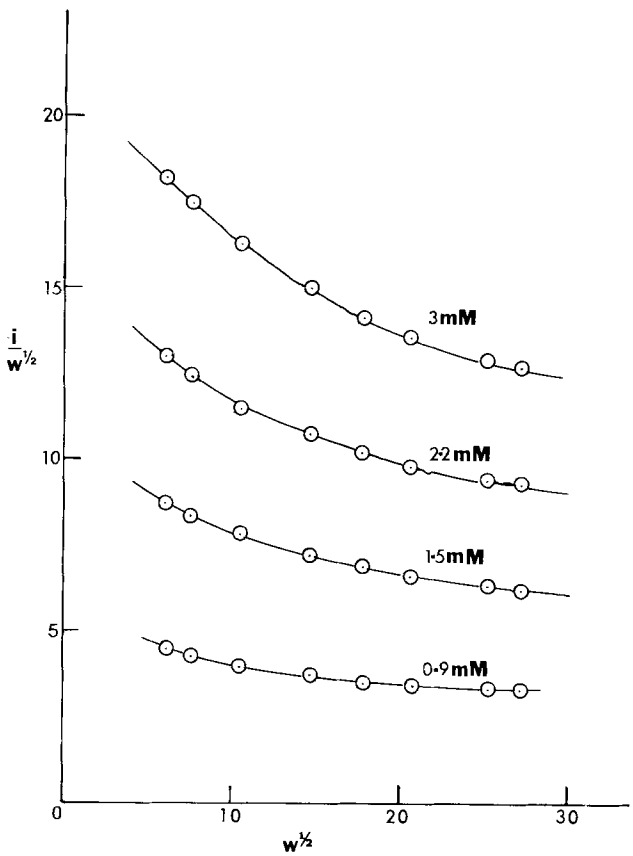

Fig. 9. The rotation speed dependence of the limiting current for the oxidation of Mo(III) at several concentrations.

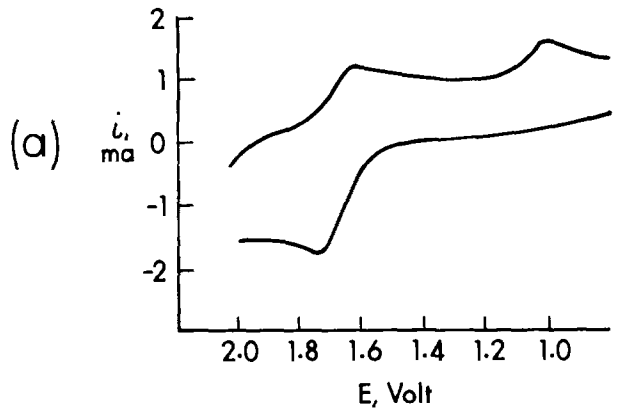
dation, and then undergoing an interconversion to the less active state. Necessarily the equilibrium constant for the two species must favor the less active species, as this is the only species observed at lower sweep rates. The other possibility is that an ECE-type mechanism for the oxidation of Mo(III) is operative. In this case, the two one-electron transfer steps are linked by a chemical step. Under these conditions the more anodic reduction peak, observed at fast scan rates, will correspond to the reduction of an intermediate, while the more cathodic reduction wave corresponds to the normal reduction of Mo(V), the final oxidation product after the passage of two electrons.

Two schemes are capable of explaining the behavior of the Mo(III) and Mo(V) in the cyclic voltammetric and RRDE experiments. These are designated Scheme A and Scheme B.



Scheme A

$Mo(III) \rightleftarrows Mo'(III)$	C
$Mo'(III) \rightleftarrows Mo(V) + 2e$	E
$Mo(V) \rightleftarrows Mo'(V)$	C

Scheme B

$Mo(III) \rightleftarrows Mo(IV) + e$	E
$Mo(IV) \rightleftarrows Mo'(IV)$	C
$Mo'(IV) \rightleftarrows Mo(V) + e$	E

Scheme A necessitates the inclusion of a preceding chemical step between two forms of Mo(III), an electrochemically active form, Mo(III), and an electrochemically inactive form, Mo'(III). The inactive form, *i.e.*, the product of Mo(V) reduction and the interconversion of these two molybdenum three states, would explain the nature of the rotating ring-disk response as the rotation speed varies. In addition, the rotation speed and sweep speed dependence of the current for the oxidation of Mo(III) may be rationalized in terms of an equilibrium constant defining almost

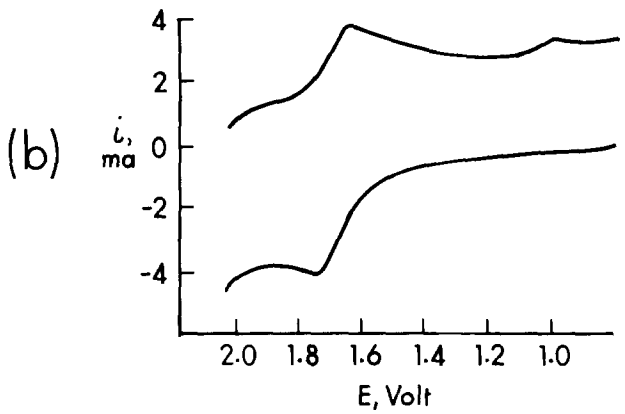


Fig. 10. Cyclic voltammograms for the oxidation of Mo(III). Concentration 1.5 mM; starting potential 1.0V; curve a sweep rate 2 V/sec; current 1 mA per division, curve b sweep rate 8 V/sec; current 0.2 mA per division; horizontal axis 1 division = 0.2V.

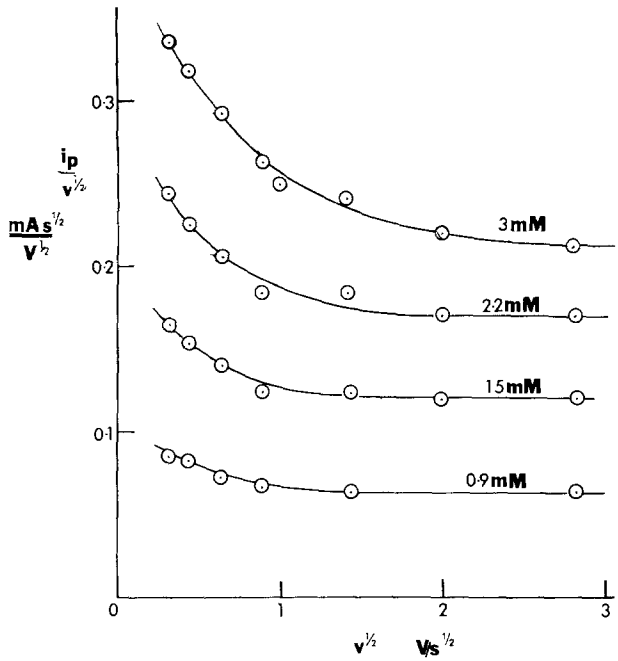

Fig. 11. The dependence of the peak current for the oxidation of Mo(III) upon sweep rate, at various concentrations of glassy carbon stationary electrode.

equal amounts of the two forms in the basic melt. Hence at higher sweep and rotation rates, the current becomes diffusion limited owing to a finite concentration of the active Mo(III) species in solution.

In Scheme B, the observed phenomena may be explained in terms of the reaction occurring at the electrode surface. An additional feature is the stability of Mo(IV) and its apparent chemical reaction. Although the rotating disk results from the reduction of Mo(V) also suggest the existence of two molybdenum three states, a fact that would support Scheme A, the observed phenomena are more readily interpreted in terms of a Scheme B-type mechanism.

The extreme values of $i_p/\nu^{1/2}$ and $i_d/\omega^{1/2}$ (*i.e.*, at low and high sweep and rotation rates) are very close to a 2:1 ratio (Fig. 9 and 11). A value of 1 for the equilibrium constant for the two postulated Mo(III) species would be very fortuitous. In addition, at high sweep rates in the cyclic voltammetry experiments, the peak for the oxidation of Mo(III) does not appear to move along the potential axis as the sweep rate is changed, suggesting that the electrochemical oxidation process occurring in the absence of the chemical step is reversible. The separation of the peaks of this anodic redox couple is 120 mV, a value closest to that expected for a reversible one-electron transfer (89 mV). Thus, the 2:1 ratio of the peak heights for the oxidation of Mo(III) to the reduction of Mo(V) can be ascribed to the reversible and irreversible nature of the charge transfer processes. Furthermore, evidence from the ring-disk examination of the Mo(V) reduction indicated that the percentage of Mo(III) retrieved on the ring as a function of $\omega^{1/2}$ varied in a manner analogous to that in Fig. 9 and 11; *i.e.*, at low rotation speeds the collection efficiency tended to 100% of that expected, and at higher rotation speeds it appeared to limit at approximately 50% of the expected value. The Mo(V)/Mo(IV) couple of Scheme B would meet these criteria.

The rest potential of the Mo(III)/Mo(V) system was linearly dependent upon the logarithm of the ratio of their two concentrations, and exhibited a slope of 42 mV decade.$^{-1}$. This is in good agreement with the theoretical slope of 44 mV decade^{-1} for a two-electron process at 175°C (Fig. 12). Scheme A could only accommodate this result if the inactive and active species of Mo(V) and Mo(III) were both monomers, in which case the active potential determining species would be linearly related to the total concentration.

The electrochemical behavior of the molydenum three and the molybdenum five states were further investigated by varying the acidity of the melt. The melt composition was varied over the range 49.78-49.98 mole percent (m/o) of $AlCl_3$. This range of composition was effective in changing the chloride concentration by a factor of 30. More acidic conditions radically affected the behavior of the species. At the mole fraction for chloride of $10^{-3.5}$, the Mo(III) appeared to precipitate from solution, and the wave corresponding to Mo(V) reduction underwent noticeable modification. Under even more acidic conditions, no wave was observed for the Mo(III) oxidation, and the Mo(V) reduction occurred as a kinetically controlled process on the surface of the electrode.

In the workable pCl^- range, *i.e.*, less than 50 m/o $AlCl_3$, the limiting currents on the rotating-disk electrode for the oxidation of Mo(III) showed no noticeable effect as the chloride ion concentration was systematically varied. However, the peak potentials at fast scan rates, *i.e.*, where the chemical step was minimal (>1 V/sec), showed a 90 mV anodic shift as the chloride concentration was altered by a factor of 10. This indicated that in the absence of the participation of the chemical step in the Mo(III) oxidation, the number of electrons involved was equal to the number of chloride ions.

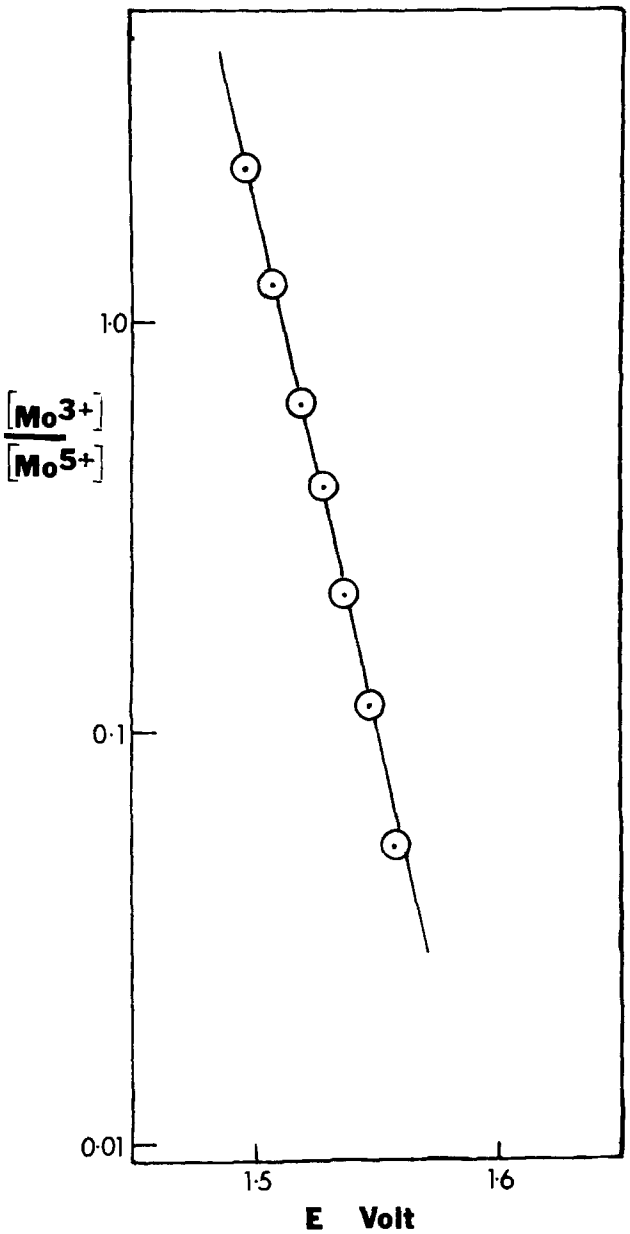

Fig. 12. The rest potential dependence upon the ratio of the total Mo(III) concentration of the total Mo(V) concentration.

The dependence of the rest potential of a fixed ratio of Mo(III)/Mo(V) upon the chloride ion concentration enabled the authors to estimate the ratio of chloride ions to electrons in the over-all reaction. As indicated by Fig. 13, a tenfold change in the chloride ion concentration resulted in a 78 mV potential change. This is close to the value of 89 mV expected for a ratio of 1 for the number of chloride ions to electrons.The acidity independence of the value of limiting current for Mo(III) oxidation at high rotation speeds renders Scheme A untenable on the basis that an equilibrium between two monomer Mo(III) species would be expected to show a chloride ion dependence.

A mechanism for the oxidation of Mo(III) is therefore proposed based on the ECE type reaction. The first electrochemical step has been proven to involve one chloride ion; however, the nature of the chemical step has not been established. Two types of chemical step are feasible: (*i*) the classical second-order disproportionation reaction as $2Mo(IV) \rightleftarrows Mo(III) + Mo(V)$, or (*ii*) a first-order interconversion between two Mo(IV) states, possibly involving an adsorbed species.

The first alternative is supported by evidence from the cyclic voltammograms (Fig. 10) as the concentration is varied. Table II shows the ratio of the anodic

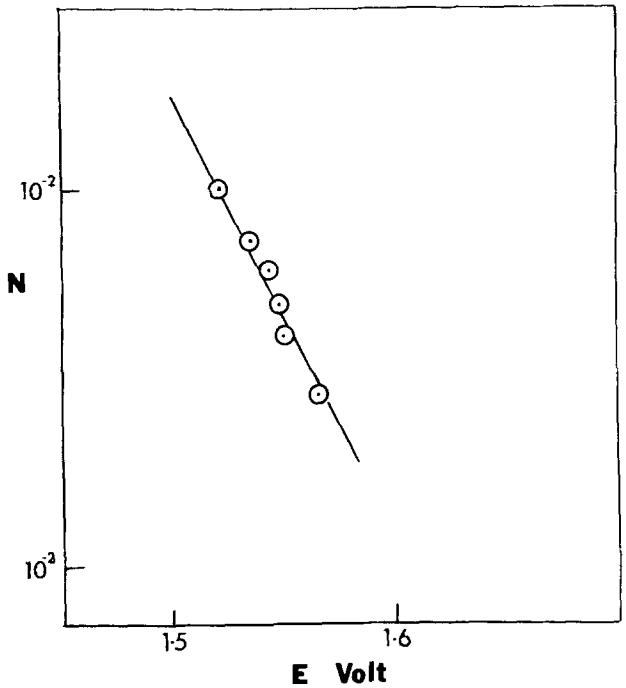

Fig. 13. The dependence of the rest potential upon the mole fraction of chloride ion at a fixed Mo(V)/Mo(III) concentration, using a GC indicator electrode.

peak current for Mo(III) oxidation to the cathodic peak current for the reduction of Mo(V) at a constant sweep rate as the concentration of Mo(III) is varied. The decreased ratio, indicating an increasing percentage of product at higher concentrations, indicates a second-order reaction. The nonlinearity of limiting current with concentration referred to earlier also supports this.

The data (from Fig. 9) was treated as suggested by Feldberg (20), and apparent n values were calculated for the currents at low rotation speeds, assuming the current at high rotation speeds for the 0.9 mM case to be diffusion limited. Figure 14 shows the requisite dependence of n apparent upon the logarithm of C/W. The rate constant for the disproportionation reaction was calculated from the working curve of Feldberg (20) and is given as

$$1.0 \pm 0.3 \times 10^3 \text{ liters mole}^{-1} \text{ sec}^{-1}$$

A mechanism was sought for the reduction of Mo(V); however, the difficulty encountered in maintaining an electrode surface of constant activity undermined an accurate determination of the order of the reaction with respect to the chloride ion. The over-all stoichiometry has been established, and the rotating-disk behavior suggested a following chemical reaction involving two Mo(III) states. On the basis of this information and the Tafel slope value of 0.6, as well as the concentration and potential independent first-order dependence upon Mo(V) a probable mechanism is

Table II. The ratios of the anodic peak current for the oxidation of Mo(III) to the cathodic peak current for the reduction of Mo(V) at concentrations $a = 0.85$ mM, $b = 1.5$ mM, $c = 2.2$ mM, and $d = 3$ mM at various sweep rates

Sweep rate, V/sec	*a*	*b*	*c*	*d*
0.8	—	2.0	2.05	1.96
2	2.9	2.3	2.08	2.06
4	—	2.75	2.8	2.3
8	5.5	4.125	4	2.64
16	—	—	4.86	4

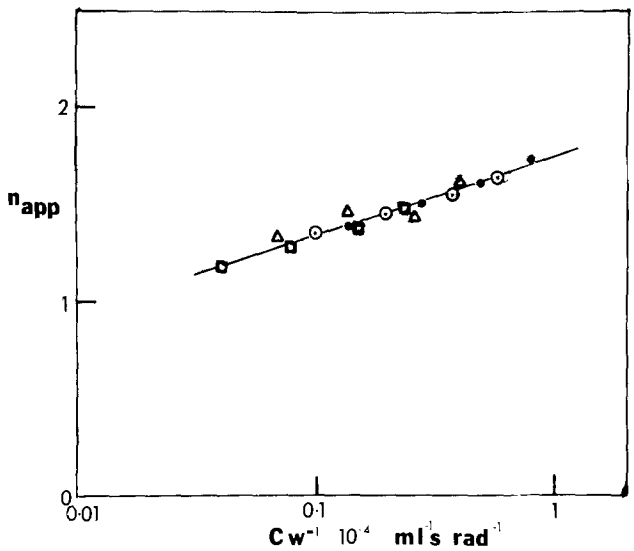

Fig. 14. The dependence of the number of apparent electrons upon the ratio of the concentration to rotation speed.

$$\text{Mo(V)} + e \xrightarrow{\text{RDS}} \text{Mo(IV)}$$

$$\text{Mo(IV)} + e \rightarrow \text{Mo'(III)}$$

$$\text{Mo'(III)} \rightleftharpoons \text{Mo(III)}$$

The latter equilibrium is assumed to greatly favor Mo'(III) in order to explain the results for the oxidation of molybdenum III.

The electrochemistry of the Mo(VI) states.—A variety of Mo(VI) compounds were added to the melt. They included MoO_3, MoO_2Cl_2, and $MoOCl_4$. Each compound exhibited a behavior similar to $MoCl_5$ in both the RRDE and cyclic voltammetric behaviors. Upon the addition of each of the three Mo(VI) compounds, there appeared at approximately 2.0V an additional reduction wave which disappeared with time. All data acquisition was carried out subsequent to the disappearance of this reduction wave. The reduction wave at 1.0V was diffusion limited, and the order of the reduction was one with respect to the active species. In each case the Tafel slope was linear, exhibiting a slope of 140 mV/decade.

Coulometry yielded an n value of 2 on the reduction wave at 1.0V, carried out upon solutions of MoO_3, and after the disappearance of the reduction wave at 2.0V. A rotating-disk electrode current-voltage curve run on the resultant melt indicated that the product of the coulometric reduction was Mo(III). Addition of a further vial of MoO_3 resulted in the immediate reduction of the wave height for Mo(III) oxidation, and the number of electrons involved in a second reduction was approximately three.

The presence of chlorine above the melt to which MoO_3 had been added was confirmed qualitatively with potassium iodide paper. The three electrons involved in the second coulometric experiment can thus be explained on the basis that either the chlorine evolved from the second addition reoxidizes the Mo(III) state present in the solution to Mo(V), or the MoO_3 oxidizes the Mo(III) state directly. Hence, the similarity in the current-voltage behavior between the Mo(V) and Mo(VI) can be ascribed to an equilibrium in the nature of $2Cl^- + 2Mo(VI) = 2Mo(V) + Cl_2$. Although this equilbrium appears to favor the formation of Mo(VI), it will, of course, be driven totally to the RHS as a result of the chlorine being able to escape from the cell. The diffusion coefficient for the Mo(V) generated from the Mo(VI) species was found to be $2.5 \pm 0.5 \times 10^{-6}$ cm^2 sec^{-1}.

Discussion

The electrochemically indistinguishable behavior of $MoCl_5$ and the molybdenum five complex derived from the oxygenated six states would suggest that $AlCl_4^-$ is instrumental in abstracting the oxygen ligands from the six state to render it unstable, particularly in view of the fact that Mo(VI) is apparently stable in the LiCl/KCl melt. These references would seem to contradict the contention of Kühn (21) that in the equimolar melt, MoO_3 "yields either MoO_2Cl_2 or a complex mixture of volatile Mo(VI) and Mo(V) oxide chlorides containing some $AlCl_3$." Certainly the latter alternative in a sealed system cannot be discounted. In an attempt to resolve the problem, the u.v. spectra of MoO_3, MoO_2Cl_2, and $MoCl_5$ were examined in a sodium chloride-saturated melt. All three compounds gave identical spectra, exhibiting a strong absorption at 305 nm and a shoulder at approximately 365 nm, suggesting that the species present was a Mo(V) complex involving no oxygen. It does remain a possibility, however, that AlOCl impurity in the melt could provide a reservoir of oxygen capable of "raising" the common denominator species to a singly oxygenated species. We believe this to be unlikely based on additional work (23). The results presented here have not directly suggested the participation of a dimeric molybdenum (III) series. Equilibrium potential measurements for the Mo(V)/Mo(III) system suggest that any equilibrium in the nature of $2MoCl_6^{3-} \rightleftarrows Mo_2Cl_9^{3-} + 3Cl^-$ lies in favor of the monomeric species. This is not entirely unexpected in view of the low molybdenum (III) concentrations and relatively basic melt conditions employed in this work. The possibility of dimer participation cannot be entirely discounted in view of the fact that two molybdenum three species are suggested by the rotation speed dependence of the second reduction wave for $MoCl_5$ at 0.5V. The kinetic nature of these currents could accommodate a dimer-monomer equilibrium favoring the monomer complex. Polymeric species certainly offer a plausible explanation for the marked changes in Mo(III) electrochemistry as the acidity of the melt is increased. Polymeric Mo species have been prepared in chloroaluminate melts (24).

Further work is necessary to unambiguously determine the final oxidation state of the molybdenum species formed on the surface of the electrode at potentials close to aluminum deposition. Coulometry experiments suggest that the oxidation state is very close to zero, and for the purpose of the mechanistic scheme this is assumed to be the final oxidation state. A scheme is proposed to account for the reduction of Mo(V), although by the very nature of the ill-defined surface chemistry it may be considered incomplete.

The Kinetics of a Chlorine Graphite Electrode in the Zinc-Chlorine Battery

Jung Taek Kim* and Jacob Jorné**

Department of Chemical and Metallurgical Engineering, Wayne State University, Detroit, Michigan 48202

ABSTRACT

The cathodic and anodic reactions for chlorine on a graphite electrode were investigated in concentrated $ZnCl_2$ solution using a rotating-disk electrode. The diffusion coefficient, Tafel kinetic parameters, rate constants, and reaction order were obtained. A likely cathodic reaction mechanism and rate-determining step is postulated.

The Zn-Cl_2 battery has been under intensive investigation and development during recent years for vehicular application and as a load leveling device (1). This secondary battery consists of a Zn electrode, Cl_2 graphite electrode, and $ZnCl_2$ aqueous solution. During charge Zn is deposited on the cathode and Cl_2 evolves at the graphite electrode. During discharge Zn and Cl_2 react to give aqueous $ZnCl_2$.

The Cl_2 graphite electrode represents a major limitation to the Zn-Cl_2 cell performance. In order to reach a stage where the design and performance of a flow-through porous graphite Cl_2 electrode is fully understood, the kinetics and the mass transfer of the Cl_2 electrode should be investigated on a nonporous graphite electrode under well-defined conditions.

In the present investigation, the kinetics of the Cl_2 electrode reaction is studied in a $ZnCl_2$ aqueous solution using a dense graphite rotating-disk electrode (RDE) under various Cl_2 concentrations. Limiting currents were detected at various Cl_2 concentrations and rotational speeds, from which the Cl_2 diffusion coefficient was determined. The kinetic parameters: exchange current density, reaction order, transfer coefficients, Tafel slopes, and apparent rate constants were determined. The mechanism of the Cl_2 electrode reaction is proposed and discussed in light of the present results.

The cathodic over-all reaction for Cl_2/Cl^- on a graphite electrode is $Cl_2 + 2e \rightleftarrows 2Cl^-$ $E^\circ = 1.36$V. The mechanism of this reaction and its kinetics have not been studied in concentrated $ZnCl_2$ aqueous solution. Most of the work in the past covered the anodic reaction in NaCl solution, and little attention was given to the cathodic reduction of Cl_2 (2-5). Frumkin and Tedoradze (2) studied the reduction of Cl_2 using a Pt rotating-disk electrode, and suggested the mechanism

$$Cl_2 + e \rightleftarrows Cl_{ads} + Cl^-$$

and

$$Cl_{ads} + e \rightleftarrows Cl^-$$

however, the mechanism is not fully substantiated. Sureno, Macagno, and Giordano (3) investigated the Cl_2 reaction in nonaqueous solvents using Pt RDE. Hine and Yasuda (6) studied the mechanism of the anodic oxidation of Cl^- on graphite RDE in NaCl solution, and found that the rate-determining step is

$$Cl_{ads} + Cl^- \rightarrow Cl_2 + e$$

Experimental

The graphite rotating-disk electrode consists of a Teflon support rod and a central dense graphite elec-

Key words: chlorine, graphite, zinc chloride, kinetics, zinc-chlorine battery.

trode ATJ Union Carbide. The central graphite electrode was embedded in the Teflon rod. The diameter of the graphite electrode was 0.95 cm, and the diameter of the Teflon rod was 1.9 cm. The rotator was a Pine Instrument ASR rotator with a rotational speed of 0-10,000 rpm. The surface of the electrode was polished with waterproof Al_2O_3 paper and a fine paper using the rotator (ω = 4000 rpm).

A 1000 ml Pyrex vessel fitted with a Teflon cover was used as the cell container. It was equipped with a 2.25 cm^2 platinum counterelectrode compartment connected to the cell by a small glass tube. A saturated calomel electrode (SCE) served as a reference electrode, and was placed in a separate reference electrode compartment connected to the main cell by a capillary extending to the side of the rotating-disk electrode. The tip of the Luggin capillary was located at a distance of 3.5 cm from the center of the disk. The ohmic drops were calculated according to Newman (7).

The potential of the graphite disk electrode was controlled by a Wenking LT 73 potentiostat. A wave form generator TWG 500 was used in conjunction with the potentiostat in order to sweep the potential of the disk electrode. The sweep rate was 10 mV/sec. The potential-current data was recorded on a Houston Instrument 2000X-Y Recorder.

The $ZnCl_2$ solution was obtained from EDA, Incorporated, where it was prepared by direct recombination of Cl_2 gas and pure Zn rods (99.999%, New Jersey). The $ZnCl_2$ concentration was measured by hydrometer. Cl_2-N_2 gas mixtures were fed into the cell by a gas expenser, and the dissolved Cl_2 concentration was maintained by measuring the Cl_2 and N_2 flow rates. The dissolved Cl_2 concentration was measured by standard titration using 1/100 normal $Na_2S_2O_3 \cdot 5H_2O$. Dissolved oxygen was removed by bubbling N_2 prior to the experiments, and the Cl_2-N_2 gas mixture was bubbled throughout the experiments. The *p*H of the solution was measured with a Beckman *p*H meter. The temperature was 25° ± 1°C, and the kinematic viscosities were corrected for temperature variations.

Results and Discussion

Cl_2 diffusion coefficient.—Cathodic polarizations of dissolved Cl_2 on a graphite rotating-disk electrode are shown in Fig. 1 and 2. The observed limiting currents depend on the rotational speed and the dissolved chlorine concentration. The cathodic reaction, $Cl_2 + 2e \rightarrow 2Cl^-$, is therefore mass transfer limited, and the diffusion coefficient of dissolved Cl_2 in $ZnCl_2$ solution can be determined from the Levich equation for convective diffusion near the rotating-disk electrode

$$i_l = 0.62nFD^{2/3}\nu^{-1/6}c_b\omega^{1/2} \qquad [1]$$

The kinematic viscosity of 37% $ZnCl_2$ solution at 25°C is 1.53 × 10^{-2} cm^2/sec (11).

Figure 3 shows the plot of the limiting current *vs.* $\omega^{1/2}$, and the average diffusion coefficient obtained from the slope is D_{Cl_2} = 0.664 × 10^{-5} cm^2/sec, and is in good agreement with the value of D_{Cl_2} = 0.633 × 10^{-5} cm^2/sec obtained in our laboratory from weight loss

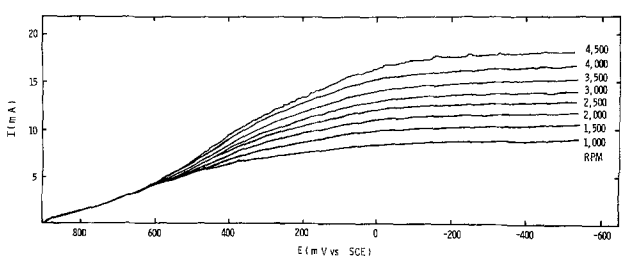

Fig. 1. Cathodic polarization of graphite electrode in 37% weight $ZnCl_2$ solution at different rotational speeds. $[Cl_2]$ = 0.95 g/l; area = 0.713 cm^2; *p*H = 3.29.

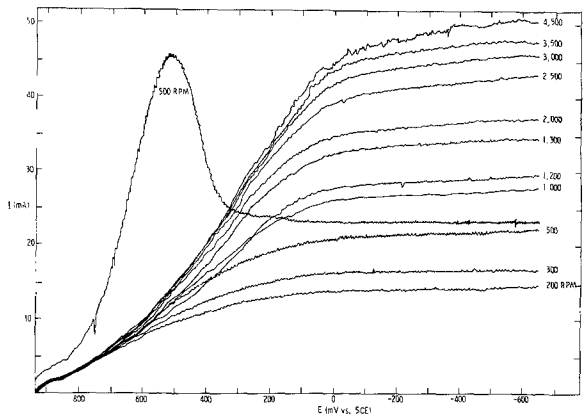

Fig. 2. Cathodic polarization of graphite electrode in 37% weight $ZnCl_2$ solution at different rotational speeds. $[Cl_2]$ = 3.02 g/l; area = 0.713 cm^2; *p*H = 3.15.

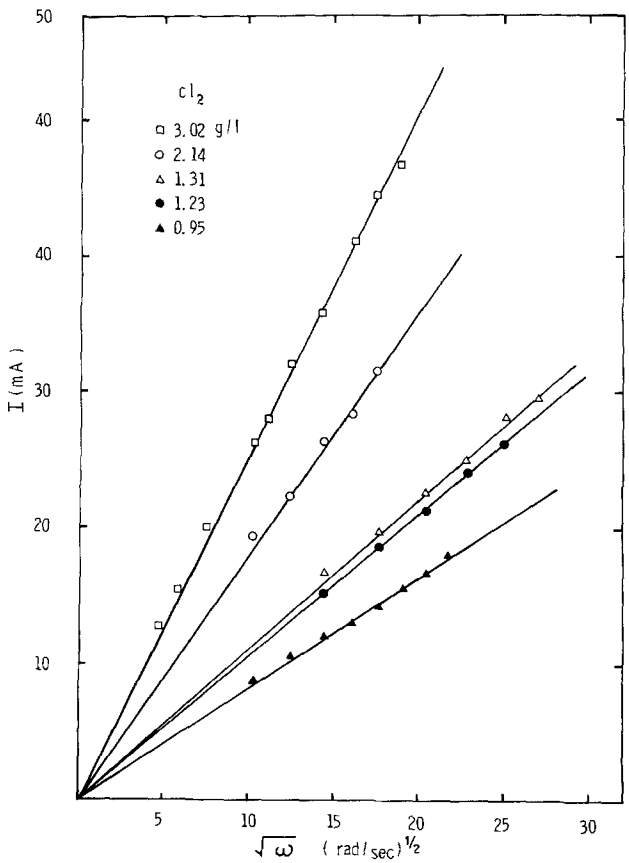

Fig. 3. The cathodic limiting current *vs.* the square root of the rotational speed at different Cl_2 concentrations.

measurements of a rotating Zn hemisphere in chlorinated $ZnCl_2$ solution (8). These values are in general agreement with the diffusion coefficient of Cl_2 in water (9), D_{Cl_2} = 1.22 × 10^{-5} cm^2/sec, after correction for different viscosities.

When the potential was scanned cathodically beyond the Cl_2 limiting current, a steep rise in the current was observed at about −1.0V *vs.* SCE, and is attributed to Zn deposition and H_2 evolution. A cathodic peak can be observed in Fig. 2 at 500 rpm during the cathodic scanning of the graphite-chlorine electrode. This current peak is due to unsteady-state effects, and was reproducible after the electrode was pretreated anodically or after leaving the graphite electrode overnight in chlorinated solution. The explanation for this peak is as follows. During anodization, Cl_2 is evolved and accumulated within the graphite porous structure.

Upon cathodic polarization, more Cl_2 is available and the current exceeds the apparent limiting current which is limited by the transport of dissolved Cl_2 to the projected apparent surface of the graphite electrode. After Cl_2 is depleted from the pores the current drops to the steady-state limiting value at the same rotational speed.

Cl_2 reaction order and rate constant.—Figure 4 shows the cathodic current as a function of the square root of the rotational speed for three fixed potentials. At $E = -390$ mV (*vs.* SCE) the potential is well within the limiting current region. The reaction is totally mass transfer limited, and a through-the-origin straight line is obtained according to the Levich convective diffusion equation. When the potential is fixed below the limiting current region ($E = 310$ or 410 mV *vs.* SCE) the reaction is partially controlled by mass transfer and surface reaction, and the I *vs.* $\omega^{1/2}$ plots are not linear (Fig. 4). Using the graphical method of Riddiford (10), the Cl_2 reaction order Z_{Cl_2} can be obtained by plotting arbitrary vertical lines ABC, DEF in Fig. 4, and Z_{Cl_2} is given by

$$Z_{Cl_2} = \frac{\log FE/CB}{\log CA/BA - \log FD/ED} = \frac{\log i_k - \log i}{\log i_l - \log (i_l - i)} \quad [2]$$

The reaction order was found to be $Z_{Cl_2} = 0.6$ in $1.75 \times 10^{-2}M$ Cl_2 in 37.6% $ZnCl_2$ solution. The reaction order was also obtained by the conventional method of varying the Cl_2 bulk concentration, as shown in Fig. 5

$$Z_{Cl_2} = \frac{\partial \log i}{\partial \log [Cl_2]} = 0.74$$

According to the present values, $Z_{Cl_2} = 0.6$ or 0.74, the reaction order can be half-order or first order. The polarization data were tested according to these two possibilities:

(*i*) If the reaction is assumed to be half-order, then the current is given by (10)

$$i^2 = i_k^2 - (i_k^2/B)(i/\omega^{1/2}) \quad [3]$$

where B is a constant ($0.62\, n\mathbf{F}D^{2/3}\nu^{-1/6}C_b$) and $i_k = n\mathbf{F}kC_b^{1/2}$ (surface reaction rate). A plot of i^2 *vs.* $i/\omega^{1/2}$ should give a straight line for a half-order reaction. As shown in Fig. 6, the behavior is not linear and the half-order assumption is incorrect.

(*ii*) If the reaction is assumed to be first order, the current is given by (10)

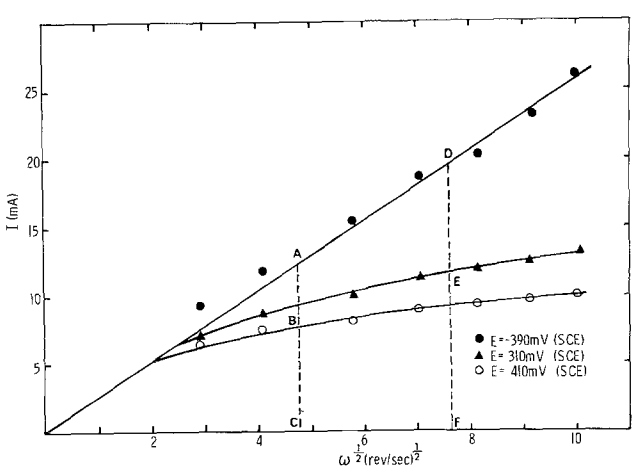

Fig. 4. The cathodic current *vs.* the square root of the rotational speed at three cathodic potentials. $[Cl_2] = 1.23$ g/l; area = 0.713 cm²; pH = 3.29.

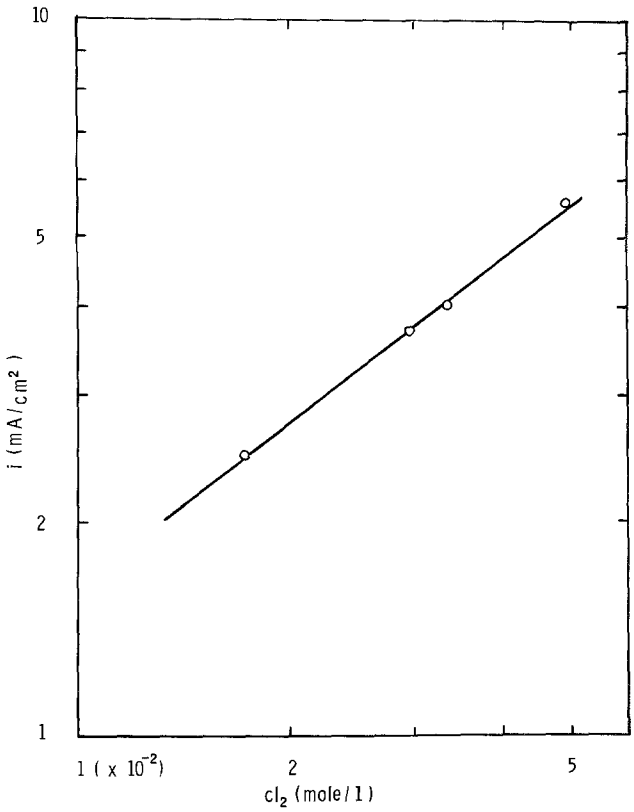

Fig. 5. The Cl_2 reaction order determination: $Z_{Cl_2} = 0.74$

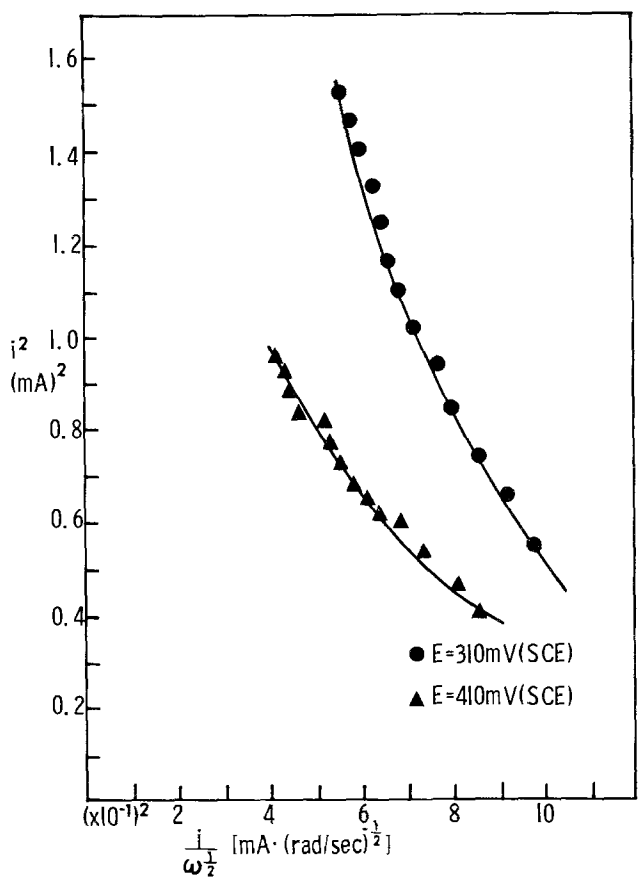

Fig. 6. The test for half-order reaction at different potentials. $[Cl_2] = 1.23$ g/l; area = 0.713 cm²; pH = 3.29.

$$1/i = 1/i_k + 1/i_l \quad [4]$$

where the limiting current is $i_l = 0.62\, n\mathbf{F}D^{2/3}\nu^{-1/6}C_b\omega^{1/2}$ and $i_k = n\mathbf{F}kC_b$. Rewriting Eq. [4] gives

$$1/i = 1/n\mathbf{F}kC_b + (1.61\nu^{1/6}/n\mathbf{F}D^{2/3}C_b)\,\omega^{-1/2} \quad [5]$$

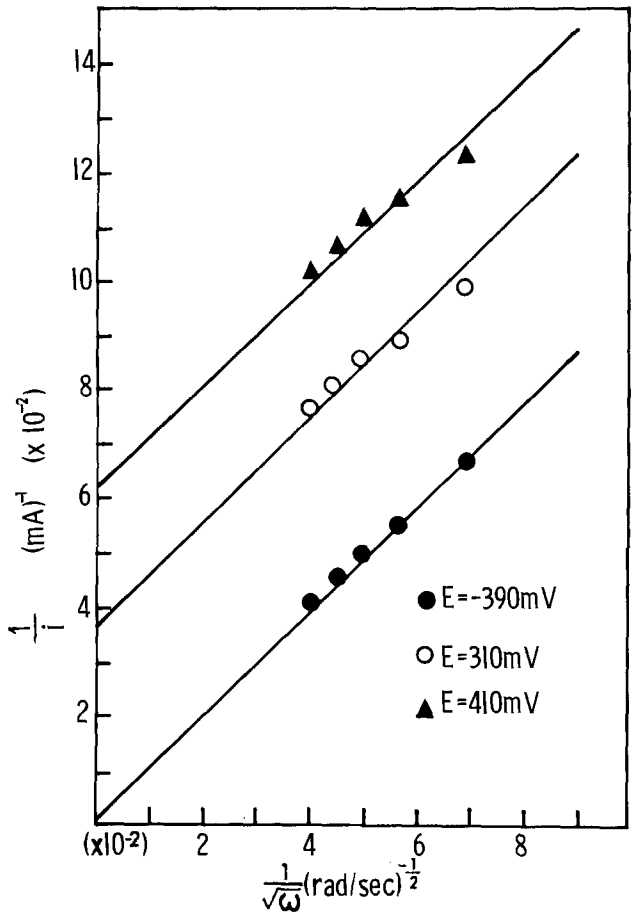

Fig. 7. The test for first-order reaction at different potentials. $[Cl_2]$ = 1.23 g/l; area = 0.713 cm^2; pH = 3.29.

Figure 7 shows the plot of $1/i$ *vs.* $\omega^{-1/2}$. The behavior is linear in accordance with Eq. [5], and the reaction is believed to be first order.

Extrapolating to $\omega^{-1/2} \rightarrow 0$ (or $\omega \rightarrow \infty$) permits the determination of the rate constant k. The obtained rate constants are 1.16×10^{-2} and 6.76×10^{-3} cm/sec for E = 310 and 410 mV *vs.* SCE, respectively. The rate constant k is a function of the potential, and increases as the potential becomes more negative (more cathodic). At the far cathodic potential, E = −390 mV *vs.* SCE, the reaction rate is very fast and can be neglected. The reaction is totally mass transfer limited, and a through-the-origin straight line is obtained according to the Levich convective diffusion equation.

Tafel's kinetic parameters.—The Tafel polarization plot for Cl_2/Cl^- on a dense graphite electrode is shown in Fig. 8. The data was corrected for ohmic drop using Newman's method (7). The apparent exchange current density, i_o = 1.11 mA/cm^2, is obtained from the intercept of the cathodic and anodic polarization branches. The anodic and cathodic Tafel slopes are b_a = 124 and b_c = −120 mV/decade, respectively. The present parameters are in agreement with the results of Hine (6) for NaCl solution (i_o = 1.2 mA/cm^2, $b_a = -b_c$ = 120 mV/decade). The deviation from linearity at the far cathodic potential range $E < 0.75$V *vs.* SCE in Fig. 8 is due to mass transfer overpotential.

The cathodic Tafel slope at a low cathodic overpotential $E > 0.810$V *vs.* SCE is b_c = −39.7 mV/decade, as can be seen in Fig. 9. In this region it is assumed that the fractional coverage is very small, $\theta_{Cl} \simeq 0$. The fractional coverage changes from θ = 0 at low current density to θ = 1 at high current density below the limiting current. The fractional coverage is assumed to follow the Langmuir isotherm form. The stoichiometric coefficient was obtained from the slope at low overpotential

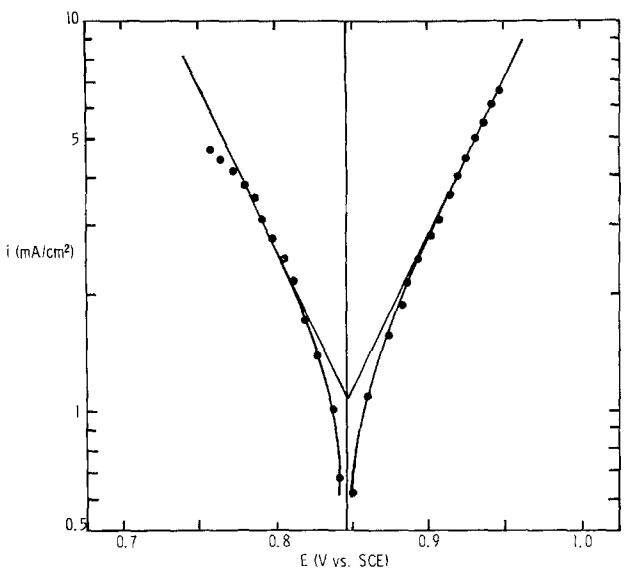

Fig. 8. Anodic and cathodic Tafel polarizations of graphite electrode in 37% weight $ZnCl_2$ solution. $[Cl_2]$ = 1.17 g/l; area = 0.713 cm^2; pH = 3.29.

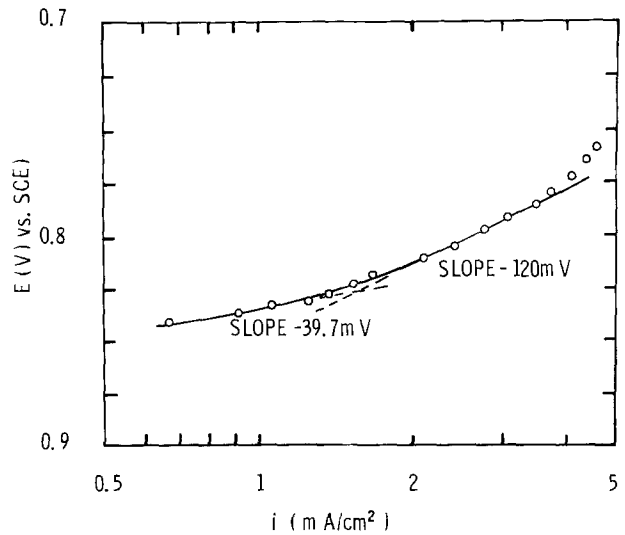

Fig. 9. Cathodic Tafel polarization of graphite electrode in 37% weight $ZnCl_2$ solution. $[Cl_2]$ = 1.17 g/l; area = 0.713 cm^2; pH = 3.29; $E > 0.810$V, b_c = −39.7 mV/decade; $E < 0.810$V, b_c = −120 mV/decade.

$$\mu = \frac{2F}{RT} i_o \left(\frac{\partial E}{\partial i} \right)_{\eta=0} = 1.2$$

The reaction mechansim.—The over-all cathodic Cl_2/Cl^- reaction is given by

$$Cl_2 + 2e \rightleftarrows 2Cl^-$$

The possible hypothetical reaction mechanisms are mechanism A

$$Cl_2 + e \leftrightarrows Cl_{ads} + Cl^- \quad [6]$$

$$Cl_{ads} + e \leftrightarrows Cl^- \quad [7]$$

mechanism B

$$Cl_2 \rightleftarrows 2Cl_{ads} \quad [8]$$

$$Cl_{ads} + e \rightleftarrows Cl^- \quad [9]$$

The theoretical parameters for the two mechanisms are shown in Table I, and were obtained from the Butler-Volmer rate equations including fractional coverage under steady-state assumption. If it is assumed that reaction [6] is the rate-determining step (rds), then the theoretical Tafel slope for reaction [6]

Table I. Parameters for cathodic Cl_2 reaction (theoretical)

Rate determining step	μ	Tafel slope $\theta \to 0$	Tafel slope $\theta \to 1$	Z_{Cl_2} $\theta \to 0$	Z_{Cl_2} $\theta \to 1$
Mechanism A					
(1) $Cl_2 + e \rightleftarrows Cl_{ads} + Cl^-$	1	$-2RT/F$	—	1	—
(2) $Cl_{ads} + e \rightleftarrows Cl^-$	1	$-2RT/3F$	$-2RT/F$	1	0
Mechanism B					
(3) $Cl_2 \rightleftarrows 2Cl_{ads}$	1	$-\infty$	—	1	—
(4) $Cl_{ads} + e \rightleftarrows Cl^-$	2	$-2RT/F$	$-2RT/F$	½	0

is $b_c = -120$ mV/decade under the assumption of $\theta_{Cl} \to 0$ at low current density (Table I). The experimental slope of −39.4 mV/decade in Fig. 9 indicates that reaction [6] is not the rds.

Assuming reaction [7] is the rds, the theoretical Tafel slopes are (Table I) $b_c = -40$ mV/decade for $\theta \to 0$, and $b_c = -120$ mV/decade for $\theta = 1$, in excellent agreement with the experimental values of −39.7 and 120 mV/decade, respectively. Thus, mechanism A appears to be correct, and reaction [7] is the rds. The experimental results are in disagreement with the theoretical parameters for mechanism B, as shown in Table I.

Although the $ZnCl_2$ solutions in the present work are acidic (pH = 3.2), and the molecular Cl_2 is the predominant species, the concentrations of hypochlorous acid HOCl and trichloride ion Cl_3^- are not negligible (8). The dissociation constant of hypochlorous acid to hypochlorite is very small $K = 4\ 10^{-8}$ (12), and in the present acidic solution hypochlorite is not present. However the transport and kinetic parameters obtained in the present work represent average values for the predominant molecular Cl_2, and minute concentrations of HOCl and Cl_3^-.

Conclusions

The cathodic reaction for Cl_2/Cl^- on a dense graphite electrode in $ZnCl_2$ solution has been investigated. Cathodic limiting currents were obtained at various rotational speeds and dissolved Cl_2 concentrations, and the Cl_2 diffusion coefficient was obtained. The reaction is first order with respect to the Cl_2 concentration.

The Tafel parameters were obtained for the anodic and cathodic polarizations. The following mechanism was established

$$Cl_2 + e \rightleftarrows Cl_{ads} + Cl^-$$

and

$$Cl_{ads} + e \overset{rds}{\rightarrow} Cl^-$$

and the second reaction is the rate-determining step.

The cathodic reaction rate constants were evaluated at several potentials. The cathodic reduction of Cl_2 was found to be partially mass transfer and kinetics limited.

The kinetics and transport parameters obtained in the present work are necessary in the design and optimization of a practical Cl_2 electrode in the Zn-Cl_2 battery. It is clear that a flow-through porous electrode is needed in order to maintain high currents.

The Effect of Phosphoric Acid on the Positive Electrode in the Lead Acid Battery

Kathryn R. Bullock*[1] and Donald H. McClelland*

The Gates Rubber Company, Denver, Colorado 80217

ABSTRACT

The effect of phosphoric acid on the positive electrode reaction in a lead-acid battery is studied by cyclic voltammetry. It is proposed that phosphate reversibly adsorbs on the PbO_2 during charge, and modifies the crystal growth of PbO_2 on the lead grid. The form of PbO_2 produced in the presence of phosphate is not easily reduced to lead sulfate and, therefore, the positive grid does not become insulated from the active material. The limit of this effect is reached at a low concentration of phosphoric acid.

Phosphoric acid and various phosphate compounds have been used as additives to lead-acid batteries since 1900 (1, 2). A number of patents have been issued since that time in which phosphates are claimed to improve battery performance (3-10). In particular, they are reported to increase cycle life by reducing the shedding and irreversible sulfation of the positive-plate active material. Eberts (11) has shown that phosphoric acid improves the cycle life of a battery with a lead-calcium grid.

Adverse effects of phosphoric acid which have been reported include capacity loss in the initial cycles, excessive mossing (7), and poor low temperature performance (12).

More recently, phosphates have been used in gelled electrolytes (13-17). In spite of their widespread use, very little is understood about the mechanisms by which phosphates affect the performance of lead-acid batteries. Tudor, Weisstuch, and Davang (18-20) used an autoradiographic technique to study the effect of phosphoric acid on the performance of thin-plate, lead-calcium grid batteries. They showed that phosphoric acid reduces the amount of sulfate on the grid of the positive electrode during float charging and cycling, and that the phosphate enters the positive plate during charge and leaves during discharge.

Several authors have found lead(IV) complexes with phosphate which can be produced both chemically and electrochemically (21-24). Amlie and Berger (25) have noted that a soluble lead(IV) species can be detected polarographically in sulfuric acid only if phosphoric acid is present.

In a previous publication (26), we have shown that phosphoric acid in the electrolyte of a sealed lead-acid cell inhibits the rate of the self-discharge reaction. The rate-determining step in that reaction is probably

$$PbO_2 + H_2SO_4 \rightarrow PbSO_4 + H_2O + \tfrac{1}{2} O_2$$

Several investigators have published voltammograms of lead in sulfuric acid (27-37). Of these papers, three have discussed the $PbO_2/PbSO_4$ electrode reaction in some detail. Panesar (29) has investigated the reaction on electrodes made from α- and β-PbO_2, as well as anodized lead at room temperature. Valeriote and Gallop (32) and Chang, Wright, and Valeriote (33) have studied the reaction in the 25° to −40°C temperature range on anodized pure lead and antimonial lead.

Experimental

Pure lead electrodes were cycled in 34 and 43% by weight sulfuric acid in the 25° to −40°C temperature range at slow scan rates. The working and counterelectrodes were made from pure lead rods set in epoxy or dental acrylic and cut off to obtain a flat, circular lead electrode with an area of approximately 0.32 cm^2. Immediately prior to cycling, the lead was polished with 600 Grit Carborundum paper and shined with a clean tissue. A $Hg/Hg_2SO_4/H_2SO_4$ electrode containing the same concentration of sulfuric acid as the experimental solution served as the reference electrode.

Reagent-grade sulfuric and phosphoric acids and doubly distilled water were used to prepare the electrolyte. Before the voltammograms were recorded, the electrodes were cycled at a scan rate of 1 mV/sec for at least 24 hr under the conditions of interest. This served to develop the PbO_2 coating on the working electrode, and to allow the electrode reactions to reach a steady state.

The temperature was controlled by a stirred water bath regulated by a Sargent Model T thermonitor. The instruments used in the study were a Princeton Applied Research Model 371 potentiostat and Model 175/99 signal source, and a Hewlett Packard Model 7035 X-Y recorder.

Results

Some typical voltammograms of lead in 43% H_2SO_4 are shown in Fig. 1 at four different temperatures. The scan is begun at 1.05V *vs.* a $Hg/Hg_2SO_4/43\%$ H_2SO_4 reference electrode, and is reversed at 1.53V. The scan rate is 1 mV/sec. On the anodic scan, the wave corresponding to the oxidation of $PbSO_4$ to PbO_2 can be seen, followed by oxygen evolution. On the return scan, the wave corresponding to the reduction of PbO_2 to $PbSO_4$ is apparent.

A comparison of the waves at the four different temperatures reveals that the separation between the anodic and cathodic peaks decreases with increasing temperature. Thus, the reaction is becoming more nearly reversible as the temperature increases. Furthermore, better resolution is obtained between the anodic peak and the oxygen evolution wave. Finally, the cathodic peak becomes sharper, and more fine structure is seen in the reduction wave. At 40°C at least three different reduction waves can be distinguished.

A similar effect can be obtained by decreasing the scan rate, as is shown in Fig. 2. The voltammogram in this figure at the 1 mV/sec scan rate is identical to that shown for 40°C in Fig. 1. As the scan rate is decreased from 5 to 0.1 mV/sec, the voltammogram continues to become more nearly reversible. Again, the most positive reduction peak becomes sharper, and the resolution between the anodic wave and the region of oxygen evolution improves.

On the basis of these results, we decided to study the wave at the lowest scan rate (0.1 mV/sec) and the highest temperature (40°C) which could consistently be obtained with our equipment. Under these conditions, the reaction became fast enough and the experimental observation became slow enough, so that the reaction appeared to be reasonably reversible, and the

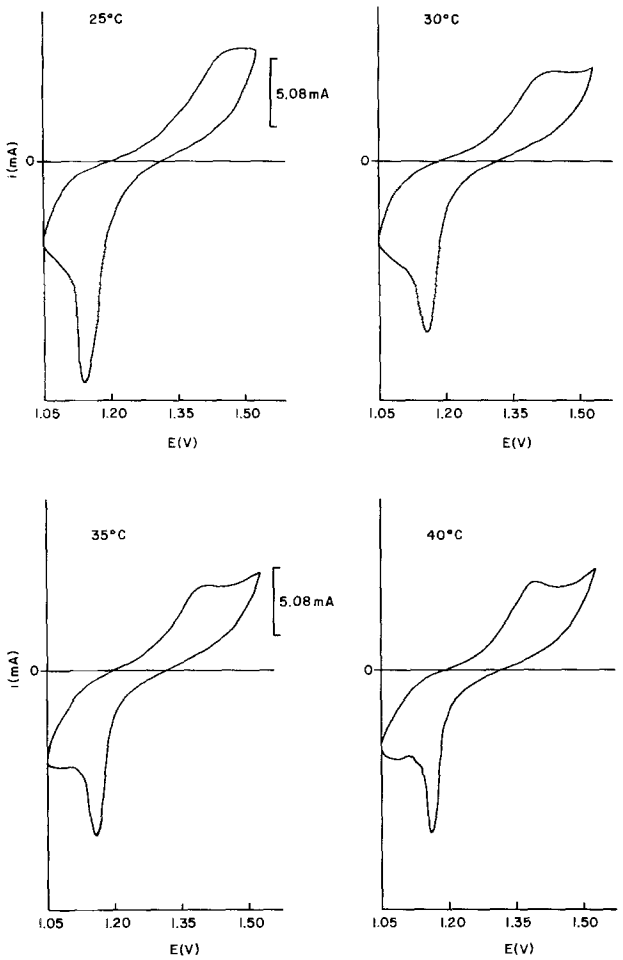

Fig. 1. Cyclic voltammograms of lead in 43% H_2SO_4. Scan rate = 1 mV/sec.

reactions being studied had rates comparable to those observed when cycling an actual lead-acid battery at a moderate rate (approximately 1.3 hr charge or discharge at 40°C).

The voltammograms in Fig. 1 and 2 were run on solutions containing very small traces of phosphoric acid. We subsequently found that care had to be taken to prevent phosphoric acid from leaking out of cracks at the interface between the lead and the epoxy surrounding it if the electrode had previously been cycled in an electrolyte containing phosphoric acid. This problem was overcome by trimming the end of the electrode before each set of experiments to insure that the electrode surface was fresh.

In Fig. 3, the voltammograms of lead cycled in 34% sulfuric acid with and without phosphoric acid are shown. It is not practical to exclude phosphate entirely from the electrolyte, since even Ultrex grade sulfuric acid contains approximately 50 ppb phosphate. Thus, the differences between the two voltammograms are those of degree rather than kind. Nevertheless, the differences are striking. The most positive reduction peak shifts to a more positive potential in the presence of phosphoric acid. At the same time, the two more negative reduction peaks, which were just barely discernible in the pure electrolyte, have grown considerably in the presence of phosphate. Furthermore, the area of the wave in the solution containing 0.1% phosphoric acid is over twice that of the wave in the pure electrolyte. Although the areas are slightly dependent on the length of time the electrode has cycled, the magnitude of this effect is too large to be explained on that basis.

Similar results were obtained in 43% sulfuric acid. In Fig. 4, the voltammograms taken in electrolyte containing 0.1% phosphoric acid are compared for 34 and

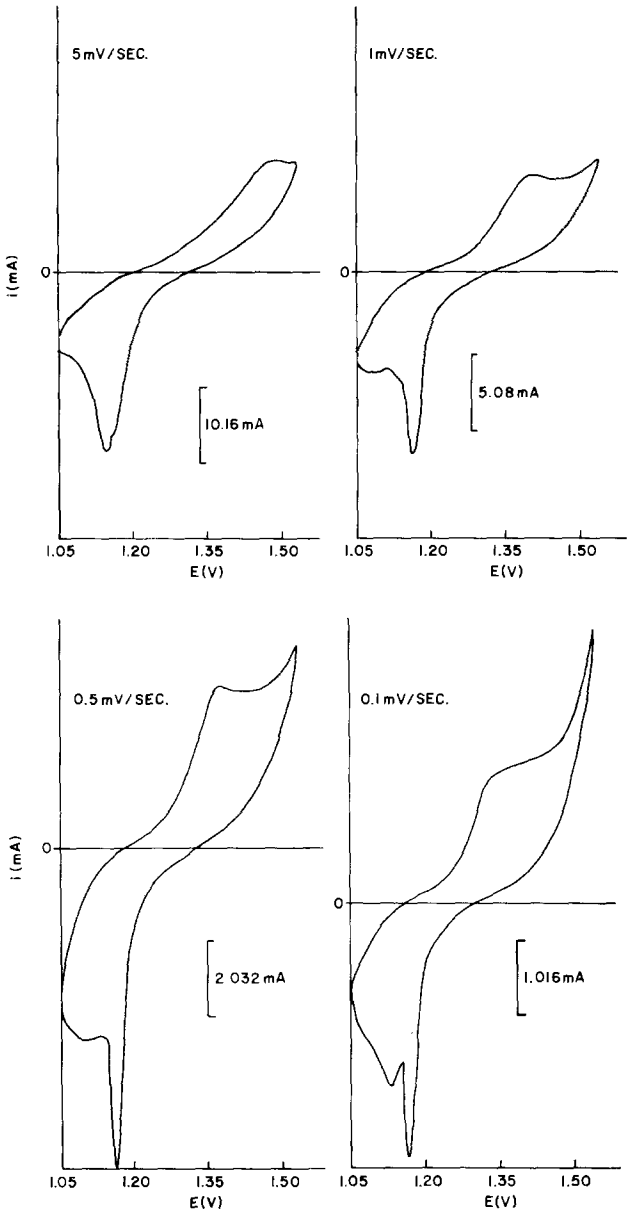

Fig. 2. Cyclic voltammograms of lead in 43% H_2SO_4 at 40°C

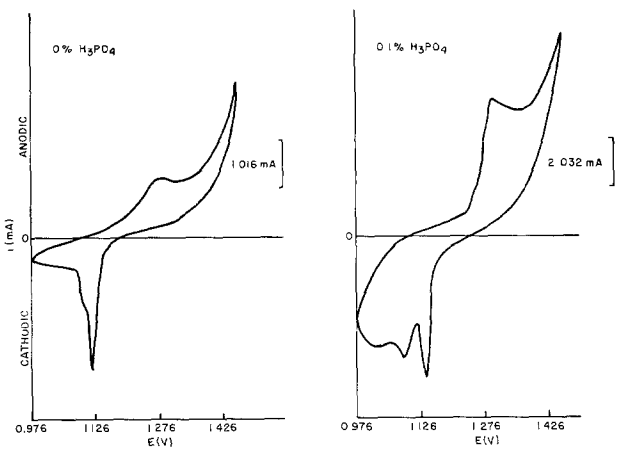

Fig. 3. Cyclic voltammograms of lead at 40°C in 34% H_2SO_4. Scan rate = 0.1 mV/sec.

43% sulfuric acid. The reversible potential of the $PbO_2/PbSO_4$ electrode at 40°C is 1.188V in 43% sulfuric acid, and 1.117V in 34% acid (38) *vs.* the $Hg/Hg_2SO_4/H_2SO_4$ reference electrode of the same acid concentration. The voltage range is adjusted accordingly for this change in electrode potential with electrolyte concentration.

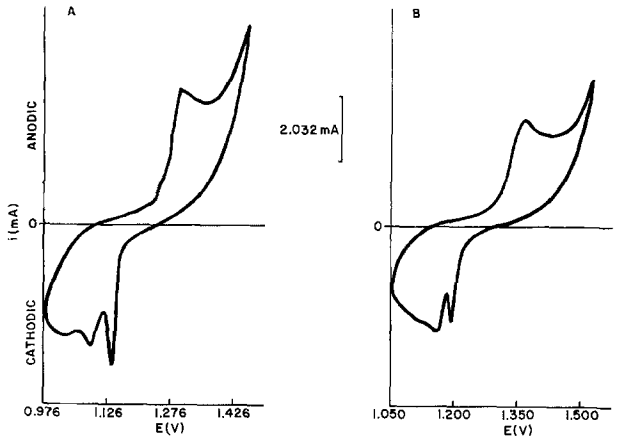

Fig. 4. Cyclic voltammograms of lead at 40°C in 34% (curve A) and 43% (curve B) H_2SO_4 containing 0.1% H_3PO_4. Scan rate = 0.1 mV/sec.

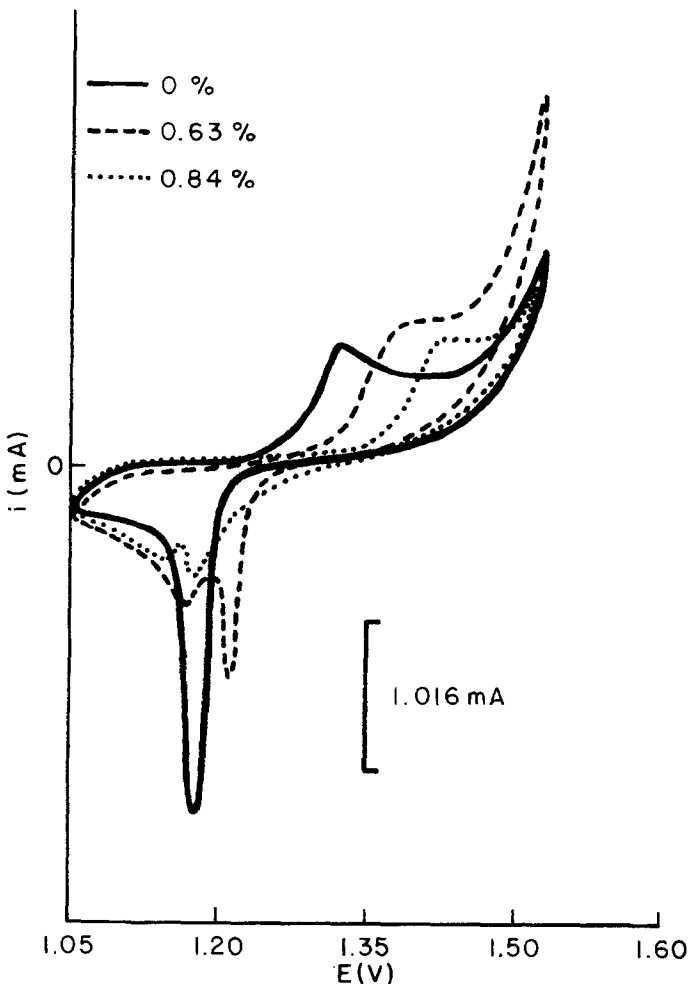

Fig. 5. Effect of H_3PO_4 additions to 43% H_2SO_4. T = 40°C. Scan rate = 0.1 mV/sec.

Figure 5 illustrates the results of an experiment in which a solution of 43% sulfuric acid was titrated with phosphoric acid in approximately 0.2% increments, and the change in the voltammogram after each addition was observed. The solid line shows the voltammogram in the pure electrolyte. With each addition of phosphoric acid, the reduction peak shifted in the positive direction and simultaneously decreased in height. As this peak shifted, the more negative peak appeared and grew in height. The dashed curve shows the voltammogram taken after 0.63% phosphoric acid had been added.

When 0.84% phosphoric acid had been added, the more positive reduction peak disappeared altogether and the more negative peak split into two peaks. This can be seen in the dotted curve in Fig. 5. It was apparent that this change did not represent a mere shift in the two peak potentials for two reasons. First, the solution was not stirred after each addition of phosphate in order to avoid disturbing the electrode surface and to observe the change in the waves as the phosphate diffused into the solution. Thus, the disappearance of the more positive wave and the splitting of the negative wave could be observed from one cycle to the next as the phosphate was mixed into the solution. Secondly, all three waves can be observed in the same voltammogram under some conditions (see Fig. 4).

Comparable changes occurred in the anodic wave, although these are more difficult to observe because of the interference of the oxygen evolution current. Nevertheless, it is apparent that the peak of the anodic wave is shifting to a more positive potential as the phosphate concentration is increased.

Further additions of phosphate caused no further changes in the voltammogram. Nor did the wave change significantly when the electrode was cycled for several days after the last addition of phosphate. Reducing the phosphate concentration by adding more electrolyte reversed the effect.

Similar results were obtained at several higher scan rates. However, since at higher scan rates the reduction waves are not as well resolved and are less reversible, the exact effect of phosphate addition on the three waves is more difficult to observe. A plot of the peak current of the most positive reduction wave as a function of the concentration of phosphoric acid added is shown in Fig. 6. The relationship is linear until the addition of 0.84% H_3PO_4 causes the peak to disappear completely.

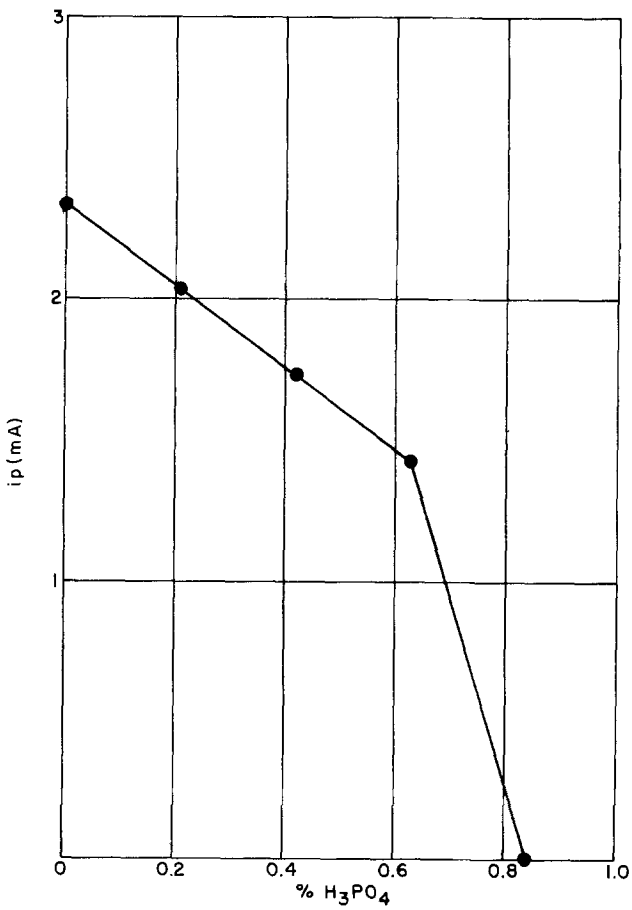

Fig. 6. Plot of current of positive reduction peak as a function of phosphoric acid concentration.

Discussion

Laitinen and Watkins have recently published similar results (23, 39) in their study of the analysis of lead in nitric acid by cathodic stripping voltammetry. In their work, Pb(II) in HNO_3 solution is electrodeposited as PbO_2 on tin oxide, and the reduction waves of the PbO_2 deposit are then observed. As the voltage is scanned in the negative direction, a single, sharp reduction wave is observed, followed by a broad, irreversible wave. Addition of phosphate to the solution causes the height of the first reduction wave to decrease and the peak potential to shift in the positive direction. Simultaneously, the second broad reduction peak increases in height. When multiple layers of PbO_2 are deposited in the presence of phosphate, three or more reduction waves are observed (23), in agreement with our results.

Kinard and Propst (40) have observed nearly identical reduction peaks in the cathodic stripping analysis of Pb(II) in dilute sulfuric acid using a conducting glass electrode. They did not, however, study the effect of phosphate on these waves. The shapes of the peaks indicate that the more positive reduction wave is reversible, while the more negative wave is irreversible. Laitinen and Watkins have substantiated this by comparing the peak potentials of the waves at stationary and rotating electrodes (39).

The same authors have studied the electrodeposition of PbO_2 on tin oxide in more detail by potentiostatic current-time curves, scanning electron microscopy, and electron spectroscopy (ESCA). They have concluded that the phosphate adsorbs on the lead dioxide monolayer and inhibits the three-dimensional growth of PbO_2 crystals in favor of two-dimensional growth of nuclei. The PbO_2 formed by two-dimensional growth is less easily reduced than that formed by three-dimensional growth. In the absence of phosphate about 3% of the surface is covered by the irreversible PbO_2 species, whereas in the presence of phosphate, a continuous monolayer of the irreversible PbO_2 species is formed. Furthermore, no phosphorus is observed on the surface of the deposit by ESCA. Apparently, the phosphate is incorporated into the bulk phase as a solid solution (41).

Carr and Hampson (42) have shown that phosphate is reversibly adsorbed on lead dioxide. This is in agreement with our observation that the magnitude of the effect of phosphate on the reactions at the positive electrode can be reduced by reducing the concentration of the phosphate.

A comparison of our results with those of other investigators (23, 39, 40, 42) leads us to propose the following model for the effect of phosphate on the positive electrode of a lead-acid battery. The phosphate adsorbs on the PbO_2 and modifies its crystal growth. The PbO_2 formed in the presence of phosphate is less easily reduced than the species formed when phosphate is absent. Thus, during reduction, the insulating sulfate layer between the positive grid and the active material is not formed. This is in agreement with Tudor, Weisstuch, and Davang (18-20), who have observed by an autoradiographic technique that the sulfate layer is not formed in cells containing phosphoric acid.

The beneficial effect of phosphoric acid limits at approximately 0.8%, as was shown in Fig. 5. This is in agreement with the patent literature, in which the recommended amount of the additive has always been a low percentage (4, 7-10). Apparently, the surface becomes saturated once phosphate has adsorbed on the active sites of the PbO_2. Higher concentrations can be detrimental to battery performance. For example, excessive "mossing" is seen at higher phosphate concentrations (7), and this may be related to the increased solubility of lead(IV) under these conditions.

Finally, the cyclic voltammograms shown in Fig. 5 give some support to the observation that phosphoric acid reduces the low temperature performance of lead-acid batteries (12). In the presence of phosphate, the potential required to oxidize the lead sulfate to lead dioxide is higher than in the absence of phosphate. At this higher voltage, the oxygen evolution reaction rate is also higher and, therefore, the charging efficiency is lower. Decreasing the temperature has a similar effect on the charging efficiency, as can be seen in Fig. 1. Thus, it appears that the presence of phosphoric acid intensifies the problems already present in low temperature charging.

and Leopold May[1]

Department of Chemistry, The Catholic University of America, Washington, D.C. 20064

ABSTRACT

In the electrode reactions of the nickel cadmium cell there is an interchange of H_2O and OH^- at the electrodes, depending on whether the cell has been charged or discharged. The calculations described below are based on a reaction involving KOH adsorption/desorption. The results from experimental cells are found to be consistent with this model. Electrolyte concentrations are calculated for different states of charge of a cell where the effect of precharge is considered. The open-circuit potentials (negative, positive, and cell) are calculated for various KOH concentrations (10.3-45.2%) and temperatures (0°-40°C). The calculated temperature coefficient for the cell potential is found to be −0.45 mV/deg, which is comparable to that found in previous experiments.

The concentration and distribution of aqueous potassium hydroxide (KOH) electrolyte in a sealed nickel cadmium cell has been the subject of considerable discussion. The reactions at both electrodes during charge and discharge involve the production or utilization of hydroxyl ion (OH^-) or water (H_2O), which directly affects concentration. The potential developed between the cadmium hydroxide (negative) electrode and the nickel hydroxide (positive) electrode depends upon the concentration of the potassium hydroxide electrolyte. The open-circuit potentials for the cell and each half-cell varies with the concentrations of the hydroxide and temperature. In addition to the changes at each electrode, there is a net change in concentration of the electrolyte in the cell as a whole. During charge there is an increase in water; during discharge, a decrease in water. If we consider a more correct reaction equation, there is also a decrease in OH^- on charge associated with KOH adsorption at the positive electrode and increase during discharge. The net effect is a significant decrease in concentration from beginning to end of charge, and an increase during discharge. The extent of precharge must also be considered in that during this process OH^- is converted to water that also dilutes the electrolyte.

The Basic Cell Reaction

The sealed nickel-cadmium cell consists of electrodes containing cadmium and nickel hydroxides as the active materials, and aqueous potassium hydroxide as the electrolyte. The open-circuit potential of the cell is determined in part by the concentration of the hydroxide, as can be seen by the equations for the half-cell potentials involving the cadmium and nickel hydroxide electrodes and the composite equation for the potential of the cell. The reaction at the positive electrode is

$$2NiOOH + 2H_2O + 2e \rightleftharpoons 2Ni(OH)_2 + 2\,OH^- \quad [1]$$

and for the negative electrode

$$Cd(OH)_2 + 2e \rightleftharpoons Cd + 2\,OH^- \quad [2]$$

The over-all reaction for the cell is therefore the difference of the two half-cell reactions

$$2NiOOH + 2H_2O + Cd \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} 2Ni(OH)_2 + Cd(OH)_2 \quad [3]$$

Changes in Electrolyte Concentration During Cell Operation

During charge at the positive electrode, 1 mole of OH^- is consumed and 1 mole of H_2O is produced for every mole of electrons produced. Based on the Faraday constant, this is equivalent to 26.8 A-hr. Therefore, the loss of OH^- (0.63 g/A-hr) and gain of water (0.67 g/A-hr) play a significant role in electrolyte dilution at the positive electrode. The depletion of OH^- at the electrode is compensated for by OH^- migrating and diffusing from the negative electrode. At the negative electrode 1 mole of OH^- is produced for every 26.8 A-hr. Thus, an increase in 0.67 g/A-hr significantly increases the concentration at the negative electrode. The net cell reaction identifies the production of 1 mole of water for every 26.8 A-hr or 0.67 g/A-hr. The result is not only a net decrease in electrolyte concentration during the charge process, but also a changing concentration as the state of charge is increased from the discharged condition to the fully charged condition. The calculations for typical 6, 12, and 20 A-hr cell sizes appear in Table I,

* Electrochemical Society Active Member.

Key words: nickel-cadmium, alkaline electrolyte, open-circuit potentials and activities.

Table I. Electrolyte concentration change after charge

A Cell capacity (A-hr)	B 31% electrolyte (ml)	C Weight of electrolyte (g) (SG = 1.300)	D Weight KOH (g)	E Weight H_2O (g)	F Estimated cell capacity (1.2 × nominal)	G Increase in water (g)	H Total weight after charge (g) C + G	I % KOH after charge D/H
6	18	23.40	7.25	16.15	7.20	4.82	28.22	25.7
12	36	46.80	14.51	32.29	14.40	9.65	56.45	25.7
20	68	88.40	27.40	61.00	24.00	16.08	104.48	26.2

which illustrates a change in concentration from 31% added initially to 26% KOH for a cell fully charged without considering the effect of precharge.

The following reactions are given for the overcharge process in sealed cells

electrode	reaction	
+	$4\,OH^- \rightarrow O_2 + 2H_2O + 4e^-$	
−	$2Cd(OH)_2 + 4e \rightarrow 2Cd + 4\,OH^-$	[4]
	$O_2 + 2Cd + 2H_2O \rightarrow 2Cd(OH)_2$	
	net reaction = 0	

During overcharge there is no net change in over-all cell with regard to electrolyte concentration. However, as indicated above, at the positive electrode the concentration diminishes and at the negative electrode the concentration increases.

In order to achieve a desirable electrode balance in a cell, additional charge is given to the cadmium hydroxide electrode over and above that given the nickel hydroxide electrode. This excess charge referred to as precharge is required for adequate oxygen recombination during overcharge, and to assure that the positive electrode is the limiting electrode on discharge. There are several methods used for this. The most common is to vent oxygen gas from a temporary sealed cell during overcharge. In this manner the negative electrode is given the excess charge, while the positive electrode is unaffected. The reactions given below describe the process and also illustrate that as oxygen is produced and eliminated, water is also produced

electrode	reaction	
+	$4\,OH^- \rightarrow O_2 + 2H_2O + 4e$	
−	$Cd(OH)_2 + 4e \rightarrow 2Cd + 4\,OH^-$	[5]
	$2Cd(OH)_2 \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftharpoons}} O_2 + 2Cd + 2H_2O$	

The net reaction involves an increase in 0.5 mole of H_2O for every 26.8 A-hr, or a gain of 0.34g H_2O/A-hr. The effect is seen in Table II, which is a continuation of Table I. The level of precharge for the 6, 12, and 20 A-hr size cell is generally 2.60, 5.20, and 9.80 A-hr, respectively.

The result of increasing the amount of water during precharge is a decrease in over-all cell electrolyte concentration to 25%. The new weight of electrolyte (L) and percent KOH final (M) represents the effect of charge and precharge. Percent KOH of the electrolyte after precharge only is found to be 29.9%.

The reverse of that described above occurs during discharge of the cell. However, the precharge is fixed, and thus, even though a cell is in the discharged and shorted condition the concentration of electrolyte in the cell is lower than the initial concentration by approximately 1%.

Table II. Effect of charge and precharge on electrolyte concentration

A Capacity (A-hr)	I % KOH after charge	J Suggested precharge (A-hr)	K Additional water (g) (0.34 g/A-hr)	L New weight of electrolyte H + K	M % KOH final D/L
6	25.7	2.60	0.88	29.10	24.9
12	25.7	5.20	1.77	58.22	24.9
20	26.2	9.80	3.33	107.81	25.4

A more correct cell reaction.—The complex reaction at the nickel hydroxide electrode is not described in the cell reactions above. Several authors (1, 2) have discussed the absorption of water and KOH at the nickel hydroxide electrode. An equation given by Falk and Salkind (3) is considered more correct than the general one given in Eq. [3]

$$2Ni(OH)_2{}^* + Cd(OH)_2 + \sim 0.1KOH_{(aq)} \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftharpoons}} 2NiOOH^* \cdot (\sim 0.1KOH_{ads}) + Cd + 2H_2O \quad [6]$$

where the asterisk represents an unknown quantity of adsorbed water. Considering this reaction in place of the general one will provide information if there is a more severe drop in electrolyte concentration during cell operation than predicted by Eq. [3].

During charge the net change is a loss of 0.05 mole of KOH from aqueous solution to the bound adsorbed state for every 26.8 A-hr (0.104 g/A-hr). This is in addition to an increase in 1 mole of water during the charge for every 26.8 A-hr (0.67 g/A-hr). The effect of using the corrected equation is given in Table III. This table is similar to Table I for the uncorrected equation. Note that the electrolyte concentration (column R) is lower by almost 2% when compared with the concentration calculated using Eq. [3] (column I, Table I). The addition of precharge to the electrode balance has the same effect of decreasing concentration during charge as in the uncorrected equation. The reason is that the corrected positive electrode reaction need not be considered during overcharge. The results (a continuation of Table III) are given in Table IV. The concentration has changed by less than 1% due to precharge, comparing column R (Table III) and column T (Table IV). Note the 2% difference in final electrolyte concentration using the uncorrected equation (column M, Table III) and using the corrected equation (column T, Table IV).

Concentration and depth of discharge (DOD).—As described above, there is an increase in water (decrease in concentration) on charge and decrease in water (increase in concentration) on discharge. The concentrations have been calculated for 25, 50, 75, and 100% (DOD), and full discharge for each of the 6, 12, and 20 A-hr size cells, and are plotted in Fig. 1 for the precharge values given in column J of Table IV. The concentration of KOH in the fully discharged cell containing precharge is found from the following equation

$$\%\ KOH(\text{discharged}) = \frac{g_{KOH}}{g_{soln}} 100 \quad [7]$$

where

$$g_{KOH} = (\%\ KOH)_i v_i d_i / 100$$

and

$$g_{soln} = v_i d_1 + 0.34\ \text{A-hr}_p$$

$(\%\ KOH)_i$ refers to the concentration of KOH in the initial volume, v_i, of the electrolyte whose density is d_i. A-hr$_p$ is the quantity of negative electrode precharge in ampere hour, d_i is the density of the initial KOH, and 0.34 is the conversion factor relating A-hr to equivalent weight of the negative electrode. The electrolyte concentration can be estimated for any condition of charge or discharge from the following equation

Table III. Change in electrolyte concentration during charge—corrected equation

A Cell capacity (A-hr)	D Weight of KOH (g)	E Weight of H_2O (g)	G Increase in H_2O (g)	N Decrease in KOH (g)	P Net KOH weight D − N	Q Weight of solution E + G + P	R Percent KOH P/Q	Δ Column R-column I (%)
6	7.25	16.15	4.82	(0.76)	6.41	27.49	23.6	−2.1

Table IV. Effect of charge and precharge electrolyte concentration—corrected equation

A Cell capacity (A-hr)	J Suggested precharge (A-hr)	K Additional water (g)	S Total solution weight K + Q (g)	T Percent KOH P/S	Δ′ Column T-column R	Δ″ Column T-column M
6	2.60	0.88	28.34	22.9	−0.7	−2.0
12	5.20	1.77	56.71	22.9	−0.8	−2.0
20	9.80	3.33	105.29	23.6	−0.8	−1.8

$$\% \text{ KOH} = \frac{g_{KOH} - \text{A-hr}_{NC}(1.2)(0.104)(CHG)}{\text{A-hr}_{NC}(1.2)(0.670 - 0.104)(CHG) + g_{soln}} \quad [8]$$

where A-hr_{NC} is the nominal capacity of the cell, 1.2 is the factor that accounts for the capacity in excess of the nominal cell capacity, 0.104 is the equivalent weight of KOH removed from electrolyte during charge, and 0.670 is the equivalent weight of water produced during charge. CHG is the fractional charge related to the cell capacity by CHG = 1.00 − DOD, where DOD is the fractional depth of discharge.

The validity of these equations was confirmed by measurements on 6 A-hr hermetically sealed, aerospace nickel-cadmium cells. These cells which are included in an accelerated test program contained varying concentrations (22-38%), volumes (17.5-21.5 ml) of electrolyte, and amounts of precharge (2.2-3.3 A-hr). As part of the program, the cells were opened and analyzed by the accepted procedure (5). The results are given in Table V. These cells had been subjected to manufacturer's electrical tests and preliminary electrical evaluation tests before electrolyte analysis. All cells were analyzed in the discharged condition. The differences between observed and calculated results are relatively consistent (2-5%) and may be related to the error introduced by the assumption that all the electrochemical reactions are completely reversible. Equation [6] is correct as written and the initial changes that occur during the cell activation processes are insignificant.

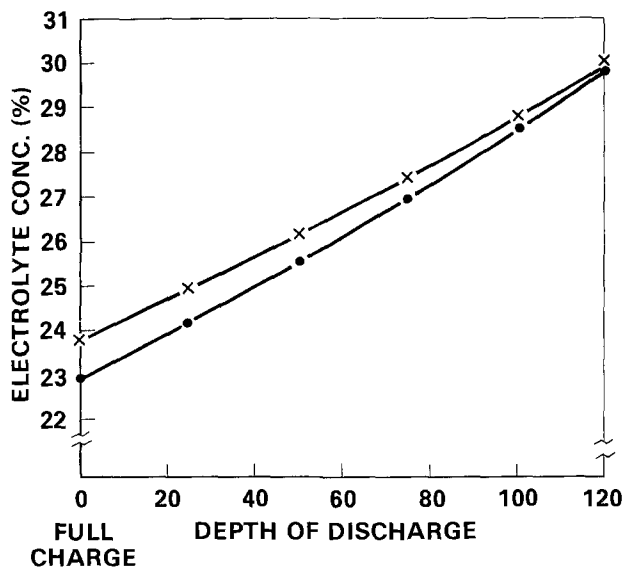

Fig. 1. Electrolyte concentration as a function of depth of discharge. 6 and 12 A-hr cell, × 20 alternating cell.

Table V. Verification of corrected Eq. [6]

Cell	Initial Percent KOH	Initial KOH ml	A-hr pre-charge	Final Total g KOH Found*	Final Total g KOH Calculated	Percent difference**

* Corrected for carbonate content.
** Percent difference = $\frac{\text{g KOH (calculated)} - \text{g KOH (found)}}{\text{g KOH (found}} \times 100.$

Open-circuit potentials.—The equilibrium potentials of the half-cells and the over-all cell depend upon the concentrations of the electrolyte and the temperature. The Nernst equations for the half-cell reactions can be written at any temperature (t) using the standard equilibrium reduction potentials

$$E_{pos}(t) = E^\circ_{pos}(t) - \frac{RT}{2F}\ln\frac{a_{OH^-}}{a_w^2} = E^\circ_{pos}(t) - \frac{RT}{F}\ln\frac{a_{OH^-}}{a_w} \quad [9]$$

$$E_{neg}(t) = E^\circ_{neg}(t) - \frac{RT}{2F}\ln a_{OH^-}{}^2 = E^\circ_{neg}(t) - \frac{RT}{F}\ln a_{OH^-} \quad [10]$$

where R is the gas constant, T is the absolute temperature in °K, $\mathbf{F}$ is the Faraday, and a_w and a_{OH^-} are the activities of the water and hydroxyl ion, respectively. $E^\circ_{pos}(t)$ is $E^\circ_{pos}(25°C) + (dE/dT)(t - 25)$ or $+0.518V - 0.0004$ V/deg $(t - 25)$ (6), and $E^\circ_{neg}(t)$ is $-0.809V - 0.000143$ V/deg $(t - 25)$ (7). $R/\mathbf{F}$ is equal to 8.619×10^{-5}. For the composite cell reaction at any temperature

$$E_{cell}(t) = E_{pos}(t) - E_{neg}(t) = E^\circ_{cell}(t) + 8.619 \times 10^{-9} \ln a_w$$

where

$$E^\circ_{cell}(t) = E^\circ_{pos}(t) - E^\circ_{neg}(t)$$

Variation of Potential with Hydroxide Concentration and Temperature

In order to calculate the variation of the cell potential with the concentration of the hydroxide in the electrolyte and the temperature of the cell, the activities of the water at various concentrations of the hydroxide must be known. These activities can be

found from the vapor pressure lowering of various hydroxide solutions. Then, Eq. [11] becomes

$$E_{cell}(t) = E°_{cell}(t) + 8.619 \times 10^{-5} + \ln (p/p°) \quad [12]$$

where p is the vapor pressure of the water over the hydroxide solution, and $p°$ is the vapor pressure of pure water at the same temperature. Bro and Kang (8) have measured the vapor pressures of hydroxide solutions at various temperatures. They found that the variation of the vapor pressure with temperature for a given hydroxide concentration can be expressed as

$$p = A \exp (-B/T) \text{ or } \ln p = \ln A - (B/T)$$

where A and B are constants for each hydroxide concentration. The values for these constants are given in Table VI for the six concentrations used in these calculations. Substituting this equation into Eq. [12], the cell potential becomes

$$E_{cell}(t) = E°_{cell}(t) + 8.619 \times 10^{-5}T(\ln A - (B/T) - \ln p°)$$

or

$$E_{cell}(t) = E°_{cell}(t) + 8.619 \times 10^{-5} [T(\ln A - \ln p°) - B] \quad [13]$$

The potentials for the whole cell at six concentrations of KOH (10.3-45.2%) whose vapor pressures were measured are given in Table VII at various temperatures (0°-40°C). The cell potentials are plotted in Fig. 2.

The calculation of the individual half-cell potentials (Eq. [9] and [10]) require the activities of the hydroxide ions as well as the activity of water. Akerlof and Bender (9) have made the electromotive force measurements that allow the calculation of the mean activity coefficient of KOH at various temperatures and at concentrations of as high as 18M. The activity of the hydroxide ion is related to the mean activity coefficient of KOH, $\gamma_\pm$ by $a_{OH^-} = \sqrt{\gamma_\pm M}$, where M is the molality of the hydroxide solution. The half-cell potentials for both the positive and negative electrodes using the activities calculated in this manner are given in Table VII at various concentrations of the hydroxide and at various temperatures. The potentials are also plotted in Fig. 3a and 3b.

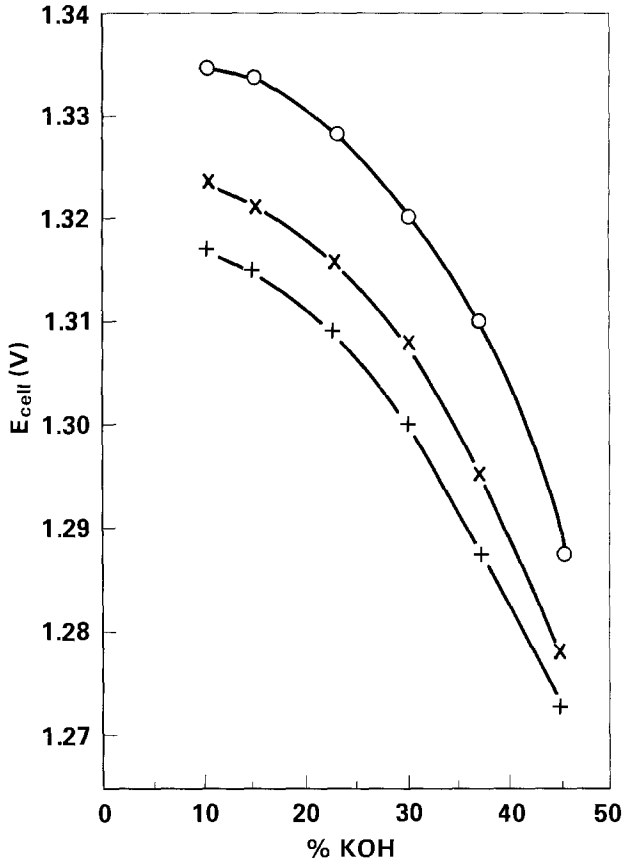

Fig. 2. Variation of cell open-circuit potential with electrolyte concentrations. ○, 0°; ×, 25°; +, 40°C.

The potential change of the negative electrode over the 20-30% KOH range at 25°C is 12 mV. The positive electrode changes by 21 mV over the same range. Although the half-cell potentials differ by 12 and 21 mV, respectively, over the 10% KOH range, the cell potential which is the difference between these half-cells changes by only 9 mV.

The average temperature coefficient for the cell potential is −0.45 mV/deg in this range of KOH concentrations. Values found experimentally vary with the type of construction of the cells (10). Pocket-plate or tubular-plate electrodes give values of −0.3 to −0.4 mV/deg, depending upon the capacity of the cell. The range with pressed-plate electrodes is −0.16 to −0.25 mV/deg, and with sintered-plate electrodes the range is −0.16 to −0.5 mV/deg.

The average temperature coefficient for the positive electrode is similar to that of the cell potential, 0.41 mV/deg. The average coefficient for the negative electrode is smaller than the others, −0.19 mV/deg. The temperature coefficient for all cases is greatest with the concentration of KOH of 37.0%.

Early in this century, Zedner (11) found that a change from 40 to 24% KOH led to a change in the calculated voltage of 0.04V, which is comparable in magnitude to the voltage changes in Table VII. Falk (12) measured the cell voltage at three concentrations of KOH, and found that the potential decreased about 0.07V as the concentration increased from 5 to 45% KOH. He also found that the experimental and theoretical variation of the negative electrode's potential

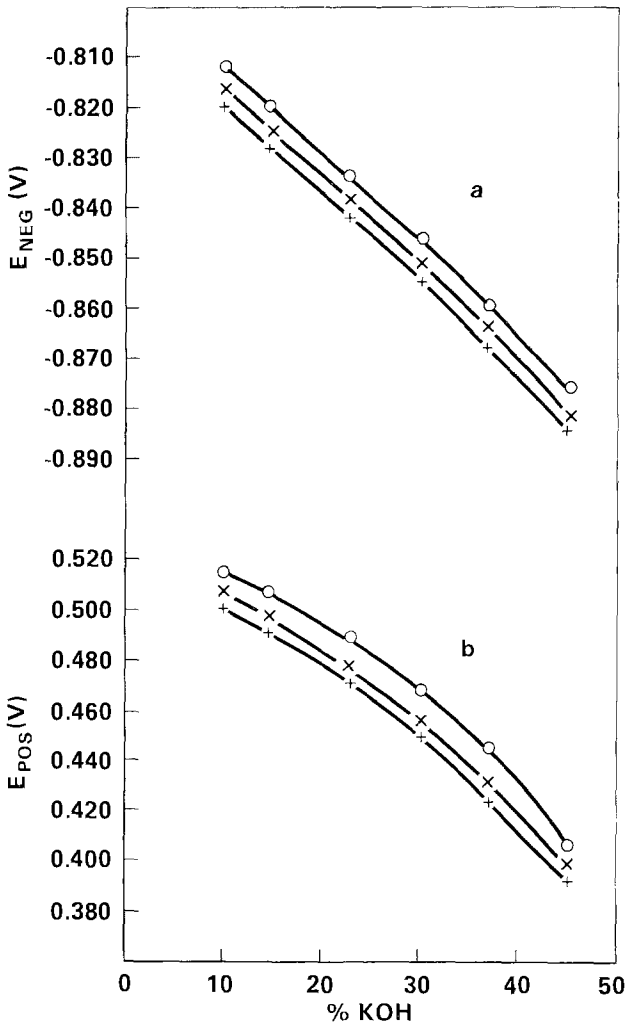

Fig. 3. Variation of open-circuit potentials of negative electrode (a) and positive electrode (b). ○, 0°; ×, 25°; +, 40°C.

with the concentration was in agreement. As can be seen from the plot in Fig. 3a, there is not quite a linear relationship, particularly at concentrations below 10%. Falk (12) also observed that the potential at the positive electrode varied in a manner similar to that shown in Fig. 3b. The experimental values differed from those calculated from the Nernst equation for the positive electrode.

Variation of Cell Potential with Depth of Discharge

Figure 1 gives the variation of the electrolyte concentration with depth of discharge. The open-circuit potential can then be evaluated from Fig. 1 and 2. The variation of the cell potential with DOD is shown in Table VIII. The variation in the cell open-circuit potential from full charge to complete discharge is in the order of 8 mV, and does not vary to any extent with the capacity of the cell.

Table VIII. Cell potentials at various depths of discharge*

Capacity Percent DOD	6 A-hr Percent KOH	E_{cell}	12 A-hr Percent KOH	E_{cell}	20 A-hr Percent KOH	E_{cell}

Pore Volumes and Densities of Unformed Pastes of Lead Acid Battery Plates

II: Tetrabasic Lead Sulfate Pastes

W. J. Schlotter and C. W. Fleischmann*

Eltra Corporation, C&D Batteries Division, Plymouth Meeting, Pennsylvania 19462

ABSTRACT

The values of specific pore volume, v, and the solids' density, d, were determined for unformed lead-acid battery pastes prepared from $4PbO \cdot PbSO_4$. v varied with D, the apparent density of the dry paste according to $v = 0.398 - 0.0698D$. The parameters d and D were related by $d = D(0.0698D^2 - 0.398D + 1)^{-1}$. By that relationship, however, d is variant with D, an unexpected result. It is proposed that the variance results because the crystals of $4PbO \cdot PbSO_4$ tend to orient in tight bundles, especially for the pastes with the highest values of D. Such bundles entrap open pits on the crystal surfaces, and the measured values of d are then reduced.

A previous report (1) dealt with the pore volumes and densities of dry pastes of acidified lead oxides when these were used to prepare the active material of electrodes for the lead-acid battery. The methods for making such electrodes are well known (2, 3). This report presents data for pastes prepared from tetrabasic lead sulfate rather than lead oxide.

Biagetti and Weeks (4) and Yarnell (5, 6) have described the use of tetrabasic lead sulfate, $4PbO \cdot PbSO_4$, for the manufacture of electrodes for the lead-acid battery. Pastes using $4PbO \cdot PbSO_4$ are prepared from water rather than acid. In contrast to the traditional mixtures (2, 3), no chemical reactions occur (6). Positive electrodes prepared from tetrabasic lead sulfate pastes were reported to provide (4, 5) improved cycling characteristics compared to electrodes from traditional pastes. Cycle life increased with the apparent density of the active material (4).

Pastes prepared from $4PbO \cdot PbSO_4$ are characterized, in this report, in terms of the relationship between the specific void volume, v (cm^3/g), the density of the solids, d (g/cm^3), and the apparent density, D (g/cm^3).

Experimental

Tetrabasic lead sulfate was obtained from both Eagle-Picher Industries and Halstab Incorporated. Several lots from each supplier were employed. Density measurements of the starting materials were by means of gas pycnometry and were a purchased service from Micromeritics Instrument Corporation, Norcross, Georgia.

Values of the wet paste density, the dry paste density, and the pore volume of the pastes were determined by techniques described earlier (1). As for conventional pastes (1), the wet and dry paste densities were found to be linearly related for a fixed grid thickness and mode of pasting. Using such relationships, any preselected dry paste density could be obtained.

Different wet paste densities were obtained by changing the amounts of water (4, 6) added to the solids and by varying the mixing time (6). The pastes were applied by hand to conventional, flat, industrial-type battery grids (2) of thicknesses 4.1, 6.8, and 7.9 mm. Grids of 6.4 mm thickness of the design used for the new cylindrical batteries for telephone exchanges (7) were loaded with paste by a special factory technique (10).

The scanning electron micrographs were obtained as a purchased service from SKF Industries, King of Prussia, Pennsylvania. Prior to examination, the samples, were gold-coated to make them conductive.

The linear regressions and simple linear correlations were calculated using the programs in the Texas Instruments Calculator, Model SR-51A.

Results and Discussions

Starting materials.—The density of the commercial tetrabasic lead sulfate was measured to be 7.94 ± 0.03 g/cm^3 by helium pycnometry. This value is 2.6% lower than the theoretical value, 8.15 g/cm^3 (8). The lower density of the commercial product is attributed to occluded voids. Numerous gross imperfections in the crystals, especially the tendency to develop hollow cores, may be seen in the scanning electron micrographs (Fig. 1-5). The crystals of $4PbO \cdot PbSO_4$ are the large prismatic masses that appear in the scanning electron micrographs. Occasionally fine filaments are visible in addition to the prisms, as in Fig. 1. These filaments develop if moist $4PbO \cdot PbSO_4$ is exposed to air. They are taken to be slight carbonation (6).

It is instructive to compare the surfaces of the crystals before and after preparation into a pasted

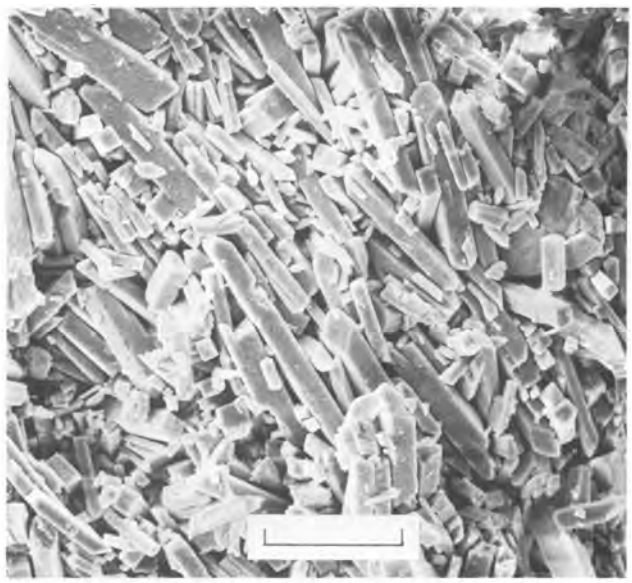

Fig. 4. Cross section of pasted plate prepared from $4PbO \cdot PbSO_4$ at a dry paste density of 4.52 g/cm^3. The random size of the crystals and the close packing in a high density paste are shown. Marker equals 20μ.

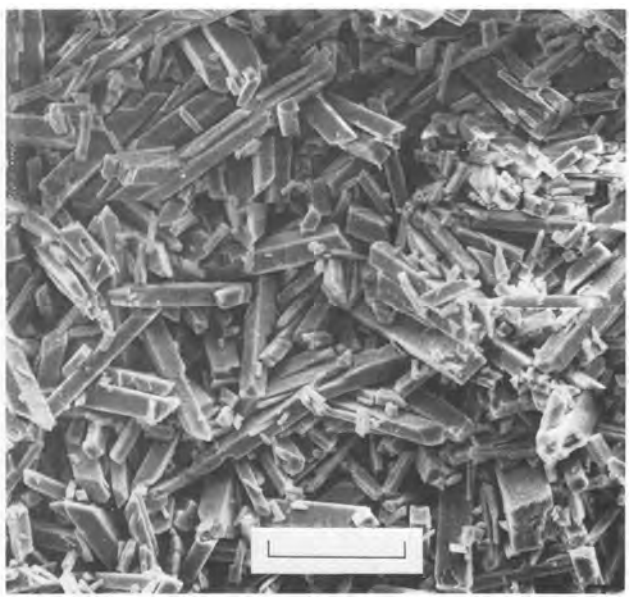

Fig. 5. Cross section of pasted plate prepared from $4PbO \cdot PbSO_4$ at a dry paste density of 3.49 g/cm^3. The random size of the crystals and the loose packing in a low density paste are shown. Marker equals 20μ.

plate, Fig. 1 and 2, respectively. The surfaces of the $4PbO \cdot PbSO_4$ crystals appear to have become rougher as a result of pasting and curing. It is assumed that the roughing is due to abrasion caused by the mixing action, and is not the result of dissolution, since the crystals do not react with the water (6). Scanning electron microscopic examination of the crystals before and after aqueous washes also confirmed no changes of the surface.

Specific void volume vs. dry paste density.—The specific pore volumes of the pastes are plotted against the dry paste densities in Fig. 6. Data are not distinguished according to plate thickness nor method of pasting because no systematic correlations were observed. The data obey the straight line given by Eq. [1] with a correlation coefficient of 0.966. In Fig. 6, Eq. [1] is described by the solid line through the data points. The meaning of the broken line is discussed below.

The relationship given in Eq. [1] is similar to that given in Eq. [R1], previously determined for conventional pastes in which $4PbO \cdot PbSO_4$ was developed *in situ* by means of a special curing process (1)

$$v = 0.398 - 0.0698D \quad [1]$$

$$v = 0.356 - 0.0569D \quad [R1]$$

$$v = 0.271 - 0.0415D \quad [R2]$$

Both Eq. [1] and [R1] are different from the line defined by Eq. [R2]. The latter was obtained from data for conventional pastes, in which the curing

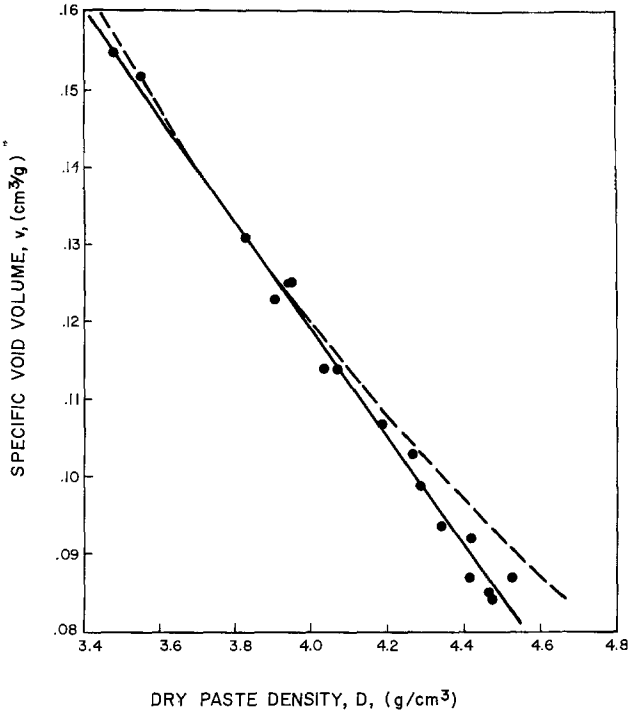

Fig. 6. Specific void volumes of dry pastes of 4PbO · $PbSO_4$ plotted against the corresponding dry paste densities (points and solid line). The broken line is calculated for the specific void volumes corresponding to pastes with solids of constant density at 3.79 g/cm³ (the maximum value in Fig. 7).

process did not develop $4PbO \cdot PbSO_4$ (1). According to Eq. [1] and [R1], both the paste that contained $4PbO \cdot PbSO_4$ crystals as the starting material and that in which $4PbO \cdot PbSO_4$ was formed *in situ* have more void volume at a given dry paste density than pastes not treated to develop $4PbO \cdot PbSO_4$. It has been previously reported (9) that pastes of $4PbO \cdot PbSO_4$ are more porous than conventional pastes, but, because of the different relationships that exist between v and D, it is misleading to compare porosities without specifying a fixed dry paste density.

The volume density, D^{-1}, occupied by a unit weight of paste must be the sum of the void volume, v, and the volume d^{-1}, occupied by the solids portion of the paste, as given in Eq. [2]

$$D^{-1} = d^{-1} + v \qquad [2]$$

From Eq. [1] and [2]

$$d = D(0.0698D^2 - 0.398D + 1)^{-1} \qquad [3]$$

The function given by Eq. [3] is plotted in Fig. 7. At D = 3.79 g/cm³, d goes through a maximum value of 7.67 g/cm³. Since pastes of $4PbO \cdot PbSO_4$ are unreactive, it was unexpected that d should be variant with D. In Fig. 6, the dashed line corresponds to an invariant value of d. That value was arbitrarily selected at 7.67 g/cm³ for comparison purposes. Observing the fit to the data of that line compared to the solid line, it is apparent that d is variant.

Yarnell (6) presented scanning electron micrographs to illustrate how the crystals of $4PbO \cdot PbSO_4$ tend to fagot. Figures 4 and 5 represent an observation, from the present study, that the fagoting increased with dry paste density. There is little adhesion between the individual crystals. Crystals which are not held in place or trapped by other crystals are often displaced by the force of the electron beam when examining the samples by scanning electron microscopy. This displacement results in loss of part of the gold coating, and an incomplete picture, as may be seen in Fig. 5 where several lines cross the photograph and the crystals appear to be sheared off.

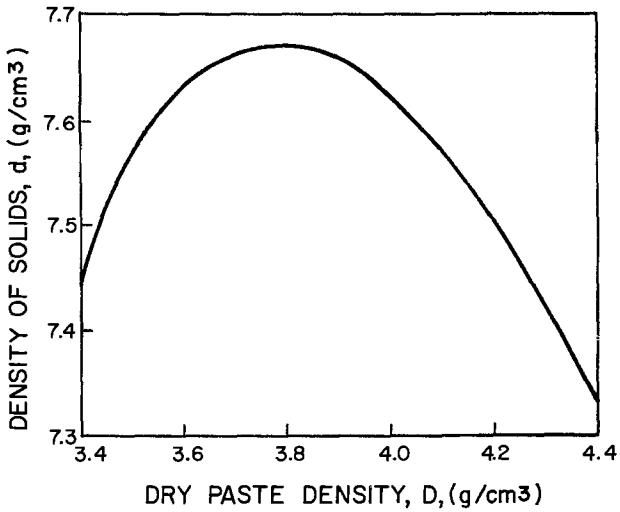

Fig. 7. Calculated density of the solids in the dry pastes as a function of the dry paste density for pastes of 4PbO · $PbSO_4$.

As the contiguous surfaces of the crystals become more tightly packed, open-surface voids become occluded voids, and the measured solids' density decreases. By that interpretation, however, a minimum of fagoting occurred when the dry paste density was 3.79 g/cm³ (Eq. [3] or Fig. 7), rather than at the lowest dry paste density. The points at the low values of D, however, could be fitted to either the variant or invariant relationships. Therefore, the decrease in d for values of D less than 3.79 g/cm³, may be an artifact due to assuming the linear relationship over the entire range of the data. On the other hand, the act of abrasion on the crystals, discussed above, may significantly contribute to the surface voids, and the abrasion may be a complex function of the variables used to adjust the paste density.

Conclusions

A linear relationship was found between specific void volume and dry paste density for battery pastes prepared from $4PbO \cdot PbSO_4$. This relationship is similar to that for conventional pastes in which the $4PbO \cdot PbSO_4$ crystals were formed *in situ*. The specific void volumes of pastes containing $4PbO \cdot PbSO_4$, regardless of origin, were greater than for pastes which did not contain $4PbO \cdot PbSO_4$. Unexpectedly, the density of the solids in the pastes made from $4PbO \cdot PbSO_4$ varied with the dry paste density. This variance may result from the dominant alignment of the faces of the $4PbO \cdot PbSO_4$ crystals in the pastes of highest densities because voids on the surface become trapped and occluded.

Lithium-Aluminum Electrode

B. M. L. Rao,* R. W. Francis,* and H. A. Christopher

Exxon Research and Engineering Company, Linden, New Jersey 07036

ABSTRACT

Lithium-aluminum anodes were investigated as a possible approach to minimizing the lithium dendrite problem in organic electrolyte secondary cells. Electroformation and pyrometallurgical techniques were used in the preparation of the electrodes. The equilibrium emf composition relationship and the cycling behavior were evaluated. This paper reports that under certain conditions Li-Al compositions approaching lithium potentials may be used, reducing the voltage penalty required to minimize the dendrite problem.

Dendritic deposition of lithium appears to be an adverse phenomenon encountered in the development of high energy density rechargeable lithium organic electrolyte cells. This has been discussed in a recent review (1). It is hypothesized that freshly deposited lithium is highly active, and it reacts with most solvents and/or associated impurities in the cells resulting in dendritic plating. Use of purified solvents that do not have any intrinsic reactivity to lithium is one other solution to the problem. Yet another approach is to reduce the activity of the deposited lithium by alloying or by using lithium intermetallics so that the anode material will not react with the purified solvent. This paper reports the behavior of lithium-aluminum electrodes studied in context with the latter approach.

Lithium alloys/intermetallics of aluminum, magnesium, silicon, and boron have been studied for application in high temperature cells. Electroformation of a large number of lithium alloys/intermetallics in organic electrolytes was demonstrated by Dey (2). Detailed investigations of the lithium-magnesium electrodes in propylene carbonate have been reported by Nicholson (3). Galvanostatic polarization of lithium alloys containing 5 atomic percent (a/o) aluminum and magnesium has been measured by Sam and Ambrus (4). Cyclic voltametric investigations of the cathodic reduction of lithium on microcrystalline silicon have been studied by Antula and Becker (5). Investigations on electrochemical behavior of Li-Al alloy intermetallics in an organic electrolyte are presented in this paper.

Experimental

Both commercial powders and foils of Li-Al and electroformed samples were used in the experiments. The commercial alloys were procured from Foote Mineral Company, and the electroformed samples were prepared in the laboratory. The investigation covered 5-80 a/o lithium in Li-Al. All the measurements were carried out at room temperature (~25°C).

Porous Li-Al electrodes were fabricated in a helium dry box by pressure ($4.1 \times 10^4 - 6.9 \times 10^4$ kPa) sintering of Li-Al powder ($\leq 150\mu$) on nickel grids at 315°-360°C for ½ hr. The resultant electrodes were 35-45% porous and contained ~60 mA-hr/cm^2 lithium. The composition of starting material for the porous electrodes ranged from 50-67 a/o lithium.

Specific experiments.—Electroformation of Li-Al and the measurement of emf composition relationship.— Electroformation of Li-Al electrodes was carried out by coulometric cathodic charging of lithium into ($2.54 \times 2.54 \times 0.013$) cm^3 aluminum foil (99.999%) with nickel foil backing in a 2M $LiClO_4$ solution in a mixed solvent of tetrahydrofuran [70 volume percent (v/o)] and dimethoxyethane (30 v/o) using solvents distilled over Na-K alloy and anhydrous salt (H_2O in solution < 10 ppm). The working electrode was held in a parallel plate configuration with a lithium counterelectrode and a layer of microporous polypropylene (Celanese Celgard 2400 and fiberglass paper (65% porous) separator using a spring clamp. The assembly was held in a limited electrolyte configuration with a stack pressure of 70 kPa. The electroformation of Li-Al was carried out at 3.8 mA/cm^2 in a successive sequence of 30 min charging and 15 min open-circuit periods. Using a lithium reference electrode in the cell, the polarization voltage as well as the open-circuit emf of the aluminum half-cell, was measured. Upon attainment of a lithium-rich composition (~75 a/o) the procedure was reversed, and the working electrode was anodically stripped of lithium. Emf measurements were taken during the process. The composition of the electroformed Li-Al electrode was derived from a comparison of the total coulometric charge passed, and the lithium-aluminum phase diagram. This was based on the fact that the faradaic efficiency was 100% for charge-discharge.

Key words: lithium cell, lithium-aluminum electrode, organic electrolyte cell.

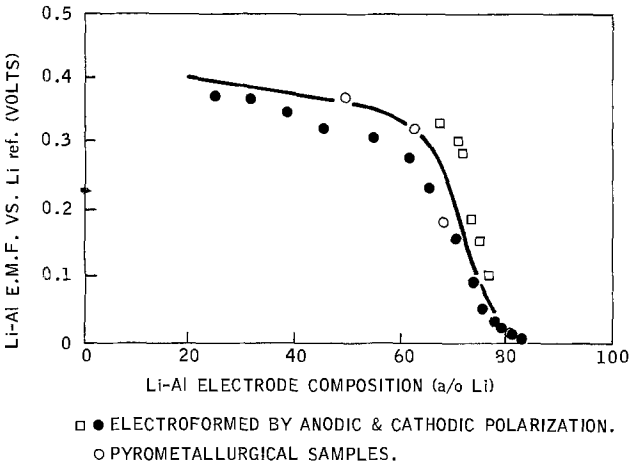

Fig. 1. Emf composition data

Data on the variation of equilibrium emf for porous Li-Al electrodes as a function of lithium content are given in Fig. 1 for both commercial and electroformed samples. Sharp variations expected in the Li-Al electrode potentials at and across phase boundaries is not delineated in the data of Fig. 1. This is not unreasonable, however, since the kinetics for complete solid-state equilibration would be more favorable at higher temperatures.

Cycling behavior of Li-Al electrodes.—In order to follow the cycling behavior of Li-Al electrodes, limited electrolyte cells containing 6.45 cm^2 Li-Al anodes (50 a/o Li) and 6.45 cm^2 pressed powder TiS_2 (6-9) cathodes were fabricated using the separators and stack pressure described earlier. The cell had suitable Li reference electrodes to monitor the anode and the cathode half-cells. The cells possessed capacity densities of 30 and 60 mA-hr/cm^2 for the TiS_2 cathode and Li-Al anode, respectively.

The Li/TiS_2 cells were cycled at 10 mA/cm^2 discharge and 2.5 mA/cm^2 charge in a continuous sequence, to 2.6 and 1.5V cut-off potentials *vs.* Li for the charging and discharging, respectively, using automatic cycling equipment. The selection of the cycling conditions adopted in the experiments was based on requirements for electric vehicle battery design (11) that would meet EPA urban cycle. The voltage-time behavior of the Li-Al anodes was followed during the process, and is presented in Fig. 2.

X-ray diffraction studies on spent anodes.—X-ray diffraction analysis of the commercial samples of Li-Al

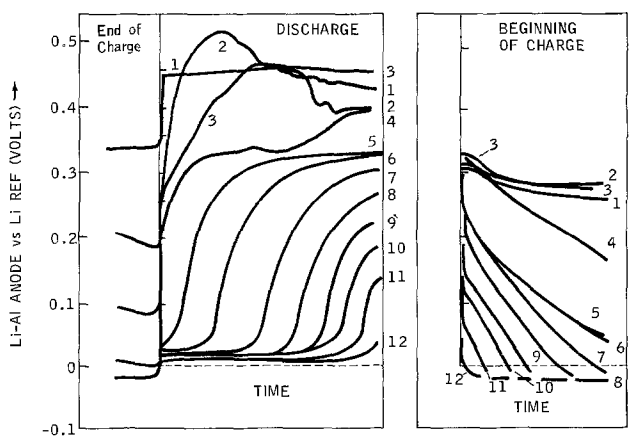

Fig. 2. Cycling data on β-LiAl in LiAl/TiS_2 cell

of composition 20, 30, and 34 weight percent (w/o) lithium was carried out to generate standards and for comparison with measurements made on cycled electrodes. A Phillips diffractometer generating CuK_α radiation was used in the analysis. Lattice spacing data obtained on spent electrodes are presented, and the composition is identified in Table I.

Results and Discussion

The equilibrium emf values of the electroformed Li-Al electrodes and those observed for commercial samples of Li-Al are given in Table II. It is noted that there is general agreement in the emf values observed during the electroformation for both charge and discharge, and these values agree with the measurements made on the electrodes from commercial samples of Li-Al at similar compositions. The former attests to the reversible behavior of Li-Al electrodes in the organic electrolyte. Based on the recent phase diagram of Settle, Myles, and Battles (10), the equilibrium emf values correspond to the compositions in Table II.

Extensive cycling of the electroformed Li-Al anodes could not be carried out because of the dendritic problem associated with the lithium counterelectrode. Examination of the electrode indicated a structural degradation of the aluminum foil with the formation of loosely adherent powder. Another difficulty associated with the electroformation was that the procedure followed was inapplicable for the formation of thick electrodes (40-60 mA-hr/cm^2) of homogeneous composition. The electrodes exhibited high overpotentials for discharge at high current densities, *i.e.*, $\eta = 0.25V$ at 10 mA/cm^2 at 50 a/o lithium. To circumvent these difficulties encountered in the case of the electroformed anodes, investigations were carried out on porous electrodes fabricated by the pyrometallurgical technique.

From a thermodynamic point of view, it is anticipated that β-LiAl may provide adequate protection as the equilibrium emf at this composition (50 a/o Li) is 0.375V more noble to the lithium potential in the same solution. Based on this, cycling of β-LiAl/TiS_2 cells was carried out. The open-circuit voltage of LiAl/TiS_2 cells was 2.175V, as expected. Data on the initial cycling behavior of the cells in a 10 mA/cm^2 discharge and 2.5 mA/cm^2 recharge is presented in Fig. 2. The

Li_9Al_4 + Li	>67	<0.275
Li	100	0.0

following behavior was observed during cycling: (*i*) The cells operated with a primary discharge of 64% cathode capacity, resulting in a change in anode composition from 50 to 35 a/o lithium, changing from β-LiAl to the ($\alpha + \beta$) Li-Al phases; (*ii*) the anode voltage exhibited a noisy discharge ± 0.005V during the first three cycles; (*iii*) there was an initial overshoot in the primary discharge of the β-LiAl half-cell. The magnitude of the overpotential gradually decreased as discharge progressed; (*iv*) the Li-Al half-cell potential gradually drifted toward the lithium electrode potential during successive recharge and discharge, and stabilized in about 12 cycles. The coulombic efficiency of the anode was 100%. The discharge behavior was similar to that observed on the 12th cycle during the next 150 cycles.

Examination of the spent anodes from extensively cycled β-LiAl/TiS_2 cells indicated active material delamination at the nickel grid, and loss of structural integrity similar to that observed on electroformed samples. The unsteady voltage behavior was attributed to these causes. It was noted that as long as the assembly was under a stack pressure, the delamination and structural degradation did not seem to interfere with the cycling capability of the electrodes. The initial overshoot is attributed to oxide film on the surface.

The change in emf of the Li-Al electrode with cycling is interesting. It appears from the data in Fig. 2 that the charging current is distributed between the reformation of the starting material, *i.e.*, β-LiAl and the formation of new phases that are rich in lithium content, *i.e.*, $Li_3Al_2 + Li_9Al_4$, $Li_9Al_4 + Li$, and the like. The formation of these lithium-rich phases was confirmed from x-ray diffraction analysis of the cycled Li-Al electrodes, and this is illustrated in Table I.

Based on the discharge-recharge potentials observed during cycling of β-LiAl electrodes in Fig. 2 and the x-ray diffraction data on the cycled half-cells, the following explanation may be hypothesized for the origin of the behavior, as illustrated in Fig. 3.

On the first discharge, lithium is removed from the initial LiAl β-phase to produce a two-phase alloy of α and β. Based on the high discharge rate and the low overpotentials, the lithium diffusion in the β-phase is apparently quite fast. According to the phase diagram (10), regions highly deficient in lithium from the α-phase, whereas adjacent regions consist of the less lithium-rich β-phase, *i.e.*, β_-. Thus, a certain ratio of β_- to α is established to account for the over-all change of lithium content from 50 to 35 a/o during discharge.

If one assumes a lithium diffusion coefficient in the β-phase which is greater than that in the α-phase, as suggested above, complete phase equilibration according to the phase diagram will not be attained on the subsequent recharge. The result is to shift the β_--phase to the lithium-rich side of the β-phase, *i.e.*, β_+. Due to the assumed lower lithium diffusion in α, this phase does not readily revert to β. As a result, the β-phase is driven on charge continuously through the β_+ boundary into the lithium-rich two-phase regions, $\beta + Li_3Al_2$ and $Li_3Al_2 + Li_9Al_4$. Successive cycling transforms the dynamic coexistence of these phases to more stable lithium-rich intermetallics, as evidenced by the lithium potential after the 12th cycle.

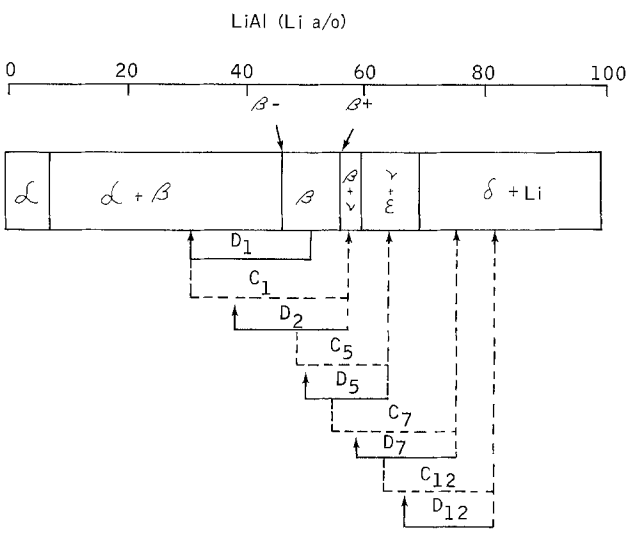

Fig. 3. Mechanism of voltage drift during cycling

It is of interest to note that no problems of cell shorting due to lithium dendrite were experienced after the 12th cycle, in spite of the negative electrode potential approaching 0V *vs.* Li^+/Li. This indicated that the chemical gradient due to the diffusion of lithium in the composition range of 60-80 a/o lithium is sufficient to absorb the deposited metal into the solid phase, thus preventing the dendritic growth. It is to be noted that problems due to dendritic growth may be encountered either by overcharging or by plating lithium at higher current densities.

The shift in lithium concentration at the Li-Al/electrolyte interface to a lithium-rich composition is time dependent, and reflects the relative lithium diffusion coefficients in the various Li-Al phases. Complete equilibration is therefore dependent on the experimental as well as any steady-state, cyclical changes in the morphology of the various phases that occur during cycling. It was observed that the electrode potential does not revert back to the initial value of 0.375V on open-circuit standing over a period of several days. Thus, it appears that the lithium-rich phases formed are stable, with the unexpected result that it has been possible to reduce the voltage penalty required to inhibit the dendrite growth by employing β-Li-Al electrodes.

Some Aspects of the Anodic Oxidation of V, Mo, and W

M. R. Arora*,[1] and Roger Kelly*

Institute for Materials Research, McMaster University, Hamilton, Ontario, L8S 4M1 Canada

ABSTRACT

V, Mo, and W can be readily anodized in an electrolyte consisting of acetic acid, 0.02M $Na_2B_4O_7 \cdot 10H_2O$, and 1.0M additional water as proposed orginally by Keil and Salomon for V. The resulting films, when formed in the presence of air, are duplex, being crystalline and of lower stoichiometry near the metal-film interface but having stoichiometries near V_2O_5, MoO_3, and WO_3 beyond the metal-film interface. The films formed on V and Mo are subject to significant dissolution such that time-independent dissolution currents (i_3) of 0.11 and 0.04 mA/cm^2 can be inferred; with W, by contrast, the dissolution current was only ~0.001 mA/cm^2. The electronic currents (i_2) are estimated to be 0.09 mA/cm^2 for V, 0.12 mA/cm^2 for Mo, and 0.03 mA/cm^2 for W, and the constant-current efficiency follows as being given by the relation $\eta = (I - i_2 - i_3)/I$, where I is the total applied current. The efficiencies for V and Mo thus lie in the interval 0.60-0.92 for $0.5 \leq I \leq 2.0$ mA/cm^2, whereas W shows essentially unit current efficiency. Efficiencies are also deduced for conditions of mixed constant current and constant voltage. That of V is unusually low, as is to be expected for such conditions, whereas that of Mo is unusually high, suggesting that the average stoichiometry of the film is measurably less than MoO_3. Again W shows essentially unit efficiency.

The pioneer work of Güntherschulze and Betz (1) initiated much of the present day interest in the formation of anodic oxide films. They fitted their data on the kinetics of anodization to an empirical relation of the type

$$i_1 = A \exp(B\mathcal{E}_d) \quad [1]$$

where i_1 is the ionic current and $\mathcal{E}_d$ is the field across the film during formation, *i.e.* the differential field. Elementary considerations relate A and B to more fundamental parameters, in particular $B \propto 1/kT$, but such elaboration will not be required in what follows. Anodic films are of considerable technological importance, for example, in corrosion protection, metal finishing, batteries, electrolytic capacitors, and semiconductor processing. Recently, major indirect uses have been developed for anodic films in the study of diffusion profiles at low temperatures (2, 3) and in the study of depth distributions of implanted ions (4, 5). In these cases, use is made of the fact that, if anodic oxidation is carried out at a constant voltage, then within a few minutes the film thickness approaches an approximately constant value and the resulting film may be assumed to be extremely uniform. If such films can be removed without affecting the substrate, then it becomes possible to remove successive layers of metal as thin as 1-5 nm and one speaks of "anodic sectioning." By contrast, a technique such as H^+ or He^+ backscattering, though having the important advantage of being nondestructive, has a resolving power of roughly 10-15 nm (6).

The purpose of the present study was to complete a project on the anodic sectioning of V, Mo, and W (5, 7, 8) by presenting a brief study of the kinetics of the formation of the relevant anodic films. The main difference from related studies, for example, the work of Ammar and Salim (9, 10), will be the use of a combination of gravimetric and electrochemical information. A further study on film structure and stoichiometry is published elsewhere (11).

Vanadium is of particular interest because of the repeated failures [*e.g.*, Ref. (12, 13)] in attempts to grow macroscopic films. The first successful results date from 1965-1968, when Keil and Salomon (14, 15) devised an electrolyte based on acetic acid, and 1974, when Pelleg (16) found a second successful electrolyte based on acetone. In summarizing the results we will distinguish between those cases where air was excluded and those where it was not. Concerning work done in the absence of air, voltages up to 110V were achieved (15), the current efficiency was close to 100% (15), no dissolution could be detected after an initial induction period (15), Eq. [1] was obeyed (17), and, most significantly, the film had the unexpected composition ~VO_2 (15). Work done in the presence of air succeeded in showing thick films to be amorphous (11) and to have a stoichiometry $V_2O_{5\pm0.3}$ (18), and thin films to be crystalline and almost certainly of lower stoichiometry than V_2O_5 (11). The average stoichiometry is thus somewhat less than that of V_2O_5. The anodic sectioning of V is described in Ref. (7, 16).

Molydenum, when polarized anodically in most electrolytes, fails to develop a macroscopic film (13, 19, 20). Lavrenko and Pen'kov (21) claim to have anodized Mo in saturated boric acid at up to 200V. We could not reproduce their results, while Ikonopisov (22) suggests that the high voltage drop observed by Lavrenko and Pen'kov may have been due to the high resistance diaphragm between the electrodes. The first successful results are accordingly those of the present authors with an acetic acid-based electrolyte (5) and of Ikonopisov with a glycol-borate electrolyte (22). The films supported up to 200-300V and were suited for anodic sectioning (5). More recently, film formation in the acetic acid-based electrolyte has been shown (23) to follow Eq. [1], thick films have been shown to be amorphous (9) and to have an average stoichiometry $MoO_{2.75}$ (23), and thin films have been shown to be crystalline and with a diffraction pattern resembling that of $MoO_2 \cdot H_2O$ (11). The tentative identification of $MoO_2 \cdot H_2O$ helps to explain why the average stoichiometry should be less than that of MoO_3.

Tungsten has, relatively speaking, been studied in great detail, including from the point of view of anodic sectioning (8, 24), and presents few problems. The only unacceptable electrolytes appear to be those based on alkaline solutions, since they cause W to go into solution rather than into a macroscopic film (9). Examples of successful electrolytes include an aqueous solution of KNO_3 (0.4M) and HNO_3 (0.04M), with which voltages as high as 75V can be achieved (24), various dilute acids, leading to voltages as high as 85V (10), and the acetic acid-based electrolyte to be used here, leading to voltages as high as 140V (8). Film growth kinetics appear (10), in general, to follow Eq. [1],

Key words: vanadium, molybdenum, tungsten, anodization, stoichiometry, differential field, current efficiency.

thick films have been shown to be amorphous (11) and to crystallize to a mixture of WO_2 and disordered $WO_{2.90}$ (25), and thin films have been shown to consist of crystalline WO_2 (11). The average stoichiometry is thus somewhat less than that of WO_3.

Experimental

Polycrystalline metal foils, with dimensions of 20 × 15 × 0.1 mm and with purities claimed to be at least 99.8%, were used as specimens. The surface preparation and other preanodizing treatment have been described previously (5, 7, 8), while the electrolyte was similar to the acetic acid-based mixture proposed by Keil and Salomon for V (15). It consisted of acetic acid, 0.02M $Na_2B_4O_7 \cdot 10H_2O$, and 1.0M additional water, and thus had roughly half the water content as in Ref. (15). The water content is to some extent an optimum, in that less than 1.0M reduces the conductivity to an inconvenient extent and more than 2.0M leads to films on V and Mo which are excessively unstable. We would emphasize that the present results are probably particular to the electrolyte used as well as to the anodizing conditions, and as evidence for this would cite the significantly different stoichiometry found here ($\sim V_2O_5$) and by Keil and Salomon ($\sim VO_2$) for the anodic film on V. As far as we can see, the origin of the difference lies simply in whether or not air was present.

The anodic films formed on V and Mo were rather unstable in that they would change interference colors and eventually disappear when exposed to air. They could be stabilized either by dipping them in glacial acetic acid followed by drying them with filter paper or by using a jet of compressed air immediately after their withdrawal from the electrolyte. Once stabilized, they could be stored in a desiccator almost indefinitely. In all anodizations, a cylindical platinum cathode 25 mm in diameter was used, the specimens were placed along the axis, the temperature was 25° ± 1°C, and air was present.

It was observed, during the course of constant-current experiments, that stirring the electrolyte affected the rate of film formation with V and Mo but not W. The curves of V *vs.* t were lowered, especially for currents of $\leq$0.5 mA/cm² (Fig. 1), and, since this may be taken as indicative of enhanced film dissolution, the present experiments were carried out with neither stirring nor gas bubbling.

Results and Discussion

Gravimetric information.—Experiments relating to the weights of anodic films on V, Mo, and W are described in detail in Ref. (5, 7, 8, 26). They were based, in the case of thick films, on direct weighing and, in the case of thin films, on techniques linked to the depth distributions of implanted ^{85}Kr. The main results are summarized in Table I. They are in all cases valid for the acetic acid-based electrolyte, for the presence of air, and for conditions of mixed constant current and constant voltage, such that the current was preset at 2.0 mA/cm², the voltage was preset at whatever value was desired, and the total anodizing time was 6 min.

Additional experiments were undertaken to determine the extent of film dissolution. Specimens were prepared with a preset current of 2.0 mA/cm², a preset voltage of 50V, and were then anodized with times of 6-60 min. If the film weights are re-expressed in terms of the metal present in the films, then the loss by dissolution is given by (metal-removal weight) minus (metal present in film). The results are shown in Fig. 2 and can also be represented by formulas based on a least squares analysis, as follows

dissolution loss of V $= -0.4 \pm 0.2$

$+ (0.0117 \pm 0.0002) \times t$ μg/cm² of metal

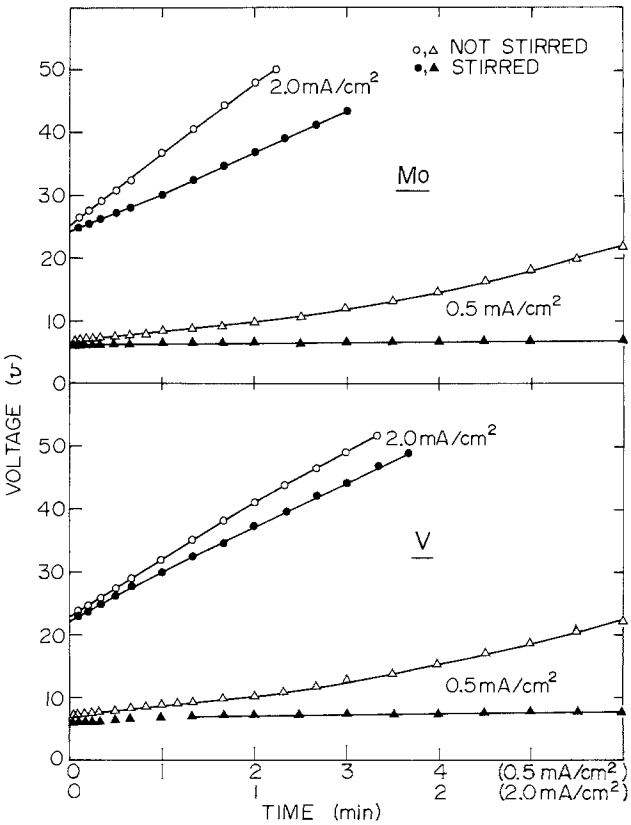

Fig. 1. Effect of stirring on film growth at constant current as revealed in voltage-time curves. The growth rates on V and Mo but not W are significantly reduced by stirring, this being a qualitative indication that film dissolution is a problem.

dissolution loss of Mo $= -2 \pm 1$

$+ (0.0069 \pm 0.0006) \times t$ μg/cm² of metal

dissolution loss of W = undetectable gravimetrically.

Here t stands for time in seconds. The main uncertainty in the approach used lies in the assumption of the stoichiometries V_2O_5 and MoO_3; if the real stoichiometries were lower, the calculated dissolution losses would also be lower.

The problem of dissolution was further investigated, in the case of W, by the following more sensitive method. Specimens were labeled with 10 keV ^{85}Kr to a dose of 5×10^{15} ions/cm² and it was shown by means of anodic sectioning (8) that the Kr had an integral concentration profile given approximately by

$$\text{integral concentration} = \exp(-x \ln 2/R_m)$$

with R_m equal to 13 μg/cm². The distribution curves,

Table I. Film and metal-removal weights for V, Mo, and W when anodized in the acetic-acid based electrolyte*

Metal	Film weight (μg/cm²)	Metal-removal weight† (μg/cm²)	Region of validity (V)
V	$2 \pm 2 + (1.15 \pm 0.04) \times V$	$6 \pm 1 + (0.63 \pm 0.01) \times V$	7.5 or 4 to 110
Mo	$1 \pm 1 + (1.58 \pm 0.02) \times V$	$5 \pm 2 + (1.05 \pm 0.03) \times V$	10 or 7.5 to 110
W	$10 \pm 3 + (1.38 \pm 0.05) \times V$	$6.5 \pm 2 + (1.09 \pm 0.03) \times V$	10 or 7 to 100‡

* The weights are taken from Ref. (26), where they are based on a least squares analysis, rather than Ref. (5, 7, 8), where the analysis was simpler.

† A metal-removal weight can also be described as the metal removed from a specimen during a full anodizing-stripping sequence.

‡ Valid to 140V if the current is present at 10.0 mA/cm² instead of 2.0 mA/cm² beyond 100V.

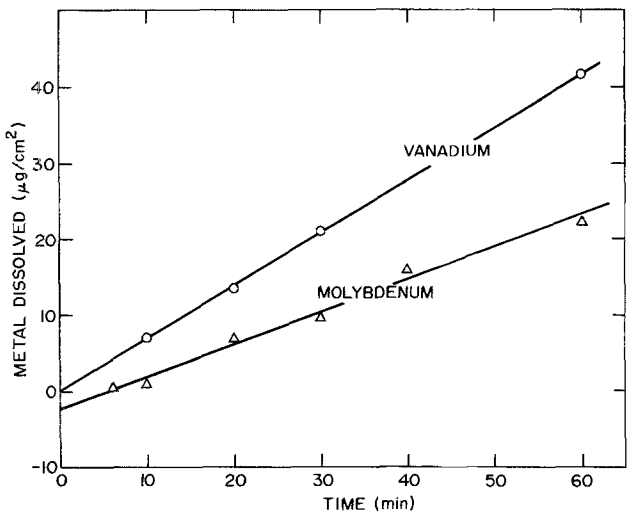

Fig. 2. Dissolution loss for V and Mo as a function of the total anodizing time. The experimental points are based on the stoichiometries V_2O_5 and MoO_3, and would have lower values if the stoichiometries were lower.

which resemble those for Kr → Mo (5), are discussed in Ref. (26). The specimens were next anodized for 6 min, with the current preset at 2.0 mA/cm² and the voltage preset at 10 or 25V, and were counted to determine the residual activity with the films still present. The normalized value was 0.992 ± 0.010, indicating a dissolution loss of about 4×10^{-4} μg/cm² sec. Loss thus occurs at about 3-6% the rate found with V or Mo.

Analysis of gravimetric information.—The first step in any discussion of anodizing transition metals is to estimate the film stoichiometry. One of the least controversial approaches is based on thickness information as in Table I, where the thicknesses will be noted to have the general form

$$\text{thickness} = C + D \times V$$

The constant terms, C, will include contributions from interfacial potentials, from pre-existing films, as well as, in the case of metal removal, from dissolution, whereas the slopes, D, will be largely unaffected by these. We have therefore deduced the stoichiometries from the slopes as detailed in Table II. The conclusion is that the stoichiometries, valid beyond the region at the metal-film interface, lie near V_2O_5, MoO_3, and WO_3 as distinct from VO_2, MoO_2, and WO_2. We would recall that the main result of Ref. (11) was to demonstrate the thinnest anodic films on V, Mo, and W to be crystalline and of known (W) or suspected (V, Mo) low stoichiometry. The over-all films are thus duplex, as in fact they must be thermodynamically, and have average stoichiometries which are somewhat low. The results of the present work together with Ref. (11) can be summarized schematically as follows

Table II. Stoichiometries of anodic films on V, Mo, and W

Metal	Slope of experimental metal-removal weight (μg/cm² · V)	Slope of inferred film weight (μg/cm² · V)	Slope of experimental film weight (μg/cm² · V)	Conclusion regarding stoichiometry
V	0.63 ± 0.01	1.03 ± 0.02 if VO_2 1.13 ± 0.02 if V_2O_5	1.15 ± 0.04	~V_2O_5
Mo	1.05 ± 0.03	1.40 ± 0.04 if MoO_2 1.58 ± 0.05 if MoO_3	1.58 ± 0.02	~MoO_3
W	1.07 ± 0.03	1.28 ± 0.04 if WO_2 1.37 ± 0.04 if WO_3	1.38 ± 0.05	~WO_3

Table III. Resistivities of oxides of V, Mo, and W

Oxide	Resistivity (Ω-cm)	Ref.
V_2O_5 (amorphous)	10^6	(27)
V_6O_{13}	10^3	(28)
VO_2 (crystalline)	10-100	(29, 30)
VO_2 (amorphous)	10^{-2}	(30)
MoO_3	$>10^{10}$	(31, 32)
$MoO_{2.88}$	~250	(33)
MoO_2	10^{-4}	(34)
WO_3	10^5-10^6	(32)
$WO_{2.90}$	Metallic	(35)
WO_2	10^{-3}	(34)

Table IV. Values of $\mathcal{E}_d$ and i_3 as obtained from gravimetric information

Metal	Differential field, $\mathcal{E}_d$* (V/cm)	Dissolution current, i_3 (mA/cm²)
V	$(2.9 \pm 0.1) \times 10^6$	0.111 ± 0.002
Mo	$(2.95 \pm 0.05) \times 10^6$	0.042 ± 0.004
W	$(5.2 \pm 0.2) \times 10^6$	~0.001

* As discussed in the text, the real uncertainties are greater than those shown.

$$V|<V_2O_5|\sim V_2O_5$$

$$Mo|MoO_2\cdot H_2O(?)|\sim MoO_3$$

$$W|WO_2|\sim WO_3$$

More subtle distinctions, as between WO_3 and $WO_{2.90}$, cannot be made with gravimetric information. Electron diffraction is often a useful alternative, but it fails in the present case owing to the amorphicity of the films formed on V, Mo, and W (11). It is more helpful to note that slightly reduced forms of transition-metal oxides tend to have metallic or near-metallic resistivities (Table III). Bearing in mind that, for an anodizing current of 2.0 mA/cm² and a differential field near $(3\text{-}5) \times 10^6$ V/cm (to be shown below), the implied resistivity is ~10^9 Ω-cm, it is clear that the films formed on V, Mo, and W must be fully oxidized.[2]

The film weights enable estimates to be made of the differential field, which is, ideally, the same field $\mathcal{E}_d$ as appears in Eq. [1]. We again use the slopes and obtain results as in Table IV, provided the densities can be taken as for crystalline V_2O_5, MoO_3, and WO_3. These values of $\mathcal{E}_d$ are subject to two conflicting errors. They will tend to be high owing to the use of crystalline densities. They will tend to be low owing to the film thicknesses being based on anodizing cycles which involve first a constant-current segment and then a constant-voltage segment rather than (as in the following sections) constant current alone. The real uncertainties are therefore greater than shown in Table IV.

Finally, the dissolution losses can be used to evaluate i_3, the current associated with film dissolution. If the dissolution losses are written in the form

$$\text{loss} = E + F \times t \quad \mu g/cm^2$$

then a time-independent i_3 follows as

$$i_3 = (FzF/M) \times 10^{-3} \quad mA/cm^2$$

where z is the cation valence, F is Faraday's constant, and M is the cation molecular weight. The results are included in Table IV.

Constant-current film growth.—Curves of V *vs.* t, obtained with a potentiometric recorder at various current densities, are shown in Fig. 3-5. The voltage first rose sharply due to the ohmic drop across the

[2] Keil and Salomon's (15) basic result that the film on V anodized in the absence of air is ~VO_2, while well-substantiated experimentally, causes some concern in view of the low resistivity of VO_2 (Table III).

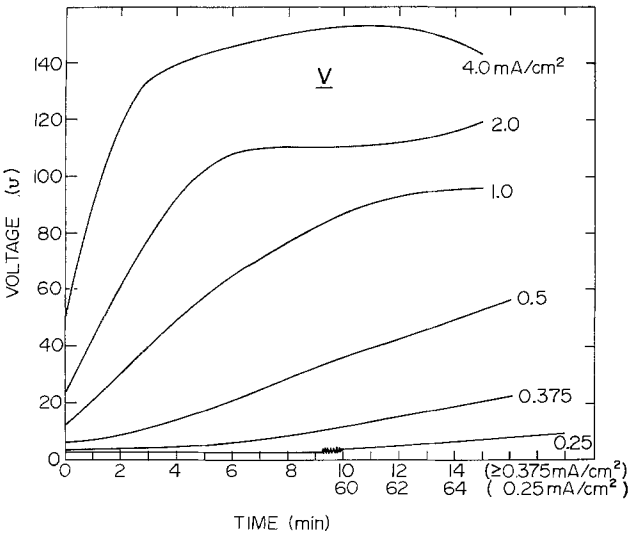

Fig. 3. Typical voltage-time curves for the anodization of V at the indicated current densities.

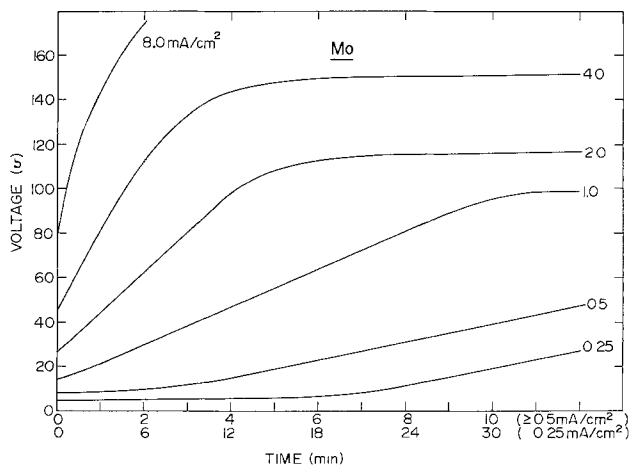

Fig. 4. Typical voltage-time curves for the anodization of Mo at the indicated current densities.

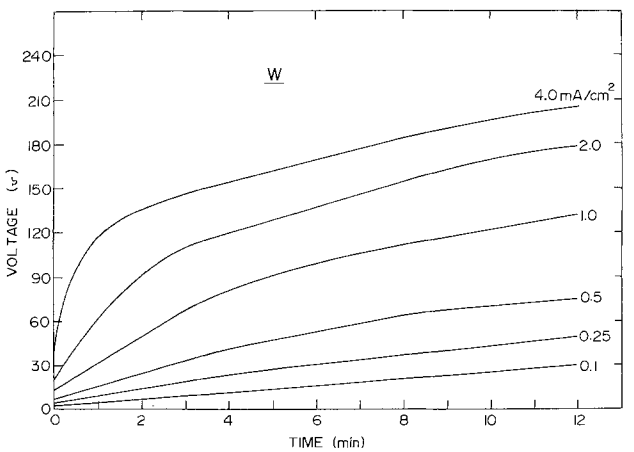

Fig. 5. Typical voltage-time curves for the anodization of W at the indicated current densities.

electrolyte and then increased linearly with time as the films grew. With V and Mo an induction period is evident for current densities of $\leq$0.5 mA/cm², such that the linear voltage rise was delayed for 4-60 min. We do not regard the induction periods as due to the formation of slightly reduced phases such as those inferred by Ikonopisov (22) using a glycol-borate electrolyte, as there was no darkening; rather we attribute them to film dissolution such as that suggested by Fig. 1 and demonstrated explicitly in the preceding section. In most cases there was a critical region of voltage beyond which breakdown can be inferred, *i.e.*, beyond which the voltage ceased to rise linearly, there was an accompanying evolution of gas, and occasional sparks appeared. Specimens anodized into the breakdown region lost their interference colors and gradually became grayish. By correcting the observed breakdown voltages for the ohmic drop one obtains true breakdown voltages of 80-100V for all three metals.

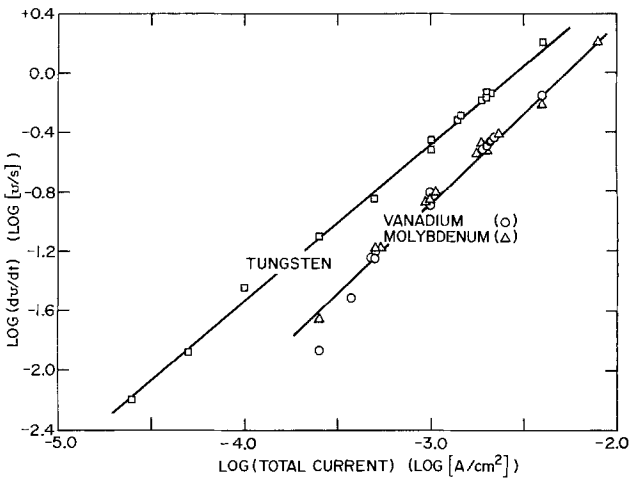

Fig. 6. Curves of log (dV/dt) vs. log I as based on material like that of Fig. 3-5. The slopes and intercepts yield the parameters a and b of Eq. [2].

Analysis of constant-current film growth.—Van Ryselberghe *et al.* (12, 36) analyze curves of V *vs.* t with an empirical relation of the form

$$dV/dt = aI^b \qquad [2]$$

where I is the total applied current and a, b are constants. That this relation applies to the present results follows from Fig. 6, with values of a and b as given in Table V.

In general, an analysis based on Eq. [2] must be regarded as unproductive as it is difficult to relate a and b to more fundamental parameters. The main exception concerns b, in that if b is observed to exceed unity so the current efficiency (η) can be inferred to be an increasing function of I and theretfore less than unity. We thus anticipate V and Mo to anodize with low efficiency but W with near unit efficiency.

More explicit information on current efficiency, together with new estimates for $\mathcal{G}_d$, follows from the conservation relation

$$dV/dt = \eta IM\mathcal{G}_d/z\mathbf{F}\rho \equiv \eta Ir\mathcal{G}_d \qquad [3]$$

where ρ is the film density and where we neglect any consideration of surface roughness. The total applied current I has three possible components, namely, ionic current leading to persistent film (i_1), electronic current (i_2), and current associated with film dissolution (i_3). As such, the efficiency is just

$$\eta = (I - i_2 - i_3)/I \qquad [4]$$

Table V. Values of the constants a and b in Eq. [2]

Metal	a* (V/sec)	b
V	480	1.20
Mo	480	1.20
W	470	1.05

* The numerical values of a are such as arise when I is in A/cm².

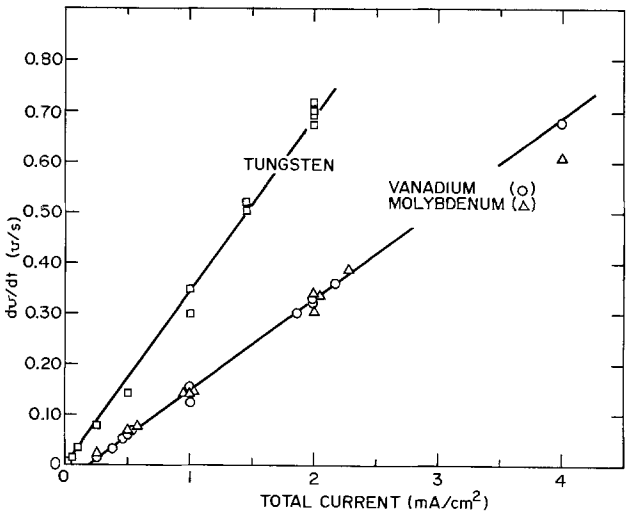

Fig. 7. Curves of dV/dt vs. I as based on material like that of Fig. 3-5. The slopes and intercepts yield approximations to the parameters $r\mathcal{E}_d$ and $(i_2 + i_3)$ of Eq. [6a] and [6b].

Also, since Eq. [1] is obeyed by V, Mo, and W (17, 23, 10), $\mathcal{E}_d$ can be written as

$$\mathcal{E}_d = (1/B) \ln [(I - i_2 - i_3)/A] \qquad [5]$$

and this enables one to conclude that a plot of dV/dt vs. I will have a slope

$$\text{slope} = r\mathcal{E}_d(1 + \{\ln [(I - i_2 - i_3)/A]\}^{-1}) \approx r\mathcal{E}_d \qquad [6a]$$

and an intercept

$$\text{intercept} = i_2 + i_3 + A \approx i_2 + i_3 \qquad [6b]$$

The slope will be a sort of average, valid for the experimental current interval.

We have assumed, in arriving at Eq. [6a], that i_2 and i_3 were both independent of I. Thus i_2 should depend only on $\mathcal{E}_d$ and the latter is, according to Eq. [1] or [5], related to I logarithmically; the dependence is thus weak. Likewise i_3 is naturally constant for a film with fixed stoichiometry, a constancy which is explicitly confirmed for those anodizing voltages for which the film weights can (as in Table I) be written in the form $C + D \times V$. The approximations indicated with Eq. [6a] and [6b] require that A be small, as it in fact often (12, 37) but not always (9, 10) appears to be.

Figure 7 shows a plot of dV/dt vs. I, while Table VI summarizes the relevant values of $r\mathcal{E}_d$ (from the slopes using a least squares analysis), $\mathcal{E}_d$ (deduced with ρ as for crystalline V_2O_5, MoO_3, and WO_3), $i_2 + i_3$ (from the intercepts using a least squares analysis), i_2 (deduced with the help of i_3 from Table IV), and η (deduced according to Eq. [4]). The values of $\mathcal{E}_d$ are subject to errors both of which make them high. These are the use of crystalline densities and the approximation in Eq. [6a], and as such the real uncertainties are greater than shown in Table VI.

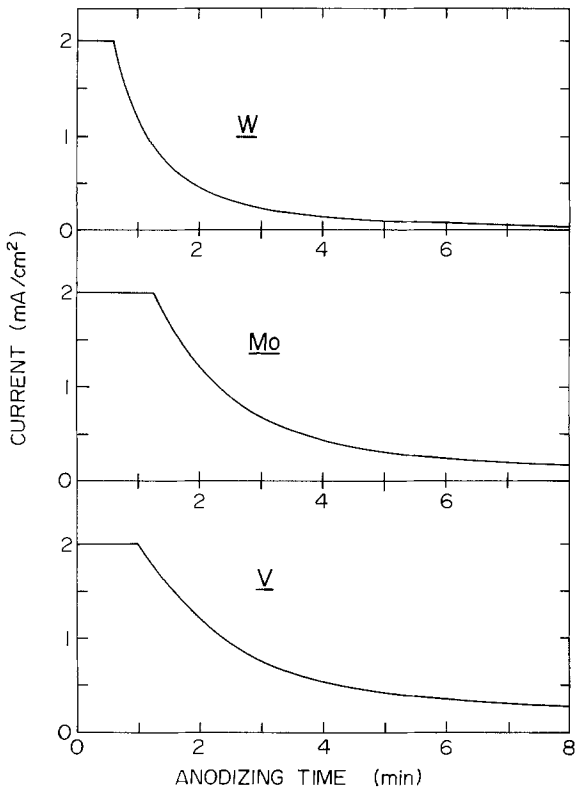

Fig. 8. Typical current-time curves for the anodization of V, Mo, and W when the current is preset at 2.0 mA/cm² and the voltage at 50V. The areas of these curves infer film weights according to Eq. [7], thence modified current efficiencies ($\eta' = \eta z\langle M\rangle / \langle z\rangle M$) by comparison with the explicit film weights of Table I.

Three indications of the self-consistency of the results are (*i*) that $\mathcal{E}_d$ of Tables IV and VI are similar, (*ii*) that $i_2 + i_3$ of Table VI exceeds i_3 of Table IV, and (*iii*) that η is less than unity with V and Mo, corresponding to b in Eq. [2] exceeding unity to a significant extent.

Film growth with mixed constant current and constant voltage.—Curves of I vs. t relevant to mixed constant current and constant voltage were obtained with V, Mo, and W by anodizing for a total time of 6 min with the current preset at 2.0 mA/cm² and the voltage preset at 50V. Typical examples are shown in Fig. 8 and are seen to be characterized by a constant-current portion during which the voltage rose to the preset value, a rapid fall in current qualitatively in accordance with Eq. [1], and an approach to what is in principle $i_2 + i_3$. They will be here used to make new estimates of current efficiency.

Analysis for mixed constant current and constant voltage.—Curves of I vs. t as in Fig. 8 infer film weights according to the conservation relation

$$\text{weight} = (\eta z\langle M\rangle/\langle z\rangle M)\,(\textstyle\int I dt)\,(M/z\mathbf{F})\,(10^6) \quad \mu g/cm^2 \qquad [7]$$

where z is the ideal valence of cations in the film (*e.g.*, 6 for Mo), $\langle z\rangle$ is the actual average valence [*e.g.*, <6

Table VI. Values of $\mathcal{E}_d$, $i_2 + i_3$, i_2, and η as obtained from information on constant-current film growth

Metal	$r\mathcal{E}_d$ (V · cm²/sec · A)	$\mathcal{E}_d$* (V/cm)	$i_2 + i_3$ (mA/cm²)	i_2 (mA/cm²)	η at 0.5 (mA/cm²)	η at 2.0 (mA/cm²)
V	180 ± 6	(3.2 ± 0.1) × 10^6	0.20 ± 0.05	~0.09	0.60	0.90
Mo	180 ± 8	(3.4 ± 0.2) × 10^6	0.16 ± 0.05	~0.12	0.68	0.92
W	350 ± 20	(6.3 ± 0.4) × 10^6	0.03 ± 0.05	~0.03	0.94	0.99

* As discussed in the text, the real uncertainties are greater than those shown.

Table VII. Efficiencies for mixed constant current and constant voltage as obtained from information as in Fig. 8

Metal	Film weights as calculated from Eq. [7] ($\mu g/cm^2$)	Experimental film weights for 50V from Table I ($\mu g/cm^2$)	Modified current efficiency η'
V	73.5 ± 2	59.5 ± 3	0.81 ± 0.05
Mo	82.5 ± 2	80.0 ± 1.5	0.97 ± 0.03
W	79.2 ± 2	79.0 ± 4	1.00 ± 0.06

for Mo (11, 23)], and M and $\langle M \rangle$ are the analogous molecular weights. Accordingly, by comparing film weights inferred from Eq. [7] with explicit weights as in Table I, one obtains a modified current efficiency, $\eta' = (\eta z \langle M \rangle / \langle z \rangle M)$. The results are summarized in Table VII.

A detailed interpretation of the current efficiencies of Table VII is difficult for two reasons. One is that the observed quantity is η' rather than η. The other is that an efficiency measured when the current is initially constant but then falls, as here, is inherently lower than one based on constant-current data, as in Table VI. Nevertheless, certain conclusions can be derived as follows:

(*i*) V shows the expected reduced current efficiency for an anodizing cycle in which current is first constant and then falls. This is consistent with V having a high value of $i_2 + i_3$ (Table VI), although it also requires that the average stoichiometry be close to V_2O_5.

(*ii*) Mo shows a higher efficiency in Table VII (0.97) than in Table VI (0.92), a result which is possible only if $z/\langle z \rangle$ is greater than unity, as when the average stoichiometry of the film is measurably low. In fact, the observed results are understandable with an average stoichiometry similar to $MoO_{2.75}$ (23), whence $z\langle M \rangle / \langle z \rangle M = 1.06$.

(*iii*) W anodizes with essentially 100% efficiency under all circumstances, as in fact it must if $i_2 + i_3$ is close to zero (Table VI) and the average stoichiometry is close to WO_3.

Conclusions

V, Mo, and W have been anodized in an electrolyte consisting of acetic acid, 0.02M $Na_2B_4O_7 \cdot 10\ H_2O$, and 1.0M additional water as proposed originally by Keil and Salomon for V (14,15). The resulting films, when formed in the presence of air, have weights as summarized in Table I and from these weights the stoichiometries, valid beyond the region at the metal-film interface, follow as being near V_2O_5, MoO_3, and WO_3 (Table II). More subtle distinctions, as between WO_3 and $WO_{2.90}$, cannot be made with gravimetric information; nevertheless, slightly reduced phases can be excluded on the grounds that, in so far as they have been studied, they tend to have metallic or near-metallic resistivities (Table III). We note in particular that the stoichiometry of the film on V appears to depend critically on air, as $\sim VO_2$ is obtained in the absence of air (15) but $\sim V_2O_5$ in the presence [here and Ref. (18)].

The film-weight information of Table I also permits $\mathcal{E}_d$, the differential field, to be estimated (Table IV). Additional weight measurements, obtained as a function of anodizing time, enable i_3, the time-independent current associated with film dissolution, to be evaluated (Table IV).

When films are grown at constant current, curves of V *vs.* t are readily obtained. Those for V, Mo, and W were in most cases characterized by segments showing an ohmic voltage drop, a linear rise as the films grew, and evidence for breakdown, although when V and Mo were anodized at ≤ 0.5 mA/cm^2 induction periods lasting 4-60 min could also be identified. The induction periods were attributed to film dissolution.

The analysis of V-t curves according to Eq. [2], *i.e.*, $dV/dt = aI^b$, is regarded as unproductive except to demonstrate that, since b exceeds unity with V and Mo (Table V), these two metals anodize with low efficiency. Equation [3], *i.e.*, $dV/dt = \eta I r \mathcal{E}_d$, is far more useful and leads to explicit estimates of the differential field ($\mathcal{E}_d$), the nonfilm forming current ($i_2 + i_3$), and the current efficiency (η) (Table VI).

When films are grown with mixed constant current and constant voltage, curves of I *vs.* t become of interest. Those for V, Mo, and W had segments showing a constant current, a rapid fall of current qualitatively in accordance with Eq. [1], *i.e.*, $i_1 = A \exp(B\mathcal{E}_d)$, and an approach to what is in principle $i_2 + i_3$. Such curves infer film weights in accordance with Eq. [7] and when these are compared with explicit film weights, as in Table I, a modified current efficiency η' is obtained (Table VII). The numerical value of η' for V is low, 0.81, as can be expected whenever films are grown with an anodizing cycle in which current is first constant and then falls. More significantly, the numerical value for Mo is high, 0.97, this being possible only if $z/\langle z \rangle$ is greater than unity, as when the average stoichiometry of the film is measurably low.

Pulsed Potentiostatic Deposition of Gold from Solutions of the Au(I) Sulfite Complex

Jean Horkans* and L. T. Romankiw*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10592

ABSTRACT

The kinetics of Au deposition from Au(I) sulfite solutions in the pH range 8.5-13 has been studied using cyclic voltammetry and single potential step methods. At potentials more positive than −0.8V *vs.* NHE, the potential step data can be explained by a C.E. mechanism, probably dissociation of the gold complex followed by charge transfer. At more cathodic potentials the mechanism may involve direct electron transfer to the complexed gold ion. The effect of pulsed potentiostatic deposition on the properties of Au films deposited from sulfite solutions was investigated. Although variation of the frequency of the potential pulse was shown to affect the distribution of Au deposited through a photoresist pattern, the stress, grain size, purity, and resistivity of gold deposited pulsed potentiostatically showed no clear dependence on frequency. This can be explained in terms of irreversibility of the Au/Au(I) couple in sulfite solution.

A number of investigators, *e.g.*, (1-12), report that the physical properties of electrodeposits can be improved when deposition is carried out under pulsed potential or pulsed current conditions rather than under the usual potentiostatic or galvanostatic conditions. The reason for this improvement is assumed to lie in the time-dependent variation of the diffusion layer thickness at the electrode surface. The period between pulses, during which no deposition takes place, allows the concentration of the metal ion or metal complex in the diffusion layer near the cathode to relax from its depleted value to a value approaching the concentration in the bulk solution. Based on this reasoning, the time-averaged diffusion layer under pulsed conditions is thinner than that prevailing under galvanostatic or potentiostatic conditions. This thinner diffusion layer more closely follows the contours of the surface and results in a deposit of more uniform thickness. In addition, Popov *et al.* (5-7) have shown that pulsed potentiostatic deposition decreases deposit porosity.

A model of pulsed potentiostatic deposition has been developed by Despic and Popov (1, 2). Their solution of Fick's second law, with the appropriate boundary conditions, for an ideally reversible electrode shows that under conditions of pulsating potential a stable, time-independent diffusion layer is established. The dependence of the diffusion layer thickness δ_N on frequency ν is $\delta_N \propto \nu^{-1/2}$. Thus the deposits with greatest thickness uniformity and lowest porosity should be attained at the highest frequency. According to this model, the criterion which must be met in order that surface roughness not be amplified is that δ_N should be less than the radius of curvature of the irregularities. Despic and Popov (1) found experimentally that the growth of dendrites of Cu and Zn was inhibited by pulsing the electrode potential.

In the case of a nonreversible electrode, the concentration of ions at the electrode surface is not able to follow the changing electrode potential. When the Despic and Popov model is applied to a nonreversible system (2), the result is a time-dependent diffusion layer thickness and the amplification of surface roughness.

The use of pulsed current to affect mass transport during metal deposition has been discussed by Braun and Ibl (4, 5). Although Despic and Popov (1, 2) claim that pulsed current should give the same results as direct current at high frequencies, Braun and Ibl report very smooth deposits of Cu using high frequency pulses at high current densities.

We have chosen to investigate the pulsed potentiostatic deposition of Au from solutions of its sulfite complex. The Au(I) sulfite complex is thought to have the composition $[Au(SO_3)_2]^{3-}$ (13, 14). Because sulfite is not toxic and is the basis of a commericial gold plating bath, this complex is becoming increasingly important in Au plating for electronic applications (15, 16). However, the electrochemistry of the gold sulfite complex is much more poorly understood than that of the gold cyanide complex, which has been more widely studied. We have studied Au deposition from unstirred sulfite solutions using cyclic voltammetry and potential step methods, and have determined the effects of pulsed potentiostatic deposition on the deposit properties.

Experimental

All solutions used in this investigation were 0.15M in the Au(I) sulfite complex, contained a total Na_2SO_3 concentration of 0.5M, and were saturated (a few tenths molar) in $Na_4P_2O_7$. No brightening or leveling agents were added. Solutions were prepared with deionized H_2O, and were deaerated by bubbling N_2 gas. The bubbler was raised above solution level during the measurements. (The presence of the reducing SO_3^{2-} eliminates O_2 from the solution. However, O_2 was excluded to maintain a constant SO_3^{2-} concentration.)

A three-electrode system under potentiostatic control was used. The cell, shown in Fig. 1, was designed to give a highly uniform primary current distribution at the surface of the working electrode in the absence

Key words: pulsed plating, gold sulfite baths, gold deposition, plating through a mask.

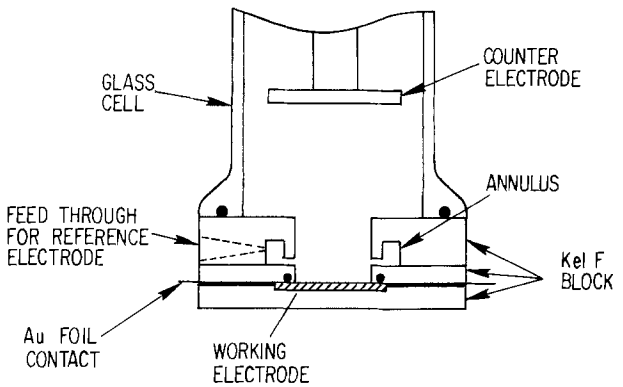

Fig. 1. Cell design

of convection. This is achieved by mounting the working electrode at the bottom of a cylindrical opening in a Kel F block, and placing the reference electrode, in a manner similar to that used by Cahan *et al.* (17), in an annulus in this block which is connected to the solution by a 0.10 in. slit just above the electrode surface. This gives a potential reference which does not block the lines of current flow. Potential control was maintained by a Tacussel-type PIT 20-2X potentiostat used in conjunction with a PAR Model 175 waveform generator.

The working electrode was an evaporated Au film on a 1¼ in. wafer of Corning 0211 glass. The thickness of the Au was 200Å for all samples studied by x-ray diffraction, and 2000Å otherwise. A 200Å film of evaporated Nb was deposited on the glass under the evaporated Au to improve adhesion. According to Adzic *et al.* (18), Nb interferes less with electrochemical measurements than other commonly used adhesion layers.

The reference electrode was Hg-Hg_2SO_4. All potentials here are quoted with reference to the normal hydrogen electrode NHE. In the potential step measurements, the short-time current response was stored in a multipurpose signal averager, Type AA1, manufactured by Hi-Tek Instruments (England), then plotted on a X-Y recorder. The thicknesses of the sheet Au deposits were determined by masking a narrow line with photoresist, etching using a KI, I_2 etch, and determining the depth of the line with a Clevite Surfanalyzer 1200 profilometer. Impurity levels in the deposits were obtained from electron microprobe measurements. Resistivities were determined using a four-point probe. In addition to the sheet films, some deposits were made through masks of Shipley AZ 1350J photoresist. The thickness of these deposits was also measured with a surface profilometer.

Results and Discussion

Kinetic measurements.—Cyclic voltammograms of a Au electrode in the Au(I) sulfite solution at three different *p*H values are shown in Fig. 2. The potential range of Fig. 2 is that in which Au deposition is expected to be the only significant electrode reaction. Comparison of cyclic voltammetry curves obtained in solutions containing no pyrophosphate with those of Fig. 2 showed that the pyrophosphate ion does not contribute to any of the electrode processes in this potential range. The current begins to rise rapidly at ~ -0.4 and peaks at ~ -0.8V. At the two extremes of the *p*H range studied, this -0.8V peak is the dominant feature of the cyclic voltammetry, although a small shoulder at more cathodic potentials is apparent, particularly in the measurement at *p*H 12.5. A second peak occurs at ~ -1.0V in the *p*H range from 9.5 to 11.5 in unstirred solutions.

The dependence on sweep speed of the two peaks observed at *p*H 10.5 is shown in Fig. 3. As the sweep speed is reduced, little change in the more anodic peak is observed. The more cathodic peak is highly dependent on sweep speed. The size of the peak decreases as the sweep speed is reduced, becoming a current plateau without evidence of a peak at 10 mV/sec. In the anodic-going portion of the scan, two plateaus are observed which correspond to the two peaks in the cathodic scan.

The current-potential profile for the measurement at *p*H 12.5 can be changed by altering the conditions of

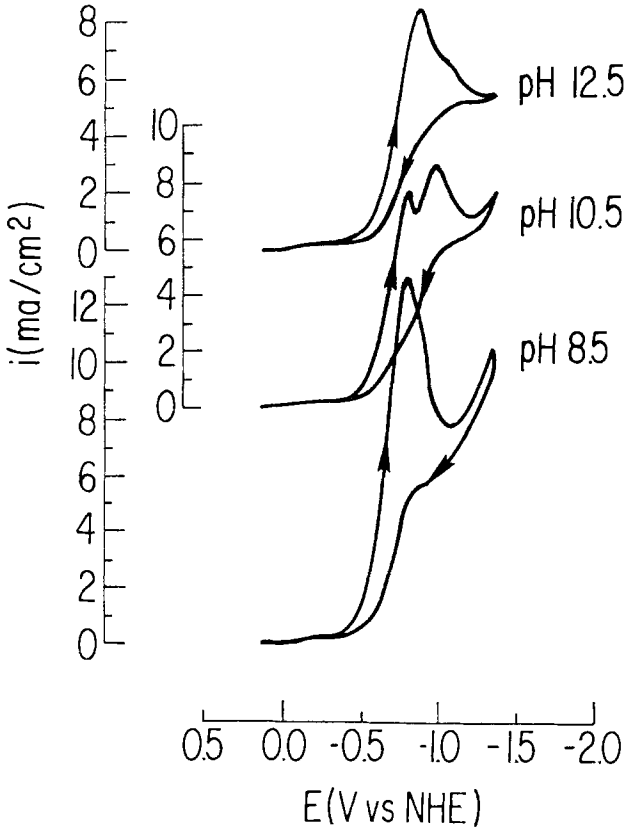

Fig. 2. *p*H dependence of the cyclic voltammetry of an Au electrode in a ~0.15M Au(I) sulfite solution containing 0.5M Na_2SO_3, and saturated with $Na_4P_2O_7$. Sweep speed 50 mV/sec.

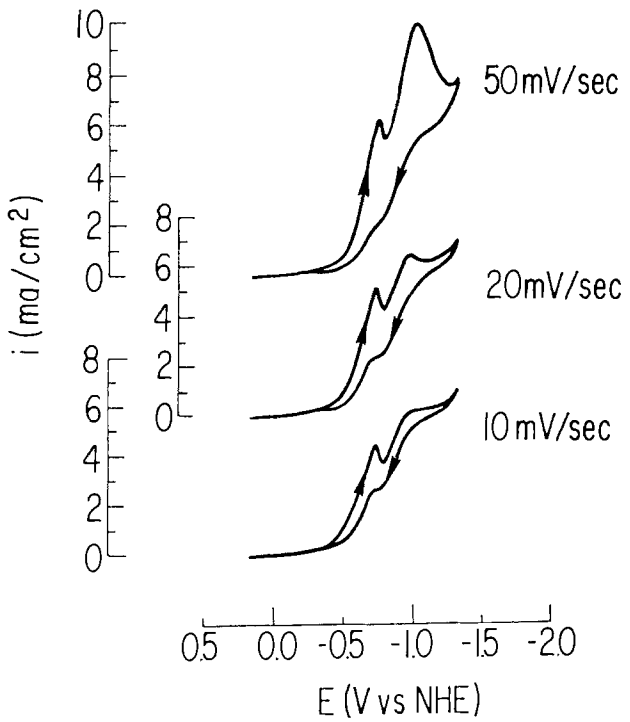

Fig. 3. Dependence on sweep speed of the cyclic voltammetry of an Au electrode in a solution with the same composition as that for Fig. 2, *p*H 10.5.

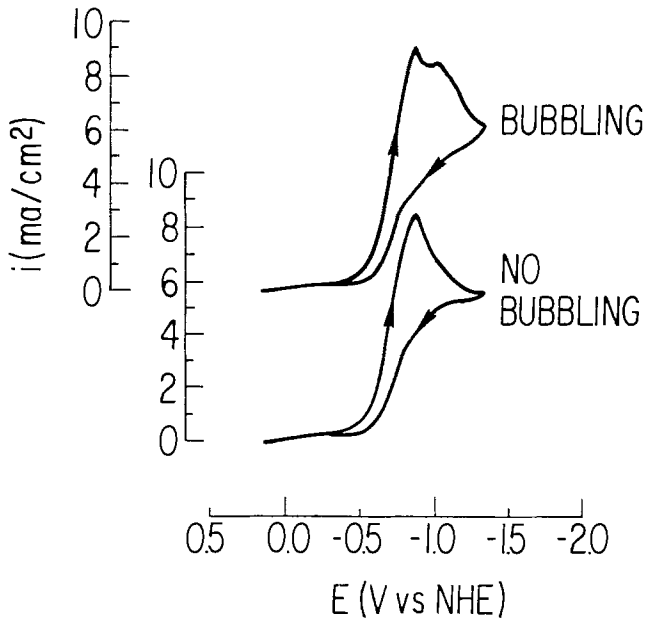

Fig. 4. Dependence on mass transport of the cyclic voltammetry of an Au electrode in a solution with the same composition as that for Fig. 2, pH 12.5. Sweep speed 50 mV/sec.

mass transport, as illustrated in Fig. 4. The lower curve was obtained in the same manner as the pH 12.5 curve in Fig. 2. The upper curve shows the current potential behavior when the N_2 bubbler remained in the solution during the measurement, thereby increasing the mass transport. In this case, the peak appearing at more negative potentials is much more distinct. This second peak is increased in size by increased mass transport at all pH values studied except pH 8.5, where it is not clearly observed.

An experiment was carried out in which the electrode potential was swept at 50 mV/sec from 0.2V to the potential of the peak, and then held at the peak potential. When the potential is swept only to the first peak (that at less negative potentials) and held there, the current decays in a uniform fashion. The current decay is much more complex when the potential is swept to the second peak and held. After an initial decay, a small increase in current is observed, followed by further slow decay.

The existence of two peaks in the cyclic voltammetry indicates that the one-electron reduction of the gold sulfite complex to metallic Au is taking place via two different mechanisms. The kinetics and mechanism of this process have been further investigated using the potential step method. The potential of the working electrode was stepped from 0.2V, where no Au deposition occurs, to a potential of active Au deposition, and the time dependence of the current was monitored. The results of a potential step from −0.2 to −0.51V, a potential (Fig. 2) well on the positive side of the first current peak, are shown in Fig. 5. (A change in the time scale occurs at the center of the abscissa in order to allow a wider range of times to be displayed conveniently in the same graph.) At this potential, the current decays in a smooth, monotonic fashion.

These data have been analyzed using the method of Gerischer (19) for study of an electron transfer preceded by a chemical reaction. This method assumes a mechanism in which the complex first loses the ligand X

$$A \underset{+\gamma X}{\overset{-\gamma X}{\rightleftarrows}} B \qquad [1]$$

and then the charge transfer occurs

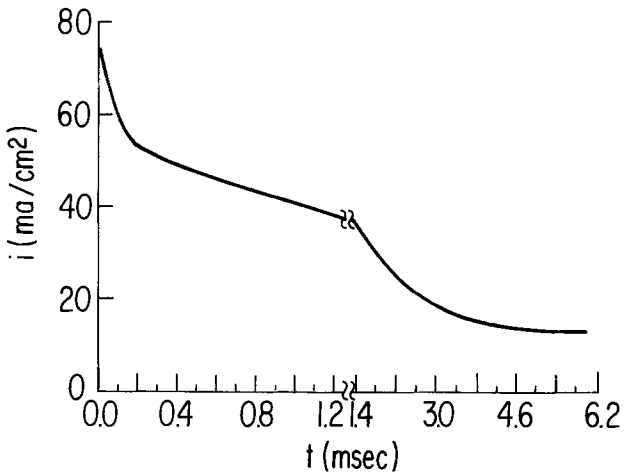

Fig. 5. Time dependence of current decay after a potential step from 0V to −0.51V for a Au electrode in a solution with the same composition as that for Fig. 2, pH 10.5.

$$B \underset{-ne^-}{\overset{+ne^-}{\rightleftarrows}} C \qquad [2]$$

For this over-all reaction [1]-[2], Gerischer (19) determined that

$$i = -2i_A(t/\pi\tau)^{1/2} \text{ when } t << \tau \qquad [3a]$$

$$i = i_A(\tau/\pi t)^{1/2} \text{ when } t >> \tau \qquad [3b]$$

where

$$i_A = n\mathbf{F}(C_A^\circ + C_B^\circ)\sqrt{D/\tau}$$

C_A° and C_B° are bulk concentrations, D is the diffusion coefficient (assumed equal for A and B)

$$\tau = k_B/k_A^2$$

and k_A and k_B are, respectively, the forward and reverse rate constants of Eq. [1]. The current in the time region where Eq. [3a] is applicable is determined by reaction rate, while [3b] describes the current under diffusion control. At times that are short compared to τ, i is a linear function of $t^{1/2}$ with a slope s_1 of $-2i_A(\pi\tau)^{-1/2}$; at times that are long compared to τ, i is a linear function of $t^{-1/2}$ with a slope s_2 of $i_A(\tau/\pi)^{1/2}$. From these two values, i_A and τ can be determined.

The analysis outlined here, which uses data at both short and long times in the determination of i_A and τ, differs slightly from that described by Gerischer (19). He describes how to determine these two parameters using data only from regions where $t << \tau$, $t >> \tau$, or t is on the order of τ. Consistency of the measured parameters in the different time regions provides a test of the mechanism. Comparison of values of i_A and τ by this method with those obtained by Gerischer's method in the range $t << \tau$ shows good agreement.

The data of Fig. 5 can be fit by the Gerischer mechanism, as shown in Fig. 6, in which the data of Fig. 5

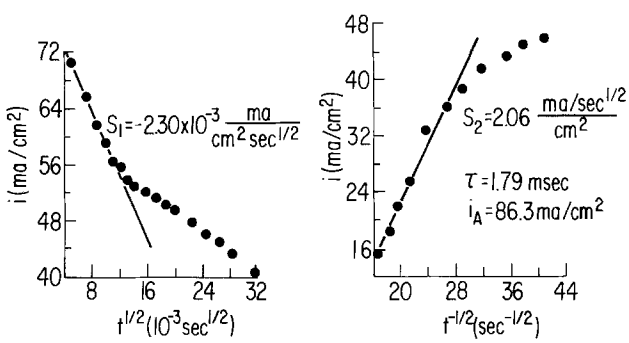

Fig. 6. The data of Fig. 5 plotted as a function of $t^{1/2}$ and $t^{-1/2}$

have been plotted as a function of $t^{1/2}$ and $t^{-1/2}$. From the linear portions of the two curves in Fig. 6, τ and i_A are determined to be 1.8 msec and 86 mA/cm^2, respectively. Since the equilibrium constant K is not known for the gold sulfite complex, k_A and k_B cannot be determined.

It was found at all pH values studied that the Au deposition process could be adequately described by Eq. [1] and [2] as long as the final potential of the step was anodic to ~ -0.8V. For larger potential steps, the current no longer decays in a monotonic fashion, and plots of i *vs.* $t^{1/2}$ and $t^{-1/2}$ do not have linear portions. These results are consistent with the results of the cyclic voltammetry shown in Fig. 2. The first current peak occurs at ~ -0.8V, and the mechanism of Au deposition becomes more complicated at potentials more negative than this.

Below the potential of the first current peak, both i_A and τ were found to increase with increasing potential of the pulse. The scatter in the data was found to be of the same order of magnitude as the variation of these parameters with pH. The results of the measurements are shown in Table I.

On the basis of the cyclic voltammetry and the potential step results, we propose that, at potentials less negative than ~ -0.8V, the deposition of Au from its sulfite complex can be described by the two-step mechanism consisting of the dissociation of the complex followed by electron transfer. This is postulated to be the following.

$$[Au(SO_3)_2]^{3-} \rightleftarrows Au^+_{ads} + 2SO_3^{2-} \quad [4]$$

$$Au^+_{ads} + e^- \rightarrow Au \quad [5]$$

At more negative potentials, a second mechanism is possible. This is thought to be a direct electron transfer to the undissociated $[Au(SO_3)_2]^{3-}$ complex. This mechanism apparently does not involve a strongly adsorbed intermediate and has a stronger dependence on mass transport than the mechanism of Eq. [4] and [5]. Increasing the rate of mass transport therefore increases the size of the second peak relative to the first peak.

The observed pH dependence is complex. The proposed direct electron transfer to the sulfite complex is unfavorable at pH 8.5. It occurs at all higher pH values but is most rapid at pH 10.5, and is again less favorable at high pH. This behavior cannot be readily interpreted in terms of the dissociation constants of the species believed to exist in solution. The $[Au(SO_3)_2]^{3-}$ complex becomes unstable at pH values lower than 8. The decreased stability of the complex at low pH may make the mechanism involving the dissociation of the complex more favorable than the direct electron transfer to the complex.

Effects of pulsed potentiostatic deposition on deposit properties.—In order to examine the effects of pulsed potentiostatic deposition on the properties of Au films deposited from the sulfite solution, a series of Au films of approximately 1 μm thickness was deposited on a substrate which had a 200Å thickness of evaporated Au on an adhesion layer of 200Å evaporated Nb. Frequencies from constant potential to 1 kHz were used with solutions of pH 8.5 and 13. The potential was pulsed from -0.19V, a potential at which no deposition occurs, to a potential E_2, at which deposition takes place. The duration of the pulse to the potential E_2 was chosen to be 10% of the total cycle in order to allow the diffusion layer to relax back as close as practical to the bulk concentration.

Table I. Kinetic parameters τ and i_A obtained from potential step measurements

pH	Final potential (V *vs.* NHE)	i_A (mA/cm^2)	τ (msec)
8.5	0.31	56	2.6
8.5	0.51	73	2.9
8.5	0.71	85	2.7
10.5	0.31	47	1.1

Gold is deposited at a constant potential of -0.56V from the additive-free gold sulfite solution at $\sim$1500 Å/min in the form of a large-grained deposit of a dull, brownish color. The potential of -0.56V was chosen because deposition at this potential from the additive-free gold sulfite solution occurs at a steady-state current of the order recommended for galvanostatic plating from commercial sulfite baths[1] (1-3 mA/cm^2). When deposition takes place under pulsed potentiostatic conditions, the appearance of the films changes somewhat with frequency and potential E_2. However, none of the conditions investigated results in bright deposits.

The over-all rate of deposition shown in Table II, falls off rapidly with increasing frequency, since at higher frequencies a larger fraction of the time at E_2 is necessary for double layer charging. (The rates given in Table II are over-all rates. Since the actual time of deposition in the pulsed mode is 10% of the total time, the instantaneous rate is about 10 times greater. This means the instantaneous deposition rates at constant potential and 5 Hz are approximately the same.) Within limits, the rate can be increased by making E_2 more cathodic, but the drop-off in rate is so rapid that for frequencies greater than 100 Hz, even for pulses to -1.81V, several hours are necessary to obtain 1 μm films. The disparity in rates also makes it difficult to compare directly films obtained at low and high frequencies, since at E_2 values which are sufficiently low to avoid gassing at low frequencies, deposition rates at high frequencies are negligible. Under any given set of conditions, the rate of Au deposition from the pH 13 solution is substantially higher than that from the pH 8.5 solution.

Table II also shows the resistivities of these films. These values were obtained from a four-point probe determination of resistance and a profilometer thickness measurement of a step etched in the film. The resistivities of these films (uncorrected for thin film effects) are low, in most cases approaching that of bulk Au (2.44 $\mu\Omega$ cm at 20°C). The resistivity appears to have no clear dependence on frequency of deposition or pH.

The main factor contributing to the low resistivities of these films is believed to be their high purity. Electron microprobe analysis showed that S, P, and Cl, the most likely contaminants, were below the limits of detection of the method (i.e., <200 ppm by weight for S and P, and <300 ppm by weight for Cl).

Information about the surface topology of these deposits has been obtained using scanning electron mi-

[1] Sel-Rex BDT 510 Au bath. Sel-Rex Corporation, Nutley, New Jersey.

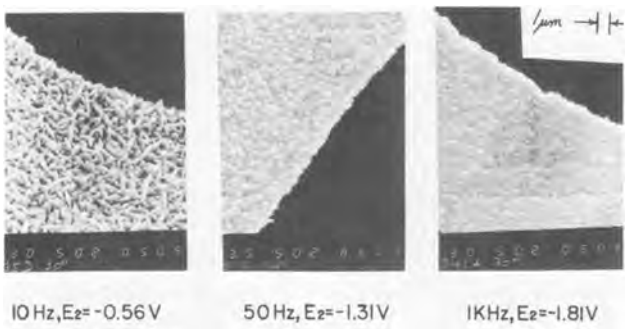

Fig. 7. SEM's of Au deposits from the sulfite solution at pH 8.5 at three different frequencies.

croscopy. Figure 7 shows SEM's of Au films deposited at three frequencies from the pH 8.5 solution. The surface morphology is found to vary with the conditions of deposition. At low frequencies the Au is deposited in the form of crystallites with clearly developed shapes and faces. As the frequency of deposition increases, the crystallites become smaller and partly rounded. Similar trends were observed for deposits from the pH 13 solution, which have somewhat larger surface features than deposits from the pH 8.5 solution.

These deposits have also been examined using x-ray diffraction methods. The defect structure of the pulsed potentiostatically deposited Au films has been investigated using a single peak variation of the multiple order Warren-Averbach analysis. The Warren-Averbach analysis is described by Warren (20); the single peak thin film variation is described by Gangulee (21). Such analyses give information about texture, macro- and microstresses, average grain size, the probability of stacking faults and twinning, and dislocation density in the Au films. These data are summarized in Table III. The values tabulated are σ_{xx}, the macrostress; D^{hkl}, the average grain size in the [hkl] direction; $\langle E_{50}^2 \rangle^{1/2}$, the root mean square microstrain averaged over a 50Å region; and N_d, the dislocation density. The negative sign of σ_{xx} indicates tensile stress. Other values which were measured but not tabulated are the probabilities of intrinsic and extrinsic stacking faults, which were approximately zero in all cases, and the probability of twinning, which was in the range 0.003-0.005.

Of the properties summarized in Table III, only the texture of the deposit shows a marked dependence on the conditions of deposition. Comparison of Tables II and III shows that the primary texture can differ from (111) when the deposition rate is high. At high rates of deposition the preferred texture becomes (110). Although Table III indicates that the primary texture of the constant potential sample varies with pH, the pole figures for these two films are similar; the film deposited from the pH 13 solution has only slightly more (100) texture.

Both the macrostresses and microstrains of these deposits are small and show no clear dependence on frequency. The macrostresses are slightly larger in the deposits from the higher pH solution. The grain size is large and not significantly decreased by the use of higher frequencies. The grain size measured by x-ray diffraction is not the same as the crystallite size which is seen in the SEM photographs of Fig. 7. The SEM indicates surface morphology, and may not reveal individual grains without etching. The quantity measured by x-ray diffraction is the grain size perpendicular to the surface.

The observed result that the use of pulsed potentiostatic deposition does not cause distinct changes in the properties of Au deposited from sulfite solutions is apparently due to the irreversibility of the Au/Au(I) couple in sulfite solution. A Au electrode immersed in the gold sulfite solution does not establish a stable reversible potential. The results in the nonreversible sulfite solution can be contrasted with the studies of the pulsed galvanostatic deposition of Au from a cyanide citrate bath by Reed and Safranek (11). The effectiveness of pulsed methods in improving the properties of Au deposited from its cyanide complex can be explained by the greater reversibility of the electron transfer in this system.

Pulsed potentiostatic deposition through a mask.— Gold was deposited pulsed potentiostatically from the pH 8.5 gold sulfite solution through a photoresist test mask. The test mask consisted of an area of lines 50 μm wide at variable spacings, a similar area consisting of 25 μm wide lines, an area of 50 μm squares at variable spacings, and a similar area of 25 μm squares. The closest spacing was 6.25 μm; the largest was about ten times the line width. A second test mask consisted of a 10 times reduction of this pattern; in the smaller pattern, the narrowest spacing, 0.625 μm, was not resolved during exposure of the photoresist. Gold was deposited through these masks at several frequencies, with the pulse to E_2 being 10% of the cycle.

Figure 8 shows the profile of Au deposited by a 100 Hz pulse to −1.81V through the portion of the mask consisting of nominally 50 μm lines. Under these conditions, the deposit was found to be substantially thicker at the edge of the line than in the center. This effect became more pronounced as the spacing between lines increased. The lines also became thicker with larger spacing, Both of these effects are explained by the crowding of lines of current flow at the edges of lines as spacing between them is increased. The thickness of the Au deposit in the squares on the same wafer was found to be 2-4 times that in the lines of the same width, a result which can also be explained by crowding of the lines of current flow at the edges, since the squares have a greater edge/area ratio than the lines.

When a 500 Hz pulse to −1.81V is used, the uniformity of the deposit in the same pattern is greatly improved, as shown in Fig. 9. Under these conditions, there is less variation in deposit thickness across a given line. A nonuniformity in line thickness with spacing still exists, but it is quite different than that observed at the lower frequency.

Table III. Summary of x-ray diffraction data for Au films deposited pulsed potentiostatically

f (Hz)	E (V vs. NHE)	pH	Primary texture	σ_{xx} (10^8 d/cm²)	D_{eff}^{200} (Å)	D_{eff}^{111} (Å)	D_{true}^{111} (Å)	$\langle E_{50}^2 \rangle^{1/2}$ (10^4)	N_d (10^{10} cm/cm³)
Constant E	−0.56	8.5	111	−6	—	650	820	6	1.1
Constant E	−0.56	13.0	100	−13	540	690	880	7	1.2
1	−0.56	8.5	111	−3	—	690	970	6	0.9
5	−0.56	8.5	111	−4	—	690	880	8	1.3
5	−0.56	13.0	111	−3	—	750	980	7	1.0
10	−0.56	8.5	111	−2	—	720	920	6	1.0
10	−1.31	8.5	110	−13	—	510	600	8	2.0
50	−1.31	8.5	110	~0	480	720	1160	6	0.8
50	−1.31	13.0	110	−24	—	570	750	4	0.8
100	−1.31	8.5	111	−14	420	550	720	7	1.4
100	−1.81	8.5	111	−9	—	590	780	8	1.5
500	−1.81	8.5	111	−12	—	480	610	9	2.2
500	−1.81	13.0	111	−25	—	440	540	9	2.4
1000	−1.81	8.5	111	~0	340	450	590	9	2.2
				±2	±5%	±5%		±2	

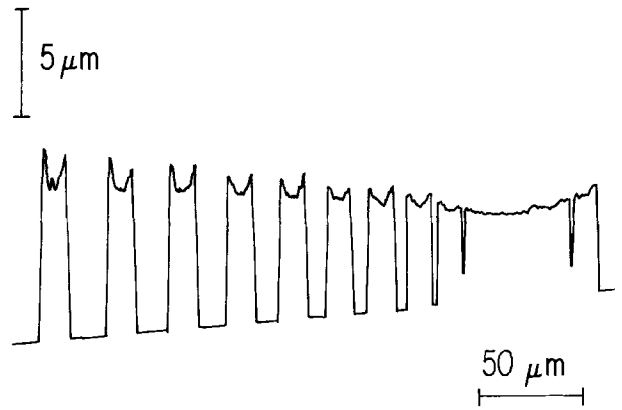

Fig. 8. Profile of Au deposited through a mask consisting of nominally 50 μm lines using a 100 Hz pulse to −1.81V. pH is 8.5.

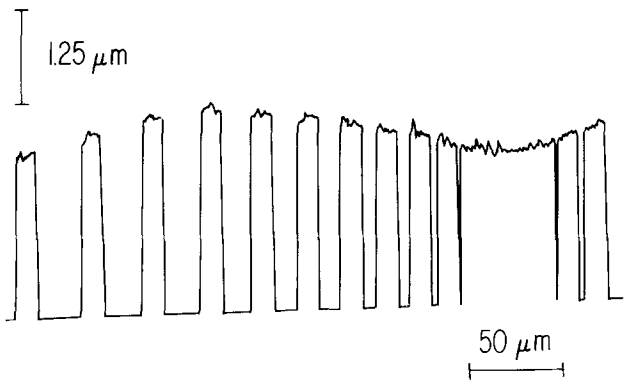

Fig. 9. Profile of Au deposited through a mask consisting of nominally 50 μm lines using a 500 Hz pulse to −1.81V. pH is 8.5.

The result of deposition at 500 Hz through the nominally 5 μm lines is shown in Fig. 10. In this case, uniformity both across the line and across the pattern is good. The total area sampled in Fig. 10 is only about 10% of that sampled in Fig. 8 and 9, and the size of the features is small compared to the distances over which nonuniformities are apparent in Fig. 8 and 9.

Rates of Au deposition through the mask are much greater than the rate of deposition of unpatterned films, due to the inceased edge to area ratio. Representative deposition rates for sheet films and patterns are given in Table IV.

Conclusions

Investigation of Au films deposited from sulfite solutions at pH 8.5-13 showed no apparent dependence of the purity, resistivity, grain size measured by x-ray diffraction, microstrain, or macrostress on the frequency of deposition. This result is consistent with the model of Despic and Popov (2) for pulse potentiostatic deposition in nonreversible systems. Those properties which were influenced by the conditions of deposition were the thickness distribution of Au deposited through a mask, the crystallographic texture, and surface morphology. The Au deposited from solutions of the Au(I) sulfite complex is a soft, low stress film with a large grain size. It has high purity and low resistivity.

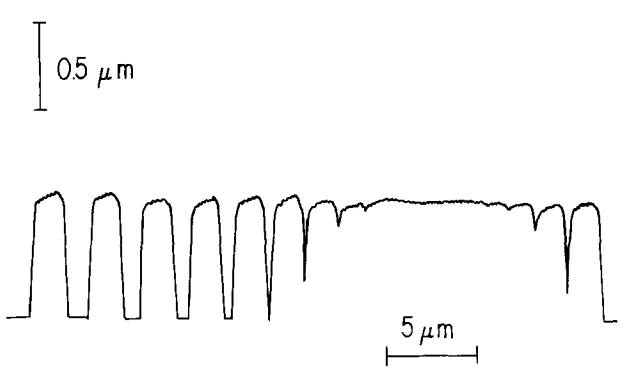

Fig. 10. Profile of Au deposited through a mask consisting of nominally 5 μm lines using a 500 Hz pulse to −1.81V. pH is 8.5.

Table IV. Comparison of deposition rates on sheet substrates and through a mask for the pH 8.5 gold sulfite solution

f (Hz)	E_2 (V vs. NHE)	Deposition rate sheet film (Å/min)	Deposition rate 50 μm lines (Å/min)	Deposition rate 5 μm lines (Å/min)
50	−1.31	625	~2800	~2500
100	−1.81	695	~3100	~1300
500	−1.81	65	~290	~350

The mechanism of deposition of Au from solutions of its sulfite complex at potentials less negative than ~ −0.8V can be interpreted as a dissociation of the complex to form Au(I) adsorbed on the electrode surface, followed by a single electron transfer. At more cathodic potentials, a second reduction mechanism occurs which is thought to be direct electron transfer to the complexed gold ion. This second process is mass transfer controlled, and exhibits a pH dependence. It becomes less favorable at low pH.

Gold deposited through a photoresist mask from solutions of its sulfite complex show large thickness variations both across any given line and from line to line across the pattern. These thickness variations can be influenced by pulsed potentiostatic deposition. Use of high frequencies is effective in eliminating nonuniformity in the thickness of a given line. Line to line variations are more difficult to eliminate.

Electro-Optic Investigations of Thin, Electrodeposited Germanium Layers

W. Paatsch

Bundesanstalt für Materialprüfung, Berlin, Germany

ABSTRACT

50Å to 30 μm thick germanium layers were electrodeposited on copper, silver, and gold substrates using organic nonaqueous electrolytes. X-ray, electrochemical, and electro-optic investigations were carried out to characterize the layers. X-ray studies show that the layers are of amorphous structure. The electrochemical properties of the thick electroplated germanium are not significantly different from the behavior of the crystalline material. From photopotential measurements it is concluded that the layers are of n-type conductivity. Electroreflectance spectra are characteristic for an amorphous semiconductor.

In spite of numerous investigations on the physical properties of germanium only a little work exists about electrodeposited thin germanium layers. Because of the potential distribution at the solid-state/electrolyte interface, using this technique for sample preparation, nucleation and the growth of crystallites takes place far away from equilibrium conditions. Therefore amorphous or at least strong disordered structures will be expected, which are of great interest.

Experimental Details

Germanium films were prepared from organic nonaqueous solutions of 7% $GeCl_4$ in ethylene glycol, $C_3H_6(OH)_2$ (1). The electrolyte temperature during electrodeposition was 59°C, the current density 400 mA cm^{-2}. Because of the codeposition of hydrogen the current efficiency was about 1%, the rate of deposition 20 Å sec^{-1}. The layer thickness was varied from 50Å to 30 μm. As substrates electroplated copper, gold, and silver were used, which were mechanically polished by diamond pastes of various sizes down to 0.25 μm and cleaned in the usual manner.

To characterize the morphology of the layers scanning electron microscope, microanalyzer, and x-ray diffraction experiments were carried out. In addition the electrochemical and optical properties of the layers were studied. The experimental equipment was previously described in detail (2, 3).

Experimental Results

The surface morphology of the copper substrate and a 10 μm thick electroplated germanium layer studied by scanning electron microscopy is shown in Fig. 1. With germanium electroplating, surface roughness and flaws of the substrate are leveled and a very smooth and mirrorlike appearance is obtained.

X-ray diffraction pattern of the germanium layers consisted only of a few broad rings; that means the thin films were amorphous as was also expected from etching experiments (4). Annealing for some hours beyond the amorphous-crystalline transition temperature of 235°C (5) (16 hr at 400°C in a protective gas atmosphere consisting of 95% nitrogen and 5% hydrogen) gives distinct 111-reflections and a lattice parameter which agrees fairly well with the value 3.27Å of crys-

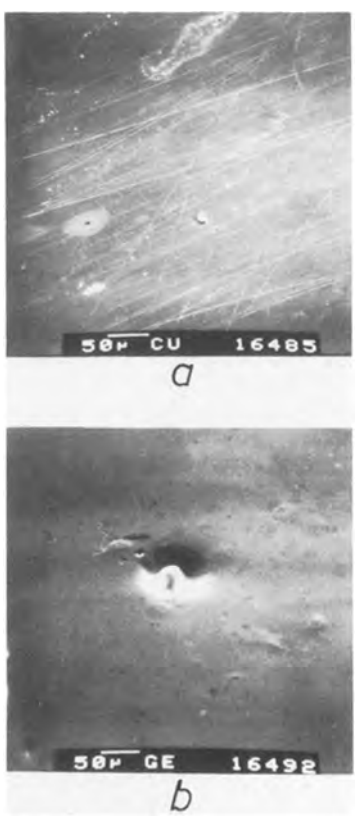

Fig. 1. Scanning electron micrograph of the copper substrate (a) and a 10 μm thick electrodeposited germanium layer (b).

Key words: amorphous semiconductors, semiconductor-electrolyte interface, photovoltage, electroreflectance.

talline material. From the diffraction experiments the crystal size can be estimated as less than 50Å.

Microprobe analysis of unannealed, approximately 500Å thick germanium layers showed that a homogeneous surface coverage of the copper substrate was formed by electroplating. For very thin layers, however, this was not always obtained because of crystal defects of the substrate in connection with an inhomogeneous field strength at the interface.

Further, the electrochemical properties of the germanium layers, as, *e.g.*, hydrogen evolution, in acid solutions were studied. It is well known that the hydrogen overvoltage is very sensitive to the energetic surface state as it was studied for the crystal orientation in the case of germanium single crystal electrodes (6). Figure 2 shows the connection between the hydrogen overvoltage and the layer thickness related to the value of the copper substrate. (Using the current density of $i = 125\ \mu A\ cm^{-2}$ the absolute values related to the potential of the saturated calomel electrode, SCE, for the copper substrate and crystalline compact germanium were −60 mV and −700 mV). The shape of the curve clearly shows that for thickness values greater than 1 μm the electrode behavior is only influenced by the germanium which proves that the layers were compact. With decreasing layer thickness, in agreement with the results of the microprobe experiments, the germanium coverages become porous and below a limiting value of about 40Å the hydrogen overvoltage is given only by the copper substrate.

Further information concerning the electrode behavior can be obtained by the measurements of the differential capacity of the interface. Figure 3 gives the relation between the current density as well as the capacity and the electrode potential for an n-doped germanium single crystal electrode. In the experiment the electrode potential was modulated by a sine wave of 5 kHz frequency and 10 mV peak-to-peak amplitude and the capacity was analyzed using a lock-in amplifier and the conventional equivalent-circuit diagram of the solid-state/electrolyte interface. Studying a semiconductor electrode it is important to remember that the space charge capacity and the Helmholtz capacity of the electrochemical double layer form a series connection. It follows that only the space charge capacity is measured because of being an order of magnitude lower than the double layer capacity. In contrast to the current density which is very low and nearly constant, the capacity changes characteristically in the potential region between the anodic dissolution of germanium and the cathodic hydrogen evolution. Changing the electrode potential in the anodic-cathodic direction near $V_E = -100$ mV a minimum is obtained which appears near $V_E = -400$ mV in the opposite polarization direction. It was shown by Gobrecht and co-workers (7) that these capacity minima belong to

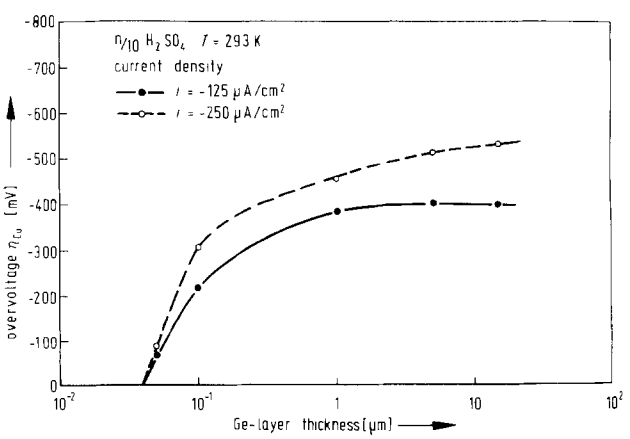

Fig. 2. Relative hydrogen overvoltage as a function of the germanium layer thickness.

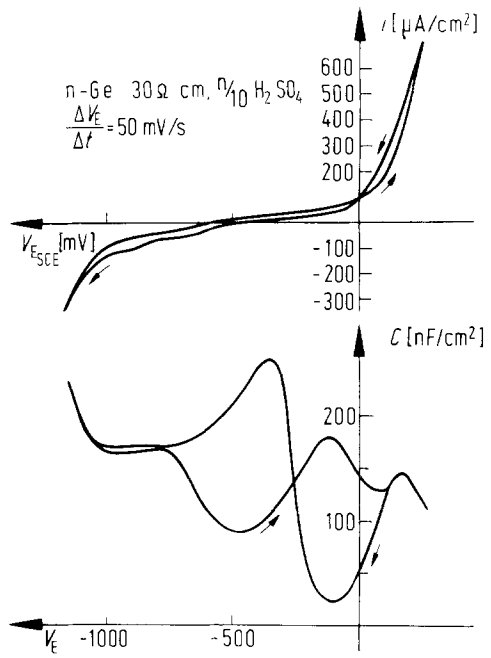

Fig. 3. Current and capacity potential characteristic of a germanium single crystal electrode.

the stable surface coverages Ge-OH and Ge-H. The transition in acid solutions is given by the following equation

$$Ge - OH + 2H^+ + 2e^- \rightleftarrows Ge - H + H_2O$$

As the potential decay in the Helmholtz layer remains constantly in the potential region between the two capacity minima every change of the electrode potential affects the space charge of the semiconductor and therefore the surface field strength. In this region investigation of the electroreflectance are possible and are discussed later.

The behavior of the current density and the capacity of 1 μm thick electrodeposited germanium are shown in Fig. 4. Very little differences are obtained between thick amorphous layers and compact crystalline material: For electroplated germanium the absolute values of the current density are lower and in this connection

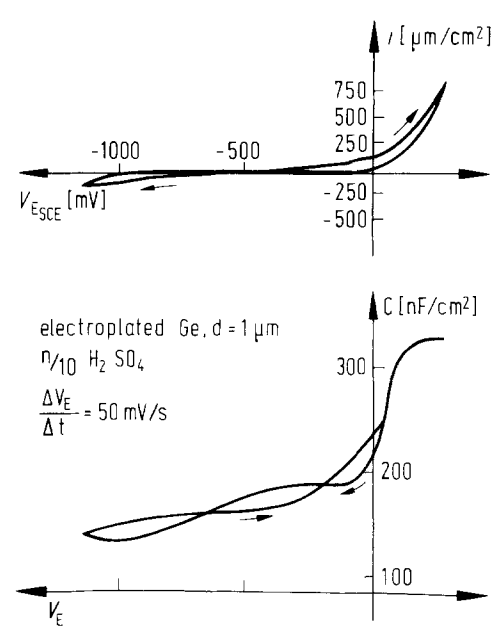

Fig. 4. Current and capacity potential characteristic of a 1 μm thick electrodeposited germanium layer.

the capacity minima are not so distinct. But obviously the same electrochemical processes and a comparable potential distribution at the interface take place. The influence of the layer thickness for values lower than 1 μm is given in Fig. 5. For clarity only the capacity for the first cycle, starting in the anodic potential region, is shown. As can be expected from the results of the hydrogen evolution studies with decreasing thickness of the germanium layer the capacity is affected by the copper-base metal. Especially the order of magnitude of the capacity changes from some nF cm^{-2} in the case of thicker layers to some μF cm^{-2} for thicknesses less than 0.1 μm, which is characteristic for metal electrodes. The capacity minimum and maximum for the copper electrode in the anodic-cathodic direction are caused by the hydrogen adsorption, which is discussed elsewhere (8).

The electro-optical properties of the electroplated germanium layers were studied by photopotential and electroreflectance measurements. In order to avoid electrochemical reactions and to obtain in agreement with the Dewald theory (9) a constant charge density at the surface, the potential region between −800 and 0 mV was studied and the electrode was illuminated with light flashes of 10^{-4}-10^{-3} sec. The photopotential V_{ph} was measured between the galvanostatically polarized germanium electrode and a second, not illuminated and nonpolarized platinum electrode using a signal averaging system (3). Figure 6 shows the dependence of the photopotential on the electrode potential for different germanium layer thickness values. The graph is characteristic for n-doped germanium; the influence of the layer thickness seems not to be very unique. It is however remarkable that the sign of the photopotential changes always at the electrode potential $V_E = -350$ mV and does not depend on the layer thickness. This value is the flatband potential if no fast surface states are present and if a correction for the Dember potential is done. The influence of fast surface states cannot be excluded *a priori* in the experiments with the thin layers on germanium on a copper substrate. Figure 6 shows, however, that the sign reversal of the photovoltage does not depend on the thickness of the germanium layers in the range between 0.6 and 15 μm. This hints at a negligible influence of fast surface states on the flatband potential. Assuming approximately the same mobility for electrons and holes

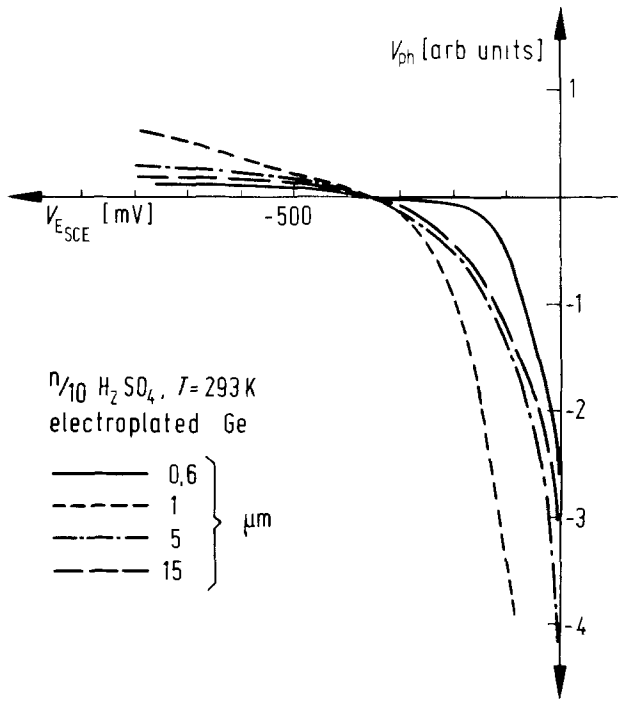

Fig. 6. Photopotential of electrodeposited germanium as a function of the electrode potential.

in the germanium layers it follows that all studied electroplated germanium layers with a thickness greater than 1 μm have the same composition and show n-type conductivity. Comparing the measured flatband potential with values on doped bulk germanium under the same experimental conditions (10) the layers have a specific conductivity of about 10 Ω cm. The reason for the doping effect is not absolutely clear. No influence of the substrate exists: Normally copper diffuses very easily into germanium and forms three valent acceptors, which give p-type conductivity (11). On the other hand, the photopotential behavior shown in Fig. 6 was obtained without any difference using silver and gold substrates, metals with lower diffusion coefficients for germanium. Doping effects are possible, however, by the incorporation of hydrogen or hydrolysis products (12) caused by the hydrogen codeposition during the germanium electrodeposition and the increase of the pH in the surface cathode film.

The electroreflectance spectrum for a germanium single crystal electrode and electrodeposited germanium for the Λ_3-Λ_1 electron transition in the 111-direction of the Brillouin zone is shown in Fig. 7. Analysis for the surface field strength value zero gives transi-

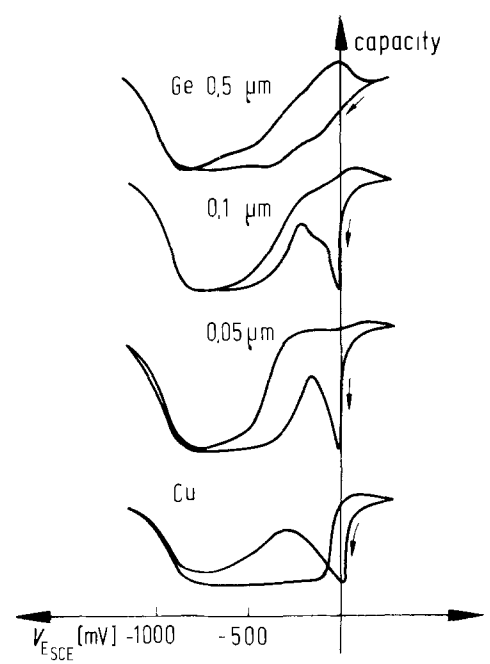

Fig. 5. Relation between the capacity potential characteristic and the thickness of electrodeposited germanium.

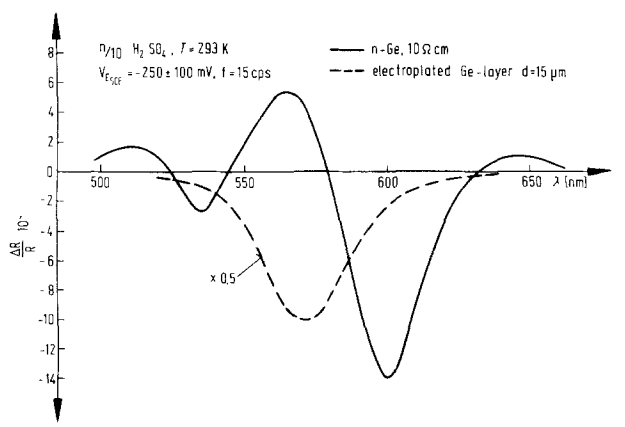

Fig. 7. Electroreflectance spectrum of a single crystal electrode and electrodeposited germanium.

tion energy values of 2.1 and 2.3 eV which belong to the Λ_3-Λ_1 transition and the corresponding split valence band term. In the case of the amorphous electrodeposited germanium layers only a broad, "unstructured" minimum of the modulated reflectance appears at lower wavelength values. This is in agreement with the investigation of the reflectance and electroreflectance of amorphous germanium layers which were prepared by other techniques (13, 14) as well as other amorphous semiconductors (15).

Summary

Germanium layers which were prepared by electrodeposition from organic nonaqueous solutions on copper, silver, and gold substrates are amorphous. Electrochemical experiments show that layers thicker than 1 μm are compact with an electrode behavior not significantly different from that of crystalline electrodes. According to photopotential measurements electroplated germanium has an n-type conductivity which does not depend on the layer thickness. The electroreflectance spectra are characteristic for amorphous semiconductors.

Kinetics of the Deposition of Alumina Particles from Copper Sulfate Plating Baths

J. P. Celis and J. R. Roos

Departement Metaalkunde, Katholieke Universiteit Leuven, de Croylaan 2, B-3030 Heverlee, Belgium

ABSTRACT

In 1972 Guglielmi proposed a physical model describing the codeposition mechanism of inert particles from electrolytic baths. The proposed mechanism was based on two successive adsorption steps. The present authors demonstrated the validity of that mechanism for the codeposition of alumina and copper from acidified copper sulfate plating baths. From an experimentally derived relationship between electrolytic conditions and codeposition, the importance of the reduction of copper ions adsorbed onto Al_2O_3 is shown. The influence of monovalent cations like thallium is discussed based on the mechanism proposed by Guglielmi.

In recent years the interest in electrodeposited composite coatings rapidly increased. This was mainly due to their expected new engineering applications. Such coatings are produced by codeposition of fine inert particles and a metal matrix from electrolytic baths. Industrial applications of composite coatings with a nickel (1) or a cobalt (2) matrix have already been developed. The codeposition of inert particles and copper seemed, however, to be more difficult to realize. Sautter (3) stated that the codeposition of alumina or silicon carbide and copper from acidified copper sulfate baths was not possible. According to Williams and Martin (4) the codeposition of alumina, silicon carbide, or boron carbide and copper from a copper cyanide plating bath could readily be obtained. Chen (5) pointed out the influence of the structure of the inert particles on the codeposition. α-alumina with a hexagonal structure could be codeposited from an acidified copper sulfate bath; while γ-alumina with a spinel-type cubic structure could not be codeposited from an analogous plating bath. Tomaszewski (6) claimed that the addition of monovalent cations to the copper sulfate plating baths promoted the codeposition.

The mechansism of electrocodeposition of inert particles and metals is far from being well understood. Three mechanisms, namely, mechanical inclusion, electrophoresis, and adsorption of inert particles onto the cathode, are generally proposed in order to explain the observed codeposition. The relative importance of these three processes cannot be deduced from published experimental work. Some of those results are even contradictory. Guglielmi (7) is the only one who proposed a mathematical model for the electrocodep-

Key words: dispersion coatings, electrodeposition mechanism, copper electrolysis.

osition of inert particles. His model is based on two successive adsorption steps. In the first step the inert particles are loosely adsorbed on the cathode and they are in equilibrium with the particles in suspension. The particles are still surrounded by aosorbed ions and solvent molecules. In the second step this screen is broken through so that a strong electrochemical adsorption of the particles on the cathode takes place. The inert particles are now permanently bound to the cathode and are consequently embedded in the deposit. For this model Guglielmi derived the following equation

$$\frac{C}{\alpha} = \frac{Wi_o}{n\mathbf{F}dv_o} \cdot e^{(A-B)\eta} \cdot \left(\frac{1}{k} + C\right) \qquad [1]$$

where C is the concentration of suspended particles, α the volume fraction of particles in the deposit, W the atomic weight of the electrodeposited metal, d the density of the same, n the valence, and $\mathbf{F}$ the Faraday constant. The parameters i_o and A are related to the metal deposition and are the constants in the Tafel equation which gives a relation between the current density (i) and the overpotential (η)

$$i = i_o \cdot e^{A\eta} \qquad [2]$$

The parameters v_o and B play a symmetrical role with the parameters i_o and A but are related to the inert particle deposition. k is derived from the Langmuir adsorption isotherm and depends essentially on the intensity of the interaction between particles and cathode. Guglielmi verified the validity of his model for the codeposition of titania and silicon carbide with nickel from a nickel sulfamate bath. The present authors investigated the validity of Guglielmi's model for the codeposition of α-alumina and copper from copper sulfate plating baths. Based on experimental evidence the codeposition mechanism is further explained.

Experimental

A plate pumping process was used as the plating cell with a stainless steel cathode and a copper anode. The plating solution was an acidified copper sulfate bath and had the following composition: $CuSO_4 \cdot 5H_2O$ 118 g/liter, H_2SO_4 120 g/liter, pH 0.3. The tests were conducted at room temperature. The following products were added to this plating solution: (i) α-Al_2O_3, mean size 0.3 μm, density 3.98 g/cm^3 (Linde A, Buehler Limited); (ii) thallium (I) sulfate, "highest purity" grade (U.C.B.). All deposits were obtained at constant current density. The quantitative determination of alumina embedded in the copper matrix was performed by chemical analysis (8).

Results

Thalliumless plating baths.—The codeposition of α-alumina and copper from thalliumless plating baths was studied at different current densities. The volume percentage of embedded alumina is plotted in Fig. 1 *vs.* the volume percentage of alumina in suspension. It can be seen that maximum codeposition is attained at 2 A/dm^2 and that the curves look like a Langmuir isotherm. Such a maximum was also determined by Kariapper and Foster (9) for the codeposition of titania and nickel from nickel sulfamate baths. If the results in Fig. 1 fulfill Eq. [1] a sheaf of straight lines must be obtained when C/α is plotted *vs.* C for different values of η. The slope of those lines is then given by

$$\tan\psi = \frac{Wi_o}{n\mathbf{F}dv_o} \cdot e^{(A-B)\eta} \qquad [3]$$

In Fig. 2 the results of Fig. 1 are plotted according to Eq. [1]. The results at 0.75 A/dm^2 are mean values of three experiments. Some other results do not fit exactly and those could not be weighted since for these electrolysis conditions it was difficult to obtain a smooth adherent deposit. If these points are thrown out a good agreement is found for current densities from 0.5 to 3.5 A/dm^2.

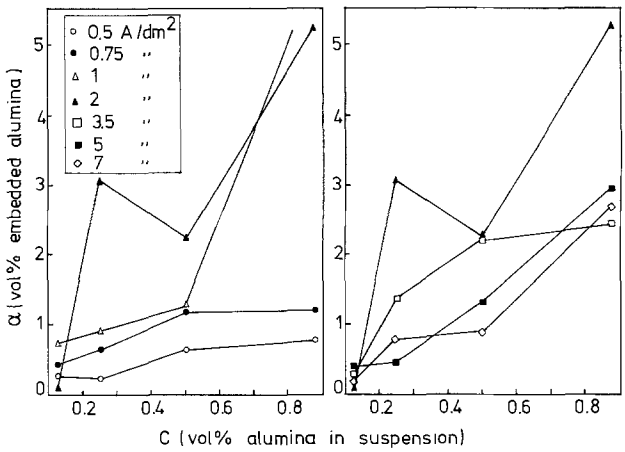

Fig. 1. Codeposition of α-alumina and copper from a copper sulfate bath.

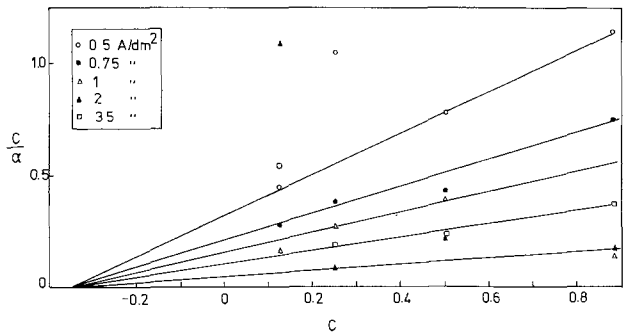

Fig. 2. Codeposition of α-alumina and copper from a copper sulfate bath, according to Eq. [1].

Plating baths containing thallium.—The results of codeposition of α-alumina and copper from copper sulfate baths containing 1 g/liter Tl_2SO_4 are plotted in Fig. 3. In the presence of monovalent thallium ions the volume percentage of embedded alumina is practically independent of the current density for values below 2 A/dm^2. For such plating baths the plots C/α *vs.* C are in accord with Eq. [1] for current density values between 0.5 and 3.5 A/dm^2. At $C/\alpha = 0$ the common intersection of the sheaf of straight lines ($1/k$) is equal to 0.35. The same value is obtained in thalliumless plating baths (Fig. 1). From this it can be seen that the interaction between the particles and the cathode,

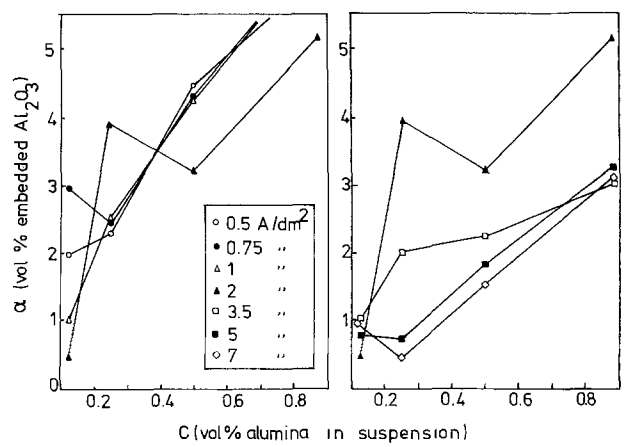

Fig. 3. Codeposition of α-alumina and copper from a copper sulfate bath containing 1 g/l Tl_2SO_4.

represented by the parameter k, seems to be unaltered by the addition of thallium to the plating baths.

Discussion

From Eq. [2] and [3] Guglielmi deduced

$$\log \tan \psi = \log \frac{Wi_0 B/A}{n\mathbf{F}dv_0} + \left(1 - \frac{B}{A}\right) \log i \quad [4]$$

which shows a linear dependence of log tan ψ on log i. The slopes of the straight lines in Fig. 2 and 4 are plotted in a log tan ψ/log i diagram (Fig. 5). For thalliumless copper sulfate baths a straight line with a negative slope is obtained for current densities below 2 A/dm^2. According to Eq. [4] B can be expressed in

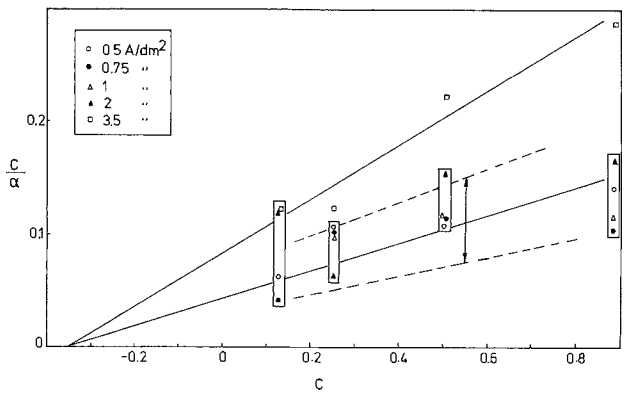

Fig. 4. Codeposition of α-alumina and copper from a copper sulfate bath containing 1 g/liter Tl_2SO_4, according to Eq. [1].

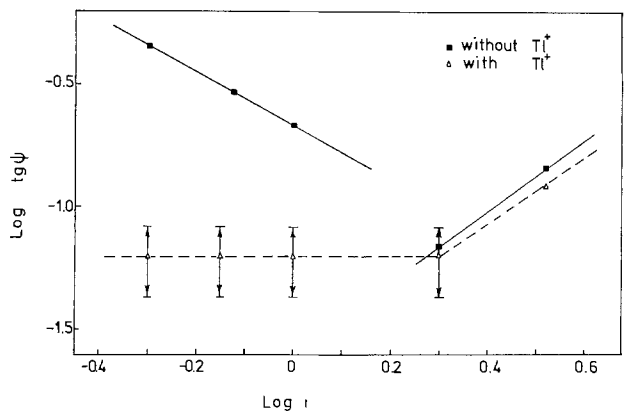

Fig. 5. Codeposition of α-alumina and copper from a copper sulfate bath, according to Eq. [4].

terms of A. For current densities below 2 A/dm^2 B is found to be equal to 1.53A. For current densities above 2 A/dm^2 the slope is positive and B is equal to 0.26A. From this it can be seen that when the current density increases the slope in Fig. 5 must change from negative to positive. This means that at a certain current density the parameter B must be equal to A. From Fig. 5 we see that this case happens at low current densities when monovalent thallium ions are added to the sulfate plating baths. Eq. [1] then reduces to

$$\frac{C}{\alpha} = \frac{Wi_0}{n\mathbf{F}dv_0} \cdot \left(\frac{1}{k} + C\right) \quad [5]$$

This fits well with the conclusions gathered from Fig. 3. The parameters W, i_0, n, $\mathbf{F}$, and d in Eq. [5] are related to the metal deposition, in this case copper, so that α is dependent on the parameters v_0 and k. As the value of k is unaltered by the presence of thallium in the plating bath, the value of α is determined by the value of v_0.

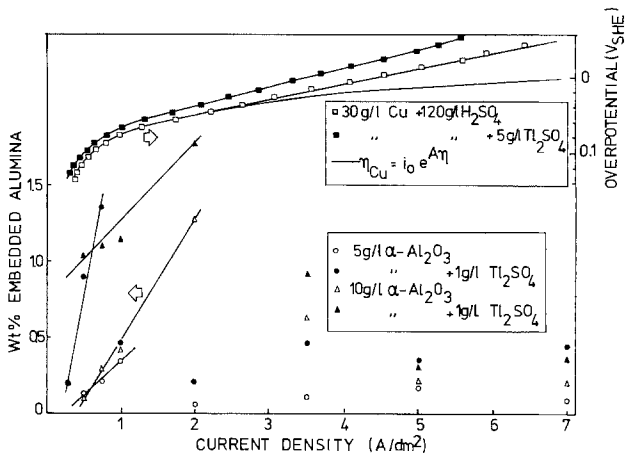

Fig. 6. Weight percentage of embedded alumina and overvoltage vs. current density.

Meaning of the parameter v_0.—The meaning of the dependence of α on v_0 can be deduced from Fig. 6. In this figure the overvoltage and the weight percentage of embedded particles are plotted *vs.* the current density for copper sulfate baths with and without thallium (I) sulfate addition. From the log i-η curves the Tafel constants i_0' and A were calculated and put in Eq. [2] which is also represented in Fig. 6. We note that in area I (below 2 A/dm^2) the experimental polarization curves and the Tafel equation curve fall together. The reduction of the copper ions is then under charge-transfer overvoltage control. In area II the experimental curves and the Tafel equation curve are divergent. Concentration overvoltage then determines the reduction rate of copper ions. In area I we find an increasing weight percentage of embedded particles with increasing current densities. Thus when the current density increases, or, in other words, when the rate of reduction of copper ions increases, the rate of embedding of alumina particles increases more than proportionally. The increase of the current density results from an increasing overvoltage. So we can say that a higher overvoltage produces an increased rate of embedding. We can conclude that in area I: (*i*) the reduction of copper ions is under charge-transfer overvoltage control, and (*ii*) an increasing weight percentage of embedded particles is formed with an increasing overvoltage. From this it seems that the codeposition rate of alumina with copper is determined by the reduction rate of copper ions which are adsorbed onto the alumina particles. Different investigators (9, 10) determined the adsorption of copper ions on alumina in diluted copper sulfate solutions. We determined colorimetrically an adsorption of 0.20 mg Cu^{++} per gram of alumina in an acidified copper sulfate bath with pH 0.3 (11).

From Fig. 6 we can also conclude that in area I the addition of monovalent thallium ions to the baths produces a shift to higher weight percentages of embedded alumina. Thallium ions have a standard potential of −0.338V SHE and are not reduced during electrolysis at the applied overvoltage. Even at 7 A/dm^2 we found, from chemical analyses of coatings, that no thallium was present in the deposits. From conductivity measurements in dilute solutions we also found no thallium ions to be adsorbed onto the alumina particles (11). We established that only small quantities of monovalent thallium ions were needed in order to obtain an increased codeposition of alumina and copper (Table I). The effect of thallium on the weight percentage of embedded alumina can be explained if thallium is considered as a catalyst for the embedding of the alumina particles by increasing the rate of reduction of adsorbed ions on alumina and thus facilitating the second adsorption step.

Table I. Effect of the addition of thallium to a copper sulfate bath on the weight percentage of embedded alumina at 1 A/dm^2 and for 10 g/l alumina in suspension

Tl_2SO_4 (mg/l)	α-Al_2O_3 (weight percent)
0	0.415
1	1.015
	1.147
10	0.949
	1.065
50	1.461
	1.361
100	1.003
	0.945
1000	1.148

We can thus conclude that the parameter v_o is related to the rate of reduction of ions adsorbed on the alumina particles. Through this reduction a permanent contact can be realized between the alumina particles and the cathode.

Conclusions

The physical model proposed by Guglielmi was shown to be valid for the codeposition of α-alumina and copper from a copper sulfate plating bath. The hypothesis of a codeposition mechanism based on a two-step adsorption process agreed well with our experimental results. From our results on the codeposition of alumina and copper from sulfate plating baths with and without addition of monovalent thallium ions we conclude that the second adsorption step is rate determining. In that adsorption step a real contact is realized between alumina particles and the cathode by the breakthrough of the layer of ions adsorbed on the alumina particles. So we found that when the reduction of the copper ions is under charge-transfer overvoltage control a considerable increase of the amount of embedded alumina particles is obtained with increasing current densities. The monovalent thallium ions promote the codeposition. We consider thallium as a catalyst for the codeposition of alumina in copper sulfate baths. Further research on the catalytic action of thallium and other monovalent cations should provide more information on the codeposition mechanism.

The Role of Metal Overlayers on Gallium Phosphide Photoelectrodes

L. A. Harris, M. E. Gerstner, and R. H. Wilson*

General Electric Company, Corporate Research and Development Center, Schenectady, New York 12301

ABSTRACT

A recent publication by Nakato *et al.*, suggested that thin gold overlayers could be made to protect GaP photoelectrodes from corrosion. Repetition of their experiments, including simultaneous measurement of the gold potential, duplicates the volt-ampere characteristics reported in that paper. Gas evolution was not observed, and the gold potential remains too low to decompose water at its surface. An alternative interpretation of the action of the Au overlayer is suggested.

In a recent paper, Nakato *et al.* (1) described two classes of behavior of gallium phosphide photoelectrodes with thin overlayers of metal on their surfaces. Type A behavior was characterized by the oxidation and reduction peaks of the metal (gold) overlayer with the onset of photocurrent more than 1V anodic of the hydrogen potential. Type B behavior exhibited an onset of photocurrent slightly cathodic of the hydrogen potential with the current rising to high well-defined plateaus resembling the volt-ampere curves reported for other semiconductor electrodes like TiO_2 (2). They reported that the type B electrodes could photoelectrolyze water without corroding. These findings appeared significant enough to warrant experimental verification and clarification.

We have been able to duplicate both types of *I-V* curves, but could not reproduce the oxygen evolution and corrosion-free operation that they described for type B electrodes. We can confirm their interpretation regarding type A behavior, but direct measurement of the metal film potential and other experiments lead us to a quite different interpretation of the type B operation, as reported briefly in an earlier communication (3). It is the purpose of the present paper to describe these experiments in greater detail and to present the basis for this alternative view of the role of the overlayer in determining the nature of the *I-V* characteristic.

Experimental

Slices of n-GaP with one side polished had contacts of gallium-silver paste applied on the unpolished face. The wafers were baked in dry N_2 at 400°C for about

* Electrochemical Society Active Member.
Key words: photoelectrochemistry, semiconductor electrodes, photoelectrolysis.

5 min to ensure ohmic contacts. After the contact sides were protected with a coat of lacquer, the polished faces were etched in aqua regia for 1 min, rinsed, and dried. The wafers were then cut into individual samples and recleaned, preparatory to overlayer deposition. Most of the experiments were done with the (100) face of GaP, but some tests with the (111) and $(\bar{1}\bar{1}\bar{1})$ faces gave essentially the same results.

Those samples to be coated with metal had their surfaces covered, except for a window about 3 mm in diam, with an ~ 25 to 100 μm thick layer of insulating photoresist lacquer (Hunt Waycoat Negative Photoresist). The resist was painted on by hand, oven dried, and polymerized by exposure to u.v. light. Metal overlayers were then applied over the entire sample, window, and lacquer.

Metal films were deposited by sputtering about 400Å of gold, or by evaporating various thicknesses (300, 50, or 10Å) of gold, silver, or palladium. The thickness of the evaporated film was calculated from the known weight of metal completely evaporated from a tungsten filament at a known distance from the sample (4).

Prior to testing in the electrochemical cell, the samples were screened for short circuits or nonohmic contacts by measuring the diode characteristics of the GaP-metal junctions. Only those specimens that exhibited the rectification characteristic of a good Schottky barrier were used (5).

The samples were tested in a previously described electrochemical cell (6). The sample was pressed against a silicone rubber gasket surrounding a small (4 mm diam) opening in the side of the cell. A quartz window facing this opening provided for illumination of the portion of the electrode in contact with the electrolyte. To measure the potential of the metal film, a fine platinum wire was placed between the gasket and the portion of the sample protected by the lacquer ring, as shown in Fig. 1. This arrangement worked well with metal films 300Å or more in thickness, but the 50 and 10Å films were not continuous enough to provide the necessary surface conductivity. The measurements of film potential to be presented later were thus made only with the thicker metal overlayers.

Current (I) dependence on half-cell potential (V_1) was measured using a potentiostat (Princeton Applied Research Model 173) controlled by a programmer (PAR Model 175) to sweep at rates of 10 or 20 mV/sec. The potential V_1 of the back contact of the GaP was measured with respect to a saturated calomel reference electrode (SCE). The metal film potential with respect to the SCE was read, point by point, from a battery-operated digital voltmeter (Danameter Model 2000), and recorded as the I-V_1 curve was swept. Curves were taken first in the dark and then with increasing intensities of full-spectrum illumination from a 150W xenon lamp (Oriel Corporation Model 7292). Full light intensity at the sample was about 620 mW cm^{-2} (measured by a Hewlett-Packard HP 8330A Radiant Flux Meter), and was reduced by inserting neutral density filters in the light path.

The electrolyte for all experiments was 0.5F K_2SO_4 adjusted to various pH values either by the addition of buffers or additional H_2SO_4. At pH = 4.3, where most experiments were done, the H^+/H_2 potential was −0.5V (SCE), and it was verified that buffered and unbuffered solutions behaved similarly. The cathode was a large area platinized Pt sheet for all experiments.

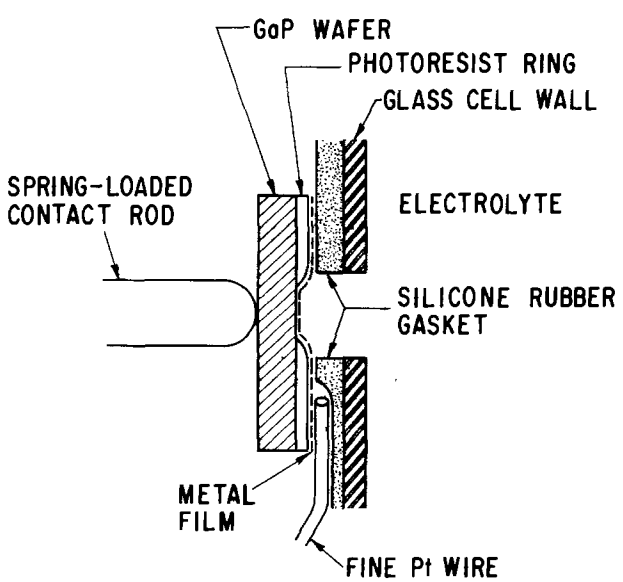

Fig. 1. A cross-sectional view of the sample loaded in the test cell. Thicknesses are exaggerated.

Results and Discussion

Type A.—Only when gold was sputtered on the GaP in a layer about 400Å thick did we reliably obtain type A behavior. No attempts were made to use other metals to obtain this mode of operation. Even when gold was slowly evaporated, type B was more likely to result, but when type A did occur it changed to B after brief operation.

As Nakato *et al.* have suggested, type A operation occurs when the metal overlayer is continuous enough to prevent effective contact of the electrolyte with the semiconductor. Such an impermeable but partially transparent layer on the GaP is equivalent to a gold electrode in series with a Schottky photodiode, which is really external to the electrochemical cell. This view is supported by the I-V_1 curves of Fig. 2 which were obtained from: (a) the gold overlayer on GaP, (b) a composite cell consisting of an illuminated Schottky diode, physically external to the electrochemical cell and consisting of an evaporated gold overlayer on GaP, connected to a metallic gold electrode in the cell, and (c) the plain gold electrode. The circuit for the composite cell (b) is illustrated in Fig. 3. Note that the independent variable, V_1 (SCE), is the potential of the GaP of the dry Schottky diode.

It is apparent from Fig. 2 that the sputtered Au overlayer on GaP when used as a photoelectrode is qualitatively equivalent to the composite cell of Fig. 3. The shift of the reduction peak of curves a and b by 0.3-0.5V in the cathodic direction relative to the peak of

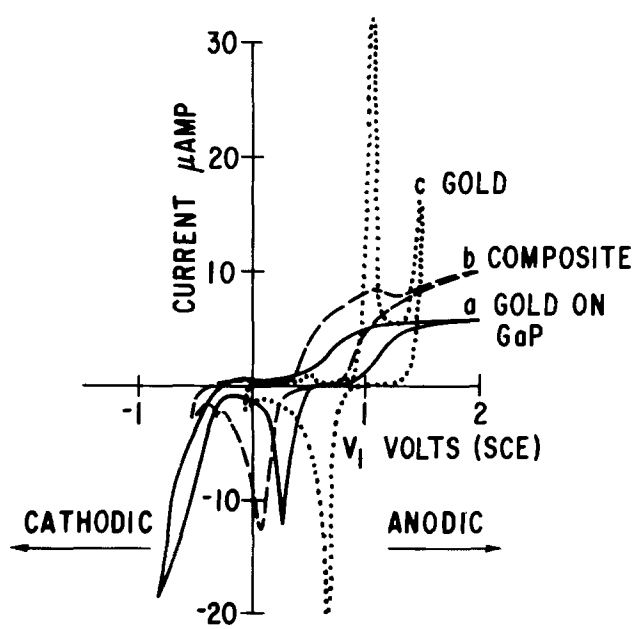

Fig. 2. The current-voltage characteristics showing type A behavior of (a) an n-GaP electrode with Au overlayer, (b) the composite cell shown in Fig. 3, (c) a plain gold electrode, all run in 0.5F K_2SO_4, pH = 4.3.

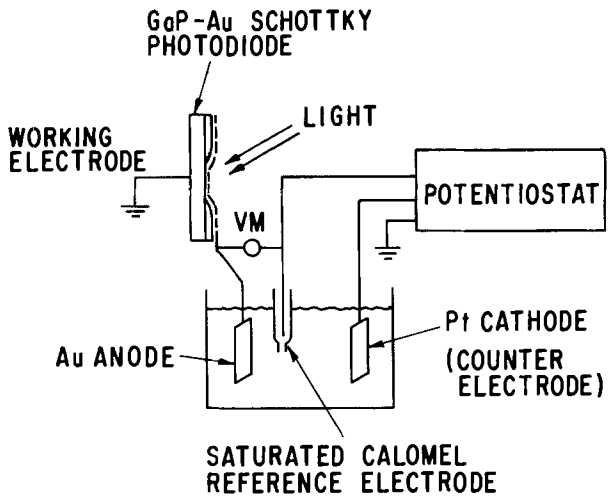

Fig. 3. The circuit diagram for the composite cell

curve c is due to the photovoltage of the Schottky diodes. The sharp peaks in the anodic region are missing from curves 2a and 2b because the GaP in each case limits the current to a value determined by the light intensity.

The measured gold potentials in cases a and b bear out this interpretation. These potentials, shown in Fig. 4, follow the GaP potential, but are displaced cathodically by the same 0.3 to 0.5V observed in Fig. 2. Ultimately the potential of the gold is limited by its own oxidation or by the liberation of O_2, the overpotential for the latter being determined by the current density, which in turn is governed by the intensity of light reaching the GaP. Figure 4 provides further evidence of the equivalence of a type A electrode and the composite arrangement of Fig. 3.

Type B.—Figure 5 shows the type B behavior of a 300Å thick film of silver on GaP, operated at pH = 4.3. Films of palladium and of gold acted similarly. The features of I-V_1 curves characteristic of this mode of operation that lead us to equate it with the type B behavior of Nakato *et al.* are the rather high, flat saturation regions with various levels of illumination, the sharp onset of current, and the open-circuit voltage (where $I = 0$) cathodic of the hydrogen potential for that electrolyte. Even at the highest light intensities we found no clear evidence of gas evolution at the

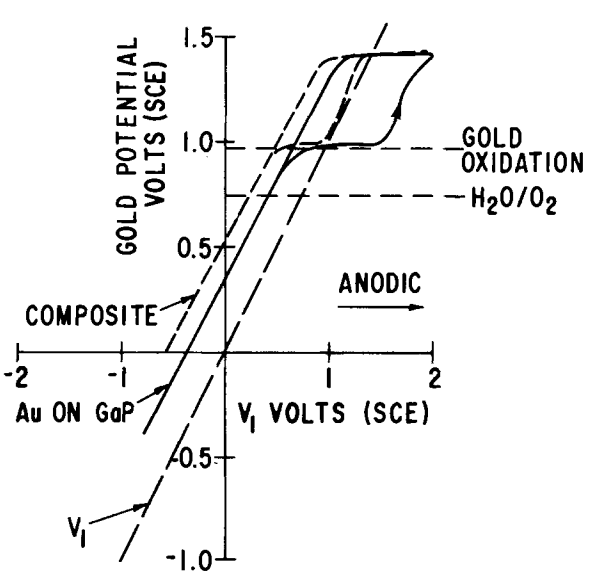

Fig. 4. The Au film potentials (SCE) in type A behavior for the gold overlayer on n-GaP and the composite cell, described as (a) and (b) in Fig. 2.

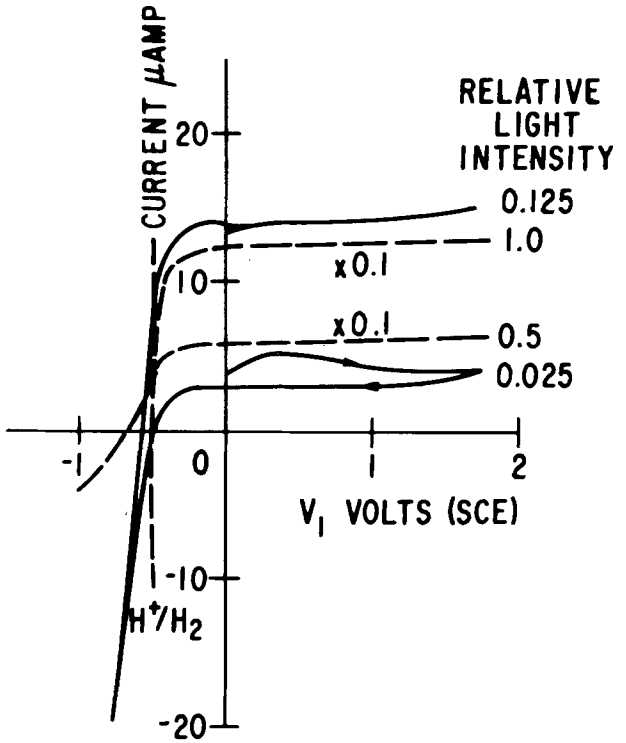

Fig. 5. Type B behavior of a 300Å rapidly evaporated Ag film on n-GaP shown for different light intensities. Full light intensity corresponds to 620 mW cm^2. The electrolyte is 0.5*F* K_2SO_4, adjusted to pH = 4.3.

semiconductor electrode, although we did observe the blister formation reported by Nakato *et al.* (1). Electrodes that had been run with full illumination for an hour or so had badly blistered or peeling overlayers, and showed clear evidence of corrosion in the form of surface roughening of the GaP.

The absence of gas evolution in type B behavior is consistent with the observed potential of the silver overlayer shown in Fig. 6. These potential measurements were made at the same time as the current mea-

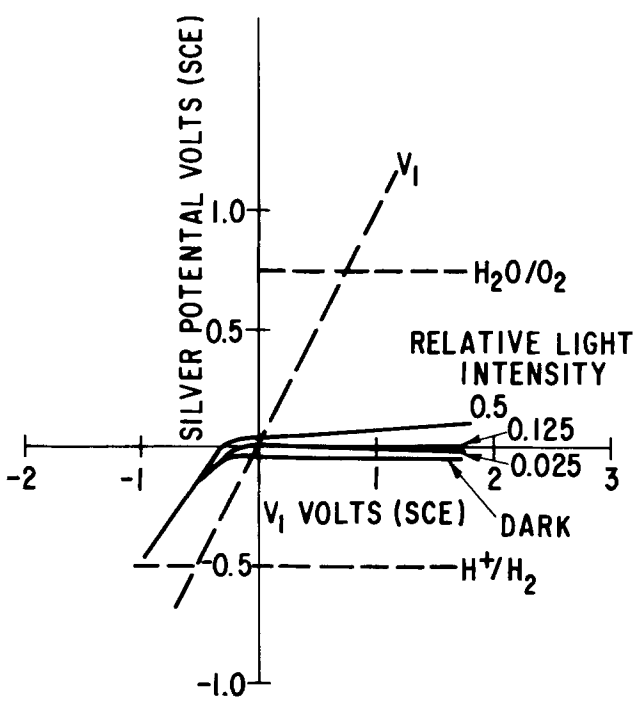

Fig. 6. The potential of the 300Å thick Ag film on n-GaP shown for various light intensities. Potential values were measured simultaneously with the data in Fig. 5.

surements in Fig. 5. The potential of the silver remains well below the oxygen potential throughout the voltage sweep. Measurements on gold and palladium films showed similar behavior. From this evidence we conclude that reactions at the metal films do not contribute to the observed current.

To understand the process responsible for the current, it is instructive to compare the curves of Fig. 5 with those obtained on bare GaP in an electrolyte of the same pH, as shown in Fig. 7. These curves show the same open-circuit voltage, but a much more gradual onset of current and a less clearly defined saturation region. At $V_1 = 0$, upon the first exposure to light, it was typical for bare GaP to produce an appreciable initial current which decayed within a few minutes to a much lower steady value. This process was often repeated each time the light intensity was increased. (The curves of Fig. 7 were recorded after this initial adjustment was completed.) As can be seen by comparing Fig. 5 and 7, the current levels are much lower for bare GaP, even though there is no metal film present to absorb the light. This current decay is similar to that observed when anodizing metals such as aluminum or tantalum, and is strongly suggestive of the formation of a surface layer which blocks the flow of current.

The open-circuit voltage from Fig. 5 coincides with that from Fig. 7 for bare GaP, suggesting that with type B electrodes the electrolyte is effectively in contact with the GaP substrate. This idea is consistent with the model of Nakato *et al.*, postulating penetration of the rapidly evaporated film by the electrolyte (1). It is also consistent with the observed changes from type A to type B with use, or even with prolonged contact with the electrolyte, and the absence of changes from B to A.

The low metal potentials preclude the metal's participation in any significant electrochemical reaction, yet its presence has clearly increased the current markedly and altered its dependence on V_1, the half-cell voltage. In order to define the role of the metal film, some additional experiments were performed. One of these was to measure the I-V_1 characteristic of bare GaP for different light intensities as in Fig. 7, but for different pH values of the electrolyte.

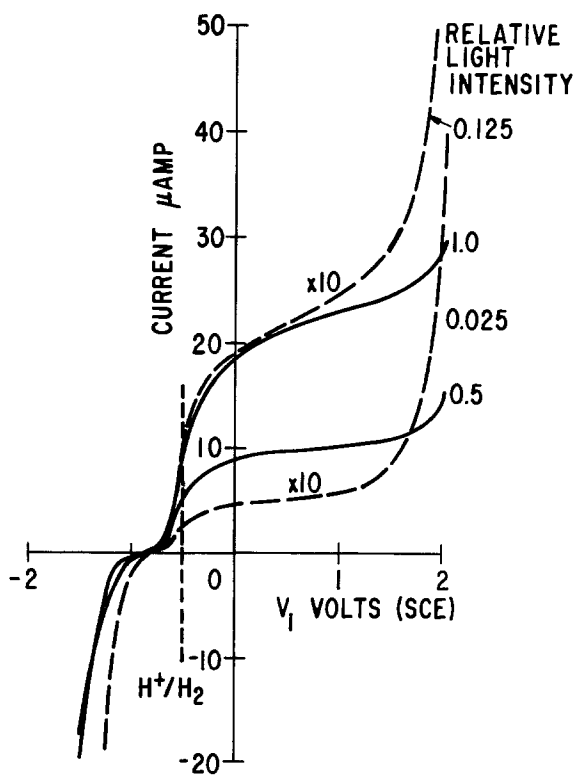

Fig. 7. The current voltage characteristics of bare n-GaP run in 0.5F K_2SO_4, pH = 4.3, for various light intensities.

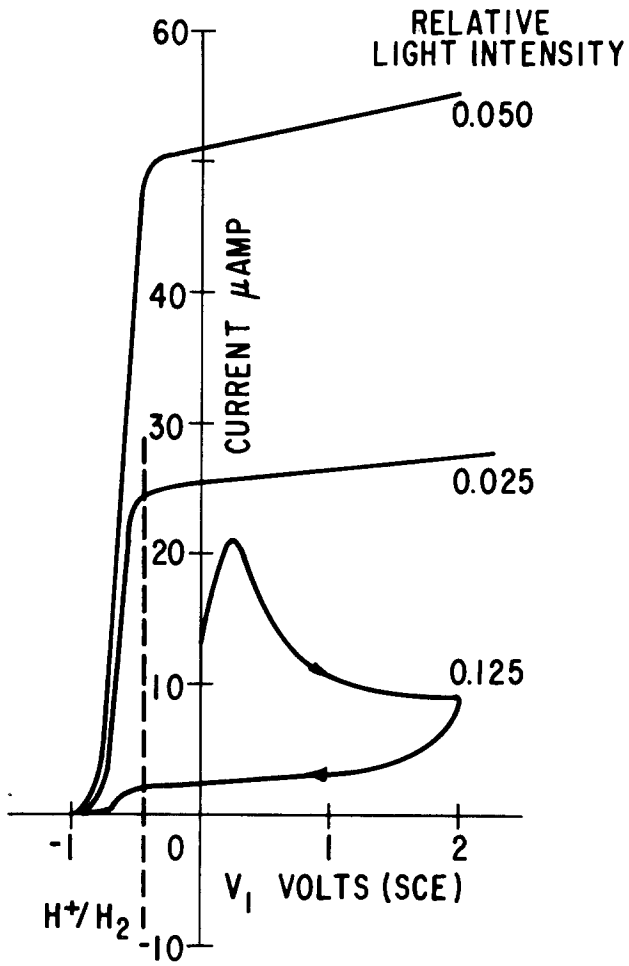

Fig. 8. The current-voltage characteristic for the same test as Fig. 7, but with electrolyte pH = 3.7.

Figure 8 shows that a remarkable change occurs in the nature of the I-V_1 characteristic's dependence on light intensity when the acidity is increased. With low illumination levels, at pH 3.7, the I-V_1 curve has all the characteristics of the type B response shown in Fig. 5 for the semiconductor with metal overlayer. When the light intensity is increased beyond a certain point, the current reverts to a smaller value, and its dependence on voltage is more like that of bare GaP at the higher pH value. Even in this regime, however, the current for a constant light intensity increases with acidity, as Fig. 9 shows.

This behavior is consistent with the notion of a blocking layer, formed on the surface of the GaP by the photostimulated anodic current flow, and removed or dissolved by the electrolyte at a rate depending on the acidity. If the rate of formation of this layer (possibly Ga_2O_3, though its nature is uncertain) is less than the rate of its removal, the surface remains clear and the current high (type B); but if the formation rate exceeds the removal rate (high light intensity, low acidity) then the blocking layer grows until it limits the current to a value where the rates are balanced.

This view of the behavior of bare GaP can be reconciled with the type B behavior of electrodes with a thin metal overlayer. Since the metal plays no electrochemical part in the electron transfer process at the interface, it must play some physical role. It acts as a diffusion barrier between the bulk of the electrolyte and the electrolyte that has penetrated to the active surface of the GaP. At the same time, the metal film attenuates the light reaching the semiconductor. If the electrochemical reaction responsible for current flow produces H^+ ions, the local acidity at the interface increases. Thus the metal film reproduces the conditions

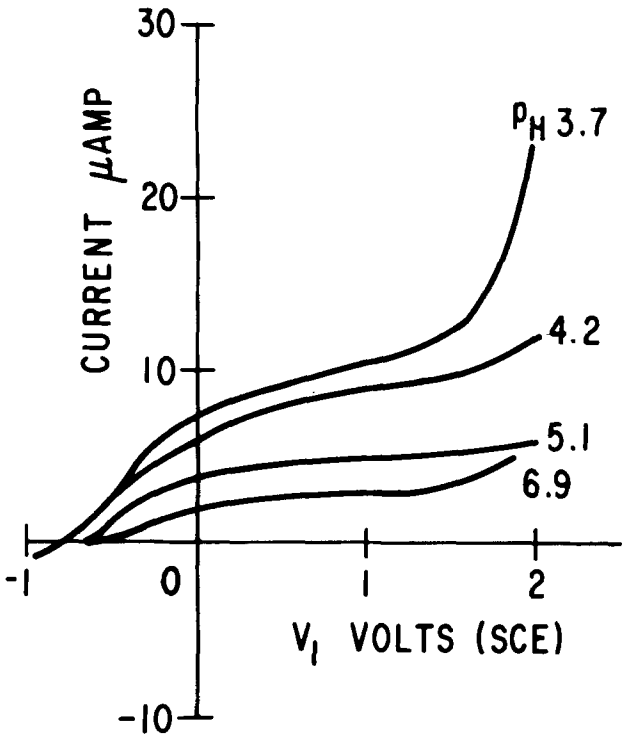

Fig. 9. The current-voltage characteristics for bare n-GaP run in 0.5*F* K_2SO_4 electrolytes adjusted to different *p*H's at a constant light intensity using a 25% transmission filter.

of low illumination and high acidity that gave us the type B curves shown in Fig. 8 for bare GaP.

To support this view of the overlayer as a simple diffusion barrier, we can demonstrate that some other chemically inactive diffusion barrier brings about the same behavior. Samples of GaP were prepared as usual and their front surfaces were covered with a very thin layer of stop-off lacquer or of photoresist lacquer, judged to be only a few microns thick from their interference patterns. These specimens, tested in electrolyte of *p*H = 4.3, resulted in very high current levels with the type B characteristic. After the tests, when the samples were removed from the cell, we could see that electrolyte was trapped under the blistered lacquer in the area that had contacted the electrolyte. These lacquer films could serve only to limit diffusion; they were too thin to attenuate the light appreciably, so the current levels were even higher than with metal films.

Figure 10 summarizes the currents observed in a number of cases of interest. Results for 10Å metal films are omitted because they were the same as those for bare GaP. In most cases the current, measured at $V_1 = 0$ (SCE), is essentially the saturation current, and is proportional to light intensity; the higher currents for 50Å films are consistent with their greater light transmission. The increase of current from bare GaP to type B metal-coated electrodes is strikingly evident; the further increase obtained with a nonopaque diffusion barrier is equally striking.

Conclusions

The experiments reported here verify the view of Nakato *et al.* that type A behavior of n-GaP electrode with a metal overlayer is obtained when the metal film is partially translucent but impermeable to the electrolyte. The electrode then acts as a Schottky photodiode in series with a simple metal electrode contacting the electrolyte.

Type B behavior occurs when the electrolyte permeates the metal overlayer. The current onset is at a potential cathodic to the hydrogen potential and is equal to that seen on bare GaP, and it rises rapidly to a high, well-defined plateau determined by light intensity.

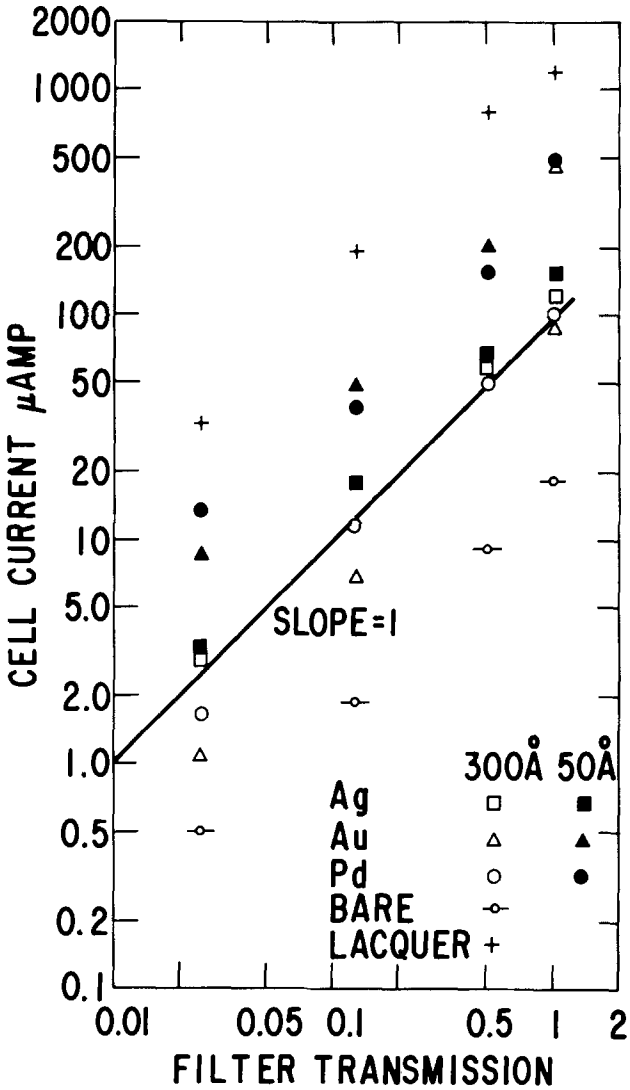

Fig. 10. The current of different samples measured at $V_1 = 0$ (SCE) as a function of filter transmission. The electrolyte in all cases is 0.5*F* K_2SO_4, *p*H = 4.3.

In our observations this behavior is independent of whether the overlayer is Ag, Au, or Pd. In each case the metal potential is too low for it to take part in the electrochemical reaction responsible for current flow.

Type B behavior can be produced on bare GaP by reducing the *p*H of the electrolyte and the illumination intensity, or by coating the electrode with a thin layer of insulating but permeable lacquer. These results suggest that the metal overlayer acts as a light attenuator and a diffusion barrier, thus changing the balance between rates of growth and removal of a surface-insulating layer. There is no evidence of water splitting, and used samples do show signs of corrosion. The current flow we observe is probably related to a corrosion reaction of the electrolyte with GaP, and the overlayers likely enhance, rather than suppress, this corrosion process.

Acknowledgments

The authors are grateful to Dr. F. Will for useful discussions, and to I. Mullin and A. Golab for depositing the evaporated and sputtered films.

Photoelectrolysis of Water in Sunlight with Sensitized Semiconductor Electrodes

Amal K. Ghosh and H. Paul Maruska*

Exxon Research and Engineering Company, Solar Energy Conversion Unit, Linden, New Jersey 07036

ABSTRACT

In all previous studies of the photoelectrolysis of water, very little attention has been paid to the carrier generation and transport properties of the optically active semiconductor electrode. To gather such information the present work theoretically analyzes the spectral response of TiO_2 photoelectrolysis cells. Comparison with experimental results allows us to determine the diffusion length of minority carriers in TiO_2 for the first time. It is the hole transport that governs the spectral response curve, not the electron transport. The quantum efficiency of carrier generation in TiO_2 electrodes in the photolysis mode can be increased to 80% by doping the crystals with Al. The sunlight conversion efficiency has been raised to 1.3% from 0.4% reported earlier by others. The spectral response of the device has been extended into the visible portion of the spectrum through sensitization of the TiO_2 with Cr dopant impurities, allowing hydrogen generation with visible light. The photoelectrolytic processes associated with the impurity doped crystals are discussed.

During the last few years, there has been an extensive study of the photoelectrolysis of water by the action of light on a semiconductor immersed in an electrolyte. Many semiconductor materials, such as TiO_2 (1-7), $SrTiO_3$ (8, 9), $KTaO_3$ (10), $BaTiO_3$ (11), SnO_2 (12), CdS (13-15), GaP (17, 18), and Si (19), have been used in such photoelectrolysis cells. By far the most popular materials have been TiO_2 and $SrTiO_3$, because even though they are transparent to visible light and, hence, relatively poor absorbers of sunlight, they remain chemically stable under anodic polarization (1, 4, 8), while many other smaller bandgap materials dissolve (20). The present work reports on techniques for improving the response of TiO_2 which have led to cells with the highest sunlight conversion efficiency demonstrated to date.

In this paper we present some theoretical studies showing how the response of an illuminated TiO_2 electrode can be expected to behave as a function of the wavelength of the incident light (absorption constant or penetration depth), carrier diffusion length (carrier lifetime and mobility), and barrier width. By using this analysis of the system, we have been able to measure important parameters, such as the minority carrier diffusion length, and to modify the TiO_2 electrodes so as to improve these parameters and hence, increase the cell efficiency. The major improvement in the response of TiO_2 in its fundamental absorption region ($\lambda < 420$ nm) has been accomplished by sensitization with the addition of aluminum impurities. Such Al-doped TiO_2 electrodes have exhibited quantum efficiencies as high as 80%, and engineering conversion efficiencies in actual sunlight (defined as the ratio of the energy content of the hydrogen produced to the energy of the incident solar flux) of 1.3%. Results are presented to show that contrary to normal beliefs, a cell with a small applied bias can actually be more efficient than one which requires no biasing.

The most important problem inherent in utilizing the wide bandgap oxides TiO_2 and $SrTiO_3$ in solar-driven water photoelectrolysis cells is that less than 10% of the solar radiation incident on the earth at AM1 is contained in the u.v. spectral region below 400 nm, where TiO_2 and $SrTiO_3$ strongly absorb (21). Since the greatest portion of the solar flux lies in the visible portion of the spectrum, the maximum sunlight conversion efficiency of cells based on these materials is severely limited, even under the best conditions. However, we will show that it is possible to extend the spectral response of TiO_2 well into the visible portion of the spectrum by sensitizing the crystals with another appropriate dopant, chromium. Doping TiO_2 with chromium has allowed us to generate hydrogen in a photoelectrolysis cell illuminated with only visible light ($\lambda > 400$ nm).

Experimental

The photoelectrolysis cell.—Two types of photoelectrolysis cells were used in this study; a homogeneous cell and a differential cell. The homogeneous cell consisted of a single compartment, 80 mm diam, quartz dish filled with an electrolyte solution into which were inserted the active semiconductor electrode, the reference saturated calomel electrode, and the platinum-black counterelectrode. The differential cell had two separate compartments connected together by a salt bridge, with electrolytes of different *p*H in each compartment. With the active electrode in a solution of *p*H = 14 (5M KOH) and the platinum-black counterelectrode in *p*H = 1 (1M H_2SO_4), a dark potential of 0.8V appears across the cell. An equivalent situation can be maintained in a homogeneous cell by applying the bias with an external power source.

Sample preparation.—Single crystal boules of TiO_2 and $SrTiO_3$ were obtained from NL Industries. TiO_2

* Electrochemical Society Active Member.
Key words: hydrogen generation, water decomposition, TiO_2, impurity dopants, sunlight conversion efficiency.

crystals were either undoped, Al doped [0.05 weight percent (w/o)], or Cr doped (from 0.0004 to 0.4 w/o), while $SrTiO_3$ crystals were not intentionally doped. These boules were 15-25 mm in diam, and slices 1 mm thick were sawed from them, exposing the (0001) surface. The slices were heated in flowing hydrogen for an hour each to make them conducting, TiO_2 at 600°C, and $SrTiO_3$ at 900°C. All of the samples then had measured resistivities of 0.1-1 Ω-cm.

Indium solder was used to make ohmic contact to the back of samples. Copper wires were electroplated with indium before bonding to the indium solder. The entire back and edges of the wafers were then coated with epoxy, followed by RTV-3140 silicone rubber, to insure the insulation of these areas from the electrolyte. The front surfaces were cleaned before use with nitric acid, but were not polished, since polishing was found to degrade performance.

Equipment.—Electrochemical measurements were made with a Princeton Applied Research PAR-170 electrochemistry system. Cell potentials were monitored with a Keithley 610C electrometer. Either of two light sources, a Bausch and Lomb 150W xenon lamp and a Schoeffel 200W mercury lamp, was used for illuminating the cells. The intensity of sunlight was measured with an Eppley pyranometer. When visible light was required, a 4 mm thick polished slab of stoichiometric TiO_2 was used as a filter to remove the u.v. component of the light output of these sources. This TiO_2 filter was placed between the lamp and the cell. Undoped or Al-doped TiO_2 electrodes exhibited no detectable photocurrents upon illumination when the filter was in place. Therefore, we are confident that the filter was sufficiently thick to entirely remove that portion of the lamp (or sunlight) spectrum containing any photons capable of exciting transitions from the valence band to the conduction band in TiO_2. The remaining photons from the visible portion of the spectrum only have enough energy to generate a photocurrent by exciting carriers from the Cr centers into the conduction band.

The Spectral Response of TiO_2 at Bandgap and Higher Energies

The short-circuit photocurrent action spectra of TiO_2 and other photocatalysts have been reported by many [see, for example, Ref. (4, 5, 7-9)]. Some of these spectra are for crystals, while others are for thin films or pressed pellets. Most spectra are for cells operating in the photoelectrolysis mode, where chemical products are created at the electrodes (specifically, hydrogen and oxygen), while some are for what are termed photogalvanic cells,[1] where a chemical couple is oxidized and reduced at the electrodes, producing electrical power but generating no net chemical products. Some of the reported spectra have been corrected for the spectral response of the measuring instruments; others have not. The spectra we are going to discuss are for a photoelectrolysis cell, *i.e.*, one in which oxygen and hydrogen are being evolved. These spectra are most conveniently presented as quantum efficiency *vs.* wavelength, where the quantum efficiency is the ratio of the number of charge carriers collected (current flowing in the external circuit) to photons incident. The spectra that we have observed are similar in shape to those presented by Wrighton *et al.* (4). The most efficient cells that we tested had Al-doped TiO_2 anodes, and such devices had quantum efficiencies as high as 80% at wavelengths less than 360 nm. Cells with undoped TiO_2 electrodes generally exhibited quantum efficiencies which were lower by a factor of 10 than the values for Al-doped material in the flat response region below 350 nm, and we attribute the high response to the effects of the Al-doping, as is discussed in the present paper. No response was found at wavelengths greater than about 420 nm, where the fundamental absorption edge of TiO_2 is located, with either undoped or Al-doped TiO_2 anodes. Quantum efficiencies as high as 0.6 have been reported by Ohnishi *et al.* (22) and by Laser and Bard (23), but the impurity content of their TiO_2 electrodes was not discussed.

Rutile (TiO_2) used in an electrolytic cell is expected to behave like a conventional Schottky barrier, and many authors have stressed the importance of this barrier region (carrier depletion region) at the TiO_2-electrolyte interface in the process of carrier generation by light absorbed in this region (2, 7, 9, 11, 17, 22-24). However, no suitable theory has been presented so far to explain the variation in spectral response that can be encountered with different samples. Even though extensive work has been done with rutile, little attention has been paid to the kinetics of photoinduced carrier generation and transport. For example, the spectral curves for TiO_2 in an electrolyte do not agree with the photoconductivity spectral response curves for rutile reported in entirely solid-state measurements (*i.e.*, both metal contacts) (25), because in the solid-state measurements the photoconductivity peaks between 375 and 410 nm. This may simply be related to the difference in experimental conditions, but it is also possible that in the case of metallic contacts the measured photocurrent may be due to majority carriers (electrons), while in a photoelectrolysis cell the dominant process will be hole transport. In highly n-type (strongly reduced) TiO_2 samples used in photoelectrolysis cells, the light-generated electrons are fewer in number than those present due to thermal ionization of the donor centers. Therefore, the excess carriers generated by the light have little effect on the electron Fermi level; on the other had, the hole quasi-Fermi level is shifted substantially. Although previous discussions of photoelectrolysis results have emphasized the electron transport in the photoconductor, we will show that the process is limited by hole transport, and that the hole diffusion length (which depends on the hole mobility and lifetime) is an important parameter. It should be noted that since TiO_2 is a n-type semiconductor, the electron lifetime in the bulk material is infinite.

In general, we can describe the spectral response of a Schottky barrier device as a function of absorption constant (and hence, wavelength of incident light) by a relationship derived in Ref. (26), as long as surface recombination is not an important factor. Since the Schottky barrier devices of interest to us can be expected to differ in several unknown parameters, we will modify the expression in Ref. (26) by a factor G to account for these differences between samples. The factor G is expected to be related to the photoconductive gain in the barrier region, as well as to the process governing the transport of the holes across the TiO_2-solution interface to ions in the electrolyte. Thus, the factor G may be controlled by transport within the Schottky barrier or by the rate of electrochemical reaction after the holes reach the interface. With this modification then, the expression becomes

$$J = qNG\left[\,[1 - \exp(-\alpha l_b)] + \frac{\alpha}{\alpha + \beta}\exp(\beta l_b)\,\{(\exp -(\alpha + \beta)l_b) - (\exp -(\alpha + \beta)l)\}\right] \quad [1]$$

where J = photocurrent/cm², α = absorption constant, q = electronic charge, N = number of photons incident/cm²-sec, l = sample thickness, l_b = barrier

[1] Usually a photogalvanic cell is considered to be one in which the light is absorbed by the solution, resulting in oxidation and reduction of species in the solution and a current in the external circuit. The type of cell we are mentioning above in which the light is absorbed by the electrode and no net chemical products are produced is an electrochemical photocell.

width, $\beta = 1/L$, and L = minority carrier diffusion length. The first part of the equation gives the charge due to carriers generated within the barrier region, and the second part accounts for carriers generated in the bulk (field-free) region of the sample. A computer program was written to generate spectral response curves predicted by the equation for a variety of combinations of barrier width and diffusion length, always using a 1 mm sample thickness. For example, the expected barrier and bulk components of the response for a diffusion length of 10^{-4} cm and a barrier width of 10^{-6} cm are shown in Fig. 1. We have determined from such plots that the total response is rather insensitive to the barrier width: The narrower the barrier, the larger the diffusion component from the bulk, so that the sum is always about the same. However, the response is strongly affected by the diffusion length, as shown in Fig. 2. In these curves we have taken the factor qNG to be unity.

In order to apply the expression above (Eq. [1]) to our experimentally determined photoelectrolysis cell response, it was necessary for us to obtain an accurate optical absorption spectrum for TiO_2. The best absorption spectrum for TiO_2 appears to be the one given by Eagles (27), which is in rough agreement with most experimental data, including ours. This spectrum is presented in Fig. 3. Using this absorption spectrum in conjunction with Eq. [1], we have determined the best fit to our experimental data for undoped and Al-doped TiO_2, as shown in Fig. 4. The ordinate axis in this plot is given in units of J/qN, which is the quantum efficiency, and the value of G for each sample has been taken so as to normalize the maximum efficiencies to unity for convenience of comparison. There is excellent agreement between the experimental data points and the calculated curves over 4-5 orders of magnitude of change in absorption constant. Although the response is not very sensitive to barrier width, we have been able to distinguish a better fit for a 10^{-6} cm width than for a 10^{-5} cm width for all samples studied. Significantly, the barrier widths determined by our C-V measurements are also of the order of 100Å. From the data presented in Fig. 4 we have determined that the diffusion length is 4.5μ for Al-doped TiO_2, and 1.2μ for undoped TiO_2.

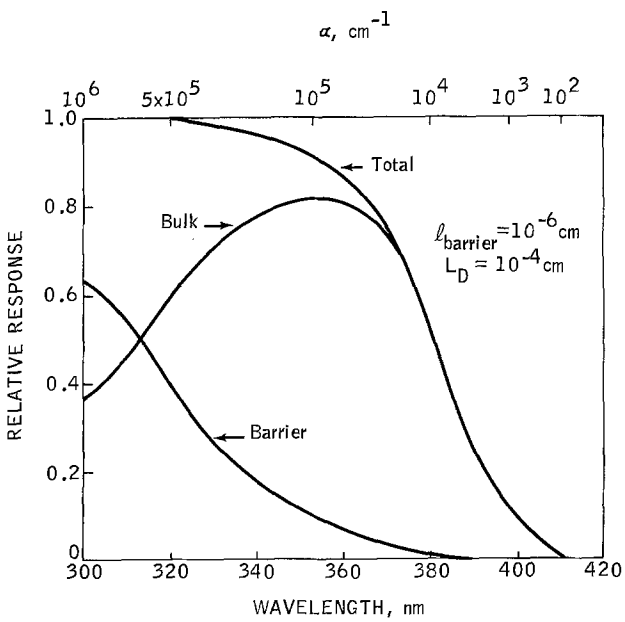

Fig. 1. Illustration of the barrier and bulk contributions to the spectral response of a Schottky barrier device having barrier width $l_b = 10^{-6}$ cm, diffusion length $L_D = 10^{-4}$ cm, and absorption constant as shown.

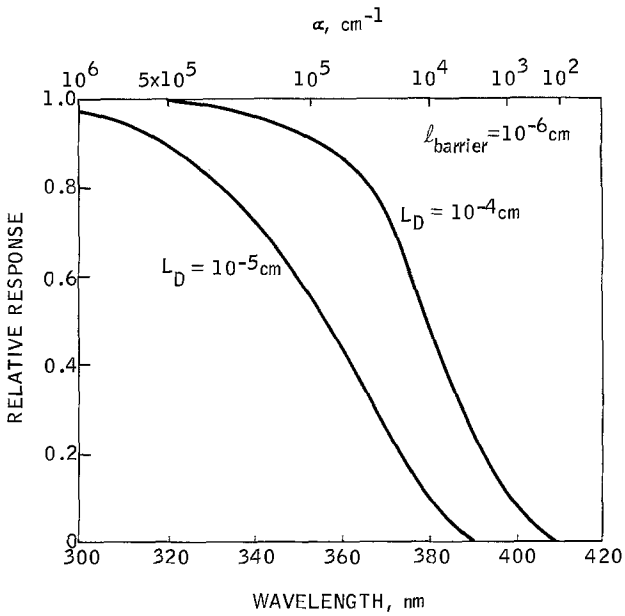

Fig. 2. Effect of an order of magnitude change in diffusion length L_D on the spectral response of a Schottky barrier device having a barrier width $l_b = 10^{-6}$ cm, and absorption constant as shown.

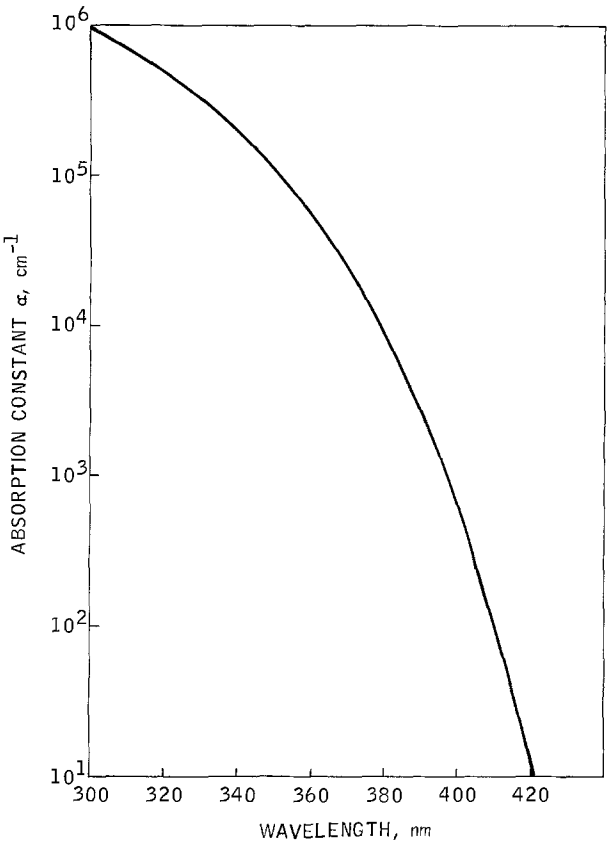

Fig. 3. Absorption constant of TiO_2

It now becomes quite apparent that surface recombination is indeed not important, because there is no reduction in response at short wavelengths; *i.e.*, the efficiency of carrier generation is not affected by how close to the surface the generation occurs.

Plots of the actual (not normalized) quantum efficiency data for two representative samples of Al-doped and undoped TiO_2 are presented in Fig. 5. For various samples the maximum plateau region quantum efficiency can vary between 0.1 and 0.3 for undoped TiO_2, and 0.8-1.0 for Al-doped material, although in

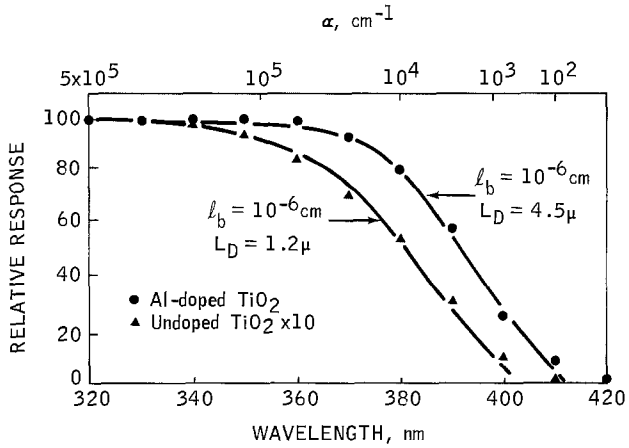

Fig. 4. Best fit of the theoretically derived Schottky barrier response curves to the experimentally determined response of undoped and Al-doped TiO_2 devices.

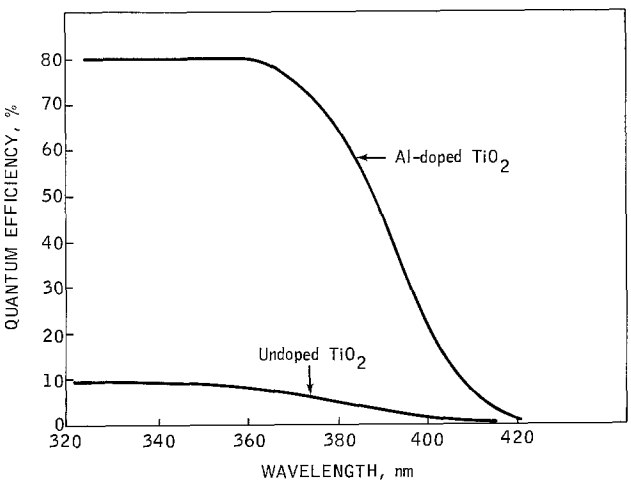

Fig. 5. Measured quantum efficiencies for undoped and Al-doped TiO_2 devices (corrected for instrument factors).

most cases the ratio of plateau quantum efficiencies for Al-doped and undoped samples is about 10:1. We attribute this difference to differences in the value of G. There are two possible processes, described above, which can determine G. Let us consider the photoconductive gain, g, in the barrier region. By definition

$$g = \frac{\tau}{T} \qquad [2]$$

where τ is the carrier lifetime and T is the transit time across the electric field region. Now

$$T = \frac{l_b^2}{V\mu} \qquad [3]$$

where l_b = barrier width, V = height of potential barrier, and μ = mobility, while

$$\tau = \frac{q}{kT}\frac{L_D^2}{\mu} \qquad [4]$$

where L_D = diffusion length. We have shown that for all of our samples, $L_D >> l_b$, so as long as L_D and μ have the same values in the barrier region as in the bulk, then $g \approx 1$ for short wavelength light absorbed entirely within the barrier region. Thus, we may conclude that for both undoped and Al-doped TiO_2 electrodes illuminated with short wavelength ($\lambda < 340$ nm) light, all of the photogenerated holes should reach the semiconductor-electrolyte interface. For light with $340 < \lambda < 420$ nm, a larger proportion of carriers are collected in Al-doped TiO_2 due to improved diffusion from the bulk.

It is possible that the hole lifetime and mobility are different from the bulk values in the barrier region, and then differences in these barrier region values from sample to sample could explain the observed variation in G. However, we feel that it is more likely that the rate-limiting step is the process of hole transfer to the electrolyte. This process may either involve the transition of the holes from the valence band to surface states in contact with the ions in the solution, or else the actual transfer of charge from the surface into the solution. The possible importance of surface states in electrochemistry at TiO_2 electrodes has been described by Frank and Bard (28). In a strongly alkaline solution, the hole transfer to the solution is usually written as

$$2p^+ + 2\,OH^- \rightarrow H_2O + \tfrac{1}{2}\,O_2 \qquad [5]$$

The surface states may in fact be introduced by absorbed OH^-, since it has been shown by photoemission studies that an absolutely clean TiO_2 (or $SrTiO_3$) surface has no filled surface states (29). The critical importance of the TiO_2 surface was further illustrated by a polishing experiment. A single crystal slice (1 mm thick) was cut from a boule, and reduced in hydrogen. When it was first tested in a photoelectrolysis cell, both sides of the wafer showed exactly equivalent photoelectrical properties. However, when one side was then polished to a mirror finish, the photocurrent from that side decreased by an order of magnitude, while the photocurrent from the unpolished side remained the same as before.

We also feel that it is possible that Al doping not only improves the carrier diffusion length, but also may introduce or modify surface states that are essential in the oxidation of OH^-. Aluminum is reported (30) to enter the rutile lattice at both substitutional and interstitial sites in a 3:1 ratio, and an EPR study (31) has shown that the substitutional and interstitial Al^{3+} will reside in reduced TiO_2 on adjacent sites in conjunction with one or two Ti^{3+} on next adjacent sites. Al^{3+} will form acceptor states which may be more properly aligned energetically at the surface (where they are assumed to be filled) with the position of the OH^-/O_2 redox level. The role of Al in enhancing the photoelectrolysis current in TiO_2 will require further study.

Sunlight Conversion Efficiency of TiO_2

There are a number of different ways to define the optical conversion efficiency of a photoelectrolysis cell. The simplest and most popular definition has been

$$\eta_1 = \frac{\text{energy output}}{\text{energy input}} \qquad [6]$$

For a cell generating hydrogen, the energy output is taken as the heat of combustion of the hydrogen that is produced under illumination (68,000 cal/mole), and the energy input is the intensity of the light source. Since this type of cell is intended for use as a solar energy device, the only appropriate light source is the sun. A number of publications have given efficiencies based on various "solar simulator" lamps (such as a xenon lamp), but such sources do not have the same spectral content as sunlight and therefore do not allow comparison. Honda (3) has measured a TiO_2 cell in sunlight and reported $\eta_1 = 0.4\%$. Another recent report (32) of this efficiency assumed the solar intensity to be only 40 mW/cm², which is considerably lower than the average value of about 100 mW/cm² expected on a clear day. All of our sunlight measurements were made on a particularly clear day when we measured a solar intensity of 105 mW/cm². For cells using Al-doped TiO_2, we found $\eta_1 = 1.3\%$, while

with undoped TiO_2, η_1 was at most 0.4%. (5M KOH electrolyte, Pt counterelectrode, and an external bias were supplied.)

It has been argued (33) that if a photoelectrolysis cell is being biased by maintaining different pH's in the anode and cathode compartments, then the heat of neutralization of H^+ by OH^- ought to be considered in the efficiency calculation. The cell reactions are

$$\text{cathode} \quad 2H^+ + 2e^- = H_2 \qquad [7]$$

$$\text{anode} \quad 2\,OH^- = 1/2\,O_2 + H_2O + 2e^- \qquad [8]$$

$$\text{neutralization} \quad 2H_2O = 2H^+ + 2\,OH^- \qquad [9]$$

$$\text{total reaction} \quad H_2O = H_2 + 1/2\,O_2 \qquad [10]$$

Thus, two charges are transferred through the circuit per mole of hydrogen produced. The heat of combustion of 1 mole of hydrogen is 68,000 cal, while the heat of neutralization of 2 moles of H^+ is 28,000 cal. We may define

$$\eta_2 = \frac{\frac{I}{nF}(68{,}000\text{-}28{,}000)}{W_L} \qquad [11]$$

where I is the cell current (A/cm^2), $n = 2$, $F = 23{,}050$ coulomb-cal/J-mole, and W_L is the energy content of the incident light (W/cm^2). For our Al-doped TiO_2 cells with 1M H_2SO_4 and 5M KOH (ΔpH = 13), $\eta_2 = 0.8\%$, while for undoped TiO_2, $\eta_2 = 0.28\%$.

Furthermore, it is possible to calculate the efficiency on the basis of free energies involved. If the hydroyen produced is to be used in a fuel cell, then it will generate a potential of 1.23V. The cell bias is now supplied by a variable voltage source, V_b, so that

$$\eta_3 = \frac{1.23I - V_bI}{W_L} \qquad [12]$$

This efficiency is strongly dependent on the magnitude of the bias voltage, as our experimental results in Fig. 6 show. Our maximum value, $\eta_3 = 0.6\%$, was found with a bias of 0.4V in an Al-doped TiO_2 cell.

It can be argued that it would probably be most beneficial to supply the bias energy chemically, because the acid and base could be generated with cheaper offpeak power at night and stored for use in the cell during the day. Furthermore, the hydrogen is most likely to be used for heating purposes, and therefore the second definition of efficiency is the most useful one for these purposes. However, the efficiency values which are reported for commercially available silicon solar cells are free energy efficiencies, and in order to allow a direct comparison of photoelectrolysis cells with silicon cells one must use the free energy efficiency η_3.

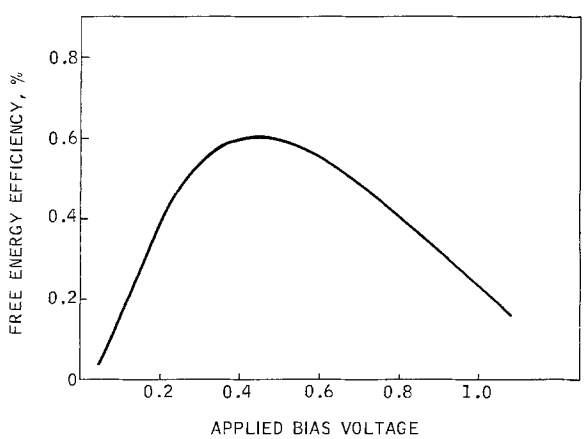

Fig. 6. Effect of applied bias voltage on the sunlight conversion free energy efficiency of a TiO_2:Al photoelectrolysis cell.

Photoelectrolysis with Cr-Doped TiO_2 and Visible Light

One of the most promising techniques that we have applied to extend the response of TiO_2 into the visible portion of the spectrum is impurity doping. The dopant that we have studied for this effect is chromium, and the absorption spectrum of chromium-doped TiO_2 is shown in Fig. 7. The presence of chromium in the rutile lattice was found to give rise to optical absorption extending from the fundamental bandedge of TiO_2 at 415 nm to well past 550 nm, a wavelength region containing a major portion of the solar radiation. Such chromium-doped TiO_2 crystals were reduced in hydrogen (which renders them equally as conducting as undoped samples), and then employed as anodes in our photoelectrolysis cells. Photocurrents were measured in these cells with light of wavelengths ranging from the u.v. up through 550 nm. The short-circuit photocurrent spectra for undoped and Cr-doped TiO_2 electrodes are compared in Fig. 8. It will be seen that the photocurrent spectrum for Cr-doped TiO_2 is substantially equivalent to the optical absorption spectrum for this material. The magnitude of the photoresponse depends upon the concentration of chromium impurity; no extended response was measured at concentrations of 0.0004 w/o (10^{17} Cr atoms/cm^3) or less, while the maximum response was obtained with a concentration of 0.4 w/o (10^{20} Cr atoms/cm^3). Higher Cr doping levels in TiO_2 are impossible because of solubility problems (34).

We have successfully generated hydrogen gas with visible light in a photoelectrolysis cell using Cr-doped TiO_2. As described in the experimental section, the visible light was obtained by using a filter of undoped

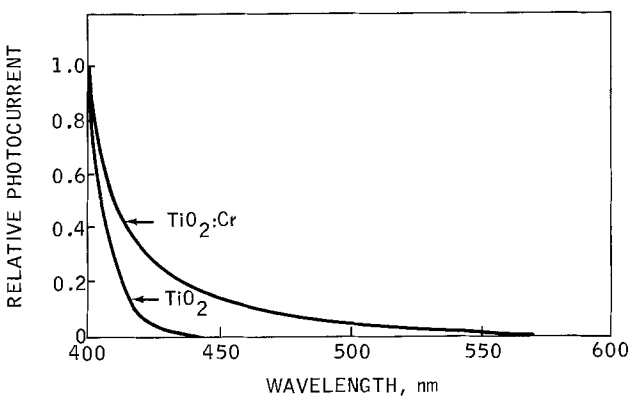

Fig. 7. Optical absorption of undoped and Cr-doped TiO_2

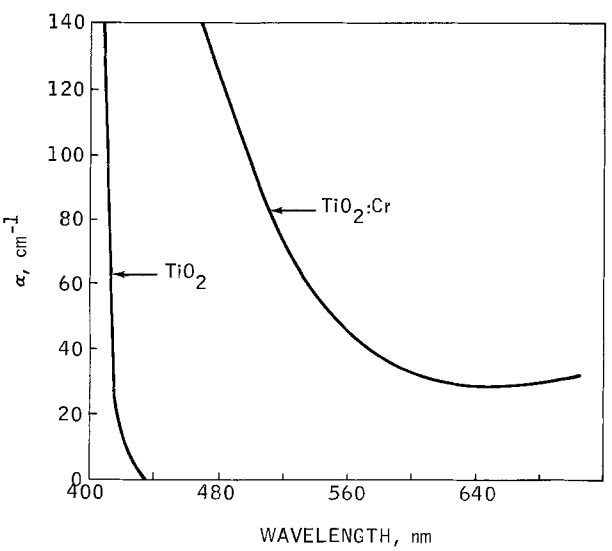

Fig. 8. Short-circuit photocurrent spectra of TiO_2 and TiO_2:Cr

TiO_2 with a 150W xenon lamp. It should be stressed that no photocurrents are measured with undoped (or Al-doped) TiO_2 electrodes when this filter is in place. The hydrogen collected at the Pt electrode was analyzed by a mass spectrometer. The quantity of gas collected corresponded exactly to the electrical current flowing in the cell. Oxygen was generated at the TiO_2:Cr anode. The maximum open-circuit photovoltage found with Xe lamp visible light excitation was 0.44V (*i.e.*, this is the shift in the electron quasi-Fermi level with illumination). No degradation in sample performance was noted, in any case, even after weeks of exposure to visible light. The electrolyte used in these cells was 5M KOH solution, and once again, just as in the case of u.v. excitation, it was determined that an external bias was necessary to allow the generation of hydrogen. The minimum bias for hydrogen generation with Cr-doped TiO_2 and visible ($\lambda > 415$ nm) light is 0.6V. It is significant that since conventional electrolysis of water requires at least 1.2V, the results with our visible light photoelectrolysis cell indicate that a savings of at least 50% in applied potential is possible in sunlight.

The measured quantum efficiency of Cr-doped TiO_2 cells in the region of 400-560 nm is shown in Fig. 9, where the response of undoped TiO_2 is also shown for comparison. For example, a quantum efficiency of 0.35% is obtained at 500 nm (where the solar irradiance is at maximum). However, when we recalculate this visible light response on the basis of carriers absorbed in the active region rather than per carrier incident, we find that the devices approach 100% collection efficiency. Measurements on cells in bright sunlight (105 mW/cm^2) showed that the Cr dopant adds 10% to the total current collection. This factor was once again determined by inserting the undoped TiO_2 filter between the sun and the sample. The expected increase in current due to the Cr dopant is readily calculated from a knowledge of the experimental quantum efficiency (Fig. 9) and the wavelength distribution of the solar flux [see, for example, Ref. (21)]. By integrating the product of these two functions over the wavelength region of interest. we have confirmed that the increase in current for Cr doping should indeed be 10%. Thus, we have effectively demonstrated the principle that adding a dopant impurity

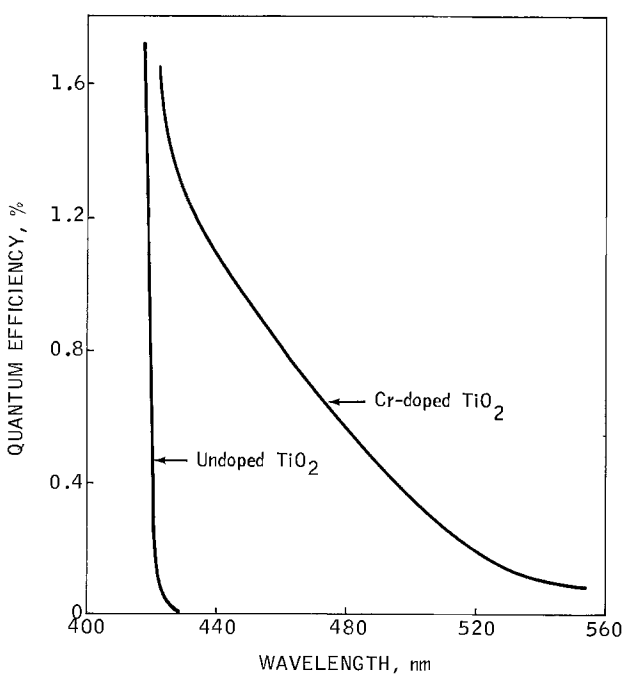

Fig. 9. Comparison of the quantum efficiencies of undoped and Cr-doped TiO_2 anodes in a differential cell.

such as Cr to TiO_2 does extend the response into the visible portion of the spectrum, from 400 to 560 nm. Our results show that the electronic holes created by the visible light excitation of the formerly filled Cr acceptor levels (which are about 0.5 eV above the top of the valence band) are in fact transported to the TiO_2 surface, where they can oxidize water. The mechanism for this hole transport has not yet been elucidated, but heating the solution as high as 90°C did not significantly increase the magnitude of the photocurrent. As we see it, a much larger increase in visible light efficiency should be possible with more suitable dopant impurities. Chromium does not give a strong enough absorption; the oscillator strength for substitutional Cr in TiO_2 is reported to be only 10^{-4} (35). Clearly, since most of the solar insolation is in the visible rather than the u.v. portion of the spectrum, a relatively small increase in visible light absorption (*i.e.*, quantum efficiency) will result in a large increase in the ratio of visible to u.v. response.

Conclusion

Impurity doping is an important technique for improving the response of TiO_2 photoelectrolysis cells. Aluminum doping increases the minority carrier diffusion length, which therefore permits an increase in collection of photogenerated carriers. In addition, Al doping may be responsible for providing surface states essential in the oxidation of OH^-. The combination of these effects has led to an improved sunlight engineering efficiency of 1.3%. Chromium doping extends the spectral response of TiO_2 into the visible portion of the spectrum, and has allowed us to generate hydrogen and oxygen using only visible light. The additional response of Cr-doped TiO_2 results in an increase by 10% in the sunlight conversion efficiency over undoped TiO_2. However, Cr centers in TiO_2 have a low oscillator strength. Therefore we must look for other dopants and combinations of dopants (such as Al + Cr), which will give still greater improvements.

Acknowledgment

The authors would like to thank NSF for supporting the early phases of this research and the work reported in Ref. (36) under Grant EPR75-13901. Thanks are due to Dr. John A. Eckert and Dr. Dale E. Hall for helpful discussions during the course of the work, and Mr. Charles Fishman for writing the computer programs.

Manuscript submitted March 14, 1977; revised manuscript received June 15, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

Publication costs of this article were assisted by Exxon Research and Engineering Company.

Photoelectrochemical Properties of the Lead Electrode during Anodic Oxidation in Sulfuric Acid Solution

D. Pavlov, S. Zanova, and G. Papazov

Central Laboratory of Electrochemical Power Sources, Bulgarian Academy of Sciences, Sofia 1000, Bulgaria

ABSTRACT

During oxidation of a lead electrode in a H_2SO_4 solution at potentials between −200 and +900 mV (*vs.* Hg/Hg_2SO_4 electrode) an anodic layer containing tet-PbO and $PbSO_4$ is formed. When oxidation is conducted in the dark, PbO does not display photoelectrochemical properties. In order to constitute a photoelectrochemical system the electrode has to be photoactivated by illumination with a given quantity of light at potentials more positive than 0 mV. In this case the PbO layer converts into a PbO_n layer with $1 < n < 2$. When a photoactivated electrode is illuminated three types of photoelectrochemical processes occur. The first type leads to photoionization of lead oxide and OH_{ad} and O_{ad} are evolved at the PbO_n/solution interface. These processes take place at potentials between −400 and 0 mV. The second kind occurs at potentials more positive than 0 mV and leads to the formation of PbO_n and photoactivation of the oxide. The mechanism according to which these processes take place includes the formation of Pb^{4+} ions in the oxide via photochemical reactions, reconstruction of the unit cell of PbO into that of PbO_2 containing oxygen vacancies, and reactions of these vacancies with water with the subsequent formation of PbO_n. The third kind of photoprocesses leads to photolysis of water at the surface of the PbO_n layer with formation of O_2.

It was found (1-4) that during anodic oxidation of a lead electrode in sulfuric acid an anodic layer with a variable phase composition originates. In our work (3, 4) the potential range between the equilibrium potential of the $Pb/PbSO_4$ electrode (−970 mV *vs.* Hg/Hg_2SO_4, in the present work all potentials are given with respect to this electrode) and the evolution potential of oxygen (about +1250 mV) was divided into three regions: (*i*) lead sulfate region, from −970 mV to about −200 mV. The anodic layer consists only of $PbSO_4$ crystals; (*ii*) lead oxide region, from about −200 mV to about +900 mV. The anodic layer is built up by a porous layer of $PbSO_4$ crystals and a layer of tet-PbO; and (*iii*) lead dioxide region, above +900 mV. The anodic layer contains the two polymorphs of PbO_2.

Key words: lead electrode—anodic oxidation, photoelectrochemical properties, photoelectrochemical oxidation; lead oxide electrode—photoelectrochemical activation, mechanism of the photoelectrochemical processes.

It appeared of interest to establish if in the PbO potential region the properties of the lead electrode are determined by PbO. The electrochemical methods do not offer many possibilities in this respect since the electrode is passivated. Therefore, other techniques were sought which could make it possible to reveal the properties of the anodic layer in the PbO potential region.

PbO is a semiconductor with a bandgap energy of 2.6-2.8 eV. Tet-PbO has a level in the bandgap with an energy of 1.9 eV (5). It displays a clearly expressed photoconductivity in the visible region of the spectrum (6-15). This property of PbO may be used in the study of the properties of the lead electrode between −200 and +900 mV.

The influence of light on the O_2 evolution at the PbO_2 electrode was investigated by Izidinov (16). A careful survey of the literature failed to reveal any

study of the photoelectrochemical properties of the lead electrode during oxidation in the PbO potential region in a H_2SO_4 solution.

The present work aims at determining the photoelectrochemical properties of the lead electrode during oxidation in the PbO potential region.

Experimental

During anodic polarization of the electrode in the PbO region an anodic deposit consisting of a porous crystalline layer of $PbSO_4$ and of a dense layer of PbO located between Pb and $PbSO_4$ is formed (4). The determination of the properties of this lead electrode upon illumination with polychromatic light was performed under potentiostatic conditions of oxidation. The lead electrode was a cylinder introduced in a Teflon holder so that only the base of the cylinder with an area of 0.5 cm^2 is in contact with 1*N* H_2SO_4 solution and is illuminated. Pb of 99.9999% purity was used. The illumination of the lead electrode was performed by means of a 100 W bulb with a tungsten filament. The infrared region of the spectrum was filtered by means of a cell containing a 2% solution of $CuSO_4$.

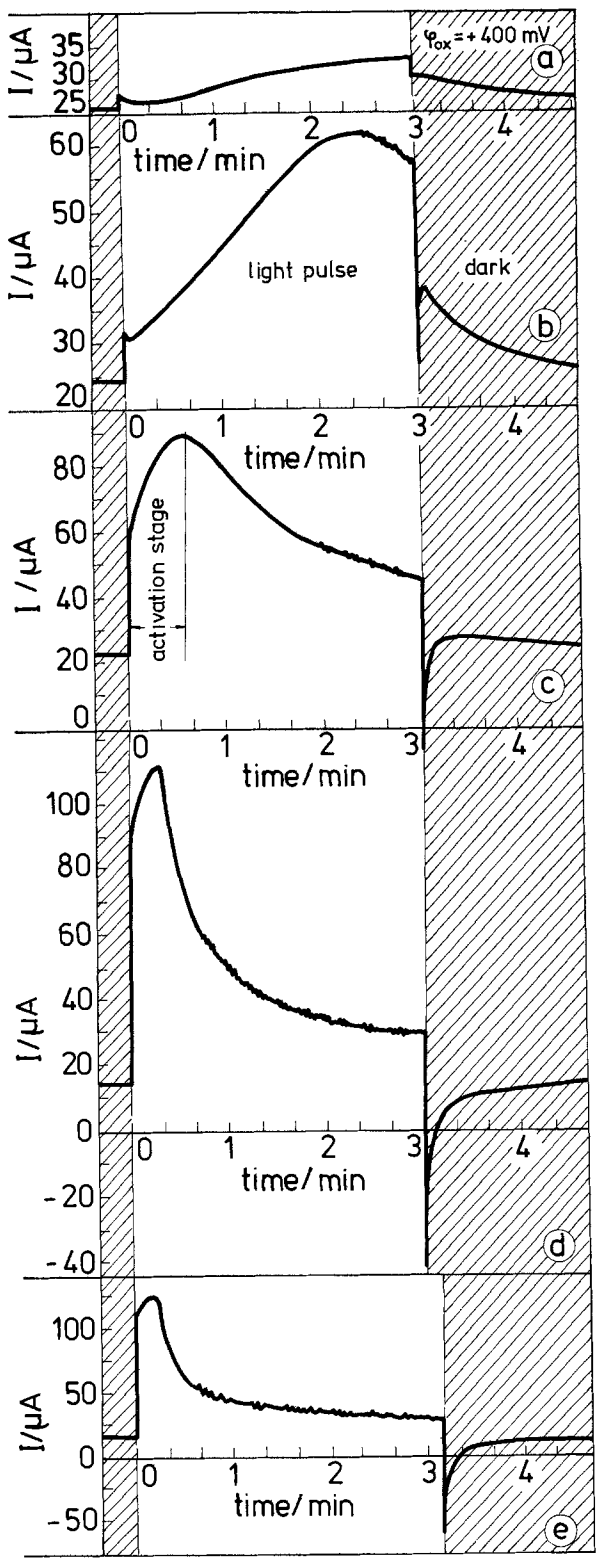

Fig. 1. Change of the current during the first five light pulses in the initial photoactivation period. Oxidation potential +400 mV. Interval between two light pulses 30 min.

Results

Photoactivation of the electrode.—The formation of tet-PbO takes place after the electrode has been covered by a $PbSO_4$ layer. The electrode was oxidized in the dark for 1 hr at a potential +400 mV. Subsequently it was illuminated by a series of light pulses with a duration of 3 min separated by 30 min intervals. Figure 1 represents the change of the current with time during the first five successive pulses.

From Fig. 1a it is seen that during the oxidation in the dark the PbO formed in the anodic layer is photoinactive. When a given amount of light energy falls on the electrode the latter transforms into a photoactive system Fig. 1e. This process may be denoted as photoactivation of the electrode. It ends when after several successive light cycles the photocurrent changes reproducibly in the dark and upon illumination. Photoactivation of the PbO layer occurs at potentials more positive than 0 mV.

The photoactivation of PbO represents, in fact, an increase of its photoconductivity. This takes place if, as a result of the photoreactions, the composition of the lead oxide is modified. It can be assumed that the compounds formed are nonstoichiometric lead oxides with a valency higher than 2. Let us denote these oxides with PbO_n with $1 < n < 2$. A method was tried to make visible the phase PbO_n formed during illumination. To this effect a slit was placed in front of the electrode. After illumination, the projection of the slit on the electrode surface turned brown. This indicates that PbO_n has a composition with $n > 1$. The electrode is shown in Fig. 2.

Influence of the oxidation potential on the nature of the photoeffect.—After an initial photoactivation at +400 mV the electrode potential was changed to the desired value. The electrode was oxidized in the dark

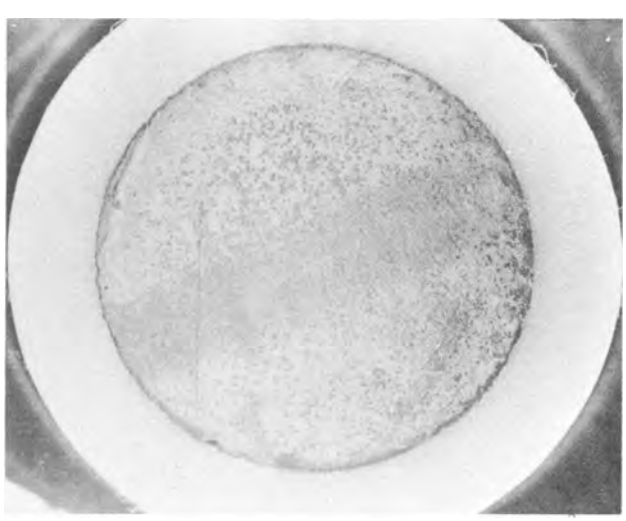

Fig. 2. Photograph of the electrode surface after dissolution of the divalent lead compounds in NH_4COOCH_3 solution. The electrode is oxidized at +400 mV for 4 hr and illuminated through a slit for 40 min. The dark portion of the electrode surface is a light brown PbO_n deposit obtained upon illumination.

for 20 min and was illuminated for 3 min after which it was left for 5 min at the same potential in the dark. In order to restore the initial state, the electrode was oxidized for 20 min at +400 mV. A 3 min light pulse was applied, and after 5 min oxidation in darkness the potential was changed once again.

Figure 3 illustrates the change in the photocurrent at potentials 0, +50, +100, and +400 mV and Fig. 4 at potentials −200, −400, and −600 mV. These results make it possible to differentiate the following three kinds of processes:

(*i*) Processes of the first kind. They proceed individually at potentials between −400 and 0 mV (Fig. 3d,

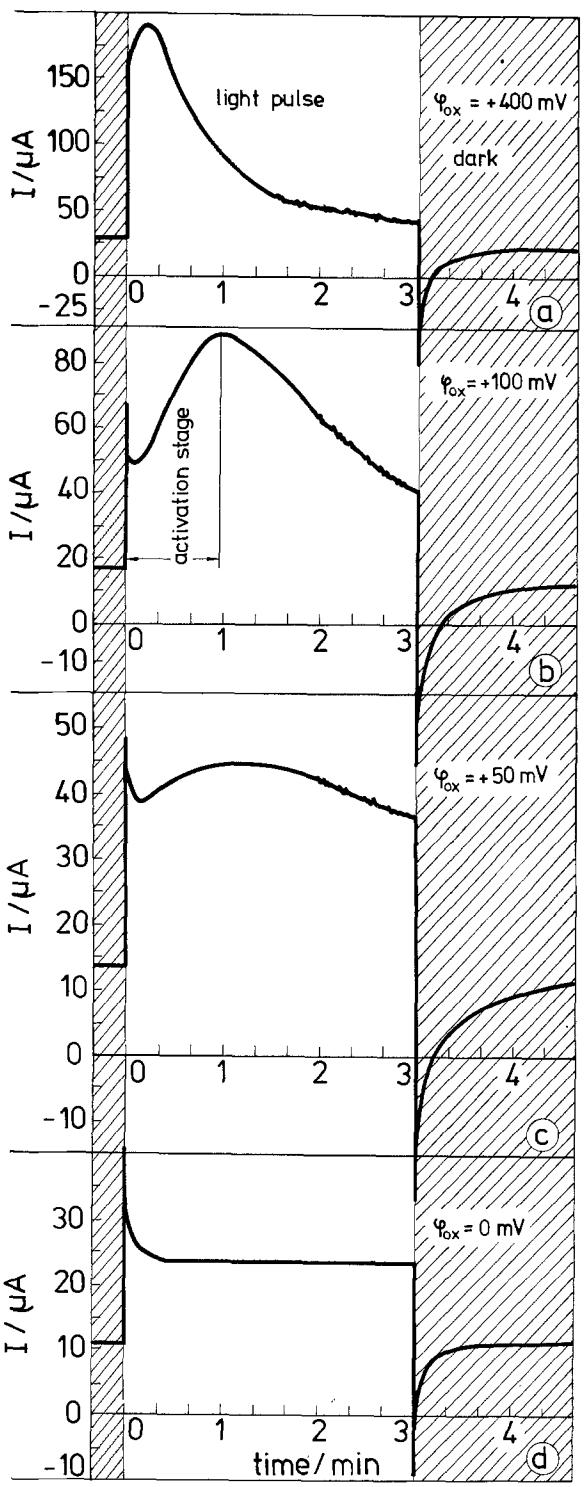

Fig. 3. Change of the current upon illumination of an initially photoactivated electrode during oxidation at potentials +400, +100, +50, and 0 mV.

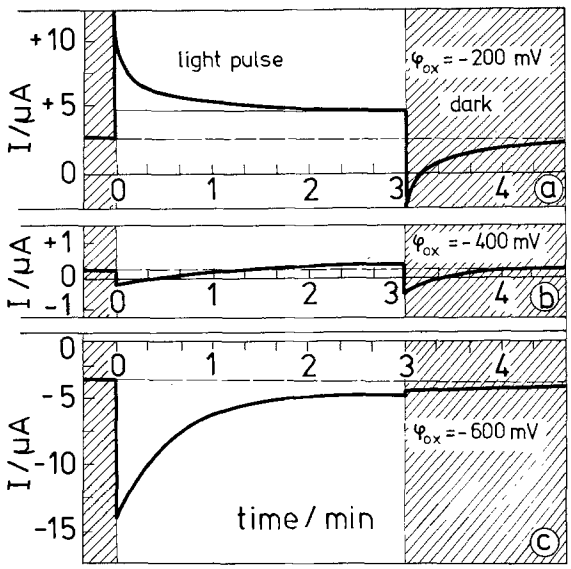

Fig. 4. Change of the current upon illumination of an initially photoactivated electrode during polarization of the electrode at −200, −400, and −600 mV.

4a). Upon illumination of the electrode a photocurrent appears which exponentially decreases down to a constant value. When light is switched off a cathodic current passes during a given interval of time. It can be assumed that as a result of the photoelectrochemical processes of the first kind positive charges are formed in PbO_n as well as products which are reduced when light is switched off. This leads to the appearance of the cathodic current.

(*ii*) Processes of the second kind. They proceed at potentials more positive than 0 mV (Fig. 3a, b, c). The photocurrent increases as a result of these processes. The appearance of a minimum in the curve of the photocurrent (Fig. 3b, c) indicates that the processes of the second kind follow these of the first kind. It was established that precisely as a result of the reactions of the second kind nonstoichiometric PbO_n originates. This means that these processes involve the transfer of oxygen ions from the solution (the water) into the crystal lattice of PbO. This reaction proceeds until n reaches a certain value in PbO_n for each determined potential and intensity of light.

(*iii*) Processes of the third kind. They follow the processes of the second kind and proceed when the current begins to decrease. Figure 5 illustrates the change of the current over various periods of time during which the processes of the third kind take place. After the 3 and 5 sec light pulses, cathodic current does not flow when light is switched off. This shows that the PbO_n phase formed is not rapidly reduced. In the case of the pulses longer than 5 sec, processes of the third kind proceed and the cathodic component of the current appears when light is switched off. This indicates that the products formed during the third kind of the photoelectrochemical processes are readily reduced in the dark. It can be assumed that these are oxygen evolution processes. The reaction of oxygen evolution proceeds in several stages in which OH radicals, O atoms, and O_2 are formed. The irregular oscillations of the current during the processes of the third kind are due precisely to the evolution of O_2. Upon switching off the light the adsorbed OH radicals and O atoms are reduced and a cathodic current begins to flow. This is observed in the case of pulses longer than 5 sec (Fig. 5).

From Fig. 4 it is seen that the photocurrent disappears at −400 mV and becomes cathodic at potentials more negative than −400 mV. A series of experiments

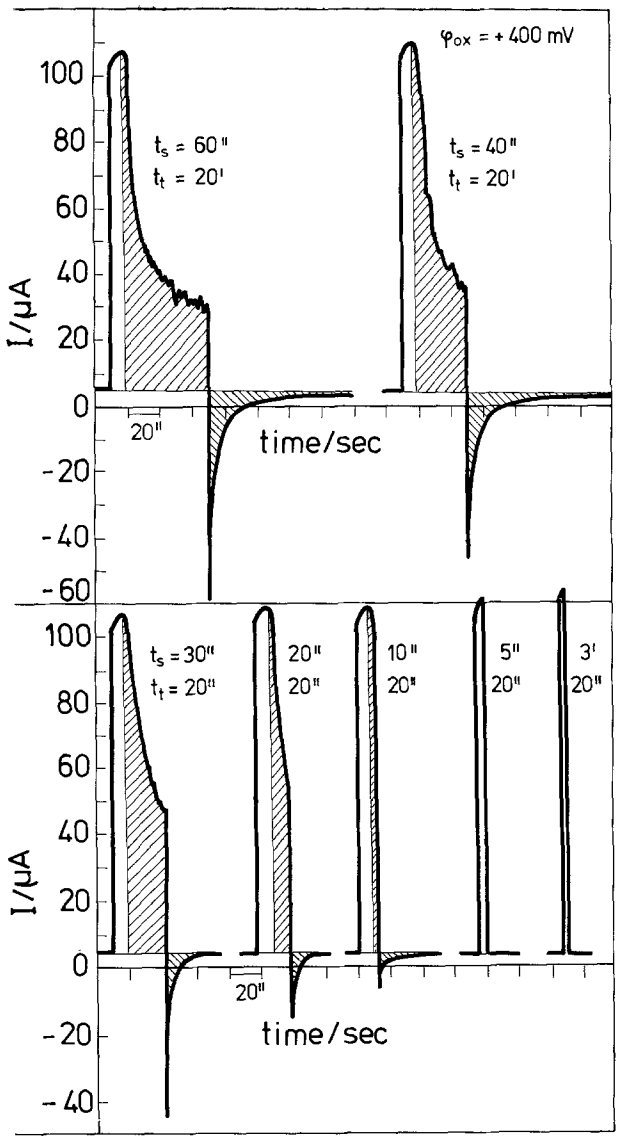

Fig. 5. Change of the current upon illumination of an initially photooctivated electrode with light pulses of decreasing duration. Oxidation potential +400 mV. t_t = interval between two light pulses 20 min, t_s = period of light pulse in seconds.

showed that the change in the sign of the photocurrent takes place in the range −400 ± 50 mV. Obviously, the zero charge potential is located in this potential range. Above this potential the potential of lead is more positive than that of PbO_n. Experiments showed that at −600 mV the photocurrent decreases with time and disappears after a given period of time. This process is connected with the decrease in photoactivity and consequently with the reduction of the PbO_n layer. When PbO_n is reduced to PbO the electrode loses its photoactivity.

It was found that the initial photocurrent which is determined by the processes of the first kind is controlled by the intensity of the white light and that the straight lines of the function photocurrent-light intensity pass through the origin of the coordinate system. This shows that to every incident photon there is a corresponding act of the photochemical process.

It was established that the electrode shows a photoreaction when it is illuminated with light with a wavelength shorter than 650 nm which corresponds to the bandgap energy (1.9 eV). This is in agreement with the results obtained for tet-PbO (5).

Photopotential at open circuit.—Figure 6 illustrates the potential change of a photoactivated electrode oxidized at +400 mV after opening the circuit. A photopotential appears upon illumination. Its magnitude

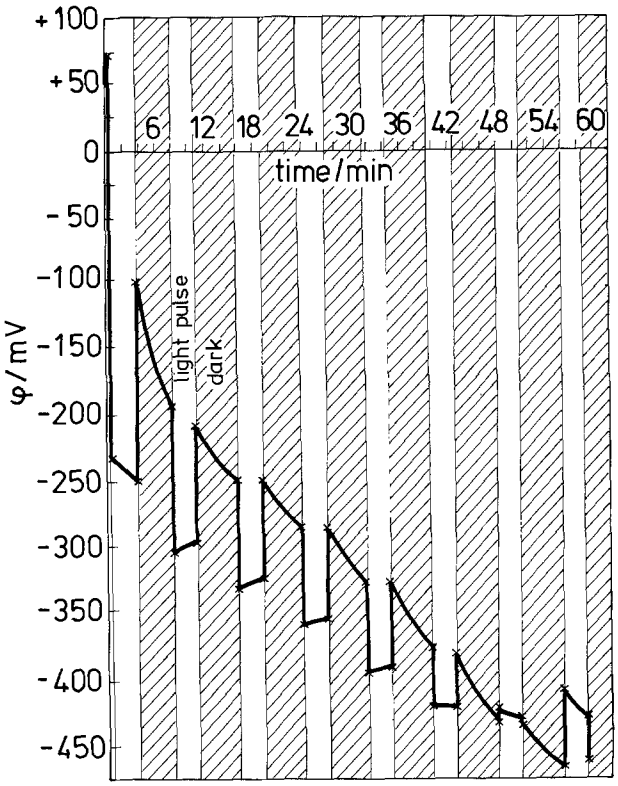

Fig. 6. Change of the electrode potential of an initially photoactivated electrode at open circuit in the dark and upon a series of the light pulses.

and sign depend on the potential in the dark. At about −400 ± 50 mV the sign of the photopotential changes due to the passage through the zero charge potential (Fig. 6). At potentials more negative than −450 mV after a certain period of polarization, the electrode loses its photoactivity. This is connected with the processes of reduction of PbO_n to PbO.

Discussion of the Results

Structure of the anodic layer in the lead oxide potential region.—As has been found (3, 4) the anodic deposit consists of two layers: a layer of $PbSO_4$ crystals and a dense layer of tet-PbO. The $PbSO_4$ layer possesses the properties of a semipermeable membrane (17-18). The current flows through it via H^+ and OH^- ions. Through the PbO layer the current flows in the solid phase. It is limited by the conductivity of the layer and by the processes which take place at the Pb/PbO and PbO/solution interfaces.

Upon oxidation of the lead electrode in the dark tet-PbO is only an ionic conductor. The thermal activation energy is 0.3-0.5 eV (19). This low value indicates that the flow of current through the PbO layer takes place via oxygen vacancies. The latter are formed at the Pb/PbO interface, Pb being oxidized to PbO. The oxygen vacancies move through the PbO layer and at the PbO/solution interface react with water which gives once again PbO. The H^+ ions obtained in this reaction migrate from the $PbSO_4$ layer toward the bulk of the solution. This is the mechanism of the reactions which determine the dark current.

When the electrode potential is more positive than 0 mV and the anodic layer is illuminated with a given amount of light the electrode is photoactivated and PbO transforms into PbO_n. The latter is an n-type semiconductor. As a result the lead electrode acquires the following structure:

metal Pb	n-type semiconductor PbO_n	semipermeable $PbSO_4$ membrane containing electrolyte	H_2SO_4 solution

$PbSO_4$ single crystals in the $PbSO_4$ layer are optically transparent and the light penetrates into the PbO layer.

Elementary reactions in the first kind of photoelectrochemical processes.—For clarity let us assume that the crystal lattice of PbO consists of individual molecules of PbO. The photoelectrochemical reactions in the first kind of processes as a result of which current flows through the anodic layer may be represented by the model given on Fig. 7.

When a $h\nu$ photon falls on a PbO "molecule" of the bulk of the PbO layer, the following photochemical reaction will take place

$$PbO + h\nu \rightarrow PbOh^+ + e^- \quad [1]$$

which results in the creation of the pair: electron e^--hole h^+. The electron jumps over the bandgap and passes into the conduction band of the oxide (Fig. 7a).

Under the action of the electric field the holes move within the layer. However, the PbO layer contains a high concentration of structural defects, traps PbOd. The holes interact with these traps

$$PbOd + h^+ \rightarrow PbOd^+ \quad [2]$$

and charged centers $PbOd^+$ are formed. Such a center contains a Pb^{3+} ion. It is unstable. By taking up a second hole it transforms into a double charged center

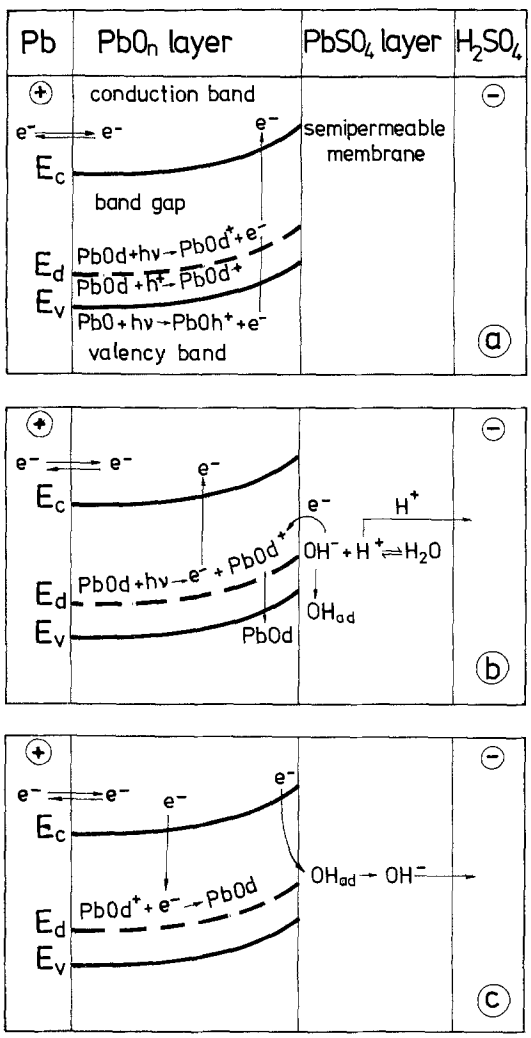

Fig. 7. a,b. Diagram of the model of the reactions of the first kind which proceed in the anodic layer of a photoactivated electrode upon illumination during polarization of the electrode at potentials between —400 and 0 mV. c. Diagram of the reactions which take place after switching off light during polarization of the electrode at potentials between —400 and 0 mV.

$$PbOd^+ + h^+ \rightarrow PbOd^{2+} \quad [3]$$

the lead ion being of fourth valency.

The traps may also accept a photon (Fig. 7a) and the next photoreaction proceeds

$$PbOd + h\nu \rightarrow PbOd^+ + e^- \quad [4]$$

Since there is an electronic equilibrium between the metal and the conduction band of the PbO_n layer the increase in the electron concentration in the conduction band brought about by reactions [1] and [4] leads to an electron transfer in the metal, *i.e.*, to the appearance of a photocurrent.

As a result of reactions [1], [2], [3], and [4] the concentration of $PbOd^+$ and $PbOd^{2+}$ in the PbO_n layer increases. This creates a bulk positive charge in the layer. The electrode potential at the PbO_n/solution interface changes in the positive direction. At this interface $PbOh^+$, $PbOd^+$, and $PbOd^{2+}$ interact with the OH^- ions of the solution and the following electrochemical reactions take place (Fig. 7b)

$$PbOh^+ + OH^- \rightarrow PbO + OH_{ad} \quad [5]$$

$$PbOd^+ + OH^- \rightarrow PbOd + OH_{ad} \quad [5']$$

$$PbOd^{2+} + 2\,OH^- \rightarrow PbOd + 2\,OH_{ad} \quad [5'']$$

$$2\,OH_{ad} \rightarrow O + H_2O \quad [6]$$

As a result of these reactions OH radicals and O atoms are obtained at the PbO_n interface.

Reactions [1]-[5"] involve the motion and transfer of electrons and holes. This is why they are rapid ones. They determine the current in the first kind of photoprocesses. The shape of the current curve of Fig. 3d and 4a can be described in terms of the above reactions. Upon illumination reactions [1], [2], [3], and [4] take place. The PbO_n layer acquires a positive space charge. Reactions [5]-[5"] proceed at the PbO_n/solution interface. The photocurrent increases with a jump.

As a result of processes [5]-[5"] and [6] on the PbO surface OH_{ad} radicals and O_{ad} atoms are obtained. They partially passivate the electrochemical reactions and the photocurrent goes down to a steady-state value (Fig. 3d and 4a).

Upon switching off the illumination OH radicals and O atoms adsorbed at the PbO_n surface accept electrons from the conducting band and the reactions

$$OH_{ad} + e^- \rightarrow OH^- \quad [7]$$

$$O_{ad} + 2e^- + H_2O \rightarrow 2\,OH^- \quad [8]$$

take place (Fig. 7c). The cathodic current flows through the electrode. Since the amount of OH_{ad} and O_{ad} decreases with time the dark current goes up to the steady-state value in the dark (Fig. 3d and 4a).

Elementary reactions in the second kind of photoelectrochemical processes.—As shown in the previous section double charged positive centers are formed during the photoprocesses of the first kind. Since the structural changes are small they may transform into $O^{2+}_{\square}$ vacancies

$$PbOd^{2+} \rightarrow PbO \cdot O^{2+}_{\square} \quad [9]$$

This process may be easily understood by using the idealized model suggested by Bode and Voss (20) and represented on Fig. 8. Under some assumptions and with certain approximations these authors showed that the structures of Pb, tet-PbO, and α-PbO_2 are closely related to one another. The unit cells contain four molecules. They are built up of a lead sublattice consisting of four lead ions. When the lead ions are divalent the oxygen sublattice contains four O^{2-} ions and is only half-filled. Tet-PbO is formed. When the lead ions are tetravalent the oxygen sublattice consists of eight oxygen ions and is completely filled.

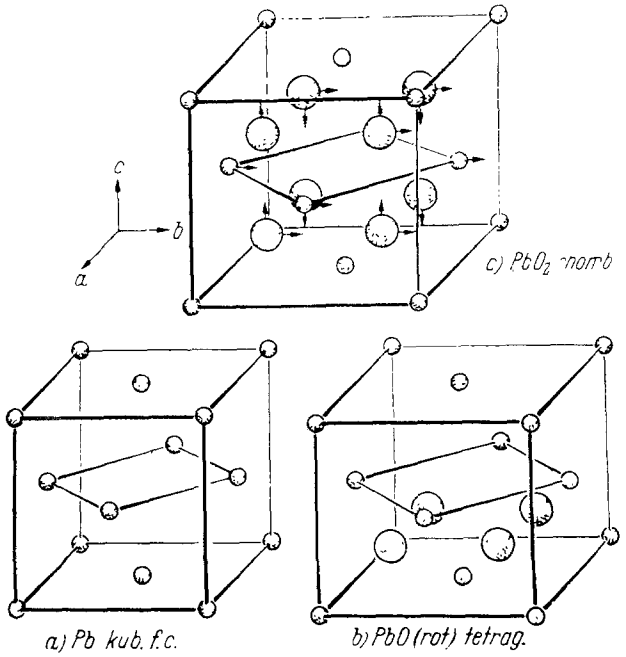

Fig. 8. Model of the unit cells of Pb, tet-PbO, α-PbO_2 according to Bode and Voss (20). The structures are represented so that the lead is located at (000). o = Lead atom, O = oxygen atom.

α-PbO_2 is formed. The O^{2-} ions are arranged in two planes.

The transformation of the unit cell of tet-PbO into that of α-PbO_2 leads to a volume increase of only 4% (21). This process does not involve any volume hindrances.

A model of the reactions by means of which current flows through the anodic layer is given on Fig. 9. The photochemical reaction is a generalization of reactions [1] and [4]. When the $O^{2+}_{\square}$ vacancies reach the PbO/solution interface the reaction

$$Pb \cdot O^{2+}_{\square} + H_2O \rightarrow PbO_2 + 2H^{2+} \qquad [10]$$

proceeds. Since the unit cell consists of four "molecules" and not all of the ions of the lead sublattice have reached the tetravalent state simultaneously, PbO_n forms

$$mPbO + kPbO_2 \rightarrow PbO_n \qquad [11]$$

where m and k are fractional numbers.

According to the experimental data given in Fig. 3 reaction [10] proceeds only if the electrode potential is more positive than 0.0V.

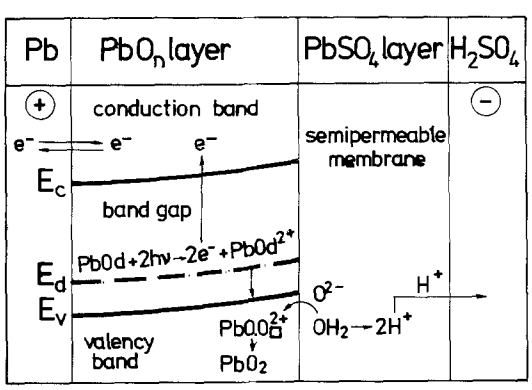

Fig. 9. Diagram of the model of the reactions of the second kind which take place in the anodic layer of a photoactivated electrode during illumination and lead to the formation of PbO_n.

When reaction [10] proceeds "PbO_2 molecules" are formed at the interface. The $O^{2+}_{\square}$ vacancy concentration at this interface goes down. This brings about the formation of a flow of $O^{2+}_{\square}$ vacancies from the bulk of the PbO_n layer. During this process n in PbO_n rises. The growth of the PbO_2 concentration in the PbO_n layer raises the mobility of the electrons in the layer (22). The ohmic drop decreases. Since upon potentiostatic oxidation the lead potential at the Pb/PbO_n interface is a support one, the decrease in the ohmic drop in the layer increases the potential at the PbO_n/solution interface in the positive direction. This accelerates the rate of reaction [10]. The concentration of $O^{2+}_{\square}$ vacancies in the layer goes down with time. This decreases the rate of reaction [10]. These processes indicate that during the photoactivation stage on illumination the rate of the processes of the second kind must pass through a maximum. Such a change of the photocurrent is indeed experimentally observed in Fig. 1 and 3.

Consequently, the processes of photo-oxidation of PbO to PbO_2 reduce to an electronic process, which leads to an increase of the valency of the ions of the lead sublattice and to an ionic process connected with the filling of the second half of the oxygen sublattice. In these processes the highest energy barrier which must be overcome is the passage of the electrons through the bandgap. The penetration of the photoelectrons into the metal creates uncompensated positive charges in the lead sublattice. The energy in the lead sublattice increases. This leads to structural rearrangements in the lattice which give rise to oxygen vacancies in the unit cell of PbO_n. They create conditions favorable for an ionic process of introduction of O^{2-} ions into the PbO_n layer through the PbO_n/solution interface. The oxygen ions are provided by water. When the potential is more positive than 0 mV, reaction [10] proceeds. The O^{2-} ions within the PbO_n layer move by a vacancy mechanism. This ensures them a good ionic conductivity. The filling of the second half of the oxygen sublattice takes place gradually which makes it possible to consider the PbO_n layer as a solid electrolyte.

Elementary reactions of the third kind of photoelectrochemical processes.—As a result of the reactions of the second kind the concentration of "PbO molecules" at the PbO_n/solution interface has become negligible and the potential has become more positive. This raises the adsorption of OH^- ions on the PbO_n surface. Since PbO_n is an n-type semiconductor it has a determined bandgap. The adsorbed OH^- ions may be considered as surface states in this band. In this case when a photon falls on the chemisorbed OH^- ion one electron may enter the conduction band and the following reactions take place

$$OH^- + h\nu \rightarrow OH_{ad} + e^- \qquad [12]$$

$$2\,OH_{ad} \rightarrow 1/2\,O_2 + H_2O \qquad [13]$$

When "PbO molecules" are present at the PbO_n/solution interface reactions [1] to [5] are also possible.

Processes in the dark.—When light is switched off the oxide layer consists of PbO_n and at the oxide/solution interface are absorbed OH_{ad} and O_{ad}. The concentrations of all products which have formed upon illumination become nonsteady state. In the PbO_n layer and at its surface processes occur which lead to a new steady state in the dark. Two types of processes proceed in the dark. The first one is relatively rapid and is connected with the reduction of OH_{ad} and O_{ad}

$$OH_{ad} + e^- \rightarrow OH^- \qquad [14]$$

$$O_{ad} + H_2O + 2e^- \rightarrow 2\,OH^- \qquad [15]$$

These processes take place immediately after light has

been switched off. They determine the current during the nonsteady-state stage in the dark (Fig. 1, 3, and 5).

The second kind of processes in the dark is connected with the reduction of "PbO_2 molecules"

$$PbO_2 + H_2O + 2e^- \rightarrow PbO + 2\,OH^- \qquad [16]$$

This reaction brings about a change in the composition of the PbO_n layer. When the electrode is left in the dark for a short time the reduction of the PbO_n is negligible. The boundary value of n in PbO_n (for the oxidation potential and light intensity of the preceding pulse) is retained. This is why upon renewed illumination the processes of the third kind begin immediately. When an electrode is left in the dark for a long period, upon renewed illumination a photoactivation period is observed. As a result of reaction [16] in the dark the concentration of "PbO_2 molecules" in the PbO_n layer decreases. Upon renewed illumination n in PbO_n will reach once again its boundary value if reactions of the second kind take place. This happens in a photoactivation period.

Reaction [16] proceeds more rapidly at open circuit and when the oxidation potential is more negative than −400 mV.

From the present investigations it becomes obvious that in the lead oxide potential region the electrochemical properties of the electrode are determined by lead oxide. By means of illumination and electrode potential the elementary physicochemical processes were differentiated. This made it possible to reveal the mechanism of the elementary processes of the oxidation of PbO to PbO_2. It can give an insight into the elementary processes which take place during formation of positive lead-acid battery plates.

A Flow-Through Porous Electrode Model: Application to Metal-Ion Removal from Dilute Streams

James A. Trainham* and John Newman*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

A one-dimensional model for flow-through porous electrodes operating above and below the limiting current of a metal deposition reaction has been developed. The model assumes that there is one primary reactant species in an excess of supporting electrolyte, and that a simultaneous side reaction may occur. The model predicts nonuniform reaction rates due to ohmic, mass-transfer, and heterogeneous kinetic limitations; the effects of axial diffusion and dispersion are included. Results are compared with the experimental data observed by various authors for the deposition of copper from sulfate solutions with the simultaneous generation of dissolved hydrogen. Satisfactory agreement between model predictions and experimental data on over-all reactor performance and deposit distributions has been accomplished. For an upstream counterelectrode, distributions of reaction rate (for both single and multiple reactions), concentration, and potential describe the detailed system behavior.

Recent publications (1-8) show that flow-through porous electrodes can remove heavy metals from dilute streams, and direct comparisons with other electrode systems (fluidized bed electrodes and parallel plate electrodes) (9-11) show that flow-through porous electrodes can perform better. However, before they are used commercially it must be demonstrated that they can compete successfully with other established processes (*e.g.*, foam fractionation, ion exchange, pre-

* Electrochemical Society Active Member.

Key words: current distribution, potential distribution, mass transfer, axial dispersion, side reaction.

cipitation, and cementation). To help design better flow-through porous electrodes so they can compete with these other processes, more sophisticated models are required.

In previous work (1, 12-15), a flow-through porous electrode operating at the limiting current was treated. Sioda (16) gave an analysis for a flow-through porous electrode operating below the limiting current for a reversible reaction described by the Nernst equation, which also includes treatment of the interfacial mass-transfer resistance. Alkire and Gracon (13) included a very general analysis of a single electrode reaction below the limiting current, including the effects of axial diffusion; results are given for an upstream counterelectrode. Recently, Alkire and Gould (17) have extended this work to multiple reaction sequences, which includes: deposition of several metals, deposition of a metal in the presence of a redox system, and an ECE sequence applicable to electroorganic synthesis; results are given for a downstream counterelectrode. Ateya and Austin (18) give an analysis similar to Sioda (16) for a single electrode reaction described by the Nernst equation, and they study the effects of axial diffusion and dispersion under conditions when the interfacial mass-transfer resistance appears to be negligible.

The present analysis complements previous work by predicting nonuniform reaction rates due to ohmic, mass-transfer, and heterogeneous kinetic limitations in the presence of a side reaction. Also included are the effects of axial diffusion and dispersion without simplification of the Danckwerts (19), Wehner-Wilhelm (20) boundary conditions, as was done in previous work (13, 17). Simplifications made possible in the treatment of the side reaction due to the small reactant concentration and the desire to operate at high current efficiencies should make this analysis attractive for design purposes.

Model

The case of metal-ion removal from dilute streams using a flow-through porous electrode with parallel current and fluid flow can be modeled with the following restrictions: (*i*) The model is one-dimensional; (*ii*) The porous cathode is of length L and has an isotropic porosity ϵ and specific surface area a which remain constant in time; (*iii*) The hydrodynamics are characterized by the superficial velocity v and an average mass-transfer coefficient k_m, where axial diffusion and dispersion account for deviations from plug-flow; (*iv*) There is one reactant species in excess supporting electrolyte; (*v*) A simultaneous side reaction may occur which is characterized by its rate at the half-wave potential of the primary reaction. Also, if the side reaction involves generation of a gas, it is assumed that the gas will remain in solution so that the velocity profile will not be disturbed; (*vi*) The conductivity of both the matrix and pore solution phases is uniform.

Assumptions (*i-iii*) simplify the calculational procedure, and are necessary due to the lack of a better description of the complex porous geometry. The validity of assumptions (*iv-vi*) rests on the small reactant concentration. As a consequence of assumptions (*iv*) and (*v*), the current efficiency should be high, which further simplifies the model by removing the need to follow any reactant species concentration which participates in the side reaction. This approach emphasizes the salient features of the interaction between the unwanted side reaction and the metal deposition reaction.

Analysis

The equations which describe the behavior of porous electrodes have been reviewed recently by Newman and Tiedemann (12).

Only one material balance is required—that for the metal-ion reactant. At steady state, this may be expressed as

$$\frac{dN_R}{dx} = aj_{Rn} \qquad [1]$$

where in the absence of migration effects the superficial flux N_R of the metal-ion reactant in the direction of the fluid flow is given by

$$N_R = -\epsilon(D_R + D_a)\frac{dc_R}{dx} + c_R v \qquad [2]$$

and the local pore-wall flux to the flowing solution is related to the average mass-transfer coefficient k_m [corrected for axial diffusion and dispersion (14)] by

$$j_{Rn} = k_m(c_{Rw} - c_R) \qquad [3]$$

The quantities c_{Rw} and c_R are the wall concentration and the pore solution concentration of the metal-ion reactant averaged over the volume of the pores. In Eq. [2], D_R is the effective diffusion coefficient of the metal-ion reactant within the pore solution, and represents a correction to the molecular diffusion coefficient D_o for tortuosity ($D_R = D_o/\tau^2$, where τ is the tortuosity factor). D_a is the axial dispersion coefficient taken to be (14)

$$D_a = \frac{3v}{a\epsilon}(1 - \epsilon) \qquad [4]$$

which is a fit of a large number of data correlated by Sherwood *et al.* (21) [see also Ref. (12)].

In the matrix phase, the transport of electrons is governed by Ohm's law

$$i_1 = -\sigma\, d\Phi_1/dx \qquad [5]$$

Since it has been assumed that the concentration of the limiting reactant is small compared to the supporting electrolyte concentration, the diffusion potential is neglected; consequently, the current density i_2 in the solution phase is governed by Ohm's law

$$i_2 = -\kappa\, d\Phi_2/dx \qquad [6]$$

where κ is the effective conductivity of the solution within the pores, related to the bulk conductivity κ_o as follows (22)

$$\kappa = \kappa_o\epsilon^{1.5} \qquad [7]$$

A consequence of electroneutrality is that charge is conserved between the matrix and pore-solution phases. Mathematically this means the divergence of the total current is zero

$$\frac{di_1}{dx} + \frac{di_2}{dx} = 0 \qquad [8]$$

The transfer current is due to the sum of the individual electrode reactions

$$\frac{di_2}{dx} = \sum_j ai_{nj} \qquad [9]$$

where i_{nj} is the average transfer current density (from the matrix phase to the pore solution phase) due to reaction j in an electrode reaction of the form

$$\sum_i s_{ij}M_i^{z_i} \rightarrow n_j e^- \qquad [10]$$

With the assumption that the principal reactant R participates only in the primary reaction, we can write

$$i_{nR} = -\frac{n\mathbf{F}}{s_R}j_{Rn} = \frac{n\mathbf{F}}{s_R}k_m(c_R - c_{Rw}) \qquad [11]$$

For the case under consideration, the mass-transfer

resistance is unimportant for the side reaction, and substitution of Eq. [11] into Eq. [9] yields

$$\frac{di_2}{dx} = -\frac{anF}{s_R} j_{Rn} + a i_{nS} \quad [12]$$

where the subscript S refers to the side reaction.

In general, the average transfer current density due to reaction j may be approximated by the Butler-Volmer equation

$$i_{nj} = i_{oj}\left[\exp\left(\frac{\alpha_{aj}F}{RT}\eta_{sj} \right) - \exp\left(-\frac{\alpha_{cj}F}{RT}\eta_{sj} \right) \right] \quad [13]$$

where i_{oj} is the exchange current density which is assumed to have a composition dependence of the form

$$i_{oj} = i_{oj,\mathrm{ref}} \prod_i \left(\frac{c_{iw}}{c_{i,\mathrm{ref}}} \right)^{\gamma_{ij}} \quad [14]$$

where $i_{oj,\mathrm{ref}}$ is the value of the exchange current density for reaction j at a reference composition $c_{i,\mathrm{ref}}$. It was further assumed that the transfer coefficients α_{aj} and α_{cj} sum to n_j (a positive number, see Eq. [10]) and that the exponents γ_{ij} have the form

$$\gamma_{ij} = q_{ij} + \frac{\alpha_{ij}}{n_j} s_{ij} \quad [15]$$

such that $q_{ij} = -s_{ij}$ for a cathodic reactant and zero otherwise.

In Eq. [13], the surface overpotential for reaction j is given by

$$\eta_{sj} = \Phi_1 - \Phi_2 - U_{jw} \quad [16]$$

where

$$U_{jw} = U_j^{\theta} - U_r^{\theta} - \frac{RT}{n_jF} \sum_i s_{ij} \ln \frac{c_{iw}}{\rho_o} + \frac{RT}{n_rF} \sum_i s_{ir} \ln \frac{c_{ir}}{\rho_o} \quad [17]$$

which is the theoretical open-circuit potential for reaction j at the local wall composition relative to a reference electrode of a given kind, where the subscript r refers to the reference electrode compartment. (The pure-solvent density ρ_o should be expressed in kg/cm³ if the concentrations are given in mole/cm³.)

For the case of metal-ion removal from dilute streams, Eq. [13]-[17] can be simplified greatly. Let the reference electrode be of the same kind as the metal deposition reaction, where the concentration of the primary reactant in the reference electrode compartment c_{Rr} and the reference concentration in Eq. [14] $c_{R,\mathrm{ref}}$ are set equal to c_{Rf} (the upstream feed concentration of the metal-ion reactant). Also assume that the stoichiometric coefficient $s_R = -1$. Then Eq. [13] for a metal deposition reaction reduces to

$$i_{nR} = i_{oR,\mathrm{ref}} \left\{ \exp\left[\frac{\alpha_{aR}F}{RT} (\Phi_1 - \Phi_2) \right] - \frac{c_{Rw}}{c_{Rf}} \exp\left[-\frac{\alpha_{cR}F}{RT} (\Phi_1 - \Phi_2) \right] \right\} \quad [18]$$

For a simultaneous side reaction, such as the decomposition of the solvent, Eq. [13] reduces to an even simpler form

$$i_{nS} = i_{oS,\mathrm{ref}} \left\{ \exp\left[\frac{\alpha_{aS}F}{RT} (\Phi_1 - \Phi_2 - \Delta U) \right] - \exp\left[-\frac{\alpha_{cS}F}{RT} (\Phi_1 - \Phi_2 - \Delta U) \right] \right\} \quad [19]$$

where ΔU is the difference in the theoretical open-circuit potentials of the side reaction and the primary reaction ($\Delta U = U_S - U_R$) at the reference concentrations, which in this case are at the upstream feed composition. Note that any explicit dependence of the rate of the side reaction on the composition has been ignored. This assumption is justified if the current efficiency is high and the ratio of the metal-ion reactant to the reactant species involved in the side reaction (*e.g.*, the hydrogen ion) is small.

Let $\eta = \Phi_1 - \Phi_2$ be defined as the local overpotential, and combine Eq. [5] and [6]

$$d\eta/dx = d(\Phi_1 - \Phi_2)/dx = -i_1/\sigma + i_2/\kappa \quad [20]$$

The elimination of c_{Rw} between Eq. [3] and [18] yields

$$j_{Rn} = -\frac{\dfrac{c_R}{c_{Rf}} - \exp\left[(\alpha_{aR} + \alpha_{cR})F\eta/RT\right]}{\dfrac{1}{c_{Rf}k_m} - \dfrac{nF}{s_R i_{oR,\mathrm{ref}}} \exp\left[\alpha_{cR}F\eta/RT\right]} \quad [21]$$

Next combine Eq. [1], [2], and [21] to eliminate N_R and j_{Rn}, which results in a material balance equation for the limiting reactant with unknowns c_R and η

$$v\frac{dc_R}{dx} = (D_R + D_a)\frac{d^2c_R}{dx^2} - a\frac{\dfrac{c_R}{c_{Rf}} - \exp\left[(\alpha_{aR} + \alpha_{cR})F\eta/RT\right]}{\dfrac{1}{c_{Rf}k_m} - \dfrac{nF}{s_R i_{oR,\mathrm{ref}}} \exp\left[\alpha_{cR}F\eta/RT\right]} \quad [22]$$

An equation for the potential distribution results from elimination of i_1, i_2, and i_{nS}, between Eq. [8], [12], and [19]-[21] by differentiating Eq. [20]

$$\frac{d^2\eta}{dx^2} = \left(\frac{1}{\kappa} + \frac{1}{\sigma}\right) a \left\{ i_{oS,\mathrm{ref}} \left[\exp\left(\frac{\alpha_{aS}F}{RT} (\eta - \Delta U) \right) - \exp\left(-\frac{\alpha_{cS}F}{RT} (\eta - \Delta U) \right) \right] - \left(-\frac{nF}{s_R} \right) \frac{\dfrac{c_R}{c_{Rf}} - \exp\left[(\alpha_{aR} + \alpha_{cR})F\eta/RT\right]}{\dfrac{1}{c_{Rf}k_m} - \dfrac{nF}{s_R i_{oR,\mathrm{ref}}} \exp\left[\alpha_{cR}F\eta/RT\right]} \right\} \quad [23]$$

Before Eq. [22] and [23] can be solved simultaneously for c_R and η, four boundary conditions are required. For c_R the following conditions were used

$$c_{Rf}v = c_R v - \epsilon(D_R + D_a)\frac{dc_R}{dx} \text{ at } x = 0 \quad [24]$$

where c_{Rf} is the upstream feed concentration, and

$$\frac{dc_R}{dx} = 0 \text{ at } x = L \quad [25]$$

—the Danckwerts (19), Wehner-Wilhelm (20) conditions when axial diffusion and dispersion are included. The conditions on η depend on the placement of the counterelectrode. For an upstream counterelectrode, the current density is zero in the matrix phase at the cathode inlet and equal to $-i$ (the total current density to the electrode) in the pore solution phase; the opposite is true at the cathode outlet. Application of these conditions to Eq. [20] yields appropriate conditions on η

$$\frac{d\eta}{dx} = -\frac{i}{\kappa} \text{ at } x = 0 \quad [26]$$

and

$$\frac{d\eta}{dx} = \frac{i}{\sigma} \text{ at } x = L \quad [27]$$

To reduce the large number of parameters, Eq. [22]-[27] may be expressed in dimensionless form: Material balance

$$\frac{d\theta}{dy} = D' \frac{d^2\theta}{dy^2} - \frac{\theta - P_1 \exp\left[(\alpha_{aR}/\alpha_{cR} + 1)\eta'\right]}{1 + \exp(\eta')} \quad [28]$$

Potential distribution

$$\frac{d^2\eta'}{dy^2} = P_2 \left\{ P_3 \exp(-\alpha_{cS}\eta'/\alpha_{cR}) \left[1 - P_4 \exp\left(\frac{\alpha_{aS} + \alpha_{cS}}{\alpha_{cR}} \eta' \right) \right] + \frac{\theta - P_1 \exp\left[(\alpha_{aR}/\alpha_{cR} + 1)\eta'\right]}{1 + \exp(\eta')} \right\} \quad [29]$$

Boundary conditions

$$\theta - D' \frac{d\theta}{dy} = 1 \text{ and } \frac{d\eta'}{dy} = P_5 I^* \text{ at } y = 0 \quad [30]$$

and

$$\frac{d\theta}{dy} = 0 \text{ and } \frac{d\eta'}{dy} = -P_6 I^* \text{ at } y = aL \quad [31]$$

where θ is the reactant concentration divided by its value upstream in the feed. Here the distance and the overpotential were made dimensionless in such a manner as to emphasize the pertinent physical phenomena. The dimensionless coordinate y, as suggested by the limiting current analysis (1), is the physical distance x divided by the quantity $1/a = v/a\, k_m$, representing the effective depth of penetration of the reaction into the electrode at the limiting current. In this way, the parameter

$$D' = (D_R + D_a)\, a\, k_m / v^2 \quad [32]$$

relates to the effect of axial diffusion and dispersion. For flow-through reactors, effects of convection, reaction, and mass transfer to the wall are dominant, while axial diffusion and dispersion are secondary. Thus, it it appropriate to have these latter effects included in only one parameter, D', and to have the dimensionless coordinate y determined by the dominant effects. However, at low Péclet numbers, $v/a\, D_o < 100$, axial diffusion and dispersion effects are not small (14), and the inclusion of the corresponding terms in Eq. [28] and in the boundary condition (Eq. [30]) is necessary.

The local overpotential η was made dimensionless by the relation

$$\exp(\eta') = -\frac{n\mathbf{F}k_m c_{Rf}}{s_R i_{oR,\text{ref}}} \exp(\alpha_{cR}\mathbf{F}\eta/RT) \quad [33]$$

which also shifts the overpotential by an additive amount based on the exchange current density $i_{oR,\text{ref}}$ of the main reaction and the feed concentration c_{Rf} of the reactant. This shift is in recognition of the fact that the electrode will be run with a relatively high electric driving force, so that the main reaction can be carried to a high degree of completion. The backward term of the main reaction is then characterized by the parameter

$$P_1 = \left(-\frac{s_R i_{oR,\text{ref}}}{n\mathbf{F}k_m c_{Rf}} \right)^{1 + \alpha_{aR}/\alpha_{cR}} \quad [34]$$

which will be insignificant when the reaction exhibits Tafel behavior.

Under these conditions, the relative importance of the ohmic potential drop within the porous electrode is characterized by the parameter

$$P_2 = \frac{\alpha_{cR} n\mathbf{F}^2 v^2 c_{Rf}}{s_R a\, k_m RT} \left(\frac{1}{\kappa} + \frac{1}{\sigma} \right) \quad [35]$$

and the side reaction is characterized by

$$P_3 = -\frac{s_R i_{oS,\text{ref}}}{n\mathbf{F}k_m c_{Rf}} e^{\alpha_{cS}\mathbf{F}\Delta U/RT} \left(-\frac{n\mathbf{F}k_m c_{Rf}}{s_R i_{oR,\text{ref}}} \right)^{\alpha_{cS}/\alpha_{cR}} \quad [36]$$

at the half-wave potential of the main reaction. The half-wave potential may be calculated from Eq. [33] by setting η' equal to zero. This is seen from the second term on the right side of Eq. [28], which represents the dimensionless transfer current of the primary reaction—setting η' equal to zero yields a value in the denominator of two. The backward term of the side reaction is characterized by the magnitude of the parameter

$$P_4 = \left(-\frac{s_R i_{oR,\text{ref}}}{n\mathbf{F}k_m c_{Rf}} \right)^{\frac{\alpha_{aS} + \alpha_{cS}}{\alpha_{cR}}} \exp\left[-\mathbf{F}(\alpha_{aS} + \alpha_{cS})\Delta U/RT\right] \quad [37]$$

The parameters P_5 and P_6 represent the relative importance of the ohmic potential drop in the pore solution phase and the matrix phase, respectively, and are related to the parameter P_2

$$P_5 = -\frac{\sigma P_2}{\sigma + \kappa} \quad [38]$$

and

$$P_6 = -\frac{\kappa P_2}{\sigma + \kappa} \quad [39]$$

so that

$$-P_2 = P_5 + P_6 \quad [40]$$

The total current density i to the reactor was made dimensionless with the limiting current density that would exist if all the reactant in the feed were completely reacted

$$I^* = \frac{s_R i}{n\mathbf{F}v c_{Rf}} \quad [41]$$

Numerical Solution

The governing Eq. [28] and [29] were first linearized about a trial solution, and then, along with the boundary conditions (Eq. [30] and [31]), cast in finite-difference form accurate to order h^2, where h is the dimensionless distance between the mesh points, and solved by a numerical technique developed by Newman (23).

Unfortunately, it was found that the standard central-difference approximations of the derivatives were not sufficiently accurate to approach the limiting-current result, which can be calculated analytically. This anomalous behavior was primarily due to the high degree of nonuniformity in the current and concentration distributions near the front of the electrode. Therefore, to obtain accurate results, new finite-difference approximations to the derivatives were developed (see Appendix).

Results

Comparisons between model predictions and experiments.—For the calculations to be presented, the counterelectrode is upstream, the primary reaction is the deposition of copper, and the side reaction is the generation of dissolved hydrogen. Two types of data on copper removal (1, 13) are utilized to demonstrate the effectiveness of the model. In the first data set (1), predictions of the over-all reactor performance are tested. This includes predicting the current-potential behavior of the porous cathode and the effluent concentration of the reactant species. The remaining data set (13) is used to test model calculations of the current distribution within the porous cathode.

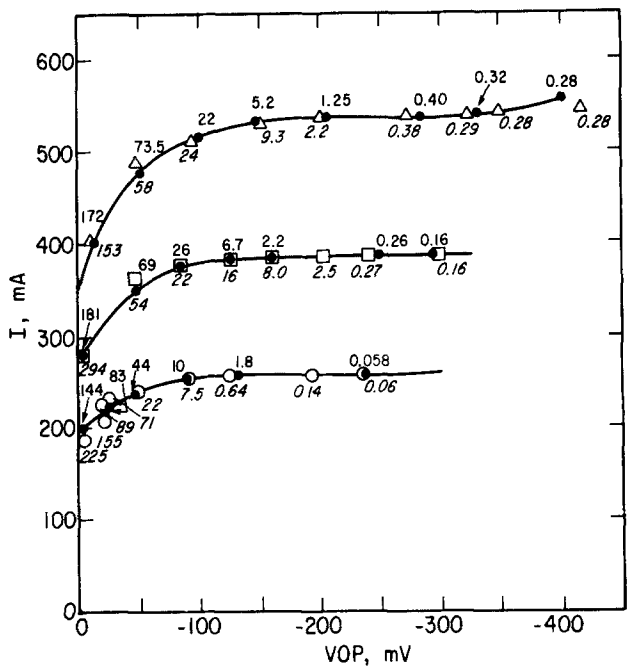

Fig. 1. Current-potential curves for an electrode 10.1 cm in diam and 6 cm deep (1), packed with porous carbon flakes and chips. Open symbols are experimental data points; closed symbols are calculated. Calculated effluent concentrations (in milligrams/liter) are indicated above the corresponding points in upright type; experimental values are given in italic type below the corresponding data points. The flow rate was 8 cm³/min for the circles, 12 cm³/min for the squares, and 16 cm³/min for the triangles.

Figure 1 displays the model fit to the data of Bennion and Newman (1) for copper removal using a porous carbon electrode. The quantities I and VOP are the total current to the reactor and the potential of the cathode current collector relative to a saturated calomel reference electrode placed in the effluent stream, respectively. The experimental effluent copper concentrations (in mg/liter) are shown as the numbers below each curve corresponding to the open triangles △, squares □, and circles ○. The numbers above each curve correspond to the solid circles ●, and are the calculated values of the effluent copper concentration. Values of the parameters used to fit the data shown in Fig. 1 are given in Table I.

Five parameters were adjusted to obtain agreement between the calculated and experimental values in Fig. 1: one value of the exchange current density for copper deposition was determined by fitting the data at the left side of the top curve; one value of the exchange current density for hydrogen evolution attempts to fit the rise in the current due to the observed onset of hydrogen evolution at the right side of the top curve; and three values of the mass-transfer coefficient k_m corresponding to the three different flow rates were determined mainly by the effluent concentration at the right side of each experimental curve.

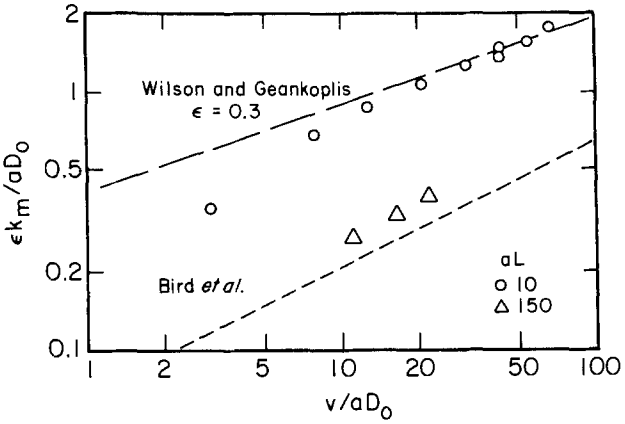

Fig. 2. Correlation of the Sherwood number as a function of Péclet number and dimensionless electrode thickness aL. Open triangles come from a fit of the data of Fig. 1; open circles are the result of Appel and Newman (26). Two correlations from the literature are also shown.

In Fig. 2, the fitted values of k_m (shown by the open triangles △) have been plotted in terms of the dimensionless Sherwood number $\epsilon k_m/aD_o$ as a function of the dimensionless Péclet number v/aD_o. The upper dashed line is the Wilson and Geankoplis correlation (24)

$$\frac{\epsilon k_m}{aD_o} = \frac{1.09}{[6(1-\epsilon)]^{2/3}} \left(\frac{v}{aD_o}\right)^{1/3} \qquad [42]$$

and the lower dashed line is a correlation suggested by Bird *et al.* (25)

$$\frac{\epsilon k_m}{aD_o} = 0.91\,\epsilon \left(\frac{v}{a\nu\psi}\right)^{0.49} \psi^2 \left(\frac{\nu}{D_o}\right)^{1/3} \qquad [43]$$

where a value of $\epsilon = 0.3$ has been used in calculating each line. Also shown in Fig. 2 by means of the open circles ○ are the data of Appel and Newman (26) where $\epsilon = 0.372$. It should be noted that it has been assumed that the dimensionless correlations for k_m (given by Eq. [42] and [43]) have been corrected for dispersion. Appel's results have not, and therefore k_m in this case is fundamentally a different quantity [see Ref. (14) for this correction and a discussion of different definitions of k_m].

Table I. Values of the parameters used in fitting the data in Fig. 1 and in generating the curves in Fig. 5-11

$\alpha = 25$ cm^{-1}	$\epsilon = 0.3$	$D_o = 6 \times 10^{-6}$ cm²/sec
$\kappa_o = 0.17$ mho/cm	$\sigma = 10^4$ mho/cm	$s_R = -1$

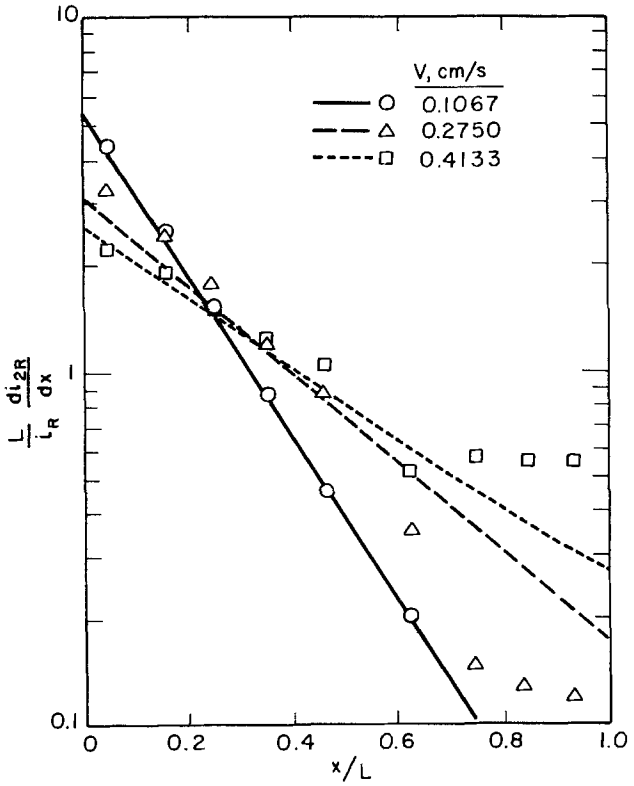

Fig. 3. Normalized distribution of copper deposition. Experimental data (13) and calculations are for deposition from a 2 mM cupric solution onto a bed 0.4 cm thick with a porosity of 0.64 and a specific surface area of 260 cm^{-1}, constructed of layers of Pt screens.

The model fit of the limiting current-distribution data of Alkire and Gracon (13) for copper deposition on platinum screen electrodes is shown in Fig. 3. The transfer current density for the main reaction di_{2R}/dx has been normalized by the total current density i_R due to the primary reaction and the electrode length L. A uniform current distribution would correspond to a horizontal line at an ordinate value of 1. Values of the parameters used to fit these data are given in Table II.

The data for the smallest flow rate (v = 0.1067 cm/sec) were fitted first by using literature values of the exchange current densities for copper deposition and hydrogen evolution on copper (23, 27) (any i_o values would work, however, since the data (13) were obtained at the limiting current), and adjusting the value of the mass-transfer coefficient k_m to obtain reasonable agreement between the calculated and experimental values. This value for the mass-transfer coefficient was then used to change the coefficient in the Wilson-Geankoplis correlation (24) (given by Eq. [42]) to 0.85

Table II. Values of the parameters used in fitting the data in Fig. 3

a = 260 cm^{-1}	ϵ = 0.64	D_o = 7.6 × 10^{-6} cm^2/sec
κ_o = 0.55 mho/cm	σ = 10^4 mho/cm	s_R = −1

$$\frac{ek_m}{aD_o} = \frac{0.85}{[6(1-\epsilon)]^{2/3}}\left(\frac{v}{aD_o}\right)^{1/3} \quad [44]$$

The remaining lines in Fig. 3 for the higher flow rates were then calculated using this expression for the mass-transfer coefficient and no additional adjustment of parameters.

It may be noted that Alkire and Gracon (13) proposed that the estimated specific interfacial area be reduced by a multiplier of 0.81 to yield an adjusted value. When used in the Wilson-Geankoplis correlation (24), this effectively reduces the coefficient to 0.947 if one continues to use the estimated value. In this case, the value of ak_m (which is the quantity which enters into the model equations) is reduced by a multiplier of 0.704 from the value which would be predicted by the Wilson-Geankoplis correlation and the estimated area. By our reducing the coefficient from 1.09 to 0.85, we have effectively reduced the value of ak_m by a multiplier of 0.78. Alkire and Gracon's choice of the multiplier of 0.81 was evidently based on the values of the total limiting current, not on a fit of the distribution data as in Fig. 3.

Theoretical predictions.—Again the results presented are divided into two categories, microscopic distributions and over-all reactor performance. For the calculations which follow, the counterelectrode is upstream, the primary reaction is again the deposition of copper, and the side reaction is the generation of dissolved hydrogen.

Figure 4 shows the reaction rate distributions for the primary electrode reaction only, at and below the limiting current, for the physical parameters and dimensionless parameters (corresponding to v = 3.328 × 10^{-3} cm/sec) in Table I, but with P_3 and P_4 equal to zero (*i.e.*, a single electrode reaction). The limiting

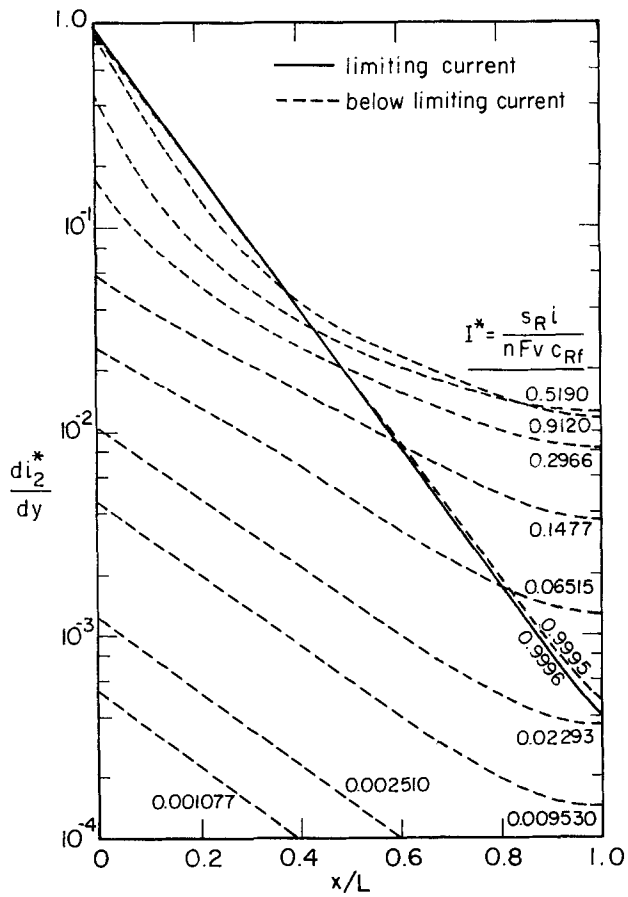

Fig. 4. Reaction distribution for copper deposition in the absence of a side reaction, calculated for αL = 8.663, D' = 0.1217, and P_2 = −3.254.

current distribution includes the effect of axial diffusion, and dispersion and was determined from the analysis of Newman and Tiedemann (14)

$$\frac{di_2^*}{dy} = \frac{Be^{-y/B} + (B-1)\,e^{By/D'} \exp\left[-\alpha L\left(\frac{1}{B}+\frac{B}{D'}\right)\right]}{B^2 - \frac{D'}{B}(B-1)\exp\left[-\alpha L\left(\frac{1}{B}+\frac{B}{D'}\right)\right]} \quad [45]$$

where

$$i_2^* = \frac{s_R i_2}{n\mathbf{F}vc_{Rf}} \quad [46]$$

and

$$B = \frac{1+\sqrt{1+4D'}}{2} \quad [47]$$

Integration of Eq. [45] from $y = 0$ to $y = \alpha L$ yields an expression for the total dimensionless limiting current density to the electrode

$$-i_2^*(0) = I^* = \frac{1 - e^{-\alpha L/B} + \frac{D'(B-1)}{B^3}\exp\left[-\alpha L\frac{1}{B}+\frac{B}{D'}\right](e^{B\alpha L/D'}-1)}{1-\frac{D'}{B^3}(B-1)\exp\left[-\alpha L\frac{1}{B}+\frac{B}{D'}\right]} \quad [48]$$

Figures 5-8 show current, potential, current efficiency, and concentration distributions within a reactor operating at conditions which correspond to the point on the upper curve of Fig. 1 where VOP = −403 mV and the outlet concentration is 0.28 mg/liter.

In Fig. 9 the solution-phase ohmic potential drop $\Delta\Phi_2$ across a reactor has been plotted as a function of the electrical driving force at the back of the reactor $(\Phi_1 - \Phi_2)_{\alpha L}$ for two cases: (*i*) the primary reaction only and (*ii*) when the side reaction is included, for values of the physical parameters and dimensionless parameters (corresponding to $v = 3.328 \times 10^{-3}$ cm/sec) in Table I. The ohmic potential drop has been made dimensionless with the quantity

$$\Delta\Phi_2' = \frac{n\mathbf{F}vc_{Rf}}{s_{R\kappa}}\frac{v}{ak_m} \quad [49]$$

which is an estimate of the ohmic potential drop across a reactor operating at the limiting current (1) when the effluent concentration is zero and the effects of axial diffusion and dispersion are negligible. The potential $(\Phi_1 - \Phi_2)_{\alpha L}$ is the potential of the cathode current collector relative to a copper reference electrode (with a concentration of c_{Rf} in the reference electrode compartment) placed at the back of the reactor.

At large negative values of $(\Phi_1 - \Phi_2)_{\alpha L}$ when only the primary reaction is considered, the ordinate approaches the value predicted by the limiting-current analysis of Newman and Tiedemann (14)

$$\frac{\Delta\Phi_2}{\Delta\Phi_2'} = \frac{\left(1+\frac{D'}{B^2}\right)[B^2 - (\alpha L + 1 + D')e^{-\alpha L/B}]}{B + \frac{D'}{B^2}(1-B)\exp\left[-\alpha L\frac{1}{B}+\frac{B}{D'}\right]} - \frac{D'}{B} \quad [50]$$

and has a value of 1.1057 in this case.

Figures 10 and 11 show that the effect on the current-potential curve if the fluid velocity is increased

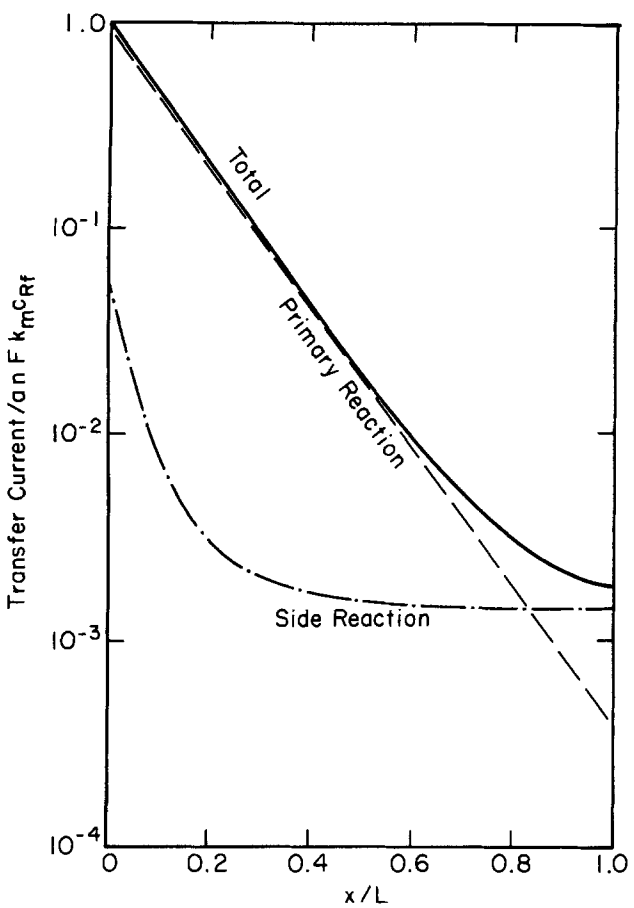

Fig. 5. Current distributions for deposition of copper and generation of dissolved hydrogen within a porous electrode with fluid flow from left to right, calculated for $v = 0.003328$ cm/sec, $a = 25$ cm^{-1}, $\epsilon = 0.3$, $L = 6$ cm, $c_{Rf} = 0.0105$ mole/liter, and VOP = −0.403V relative to a calomel reference electrode in the dilute-product stream.

or the feed concentration decreased. The curve labeled with a v in Fig. 10 corresponds to the upper curve in Fig. 1, and the curve labeled $10^{-2}M$ in Fig. 11 corresponds to the lower curve in Fig. 1. (See also Table I.)

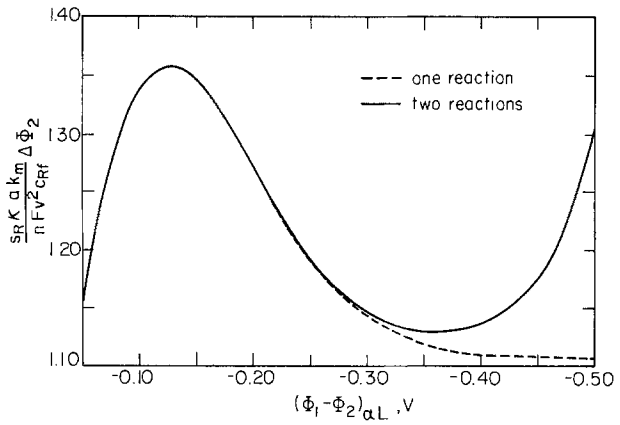

Fig. 9. Ohmic potential drop across the solution within the porous electrode—under the conditions of Fig. 4 and also with simultaneous generation of dissolved hydrogen.

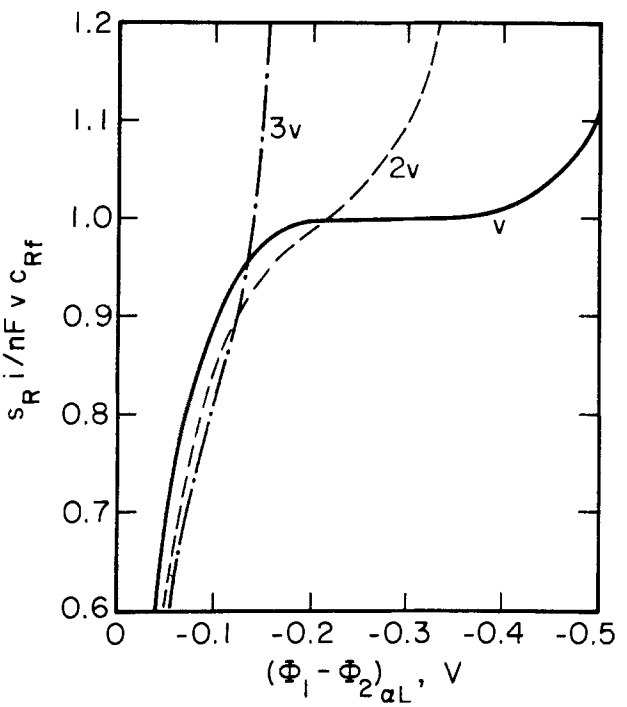

Fig. 10. Effect of flow rate on the current-potential curve. Operation at flow rates substantially above the design value (1) (here v = 0.003328 cm/sec) obscures the limiting-current plateau because of the high ohmic potential drop in the solution phase. For parameter values, see Table I.

Discussion

Agreement between model calculations and the experimental data of Bennion and Newman (1) shown in Fig. 1 should be considered satisfactory. However, the values of the parameters found by fitting the data need some clarification.

The fitted values of the exchange current densities for copper deposition and hydrogen evolution on carbon (see Table I) are 0.035 and 70 times the reported literature values ($i_{o,Cu} = 10^{-3}$ A/cm^2 (23) and $i_{o,H_2} = 10^{-7}$ A/cm^2 (27)) for these reactions on copper, respectively. However, it should not be interpreted that there is anything fundamental about these fitted values since the data are insufficient at the extreme values of the current to provide for their accurate evaluation. We also wish to emphasize that we do not suggest this as a method for determining fundamental kinetic parameters, since the bed is operating with a highly

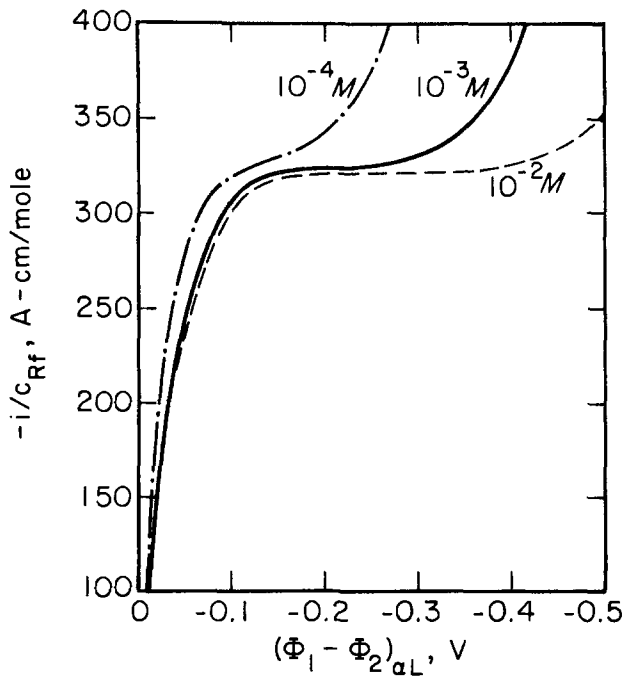

Fig. 11. Effect of feed concentration on the current-potential curve. Low concentrations correspond to low currents for the primary reaction, and these are easily obscured by the side reaction even in the absence of a significant ohmic potential drop within the reactor. For parameter values, see Table I.

nonuniform current density and mass-transport limitations dominate the data in certain regions.

The fitted values of k_m (given in Table I), determined mainly by the effluent concentration at the right on the experimental curves of Fig. 1 and plotted in Fig. 2, show a clear dependence on the velocity as follows

$$\frac{\epsilon k_m}{aD_o} = 0.07054\left(\frac{v}{aD_o}\right)^{0.5454} \qquad [51]$$

Data obtained in this manner (1) yield fundamental information about k_m [*e.g.*, Appel and Newman (26)]. Unfortunately, the value used for the specific interfacial area a of 25 cm^{-1} is an effective value and may be low by a factor of 4 to 12 (28). If larger values of a are used, the value of k_m will decrease, and the triangles plotted in Fig. 2 would move down and to the left toward lower values of the Sherwood and Péclet numbers.

The purpose of Fig. 2 is to call attention to the fact that the behavior of k_m is not well established in this flow region. Newman and Tiedemann (14) have suggested, for a restricted range of flow rates: $1 \leq Pe < 10^4$ and $Re < 10$, where Pe is the Péclet number v/aD_o and Re is the Reynolds number $v/a\nu$, there should exist an entry region such that the local mass-transfer coefficient is larger than the asymptotic value for deep bed electrodes, and that the average value of the mass-transfer coefficient will be dependent on the quantity aL. Since most measurements for k_m involve short electrodes, small aL (*e.g.*, Eq. [42] of Wilson and Geankoplis (24), where $1.8 \leq aL \leq 27$), the entire electrode may be within the entry region and will therefore predict too large a value for k_m when aL is large (deep beds), as is the case for Bennion and Newman's data (1).

Also in Fig. 2, a correlation found in Bird *et al.* (25) (Eq. [43]) has been extrapolated by at least an order of magnitude in Reynolds number below the range for which the correlation has been tested. However, this equation appears to give a conservative estimate for k_m, and may be useful for design purposes until better correlations are developed for this region of flow.

In Fig. 3 agreement between model calculations and the experimental data of Alkire and Gracon (13) for the smallest flow rate (0.1067 cm/sec) is good. The almost linear behavior on the semilog plot for the predicted limiting current distribution is expected based on the analysis of Bennion and Newman (1) for the special case of mass-transfer control. As expected, the value of k_m which best fits the data (given by Eq. [44]) is less than that predicted by Eq. [42] of Wilson and Geankoplis (24) due to the large value of $aL = 104$. The reason for using Eq. [44] at the two higher flow rates is to have some basis for changing k_m with the velocity since no data on the effluent concentration are given in Ref. (13) to enable an estimation of k_m as was done with the data of Bennion and Newman (1) in Fig. 1. (A graph of the total limiting current is presented by Alkire and Gracon (13), from which one could infer the effluent concentration if side reactions are negligible. However, values from this graph cannot be obtained with great precision, and, as pointed out by Appel and Newman (26), the total current is an inherently inaccurate method of measuring the mass-transfer coefficient when the overall conversion is close to 100%.)

In Fig. 3, at least two reasons are responsible for the discrepancies between the model calculations and the experimental data at the higher flow rates. First, the data are a replot of data taken from an arithmetic plot and are subject to error. Second, k_m may not be a constant throughout the electrode as assumed in the model. However, the discrepancies in Fig. 3 are considerably less than those between Alkire and Gracon's Fig. 6 and 9, where the lack of explanation has already been noted in the literature (18). One may speculate as to why the agreement between the model of Alkire and Gracon and their data is poor. This is perhaps due to the inadequate representation of the derivatives in the governing equations at the limiting current by standard central-difference approximations. New finite-difference approximations to the derivatives (developed in the Appendix) are required as discussed earlier.

The reaction rate distribution when only the metal deposition reaction is considered is plotted in Fig. 4 for various fractions of the limiting current. The effect of axial diffusion and dispersion is apparent in the limiting current distribution as di_2^*/dy is less than one at x/L equal to zero. The fact that I^* is not equal to one for the limiting current distribution is because mass-transfer limitations exist within the electrode, and therefore a small fraction of the feed concentration will escape unreacted.

For an appreciable fraction of the limiting current ($I^* > 0.9$), the reaction rate near the front of the electrode is high and decreases almost exponentially, similar to the behavior of the limiting current distribution (see Eq. [45]). Near the back of the electrode, the rate of reaction for the limiting current distribution is small because most of the copper is removed near the front of the electrode. Therefore, the reaction rates below the limiting current are greater at the back of the electrode (for values of $I^* > 0.03$), and are more uniform than the limiting current distribution. Actually, the reaction rate at the back of the electrode ($di_2^*/dy|_{y=aL}$) increases as the value of I^* decreases from 0.9996 to 0.7273, passes through a maximum at $I^* = 0.7273$, and then decreases monotonically with I^*. Thus, the effective depth of penetration of the reaction into the electrode also has a maximum near $I^* = 0.7273$.

For small values of the current ($I^* < 0.03$), the reaction rate distributions take on the same shape and can be described by a model with linear electrode

kinetics and no concentration variations [see Euler and Nonnenmacher (29) and Newman and Tobias (30)].

Figure 5 shows the relative rates of reaction for the primary reaction and the side reaction as they are distributed throughout the porous electrode. The total current density to the electrode was chosen close to the limiting current ($I^* = 1.038$) for the deposition of copper. Consequently, the reaction rate for the primary reaction decreases almost exponentially with distance (see Eq. [45]), as the solution is depleted with copper while flowing through the electrode. The side reaction, generation of dissolved hydrogen, responds mainly to the electric driving force between the solid matrix and the electrolytic solution. Its rate is high near the entrance to the porous electrode, and drops to a nearly constant value near the rear. The reason for this can be seen in Fig. 6, which represents the variation in the solution-phase potential Φ_2 for a counterelectrode placed upstream of the working electrode. The matrix conductivity is high, and therefore its potential Φ_1 is nearly a constant. The solution potential Φ_2 varies little near the rear because the current carried in the solution is small in this region. Because the driving force $(\Phi_1 - \Phi_2)$ is essentially uniform for some distance at the back of the electrode, measurement of $(\Phi_1 - \Phi_2)_{\alpha L}$ can lead to a lower bound thermodynamic estimate of the minimum concentration attainable in a flow-through porous electrode [see Trainham and Newman (31) for details].

In Fig. 7, the local current efficiency actually goes through a slight maximum near $x/L = 0.18$. The current efficiency is low at the entrance because the high electric driving force leads to a relatively high rate for the side reaction. For somewhat larger values of x, the rate of the side reaction decreases more rapidly than the primary reaction, and the local current efficiency rises. However, the primary reaction rate continues to decrease with distance because of the depletion of copper ions, and consequently the local current efficiency eventually drops to about 23% at the rear of the electrode. One might well ask, "Why not eliminate the last 40% of the thickness of the electrode?"

Figure 8 shows the concentration of copper ions through the thickness of the electrode. The high electric driving force at the entrance results in a very low wall concentration there. As the electric driving force decreases with x, the wall concentration rises toward the bulk value. With the diminishing reaction rate through the next part of the electrode, the wall concentration is able to decrease also, despite the smaller electric driving force in this region. We can also see from this figure that the bulk concentration is depleted by an additional factor of 20 in the last 40% of the electrode, despite the lowered current efficiency in this region. This additional metal ion removal can be achieved with relatively little additional expense for the added electrode thickness, and virtually no added cost due to added ohmic potential drop.

In Fig. 9, the ohmic potential drop across the solution within the reactor exhibits a maximum and then a minimum as the driving force increases at the back of the reactor. The maximum occurs at $I^* = 0.95$, and is due to a combination of effects: (*i*) the driving force is high, and the current is only increasing slowly, (*ii*) the reaction rate at the back of the electrode goes through a maximum at a value of $I^* = 0.7273$ as discussed previously in Fig. 4, and (*iii*) the driving force, though high, is not large enough for the side reaction to contribute substantially to the ohmic potential drop. For larger values of $(\Phi_1 - \Phi_2)_{\alpha L}$, the ohmic potential drop decreases due to a decreasing rate of reaction at the back of the electrode. Thus, the depth of penetration of the reaction is decreasing at $I^* = 0.95$. This was shown clearly in Fig. 4 as the primary reaction approaches the limiting current distribution.

The minimum in the ohmic potential occurs simultaneously with the minimum in the total reaction rate at the back of the electrode $(di_2^*/dy)|_{\alpha L}$. At this point the rate of the side reaction becomes significant, and the ohmic drop increases accordingly.

We wish to emphasize that the existence of a local maximum and local minimum is dependent on the physical parameters and operating conditions. For example, if the exchange current density for the side reaction were significantly larger relative to the primary reaction, the driving force required to make the side reaction occur to a significant extent would be much less. Thus instead of the ohmic potential drop exhibiting a local maximum due mainly to the effects of the primary reaction (or lack of effect of the side reaction), the side reaction becomes the controlling factor and $\Delta\Phi_2$ increases monotonically with increasing $(\Phi_1 - \Phi_2)_{\alpha L}$.

Another way to achieve a similar result (using the same physical parameters) is to increase the ohmic potential drop by increasing the superficial velocity as shown in Fig. 10. The reactor cannot be operated at even twice the superficial velocity without loss of the limiting current-plateau and a lack of a local maximum and a local minimum in the ohmic potential drop, which is due to extensive interference by the side reaction. In harmony with the quantitative design principles (1), these calculations show that an increase in the superficial velocity increases the ohmic potential drop in the solution so that there is either excessive side reaction at the entrance to the porous electrode or a failure to maintain the limiting-current condition near the exit. A decrease in the feed concentration as shown in Fig. 11 will also increase the side reaction relative to the primary reaction and cause the limiting-current plateau to become less distinct. The ability to calculate the current distributions below the limiting current and in the presence of a side reaction permits one to determine the economically optimum operating conditions and even permissible operating conditions when the side reaction accounts for a substantial fraction of the total current, and there is a penalty for making the electrode thicker because the side reaction does not necessarily decrease with increasing distance through the electrode.

Conclusion and Summary

A theoretical model for flow-through porous electrodes has been described for the specific application to metal-ion removal from dilute streams. A new set of dimensionless parameters has been suggested from the analysis, which characterize the relative importance of the following physical phenomena within a flow-through porous electrode: axial diffusion and dispersion (D'), backward rate of the primary reaction (P_1), ohmic potential drop (P_2), and forward (P_3) and backward (P_4) rates of the side reaction. Satisfactory agreement between model predictions and experimental data on over-all reactor performance and deposit distributions has been achieved.

The knowledge of distributions of current, potential, and concentration in the presence of a side reaction above and below the limiting current of the primary reaction makes it possible to design and optimize an electrode system for the most economical removal of metal ions, but this design may only be accomplished if there are sufficient experimental data. Most important are values for the specific interfacial area a, the mass-transfer coefficient k_m, and the exchange current densities for the primary reaction and the side reaction.

APPENDIX

To obtain a more accurate representation of the derivatives in Eq. [28]-[31] more of the physics needed to be incorporated in their dependence. This was done by considering the concentration distribution at the limiting current, which decreases exponentially with electrode thickness (1, 14). With this in mind, a new variable was defined

$$\theta = e^C \qquad [A\text{-}1]$$

Now apply this equation to the upstream boundary condition on the concentration (Eq. [30]) to obtain

$$e^C\left(1 - D'\frac{dC}{dy}\right) = 1 \qquad [A\text{-}2]$$

Next introduce the central-difference approximations at the first real mesh point ($j = 2$, mesn point 1 is an image point)

$$\theta_2\left(1 - D'\frac{C_3 - C_1}{2h}\right) = 1 \qquad [A\text{-}3]$$

or

$$\theta_2\left(1 - \frac{D'}{2h}\ln\frac{\theta_3}{\theta_1}\right) = 1 \qquad [A\text{-}4]$$

If θ is approximately exponential in distance, then C will be approximately linear, and less error will be introduced when the derivative is approximated by a finite-difference form in the variable C.

Similarly, a central-difference approximation for the axial diffusion and axial dispersion term in Eq. [28] can be derived for any interior mesh point j

$$D'\frac{d^2\theta}{dy^2} = \frac{D'\theta_j}{h^2}\left[\frac{1}{4}\left(\ln\frac{\theta_{j+1}}{\theta_{j-1}}\right)^2 + \ln\left(\frac{\theta_{j+1}\theta_{j-1}}{\theta_j^2}\right)\right] \qquad [A\text{-}5]$$

The resulting material balance equation at any interior mesh point j now becomes

$$\frac{\theta_j}{2h}\ln\frac{\theta_{j+1}}{\theta_{j-1}} = \frac{D'\theta_j}{h^2}\left[\frac{1}{4}\left(\ln\frac{\theta_{j+1}}{\theta_{j-1}}\right)^2 + \ln\left(\frac{\theta_{j+1}\theta_{j-1}}{\theta_j^2}\right)\right] - J_{Rj} \qquad [A\text{-}6]$$

where

$$J_{Rj} = \frac{\theta_j - P_1 e^{(\alpha_{aR}/\alpha_{cR}+1)\eta'_j}}{1 + e^{\eta'_j}} \qquad [A\text{-}7]$$

To check *a posteriori* the over-all application of Faraday's law, whereby the integral of the transfer current J_R for the principal reaction should be related to the difference between the inlet and outlet concentrations of the principal reactant, one should use an integration formula J_R which also takes account of the approximately exponential dependence of J_R on distance.

So that the integrated current is also correct for the side reaction, combine Eq. [28] and [29] by eliminating J_R from both equations to yield

$$\frac{d}{dy}\left(\frac{1}{P_2}\frac{d\eta'}{dy} + \theta - D'\frac{d\theta}{dy}\right) = J_S \qquad [A\text{-}8]$$

where

$$J_S = P_3 \exp\left(-\alpha_{cS}\eta'/\alpha_{cR}\right)\left[1 - P_4\exp\left(\frac{\alpha_{aS} + \alpha_{cS}}{\alpha_{cR}}\eta'\right)\right] \qquad [A\text{-}9]$$

Next express the outer derivative in Eq. [A-8] as a central difference written between points halfway between mesh points

$$\frac{1}{h}\left[\left(\frac{1}{P_2}\frac{d\eta'}{dy} + \theta - D'\frac{d\theta}{dy}\right)_{j+1/2} - \left(\frac{1}{P_2}\frac{d\eta'}{dy} + \theta - D'\frac{d\theta}{dy}\right)_{j-1/2}\right] = J_S \qquad [A\text{-}10]$$

Now express the terms $\theta - D'd\theta/dy$ halfway between two mesh points using Eq. [A-1] and the values of θ at the adjacent mesh points (see also Eq. [A-2])

$$\left(\theta - D'\frac{d\theta}{dy}\right)_{j+1/2} = \sqrt{\theta_j\theta_{j+1}}\left(1 - \frac{D'}{h}\ln\frac{\theta_{j+1}}{\theta_j}\right) \qquad [A\text{-}11]$$

and

$$\left(\theta - D'\frac{d\theta}{dy}\right)_{j-1/2} = \sqrt{\theta_j\theta_{j-1}}\left(1 - \frac{D'}{h}\ln\frac{\theta_j}{\theta_{j-1}}\right) \qquad [A\text{-}12]$$

With these approximations and a central-difference expression for the derivative of η', the resulting equation for the potential at any interior mesh point j becomes

$$\frac{1}{P_2}\frac{\eta'_{j+1} + \eta'_{j-1} - 2\eta'_j}{h^2} + \frac{\sqrt{\theta_j\theta_{j+1}}}{h}\left(1 - \frac{D'}{h}\ln\frac{\theta_{j+1}}{\theta_j}\right) - \frac{\sqrt{\theta_j\theta_{j-1}}}{h}\left(1 - \frac{D'}{h}\ln\frac{\theta_j}{\theta_{j-1}}\right) = J_{Sj} \qquad [A\text{-}13]$$

Similarly, to treat the upstream boundary condition for the potential, integrate Eq. [A-8] from zero to $h/2$ to yield

$$\left(\frac{1}{P_2}\frac{d\eta'}{dy} + \theta - D'\frac{d\theta}{dy}\right)_{h/2} - \left(\frac{1}{P_2}\frac{d\eta'}{dy} + \theta - D'\frac{d\theta}{dy}\right)_0 = \frac{h}{2}J_{Sj} \qquad [A\text{-}14]$$

Use the same approximations as above for $y = h/2$, and use the boundary conditions in Eq. [30] to obtain (for $j = 2$)

$$\frac{2}{h}\frac{1}{P_2}\frac{\eta'_{j+1} - \eta'_j}{h} + \frac{2}{h}\sqrt{\theta_j\theta_{j+1}}\left(1 - \frac{D'}{h}\ln\frac{\theta_{j+1}}{\theta_j}\right) - \frac{2}{h}\left(\frac{P_5}{P_2}I^* + 1\right) = J_{Sj} \qquad [A\text{-}15]$$

With Eq. [A-13] at the interior mesh points, this corresponds then to a trapezoidal integration of the transfer current J_S over the thickness of the porous electrode.

The governing finite-difference Eq. [A-6] and [A-13], along with the upstream boundary conditions [A-4] and [A-15] were then linearized about a trial solution and solved simultaneously with the downstream boundary condition for θ and η' using Newman's technique (23). The new approximations to the derivatives in concentration provided accurate values for θ and η' at the mesh points without introducing anomalous values for the integrated current.

Steady-State Polarization at Porous, Flow-Through Electrodes with Small Pore Diameter

II. Irreversible Kinetics for One-Electron and Consecutive Two-Electron Transfer Reactions

B. G. Ateya*,[1] and L. G. Austin*

ABSTRACT

In this paper a model is proposed for the performance of a porous flow-through electrode working on a redox couple, for one-dimensional systems with fine pores. The model includes the combined effects of mass transfer by forced convection and axial diffusion, ohmic potential drop in the pore electrolyte, and activation polarization, on the over-all current-polarization relations. The cases of front and rear reactant supply are treated. The treatment is extended to the case of a consecutive two-electron transfer reaction where the rate equation is rather complicated. Experimental results are presented to test several aspects of the model. The agreement between theory and experiment is generally good for moderate ohmic effects.

Porous flow-through electrodes have several advantages over porous diffusion electrodes mainly because of the high mass transfer rates and high limiting currents possible. It is, therefore, desirable to be able to describe quantitatively the dependence of the over-all rate of reaction in such an electrode on the physical and catalytic properties of the electrode matrix and the properties of reactant-product system and supporting electrolyte.

This system is currently attracting considerable attention. It has been suggested for removing dissolved copper (1-3) and antimony ions (4) and for converting ferrous into ferric ions in industrial waters (5). The original work on this system is due to Perskaya and Zaidenman (6) and was subsequently extended simultaneously by Gurevich and Bagotsky (7) and Austin *et al.* (8). There are several other treatments, some of which are concerned with mass transfer and ohmic effects, neglecting activation polarization (1, 3), or with activation and ohmic polarizations in the near reversible region and neglecting concentration polarization (9, 10). Wroblowa *et al.* (11, 12) have also presented theoretical treatments of this system and experimental results using the I_2/I^- reversible system (11). They recently (12) treated the effects of a pre-electrode diffusional boundary layer and of axial diffusion on the limiting current and on concentration, current, and potential distributions under conditions of very low flow speeds, $u \simeq 10^{-5}$-10^{-3} cm/sec. Only the case of rear reactant supply was considered and no experimental testing was offered.

There is a large body of semiempirical treatments presented by Sioda (13) essentially for packed and folded (80 mesh) screen electrodes operating on reversible reactions. Alkire *et al.* (14), using packed (100 mesh) screen electrodes, found that the limiting current is critically dependent on flow rate and electrode thickness. They presented a mathematical model to explain the lower efficiency (obtainable at high flow rates and/or thin electrodes) in terms of internal mass transfer limitations.

The experimental results presented in the above works were obtained on reversible electrode reactions and mostly at electrodes of very low specific surface area (large pore diameter). Such electrodes are of limited importance because of their low reactive surface area and the loss of their efficiency (poor reactant utilization) due to radial diffusion limitations (15-18).

This paper deals with the case of irreversible, one-electron transfer kinetics where activation polarization is needed to support large reaction rates, and it considers rear and front reactant supply over the entire current-polarization range. The treatment is extended to the case of a consecutive two-electron transfer kinetics where the rate equation is considerably more complicated. The theoretical predictions are tested experimentally by using the Sn^{2+}/Sn^{4+} redox couple which is highly irreversible, and has reasonably well-understood kinetics (19-21). The corresponding model for reversible kinetics has been presented and tested in part I (22).

Theoretical Steady-State Treatments

The system is assumed to be one dimensional such that radial diffusion is fast and velocity and concentration entrance effects are negligible. The electrode has narrow (~1 μm radius) and highly interlinked pores such that velocity, current, concentration, and potential are uniform at any depth inside the electrode. The electrical resistivity of the electrode material is very low compared to that of the electrolyte which is assumed to be constant and independent of reactant concentration. The latter is achieved by using a supporting electrolyte which also ensures that effects of ionic migration and streaming potential are negligible.

Key words: flow-through electrodes, polarization, axial diffusion, single and consecutive electron transfer, rear and front supply.

An isothermal system is considered, and for simple one-electron transfer kinetics the rate expression is chosen as

$$i = i_o[(R/R_b)\exp(\alpha\eta/b) - (P/P_b)\exp(\beta\eta/b)] \quad [1]$$

Figure 1 illustrates rear and frontal reactant supply.

In the absence of significant diffusion, or assuming equal diffusion coefficients of reactant and product, a mass balance gives $R(x) + P(x) = R_b + P_b$. Thus

$$i = i_o\{(R/R_b)[\exp(\alpha\eta/b) + \gamma\exp(\beta\eta/b)] - (1+\gamma)\exp(\beta\eta/b)\} \quad [2]$$

where $\gamma = R_b/P_b$. The steady-state mass transfer equation in dimensionless form is (22)

$$d\bar{i}(\bar{x})/d\bar{x} = \theta d^2\bar{R}(\bar{x})/d\bar{x}^2 - d\bar{R}(\bar{x})/d\bar{x} \quad [3]$$

where $\theta = D_{eff}/Lu$, $\bar{i}(\bar{x}) = i(\bar{x})/i_L$, $\bar{x} = x/L$, and $\bar{R}(\bar{x}) = R(x)/R_b$. A kinetic balance on an element dx using the dimensionless form of Eq. [2] gives

$$d\bar{i}(\bar{x}) = \bar{i}_o\{\bar{R}(\bar{x})[\exp(\bar{\alpha\eta}(\bar{x})) + \gamma\exp(\bar{\beta\eta}(\bar{x}))] - (1+\gamma)\exp(\bar{\beta\eta}(\bar{x}))\}d\bar{x} \quad [4]$$

where $\bar{i}_o = i_oSL/i_L$, $\bar{\eta}(\bar{x}) = \eta(x)/b$, and $\bar{R}(\bar{x})/R_b\cdot\bar{i}_o$ is an index of the effective rate constant *vs.* the rate of reactant input and hence is called the reversibility index. For algebraic convenience, the bars are dropped and it is to be understood that the parameters are in dimensionless form. Combining Eq. [4] with [3] gives

$$\theta\frac{d^2R(x)}{dx^2} - \frac{dR(x)}{dx} - i_o\{R(x)[\exp(\alpha\eta(x)) + \gamma\exp(\beta\eta(x))] - (1+\gamma)\exp(\beta\eta(x))\} = 0 \quad [5]$$

This equation relates concentration and potential distributions to the independent variables of the system, *e.g.*, i_o, α, θ, γ, and x, based on a combination of kinetic and mass transfer relations. In general this must also be combined with Ohm's law. Solutions are presented for various cases of ohmic and mass transfer control.

Case 1. Mass transfer effects, negligible ohmic effects.—If the effect of mass transfer dominates over the effect of ohmic resistance in the pore electrolyte, as would apply for low values of R_b and high specific conductivity of electrolyte, the equation simplifies considerably since η is then independent of distance x. In this case, frontal or rear supply gives the same answer; we will consider rear supply. The boundary conditions are taken as (22)

$$1 = R(+0) - \theta(dR/dx)_{x=+0} \quad [6a]$$

$$(dR/dx)_{x=1} = 0 \quad [6b]$$

Formally, at $x = -0$, $R(-0) = 1$, since no reaction occurs before $x = 0$. As discussed before (22), however, when the reaction approaches reversible kinetics (large i_o), the concentration change at $x = 0$ approaches a δ function and the concentration gradient from the $+0$ direction can be nonzero. In practice, some reaction will occur on the outer face and in the two-dimensional pore mouth so that a gradual change of concentration gradient would occur over $x = \pm 0$.

Equation [5] is put into a form suitable for solution with these boundary conditions by using the substitutions $f = \exp(\alpha\eta) + \gamma\exp(\beta\eta)$, $\psi(x) = R(x) - [(1+\gamma)\exp(\beta\eta)/f]$ giving

$$d^2\psi(x)/dx^2 - d\psi(x)/dx - i_of\psi(x) = 0 \quad [5a]$$

The solution to Eq. [5a] is

$$R(x) = ((1+\gamma)\exp(\beta\eta)/f) + C_1\exp(m_1x) + C_2\exp(m_2x) \quad [7]$$

where

$$m_1 = (1/2\theta)(1 + \sqrt{1 + 4i_o\theta f})$$

$$m_2 = (1/2\theta)(1 - \sqrt{1 + 4i_o\theta f})$$

$$C_1 = -C_2m_2\exp(m_2)/(m_1\exp(m_1))$$

$$C_2 = \frac{1 - (1+\gamma)\exp(\beta\eta)/f}{(1-\theta m_2) - (1-\theta m_1)m_2\exp(m_2)/m_1\exp(m_1)}$$

The relation between current and concentration is given by (22)

$$i(x) = 1 - R(x) + \theta dR(x)/dx \quad [8]$$

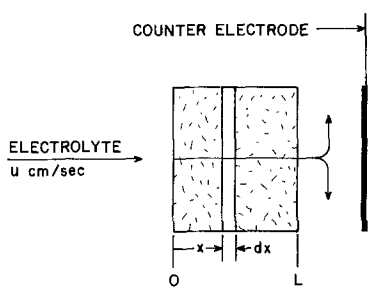
And since $dR(x)/dx = 0$ at $x = 1$, Eq. [7] and [8] lead to

$$i = 1 - [((1+\gamma)\exp(\beta\eta)/f) + C_1\exp(m_1) + C_2\exp(m_2)] \quad [9]$$

where i is the dimensionless total current density at $x = 1$.

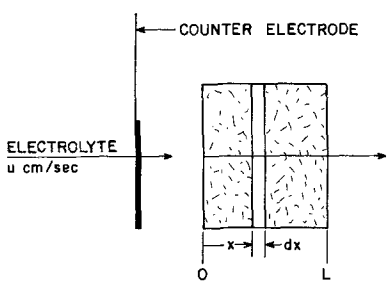
When $\eta = 0$, Eq. [7] gives $R(x) = 1$ for any value of x, which corresponds to open-circuit conditions. At $x = 0$ and i_o is very large, both Eq. [7] and [10] reduce to the case of reversible reaction as considered previously, giving $R(+0) < 1$ and $i(+0) > 0$ for $\eta > 0$.

For the special case of the diffusion coefficient tending to zero, θ tends to zero, and it is readily shown that the limit of Eq. [7] for $\theta = 0$ is



$$R(x) = (1/f)[(1+\gamma)\exp(\beta\eta) + (\exp(\alpha\eta) - \exp(\beta\eta))\exp(-i_ofx)] \quad [10]$$

which is the expression obtained previously by Austin *et al.* (8). As the diffusion coefficient tends to zero, the total current density is given by $i = 1 - R(1)$ where $R(1)$ is given by Eq. [10] with $x = 1$. Thus



$$i_{\theta=0} = (1/f)[\exp(\alpha\eta) - \exp(\beta\eta)][1 - \exp(-i_of)] \quad [11]$$

For irreversible conditions such that $\exp(\beta\eta) \simeq 0$, $i = 1 - \exp[-i_o\exp(\alpha\eta)]$ or

$$\eta = (2.3/\alpha)\log[\log(1/(1-i))] - 2.3\log(i_o/2.3) \quad [12]$$

a. REAR REACTANT SUPPLY

b. FRONT REACTANT SUPPLY

Fig. 1. Model of a flow-through electrode showing rear and front reactant supply.

Thus if axial diffusion is negligible a plot of the polarization *vs.* log (log $(1/(1-i))$) in the irreversible region for the case of negligible ohmic potential drop in the pore electrolyte gives a straight line of a slope of 120 mV (for $\alpha = 0.5$ at 25°C).

Case 2. Mass transfer and ohmic effects, rear supply.—Assuming the specific conductivity of the electrolyte is constant Ohm's law in dimensionless form is

$$i(x) = (1/\Delta)d\eta(x)/dx \qquad [13]$$

where Δ is the index of ohmic effect, $\Delta = i_L L\rho/b$. The boundary conditions are $(d\eta/dx)_{x=0} = 0$ and $(d\eta/dx)_{x=1} = i\Delta$ in addition to those of Eq. [6]. Under conditions used in the computations, which are not near reversible, it was assumed that $(d\eta/dx)_{x=+0} = 0$. In addition, the relation between total current i and the exit reactant concentration is clearly $R(1) = 1 - i$. Equations [4], [8], and [13] plus the boundary conditions were simultaneously solved using a finite difference numerical technique (see later). The solutions gave η_0 and η_L as a function of i_o, Δ, θ, and i where η_L and i are the effective over-all polarization and current density of the electrode.

Case 3. Mass transfer and ohmic effects, front supply.—For front reactant supply where the direction of current flow is the same as fluid flow (see Fig. 1), Ohm's law is

$$i(x) = -(1/\Delta)d\eta(x)/dx \qquad [14]$$

In addition to the mass transfer boundary conditions of Eq. [6], the boundary conditions of polarization are now $(d\eta/dx)_{x=0} = i\Delta$ and $(d\eta/dx)_{x=1} = 0$. The integration of Eq. [3] for this case gives

$$i(x) = i - [1 - R(x) + \theta dR(x)/dx] \qquad [15]$$

The simultaneous solution of Eq. [4] with Eq. [14] and [15] using these boundary conditions was performed using a finite difference technique (see later).

Case 4. Mass transfer and ohmic effects, rear supply, consecutive two-electron transfer reaction.—The mechanism of a consecutive two-electron transfer reaction, *e.g.*, Sn^{2+}/Sn^{4+}, is

$Sn^{2+} \rightarrow Sn^{3+} + e^-$	Step r
$Sn^{3+} \rightarrow Sn^{4+} + e^-$	Step o
$Sn^{2+} \rightarrow Sn^{4+} + 2e^-$	Over-all reaction

and the over-all kinetic equation has the form (19-21)

$$i = 2i_{o,r} \exp(\alpha_r \eta/b)$$

$$\frac{(R/R_b) - (1 + \gamma - \gamma R/R_b)\exp(-2\eta/b)}{1 + (i_{o,r}/i_{o,o})\exp(-(1 - \alpha_r + \alpha_o)\eta/b)} \qquad [16]$$

At higher anodic polarizations, the denominator of Eq. [16] is approximately one and it reduces to the simpler form

$$i = 2i_{o,r}(R/R_b)\exp(\alpha_r \eta/b) \qquad [17]$$

where the first step becomes rate limiting. At lower currents the polarization obtained from Eq. [16] is higher than that obtained from Eq. [17]. At low anodic polarization such that $1 << (i_{o,r}/i_{o,o})\exp(-(1 - \alpha_r + \alpha_o)\eta/b)$ Eq. [16] becomes

$$i = 2i_{o,o}\exp((1 + \alpha_o)\eta/b) \qquad [18]$$

and the second step becomes rate limiting. Equation [18] is a Tafel equation with an apparent anodic transfer coefficient greater than one. As pointed out by Vetter (19) this arises from a fairly rapid charge transfer reaction (step r) preceding a slow charge transfer reaction (step o) on the reduction side.

Equations [8], [13], [16], and the boundary conditions were solved simultaneously by the method used in case 2.

Numerical Solution Technique

Equations [4] and [13] were combined in finite difference form. Analysis of the resulting algorithm showed that accurate and stable computations were only obtainable for

$$\epsilon < 0.2/\alpha\Delta \qquad [19]$$

where ϵ is the dimensionless spatial interval, that is, the electrode thickness is divided into $1/\epsilon$ elements. It was found that $\epsilon = 0.01$ was satisfactory for most of the values of Δ used in the computations.

As was concluded in part I one can arbitrarily chose only one variable out of η_o, η_L, i, $R(+0)$. It is necessary to search for the unique set of values of the rest of variables which satisfies all of the differential equations and the boundary conditions.

Mass balance on the first spatial element gives $i(1) + R(1) - \theta(dR/dx)_{x=\epsilon} = 1$, where $(dR/dx)_{x=\epsilon}$ is the diffusive flux out of the first element and $i(1)$ is the amount of current generated by the reaction in the first element and the total amount of current at $x = \epsilon$. In finite difference form this mass balance equation and the boundary condition of Eq. [6] are

$$R(1) - (\theta/\epsilon)(R(2) - R(1)) = 1 - i(1) \qquad [20]$$

$$R(0) + (\theta/\epsilon)(R(0) - R(1)) = 1 \qquad [21]$$

Thus we must search for a value of $R(0)$ such that $0 < R(1)/R(0) < 1$. The correct $R(0)$ is that which satisfies $0 \leq R(I)/R(I-1) \leq 1$, $I = 1$ to N where N is the total number of space elements. In addition the final boundary condition must be satisfied, *i.e.*, $i(N) + R(N) = 1$. This equation is obtained from Eq. [6] and [8]. The search technique used to find the correct value of $R(0)$ was a simple dichotomous search method. A first try value of $R(0)$ was obtained as below. If $R(I)/R(I-1)$ exceeded unity then $R(0)$ was decreased by $\Delta R(0)$. This was continued until either the correct $R(0)$ was obtained or $R(I)/R(I-1)$ became ≤ 0. At that stage $R(0)$ was increased by $(1/2)\Delta R(0)$ and computations were repeated. The next step involved $(1/4)\Delta R(0)$ and the process was continued until the above conditions were satisfied simultaneously. A maximum of about 15 iterations were needed to converge on the correct $R(0)$ for large θ values, whereas for small θ values 5 iterations were sufficient.

At low θ values, a simpler procedure is to assume the diffusive flux in and out of the first element to be equal, *i.e.*, $R(2) - R(1) = R(1) - R(0)$ and then subtract Eq. [20] from [21]. Thus $i(1) = R(0) - R(1)$. Substituting in [21] and rearranging gives $R(0) = 1 - (\theta/\epsilon)i(1)$. Thus, starting with $R = 1$ a value of $i(1)$ was obtained using the kinetic equation (Eq. [4] with $dx = \epsilon$). This value was used to get improved $R(0)$ and $R(1)$ values using the above two equations. The average of $R(0)$ and $R(1)$ was substituted in Eq. [4] to get an improved $i(1)$ which was used to get a better set of $R(0)$ and $R(1)$ and so on. This iteration was continued until [error in $R(0)$] $\leq 0.01\%$.

The choice of η_o depends on the magnitudes of Δ, θ, and $\bar{i}_o$. For large values of Δ and $\bar{i}_o$ or a small value of θ, a small η_o produces a large total current. η_o was chosen such that the current produced by the entire electrode is less than or equal to the limiting current.

For the solution of case 3, the technique involved choosing a value of total current i, which defines the exit reactant concentration $R(L)$, and then searching for the correct value of exit polarization which simultaneously satisfies the boundary conditions and differential equations and gives the current at the entry side the same as that originally chosen. A dichotomous search technique was again used. The compiler time was about 0.3 sec on an IBM 360. An execution time of 7 sec was sufficient to compute the entire current-polarization curve in more than 10 increments for case 3 under the following conditions: $\theta = 0.005$, $\bar{i}_o = 10^{-2}$, $\alpha = 0.5$, $\Delta = 100$, and $\epsilon = 0.01$.

Results of Computations

The orders of magnitude of the values of controlling parameters were calculated to be $\Delta = 0$ to 200; $\theta = 0$ to 1.0, and $\bar{i}_o = 10^{-4}$ to 10.

For case 1, negligible ohmic effects, it was found that the solution of Eq. [9] with $\theta = 0$ to $\theta = 10^{-2}$ gave essentially identical results over all ranges of $\bar{i}_o$. It must be concluded that axial diffusion does not play a significant role for θ values within this range under conditions of pure mass transfer control. Its influence became detectable, however, at $\theta > 0.1$. The results are shown in Fig. 2 where the curves are the same for $\theta = 0$ or 10^{-2}. Figure 2 also shows that as axial diffusion increases, the polarization needed to support a certain current increases. As reasoned previously (8), in the irreversible region ($\bar{\eta} > 4$) the shape of the curve is independent of $\bar{i}_o$ but is displaced parallel to the current axis by a factor $(2.3/\alpha)$ for each decade change of $\bar{i}_o$, *i.e.*, 0.12V, for $\alpha = 0.5$, $b = 0.025$V (room temperature).

For case 2, rear supply, Fig. 3 shows the results for values of θ up to 10^{-3} and $\bar{i}_o = 10^{-2}$. It is again concluded that the influence of axial diffusion is insignificant for small values of θ ($\theta \leq 10^{-3}$) for the values of Δ used. The effect of Δ, of course, is to increase η_L and to decrease η_o, hence it forces the reaction to occur closer to the exit face. This is shown in Fig. 4, where the profiles of current density and polarization through the electrode are given for $i/i_L \to 1$. It is readily appreciated that the value of $\bar{i}_o$ affects the polarization at which some value of i/i_L is obtained, but does not affect the current density profiles for a given i/i_L and Δ, whereas Δ does have a strong influence on these profiles.

As the value of Δ increases the reaction becomes more concentrated into a smaller space, consequently the concentration and current density profiles become steeper and axial diffusive flux increases. It is expected, therefore, that as Δ increases the effect of axial diffusion becomes detectable at smaller values of θ. This is consistent with the product $\Delta\theta$ being the controlling parameter for axial diffusion, which was concluded from the analytical solutions in part I (22).

Figures 5 and 6 show the equivalent results for case 3, frontal supply. Again, changing $\bar{i}_o$ does not affect the shape of the profiles in Fig. 6, although it would change the position of the polarization curves. It was again concluded that the effect of axial diffusion was insignificant for θ up to 10^{-3}. As would be expected, the value of θ at which axial diffusion effects became noticeable is lower for frontal than for rear supply

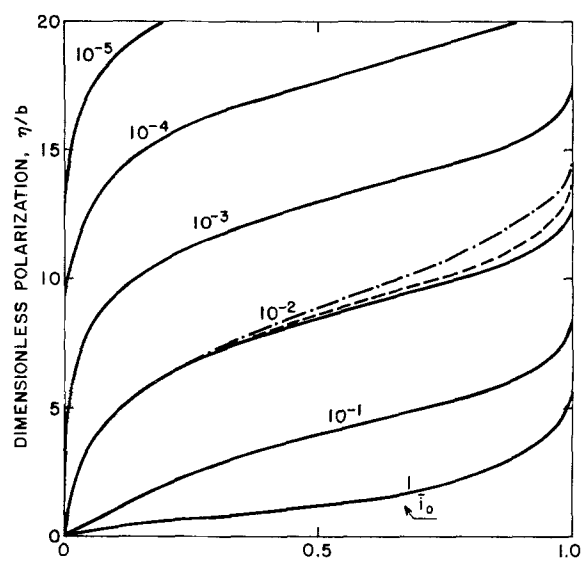


Fig. 2. Effect of $\bar{i}_o$ and θ on the current-polarization curves for case 1: – – – $\theta = 0.1$, –·–·– $\theta = 1$, ——— $\theta \leq 10^{-2}$.

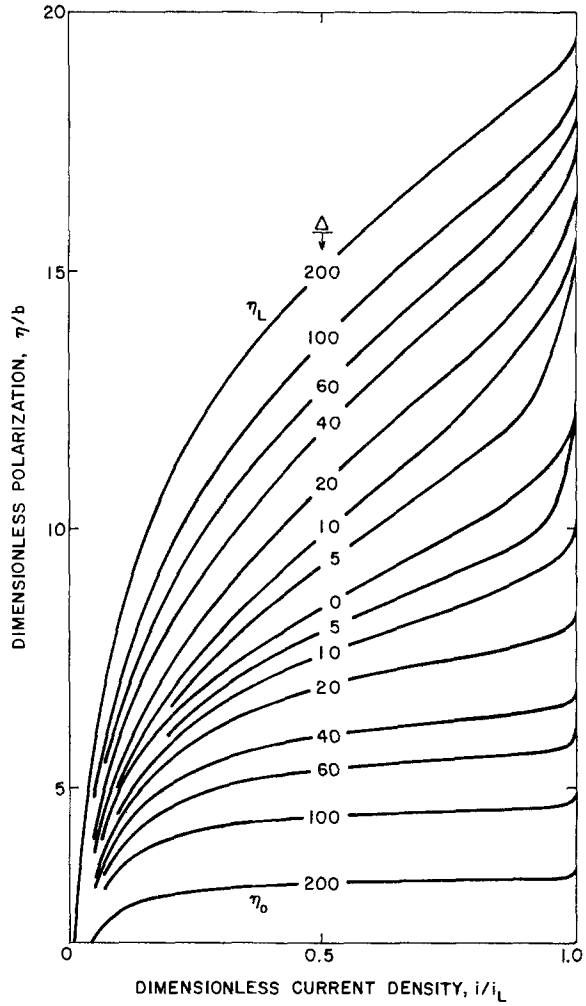

Fig. 3. Effect of ohmic parameter Δ on current-polarization curves; rear supply, case 2: $\bar{i}_o = 10^{-2}$, $\alpha = 0.5$, $\gamma = 1$, and $\theta \leq 10^{-3}$.

since for a given θ, Δ, and i/i_L the concentration profile has a steeper maximum gradient at $x = 0$ for case 3 than for case 2. For $\Delta = 50$, this value of θ is $(5)(10^{-3})$. At total currents less than i_L, the effect of axial diffusion is less, and, of course, a finite reactant concentration exits at the emergent face, see Fig. 7. At high values of θ, Eq. [6] shows that the entering concentration, $R(0)/R_b$, can be significantly less than 1.0, depending on the value of θ. This is demonstrated in Fig. 8; the effect is also noticeable in Fig. 7.

Comparison of Fig. 3 and 5 shows that for a certain current output and otherwise identical conditions the

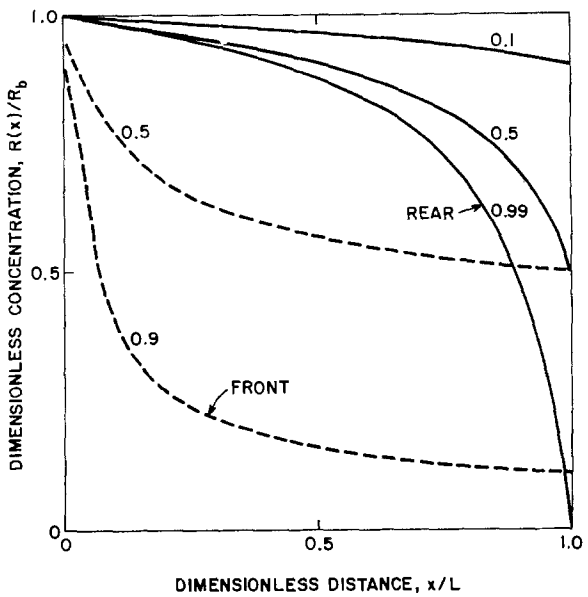

Fig. 7. Concentration profiles within the electrode as a function of i/i_L, $\Delta = 60$, $\theta \leq 10^{-3}$. The numbers on the curves refer to i/i_L; $\bar{i}_o$, α, and γ are the same as in Fig. 5.

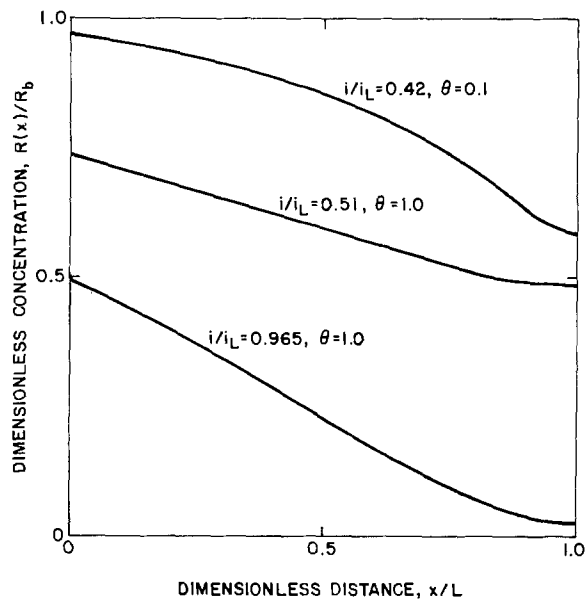

Fig. 8. Concentration profiles under conditions of high θ for case 2: $\Delta = 50$. Both i/i_L and θ are indicated on the curves, $\bar{i}_o = 10^{-2}$, $\alpha = 0.5$, and $\gamma = 1$.

frontal supply mode requires less total polarization than that of rear supply. The difference increases as the limiting current is approached.

Considering case 4, the consecutive two-electron transfer case, one limiting case is at low anodic polarization when Eq. [16] reduces to Eq. [18]. The computed current-polarization relations then have the same shape as those in Fig. 3, but the value of the η/b scale is reduced by the factor $0.5/(1 + \alpha_o)$, since the apparent value of α is $1 + \alpha_o$, and the same numerical result is obtained in the integration for any definite value of $\alpha_{app}\eta/b$.

At high anodic polarizations, the first step becomes rate limiting with a normal Tafel slope and the computed current-polarization curves become exactly superimposible on those of Fig. 3 (23) for the same values of i_o, α, γ, Δ, and θ. At the intermediate polarizations, as in the experimental work reported later, both steps affect the rate but to different extents. Fig-

ure 9 shows the effect of the exchange current of the second step, $i_{o,o}$ on the current-polarization curves. These results are computed using $i_oSL/i_L = (2.1)(10^{-2})$, $\Delta = 8$, and $\alpha_o = \alpha_r = 0.41$ (20). The ratio of the exchange currents of second to first steps was taken as 0.5, 0.1, 0.01, and 0.001 and only the front face polarization was plotted. When the value of this ratio is 0.5 or 0.1 each curve falls exactly on the curve obtained by assuming no rate limitation due to the second step (solid line). As the ratio $i_{o,o}/i_{o,r}$ is decreased the second step becomes slower and starts to affect the over-all rate. Obviously the smaller the exchange current of the second step the more its effects become apparent.

As the value of the normalized exchange current of the first step is increased, a larger portion of the limiting current will occur at relatively low polarization and the second step becomes more predominant.

Experimental Techniques

To test the equations it was necessary to use redox couples with known irreversible kinetics. The couple chosen was stannous-stannic chlorides in 4*N* HCl. Determination of the diffusion coefficient and kinetic parameters of this couple on basal and edge planes of nonporous pyrolytic graphite were reported elsewhere (21). The porous electrodes were prepared from SP1 graphite used previously (22). The graphite particles are flakes of 20-30 μm average diameter and 0.3-0.4 μm thickness. The pore radius was ~1 μm as estimated using the technique of liquid permeability (23). The details of the experimental technique, *e.g.*, cell design, flow systems, etc. were the same as in part I (22).

The double layer capacity of the porous electrode was measured by a triangular voltage sweep technique (24), using 0.5M K_2SO_4 at potentials between 0.1 to 0.6V *vs.* SCE. The electrode used for double layer capacity measurements was thin (~0.1 cm) and a scan rate of 80 mV/sec was used to minimize distributed capacitance effects.

Experimental Results

Results were obtained using the rear mode of reactant supply. The double layer capacity of basal plane of pyrolytic graphite in 0.5M K_2SO_4 was found to be 32 ± 3 μF/cm^2 (25) in the potential range of 0.1 to 0.6V *vs.* SCE. Allowing for some residual surface roughness, the true specific double layer capacity must be somewhat less than this. Using a value of 25 μF/cm^2, the measured double layer capacity of the porous electrode gave a value of almost (2)(10^4) cm^2/g. This compares with a BET area of about (2)(10^4) cm^2/g, and a liquid permeability area of (6)(10^{-3}) cm^2/g. These areas are in the expected order, since the permeability area is a smoothed area and less than the true area. It was concluded from double layer capacity measurements that for an electrode of 50% porosity, S was about (2.2)(10^4) cm^2/cm^3. For an electrode of 0.5 cm thickness, i_oSL is (1.1)(10^4)i_o.

Kinetic data on 0.005M Sn^{2+} and 0.012M Sn^{4+} in 4*N* HCl showed that even with the relatively high internal area of the porous graphite electrodes, the reversibility index was still low enough to obtain irreversible conditions, since $2i_{o,r}$ is ~0.1 μA/cm^2 of basal plane surface.

For small limiting currents, the value of Δ is small and the difference between entrance and exit face polarization is then negligible and case 1 applies. If axial diffusion is negligible a plot of experimental results according to Eq. [12], case 1, should be a straight line of slope $(2.3b/\alpha)$ and intercept 2.3 log $(i_oSL/2.3i_L)$. Figure 10 shows this plot for a value of Δ of about 2; the low current region should be ignored since it represents the more complex kinetic form of Eq. [16] at low currents. The slope is 145 mV/decade, giving $\alpha = 0.43$ which is in good agreement with the value $\alpha = 0.41$-0.43 measured on a rotating disk electrode (21). Again, the intercept gives an experimental value of i_oSL of 0.65 mA/cm^2, and since SL based on double layer capacity measurements is (1.1)(10^4), the value of $2i_{o,r}$ per unit of true area is (0.6)(10^{-7}) A/cm^2. This compares with $2i_{o,r} = (1.1)(10^{-7})$ A/cm^2 measured on basal plane of pyrolytic graphite. (Areas determined using a double layer capacity of 25 μF/cm^2.) Table I lists the experimental conditions and the values of the various parameters used in the computations for the results shown in Fig. 10, 13, and 14.

At higher current densities, the separation between η_L and η_o increases and a technique was derived for handling the data based on the theoretical computations in Fig. 3. Figure 11 shows the values of $(\eta_L - \eta_o)$ at $i/i_L = 0.5$ as a function of Δ, taken from Fig. 3. Since α is 0.43 and $b = 63$ mV, $(\eta_L - \eta_o)_{0.5}$ for experimental results can be converted to dimensionless values; then Fig. 11 was used to estimate Δ. Since for a

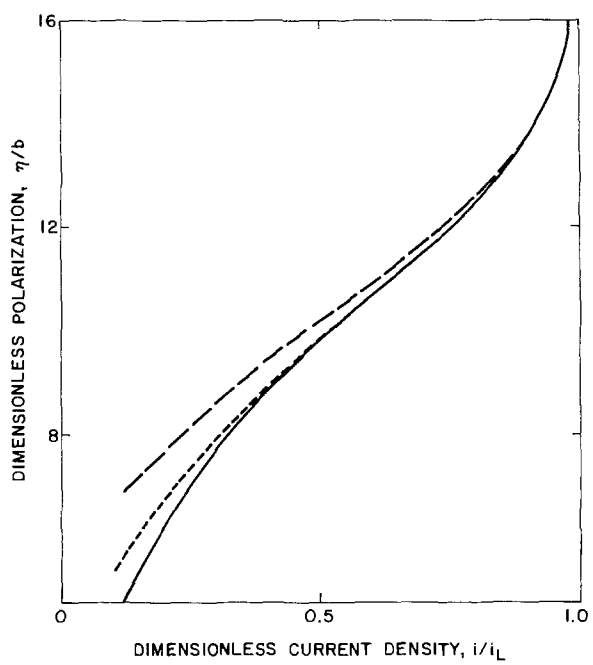

Fig. 9. The effect of the exchange current density of the second step $i_{o,o}$ on the current-polarization curves of a consecutive two-electron transfer reaction, case 4: $i_{o,o}/i_{o,r} = 0.01$ for – – – and 0.001 for – – –, $i_{o,r} = 10^{-2}$, $\alpha_r = 0.43$, $\gamma = 1$, and $\Delta = 8$.

Table I. Experimental and theoretical conditions used in Fig. 10, 13, and 14

Figure	Experimental conditions			Theoretical parameters					
	u (cm/min)	$[Sn^{2+}]$ (M)	i_L (mA/cm²)	$\bar{i}_o$	Δ	α_r	α_o	γ	$i_{o,r}/i_{o,o}$
10	0.80	0.005	14	0.046	0	0.43	—	0.42	—
13	3.42	0.005	55	0.021	8	0.41	0.41	0.42	1000
14	4.02	0.03	388	0.009	50	0.41	0.41	0.20	1000

given electrode system, Δ is proportional to the limiting current, a plot of Δ values determined in this way for a number of limiting currents should be a straight line of slope $L\rho_{eff}/b$. This is shown in Fig. 12, and gives $\rho_{eff} = 7.3$ Ω-cm and, hence, a tortuosity factor of 2.4. This technique illustrates that numerical or analytical solutions which report η_L and η_o are more useful than solutions which report only η_L, since η_o is very easily measured experimentally and additional useful information can then be obtained.

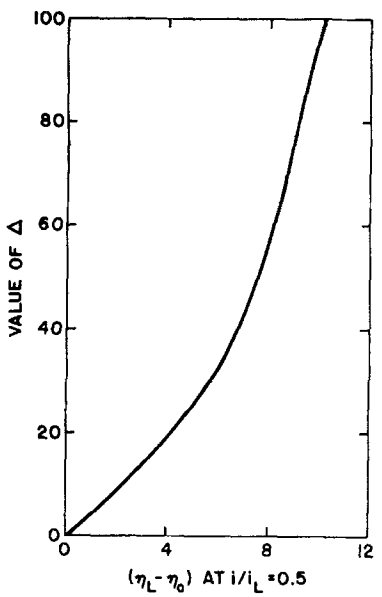

Fig. 11. Effect of ohmic parameter Δ on the difference between entrance and exit face polarizations at $i/i_L = 0.5$; obtained from Fig. 3.

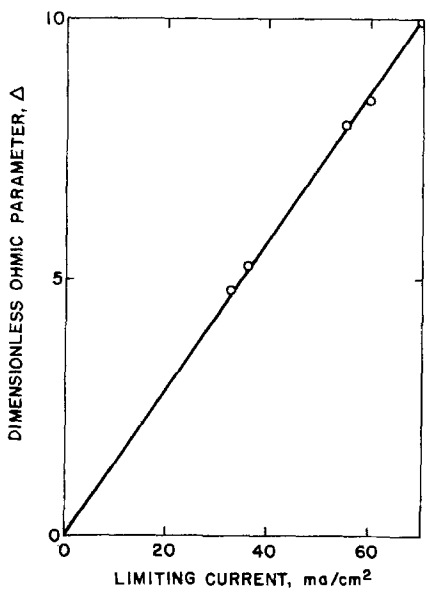

Fig. 12. Plot of value of ohmic parameter Δ vs. limiting current, Sn^{2+}/Sn^{4+}, 4N HCl. Δ was obtained from experimental results using Fig. 11.

We now have all the data necessary to compute theoretical values of η_L and η_o *vs.* i/i_L for comparison with the equivalent experimental results for case 4. A typical plot is shown in Fig. 13 for $i_L = 52$ mA/cm². By trial and error the value of $\bar{i}_o$ which gives the best agreement between the experimental and theoretical curves was found to be $(2.1)(10^{-3})$, assuming $\Delta = 8$, $\gamma = 0.4$, $\alpha_r = \alpha_o = 0.41$, and $i_{o,r}/i_{o,o} = 1000$. The last two values were reported by Lerner and Austin (20) and the value of Δ was obtained from the experimental results using Fig. 11.

Since $i_L = 55$ mA/cm² and $SL = (1.1)(10^4)$, the value of $2i_{o,r}$ per unit of true (basal plane) surface area obtained from this data is 10^{-7} A/cm². Again this compares well with the value of $(1.1)(10^{-7})$ A/cm² measured on the basal plane of pyrolytic graphite (21). The dashed lines in Fig. 13 show the model predictions for a one-electron transfer and otherwise identical conditions. Good agreement is obtainable only in the high polarization region where a single electron transfer controls the over-all rate, the rate of which is given by Eq. [17]. The experimental values of Δ and $\bar{i}_o$ obtained from Fig. 13 were used to predict the corresponding values for $i_L = 30$ and 66 mA/cm², and the current-polarization curves were computed for these conditions. The computed results were in good agreement with the experimental results.

For a large limiting current of 388 mA/cm², that is $\Delta = 55$, the results are shown in Fig. 14. The theoretical line in Fig. 14 was obtained using $(2i_{o,r}SL/i_L) = 0.009$, $\alpha_r = \alpha_o = 0.41$, and $i_{o,r}/i_{o,o} = 1000$. It is clear

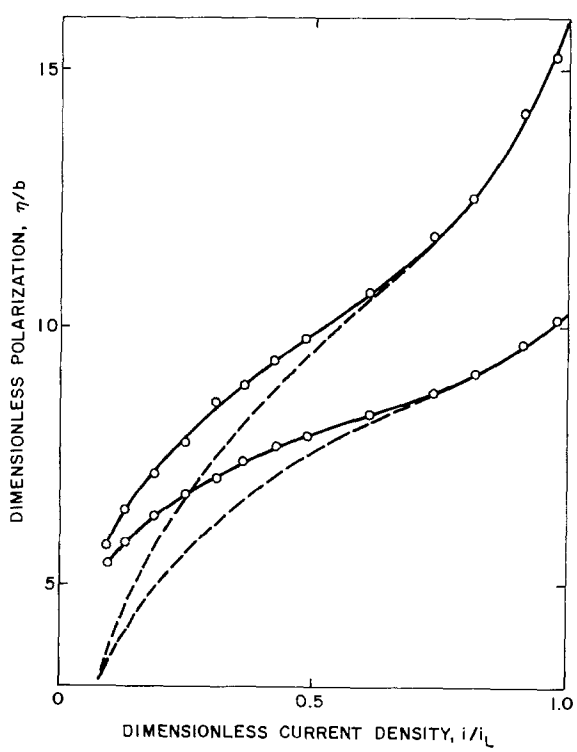

Fig. 13. Comparison of theoretical (solid line) and experimental (0-0-0) current-polarization relations for case 4: $i_L = 55$ mA/cm², $\Delta = 8$, $\bar{i}_{o,r} = 0.021$, $\alpha_o = \alpha_r = 0.41$, $i_{o,r}/i_{o,o} = 1000$, and $\gamma = 0.42$. The dashed lines show the solution for a one-electron transfer reaction; step r is rate limiting, see Table I.

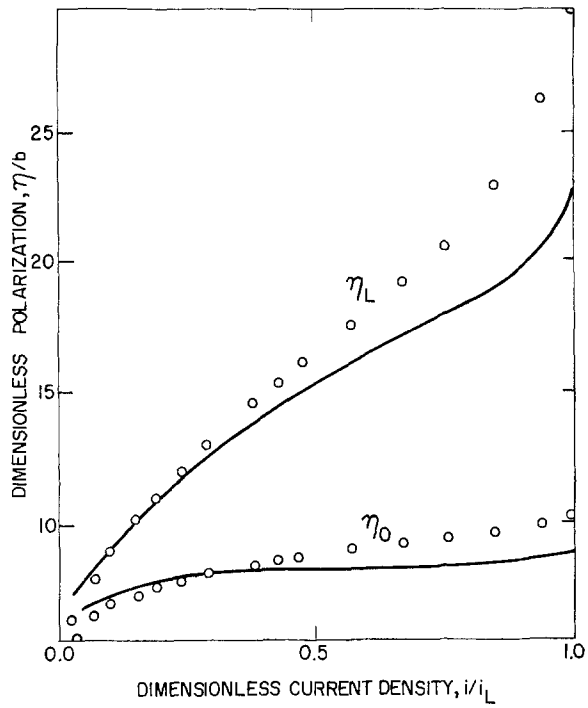

Fig. 14. Comparison of theoretical and experimental results for a consecutive two-electron transfer reaction at a large value of ohmic index Δ, see Table I. i_L = 388 mA/cm², $\bar{i}_{o,r}$ = 0.009, $\alpha_r = \alpha_o$ = 0.41, $i_{o,r}/i_{o,o}$ = 1000, Δ = 55, and γ = 0.2.

that the experimental results deviate considerably from the theoretical results. As the current increases both η_o and η_L increase more than predicted by the theory.

Discussion of Results and Conclusions

The equations for the system considered include three controlling parameters, all expressed in dimensionless form. The parameters are: (*i*) the reversibility index $\bar{i}_o = i_o SL/i_L$, which is a measure of the speed of the electrochemical reaction compared to the reactant input rate; (*ii*) the ohmic index Δ, which is a measure of the ohmic effect in the pore electrolyte, and increases with limiting current density and pore electrolyte resistivity; and (*iii*) the index of diffusion θ, which is a measure of the relative influence of axial diffusion compared to axial convective flow. Table II lists the parameter regions which characterize each case. The effect of axial diffusion becomes detectable only for θ greater than 0.01 for rear supply and 0.005 for front supply. The effect of axial diffusion is to increase the polarization corresponding to a certain current density. The front supply case requires less total polarization than the rear supply case for the same current output, all other conditions being the same.

The agreement between theory and experiment for the various results is good, with considerable internal consistency up to a value of Δ of about 20. The disagreement between theory and experiment at higher values of Δ does not appear to be the result of axial diffusion because the values of the index of diffusion θ necessary to produce the disagreement is much higher than is expected for the experimental system used, nor is it due to radial diffusion limitations.

The effect of radial diffusion is discounted as the reason for this deviation by using a simplified model of superimposed linear combinations. Assuming the current is supported by radial diffusion, a mass balance over a differential element gives rise to

$$di(x)/dx = (DSL/ur)[R_m - R_w]$$
$$= (DSL/ur)\, R_m[1 - R_w/R_m]$$

where r is the pore radius in cm, R_m is the concentration at the center of the pore, R_w is that at the wall, and i, x, r_m, and R_w are all dimensionless. For the set of results in Fig. 14 where $D = 10^{-5}$ cm²/sec, $S = 1.1 \times 10^4$ cm²/cm³, L = 0.5 cm, u = 0.067 cm/sec, and $r \simeq 1$ μm, the value of the multiplier $(DSL/ur) \simeq 10^4$. Taking the case of $i/i_L = 0.9$, then $R_m = 0.1$ assuming negligible axial diffusion. The largest value of di/dx in Fig. 4 (for Δ = 200) is 2.0, hence $R_w/R_m = 0.998$ and radial diffusion is negligible. In fact if the current profile is ten times steeper, *i.e.*, $di/dx = 20$, $R_w/R_m = 0.98$. For the experimental results in Fig. 14, such calculation gives rise to $R_w/R_m > 0{,}99$, hence the deviation could not be due to radial diffusion limitations. The effects of specific adsorption, slow intermediate chemical reaction, or decreased catalytic activity due to the oxidation of the electrode material are ruled out as possible reasons in view of the present results and the previous work on planar electrodes (21). We do not understand the reason for this discrepancy at the present time.

In designing an efficient electrode for an electrochemical reaction in a porous flow-through electrode system, it is clear that an optimization problem exists. Using a thick electrode gives a high $i_o SL$, but ohmic polarization parameter Δ also increases. Similarly, a high S value can be obtained with a low porosity but this again increases Δ. The equations and curves presented here provide a quantitative basis for evaluating the effect of any combination of parameters on the over-all current *vs.* polarization relations. In that respect, the present work is more comprehensive than that previously published (1, 3) where mass transfer and ohmic effects were included and activation polarization was neglected.

LIST OF SYMBOLS

b	$b = RT/\mathbf{F}$
C_1, C_2	constants defined by Eq. [7]
D	diffusion coefficient of reactant, cm²/sec
f	a dimensionless quantity, $f = \exp(\alpha\eta) + \gamma \exp(\beta\eta)$

Table II. Controlling parameters and conditions for the various cases treated

Case	Controlling parameters and conditions: Δ	Direction of current and electrolyte flow	Current and polarization
Case 1*	Δ ≃ 0	Parallel or opposite	No limitation
Case 2	Δ > 2	Parallel (front supply)	Single electron transfer
Case 3	Δ > 2	Opposite (rear supply)	Single electron transfer
Case 4*	Δ > 2	Opposite (rear supply)	$1 \sim (i_{o,r}/i_{o,o}) \exp(-(1 - \alpha_r + \alpha_o)\eta/b)$

* Modification of case 1 to consecutive electron transfer and of case 4 to frontal supply is only a minor modification of these cases.

$\mathbf{F}$	Faraday constant, 96,500 C/equiv.
i_L	limiting current density, $i_L = n\mathbf{F}uR_b$ A/cm²
i_o	exchange current density, A/cm²
$\bar{i}_o$	dimensionless exchange current density (reversibility index), $\bar{i}_o = i_oSL/i_L$
$i_{o,r}$, $i_{o,o}$	exchange current densities of the first and second steps of a consecutive two-electron transfer reaction, respectively, A/cm²
i	total current produced by the electrode as a fraction of the limiting current
$i(x)$	the current flowing at a distance x in the electrode as a fraction of the limiting current
L	electrode thickness, cm
q	tortuosity factor
R, R_b	reactant concentration at the electrode surface and in bulk electrolyte, respectively
S	specific surface area of the porous electrode, cm²/cm³
T	absolute temperature, °K
u	superficial flow speed, cm/sec
x	distance inside electrode, cm
α	transfer coefficient of the anodic electrode reaction
α_r, α_o	same for the first and second steps in a consecutive two-electron transfer anodic reaction
β	same for cathodic reactions, $\beta = \alpha - 1$
Δ	index of ohmic effect, $\Delta = i_LL\rho_{eff}/b$
θ	dimensionless parameter of axial diffusion, $\theta = D_{eff}/Lu$ (reciprocal of Peclet number)
γ	ratio of the bulk concentration of the reactant to that of the product
η	polarization, V
η	dimensionless polarization, η/b
η_o	dimensionless polarization at $x = 0$
η_L	dimensionless polarization at $x = L$
ρ	specific resistivity of electrolyte, Ω-cm
ρ_{eff}	effective specific resistivity of electrolyte, $\rho_{eff} = \rho q$/porosity

Mass Transport Processes at Porous Electrocatalysts in the Electrogenerative Reactor

George P. Sakellaropoulos*,[1] and Stanley H. Langer*

Department of Chemical Engineering, University of Wisconsin, Madison, Wisconsin 53706

ABSTRACT

Mass transport limitations were investigated in the electrolyte, gas phase, and in the pores of platinum and palladium black porous electrocatalysts using the electrogenerative reactor. Limiting currents were identical for both catalysts, depending on a power of the bulk reactant concentration, $i_L = K_J C_{J_\infty}^{\nu_J}$, where C_{J_∞} can be the electrolyte concentration of hydrogen ions or of dissolved ethylene. Mathematical modeling and comparison with the experimental equation provided information regarding limiting processes. In a matrix cell diffusion limited ionic transport at the ethylene cathode. In free electrolytes, free convection can assist mass transport and improve limiting currents. Gas phase limiting current densities were examined in terms of a model involving limiting radial diffusion of dissolved ethylene with a concentration-dependent surface area and pore utilization.

The ease of mass transport in electrogenerative and fuel cell systems can influence reaction rates and overpotentials at each electrode, hence the feasibility of utilizing the electrodes for electrochemical processing and energy generation. Limiting currents, usually associated with slow reactant transport at relatively low concentrations, are undesirable in practical cells, representing severe voltage and energy losses. Because of this, few reactions have been examined in detail as

* Electrochemical Society Active Member.

Key words: porous electrodes, limiting current, catalysis, mass transport, ethylene.

they approach limiting current on gas diffusion, porous, fuel cell type electrodes (1-7). Fortuitously, most of the investigated systems obeyed the simple diffusion layer theory (8). However, observed limiting currents in electrogenerative hydrogeneration are not always proportional to reactant concentration (9). This apparent discrepancy is not unique for the electrogenerative process. Situations may arise where hydrocarbon fuel cell systems could behave similarly. To understand this and similar behavior, a more detailed picture of physical processes at porous catalytic electrodes is required.

Understanding the nature and location of mass transfer limitations could lead to improved electrode designs and contact patterns of reactants for electrochemical energy generation. The experimental and mathematical results here establish the nature and regions of appearance of mass transport limitations in electrocatalytic processing and provide a basis for possible development of the electrogenerative cell as an analytical tool.

The electrogenerative reactor was employed in this work to investigate mass transport processes and reaction limitations at partially wettable, porous catalytic electrodes. The well-established kinetics and cell polarization of ethylene electrogenerative hydrogenation (9, 10) lend themselves to further modeling of the electrogenerative cell. Under kinetic control, the rate-limiting reaction step is believed to be

$$C_2H_5 - * + H^+ + e \rightarrow C_2H_6 + * \qquad [1]$$

with the over-all reaction rate given by (9, 10)

$$i = \mathbf{F}k'C_{C_2H_4}{}^0C_{H^+}{}^2 \exp(-\alpha E\mathbf{F}/\mathcal{R}T) \qquad [2]$$

The electrogenerative cell here involves separate electrochemical oxidation of hydrogen gas and reduction of an alkene on partially wet-proofed electrocatalysts placed at the boundaries of the invariant electrolyte barrier. Electrolytes used in this work are representative of types commonly employed in electrogenerative and fuel cell investigations. The "free" electrolyte type is held between liquid impermeable, gas permeable porous electrodes. The "matrix" type is immobilized on filter paper. With porous electrodes mass transport limitations can develop in the electrolyte, in the gas phase, or in the pores of the electrodes. By deliberately altering concentrations so that mass transport becomes limiting either in the electrolyte or at the gas side of the electrodes, the limiting processes can be characterized. Kinetic limiting currents were excluded from consideration on the basis of the relative magnitude of reaction rates on platinum and palladium (9, 10). It should be noted that common techniques for discriminating between diffusion and kinetic limiting currents (8) are not practical for this system because of fast gas flow rates and low apparent activation energies (1.5-5 kcal/mole) for the catalytic reaction [9].

Diffusion limiting currents predicted from porous electrode models apparently are proportional to reactant concentration. Such treatments normally consider one- or two-dimensional diffusion of gaseous reactants or ions (7, 11-14) and possible counterdiffusion of reactants and products in the presence of inerts (15, 16). However, ionic transport by electrolyte-free convection has not been observed, although possible convective transport due to local heating in the pore meniscuses has been described (17). Similarly, a concentration-dependent change of the available catalytic area and its effect on observed limiting currents has not been anticipated or observed previously. The mathematical analysis below predicts observed operation of porous electrocatalysts at the approach of limiting currents in the electrolyte and in the gas phase (9, 10).

Theoretical Development

Mass transport in the electrolyte.—The examined systems utilized matrix-immobilized or free liquid electrolytes. In the presence of added supporting electrolyte, migration effects on the limiting current can be neglected. The contribution of migration is considered later in the discussion.

Equations describing mass transport of one electroactive species J in the bulk of static dilute electrolytes (18) can be written in dimensionless form

$$\frac{DC_J^*}{Dt^{**}} = \frac{1}{Sc} \nabla^{*2} C_J^* \qquad [3]$$

$$i^* = -\nabla^* C_J^* \qquad [4]$$

where $D/Dt^{**} = \partial/\partial t^{**} + v^{**} \cdot \nabla^*$. Asterisks denote dimensionless quantities defined in the list of symbols and in standard transport phenomena texts (19). The dimensionless current density is defined by Eq. [5]

$$i^* = \frac{iD}{n_J\mathbf{F}\mathcal{D}_J(C_{JS} - C_{J_\infty})} \qquad [5]$$

where D is a characteristic length, *e.g.*, the electrode diameter. Other symbols are defined in the list of symbols. For possible free convection in liquid electrolyte containing nonelectroactive ions, the equation of motion (19) becomes

$$\frac{Dv^{**}}{Dt^{**}} = \nabla^{*2} v^{**} - \mathrm{Gr}\, C_J^* \frac{g}{gc} \qquad [6]$$

where Gr is the Grashoff number and ζ is the densification coefficient (19, 20) (see notation).

Solution of Eq. [3] and [4] with appropriate boundary conditions gives the current density for purely diffusion transport. In the presence of free convection solution of the coupled differential equations [3] and [6] is required to obtain a concentration profile.

Steady-state, one dimensional diffusion.—For steady-state diffusion in the x-direction normal to a vertical disk, solution of Eq. [3] and [4] with usual boundary conditions (19) gives the concentration profile

$$C_J^* = 1 - \frac{D}{\delta} x^* \qquad [7]$$

where δ is the thickness of the electrolyte diffusion layer in contact with the electrode. The average dimensionless current density, or electrochemical Nusselt number, Nu_i, is given by

$$Nu_i = i^* = -\left(\frac{dC_J^*}{dx^*}\right)_{x^*=0} = \frac{D}{\delta} \qquad [8]$$

From this and Eq. [5] the diffusion limiting current is obtained for $C_{JS} = 0$

$$i_L = -\frac{n_J\mathbf{F}\mathcal{D}_J C_{J_\infty}}{\delta} \qquad [9]$$

This is a well-known equation from the diffusion layer theory (8). The negative sign denotes a cathodic reaction (8). Here, subscript J denotes a reacting hydrogen ion.

For constant δ, Nu_i depends on the electrode diameter and i_L is proportional to the bulk electrolyte concentration. Thickness δ is of the order of 0.03 cm for stationary electrolytes (21), but it depends on ionic strength, increasing with decreasing ionic strength.

Steady-state electrolyte-free convection.—Solution of Eq. [3] and [6] is analogous to heat and mass transfer with nonelectrolytes (19, 22, 23). For a vertical disk, the average Nu_i becomes

$$\mathrm{Nu_i} = \frac{i_{avg}D}{n_J\mathbf{F}\mathcal{D}_J(C_{JS} - C_{J_\infty})} = \frac{\int_0^{2\pi}\int_0^{r^*=1/2} i^* r^* dr^* d\theta}{\int_0^{2\pi}\int_0^{r^*=1/2} r^* dr^* d\theta}$$

$$= \frac{2}{\pi}\int_0^{2\pi}\int_0^{r^*=1/2} -\left(\frac{dC_J^*}{dx^*}\right)_{x^*=0} r^* dr^* d\theta \quad [10]$$

where $C_J^* = C_J^*(x^*, r^*, \theta, \mathrm{Gr}, \mathrm{Sc})$ and $\mathrm{Nu_i}$ should depend only on Sc and Gr numbers (19, 20).

For laminar-free convection ($10^4 < \mathrm{GrSc} < 10^9$)

$$\mathrm{Nu_i} = k(\mathrm{ScGr})^{0.25} \quad [11]$$

The constant k is 0.66 for flat vertical plates (20, 23). Using the definitions of Sc and Gr numbers (list of symbols) and of $\mathrm{Nu_i}$, Eq. [8], the average limiting current density becomes for $C_{JS} = 0$

$$i_{L,avg} = -n_J\mathbf{F}\mathcal{D}_J k\left(\frac{\rho g\zeta}{D\mathcal{D}_J\mu}\right)^{0.25} C_{J_\infty}^{1.25} \quad [12]$$

With approximately constant physical properties, total concentration, and densification coefficient (24), the average limiting current density is proportional to the 1.25 power of the bulk concentration of the electroactive ions, and inversely proportional to the 0.25 power of the electrode diameter. Wagner (25) and Tobias and co-workers (20, 24) have tested Eq. [11] and [12] for deposition of metal ions and dissolution from vertical rectangular plates of varying height under well-controlled experimental conditions. However, development of free convection on the exterior surface of porous electrocatalysts, in relatively narrow channel geometry, has not been reported previously to our knowledge.

In this work platinum or palladium circular porous electrocatalysts were used to obtain limiting currents and to test the applicability of Eq. [12] to transport of hydrogen ions external to these electrodes. The use of circular electrodes was dictated by our cell design to eliminate corner effects, by the fragility of the test electrodes, and by the need to identify possible kinetic limitations. Previous kinetic information and current density-voltage data existed only for electrocatalysts of circular geometry. This geometry should be distinguished from the rectangular geometry of other workers (20, 24, 25) where the electrode height appears as the characteristic length in Eq. [10]-[12]. Here, the dimensionless $\mathrm{Nu_i}$, Sc, and Gr numbers are defined using the electrode diameter, D, as a characteristic length, hence its appearance in the 0.25 power in Eq. [12].

Mass transport from the gas side of the electrode.— To obtain some insights into limitations on the gas side of an electrode, adoption of a pore model is helpful. The models considered here are the simple pore (11, 12) and the thin film model (26), represented schematically in Fig. 1. Other more elaborate and more realistic models which lead essentially to similar results have been proposed [*e.g.*, (13)]. All models assume diffusion of gas in the pores, dissolution in the electrolyte (whether thin film or meniscus), and further diffusion to the catalytic sites.

A limiting current would be observed in these pores if: (*i*) axial diffusion of gas through a stagnant gas film is slow, with the limiting current generated at the tip of the meniscus or the film; and (*ii*) radial diffusion of gas for the thin film, or of dissolved gas for the simple pore, is slow; then axial diffusion will also be slow and reactant concentration will vary along the electroactive part of the pore.

In this work, ethylene molecules react on the surface to form ethane which diffuses out of the electrolyte into a gas stream that contains inert nitrogen. A counterdiffusion model is, therefore, necessary.

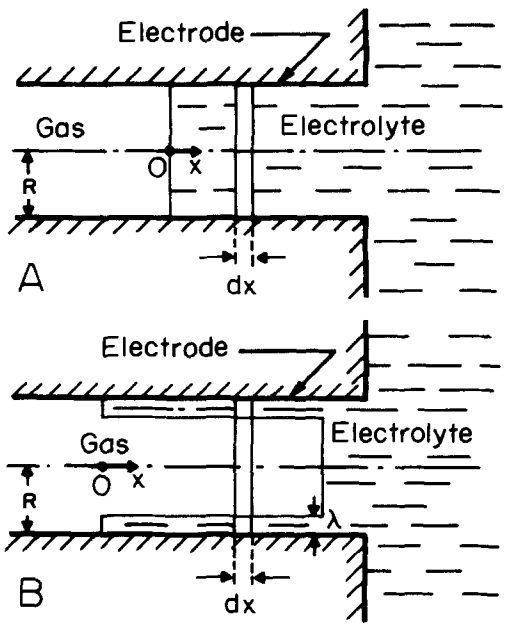

Fig. 1. Schematic representation of a simple pore (A) and a thin film (B) model.

For the first case (*i*) above and for steady-state one-dimensional counterdiffusion, expressions similar to Eq. [8] or [9] will hold. Here C_{J_∞} is the bulk concentration of the gaseous reactant, $\mathcal{D}_J$ the effective diffusivity of J in the gas phase, and δ the thickness of the stagnant gaseous film. Considering the high values of C_{J_∞} and $\mathcal{D}_J$ for gaseous pore diffusion, it appears unlikely that case (*i*) could be limiting here. For example, with $C_{J_\infty} = 4 \times 10^{-6}$ mole/ml (0.1 atm), $\mathcal{D}_J \simeq 0.2$ cm^2/sec, $\delta = 0.02$ cm (half the electrode thickness), a two-electron reaction such as ethylene reduction would give $i_L = 7.7$ A/cm^2.

In case (*ii*) a two-dimensional model is required. Treatments for the simple pore and the thin film model assume generally zero reactant concentration at the end of an infinite pore (11) or a fast (compared to diffusion) first-order reaction over the total pore length (12). For the first-order oxygen reduction on oxide-free platinum (27, 28), these treatments are adequate, predicting limiting current densities proportional to oxygen partial pressure at low pressures (2, 29). However, they do not consider possible change of the available pore surface area at the limiting current for various reactant concentrations.

First-order reactions do not allow experimental determination of the pore length which is under limiting current conditions. The peculiarity of zero-order reactions in exhibiting a defined "critical" penetration length, beyond which reactant concentration becomes zero, proves advantageous. In this work the irreversible zero-order ethylene hydrogeneration of Eq. [2] at positive potentials (9, 10) was used as a model for mass transport in gas diffusion porous electrocatalysts.

Mathematical analysis of a two-dimensional porous model with simultaneous reaction in the pores is complex. Analysis has been simplified here by considering one-dimensional, axial diffusion and reaction in the pores (Eq. [13] below) and by approximating radial diffusion to the pore walls by an algebraic equation, Eq. [15]. Similar approximations have been made by others for flow-through and flooded porous electrodes (30-32).

Kinetic behavior with simultaneous slow axial diffusion was discussed previously (33). Mass balance along the element dx of a simple pore or a thin film gives for a zero-order reaction (33)

$$\frac{d^2\theta}{dx^{*2}} - h_0^2 = 0 \quad [13]$$

where

$$\theta = C_J/C_{J_\infty},\ x^* = x/L$$

and

$$h_o = L\sqrt{\frac{2k_J^o}{R\mathcal{D}_J C_{J_\infty}}\exp\left(-\frac{\alpha EF}{\mathcal{R}T}\right)} \quad [14]$$

h_o being an electrochemical Thiele modulus for the electrocatalyst (33). The potential, E, in Eq. [14] is the electrode potential with reference to the normal hydrogen electrode (NHE). With the strong electrolytes used in this investigation and for thin electrodes, the ohmic overpotential in the pores can be neglected as discussed previously (10, 33, 34). The constant k_J^o at zero potential *vs.* NHE contains inherently the hydrogen ion concentration (cf. kinetics Eq. [2], $k_J^o = k'C_{H^+}{}^2$). The latter was maintained constant here while the ethylene concentration, C_{J_∞}, was varied.

Diffusion at the wall in the radial direction can be approximated by

$$\left(\frac{\partial\theta_{J,x}}{\partial r^*}\right)_{r^*=1} \simeq \frac{\theta_{J,x} - \theta_{J,S}}{\lambda^*} \quad [15]$$

assuming a linear concentration gradient (dimensionless) across a thin film or a stagnant electrolyte layer. Here, $\lambda^* = \lambda/R$, is the dimensionless thickness of the thin film or of the stagnant layer.

If $h_o < \sqrt{2}$, the entire pore length maintains a reactant concentration $\theta > 0$. For $h_o > \sqrt{2}$, θ becomes zero at a critical pore penetration length x_c. For $x^* > x_c{}^*$ no reaction takes place. The boundary conditions for Eq. [13] become then

$$\theta = 1 \text{ at } x^* = 0 \quad [16]$$

$$\theta = 0 \text{ at } x^* \geq x_c{}^* \quad [17]$$

$$\frac{d\theta}{dx^*} = 0 \text{ at } x^* = x_c{}^* \quad [18]$$

Boundary conditions [16]-[18] apply to the reactant ethylene molecules inside the pore and assume high concentration and fast transport of electroactive ions in the electrolyte. The latter assumption is justified as shown by experimental evidence later. Equation [13] with Eq. [16]-[18] give a concentration profile along the pore

$$\theta = 1 - h_o{}^2 x_c{}^{*2}\left[\frac{x^*}{x_c{}^*} - \frac{1}{2}\left(\frac{x^*}{x_c}\right)^2\right] \text{ for } x^* < x_c{}^* \quad [19]$$

The critical length is obtained from Eq. [19] using the equality of boundary conditions [17]

$$x_c{}^* = \frac{\sqrt{2}}{h_o} = \frac{1}{L}\sqrt{\frac{R\mathcal{D}_J C_{J_\infty}}{k_J^o \exp(-\alpha EF/\mathcal{R}T)}} \text{ for } h_o > \sqrt{2} \quad [20]$$

Therefore

$$\theta = 1 - 2\left[\frac{x^*}{x_c{}^*} - \frac{1}{2}\left(\frac{x^*}{x_c{}^*}\right)^2\right] \text{ for } 0 \leq x^* < x_c{}^* \quad [21]$$

A limiting current density can be estimated for radial diffusion of reactant, for $0 \leq x \leq x_c$, with reactant concentration along the pore given by the above axial diffusion model, Eq. [21]

$$I_p = 2\pi RnF\mathcal{D}_J \int_0^{X_c}\left(\frac{\partial C_{J,x}}{\partial r}\right)_{r=R} dx \quad [22]$$

where I_p is the total current in a pore. In dimensionless form, Eq. [22] and [15] yield for the limiting current ($\theta_{JS} = 0$)

$$\frac{\lambda I_{P,L}}{2\pi RLnF\mathcal{D}_J C_{J_\infty}} = \int_0^{x_c{}^*}\theta(x^*)dx^* \quad [23]$$

The ratio

$$i_{P,L} = \frac{I_{P,L}}{2\pi RL} \quad [24]$$

is an apparent limiting current density per pore for total pore length utilization with an area of $2\pi RL$. With a uniform pore distribution and $\mathcal{P}$ pores per unit geometric area of the electrode, the geometric limiting current density i_L, is obtained

$$i_L = i_{P,L}\mathcal{P} = \frac{\mathcal{P}I_{P,L}}{2\pi RL} \quad [25]$$

Equation [25] defines the experimentally measurable limiting current density, since the extent of pore utilization and the true electroactive area per pore, $2\pi Rx_c$, are often not known *a priori*. Correlations are, then, based on the geometric i_L, although the higher, true limiting current density depending on x_c should be used. Therefore, the following equations are derived for the apparent geometric current density, to correlate measurable quantities. From Eq. [21], [23], and [25]

$$\frac{\lambda i_L}{nF\mathcal{P}\mathcal{D}_J C_{J_\infty}} = \int_0^{x_c{}^*}\left\{1 - 2\left[\frac{x^*}{x_c{}^*} - \frac{1}{2}\left(\frac{x^*}{x_c{}^*}\right)^2\right]\right\} dx^* = \frac{x_c{}^*}{3} \quad [26]$$

Equations [20] and [26] give then the ethylene limiting current due to slow axial and radial diffusion with partial pore utilization on the electrode gas side

$$i_L = \frac{nF\mathcal{P}\mathcal{D}_J{}^{3/2}}{3\lambda}\sqrt{\frac{R}{k_J^o \exp\left(-\frac{\alpha EF}{\mathcal{R}T}\right)}}\, C_{J_\infty}{}^{3/2} \quad [27]$$

Equation [27] predicts that for a given zero-order reaction and electrocatalyst the geometric limiting current density depends on the 1.5th power of the bulk reactant concentration. This is a result of the concentration dependence of the available pore area A, for reaction,

$$A = 2\pi R\mathcal{P}x_c \quad [28]$$

where $x_c = x_c{}^*L$ and $x_c{}^*$ is a function of concentration given by Eq. [20]. By differentiating Eq. [28] with respect to bulk concentration the variation of this area becomes inversely proportional to the square root of the concentration

$$\frac{dA}{dC_{J_\infty}} = 2\pi R\mathcal{P}\frac{dx_c}{dC_{J_\infty}} = \pi\mathcal{P}\sqrt{\frac{\mathcal{D}_J R^3}{k_J^o C_{J_\infty}\exp\left(-\frac{\alpha EF}{\mathcal{R}T}\right)}} \quad [29]$$

The predicted dependence of i_L on the kinetic rate constant and the potential at the onset of the limiting current, arises from the approximation that the local reactant concentration will be determined by the superimposition of only axial diffusion on the reaction kinetics.

If the thin film model is applicable, i_L is proportional to the square root of the pore radii. For the simple pore model, assuming $\lambda = R$, the limiting current becomes inversely proportional to the pore radii. With practical porous electrodes use of a pore size distribution would be appropriate. However, the general dependence of i_L on reactant concentration should be the same.

Experimental

Cell designs and electrodes.—Two basic cell designs were used in this study, both oriented vertically: (*i*) a free electrolyte cell (9) with stationary liquid electrolyte contained in a compartment of about 1.25 cm thickness × 2.5 cm diam. This cell design was used for determining limiting currents for hydrogen ion transport by free convection in the bulk electrolyte; and (*ii*) a matrix cell (35) with electrolyte immobilized

on five disks of filter paper, Whatman no. 42, to eliminate free convective transport. This design permitted measurement of purely diffusion limiting currents in the electrolyte. Both cell designs were also used to obtain ethylene limiting currents with identical results. The flow rates of excess reactant gases at the back of the cathode and the anode were adjusted so that limiting currents were independent of flow rate. With very dilute ethylene mixtures, however, fast flow rates were dictated by the mixing process for ethylene and nitrogen, to assure steady composition.

Both cathode and anode were American Cyanamid commercial type porous electrodes, partially wetproofed with polytetrafluoroethylene and containing 9 mg/cm^2 platinum (or palladium) black (36). Type AA-2 electrodes were used with the matrix cell. In free electrolyte cells, Type LAA-2 electrodes which incorporated a thin liquid impermeable polytetrafluoroethylene backing were used. All electrodes were 2.5 cm diam (D), with an exposed geometric area of 5.07 cm^2 and a total surface area for the catalyst of 20-25 m^2/g (37). Platinum or palladium black electrodes were used as the cathode. The anode was always a platinum black electrode.

Materials.—Commercial prepurified nitrogen and hydrogen were used. Ethylene mixtures in nitrogen were prepared from CP grade ethylene (Matheson Company) by a procedure described previously (9). The mixture composition varied less than ±0.002 atm within a run. Electrolyte solutions were normally adjusted to the ionic strength of a 2N solution by mixing appropriate amounts of perchloric acid (AR, Baker Chemical Company) and lithium perchlorate (AR, Alfa Inorganics-Ventron) (9).

Procedure.—The gas flow system, the electrical equipment, and the procedure followed to reduce surface oxides and to eliminate oxygen impurities have been discussed before (9). Reactant conversion was occasionally tested by gas chromatographic analysis of gas samples at the cathode exit (9).

Electrolyte limiting currents were obtained at a constant pressure of 1 atm of pure ethylene gas and at constant electrolyte ionic strength, by varying the hydrogen ion concentration. Ethylene limiting currents were determined at various ethylene partial pressures with a constant electrolyte concentration of 2N $HClO_4$.

The limiting current region was reached through steady-state polarization runs by stepwise adjustment of the cell current with a variable resistor (9, 35). At the vicinity of the limiting current, a constant current supply (Quantech, Model 151B) helped stabilize the current and allowed for voltage variation only (9). Limiting currents were determined graphically from the tangent of the voltage-current density curve. All current densities are based on the exposed geometric electrode area.

Results and Discussion

Electrolyte limiting currents.—A wide range of acid concentrations were examined, between 3 and 0.1N $HClO_4$. Figure 2 shows IR-corrected polarization curves obtained on platinum black in a static-free electrolyte cell. In the Tafel region, the acid concentration had little effect on the cathode voltage (ethylene) *vs.* a hydrogen electrode (anode) in the same electrolyte. This is not a discrepancy from previous kinetic results (9, 10) since hydrogen electrode potentials vary here with the hydronium ion concentration in an inverse fashion from that of the ethylene electrode. This simultaneous change of the ethylene and hydrogen electrode potential in the same electrolyte results in small variations of the cell voltage at low concentrations. Therefore, the energy losses of the hydrogen-ethylene cell are considerably smaller than anticipated from the ethylene (cathodic) reaction kinetics alone at low hydrogen ion concentrations.

Figure 2 shows that no limiting currents were observed in the positive potential region for hydrogen

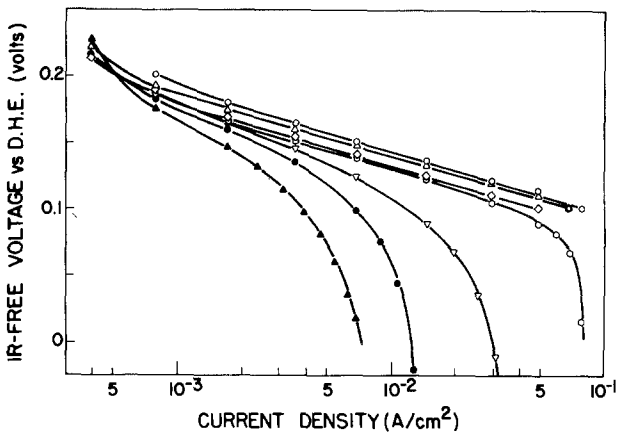

Fig. 2. Current density-voltage curves for varying electrolyte concentration. Electrogenerative hydrogenation of ethylene on platinum black in a free electrolyte cell. Temperature 25°C. (○, C_{H^+} = 3, C_{Li^+} = 0(equiv./liter); △, 2-0; ◇, 0.5-1.5; ○, 0.4-1.6; ▽, 0.2-1.8; ●, 0.1-1.9; ▲, C_{H^+} = 0.1, C_{Li^+} = 3.4).

ion concentrations above 0.5N. Below this concentration, the limiting currents decreased with decreasing hydronium ion concentration.

In the same figure, the effect of electrolyte properties on the limiting current is also shown. With 0.1N $HClO_4$ electrolyte, the ionic strength was varied by using 1.9 or 3.4N $LiClO_4$ supporting electrolyte. The observed limiting current densities were approximately inversely proportional to electrolyte concentration, although a decrease in the diffusion layer thickness is anticipated. This behavior can be explained if one considers that high salt concentrations presumably increase electrolyte viscosity to give lower conductivity and diffusivity and low limiting currents. Decreased cell performance at 3.5N total concentration and at 4N $HClO_4$ (10) further supports this assumption. It should be remembered that Eq. [9] and [12] for the limiting current densities were derived with the assumption of constant total concentration and physical properties. An estimate of the change of diffusivity at the two concentrations can be obtained from the observed limiting currents in a free electrolyte cell in the presence of free convection, discussed later. From Eq. [12], limiting currents are related by

$$\frac{i_{L,1}}{i_{L,2}} = \left(\frac{\mathcal{D}_{J,1}}{\mathcal{D}_{J,2}}\right)^{0.5} \left(\frac{\rho_1 \mathcal{D}_{J,1}}{\mu_1}\right)^{0.25} \left(\frac{\mu_2}{\rho_2 \mathcal{D}_{J,2}}\right)^{0.25} \left(\frac{C_2 \zeta_1}{C_1 \zeta_2}\right)^{0.25} \quad [30]$$

where subscripts 1 and 2 refer to 2 and 3.5N total electrolyte concentration, respectively. With small variation in the Schmidt number and the densification coefficient ζ (24), the ratio of diffusivities in the two electrolytes becomes $\mathcal{D}_{J,1}/\mathcal{D}_{J,2} \simeq 2.4$, *i.e.*, diffusivity is less in 3.5N electrolyte.

Because of low diffusivity in 0.1N $HClO_4$ + 3.4N $LiClO_4$ the observed limiting current was practically identical to that of 0.1N $HClO_4$ without supporting electrolyte but below that in 0.1N $HClO_4$ + 1.9N $LiClO_4$. The low i_L value in the unsupported electrolyte results from an increase in the diffusion layer thickness at low ionic strength. The qualitative results support the practice of maintaining constant electrolyte ionic strength in correlating limiting currents in electrogenerative and fuel cells. All results here were obtained at a constant ionic strength in 2N electrolyte.

Limiting currents in the free electrolyte cell, above, were 3-5 times higher than those observed in a matrix cell. With the latter, limiting currents were observed at positive potentials even in 1N $HClO_4$ electrolyte. With the electrolyte on a matrix, free convective transport is eliminated. This with the decreased ion dif-

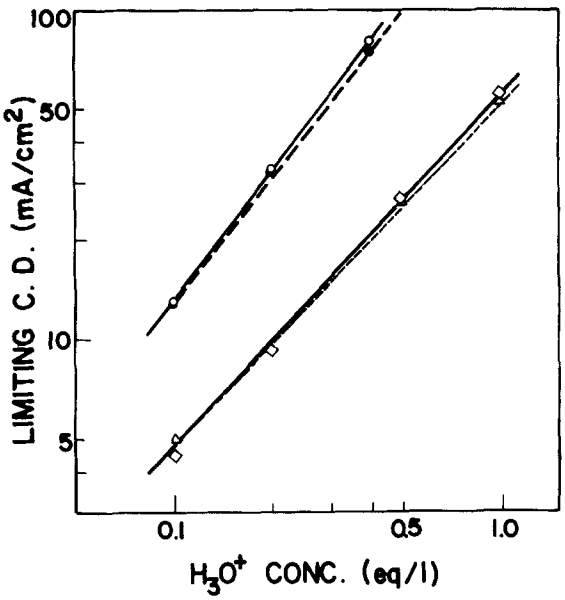

Fig. 3. Limiting current density dependence on hydrogen ion concentration for electrogenerative hydrogenation of ethylene on platinum (○, △) and palladium (◇). Temperature 25°C. (Full symbols, corrected for H^+ migration. Dotted lines: calculated lines for diffusion and free convection, Eq. [9] and [12]. ○, Free electrolyte cell.

fusivity in the matrix result in more severe mass transport limitations compared with free electrolyte. Figure 3 shows the magnitude and the concentration dependence of observed limiting current densities on platinum and palladium electrodes for the two cell designs used. Platinum and palladium electrocatalysts showed identical limiting current densities in a matrix cell. Since the reaction rate on palladium is twice that on platinum (10), the observed limiting currents should result from slow mass transport.

Similar experiments were conducted in a Nernst concentration cell, with ethylene replaced by nitrogen at the cathode (38). Because of the low cell voltage and slow hydrogen gas evolution compared to ethylene reduction (9), current densities at zero cell voltage were lower than with ethylene and limiting currents were not attained. However, deviations of Tafel curves from linearity indicated the approach of mass transport limitations in about the same region as with ethylene.

The observed limiting currents of Fig. 3 obey the relation

$$i_L = K_J C_{J_\infty}{}^{\nu_J} \qquad [31]$$

with a reproducibility of about ±5%. K_J is constant and ν_J can be obtained from the slopes of Fig. 3, at constant temperature, ionic strength, j, and other reactant concentrations

$$\nu_J = \left(\frac{\partial \log i_L}{\partial \log C_{J_\infty}}\right)_{T,\,j,\,C_K \neq J} \qquad [32]$$

The concentration dependence of i_L and estimated values of K_J, obtained by linear regression analysis, are given in Table I. K_J corresponds to the limiting current density at unit reactant concentration. The calculation is straightforward for the matrix cell but involves significant extrapolation of the i_L-C_{H+} curve for the free electrolyte system.

It is important to notice the different dependence of limiting currents on hydrogen ion concentration for the two cell designs. This is a result of the different ionic transport mechanisms operative in each cell. In a matrix-supported electrolyte, hydrogen ions are transported to the cathode by diffusion and migration. In a free electrolyte cell, consumption of hydrogen ions at the cathode can cause density gradients along this electrode. Free convection can, then, operate to enhance mass transport to the cathode. Free convection in the pores, induced either by thermal effects or by the development of a dynamic gas-liquid interface (17), is probably unimportant here since such effects would also be present in a matrix cell. Possible pore "blanketing" does not seem significant in either cell design, considering the high mobility of hydrogen ions and the absence of pore diffusion limitations in the Tafel region (9, 10).

The migration contribution to limiting currents was calculated for steady-state diffusion through a stagnant layer using Newman's numerical, iterative procedure (18). Migration effects resulted in about 5% deviation of the concentration dependence of i_L from the theoretical one, Eq. [9] and [12]. When corrected for migration, limiting currents obey the theoretical correlations, Table I. Correction is approximate, based on dilute solution theory, with mobilities and diffusion coefficients for infinite dilution (18).

The physical constants in Eq. [12] were not known precisely for the binary mixture $HClO_4$-$LiClO_4$. However, differences in some reported values for $HClO_4$ and $LiClO_4$ are relatively small (~10%). Using available values for 1N $HClO_4$, $\rho = 1.053$ g/cm³, $\mu = 9.058 \times 10^{-3}$ poise (39, 40), $\mathcal{D}_{H+} = 4 \times 10^{-5}$ cm²/sec, and the variation of ρ with concentration for $HClO_4$ (40), rough estimates of Sc, Gr, and ζ were obtained: Sc = 215; Gr = 1.16×10^7; $\zeta = -53.8$ cm³/mole. The product ScGr = 2.5×10^9 is at the limit for laminar-free convection (Eq. [11]). Using the above values and other physical characteristics of the system, limiting current densities were calculated for various hydrogen ion concentrations with the aid of Eq. [12]. The dashed line, Fig. 3, shows excellent agreement between calculated and migration-corrected limiting currents for free electrolyte.

For a matrix-supported electrolyte, $\mathcal{D}_{H+}$ would be about one-third of that in free electrolyte, since $i_{matrix}/i_{free} \simeq 1/3$ at low H^+ concentrations (0.1N). With $\mathcal{D}_{H+} = 1.3 \times 10^{-5}$ cm²/sec and a reasonable value of $\delta = 0.026$ cm (21), limiting current densities

Table I. Dependence of limiting current density on reactant concentration

Electrolyte	Catalyst	$K_{H^+}\left[\frac{A}{cm^2}\left(\frac{liter}{mole}\right)^{\nu_J}\right]$	ν_{H^+}*	$K_{C_2H_4}\left(\frac{A}{cm^2\ atm^{\nu_J}}\right)$	$\nu_{C_2H_4}$†	Remarks

* $\nu_{H^+} = \left(\frac{\partial \log i_L}{\partial \log C_{H^+\infty}}\right)_{T,j,P_{C_2H_4}}$

† $\nu_{C_2H_4} = \left(\frac{\partial \log i_L}{\partial \log P_{C_2H_4}}\right)_{T,C_{H^+}}$

were calculated using Eq. [9]. The dotted line of Fig. 3 predicts accurately the experimental, migration-corrected limiting currents.

Gas phase limiting currents.—Transport limitations on the gas side of the electrodes were investigated by varying the ethylene partial pressure between 1 and 0.027 atm in nitrogen. Both matrix and free electrolyte cells were used with a constant, 2*N* $HClO_4$, electrolyte concentration. With this concentration, hydrogen ion transport limitations were eliminated in the pores (9, 33) and in the bulk, discussed above.

Electrogenerative hydrogenation of ethylene on platinum black achieved a maximum reaction rate at several low partial pressures of ethylene (9). Similar behavior was exhibited with palladium black cathodes, at positive potentials (10). Limiting currents were observed only at ethylene partial pressures below about 0.3 atm. Above this partial pressure, the operating cell voltage reached zero before any distinct limitations developed.

The dependence of the limiting current density on inlet ethylene concentration in the gas phase is shown in Fig. 4. The reported limiting current densities are the average of two to three values obtained from steady-state polarization curves. Reproducibility was within 5-10%, as indicated by two individual limiting current densities at 0.103 atm, Fig. 4. At 0.03 atm, an abnormally high limiting current was observed, probably because of turbulence associated with the fast flow rate of the gaseous mixture in that experiment. Reactant conversions estimated from Faraday's law are in good agreement with the observed ones.

The limiting current densities for both platinum and palladium black electrocatalysts were equal at the same reactant partial pressure for either a matrix or a free electrolyte cell, Fig. 4. This and the significantly faster reduction of ethylene on palladium than on platinum away from the limiting current condition (10) suggest slow mass transport rather than kinetic limitations. Efforts to correlate the data for convective transport (18), gas phase counterdiffusion of reactant and product or for differential reactor operation were not successful. As shown in Fig. 4, the observed limiting current densities are proportional to a power of the inlet partial pressure of ethylene, obeying an equation similar to Eq. [31]. Here the ethylene concentration in the gas phase is assumed to be in equilibrium with the liquid phase bulk concentration of ethylene, C_{J_x}. The concentration exponent $\nu_{C_2H_4}$ and the constant $K_{C_2H_4}$ are given in Table I. Comments on extrapolation to unit concentration discussed earlier apply here also.

Results suggest partial utilization of the pore, with the extent of utilization depending on reactant concentration. For the zero-order ethylene reduction on platinum and palladium (9, 10, 33), Eq. [20] gives an estimate of the critical penetration length of ethylene as a function of bulk concentration, potential, and rate constant. Figure 5 shows the concentration drop in the pores for varying h_0. Equation [27] then predicts the observed i_L-C_{J_∞} relation of Fig. 4, assuming Henry's law for dissolved ethylene [$C_{J_\infty} = K_H P_{J_\infty}$, where $K_H = 6.1 \times 10^{-6}$ mole/cm³ atm (42)].

Both platinum and palladium limiting currents appear at about the same potential, $E = 0.13$V, *vs.* the normal hydrogen electrode, although rate constants for the two catalysts are different: $k_{Pt}^\circ = 3.2 \times 10^{-3}$ (9), $k_{Pd}^\circ = 0.452$ (10). Identical limiting currents probably result from different pore diameters. The potential at which limiting currents appear is about 0.05V above the potential at which hydrogen evolution is observed (9, 10). This and the agreement between observed and calculated reactant conversions suggest that reaction takes place electrocatalytically and not by reaction of gaseous hydrogen and ethylene on electrolyte-free catalytic surface.

Pore radii and ethylene penetration into the electrode pores can be estimated from the model developed above. Assuming a close cubic packing of uniform pores with $\mathcal{P} = 1/4R^2$ (12), $n = 2$, $\mathcal{D}_J = 10^{-5}$ cm²/sec, and the above values for k_{Pt}°, E, and K_H, the pore radius for platinum can be estimated from Eq. [27] and the value of constant K_J given in Table I at 1 atm ethylene pressure

$$K_J = \frac{n\mathbf{F}\mathcal{D}_J^{1.5} K_H^{1.5}}{12\lambda R^{1.5}\sqrt{k_J^\circ}\exp(-\alpha E\mathbf{F}/2\mathcal{R}T)} \qquad [33]$$

For the thin film model, assuming $\lambda \simeq 0.025R$, a pore radius $R_{Pt} = 40\mu$ and $\lambda = 1\mu$ is estimated for platinum. With similar assumptions, $R_{Pd} = 15\mu$ and $\lambda \simeq 0.4\mu$ are estimated for palladium. This trend is in agreement

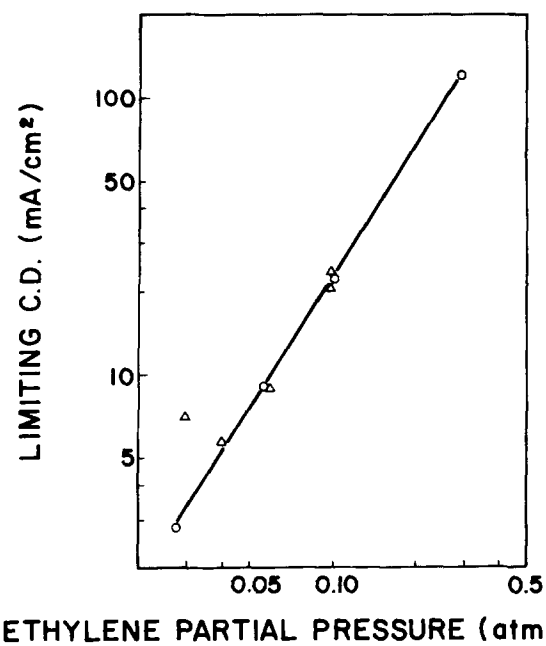

Fig. 4. Dependence of gas phase limiting current on reactant partial pressure. Electrolyte 2*N* $HClO_4$, temperature 24°C (○, palladium-matrix cell; △, platinum-free electrolyte).

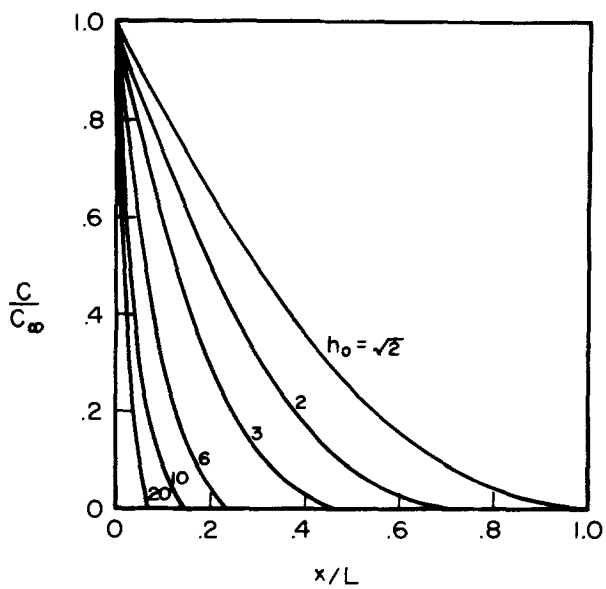

Fig. 5. Dimensionless concentration change along the pore length for various electrochemical Thiele moduli.

with observed slow pore diffusion of ethylene on palladium in the Tafel region (10, 33). For the simple pore model, if $\lambda \simeq R$, the pore radii become $R_{Pt} = 9\mu$ and $R_{Pd} = 3.4\mu$.

Using the thin film model values of R_{Pt}, R_{Pd}, and $L = 0.02$ cm (half the electrode thickness), h_o has been estimated for various ethylene partial pressures using Eq. [14]. Calculated values of h_o at the potential of the limiting currents are given in Table II. At 1 atm ethylene, this potential was not reached nor was a limiting current observed. Therefore, the high values of h_o at 1 atm do not correspond to any experimental currents. At the potential of the limiting currents, the length in the pores where ethylene concentration becomes zero is at the most 0.0015 cm or 7.5% of the pore length for 0.29 atm on platinum. Such a pore penetration length corresponds to about one-fifth of the pore diameter. This justifies the derivation of the limiting current density, Eq. [22]-[27], assuming radial diffusion only, with concentration varying along the pore according to the axial kinetic model.

Although the critical penetration is only a fraction of the pore, the surface area variation with concentration (Eq. [29]) is significant enough to yield the i_L-C_{J_∞} relations of Eq. [27] and [31]. Equation [27] was used with the previously given values of constants to estimate limiting current densities. The calculated solid line of Fig. 4 shows excellent agreement with experiment.

The determined dependence of the limiting current density on a power of the inlet reactant partial pressure, and the agreement between theory and experiment, suggest possible use of the electrogenerative reactor for analytical and control processes. Because of the relatively low degree of pore utilization of the examined electrodes at the limiting current, partially wet-proofed catalytic electrodes should be designed with short, large diameter pores.

Conclusions

The well-characterized kinetics of ethylene hydrogenation on platinum and palladium porous electrocatalysts make this reaction suitable for investigation of mass transport processes and limitations in catalyst pores. Successful modeling of this system makes it useful for analytical purposes, possible process control, and electrocatalyst characterization.

In a matrix-supported electrolyte hydrogen ion diffusion was 3-5 times slower than in a free electrolyte. Identical limiting currents for platinum and palladium black electrodes resulted from slow ionic transport through a stagnant diffusion layer on the external electrode surface. No ionic pore diffusion limitations were observed. Ionic transport in a free electrolyte was enhanced by free convection in the presence of indifferent lithium ions, even in the relatively narrow channel geometry of the examined cell. Free convection theory predicts the observed dependence of limiting currents on hydrogen ion concentration to the 1.25 power.

Gas phase limitations external to the pores were not observed at fast ethylene flow rates. The concentration dependence of limiting currents apparently can be explained by a change of the available reaction area or the pore penetration of reactant, dependent on the inverse of the square root of ethylene partial pressure. The developed model permits determination of electrocatalyst pore utilization for zero-order kinetics. Further testing and application to other systems is desirable.

LIST OF SYMBOLS

A	surface area (cm²)
C	total concentration (mole/cm³)
C_J	concentration of J (mole/cm³)
C_J^*	dimensionless concentration $= (C_J - C_{J_\infty})/(C_{JS} - C_{J_\infty})$
C_{J_∞}	bulk concentration of J (mole/cm³)
C_{JS}	surface concentration of J (mole/cm³)
D	electrode diameter (cm)
$\mathcal{D}_J$	diffusion coefficient of J (cm²/sec)
E	electrode potential (V)
$\mathbf{F}$	Faraday's constant (A sec/mole)
g, g_c	acceleration of gravity (cm/sec²)
Gr	Grashoff number (dimensionless) $= \rho^2 g \zeta D^3 (C_{JS} - C_{J_\infty})/\mu^2$
h_o	electrochemical Thiele modulus (Eq. [14], dimensionless)
I_p	total pore current (A)
i	current density (A/cm²)
i_L	limiting current density (A/cm²)
j	ionic strength
K_H	Henry's constant (mole/cm³ atm)
K_J	constant, Eq. [31] [A cm^{-2} (liter/mole)$^{\nu_J}$]
k	constant for free convection (Eq. [11])
k_J°	reaction rate constant at zero potential $= k' C_{H^+}^2$ (mole/cm² · sec)
L	pore length = 1/2 electrode thickness = 0.02 (cm)
n	number of electrons
n_J	charge of ion J
Nu_i	average Nusselt number or dimensionless current density (Eq. [13], [16])
$\mathcal{P}$	number of pores per cm² $(= 1/4R^2)$
P_{J_∞}	bulk partial pressure of J (atm)
$\mathcal{R}$	universal gas constant (J/mole °K)
R	pore radius (cm)
r	cylindrical reaction coordinate
r^*	dimensionless radial distance $= (r/D)$
Sc	Schmidt number (dimensionless) $(= \mu/\rho\mathcal{D}_J)$
T	temperature (°K)
t	time (sec)
t^{**}	dimensionless time $(= \mu t/\rho D^2)$
v	velocity (cm/sec)
v^{**}	dimensionless velocity $(= v D\rho/\mu)$
x	reaction coordinate
x^*	dimensionless distance $(= x/D$ or $x/L)$ (Eq. [11]
x_c	critical penetration length (cm)

Greek letters

α	transfer coefficient
δ	diffusion layer thickness for ion transport (cm)
ζ	densification coefficient (cm³/mole) $\left[= -\frac{1}{\rho}\left(\frac{\partial\rho}{\partial C_J}\right)_{T,P} \simeq -\frac{1}{\rho}\left(\frac{\Delta\rho}{\Delta C_J}\right)_{T,P} \right]$
θ	dimensionless concentration $(= C_J/C_{J_\infty})$
λ	diffusion layer thickness for molar transport (cm)

μ viscosity (g/cm · sec)

Technical Notes

Electrochemical Formation and Chemical Characterization of a Djerfisherite-Like Compound

Franklin C. Mrazek and James E. Battles*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

A djerfisherite-like material has been identified as an intermediate reaction product formed during the cycling of Li-Al/FeS_x cells using a LiCl-KCl electrolyte. Djerfisherite, an alkali copper-iron sulfide, was first characterized in 1966 as a new mineral occurring in some meteorites; but attempts to synthesize single phase djerfisherite by heating stoichiometric mixtures of normally available chemicals in sealed, evacuated silica tubes were unsuccessful (1). The djerfisherite-like material which is discussed in this article was

* Electrochemical Society Active Member.

Key words: djerfisherite, J-phase formation.

separated from the positive electrode of an electrochemical cell where it is formed as an intermediate product on the charge and discharge cycle. This particular cell, DS-11C (2), contained a Li-Al negative electrode, a FeS positive electrode, and LiCl-KCl electrolyte of the eutectic composition [58.2 mole percent (m/o) LiCl-41.8 m/o KCl]. The cell was operated for 136 cycles and 2009 hr at 450°-500°C; operation was terminated in an intermediate stage of a charging cycle. The charge and discharge cutoff voltages used in this cell were 1.65 and 1.00V, respectively. Subsequent to these results, an out-of-cell preparation of a similar material was accomplished by reacting Li_2FeS_2 with Fe in molten LiCl-KCl at 400°-450°C (3).

Metallographic examination of the positive electrode of cell DS-11C in a dry nitrogen atmosphere glove box revealed the principal phase to be light olive brown in color and isotropic in reflected polarized light. In addition, there was a small amount of fine metallic spheres in the electrolyte matrix. A sample of this material was submitted for x-ray powder diffraction analysis; the detected phases, in addition to the electrolyte, were a material labeled J-phase (4), with a diffraction pattern similar to that of the mineral djerfisherite, and α-Fe. No other phases were detected by either metallography or x-ray diffraction.

Samples of representative single phase material were obtained for chemical analysis to confirm any similarity between J-phase particles and djerfisherite. The electrolyte, which is water soluble, was removed by repeated leaching with water, and the α-Fe was removed from the insoluble J-phase by multiple magnetic separations. Other intermediate products of the cell reaction, Li_2FeS_2 and Li_2S, are water soluble. The wet sample was dried in flowing helium to minimize any oxidation of this very fine J-phase particulate. Density measurements (pycnometer method) and chemical analyses were performed on this material. The results of these analyses are presented in Table I, where they are compared with analyses of djerfisherite from meteoritic sources. Note that no copper, nickel, or sodium was present in the original positive FeS electrode, and therefore these constituents were not found in the product. Additional x-ray diffraction studies were conducted by Tani (5) on this single phase material isolated from cell DS-11C. Based on a model calculated from the x-ray diffraction data, Tani (5) assigned a value of 24 to the number of iron atoms per unit cell, and proposed a formula of $K_6LiFe_{24}S_{26}Cl$. His calculated density of 3.66 g/cm^3 agrees well with the measured density of 3.7 g/cm^3. The stoichiometry of this material, based on the chemical analysis (Table I), can be expressed as $K_{5.5}Li_{0.6}Fe_{24}S_{25.9}Cl_{1.0}$, which agrees well with the formula based on x-ray data. Also, from the chemical analysis presented in Table I, the stoichiometry of the St. Marks mineral is

$$K_{2.93}(Na_{0.17}Cu_{0.87})_{1.04}(Fe_{11.82}Ni_{0.18})_{12.00}S_{13.93}$$

This formula may be generalized to $K_3(Na,Cu)(Fe,Ni)_{12}S_{14}$, which when doubled is indeed very similar to electrochemically prepared J-phase material.

Table I. Chemical compositions of J-phase and two different meteorites

Element	J-phase* (w/o) (4)	St. Marks (w/o) (1)	Penta Blanca Springs (w/o) (6)

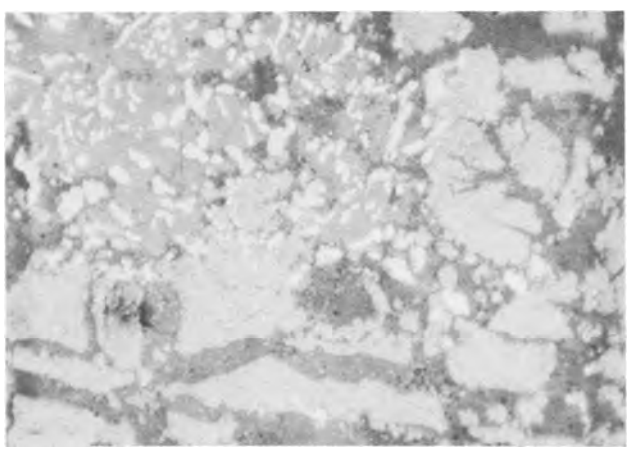

Fig. 1C. Cell 35% discharged. Phases: J-phase Li_2S, Fe (white)

Fig. 1. Photomicrographs of J-phase in partially discharge FeS electrodes (as-polished, all phases identified).

Three other cells, each with an FeS-positive electrode containing 20 atomic percent (a/o) Cu_2S as an additive, were examined metallographically after their first partial discharge cycle. These cells were prepared by Elliott and Cooper (7) as part of a program to study the initial swelling behavior of FeS positive electrodes as a result of the formation of J-phase. Figure 1 presents photomicrographs as well as x-ray diffraction phase identification results for the three positive electrodes which had been discharged by 5, 15, and 35% of theoretical capacity. Note that in one electrode (Fig. 1B), some of the iron was replaced by copper in the compound Li_2FeS_2, which is a normal intermediate product in the electrode reaction. This substitution occurs only in FeS electrodes with Cu_2S additives. This series of photomicrographs shows the morphology of the formation of J-phase during the discharge of cells having FeS positive electrodes and LiCl-KCl electrolyte. The photomicrograph in Fig. 1A shows the adherent dense layer of J-phase formed initially on the surface of an FeS particle. With additional discharge the J-phase layer breaks up as shown in Fig. 1B, and the resulting irregular growth of the reaction product is a contributing factor in the excessive volume expansion (swelling) of the electrode beyond that accountable by the density differences between J-phase and Li_2S. As shown in Fig. 1C, the FeS particles have been consumed, and the next step of the over-all discharge reaction (namely, the formation of Li_2S and Fe) has begun.

Conclusion

An unusual compound with the formula $K_6LiFe_{24}S_{26}Cl$ has been identified as an intermediate product in the positive electrode reactions of Li-Al/LiCl-KCl/FeS cells. Characterization studies of this compound indicate that it is very similar to djerfisherite in crystal structure and chemical composition. Djerfisherite is a sulfide mineral (general formula $K_3(Na,Cu)(Fe,Ni)_{12}S_{14}$) found only in meteorites, such as the St. Marks, and previous attempts to synthesize this material have been unsuccessful. This work has demonstrated that a sulfide material essentially identical to djerfisherite can be prepared in large quantities for further studies.

On the Electropolishing of Molybdenum

M. Zamin,* P. Mayer,[1] and M. K. Murthy

Ontario Research Foundation, Sheridan Park Research Community, Mississauga, Ontario, Canada L5K 1B3

There is relatively limited information on the electropolishing of molybdenum (1). Possibly the earliest use of an electrolytic polishing method for molybdenum is a reference in Coon's paper (2) to a laboratory report by Pierce where "the surface brightening of molybdenum was stated to be possible by using the molybdenum as the anode in an electrolytic bath of an aqueous solution of concentrated sulfuric acid." Most electropolishing solutions for molybdenum contain varying quantities of sulfuric acid (1-5). Sulfuric acid is an aggressive acid, and when molybdenum is made anodic in it, its effect on the metal is quite evident. Among the solutions that were considered for the electropolishing of molybdenum for this study are:

Solution No. 1 [Hopkins *et al.* (5)]: methanol, 175 ml; sulfuric acid, 25 ml; current density, 0.8-1.2 A/cm^2; temperature, 25°C max; time, 1 min.

Solution No. 2 [Coon (2)]: sulfuric acid, 35 ml; water, 140 ml; voltage, 12V; temperature, ~52°C (125°F); time, 25-35 sec.

Stainless steel is recommended as the cathode material, and it is mentioned that the blue film formed as a result of electropolishing can be removed by a 10 sec dip in concentrated ammonium hydroxide solution (2).

In evaluating any solution for the electropolishing of metals and alloys, the following points need to be considered: (*i*) the solution must produce a mirror finish; (*ii*) it must be operational under practical conditions of temperature, voltage, current density, and time; (*iii*) it must be stable over long periods of time; and (*iv*) it must be safe and pollution free. Most electropolishing solutions for molybdenum are safe to operate, and assuming that they produce a satisfactory surface finish, one is left to evaluate them on the basis of the other two requirements mentioned above. Solutions No. 1 and 2 require very short polishing times, and are, therefore, suggestive of the fact that metal removal rates are relatively high. As has already been pointed out (6), lower metal removal rates are preferable since they offer better control of the polishing process. Another practical consideration is the stability of the solution. Most solution compositions found in the literature for electropolishing molybdenum contain substantial volumes of methanol

* Electrochemical Society Active Member.
[1] Present address: Ontario Hydro Research Laboratory, 800 Kipling Avenue, Toronto, Ontario, Canada, M8Z 5S4.
Key words: electropolishing, molybdenum, phosphoric acid solution, Wagner's theory, metal removal rate.

(2-5). Such solutions may operate satisfactorily when they are "new" but would tend to deteriorate with time owing to methanol loss. It is felt, therefore, that the need exists for the development of other solutions which can overcome some, or perhaps all, of the discussed limitations.

A new solution has been developed at ORF for the electropolishing of molybdenum, the composition and operational details of which are presented here. The evaluation of all solutions has been performed on the basis of the four points discussed before. As an extension of the present work, the applicability of Wagner's theory (7) to the polishing process has also been investigated. For a detailed account of Wagner's theory the reader is referred to the original paper (7). However, the theoretical equations used are briefly explained below.

Consider a surface whose roughness can be described by a sine wave profile with a wavelength, a, and an amplitude, b. If an "ideal electropolishing process" is considered, then the metal ions are consumed immediately upon arrival to the outside of the hydrodynamic polishing layer of thickness, δ. For such a process the displacement, u, for a decrease of the amplitude from b_0 to b is given by

$$u = \frac{a}{2\pi} \ln \frac{b_0}{b} \qquad \text{if } b << a,\ a << \delta \qquad [1]$$

where b_0 and b are the amplitudes of the sine wave surface profile at times $t = 0$ and $t = t$, respectively. The correspondping loss of metal per unit area, $\Delta m/A$ is

$$\frac{\Delta m}{A} = u\rho = \frac{a\rho}{2\pi} \ln \frac{b_0}{b} \qquad [2]$$

where ρ is the density of the metal.

Experimental

Specimens were made from molybdenum of 99.9% purity which was in the form of rods, 0.3 cm diam and 5.5 cm in length. Specimen preparation, apparatus, and experimental procedure were similar to that reported elsewhere (6). The polishing cell consisted of a glass beaker 9 cm in diam and 7 cm deep with a flat-plate cathode of an immersed area of about 44 cm^2. The anode cathode distance was about 4 cm. The temperature of the solution was maintained within ± 3°C by heating or cooling in a constant temperature water bath. The surface profile was determined by the Talysurf 4.[2] For weight loss determinations, the specimens were weighed using a microbalance (Mettler, Gramatic Balance). Following polishing in solution No. 2, the blue film was stripped by alternate 10 sec dips in concentrated ammonium hydroxide and 1g/liter KOH solution. It was found that this method was more effective at stripping the film than the 10 sec dip in concentrated ammonium hydroxide solution, as recommended in the original formulation (2).

Potentiostatic polarization was performed on strips (area ~8.5 cm^2) at the electropolishing temperature, according to the procedure described elsewhere (8). Potentials were measured against a saturated calomel electrode (SCE) and the potential scan rate was 25 mV/min.

Results and Discussion

Development of new solution.—A new solution has been developed for the electropolishing of molybdenum whose composition and operating conditions are:

Solution No. 3 (ORF Formulation)	Presently used	Possible range
Orthophosphoric acid (85%)	100 ml	30-160 ml
Sulfuric acid (conc.)	20 ml	10-80 ml
Water	40 ml	10-40 ml
Molybdic anhydride[3]	0.25g	0-0.5g

[2] Manufactured by Rank Precision Industries Limited, Leicester, England.

[3] Molybdenum Trioxide, MoO_3, 99.7% purity. Fisher Scientific Company, Reagent Grade.

Operating conditions	Presently used	Possible range
Voltage	8V	6-40V
Current density	0.6-0.9 A/cm^2	0.6-4.0 A/cm^2
Temperature	70°C	40°-90°C
Cathode	Stainless steel	Stainless steel, graphite, lead, platinum.

The composition and conditions presently used perform satisfactorily, and a temperature of 70°C appears to be the optimum. Lower solution temperatures are not recommended, because they require higher voltages to produce the same current density owing to the decrease in the ionic mobility and, consequently, in the throwing power of the electrolyte. Possibly the best procedure for electropolishing in the above solution is to fix the voltage and let the current "take care of itself." In the search for the optimum polishing conditions, it was found that even voltages as high as 25V did not produce any burn marks on the specimen.

A freshly prepared solution has a milky appearance since only part of the molybdic anhydride dissolves in it. The remainder eventually settles to the bottom in an unstirred solution. Before commencing the electropolishing, the solution should be thoroughly stirred so as to suspend the anhydride throughout the solution. Mechanical stirring of the specimen, which further aids in keeping the anhydride suspended, is necessary during polishing in order to eliminate pitting. The suspension of the anhydride is important because the anhydride polarizes the anodic reaction [$Mo \rightarrow Mo^{6+} + 6e^-$, (9)] producing more uniform polishing, which is possibly an important factor behind the relatively low metal removal rate observed.

The effect of the amount of molybdic anhydride on the experimentally determined metal removed in solution No. 3 is shown in Fig. 1. Even a solution containing no anhydride produced a good polish on the specimen surface. However, as is evident from the values noted

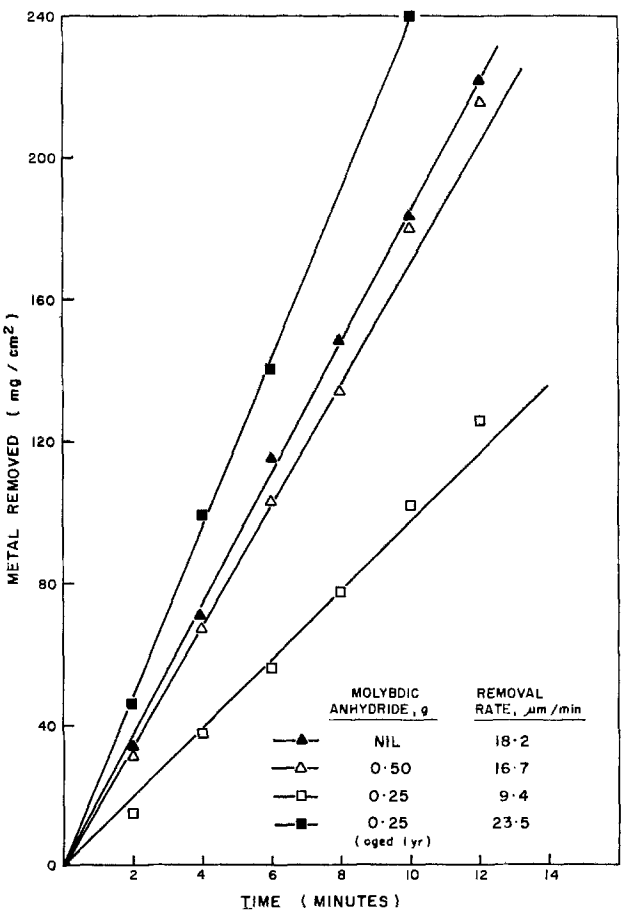

Fig. 1. Effect of molybdic anhydride on the experimental metal removed as a function of time for the new solution.

in Fig. 1, a solution containing 0.25g of the anhydride has the lowest metal removal rate. At present, no reason can be given for the experimental observations of Fig. 1.

Although austenitic stainless steel was used in this investigation for the cathode material owing to its ready availability, its choice is not recommended, because it may be attacked by the solution. Graphite, platinum, and chemical lead are good alternatives and work equally effectively.

Electropolishing results.—The values of a and b, the wavelength, and the amplitude as determined from the surface profile are given in Tables I-III for the three solutions investigated. As expected, with increasing time of electropolishing, the amplitude (b) decreases signifying smoothening, although the wavelength (a) does not change.

Solution No. 1 (H_2SO_4-methanol).—Molybdenum polished relatively easily in this solution, and no significant rise in temperature occurred as long as the area of the specimen in solution was small (~3 cm² in 300 ml). However, when a strip of molybdenum of an area ~11.0 cm² was polished, the temperature rose quickly to 50°C, resulting in etching of the specimen. In order to obtain good polishing, the solution was cooled in an ice bath to about 18°C. A voltage of 30V was required to yield a current density of about 1.0 A/cm², and to produce a satisfactory polish (Fig. 2 and 3) on the side of the specimen facing the cathode (the other side did not polish well, and was partly etched).

Solution No. 2 (H_2SO_4-water).—It was almost impossible to polish molybdenum to a satisfactory finish in this solution. Even short immersion times of 15 sec produced a thick blue film which seemed to prevent further metal dissolution. Although the recommended voltage for polishing is 12V, it was found necessary to decrease this to 6V in order to have some control over the process, and even then the metal dissolved very unevenly. Figure 2 shows two instances where the polishing was performed at 6 and 12V under the conditions specified. The results are far from satisfactory. In fact, when the strip was polished at 12V and 52°C, the current density increased abruptly, overheating the contact clips and igniting the hydrogen liberated at the cathode.

Fig. 3. Photograph showing the reflectivity and luster of electropolished molybdenum strips. Left strip, H_2SO_4-methanol solution; right strip, new solution. The strips are the ones shown in Fig. 2(c) and (d).

Solution No. 3 (new solution).—Extremely satisfactory results were obtained in this solution. No blue film was found on the specimen as a result of electropolishing. Figure 2 shows a photograph of a molybdenum strip in comparison with those polished in the other solutions. Figure 3 is presented to specifically demonstrate the superior surface finish and luster produced by the new solution as compared to solution No. 2 which is the best result obtained from the other two solutions. In contrast to solution No. 2, the new solution produced a brilliant surface finish on both sides of the strip.

The amount of metal removed as a function of time as estimated from Eq. [2] using the results of Tables I-III is presented in Fig. 4(a). Similar data determined experimentally are presented in Fig. 4(b). The metal removal rates as determined from the slope of the lines in Fig. 4 are given in Table IV for the three solutions. It can be seen that the metal removal rate is the highest for the H_2SO_4-water solution and lowest for the new solution, a result which is consistent with visual observations of solution aggressiveness during the electropolishing process. The desirability and advantage of low metal removal rates has already been pointed out (6). It is interesting to note that the experimentally determined metal removal rate in the three solutions is higher than that calculated from Wagner's theory. In principle, therefore, this observation implies that Wagner's theory is not valid for the electropolishing of molybdenum in the three solutions. A possible reason for this inference may be obtained from the assumptions in the mathematical analysis of the theory. As has been pointed out by Wagner (7), if the wavelength, a, is not much smaller than the thickness of the boundary layer, the decrease in the amplitude will be less than calculated from Eq. [1]. Consequently, the amount of metal removed as estimated

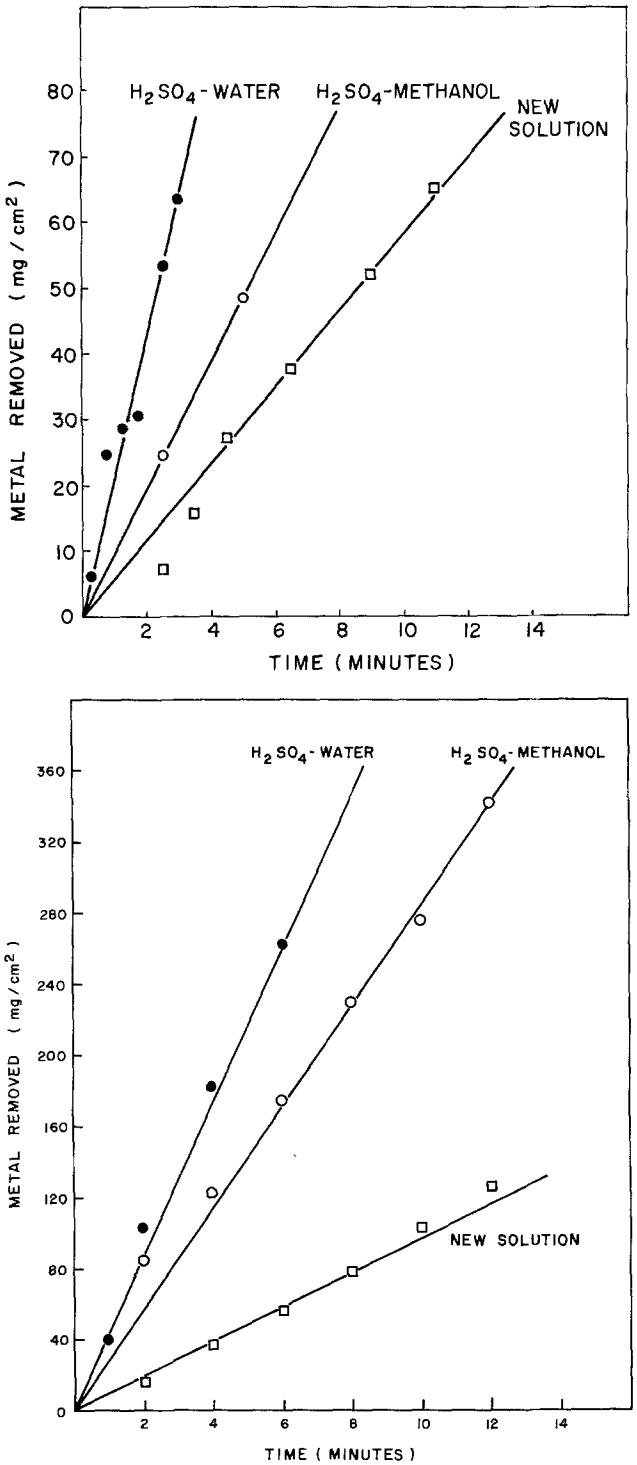

Fig. 4. Metal removed as a function of time for the electropolishing of molybdenum in various solutions. (a) Theoretical from Wagner's theory; (b) experimental.

from Eq. [2] will also be lower. Although the condition $b<<a$ can be verified, it is difficult to determine the validity of the assumption $a<<\delta$. It may be pointed out that the inapplicability of Wagner's theory for the present systems is the result of a mathematical limitation, and is not to be taken as evidence against the theory per se or the "acceptor hypothesis." Data on the electropolishing of tantalum show (10) that Wagner's acceptor hypothesis (7) is indeed valid, and that the results cannot be interpreted on the basis of Nicholas and Tegart's analysis (11) which does not make any assumptions about the mechanism of the polishing process.

Table IV. Rate of metal removal for molybdenum in various electropolishing solutions

Solution	Rate of metal removal, μm/min	
	Theoretical	Experimental
H_2SO_4-water	21.0	42.3
H_2SO_4-methanol	9.5	27.6
New solution	5.7	9.4

The potentiostatic polarization curves limited by the capacity of the potentiostat are given in Fig. 5. The temperature of the solutions were 18°, 52° and 70°C for solutions No. 1, 2, and 3, respectively. It can be seen that in comparison to the other two solutions, solution No. 1 requires much higher voltages to produce the same anodic current density which is consistent with observations during electropolishing. The corrosion potential (E_{corr} in Fig. 5) is the noblest for the new solution and the most active for the H_2SO_4-water solution, which is again an indication of the aggressiveness of the solutions. Vigorous gas evolution (hydrogen) was observed at the cathode in solution No. 2 at potentials beyond +200 mV (SCE); it was almost negligible in solution No. 1 and moderate in solution No. 3. After removal from solution No. 2, the surface of the molybdenum was found to be covered with a black film which was quite adherent to the metal. It did not dissolve in the solution, and could be partially removed by immersing in 1 g/liter KOH solution and scrubbing with cotton. For the new solution, the film was flaky, dissolving slowly in the solution and very readily upon immersion in the KOH solution. No film was observed on the molybdenum in solution No. 1 up to a potential of +1000 mV (SCE).

Although different views exist on the mechanism of electropolishing (7, 12-14) it is generally agreed that a viscous film (or salt film) exists next to the anode (7, 12-16) through which mass transport is diffusion controlled (7, 12-17). As has been pointed out by Hoar (18), the film should be capable of dissolving rapidly at its outer surface as fast as it forms at the metal/film interface. The importance of the thickness of this film is therefore evident. In light of this view, when the potentiostatic polarization observations are combined with the electropolishing results, it is realized that the solution which produces the best surface finish also yields a film which is readily soluble (solution No. 3) in direct comparison to the unsatisfactory surface finish obtained from solution No. 2 where the film is insoluble. Although the composition and structure of the film will possibly change with potential, there seems to be a direct correlation between the film formed at

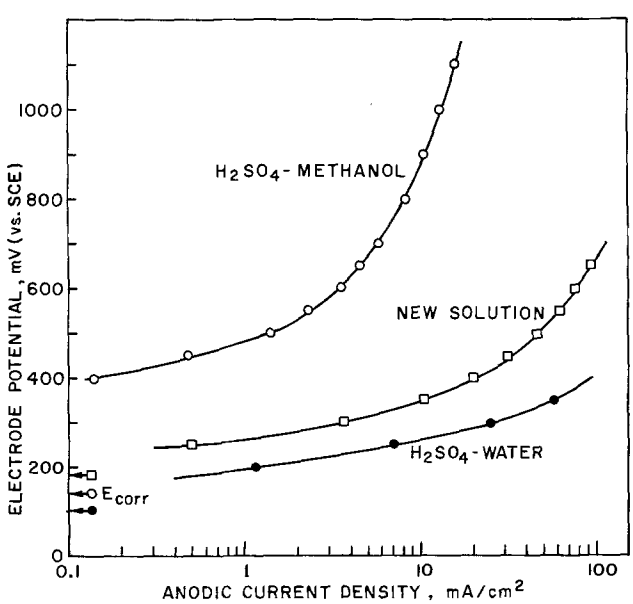

Fig. 5. Potentiostatic polarization curves for molybdenum in various solutions used for electropolishing.

lower voltages during potentiostatic polarization and the one that exists during electropolishing at relatively higher voltages.

It was mentioned earlier that solutions containing methanol would not polish well after storage, owing to methanol loss. In order to determine the validity of this statement, the three solutions were stored in closed (not air-tight) polyethylene bottles for a period of one year. After this period a qualitative assessment of their polishing ability was performed. It was found that solutions No. 1 and 2 had reduced to 1/4-1/5 their original volume, and produced unsatisfactory polishing (unpolished areas, pitting, formation of a thick flaky blue film, vigorous gas evolution, and overheating of the contact clip were encountered). On the other hand, solution No. 3 had decreased only slightly in volume, and polished readily under its normal conditions. The metal removed in this solution is shown in Fig. 1. It thus appears that aging the solution has a significant effect on the metal removal rate. However, the reason for this observation does not seem to be clear.

High Oxide Ion Conduction in Sintered Oxide of the System Bi_2O_3-M_2O_5

Takehiko Takahashi,* Hiroyasu Iwahara, and Takao Esaka

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya 464, Japan

ABSTRACT

The electrical conduction in the sintered oxides of the systems Bi_2O_3-M_2O_5 (M = V, Nb, or Ta) has been investigated by measuring the conductivity and the ion transference number. The face-centered cubic (fcc) phase in these systems was found to show a high oxide ion conduction, and this highly conductive phase could be stabilized by adding a certain amount of M_2O_5 over a wide range of temperatures. The oxide ion conductivities of this phase decreased with increasing content of M_2O_5, and a maximum value was obtained at the lower limit of the fcc solid-solution formation range. Of these systems, Nb-containing specimens had the highest conductivity over a wide range of compositions and temperatures. $(Bi_2O_3)_{0.85}$ $(Nb_2O_5)_{0.15}$ was the best conductor, with conductivities of 1.9×10^{-1} Ω^{-1} cm^{-1} at 700°C and 1.1×10^{-2} Ω^{-1} cm^{-1} at 500°C; these values were more than ten times higher than the conventional oxide ion conductors such as the stabilized zirconias. X-ray diffraction and density studies of fcc phase in the Bi_2O_3-Nb_2O_5 system have confirmed that there is an appreciable amount of oxide ion vacancies which is prescribed by the content of pentavalent oxide. The relation of activation energy for conduction to the composition in this phase is discussed by comparing that of the trivalent oxide-doped system Bi_2O_3-M_2O_3.

The high temperature phase of bismuth sesquioxide (δ-phase) is known to have a defect fluorite-type structure including a large amount of vacant sites in the oxide ion sublattice (1, 2). This material exhibits extremely high oxide ion conduction accompanied by little electronic conduction under ordinary atmosphere (3-6); the conduction mechanism is probably analogous to that of the stabilized zirconias. This phase is, however, stable only in the narrow temperature range from 730° to 825°C (mp) (1), and the conductivity falls remarkably below 730°C where the monoclinic structure (α-phase) is a stable phase (5, 7) and the conduction is electronic (p-type). Furthermore, this material is apt to collapse because of the large volume change due to the phase transition (8), and, therefore, it is not suitable for practical use as a solid electrolyte.

However, the present authors have found that the high oxide ion conductivity can be held far below 730°C by adding a certain amount of WO_3 (6), Y_2O_3 (9), or Gd_2O_3 (10) to the bismuth sesquioxide. The highly conductive phases in these systems were face-centered cubic (fcc) phases which were closely related to that of the high temperature form of pure bismuth sesquioxide (δ-Bi_2O_3) in their crystal structures. The conductivities of these phases were much higher than those of the conventional stabilized zirconias at corresponding temperatures. Outwardly, this means that the δ-form can be stabilized even at lower temperature than 730°C by suitable additives.

According to Roth *et al.* (11), a stable fcc phase exists in the system Bi_2O_3-Nb_2O_5 at temperatures lower than 730°C. The authors also suggested the existence of the analogous phase in Bi_2O_3-V_2O_5 (12), although the detailed phase diagram was not proposed. These systems may be expected to have high oxide ion conduction, like the above described materials. Since tantalum is very similar to niobium in physical and chemical properties, the system Bi_2O_3-Ta_2O_5 may also possess a highly conductive phase due to oxide ions.

Therefore, we studied both the electrical conduction in the binary oxide system Bi_2O_3-M_2O_5 in the sintered state, where M is the transition element of VB group in the Periodic Table, that is, V, Nb, or Ta, and the conduction properties in relation to the kind of M-type elements and their composition. The defect structure and the activation energy for conduction were also studied and compared to those for other oxide ion conductors. As attention has been mainly centered on the ionic conduction in these systems, the complex phase relationships in relatively low and high contents of M_2O_5 have been roughly examined.

Experimental

Preparation of the sintered oxides.—The specimens were prepared by the solid-state reaction between bismuth sesquioxide and vanadium, niobium, or tantalum pentoxide. The bismuth sesquioxide was obtained by thermal decomposition of bismuth nitrate (JIS special grade) at 750°C for 2 hr. The purities of the pentoxides were higher than 99.9%. The powders were mixed and calcined at 800° ~ 900°C for 10 hr in air, then they were finely ground and pressed hydrostatically into the shapes of rods ($4 \sim 6 \times 8 \sim 12$ mm) or disks ($13 \times 2 \sim 3$ mm) under 2700 kg/cm², and sintered in air for 10 hr. The temperatures for sinter-

Table I. The temperatures for sintering

M	x in $(Bi_2O_3)_{1-x}(M_2O_5)_x$	Temperature (°C)
V	0.05 ~ 0.40	800
	0.05 ~ 0.10	850
Nb	0.12 ~ 0.22	900
	0.25 ~ 0.30	1000
Ta	0.03 ~ 0.10	850
	0.14 ~ 0.33	900

ing shown in Table I were selected for each sample to obtain the best sintered state.

Each crystal phase was identified by x-ray diffraction at room temperature using CuKα radiation with a nickel filter. Both quenched and annealed samples were used for this experiment to examine the stability of each phase. The annealing procedure was as follows: The oxides were cooled from sintering temperature to 500°C in several hours and were kept at that temperature for at least 15 hr, after which they were cooled slowly to room temperature. In the quenching procedure, the samples were moved directly from the 800°C furnace to the room, and cooled rapidly by an air blower. Lattice parameters of the fcc phase were measured using sodium chloride as an internal standard of the x-ray diffraction. Densities of the powdered specimens were determined by a standard pycnometric method using n-butanol at 25°C.

Measurement of ionic conduction.—Ionic conduction in the specimens was examined by measuring the electrical conductivity and the emf of an oxygen concentration cell. The conductivity was measured by an a-c bridge equipped with a capacity compensator. The column-shaped specimens were used in this case, and platinum paste was adopted as the electrode material. The frequency for the a-c bridge was 10 kHz, since the dependence of the conductivity on frequency was negligibly small in the range of 2 ~ 20 kHz. The measurement was carried out in air as well as in the low partial pressure of oxygen atmosphere (10^{-1} ~ 10^{-5} atm). In the latter case, the mixed gases of air and argon in various ratios were applied.

The following concentration cell was constructed using the disk-shaped specimen as the electrolyte

$$O_2(p_{O_2,a}), Pt \mid \text{specimen disk} \mid Pt, O_2(p_{O_2,c}) \quad [1]$$

If the conduction in the specimen is purely ionic, the emf of the cell E_0 is given by

$$E_0 = \frac{RT}{4F} \ln \frac{p_{O_2,c}}{p_{O_2,a}} \quad [2]$$

where R, T, and $\mathbf{F}$ have their usual meaning, and $p_{O_2,a}$ and $p_{O_2,c}$ are oxygen partial pressures at anode and cathode, respectively.

In the mixed conductor, in which the conduction is partially ionic and partially electronic, the emf is lowered from E_0 to some extent because of the discharge of the cell due to the electronic conduction in it. In this case, the ratio of the ionic conductivity to the total value $\sigma = \sigma_i + \sigma_e$ (where σ_e is the electronic conductivity), that is, the ion transference number, t_i, can be determined as a ratio of the measured emf, E, to the theoretical value, E_0 (13)

$$t_i = \frac{\sigma_i}{\sigma_i + \sigma_e} = \frac{E}{E_0} \quad [3]$$

when the reversibility of the electrode reaction is good.

The construction of the cell in the present experiment was the same as that previously reported (5, 14). Pure oxygen at 1 atm was used as cathode gas. Air free from H_2O and CO_2 was usually adopted as anode gas. The reversibility of the electrode was examined by discharging the concentration cell through an outer circuit.

Table II. The phases observed in the annealed and the quenched specimens

M	x in $(Bi_2O_3)_{1-x}(M_2O_5)_x$	Phases observed* Annealed sample	Quenched sample

	0.33	fcc + ?	fcc + ?

* fcc = face-centered cubic phase corresponded to δ phase of Bi_2O_3; bcc = body-centered cubic phase; tetr = tetragonal phase; ? = unidentified.

Results

Specimens prepared.—The specimens thus prepared were well sintered except pure Bi_2O_3, and had no open pores to allow the penetration of gas. The porosities which were calculated as a ratio of the apparent density of the sinters to the powder density were within 5% in most cases. The color of these materials changed from reddish brown to pale orange as the content of M_2O_5 increased.

The fcc single phase having the x-ray diffraction patterns analogous to that of pure δ-Bi_2O_3 was observed in the annealed samples of the systems Bi_2O_3-Nb_2O_5 and Bi_2O_3-Ta_2O_5 in the composition ranges of 15 ~ 25 mole percent (m/o) Nb_2O_5 and 18 ~ 25 m/o Ta_2O_5, respectively. This phase spread to lower content of M_2O_5 on quenching the sample from 800°C to room temperature in a few minutes. Although the annealed samples of the system Bi_2O_3-V_2O_5 also had the fcc phase accompanied by some other phase, a single phase could not be isolated, suggesting that the fcc phase had a very narrow composition range, or that some metastable phases were mixed under this condition. The composition and the phases observed by x-ray diffraction of the annealed and the quenched samples are summarized in Table II. Figure 1 shows the relation between the composition and the lattice parameter of the fcc phase in the quenched Bi_2O_3-Nb_2O_5 system. It obeys Vegard's rule, and the values are in good agreement with those of Roth's work (11).

Conductivity.—Typical examples of Arrhenius plots of the system Bi_2O_3-M_2O_5 measured in air are represented in Fig. 2(a) and (b). As previously reported and shown in Fig. 2(a) with the dotted line, the conductivity of pure Bi_2O_3 is relatively low below 730°C, and an abrupt increase in conductivity appears at this

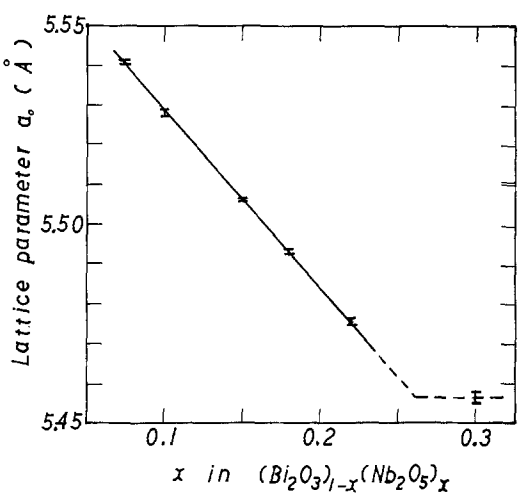

Fig. 1. Lattice parameters of fcc phase in Bi_2O_3-Nb_2O_5 system

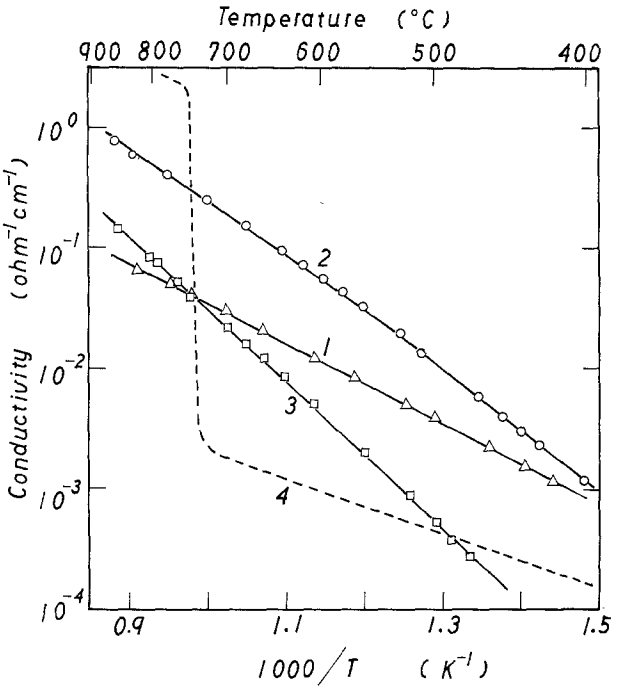

Fig. 2(a). Arrhenius plots of conductivity of sintered oxides of the system Bi_2O_3-M_2O_5. Curve 1, $(Bi_2O_3)_{0.875}(V_2O_5)_{0.125}$; Curve 2, $(Bi_2O_3)_{0.85}(Nb_2O_5)_{0.15}$; Curve 3, $(Bi_2O_3)_{0.80}(Ta_2O_5)_{0.20}$; Curve 4, pure Bi_2O_3.

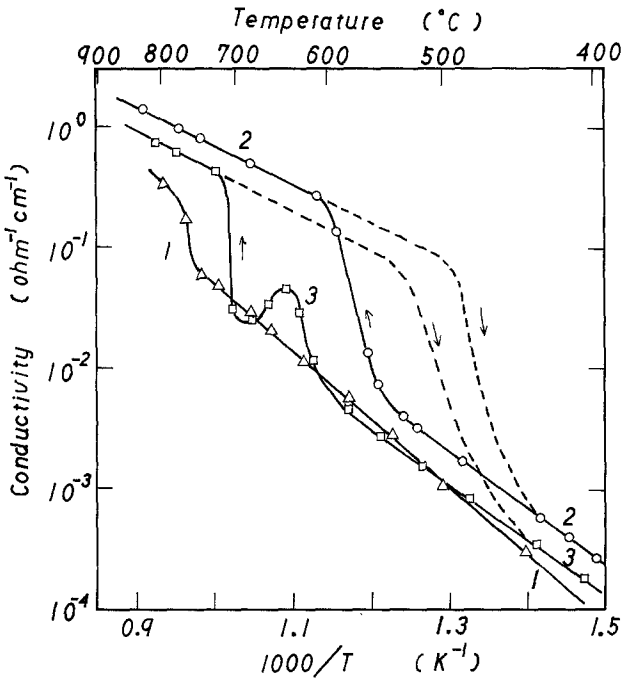

Fig. 2(b). Arrhenius plots of conductivity of sintered oxides of the system Bi_2O_3-M_2O_5. Curve 1, $(Bi_2O_3)_{0.91}(V_2O_5)_{0.09}$; Curve 2, $(Bi_2O_3)_{0.925}(Nb_2O_5)_{0.075}$; Curve 3, $(Bi_2O_3)_{0.90}(Ta_2O_5)_{0.10}$.

temperature corresponding to the transformation temperature from monoclinic (α-phase) to fcc phase (δ-phase). However, as shown in Fig. 2(a) with solid lines, the sintered specimens containing more than a certain amount of M_2O_5 showed no jump in conductivity over the whole range of temperature examined. The conductivities of these oxides below 700°C were, in general, higher than those of pure Bi_2O_3, while the values in the high temperature region were lower than those of pure Bi_2O_3. The specimens containing a relatively small amount of M_2O_5 had an abrupt increase in conductivity, as shown in Fig. 2(b), and these exhibited thermal hysteresis in the Arrhenius plot, as indicated by the dotted lines in the figure. More detailed data of the Arrhenius plots and the composition are shown in Fig. 3 for the Bi_2O_3-Nb_2O_5 system.

The minimum contents which showed no jump in conductivity were 12.5 m/o for V_2O_5, 15 m/o for Nb_2O_5, and 18 m/o for Ta_2O_5; the greater the atomic number of M, the higher the critical concentration in which the jump in conductivity was not observed. These critical values correspond with the lower limit of the fcc solid solution composition ranges for Nb_2O_5 and Ta_2O_5. These conductivity behaviors are same as those of the systems Bi_2O_3-WO_3 (6), Bi_2O_3-Y_2O_3 (9), and Bi_2O_3-Gd_2O_3 (10).

Figure 4 shows the isothermal conductivity plots *vs.* the content of M_2O_5 at 750° and 500°C. These temperatures are above and below the temperature of jump in conductivity, respectively. In high temperature range where the fcc single phase is stable, the

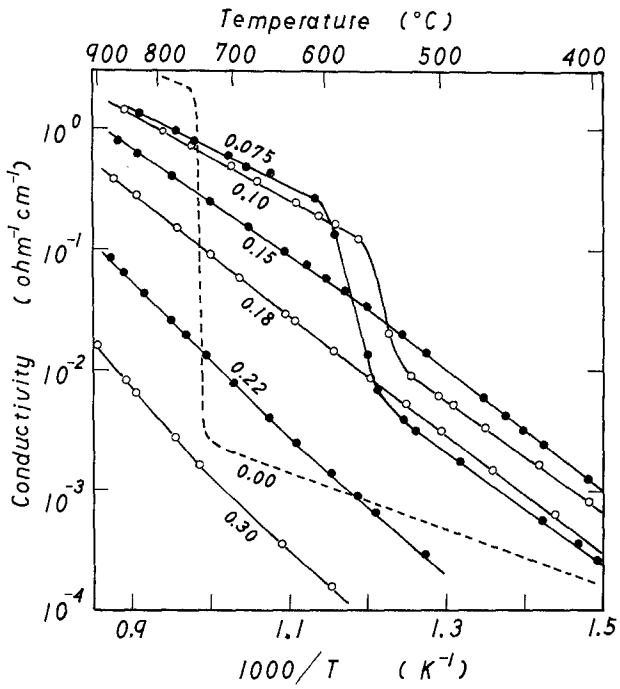

Fig. 3. Arrhenius plots of conductivity of the sintered oxides $(Bi_2O_3)_{1-x}(Nb_2O_5)_x$. (The figures in the graph indicate the values of x.)

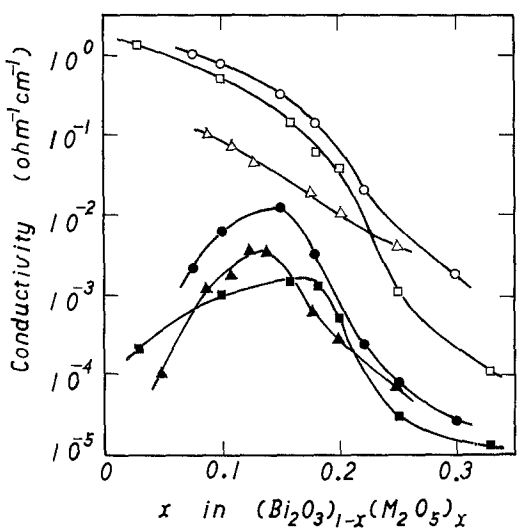

Fig. 4. Isothermal conductivities of $(Bi_2O_3)_{1-x}(M_2O_5)_x$. At 500°C: ▲, M = V; ●, M = Nb; ■, M = Ta. At 750°C: △, M = V; ○, M = Nb; □, M = Ta.

conductivities decrease monotonically with increasing content of M_2O_5. In the low temperature region where two phases coexist in the low content of pentavalent oxides, the conductivities have a maximum value at 14 ~ 18 m/o M_2O_5. These compositions correspond to the lower limit of the fcc solid solution formation range for the Bi_2O_3-Nb_2O_5 and Bi_2O_3-Ta_2O_5 systems. For the latter system, however, the maximum is relatively flat in the Ta_2O_5-poor side (fcc + tetragonal mixed phases), suggesting that the tetragonal phase is also highly conductive. The conductivity-composition curves for the Bi_2O_3-V_2O_5 system in the low temperature range were also similar to the above two systems, although the fcc phase was not recognized as a single phase in this system.

As to the conductivity value, the Nb_2O_5-containing sample was the highest among the Bi_2O_3-M_2O_5 specimens over the whole range of temperatures and compositions examined. An abnormal conductivity behavior was observed in the low content range of Ta_2O_5, as shown in Fig. 2(b). This phenomenon was reproducible. High temperature x-ray diffraction and DTA studies on these substances showed hysteresis in the phase transition as follows: During heating, they had tetragonal phases up to 580°C and transformed to monoclinic at this temperature, and then, changed to fcc above 700°C; on cooling, however, they transformed directly from cubic to tetragonal at about 500°C without changing to monoclinic. These results were in accordance with the conductivity behavior.

Conduction properties.—Table III lists the E/E_0 values of the oxygen concentration cell for representative specimens under the condition of $p_{O_2,a} = 0.21$ and $p_{O_2,c} = 1.0$ atm. As previously reported, the emf of the cell using pure Bi_2O_3 could not be detected up to 730°C, where it appeared suddenly and increased rapidly to the theoretical value as the temperature was raised.

In contrast, the specimens containing a certain amount of M_2O_5 showed the emf even in the temperature range below 700°C, indicating the existence of ionic conduction. In the specimens in which the fcc single phase was stable, E/E_0 values were greater than 0.9 in the temperature range examined. This means that the conduction in this phase is essentially ionic. In the sample which showed the jump in conductivity, the conduction was also essentially ionic even in the low temperature range, suggesting that the electronic conduction in other phases was not so remarkable.

Considerably high current could be drawn out from these concentration cells, as shown in Fig. 5. The cells were stable and reproducible even after they had been short circuited for a long time. These behaviors are the same as in the case of Y_2O_3- or WO_3-doped Bi_2O_3 and indicate that the conductive ions should be oxide ions. The highest oxide ion conductor among the sintered oxides of the system Bi_2O_3-M_2O_5 was $(Bi_2O_3)_{0.85}(Nb_2O_5)_{0.15}$. The oxide ion conductivity of this material was 1.9×10^{-1} Ω^{-1} cm^{-1} at 700°C and 1.1×10^{-2} Ω^{-1} cm^{-1} at 500°C, respectively, which is the same order of magnitude as that of $(Bi_2O_3)_{0.75}(Y_2O_3)_{0.25}$ previously reported (9), and is more than one order

of magnitude higher than the conventional oxide ion conductors such as the stabilized zirconias.

Determination of oxide ion transference numbers by various methods.—In Table III, the values E/E_0 for the fcc single phase in the Bi_2O_3-Nb_2O_5 system were almost unity within experimental error, whereas these values in the Bi_2O_3-Ta_2O_5 system deviated from unity. This deviation, however, does not always correspond directly to the ratio of the electronic contribution since E/E_0 shows somewhat lower values than true transference number of ions if the electrodes of the cell are easily polarizable. In order to avoid this polarization effect, the following method (15, 16) was adopted.

If the theoretical emf E_0 is applied to the cell (1) from the outer circuit in charging polarity, no ionic current passes through the specimen disk, and the observed current i_e is to be ascribed to electrons. In this condition, the electronic conductivity σ_e of the specimen is obtained from the electronic current and applied voltage as $\sigma_e = \dfrac{|i_e|}{E_0}$. Then, the transference number of ions can be determined as

$$t_i = \frac{\sigma_i}{\sigma_i + \sigma_e} = 1 - \frac{|i_e|}{E_0\sigma} \qquad [4]$$

where σ is the total conductivity of the disk sample measured with an a-c bridge. As represented in Table IV, the transference numbers thus obtained were almost the same as those from E/E_0, indicating that the polarization effect was fairly small in these cases. As a result, it can be concluded that the fcc phase in the Bi_2O_3-Ta_2O_5 system has some electronic conduction with predominant ionic conduction, while that in the Bi_2O_3-Nb_2O_5 system has little electronic conduction.

These results could be supported by the dependence of total conductivity on oxygen partial pressure p_{O_2} of the surrounding atmosphere. Figure 6 shows the example of the pressure dependence of conductivity.

Table IV. Transference numbers of oxide ions determined by different methods

Specimens	Temperature (°C)	E/E_0	$1 - \dfrac{\lvert i_e \rvert}{E_0\sigma}$	$\dfrac{\sigma_i}{\sigma(p_{O_2})}$
$(Bi_2O_3)_{0.85}(Nb_2O_5)_{0.15}$	600	0.98	0.99	—
	700	1.00	1.00	—
	800	1.00	1.00	1.00
$(Bi_2O_3)_{0.80}(Ta_2O_5)_{0.20}$	700	0.91	0.92	0.90 ~ 0.93
	800	0.94	0.93	0.91 ~ 0.96

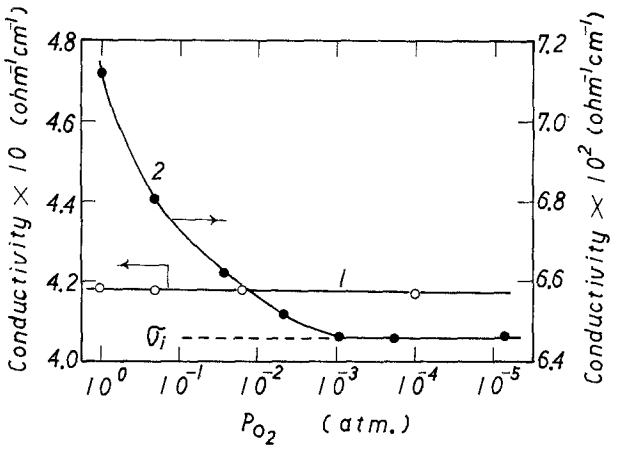

Fig. 6. Dependence of the conductivity on the oxygen partial pressure at 800°C. Curve 1, $(Bi_2O_3)_{0.85}(Nb_2O_5)_{0.15}$; Curve 2, $(Bi_2O_3)_{0.80}(Ta_2O_5)_{0.20}$.

The conductivities of $(Bi_2O_3)_{0.8}(Ta_2O_5)_{0.2}$ increased with the increase in p_{O_2} subsequent to the pressure-independent region below $p_{O_2} = 10^{-3}$ atm, while the conductivities of $(Bi_2O_3)_{0.85}(Nb_2O_5)_{0.15}$ were not dependent on the p_{O_2} over the whole range of pressure examined. This means that the conduction in the former oxide is partly electronic (p-type) due to the electron hole at a relatively high partial pressure of oxygen, whereas the contribution of electronic conduction in the latter may be negligibly small. If the assumption that the electronic conductivity is pressure dependent and the ionic conductivity is pressure independent [as in the case of many oxide ion conductors having a large number of oxide ion vacancies (17)] can be applied in this case, the transference number of oxide ion t_i at any p_{O_2} is given by

$$t_i = \frac{\sigma_i}{\sigma(p_{O_2})} \qquad [5]$$

where $\sigma(p_{O_2})$ is the total conductivity at p_{O_2} and σ_i is the pressure-independent part of the conductivity. The values of t_i obtained at $p_{O_2} = 1.0$ and 0.21 atm are listed in the last column of Table IV. The values are again in good agreement with those of the previous two methods if it is considered that the previous ones are the result obtained in an asymmetrical atmosphere ($p_{O_2,a} = 0.21$ and $p_{O_2,c} = 1.0$ atm).

Identification of the presence of oxide ion vacancies.—High oxide ion conduction in the fcc phase of these materials is considered to relate to the presence of the oxide ion vacancies as in the case of δ-Bi_2O_3 and other Bi_2O_3-based electrolytes reported previously. In pure δ-Bi_2O_3, which has the fluorite-type structure, two of the eight lattice sites for the oxide ion per unit cell are, on the average, vacant, since the formula of a perfect fluorite-type oxide is represented as A_4O_8 (A is a cation) per unit cell. When the pentavalent cations are partially substituted for trivalent Bi^{3+} keeping the original fcc lattice, the main possible situations in the unit cell $(Bi_2O_3)_{1-x}(M_2O_5)_x$ are as follows:

(*i*) All cations occupy their normal site in the fluorite-type lattice and (2-4*x*) of the eight oxide ion sites per unit cell are vacant; *i.e.*, the composition of unit cell is expressed as

$$Bi_{4(1-x)}M_{4x}O_{6+4x}\square_{2-4x}$$

where □ is oxide ion vacancy.

(*ii*) All cations and oxide ions occupy their normal sites, respectively, and the above vacant sites are occupied by oxygen atoms or ionized oxygens accompanied by electron holes; *i.e.*

$$Bi_{4(1-x)}M_{4x}O_8$$

(*iii*) All oxide ions occupy their normal sites fully and excess cations are situated at interstitial sites; *i.e.*

$$Bi_{4(1-x)}M_{4x}(Bi_\alpha M_\beta)_{int.}O_8$$

where $(\ )_{int.}$ indicates the interstitial sites.

(*iv*) All Bi^{3+} ions occupy their normal sites and all M^{5+} ions are situated at the interstitial sites; *i.e.*

$$Bi_4(Nb_{4x/1-x})_{int.}O_{6+(10x/1-x)}\square_{2-(14x/1-x)}$$

The theoretical densities of the fcc phase in the Bi_2O_3-Nb_2O_5 system have been calculated from the observed lattice parameters, assuming the above models. In Fig. 7 the calculated densities and the pycnometric densities measured on quenched samples are plotted against the content of Nb_2O_5. The observed values are in good agreement with case (*i*), indicating that the crystals have an appreciable amount of oxide ion vacancies, the number of which are given by (2 — 4*x*) per unit cell. A similar result was also obtained in the specimen $(Bi_2O_3)_{0.80}(Ta_2O_5)_{0.20}$.

Discussion

From the results described above, it is concluded that the fcc phase in the Bi_2O_3-M_2O_5 system is a highly conductive oxide ion conductor, and that this highly conductive phase can be stabilized at low temperature by adding an appropriate amount of Nb_2O_5 or Ta_2O_5. The conductivity of this phase increases with decreasing content of M_2O_5 and, as a result, the maximum conductivity in the low temperature region lies on the lower limit of the fcc solid solution formation range. This tendency is analogous to those for the Bi_2O_3-WO_3, Bi_2O_3-Y_2O_3, and Bi_2O_3-Gd_2O_3 systems reported previously (6, 9, 10) and is coincident with the general trend for stabilized zirconias that the increase in the content of the second cation (stabilizer) makes the conductivity decrease within the fcc solid solution formation range.

It is interesting to speculate on the direct cause of the conductivity decrease with the increasing content of the stabilizer. In the stabilized zirconias, the increase in the content of stabilizers makes the concen-

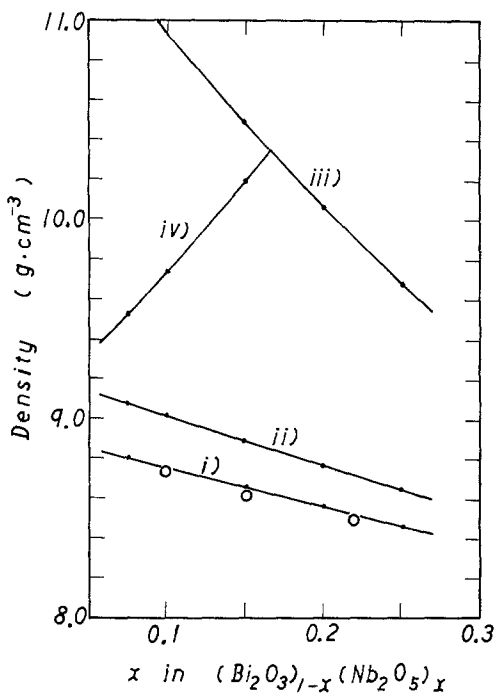

Fig. 7. Comparison of calculated densities with the observed values (open circles). (The number on each line corresponds to the density calculated from each model described in the body.)

tration of oxide ion vacancies increase since the stabilizers are di- or trivalent cations which are substituted for tetravalent zirconium ions; for example

$$(1-x)ZrO_2 + xCaO \rightarrow Zr_{1-x}Ca_xO_{2-x}\square_x$$

In the fluorite-type phase in the Bi_2O_3-M_2O_5 system, however, the situation is quite the reverse, that is, the vacancy concentration decreases with the content of M_2O_5 as described above, and is written as

$$(1-x)BiO_{1.5}\square_{0.5} + xMO_{2.5} \rightarrow Bi_{1-x}M_xO_{1.5+x}\square_{0.5(1-x)}$$

Therefore, the conductivity decreases with increasing vacancy concentration in the former case, while it increases with increasing content of vacancies in the latter case. This suggests that it is not the interaction between oxide ion vacancies themselves, but the interaction between oxide ion vacancies and doped cations that affect the conductivity lowering directly.

The activation energies for conduction in the fcc phase of Bi_2O_3-M_2O_5 increased with increasing content of doped cations. They were calculated from the Arrhenius plot of the conductivity, and are represented in Fig. 8 with respect to the composition. Clearly, the plots lie almost on a straight line irrespective of the sort of M_2O_5. This may indicate that the conduction mechanism in the fcc phase is the same regardless of the sort of M_2O_5. As shown in the same figure, a similar tendency can also be seen in the case of Bi_2O_3-M_2O_3 (M = Y and Gd), the oxide ion conductivities of which were reported previously (9, 10). It is noticeable that, although each slope is different, the extrapolations to $x = 0$ give almost the same value which is close to the observed activation energy for the fcc phase of pure Bi_2O_3 (δ-Bi_2O_3). This suggests that the conduction mechanism in both systems is essentially identical with that for δ-Bi_2O_3 in which the oxide ion may conduct in the same way as in the case of a stabilized zirconia because of a similar defect fluorite-type crystal structure.

Higher slope in the case of pentavalent dopants than that of the trivalent dopants can be explained as follows. When M_2O_5 is added to Bi_2O_3 within the fcc phase, trivalent host cations Bi^{3+} are replaced by pentavalent cations M^{5+}, and defect chemistry can be written using Kröger's notation as

$$2Bi_{Bi}^{\times} + Nb_2O_5 + 2V_o^{\cdot\cdot} \rightarrow 2Nb_{Bi}^{\cdot\cdot} + 2O_o^{\times} + (Bi_2O_3)_{cryst.}$$

The substituted cation sites should charge twice as positively relative to the initial cation sublattice field,

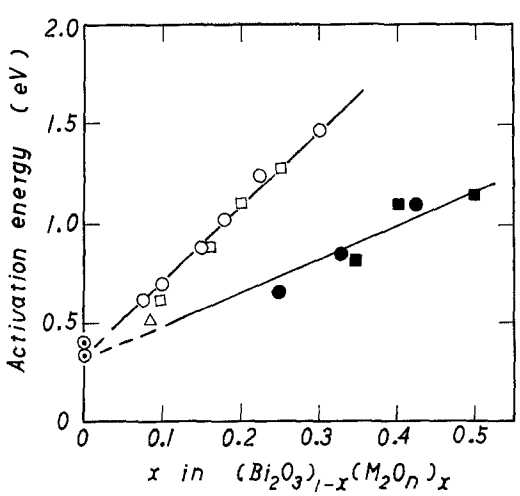

Fig. 8. Relation between the composition and activation energy for conduction in fcc phase of the system Bi_2O_3-M_2O_5 and Bi_2O_3-M_2O_3. ($n = 5$): △, M = V; ○, M = Nb; □, M = Ta. ($n = 3$): ●, M = Y; ■, M = Gd.

and might repulse the native vacancies $V_o^{\cdot\cdot}$ because of the same positive charge. As a result, the association between the substituted cations and the movable oxide ions

$$M_{Bi}^{\cdot\cdot} + O_o^{\times} \rightarrow (M_{Bi}^{\cdot\cdot}O_o^{\times})$$

may take place, which makes the activation energy for oxide ion conduction increase. This effect will grow remarkably as the content of pentavalent dopant increases, and, accordingly, the activation energy rises as shown in Fig. 8. While replacement by M^{5+} disturbs the uniformity of the electrostatic field on the cation sublattice, the replacement by M^{3+} leaves the potential field unchanged (uniform) because of the equicharge of M and Bi. The defect chemistry can be given as

$$2Bi_{Bi}^{\times} + M_2O_3 + 2V_o^{\cdot\cdot} \rightarrow 2M_{Bi}^{\times} + (Bi_2O_3)_{cryst.} + 2V_o^{\cdot\cdot}$$

There exists much less interaction between $M_{Bi}^{\times}$ and $V_o^{\cdot\cdot}$ than between $M_{Bi}^{\cdot\cdot}$ and $V_o^{\cdot\cdot}$ since $M_{Bi}^{\times}$ has no effective charge relative to $Bi_{Bi}^{\times}$. Nevertheless, the uniformity of the potential field on the cation sublattice may be actually disturbed to some extent by the difference in electronegativity, polarizability, or ionic radius between the host Bi^{3+} and dopant M^{3+}, and this will make the activation energy increase even if it is not so remarkable as in the case of M^{5+}. As a result, it is rational that the increment of activation energy with the composition is more remarkable in the case of M_2O_5 dopant than that in the case of M_2O_3 dopant.

A linear relationship between the activation energy and the composition shown in Fig. 8 could not quantitatively be explained. It is probable that rather an approximate form of the more complex expression exists which includes the association energy among the defects. These problems are under study.

As to the oxide ion conductivity, the Bi_2O_3-based specimens, especially $(Bi_2O_3)_{0.85}(Nb_2O_5)_{0.15}$ as well as $(Bi_2O_3)_{0.85}(Y_2O_3)_{0.25}$ can be said to belong to the best conductor. A demerit of the Bi_2O_3-based electrolytes is that they are apt to be reduced under reducing atmosphere at high temperature. However, according to our recent study (15) on $(Bi_2O_3)_{0.83}(Y_2O_3)_{0.27}$, it is stable down to 10^{-13} atm O_2 at 600°C keeping the properties of pure electrolyte. Therefore, they may be available as a conventional solid electrolyte under the relatively high partial pressure of oxygen.

Conclusion

The fcc phase present in the systems Bi_2O_3-M_2O_5 (M = V, Nb, or Ta) was confirmed to be a highly conductive oxide ion conductor. Although this phase is not stable in the low content of M_2O_5 at low temperatures, it can be stabilized at low temperatures by adding more than a certain amount of M_2O_5 (Nb, 15 m/o; Ta, 18 m/o). The oxide ion conductivity of this phase, however, decreases with increasing content of the stabilizer, and a maximum conductivity is obtained at the lower limit of the fcc solid solution formation range. The activation energy for conduction in this phase increases with the content of dopants irrespective of their sort, and the value is higher than that for M_2O_3-doped specimen at the corresponding concentration. The crystal structure of this phase is the defect fluorite type having an appreciable amount of oxide ion vacancies, which contribute to the oxide ion conduction.

Of these systems, the Nb-containing specimen has the highest conductivity over a wide range of compositions and temperatures. The best conductor $(Bi_2O_3)_{0.85}(Nb_2O_5)_{0.15}$ has the conductivities of 1.9×10^{-1} Ω^{-1} cm^{-1} at 700°C and 1.1×10^{-2} Ω^{-1} cm^{-1} at 500°C which are more than ten times higher than those of the conventional stabilized zirconias. Although this material is apt to be reduced under a reducing atmo-

sphere, it may be available for practical solid electrolytes under oxidizing atmosphere because of its high conductivity and easy preparation.

Determination of the Kinetic Parameters of Mixed-Conducting Electrodes and Application to the System Li_3Sb

W. Weppner and R. A. Huggins*

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

An electrochemical galvanostatic intermittent titration technique (GITT) is described which combines both transient and steady-state measurements to obtain kinetic properties of solid mixed-conducting electrodes, as well as thermodynamic data. The derivation of quantities such as the chemical and component diffusion coefficients, the partial conductivity, the mobility, the thermodynamic enhancement factor, and the parabolic rate constant as a function of stoichiometry is presented. A description of the factors governing the equilibration of composition gradients in such phases is included. The technique is applied to the determination of the kinetic parameters of the compound "Li_3Sb," which has a narrow composition range. For $Li_{2.9994}Sb$ the chemical diffusion coefficient is 2×10^{-5} cm^2 sec^{-1} at 360°C. This value is quite high, due to a large thermodynamic enhancement factor of 1.3×10^4. The lithium component diffusion coefficient is comparatively small at this composition, 1.5×10^{-9} cm^2 sec^{-1}. The partial conductivity and electrical mobility of lithium are 1.5×10^{-4} Ω^{-1} cm^{-1} and 3×10^{-8} cm^2 V^{-1} sec^{-1}, respectively, at the same stoichiometry and temperature. Because of the very large values of the chemical diffusion coefficient and the fact that 3 moles of lithium can react per mole of antimony, this system may be of interest for use in new types of secondary batteries.

Quantitative knowledge of transport kinetics in solids is of importance both for increased understanding of transport mechanisms and the disorder in solid materials and for the technological application of many solid-state reactions. Especially in the current search for new types of high power density batteries, success in several approaches strongly depends on the availability of solid electrodes which incorporate electroactive species from the electrolyte into their crystal structures and in which the equilibration of local differences in composition occurs rapidly.

In general, in the presence of a compositional (stoichiometric) gradient the transport parameters of the different mobile species are interrelated. The quantity usually used to describe the complex process of compositional equilibration (relaxation) is the chemical diffusion coefficient, $\tilde{D}$. Besides the thermogravimetric, conductometric, and radiotracer methods which have been used for a long time for the observation of the exchange of solid compounds with adjacent liquid or gaseous species, electrochemical techniques have recently come into use (1-4). The important advantage of this latter approach is that the voltage of a suitable galvanic cell is directly related to appropriate thermodynamic quantities, and the current can provide easily measurable kinetic information at the same time. For the case of ideal solutions and concentration-independent diffusion coefficients, electrochemical methods have also been used in several earlier investigations [*e.g.*, (5-7)].

To study chemical diffusion in mixed-conducting solids one may employ transient methods similar to those used for the electrochemical investigation of the kinetics in the vicinity of chemically inert solid electrodes in liquid electrolytes (chronopotentiometry, chronoamperometry, voltammetry) [*e.g.*, (8)]. In the case discussed here, however, the transport in the bulk of the electrode acts as the rate-determining step.

* Electrochemical Society Active Member.
Key words: chemical diffusion, galvanostatic intermittent titration, partial ionic conductivity, thermodynamic enhancement factor, parabolic tarnishing rate constant, ionic mobility.

Steady-state measurements are often used to measure the conductivity. However, they give information concerning the product of the concentration and the diffusion coefficient, rather than either one separately, without additional information. On the other hand, transient methods may sometimes be used to separate these quantities. An example is the so-called "Rosenburg method" for the evaluation of defect concentrations and chemical diffusion in oxide layers (9-11).

In this paper, the application of an electrochemical cell method is introduced for the acquisition of both kinetic and thermodynamic information in mixed conductors, such as insertion compound electrodes. This method allows separate determination of the chemical diffusion coefficient, as well as other useful quantities, in one set of experiments. This approach employs an experimentally tractable galvanostatic intermittent titration technique (GITT), which combines transient and steady-state measurements. It eliminates the customary problem of interference due to resistance polarization in the use of potentiostatic techniques. The desired data are conveniently accessible, and a precise coulometer or independent determination of coulometric titration curves are not necessary.

The investigation of trilithium antimonide, "Li_3Sb," by the use of this new technique is described here. Li_3Sb is a mixed-conducting compound whose features make it potentially interesting for use as an electrode constituent. Although the range of stoichiometry of this phase is rather narrow, so that only small stoichiometric variations may occur, this method is shown to be extremely sensitive and quite precise.

Basic Relations

Chemical diffusion is a process in which the transport of all species within the solid is involved. General equations will be derived for its microscopic description and its relation to other kinetic parameters of the material. The particle fluxes will be expressed in terms of the individual kinetic and thermodynamic properties of the different ionic and electronic species. This approach will show which factors control chemical diffusion under various circumstances. Effects resulting from volume changes and macroscopic movements will not be considered. For this purpose, one may often use the sublattice of one component as the frame of reference for the motion of all the other species (12). If necessary, other reference systems should be considered (13), of course. Also, it will be assumed that the diffusion length is small compared to the dimensions of the whole system.

In general, in an isothermal and adiabatic system and if Onsager's cross-coefficients (12) are negligible, the flux density of species i (in particles per square centimeter second) under the influence of a gradient of the electrochemical potential η_i (related to one particle) is given in the one-dimensional case by

$$j_i = -\frac{\sigma_i}{z_i^2 q^2}\frac{\partial \eta_i}{\partial x} \qquad [1]$$

σ_i, z_i, and q are the partial electrical conductivity due to the transport of species i, the charge number (valence), and the elementary charge, respectively. The electrical conductivity σ_i may be replaced by an expression including the product of the concentration c_i and the electrical mobility u_i or, alternatively, the general mobility b_i (the mean particle velocity per unit general acting force), where $b_i = u_i/|z_i|q$

$$\sigma_i = |z_i| q c_i u_i = z_i^2 q^2 c_i b_i \qquad [2]$$

Also, the electrochemical potential η_i may be divided into two terms, one containing the chemical potential μ_i (per particle) or the activity a_i, and the other the local electrostatic potential ϕ

$$\eta_i = \mu_i + z_i q\phi = \mu_i^\circ + kT \ln a_i + z_i q\phi \qquad [3]$$

μ_i°, k, and T are the chemical potential of species i in the standard state ($a_i = 1$), Boltzmann's constant, and the absolute temperature, respectively. Inserting Eq. [2] and [3] into Eq. [1] yields for the flux density of the component i

$$j_i = -\frac{kTu_i}{|z_i|q}\left[\frac{\partial \ln a_i}{\partial \ln c_i}\frac{\partial c_i}{\partial x} + \frac{z_i q c_i}{kT}\frac{\partial \phi}{\partial x}\right] \qquad [4]$$

The factor in front of the bracket has the dimensions of a diffusion coefficient and is the component diffusion coefficient D_{Ki}, or the "diffusivity of the species i as a component" (12)

$$D_{Ki} = \frac{kTu_i}{|z_i|q} = b_i kT \qquad [5]$$

This quantity is thus simply proportional to the mobility of the species in question and reflects the same microscopic kinetic phenomena. This diffusion coefficient obeys the Nernst-Einstein equation regardless of whether the solution is ideal or nonideal, and is the diffusion coefficient which is directly measured in the case of ideal dilute solutions of neutral species. D_{Ki} is a measure of the random motion of the particles of species i in the crystal, and is related to the (radio) tracer diffusion coefficient D_{Ti} by $D_{Ti} = f_i D_{Ki}$, where f_i is the correlation factor.

The inner electric field $\partial\phi/\partial x$, which cannot be experimentally determined, may be eliminated from Eq. [4] by the condition that, except for transient conditions involving the accumulation of a significant space charge, charge flux balance must be maintained. That is, for all species, if there is no externally applied electric potential difference

$$\sum_i z_i j_i = 0 \qquad [6]$$

Inserting Eq. [4] into Eq. [6], and solving for $\partial\phi/\partial x$, and then using this expression in Eq. [4] yields the flux density for species i in terms of transport quantities and activity gradients related to it and to all other species j

$$j_i = -D_{Ki}\left[\frac{\partial \ln a_i}{\partial \ln c_i} - \sum_j t_j \frac{z_i}{z_j}\frac{\partial \ln a_j}{\partial \ln c_i}\right]\frac{\partial c_i}{\partial x} \qquad [7a]$$

$$= -D_{Ki}\left[(1 - t_i)\frac{\partial \ln a_i}{\partial \ln c_i} - \sum_{j\neq i} t_j \frac{z_i}{z_j}\frac{\partial \ln a_j}{\partial \ln c_i}\right]\frac{\partial c_i}{\partial x} \qquad [7b]$$

The summations include all other ionic and electronic species. The symbol $t_i = \sigma_i \Big/ \sum_j \sigma_j$ is the transference number for species i.

As a result of the ionization equilibrium, in which the activities of neutral species are related to those of their ionic and electronic constituents within solids, we have

$$d \ln a_i + z_i d \ln a_e = d \ln a_i - z_i d \ln a_h = d \ln a_i^* \qquad [8]$$

where e, h, and i* represent electrons, holes, and neutral i species, respectively. Equation [7] may now be transformed into an expression containing only the (physically more relevant) activities and concentrations of neutral atomic species

$$j_i = -D_{Ki}\left[\frac{\partial \ln a_i^*}{\partial \ln c_i^*} - \sum_{j\neq e,h} t_j \frac{z_i}{z_j}\frac{\partial \ln a_j^*}{\partial \ln c_i^*}\right]\frac{\partial c_i}{\partial x} \qquad [9a]$$

$$= -D_{Ki}\left[(1 - t_i)\frac{\partial \ln a_i^*}{\partial \ln c_i^*} - \sum_{j\neq i,e,h} t_j \frac{z_i}{z_j}\frac{\partial \ln a_j^*}{\partial \ln c_i^*}\right]\frac{\partial c_i}{\partial x} \qquad [9b]$$

These equations give the flux density for any chemical component and hold both for the ionic species within the solid or for the effective flux density of such species in their neutral form. These equations are distinct from those which appeared in the earlier discussion [7], however, in that the activity and concentration terms only involve neutral chemical species, and neither electrons nor holes.

These general equations have a form similar to the familiar Fick's first law

$$j_i = -\tilde{D}_i \frac{\partial c_i}{\partial x} \qquad [10]$$

where $\tilde{D}_i$ is the chemical diffusion coefficient (the effective diffusion coefficient) for species i (with reference to the crystal lattice, which in the cases discussed below, is identical to the laboratory frame) and

$$\tilde{D}_i = D_{K_i} W \qquad [11]$$

where the factor W is an enhancement factor, defined by the quantity in the square brackets

$$W = \left[(1 - t_i) \frac{\partial \ln a_i^*}{\partial \ln c_i^*} - \sum_{j \neq i,e,h} t_j \frac{z_i}{z_j} \frac{\partial \ln a_j^*}{\partial \ln c_j^*} \right] \qquad [12]$$

The symbol W was selected for this purpose in honor of Carl Wagner, who first showed (14) the influence of the transport of charged species upon each other.

$\tilde{D}_i$ is sometimes called the "intrinsic diffusion coefficient" of species i, when referred to the laboratory frame. In the case that the crystal and laboratory frames are identical, these quantities are the same. In cases in which two atomic species interdiffuse, the term "interdiffusion coefficient" is sometimes used with reference to the crystal frame, which may move with respect to the laboratory frame.

In many systems of practical importance, including tarnishing processes (14), the situation is simplified by the fact that two types of species (either two different ionic species, or one ionic and one electronic species) dominate the transport phenomena. Under this situation, the chemical diffusion coefficients of the two species are equal, and we can use the symbol $\tilde{D}$ for both (15). For the case in which only one ionic and one electronic species have to be considered, so that $t_e = 1 - t_i$, the enhancement factor becomes

$$W = t_e \frac{\partial \ln a_i^*}{\partial \ln c_i^*} \qquad [13]$$

and

$$\tilde{D} = D_{K_i} t_e \frac{\partial \ln a_i^*}{\partial \ln c_i^*} \qquad [14]$$

If the sample is predominantly an electronic conductor, so that $t_e \rightarrow 1$, we have simply

$$W = \frac{\partial \ln a_i^*}{\partial \ln c_i^*} \qquad [15]$$

and

$$\tilde{D} = D_{K_i} \frac{\partial \ln a_i^*}{\partial \ln c_i^*} \qquad [16]$$

This is the case previously discussed by Wagner (16). Using the definition of the activity coefficient $\gamma_i = a_i/c_i$, the enhancement factor can be written in the form

$$W = \left[1 + \frac{\partial \ln \gamma_i}{\partial \ln c_i} \right] = \left[1 + c_i \frac{\partial \ln \gamma_i}{\partial c_i} \right] \qquad [17]$$

derived for metals by Darken (17).

On the other hand, if the transference number of the ionic species is much larger than that for the electronic species, Eq. [13] can be rewritten as

$$W = \left(\frac{\sigma_e}{\sigma_i} \right) \frac{\partial \ln a_i^*}{\partial \ln c_i^*} \qquad [18]$$

and by using Eq. [2] and [5], we get

$$W = \frac{c_e D_{K_e}}{z_i^2 c_i D_{K_i}} \frac{\partial \ln a_i^*}{\partial \ln c_i^*} \qquad [19]$$

and then

$$\tilde{D} = \frac{c_e D_{K_e}}{z_i^2 c_i} \frac{\partial \ln a_i^*}{\partial \ln c_i^*} \qquad [20]$$

Thus we see that, in this case, the chemical diffusion coefficient for the ionic species is dependent on the component diffusion coefficient of the electrons, not the ions.

Let us now further examine the value of the enhancement factor for several different situations for the common and important case in which only one ionic species and one electronic species (assumed to be excess or mobile electrons) have to be considered, the transference numbers of all other species being negligible. From Eq. [8] and [13], the enhancement factor for the ions becomes simply

$$W = t_e \left[\frac{\partial \ln a_i}{\partial \ln c_i} + z_i \frac{\partial \ln a_e}{\partial \ln c_i} \right] \qquad [21]$$

For the special case in which we can assume that both the ionic species and the electrons obey either Henry's or Raoult's law, *i.e.*, γ_i and γ_e are constant, and considering the electroneutrality condition

$$dc_e = z_i dc_i \qquad [22]$$

we derive from Eq. [21]

$$W = t_e \left[1 + z_i^2 \frac{c_i}{c_e} \right] \qquad [23]$$

We can thus conclude that if $t_e << 1$, *i.e.*, in the case of a solid electrolyte with dilute mobile ionic species, W will tend toward zero, and the chemical diffusion of ions in response to a composition gradient will be very sluggish.

On the other hand, if electronic conduction predominates, $t_e \rightarrow 1$, the value of W will depend sensitively upon the value of c_i/c_e. If $c_i << c_e$, W will approach unity, so the chemical diffusion coefficient for the ionic species becomes the same as the component diffusion coefficient. If $z_i^2 c_i = c_e$, W becomes 2.

There are many cases in which electronic conduction predominates ($t_i << 1$), and yet $c_i >> c_e$. This is possible if the electrons have a much greater mobility than the ionic species and can lead to unusually large values of W, and thus of $\tilde{D}_i$, as pointed out by Wagner (18), who cited a number of materials in which this has been found. It will be shown later in this paper that this is also true for Li_3Sb.

Very large enhancement factors can also be present for materials in which one can assume that only the electronic species exhibit ideal solution behavior. In that case Eq. [21] becomes

$$W = t_e \left[\frac{\partial \ln a_i}{\partial \ln c_i} + z_i^2 \frac{c_i}{c_e} \right] \qquad [24]$$

The large enhancement (or reduction) factor W is sometimes explained in terms of a microscopic model in which the more mobile species tend to move ahead of the others. If they have different charges (or species of the same sign move at different rates in opposite directions), this creates an internal electric field in which the slower species are accelerated, and the

Table I. Value of enhancement factor under various conditions

faster ones retarded, in order to maintain local charge flux neutrality.

It should be mentioned that if the second term in either Eq. [23] or [24] is significantly greater than unity, we should expect the temperature dependence of the chemical diffusion coefficient to be different from that of the component or tracer diffusion coefficients, due to the temperature dependence of c_i/c_e.

The values of the enhancement factor W that are expected under these various conditions are presented in Table I.

Determination of the Chemical Diffusion Coefficient by Use of the Galvanostatic Intermittent Titration Technique

The chemical diffusion coefficient of species A and other kinetic and thermodynamic parameters may be investigated in a mixed conductor $A_{y+\delta}B$, (δ symbolizes the deviation from the ideal stoichiometric composition) by the use of a galvanic cell with $A_{y+\delta}B$ as one electrode, as shown in Fig. 1. Because of potential problems with electrode polarization, separate counter (A) and reference (A°) electrodes generally have to be employed. Instead of pure A, another material with a different activity of A may also be used for these two electrodes. As will become obvious later, the location at which the reference electrode is attached to the electrolyte is unimportant, *e.g.*, the left-hand electrode may be divided into two parts, and partially used as a counter and partially as a reference electrode.

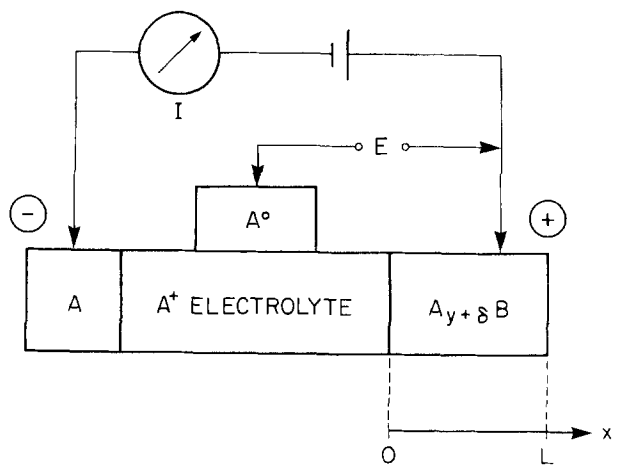

Fig. 1. Schematic illustration of experimental galvanic cell arrangement. The electrolyte-sample interface is at $x = 0$. The sample thickness is L.

According to the Nernst equation

$$E = \frac{kT}{z_A q} \ln \frac{a_{A^*}(A^\circ)}{a_{A^*}(A_{y+\delta}B)} \qquad [25]$$

the cell voltage E is thus a measure of the thermodynamic activity of neutral A in the $A_{y+\delta}B$ sample at the interface with the electrolyte.

An electric current I which is driven through the galvanic cell by an external source determines the transport of the relevant mobile ionic species within the sample just inside the phase boundary with the electrolyte (where $x = 0$)

$$I = -Sz_i q\tilde{D}\frac{\partial c_i}{\partial x}\bigg|_{x=0} \qquad [26]$$

with i being either A or B, depending on which one has the predominant conductivity. S is the area of the sample-electrolyte interface.

The principles underlying this procedure for the determination of the kinetic and thermodynamic parameters of a mixed conductor are illustrated in Fig. 2. Starting with a sample of known stoichiometric composition and with the galvanic cell in thermodynamic equilibrium, *i.e.*, the concentrations of all species are homogeneous throughout the electrode $A_{y+\delta}B$, corresponding to cell voltage E_0, a constant current I_0 is applied to the cell at time t_0 by a galvanostat, or simply by a battery and a large resistor. According to Eq. [26] this produces a constant concentration gradient $\partial c_i/\partial x$ within the $A_{y+\delta}B$ at the phase boundary with the electrolyte ($x = 0$). In order to maintain this constant concentration gradient, the applied cell voltage increases (or decreases, depending on the direction of the current) with time. A voltage step, corresponding to the IR drop due to the current flux through the electrolyte and the interface is superimposed, whose magnitude depends on the position of the reference electrode. However, it is always time-independent (on the scale of this experiment), and acts as a constant that merely shifts the measured

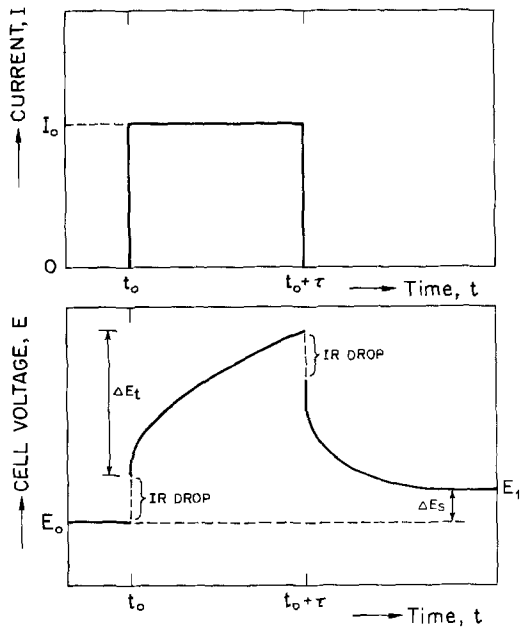

Fig. 2. Schematic illustration of a single step of the galvanostatic intermittent titration technique (GITT). ΔE_t is the total transient voltage change of the galvanic cell for an applied galvanostatic current I_o for the time τ. ΔE_s is the change of the steady-state voltage of the cell for this step.

voltage by a constant value but does not change the geometrical shape of the voltage-time curve.

After a time interval τ, the current flux is interrupted, whereupon the composition within the $A_{y+\delta}B$ sample tends to again become homogeneous by diffusion of the mobile species. During this equilibration process the surface composition of the sample, and therefore the cell voltage, drifts back toward a new steady-state value E_1, corresponding to a new activity of A in the sample as a result of the change of the stoichiometry $\Delta\delta$ caused by the coulometric titration of A ions into it by the current

$$\Delta\delta = \frac{I_o \tau M_B}{z_A m_B \mathbf{F}} \qquad [27]$$

M_B, m_B, I_o, and $\mathbf{F}$ are the atomic weight of B, the mass of the component B in the sample, the constant current, and Faraday's constant, respectively. After the electrode is again in equilibrium, the procedure may be repeated, starting now with the new cell voltage E_1. This process may be continued until a phase change occurs in the electrode, or the electrolyte decomposes or becomes electronically conductive.

In order to calculate the voltage E as a function of time t during which the current is applied, the time dependence of the concentration c_i at the interface $x = 0$ has to be determined by solving Fick's second law

$$\frac{\partial c_i(x,t)}{\partial t} = \tilde{D}\frac{\partial^2 c_i(x,t)}{\partial x^2} \qquad [28]$$

with the initial and boundary conditions

$$c_i(x, t=0) = c_o \quad (0 \leqq x \leqq L) \qquad [29]$$

$$-\tilde{D}\frac{\partial c_i}{\partial x}\bigg|_{x=0} = \frac{I_o}{S z_i q} \quad (t \geqq 0) \qquad [30]$$

$$\frac{\partial c_i}{\partial x}\bigg|_{x=L} = 0 \quad (t \geqq 0) \qquad [31]$$

The last condition is due to the fact that the right-hand phase boundary of the sample is assumed to be impermeable.

The solution of the differential Eq. [28] under conditions [29]-[31] is known (19, 20) and can be cast in the following form for $x = 0$

$$c_i(x=0,t) = c_o + \frac{2I_o\sqrt{t}}{S z_i q\sqrt{\tilde{D}}} \sum_{n=o}^{\infty} \left(\text{ierfc}\left[\frac{nL}{\sqrt{\tilde{D}t}}\right] + \text{ierfc}\left[\frac{(n+1)L}{\sqrt{\tilde{D}t}}\right]\right) \qquad [32]$$

with $\text{ierfc}(\lambda) = [\pi^{-1/2}\exp(-\lambda^2)] - \lambda + [\lambda\,\text{erf}(\lambda)]$, the first integral of the complement of the error function. At times $t << L^2/\tilde{D}$ the infinite sum can be approximated by the first term. Then, we have for the variation of c_i with the square root of time

$$\frac{dc_i(x=0,t)}{d\sqrt{t}} = \frac{2I_o}{S z_i q\sqrt{\tilde{D}\pi}} \quad (t << L^2/\tilde{D}) \qquad [33]$$

If changes of the molar volume with composition may be neglected, the changes in the concentration and the stoichiometry are related through

$$dc_i = \frac{N_A}{V_M} d\delta \qquad [34]$$

where N_A is Avogadro's number and V_M is the molar volume of the sample. Inserting this expression in Eq. [33] and expanding by dE yields the following expression for the expected time dependence of the cell voltage

$$\frac{dE}{d\sqrt{t}} = \frac{2V_M I_o}{S\mathbf{F}z_i\sqrt{\tilde{D}\pi}}\frac{dE}{d\delta} \quad (t << L^2/\tilde{D}) \qquad [35]$$

$dE/d\delta$ is the slope of the coulometric titration curve, which is found by plotting the steady-state voltages, measured after each titration step, against the composition, calculated from the current flux times the applied time interval with the help of Eq. [27]. With this information, the chemical diffusion coefficient may be calculated from Eq. [35] because all other quantities are known or measurable

$$\tilde{D} = \frac{4}{\pi}\left(\frac{V_M}{S\mathbf{F}z_i}\right)^2 \left[I_o\left(\frac{dE}{d\delta}\right) \Big/ \left(\frac{dE}{d\sqrt{t}}\right)\right]^2 \quad (t << L^2/\tilde{D}) \qquad [36]$$

If the electrolyte is in contact with both sides of the sample, *e.g.*, in the case that a liquid electrolyte is used, the middle plane, rather than the far side, of a pellet sample is equivalent to the position $x = L$. Because of symmetry, there will be no transport of species across this plane. In this case, the total area of contact between the electrolyte and the electrode has to be taken into account when calculating the area S.

If by using a sufficiently small current the change of the steady-state (equilibrium) voltage $(E_1 - E_o) \simeq \Delta E_s$ over a single galvanostatic titration is small, $dE/d\delta$ may be considered to be constant and may be replaced by the ratio of the finite quantities, $\Delta E_s/\Delta\delta$. Thus, by inserting Eq. [27] for the change of the stoichiometry in Eq. [36] we have

$$\tilde{D} = \frac{4}{\pi}\left(\frac{m_B V_M}{M_B S}\right)^2 \left[\frac{\Delta E_s}{\tau\left(\frac{dE}{d\sqrt{t}}\right)}\right]^2 \quad (t << L^2/\tilde{D}) \qquad [37]$$

This expression may be transformed once more to an even simpler algebraic form if E *vs.* $\sqrt{t}$ shows the expected straight line behavior over the entire time period of the current flux

$$\tilde{D} = \frac{4}{\pi\tau}\left(\frac{m_B V_M}{M_B S}\right)^2\left(\frac{\Delta E_s}{\Delta E_t}\right)^2 \quad (\tau << L^2/\tilde{D}) \quad [38]$$

ΔE_t is the total change of the cell voltage E during the current pulse, neglecting the IR drop.

Determination of Other Kinetic and Thermodynamic Quantities

Besides the determination of the chemical diffusion coefficient $\tilde{D}$, it is possible to evaluate other kinetic and thermodynamic parameters by use of the galvanostatic intermittent titration technique. The methods for obtaining some of the more important quantities are as follows.

The enhancement factor.—As discussed earlier the chemical diffusion of species A is enhanced by the thermodynamic factor $\partial \ln a_{A^*}/\partial \ln c_{A^*}$ relative to the component diffusivity. This enhancement factor can be determined from the local slope of the coulometric titration curve, $dE/d\delta$, at any composition. The change of $\ln a_{A^*}$ is given by the change of the voltage E of the cell times $z_A q/kT$, and the change in the concentration c_A is $N_A d\delta/V_M$. Therefore, we have

$$\frac{\partial \ln a_{A^*}}{\partial \ln c_{A^*}} = -\frac{z_A q c_A V_M}{kTN_A}\frac{dE}{d\delta} = -\frac{z_A q(y+\delta)}{kT}\frac{dE}{d\delta} \quad [39]$$

By determining the slope of the coulometric titration curve at different stoichiometries the thermodynamic factor may be obtained as a function of the composition.

The partial conductivity.—For the case in which the chemical diffusion is predominantly determined by one kind of ionic species, A^{z_A+}, and either electrons or holes, Eq. [14] yields, with the substitution of D_K by σ according to Eq. [2] and [5]

$$\sigma_A t_e = \frac{(z_A q)^2 c_A \tilde{D}}{kT}\left(\frac{\partial \ln a_{A^*}}{\partial \ln c_{A^*}}\right)^{-1} \quad [40]$$

By using Eq. [39] the thermodynamic factor can be replaced by a term containing the slope of the coulometric titration curve, $dE/d\delta$, which is determined from the steady-state values of the cell voltages in between titrations and the corresponding change of the composition. This yields

$$\sigma_A t_e = -\frac{z_A F \tilde{D}}{V_M}\left(\frac{dE}{d\delta}\right)^{-1} \quad [41]$$

from which $\sigma_A t_e$ may be calculated if the chemical diffusion coefficient $\tilde{D}$ has been determined as described above. It is obvious that if the sample is predominantly electronically conducting, the product $\sigma_A t_e$ is the partial ionic conductivity of the A species, σ_A. For a predominantly ionic conductor $\sigma_A t_e$ is the partial electronic conductivity, σ_e, since $t_e = \sigma_e/(\sigma_e + \sigma_A) \approx \sigma_e/\sigma_A$.

If the coulometric titration curve can be considered linear over the range of a single galvanostatic titration step, replacement of dE and $d\delta$ by their finite values and using Eq. [37] for $\tilde{D}$ yields

$$\sigma_A t_e = -\frac{4}{\pi}\frac{V_M m_B I_o \Delta E_s}{M_B S^2 \tau\left(\frac{dE}{d\sqrt{t}}\right)^2} \quad (t << L^2/\tilde{D}) \quad [42]$$

Furthermore, if τ is also small compared to $L^2/\tilde{D}$, *i.e.*, E is proportional to $\sqrt{t}$ over the entire period of the application of the constant current during one titration step, we have

$$\sigma_A t_e = -\frac{4}{\pi}\frac{m_B V_M I_o \Delta E_s}{M_B S^2 (\Delta E_t)^2} \quad (\tau << L^2/\tilde{D}) \quad [43]$$

Thus, like the chemical diffusion coefficient, the conductivity term $\sigma_A t_e$ may be determined from the change in the steady-state voltage, ΔE_s, and the magnitude of the voltage increase during one titration, ΔE_t.

The component diffusion coefficient, the mobilities, and the tracer diffusion coefficient.—For a predominantly electronically conducting electrode containing mobile A^{z_A+} ions, D_{KA} may be determined from Eq. [16] using the expressions [39] and [36]-[38] for the enhancement factor and the chemical diffusion coefficient, respectively. As previously, if $dE/d\delta$ may be considered as constant for a single titration step, we have

$$D_{KA} = -\frac{4kTm_B V_M I_o}{\pi q^2 c_A z_A^2 M_B S^2 \tau}\frac{\Delta E_s}{\left(\frac{dE}{d\sqrt{t}}\right)^2} \quad (t << L^2/\tilde{D}) \quad [44]$$

If, additionally, E *vs.* $\sqrt{t}$ is linear over the entire titration period τ, the component diffusion coefficient may also be determined from

$$D_{KA} = -\frac{4kTm_B V_M I_o}{\pi c_A z_A^2 q^2 M_B S^2}\frac{\Delta E_s}{(\Delta E_t)^2} \quad (\tau << L^2/\tilde{D}) \quad [45]$$

The electrical mobility, u_A, and the general mobility, b_A, are obtained from this expression by use of the Nernst-Einstein relation [5]. Also, it is possible to calculate the tracer diffusion coefficient D_T from the results of galvanostatic intermittent titration experiments if an assumption can be made concerning the value of the correlation factor f_A (or more generally, the Haven ratio) (21)

$$D_{TA} = f_A D_{KA} \quad [46]$$

The parabolic tarnishing rate constant.—If the range of stoichiometry of the electrode material is exhausted by continual titrations, further ionic current through the galvanic cell results in the growth of a second phase outside the first one. The relevant quantity used to describe the growth of such a layer is the parabolic tarnishing rate constant k_t in cases in which the process is determined by bulk diffusion. When ions A^{z_A+} and either electrons or holes are the predominantly mobile species, the ionic flux in the parabolically growing layer may be either described by Fick's first law with the diffusion coefficient given by Eq. [14] or

$$|j_A| = c_A\frac{dL'}{dt} = c_A\frac{k_t}{L'} \quad [47]$$

if the average concentration c_A may be regarded as approximately constant. L' is the instantaneous thickness of the tarnishing layer. Equating Fick's first law and Eq. [47], and integrating over the thickness of the layer, L', results in an equation from which the parabolic rate constant may be calculated as a function of the activity of A* or the compositional parameter δ at the interface with the electrolyte ($x = 0$)

$$k_t = \frac{1}{y+\delta}\left|\int_0^{L'}\tilde{D}d\delta\right| \quad [48]$$

The integral is the area under a plot of the chemical diffusion coefficient, as determined by galvanostatic intermittent titration using the tarnishing product (outer) phase as the electrode material, as a function of the stoichiometric parameter δ between the value in equilibrium with the first (inner) phase and the value at the outer surface. Alternatively, k_t may be calculated for a predominantly electronic conductor

by plotting D_{K_A}, which is determined according to Eq. [44] or [45], as a function of the cell voltage E. This follows from Eq. [48] by using Eq. [16] for $\tilde{D}$ and Eq. [39] for the enhancement factor

$$k_t = \frac{q}{kT} \left| z_A \int_0^{L'} D_{K_A} dE \right| \qquad [49]$$

The integration extends from the voltage at the two-phase equilibrium to the voltage corresponding to the activity a_{A^*} or the stoichiometric parameter δ for which k_t is evaluated.

In contrast to the usual tarnishing experiments in which the material is typically maintained in contact with a constant activity of A*, *e.g.*, that corresponding to equilibrium with another phase, the method described here permits the tarnishing rate constant to be evaluated as a function of the activity of A* over the whole stoichiometric range of the tarnish product phase.

Application to Trilithium Antimonide, Li_3Sb

The galvanostatic intermittent titration technique has been applied to Li_3Sb as a model electrode constituent. Its kinetic parameters determine the rate of alloying antimony with lithium at high lithium activities. Due to the large amount (3 moles) of lithium that can react per mole of antimony, this binary system may be of practical interest for application in new types of high power density batteries, either at room temperature (22, 23) or at elevated temperatures. From the point of view of testing the general applicability of the galvanostatic intermittent titration technique it should be pointed out that Li_3Sb actually offers less than optimum conditions, for it has a comparatively narrow range of stoichiometry and a very composition-dependent enhancement factor.

A eutectic mixture of molten LiCl-KCl salt (spectroscopically pure, Anderson Physics Laboratories, Urbana, Illinois) has been used as an electrolyte for lithium ions in a set of experiments on the Li_3Sb phase. Both reference and counterelectrodes were composed of the solid-state two-phase system of lithium-saturated Al and the adjacent phase "LiAl," which has a composition at the phase boundary of about 47 atomic percent Li. This system has a potential about 300 mV less negative than pure liquid lithium at 400°C. The Li_3Sb electrode was prepared by coulometric titration of lithium into an antimony disk. The electric leads were made of molybdenum, which exhibits a negligible solubility for lithium. The experiments were conducted within a Vacuum/Atmospheres Company recycling helium dry box. No impurity effects were observed.

The voltage range of the existence of the Li_3Sb phase is between about +0.88 and 0V with reference to pure lithium at 400°C. This corresponds to a range of lithium activity from about 2.6×10^{-7} to 1. Figure 3 shows a typical voltage-time dependence for the case of galvanostatically titrating lithium into the $Li_{3+\delta}Sb$ sample with a current density of 0.25 mA/cm², applied for 300 sec at 360°C. The corresponding change of the stoichiometric parameter δ of the sample is about 2.5×10^{-4}. The voltage is plotted as a function of the square root of time for the same measurement in Fig. 4. In agreement with theoretical considerations (Eq. [35]), a straight line is observed for times up to 200 sec. The deviation from linearity at longer times is discussed later.

A sequence of selected galvanostatic titrations of lithium out of Li_3Sb, distributed over the entire range of the thermodynamic existence of the compound, is plotted in Fig. 5. The polarization of the voltage is observed to be much greater in the center of the stoichiometric range of existence than near both ends.

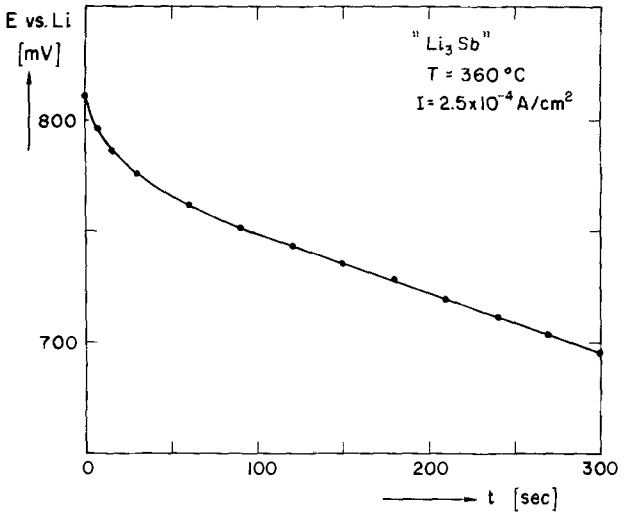

Fig. 3. Typical transient voltage change of the galvanic cell with a Li_3Sb sample after a constant current of 2.5×10^{-4} A cm² was applied. LiCl-KCl(e) was used as a molten salt electrolyte, and two-phase Al, LiAl mixtures used as counter and reference electrodes.

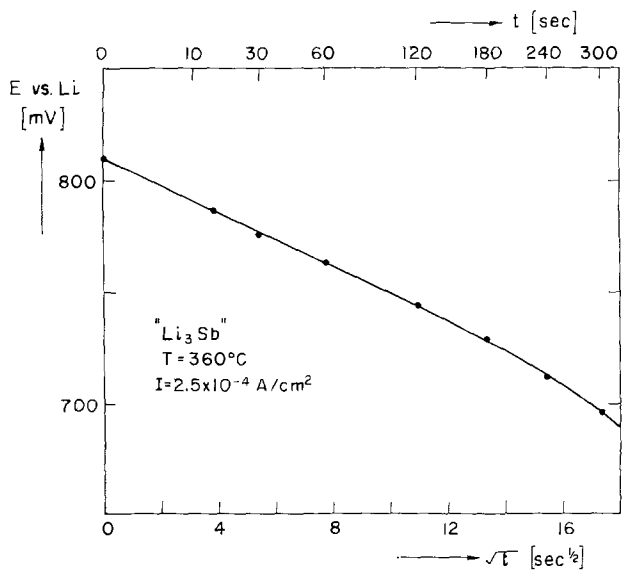

Fig. 4. Representation of the transient voltage of the galvanic cell as a function of the square root of the time. The experimental conditions were the same as those of Fig. 3.

This is closely related to the shape of the coulometric titration curve, determined from the steady-state cell voltages observed between titrations as a function of composition. The data for several runs (in both compositional directions) are shown in Fig. 6. Near the middle of the composition range the slope $dE/d\delta$ has a marked maximum, producing the greatest changes of the transient voltage with time, in accordance with Eq. [35].

The thermodynamic enhancement factor, $\partial \ln a_{Li}/\partial \ln c_{Li}$, was calculated from the slope of the coulometric titration curve and plotted in Fig. 7 as a function of the stoichiometry. As can be seen, the chemical diffusion of the lithium is enhanced by up to a factor of nearly 70,000 relative to the component diffusion coefficient (or the tracer diffusion coefficient divided by the correlation factor).

In order to further test this technique, several additional parameters have been varied, and the results compared with the theoretical considerations. At the same voltage, or stoichiometric composition, the values of the kinetic parameters should be independent of the direction of the current flux. The slopes of the

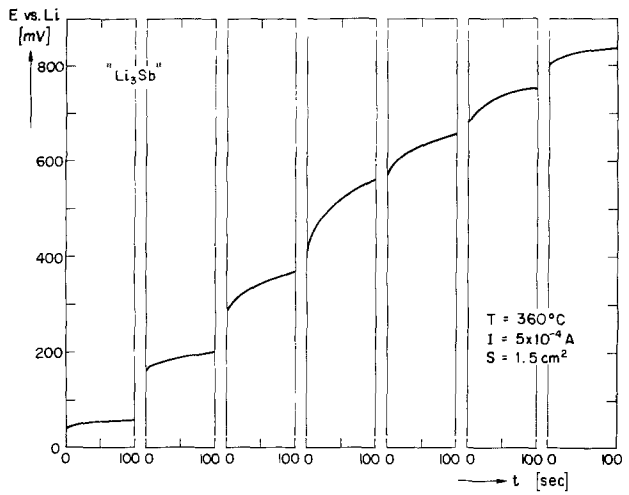

Fig. 5. The transient voltages of the galvanic cell containing Li_3Sb as a function of the time t for several different initial steady-state voltages plotted vs. pure lithium using the same galvanostatic current density of 3.3×10^{-4} A cm^{-2} contact area between the electrolyte and the sample. The different starting voltages represent different stoichiometries of $Li_{3+\delta}Sb$ as determined from Fig. 6.

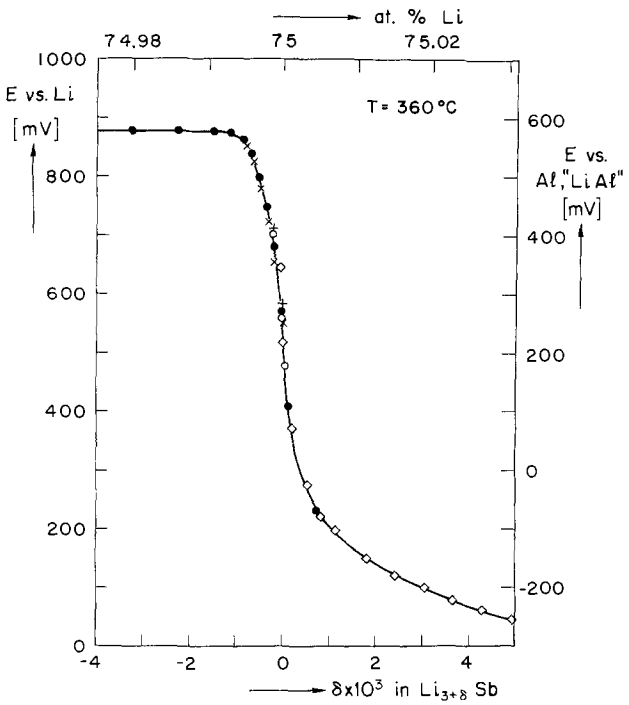

Fig. 6. The steady-state voltages of the galvanic cell with a Li_3Sb sample vs. pure lithium and an Al, LiAl electrode as a function of the stoichiometry δ, *i.e.*, the amount of lithium which is electrochemically pumped into the sample (coulometric titration curve). The horizontal part of the curve represents the two-phase region of Li_3Sb in equilibrium with Li_2Sb.

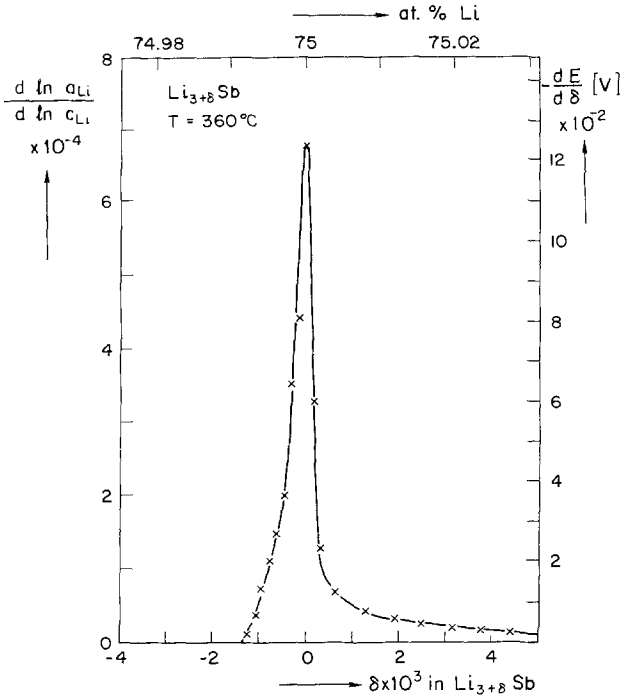

Fig. 7. The composition dependence of the enhancement factor in $Li_{3+\delta}Sb$, which causes the chemical diffusion coefficient to be much greater than either the component diffusion coefficient or the tracer diffusion coefficient of lithium. The enhancement factor is determined from the slope of the coulometric titration curve (Fig. 6), which is plotted at the right-hand ardinate.

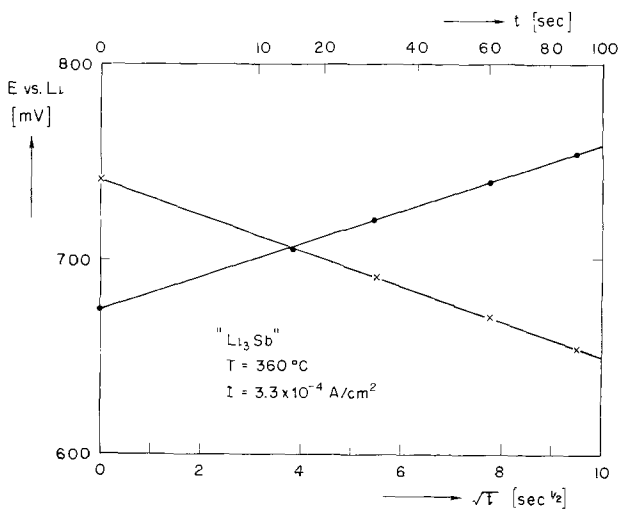

Fig. 8. Two transient voltage changes of the galvanic cell with a Li_3Sb electrode with reference to pure lithium as a function of the square root of time for adding lithium to the sample and removing it with the same current density at about the same mean composition, *i.e.*, cell voltage. The absolute value of the slopes is seen to be the same for both procedures.

E *vs.* $\sqrt{t}$ curves should be the same but of opposite sign for the same current density. This was found to be true, as demonstrated in Fig. 8. Also, the calculated kinetic quantities should be independent of the actual value of the current. According to Eq. [35] the slope of the plots of the voltage *vs.* the square root of time should be proportional to the current I_0 applied. The results of experiments carried out with current densities differing by a factor of 12 are shown in Fig. 9. Good agreement between experiments and theory is seen.

The chemical diffusion coefficient that was calculated from the slope of the straight line in Fig. 4 and the corresponding change of the steady-state cell voltage according to Fig. 6 is $\tilde{D} = 2 \times 10^{-5}$ cm^2 sec^{-1} at the stoichiometric deviation $\delta = -6 \times 10^{-4}$ and 360°C. This value is strongly enhanced by the enhancement factor of $\partial \ln a_{Li}/\partial \ln c_{Li} = 1.3 \times 10^4$, thus being related to a much lower component diffusion coefficient, $D_{KLi} = 1.5 \times 10^{-9}$ cm^2 sec^{-1} at the same stoichiometry and temperature. The tracer diffusion coefficient has also the same order of magnitude, since the correlation factor is of the order of 1. The corresponding partial lithium ionic conductivity was calculated to have a value of $\sigma_{Li} = 1.5 \times 10^{-4}$ Ω^{-1} cm^{-1} for that composition, according to the general equations of the previous section. Using the Nernst-Einstein equa-

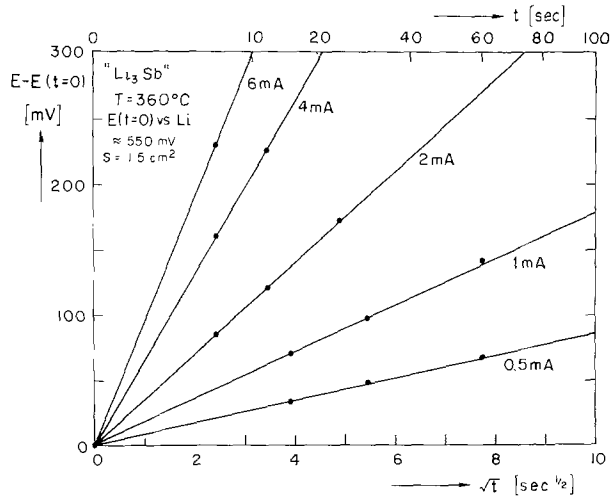

Fig. 9. The transient voltage of the galvanic cell with a Li_3Sb sample referenced to an initial cell voltage of approximately 550 mV *vs.* pure lithium as a function of the square root of time. The results are shown for several current densities. The slopes increase almost linearly with the current density.

tion the general lithium mobility was found to be $b_{Li} = 2 \times 10^{11}$ cm^2 V^{-1} A^{-1} sec^{-2}, and the electrical lithium mobility is $u_{Li} = 3 \times 10^{-8}$ cm^2 V^{-1} sec^{-1} at this composition. The parabolic rate constant k_t for the formation of a Li_3Sb tarnishing layer on a Li_2Sb (24, 25) substrate is of the order of 10^{-8} cm^2 sec^{-1} at a lithium activity $a_{Li} = 4 \times 10^{-7}$ and of the order of 10^{-7} cm^2 sec^{-1} at a lithium activity $a_{Li} = 1$.

By use of this same procedure, values of the chemical diffusion coefficient $\tilde{D}$ have been determined over the whole range of stability of the Li_3Sb phase, as illustrated in Fig. 10.

Extensive experiments utilizing this galvanostatic intermittent titration technique to study the systems Li-Sb and Li-Bi will be reported elsewhere (25, 26).

Discussion

The galvanostatic intermittent titration method combines transient and steady-state electrochemical measurements. In one set of experiments a number of kinetic and thermodynamic quantities may be readily determined with considerable precision as a function of composition within a single phase. The compositional resolution in this technique is quite high, so that phases with only small ranges of stoichiometry can be investigated. The experimental equipment requirements are quite modest, consisting primarily of a constant current source and an instrument that can measure voltage *vs.* time.

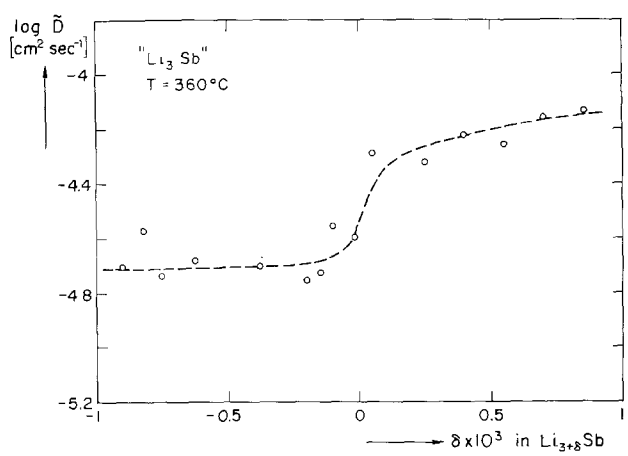

Fig. 10. Variation of the chemical diffusion coefficient with composition over the whole range of stability of Li_3Sb at 360°C.

The information that is obtained from the observation of the time dependence of the cell voltage during a galvanostatic current pulse is in principle no greater than that which can be obtained by using other transient methods. However, experimental problems in other techniques related to resistance polarization, which are typically only reduced by the use of reference electrodes, are here totally eliminated.

In the common potentiostatic voltage step method, the current should theoretically be infinite in the first moment. This is not experimentally realizable, and the imposed voltage difference creates large transient polarization effects. Thus the initial and boundary conditions usually applied to the assumed solution of Fick's second law are not exactly fulfilled. The result is a deviation from the theoretically expected linear relation between the current and $1/\sqrt{t}$ at short times. Additionally, because of the inverse time scale, this part of the plot is expanded whereas the part with the more useful information is compressed. In the case of the galvanostatic titration method, however, the initial period contains the most valuable information because any effects due to a change in the enhancement factor or to the finite thickness of the sample do not become important until later. This early part of the experiment is fortuitously expanded by the use of the square root of time scale in the voltage plot.

If a deviation from the linear dependence of the voltage on the square root of time is found at longer times in galvanostatic experiments it may have one or more of several explanations. Either the solution to the assumed boundary value problem is not valid at long times because of finite length effects due to a high diffusion coefficient or a thin sample, or there may be a significant change of either the thermodynamic enhancement factor or the chemical diffusion coefficient over the pertinent stoichiometric range. These different possibilities may be evaluated from the experimental results on the magnitude and composition dependence of the chemical diffusion coefficient and the enhancement factor. If necessary, a current pulse of shorter duration or a smaller value of current might be used.

Another way to eliminate the influence of a composition-dependent enhancement factor is to determine the stoichiometry δ from the measured cell voltage E by using data from the coulometric titration curve and to plot δ as a function of $\sqrt{t}$. According to Eq. [35] the following relation should be found

$$\frac{d\delta}{d\sqrt{t}} = \frac{2V_M I_0}{SFz_i\sqrt{\tilde{D}\pi}} \quad (t \ll L^2/\tilde{D}) \qquad [50]$$

Then, $\tilde{D}$ may be determined from the slope of the δ *vs.* $\sqrt{t}$ plot. An equivalent procedure is to divide the measured cell voltage by the corresponding thermodynamic factor and to plot this quantity as a function of $\sqrt{t}$. However, because of the large variation in the values for diffusion coefficients, often only an order of magnitude estimate is of interest, and these refinements may not be necessary.

Experimental errors might appear if the electrochemically active species are not exclusively used to change the stoichiometry of the sample during the titration, but, after being discharged and becoming neutral, diffuse back into the electrolyte or diffuse into the electrical lead connected to the sample. These possibilities could be checked in a separate experiment with a blank sample, operating over the same voltage range.

In conclusion, it has been demonstrated that the galvanostatic intermittent titration technique is a pow-

erful tool which can be employed to determine a number of important kinetic and thermodynamic quantities in mixed conductors. Of special interest is its ready application to compounds with small stoichiometric ranges and appreciable variation of the thermodynamic enhancement factor with composition.

The values of chemical diffusion coefficient observed in the case of Li_3Sb are several orders of magnitude greater than those found necessary to produce negligible diffusional polarization in fine particle battery electrodes.

Solid-State Detectors for the Potentiometric Determination of Gaseous Oxides

I. Measurement in Air

M. Gauthier* and A. Chamberland

Hydro-Quebec Research Institute, Varennes, Quebec J0L 2P0, Canada

ABSTRACT

This paper suggests that the potentiometric detection of sulfur oxides in air is feasible with solid-sulfate electrolytes, and presents experimental results on the electrode Pt, SO_2, $O_2/SO_4^=$. Several experimental parameters, namely, p_{SO_2}, temperature, and flow rate, are studied with concentration cells using potassium sulfate, as the electrolyte. A solid reference electrode based on an Ag/Ag^+ electrochemical couple is also studied as a replacement for the gas reference electrode. The authors conclude that rapid conversion of several gaseous sulfur compounds, namely, H_2S, CH_3SH, etc., into oxides occurs under the cell operating conditions, and that rapid equilibrium is reached between SO_2, SO_3, and O_2 at the electrode. Preliminary results of tests using solid electrolytes to detect other gaseous oxides in air are also given for the Pt, CO_2, $O_2/CO_3^=$, and Pt, NO_2, O_2/NO_3^- systems.

Success with solid-state oxygen detectors based on stabilized zirconia in the ppm concentration range has led the authors to undertake research into other types of detectors for the measurement of ambient and industrial pollutants such as sulfur dioxide, carbon monoxide, carbon dioxide, and the different nitrogen oxides. Originally, potentiometric rather than polarographic methods of analysis were selected to avoid relying on high ionic conductivity electrolytes, which are scarce. Furthermore, this choice dispenses with the complex process of determining the anionic-to-cationic nature of the conductivity, and all that remains to be done is to ensure there is no electronic conductivity at all. In the selection of suitable electrolytes, attention can then be focused on the possible electrode reactions.

Several studies of electrode reactions between molten oxyanions and oxides, such as nitrate and sulfate electrodes, may be found in the literature (1, 2). The mechanisms involved are still disputed, moreover, because of their complexity and dependence upon several experimental parameters.

The initial step in this research was to try to adapt previous studies on fused-salt systems to solid-electrolyte techniques using sulfate and sulfur oxides. A systematic study was made of a solid electrolyte of potassium sulfate with sulfur dioxide as the gaseous oxide. The tests were based on the following reaction mechanism as described by Salzano for the SO_3, O_2, Pt/SO_4^{-2} electrode (2).

$$\tfrac{1}{2}\,O_2 + 2e^- \rightleftarrows O^{-2} \text{ (electrochemical reaction)} \quad [1]$$

$$SO_3 + O^{-2} \rightleftarrows SO_4^{-2} \text{ (chemical reaction)} \quad [2]$$

These two reactions can be combined to yield the overall equation

$$SO_3 + \tfrac{1}{2}\,O_2 + 2e^- \rightleftarrows SO_4^{-2} \quad [3]$$

The resulting Nernst equation for the following cell

$$\begin{matrix} SO_3, & Pt/K_2SO_4/Pt, & SO_3' \\ O_2 & & O_2' \end{matrix} \quad [4]$$

is

$$E = \frac{RT}{2F} \ln \frac{(p_{O_2})^{1/2}\, p_{SO_3}}{(p_{O_2'})^{1/2}\, p_{SO_3'}} \quad [5]$$

or

$$E = \frac{RT}{4F} \ln \frac{p_{O_2}}{p_{O_2'}} + \frac{RT}{2F} \ln \frac{p_{SO_3}}{p_{SO_3'}} \quad [6]$$

* Electrochemical Society Active Member.

Key words: solid electrolytes, emf measurements, SO_3-SO_2-O_2 platinum electrode, sulfates, sulfur dioxide analysis.

Since sulfur dioxide is the major pollutant, and is easier to handle in a laboratory, it can be used to replace SO_3 in the experiments. In this case, either the equilibrium

$$SO_3 \rightleftarrows SO_2 + \tfrac{1}{2}\,O_2 \quad [7]$$

with

$$K = \frac{(p_{SO_2})\,(p_{O_2})^{1/2}}{(p_{SO_3})} \quad [7']$$

must be reached rapidly or the SO_2 to SO_3 conversion must be small and occur at constant rate for a given gas flow, whatever the initial SO_2 concentration, in accordance with Salzano's interpretation of his own laboratory observations (2). Taking this into account, the following expression for SO_2 is obtained

$$E = \frac{RT}{2F} \ln \frac{p_{O_2}}{p_{O_2'}} + \frac{RT}{2F} \ln \frac{p_{SO_2}}{p_{SO_2'}} \quad [8]$$

which, in air, simplifies to

$$E = \frac{RT}{2F} \ln \frac{p_{SO_2}}{p_{SO_2'}} \quad [9]$$

Experimental

Different models of oxide concentration cells have been devised and studied experimentally; a general device is illustrated schematically in Fig. 1. The arrangement comprises two alumina tubes between which the potassium sulfate pellet is pinned. Two small single bore alumina tubes allow the gas to circulate

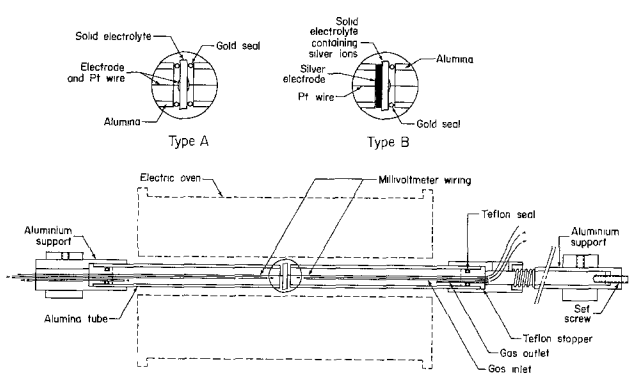

Fig. 1. Experimental apparatus used to study the SO_2, O_2, Pt/SO_4^{--} system. A, two-compartment cell; B, cell with a silver/silver ion reference electrode.

near the measuring electrode. Platinum wire and platinum powder obtained by vacuum deposition ensure electrical contact. In the hot zone, the seal is made by pressing gold rings between the alumina tubes and the electrolyte while conventional O-rings are used for sealing outside the furnace.

An optimized device derived from the first one (Fig. 1A) was used, in particular, for response time and flow rate studies. As illustrated in Fig. 2, the two compartments here are located on the same side of the electrolyte. The seal is made by applying appropriate pressure between the alumina tube and the electrolyte at high temperature before the first utilization. The resulting slight deformation of the electrolyte ensures gas tightness between the two compartments and between each compartment and the outside. The dead volume of the complete gas circuit inside the sensor is around 0.8 cm^3 including the four-hole alumina rod (998 McDannel, 0.250 in. OD, 0.067 in. ID) and the 316 stainless steel gas feedthrough, 1/16 in. OD. Powdered potassium sulfate 100-mesh (Baker analyzed, reagent grade) was used for the electrolyte because this nonhygroscopic salt becomes a relatively good conductor in the hexagonal form above 579°C (3), and can be easily sintered. The powder was subjected to unidirectional pressure of 2 ton/cm^2, then sintered at 940°C for at least 2 days. The pellets thus obtained can hold 760 mm Hg pressure difference for hours without apparent leakage both at room temperature and, once fitted in the sensor, at operating temperature. The gas mixtures are prepared by injecting pure oxides into 10 and 100 liter Mylar bags already filled with ambient or synthetic air; the precision for this technique is approximately 3%. The SO_2 mixtures are then stable for the duration of the test. The temperature is maintained at ± 2°C by a Thermoelectric proportional control, Model 100, with Chromel-Alumel thermocouples. A Tacussel Aries 10,000 high impedance ($\approx 10^{13}\Omega$) millivoltmeter is used to measure the electromotive force (emf), and signals are recorded on a Hewlett-Packard strip chart recorder, No. 7100-B.

Results and Discussion

Different tests were made using the apparatus illustrated in Fig. 1A and 2 with sulfur dioxide and potassium sulfate, at temperatures ranging between 600° and 925°C. Unless otherwise specified, the reference electrode is a mixture of 100 ppm SO_2 in air, and all gas flow rates are fixed at 100 cm^3/min.

Emf variation with SO_2 partial pressure.—The emf time plot with different values of the SO_2 partial pressure is given by way of example in Fig. 3. The concentrations given in this and the following figures correspond to the initial partial pressures obtained by injecting SO_2 at room temperature, $(p_{SO_2})_{in.}$ The results presented in this figure were obtained with the apparatus illustrated in Fig. 2.

Generally speaking, the response times vary from a few seconds to several minutes, mainly according to

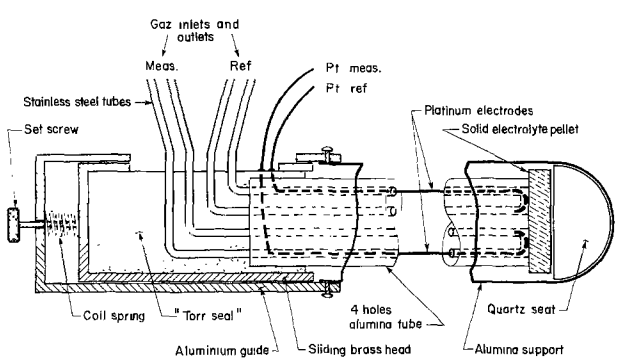

Fig. 2. Simplified experimental device with a reduced dead volume and both gas circulating compartments on the same side of the electrolyte.

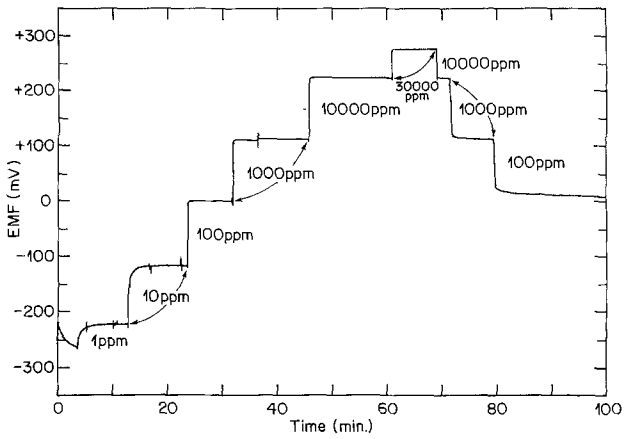

Fig. 3. Typical response time to SO_2 variations obtained with the experimental device of Fig. 2. Temperature, 820°C, reference electrode, 100 ppm SO_2 in air; gas flow rates, 100 cm^3/min.

the flow rate, the concentration range under study, and the geometry of the apparatus. The chemical properties of the sulfur oxides make it extremely complex to perform a detailed analysis of the processes determining the rise and fall of the emf signal. Adsorption definitely has a significant influence, especially in view of the wide variation of the concentration under study (over 4 decades).

Typical experimental results with the SO_2 detector are presented as emf *vs.* log $(p_{SO_2})_{in.}$ in Fig. 4. The experimental slope coincides with a two-electron reaction ($n = 2.12$) in accordance with Eq. [3]. Expressed in parts per million (10^{-6} atm), the concentration range extends from 0.5 to 40,000 ppm. The experimental signal obtained at lower concentrations coincides with the limit of gas-mixture preparation by microinjection techniques, which means that it is impossible to determine the lower operating limit of the SO_2, SO_3, O_2, Pt/SO_4^{-2} electrode in air using this particular method of preparation.

Emf dependence on temperature.—Experimental and calculated values of emf for a concentration cell filled with SO_2 in air, namely 10 ppm on one side and 100 ppm on the other, at different temperatures between 600° and 925°C are reported in Fig. 5. Below 650°C, experimental emf values are erratic and decrease rapidly compared with the calculated values. How-

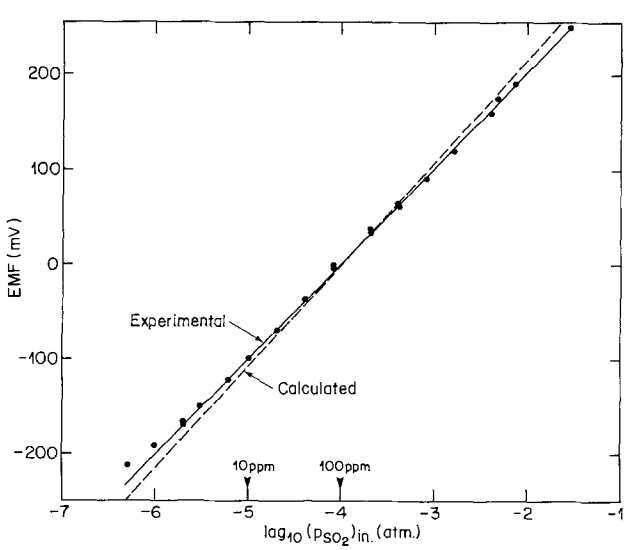

Fig. 4. Plot of emf vs. logarithm of the SO_2 partial pressure expressed in atmospheres. A concentration of 100 ppm SO_2 in air was circulated in the reference compartment. Temperature, 820°C; flow rate, 100 cm^3/min in both compartments. The dashed curve represents the calculated slope 2.3 *RT*/2F.

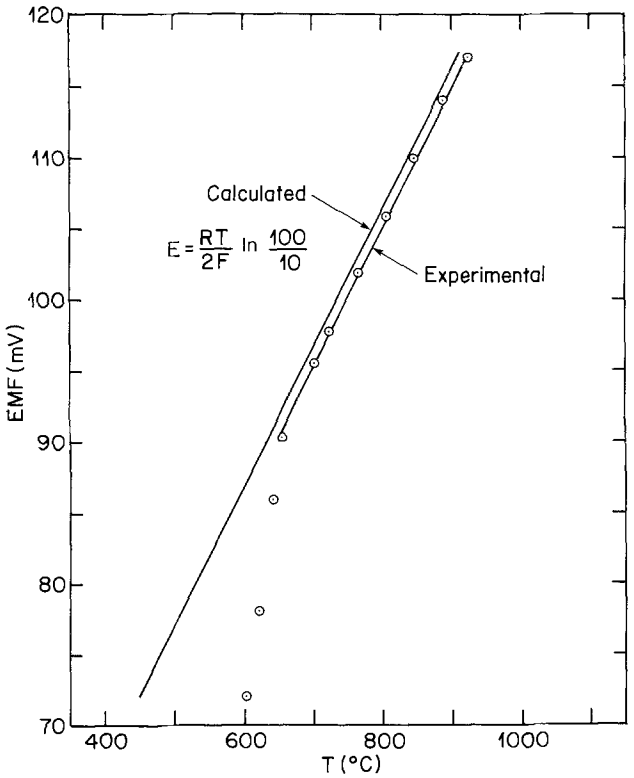

Fig. 5. Plot of emf vs. temperature (°C). Measuring compartment, 100 ppm SO_2 in air; reference compartment, 10 ppm SO_2 in air; flow rate, 100 cm³/min in both compartments.

ever, above this temperature, the emf values agree within $\simeq$ 1 mV. Special care was taken in this test to control and measure the temperature of the electrolyte; nevertheless, a bias potential of 1.2 $\pm$ 0.2 mV was found between the two electrodes as a single preparation of 10 ppm SO_2 in air was circulated on both sides of the cell, a value which corresponds to the difference between the experimental and calculated emf found in Fig. 5. Application of the emf technique (4) to the results of Fig. 5 shows that the ionic transport number, t_i, in potassium sulfate is one within the precision of the present experiments.

Emf dependence on flow rate.—Various tests to determine the influence of the flow rate are reported in Fig. 6, which shows the effect of the concentration, the temperature, and the presence of a catalyst when the flow rate is varied from a few cm³/min to 500 cm³/min. It may be noted that an operating range exists in which the emf almost ceases to vary with the flow rate. From this, it was concluded that under such conditions, thermodynamic equilibrium between SO_2 and SO_3 is reached rapidly, at least in the vicinity of the platinum electrode. This result differs from those obtained by Salzano with molten sulfates in which he observed a 55 mV dependence for each variation of 1 decade in the flow rate. It therefore seems justified to use Eq. [7] and [7'] without any need to consider a fixed SO_2-SO_3 conversion rate as Salzano did (2). Under equilibrium conditions, therefore, the detector validates the equation

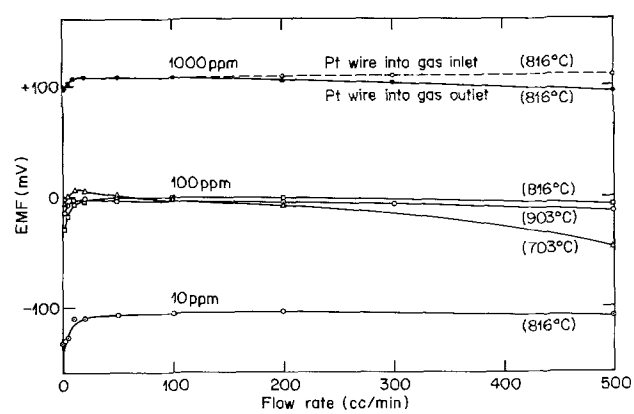

Fig. 6. Emf dependence on flow rate at three different SO_2 partial pressures; 10, 100, 1000 ppm. Also illustrated here is the effect of the operating temperature and platinum catalytic activity on the emf dependence on flow rate.

$$(p_{SO_2})_{in.} = (p_{SO_2}) + (p_{SO_3}) \qquad [10]$$

where $(p_{SO_2})_{in.}$ is the gas partial pressure initially introduced, and (p_{SO_2}) and (p_{SO_3}) are the partial pressures in equilibrium at the electrode. Thus, the detector signal is equivalent to an over-all measurement of the quantity of sulfur oxide regardless of whether the gas is introduced as SO_2 or SO_3.

The range of flow rates in which the sulfur-oxide detector operates at equilibrium depends on several parameters; its geometry, the types of material used, operating conditions, etc. At high flow rates (Fig. 6) the range is limited, particularly with strong SO_2 concentrations or when the temperature drops to around 700°C. This may be explained by the fact that the conversion of SO_2 into SO_3 no longer reaches equilibrium value under these conditions. Moreover, this seems to confirm the catalytic nature of the platinum wire of the electrode when placed at the inlet rather than at the outlet of the test gas. Meanwhile, at low flow rates, the limit could be a result of convection competing with the forced circulation of the gas, which could result in condensation (SO_3 or H_2SO_4) in the cold zones of the detector. This would naturally modify the SO_2-SO_3 mixture. Only devices with zero or under 10 mV emf dependence on the flow rate were used for the studies described here.

Solid reference electrode.—For reasons of convenience, one of the two gas electrodes of the cell [4] was replaced by a solid-state reference electrode such as Ag°/Ag^+ in which the silver ion was present as a solid solution. The following experimental cells were studied

$$Ag^\circ/Ag_2SO_4 \text{ in } K_2SO_4//K_2SO_4/SO_2, O_2, Pt \qquad [11]$$

and

$$Ag^\circ/Ag_2SO_4 \text{ in } K_2SO_4/SO_2, O_2, Pt \qquad [11']$$

whose over-all cell equation is

$$Ag^\circ + SO_2 + O_2 \rightleftarrows Ag_2SO_4 \text{ (as a solution in } K_2SO_4) \qquad [12]$$

The emf of cells [11] and [11'] can be expressed as

$$E = \text{const.} - \frac{RT}{F} \ln a_{Ag^+} + \frac{RT}{2F} \ln p_{SO_2} + \frac{RT}{2F} \ln p_{O_2} \qquad [13]$$

where const. is a constant that includes the E° of pure solid silver sulfate. This expression of the emf is valid as long as there is a solid solution of Ag_2SO_4 in K_2SO_4. In air and at constant silver-ion activity, a_{Ag^+}, the emf depends only on the SO_2 partial pressure

$$E = \text{const.}' + \frac{RT}{2F} \ln p_{SO_2} \qquad [14]$$

A modification to the earlier experimental arrangement made it possible to use the silver/silver-ion reference electrode for the tests (Fig. 1B).

Emf dependence on $(p_{SO_2})_{in.}$ with Ag°/Ag^+ as the reference electrode.—Signals obtained at different SO_2 partial pressures are presented in Fig. 7. The silver-sulfate concentration was prepared at a 1% mole fraction by melting known proportions of silver sulfate and potassium sulfate, ball-milling them to 100 mesh, and then sintering. The results are in good agreement with

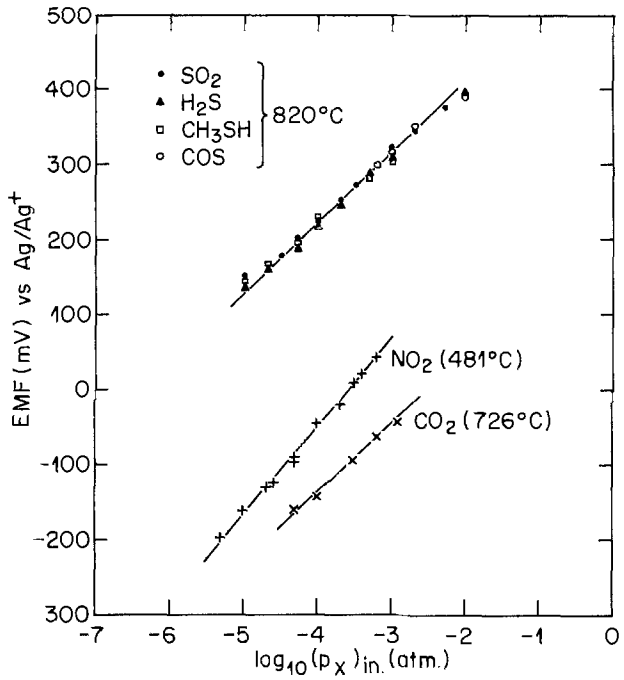

Fig. 7. Dependence of the emf on the logarithm of the concentration of different anhydrides. For SO_2, H_2S, CH_3SH, and COS, a K_2SO_4 electrolyte is used while K_2CO_3 and $Ba(NO_3)_2$ electrolytes are used for CO_2 and NO_2, respectively. In all cases, results were obtained with Ag/Ag^+ reference electrodes (see text).

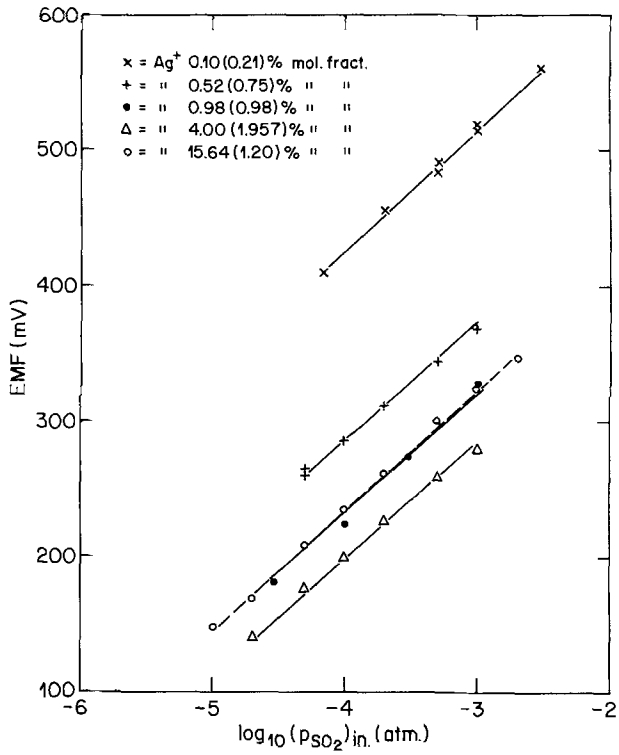

Fig. 8. Dependence of the emf on the logarithm of the SO_2 concentration in air for different mole fractions of Ag_2SO_4 in K_2SO_4. Given in parentheses are the concentration values obtained by atomic absorption analysis after the test. Test temperature, 820°C; fixed flow rates, 100 cm^3/min.

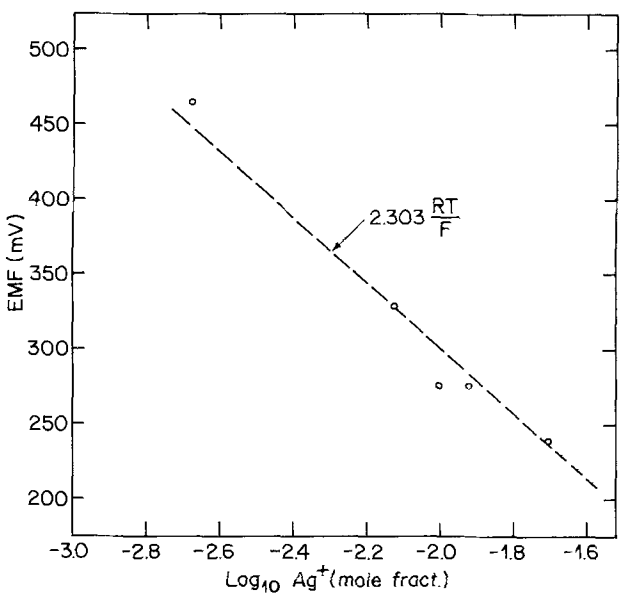

Fig. 9. Dependence of the emf on the logarithm of the silver ion concentration in K_2SO_4 for a constant SO_2 concentration in air; 3×10^{-4} atm. The silver-ion concentrations used here were obtained by atomic-absorption analysis. The dashed curve shows the calculated value of 2.3 RT/F in accordance with Eq. [13]. Temperature, 820°C; flow rate, 100 cm^3/min.

relation [14]. Cells [11] and [11'] both present the same behavior.

Emf dependence on a_{Ag^+}.—In order to check the validity of Eq. [13] for the Nernst dependence of the signal on the silver-ion activity, an attempt was made to study different concentrations of silver sulfate in the electrolyte fixed during the preparation, and ranging from 0.1 to 15.0% mole fractions. For each of the 5 silver-sulfate concentrations, a cell similar to [11'] was prepared and studied from the point of view of the SO_2 partial pressure (Fig. 8). Also included in this figure are the results of an atomic-absorption analysis of the silver-ion concentrations in the electrolyte after each test, compared to the values fixed during preparation. A large difference between prepared and observed concentrations is observed, particularly for the two higher prepared concentrations where metallic silver was visible after sintering at 900°C. This is probably a result of partial decomposition of the silver sulfate.

When the emf values of Fig. 8 are plotted as a function of the logarithm of the silver-ion mole fraction for a given $(p_{SO_2})_{in.}$ of 3×10^{-4} atm in air, the results appear to be in good agreement with the slope calculated from Eq. [13], Fig. 9. The silver-sulfate concentration used is those of the atomic-absorption analysis. Consequently, even if the concentration range studied is in fact limited, it may be reasonably concluded that an authentic solid solution of silver sulfate exists in potassium sulfate, at least around the 1% mole fraction.

The tests reported here do not eliminate the possibility that the silver/silver-ion electrode reaction is just one of several electrochemical reactions; indeed, others such as the $O_2/O^=$ couple may well exist at these temperatures. Nevertheless, this solid reference electrode greatly simplifies the experimental procedure and, as shown by the tests, provides satisfactory results.

Emf dependence on other sulfur compounds.—The solid reference cell used with SO_2 was also tested under the same experimental conditions with other sulfur-containing compounds such as hydrogen sulfide, carbonyl sulfide, and methyl mercaptan. The results, shown in Fig. 7, are almost identical to those with SO_2, whatever gas enters the cell. In fact, even by varying the temperature, the concentration, or the flow rate of these gases, it was impossible to distinguish between the signals they produced and the signal from an equivalent concentration of SO_2. It may therefore be assumed that in air these gases are rapidly oxidized and quantitatively converted into sulfur oxides at the electrode. This conclusion is borne out by the existence of excessive quantities of oxygen compared with the

test gases, by the high operating temperature of the sensor, and also by the presence of platinum at the electrode.

Tests on other oxide-oxyanion systems.—The last experimental results to be presented are those of tests conducted on other oxide-oxyanion systems to see how far the application of solid-state electrochemical cells is feasible for potentiometric determination of different gaseous oxides. The experimental procedure and conditions were the same as those described for the tests on sulfur oxides except that the operating temperatures were limited by the melting point of the electrolytes used. The Ag/Ag^+ reference electrode type illustrated in Fig. 1B was selected to make the tests easier to perform. The performance of a carbon dioxide detector was studied using potassium carbonate as the electrolyte. This was prepared by melting a mixture of a 1% mole fraction of silver sulfate in potassium carbonate at 900°C, and sintering at 750°C for 24 hr. No subsequent control of the composition was performed.

The emf variation with logarithm of the CO_2 partial pressure in air is presented in Fig. 7. The slope corresponds to a two-electron mechanism ($n = 2.12$), as suggested by the reaction

$$CO_2 + \tfrac{1}{2}\,O_2 + 2e^- \rightleftarrows CO_3^= \qquad [15]$$

The possibility of building a nitrogen oxide detector was also investigated using a solid electrolyte obtained by melting a mixture of a 1% mole fraction of silver chloride in barium nitrate at 600°C, and sintering at 540°C for 24 hr. The results obtained from the NO_2 partial pressure variations in air are given in Fig. 7. The slope seems to correspond to a single electron mechanism ($n = 1.22$), as expected from the electrode reaction

$$NO_2 + \tfrac{1}{2}\,O_2 + 1e^- \rightleftarrows NO_3^- \qquad [16]$$

The response times observed for the nitrogen dioxide and carbon dioxide detectors are of the same order of magnitude as those obtained with the sulfur oxide detector.

Conclusion

This study has shown that electrochemical cells based on solid electrolytes containing oxyanions can be used for the potentiometric determination of SO_2, SO_3, CO_2, and NO_2 in air, or in any gas with a fixed oxygen content. The sensors bear a strong similarity to oxygen-zirconia detectors even if the electrolytes are poor-to-moderate cationic conductors, and despite the relatively complex reactions of the oxides. The reasons for this can be traced to the utilization of solid electrolytes and the high operating temperatures of the solid-state detectors. Solid electrolytes enhance rapid surface equilibria because of the total absence of convection; furthermore, the oxide-oxyanion systems become simpler as the temperature rises.

Further analysis of the SO_3, O_2, $Pt/SO_4^=$ electrode reveals that under certain given conditions, equilibrium between sulfur dioxide, oxygen, and sulfur trioxide is reached rapidly, at least in the area closest to the electrode. The study also shows that gaseous sulfur-bearing components circulated in the detector produce a signal identical to the one produced by SO_2. This seems to be due to the rapid conversion of the gases to oxides inside the device.

Finally, the results obtained are in agreement with the over-all electrode reaction proposed by Salzano (2) for molten sulfates, and seem to indicate that similar electrode reactions may be extended to other oxide-solid oxyanion systems.

Solid-State Detectors for the Potentiometric Determination of Gaseous Oxides

II. Measurements in Oxygen-Variable Gases in the SO_2, SO_3, O_2, $Pt/SO_4^=$ System

ABSTRACT

This paper describes an extended application of potentiometric solid-state detectors for measuring oxides in oxygen-variable gases. The SO_2, SO_3, O_2, $Pt/SO_4^=$ system examined in Part I for oxide detection in air is studied here with respect to the total sulfur oxide and oxygen partial pressures. A study of the experimental parameters, operating temperatures, and the oxygen partial-pressure range revealed the possibility of a simple method of compensating the effect of the oxygen partial pressure on the signal from the oxide detector. An entirely solid-state device consisting of a potassium-sulfate oxide detector, a stabilized-zirconia oxygen detector, and usual electronic components is described, and results of tests with synthetic gas mixtures are presented. Experimental findings confirm calculations based on the electrode reactions and on the rapidly established equilibrium at the platinum electrode.

The feasibility of high temperature solid-state detectors for the potentiometric measurement of oxides in gaseous mixtures has been demonstrated in IREQ laboratories (1, 2). Different models of these solid-state detectors were discussed at the Spring Meeting of the Ontario-Quebec Section of The Electrochemical Society together with possible fields of application (3). Part I of this work presented the results of quantitative measurements of gaseous sulfur oxides using solid potassium sulfate as the electrolyte, and examined the influence of various experimental parameters such as the sulfur oxide partial pressure, operating temperature, and flow rates. Replacement of the circulating gas reference electrode by an Ag/Ag_2SO_4 1% in a K_2SO_4 solid reference electrode was also suggested and tested. So far, however, all results have been obtained with low sulfur oxide concentrations prepared in air where the oxygen partial pressure is constant.

The object of the present paper is to expand the possibilities of these detectors by adapting them to gases with a variable oxygen content such as stack gases. According to previous results, the concentration of sulfur oxides in air is determined using solid-electrolyte concentration cells such as

$$SO_3, O_2, Pt/K_2SO_4/Pt, O_2', SO_3' \qquad [1]$$

for which the over-all electrode reaction is written as

$$SO_3 + \tfrac{1}{2}\, O_2 + 2e^- \rightleftarrows SO_4^= \qquad [2]$$

The emf of this electrochemical cell is

$$E = \frac{RT}{4F} \ln \frac{p_{O_2}}{p_{O_2}'} + \frac{RT}{2F} \ln \frac{p_{SO_3}}{p_{SO_3}'} \qquad [3]$$

in which p_{O_2}, p_{O_2}', p_{SO_3}, and p_{SO_3}' represent the partial pressures of the gases at thermodynamic equilibrium.

As shown by Eq. [3], a double dependence of the emf on p_{O_2} and p_{SO_3} is observed. Moreover, this is not peculiar to the SO_3, $O_2/SO_4^=$ system, but is a general characteristic of all oxide/oxyanion systems, such as $CO_2/CO_3^=$ and NO_2/NO_3^-, which were discussed briefly in Part I. The system chosen for the present work is the sulfate-sulfur oxide system, which, owing to the coexistence of SO_2 and SO_3 over a wide range of temperatures and oxygen partial pressures, represents a fairly complex case. Another reason for choosing this particular system is its wide field of application. Indeed, this type of solid-state detector has an important role to play in the measurement of the sulfur oxides present in stack gases in which the sulfur content varies from one to several thousand ppm. Since it is particularly suited for the stringent analysis conditions of industrial chimneys, namely high temperatures and necessary use of refractory materials, research in the area of stack gases seemed not only interesting but fully justified.

Simultaneously with the variation in SO_2 concentration, the p_{O_2} found in chimneys changes from 5 to 0.1% and even less. The emf expressed by Eq. [3], therefore, cannot be interpreted simply in terms of the sulfur oxide concentration. The aim of the present study is to show that, under certain conditions of approximation, it is possible to eliminate or compensate for the effect of the p_{O_2} on the emf with a zirconia-stabilized oxygen detector in conjunction with an electronic compensation device developed specifically for the purpose.

Experimental

For this study, the simplified experimental device illustrated in Fig. 2 of Part I was used as the sulfur oxide detector. The oxygen detector consisted of a calcia-stabilized tube (Zircoa) designed for operation at high temperatures (4); the tube was platinized over a 1 in. length both inside and outside, in the hot zone. The ambient air is used as an external reference. The test gas was directed onto the inside electrode through a small diameter alumina tube. For the sake of convenience, both the oxygen detector and the oxide detector in the compensating device were housed in a common 10 in. furnace. The measuring equipment and the experimental procedures relating to the preparation of the gas mixtures and the electrolyte were described in Part I. Commercially available calibrated oxygen preparations in nitrogen were used for the tests.

Results and Discussion

General expression of the emf.—An important observation drawn from previous work on sulfate-sulfur oxide systems is that both SO_2 and SO_3 are present under the experimental conditions, and that thermodynamic equilibrium between SO_2, SO_3, and O_2 is rapidly attained at the electrode in accordance with the following equations

* Electrochemical Society Active Member.
** Electrochemical Society Student Member.
Key words: solid electrolytes, emf measurements, sulfates, sulfur dioxide analysis, electrochemical cell.

$$SO_3 \rightleftarrows SO_2 + \tfrac{1}{2} O_2 \quad [4]$$

$$K = \frac{(p_{SO_2})\ (p_{O_2})^{1/2}}{(p_{SO_3})} \quad [5]$$

For any given temperature, therefore, the oxygen partial pressure determines the ratio between p_{SO_2} and p_{SO_3}. Part I described tests performed in air at low sulfur oxide concentrations ($p_{O_2} > p_{SO_2}$) where the p_{SO_2}/p_{SO_3} ratio was constant and hence not included as a variable in the expression of the emf. In systems in which the oxygen content does vary, however, the emf dependence *vs.* p_{O_2} (Eq. [3]) is complicated by the fact that both right-hand terms in the equation vary with p_{O_2}.

A more explicit expression of the emf as a function of the oxygen partial pressure is obtained by introducing into Eq. [3] the equilibrium constant expression [5] and the total sulfur relation

$$(p_{SO_2})_{in.} = p_{SO_2} + p_{SO_3} \quad [6]$$

where $(p_{SO_2})_{in.}$ is the total sulfur-oxide partial pressure fixed experimentally at room temperature using sulfur dioxide, and p_{SO_2} and p_{SO_3} are equilibrium values.

The new expression of the emf as a function of the partial pressure of the gases at the measuring electrode is

$$E = C_1 + \frac{RT}{2F} \ln (p_{SO_2})_{in.} + \frac{RT}{2F} \ln p_{O_2} - \frac{RT}{2F} \ln (K + (p_{O_2})^{1/2}) \quad [7]$$

Where the constant term, C_1, includes the contribution from the second electrode, defined as the reference electrode.

The validity of this general expression is then checked experimentally by two series of tests. In the first, the oxygen partial pressure is kept constant at three different levels; 1.00, 0.21, and 0.012 atm, while the total sulfur anhydride partial pressure $(p_{SO_2})_{in.}$ is varied between 3 and 10,000 ppm. The experimental results appear in good agreement with calculated values, as shown in Fig. 1. The emf varies linearly as a function of log $(p_{SO_2})_{in.}$, and the slope of Fig. 1 corresponds to the term $RT/2F$ in Eq. [7] when p_{O_2} is constant. The concentration range studied did not reveal any value for p_{O_2} or $(p_{SO_2})_{in.}$ for which Eq. [7] is not valid, at least within the limits of experimental accuracy.

In the second series of tests, $(p_{SO_2})_{in.}$ is fixed at 100 ppm and the oxygen partial pressure changes from 1 to 3 $\times$ 10^{-4} atm. Results are reported for three temperatures, namely 696°, 807°, and 901°C, and are compared with calculated values in Fig. 2. The relatively good agreement between the calculated emf and the experimental measurements confirms the validity of Eq. [7], which is based on the rapidly attained equilibrium between SO_2, O_2, and SO_3 at the electrode. When the operating temperature approaches or drops below 700°C, the difference between the calculated and the measured values increases. This may be linked with the appearance of a dependence of the emf on the flow rate as noted in Part I under similar test conditions. In both cases, it seems to be a matter of the inability of the SO_2 to SO_3 conversion rate to reach the equilibrium value in the actual operating conditions of this detector.

Limiting conditions for oxygen compensation.—To introduce the concept of oxygen compensation, it is useful to differentiate Eq. [7] as follows

$$\frac{dE}{d \ln p_{O_2}} = \frac{RT}{2F} - \frac{RT}{4F} \left(\frac{(p_{O_2})^{1/2}}{(p_{O_2})^{1/2} + K} \right) \quad [8]$$

It is only when the derivative $dE/d \ln p_{O_2}$ is a constant, *i.e.*, independent of O_2, that the signal's oxygen dependence can be compensated without difficulty.

Equation [8] allows two limiting conditions where $dE/d \ln p_{O_2}$ becomes constant. The first case involves low oxygen partial pressures and high operating temperatures where K is high ($K \simeq 2$ at 900°C) (5), and $dE/d \ln p_{O_2}$ becomes equal to $RT/2F$, experimentally this approximation corresponds to conditions where SO_2 is the predominant sulfur oxide. The second case involves high oxygen partial pressures and low temperatures where K is low ($K \simeq 4 \times 10^{-3}$ at 450°C), and $dE/d \ln p_{O_2}$ becomes equal to $RT/4F$; experimentally, the predominant sulfur oxide here is SO_3.

The first case is of greater interest in this study which deals with low oxygen-content mixtures as found in stack gases. When those limiting conditions prevail, then Eq. [7] can be rewritten as an approximation

$$E\ (1) = C_2 + \frac{RT}{2F} \ln (p_{SO_2})_{in.} + \frac{RT}{2F} \ln p_{O_2} \quad [9]$$

Thus, it is possible in these conditions of approxima-

tion, to eliminate the emf dependence on oxygen partial pressure simply by offsetting the signal from an oxide detector, as represented in Eq. [9], with a suitable signal from an oxygen detector.

Oxygen compensating device.—Oxygen detectors based on solid electrolytes and similar in technology to the one described here not only exist but operate in exactly the same experimental conditions. In order to test the proposed compensation system, therefore, well-known oxygen concentration cells based on stabilized zirconia (4) were adopted with potentiometric signals expressed by

$$E\ (2) = C_3 + \frac{RT}{4F} \ln p_{O_2} \qquad [10]$$

where C_3 comprises the reference electrode. A simple electronic device was built that produces an oxygen-compensated signal.

$$E\ (3) = E\ (1) - 2E\ (2) = C + \frac{RT}{2F} \ln\ (p_{SO_2})_{in.} \qquad [11]$$

The compensation system consisting of the oxide detector, the oxygen detector, and the electronic device, is illustrated in Fig. 3. The three steps in the signal-conditioning process are described as follows: (*i*) electrical insulation of the input signal to ensure high impedance of the measuring system ($10^9\Omega$); (*ii*) inversion of the oxygen-detector signal; and (*iii*) addition of twice the modified signal from the oxygen detector to the oxide-detector signal plus an offset output signal to account for different types of reference electrode in the two detectors.

Results of tests on the compensating device.—To check the performance of the compensation system depicted in Fig. 3, it was decided to use a circulating gas reference electrode with the sulfur oxide detector (100 ppm SO_2 in air). The reason for this was that although the Ag/Ag^+ reference electrode described in Part I proved easy to operate and suitable for measuring sulfur oxides in air, preliminary tests revealed that when p_{O_2} and p_{SO_2} are very low, the silver sulfate present in the electrolyte in certain circumstances could be reduced to the metallic state, and the detector performance would be inevitably affected.

A common operating temperature of 827°C was selected for the two detectors as representing the minimum temperature at which the approximation of Eq. [7] is still valid in stack-gas compositions containing oxygen in concentrations up to 5%. Three sulfur dioxide concentrations (10, 100, and 1000 ppm) representative of stack-gas compositions were assayed in gaseous mixtures containing various oxygen/nitrogen ratios. The results are presented in Fig. 4 as emf *vs.* $\log_{10} p_{O_2}$. The signals from the oxide detector and the oxygen detector are shown with their corresponding compensated signal. For each concentration level the compensated signal appears independent of the oxygen partial pressure at ± 6 mV when the oxygen content of the gas is under 5%, but above this concentration, the signal becomes oxygen-dependent because the approximation of Eq. [9] is no longer valid. As expected, different sulfur oxide concentrations do not affect the signal of the oxygen detector since the prepared oxygen concentrations are always greater than the oxide concentrations.

Translated in terms of parts per million, the mean values of the compensated signals obtained at 5% oxygen partial pressure are 9.7, 106, and 1150 ppm of SO_2, respectively. The agreement between the measured compensated results and the prepared values therefore appears satisfactory, although higher accuracy could probably be attained with greater sophistication of the compensating apparatus and more adequate control of experimental conditions.

Table I presents further results of tests in which low oxygen content gases are circulated in the detector while $(p_{SO_2})_{in.}$ is set at 100 ppm. The signals from both the oxide detector and the oxygen detector are given in addition to compensated signal, and are compared with the calculated compensated values obtained from Eq. [11]. In some mixtures, the oxygen concentrations are too low to be controlled by preparation, and the partial pressure indicated is actually determined by means of the oxygen detector. The table also presents results of interference tests with 20% CO_2 and 1000 ppm NO contamination of different gaseous mixtures, and the results of one test with a nonoxidized sulfur compound, H_2S. The predicted compensated signal for 100 ppm total sulfur is observed for all the tests performed with these synthetic gases, even with extremely low oxygen partial pressures and even in the presence of the interference usually found in stack-gas analysis in the field.

Preliminary studies were also conducted to assess the sulfur oxide detector's performance when the circulating gas is a more or less reducing mixture of CO and CO_2 containing parts per million of SO_2. No quantitatively reproducible results have yet been obtained under such conditions as a function of the SO_2 content. It was observed that mixtures with a low CO

* p_{O_2} evaluated with oxygen detector.

content, for example 100 ppm SO_2 in 5% CO in CO_2 ($p_{O_2} \approx 10^{-16}$ atm at 815°C), circulating in the detector has no effect on its operation when concentrations return to normal, although at such low partial pressures of oxygen, gaseous sulfur $S_2(g)$ coexists with the SO_2 to a significant degree (7). However, if the gas is a stronger reducing agent, for example 95% CO-5% CO_2 ($p_{O_2} \approx 10^{-21}$ at 815°C), the detector will be irreparably affected, probably because of the reduction of the electrolyte to sulfur. The reduction of potassium sulfate by CO-CO_2 atmospheres has already been noted in the literature (6).

The various tests described above point to the possibility of using solid-state oxide detectors in industrial chimneys under normal operating conditions (slight excess of oxygen). The success of these experiments seems to be due in large part to the catalytic activity of the electrode and to the thermal and chemical stability of the materials used to build the detector.

Conclusion

The potentiometric detection of oxides in air with solid electrolytes containing oxyanions is extended in this work to gaseous mixtures with a variable oxygen content. In the case studied here, potassium sulfate is used as the solid electrolyte and sulfur dioxide and trioxide as the oxides.

Calculations showed that specific experimental conditions can be found where it becomes feasible to compensate the oxygen dependence of an oxide detector with the signal from another detector; a stabilized-zirconia oxygen detector, for example. An electronic apparatus was therefore devised to perform this operation with the emf of both detectors; the resulting signal is then proportional only to the logarithm of the total sulfur oxides

$$E = C + \frac{RT}{2F} \ln (p_{SO_2})_{in.}$$

Experimental results of tests with the compensation system confirm the validity of the calculations and approximated conditions which rely, as they do, on rapid equilibrium between SO_2, SO_3, and O_2 at the electrodes, and similar catalytic activities at both the oxygen and oxide electrodes.

Several concentrations of sulfur dioxide in synthetic gas mixtures akin to industrial stack-gas compositions have been scanned with this compensation system. So far, the results seem to confirm the possibility of using oxide detectors in stack-gas analysis wherever solid-state detectors for continuous oxygen measurement and combustion control have proven to be technologically sound.

Acknowledgments

Sincere thanks are owed to the Hydro-Quebec Research Institute for financial support of this work through an approved research and development project.

The authors wish to express their appreciation to Roger Bellemare and Denis Ricard for carrying out the experimental part of this work, and to Guy Bélanger and Pierre Gervais for fruitful discussions.

ABSTRACT

The tarnishing of nickel in air has been investigated at temperatures from 23° to 200°C and relative humidities from ambient to 95%. Auger electron spectroscopy with argon ion sputtering was used to determine the composition and the thickness of the oxide films. The films formed under all conditions have the same composition. Their thicknesses range from <1 nm at low relative humidities at all temperatures to about 3 nm at high relative humidities. We present a hypothesis that can account for the thicker films at high humidities.

Low voltage, low force electrical connectors usually have a noble metal contact surface to insure a low and stable contact resistance. The most commonly used contact material is gold. Electroplated nickel is frequently used in these contacts as a diffusion barrier between a copper or copper alloy substrate and the gold plate. The escalating cost of gold has led to numerous programs to reduce gold usage on contacts by reducing either the thickness of the gold plate or the area covered by the gold. As a result, nickel is more likely to be exposed to the service environment at the bases of pores in the gold plate. Also, the edges of the gold-plated area are likely to be closer to the actual points of contact.

Many studies of the oxidation of nickel have been made at temperatures above 190°C. The literature up to 1964 has been reviewed by Hauffe (1). The more recent literature has been cited by Khoi *et al.* (2). Monolayer and submonolayer structures have been grown and identified on individual faces of nickel single crystals under nearly ideal conditions of surface preparation and cleanliness. These, as well as other surface studies on nickel, have been reviewed by Lawless (3). Graham and Cohen (4) have measured the steady-state thickness of the oxide that forms at 23° and at 200°C on high purity nickel crystals after careful surface preparation. Unfortunately, little is known about the corrosion behavior of nickel under real atmospheric exposure conditions.

The present work is concerned with the tarnishing in air of electroplated nickel on copper at temperatures from 23° to 100°C and relative humidities from ambient to 95%. It attempts to assess the corrosion behavior of a real nickel surface in a real environment. Some data were also obtained at 200°C.

Experimental

Copper coupons, 14 mm square and 0.5 mm thick, were cleaned in the following manner prior to plating: vapor degrease with 1,1,1-trichloroethane, etch in 1:1 HNO_3:H_2O, rinse in water, dry with compressed air, chemically polish in 4:5:11 HNO_3:HAc:H_3PO_4 at 75°C, rinse again in water, and immediately transfer to the plating bath. A layer of nickel, 9 μm thick, was electroplated from a standard nickel sulfamate bath (Table I).

The nickel-plated specimens were vapor degreased in trichloroethylene and immediately suspended in the environmental test chamber, a 1 liter closed glass jar containing air and a suitable saturated salt solution to give the desired relative humidity (RH) at the test temperature. The chamber was placed in a mechanical convection oven, the temperature of which was controlled to better than ±1°C. The chamber and the salt solution were equilibrated at temperature in the oven before the specimens were inserted.

The corrosion films were analyzed for the elements present by Auger electron spectrometry (AES), and for the thickness and distribution of the elements with distance into the film by depth profiling using argon ion sputtering in conjunction with AES. A PHI Thin Film Analyzer system was used. Normal operating conditions were 5 kV electron gun voltage, 30 μA beam current, and 3 eV modulation amplitude. For sputtering, the argon gas pressure was 7 mPa (5×10^{-5} Torr), and the ion beam voltage and current were 0.5 kV and 5 mA, respectively. By means of a multiplexer in the system, the Ni 848 eV peak and the O 510 eV peak were monitored and plotted continuously to obtain the depth profiles. Film thicknesses were determined from the time to sputter through the film and the sputter rate. The time to sputter through the film was taken as the inflection point in the oxygen depth profile.

The sputter rate was determined in the following manner. A 2.5 μm layer of nickel, deposited onto the copper coupon, was overplated with a thin (0.25 μm), porous layer of gold. The porosity of the gold coating, as measured by the nitric acid porosity test at 10X magnification (5), was 40-50 pores/cm^2; the pore corrosion products were generally 0.1 mm or less in diameter. Twelve specimens were exposed to air at 100°C and 95% RH for an extended period of time to produce a thin layer of nickel oxide on the surface of the gold. The AES spectrum in Fig. 1 is typical of that observed on these specimens. The presence of nickel oxide is evidenced by the nickel peaks and the oxygen 510 eV peak. The oxide is sufficiently thin so that the gold 69 eV peak is still visible. Using this peak, the thickness of the oxide film was calculated from the ratio of the peak-to-peak heights in the presence and absence of the oxide film, the escape depth (0.5 nm) of the Au 69 eV electrons and Lambert's law. The thickness was reasonably uniform over each specimen, and varied from 0.5 to 2 nm for the twelve specimens. From the time required to sputter through these oxide films and

their thicknesses, the rate of sputtering nickel oxide was calculated to be 1.7 pm/sec with a standard deviation of 0.5 pm/sec.

Results

AES spectra of the nickel-plated specimens, both as electroplated and after the environmental exposure tests, exhibited the standard nickel and oxygen peaks. A small sulfur peak was also detected on most spectra. This peak did not disappear as the specimen surface was sputtered, indicating that the sulfur was incorporated in the electrodeposit, probably from the sulfamate bath. Copper was not detected in the spectra, indicating complete coverage of the substrate by the nickel.

The corrosion film thickness is plotted as a function of exposure time at 40°C and 95% RH, and at 200°C and ambient humidity (<1% RH) in Fig. 2 and 3. Each point is the average of 2-4 determinations. Although the scatter in the data is substantial (Fig. 2), the growth of the film at short times and the approach to a limiting thickness at longer times is evident.

The effect of temperature and humidity on the corrosion film thickness was studied over the ranges 23°-100°C, and ambient to 95% RH at a constant exposure time of 173 ksec. The resulting film thicknesses are plotted as a function of temperature and relative humidity in Fig. 4, and as a function of temperature and absolute humidity in Fig. 5. These thicknesses are either limiting or near limiting values.

Discussion

The thicknesses of the oxide films formed on nickel over wide ranges of temperature (23°-200°C) and humidity (ambient to 95% RH) range from 0.25 to 2.8

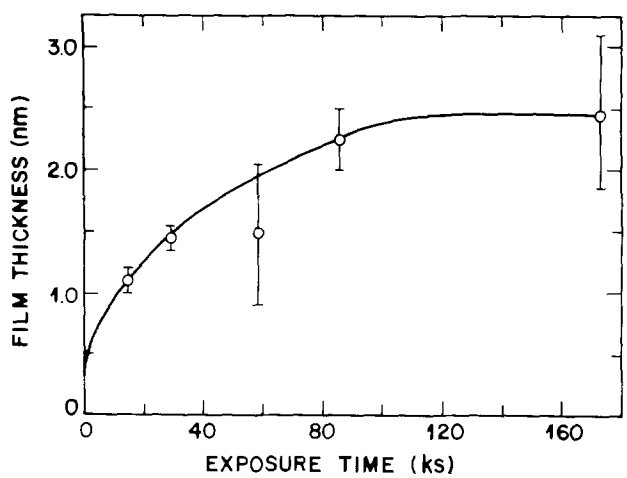

Fig. 2. Tarnish film thickness as a function of exposure time at 40°C and 95% RH.

nm, or from about a monolayer of oxide to multilayer films more than an order of magnitude thicker. To interpret the data, it is necessary to determine whether the films formed under the various conditions have the same composition.

The AES analyses indicated that all of the films were nickel oxide. The atomic composition ratio Ni/O can be estimated from the ratio of the peak-to-peak heights of the principal Auger electron peaks of the two elements,

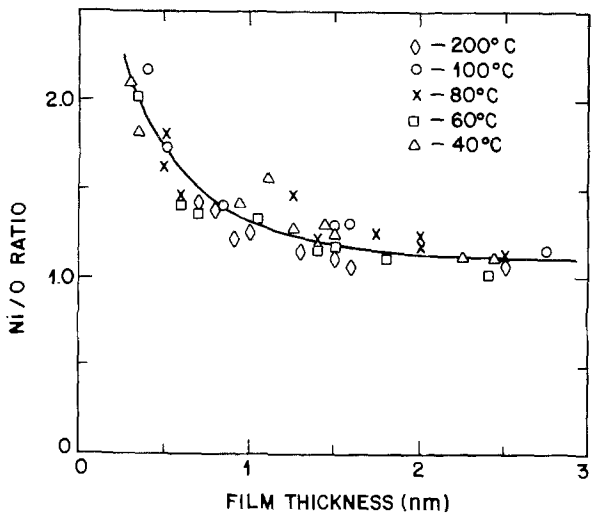

Fig. 6. The Ni/O composition ratio as a function of tarnish film thickness for all temperatures and relative humidities studied. All points lie on the same curve, indicating that films formed under all conditions have the same composition.

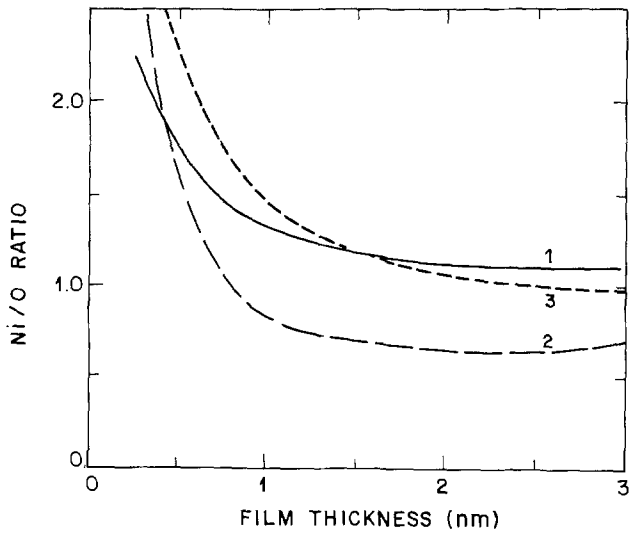

Fig. 7. The Ni/O composition ratio as a function of tarnish film thickness. 1, Experimental data (see Fig. 6); 2, Calculated assuming escape depth of Ni electrons is same in Ni and in NiO; 3, Calculated assuming $\lambda_{Ni(NiO)} = 1.5$ nm and $\lambda_{Ni(Ni)} = 1.1$ nm.

assuming that the heights are proportional to concentration. Using the Ni 848 eV peak and the O 510 eV peak, and correcting for their relative sensitivities (6), the Ni/O ratios were calculated and are plotted as a function of film thickness for the various experimental conditions (Fig. 6). All the points fall reasonably well on one curve.

Since the films are very thin, the electroplated nickel substrate contributes to the intensity of the Ni 848 eV signal. This contribution increases as the film thickness decreases, accounting for the curvature in the plot (Fig. 6). This can be demonstrated by an approximate calculation of the Ni/O intensity ratio.

$$\frac{I_{Ni}}{I_O} = \frac{\int_o^d \exp(-l/\lambda_{Ni})\,dl + \alpha \exp(-d/\lambda_{Ni}) \int_o^\infty \exp(-l'/\lambda_{Ni})\,dl'}{\sigma \int_o^d \exp(-l/\lambda_O)\,dl} \quad [1]$$

in which the I's are the peak-to-peak intensities of the indicated species, d is the thickness of the oxide film, l and l' are the distances from the air-oxide and the oxide/metal interfaces, respectively, λ_{Ni} is the escape depth of the Ni 848 eV electrons, λ_O is the escape depth of the O 510 eV electrons, α is the ratio of the concentration of Ni in the metal to that in the oxide, and σ is the ratio of the intensities of the standard spectral peaks, I^∞_O/I^∞_{Ni}. The left-hand term in the numerator is the peak intensity from Ni in the oxide; the right-hand term is the peak intensity from Ni in the substrate metal. The denominator is the peak intensity from O in the oxide. Integrating Eq. [1], one obtains

$$\frac{I_{Ni}}{I_O} = \frac{\lambda_{Ni}}{\sigma\lambda_O} \left\{ \frac{1 - (1-\alpha)\exp(-d/\lambda_{Ni})}{1 - \exp(-d/\lambda_O)} \right\} \quad [2]$$

λ_{Ni} and λ_O were estimated to be 1.1 and 0.8 nm, respectively (7). α was calculated to be 1.655 from the molar volumes of NiO and Ni, 10.90 and 6.588 cm³/mole, respectively. From the standard spectra (6), σ was determined to be 2.0.

From Eq. [2] and these parameters, the intensity ratio was calculated and is plotted as a function of oxide thickness, d, in Fig. 7 (curve 2). The curve for the experimental data from Fig. 6 is shown for comparison (Fig. 7, curve 1). The principal approximations in the calculation are the estimation of the electron escape depths, the assumption that these escape depths are the same in the oxide and in the metal, the neglect of backscattering of electrons, the assumption that σ calculated from the standard spectra is applicable to this system, and the assumption that attenuation of the incident electrons with depth into the oxide and metal can be neglected.

The agreement between the calculated curve and the experimental data is reasonably good at low film thicknesses. At higher film thicknesses, the high value of the experimental Ni/O ratio is probably a reflection of an escape depth of the Ni 848 eV electrons that is greater in NiO than in Ni, much as Palmberg (8) has suggested that the escape depth of the electrons from magnesium is greater in MgO than in the metal. If it is assumed that the escape depths of the Ni 848 eV electrons are different in the oxide and in the metal, then the right-hand term in the numerator of Eq. [1] becomes

$$\alpha \exp[-d/\lambda_{Ni(NiO)}] \int_o^\infty \exp[-l'/\lambda_{Ni(Ni)}]\,dl' \quad [3]$$

in which $\lambda_{Ni(NiO)}$ and $\lambda_{Ni(Ni)}$ are the escape depths of the Ni electrons in NiO and Ni, respectively. This leads to

$$\frac{I_{Ni}}{I_O} = \frac{\lambda_{Ni(NiO)} - [\lambda_{Ni(NiO)} - \alpha\lambda_{Ni(Ni)}] \exp[-d/\lambda_{Ni(NiO)}]}{\sigma\lambda_O[1 - \exp(-d/\lambda_O)]} \quad [4]$$

The intensity ratio calculated from Eq. [4] is plotted in Fig. 7 (curve 3) for $\lambda_{Ni(NiO)} = 1.5$ nm and $\lambda_{Ni(Ni)} = 1.1$ nm. The improved agreement with the experimentally determined curve indicates that the electron escape depths are indeed a function of the matrix composition.

These calculations indicate that the compositions of the various films are essentially the same, the apparent variation in the Ni/O ratio (Fig. 6) being due to contributions from the substrate nickel. The composition is assumed to be NiO, which is known to be the film that forms both under ambient conditions and at 200°C in oxygen (4). NiO is cation deficient, *i.e.*, $Ni_{1-x}O$, in which x is small over a wide range of oxidation conditions (9).

The chemisorption of oxygen onto a clean nickel surface and the subsequent formation of the first monolayers of NiO is very rapid (4). In the present study, this film was always present before the specimens were exposed to the test environment. AES and the sputtering process detect and remove this film, as well as that formed during the test exposure.

Nickel does not undergo appreciable oxidation at temperatures below 300°C (1, 4, 10). In the present study, the limiting thickness at 200°C, approximately 1.5 nm, is in excellent agreement with the value of 1.7 nm reported by Graham and Cohen (4). Campbell and Thomas (10) measured a thinner film at 194°C. However, this was determined from the uptake of oxygen on nickel already covered with the oxide formed at room temperature. Graham and Cohen (4) reported the limiting thickness at room temperature to be 1 nm, which is slightly higher than the average value of 0.4-0.5 nm measured here. This difference may be accounted for by the different surface preparation techniques, which result in different surface structures, roughnesses, and compositions. The surfaces prepared by Graham and Cohen were exceptionally clean and reproducible, while the objective of the present study was to approximate conditions that exist in the field. The measurement techniques are also different, and since the calculation of film thickness from the data obtained by each of these techniques requires different assumptions, some of the differences in results may be attributed to these.

The film thickness is clearly a function of humidity and temperature (Fig. 4 and 5). Up to 20% RH, the film thickness does not exceed 0.85 nm. For NiO, which has a rock salt structure, the unit cell dimension a_o is 0.41769 nm (11). Thus, the films formed at low humidity are no more than 2 unit cells in thickness at temperatures up to 100°C, in agreement with Holloway and Hudson (12). Even at 200°C and ambient humidity (RH < 1%), the limiting thickness is only 1.3 nm, or 3 unit cells (Fig. 3). At high relative humidities, *e.g.*, 95%, there is also only a small effect of temperature on film thickness. However, in the intermediate range of relative humidity, from 20 to 75%, the effect of temperature on film thickness is significant.

In the absence of water vapor, the oxidation of nickel is self-limiting, and ceases after one to two monolayers of the oxide have formed. The presence of water increases the thickness of the oxide. As the temperature is increased, a greater partial pressure of water vapor is required to achieve the same film thickness (Fig. 5). Since most gases desorb with increasing temperature, it must be the water adsorbed on the oxide, and not the partial pressure of water vapor, that is responsible for the oxide growth.

NiO is a p-type semiconductor with a cation deficiency, and it grows by the diffusion of cation vacancies (1). We speculate that the increased growth of the oxide in the presence of adsorbed water may be due to an increase in the cation vacancy concentration at the surface, this increasing the driving force for diffusion. The excess vacancies could be introduced by the oxidation of Ni^{2+} to Ni^{3+}. But this appears unlikely since oxidation by O_2 is thermodynamically much favored over that by H_2O. A more likely explanation is that the surface layer of NiO reacts with H_2O to form $Ni(OH)_2$. The molar volume of $Ni(OH)_2$, 23.47 cm^3/mole, is more than twice that of NiO, 10.97 cm^3/mole (13). Thus the formation of the hydroxide is likely to displace the Ni^{2+} ion from its lattice position, and create a vacancy. The increase in the vacancy concentration, according to this hypothesis, is directly proportional to the concentration of adsorbed water, which is proportional to the relative humidity. Above a certain relative humidity, the surface layer becomes saturated with vacancies. At these humidities, *e.g.*, 95%, differences in film thickness with temperature reflect only the effect of temperature. The same is true at low humidities

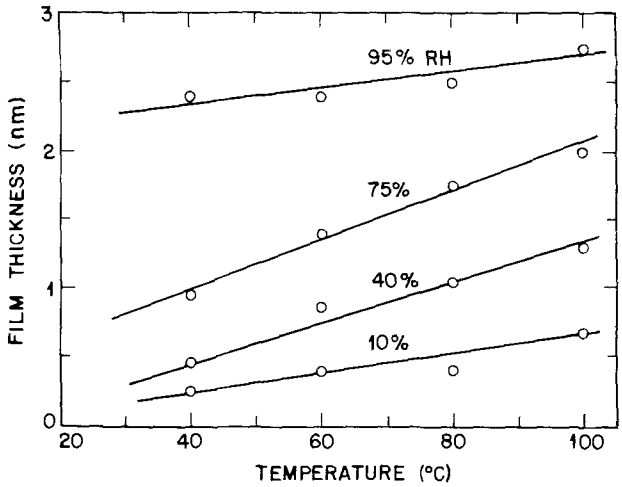

Fig. 8. Film thickness as a function of temperature for various relative humidities showing a significantly greater temperature coefficient at intermediate RH than at low or high RH.

(< 20% RH), at which it might be expected that little, if any, water is adsorbed. The temperature coefficients of the film thickness are essentially the same at the low and high relative humidities, but are considerably greater at intermediate relative humidities, at which the humidity significantly affects the amount of adsorbed water (Fig. 8).

The surface will be approximately saturated with cation vacancies when a monolayer of $Ni(OH)_2$ has formed. Kim and Winograd (14) have followed the interaction of H_2O with NiO by x-ray photoelectron spectroscopy. A thin layer of $Ni(OH)_2$ was formed, reducing the intensity of the NiO O 1s peak by about 15%. Using Lambert's law and assuming an escape depth of 1 nm for the NiO O 1s electrons (whose kinetic energy is 957 eV), an attentuation of 18% is calculated for these electrons by a 0.2 nm film of $Ni(OH)_2$. This is in good agreement with the proposed mechanism.

Summary

The oxidation of nickel in air has been studied as a function of temperature (23°-200°C) and relative humidity (ambient to 95%). At low relative humidities, oxide films grow no thicker than 1.3 nm at 200°C, and significantly less than that at temperatures of 100°C or less. The presence of water vapor markedly increases the thickness of the oxides that form at all temperatures. At 95% RH, the film thickness is between 2.5 and 3.0 nm for temperatures from 40° to 100°C.

It has been suggested that the increase in film thickness with increasing relative humidity may be due to the formation of a layer of $Ni(OH)_2$ at the surface of the NiO film with the concurrent creation of cation vacancies in the surface of the oxide. These vacancies increase the driving force for diffusion and the growth of the oxide.

Efficient Luminescent Energy Transfer from Mn^{2+} to Yb^{3+} in CaF_2

J. A. DeLuca* and F. S. Ham

General Electric Company, Research and Development Center, Schenectady, New York 12301

ABSTRACT

The system CaF_2:Mn:Yb was selected for study because it held promise for the experimental realization of Dexter's hypothesized simultaneous transfer of energy from one sensitizer to two activators. Emission, excitation, and decay measurements show that efficient Mn^{2+} to Yb^{3+} energy transfer does occur. However, analysis of the data indicates that the mechanism of energy transfer involves the more familiar direct ion-to-ion transfer.

Our interest in phosphors having a luminescent quantum yield greater than unity (1) has led us to consider the cooperative deexcitation mechanism originally proposed on theoretical grounds by Dexter (2) but never observed experimentally. We have sought evidence for the operation of this mechanism in CaF_2 doped simultaneously with Mn^{2+} and Yb^{3+}, since the properties of the Mn^{2+} and Yb^{3+} ions in this host are particularly well suited to the requirements of Dexter's proposal. The purpose of this paper is to report the results of experiments that show that energy transfer with a high quantum efficiency does indeed occur in this system. Our data do not, however, exhibit the dependence on Yb^{3+} concentration expected for the Dexter mechanism, and we conclude that this mechanism is not responsible for the energy transfer in CaF_2:Mn:Yb. We propose an alternative model to explain the data, based on evidence that a Yb^{3+} ion close to a Mn^{2+} ion significantly changes the Mn^{2+} energy levels.

In the Dexter mechanism a sensitizer ion, excited by absorption of a photon, transfers its energy to two nearby activator ions, each of which then returns, for the simplest possible system of this type, by a single radiative step to its ground state. If this were the dominant decay process and there were no losses, and if all the activator ions were of the same species, the number of emitted photons would then be approximately twice the number of photons absorbed by the sensitizer, while their frequency would be somewhat less than half that of the original quantum. The crucial energy-transfer step in this process, from one sensitizer to two activators, is allowed by the interaction (coulomb multipole and exchange) between the two activators. In fact, the process is very similar to the cooperative absorption of one photon by two ions, as first observed by Varsanyi and Dieke (3) for Pr^{3+} ions in $PrCl_3$, the only difference being that, whereas in the cooperative absorption the excitation is due to the electronic coupling to the radiation field, in the Dexter mechanism the excitation results from the multipole or exchange interaction of the activators with the sensitizer. The cooperative sensitization of Tb^{3+} by Yb^{3+} has been observed in several hosts (4, 5).

It is clearly required for the Dexter mechanism to be operative that the energy of the excited state of the sensitizer be approximately twice that of the excited state of the activator, so that the emission spectrum of the sensitizer can overlap significantly the convolution of the activator absorption spectrum with itself and thereby make possible energy conservation in the transfer process. It is also required that there be no intermediate states of the sensitizer, and no higher excited states of the activator with energies close to the excited state of the sensitizer, so that energy transfer involving the excitation of a single activator is very unlikely. Also, the lifetime of the excited state of the sensitizer must be sufficiently long to allow the cooperative transfer process to compete favorably with simple radiative and nonradiative decay.

The energy levels of Mn^{2+} and Yb^{3+} in CaF_2 satisfy these requirements very well. In cubic symmetry with not too strong a crystal field the lowest excited state of the Mn^{2+} ion ($3d^5$ configuration) is the $^4T_{1g}$ state derived from the ^4G term of the free ion (6), and this is the initial state for Mn^{2+} fluorescence. In CaF_2 the $^4T_{1g}$ state of Mn^{2+} must lie ~21,000 cm^{-1} above the $^6A_{1g}$ ground state, since the Mn^{2+} fluorescence is a broad band in the green with its peak at ~500 nm, as shown by our data. The only excited states of the $4f^{13}$ configuration of Yb^{3+} have almost exactly half as much excitation energy: These are the $^2F_{5/2}$ states, which lie ~10,000 cm^{-1} above the $^2F_{7/2}$ ground state (7). There are no other states of Yb^{3+} with energies near that of the $^4T_{1g}$ state of Mn^{2+}, the nearest being the levels of the $4f^{12}5d$ configuration lying above ~66,000 cm^{-1} (8). Also, the lifetime of the Mn^{2+} fluorescence is extremely long, ~85 msec at 300°K as shown by our data. Thus the prospects of observing the Dexter mechanism in this system appear particularly favorable, while the likelihood of transfer from one Mn^{2+} to a single Yb^{3+} should be small as a result of the large difference in excitation energy for these two ions.

* Electrochemical Society Active Member.
Key words: energy transfer, luminescence, CaF_2:Mn:Yb.

In our experiments we have recorded the excitation and emission spectra of several series of samples of CaF_2 doped with various concentrations of Mn^{2+} and Yb^{3+}. Emission spectra were recorded at room temperature and 77°K in both the visible and infrared regions of the spectrum. The visible emission is due to the direct fluorescence of the Mn^{2+}, and the infrared band at ~10,000 nm to the Yb^{3+} fluorescence sensitized by Mn^{2+}. The absolute and relative values for the rate of energy emission in these two bands were measured at room temperature under conditions of steady-state illumination. Also measured was the time dependence of the decay of the fluorescence in each band when the exciting light was shut off. We also measured the decay of the Yb^{3+} fluorescence following direct excitation of the Yb^{3+} by illumination in the infrared.

Experimental

Sample preparation.—The basic starting materials used were $CaCO_3$ (G.E. Chemical Products Ultrapure), Mn metal (Johnson Matthey Specpure), Yb_2O_3 (Molycorp 4N's), and Y_2O_3 (Kerr-McGee 6N's). From these materials were prepared samples of $CaCO_3$, $CaCO_3$: $x MnCO_3$, and $CaCO_3 + y Ln_2O_3$ (Ln = Y, Yb) in quantities sufficient to insure that all samples of a particular series were prepared from the same starting materials.

The sample series CaF_2:1%Mn:x%Yb[1] ($0.01 \leq x \leq 20$), CaF_2:x%Mn:5%Yb ($0.1 \leq x \leq 20$), and CaF_2:1%Mn:x%Yb:$(20 - x)$%Y ($0.01 \leq x \leq 20$) were prepared by firing the appropriate carbonate-oxide mixtures in a stream of argon and hydrogen fluoride. A platinum boat and reaction tube were used. Teflon fittings and tubing were used in the gas train.

Each sample was prepared by heating the appropriate carbonate-oxide mixture (~6g) to 400°C under flowing argon (100 cm^3/min, Linde Ultrahigh Purity). At that point the hydrogen fluoride flow was initiated (100 cm^3/min, Matheson Gas Company) and the reaction allowed to proceed for 1 hr. The temperature was raised to 700°C, and the sample was allowed to react for an hour. Upon removal from the reaction furnace the sample was ground and sieved through a 200 mesh screen. The sieved sample was refired in an argon-HF stream for 2 hr at 1100°C. Finally, the sample was sieved through a 400 mesh screen. It was determined that this preparative method insured samples with reproducible emission properties.

Excitation spectra.—The monochromator of a Cary 14 spectrophotometer was used as the variable wavelength excitation source and a cooled RCA 7102 photomultiplier with appropriate filters detected the sample emission. Corning no. 3-71 and no. 4-96 filters were used in tandem between the sample and the photomultiplier (detection band ~470 to ~590 nm) when recording excitation spectra for the visible emission. A Corning no. 7-56 filter (detection band ~750 to ~1200 nm) was used for recording excitation spectra for infrared emission. The excitation spectra were not corrected for the spectral distribution of the excitation source.

Emission spectra.—Sample emission was excited by the 457.9 nm line of an argon ion laser (Spectra Physics Model 166). An interference filter was placed in the laser beam to reduce the background. Emission spectra were recorded with a 0.5m Jarrell-Ash scanning monochromator coupled to a cooled RCA 7102 photomultiplier. The sample image was focused on the entrance slit of the monochromator and an appropriate filter (Corning no. 3-71 for visible spectra, Corning no. 2-64 for infrared spectra) was placed between the sample and slit to minimize contributions to the signal from second-order spectra and scattered laser light.

The spectral response of the detection system (everything beyond the sample) was determined by recording the reflection spectrum of a $BaSO_4$ sample irradiated by a calibrated lamp. A "base line" correction spectrum was obtained by exciting a sample of CaF_2 with the laser. This spectrum was used to correct the emission spectra for contributions from impurity emission of the host CaF_2 and filter fluorescence. The magnitude of the correction was determined for each spectrum by measuring the signal strength at a wavelength removed from the emission spectrum of interest. All recorded spectra were digitized and a computer program was used to fold in the spectral response and appropriately scaled base line corrections. The program generated corrected emission spectra and computed the integrated power and the value of $\bar{\lambda}$ (mean wavelength for the spectral power distribution) for the emission bands.

Decay measurements.—The sample image (457.9 nm laser excitation or 975 nm from a tungsten lamp and monochromator combination) was focused with two large-aperture aspheric condenser lenses on a cooled RCA 7102 photomultiplier. A combination of Corning no. 3-71 and no. 4-96 filters was used to isolate the visible emission band and a Kodak no. 87-C filter was used for the infrared. The photomultiplier signal was passed first through a logarithmic amplifier (Analog Devices Model 755P) and then into the memory input of a Nicolet 1090 storage oscilloscope. An evaluation of the performance of the logarithmic amplifier confirmed that the log conformity error was within the manufacturer's specifications. Decay curves (log I *vs.* t) were obtained by interrupting the laser beam with a shutter and synchronously triggering the time sweep of the storage scope. Samples were measured at both room temperature and 77°K.

Results

Excitation spectra.—A typical excitation spectrum for the visible emission in samples containing manganese or manganese plus ytterbium is shown in Fig. 1a. This spectrum was not found for CaF_2 or CaF_2:Yb samples. An almost identical excitation spectrum, shown in Fig. 1b, was observed for the infrared emis-

sion in CaF_2:Mn:Yb samples, but was not observed in CaF_2, CaF_2:Yb, or CaF_2:Mn samples.

Emission spectra.—*CaF_2:1%Mn:x%Yb.*—Samples doped with both Mn^{2+} and Yb^{3+} show emission in the infrared in addition to the Mn^{2+} emission in the visible. The infrared emission is shown in Fig. 2 and is attributed to Yb^{3+}. This spectrum resembles the luminescence spectra of Yb^{3+} in CaF_2 observed by Voron'ko *et al.* (9) and shows a similar variation with Yb^{3+} concentration. A peak ~970 nm characterizes the spectrum at very low concentrations of Yb^{3+}. As the concentration increases, peaks ~980 nm begin to dominate. These lines persist at even higher concentrations where a broad emission >1000 nm appears.

Visible emission spectra, which are observed only in samples containing Mn^{2+}, are shown in Fig. 3 and are attributed to radiative decay from the $^4T_{1g}$ state of Mn^{2+} ions which substitute for Ca^{2+} in the CaF_2 lattice.

As the Yb^{3+} concentration is increased, the intensity of the Mn^{2+} emission diminishes and this band shifts to longer wavelengths. This shift is shown by the spectra in Fig. 3; the average wavelength of the band shifts from 504 nm when Yb^{3+} is absent to 528 nm for CaF_2:1%Mn:20%Yb.

The relative intensities of the two emission bands as a function of Yb^{3+} concentration, under conditions of steady-state excitation of the sample, are shown in

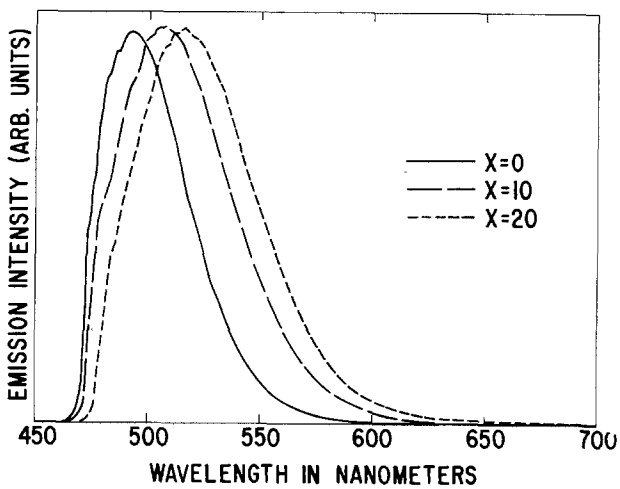

Fig. 3. Mn^{2+} emission spectra (corrected) for the series CaF_2: 1%Mn:x%Yb showing the effect of Yb^{3+} concentration on the Mn^{2+} band.

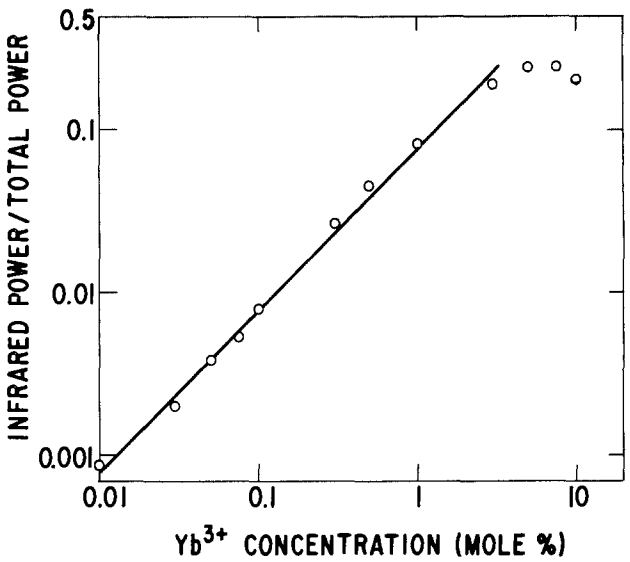

Fig. 4. Log-log plot of infrared power/total emitted power vs. Yb^{3+} concentration for the series CaF_2:1%Mn:x%Yb.

Fig. 4. Shown is the ratio of the total power emitted in the infrared band (obtained by integrating the power density over this band) to the total power emitted in both the visible and infrared bands. This ratio is proportional to the Yb^{3+} concentration up to a concentration of ~3% as shown by the line of unit slope drawn through the data points of Fig. 4. The absolute value of the total power emitted in both bands is approximately independent of Yb^{3+} concentration for samples of the same thickness and identical conditions of sample illumination. Evidently the absorption of the exciting light by the Mn^{2+} does not depend appreciably on the Yb^{3+} concentration. We could not measure the absorption of these samples directly because of its low value.

CaF_2:x%Mn:5%Yb.—The visible emission spectra for this series are similar to the above. The value of $\bar{\lambda}$ ranges from 512 nm for $x = 0.1$ to 551 nm for $x = 20.0$. Careful measurement of the visible emission spectrum for samples with $x \geq 5$ reveals that the long wavelength tail extends to ~820 nm. The infrared spectrum for all samples is similar to that shown in Fig. 2 for CaF_2:1%Mn:5%Yb.

CaF_2:5%Mn:x%Yb:(20 − x)%Y.—The visible emission spectrum for the sample CaF_2:5%Mn:20%Y has a peak at 560 nm and a long wavelength tail that extends out to 860 nm. As the Yb^{3+} content is increased, the emission peak shifts to shorter wavelengths and the extent of the tail diminishes until at $x = 20.0$ the emission peak is at 525 nm and the tail extends to 820 nm. These effects are evident in the emission spectra shown in Fig. 5. The infrared spectra for the various Yb^{3+} concentration levels were similar to those recorded for the samples CaF_2:1%Mn:x%Yb.

Decay measurements.—Curves showing the intensity of fluorescence in both the visible and infrared bands as a function of the time following the cessation of sample illumination were recorded at room temperature and 77°K for samples in the several series described previously. Representative decay curves obtained using argon ion laser excitation are shown in Fig. 6 for the visible and the infrared bands. Some of these curves are approximately exponential, but most show a slope which diminishes appreciably on a logarithmic plot as the decay proceeds. All the curves have a nonzero initial slope, characterized by a decay time $\tau(O)$ which depends upon sample composition and temperature. This initial decay time is in all cases much shorter for the infrared fluorescence than for the visible. Representative values of $\tau(O)$ are listed in Table I.

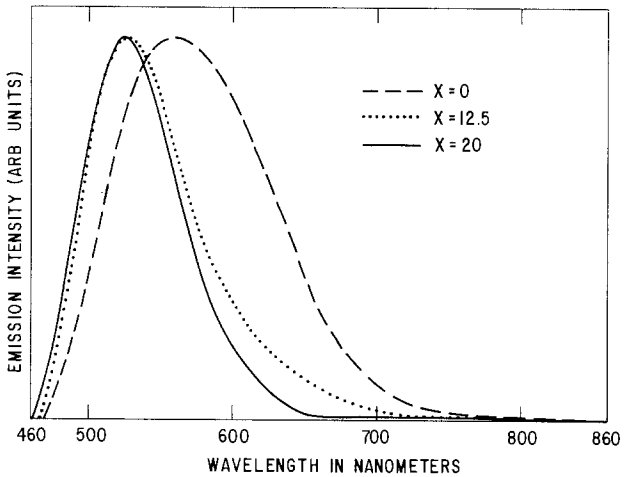

Fig. 5. Mn^{2+} emission spectra (corrected) for the series CaF_2: 5%Mn:x%Yb:(20 — x)%Y showing the effect of the Yb^{3+} concentration on the Mn^{2+} band.

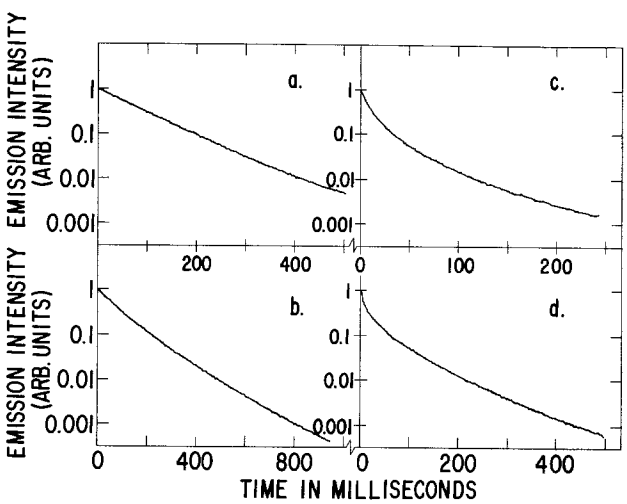

Fig. 6. Decay curves (457.9 nm excitation) for visible emission in (a) CaF_2:1%Mn at 300°K; (b) CaF_2:5%Mn:5%Yb at 77°K; and for infrared emission in (c) CaF_2:1%Mn:5%Yb at 300°K; (d) CaF_2:3%Mn:5%Yb at 77°K.

Also recorded were the decay curves for the Yb^{3+} fluorescence following infrared excitation. Representative curves are shown in Fig. 7. Values of 3 msec at room temperature and 2.4 msec at 77°K were typical of the $\tau(O)$ values derived from these curves and are similar to the decay times reported by Livanova (4) for Yb^{3+} in CaF_2.

Interpretation

The excitation spectra for both the visible emission, which originates in transitions from the $^4T_{1g}$ level of Mn^{2+}, and the infrared emission, which originates in transitions from the $^2F_{5/2}$ Yb^{3+} levels, correlate well with peaks in the absorption spectrum of Mn^{2+} in CaF_2 (10) and MnF_2 (11), and demonstrate that in the system CaF_2:Mn:Yb energy is transferred from Mn^{2+} ions to Yb^{3+} ions.

We have seen that the necessary conditions for energy conservation in the energy transfer step of the

Dexter mechanism are satisfied for Mn^{2+} and Yb^{3+} in CaF_2. However, our data provide evidence that this is not the mechanism operative in the system CaF_2:Mn:Yb. The Dexter mechanism requires two Yb^{3+} ions to be close to the same Mn^{2+} ion. Thus, the quantum yield for the Yb^{3+} luminescence should increase as the square of the Yb^{3+} concentration if the Dexter mechanism is the principal mechanism for the sensitization of the Yb^{3+}, at least for sufficiently low Yb^{3+} concentrations. As shown in Fig. 4, the power emitted in the Yb^{3+} infrared band is accurately linear in the Yb^{3+} concentration over a range of two decades. These data point to the unambiguous conclusion that the sensitization of the Yb^{3+} involves energy transfer from a Mn^{2+} ion to a single Yb^{3+} ion. The efficiency of this transfer is surprisingly high, as shown by Fig. 4, in view of the large energy difference (~10,000 cm^{-1}) between the excited states of Mn^{2+} and Yb^{3+}. For example, for the sample CaF_2:1%Mn:5%Yb the infrared emission accounts for 26% of the total emitted power. Since the quantum energy in the infrared band is only half that of the visible band, very nearly as many Mn^{2+} must transfer energy to Yb^{3+} in this sample as radiate their energy directly.

We should be able to derive the rate at which energy is transferred from Mn^{2+} to Yb^{3+}, and thus gain insight into this process, by attempting an analysis of our data on the rate of decay of luminescence after the exciting light is shut off. We let τ_{Mn}^{-1} denote the probability per unit time for an isolated Mn^{2+} ion, in its excited state, to return to the ground state via a radiative process, and we assume that this rate is unaffected, at least to a good approximation when Yb^{3+} ions are introduced into the crystal. (We will neglect for simplicity the nonradiative decay of both the Mn^{2+} and Yb^{3+} ions on the assumption that the quantum efficiency for the fluorescence of both ions is approximately unity.) The rate ω_i at which the ith Mn^{2+} ion, in its excited state, decays by transferring its energy to a nearby Yb^{3+} ion should be different for different Mn^{2+} ions and should depend on the distribution of Yb^{3+} ions on neighboring sites

$$\omega_i = \Sigma_n \omega(R_{ni})$$

This summation is over only those sites occupied by Yb^{3+}; $\omega(R)$ is the transfer rate for a pair separated by a distance R, and R_{ni} is the distance from the site of the nth Yb^{3+} to the ith Mn^{2+} ion. The equation describing the probability $S_i(t)$ that the ith Mn ion remains in its excited state is then

$$\frac{dS_i(t)}{dt} = -S_i(t)\,(\tau_{Mn}^{-1} + \omega_i) \qquad [1]$$

In writing Eq. [1] we ignore the possibility that transfer of excitation may take place from one Mn^{2+} ion to another. Such transfer would tend to cause all Mn^{2+} ions to decay at a common rate, whereas our data indicate that the Mn^{2+} ion decay rates are very different for different ions in the same sample, when transfer to Yb^{3+} occurs.

The rate at which Yb^{3+} ions are excited by transfer from Mn^{2+} is then obtained by summing $S_i\omega_i$ over all Mn^{2+} ions and multiplying this sum by a factor η giving the number of Yb^{3+} ions excited by the decay of a single Mn^{2+}. We would then have $\eta = 2$ if the Dexter mechanism were effective, or $\eta = 1$ if the transfer is one-to-one. If τ_{Yb}^{-1} denotes the rate of radiative decay of the Yb^{3+}, which we will assume is the same for all Yb^{3+} ions, the number of excited Yb^{3+} is given by $a(t)$, which satisfies the equation

$$\frac{da(t)}{dt} = -a(t)\tau_{Yb}^{-1} + \eta \sum_i S_i(t)\omega_i \qquad [2]$$

Our data for the series CaF_2:x%Mn:5%Yb under infrared excitation show that τ_{Yb} is independent of the Mn^{2+} concentration up to at least 12% Mn^{2+}. Equation [2] holds even though diffusion of the excitation occurs from one Yb^{3+} ion to another (9), provided that no significant fraction of the excitation energy is lost thereby through diffusion to traps where nonradiative decay occurs.

Under conditions of steady-state excitation we must add to the right-hand side of Eq. [1] a term gI giving the rate of excitation of the Mn^{2+} for an illumination intensity I, and set the left-hand side equal to zero. We obtain, therefore, for the steady-state probability that a Mn^{2+} ion is excited the value

$$S_i(O) = \frac{gI\tau_{Mn}}{1 + \omega_i\tau_{Mn}} \qquad [3]$$

which is also the initial value, at the time the exciting light is shut off, for use in solving Eq. [1] for the decay. Similarly, the steady-state number of excited Yb^{3+} is obtained by setting the left-hand side of Eq. [2] to zero and substituting from Eq. [3]

$$a(O) = \eta\tau_{Yb}\sum_i S_i(O)\omega_i = \eta\tau_{Yb}gI\sum_i \frac{\omega_i\tau_{Mn}}{1 + \omega_i\tau_{Mn}} \qquad [4]$$

The decay of the excitation of the ith Mn^{2+} ion after the exciting light has been shut off is given by the solution of Eq. [1] subject to the initial condition of Eq. [3]

$$S_i(t) = S_i(O)\exp(-t/\tau_i) \qquad [5]$$

where

$$\tau_i^{-1} = \tau_{Mn}^{-1} + \omega_i \qquad [6]$$

The Mn^{2+} luminescence rate is then obtained by summing Eq. [5] over all ions and dividing by τ_{Mn}

$$L_{Mn}(t) = \tau_{Mn}^{-1}\sum_i S_i(O)\exp(-t/\tau_i) \qquad [7]$$

The general solution of Eq. [2] for the decay of the Yb^{3+} excitation is given by

$$a(t) = a(O)\exp(-t/\tau_{Yb}) + \eta\exp(-t/\tau_{Yb})\int_0^t dt'\exp(t'/\tau_{Yb})\sum_i S_i(t')\omega_i \qquad [8]$$

Substituting into Eq. [8] from Eq. [5] and carrying out the integration, we can express the result as the luminescence rate of the Yb^{3+}

$$L_{Yb}(t) = a(t)\tau_{Yb}^{-1} = \eta\sum_i \frac{S_i(O)\omega_i}{1 - \frac{\tau_{Yb}}{\tau_i}}\left[\exp(-t/\tau_i) - \frac{\tau_{Yb}}{\tau_i}\exp(-t/\tau_{Yb})\right] \qquad [9]$$

The sum of the first term in the bracket in Eq. [9] has a similar form to that of Eq. [7]: Each term exhibits a simple exponential decay with the same set of decay times τ_i appearing in Eq. [9] as in Eq. [7]. However, the individual terms in this sum have a different relative weighting than in Eq. [7], principally because of the appearance of the factor ω_i in Eq. [9]. If we have $\tau_{Yb} < \tau_i$, all of these terms in the first sum in Eq. [9] are positive, like those in Eq. [7]. Under the same condition, however, the second term in the bracket in Eq. [9] is negative, and these terms decay with a common lifetime τ_{Yb}, the radiative decay time of the Yb^{3+}. The sum of the second term, therefore, has the effect of causing the total luminescence rate $L_{Yb}(t)$ to be lower and to have a lower slope, for a period of time extending to $t \sim \tau_{Yb}$, than one would estimate by extrapolating the curve backward from larger t. Indeed, taking the derivative of Eq. [9], we see that the slope of the curve is identically zero at $t = 0$. This result is, of course, simply due to the fact that the left-hand side of Eq. [2] is zero at $t = 0$, since the steady-state relationship exists between $a(t)$ and $\sum_i S_i(t)\omega_i$ at the moment the light is shut off.

On the other hand, if we have $\tau_i < \tau_{Yb}$ in some of the terms of Eq. [9], it is convenient to rewrite this equation in the form

$$L_{Yb}(t) = \eta\sum_{i(\tau_i<\tau_{Yb})} \frac{S_i(O)\omega_i}{1 - \frac{\tau_i}{\tau_{Yb}}}\left[\exp(-t/\tau_{Yb}) - \frac{\tau_i}{\tau_{Yb}}\exp(-t/\tau_i)\right] + \eta\sum_{i(\tau_i>\tau_{Yb})}' \frac{S_i(O)\omega_i}{1 - \frac{\tau_{Yb}}{\tau_i}}\left[\exp(-t/\tau_i) - \frac{\tau_{Yb}}{\tau_i}\exp(-t/\tau_{Yb})\right] \qquad [10]$$

In particular, if we have $\tau_i \ll \tau_{Yb}$ in the terms in the first sum in Eq. [10], we can neglect the very small terms proportional to τ_i/τ_{Yb} in the first bracket. We can then express Eq. [10] as the ratio of the Yb^{3+} luminescence rate at t to the steady-state rate at $t = 0$

$$\frac{L_{Yb}(t)}{L_{Yb}(O)} = (1 - \Sigma_i'f_i)\exp(-t/\tau_{Yb}) + \Sigma_i' \frac{f_i}{1 - \frac{\tau_{Yb}}{\tau_i}}\left[\exp(-t/\tau_i) - \frac{\tau_{Yb}}{\tau_i}\exp(-t/\tau_{Yb})\right] \qquad [11]$$

Here we have defined

$$f_i = S_i(O)\omega_i/L_{Yb}(O) \qquad [12]$$

for those components for which $\tau_i > \tau_{Yb}$, so that f_i is the relative fraction of steady-state Yb^{3+} luminescence rate due to each such component. Only the components for which $\tau_i > \tau_{Yb}$ are to be included in the primed sums in Eq. [11]. We see, therefore, from Eq. [11] that under the stated conditions the Yb^{3+} luminescence may be decomposed into one component decaying with the Yb^{3+} radiative lifetime, plus a sum of other components having the same decay times as the components of the Mn^{2+} fluorescence. Each of these

latter components in Eq. [11] is accompanied by a small correction tending to reduce the contribution of this component but decaying with a lifetime τ_{Yb}.

Finally, the initial slope of Eq. [11] defines an apparent initial luminescence lifetime $\tau(O)$ given by

$$\tau(O)^{-1} = -\frac{d}{dt}\left[\frac{L_{Yb}(t)}{L_{Yb}(O)}\right] = (1 - \Sigma'_i f_i)\ \tau_{Yb}^{-1} \quad [13]$$

This is the apparent lifetime which we obtain from the initial slope of the luminescence curve if we are unable to resolve the change in slope that occurs at time $t \lesssim \tau_i$ for those components with $\tau_i << \tau_{Yb}$ and which corresponds to those terms proportional to (τ_i/τ_{Yb}) which we dropped in going from Eq. [10] to Eq. [11]. We see that $\tau(O)$ has no fundamental significance in terms of the decay times of the various components contributing to the Yb^{3+} luminescence, but that together with τ_{Yb}^{-1} it provides a means of determining the fraction $(1 - \Sigma'_i f_i)$ of the Yb^{3+} luminescence that results from a very fast transfer of excitation ($\tau_i << \tau_{Yb}$) from the Mn^{2+}.

In attempting to interpret our data for the Yb^{3+} luminescence decay on the basis of the theoretical model thus developed, we note first that all of our data curves appear to have a nonzero initial slope and that in every case the slope on a logarithmic plot diminishes with increasing time. Thus, in no case does the Yb^{3+} decay curve show the vanishing initial slope or the region of increasing slope at small t expected on the basis of Eq. [9]. If our model is applicable, therefore, these data suggest the existence of a sizable component having a very fast transfer of excitation from the Mn^{2+} (*i.e.*, ω_i large so that $\tau_i << \tau_{Yb}$), as described by Eq. [11] and [13].

To attempt a quantitative analysis of these data on the basis of Eq. [11]-[13], we have first picked out those samples in which the decay time τ_{Yb} is approximately the same for most of the Yb^{3+} ions, as we assumed in the analysis. From our data on the decay of Yb^{3+} fluorescence following infrared excitation, this requirement eliminates samples with Yb concentration both above and below the range of 1-5%. We have also avoided samples with too high a Mn^{2+} concentration, which show evidence that the luminescence efficiency is reduced by concentration quenching, perhaps by migration of the excitation to traps by diffusion among the Mn^{2+} ions. The most suitable set of samples consists of those from the CaF_2:x%Mn:5%Yb series, with $x < 10$, for which the decay curves for Yb^{3+} fluorescence following infrared excitation follow very nearly a simple exponential for the first decade. We have obtained the value for τ_{Yb} for a sample from the initial slope of this curve.

Next, we have attempted to fit the curve of Yb^{3+} luminescence following Mn^{2+} excitation to an expression of the form of Eq. [11]. Taking the decay time equal to τ_{Yb} in one of these terms, we then matched the initial slope as in Eq. [13] and chose f_i and τ_i in the remaining terms to fit the curve over a range covering somewhat more than the first two decades of the decay. Two additional terms involving the decay times τ_1 and τ_2 served to give a reasonably good fit over this range, both at room temperature and 77°K. At room temperature the longer decay time τ_2 was found always to lie in the range 70-80 msec, with the corresponding amplitude factor f_2 in the range 0.04-0.07. This value for τ_2 is only a little shorter than the decay time $\tau_{Mn} = 85$ msec for the Mn^{2+} fluorescence obtained from the initial slope of the decay curve in a sample containing 1% Mn^{2+} and no Yb^{3+}. This component of the Yb^{3+} luminescence is thus consistent with excitation transferred from excited Mn^{2+} ions that are not too close to an Yb^{3+} ion and thus have a relatively small probability of transferring the excitation to the Yb^{3+}. The shorter decay time τ_1 was found in the various samples to lie in the range 15-17 msec, with f_1 in the range 0.55-0.65. This component is evidently due to those Mn^{2+} that lie sufficiently near one or more Yb^{3+} to have a probability about five times greater of transferring excitation to the Yb^{3+} than of decaying by a direct radiative process. Finally, the component that decays with the Yb^{3+} radiative decay time τ_{Yb} ($\cong$ 3.0 msec at 300°K) has an amplitude factor $(1 - f_1 - f_2)$ in the range 0.3-0.4 and evidently is to be associated with certain Mn^{2+} ions that have a very fast excitation transfer to Yb^{3+} and for which the resulting decay time τ_i is very much shorter than τ_{Yb}.

The analysis of the decay curves taken at 77°K presents a very similar picture. The longer decay time τ_2 remains in the range 70-80 msec, even though τ_{Mn} is found to lengthen somewhat to 155 msec, but f_2 increases to ~0.15. This change is consistent with Eq. [3] and [12] if the product $\omega_2\tau_{Mn}$ increases from a value ~0.1 at 300°K to ~1 at 77°K, an increase also consistent with the observed decay times and Eq. [6] if ω_2 is larger at the lower temperature by a factor ~5. The shorter decay time τ_1 is found to be ~19-21 msec, a bit longer than at 300°K, with f_1 reduced somewhat to 0.4-0.5. The component decaying with τ_{Yb} (~2.4 msec at 77°K) has about the same relative amplitude as at 300°K: $(1 - f_1 - f_2)$ ~0.35-0.45.

A conclusion indicated by this analysis is that the mechanism responsible for the energy transfer from Mn^{2+} to Yb^{3+} is equally effective at 77°K as at room temperature and that the transfer rates ω_1 and ω_2 corresponding to the components with τ_1 and τ_2 are either approximately independent of temperature over this range or possibly even somewhat higher at the lower temperature. This conclusion appears to rule out the possibility that coupling to the phonon spectrum of the crystal makes energy conservation possible in the energy transfer step if the transfer is from a Mn^{2+} ion to a single Yb^{3+} ion, since to take up 0.3 eV or more of energy by emitting a burst of phonons would necessarily make the transfer rate strongly temperature dependent and very much lower at 77°K than at 300°K.

The analysis we have given indicates that there should be components in the Mn^{2+} luminescence decay given by Eq. [7] which have the same values of τ_i as the components found in the Yb^{3+} luminescence. However, because of the weighting factor ω_i in Eq. [12] the relative importance of the various components is very different in the two emissions. Clearly components having a much greater probability that the Mn^{2+} will transfer to Yb^{3+} than that it will radiate directly ($\omega_i >> \tau_{Mn}^{-1}$ and, therefore, $\tau_i << \tau_{Mn}$) will be relatively far more prominent in the Yb^{3+} emission than in the Mn^{2+} emission. We have made a quantitative analysis, on the basis of Eq. [7] and [11], of the contribution to the Mn decay curves to be expected from the components of the Yb^{3+} luminescence associated with decay times $\tau_i << \tau_{Mn}$, and we conclude that this contribution is too small to be distinguished in the experimental curves.

The near independence of temperature for the energy transfer mechanism indicated by our analysis, combined with our earlier conclusion from the efficiency of the transfer process as a function of Yb^{3+} concentration that transfer occurs from a Mn^{2+} ion to a single Yb^{3+} ion, suggests that the transfer of energy involves direct ion-to-ion transfer, in which the emission spectrum of one overlaps the absorption spectrum of the other. We have already noted that the emission spectrum of Mn^{2+} shifts to longer wavelength in samples containing increasing amounts of Yb^{3+}. In particular, there is a small tail of the Mn^{2+} band that extends to 820 nm, almost to the edge of the Yb^{3+} absorption. We suggest that when a Mn^{2+} ion is very close to an Yb^{3+} ion, the $^4T_{1g}$ state of Mn^{2+} is split by the field of the Yb^{3+}, and that emission from the lowest level of this state overlaps the Yb^{3+} absorption, making trans-

fer possible with energy conservation. If the transfer rate is a strong function of the separation of the ions, as one then expects, the Mn^{2+} will fall predominantly into two classes. On one hand, a Mn^{2+} ion has no Yb^{3+} ion sufficiently close for an appreciable probability of transfer, in which case the Mn^{2+} decays radiatively with a lifetime and spectrum little changed from that of an isolated Mn^{2+}; or, a Mn^{2+} is close enough to an Yb^{3+} to have a strongly distorted spectrum but also a transfer probability appreciably greater than the probability for radiative decay. Mn^{2+} ions of the latter type will thus excite the Yb^{3+} luminescence most of the time and will contribute only a very weak component to the Mn^{2+} luminescence. Just as the contribution of the short-lived components of the luminescence was found to be unobservable against the body of the Mn^{2+} luminescence, so the intensity of the strongly perturbed emission spectrum due to these ions is very weak compared with the spectrum of the less strongly perturbed Mn^{2+} ions that do not transfer. In support of this suggestion is the observed dependence of the Mn^{2+} emission spectrum on Yb^{3+} concentration in the series CaF_2:5%Mn:xYb:(20 − x)%Y. The Mn^{2+} emission in the sample with $x = 0$ has a $\bar{\lambda}$ of 560 nm and a long wavelength tail that extends to 860 nm which does overlap with the absorption band of Yb^{3+} in CaF_2. The shift of $\bar{\lambda}$ and the extent of the tail to shorter wavelengths as the Yb^{3+} concentration is increased is consistent with the idea that the longer wavelength Mn^{2+} emission present in the CaF_2:5% Mn:20%Y spectrum does not appear in samples containing Yb^{3+} because of the efficient transfer of this energy from Mn^{2+} ions to Yb^{3+} ions. The key to our interpretation of the system is, therefore, its inhomogeneity; transfer probabilities and spectral shapes depend strongly on the Mn^{2+}-Yb^{3+} separation, so that most pairs that contribute to the Yb^{3+} luminescence contribute negligibly to the Mn^{2+} luminescence, and vice versa.

We have also considered the possibility that an excited Mn^{2+} ion decays by exciting a single Yb^{3+} ion and radiating the energy difference. A similar process has been observed (12) in the decay of the ^2E_g level of Cr^{3+} in $EuAlO_3$. Such a process could provide an alternative quantum-splitting mechanism, the probability for which would be expected to be linear in the Yb^{3+} concentration in agreement with our data in Fig. 4. However, the resulting infrared emission spectrum should then contain not only the bands due to the Yb^{3+} luminescence but also an equally intense broad band representing the difference between the Mn^{2+} and Yb^{3+} excited states. The breadth in energy of this second band should be the same as that of the Mn^{2+} visible luminescence in Fig. 3. There is no evidence for such a broad band in our infrared data (Fig. 2), and we conclude that this alternative quantum-splitting mechanism also does not operate in the CaF_2:Mn^{2+}:Yb^{3+} system.

Summary

Energy transfer has been observed from Mn^{2+} to Yb^{3+} in CaF_2. However, the emission and decay data are consistent with a direct ion-to-ion transfer of energy and not with the Dexter mechanism or other mechanisms involving the deexcitation of the Mn^{2+} ion with the emission of two photons. We suggest that the direct transfer, which was unexpected on the basis of the known properties of CaF_2:Mn and CaF_2:Yb, is made possible by the splitting of the $^4T_{1g}$ state of Mn^{2+} by the field of a neighboring Yb^{3+}.

On the Use of Photomask Coatings in Photolithography

Dervin L. Flowers* and Henry G. Hughes*

Motorola, Semiconductor Research and Development Laboratory, Phoenix, Arizona 85008

ABSTRACT

Three coating solutions have been used to coat emulsion masks to determine whether any benefits might be realized. It was found that these coatings enable one to increase mask life and reduce the defect density. Capacitor yields and pinhole counts have been determined which show significant yield enhancement over noncoated emulsion masks. It has been further shown that an adequate soft bake cycle of photoresisted wafers to remove solvents prior to exposure is essential in obtaining maximum yield with or without coatings on the masks.

Device yield in the semiconductor industry is strongly dependent upon effective photoresist processing which minimizes photolithographic defects. Schnable *et al.* have published an excellent review of passivation coatings on silicon including such defects in passivation glass (1). Pinholes and cracks in passivation glass can lead to severe reliability problems. A more immediate effect is to lower device yield (2). Such defects in passivation glass can be due to a variety of causes. Some may be formed during glass deposition (3). Pressure contact of glass passivation over aluminum can cause cracks (4). Etching of passivation glass to open bonding pads may produce pinholes due to holes in the photoresist layer (1). In multilayer IC manufacture, etching of vias can produce pinholes due to holes in the photoresist. These can fill with metal on the next evaporation and cause interlayer shorts (5).

One factor in this operation which has gained little attention in the literature concerns resist-mask interactions (6). It is well known that yield is strongly affected by wafer-to-mask contact problems arising from dust particulates, epi spikes, and resist-mask sticking. These lead to mask damage, transfer of photoresist polymer onto the mask, and the transfer of this residual back to subsequent wafers during alignment. With multiple mask use, pieces of photoresist adhering to the mask from previous alignments will "print" causing latent defects in the resist which on subsequent wafers develop out allowing more unwanted etching and pinholes to form. Thus, each piece of photoresist torn from a wafer causes two or more yield limiting pinholes which can lead to electrical shorts and poor definition. The introduction of some mask lubricating agent or protect coat to reduce photoresist to mask adhesion is thus highly desirable.

The use of hard surface masks and proper photoresist processing are well documented but little is found regarding ways to improve emulsion mask usage. Emulsion mask protect coatings to increase hardness, decrease friction, reduce resist-mask sticking, and, in general, increase emulsion mask life with low defect levels seem to offer great promise.

Three such coatings [Parylene N (7), polyvinyl alcohol (8), and spin-on glass (9)] have been investigated in this laboratory. Results indicate that these three coatings do increase mask life and reduce defect densities *vs.* uncoated masks.

Baseline criteria were performed to determine the effect of soft bake cycles, mechanical contact, and exposure on pinhole generation.

The experimental work reported herein has been collected using a negative polyisoprene-base photoresist but one example of a protect mask coating used in conjunction with a positive resist is outlined. The combined use of a lubricating resist protect coat (5) and a coated mask is also mentioned. Capacitor yields and pinhole counts were used for evaluation comparisons.

Key words: mask coating, pinhole density, capacitor yield, photoresist

Experimental

The experimental procedures investigated included establishing a baseline criteria for photoresist processing for comparison data and optimization. These included resist soft bake, resolution, and mechanical contact wafer-mask damage.

Photoresist processes.—The photoresists were processed as follows unless stated differently elsewhere.

Negative photoresist was applied by spinning to give a thickness of 1050 nm, and soft baked for 20 min at 70°C (N_2) or 30 min at 80°C. The latter was used for all experiments except for establishing a baseline bake. A 12 sec exposure (2500 $\mu W/cm^2$ intensity) was used with a standard aligner, contact pressure 5-6 psig. Spray develop was 20 sec xylene plus 20 sec n-butyl-acetate rinse. Hard bake was 30 min at 180°C (N_2).

One experiment using positive photoresist (2200 nm) was performed. Processing was air dry for 15 min, soft bake 70°-80°C for 20 min, expose for 20 sec, develop 1:1 developer/water, water rinse, and hard bake 180°C for 30 min.

Pinhole determination and soft bake.—Two pairs of 2.3 × 2.3 mm chip wafers, patterned first with aluminum (32% of chip area), were passivated with 1000 nm of standard phosphorus-doped CVD glass. After a 1 hr dehydration bake the wafers were coated with negative photoresist. The resisted wafers were baked for 20 min in nitrogen ambient at either 70° or 80°C. The wafers were then exposed with a blank mask in contact mode. After normal development and rinse the resist was baked at 180°C for 30 min.

The wafers were then etched for 4.5 min (50% overetched) in 1:1 ammonium fluoride/acetic acid at room temperature. This etch serves to open latent pinholes in the passivation layer due to missing resist pulled from the wafer in contacting the mask. Pinholes in the "as applied" photoresist were negligible (< 1%). The wafers were next stripped of resist and etched with a standard aluminum etch for 2 min at 65°C to open a circular area in the underlying aluminum for easier defect counting as a result of pinholes in the passivating glass. Twenty eight dies per wafer were counted.

Pinhole density due to contact and exposure.—The effect of pinholes resulting from contact of passivation only and exposure *vs.* no exposure after contact was next investigated. Following the procedure for pinhole determination outlined earlier and using an 80°C-30 min bake the wafers were processed four different ways: (*i*) aluminum etched after CVD to determine initial pinhole density; (*ii*) aluminum etched after two mask contacts, no exposure, and resist stripped to determine mechanically formed pinholes; (*iii*) passivation etch, then aluminum etched after two mask contacts, no exposure, to determine effect of exposure; and (*iv*) same as item (*iii*), with standard exposure

and develop before etchings. Pinholes in 28 dies per wafer were counted for each step. Die size was 3.0 × 3.4 mm.

Emulsion mask coatings.—Three emulsion mask coatings were investigated. These were Parylene, spin-on glass, and polyvinyl alcohol. Not all experiments were run with all three mask coatings because of limited man-hours and large sample sizes that would be involved.

Parylene was vapor phase deposited (20 nm) by Nova Tran Corporation, Clearlake, Wisconsin.

Spin-on glass (200 nm) was applied with an eyedropper, spun at 3000 rpm for 20 sec, then baked at 130°C for 30 min in an oven.

A solution of 3% w/v polyvinyl alcohol (medium molecular weight) in water was prepared and masks were dip coated and baked 20 min at 80°C (250 nm).

Pinhole count of coated and uncoated masks.—The effects of uncoated and coated masks in relationship to pinhole density were determined by using standard negative photoresist and pinhole detection as outlined earlier. Parylene, spin-on glass, and uncoated masks were evaluated. Three wafer samples with 28 (3.0 × 3.4 mm) die/wafer were counted at 50X magnification.

Mask coatings and "acceptable" definition.—A procedure often used that relates to mask life is to align that number of wafers that will still give acceptable pattern definition by some arbitrary criteria that relates to device yield. To determine what effect mask coatings may have in longer photomask use, an experiment was designed to determine how many wafers could be exposed with one mask (a memory device with 0.005 mm emitter openings) before definition problems became too severe. Chip size here was 2.3 × 2.3 mm. Fail criteria was defined as being when two or more fields inspected out of nine had incomplete emitter openings (not etchable due to undesired polymerization) to allow a functioning device. A Parylene-coated mask was chosen for this study. To increase test severity, 23 psig contact pressure was used.

Mask coatings and capacitor yields.—Capacitor yields were investigated to more nearly relate to device yield. An increase in capacitor yield was expected using coated masks based on a decrease observed earlier in pinhole counts.

Patterned first metal, 3.0 × 3.4 mm chips were passivated with 1000 nm phosphosilicate glass, photoresisted, then overetched by 1.5 min using 1:1 ammonium fluoride/acetic acid at room temperature. The wafers were stripped of photoresist and metallized with second layer 1000 nm aluminum. The top metal was expected to fill in pinholes thereby contacting the underlying aluminum. Wafers were again photoresisted for delineating each chip as a capacitor.

Capacitor measurements were taken using a Motorola IC automatic probe interfaced with a CDC 8090 computer. Readings were taken at 30V. Where there were no device failures, the leakage was less than 10 μA. If a reading of > 10 μA was measured, a device failing pinhole, filled with aluminum and contacting first metal, was assumed. Usually the "fail" readings were in excess of 100 μA so little ambiguity existed.

Five capacitor experimental conditions were run; (*i*) 3 control (noncoated masks) sets, negative photoresist; (*ii*) 2 spin-on glass coated mask sets, negative photoresist; (*iii*) 1 polyvinyl alcohol coated mask set, negative photoresist; (*iv*) 2 Parylene coated mask sets, negative photoresist, and one of the photoresists sets had an experimental lubricating resist protect coat (5), 15 nm thick on the wafer; and (*v*) 1 Parylene coated mask set positive photoresist. The experiments were run each with a control (uncoated mask). The full number of wafers noted in the data were processed but only every second or third was probed to save time yet present the most meaningful spread of data possible. One hundred dies per wafer were probed.

Results and Discussion

Initial baseline criteria, which show the importance of using proper bakes and the effect exposure and mechanical damage have in device fabrication, are outlined in the first section. The influences of mask coatings on reducing pinholes, influencing resolution, and increasing capacitor yields are discussed in the last part of this section.

Photoresist processes.—It was determined that a 20 min 70°C soft bake resulted in an average of 0.80 pinhole/die *vs.* 0.43 pinhole/die using a 30 min 80°C bake (Table IA). The latter temperature has become more of a standard practice recently and should be used for increased yields.

Mechanical damage plays a significant role in pinhole formation and becomes more pronounced as multilayers are built up (Table IB).

First, the loss due to mechanical contact with the mask of the passivation layer increased elevenfold in pinholes over that of the base glass. This serves to point out the necessity for smooth and uniform passivation and metallization. Part of the mechanical loss was probably due to contacting glass over metal edges where large stresses are exerted (though contact pressure was only 5-6 psig).

Second, the passivation layer was etched prior to aluminum etching to determine the latent pinholes formed in the resist when not exposed. A sevenfold average pinhole increase, presumably due to cracking or pulling out of photoresist on mask contact, was recorded. This result was higher than expected but consistent with Scotch tape tests of negative resist on wafers. Before exposure and cross-linking (insolubilization) of negative photoresist, film strength (adhesion and cohesion) is very weak and the resist is readily ripped and pulled from wafers in such a test. Once exposed, however, Scotch tape is pulled with some difficulty from the resist with only a few small pieces adhering to the tape. These observations indicate the need to use an absolute minimum number of contacts between mask and resist during alignment before exposure in order to significantly reduce resist damage and yield loss.

Third, the addition of standard exposure and processes resulted in a decrease of pinholes from 7.7 to 2.7 per chip.

From these experiments it is concluded that 1.1 pinholes/die are due to mechanically induced damage and 1.6 pinholes/die induced due to photoresist-mask sticking and the tearing out of tiny pieces of photoresist from the passivation layer.

Having established baseline data relating to pinhole formation in photolithographic processes, photomask coatings were next investigated.

Pinhole density from uncoated and coated masks.—Comparisons of uncoated, Parylene, and spin-on glass

Table I. Effect of process parameters on pinhole density in die

Set	Process	Average pinhole/die
A.	Soft bake cycle (chip size 2.3 × 2.3 mm)	
1.	20 min, 70°C, N_2	0.80
2.	30 min, 80°C, N_2	0.43
B.	Mechanical contributions (chip size 3.0 × 3.4 mm)*	
1.	Base glass on metal pattern	0.10
2.	Aluminum etch after 2 contacts, no exposure	1.10
3.	Passivation etch then aluminum etch after 2 contacts, no exposure	7.70
4.	Repeat 3 with exposure and develop (standard process)	2.70
C.	Noncoated *vs.* coated emulsion mask	
1.	Uncoated mask	1.63
2.	20 nm Parylene	0.93
3.	200 nm spin-on glass	1.09

* Chip sizes varied because of wafer availability. All following data from this chip size.

Table II. Photomask life with and without Parylene lubricating coat

Photomask	No. wafers in set	Pass	Fail
Uncoated emulsion	10	5	5
Parylene-coated emulsion	26	25	1

coated masks (Table IC) have shown as much as 42 and 33%, respectively, pinhole reduction.

If one considers that photomasks have polar groups at the surface (amide and carbonyl for gelatin, hydroxyl for chrome and iron oxide) and olefinic groups both *exo* and *endo* in the resist chain, pressure contact, particularly at asperities and metal edges, exerts sufficient force for the polar groups and olefinic groups to react and form chemisorbed bonds between mask and resisted wafers. These bonds are apparently strong enough to pull out tiny pieces of resist, leaving them deposited on the mask when separation occurs. Both Parylene and spin-on glass should have low energy surfaces lacking polar groups to form these chemisorbed bonds, hence, less sticking and damage are expected. Although this work was done with emulsion masks, similar benefits are expected with hard surface masks.

Mask coating and "acceptable" definition.—It was established that a Parylene-coated mask could be used five times as long as an uncoated mask and still give acceptable definition (0.005 mm emitter openings; Table II.) The uncoated emulsion mask gave acceptable definition on the first five wafers but the last five failed by the criteria used. In the Parylene-coated mask, 25 out of 26 wafers passed. The failed wafer was number 15 of the set and may have had epi spikes or dirt holding it out of even contact. The uncoated masks on inspection showed an increasing number of specks of photoresist with increased use. The Parylene-coated plates also had a buildup but the particles were fewer in number and smaller in size.

Mask coatings and capacitor yields.—Mask coatings were found to give significantly higher capacitor yields over uncoated control masks (Fig. 1-4).

From the data of Fig. 1 through 3, the reproducibility of the tests may be gauged by comparing the average yields for the first nine wafers (18 contacts) processed as the control group (uncoated mask) for each set. The averages for the three control sets are:

set 1, 1st 9 wafers (2 contacts/exposure) 39 ± 5% yield; set 2, 1st 9 wafers (2 contacts/exposure) 33 ± 2% yield; and set 3, 1st 7 wafers (3 contacts/exposure) 33 ± 7% yield. Considering that the sets contained different samples of epi wafers and different diffusion and passivation runs, the agreement is quite good.

A decrease in capacitor yield with continued uncoated mask usage is what is usually observed with a severe yield break occurring around 20-30 contacts. The lowest yield for the first wafer exposed relative to

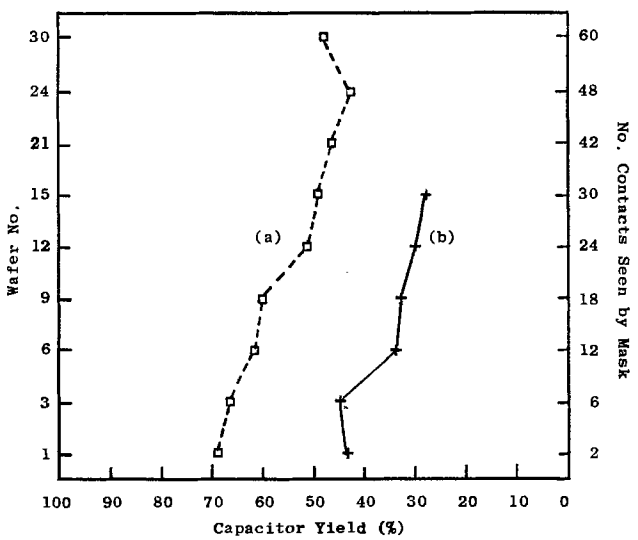

Fig. 1. Percent capacitor yield using negative photoresist. (a) Spin-on glass mask coat. (b) Uncoated mask.

later wafers as seen in Fig. 3e, has been seen many times before. There may be some unadhered dirt or bumps not blown off the mask prior to first contact causing cracks in the photoresist and transferred additionally to the first exposed wafer.

The use of spin-on glass and polyvinyl alcohol protect coats promotes significant capacitor yield increases over uncoated masks. A summary of average percent capacitor yields for these two coatings is shown in Table III. Set 1 wafers were processed with spin-on glass coated masks, and set 2 wafers were processed with spin-on glass or polyvinyl alcohol coated masks.

Here it is seen that capacitor yields, for a given number of contacts, are increased by factors of 1.6-2.1 (60-107%) by use of mask coatings. In fact, the final yield, even after 30 exposures (60 contacts) using spin-on glass is considerably higher than the initial yield of uncoated mask. Both spin-on glass and polyvinyl alcohol gave considerable yield improvements but the glass tends to provide a harder film.

Parylene-coated masks also show a substantial yield improvement over noncoated masks (Fig. 3c, e) with additional benefits realized by the added application of the resist protect coat (Fig. 3d.) The average capacitor yields, normalized to three contacts per mask for the uncoated sets, are outlined in Table IV and Fig. 3c. A large yield breakdown occurred after the 7th wafer processed. This may be a result of the ultrathin Parylene coating (20 nm) wearing off. This reduction in wear may be reduced with the application of the resist protect coat (as no yield break occurred with higher yields to 34 wafers) or by application of a thicker Parylene coating.

The effect of using coated masks when working with positive photoresists was next demonstrated. Parylene-coated masks were used in this study. The results of these tests using three contacts per mask are shown in Fig. 4. Average capacitance yields comparing positive resist and negative resist processing are summarized in Table V.

This data, although showing some improvement in yield on positive resist (excluding wafer 1) with use of a Parylene-coated mask, is not as substantial as that noted with negative photoresist. It was also observed that mask to positive resist sticking was not as great as indirectly indicated by capacitor yield (49% base yield with positive and 29% with negative per 12 wafers.) The Parylene-coated mask maintained its high intermediate yield level through 34 wafers with positive resist which is noteworthy in simply comparing the two photoresists. It should be kept in mind, however, that positive resist was substantially thicker than the negative. The resist protect coat used in conjunction with Parylene-coated masks proved to be the best performer of all investigated and bears further investigation.

Table III. Average capacitor yields (%) at various levels of mask use

Summary

It has been shown that mask coatings can have a significant impact on device yield and prolonging mask life by reducing pinholes and by improving resolution in reducing the amount of resist buildup on the mask substrate. The most significant increases were observed when negative resist was used. The over-all yields were found to be further enhanced by use of lubricating resist coat formulations. Furthermore, it has been demonstrated that sufficient bake temperature and time are necessary to minimize resist mask sticking, thus reducing pinhole formation prior to exposure.

It is recognized that not all pinholes and capacitors measured in these tests are device yield limiting. Certainly a high percentage are, however. Mask coatings used on emulsion masks should result, therefore, in significant yield improvements, particularly in multilevel LSI devices. Additionally, considerable mask cost savings are implied.

Characterization of n-Type Semiconducting Indium Phosphide Photoelectrodes

Stabilization to Photoanodic Dissolution in Aqueous Solutions of Telluride and Ditelluride Ions

Arthur B. Ellis, Jeffrey M. Bolts, and Mark S. Wrighton*

Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

n-type semiconducting single crystal InP (bandgap, E_{BG}, = 1.25 eV) has been studied as a photoanode in aqueous electrolytes. Irradiation of the InP with light of energy greater than or equal to the value of E_{BG} results in the flow of anodic current. In 1.0*M* NaOH solutions, the onset of photocurrent is at about −1.1V *vs.* SCE, and the current is accompanied by anodic dissolution of the electrode. The behavior of the reductants X^{2-} (X = S, Se, Te) was investigated, and only Te^{2-} was found to be oxidized completely efficiently at the irradiated InP. For S^{2-} we could see no oxidation to elemental S, but oxidation of Se^{2-} was found to be partially competitive with photoanodic dissolution of the electrode. The band positions of InP have been determined in all electrolytes by measuring the photopotential, or from differential capacitance measurements. The band positions are dependent on the electrolyte *p*H and on the presence of X^{2-}. For the Te^{2-} electrolyte, the oxidation product, Te_2^{2-}, is reducible at the Pt counterelectrode, ultimately resulting in an electrolyte with a constant composition. The maximum voltage output in the Te^{2-}/Te_2^{2-} electrolyte is ~0.4V at high light intensity, and the short-circuit quantum efficiency for electron flow is ~0.2 at low light intensity. The energy conversion efficiency for conversion of 632.8 nm light to electricity is of the order of one percent.

We (1-5) and others (6, 7) have recently shown that n-type semiconductors such as CdX (X = S, Se, Te), GaAs, GaP, and Bi_2S_3 can be stabilized to photoanodic dissolution by using electrolytes which contain electroactive X^{2-} (X = S, Se, Te) ions. The notion of using competitive electron transfer from reductants in the electrolyte to stabilize n-type semiconductors now seems to be a viable approach to the development of photoelectrochemical cells for the conversion of light to electricity. But we do not presently have a detailed understanding of why competitive electron transfer works in some cases and not in others. For example, the oxidation of X^{2-} should be energetically feasible at all of the following electrodes: CdX (X = S, Se, Te), GaAs, and GaP. However, the oxidation of the X^{2-} only occurs completely efficiently in a limited number of situations (1-5).

In this paper we wish to describe the characterization of n-type InP-based photoelectrochemical cells employing electrolytes containing X^{2-} species. Again, energetics are found to be a poor indicator of whether efficient oxidation of X^{2-} occurs. Stabilization of InP is significant in part because of its low bandgap, E_{BG}, of 1.25 eV (8) and high absorptivity. However, the band positions relative to the redox potential in the stabilizing Te^{2-}/Te_2^{2-} electrolyte preclude efficient optical to electrical energy conversions.

Results and Discussion

Stability.—When n-type, single crystal InP is irradiated as the photoanode *vs.* a dark Pt cathode in an electrolyte of 1*M* NaOH, anodic decomposition of InP results. The black, originally mirror-like surface becomes rough and gray, and weight loss in the crystal is evident. We find that between 6 and 8 moles of electrons are required to decompose 1 mole of InP, consistent with Eq. [1] and/or [2].

$$InP \xrightarrow{h\nu} In^{+3} + P^{+3} + 6e^- \qquad [1]$$

$$InP \xrightarrow{h\nu} In^{+3} + P^{+5} + 8e^- \qquad [2]$$

Photoanodic decomposition according to Eq. [1] has been demonstrated for other III-V semiconductors like GaP and GaAs (9, 10). Anodic photocurrents from the InP are observed at potentials more positive than about −1.1V *vs.* SCE. In an electrolyte of 1.0*M* NaOH/1.0*M* Na_2S or 1.0*M* NaOH/1.0*M* Na_2S/1.0*M* S at 25° we find that the photoanodic dissolution of InP still occurs, despite the fact that the onset of photoanodic current may be ~0.1V more negative. Thus, the oxidation of S^{2-} to elemental S apparently does not compete with the electrode dissolution. Likewise, we find that Se^{2-} is inefficiently oxidized at an irradiated InP. An electrolyte of 5.0*M* KOH containing up to 0.5*M* Na_2Se at 60° does yield some competitive Se^{2-} oxidation as evidenced by the appearance of the colored Se_2^{2-} (λ_{max} = 425 nm, $\epsilon \approx$ 1000 liter mole^{-1} cm^{-1}) (4). But the oxidation is relatively inefficient and the InP is rapidly corroded.

In marked contrast, we find that electrolytes containing 5.0*M* NaOH and 0.1*M* Na_2Te at 50° do stabilize InP. Oxidation of Te^{2-} is initially obvious by the appearance of a purple color near the photoelectrode associated with the oxidation product Te_2^{2-} (λ_{max} = 512 nm, $\epsilon \approx$ 1000 liter mole^{-1} cm^{-1}) (3). Prolonged stability of InP is established by constant photocurrents and constant composition electrodes, Table I. We have previously established that the Te_2^{2-} is reducible to Te^{2-} in photoelectrochemical cells at the Pt counterelectrode (3, 4). Thus, for the InP-based cell with the Te^{2-}/Te_2^{2-} electrolyte, Eq. [3] and [4] represent the cell chemistry

$$2Te^{2-} \rightarrow Te_2^{2-} + 2e^-$$

and/or

$$Te_2^{2-} + 2Te^{2-} \rightarrow 2Te_2^{2-} + 2e^- \quad \text{(anode)} \qquad [3]$$

$$Te_2^{2-} + 2e^- \rightarrow 2Te^{2-} \quad \text{(cathode)} \qquad [4]$$

The current-voltage characteristics are described in detail below.

* Electrochemical Society Active Member.

Key words: photoelectrochemistry, indium phosphide, optical energy conversion, photoanodic dissolution.

Table I. Stabilization of n-type InP photoelectrodes in telluride electrolyte[a]

Crystal[b]	Moles × 10^4 Crystal before	Crystal after[c]	Electrons[d]	Average i, mA[e]	V appl[f]	t, hr	Light source[g]
InP-A	1.67	1.66	3.19	0.21	+0.02	41.5	633 nm
InP-A	1.72	1.71	4.06	0.71	+0.10	15.3	tungsten
InP-B	2.53	2.53	15.90	0.97	+0.04	44.0	Hg

[a] Electrolyte is initially 5.0*M* NaOH/0.1*M* Na_2Te at ~50°C, and is stirred under Ar. The only oxidation product is Te_2^{2-}.
[b] All InP samples are n-type single crystals ~5 × 5 × 0.35 mm with the (100) face exposed to the electrolyte. The resistivities of InP-A and InP-B are 0.005-0.016 and 0.4 Ω-cm, respectively.
[c] Moles of crystal before and after the experiment as determined by weighing the crystal.
[d] Moles of electrons in the external circuit determined by integrating a plot of photocurrent *vs.* time.
[e] For current density, multiply by 4 cm^{-2}. Photocurrent was constant to ±5% during course of the experiment.
[f] Applied bias from an external power supply in series with the photoanode and Pt-cathode. A positive bias means that the (+) lead from the power supply is connected to the photoanode.
[g] The 633 nm source is a 6x beam-expanded He-Ne laser supplying ~3 mW of uniform irradiation to the photoanode. Tungsten source is the full output of a 650W tungsten-halogen lamp. The Hg source is the full output of a 200W superhigh pressure Hg arc lamp; output from both of these sources is filtered in the near infrared and u.v. by 18 cm of H_2O and a Corning CS 3-73 filter, respectively.

The InP is even stabilized at very high input power with the Te^{2-}-containing electrolyte. For example, 500 mW/cm^2 of 632.8 nm light from a 1 mm He-Ne laser beam leads only to Te^{2-} oxidation. However, at this power density elemental Te forms a coating on the photoelectrode, and is observable as a gray spot on the InP which is "washed away" by reaction with Te^{2-} to form the Te_2^{2-}. The formation of elemental Te was noted previously (4), and is a contributor to inefficiency in that the Te film (at the very least) absorbs the incident irradiation. Thus, at high intensity steady-state irradiation a Te film serves to reduce quantum efficiency. Competing with its formation, the film of Te is removed to give the final oxidation product, Te_2^{2-}.

It is important to note that no truly long-term stability experiments have been performed. Moreover, no tests have been carried out in sunlight, since the low output parameters (*vide infra*) with monochromatic 632.8 nm light are not sufficiently encouraging to merit such a study. What we can say is limited by the actual data given in Table I; the n-type InP photoelectrode is completely stable on the time scale of ~40 hr at current densities of ~4 mA/cm^2. However, the lack of weight loss and the constancy of output parameters for the entire duration suggest that InP will be stable much longer than 40 hr. Concerning experiments at >500 mW/cm^2 632.8 nm excitation, we find constant outputs and no obvious surface damage for ~3 hr periods where the short-circuit current density exceeds 10 mA/cm^2. The main point from our results is that InP is obviously unstable in the S_n^{2-} or Se_n^{2-} electrolyte, but in the Te^{2-}/Te_2^{2-} the stabilization to photoanodic dissolution is considerable.

Wavelength response.—Figure 1 shows the wavelength response of the InP-based photoelectrochemical cell employing the Te^{2-}/Te_2^{2-} electrolyte. For comparison, the absorption edge of InP is shown in the figure. The onset of photocurrent and absorption corresponds to the known (8) E_{BG} of 1.25 eV for InP. The sharp rise in absorption and photocurrent is characteristic of direct bandgap semiconductor photoelectrodes.

Current-voltage properties and energy conversion efficiency.—The current-voltage properties of InP in the Te^{2-}/Te_2^{2-} electrolyte are shown in Fig. 2. The

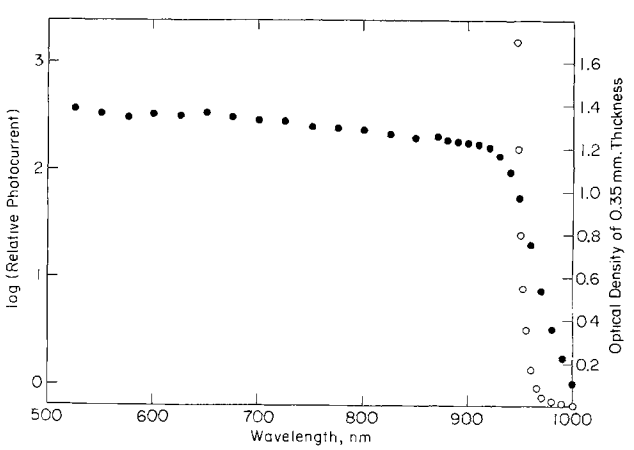

Fig. 1. Absorption and wavelength response curves for an n-type InP single crystal. Open circles represent the absorption of an optically polished 0.35 mm thick InP crystal. Filled circles represent photocurrent obtained when InP is the photoanode in an optically clear 0.1*M* Te^{2-} (50°C) electrolyte after correction for variation in light intensity (*cf.* Experimental).

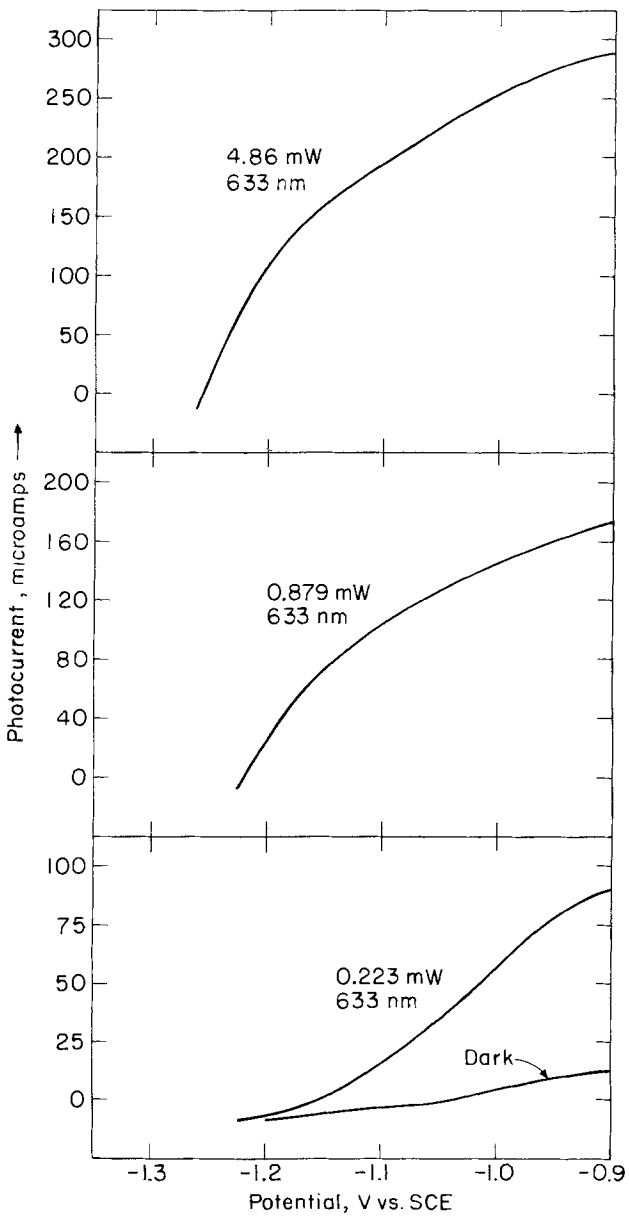

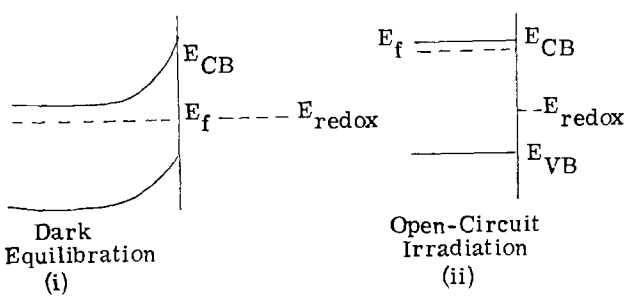

Fig. 2. Current-voltage curves as a function of light intensity for an n-type InP-based photoelectrochemical cell in 0.1*M* Te^{2-} at 50°C. The sweep rate was 1 mV/sec, and the Pt dark potential was always −1.10V *vs.* SCE. Irradiation was performed with a 1 mm He-Ne laser (632.8 nm) beam. To obtain intensity, multiply by 127 cm^{-2}.

dark anodic current is small, but finite, as is usual for n-type semiconductors, since no minority charge carriers, holes, are present. Irradiation to produce holes in the valence band does yield a significant anodic current, and the onset moves more negative with increasing light intensity. It is important that the onset of the anodic photocurrent is more negative than the potential for oxidizing Te^{2-}. The Te^{2-}/Te_2^{2-} potential is at ~ -1.10V *vs.* SCE (11), and the onset of photocurrent at very high light intensity is near -1.45V *vs.* SCE. The difference in the onset potential for photoanodic current and the Te^{2-}/Te_2^{2-} thermodynamic potential is the open-circuit photopotential. Photocurrent at potentials more negative than the Te^{2-}/Te_2^{2-} potential reflects conversion of light to electricity. The power output of the cell (current times voltage) can be determined from the current-voltage curves in Fig. 2. For each curve the maximum optical to electrical energy conversion efficiency is only of the order of one percent. The maximum efficiency occurs at a voltage output of between $\sim$0.05 and 0.20V. Increasing photopotential at the higher input optical power levels is offset by a decrease in the quantum efficiency for electron flow. In the three curves shown, the light intensities increase in the ratio 1.0:3.9:21.8, while the corresponding photocurrents at -0.9V vs. SCE increase by 1.0:2.1:3.5. From the discussion above, the saturation of the photocurrent may be due, in part, to the deposition of elemental Te on the InP. At the lowest light levels the quantum efficiency for electron flow approaches unity at a sufficiently positive bias, but there is poor energy conversion efficiency because of the low output potential. At high light intensity the output potential does become a significant fraction of the bandgap, but the quantum efficiency for electron flow is so low that the energy conversion efficiency remains poor.

Band positions of InP.—According to Gerischer's development (12), the maximum open-circuit photopotential in a n-type semiconductor-based photochemical cell is just the initial difference in the value of the redox potential of the couple in equilibrium, E_{redox}, and the conduction band position, E_{CB}, at the interface. Thus, measuring the band positions of the semiconductor exposed to the electrolyte can be useful in evaluating the theory, and in providing a measure of the ultimate energy conversion efficiency. The energetics of the semiconductor/electrolyte interface are sketched in Scheme I. For a heavily doped n-type semiconductor,

Scheme I

the Fermi level, E_f, is at nearly the same position as E_{CB} in the bulk. Irradiation at open circuit can raise the E_f, then, to a value nearly equal to the E_{CB} level at the interface. At this maximum level of E_f there is no band bending, and this maximum E_f is called the flatband potential, E_{FB}. For a given electrolyte, the E_{CB} and E_{VB} positions are taken to be fixed.

In a given electrolyte the open-circuit photopotential should allow evaluation of the positions of E_{VB} and E_{CB}. Open-circuit photopotentials of InP in 3 X^{2-}/X_n^{2-} electrolytes are shown in Fig. 3 as a function of incident optical power. Unfortunately, we were

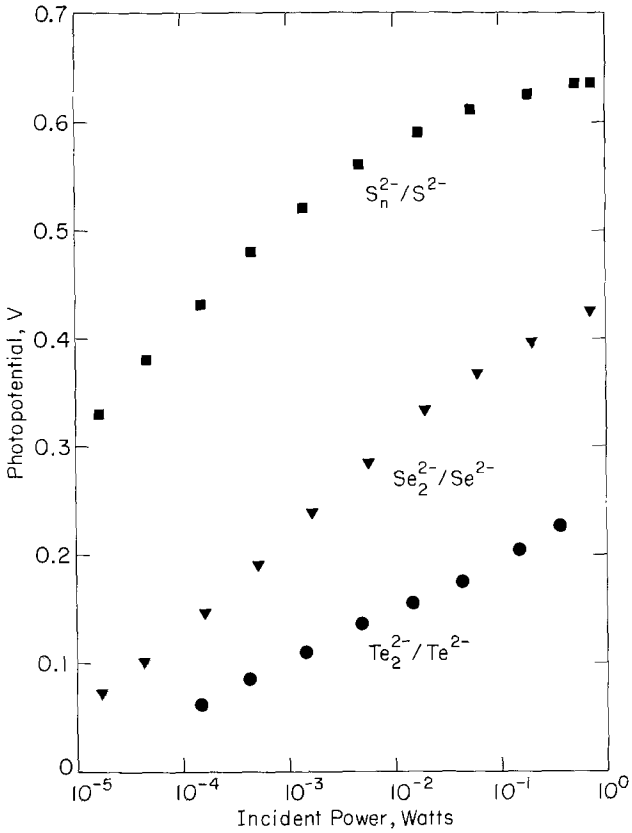

Fig. 3. Open-circuit photopotential between InP and Pt in S^{2-}/S_n^{2-} (1.0M NaOH, 1.0M Na_2S, 1.0M S at 25°), Se^{2-}/Se_n^{2-} (5.0M NaOH, 0.024M Na_2Se, 0.003M Na_2Se_2 at 60°), and Te^{2-}/Te_2^{2-} (5.0M NaOH, 0.08M Na_2Te, 0.01M Na_2Te_2 at 50°) electrolytes.

unable to obtain the maximum photopotential with light intensities available. Consequently, from the data in Fig. 3 we can only place limits on the band positions. The E_{redox} values are (11, 13) -0.7, -0.9, and -1.1V *vs.* SCE for S^{2-}/S_n^{2-}, Se^{2-}/Se_n^{2-}, and Te^{2-}/Te_2^{2-}, respectively. The photopotentials place the E_{CB} position at least as negative as -1.3V *vs.* SCE for each of the three electrolytes. It is interesting to note that the highest photopotential that we see depends on the electrolyte in a manner consistent with theory. That is, the photopotential at a given light intensity is lowest for the Te^{2-}/Te_2^{2-} electrolyte, and highest for the S^{2-}/S_n^{2-} electrolyte, while intermediate values are obtained in the Se^{2-}/Se_n^{2-} electrolyte. This ordering is expected if E_{CB} is constant in all three electrolytes, since the difference in E_{redox} and E_f controls the open-circuit photopotential.

Since the open-circuit photopotential measurements given in Fig. 3 only place a limit on the value of E_{CB}, we have determined E_{FB} by an independent method involving measurement of the differential capacitance, C, associated with the band bending region of the semiconductor as a function of semiconductor potential (14). Plots of $1/C^2$ against potential generally are linear with a slope inversely proportional to the donor density and an intercept equal to E_{FB} (14). A typical plot for InP is given in Fig. 4. Since $E_{FB} \approx E_{CB}$ (within 0.2V), the value of E_{VB} can be determined by knowing E_{BG}. The band positions of InP from the differential capacitance plots are given in Fig. 5 for a number of electrolytes. We regard the error in E_{FB} as at least ± 0.1V. The value of E_{redox} for several couples is included in Fig. 5. First, we note that in aqueous electrolytes the band positions are sensitive to pH as has been found previously (15, 16) for GaAs and GaP. Additionally, note the similar position of E_{VB} and E_{redox} for O_2 evolution from H_2O. This

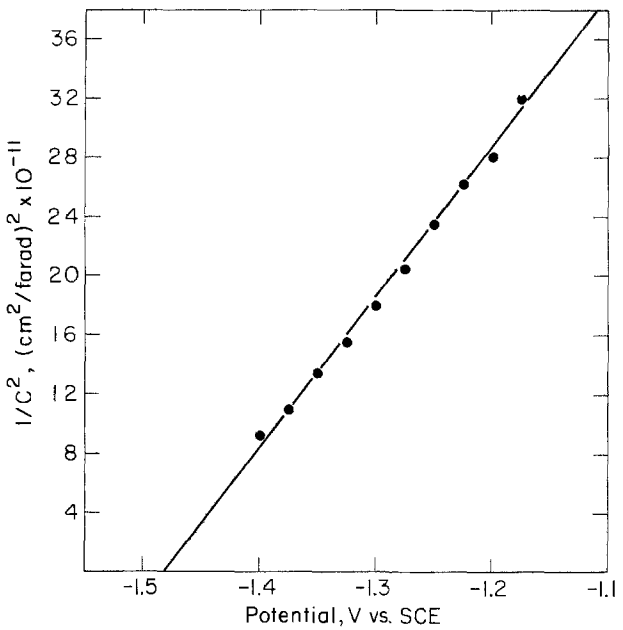

Fig. 4. Plot of (differential capacitance)$^{-2}$ against potential for InP in 5.0M NaOH, 0.08M Na_2Te, 0.01M Na_2Te_2 electrolyte at 50°.

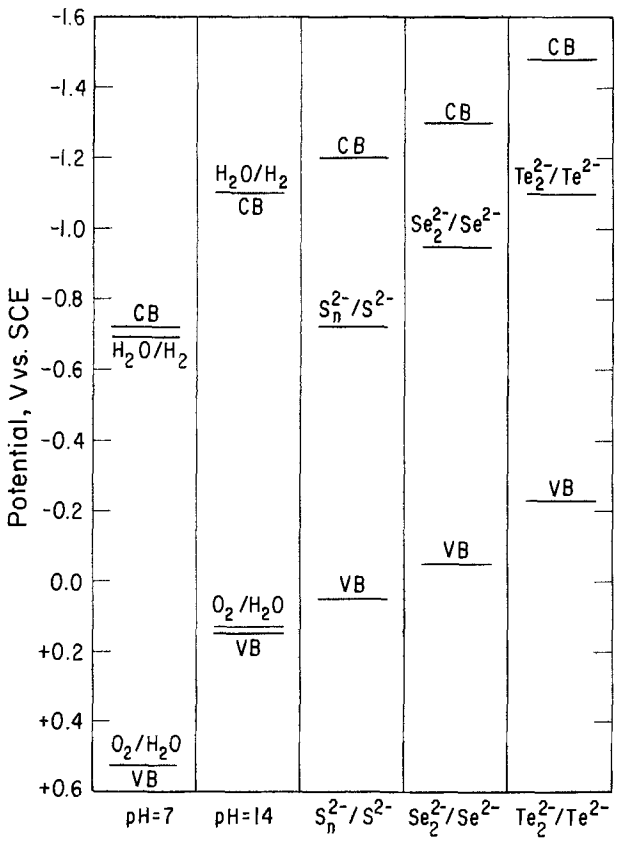

Fig. 5. Valence band (VB) and conduction band (CB) positions for InP in X^{2-}/X_n^{2-} electrolytes and in aqueous solutions at pH = 7 and 14. Data are from differential capacitance curves like that shown in Fig. 4. Band positions are ± 0.1V. Electrolyte redox levels are also given.

means that holes photogenerated in the valence band of InP will not have significant oxidizing potential towards H_2O. The band positions in the X^{2-}/X_n^{2-} electrolytes move slightly more to the negative as X changes from S to Se to Te. There is satisfactory consistency between the measured open-circuit photopotentials and those expected from the energetic picture in Fig. 5. The small movement of the bands to a more negative potential in the heavier chalcogenide ion electrolytes is interesting, but the large error in the measurements does not allow a detailed comment.

The really noteworthy point in the energetic picture for InP exposed to X^{2-}/X_n^{2-} is that the difference in E_{redox} and E_{VB} is roughly constant. Despite this fact, however, only in the Te^{2-}/Te_2^{2-} electrolyte do we find that the InP is stable to photoanodic dissolution. It is apparent that factors other than simple energetics must control whether the interfacial oxidation will compete effectively with the semiconductor electrochemistry. We (4, 5) and others (14, 17-20) have speculated that surface states may play a key role in mediating interfacial electron transfer at semiconductor electrodes, and such may be the case here.

One final point concerning energetics is worth noting. We find that the E_{VB} position for InP in aqueous electrolytes is very similar to that found for GaP (15, 16). This result parallels the findings that the E_{VB} position for a number of III-V and II-VI semiconductors is controlled only by the anion of the semiconductor for Au Schottky barriers (21). Our finding here for InP-electrolyte "Schottky barriers" may represent the first experimental substantiation of the suggestion of McCaldin and McGill (22) that the anion may control the E_{VB} position at such interfaces. However, our ability to stabilize GaP (5), but not InP, with Se^{2-} again signals an important, but as yet unpredictable, role for the electrolyte in photoinduced interfacial electron transfer properties.

Experimental

Materials.—Single crystals of n-type InP were obtained from Metals Research Company (Melbourn, England) and Varian Associates. All samples were cut to expose the (100) face, and were chemically polished to ~0.35 mm thickness. Samples denoted InP-A have resistivities of 0.005-0.016 Ω-cm and carrier concentrations of 1.4-6.1 × 10^{17} cm^{-3}; resistivities and carrier concentrations of InP-B samples are 0.4 Ω-cm and 3.6 × 10^{15} cm^{-3}, respectively. Except for the data in Table I and Fig. 1, all experiments were carried out with the InP-B samples. The crystals were irregularly shaped as obtained and cut into ~5 × 5 mm squares. Electrodes were prepared by rubbing gallium indium eutectic on one face of the crystal, then setting the eutectic-covered surface on a glass-encased Cu wire whose end had been coated with Ag epoxy. Ordinary epoxy was then used to insulate the electrical contact from the electrolyte. The chemically polished (100) surface was always exposed to the electrolyte. Preparation and handling of electrolytes of Na_2Se, Na_2Te, and Na_2S has been described previously (1-5). Photoelectrochemical cells described previously were used in all experiments (1-5).

Electrode stability.—Before being mounted as electrodes, InP crystals were weighed (±0.1 mg). After prolonged photoelectrolysis they were demounted by removing the epoxy with CH_2Cl_2, and then reweighed. Conditions under which stability was tested are given in Table I. Instability was recognized by surface damage as well as weight loss.

Irradiation equipment.—InP photoelectrodes were irradiated with Spectra Physics He-Ne (632.8 nm) and Model 164-003 Ar ion (514.5 nm) lasers, a Bausch and Lomb light source equipped with an Osram 200W superhigh pressure Hg arc lamp, or a 650W GE tungsten-halogen lamp. Output from the latter two sources was used for stability experiments; excessive heat was dissipated through 18 cm of H_2O, and u.v. output was absorbed by a Corning CS 3-73 filter. A 6X beam expander was used to enlarge the 1.5 mm (Ar ion) and 1.0 mm (He-Ne) diam beams; laser

intensities were varied with laser power and/or colored filters. Light intensity was measured either with a Tektronix J16 digital radiometer equipped with a J6502 probe (500-900 nm) or a Coherent Radiation Model 212 power meter (1200-675 nm). A beam splitting technique was used to monitor light intensity continuously, where required. Visible and near infrared monochromatic light was obtained by using a Bausch and Lomb high intensity monochromator with the tungsten-halogen lamp.

Wavelength response.—The absorption of optically polished InP-A was recorded on a Cary 17 spectrophotometer. A plot of relative photocurrent as a function of excitation wavelength (500-1000 nm) was obtained by first monochromatizing the output of a tungsten-halogen lamp, and determining the output intensity as a function of wavelength. InP-A was then irradiated as the photoanode in optically clear 0.1*M* Te^{2-} (50°C) electrolyte, and the photocurrent was recorded as a function of excitation wavelength at −1.10V *vs.* SCE. The photocurrent was then corrected for variation in light intensity, yielding a corrected photoaction curve.

Current-voltage curves.—Current-voltage curves for InP were obtained using a PAR 174 polarographic analyzer with a saturated calomel reference electrode (SCE) and a Pt counterelectrode. All curves are for stirred solutions under Ar.

Open-circuit photopotentials.—A sample of InP-B was irradiated in each of three polychalcogenide electrolytes, and its potential relative to Pt gauze was measured by a high impedance Varian A-25 recorder in series with the two electrodes. The light source was the 514.5 nm line of the Ar ion laser; the beam was masked to just fill the photoanode surface. Light intensity was continuously monitored by a beam-splitting technique, and open-circuit photopotential was recorded as a function of light intensity.

Differential capacitance measurements.—The same InP-B sample used for open-circuit photopotential studies was also used for differential capacitance measurements. An HP 4260A Universal Bridge was employed. Bias was applied through the bridge leads to the Pt and InP-B electrodes in 25 mV steps. A Data Precision 1450 multimeter indicated the potential of the anode relative to SCE. Experiments were performed at 1 kHz in the dark, allowing for a suitable equilibrium period after each voltage adjustment. Besides the three polychalcogenide electrolytes, 1*M* NaOH and 1.0*M* $NaClO_4$ at pH 7 were also used as electrolytes in which to examine the differential capacitance behavior of the InP-B electrode.

Lubrication in Photolithography

Resist Protect Coats

D. L. Flowers*

Motorola Semiconductor Research and Development Laboratory, Phoenix, Arizona 85036

ABSTRACT

Defects in photolithographic processing account for large yield losses in semiconductor device fabrication. A major factor contributing to these defects is pinholes formed by photoresist pieces pulled from the resisted layer with subsequent undesired etching of oxide, metal, or passivation glass during processing. Further, for negative photoresist, pieces on the mask "print" during exposure forming latent defects which etch during processing also giving shorts, parted metal, and the like. Using surface chemical principles of lubrication, a resist protect coat (RPC) formulation based on polyvinyl alcohol, a surfactant, and a lubricant has been developed which greatly minimizes these defects. Significant increases in effective mask use and increased yields for three layer metal devices are shown.

It is well known that repeated mask-wafer contacts in semiconductor photolithography severely deteriorate process yield and photomasks. Pieces of resist torn from the wafer allow etching in undesirable places. Optically opaque pieces of resist stuck to the mask frequently "print" during exposure. This results in latent pinholes which form during the etching procedure. Buildup of resist on mask causes inadequate contact during exposure and results in poor pattern definition. Thus, limited mask use results. These defect modes are due to adhesion between the mask and the photoresist. They are particularly severe when there are irregularities such as hillocks of aluminum, pieces of CVD glass, sharp line patterns, or dirt present on the mask or wafer such that large contact pressures are produced (1). Adhesion is caused by hydrogen bonding or chemisorption of a variety of polar groups present at the resist and mask interfaces (2, 3). Cohesion of the resist film and its adhesion to the wafer are weaker than the force binding the resist to the photomask in localized areas. On separation of mask and wafer, the observed damage and contamination occur.

This paper describes the development and effectiveness of a lubricating surface coating for photoresists. Lubrication is achieved by minimizing hydrogen bonding and chemisorption between mask and resist (4).

Preliminary work was devoted to optimizing a resist protect coat to obtain the minimum number of photodefects as judged by a capacitor evaluation technique. Greatly extended photomask life was shown with the optimized formulation. Production wafers were processed both with and without the resist protect coat. Substantial yield improvement was shown and defect reduction was calculated. A mechanism for resist-mask adhesion and effective lubrication of the resist surface is presented to explain defect reduction in finished devices.

Experimental

Materials.—The wafers used in the capacitor part of this study were p-type substrates, patterned, first layer metal. They were targeted for a large, three layer metal, gate array. Chip size was 19×10^3 mils^2.

Actual product wafers of the same device type were also processed with and without resist protect coats to determine yield benefits achieved by the protect coat formulation and process.

Equipment.—Automatic capacitor data were taken using a Motorola IC automatic probe interfaced with a CDC 8090 computer. The alignment tool for the capacitor pinhole experiments had 15 psig contact pressure. It was also used for the passivation layers of the manufacturing lots processed except two lots where the proximity mode was used.

Procedures.—A resist protect coat (RPC) solution used in this work was prepared by dissolving 16.2g of polyvinyl alcohol (J. T. Baker, No. U229) in 2700 ml of DI water at 45° ± 5°C with stirring. To this was added 300 ml of isopropyl alcohol (Baker and Adamson, Electronic Grade) containing 0.3g of glyceryl monostearate (C. P. Hall of Illinois) and 1.5g of Triton X-100 (Rohm and Haas). The solution was mixed well, cooled, and filtered through a RAMP 074-00 1.2μ Millipore filter using 15-20 psig air or N_2 pressure. Other compositions noted in this report were prepared similarly. The solutions were stable indefinitely.

The wafers for a given capacitor experiment were given a standard first metal clean after which 10k Å of phosphorus-doped (3.5×10^{20} atoms/cm^3) glass was deposited (CVD) on the metal. Wafers used to establish an as-deposited dielectric pinhole baseline were again metallized, masked, and metal etched using a scribe grid mask for the device. Use of this mask on second metal defined each chip as a capacitor with the first metal. The capacitor yield relates to pinholes in the as-deposited glass between the first and second metal layers that filled with second metal and test as shorts or high leakage capacitors. The remainder of the wafers for an experiment with 10k Å of dielectric on first metal were processed with and without RPC on photoresist to compare capacitor yields. The photoresists used were negative (53 Hz) or positive (20.5 Hz). After resist soft bake (80°C, 20 min, N_2), RPC was spun at 3k rpm unless otherwise noted and the wafers rebaked (80°C, 15 min, N_2) after which they were ready for alignment.

Masks were blank for the capacitor-pinhole experiments, *i.e.*, clear emulsion for negative photoresist and opaque emulsion for positive photoresist. Two contacts were made on each wafer unless otherwise noted. Each mask was used for four wafers (one experiment) and discarded. Exposure times for the photoresist were those normally used for that resist thickness. Control wafers were run with each related set of experiments.

After alignment the RPC was removed: (*i*) for the negative photoresist, 5 min immersion in 40° ± 2°C DI water containing 0.1% Triton X-100 surfactant followed by a 5 min cascade DI water rinse, an isopropyl alcohol dip, and spin dry; and (*ii*) for the positive photoresist, 10 min soak in room temperature DI water, a 5 min cascade rinse, and spin dry.

Next, the wafers went through the development cycle and were "hard" baked prior to etch. For negative photoresist, the bake was 180°C (N_2) for 30 min. For positive photoresist, the bake was 100°C (N_2) for 30 min.

* Electrochemical Society Active Member.
Key words: photomask, adhesion, defects, pinholes.

Finally, the wafers were etched in buffered HF to form pinholes in the passivation glass (dielectric) resulting from defects in the photoresist. After resist removal and clean, second metal was evaporated and conventionally patterned using the scribe grid mask to form capacitors.

Capacitor (19×10^3 mils^2) measurements were made at 30V. For these measurements, the back of the wafer was biased positively, thereby forward biasing the collector substrate junction. Capacitor yield at 30V is meaningful for this study because at this voltage, the reverse biased collector-base breakdown is overcome. Interpreting data at higher stresses may not be safe because strain or weaknesses in the dielectric glass may cause punch through and cloud the issue of photo-induced defects.

Results and Discussion

Process development.—To develop a RPC, preliminary experiments were run, spinning polyvinyl alcohol (PVA) solutions on resisted wafers (5). It was found that PVA solutions do not readily wet photoresist, but that the addition of small amounts of a surfactant, *e.g.*, 0.01-0.2% Triton X-100 or Aerosol OT (American Cyanamid) promotes sufficient wetting for uniform coats (5-7).

The lubricant glyceryl monostearate (GMS) or calcium stearate (Ca St, American Cyanamid) was next introduced into the coating formulation (8). Because of very limited and slow solubility of GMS in water solution, it was introduced to the aqueous PVA-surfactant solution in an isopropyl alcohol carrier. Calcium stearate was formulated similarly. The final solution formulation was in a 90/10 v/v DI water/isopropyl alcohol mixture.

Once smooth and uniform coatings were obtained from the formulation, attention was turned to an effective bake cycle. Sufficient baking of the protect coat in nitrogen to remove solvent and develop nonsticking capability in the formulation was achieved in 15-20 min at 80° ± 2°C for both negative and positive photoresist. Exposure times on the alignment tools used were unaffected by the protect coats which absorb very little of the active radiation. The protect coat was removed as described earlier.

Coatings were spun on resisted wafers from 2.7 and 0.54% PVA solutions, then baked, and exposed to check ease of coating removal. It was found that for spin speeds from 1-5k rpm, the coating was removed more easily from the 0.54% solution coats. This concentration was therefore used. Coating thickness was estimated to be 170 ± 30Å when spun at 3k rpm. It was obtained from the IBM 7840 film thickness analyzer.

With the mechanics and details of a process defined, capacitor experiments could be used to examine and optimize the formulation of a RPC. Table I details the results of these experiments.

Capacitor yield improvement for a nonionic surfactant, TX-100 and an anionic surfactant, Aerosol OT are shown in Table IA. The arbitrarily chosen lubricant concentration was held constant as shown. Triton X-100 at 0.05% weight gave the most improved capacitor yield. Decreasing amounts have not apparently reached maximum effectiveness. Increasing amounts may impair the cohesive film strength. The data suggest that Aerosol OT may have a maximum effectiveness around 0.05% but was not pursued further.

The lubricant evaluations shown in Table IB predict an optimum effectiveness for GMS to lie at 0.01% weight, decreasing sharply above or below that value. Calcium stearate is also effective as a lubricant but requires more material for activity. This relates to several molecules required to form a micelle compared to single molecule activity for the GMS (9).

An optimum film thickness (spin speed) was determined for the protect coat with the formulation derived above. This is shown in Table IC. Here it is seen that a dip coat with the formulation (~2k Å film) gives very poor capacitor yields indeed. This relates to difficulties in drying the thick polyvinyl alcohol film. Spinning the coat yields a broad maximum in capacitor yield peaking at 3000 rpm (150-200Å). There is a noticeably thicker edge on the film spun at 1000 rpm and, as expected, the film thickness probably approaches a monolayer at higher spin speeds.

Table I. Optimizing concentration of additives and spin speed for RPC films

Experiment	Variable	Capacitor yield (%)
	A. Optimize surfactant with 0.01% weight GMS	
1	Base glass	95 ± 2

	C. Optimize spin speed for RPC film (0.01% weight GMS, 0.05% weight TX-100)	
1	Base glass	85 ± 3
2	Control-no RPC	32 ± 6
3	Dip coat RPC	28 ± 12
4	1k rpm	54 ± 6
5	3k rpm	56 ± 5
6	5k rpm	50 ± 6
7	7k rpm	46 ± 7
8	9k rpm	33 ± 9

Having optimized the formulation for RPC, a capacitor matrix was designed to evaluate the individual effect of the ingredients present. The concentrations used were chosen as a result of the process development experiments discussed above. The matrix used with the constituents and concentration parameters noted are found in Table II.

Here it is seen that a standard process with negative resist gives a capacitor yield of only 38%. The as-deposited dielectric glass yield was 88%. With the addition of a protect coat of PVA only, a 50% capacitor yield or 12% improvement is noted. Addition of the surfactant (0.05% weight TX-100) to the coating solution did not sensibly change the yield over that of PVA alone. The use of 0.01% weight GMS lubricant in the PVA coating, however, gave a yield increase over that of the PVA alone (57% *vs.* 50%). When the coating formulation contains both the lubricant and the surfactant in the carrier film at the concentrations noted, a 75% yield is realized. Thus, glass dielectric photoprocess yield is doubled using RPC. Since the GMS was noted to agglomerate or clump at the coating surface when surfactant TX-100 was absent, but not when it was present, the increased activity of the combination surfactant TX-100–lubricant GMS is apparently due to a more uniform distribution of the lubricant at the interface.

The RPC formulation recommended by the above evaluation is: 90/10 H_2O/IPA by volume, 0.54% w/v PVA, 0.05% TX-100, and 0.01% GMS.

Table II. Effect of various RPC constituents on improving capacitor yield of passivation glass

Experiment	Coating composition	Capacitor yield (%)
1	Base glass-no photo process	88 ± 2
2	Negative resist at 5k rpm-no RPC	38 ± 5
3	Expt. 2 + 0.54% PVA at 3k rpm	50 ± 3
4	Expt. 2 + 0.54% PVA with 0.05% TX100 at 3k rpm	52 ± 6
5	Expt. 2 + 0.54% PVA with 0.01% GMS at 3k rpm	57 ± 5
6	Expt. 2 + 0.54% PVA with 0.05% TX100 + 0.01% GMS as RPC at 3k rpm	75 ± 7

The pinhole protection given by the coating on positive and negative photoresists was investigated at various coating thicknesses before working with production wafers. The results are shown in Table III.

Significant capacitor yield increases are seen for both negative and positive photoresist with the use of RPC. For the thinner (8.5k Å) negative resist coatings, the yield is doubled. For thicker resist (11.5k Å), the yield improvement is not so pronounced, ~8% over-all. At an intermediate resist thickness (10k Å), the interpolated yield improvement with RPC is predicted to be 21%. In the positive resist case at a commonly used thickness (22k Å), the capacitor yield improvement is 22%.

Extended mask life.—With improved capacitor yields shown by using RPC, it was desirable to investigate its use on longer photomask life (5). Table IV shows the results of experiments run to determine if good definition on individual wafers could still be achieved with longer mask use and RPC process. Standard production wafers were started at the preohmic masking step. The smallest geometry was 0.3 mil. A tool with a contact pressure of 15 psig was used. Each wafer was contacted an average of three times.

In this table, "pass" means the developed wafers had less than two defective die on them out of nine inspected with a standard "after develop" inspection criteria. "Fail" means three or more die of nine were defective on a 2 in. wafer for photoresist defects. Of particular interest here was the "fail" mode for "poor definition" arising from improper mask-wafer contact due to pieces of photoresist on the mask from previous use. The "failed" wafers occurred in sequence after the "passed" wafers.

Mask life with acceptable pattern definition was increased by a factor of three to four using RPC. The spread between five and eleven pass for the noncoated wafers of the two experiments shows the spread that occurs under these process conditions. Pinhole protection with extended mask use is reported next. Nonpatterned p-type wafers were selected for this experiment. Standard phosphorus-doped glass (10k Å) was deposited to simulate the passivation conditions earlier in this report. Capacitor size was 2500 mil^2 compared to 19,000 mil^2 in the previous experiments. The relative trends in this experiment are therefore points of note. Results are shown in Table V.

A significant increase in mask life coupled with increased capacitor yields is shown with RPC. There is a decided break of capacitor yield with mask use in both cases however; about nine exposures before the yield break for RPC and five or six exposures for the control. The yield in both cases after the break occurs drops to a scattered low between 30 and 50%.

The capacitor yield at the eighth RPC wafer of 73% is almost as high as the 75% of the first non-RPC wafer. The average yield for the first eight RPC wafers is 82.7%. That for the first eight non-RPC wafers is 64.3%. Thus, on flat capacitors, an 18% yield increase is noted for the RPC process.

Neither this case nor the preceding ones correspond exactly to the real world. To determine more accurately the effect of RPC, production lots were run with pertinent layers involved to determine the magnitude of the benefit achieved.

Completed device evaluation of RPC (eight wafers per mask).—The advantage of RPC on final device yield when used on the first and second passivation layers is shown next (three layer metal, 19 × 10^3 mil^2 chip). Layers were processed with 22k Å of positive resist. It is here that pinholes are suspected of being a major problem. Table VI summarizes average die per wafer yield. There were 15 ± 3 wafers remaining in each half-lot on completion with some being broken and discarded at various earlier process steps.

Data from lots one and two show that the yields are doubled with the use of RPC in contact printing. When it was used on wafers aligned in the proximity mode of operation, the benefit of lubrication, as expected, was not as great. It is worthy of note that contact printing with the RPC approaches the lower defect level of proximity printing and should allow better fine line definition as well.

With yield improvement shown on the multilevel gate array circuit, it is possible to derive an estimate of defect densities and their reduction brought about by the RPC process. Studies on the effect of point defects (pinholes) have been treated by Warner (10) and Gupta *et al.* (11). Turley and Herman (12) have discussed LSI yield projections referenced to multilevel metal structures. Such projections can be derived assuming a Poisson distribution of defects. Conversely, with yield improvement due to a process change to reduce pinholes, the effect in terms of decreased defect density can be calculated using the formula $Y \simeq e^{-X} \simeq e^{-AD}$. Here, X is the defect density per die, Y is the yield, A is the area, and D is the defect density per unit area. In Table VII, yields are compared to defect density of the die. For these calculations, the area of the 19 × 10^3 mil^2 chip was normalized to the area covered by first and second layer metal. First layer metal covered 37.2% of the chip and second metal covered 20.0% of the chip. The total area of metal combined in

C	23.3	28.2	1.55	1.36	22.5	19.7

first and second layers is 10.7×10^3 mils^2 where pinholes in the capping passivations can lead to shorts.

The data show that the yield varies from 8.5 to 28.2% with a statistical defect density of 2.56 per die decreasing to 1.36 per die. Defect improvements range from 12.3%, lot C, proximity printing, to 34% when the first and second passivation layers were contact printed. It is seen for yields below 30% that a relatively small improvement in defect density results in large yield increases.

Mechanism of lubrication by RPC.—The mechanism of adhesion of photoresist and mask that produces "photo defects" relates to the surface chemistry of the contacting species. As a zero-order explanation, a model of the pertinent interfaces is presented in Fig. 1. The polar groups present that interact to cause adhesion are indicated. The photomask may be of gelatin, chrome, or iron oxide construction. Active polar groups present at the surface are amide (—CHNH—), carbonyl (=C=O), or hydroxyl (—OH). Similarly, at the photoresist surface, carbonyl (=C=O), hydroxyl (—OH), or unsaturated (—C=C—) groups are present as shown. Hydrogen bonding can occur when the photoresisted wafer and mask come in contact. Since hydrogen bonds have a free energy of formation of ~5.0 kcal/mole, and, since there are many possible hydrogen bonding sites in every resist and gelatin molecule or inorganic crystal, it is apparent that total bonding energies of many kilocalories per mole can be generated (13). Further, the enormous energy density generated when mask and wafers are contacted at asperities, epitaxial spikes, dirt, or sharp lines and corners probably cause even stronger, fully chemisorbed bond formation by addition of hydroxyl and/or amide groups of the mask to the olefinic groups of the photoresist. Finally, exposure of the contacting mask and photoresist might be expected to promote further the reaction between polar groups and the unsaturation present in the photoresist. Hence on separation of mask and exposed wafer, small pieces of resist are torn from the surface to leave a latent pinhole in the device. The accumulation of photoresist pieces on the photomask after several wafers have been aligned soon causes "definition" problems in contact printing due to lack of sufficient mask-wafer contact during exposure. This must be minimized for longer mask life.

The RPC applied to wafers shields the polar groups on the mask from those of the photoresist thus minimizing or preventing hydrogen bonding. This is shown in Fig. 2. The necessary shielding is primarily provided by the lubricant, *e.g.*, glyceryl monostearate shown here. The polar part at the molecule is energetically favored to be in the high dielectric constant, polyvinyl alcohol film. The nonpolar ($—CH_2)_{16}$-CH_3) tail of the molecule favors the low dielectric constant air media and hence orients as shown. Because of this orientation, contact of the mask and photoresist does not produce adhesion. The polar groups at the two interfaces do not sufficiently approach each other for intermolecular hydrogen bonding and lubrication is achieved. Similar arguments may be derived for the micelle-forming lubricants, *e.g.*, calcium stearate.

Classical studies as described in a review by Reinhart could be used to more quantitatively define the nature of adhesion between photoresist and photomask (14). The techniques of Levine and Zisman could be used to characterize the lubrication provided by RPC in a more controlled and definitive way (15).

Summary and Conclusions

Consideration of the surface chemistry involved in contact printing of photoresisted semiconductor wafers has led to a postulated mechanism for wafer-mask interaction. Based on this mechanism a RPC was formulated and optimized to eliminate or minimize attendant photodefects. Lubrication between the photoresist and photomask was achieved. Wafer-mask sticking was substantially minimized.

Without lubrication, a large, three layer metal, LSI device had severe yield losses due to pinholes in the first and second passivation layers. These filled with evaporated metal and caused excessive interlayer leakage and device failure. A capacitor evaluation technique was used to simulate the failure mechanism. Negative photoresist showed only a 38% capacitor yield but when covered with the RPC produced a 75% yield. Similarly positive photoresist as commonly used had a 50% capacitor yield but with RPC reached a 73% yield. Using the capacitor yield improvement, it was estimated that the large device being studied should yield 100% better with protect coat on the photoresist. Such was indeed observed.

In the proximity mode of operation, where pinholes caused by contact are considerably minimized, some yield benefit was still realized with RPC. This is probably due to protection derived during handling and some inadvertent partial contact during alignment of the wafers.

The subject of increased mask life when the wafers were resist protect coated was also investigated. For wafers processed without RPC, poor definition of pattern failed wafers after five to eleven alignments. With

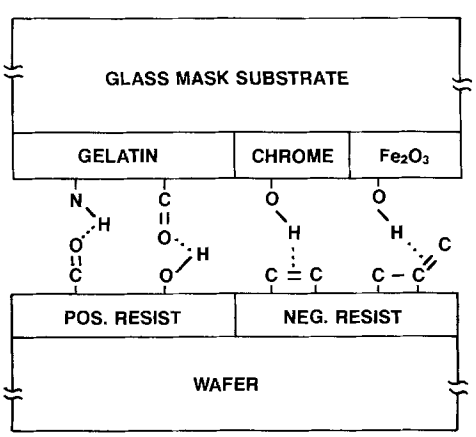

Fig. 1. Hydrogen bonding of mask and photoresist

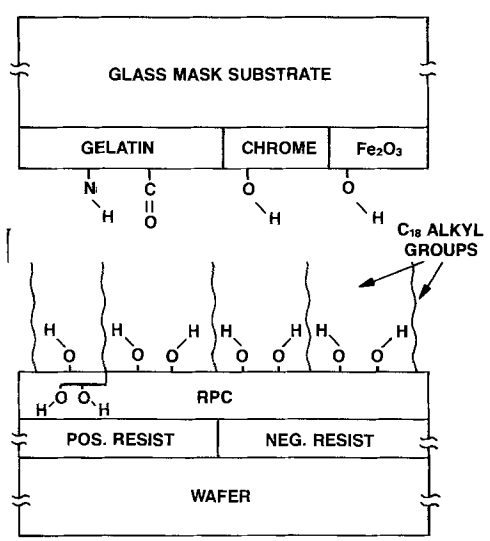

Fig. 2. Lubricated, resisted wafer and mask

RPC, 20-30 wafers could be aligned without encountering definition problems. Maintenance of capacitor yields with extended mask use did not prove quite as promising although substantial benefits were realized. The net result was a 16% (to 83%) yield increase on small chips (2500 mil^2) with 60% more mask life.

In summary, this study has demonstrated a major yield limiting defect mechanism in semiconductor fabrication and has shown an approach to minimizing it.

Acknowledgments

The author would like to thank Mrs. Louise Rice and Mrs. Kelly Nicely for laboratory and production processing reported in this paper. He also wishes to thank Dr. Henry Hughes as well as Messrs. James Black, George Stickney, and Joe Wise for valuable discussions and assistance in this project. Finally, it is with great appreciation for preparing this manuscript, he wishes to thank Mrs. Isabelle Kast.

The Phototransition in ZnO at 380 nm Studied by Anodic Photocurrents

D. M. Tench*,[1] and H. Gerischer*

Fritz-Haber-Institut der Max-Planck-Gesellschaft, Berlin, Germany

ABSTRACT

Anodic photocurrent spectra from 350 to 450 nm were determined in aqueous solutions for single crystalline ZnO electrodes which had been mechanically polished but not etched. The over-all photocurrent was much less than for etched crystals, presumably because of enhanced recombination through mechanically generated hole traps, and a sharp peak was observed at 383 nm. This peak was investigated by intermittent illumination and phase-sensitive detection, with and without superimposed steady light. The effects of polishing and light on the differential capacitance of the electrode were also studied. The data are interpreted in terms of the interaction between excitons and mechanically introduced lattice defects.

Many publications (1-7) dealing with the effect of light on the ZnO-electrolyte interface have appeared in the last two decades. In most cases involving single crystals, freshly cleaved and etched surfaces of the semiconductor were used, presumably to insure that extraneous effects related to mechanically damaged surface layers were not introduced. Similarly, in solid-state studies (8) on ZnO, care has generally been exercised to avoid interference from lattice defects and impurities.

One recent paper (9), however, has considered the effect of mechanical polishing on the differential capacitance of the single crystalline ZnO-electrolyte interface. It was found that abrasive pretreatment of the ZnO surface generates lattice defects to a depth comparable to the particle size of the abrasive, whose state of charge can be altered by capture of optically generated holes or direct optical ionization. From the spectral dependence of the charging of the trapping levels, two groups of energy states were detected; one about 0.8 eV below the conduction band, attributed to Zn donors bound to lattice defects, and the other 0.7 eV above the valence band.

In the present work, abrasive pretreatment of ZnO single crystalline electrodes has been found to result in an over-all reduction in the anodic photocurrent, presumably because of enhanced recombination through mechanically generated lattice defects. This effect has been used to suppress the photocurrent arising from the fundamental absorption in order that a weaker phototransition near the bandedge could be studied. This phototransition manifests itself as a peak at 383 nm in the photocurrent spectrum, and has a time constant for decay of 1-5 sec for the light intensities used here.

For single crystalline ZnO electrodes in aqueous electrolytes, Kiess (5) has reported an anomalous increase in the photocurrent at voltages >130V, which

* Electrochemical Society Active Member.

Key words: semiconductor, zinc oxide, photoeffect, photoelectrolysis.

is observed for light between 375 and 390 nm, but not at shorter wavelengths. The photocurrent increase exhibits a fast component corresponding to a quantum efficiency of unity, and a slow component with a time constant of 1-10 sec for which the quantum efficiency is greater than one. Kiess suggests that the electric field at the electrode surface is increased by trapped holes produced by penetration of the longer wavelength light into a region of the space charge layer containing a low concentration of ionized deep donors. This supposedly results in an enhanced rate of tunneling from surface states, and thus, an increased photocurrent. The similarities between the results of Kiess and those reported here suggest that the process studied in each case was the same. The present studies, however, indicate that the greater penetration depth of the longer wavelength light alone cannot adequately explain all of the experimental results.

Experimental

Electrodes were fabricated from undoped single crystals of ZnO, having donor densities of about 10^{16} cm^{-3} and 0001 surface areas of approximately 7 mm^2, which were obtained from Prof. Heiland (TH Aachen). After cleaving perpendicular to the c-axis and making ohmic contacts with indium, the zinc $(000\bar{1})$ and oxygen (0001) surfaces were mounted flush with the ends of cylindrical Teflon holders using epoxy resin. The electrodes were polished by hand using Diaplast diamond powder with distilled water. Since this pretreatment produced a relatively large, easily measurable effect, all of the results reported here were obtained using ZnO electrodes which had been polished with diamond powder of 15μ particle size, without subsequent etching.

Electrolytes were prepared using reagent grade chemicals and doubly distilled water. Most of the data reported here were obtained in 0.5*M* $LiClO_4$ aqueous solutions, but 1*M* KCl and 0.5*M* K_2SO_4 yielded similar results. In acidic solutions, time dependence was observed, presumably because of dissolution of the ZnO electrode surface.

A Heath monochromator was scanned at 0.5 nm/sec to obtain photocurrent spectra, whereas for the second light beam a Bausch and Lomb double grating monochromator was used. Xenon lamps were used for both light sources. The scanned light impinged upon the electrode at right angles, whereas the angle of incidence of the second light beam was about 25°.

The quantum flux density of the lamp/monochromator combination was determined using a solution of erythrosin yellow in methanol. This substance absorbs the incident light completely in the wavelength range of interest and fluoresces strongly. Using a photomultiplier tube, the long wavelength tail of the broad fluorescence band was monitored, which reduced effects caused by reabsorption of the emitted fluorescence. The measured fluorescence intensity in this case is proportional to the incident quantum flux. Thus, the photocurrents reported here have been corrected for the spectral dependence of the intensities of the lamps. When two light sources were employed this was done graphically since the relationship between the increase in the photocurrent produced by the second light source and the wavelength is complex.

Photocurrents were measured under nitrogen atmosphere in a Pyrex cell with an optical glass bottom by intermittent illumination and phase-sensitive detection. The modulation frequency of the light was 30 Hz, unless otherwise specified. Since the photocurrent decreased with chopping frequency (30% less at 60 Hz), the values at 30 Hz should be considered approximate low frequency limits. After preamplification and filtration by a PAR 113 amplifier, the signal across a 1000 Ω resistor was amplified by a Keithley Model 840 lock-in amplifier. The output was displayed on a Hewlett-Packard 7001 AM X-Y recorder. All measurements were performed at room temperature under controlled potential conditions using a Wenking potentiostat. The reference electrode was always a saturated calomel electrode (SCE).

A-C impedance measurements were made by applying a 100 Hz a-c signal (14 mV peak to peak) across the working electrode using a PAR Model 173 potentiostat/galvanostat, and measuring the current response with a PAR Model 176 current follower and Model HR-8 lock-in amplifier. Some photocurrent measurements were also made with these instruments as a check, and comparable results were obtained.

Experimental Results

Experiments with one light source.—A typical photocurrent spectrum from 350 to 410 nm for a polished zinc interface in 0.5*M* $LiClO_4$ at 6.00V *vs.* SCE is shown in Fig. 1 for a relative light intensity of 1X. A sharp peak is evident at 383 nm and the photocurrent over the whole range is more than a factor of 2 lower than that obtained on etched crystals under the same conditions. This photocurrent suppression is probably caused by enhanced recombination through mechanically generated lattice defects, possibly the hole traps previously observed by capacitance measurements (9). It is evident that light of about 380 nm wavelength can produce an effect not observed at shorter wavelengths.

When the zinc interface is polished with diamond powders of smaller grain size (7-0.7μ), the over-all photocurrent increases until the peak at 383 nm becomes masked. In this case and for crystals etched in 5*N* HCl, the photocurrent peak, although shifted slightly to shorter wavelengths, can still be observed at sufficiently negative potentials (U = 0 *vs.* SCE) and low intensities (~0.1X) as a distinct shoulder on the curve corresponding to the interband transition. These observations and those of Kiess (5), made on etched crystals in the same spectral region, indicate that the peak at 383 nm in the photocurrent spectrum

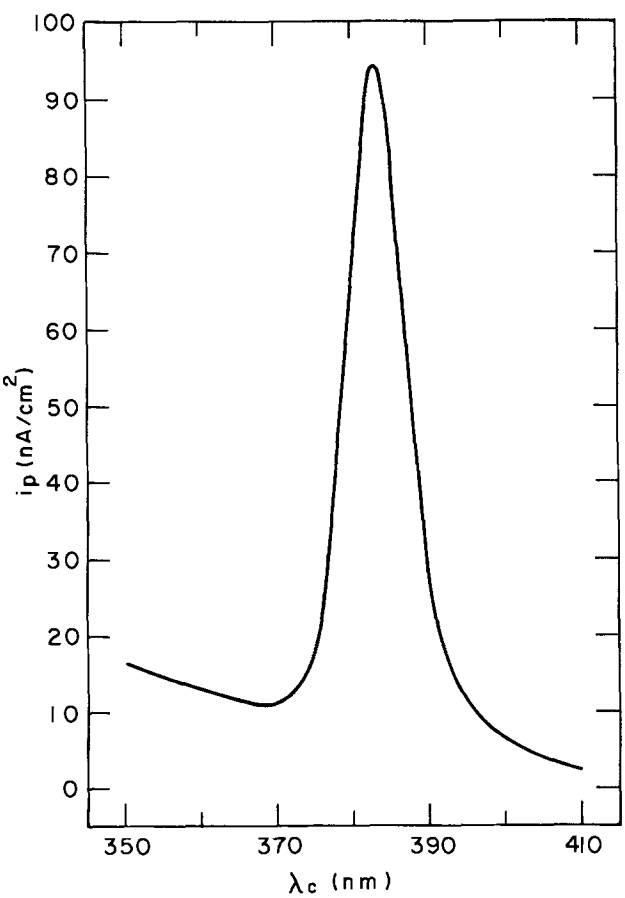

Fig. 1. Photocurrent (i_p) as a function of the wavelength of chopped light (λ_c) of 1X intensity for an unetched zinc interface of ZnO in 0.5*M* $LiClO_4$ at 6.00V *vs.* SCE.

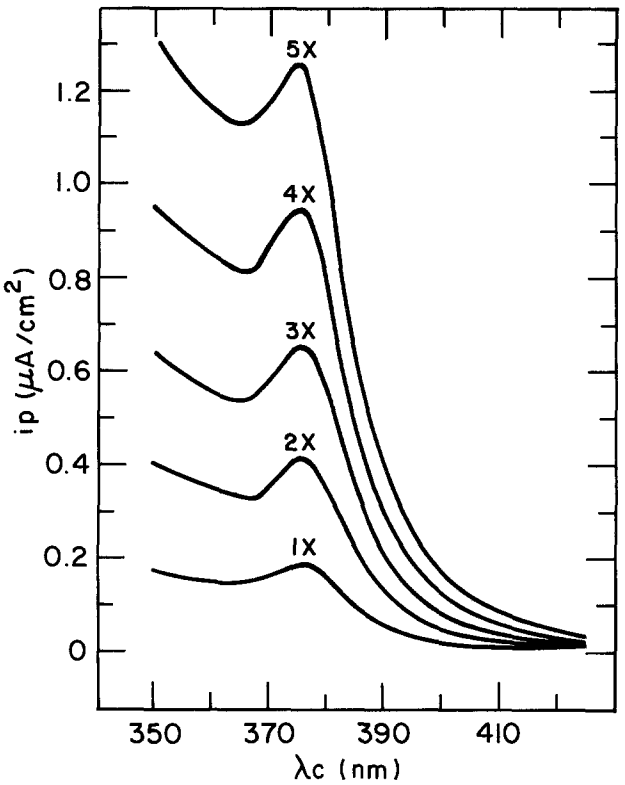

Fig. 2. Photocurrent (i_p) as a function of wavelength of chopped light (λ_c) at various intensities (1-5X) for an unetched oxygen interface of ZnO in 0.5M $LiClO_4$ at 6.00V vs. SCE.

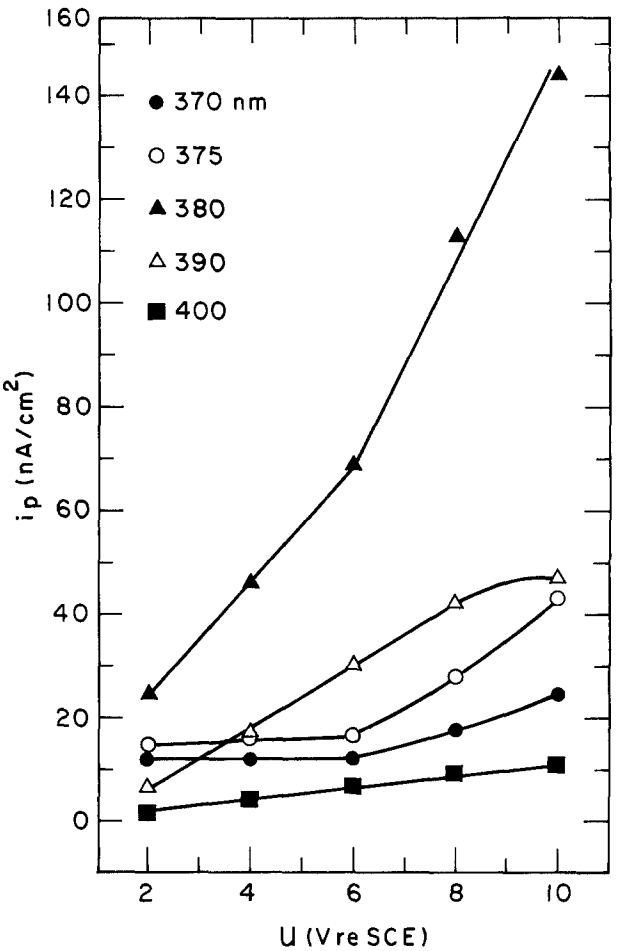

Fig. 3. Photocurrent (i_p) as a function of electrode potential (U) at various wavelengths of light (370-400 nm) of 1X intensity for an unetched zinc interface of ZnO in 0.5M $LiClO_4$.

is related to an intrinsic property of ZnO and is not entirely an artifact of the abrasive pretreatment.

As shown in Fig. 2, the oxygen interface exhibits a similar photocurrent spectrum, except that the peaks appear to be broadened and shifted to shorter wavelengths (375 nm) by the greater background current corresponding to the interband transition. Because of the much faster dissolution rate of the oxygen surface, a significant portion of the damaged ZnO surface could be removed even in neutral solutions. This, and the associated increase in surface roughness, could account for the broadened photocurrent peaks for the oxygen surface.

The electrode potential dependence of the photocurrent at various wavelengths for light of 1X intensity is shown in Fig. 3. At potentials below 6V, the photocurrent at 380 nm increases linearly with a slope of 11 nA/cm²-V, whereas above this potential the slope is greater by a factor of two (20 nA/cm²-V). The potential at which the change in slope is observed, as well as the slopes themselves, are dependent on the intensity of the light. The change in slope occurs at more cathodic potentials, and the slope increases at greater intensities. At 3X intensity the slope for the 380 nm light is constant from 0-10V at 50 nA/cm²-V. For all other wavelengths shown, the potential dependence is considerably less.

Some difficulties were encountered in obtaining reproducible spectra for ZnO electrodes. This appears to be due to several factors. One problem seemed to involve impurities in the solution since electrodes allowed to rest unbiased in the electrolyte overnight exhibited photocurrents reduced by as much as 50%. This effect, however, could be reversed or prevented by biasing the electrode a few volts anodic. At potentials greater than about 6V, the photocurrent was somewhat greater after long periods than for a freshly polished electrode, possibly because of increased surface roughness from dissolution of the crystal. When operating at moderately anodic potentials (2-6V *vs.* SCE), time dependence of the photocurrents was found to be negligible over the times of the experiments. Another problem was the difficulty involved in exactly reproducing the electrode surface region. Although small, after several hours of polishing by hand with 15μ powder, a discernible cumulative decrease in the photocurrent in the short wavelength region was still evident. Since the photocurrent peak at 383 nm occurs on the tail of the shorter wavelength curve, quantitative inferences become tenuous because the photocurrents for the two processes mutually interfere and cannot be separated.

Experiments with two light sources.—To elucidate the nature of the 380 nm effect and the reason for suppression of the interband transition, it is of great importance to know how these two processes interact. This is determined by illuminating the electrode with two light beams of differing wavelengths, one chopped and one steady. Only the photocurrent for the chopped light is measured by the lock-in amplifier, but the effect of the unchopped light on this photocurrent is observed. This is illustrated in Fig. 4, which shows the photocurrent spectrum for the zinc interface (measured with chopped light), with and without superimposed steady light of 380 nm. It is evident that the 380 nm light has little effect on the chopped photocurrent above 380 nm, but produces a large increase at shorter wavelengths.

Somewhat more information can be obtained by measuring the photocurrent at one frequency of chopped light and scanning the wavelength of the superimposed steady light. Changes in the photocurrent (Δi_p) at 360 nm produced by various intensities (1-10X) of unchopped light are plotted as a function of the wavelength of the unchopped light (λ_{uc}) in Fig. 5 for the zinc interface. Similar curves are shown for the oxygen interface in Fig. 6.

A reasonably sharp peak is observed at about 383 nm (380 nm for oxygen surface), which approaches satura-

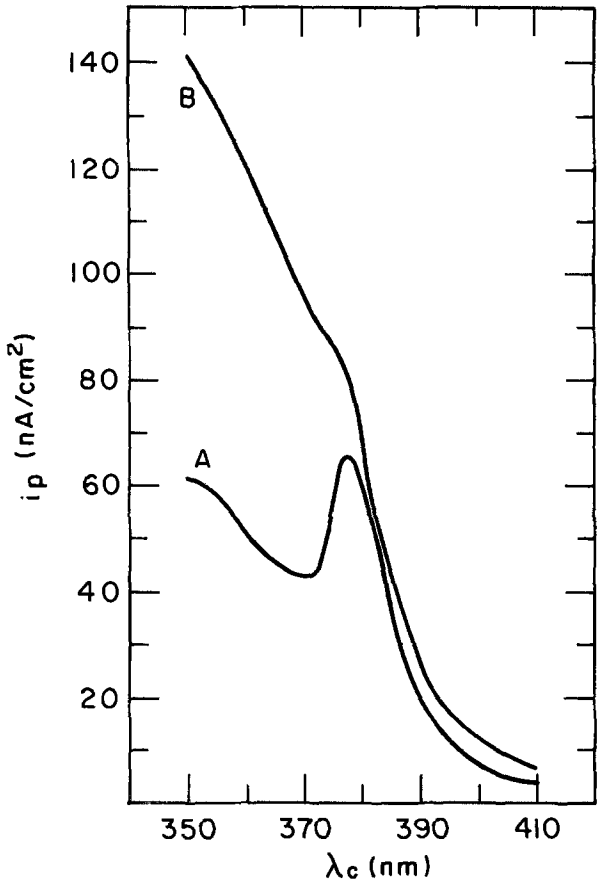

Fig. 4. Photocurrent (i_p) measured with chopped light of 1X intensity as a function of the wavelength of the chopped light (λ_c) without (A) and with (B) superimposed unchopped light of 380 nm wavelength and 1X intensity for an unetched zinc interface of ZnO in 0.5M $LiClO_4$ at 2.00V vs. SCE.

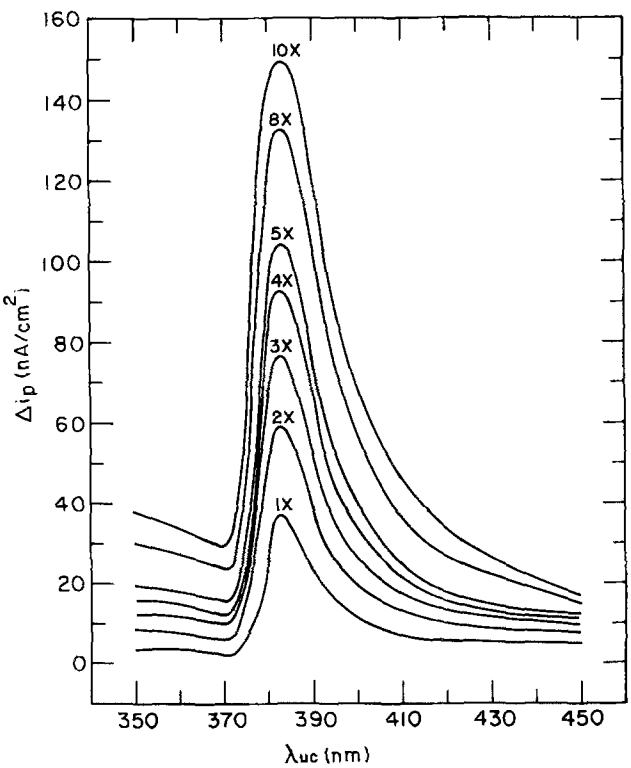

Fig. 5. Increase in photocurrent (Δi_p), measured at 360 nm using chopped light of 1X intensity, produced by various intensities (1-10X) of unchopped light as a function of the wavelength of the unchopped light (λ_{uc}) for an unetched zinc interface of ZnO in 0.5M $LiClO_4$ at 6.00V vs. SCE.

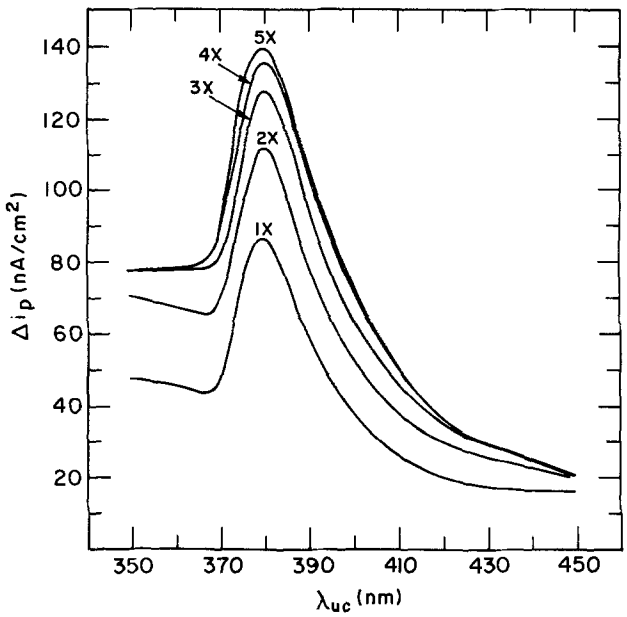

Fig. 6. Increase in photocurrent (Δi_p), measured at 360 nm using chopped light of 1X intensity, produced by various intensities (1-10X) of unchopped light as a function of the wavelength of the unchopped light (λ_{uc}) for an unetched oxygen interface of ZnO in 0.5M $LiClO_4$ at 6.00V vs. SCE.

tion at higher intensities of superimposed steady light. For the oxygen interface, the peak is somewhat broader and saturation is reached at a lower intensity (~5X). The peak saturation value is about the same in each case (140-150 nA/cm^2). By following the photocurrent at 360 nm after stopping the steady light, a decay time of 1-5 sec was determined for the 380 nm process.

Capacitance studies.—Variations of the semiconductor space charge with polishing and under illumination were followed by differential capacitance (C) measurements of the interface. Plots of $1/C^2$ *vs.* electrode potential (U), according to the well-known Mott-Schottky (10-11) equation, are shown in Fig. 7 for a zinc surface of ZnO after polishing and after etching (10 min in 5N HCl). The etched surface yields the expected straight line whose slope gives the charge carrier concentration of the electrode (1.0×10^{16} carriers/cm^3). After polishing, the space charge capacitance is less at a given potential and the Mott-Schottky plot is nonlinear.

The effect of illumination on the differential capacitance of a polished zinc interface is shown by the curves of C *vs.* wavelength of steady illumination in Fig. 8. A large peak in C is evident at 380 nm corresponding to an appreciable decrease in the thickness of the semiconductor space charge region. After etching (10 min in 5N HCl), a small capacitance peak is still observed at 380 nm, but amounts to only 5 nF/cm^2.

Discussion

Any model proposed must explain the following experimental results obtained for polished, unetched ZnO electrodes in contact with aqueous electrolytes:

1. Photocurrents measured for mechanically polished electrodes are considerably smaller than those for etched crystals under the same conditions, indicating that very effective recombination centers are introduced by the mechanical treatment. This effect is accompanied by a decrease in the concentration of ionized donors in the space charge region, as indicated by the capacitance measurements and earlier work (9).

2. A peak is observed at 380 nm in the photocurrent spectrum. This indicates a strong interaction between light of this wavelength and the recombination centers, which results in the introduction of electrons into the conduction band.

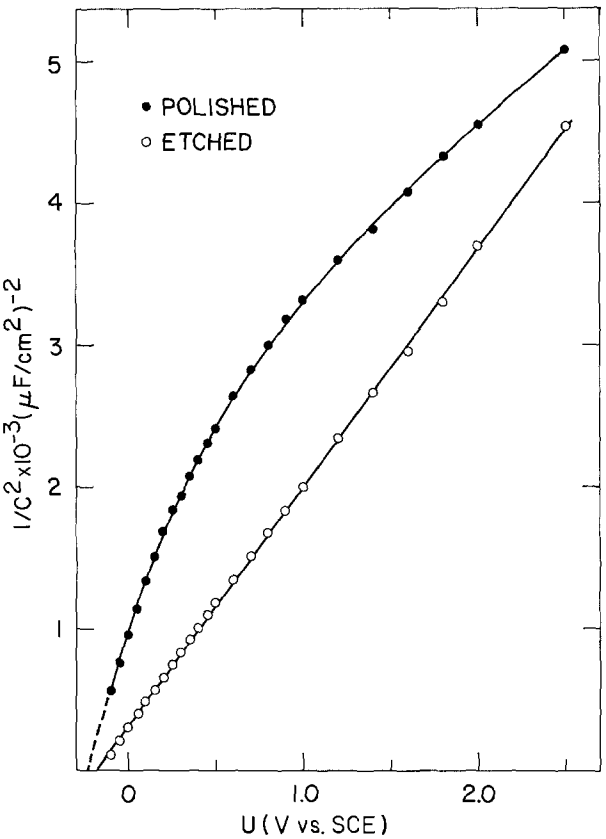

Fig. 7. Plots of inverse square of capacitance at 100 Hz ($1/C^2$) vs. electrode potential (U) for polished and etched zinc surfaces of ZnO in 0.5M K_2SO_4.

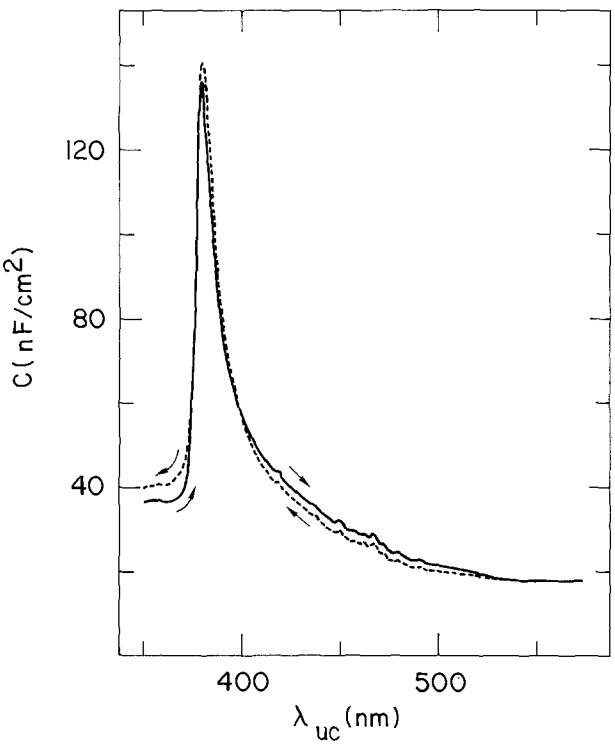

Fig. 8. Differential capacitance at 100 Hz (C) vs. wavelength (λ_{uc}) of steady light of 10X intensity swept at 0.1 nm/sec for a zinc interface of ZnO at 1.5V vs. SCE in 0.5M K_2SO_4.

3. The potential dependence of the photocurrent at 380 nm is relatively large compared to shorter and longer wavelengths.

4. Illumination with light of 380 nm wavelength sharply increases the space charge capacitance (by more than a factor of 3 in Fig. 8), denoting increased positive charge density in the space charge region.

5. The photocurrent measured for shorter wavelength light (*e.g.*, 360 nm) is greatly enhanced by simultaneous illumination with light of 380 nm wavelength. Two factors should be important here. The greater field strength resulting from the enhanced positive charge density should reduce recombination by accelerating charge transfer through the space charge layer. In addition, interaction with 380 nm light may result in a decrease in the concentration of available recombination centers.

6. The effect produced by the 380 nm illumination has a slow decay time of 1-5 sec.

Depth of light penetration.—One possible origin of the specific effects observed for 380 nm light is its greater penetration depth in ZnO, which is at least an order of magnitude deeper than for light of 370 nm wavelength (12). The data could be explained if the 380 nm light penetrated into a region of the space charge layer which lay deeper than the penetration depth for shorter wavelength light and in which the recombination rate were lower. Holes produced in this region would migrate toward the surface where they would become trapped, decreasing the thickness of the space charge region and raising the capacitance. The recombination rate nearer the surface would be lowered by the increased electric field gradient. This model is represented in a simplified way in Fig. 9, where the shorter dashed line represents the hole traps, and the two longer dashed lines show the modified band bending caused by the trapped holes.

There are some significant difficulties with any model based solely on light penetration depth. Only light absorbed within the space charge region is effective in increasing the concentration of free charge carriers and contributing to the photocurrent, since the recombina-

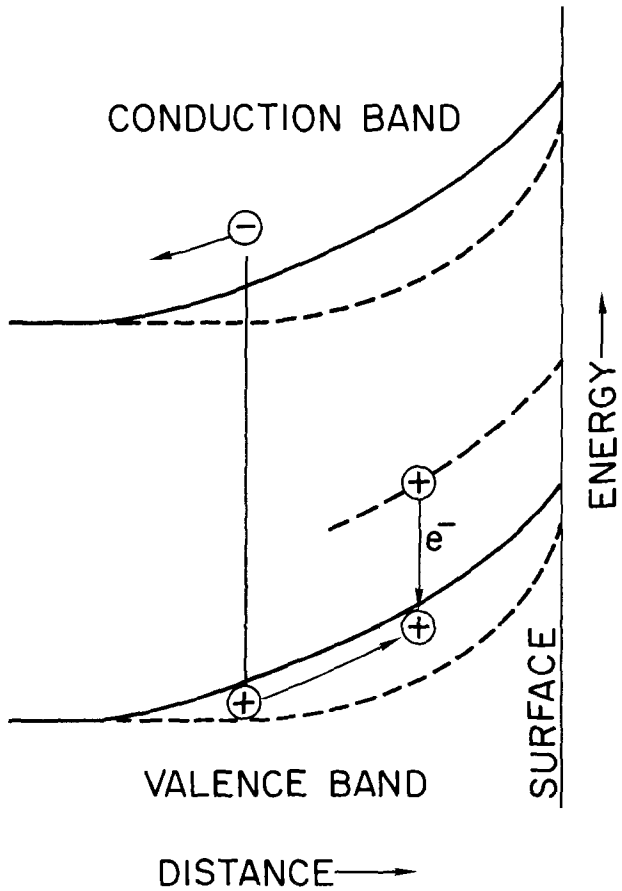

Fig. 9. Representation of ZnO space charge depletion region with trapping of holes generated by illumination deeper in the crystal (see text).

tion rate is high in the absence of an electric field. But the depth of penetration of 370 nm light in ZnO is $\sim 0.2\mu$, which is comparable to the thickness of the space charge layer (Debye length $=0.03\mu$ for 10^{16} carriers/cm^3), and that for 380 nm light is an order of magnitude greater (12). Thus, a large fraction of the 380 nm light is absorbed outside the space charge region and should not make a significant contribution to the photocurrent, while most, if not all, of the remainder is absorbed in the same region as 370 nm light and should have no special effect. Polishing probably does extend the space charge layer somewhat deeper into the crystal by introducing electron traps and destroying electron donors as indicated by the mildly decreased capacitance, but this should change the space charge thickness by considerably less than a factor of 2.

There are even more serious objections to a model based on light penetration depth. First, by following the electrode capacitance for slowly dissolving ZnO crystals, mechanically introduced hole traps have been shown to extend to depths comparable to the grain size of the polishing compound (9), which was as large as 15μ for our crystals. Thus, the recombination rate should be high throughout the entire space charge layer and all regions of light absorption in our experiments. In addition, it is evident from the literature that light in the 380 nm range is associated with some specific transition. In particular, both u.v. illumination (12) and electron bombardment (13) are known to produce a room temperature luminescence peak at about 380 nm.

A model proposed.—In ZnO without intentional dopants, Zn donors, which probably occupy interstitial lattice sites, lie about 0.05 eV below the conduction band (14, 15), and act as traps for electrons at lower temperatures (16). Deeper electron traps, up to 1 eV underneath the conduction band, have also been observed for doped and undoped ZnO by several authors (4, 7, 9, 17-20) using various techniques. In addition, hole traps are also known to occur in ZnO (8, 15, 16), and their concentration is enhanced by mechanical working (9). These various energy levels are represented schematically by dotted lines in Fig. 10, which also illustrates the assumptions made below concerning the origin and nature of the trap levels. Empty hole and electron traps are represented by simple -, whereas bound charge carriers are circled. The arrows represent the direction of charge carrier motion, and e^- and h^+ are free electrons and holes, respectively.

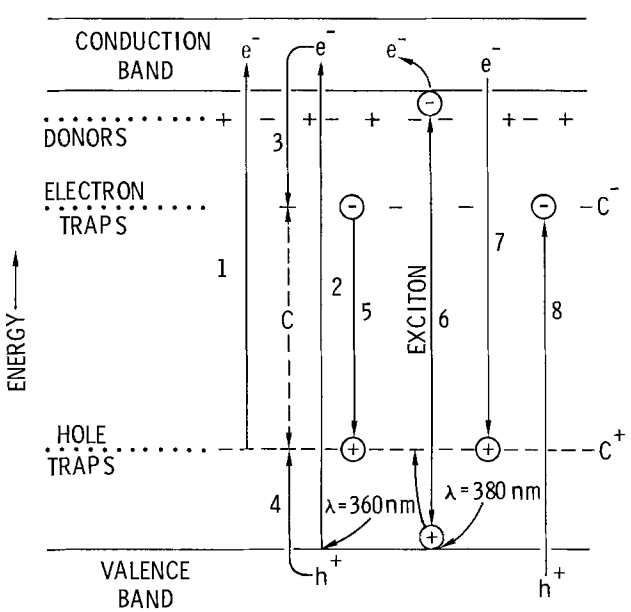

Fig. 10. Schematic representation of the energy levels and electronic transitions in ZnO (see text).

Direct interaction between the 380 nm light and the trap levels involved in recombination (transition 1 in Fig. 10) cannot adequately explain the present data. Transitions between traps and the relatively wide band structures should be effected equally well by shorter wavelength light. Also, traps involved in the recombination process, after emptying, would quickly be filled by electrons, which could also be accomplished by greater intensities of bandgap illumination. Likewise, transitions between two trap levels involved in recombination would quickly be reversed by recombination.

For our model, we assume that mechanical abrasion introduces lattice defects into ZnO, which can act as hole traps. Dislocations or possibly Zn vacancies may be involved. When a defect occurs adjacent to a Zn donor, weakening or breaking bonds, the donor sinks energetically into the bandgap (9), becoming an electron trap. The resulting hole-electron trap complex (C) should be an extremely effective recombination center for free holes and electrons, which are generated by bandgap light (transition 2 in Fig. 10). The charge carriers become trapped at the same center C, according to

$$e^- + C \rightarrow C^- \qquad \text{(transition 3)}$$

$$h^+ + C \rightarrow C^+ \qquad \text{(transition 4)}$$

where they recombine

$$C^- + C^+ \rightarrow C \qquad \text{(transition 5)}$$

The reverse reactions are assumed to be slow, and the numbers correspond to the transitions in Fig. 10. Efficient recombination through these mechanically introduced centers accounts for the over-all photocurrent suppression for polished ZnO. Since, in this model, donors become electron traps by association with defects, polishing should also decrease the electrode capacitance measured in the dark, as observed.

The specific effects observed for 380 nm light can be explained by assuming that this wavelength corresponds to an exciton transition in ZnO. This appears to be a reasonable assumption since ground state and bound excitons have been reported for ZnO in the literature (21-23). A luminescence peak is also observed in the same wavelength region (370 nm at 90°K), which is shifted to 380 nm at room temperature (12,13). It, therefore, seems probable that the 380 nm luminescence peak is associated with the decay of excitons. This is supported by the interpretation (8) of the luminescence decay in ZnO in terms of excitons.

We propose then that excitons produced by 380 nm light dissociate at lattice defects into free electrons and trapped holes (transition 6 in Fig. 10). Those holes trapped at defects isolated from recombination centers are removed only by direct recombination with free electrons (transition 7 in Fig. 10), which is expected to be a slow process compared to recombination via centers involving electron traps. Direct annihilation of these isolated trapped holes should be even slower because of electron trapping at C sites which reduces the free electron concentration. This buffered recombination for isolated hole traps accounts for the slow decay rate of positive charge introduced into the space charge region by 380 nm illumination. The specificity of the 380 nm light then arises because excitons produced at this wavelength are able to populate isolated hole traps which are not readily populated by free holes. The inefficacy of positive holes in filling these traps could be due to electrostatic repulsion, since an isolated defect would appear more positively charged than one associated with a filled electron trap. Some of the electrons introduced by the dissociating excitons migrate into the bulk producing the peak at 380 nm in the photocurrent spectrum.

Two factors are responsible for the effect of 380 nm light on the photocurrent measured at shorter wavelengths. The first is that holes trapped at isolated defects increase the field gradient within the space charge region by decreasing the Debye length of the

semiconductor, which enhances charge carrier migration and lowers the over-all recombination rate. With the increased positive charge available in the semiconductor, changes in the electrode potential have more effect on the potential gradient in the region of light absorption. Thus, the potential dependence is somewhat greater for the photocurrent around 380 nm and increases with light intensity.

The second factor responsible for the effect of 380 nm light on the photocurrent measured at shorter wavelengths involves the availability of electron traps. For an n-type semiconductor like ZnO, it is probable that the electron traps at C sites are highly populated, so that the recombination rate for the interband transition is limited by the supply of holes. In this case, the additional free electrons from the dissociation of excitons tie up more of the traps, reducing the trapping rate for electrons introduced by the interband transition. Since holes introduced by exciton dissociation are trapped at defects isolated from C sites, they have little effect on the over-all recombination rate.

In a modified version of the model presented above, the recombination center C can trap either an electron or a hole, but not both concurrently. In this case, the recombination process responsible for the over-all photocurrent suppression would still involve trapping of electrons by C, but C^- would be emptied by direct reaction with free holes. Fast recombination would then be represented by

$$e^- + C \rightarrow C^- \qquad \text{(transition 3)}$$

$$C^- + h^+ \rightarrow C \qquad \text{(transition 8)}$$

where the numbers correspond to the transitions in Fig. 10.

This modified model still requires excitons to explain the specificity of the 380 nm light. Trapped positive charge would then be introduced into the space charge region by reaction of excitons with C to produce C^+ (transition 6 in Fig. 10). The latter would presumably be slow to recombine with electrons (transition 7) because of the greater required energy transfer compared to reaction of C^- with free holes. In this model, two factors account for the photocurrent peak at 380 nm and the effect of 380 nm illumination on the photocurrent measured at 360 nm. One is the enhanced rate of charge transfer through the space charge layer caused by the accumulation of positive charge, as cited for the original model. In addition, as C is ionized to C^+, the concentration of active centers for trapping electrons (transition 3) diminishes, so that the rate of recombination via consecutive transition 8 is reduced.

Summary

Our results show that polishing of ZnO single crystals produces hole traps near the surface which act as efficient recombination centers, probably in conjunction with electron traps, reducing the photocurrent measured at a reverse-biased electrolyte contact. A specific transition is effected in ZnO by light of about 380 nm wavelength, resulting in the introduction of electrons into the conduction band and filling of the mechanically generated traps with holes. These traps are not filled effectively by free holes produced by illumination with light of shorter wavelengths.

It is proposed here that mechanically induced defects, when isolated from electron traps, do not capture free holes efficiently because of electrostatic repulsion. Excitons which migrate to isolated lattice defects, or are possibly bound to such defects, however, are produced by light of about 380 nm wavelength and effectively populate the hole traps because of their net charge neutrality. The trapped holes thus introduced are protected from recombination by their isolation from electron traps. Alternatively, the mechanically induced defects can trap either holes or electrons, but not both concurrently. If this is the case, the data can be understood if the hole traps can be filled only by excitons and are protected from recombination by energetic considerations.

It may seem surprising that no attempt has been made to interpret our results in terms of surface effects since holes might be expected to be stabilized through solvation with electrolyte species. The problem with the specificity of the 380 nm light would still remain, however, and would be difficult to explain. The arguments presented here are in fact equally applicable to processes occurring at the surface.

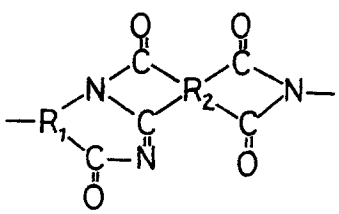
A New Transistor with Two-Level Metal Electrodes

Atsushi Saiki, Seiki Harada, Toshio Okubo, Kiichiro Mukai, and Takeshi Kimura

Hitachi, Limited. Central Research Laboratory Kokubunji 185, Tokyo, Japan

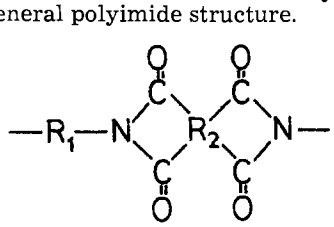
ABSTRACT

A new transistor with two-level metal electrodes is developed in order to allow for the automatic wire bonding process and at the same time to minimize the chip area. To meet these requirements, the second-level electrodes are formed right above the active area of a conventional transistor by utilizing the PMP (planar metallization with polymer) technology (1) with PIQ (polyimide iso-indroquinazolinedione) film as an insulating layer. PIQ is a thermally stable polyimide-type resin specially synthesized by us for the semiconductor devices. Through several types of reliability tests, it is shown that the new transistor exhibits excellent reliability in its device characteristics, indicating that the new structure satisfies the stringent reliability and productivity requirements for transistors molded in plastics.



In discrete transistors, reliability and productivity requirements are very stringent. In order to satisfy these requirements, a new transistor with two-level metal electrodes has been developed. The second-level electrodes of this transistor were formed on the surface of a conventional transistor utilizing PMP technology (1, 2). The second-level electrodes were formed on the whole surface of transistor pellet so as to obtain a larger area for wire bonding than the first-level electrodes. Therefore, this electrode structure has improved the productivity of the wire bonding. This is one of the features of the new transistor. In this electrode structure, PIQ film is utilized as an insulating layer. PIQ is a polyimide-type resin specially synthesized by us for semiconductor devices. It has been shown that the PIQ film has the ability to protect the transistor surface. Therefore, the stability and reliability of transistors with PIQ as a protection film are excellent. This is another feature of this new transistor.

The Process for Two-Level Electrodes



The two-level metal electrode structure is fabricated as shown in Fig. 1. A PIQ prepolymer solution is coated on the surface of a conventional transistor in the same manner as photoresist polymer, and is thermally cured (a). Then through-holes are formed by the conventional photoetching technique (b). In this process, a hydazine solution is utilized as an etchant for the PIQ film. Then aluminum is evaporated and photoetched to form the second-level metal electrodes (c). Finally, Au-wires are bonded to the second-level electrodes (d).

Properties of PIQ Film

PIQ contains a thermally stable isoindroquinazolinedione ring, represented by the following general formula

where R_1 and R_2 are aromatic rings. Isoindroquinazolinedione gives additional thermal stability to PIQ compared with general polyimide structure.

Key words: transistor, electrode, polyimide, productivity, reliability.

Figure 2 shows the heat-resisting properties of the PIQ compared with commercially manufactured polyimide. The comparison was carried out as follows: A solution of each polymer with proper viscosity was coated on silicon wafers and thermally cured at the proper temperature. The polymer films thus formed were kept at temperatures of from 200° to 450°C for 5 hr in air. After this heat-treatment, the thickness of each film was measured and compared with the inital thickness.

From Fig. 2 it is shown that the PIQ film keeps its initial thickness even after heating at 450°C for 5 hr; on the other hand, commercially manufactured polyimide losses 15-20% of its initial thickness after the same thermal test. This shows that PIQ is thermally stable enough to be used as an insulating layer in this structure.

In the new transistor the PIQ film was formed about 4 μm thick, so as not to increase the capacitance between the second-level electrodes and the silicon substrate. In order to form a 4 μm thick film, PIQ must

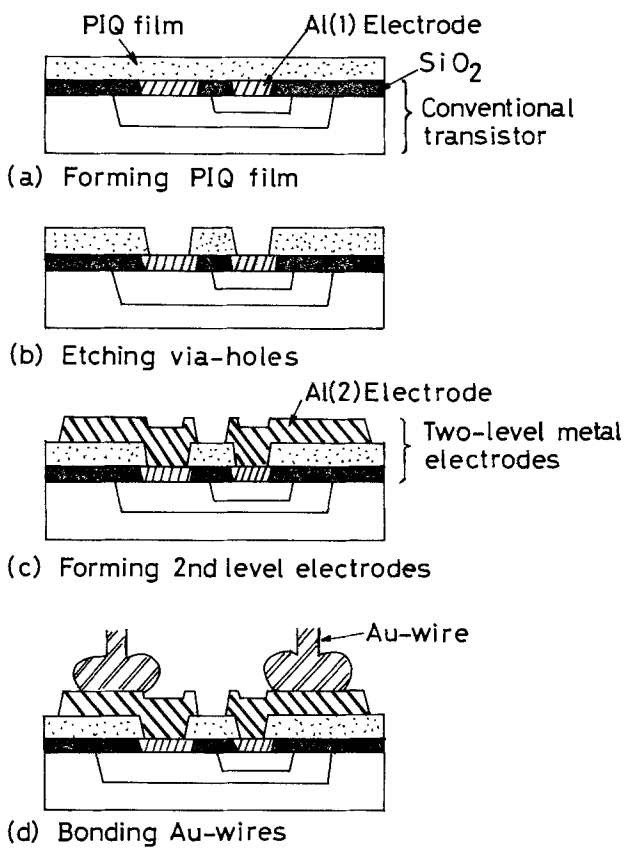


Fig. 1. Process for two-level metal electrodes

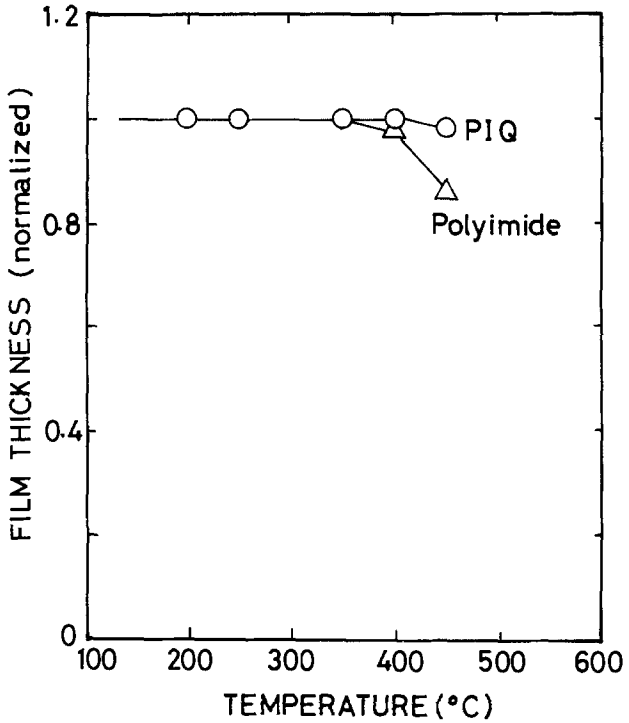

Fig. 2. Thermal degradation of polymers

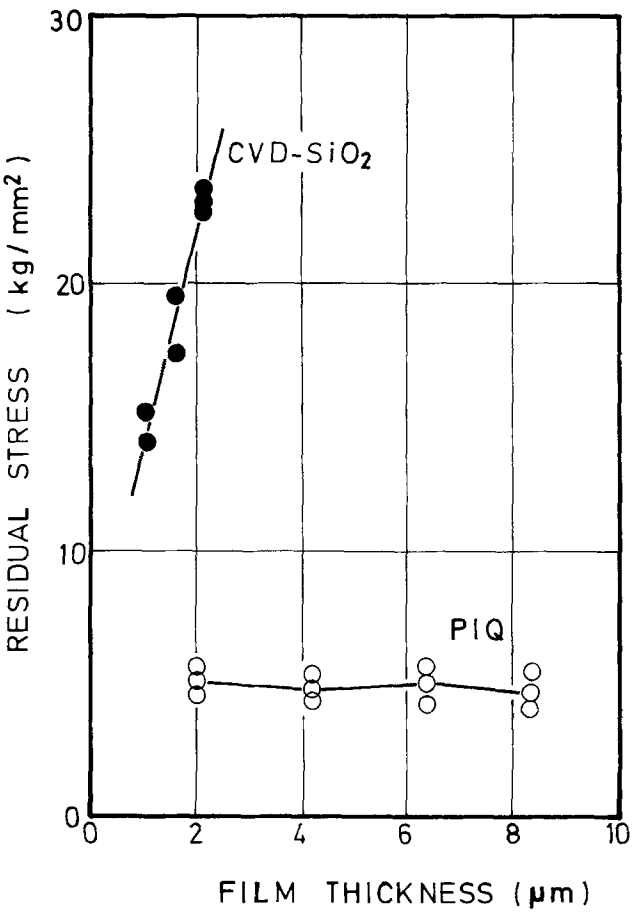

Fig. 3. Residual stresses of the thin films formed on silicon wafers

have a low residual stress. Figure 3 shows the residual stress of the PIQ film as a function of the film thickness, compared with that of silicon dioxide formed by chemical vapor deposition. The stress was obtained by measuring the curvature of the silicon wafers on which the films were formed. The PIQ residual stress is independent of film thickness, and is much smaller than that of the silicon dioxide. Very low stress in the PIQ film makes it possible to form a film as thick as 4 μm without any cracks. In addition to these properties, PIQ film has a breakdown voltage as high as 300V at 1 μm thickness. The dielectric constant of PIQ is about 3.8 at 1 MHz, which is similar to that of silicon dioxide (1).

Influence of PIQ Coating on Device Characteristics

Diode leakage current.—Test diodes with two-level metal electrodes were fabricated and the diode leakage current characteristics during a high temperature reverse bias test were evaluated. The results are shown in Fig. 4. The second electrode of the diode is formed to the same dimensions as the p^+-diffused resin, which has a diameter of 500 μm. The leakage currents were measured at a temperature of 125°C and a reverse bias voltage of 200V.

The reference diode without any protective coating shows a rapid increase in leakage current. On the other hand, the test diode shows little increase, and the amount is 2 orders smaller than that of the reference diode. These results show that the charge migration along the PIQ surface from the second electrode hardly affects the leakage current.

Transistor characteristics.—Two-level electrodes were formed on the transistor surface. The first-level electrodes of this transistor do not completely cover the SiO_2 contact windows, as shown in Fig. 5. This transistor was exposed to temperatures of from 100° to 450°C in air for several minutes, and current amplification factors were measured and compared with the initial values. In fabricating the electrodes, two kinds of polymers were used as insulating film. One is PIQ and the other is commercially manufactured polyimide. The results are shown in Fig. 4. In both devices of the pnp- and the npn-type, no change in this factor in transistors in which the PIQ film was used was observed after exposure at 450°C. On the other hand, in the transistors using polyimide, a decrease in this factor was observed over 200°C. This decrease is considered to be due to the penetration of contaminants such as sodium ions which were contained in the polyimide film, through the portion not covered by aluminum.

It has been verified by atomic absorption spectroscopic analysis that the sodium content of PIQ film is less in quantity than that of silicon dioxide film formed by chemical vapor deposition. Therefore, neither metallic impurities nor ionic contaminants which degrade transistor characteristics are contained in the PIQ film.

Another evaluation of the current amplification factor was carried out on the same transistor as that described above, as follows: After two-level metal electrodes were formed, the transistors were molded in plastics and were subjected to a 48 hr high temperature reverse bias test at 150°C, 100V. Figure 6 shows a comparison of the current amplification factors of the npn-

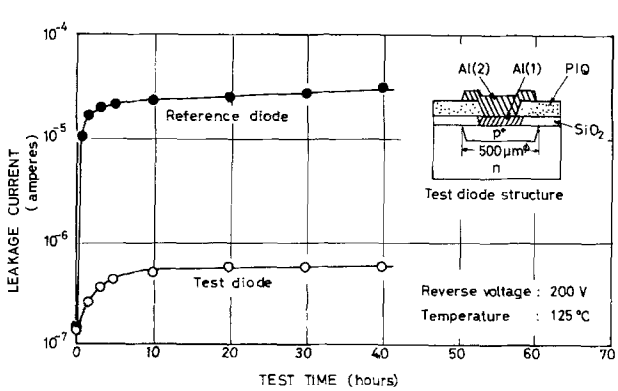

Fig. 4. Reverse current characteristics in the high temperature reverse bias test at 125°C, 200V.

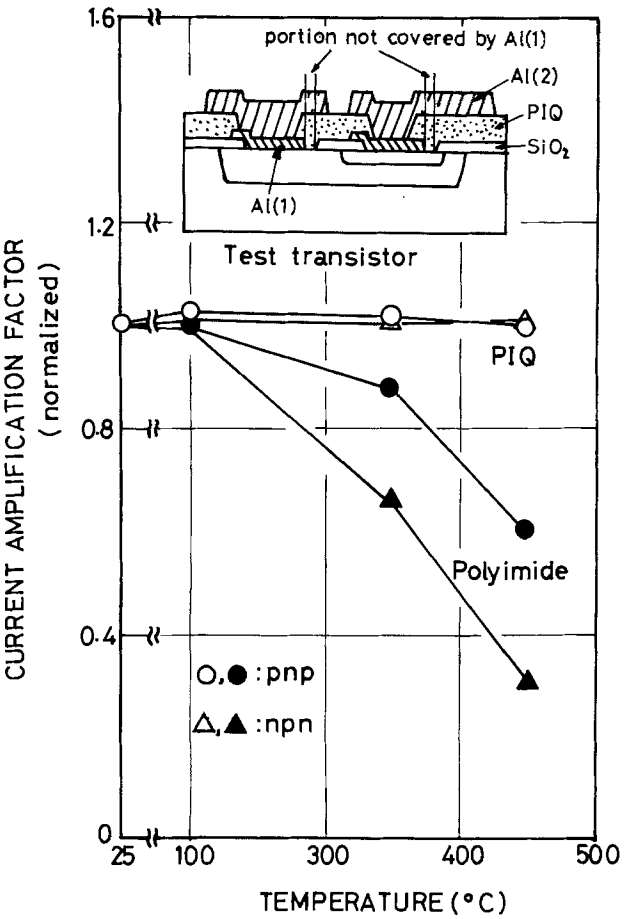

Fig. 5. Changes in current amplification factors vs. temperature

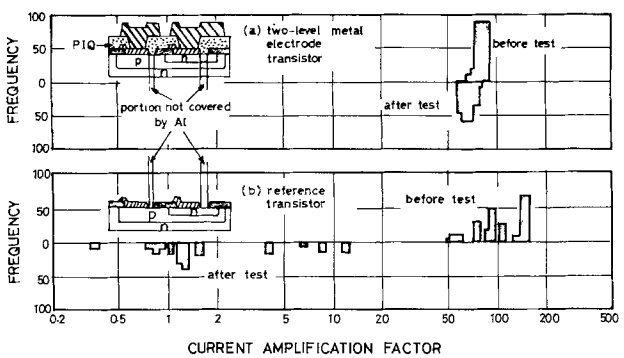

Fig. 6. Changes in the current amplification factors during the 48 hr high temperature reverse bias test (150°C, V_{CES} = 100V).

type transistors before and after the test. In the new transistors, changes in this factor were hardly observed, as is shown in Fig. 6(a). On the contrary, in the reference transistors without any protective coating, a drastic decrease in this factor was observed, as shown in Fig. 6(b). This decrease is considered to be due to the penetration of contaminants contained in the mold resin into the semiconductor body. Therefore, the stable properties of the new transistor are attributable to the ability of the PIQ to protect the transistor surface.

Figure 7(a) shows a transistor pellet made by this new technique. The PIQ film is formed so as to cover the whole surface of the conventional transistor pellet, which is shown in Fig. 7(b). After through-holes are etched, the second electrodes are formed. The effective area of the electrodes for wire bonding is larger than that of conventional electrodes without enlarging the size of the transistor pellet. After the second electrodes are formed, Au-wires are bonded to them. Figure 8 shows a cross section of the wire bonded portion. No

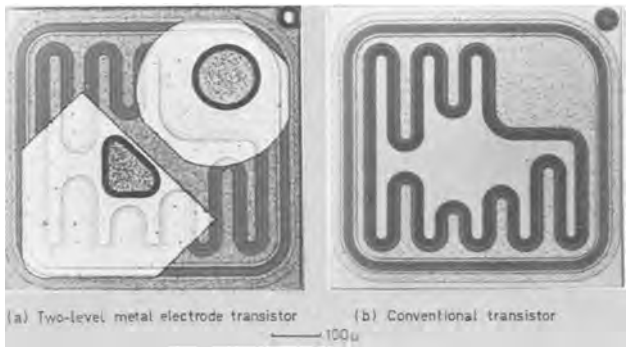

Fig. 7. An example of the two-level metal electrode transistor, (a) two-level metal electrode transistor, and (b) conventional transistor.

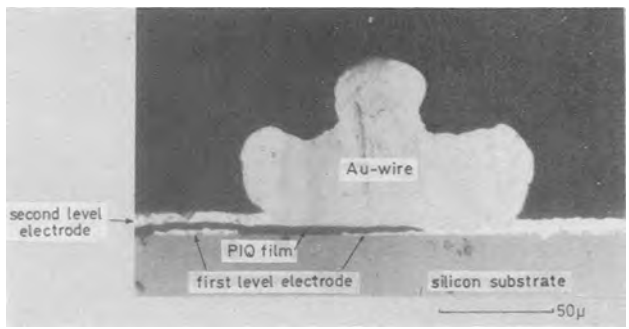

Fig. 8. Cross section of the wire bonded portion

plastic deformation was observed in the PIQ film right under the wire bonded portion of the second electrode. This electrode structure has remarkably improved the productivity of transistors in automatic wire bonding. It can also be seen from Fig. 8 that the coverage of the second-level electrode at the PIQ through-hole edge is very good. This is because of the gentle slope of the edge which is formed by hydrazine solution etching.

Reliability

The reliability and stability of transistors molded in plastics were evaluated by many kinds of tests. Table I shows the results of the reliability test. An operational life test was carried out under twice the maximum power dissipation specifications. After 500 hr of operation, only two of 250 samples of pnp and one of 100 samples of npn devices were degraded. This degradation was found not to be due to the electrode structure as a result of failure analyses. In the humidity test at 80°C and 90% RH, neither degradation of collector-base breakdown voltage nor collector-base junction leakage current was observed even after 3000 hr. In the

Table I. Results of reliability test

	Test conditions	Test time (hr)	Results* pnp	Results* npn
Operational life test	Twice the maximum power dissipation specifications	500	2/250	0/100
		1000	0/248	1/100
Humidity test	80°C, 90% RH	1000	0/50	0/100
		2000	0/50	—

* Denominators are the number of test samples, and numerators are number of degraded samples.
** High temperature reverse bias test.

pressure cooker test, samples were exposed in water vapor at 125C and 2 atm. This is one of the most severe tests for transistors molded in plastics. In this test, only one of 200 samples was degraded. However, this degradation was found to be due to defects in the photoresist film and not due to the PIQ film itself. In the thermal cycle test, samples were kept at 100°C for 30 min at first, and then cooled to −30°C and kept at this temperature for 30 min. No sample degraded in this test after 300 cycles. A high temperature reverse bias test (HTRB) was carried out at 110°C, and maximum reverse voltage was applied. After a 300 hr test, no degradation in the collector-base junction leakage current was observed.

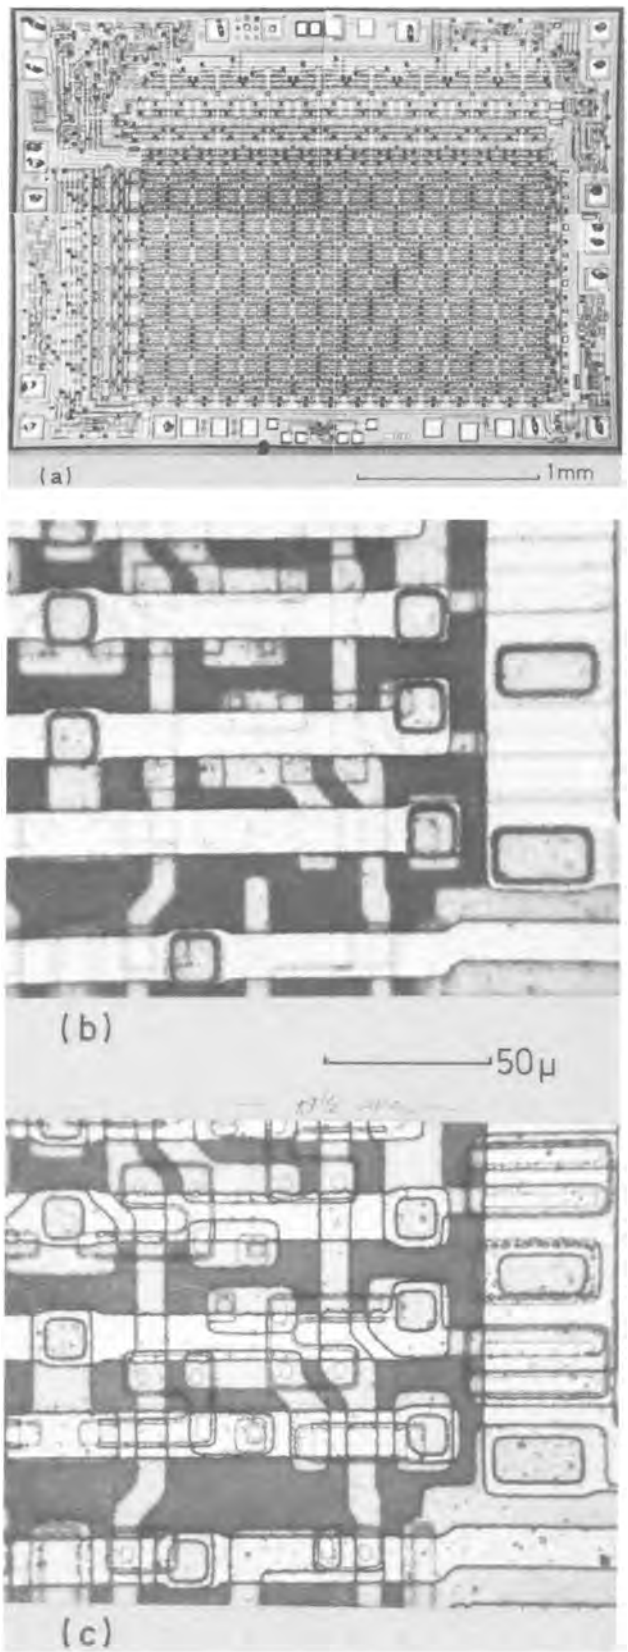

Fig. 9. Two-level metallization on LSI utilizing PIQ film. (a) LSI pellet with about 2000 elements; (b) enlarged photograph of a portion of the LSI made by PMP technology utilizing PIQ film as an insulating layer; (c) same portion as (b) made by conventional technique utilizing CVD SiO_2 as an insulating layer.

Application to LSI's

It has been verified as a result of developing the new transistor that the process and structure of two-level metallization utilizing PIQ is very reliable. This PMP technique can be applied also to multilevel interconnection on monolithic LSI's.

Figure 9(a) shows an example of two-level metal interconnections on a LSI utilizing 2 μm thick PIQ film. Fig. 9(b) is an enlarged photograph of a portion of the LSI made by PMP, and Fig. 9(c) is the same portion of the LSI made by the conventional technique utilizing CVD SiO_2 as an insulating layer. From Fig. 9(b), it can be seen that the second-level metallization is formed on a planar surface, and that the coverage of the second aluminum at the crossover is excellent. In the conventional structure, however, the steps of the second metallization are very clearly observed. Therefore, this new structure can improve the reliability and yield multilevel interconnections. Even a three or more level structure can easily be formed by using this planar technique.

Conclusions

A new transistor with two-level metal electrodes has been developed utilizing PIQ film. PIQ is a polyimide-type resin specially synthesized by us for semiconductor device, and has excellent physical, thermal, and electrical properties. It is shown that the productivity and reliability of transistor characteristics is met by this new electrode structure. This metallization technique is also applied to multilevel interconnections on monolithic LSI's, taking advantage of its planar characteristics.

ABSTRACT

Impedance measurements were made at the dark n- and p-type GaP single crystal electrodes in aqueous indifferent electrolyte solutions as a function of applied voltage and of frequency. The results allow the determination of the flatband potential and hence of the position of the Fermi level and the conduction and valence band edges at the electrode surface. The observed frequency dependence of the capacitance can be attributed to dipole relaxation phenomena in the space-charge layer of the semiconductor electrode. The influence of preliminary etching on the frequency behavior is discussed.

Gallium phosphide is an interesting semiconductor electrode from both the fundamental and the applied point of view. Indeed, since GaP has a relatively wide bandgap (2.25 eV) and exists as well in n-type as in p-type form, it constitutes an appropriate material for distinguishing between electrochemical processes involving the conduction band and the valence band, respectively, and hence for testing the validity of the current theories concerning electron exchange at the semiconductor/electrolyte interface. Some interesting reactivity studies on the GaP electrode have been reported by Memming (1, 2). The practical importance of the GaP electrode is associated with the fact that p-type GaP can be used as the photocathode in electrochemical cells in which water is decomposed by solar energy, although at present, the actual operation of such cells still gives rise to problems (3).

It is clear that for both fundamental and practical purposes it is essential to possess reliable information concerning the GaP/electrolyte interface. Such information is generally obtained from capacitance measurements. As has repeatedly been observed with other semiconductor electrode materials, difficulties usually arise in the interpretation of such measurements and more specifically in the determination of the flatband potential V_{fb}, due to the frequency dependence of the capacitance.

From a study which we made earlier on the frequency dependence of the impedance of several semiconductor electrodes such as CdS, CdSe, and TiO_2, we have developed a theory which gives an interpretation of the observed frequency laws and which permits, in certain cases, the determination of V_{fb} in spite of the frequency dispersion of the cell capacitance (4). Impedance measurements as a function of applied voltage at the GaP electrode in aqueous electrolyte, made by Memming (1) and by Eletskii (5), were restricted to one frequency only. On the other hand, Mott-Schottky plots, measured by Dehmlow *et al.* (6) at the n-type GaP electrode in aqueous and in organic medium at different frequencies, show a rather unusual frequency behavior, since the capacitance appears to increase with frequency. Therefore, we thought it would be interesting to investigate the frequency dependence of the impedance of n- and p-type GaP in contact with an aqueous electrolyte, not only in order to check the generality of the frequency laws observed earlier on other semiconductor electrodes and of the theory interpreting these laws, but also in order to deduce the exact value of the flatband potential, which is an essential parameter in semiconductor electrochemistry.

The present work contains the results of a study of the impedance of single crystal n- and p-type GaP electrodes as a function of frequency, applied voltage, composition of the aqueous electrolyte, and pretreatment of the crystal surface.

Key words: semiconductor, electrochemistry, dielectrics, surface phenomena, energy levels.

Experimental

The apparatus consisted of an electrochemical cell and an electrical measuring circuit. The electrochemical cell contained a GaP single crystal electrode, a Pt counterelectrode, a saturated KCl calomel reference electrode, and an aqueous electrolyte. This cell was mounted in a grounded metallic box in order to exclude electrical disturbances as well as light.

The electrical circuit permitted the application of a variable voltage between the semiconductor and counterelectrode, and the measurement of the potential of the semiconductor electrode with respect to the reference electrode by means of a Solartron 7040 voltmeter, the cell current by a Hewlett Packard 425 A d-c microvoltammeter, and the impedance between the semiconductor and the counterelectrode by means of an Electro Scientific Industries capacitance bridge 277 and a-c generator-detector 861 A (frequency range between 20 and 20,000 Hz).

The n- and p-type GaP single crystals, which had the form of slabs, cut perpendicular to the [111]-axis, were obtained from Elcomat-Cmf (Mechelen, Belgium). Since no equipment for making Hall measurements was available in our laboratory, we used the manufacturer's specifications, which were for the n-type samples: specific conductivity $\sigma \simeq 1000\ \Omega^{-1}\ m^{-1}$ and donor concentration $N_D \simeq 4.8 \times 10^{23}\ m^{-3}$; for the p-type samples: $91 < \sigma < 670\ \Omega^{-1}\ m^{-1}$ and acceptor concentration $7.8 \times 10^{22} < N_A < 7.5 \times 10^{23}\ m^{-3}$.

Damage caused by cutting the crystals was removed by subsequent mechanical polishing and chemical etching and polishing. The mechanical polishing was performed as follows: the crystals were polished first with 15 μm Al_2O_3 powder (Buehler) on a glass plate until homogeneous roughness, and afterward with Al_2O_3 of diminishing particle size (5-1 μm and sometimes 0.3 μm) on a polishing cloth (AB Rayvel® from Buehler), in order to obtain a shiny, scratch-free surface.

A solution of 0.5M KOH and 1M $K_3Fe(CN)_6$ in water allowed differentiation between the smooth $(\bar{1}\bar{1}\bar{1})$-face (P) and the pitted (111)-face (Ga) (7). In one particular case, we used a H_2SO_4:H_2O_2:H_2O (3:1:1) etch. A concentrated HCl solution, which was the etchant for GaP used by Memming (1), was also used but appeared to remove much less material than the former etching solutions, as proved by weighing the crystals.

For both n- and p-type, the $(\bar{1}\bar{1}\bar{1})$-face was exposed to the electrolyte in our experiments. Ohmic contact to n-type GaP was made by melting In on the Ga-face of the crystal at 400°C under a hydrogen stream. On p-type GaP, contact was made by means of a Ag-In-Zn (8:1:1) or a Au-Zn alloy evaporated on the Ga-face and melted at 650°C under an argon stream.

An insulating paint was used to separate the contact from the electrolyte. All chemicals, used as indifferent electrolyte, were reagent grade. Before each measurement, high purity nitrogen was bubbled through the solution in order to remove dissolved oxygen. The measurements were made at room temperature and in darkness. In what follows, the GaP electrode potential is expressed with respect to the standard hydrogen electrode (SHE).

Results

N-type GaP.—Current-voltage and capacitance-voltage measurements.—The n-GaP/indifferent electrolyte contact demonstrated blocking properties under anodic bias. Under these circumstances, the impedance measurements were performed. The capacitance data for an n-GaP electrode in a solution of 1M KCl and 0.01M HCl in water are represented in Fig. 1a as C_s^{-2} *vs.* V (Mott-Schottky plot), C_s being the series equivalent capacitance in $f \cdot m^{-2}$. In acid solutions, the slope of the Mott-Schottky plots was only slightly frequency dependent; the point of intersection with the V-axis was frequency independent and could hence be used for the determination of the flatband potential V_{fb} (see discussion). The following values were found for our samples: $V_{fb} = -1.10V$ *vs.* SHE at $pH = 2.1$ and $-1.21V$ *vs.* SHE at $pH = 4.8$. The shift of V_{fb} toward more negative voltages with increasing pH suggests that an acid-base equilibrium is established at the GaP surface.

For the rest potential V_R in $pH = 2.1$ (corresponding to zero current through the external circuit), we found $V_R = V_{fb} + 1.35V$, so that, assuming that the Helmholtz potential is independent of applied voltage (see discussion), it can be concluded that at $V = V_R$, a depletion region is present, the band-bending being 1.35 eV.

In alkaline solutions, *i.e.*, at $pH = 9.2$ and 12, no reproducible measurements could be carried out. The Mott-Schottky curves exhibited a large frequency dispersion and the intersection with the V-axis was also frequency dependent. The frequency dispersion still increased after long anodic prepolarization. When the sample was subsequently brought to acid medium ($pH = 2.1$), the frequency dependence was drastically reduced and the Mott-Schottky plots had again the aspect as shown in Fig. 1a. In what follows, only results obtained in acid medium are considered.

Frequency laws.—As can be seen from Fig. 1a, the cell capacitance is slightly frequency dependent in acid medium, the slope of the Mott-Schottky plots increasing with frequency, in contrast to the case observed by Dehmlow (6). To a frequency-dependent series capacitance C_s corresponds a frequency-dependent series resistance R_s, the functions describing the frequency dependence of both quantities being interrelated by the Kramers-Kronig relations (8). Therefore, in order to study the frequency dispersion of

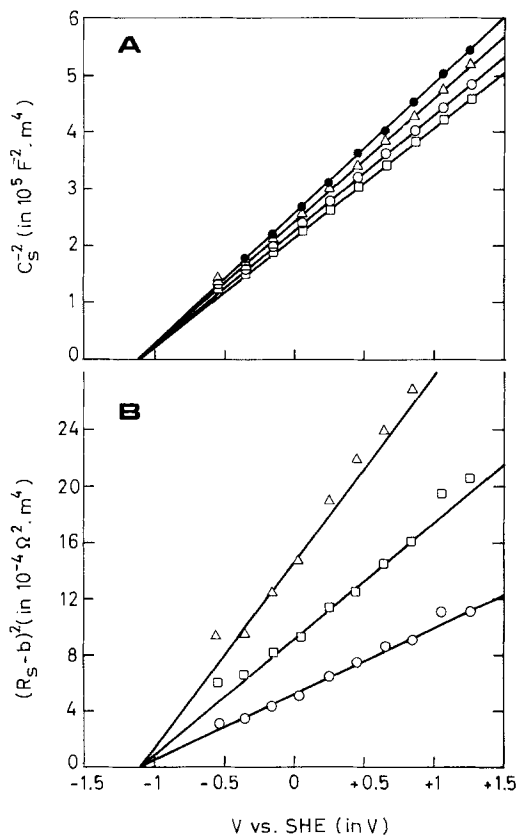

Fig. 1. A. Mott-Schottky plot, n-type GaP in an aqueous solution of 1M KCl + 0.01M HCl. □, 130 Hz; ○, 800 Hz; △, 20,000 Hz; ●, C_{ex}^{-2} (see discussion). (The dashed line has a slope -1.)

the impedance, it is sufficient to consider the frequency dependence of R_s, which is much more pronounced than that of C_s.

At constant voltage, the following law, which was found before in the case of TiO_2, CdS, and CdSe (4), was observed to hold in the present case as well

$$R_s = a \cdot f^n + b \qquad [1]$$

where f denotes the frequency, and where in all cases observed

$$-1.70 < n \leq -1.09 \qquad [2]$$

Some examples are shown in Fig. 2, where $\log(R_s - b)$ is plotted *vs.* $\log f$, yielding, linear plots with slope n. The value of the term b was determined by consecutive approximations (4). This term represents the sum of all frequency-independent series resistances in the cell circuit, the main contribution being that of the electrolyte.

The value of n appeared to be independent of the voltage over a range of $\simeq$ 1.5V, but to depend on the pretreatment of the sample. This is clearly demonstrated in Fig. 2, showing results obtained on one particular sample, which was etched in HCl on one occasion, yielding $n = -1.09$, and in $H_2SO_4/H_2O_2/H_2O$ (3:1:1) on an other occasion, leading to $n = -1.43$. This trend was found to be general: etching in HCl, a procedure by which only little surface material was removed, leads to n-values close to -1, whereas thorough etching, such as in $H_2SO_4/H_2O_2/H_2O$ or in $KOH/K_3Fe(CN)_6/H_2O$, causes n to be more negative. Hence, the value of n seems to be determined by the degree to which surface damage has been removed from the electrode. The influence of the pretreatment was also observable in the Mott-Schottky plots, in the sense that the frequency dispersion was more pronounced when the samples had been etched in HCl than when a more drastic etching procedure had been used.

Anticipating the discussion, it can be said here that the theory (4), accounting for the type of results such as represented in Fig. 1a, predicts that a linear relationship should exist between $(R_s - b)^2$ and V, the linear $(R_s - b)^2$ *vs.* V plots registrated at different frequencies converging to the same common point on the V-axis as the Mott-Schottky plots. This expectation is indeed fulfilled in the present case, as can be seen from Fig. 1b.

P-type GaP,—Current-voltage and capacitance measurements.—To obtain blocking properties for the p-GaP/indifferent electrolyte contact under cathodic bias, a longer mechanical and chemical polishing procedure than for the n-type specimen was necessary. This fact has been observed before by Memming (9). In all further experiments with p-type GaP, an alkaline hexacyanoferrate etch was used. All measurements were made in acid medium. The impedance measurements were restricted to samples which were characterized by a very low cathodic dark current density ($< 10^{-3}$ A·m^{-2}).

Typical Mott-Schottky plots at different frequencies, converging to a common point on the V-axis, are shown in Fig. 3a. The frequency effect was generally smaller than for n-type GaP electrodes. The following values were found for the flatband potential of our samples: $V_{fb} = +0.83$V at pH = 2.1, $V_{fb} = +0.70$V at pH = 4.0, and $V_{fb} = 0.67$V at pH = 4.8.

The rest potential of p-GaP was found to be $V_R = V_{fb} - 0.50$ at pH = 2.1.

Frequency laws.—In the cases investigated, the frequency dependence of C_s and R_s was very low. Nevertheless, the results permitted the conclusion that also here Eq. [1] holds, n being approximately equal to -1 and independent of voltage. As shown in Fig. 3b, the $(R_s - b)^2$ *vs.* V plots are linear (except for the region near V_R where R_s increases considerably) and intersects the V-axis at the same voltage as the Mott-Schottky plots.

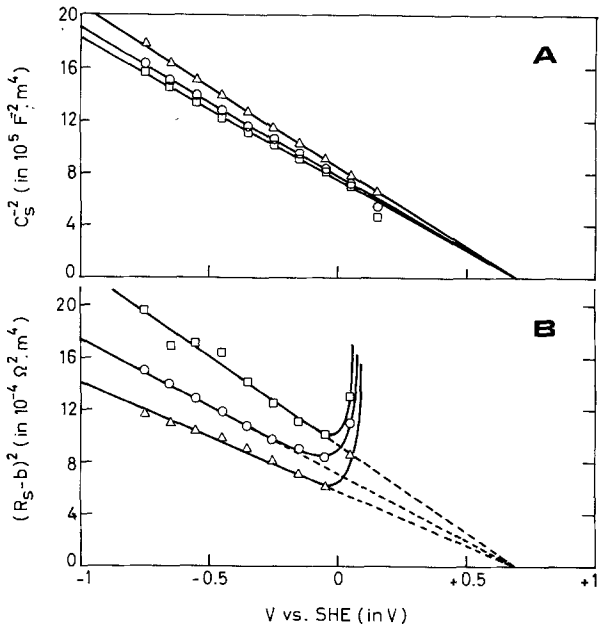

Fig. 3. A. Mott-Schottky plot, p-type GaP in an aqueous solution of 1M KCl + 0.8M HAc + 0.2M NaAc. □, 220 Hz; ○, 800 Hz; △, 20,000 Hz. B. $(R_s - b)^2$ *vs.* V for the same measurement. △, 320 Hz (all values are multiplied by 6); □, 800 Hz (all values are multiplied by 80); ○, 1330 Hz (all values are multiplied by 200).

Discussion

Voltage and frequency dependence of the impedance components.—From the facts that a blocking contact is formed and that the Mott-Schottky relationship is obeyed over a considerable voltage range with both n- and p-type GaP, it can be concluded that in both cases, a depletion region is present at the semiconductor electrode surface.

The observed frequency dependence of the series equivalent resistance is of the same type as observed before with other semiconductors (4, 10).

In a previous paper (4), arguments have been presented which show that the frequency dependence of C_s and R_s cannot be attributed to trivial causes such as seepage of solution between the electrode and its insulation, nor to the conversion to series elements of a parallel circuit which would consist of a frequency-independent capacitance and resistance. Moreover, a recent comparative study on GaAs/electrolyte and GaAs/metal interfaces demonstrates the validity of the same frequency laws in both cases, indicating that the origin of the effect is located within the semiconductor (11). A theory has been presented (4), in which it was assumed that the frequency effects are caused by dielectric relaxation phenomena, occurring in a layer at the semiconductor surface. The following expressions were then derived theoretically for the series equivalent capacitance $C_{L,s}$ and resistance $R_{L,s}$ of this layer, assuming that the dissipation is small

$$C_{L,s} = \frac{\epsilon_0 \epsilon(f)}{L} = \frac{\epsilon_0}{L}[\epsilon(\infty) + A_C \cdot f^{n+1}] \qquad [3]$$

and, in case that $\epsilon(\infty) >> A_C \cdot f^{n+1}$

$$R_{L,s} = A_R \cdot L \cdot f^n \qquad [4]$$

In these equations, L is the thickness of the layer in which the relaxation processes take place, $\epsilon(f)$ is the dielectric constant of this layer at frequency f, and $\epsilon(\infty)$ is the dielectric constant of this layer in the absence of the dielectric relaxation effects considered

here, and hence merely consisting of the ionic and electronic contributions of the perfect crystal, whereas A_C and A_R are coefficients, independent of applied voltage and of frequency. The possible values of the exponent n are limited by the inequality

$$-2 < n < -1$$

The value of n in a given case is determined by the shape of the distribution curve which describes the number of oscillating dipoles as a function of the corresponding activation energy in this sense that, the sharper the distribution curve, the more negative the value of n. Our results on the influence of etching on the value of n, as represented in Fig. 3, imply, in the framework of this theory, that a more thorough etch leads to a sharper distribution of activation energies and to a smaller frequency effect. Apparently, the number of dipoles causing the effect studied here is affected by appropriate etching.

In cases such as those observed in this work, where the Mott-Schottky plots corresponding to different frequencies intersect in one common point on the V-axis, and where the $(R_s - b)^2$ *vs.* V plots are linear and converge to the same common point on the V-axis, it must be assumed that the dielectric relaxation phenomena occur throughout the depletion layer at the semiconductor surface. Accepting this, L in the foregoing equations acquires the significance of the thickness of the depletion region, which, according to the Mott-Schottky theory, varies with applied voltage V according to the following relationship (taking, *e.g.*, the case of an n-type semiconductor)

$$L^2 = (2\epsilon_0\epsilon(o)/eN_D)(V - V_{fb} - kT/e) \quad [5]$$

In this equation, $\epsilon(o)$ is the static dielectric constant, comprising all polarization effects, and N_D is the donor density. Considering Eq. [3], [4], and [5] and the fact that, under the present conditions, $C_{L,s}$ equals the total measured capacitance C_s, whereas $R_{L,s} = R_s - b$, one finds

$$C_s^{-2} = \{2\epsilon(o)/\epsilon_0[\epsilon(f)]^2eN_D\}(V - V_{fb} - kT/e)$$
$$= [2\epsilon(o)/\epsilon_0eN_D][\epsilon(\infty) + A_C \cdot f^{n+1}]^{-2} \cdot (V - V_{fb} - kT/e) \quad [6]$$

$$(R_s - b)^2 = (A_R \cdot f^n)^2[2\epsilon_0\epsilon(o)/eN_D](V - V_{fb} - kT/e) \quad [7]$$

Equations [6] and [7] are in agreement with the experimental data on the voltage dependence enumerated above, and indicate that the common point of intersection of the linear plots corresponding to different frequencies is at $V = V_{fb} + kT/e$. This conclusion forms the justification for using this point to determine the flatband potential, as has been done in the results. From Eq. [3] and [5], it can be seen that, at given applied voltage, the relationship between the measured capacitance and f^{n+1} should be linear, the extrapolated value of the capacitance C_{ex} for $f^{n+1} \to 0$ being

$$C_{ex} = \epsilon_0\epsilon(\infty)[2\epsilon_0\epsilon(o)/eN_D]^{-1/2}(V - V_{fb} - kT/e)^{-1/2} \quad [8]$$

An experimental example is shown in Fig. 4 for a case where, from the frequency dependence of $R_s - b$, n was found to be equal to -1.18. It can be seen that the plot of C_s *vs.* $f^{-0.18}$ is indeed linear, permitting the determination of C_{ex} at $f^{-0.18} \to 0$, *i.e.*, at $f \to \infty$. Equation [8] implies that the plot of C_{ex}^{-2} *vs.* V should be linear. This point is confirmed experimentally as shown in Fig. 2a. As appears from Eq. [8], the slope of this linear plot equals

$$\Delta C_{ex}^{-2}/\Delta V = 2\epsilon(o)/\epsilon_0[\epsilon(\infty)]^2eN_D \quad [9]$$

By dividing this value by the slope of each individual

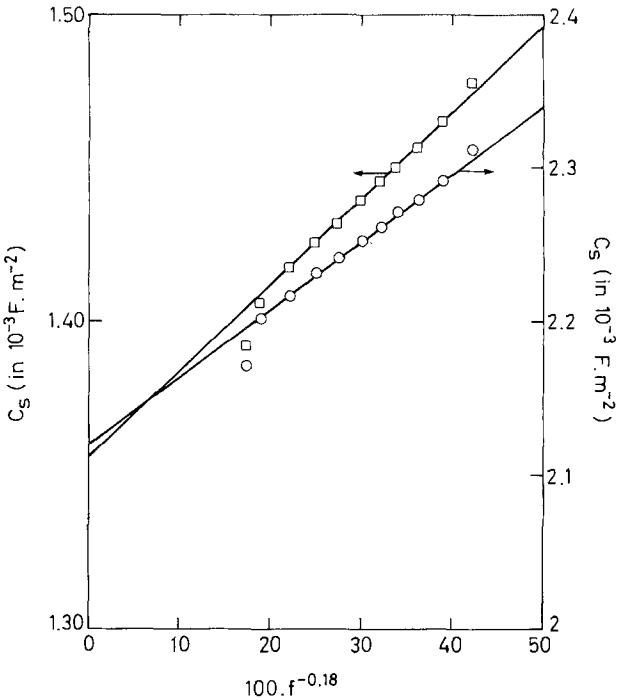

Fig. 4. C_s as a function of $f^{-0.18}$ for a sample with $n = -1.18$. □, At $V = +1.25$V *vs.* SHE (values on the ordinate on the left); ○, at $V = -0.15$V *vs.* SHE (values on the ordinate on the right).

Mott-Schottky plot registered at given frequency f, as given by

$$\Delta C_s^{-2}/\Delta V = 2\epsilon(o)\epsilon_0[\epsilon(f)]^2eN_D \quad [10]$$

(see Eq. [6]), the ratio $\epsilon(f)/\epsilon(\infty)$ can be deduced. In the frequency range of our experiments, this ratio varies from 1.18 at 130 Hz to 1.045 at 20,000 Hz, indicating that the frequency effect is relatively small in this frequency range.

Energy levels at the electrode surface.—In order to determine the position of the conduction bandedge E_c^s and of the valence bandedge E_v^s at the electrode surface, it is necessary to know not only the value of the flatband potential, but also that of the donor density N_D or the acceptor density N_A, respectively. Indeed, one has (12)

$$E_{F,fb}(n) = -eV_{fb}(n) \quad [11]$$

$$E_{F,fb}(p) = -eV_{fb}(p) \quad [12]$$

$$E_c^s(n) = E_{F,fb}(n) - kT\ln(N_D/N_c) \quad [13]$$

$$E_v^s(p) = E_{F,fb}(p) + kT\ln(N_A/N_v) \quad [14]$$

$$\Delta E_g = E_c^s - E_v^s \quad [15]$$

In these formulas, $E_{F,fb}(n)$ and $E_{F,fb}(p)$ represent the position of the Fermi level at flatband potential in the n- or p-type material, respectively, N_c and N_v the effective density of states of the conduction band and of the valence band, respectively; N_c and N_v were calculated to be approximately 10^{25} m^{-3} from a literature value for the effective mass of both electrons and holes in GaP being 0.5 × the electron mass (13). In Eq. [13] and [14], it is assumed that all donor levels are empty and all acceptor levels filled.

In view of the foregoing discussion, it is clear that difficulties arise in the determination of N_D or N_A from Mott-Schottky plots in case that the slopes are frequency dependent (see Eq. [10] for n-type). For the exact determination of N_D and N_A, the value of $\epsilon(o)$ and of the corresponding slope should be known which, as mentioned above, includes the contribution

of the dipoles causing the frequency effect observed here. Considering the fact that, in the frequency range studied, this effect is small, and assuming that the total effect over the entire frequency range is small also [*i.e.*, that $\epsilon(0)/\epsilon(\infty)$ is of the order of 1], the experimental results enabled us to determine the following approximation values for our samples: $N_D = 6 \times 10^{23}$ m^{-3} and $N_A = 1 \times 10^{23}$ m^{-3}. Note that the value for the n-type case is in satisfactory agreement with the specifications of the manufacturer, considering the fact that our results pertain to a thin layer underneath the surface only, and that the donor density distribution may be inhomogeneous.

The values of $E_{F,fb}$ at the given charge carrier concentration and of E_c^s and E_v^s, thus deduced from Eq. [11]-[15], are shown in Table I.

These results suggest that the semiconductivity type (n or p) has little influence on the structure of the Helmholtz layer at the GaP surface.

In view of the relatively low values of the dielectric constant of GaP, and of N_D and N_A in our samples, it is reasonable to assume that the fraction of the applied voltage change ($V - V_{fb}$) which occurs over the Helmholtz layer is negligible (14), so that the tabulated values of E_c^s and E_v^s can be considered to be fixed with respect to the SHE and hence to be also valid at voltages different from V_{fb}.

The high value calculated for $E_{F,fb}(n)$ is qualitatively in agreement with the high anodic band bending observed with the n-type GaP electrode at the rest potential and suggests that this electrode should yield high photovoltaic effects (15). Accordingly, preliminary measurements on this system yield a curve representing the photovoltage *vs.* the logarithm of the light intensity which, at a photovoltage of about 1V, does not show any saturation yet.

Table I. Energy levels at the GaP electrode surface

Energy level	Position (in eV *vs.* SHE) pH = 2.1 n	pH = 2.1 p	pH = 4.8 n	pH = 4.8 p
$E_{F,fb}$	+1.10	−0.83	+1.21	−0.67
E_c^s	+1.19	+1.29	+1.30	+1.45
E_v^s	−1.06	−0.96	−0.95	−0.80

Kinetics of the Epitaxial Growth of Silicon from a Tin Melt

B. Jayant Baliga*

General Electric Company, Corporate Research and Development Center, Schenectady, New York 12301

ABSTRACT

The growth of epitaxial layers of silicon from a tin melt has been examined over a range of cooling rates (0.2°-7°C/min). It is found that at cooling rates below 1°C/min, the growth rate increases with cooling rate, while at higher cooling rates the growth rate saturates. This behavior is due to the transition from mass transport limited growth to surface kinetically controlled growth. This has been confirmed by the measurement of the variation in epitaxial layer thickness across the wafer with and without stirring, at both slow and fast cooling rates.

The chemical vapor deposition of expitaxial layers of silicon has been extensively studied (1, 2). In contrast, very little work has been reported on the epitaxial growth of silicon films from the liquid phase. D'Asaro *et al.* (3) have reported on the growth of epitaxial layers of silicon with tin and tin-lead as solvents. However, their work was aimed at reducing epitaxial layer defects, and no information on the growth kinetics was provided. More recently, Kim (4) has described the use of liquid epitaxial growth of silicon for the formation of silicon pedestals as ohmic contacts to planar-diffused diodes. This paper examines the growth rate of epitaxial layers of silicon for the case of growth from a tin melt by using the dipping technique.

The growth of layers from the liquid phase has the advantage of requiring lower temperatures as compared to vapor phase epitaxial growth. This is important in the fabrication of silicon devices, because it

* Electrochemical Society Active Member.
Key words: silicon, liquid phase epitaxy, growth kinetics.

minimizes the changes in prediffused regions during epitaxial growth, and also allows the growth of an abrupt interface between the epitaxial layer and the substrate. In addition, most metallic impurities are expected to have segregation coefficients of less than unity. Consequently, the growth of layers from the liquid phase is expected to have a low concentration of such impurities. This is desirable for the fabrication of devices requiring high minority carrier lifetime for achieving good device characteristics.

In this paper it is shown that the growth rate of silicon epitaxial layers from a tin melt depends upon the cooling rate. At slow cooling rates the growth is demonstrated to be mass transport limited, while at fast cooling rates the growth becomes kinetically controlled. These observations have been confirmed by growth rate measurements with and without stirring during the growth. The author believes that this is the first time that kinetically controlled growth has been experimentally observed during the growth of liquid phase epitaxial layers.

Experimental Conditions

Apparatus.—All the epitaxial growth reported in this paper was performed using tin as the solvent. Tin was chosen as a solvent because its incorporation into the silicon during epitaxial growth does not introduce either shallow doping levels or deep lying recombination centers. Further, the solubility of silicon in tin, at growth temperatures of around 950°C, is sufficient to allow the growth of thick layers (up to 100μ) without serious depletion of the melt. High purity tin (5*N* purity) was cleaned in the laboratory by repeated heating in a quartz tube under vacuum until the impurities formed a slag on its surface, followed by removal of this slag by etching in concentrated hydrochloric acid.

The tin melt was heated to growth temperatures in a quartz crucible with a hydrogen ambient. The epitaxial reactor, as illustrated in Fig. 1, consisted of a quartz tube with a gate valve on top connecting the tube to a stainless steel baffle chamber. The melt was always maintained in a stream of hydrogen flowing from the bottom of the tube towards the top. This hydrogen was purified using a palladium diffuser to minimize contamination. The temperature of the melt was maintained to within ±1°C using a controller with a

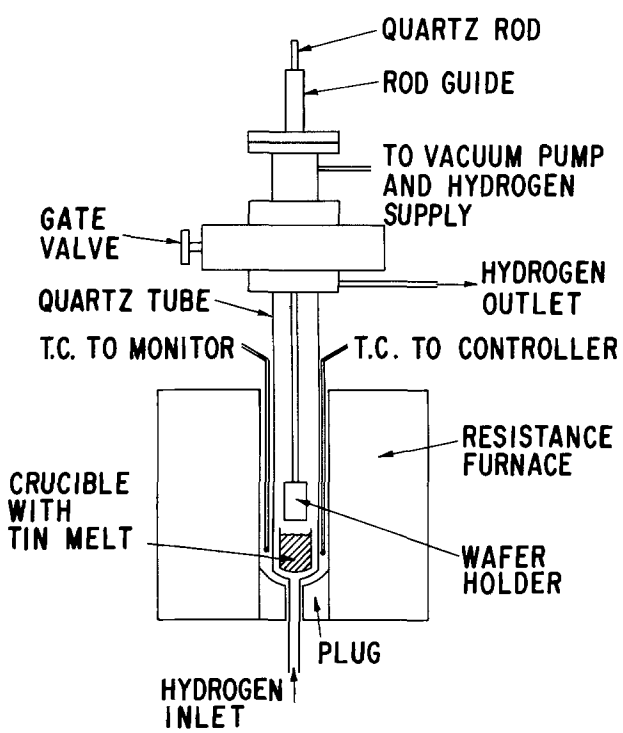

Fig. 1. Schematic diagram of liquid epitaxial growth system

Pt/Pt-Rd thermocouple to control the power fed to the furnace elements. The temperature of the melt was monitored by using another Pt/Pt-Rd thermocouple placed outside the quartz tube and positioned at the center of the crucible as shown in Fig. 1. The emf of this external monitor thermocouple was calibrated to the melt temperature by inserting a Pt/Pt-Rd thermocouple (in a quartz tube) into the melt, and maintaining the melt at various temperatures.

Growth Procedure.—The substrates and saturation wafers were inserted into the melt using quartz holders with a graphite bolt and nut assembly which held the wafer between quartz surfaces. The quartz holder was first inserted into the rod guide and the flange bolted to the baffle chamber to form a vacuum tight fit with an o-ring. The baffle chamber was then evacuated and backfilled with hydrogen. The gate valve was then opened to allow lowering of the holder into the melt.

Prior to each growth, the melt was saturated using a 100 Ω-cm, phosphorus-doped, float zone silicon wafer. During saturation the melt was stirred by oscillation of the quartz holder about a vertical axis. The saturation was conducted until no further loss in the weight of the saturation wafer could be detected. It was observed that 0.47g of silicon were required to saturate a fresh 99g tin melt at 950°C. This is in good agreement with the 2 atomic percent (a/o) solubility of silicon in tin at this temperature (5). After each epitaxial growth, the silicon in the melt was replenished using the same procedure.

The epitaxial layers were grown on (111) oriented, 0.01 Ω-cm, boron-doped silicon substrates. The growth was conducted on the polished face of the wafers as received from the vendor. The wafers were degreased and given a dip in hydrofluoric acid just before loading into the reactor. The substrate temperature was brought up to the melt temperature by holding the wafer above the melt for 10 min. The wafer was then inserted into the melt and the temperature of the melt lowered at known cooling rates ranging from 0.2° to 7°C/min. The fastest cooling rate of 7°C/min was achieved by turning off the power to the furnace for the duration of the growth. The growths reported in this study were conducted with no supersaturation of the melt, *i.e.*, the melt was always saturated at the temperature at which the substrate wafer was introduced into the melt. Growth times ranging from a few minutes up to several hours were used, depending upon the cooling rate, to achieve undercooling of the melt of up to 100°C. In all cases, the epitaxial growth was initiated at 950°C. After the growth period, the substrate was first removed from the melt and then the furnace cooling terminated to avoid any possible melt-back effects. Some tin was usually found to be present on the bottom edge of the wafer after growth. This tin was removed by etching in aqua regia.

The layers grown in this study were observed to be of n-type conductivity because the melt was saturated with phosphorus-doped wafers. Since the growth was conducted on p-type substrates, the epitaxial layer could be defined by angle-lapping and delineating the junction with a copper sulfate solution. The epitaxial layer thickness was then measured using an interferometer. Using this procedure, the epitaxial layer thicknesses were measured to within ±0.2μ. In the absence of stirring, the thickness of the epitaxial growth was found to be within ±10% over the entire wafer. With stirring, the layer thickness was found to vary radially from the axis of rotation as explained in the discussion section of the paper. All the results given in the next section were obtained without any stirring of the melt.

Experimental Results

The variation of the epitaxial layer thickness was measured as a function of both cooling rate and the time duration of the growth. The five different cooling rates that were used in this study were 0.2°, 0.5°,

0.75°, 2.5°, and 7°C/min. The fastest cooling rate of 7°C/min was achieved by turning off the power to the furnace. At the slowest cooling rate setting of 0.2° C/min, the cooling rate was found to vary from run to run, and ranged from 0.165° to 0.25°C/min. Such variations were not observed at the higher cooling rates.

Figure 2 shows the variation in the epitaxial layer thickness as a function of the growth time with cooling rate as parameter. In this figure, the cooling rate of 0.2°C/min represents data points taken with cooling rates ranging from 0.165° to 0.25°C/min. As can be seen in this figure, the layer thickness increases linearly with growth time at each cooling rate. It is, therefore, possible to define a growth rate corresponding to each cooling rate. It is also observed that this growth rate increases with increasing cooling rate until a cooling rate of 2.5°C/min is reached, beyond which no further increase in growth rate occurs.

As seen in Fig. 2, thin epitaxial layers are formed for short growth periods (less than 30 min.) at low cooling rates. With longer cooling durations at these low cooling rates, thicker epitaxial layers can be achieved. An interesting correlation between epitaxial layer thickness and undercooling (temperature drop during the growth interval) is observed for such layers as shown in Fig. 3. It is observed that the layer thickness increases linearly with the undercooling. Further, the epitaxial layer thickness grown for any specific temperature drop during growth is independent of the cooling rate, as long as the cooling rate is less than 1°C/min. In this case it is possible to define a constant layer thickness per degree centigrade of undercooling. Thus, at the low cooling rates, the same layer thickness is obtained per degiee centigrade of temperature drop. This change in growth kinetics from fast to slow cooling rates is discussed below.

Discussion

The mechanisms that control the growth rate during flux growth have been reviewed by Elwell (6), and discussed in more detail by Scheel and Elwell (7), and by Gilmer *et al.* (8). The process of crystal growth from solution may be treated as a combination of the following steps: (*i*) transport from the bulk solution by diffusion, convection, or forced flow, (*ii*) volume diffusion through a boundary layer, (*iii*) adsorption on the crystal surface, (*iv*) surface diffusion to a step, (*v*) attachment at a step, (*vi*) diffusion along the step, and (*vii*) integration into the crystal at a kink in the step. The first two steps in the process are regarded as mass transport processes, while the remaining steps are governed by surface kinetics. If the surface kinetic mechanisms are rapid compared with the mass transport flow, the growth rate will become mass transport limited. In this case, if a linear gradient of solute is considered to exist over a boundary layer thickness δ normal to the surface, the growth rate is given by (6)

$$v = \frac{D\sigma n_e}{\rho\delta} \qquad [1]$$

where D is the solute-effective diffusion coefficient, ρ is the density of the crystal, n_e is the equilibrium solute concentration, and σ is the supersaturation. For the case of a linear dependence of solute solubility upon temperature, and this is indeed true for the case of silicon dissolved in tin over a temperature range of 800°-950°C under which the growths in this study were conducted (5), and a constant cooling rate, C, the growth rate is given by

$$v = \frac{D}{\rho}\frac{kC}{\delta} \qquad [2]$$

where k is a proportionality constant. Thus, the thickness grown per unit time will be proportional to the temperature drop per unit time, or in other words, the epitaxial layer thickness will be proportional to the temperature drop. Thus, at low cooling rates, when the surface kinetics are rapid compared with mass transport, the epitaxial layer thickness will vary in proportion to the temperature drop, irrespective of the cooling rate. This is observed for the experimental results obtained for cooling rates of 0.2°, 0.5°, and 0.75° C/min, as shown in Fig. 3. Similar results have been observed in the case of the growth of GaAs from a Sn-GaAs solution by Mitsuhata (9).

With increasing cooling rates, the mass transport rate will increase correspondingly and will eventually exceed the surface kinetic limited growth rate. Once the growth rate becomes kinetically controlled, the epitaxial layer thickness will be proportional to the time duration of the growth, irrespective of the cooling rate. This is observed for the layers grown in this study at cooling rates of 2.5° and 7°C/min, as illustrated in Fig. 2.

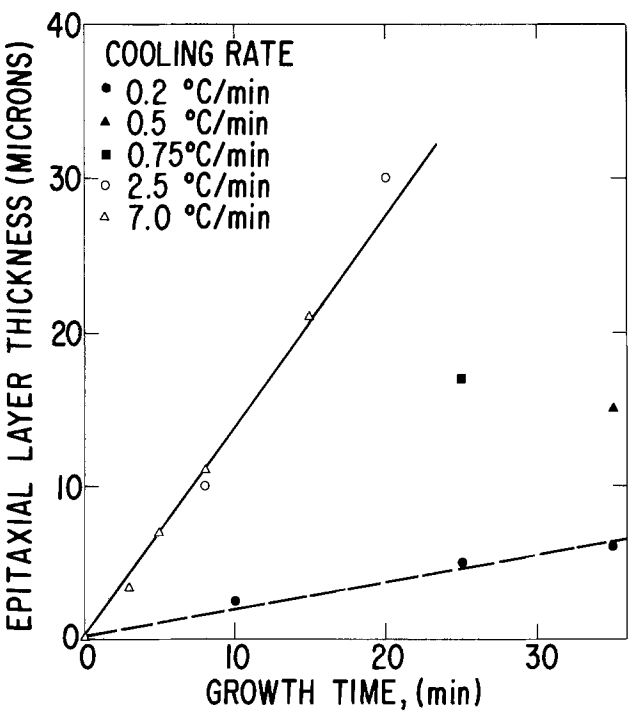

Fig. 2. Experimentally observed variation in the epitaxial layer thickness with growth time, cooling rate as parameter.

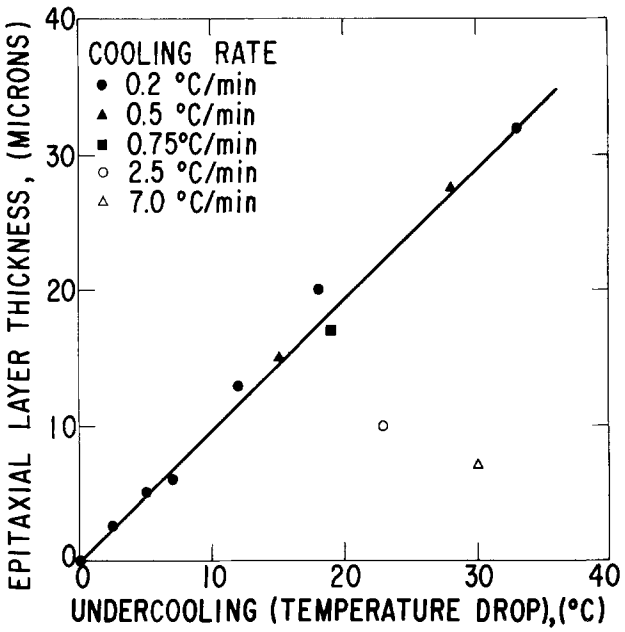

Fig. 3. Experimentally observed variation in the epitaxial layer thickness with undercooling, cooling rate as parameter.

Thus, as the cooling rates increases, the growth rate will increase in proportion to the cooling rate as long as the growth rate is mass transport limited, and then saturate with cooling rate once the growth rate becomes limited by surface kinetics. Figure 4 shows the variation in the growth rate as a function of the cooling rate for the data presented earlier in Fig. 2 and 3. It is observed that up to cooling rates of less than 1° C/min, the growth of the silicon epitaxial layers in this study occurred under mass transport limited conditions, while growths at cooling rates above 2°C/min occurred under kinetically controlled conditions. The cooling rate at which this transition occurs is a function of the size and geometry of the crucible as well as the substrate holder.

In order to confirm these observations, additional experiments were conducted with stirring of the melt. To achieve the stirring, the substrate holder was rotated about a vertical axis using a rotation cycle consisting of 3 revolutions per minute for 10 sec, followed by reversal of the direction of rotation. Since the substrate was rotated about a vertical axis near its center, the boundary layer thickness was considerably reduced at the edges of the wafer as compared with the middle. Thus, under mass transport controlled growth conditions, the epitaxial layer thickness at the edges of the wafer should be higher than at the axis. This was indeed observed at slow cooling rates. A typical example of the variation in the layer thickness as a function of distance from the axis of rotation for a cooling rate of 0.5°C/min is shown in Fig. 5C and 5D. It is observed that, without stirring (Fig. 5C), layer thickness at the edges is within ±10% of the thickness at the axis, and there is no systematic variation in thickness from one edge to the other. In contrast, with stirring (Fig. 5D), it is observed that the layer thickness at the edges is about three times greater than at the axis.

Under kinetically controlled growth conditions, the reduction in boundary layer thickness should not change the growth rate at the edges of the wafer. Indeed it is observed in Fig. 5A and 5B that there is no systematic change in epitaxial layer thickness from the edge of the wafer to the axis of rotation. both with or without stirring at a cooling rate of 7°C/min.

Conclusions

The growth rate of epitaxial layers of silicon grown from a tin melt have been examined at cooling rates ranging from 0.2° up to 7°C/min. It is observed that at slow cooling rates the layer thickness varies linearly with undercooling, while at fast cooling rates the layer thickness varies linearly with time, in each case, irrespective of the actual cooling rate. This is because at slow cooling rates the growth is mass transport controlled, while at fast cooling rates surface kinetics control the growth rate. These observations have been confirmed by measurement of the variation in the epitaxial layer thickness across the wafer, with and without stirring, at both slow and fast cooling rates. At present, using this liquid epitaxial growth system, silicon layers of up to 100μ in thickness have been grown with growth rates in excess of 1μ per minute. This technique for epitaxial growth of silicon layers is currently under investigation for the fabrication of devices.

Pseudostable MNOS Structures

L. A. Kasprzak,* A. K. Gaind,* and A. Hornung

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Thick oxide MNOS structures as studied by Frohman-Bentchkowsky and Lenzlinger exhibit a flatband shift (ΔV_{fb}) which saturates with time at bias. We have studied a MNOS structure (300Å of nitride and 300Å of oxide) with low conductivity nitride (10^{-8}A cm^{-2} at 4×10^6V cm^{-1}, 373°K) which exhibits an increase in the rate of flatband voltage shift (ΔV_{fb}) after an apparent saturation. This effect was observed on long time (2650 hr) bias-temperature stress. Typical times to reach apparent saturation at 85°C varied from 200 to 1000 hr at 15 and 8.5V, respectively. At 165°C and 15V, the initial saturation almost merges with the subsequent rate increase of ΔV_{fb}. Processing, characterization, and the bias temperature stress results for these structures are discussed. We propose that the stored charge is distributed throughout the Si_3N_4 rather than only at the SiO_2-Si_3N_4 interface.

The memory effect in MNOS structures with a thin (<30Å) SiO_2 layer is a well-known phenomena. In memory MNOS structures, the mechanism of charge buildup is indicative of charge injection from the silicon. The charge buildup at the oxide-nitride interface is thought to cease when the conduction current in the oxide (Jo) is equal to that in the nitride (Jn) (1). This paper deals with MNOS structures in which the oxide thickness is significantly greater than the maximum thickness for tunneling (*i.e.*, >> 30Å). It is our purpose to show that the presently accepted mechanism of charge buildup at the oxide-nitride interface is inadequate. We demonstrate the inadequacy of previous theory when specifically applied to MNOS structures in which the oxide and nitride are both ~300Å.

The first difference encountered was a change in the sign of the charge at the nitride-oxide interface. This was expected. It is consistent with the mechanism proposed herein: for the case of thick (>> 30Å) SiO_2 under the nitride, the charge is injected from the metal electrode rather than the silicon. Subtleties not expected from previous theory (1) were also observed; for example, opposite asymmetries in the amount of stored charge for short and long time bias-temperature stress, and an eventual increase (EI) in the rate of flatband voltage shift (ΔV_{fb}) sometime after apparent saturation (see Fig. 1).

Sample Preparation

The dual dielectrics (oxide-nitride) were formed on n-Si (100) wafers that had been ion implanted such that half of the wafer was phosphorous doped and the other half was boron doped. After annealing (to activate the implanted species) and an oxidation drive-in at 1050°C, surface concentrations were 1×10^{16} phosphorous and 8×10^{16} boron. Next, all existing oxide was removed and the wafers were cleaned in hot deionized water at 85°C (10 min), followed by 10 min in hot (120°C) H_2SO_4:HNO_3 (3:1) mixture, and followed by 5 sec dip in 10:1 dilute HF. The wafers were then rinsed in running deionized water (10 min) and spin dried. The wafers were hydrophobic (~8Å SiO_2, as measured by ellipsometry) after the above cleaning.

The thermal oxide (~300Å) was then grown in O_2 with 3% HCl at 1050°C. After a 15 min anneal in N_2 at 1050°C, the Si_3N_4 (~300Å) was deposited using the system of Gaind *et al.* (2) at 1000°C (110 liters min^{-1} H_2, 60 cm^3 min^{-1} SiH_4, and 800 cm^3 min^{-1} NH_3). Finally, blanket aluminum (resistance-heated source) was deposited on the back side, and 0.5 mm diam (nominal) aluminum dots were deposited on the dual dielectric. Postaluminum annealing was performed in N_2 for ½ hr at 400°C.

Sample Properties

The Si_3N_4 properties for films ~1000-3500Å were measured on <100> silicon wafers which were cleaned

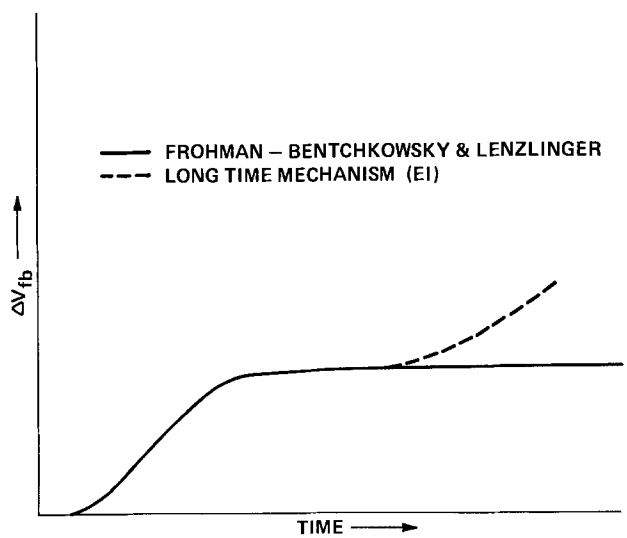

Fig. 1. Flatband voltage shift (V_{fb}) vs. time

* Electrochemical Society Active Member.

Key words: thin films, thick oxide structures, MNOS structures, dual dielectrics.

in the same manner as the MNOS wafer prior to oxide growth. The Si_3N_4 index of refraction was 2.02 ± 0.01 fpr at a 5460Å wavelength. Its etch rate in 49% HF was 100 ± 10Å min^{-1}. The infrared absorption spectra, measured in transmission mode, showed a broad peak at ~835 cm^{-1}, indicating that there was no SiO_2 under the nitride film (3). In conjunction with the MNOS samples, some MNS (~300Å Si_3N_4) samples were prepared. The dielectric constant of the Si_3N_4 was ~8 (determined from C_{max} in accumulation), and the average breakdown field was 8.5 × 10^6 Vcm^{-1}. The current density (J) *vs.* voltage (V) was measured at 100°C for Si_3N_4 thicknesses of ~250 and 646Å (Fig. 2).

The conductivity of the as-deposited Si_3N_4 is quite low, and compares with 3000Å films previously reported (3-5). The MNS and MNOS fast-state density near midgap was measured using the quasistatic technique of Kuhn (6) as modified after Castange (7) and Kerr (8) (*i.e.*, we used the high frequency C-V trace from accumulation to inversion as ideal). The MNS and MNOS structures exhibited midgap fast-state densities of $<1 \times 10^{11}$ cm^{-2} and $<1 \times 10^{10}$ cm^{-2}, respectively (Fig. 3 and 4). Fixed and mobile charges

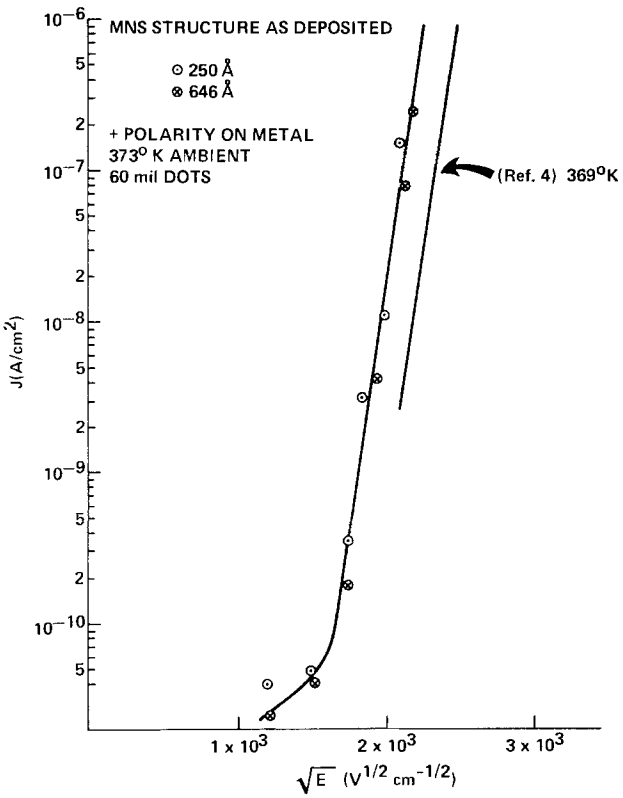

Fig. 2. Current density (J) *vs.* applied field (E) at 373°K

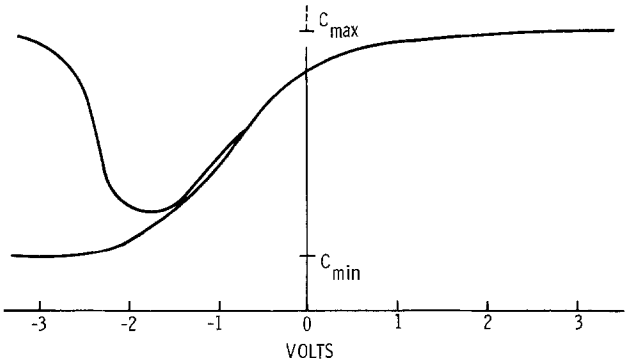

Fig. 4. Quasistatic and 1 MHz C-V curves for MNOS structures

in the MNOS structures were 5-10 × 10^{10} cm^{-2} and 2-5 × 10^{10} cm^{-2}, respectively. Mobile charges were confirmed using MOS structures processed simultaneously at oxidation and metal deposition.

Bias-Temperature Stressing (BTS) and Measurement Technique

The MNOS and MNS structures were subjected to bias-temperature stress in inversion at 85°, 125°, and 165°C. Bias voltages of 8.5, 12, and 15V were applied to the aluminum dots with the back side aluminum grounded. The change in flatband voltage (ΔV_{fb}) was determined at discrete read-out times by an automatic tester which measured device leakage, capacitance in accumulation (C_{max}), flatband voltage (V_{fb}), and capacitance at flatband (C_{fb}). The measurement of V_{fb} and C_{fb} was accomplished by use of a subroutine which calculated equivalent oxide thickness (t_{eq}) from the measured value of C_{max}. C_{fb} was then automatically computed from the calculated value of t_{eq} and the known Si surface doping level. The value of V_{fb} was measured by searching the C-V curve via automatic tester for the calculated value of C_{fb}. The complete test program with subroutines was used at each readout time with control devices prior to actual MNOS and MNS device measurements. Further, the complete test program was used at each readout on the MNOS and MNS devices to eliminate erroneous values of V_{fb} caused by degradation in device leakage or C_{max}. The repeatability of the automatic test system was ± 7 mV for V_{fb}. The stressing sequence consisted of a time zero readout prior to stress, application of stress bias, heating to stress temperature, BTS for time t_1, cooling to room temperature, removal of bias, readout, application of bias, heating to stress temperature, etc. Total BTS time was 2650 hr, with readouts at 15, 89, 185, 350, 722, 1050, 1548, 2052, and 2650 hr.

The specific bias and temperature conditions applied were: n-silicon −8.5 and −15V at both 85° and 165°C, −12V at 125°C; (for p-silicon +8.5 and +15V at both 85° and 165°C, and +12V at 125°C). As previously mentioned, all biases were applied to the metal dots with the silicon grounded. Since all of the devices at one bias and temperature were stressed in parallel, a 10 kΩ current-limiting resistor was placed in series with each device to prevent bias fluctuation in the event that a particular device shorted. Very few shorts were actually experienced. Sixteen devices were stressed per condition, which resulted in a total sample size of 160 devices. The flatband voltage shifts (ΔV_{fb}) reported are the average of all 16 devices at a particular stress condition. Excellent tracking was observed among the devices at a stress condition (<25 mV spread).

Results and Discussion

MNS structures.—The flatband shifts (Fig. 5) for the MNS structures are similar to those previously reported for MNOS tunneling structures (1). The sign

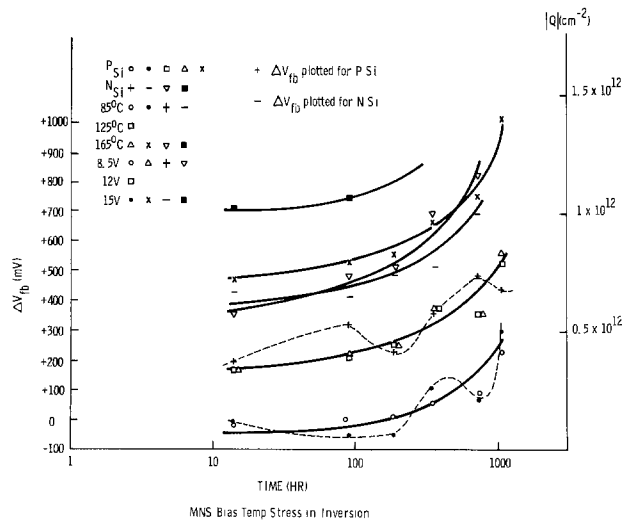

Fig. 5. Flatband voltage shift *vs.* time for MNS structures

of ΔV_{fb} is positive under positive bias and negative for negative bias. This characteristic is explained by tunneling of electrons from the Si to the Si_3N_4 for positive bias, and from the Si_3N_4 to the Si for negative bias. Oscillatory behavior in V_{fb} (dotted curves in Fig. 5) was also observed. This may be due to local variations in the conductivity of the Si_3N_4 which cause a large local change in the charge stored at the Si-Si_3N_4 interface, and in turn a nonuniformity in Si surface potential (ψ_s) at apparent V_{fb}. The subsequent reduction in V_{fb} could be due to lateral diffusion of the resulting charge near the Si-Si_3N_4 interface. This diffusion would result in a more uniform surface potential.

The absence of a saturation level of charge in the Si_3N_4 is an important result. It indicates that the stored charge in the Si_3N_4 is most likely distributed through the entire thickness of the Si_3N_4 after long time at large applied d-c fields. This is not unexpected for 300Å Si_3N_4 films (9). However, it may indicate a propensity in Si_3N_4 to attain a uniform level of charge through the film after a sufficient time under d-c bias. Most of the work on MNOS tunneling structures has been carried out under pulse conditions, and as a result the centroid of charge could be quite different for d-c bias conditions.

MNOS structures · (300Å Si_3N_4, 300Å SiO_2).—The charge buildup at a SiO_2-Si_3N_4 interface is expected to cease once the interface has sufficient charge to change the fields in the oxide and nitride such that continuity of current exists (1) (Fig. 6). However, for the MNOS structures we studied, saturation of SiO_2-Si_3N_4 interface charge was not observed.

From Grove (10), we know that for a MOS structure

$$V_{fb} = \phi_{ms} - \frac{Q_{ss}}{C_o} - \frac{1}{C_o}\int_o^{X_o} \frac{X}{X_o}\rho(x)\,dx \qquad [1]$$

where $\phi_{ms} = \phi_m - \phi_s$ (volts); ϕ_m = metal work function (volts); ϕ_s = silicon work function (volts); Q_{ss} = fixed charge in SiO_2 (cm^{-2}); C_o = oxide capacitance = $K_o\epsilon_o/X_o$ F/cm^2; $\rho(x)$ = distributed charge in SiO_2 (cm^{-3}); X_o = oxide thickness (cm); K_o = dielectric constant of $SiO_2 \approx 4$; $\epsilon_o = 8.85 \times 10^{-14}$ Fcm^{-1}; and X = distance from metal. For a MNOS structure, this reduces to

$$V_{fb} = \phi_{ms} - \frac{Q_{ss}}{C_o} - \frac{1}{C_n}\int_o^{X_n} \frac{X}{X_n}\rho_n(x)\,dx \qquad [2]$$

where n refers to nitride parameters, and we finally obtain for charge at a nitride-oxide interface (Q_I). Then

$$Q_I = C_n\,\Delta V_{fb} \text{ and } C_n = \frac{K_n\,\epsilon_o A}{t_n} \qquad [3]$$

where K_n = dielectric constant of nitride $\simeq 8$; $\epsilon_o = 8.85 \times 10^{-14}$ Fcm^{-1}; A = area of Al dot (cm^2); and t_n = Si_3N_4 thickness (cm). The structures were biased in inversion, and in all cases injection from the contact was observed (note sign of ΔV_{fb} and Q_I in Fig. 7). The sign of Q_I in all cases was opposite to that observed in MNOS tunnel devices ($SiO_2 \leq 300$Å). We observed an apparent saturation of Q_I prior to 1000 hr of stress; however stressing to 2650 hr revealed a subsequent increase in Q_I. In addition, two asymmetries were observed; first, for stress time less than 100 hr Q_I was 5-10 times lower for negative bias than for positive bias; second, for stress time of about 1000 hr Q_I was $\simeq$2 times greater for negative bias than for positive bias. The asymmetries of Q_I for short time can be explained by an increase in oxide charge (Q_{ss}) at the Si-SiO_2 interface, such that

$$(Q_I) \text{ net} = Q_{ss} + \alpha Q_I \qquad [4]$$

where $\alpha = K_{ox}/K_n\ t_n/t_{eq}$; $t_{eq} = t_{ox} + K_{ox}/K_n\ t_n$; K_{ox} = dielectric constant SiO_2; and t_{ox} = oxide thickness (cm).

For negative bias on N-Si, Q_I is negative (Fig. 8). Drift VI (11) is known to result in positive charge at the Si-SiO_2 interface (Q_{ss}), and in increased fast state density N_{fs}. Hence, Q_{ss} reduces (Q_I) net for negative bias, and increases or does not reduce (Q_I) net for positive bias (Fig. 8).

Fast-state densities were measured (3) on all samples after completion of 2650 hr of stress. N_{fs} had increased to 10^{12} for the 165°C ± 15V samples after stress. All other samples had $N_{fs} \simeq 1\text{-}2 \times 10^{11}$. The long-term asymmetry of Q_I can be explained if we assume either that the contact injection is asymmetrical with bias polarity, or that for our Si_3N_4 the density of available traps is greater than the density of filled traps. Most likely some combination of both effects occurs. Slight discontinuities in the ΔV_{fb} *vs.* time plots were observed (arrows in Fig. 7). It is felt that these

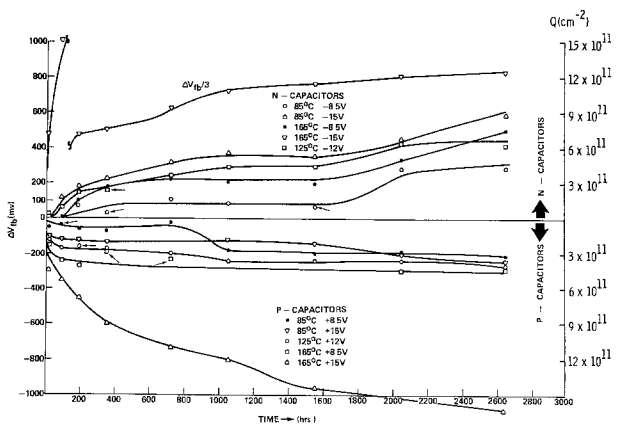

Fig. 7. Flatband voltage shift *vs.* time for MNOS structures. Top curve extends beyond scale. Data points beyond 100 hr are plotted at 1/3 value (*i.e.*, $\Delta V_{fb}/3$).

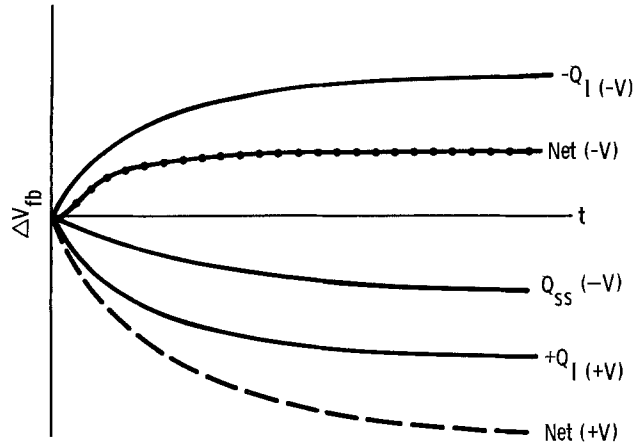

Fig. 8. Interface (Q_I), oxide (Q_{SS}), and net charge vs. time

are due to inadvertent charging or discharging of the sample as a result of handling between readouts.

It remains to discuss the eventual increase (EI) in the rate of flatband voltage shift (ΔV_{fb}) after apparent saturation. We assume that the apparent saturation takes place when $J_n = J_o$. However, it is important to remember that at no time does $J_n = 0$. The charge is most likely very close to the SiO_2-Si_3N_4 interface when $J_n \simeq J_o$. We suggest that the passage of the d-c current through the Si_3N_4 for a long time causes further trapping (detrapping) of charge under negative (positive) bias, and that this is the cause of the EI. The EI ceases when all available traps are filled or emptied (Fig. 9). The difficulty in characterizing the EI is that the charge responsible is populating or depopulating traps closer and closer to the metal. As a result, the sensitivity of ΔV_{fb} to this charge is a decreasing function of time. The bulk trap nitride charge density (assuming a constant bulk charge) obtained by integrating the $\rho_n(x)$ term in Eq. [2] was equated to the measured interface charge (Q_I)

$$\frac{\rho_n X_n}{2} = Q_I \qquad [5]$$

An approximation of the bulk-filled trap density[1] from Fig. 7 yields a bulk-filled trap density (t_B) of $\simeq 3 \times 10^{18}$ cm^{-3} at 2650 hr. Yun (9) has also been able to trap 3×10^{18} cm^{-3} charges in Si_3N_4. A further complication is that at 165°C the EI appears to merge with the initial saturation, with the result that the only evidence for the EI is the nonsaturating slope for long stress times. The EI has not saturated at 2650 hr, therefore we can place no upper bound on t_B for our Si_3N_4 films.

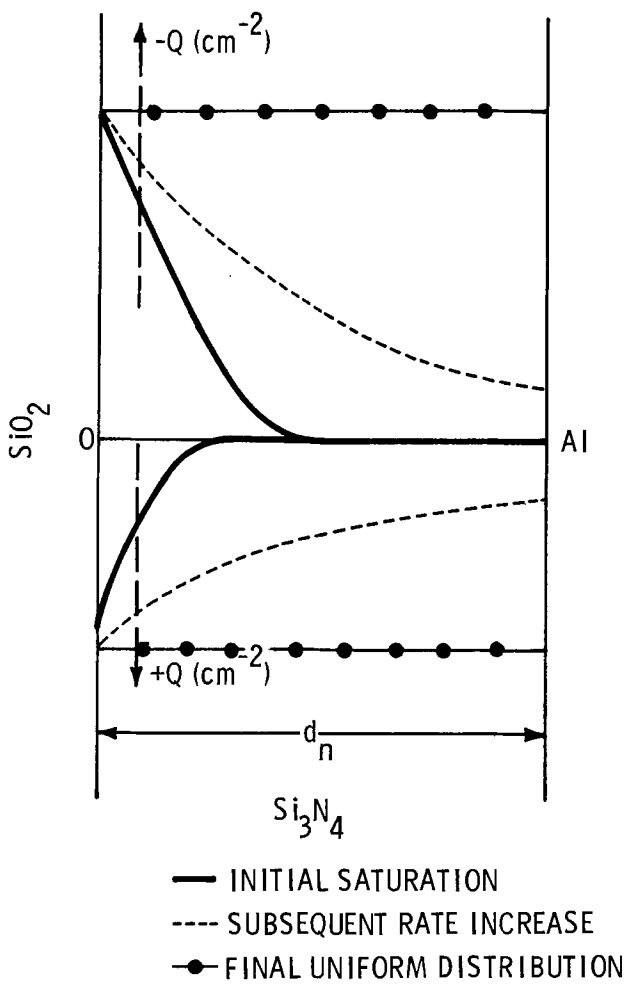

Fig. 9. Proposed charge distribution in Si_3N_4 at various times

Conclusions

An increase in the rate of charge storage (EI) some time after apparent saturation has been observed for MNOS structures with equal oxide and nitride thicknesses. The EI is probably due to charge distributed throughout the Si_3N_4 rather than at the SiO_2-Si_3N_4 interface. Certain asymmetries in the magnitude of the charge stored at various times under bias-temperature stress indicate an increase in oxide charge (Q_{SS}), the generation of fast states at the Si/SiO_2 interface, and higher density of available traps than filled traps for our Si_3N_4.

Acknowledgments

Growth of Iron-Doped Epitaxial Layers for GaAs Field Effect Transistors

Kenya Nakai, Kuninori Kitahara, Akihiro Shibatomi, and Shinji Ohkawa

Fujitsu Laboratories Limited, Nakahara, Kawasaki, 211, Japan

ABSTRACT

Iron-doped GaAs epitaxial layers were grown using the $Ga/AsCl_3/N_2$ vapor phase system and with a new doping method. The characteristics of the iron-doped layer were investigated, and the layer was used as the buffer layer of the epitaxial layer for FET. It was found that the iron concentration in the epitaxial layer was proportional to the vapor pressure of the iron-doping gas ($FeCl_2$). The layer with a resistivity higher than 10^4 Ω-cm could be prepared without increasing the crystal defects and impurities except iron. It was observed that the electrical characteristics of the submicron active layer on the chromium-doped substrate were improved by the insertion of the iron-doped buffer layer between the active layer and the substrate. It was found that the performance of FET's fabricated of the epitaxial layer was the iron-doped buffer layer was higher than the performance of those without the buffer layer.

Recent developments of GaAs microwave devices require a high quality epitaxial layer to improve device performance. For planar devices such as field effect transistors (FET's) and Gunn effect logic devices, n-type epitaxial layers grown on semiinsulating substrate doped with chromium are used. It has been reported that the electrical characteristics of the epitaxial layer are abnormal near the interface between the layer and the substrate (1-3), and that insertion of a buffer layer between the layer and the substrate is effective in improving the device performances (4-8). Hence, growth techniques for the buffer layer, which was an undoped high purity layer (4, 5) or chromium-doped high resistivity layer using chromyl chloride (9), were applied.

These techniques require extremely close control on the growth conditions to obtain high resistivity and a good epitaxial layer surface. For practical applications, a simpler growth method for the buffer layer is desirable. It has been reported that an epitaxial layer with a high resistivity (10^4-10^5 Ω-cm) can be obtained by iron doping, and the activation energy of a deep iron level is estimated to be about 0.5 eV (10-12). This suggests the possibility of using the iron-doped layer as a buffer layer, but it has never been realized. It is therefore significant to investigate this possibility.

The iron doping method reported previously (10) is not suitable to buffer layer growth which must be able to grow the buffer and the active layer without interruption. We have developed an iron-doping method to grow the high resistivity buffer layer and the active layer sequentially, and to minimize iron contamination in the active layer. In this paper, we describe the doping method and the characteristics of the iron-doped epitaxial layer. It is demonstrated that the epitaxial layer with a high resistivity of 10^5 Ω-cm can easily be obtained with high reproducibility. Effects of insertion of the iron-doped layer between the chromium-doped substrate and the active layer on the electrical characteristics of the active layer are reported. Further, as an application, metal-semiconductor field effect transistors (MESFET's) were fabricated by using an epitaxial wafer with or without the iron-doped buffer layer, and their characteristics were compared.

Experimental Procedure

Epitaxial layers were grown from the $Ga/AsCl_3/N_2$ system. The growth conditions were similar to those reported previously (13). A schematic diagram of the growth apparatus with the iron- and sulfur-doping system is shown in Fig. 1. The iron doping was performed by introducing iron chloride ($FeCl_2$) vapor into the reactor during epitaxial growth. $FeCl_2$ was formed by the reaction of iron (Fe) and hydrogen chloride gas (HCl) as follows: $Fe + 2HCl = FeCl_2 + H_2$. HCl gas was produced by the decomposition of $AsCl_3$ in a hydrogen ambient. High purity iron powder of 99.99% was employed as the iron source. The vapor pressure of $FeCl_2$ was controlled by adjusting the temperature of the iron source (370°-550°C). The flow rates of the doping gas and the total gas in the reactor were 20 and 1000 ml/min, respectively. The doping gas line between the iron source and the reactor was usually maintained at a higher temperature than the iron source to prevent deposition of $FeCl_2$.

The iron-doped layer with high resistivity can be used as a buffer layer for a sulfur-doped active layer on the chromium-doped substrate. For this purpose, sequential growth of the iron-doped layer and the sulfur-doped layer was carried out by changing the doping gas of the iron chloride to sulfur. The doping level of sulfur was controlled by adjusting the temperature of the sulfur source.

Electrical characteristics of the epitaxial layer; carrier concentration N, Hall mobility μ, and resistivity ρ, were determined by the Schottky diode capacitance method (14), and Van der Pauw's method (15). In the determination of the resistivity of the iron-doped layer, the effect of parallel conductance of the chromium-doped substrate was taken into account. The temperature dependence of the resistivity of the iron-doped layer was measured in the temperature range of −10°-200°C.

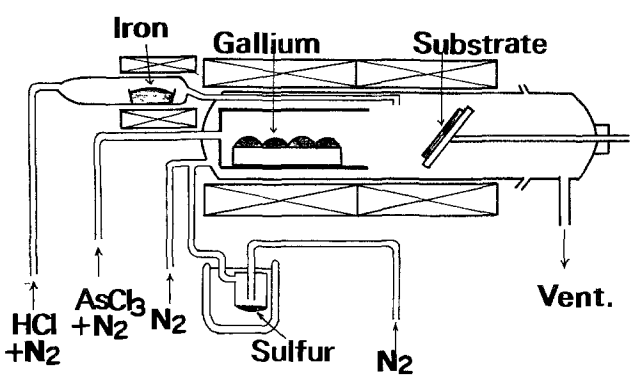

Fig. 1. Vapor phase epitaxial growth apparatus of the iron-doped GaAs layer and the sulfur-doped active layer for FET.

Key words: gallium arsenide, epitaxial growth, iron doping, high resistivity GaAs, and buffer layer.

Power MESFET's were fabricated by using the epitaxial wafers with or without the iron-doped buffer layer. D-c and high frequency characteristics of the FET's were measured. The fabrication process and the measurement method of the characteristics were similar to those in a previous paper (16).

Results and Discussions

The iron-doped epitaxial layer.—Figure 2 shows the electron concentration of the iron-doped layer as a function of the iron source temperature. Background electron concentrations of samples A, B, C, and D were adjusted to 1-2 $\times$ 10^{14}, 0.7-1 $\times$ 10^{15}, 8-10 $\times$ 10^{15}, and 2-3 $\times$ 10^{16} cm^{-3}, respectively, by sulfur doping. As the background electron concentration is increased, the temperature of the iron source is increased in order to obtain a high resistivity layer, that is, low carrier concentration.

Figure 3 shows the photoluminescence spectra at 4.2°K for three kinds of GaAs crystal, (a) undoped high purity epitaxial layer, (b) chromium-doped substrate, and (c) iron-doped layer. The measurement method was similar to that reported previously (17). The edge emission of the high purity epitaxial layer, of which Hall mobility at 77°K is 1.3 $\times$ 10^5 $cm^2V^{-1}sec^{-1}$, is split into several peaks as shown in (a). The relative intensities of donor-acceptor pair emissions, which have been found to relate with carbon and zinc (17, 18) to the edge emission, are low. The spectrum of the chromium-doped crystal grown from the GaAs melt shown in (b) suggests that this crystal contains much unknown impurity or crystal defects since the band-edge emission is broad and another broad emission is observed near the bandedge (19). The edge emission of the iron-doped layer is split, and the relative intensities of donor-acceptor pair emissions are almost the same as those of high purity layer shown in (c). These results show that the iron-doped layer contains shallow acceptors and crystal defects similar to those of the high purity layer. Therefore, it is considered that the concentration of impurities (except iron) and the density of crystal defects are low enough to use the iron-doped layer as a buffer layer on the chromium-doped substrate.

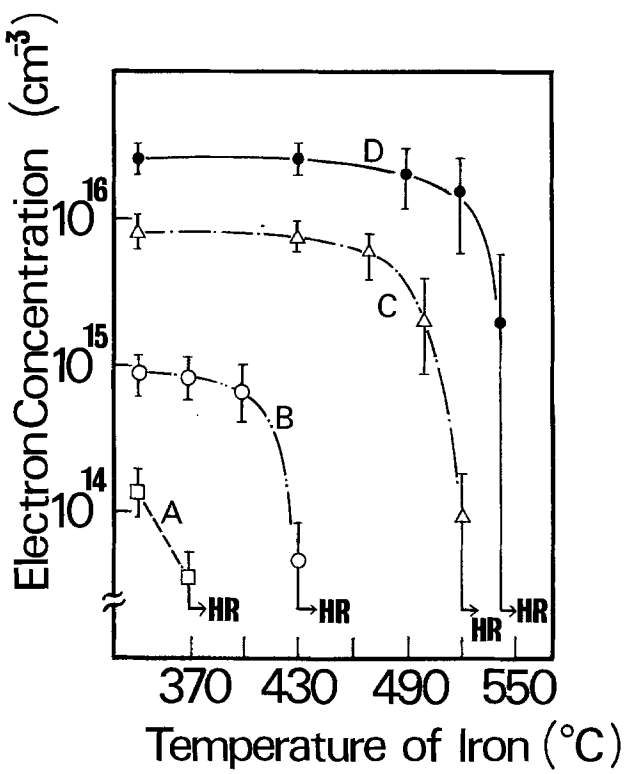

Fig. 2. Electron concentration as a function of the temperature of the iron source. The background electron concentration was adjusted by the sulfur doping: A, 1-2 $\times$ 10^{14}; B, 0.7-1 $\times$ 10^{15}; C, 8-10 $\times$ 10^{15}; and D, 2-3 $\times$ 10^{16} cm^{-3}. HR indicates that the layer is highly resistive.

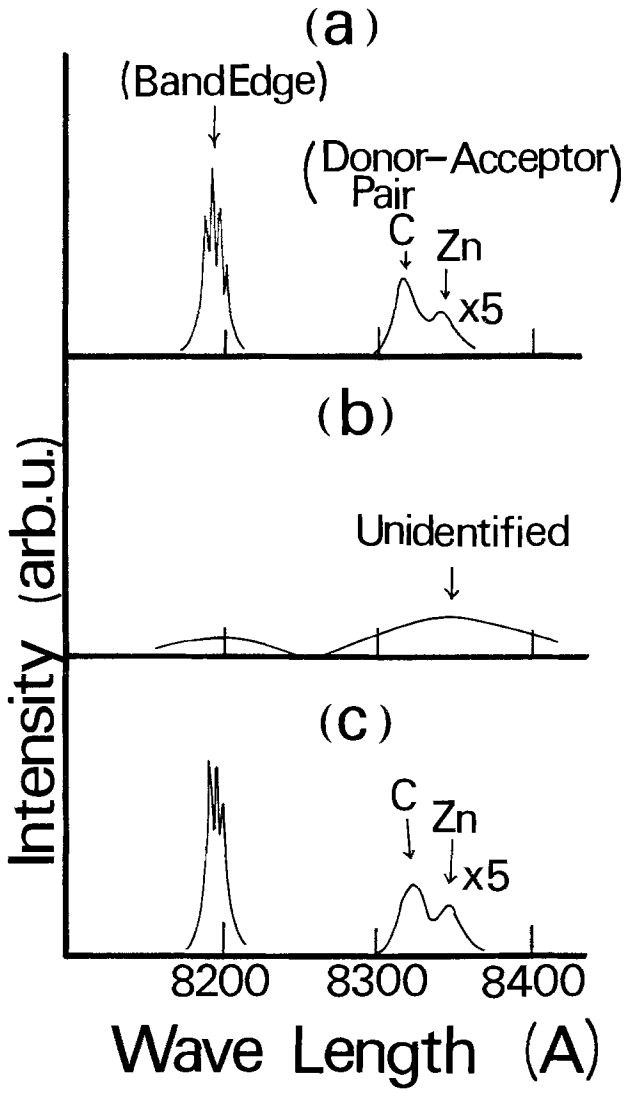

Fig. 3. Photoluminescence spectra measured at 4.2°K. (a) Undoped high purity epitaxial layer; (b) chromium-doped semi-insulating substrate; (c) heavily iron-doped epitaxial layer.

It has been reported that iron acts as a deep level acceptor or two deep acceptors in GaAs crystal (10-12, 20-23). It is surmised, therefore, that the decrease of the electron concentration by iron doping, as shown in Fig. 2, is caused by compensation of the deep acceptors.

It was observed that the iron source was usually covered with solid $FeCl_2$ after the doping experiment. When the temperature of the doping gas line between the iron source and the reactor was lowered below that of the iron source, the solid $FeCl_2$ was observed near the lowest position. In this case, the compensation level depended on the temperature of the lowest position of the line rather than on the iron source temperature. This indicates that the doping gas is saturated with $FeCl_2$ vapor and the amount of the $FeCl_2$ introduced into the reactor is controlled by the saturation vapor pressure determined by the temperature.

Figure 4 shows the compensation level by the iron doping as a function of $FeCl_2$ concentration in the vapor phase. The compensation level was estimated from the difference between the background electron concentration and the electron concentration of the iron-doped layer. The iron concentration in the vapor phase was calculated from the vapor pressure data presented in Ref. (24) and the ratio of the doping gas flow rate to the total gas flow rate (20/1000). This figure indicates

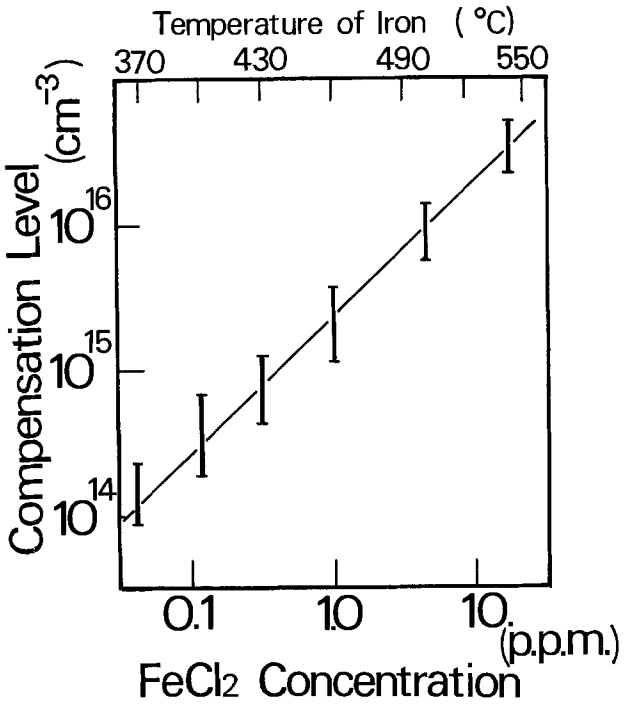

Fig. 4. The compensation level by the iron doping as a function of the $FeCl_2$ concentration in vapor phase. The compensation level was estimated from the difference between the electron concentration of the iron-doped layer and the background electron concentration. The $FeCl_2$ concentration was calculated from the saturation vapor pressure data.

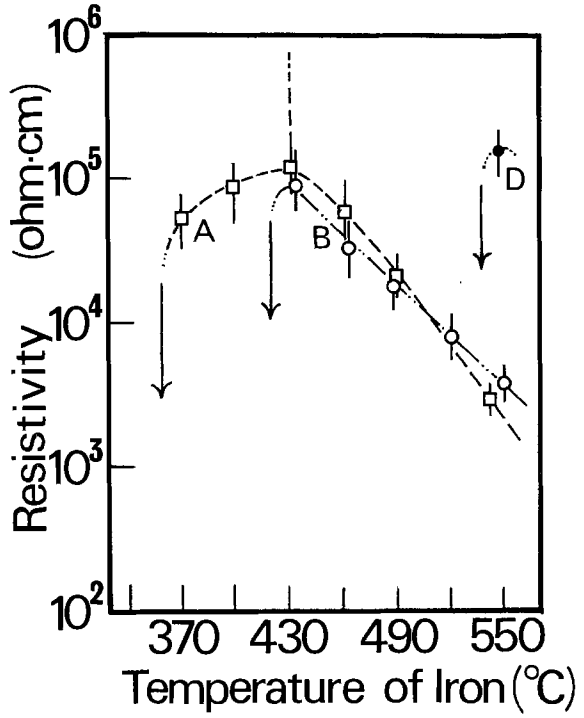

Fig. 5. The resistivity of the iron-doped layer as a function of the iron source temperature. The background electron concentration; A, 1-2 × 10^{14}; B, 0.7-1 × 10^{15}; D, 1-2 × 10^{16} cm^{-3}. Arrows indicate the temperature where the resistivity scatters between the undoped level and 10^4 Ω-cm.

that the compensation level is almost proportional to the $FeCl_2$ concentration.

As the iron concentration is increased beyond the background electron concentration, the layer becomes highly resistive. Figure 5 shows the resistivity of the iron-doped layers as a function of the iron source temperature. The background electron concentrations of the samples are similar to those in Fig. 2. Arrows indicate temperature where the resistivity scatters between the background electron concentrations of the undoped layer (less than 1. Ω-cm) and about 10^4 Ω-cm across the wafer or from run to run. This shows that the background electron is not entirely compensated for by the iron deep acceptors, and that the carrier concentration of the iron-doped layer strongly depends on the dispersion of the background electron concentration at these temperatures. The resistivity is almost in the range 10^4-10^5 Ω-cm, which agrees with the results reported previously (10-12), in perfectly compensated doping range.

In a semiconductor doped with a deep acceptor, the hole concentration p is approximately given by the equation (12)

$$p \simeq \left(\frac{N_t}{N_d - N_a} - 1\right)\frac{N_v}{g}\exp\left(-\frac{E_t}{kT}\right) \qquad [1]$$

under the condition of $p << (N_d - N_a) < N_t$ where N_t, N_d, N_a, N_v, g, and E_t are the concentrations of the deep level acceptor and the shallow level donor and acceptor, the state density of the valence band, the degeneracy factor associated with the deep level, and the activation energy of the deep level, respectively. Therefore, the decreasing inclination of the resistivity with the increase of the iron concentration, shown in Fig. 5, can be explained by using the above equation. That is, the concentration of the deep acceptor N_t increases as the iron concentration is increased.

Figure 6 shows the temperature dependence of the resistivity of the iron-doped layer. The doping condition and the results from Hall measurement for the samples are summarized in Table I. The high resistivity of samples A and B resulted in large measurement errors of their Hall coefficients. Hence, the Hall mobility of these samples is not listed in Table I. Hall mobility of samples A and B, however, is estimated to be larger than 350 cm^{2}V^{-1}sec^{-1} by extrapolation of the Hall mobility of samples C, D, and E to higher resistivity range.

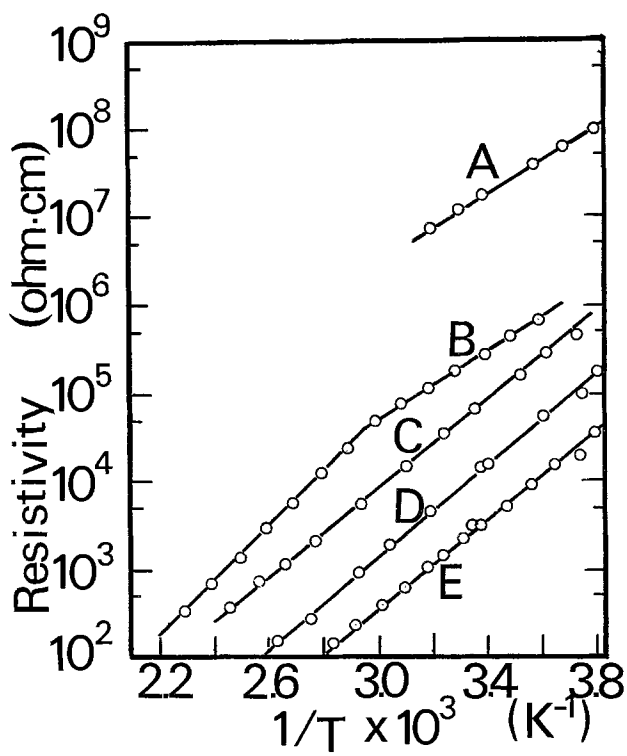

Fig. 6. The temperature dependence of the resistivity of the iron-doped layer. The doping condition of the samples is shown in Table I.

Table I

Sample	Iron temperature ($FeCl_2$ concentration) (°C, ppm)	Hall measurement at room temperature		
		Resistivity Ω-cm)	Hole concentration (cm^{-3})	Hole mobility (cm^2/V sec)
A	430 (0.5)	10^7	—	—
B	430 (0.5)	2×10^5	—	—
C	460 (1.0)	7×10^4	2×10^{11}	400
D	500 (5.0)	1×10^4	1.3×10^{12}	430
E	540 (15.0)	3×10^3	5.1×10^{12}	450

The iron concentration doped in the layer increases from sample A to E, since the iron temperature was increased in this order. For the sample with a higher doping level, the thermal activation energy of the resistivity is about 0.5 eV, which corresponds to the results reported previously (10, 12, 20). For the lightly doped samples, the activation energy is estimated to be about 0.35 eV near room temperature. This energy of about 0.35 eV is similar to the energy of the iron deep level determined from electroluminescence measurement (21). We have reported that two deep levels related with iron are observed in photoconductivity measurements of the iron-doped layer (25). The activation energies of the resistivity of the iron-doped layer observed here agree with those obtained by the photoconductivity measurement. This corresponds to a suggestion that iron acts as two deep acceptors in GaAs crystal (11, 22, 23).

The characteristics of the sulfur-doped layer on the iron-doped layer.—The iron-doped layer with high resistivity was applied to a buffer layer of a n-type layer (active layer) grown on semiinsulating substrate. Effects of the iron-doped buffer layer on the characteristics of the active layer were studied. The iron-doped layer, which was 4-5 μm thick, and had a resisivity of 5-10 $\times$ 10^4 Ω-cm, was grown on the chromium-doped substrate. After stopping the iron-doping gas, sulfur vapor was introduced into the reactor. Thus, by changing only the doping gas, sequential growth of the buffer and the active layers was performed without interruption.

Figure 7 shows concentration profiles of electron (A) and iron on the epitaxial layer which was grown at 720°C at a growth rate of 0.11 μm/min. The profile (B) represents the background electron concentration. The iron concentration was estimated from the temperature of the iron source using the relation between the compensation level and the iron source temperature shown in Fig. 4. The growth with iron doping was carried out for 37 min, after which epitaxial growth was continued for 23 min, corresponding to a layer thickness of 2.5μ. Within a depth of 2μm from the surface, profile (A) is flat and its level coincides to the background, as shown in Fig. 7. Since the iron doping effects on the characteristics of the epitaxial layer can be neglected in this region, the effects to be considered are within the 0.5μ region near the interface, that is, about 5 min after stopping the doping gas. The diffusion length of iron is estimated to be much smaller than 0.5 μm, hence, 5 min may be needed to exhaust the doping gas from the reactor. In order to prevent the iron contamination in the active layer, sulfur doping of the active layer must be started at more than 5 min after ending growth of the iron-doped layer.

Figure 8 shows the profiles of electron mobility μ measured with the Hall-bars with Schottky barrier (3) and the density of deep level N_t determined from the transient capacitance of the Schottky barrier (26). The measurements were carried out for two samples.

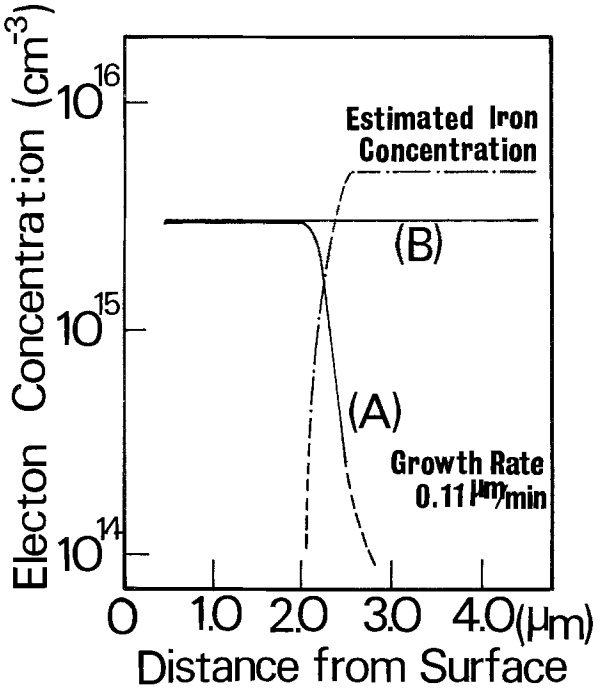

Fig. 7. Profiles of the electron concentration and the iron concentration. (A) Epitaxial layer grown sequentially on the iron-doped layer after stopping the iron doping gas; (B) background electron concentration.

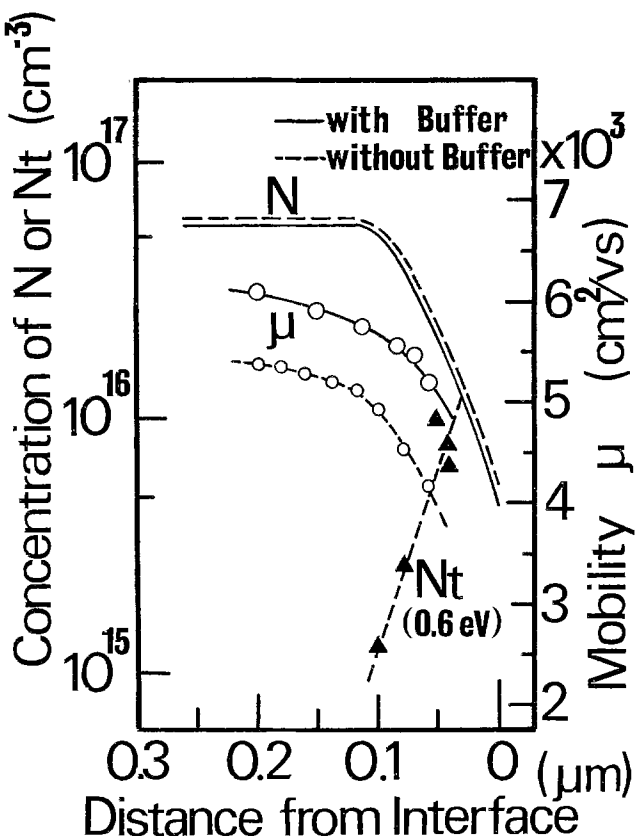

Fig. 8. Profiles of the carrier concentration, Hall mobility, and density of the deep level in the submicron active layer for FET's.

One of the samples has the sulfur-doped active layer of 0.3μm thick grown directly on the chrominum-doped substrate. The other active layer, whose thickness and carrier concentration were similar to those of the sample without the buffer layer, was grown on the iron-doped layer (5μm thick) without interruption. In the growth procedure of the latter sample, the sulfur-dop-

ing gas was introduced at 6 min after stopping the iron-doping gas.

Figure 8 indicates that the insertion of the buffer layer improves the mobility by about 20%. This improvement is considered to be due to a reduction of the space charge which is introduced at the initial stage of the epitaxial growth (3). It is observed that a deep level exists in the interface region between the active layer and the substrate. The thermal activation energy of this deep level was estimated to be about 0.6 eV, and its density was more than 10^{16} cm^{-3} near the interface. On the other hand, in the active layer grown on the iron-doped layer, any deep level could not be detected by this measurement. It is therefore suggested that the iron-doped buffer layer prevents the formation of the deep level at the initial stage of the epitaxial growth, as well as diffusion from the substrate into the active layer.

Application to the FET.—As shown in the previous section, the electrical characteristics of the active layer are found to be improved by the insertion of the iron-doped buffer layer between the active layer and the chromium-doped substrate. In this section, we describe the improvements of the device performance of GaAs FET by using the epitaxial wafer with the iron-doped buffer layer. The geometries and the fabrication processes of the FET are similar to those reported previously (16).

It has been reported that the high frequency characteristics of the GaAs FET strongly depend on the characteristics of the substrate, and that the substrate can be evaluated by change in resistivity caused by heat-treatment (27). The substrate wafers employed in this study were thus sliced from a narrow portion of the same ingot. Before epitaxial growth, differences of the characteristics among these substrate wafers were investigated. Randomly selected wafers were heated at 830°C for 30 min in nitrogen ambient. This heat-treatment corresponds to the heating process of the epitaxial growth. Then, ohmic contact pairs 10μm apart and 650μm wide were formed on the heat-treated surface. The voltage-current measurement on these substrate wafers indicated that the current was about 0.1 mA at 15V, and the dispersion of the current among the substrate wafers or across the wafer was within 30%. It is taken into consideration that this dispersion of *I-V* characteristics makes little dispersion on the high frequency characteristics of the FET from one wafer to another (27).

Figure 9 shows the *I-V* characteristics of the MESFET on the curve tracer. The hysteresis loops are observed in the source-drain currents of the FET (a), which were fabricated by using the epitaxial wafer without the buffer layer. The loops are eliminated in the FET (b), which was fabricated by using the wafer with the iron-doped buffer layer. Hower *et al.* have shown that the hysteresis loops are due to the electron traps in the interface region between the epitaxial layer and the substrate (1). It is therefore considered that the elimination of the hysteresis loops by the buffer layer corresponds to the reduction of the deep level near the interface.

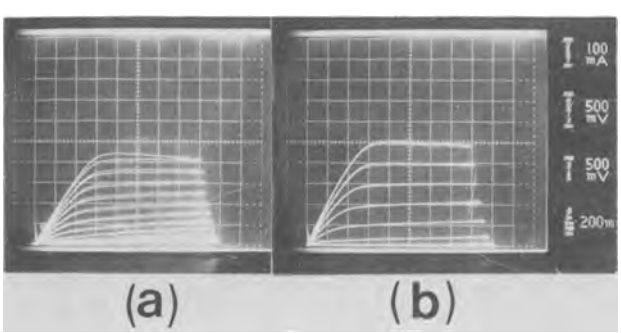

Fig. 9. Photographs of the I-V characteristics of the FET on the curve tracer. (a) FET without the buffer layer; (b) with the iron-doped buffer layer.

Figure 10 shows the characteristics of the FET's the transconductance g_m and the power gain at 6 GHz G, as a function of the carrier concentration of the active layer. The results were obtained for the MESFET's having a gate which was 1300μm wide. The error bar of each data point indicates the dispersion across the wafer (2 × 1.5 cm^2). The scattering among the data points is considered to be due to unknown parameters in the epitaxial growth and the fabrication processes.

The highest values of g_m and G are obtained in the FET's fabricated by using the epitaxial wafer with the iron-doped buffer layer at a certain carrier concentration. The average values of g_m and G of FET's with the buffer layer are higher than those of FET's without the buffer layer over the whole range of the carrier concentration. Therefore, g_m and G may be improved by the insertion of the buffer layer between the active layer and the substrate.

The transconductance of FET, g_m, is given approximately by the equation

$$g_m = A\mu N \qquad [2]$$

where A, μ, and N are the factors given by the structure and the geometries of the FET, the mobility of the carrier, and the carrier concentration of the active layer, respectively. Because the factor A is equal among all FET's in this study, it is suggested that the improvement of g_m by the buffer layer is due to the increase of the mobility. This corresponds to the result described in the previous section.

Summary

Iron-doped GaAs epitaxial layers were prepared by the $Ga/AsCl_3/N_2$ vapor phase growth system with a new doping method, and the characteristics of the layers were investigated. The results are summarized as follows:

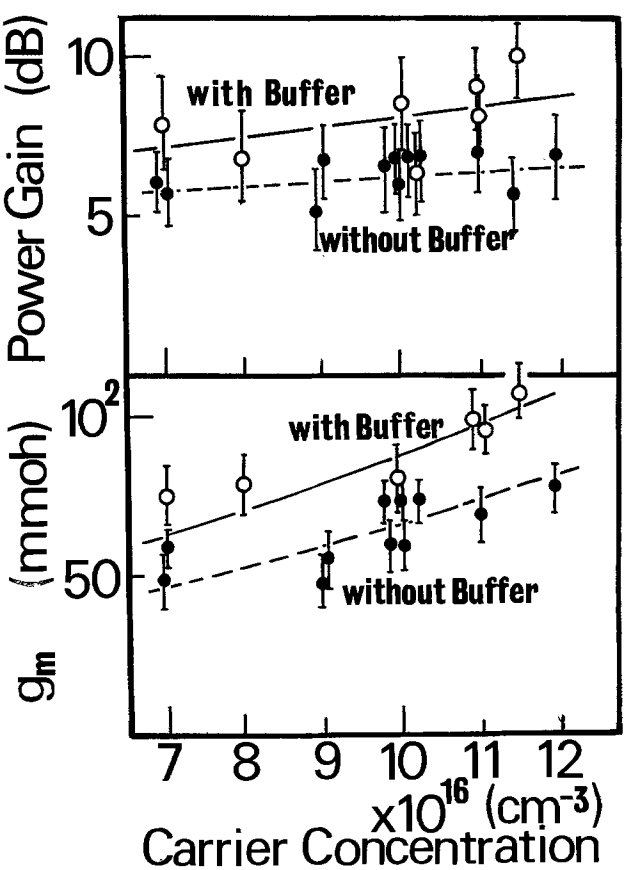

Fig. 10. The characteristics of MESFET's with and without the iron-doped buffer layer; the power gain at G6 GHz and the transconductance g_m.

1. When iron is introduced into the reactor as iron chloride vapor, iron is incorporated into the epitaxial layer proportional to the vapor pressure. A high resistivity layer can be obtained even if the background electron concentration is higher than 10^{16} cm^{-3}.
2. The concentration of shallow level acceptors and the density of crystal defects never seem to be increased by iron doping.
3. The resistivity of the iron-doped layer is in the range 10^4-10^5 Ω-cm, and depends on the $FeCl_2$ concentration in vapor phase.
4. The thermal activation energies of 0.5 and 0.35 eV are obtained by the temperature dependence measurement of the resistivity. The effects of the insertion of the iron-doped layer between the sulfur-doped active layer and chromium-doped substrate on the electrical characteristics of the active layer were investigated.
5. The insertion of the iron-doped layer as a buffer layer increases the Hall mobility in the active layer by about 20%, and eliminates the influence of the deep level which exists near the interface between the epitaxial layer and the substrate.
6. The insertion of the iron-doped buffer layer improves the characteristics of FET, the transconductance, and the power gain.

Acknowledgments

The authors wish to thank O. Ryuzan and K. Dazai for helpful discussions. They thank M. Ozeki and K. Nagata for the characterization of the epitaxial layers, and special thanks go to N. Yokoyama and M. Fukuta for providing data of the FET characteristics.

Manuscript submitted March 28, 1977; revised manuscript received June 24, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

Publication costs of this article were assisted by Fujitsu Laboratories Limited.

The Hot Corrosion of CoCrAlY Turbine Blade Coatings by Na_2SO_4 and Vaporous NaCl

R. L. Jones* and S. T. Gadomski

Naval Research Laboratory, Washington, D.C. 20375

ABSTRACT

To investigate whether unsaturated NaCl vapor can have effects in hot corrosion, experiments have been conducted wherein specimens cut from CoCrAlY-coated turbine blades were sprayed with Na_2SO_4 (1-2 mg/cm^2), and then exposed in a tube furnace at 1625°F under an air stream containing 300 ppm NaCl (1/20 the NaCl saturation pressure at 1625°F) with inspection and sulfate recoating every 24 hr. Several chloride effects were evident within 100-200 hr under this test regime. These included: (*i*) increasing the Na_2SO_4 vaporization rate; (*ii*) causing formation of a spalling Al_2O_3 surface oxide; (*iii*) removing Cr by the formation of volatile complexes which apparently contain S and Na as well as Cr and Cl; (*iv*) interacting with Ti at the coating-blade interface; and (*v*) accelerating sulfidation-oxidation attack upon the CoCrAlY coating. This latter attack occurs when both blade metal and coating are exposed simultaneously to the sulfate, as at a cut edge. It is confined to the CoCrAlY layer, and consists of a sulfidation front and oxidation front which traverse the coating successively, effectively stripping the coating from the supposedly less resistant blade alloy. Sodium chloride increases the kinetics of attack and appears to promote the formation of "Cr_3S_4" over CrAlS as the predominate sulfide phase. A search for chloride was made by energy-dispersive x-ray analysis in the SEM, but despite the obvious NaCl influences, no trace of chloride was found except possibly in the Ti interaction. The individual NaCl effects are discussed in relation to earlier research results and as they may pertain to shipboard hot corrosion.

Despite improved coatings and alloys, hot corrosion remains a limiting factor in the application of gas turbine engines for ship propulsion. Engine performance and endurance could be substantially improved if this problem were solved. Hot corrosion attacks the blades and vanes in the turbine section of the engine, and is generally considered to result from the buildup of molten sulfate films, principally Na_2SO_4, on these components. The sodium sulfate derives from sea salt ingested by the engine, either in the air or as a contaminant in the fuel. Sea water contains the equivalent of 3900 ppm Na_2SO_4 directly, and there is the possibility that NaCl (30,000 ppm) itself can react with sulfur in the fuel to produce additional Na_2SO_4.

Numerous hot corrosion investigations have been conducted and several mechanisms have been proposed (1), but it is still not clear whether or not NaCl, which is after all the major component of sea salt, has any significant role in hot corrosion. The English have been most active in this area, and they have accumulated considerable evidence, as reviewed by Conde (2, 3), that NaCl can be important, particularly at lower engine temperatures. Those who doubt the NaCl effect point out, however, that the vapor pressure of NaCl is so high that the turbine should be effectively exposed only to vapor-state NaCl, and NaCl or chloride per se is seldom found on corroded turbine components. These arguments are countered to a certain extent by reports that chloride-rich particles can in fact be found in corroded engines (4, 5), and by considering that NaCl may come to the blade surface mainly by impact of compressor salt particles (6) or droplets of sea water contamination in the fuel (7), rather than by condensation from the vapor phase. Nonetheless, it is still of interest to test the ideas implicit in the two arguments above, *i.e.*, that NaCl vapor should have no role in hot corrosion as long as its partial pressure is below the condensation pressure, and that the absence of a chloride residue proves that NaCl had no part in the corrosion process.

The experiments described below have therefore been conducted where the influences of NaCl vapor were investigated by comparison of the corrosion behaviors of Na_2SO_4-sprayed blade specimens exposed at 1625°F under flowing air, and under flowing air containing unsaturated NaCl vapor. Vaporous NaCl is known, mostly through the work of Hancock and associates (8), to corrode many turbine metals and alloys in the 1300°-1650°F range, but the effects of NaCl vapor over Na_2SO_4-coated specimens have been little studied, and little is known except for one suggestion (9) that the presence of a sodium sulfate film on the surface may provide protection against the action of vapor phase chloride.

Experimental

For the experiments, a two-zone hot tube furnace was devised (Fig. 1) wherein filtered air, after being bubbled through water, was flowed at a rate of 200 ml/min first over NaCl at 1400° ± 10°F, and then over the Na_2SO_4-sprayed blade specimen at 1625° ± 10°F. The NaCl and Na_2SO_4 were reagent grade chemicals, the boats were Alundum (TM), and the furnace was fitted with a fused silica liner. The thermocouple insulating tubing was used to position and withdraw the boats.

The 1625°F temperature was chosen as being high enough that hot corrosion could proceed readily, but not at such an overwhelming rate as to mask any NaCl effects which might be operative. It was also thought that this temperature, being very near the melting point of Na_2SO_4 (1623°F), might more readily make apparent any action of the NaCl which results from its lowering of the Na_2SO_4 melting point. The rationale in

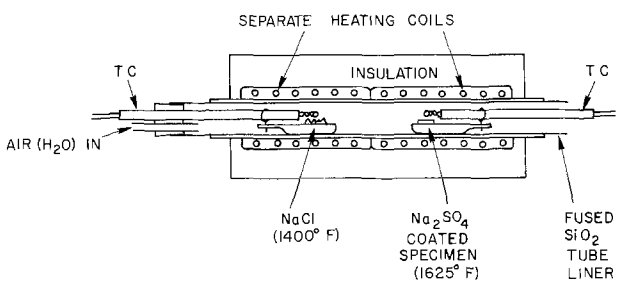

Fig. 1. Hot corrosion tube furnace apparatus

* Electrochemical Society Active Member.
Key words: hot corrosion, NaCl effects, CoCrAlY coating.

selecting the NaCl temperature was to begin with a low NaCl boat temperature (1200°F) and then raise it (and the NaCl input into the air stream) in progressive tests until chloride effects could be observed within reasonable times. At 1400°F, definite chloride manifestations were apparent within 100 hr exposure, and accordingly this temperature was adopted as the standard NaCl temperature.

The routine of testing was to spray the specimens, approximately 0.4 in. square, and cut from the blade with a dry tungsten carbide saw, with 1*N* Na_2SO_4 under a hot air gun, so as to deposit 1-2 mg/cm^2 of Na_2SO_4 on their surface. Then they were placed in the 1625°F zone of the furnace to be exposed to the flux of air, water vapor, and gaseous NaCl. Every 24 hr the specimens were removed, examined by light microscopy, and resprayed with Na_2SO_4. At the same time, the NaCl boats were removed and weighed so the NaCl loss per 24 hr could be determined. The NaCl weight losses averaged 0.1 ± 0.02 g per day, which at 200 ml/min air flow, corresponds to a NaCl concentration in the air of about 300 ppm, or a partial pressure of about 0.1 Torr. The equilibrium vapor pressure of NaCl is 0.16 Torr at 1400°F, and 1.8 Torr at 1625°F (10). The NaCl is therefore only approximately 1/2 saturated at 1400° and 1/20 saturated at 1625°.

It may not be accurate, however, to simply describe the specimen as exposed to 300 ppm NaCl, because appreciable reaction occurs between the NaCl vapor and the silica tube furnace liner, as evidenced by an opaque whitening and embrittlement of the silica. Hydrogen chloride is known to be generated when NaCl reacts with hot silica in the presence of water, and it is likely, therefore, that the air stream contained at least some HCl. Sizable NaCl deposits developed where the air cooled near the tube exit, indicating that the majority of chloride remained as gaseous NaCl, but even small amounts of HCl may accelerate the attack or have other unknown effects. This was a point of concern, but since HCl is predicted to be formed also in sea salt-contaminated turbines (11), it was ultimately concluded that the apparatus was adequate for the purpose, *i.e.*, to produce and study "NaCl" vapor phase corrosive effects as might occur in sea-going engines.

The blade specimens were cut from two unused marine turbine blades supplied through the auspices of J. W. Fairbanks of NAVSEC. The first blade, blade A, was a first-stage air-cooled blade fabricated from Rene' 80 (Ni-base; weight percent (w/o) 10Co, 14Cr, 3Al, 5Ti, 4Mo, 4W, 0.2C, with traces of B and Zr), and coated with BC21 (CoCrAlY containing nominally w/o 25Cr, 10Al, and 1Y). The second blade, blade B, was a second-stage blade made from IN738 (Ni-base; w/o 8.5Co, 16Cr, 3.4Al, 3.4Ti, 1.7Mo, 2.6W, 1.7Ta, and 0.9Cb), and coated with PWA268 (CoCrAlY, w/o 15-21Cr, 10-12Al, and 0.3-0.9Y). There is no significance in the choice of blades, aside from NAVSEC interest in CoCrAlY blade coatings. They merely represent state-of-the-art blades which were available for experimentation. In particular, it is to be emphasized that the present tests and their results do not necessarily relate to sea performance, and should not be construed as indicating that one blade alloy or coating is superior to the other.

Results and Observations

Through careful comparison with control experiments where all conditions were the same except only Na_2SO_4 was used, it has been possible to show that NaCl vapor at a nominal 300 ppm can produce the following effects:

1. NaCl promotes vaporization of Na_2SO_4 from the blade surface.
2. It causes flaking of the normally protective Al_2O_3 surface oxide which tends to form on CoCrAlY even in the presence of Na_2SO_4.
3. It generates volatile chromium compounds which condense as yellowish deposits in the colder regions near the tube exit. These deposits show a characteristic sulfur content by EDXA (energy dispersive x-ray analysis) analysis, and thus differ from volatile Cr compounds which have been found in earlier works with NaCl alone.
4. NaCl apparently can "dealloy" the blade metal of titanium under some circumstances (particularly observed with blade A specimens).
5. Finally, NaCl hastens a certain type of sulfidation-oxidation attack to which CoCrAlY is subject when exposed as a "cut-edge" specimen. This attack is surprising in that it degrades the CoCrAlY in preference to the supposedly less resistant blade metal.

Vaporization of Na_2SO_4 by gaseous NaCl.—It was noted early in the investigation that the Na_2SO_4 tended to build up on the blade specimen surface from the daily sprayings of Na_2SO_4 in the sulfate-only experiments. However, when NaCl was present, no such buildup ever occurred. This led to experiments where a deposit of Na_2SO_4 was allowed to accumulate, and then without any other change, the NaCl boat was introduced into the furnace so as to bring the sulfate-deposited specimen in contact with NaCl vapor. In each instance, the Na_2SO_4 deposit disappeared rapidly, usually within 24 hr, once NaCl was introduced.

This phenomenon was also studied using Na_2SO_4-sprayed platinum foil to avoid corrosion complications and to facilitate accurate measurement of the sulfate loss. Somewhat heavier (2-3 mg/cm^2) sulfate films were used and the foil temperatures were 1600°F, but otherwise all arrangements were the same as in the corrosion runs. With NaCl vapor under "dry" conditions [predried NaCl, and the incoming air passed through Drierite (TM)], sulfate weight losses of 0.03-0.05 mg/cm^2-hr were measured. Under wet conditions, where the incoming air was bubbled through water, the weight losses were of the order of 0.1 mg/cm^2-hr, or about twice as high. Wet air alone did not increase the sulfate weight loss rate. These weight losses are equivalent, as shown by comparison runs with Na_2SO_4 alone, to an increase in the Na_2SO_4 vaporization rate of 100 times or more.

Sodium chloride has been reported to behave ideally (12) with Na_2SO_4, which would predict 4-5 mole percent (m/o) dissolution of NaCl in the sulfate at the partial pressures involved. No evidence of chloride could be found by EDXA however, under either wet or dry conditions, when the runs were stopped in midterm and the remaining sulfate deposits examined.

An attempt was also made to determine whether dissociation occurred in the vaporization by passing the exiting gas through SO_2 detector tubes. Assuming complete dissociation, the effluent would have contained 1-2 ppm of SO_2, a concentration just within the sensitivity of the tubes employed. No positive test for SO_2 was obtained. Either dissociation to SO_2 is limited, or the test and apparatus are not adequate for the task.

Spalling of Al_2O_3 from CoCrAlY surfaces.—The second NaCl effect, *i.e.*, causing the formation of a spalling oxide on the CoCrAlY surface, became apparent after 24-48 hr at temperature. One would observe on withdrawing the specimen that a thin brownish-gray film, with bluish tinges at some sites, had formed on the CoCrAlY, and that this film detached and popped free as the specimen cooled under the microscope. No quantitative measurement of the thickness of the spalling film was attempted, but it was clearly much thicker than any (nonspalling) Al_2O_3 film formed within the same time period when the exposure was to Na_2SO_4 alone. The CoCrAlY uncovered by the spalling film was a bright, highly reflecting silver in the light microscope.

The spall sites were subsequently examined by SEM and EDXA for morphology and elemental composition. A representative site is shown in Fig. 2, where the residual Al_2O_3 film is on the right, and the spall site on the left. EDXA indicates the film to be very rich in

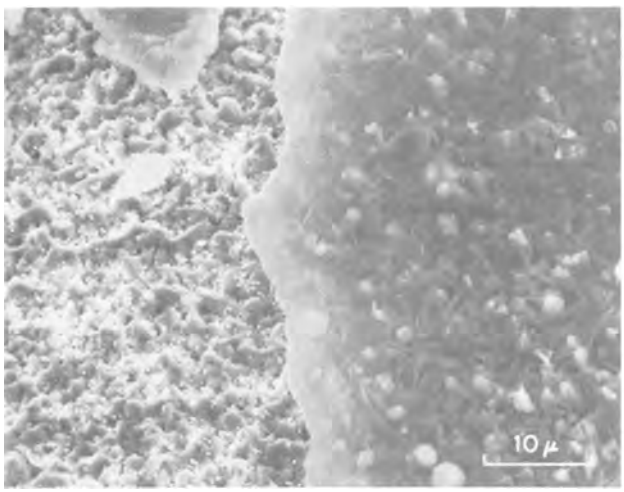

Fig. 2. Spalling Al_2O_3 surface film which forms on CoCrAlY in the presence of NaCl vapor. The film is on the right.

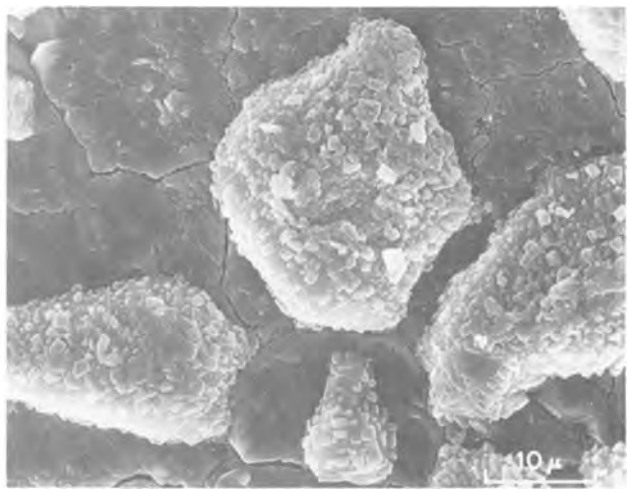

Fig. 3. Chromium-containing deposits which condensed downstream in the presence of NaCl vapor.

Al as expected, but also to contain traces, listed in order of decreasing peak height, of Cr, Co, and Ti. The film also appears to contain numerous acicular, or needle-like, particles. This is a characteristic morphology of these films and may relate to the NaCl action.

The newly exposed CoCrAlY has a granular, somewhat porous (at higher magnification) surface. EDXA shows strong Cr and Co, moderate Al, considerable Ti, and some S. The Al peak height is substantially lower than it is with fresh CoCrAlY, as would be expected considering the CoCrAlY to be depleted locally of Al by formation of the Al_2O_3 surface film. The sulfur and titanium seem to be randomly distributed, and could not be associated with a particular phase or structure. Interestingly, while S was routinely found on the exposed CoCrAlY, it was not detected on the Al_2O_3 film. The significance of the tiny white crystallites on the CoCrAlY in Fig. 2 is uncertain. They were normally not found in such profusion. They give Al-rich EDXA spectra and are not related to the Ti or S impurities. An important final point to be noted is that while the formation of the spalling Al_2O_3 is manifestly a NaCl effect, no trace of chloride was ever detected either in the spalling film or on the exposed CoCrAlY surface.

Formation of volatile chromium species.—The third NaCl effect was detected by the formation of distinctive yellowish deposits which developed in the cool downstream sections of the tube furnace when NaCl was present, but not when it was absent. An example of the structure of these deposits is shown by SEM in Fig. 3. The deposits are rich in Cr and Cl (Fig. 4), and therefore could be thought of as being produced by condensation of volatile chrom-chlorides or chrom-oxychlorides, as others have postulated in earlier work with NaCl vapor. However, our system also contains Na_2SO_4, and the EDXA spectra characteristically show both S and Na to occur in abundance in the deposits (Fig. 4). This suggests that the deposits here are not formed from Cr-O-Cl compounds, but from volatile compounds or complexes which also contain Na and S.

Titanium interactions.—With blade A, there was a tendency for the coating to crack away slightly during sawing and also for the coating to detach from the blade during corrosion testing. (*NB*, coating detachment is not a problem in Navy marine turbines, and this is not representative behavior. The experiments are being reported for the interest they may have pertaining to mechanisms.) Coating detachment occurred in some cases when only Na_2SO_4 was used, but the particular morphologies described below were found only when NaCl vapor was present, and therefore are classified as NaCl effects.

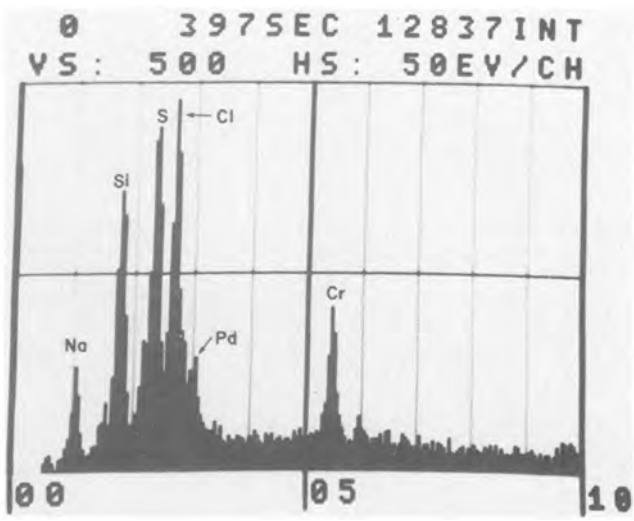

Fig. 4. Energy-dispersive x-ray spectrum from the deposits shown in Fig. 3. The Pd peak is from the Au-Pd SEM coating (Au peak hidden). The Si peak is probably from the substrate.

The initial observation with NaCl was that where the coating had broken away at the saw cut edge, golden needlelike crystals were formed, usually within the first 24 hr of exposure (Fig. 5). At higher

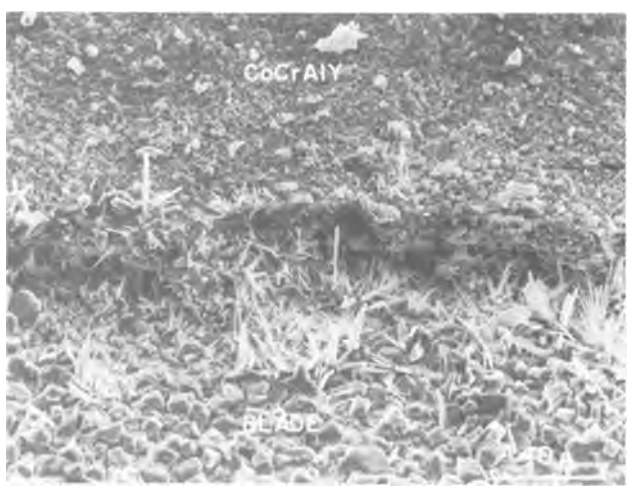

Fig. 5. Needlelike titanium oxide crystals formed under NaCl vapor at a site where the CoCrAlY had cracked away on blade A.

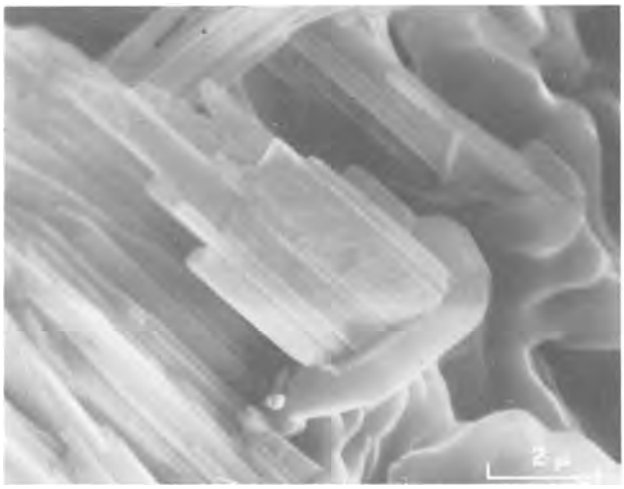

Fig. 6. A high magnification view showing the unusual growth relationship of the titanium oxide crystals in Fig. 5.

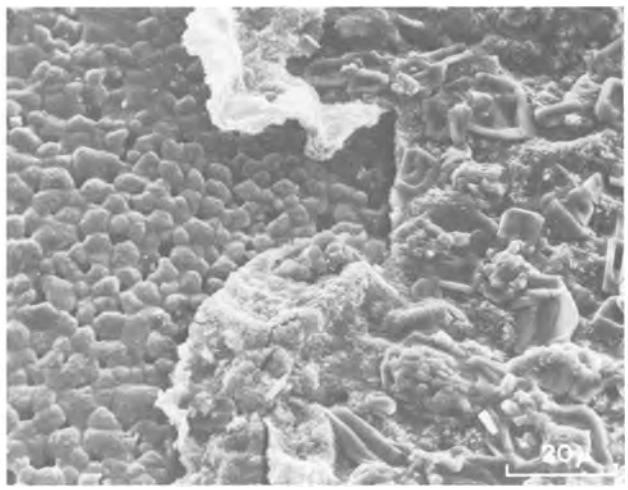

Fig. 8. The "reaction" film formed between the coating and blade substrate in Fig. 7. It appears to consist of a thin Al_2O_3 matrix film in which are embedded polyhedral titanium oxide crystals.

magnification, the needlelike structures often appear to originate from or nucleate on a "parent" crystal (Fig. 6). Both the needle and parent crystals are indicated by EDXA to be predominantly Ti (probably TiO_2 under the circumstances; EDXA does not detect oxygen), but with some Cr and Al, and possibly a slight amount of chloride. The needle crystals seem consistently to contain slightly more Al than the polyhedral crystals.

After longer exposure times, but still usually under 200 hr, several instances were found where the coating had detached from blade A specimens and could be peeled back, as in Fig. 7. (The very fact that the coating can be "peeled back" indicates that its properties have been altered, probably by Al depletion, because normal CoCrAlY coatings are brittle below about 1200°F.) A very thin "reaction" film was found to have formed in these cases between the coating and blade metal. This film (Fig. 8, right-hand side) appears to consist of a thin, essentially continuous Al_2O_3 layer in which are "embedded" a high density of TiO_2 crystallites. The blade substrate is left in a granular, porous state and yields EDXA spectra which show, in order of decreasing peak height, Ni, Co, Cr, Al, and S, but little or no Ti.

Most indications were that the corrosive attack preceded from the cut edge along the coating-blade interface, additional access of Na_2SO_4 and NaCl vapor being allowed as the coating progressively detached. However, in one run, a localized site of corrosion on the coating, marked by a bluish-brown hillock, was observed to develop in the body of the specimen in advance of the detachment front. Post-run examination showed that the blade had been attacked beneath this side with the formation of the characteristic inner reaction film and pored substrate. Both polyhedral and needle or blade like TiO_2 crystals (Fig. 9) were found here, with the latter crystals giving evidence of containing some chloride (Fig. 10). This was the most positive identification of chloride on the corrosion specimens that was found during the total investigation.

Sulfidation-oxidation of CoCrAlY.—After the specimens were exposed to Na_2SO_4 under vaporous NaCl at 1625°C for 100 hr or so, a particular type of corrosive attack would be observed to initiate at the cut edge (often at a corner) and then, once initiated, propagate rapidly at rates of a millimeter or more per day across the surface of the specimen, as shown in Fig. 11. The attack consists, as Fig. 11 indicates, of a sulfidation front which is then followed by an oxidation front. When viewed in cross section, the attack can be seen to be essentially confined to the CoCrAlY layer (Fig. 12 and 13). There are some differences in behavior between blade A and blade B specimens, one of the first and most obvious being that, under NaCl, the sulfidation and oxidation fronts tend to be more widely separated with blade A (Fig. 12) than with blade B (Fig. 13).

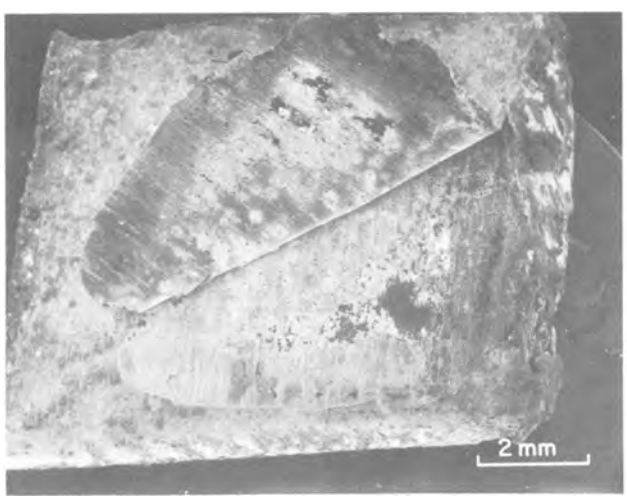

Fig. 7. Detached CoCrAlY coating on a blade A specimen after 113 hr exposure at 1625°F to Na_2SO_4-vaporous NaCl.

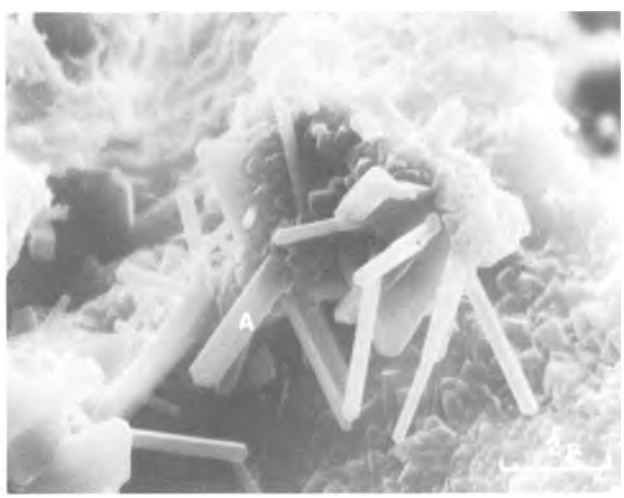

Fig. 9. Bladelike titanium oxide crystals formed under a pit through the CoCrAlY coating. Compare with Fig. 5 and 6.

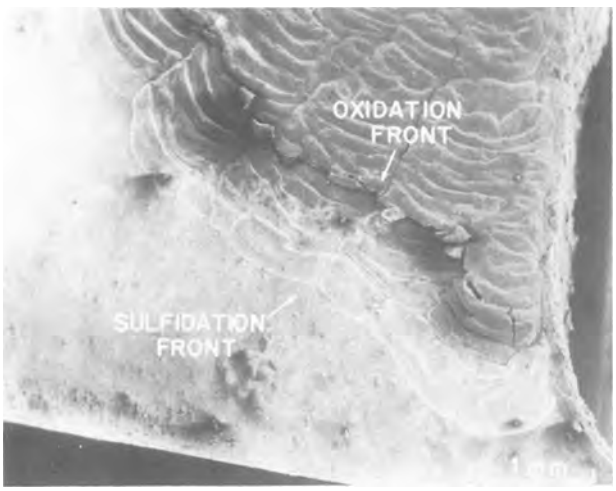

Fig. 11. Progressive sulfidation-oxidation attack across a blade A specimen surface after 142 hr exposure at 1625°F to $NaSO_4$-vaporous NaCl.

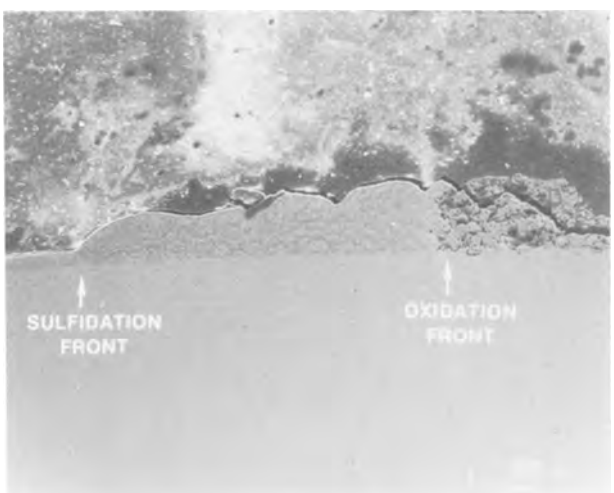

Fig. 12. An SEM photograph showing sulfidation-oxidation attack on the CoCrAlY coating on a blade A specimen in cross section.

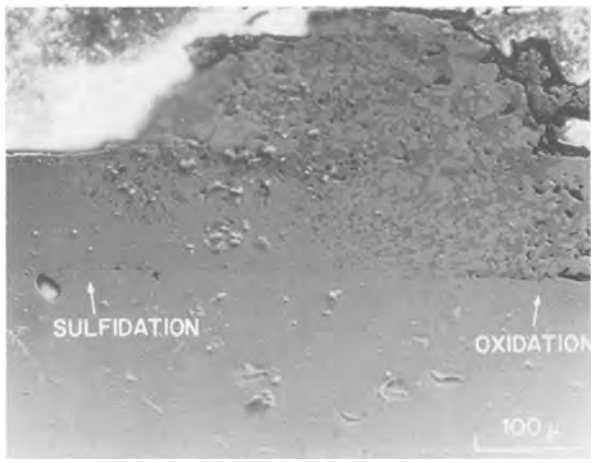

Fig. 13. Sulfidation-oxidation of CoCrAlY on a blade B specimen. Oxidation front follows more closely here than with blade A specimens.

A similar attack was seen in control runs with Na_2SO_4 alone, except that the incubation time before attack was observed was substantially longer, being of the order of 300-500 hr, the distance between sulfidation and oxidation fronts was short for both blade A and blade B specimens, and a chromium sulfide phase containing aluminum, *i.e.*, "CrAlS," was formed exclusively, whereas under NaCl, the tendency was to form "Cr_3S_4" in addition or in preference to "CrAlS" (see below). The rate of propagation across the surface also seemed to be slower in the absence of NaCl, although this was not verified quantitatively.

The sulfidation front of a blade A specimen corroded under Na_2SO_4-vaporous NaCl is shown in Fig. 14. The sulfidation zone is on the left and the as yet unsulfided CoCrAlY on the right. The CoCrAlY is depleted in aluminum at the sulfidation front and at its outer surface, as evidenced by lack of β phase at these sites (also verified by EDXA). The layer visible at the outer coating surface just above the sulfidation zone-CoCrAlY intersection gives an Al signal by EDXA, indicating it to be Al_2O_3. Notice that the CoCrAlY itself is cracked away from the substrate here, but this has had no effect on the course of the sulfidation attack.

Three corrosion phases can be identified in the sulfidation zone. The lightest (gray) phase is a metallic phase (proven by an electron microprobe test for

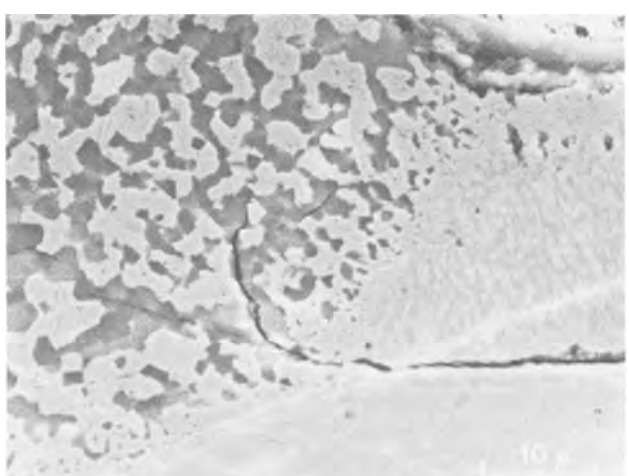

Fig. 14. The sulfidation front on a blade A specimen. CoCrAlY coating ot the right, sulfidated zone at the left. Notice that the coating has detached, but this has had little effect on the sulfidation reaction.

oxygen) comprised essentially of Ni and Co, the composition being approximately 50/50 as judged by EDXA peak heights, and effectively constant whether the phase occurs at the outer surface or adjacent to the coating-blade interface. Since no intermetallic compounds are formed in the Co-Ni system, this "constant" stoichiometry is assumed to result from the mechanism of formation. The two gray phases are chromium sulfides and they are distinctive in that the globular, light gray matrix normally contains traces of Co and Ni, and often somewhat larger concentrations of Ti, but never Al, whereas the darker blocky, or rectilinear, phase dispersed within it (shown more clearly in Fig. 15) always contains Al and excludes Ti. These chromium sulfide phases have been observed in earlier hot corrosion studies [*e.g.*, Ref. (13)] with the most thorough characterization being given by Erdoes (14). He also noticed the unusual Al and Ti solubilities and identified the light gray, globular phase as Cr_3S_4, and the darker, rectilinear phase as CrAlS, a thiospinel. We have adopted his identifications, but with some reservation as to the strict validity of Cr_3S_4 since there are several closely related sulfide species which could be formed.

The blade B specimens showed essentially the same behavior with Na_2SO_4-vaporous NaCl except the depletion zone at the sulfidation front was broader and more porous, very little CrAlS was produced, and as noted, the sulfidation and oxidation fronts were closer together. Figure 16 is a higher magnification view of the intersection of the very front of the sulfidation zone and the coating outer surface. Certain sites can be seen here where the β CoAl phase appears to be directly and preferentially attacked with void formation. More usually, however, a depletion zone separates the voids from the unattacked CoCrAlY. The white (SEM charging effect) layer at the very top of Fig. 16 is Al_2O_3 as indicated by EDXA.

The oxidation phase of the attack involves preferential oxidation of the chromium sulfide phases. This can be seen in Fig. 17, the oxidation front on a blade A specimen, and Fig. 18, the oxidation front on a blade B specimen. A large volume diminishment occurs and voids are formed. There is no buildup of sulfides or sulfur in the blade below the oxidation zone, so the sulfur is either displaced as sulfur oxide gas, or moves forward into the sulfidation zone to maintain the sulfur activity there. Unfortunately, no SO_2 evolution tests were made at this stage of the investigation. However, a later study (15) was made where "cut-edge" CoCrAlY-coated blade specimens were impregnated with NiS at the coating-blade interface, and it was found that the characteristic sulfidation-oxidation attack did not commence until oxygen was admitted into the system. This suggests that some "release of sulfur" by the oxidation of the sulfide phases is critical

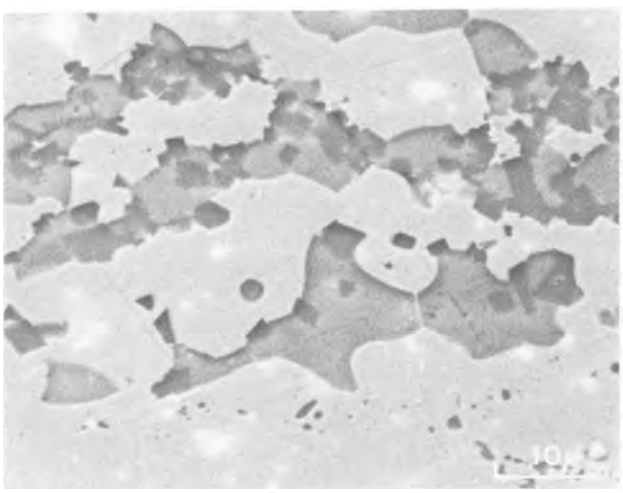

Fig. 15. Rectilinear CrAlS and globular "CrS" (probably Cr_3S_4) phases at the CoCrAlY-blade interface on a blade A specimen.

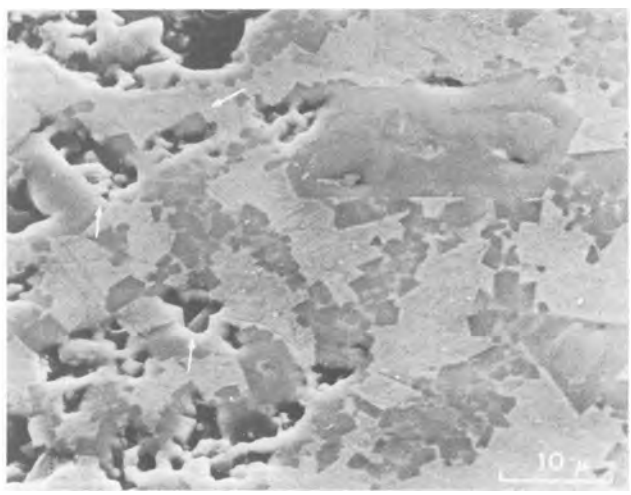

Fig. 17. Oxidation of chromium sulfide phases with blade A specimen. Arrows mark sites where rectilinear CrAlS persists after "Cr_3S_4" has apparently been oxidized away.

in this type of corrosion. The arrows in Fig. 17 point out residual particles of CrAlS left after oxidation of the Cr_3S_4 which originally surrounded them, *i.e.*, CrAlS appears to be more resistant to oxidation under these circumstances than Cr_3S_4.

Discussion

The experiments here are an example of deductive research where one approaches the complex whole and attempts to break it down into elements. Deductive research is a valid alternative, especially for involved problems of urgent concern such as hot corrosion, to the more traditional inductive research where one begins with the simplest element and attempts in a long series of experiments to factor in each new parameter to reach an ultimate understanding of the whole. An unavoidable consequence of deductive research, however, is that in the initial work there is not time, nor in fact is it the goal, to study each new element in depth as it is revealed. The discussion that can be made of each individual NaCl effect is therefore necessarily limited, but it may nonetheless be useful in relating the present results to earlier hot corrosion studies or in pointing new directions of research.

Enhanced vaporization of Na_2SO_4.—This experiment has been duplicated at another laboratory using Pt foil specimens in Al_2O_3 furnace tubes at 1650°F (16). The vaporization rates were higher because of the higher temperature, but the same results were obtained. Both "dry" and wet NaCl vapor increased the rate of Na_2SO_4 vaporization by approximately 100 times.

Concerning mechanisms, it is known that HCl can dissociate Na_2SO_4 deposits (17), presumably by reversal of the reaction

$$2NaCl + SO_2 + 1/2\ O_2 + H_2O \leftrightarrows Na_2SO_4 + 2HCl$$

It might be suspected, therefore, that the "dry" system still contains traces of H_2O, and that in a separate upstream reaction the NaCl is hydrolyzed to HCl which affects removal of the Na_2SO_4. The fact that deliberately adding H_2O only slightly increased (doubled) the Na_2SO_4 vaporization rate here might argue against this idea, as might the fact that both Al_2O_3 and silica tube liners, assuming a catalytic effect of the liner in the hydrolysis reaction, gave essentially the same results.

In any event, it is now clear that NaCl may actually tend to remove Na_2SO_4 deposits from gas turbine blades (turbine gases contain up to 5% H_2O (2) under some circumstances, a possibility little appreciated before in hot corrosion studies. The reaction needs further study, taking proper account of SO_2 and other species which may be pertinent.

Spalling of Al_2O_3 oxide.—Given the previous effect of NaCl vapor in removing Na_2SO_4, it is not certain that the Al_2O_3 spalling actually occurred in the presence of Na_2SO_4 and that our conditions were truly different from those of earlier investigators. The salient points from our work are: (*i*) an abnormally thick, spalling Al_2O_3 film formed when NaCl was present; (*ii*) this film showed some evidence of "restructuring," *i.e.*, the formation of the small needlelike particles in the film in Fig. 2, and (*iii*) no trace of chloride was found associated with the film, although the spalling was undoubtedly chloride-induced. With the exception of the "restructuring," these results are the same as those established earlier with the NaCl alone. Vapor phase NaCl has been reported to have caused chromium oxide films on Nimonic alloys to recrystallize into a porous mass of hexagonal crystals, possibly through a gaseous intermediate (18), and one might suspect a similar reaction in the restructuring of the Al_2O_3 films here, but the suspicion remains to be proved.

Volatile chromium species.—The discovery of S and Na in the condensed downstream Cr-containing deposits (Fig. 3 and 4) is new, and good evidence that the volatile chromium compounds which form under exposure to Na_2SO_4-vaporous NaCl (a salt system more related to engine operation than pure vapor phase NaCl) are not simply chromium chlorides or oxychlorides. It is conceivable that the deposits are produced by "cocondensation" of two or more vapors, but it seems unlikely that low vapor pressure Na_2SO_4 would happen to condense at the same site as the much more volatile chromium compounds. Recently it has been shown that the predominant volatile species produced in 1650°F oxidation of chromium under NaCl vapor are addition complexes, $(NaCl)_xCrO_3$, where $x = 1$, 2, and 3 (19). One can speculate that the deposits in Fig. 3 could result from a similar addition complex, but one now containing SO_2 or a related compound since Na_2SO_4 is present.

Titanium interactions.—Sodium chloride has been observed in the past to promote recrystallization of certain oxides into large, well-faceted crystal masses, presumably by the action of unstable gaseous intermediates [*e.g.*, Ref. (18)]. We believe an analogous reaction may be involved here, particularly since evidence of chlorine (chloride) has been found in the TiO_2 bladelets (Fig. 10).

Our interpretation is that NaCl vapor penetrates along the coating-blade interface and reacts with (dealloys) the Ti-rich blade surface, titanium being known to tend to segregate disproportionately to alloy surfaces. The reaction probably involves the formation of a volatile, metastable titanium chloride which decomposes forming TiO_2 (with some Cr and Al impurity) when the crack opens, reducing the chloride concentration and allowing free access of oxygen. The well-faceted structures of the TiO_2 crystals and the porosity of the dealloyed substrate seem consistent with such a vapor phase transport.

Some U.K. experiments (3) wherein IN587 was preoxidized and then exposed to NaCl vapor at 1740°F may represent another example of this type of reaction. The preoxidized layer ultimately spalled off under this treatment, exposing a porous Ni-rich substrate clustered with localized deposits of large, prismatic TiO_2 crystals. This is essentially the same morphology as observed here, and we presume formed by the same mechanism. Another indication of TiO_2-NaCl interaction is given in the report that superalloys containing TiO_2 in the oxidation scale are sensitive to NaCl attack (20). More proof of the mechanism is required, but the reaction is obviously important and may relate to the performance of Ti-containing alloys in marine turbines.

Sulfidation-oxidation of CoCrAlY.—After our discovery, we learned that this phenomenon had been observed in other laboratories (16) and studied in some detail (21), although nothing had been published. Felten and Pettit (16) subsequently found several clear examples of the sulfidation-oxidation attack morphology on a blade removed after 4800 hr of sea service, indicating the reaction has relevance in marine hot corrosion. We have shown in later experiments that NiS, formed under Na_2SO_4 at the coating-substrate interface exposed at the cut-edge, is the critical species in the attack (15).

The effect of NaCl vapor on this reaction seems to be to change the kinetics (reduces incubation time before attack, alters separation between sulfidation and oxidation fronts presumably by affecting the kinetics of one or the other) and to promote the formation of "Cr_3S_4" over CrAlS. Erdoes (14) observed that CrAlS was found more prevalently in his laboratory specimens (where no NaCl was used) than in specimens removed from industrial turbines (where chloride was possible). This encourages us to believe that our results are not artifactual and do pertain to turbine corrosion. The finding of this apparent ability of NaCl to influence which chromium sulfide phase is formed may be highly significant, since it represents

one of the few items of physical evidence, aside from oxide spalling, which has yet been associated with NaCl in hot corrosion.

Relevance to shipboard corrosion.—Obviously 300 ppm is a much higher NaCl concentration than ship engines are exposed to, although it could be argued that concentrations of this magnitude prevail temporarily near points of sea salt particle or seawater droplet impact on the blades. However, as will be recalled, 300 ppm was chosen because it gave chloride effects within 100 hr. It is likely that 30 ppm or even less could produce chloride effects if longer test periods were allowed.

Furthermore, since even 300 ppm corresponds to only about 1/20 saturation of the NaCl vapor, we consider that the points originally raised for investigation have been proven. There is no necessity for the NaCl to condense (or perhaps to even dissolve to any appreciable extent in the Na_2SO_4, based on our failure to detect chloride in the Na_2SO_4 vaporization experiments) to exert its influence, and only under special circumstances will even traces of chloride be left to mark its involvement. It is therefore unrealistic to expect to disprove chloride effects in shipboard hot corrosion by calculating condensation pressures or examining corroded parts for chloride.

Technical Notes

Poly (Fluoro Methacrylate) as Highly Sensitive, High Contrast Positive Resist

Masami Kakuchi, Shungo Sugawara, Kei Murase, and Kentaro Matsuyama

Nippon Telegraph and Telephone Public Corporation, Ibaraki Electrical Communication Laboratory, Tokai, Ibaraki, 319-11, Japan

Recently, the necessity for manufacturing very fine patterns of submicron size on integrated circuit devices has increased. X-ray lithography is a useful technique for exposing whole wafers (1). Most x-ray resist materials have been appropriated from electron beam resist materials. Poly (methyl methacrylate), PMMA, is most widely used, however, it has only low sensitivity, about 5×10^{-5} C/cm^2 for electron beam (AV: 10 kV) (2) and 2400 mJ/cm^2 for x-rays of Mo L line. In order to overcome this low sensitivity, modified PMMA resists with methyl isopropenyl ketone (3), anhydride bridge (4), isobutylene (5), acrylonitrile (6), methacrylic acid (7), and α-chloroacrylate (8) have been

Key words: x-ray lithography, polymer resist, positive resist.

*** T_g was measured by thermomechanical analysis (TMA).

studied, but in many cases their contrast is too low. The newly developed resist materials described in this paper consist of fluorobutyl methacrylate homopolymers, and were found to have both higher contrast and much higher sensitivity than PMMA.

Poly (hexfluorobutyl methacrylates), FBM, were synthesized by radical polymerization of hexafluorobutyl methacrylates from methacrylic acid and 2, 2, 3, 4, 4, 4-hexafluoro-, 1-methyl-2, 2, 3, 4, 4, 4-hexafluoro-, 1-ethyl-2, 2, 3, 4, 4, 4-hexafluoro-, 1-n-propyl-2, 2, 3, 4, 4, 4-hexafluoro-, 1,1-dimethyl-2, 2, 3, 4, 4, 4-hexafluoro-, and 1-methyl-1-ethyl-2, 2, 3, 4, 4, 4-hexafluorobutyl alcohol, respectively. The properties of FBM's are shown in Table I.

The resist materials were dissolved in methyl isobutyl ketone (MiBK), and were spin coated on the silicon substrate with or without oxide layer. After prebaking at 120°-140°C in vacuum in order to attain a suitable adhesion to the substrate, the resists were irradiated with soft x-ray through a stainless steel aperture for determining sensitivity, or through a Si mask (4 μm thick) with an Au absorber (4000Å) for replicating fine patterns. The x-ray exposing apparatus was a modified Rota Unit RU-200PL made by Rigaku Denki Company. Molybdenum was used for the target (Mo L, 5.4Å), and the target chamber atmospheric pressure was 10^{-6} Torr. A vacuum window was made of a 12 μm polyester film.

Resist samples were exposed on a 6 mm diam area, and the sample chamber was maintained at 10^{-3} Torr during exposure. Target to sample distance was 12 cm. X-ray intensity irradiated was measured with a gas flow proportional counter using P-10 gas. It was 0.19 mW/cm^2 at 16 kV/200 mA electron beam bombardment, corrected with a resist whose sensitivity is easily measurable, such as epoxidized polybutadiene and chloroethyl vinyl ether copolymer (9).

Irradiated resist was developed using isopropyl alcohol (IPA) with or without MiBK. Developed resist was postbaked to remove any remaining developing solvent.

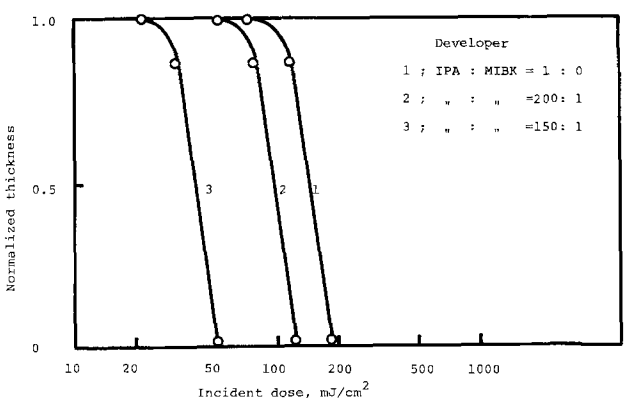

Fig. 1. Plot showing normalized FBM-1 resist thickness vs. incident Mo L x-rays dose for various IPA-MIBK developer combinations. Resist film was coated on the Si wafer to 0.5 μm thickness.

Table II. X-ray irradiation characteristics of FBM resists

Name	Sensitivity,* mJ/cm^2	γ value	Developer
FBM-2	80	4.5	IPA, 2 min
FBM-3	46	4.5	IPA, 2 min
FBM-4	70	2.5	IPA, 20 sec
FBM-5	53	2.5	IPA, 2 min
FBM-6	62	2.5	IPA, 2 min

PMMA***	1 × 10^{-4} C/cm^2†	3.3	IPM:MiBK (1:1), 3 min

* Mo L line at 16 kV, 200 mA
** M_w: 500,000.
*** Elvacite 2041, M_w: 496,000.
† Electron beam sensitivity (20 kV).

The sensitivity was determined by measuring the remaining resist thickness on a surface roughness meter from Kosaka Laboratory Limited. The postbaked substrate, with replicated resist pattern, was etched at 23°C with buffered hydrofluoric acid solution for 3 min, or chromium etching solution for 1 min.

FBM-1 sensitivity curves for x-ray are shown in Fig. 1 for several developing conditions and various combinations of IPA and MiBK. By changing the IPA

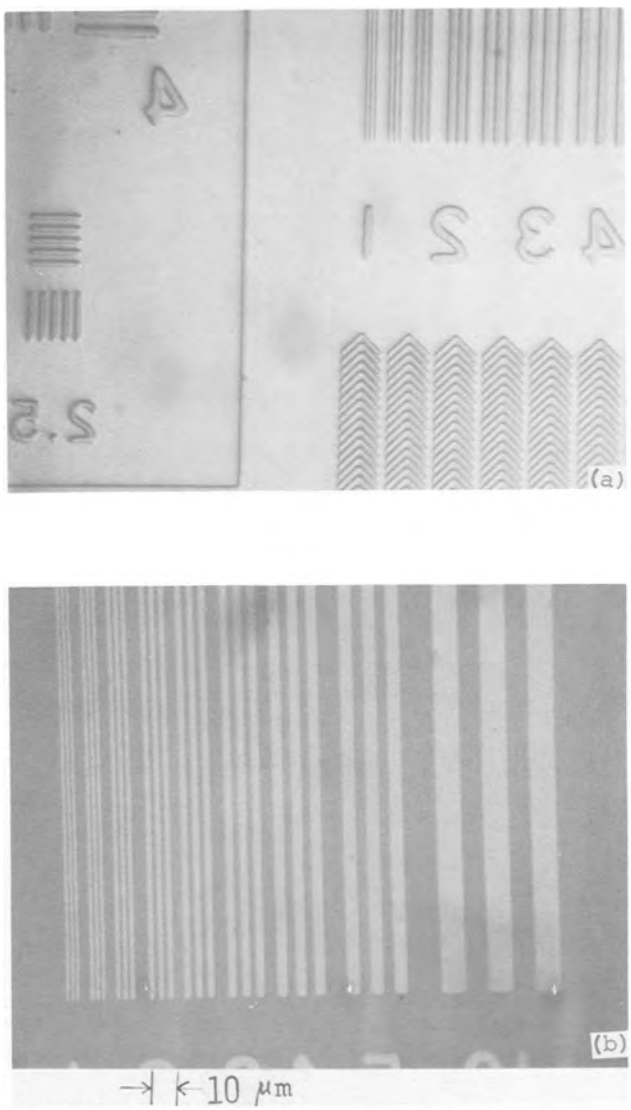

Fig. 2. Photomicrographs of FBM positive resist pattern on SiO_2/Si substrate. (a) and (b) are the same scale. (a) FBM-1 resist resolution pattern formed by 10 kV and 100 mA Mo L x-rays for 45 min, incident dose is 140 mJ/cm^2, and developed with IPA-MIBK (150:1) developer. (b) FBM-2 resist line and space pattern developed with IPA-MIBK (25:1) developer.

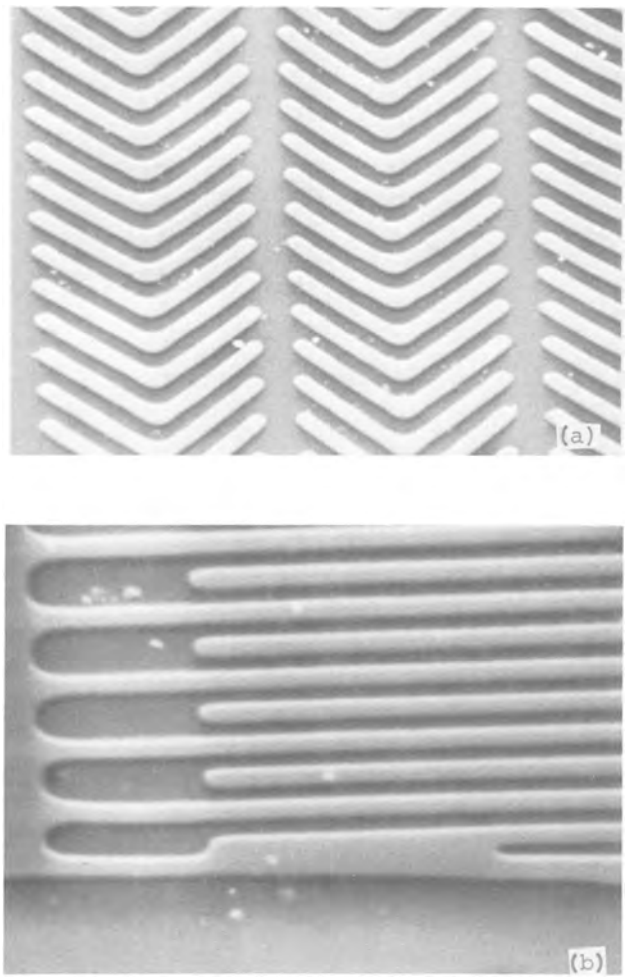

Fig. 3. Scanning electron micrographs of silicon oxide pattern using FBM-1 resist as etching mask. Resist pattern was formed as Fig. 2(a), postbaked at 75°C for 30 min, and etched with buffered hydrofluoric acid. (a) 1.5 μm line and space chevron pattern. (b) 1 μm interdigital pattern.

and MiBK volume ratio from 1:0 to 150:1, the sensitivity improved without contrast reduction (γ4.5). Contrast γ is defined as rising slope, and may be expressed as $\gamma = [\log D_0 D_1]^{-1}$ where D_0 and D_1 are the dose of 0 and 100% film remaining (10). However, when the ratio becomes 100:1, the unexposed region dissolves, and at the best developing condition (150:1 ratio), the sensitivity is 52 mJ/cm^2 for the Mo L line, 46 times more sensitive and higher in contrast than PMMA developed with IPA-MiBK, as shown in Table II. The properties of other FBM resists are shown in this table. They have comparably good sensitivity with FBM-1.

The sensitivity of FBM-1 for an electron beam is 4×10^{-7} C/cm^2, and γ value is 5 at 20 kV accelerating voltage and IPA-MiBK (160:1) developer.

A high resolution FBM resist pattern was produced by the x-ray replicating system using a Si/Au mask. Figure 2 shows resolution patterns of 0.5 μm thick FBM-1 and -2 resist on Si substrate with SiO_2 surface. Figure 3 shows a SiO_2/Si pattern etched using the resist mask of Fig. 2. Figure 4 shows a chromium pattern etched using FBM-5 resist. The resistance to buffered HF solution and chromium etchant is more than 10 and 3 min, respectively.

The resist resolution limit is dependent on the irradiation system. The FBM-1 resolution is recognized as being at least 0.3 μm by the electron beam exposure system. Figure 5 shows FBM-1 resist pattern after development. The pattern is scanned with a 0.1 μm electron beam of the Thomson-CSF exposure system. The minimum line width obtained was 0.3 μm.

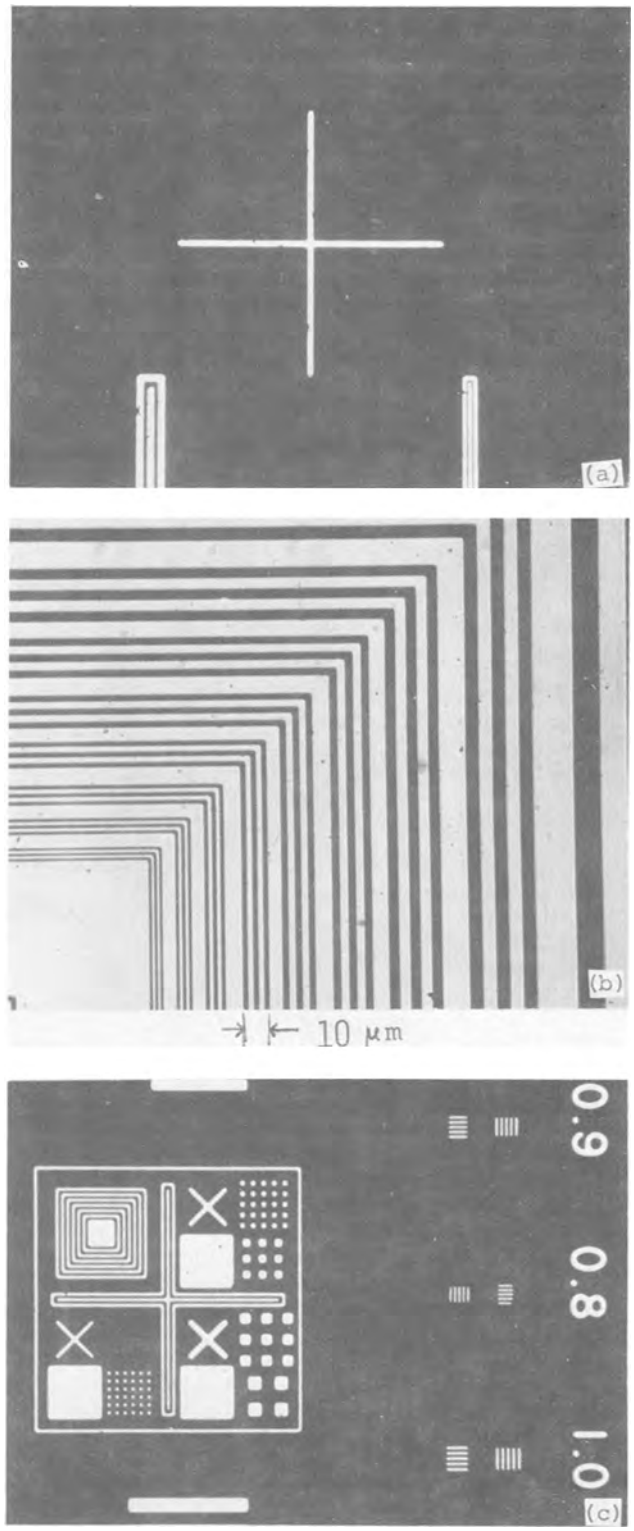

Fig. 4. Photomicrographs of chromium etched pattern viewed in transmission. Substrate consists of 400Å chromium oxide and 800Å chromium evaporated on glass plate. (a) FBM-5 was used as etching mask. Line width is 1 μm. (b) and (c) FBM-6 was used as mask. Minimum line width is 1 μm in (b) and 0.8 μm in (c), respectively. In (c), pattern edges of pair bars are round because original mask pattern, made from photolithography, was round. (b) and (c) are the same scale.

FBM-1 resist is sufficiently useful in a dry process, such as plasma etching, with a suitable thermal control. FBM-1 replicated pattern begins to flow at a higher temperature than its T_g (Table I).

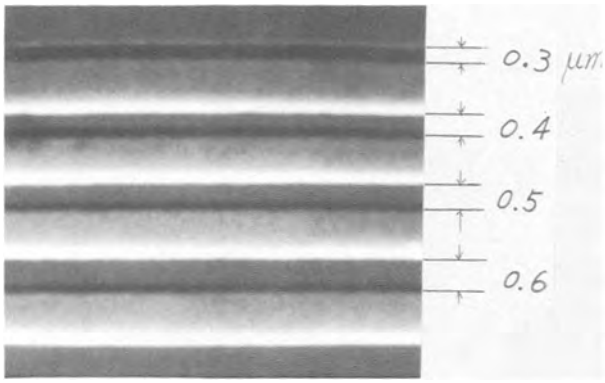

Fig. 5. Scanning electron micrograph of FBM-1 resist pattern delineated by electron beam exposure at 20 kV and 10^{-6} C/cm^2 dose, and developed with isopropyl alcohol.

Rutherford Backscattering Analysis of Ion-Implanted, Thermally Oxidized Silicon

C. E. Christodoulides, W. A. Grant, and J. S. Williams

Department of Electrical Engineering, University of Salford, Salford M5 4WT, England

It is well documented (1-3) that many impurities redistribute during thermal oxidation of silicon. Impurities may be incorporated within the oxide or be pushed ahead by the advancing oxide-silicon interface. Other factors, including the segregation coefficient at the interface, the rate of oxidation, and the impurity diffusion coefficient, determine the final distribution. Since ion implantation is now widely employed for doping silicon, data on redistribution in oxidized, implanted samples (2, 3) is essential to complement that for diffused samples.

Rutherford backscattering (RBS) provides a simple experimental technique (2) for investigating the thermal oxidation of silicon implanted with heavy implants (*i.e.*, impurities heavier than silicon). The technique provides information on the concentration and distribution of implanted species, and on the stoichiometry of compound substrates. When combined with channeling (2), it also provides information on the location of impurities within the silicon lattice. Using conventional RBS apparatus (*e.g.*, 2 MeV He^+ as the analyzing beam and a solid-state detector for energy analysis of the scattered beam), typical depth resolutions of ~ 250Å are obtainable. Recently, however, it has been demonstrated that, using the same apparatus, this resolution can be improved to ~ 30Å by employing a He^+ analyzing beam that enters and leaves the sample at small angles to the surface (4). With this improvement, RBS becomes a powerful technique for investigating, with high resolution, parasurface layers of solids containing heavy impurities (5).

It is the purpose of this short communication to demonstrate the use of high resolution RBS in the analysis of thin layers of thermally oxidized silicon containing implanted impurities. Samples of <111> orientation silicon were implanted with various species including Xe^+, Pb^+, and Dy^+ at energies of 20-80 keV and to a dose 1-3 $\times$ 10^{15} ions cm^{-2}. Oxidation was carried out in air at 700°C to produce oxide layers between 100 and 2000Å, and Fig. 1 shows typical RBS data. Immediately following implantation (Fig. 1a) the backscattering spectrum consists of a signal from the silicon together with a well-resolved peak from the implanted Dy^+ ions. A depth scale can be fitted (3) along the abscissa and the projected range, *Rp*, of the Dy implanted into Si, is measured as 175Å. A thermal oxidation step results in the spectra shown in Fig. 1b, where the shaded areas can be used to calculate the oxide thickness [oxide stoichiometry and oxidation rate can also be measured, and are reported elsewhere (6)]. The position of the Si/SiO_2 interface is indicated by an arrow in Fig. 1. Changes in the distribution profile of the implanted Dy due to this oxidation are apparent. The advancing oxide-silicon interface has pushed some of the impurity ahead of it, but some has been incorporated within the oxide. A second oxidation stage, sufficient to take the oxide layer completely past the original impurity distribution within the silicon, is shown in Fig. 1c. Dysprosium retreats further before the oxide-silicon interface, leaving a proportion as a clearly resolved peak located at its original, implanted position. The data of Fig. 1 illustrate the high resolution of the RBS technique employed here; impurity redistribution can be monitored with precision as the oxide-silicon interface gradually moves through the shallow (~350Å wide) implanted distribution in silicon.

In order to more readily compare spectra of the type presented in Fig. 1 it is more convenient to have a single depth scale for the abscissa, and this is achieved by presenting all impurity distributions as a function of depth within pure silicon, as in Fig. 2.

Key words: Dy^+, Pb^+, and Xe^+ impurities, RBS, thermally oxidized silicon.

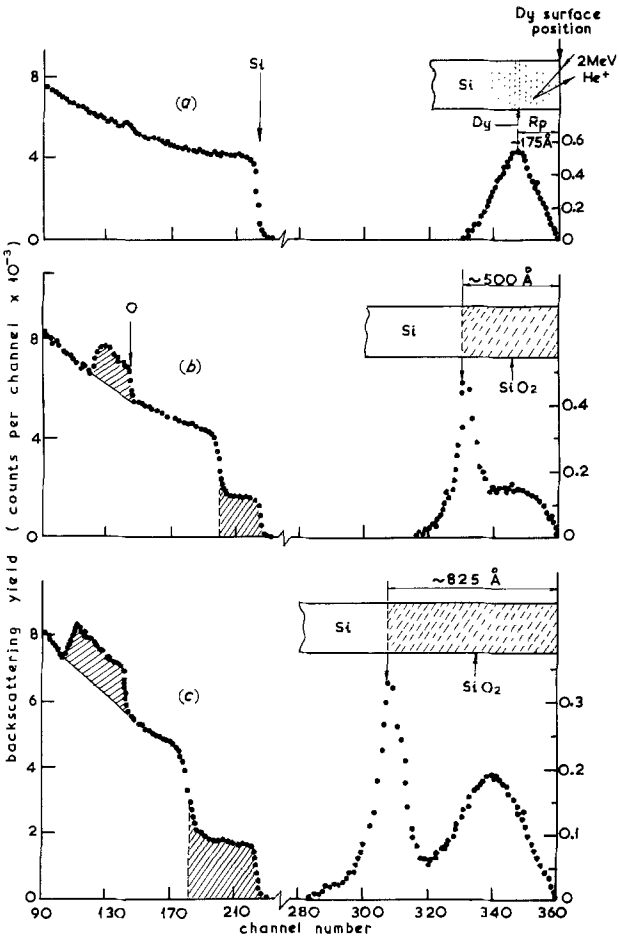

Fig. 1. Rutherford backscattering spectra for silicon implanted with 20 keV Dy^+: (a) immediately following room temperature implantation; then (b) thermally oxidized to produce 500Å SiO_2; and (c) thermally oxidized to produce 825Å SiO_2.

Thus, the distribution of an impurity within a particular SiO_2 layer is converted to the distribution within the equivalent thickness of Si consumed during the oxidation. The spectra of Fig. 2 now more easily indicate any movement of impurities relative to the silicon consumed in the oxidation process. Consequently, the thickness of all silicon and SiO_2 layers are quoted in terms of $\mu g\ cm^{-2}$ of silicon. (For convenience, thicknesses are also shown in Å.) As a specific example, 100Å of SiO_2 is formed from oxidation of 45Å (1.05 $\mu g\ cm^{-2}$) of Si.

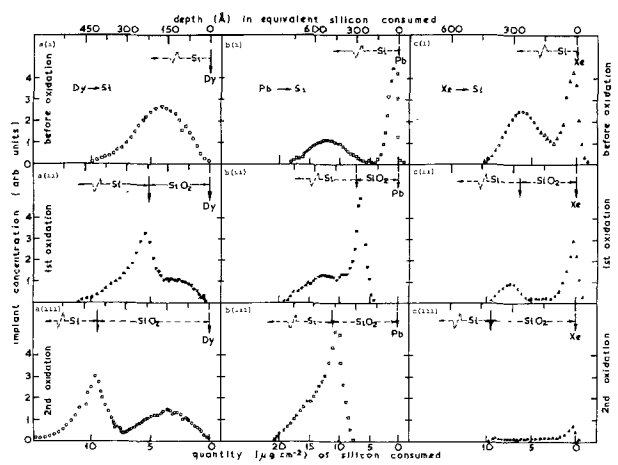

Fig. 2. The distribution of impurities Dy^+, Pb^+, and Xe^+ implanted into silicon: (*i*) top, before oxidation; (*ii*) center, after first oxidation; (*iii*) bottom, after second oxidation. All depth distributions, whether in Si or SiO_2, are shown relative to the amount of original silicon substrate converted to SiO_2 (see text for explanation).

The species Dy, Pb, and Xe shown in Fig. 2 illustrate typical behavior found from investigations (7) of a wide range of impurities. Figure 2a (i), (ii), and (iii) repeat the Dy data of Fig. 1, but using the depth scale described above, and show part of the impurity retreating before the oxide-silicon interface and part remaining at its original, implanted position. Figures 2b (i) and 2c (i) show the distributions of implanted Pb^+ and Xe^+ annealed to 700°C for ½ hr prior to oxidation. This annealing stage was necessary to stabilize the impurity profiles against further diffusion during the oxidation stages. It can be seen that both Pb and Xe diffuse partly to the surface through disordered silicon to produce a double peaked distribution profile. As shown previously (8, 9), the surface peak corresponds to impurities trapped behind the thin (< 20Å) layer of oxide normally present at room temperature on silicon.

Figures 2b (ii) and (iii) show a total push-back of Pb in front of the advancing oxide-silicon interface. The complete retreat of Pb occurs even for high implant doses, and recent results (7) show that greater than 20 monolayers of lead can be accommodated at, or close to, the Si/SiO_2 interface. In Fig. 2c (ii) the first oxidation step encompasses the Xe trapped behind the original, thin surface oxide. Rapid diffusion at the oxidation temperature causes loss of this gas except for a small percentage trapped at stable sites near the surface. The second oxidation, Fig. 2c (iii), passes the oxide-silicon interface completely through the implanted Xe, causing further gas loss by diffusion, although a small fraction remains trapped in its original implanted position.

The results presented above are a clear demonstration of the use of RBS in monitoring impurity distribution during thermal oxidation of silicon. In particular they illustrate the high depth resolution that can be obtained by optimizing the scattering geometry of the analyzing He^+ beam. With this high resolution it is clearly possible to follow the progress of the oxide-silicon interface as it proceeds through a silicon substrate, causing redistribution of shallow, implanted impurities.

The examples discussed above illustrate the three types of behavior we have found with a wide range of implanted species (7). Some species are completely pushed back by the advancing oxide (*e.g.*, Pb); some are partially pushed back and partially incorporated (*e.g.*, Dy); and some are incorporated by the advancing oxide, but diffuse readily in the oxide (*e.g.*, Xe). Implanted species have also been found to affect both the rate at which oxidation occurs and the stoichiometry of the resulting oxide (7).

Manuscript submitted Feb. 23, 1977; revised manuscript received June 27, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

ABSTRACT

A number of observations on the electrooxidation of lead in 5M H_2SO_4 are presented. It is shown that the induction period in the potentiostatic oxidation to PbO_2 is due to the thickening of the $PbSO_4$ film and that a rising current transient signals the development of phase PbO_2; the minimum overpotential for this is ~200 mV. On a Pb|PbO_2|$PbSO_4$ electrode a rising current response to a potentiostatic experiment is not generally obtained due to the presence of adequate growth centers. Battery behavior is in agreement with the observations.

The oxidation of lead and lead sulfate to lead dioxide in sulfuric acid solutions has been extensively studied because of the technical importance of the lead dioxide (positive) battery electrode (1). Studies have ranged from elegant investigations to simple battery cycling tests.

There are three possible reactions which occur when a lead electrode is anodically polarized in sulfuric acid solution

$$Pb + SO_4^{2-} = PbSO_4 + 2e \quad [1]$$

$$PbSO_4 + 2H_2O = PbO_2 + 4H^+ + SO_4^{2-} + 2e \quad [2]$$

$$2\,OH^- = H_2O + \tfrac{1}{2}\,O_2 + 2e \quad [3]$$

$$(H_2O = 2H^+ + \tfrac{1}{2}\,O_2 + 2e)$$

Under specific conditions either or all of these occur and the electrode behavior has to be inferred from current-potential-time data coupled, where possible, with analytical and morphological studies of the electrode. Often these latter are of limited help due to the occurrence of the redox reaction

$$PbO_2 + Pb + 2H_2SO_4 = 2PbSO_4 + 2H_2O \quad [4]$$

Reaction [4] occurs when lead contacts lead dioxide under conditions of externally uncontrolled potential, the potential of the electrode being defined kinetically by the requirement that reactions [1] and [2] must occur at the same rate. The detailed response of lead to oxidation is complex and has, therefore, been built up gradually with many investigations contributing to the over-all picture.

The pioneering work of Fleischmann and Thirsk (2) showed that the development of a new phase of lead dioxide by the electrooxidation of lead sulfate required that centers of PbO_2 were nucleated. The growth of these centers gave rise to an increasing current (rising transient) until the growing areas overlapped and the current was reduced (falling transient) as the available unoxidized area became smaller.

Equations describing the current response to a potentiostatic experiment have been developed by Thirsk and co-workers (3). These equations have been applied to the process of initial oxidation of lead sulfate to lead dioxide (first charge) and subsequent cycle of charge/discharge in these laboratories (4). For the initial conversion (1st charge), the oxidation of the lead sulfate surface grown on lead produced data which confirmed earlier work (2) that progressive nucleation and growth followed by overlap was a satisfactory description of the process. Application of the Armstrong equation (3c) to the experimental data showed that by invoking a three-dimensional growth habit it was possible to provide a complete mathematical simulation of the current response to a potential step. The electrocrystallization process on a lead sulfate electrode produced by exhaustively reducing a lead dioxide electrode in sulfuric acid was more complicated than the initial $PbSO_4 \rightarrow PbO_2$ conversion. Two instantaneous nucleation and growth processes were observed, the first being two dimensional; the second, later process, in which the remainder of the lead sulfate was converted, occurring with the evolution of oxygen.

Under most practical conditions of lead cell operation, rising and falling outputs are not considered. There is no doubt that on a lead dioxide base in 5M sulfuric acid only a simple falling transient is observed as the current response in a potential step experiment (5). This system resembles that of the lead acid positive in that the electrochemistry occurs on a lead dioxide base, however, in the lead cell the lead dioxide is spongy (porous—this form of lead dioxide always results from the oxidation of $PbSO_4$ in H_2SO_4) whereas in our experiments it was massive (5). In order to consolidate the understanding of the lead cell positive electrode behavior and reconcile the two observed responses, some experiments have been carried out with lead electrodes using both the potentiostatic and potentiodynamic techniques. The present paper describes these experiments and discusses the results in the context of presently available practical observations and theoretical ideas. An attempt to apply electrocrystalli-

zation concepts to the charge in a part of the lead-acid cycle has proved satisfactory.

Experimental

The working electrode was a mechanically polished (roughened glass followed by filter paper) lead disk (Johnson Matthey 99.999%) shrouded in Teflon. In most of the experiments a layer of lead was electrodeposited (5 mA/cm^2 for 15 min) from acid perchlorate electrolyte (2.25M Pb^{2+}, 0.1M H^+, 4.6M ClO_4^-). Experiments were made using a function generator (J. Dawson, Newcastle-upon-Tyne) and a potentiostat (Chemical Electronics, Type TR 70 2A). The electrode response was recorded on either an oscilloscope (Hewlet Packard, Type 130c and camera) or a pen recorder (Bryans Series 26000, X-Y-t). The counterelectrode was platinum gauze of large surface area and the reference electrode was $Hg|Hg_2SO_4|H_2SO_4$, 5M introduced at the electrode surface via a Luggin electrode probe system. All measurements were made at 23° ± 1°C. Battery tests were made using a Davenset constant potential (13.9V) charging device operating on a 12V, 40 A-hr battery. The current input was recorded automatically (Bryans Series 26000).

Results and Discussion

The rest potential of the lead electrode in 5M H_2SO_4 was found to be −963 mV; at potentials more positive than this lead sulfate was formed. Figure 1 shows a cyclic voltammogram on lead around the reversible potential (from −1400 to −700 mV) showing that at slightly more positive potentials than the reversible potential there exists a region of active dissolution. Potentiostatic experiments at −700 mV showed that the electrode is in the "passive region" although current continues to cross the electrode interphase by the process of high field conduction through a highly resistive film of lead sulfate. This film reduces the current flow to a very small value. However, for this current flow a limit exists due to the fact that the small solubility of $PbSO_4$ in 5M H_2SO_4 causes the film to need constant repair and this is offset by the high field conduction process.

Figure 2 shows a number of cyclic sweeps made around the lead dioxide equilibrium potential (700-1800 mV) at 10 mV/sec on an electrode at which PbO_2 had been produced from $PbSO_4$ at 1800 mV. Only one peak due to the reduction of PbO_2 and a wave due to oxygen evolution were observed, the PbO_2 formation peak being buried in the oxygen wave. These experiments indicate that the investigation of the behavior of systems in which lead dioxide and oxygen are produced simultaneously in sulfuric acid is limited to low

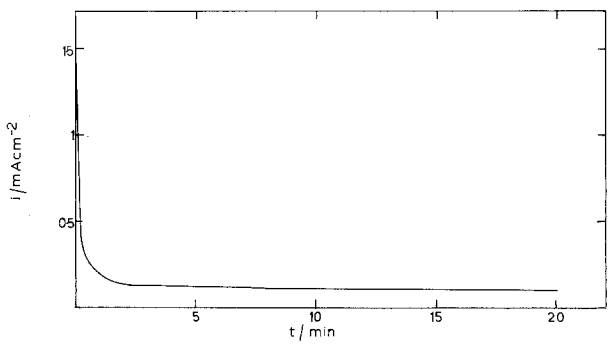

Fig. 3. Potential step from −700 to 700 mV on lead sulfate filmed lead electrode (thickening of $PbSO_4$ layer) in 5M H_2SO_4.

sweep speeds and potential step experiments. Figure 3 shows the effect of stepping an electrode covered with a stable $PbSO_4$ film (−700 mV) to a more positive potential in the sulfate region (+700 mV). A falling transient represents the thickening of the lead sulfate film.

Experiments showed that the reversible potential for the $Pb|PbO_2|PbSO_4$ H_2SO_4, 5M electrode was 1089 mV, and although the formation of PbO_2 is thermodynamically possible at this potential it was formed only after a considerable time period. In fact no formation of PbO_2 was observed until a significant overpotential was applied. Figure 4 shows the results of a step from −700 to 1492 mV. A long period of very gentle current fall is first observed which corresponds to the thickening and development of the $PbSO_4$ layer. This is followed by a rising and subsequently falling transient which signifies the formation of PbO_2. The form of the transient is similar to that previously reported for the progressive nucleation and growth of a three-dimensional deposit (2, 4). The data of Fig. 4 emphasize the importance and interplay of overpotential and time on this system. Presumably the potential across the lead sulfate/solution interphase was not sufficient for the oxidation of the Pb(II) species because of the potential drop within the lead sulfate layer itself due to the highfield conduction process which accounted for too much of the applied overpotential. It is only when the current flow through the thickening film has been reduced that oxidation starts. Another view of the process is that the lead has to be sufficiently passivated for the oxidation to commence to any net extent; any Pb(IV) species produced at a lead surface covered by an incomplete lead sulfate layer reacts according to Eq. [4]. The identities of the phases at the electrode

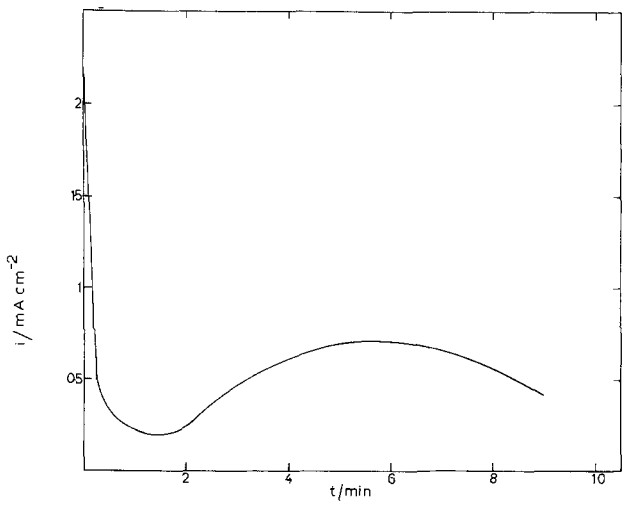

Fig. 4. Potential step from −700 to 1492 mV on lead sulfate filmed lead electrode.

were confirmed by subsequent linear sweep experiments from the final potential (1492 mV). Before the rising portion, no peak due to the reduction of PbO_2 was observed, and after the rising and falling portion a single peak due to the reduction of PbO_2 was observed. A prolonged period at 1492 mV showed a distorted peak indicating that oxygen had been produced by reaction (3) (see below).

Figure 5 shows the effect of a step into the lead dioxide region from a potential at which the lead electrode is covered with a stable film of sulfate. The results are presented as a series of reductive sweeps from the higher positive potentials to 700 mV. It is clear that only at potentials greater than 1300 mV is product lead dioxide observed at the electrode (shown by the presence of a reduction peak at ~1040 mV) within the experimental time scale. These data confirm that a considerable overpotential is required for the development of lead dioxide on an exclusively lead sulfate surface in sulfuric acid. These observations agree with those of Fleischmann and Thirsk (2) and the orders of the minimum overpotentials observed agree well with what has previously been reported. It is interesting to note that at the lower overpotentials at which lead dioxide development does start, the form of the rising time transient is very elongated. This is what would have been predicted from our previous work (4) when a correlation of potential with log (time for maximum current to occur) gave a straight line with a positive slope.

The importance of the reaction [4] in the oxidation of lead is shown by the results of a series of experiments in which lead dioxide was formed potentiostatically at 1800 mV for 30 min and then allowed to remain isolated in the electrolyte solution. Initially the potential was a stable 1157 ±1 mV for times of the order of hours and represented the reversible potential of the Pb|PbO$_2$|PbSO$_4$|H$_2$SO$_4$ (5M) electrode, in the absence of oxygen. However, when the electrode had stood for periods of days, the potential fell to −0.4V, showing that the lead dioxide layer was not perfect enough to exclude the hydrogen ion from the Pb|PbO$_2$ junction and therefore furthering reaction [4]. Polarized for sufficient times in the oxygen region, the electrode potential remained effectively constant at 1157 mV (the potential of electrodeposited PbO_2 was 1030 mV and presumably this difference is due to strongly adsorbed oxygen).

Potentiostatically oxidized and stabilized electrodes with electrode potentials of 1157 mV were uncomplicated by adsorbed oxygen (absorbed oxygen would, of course, be present) as shown by a single (PbO_2) reduction peak in the L.S.V. caused when swept to 927 mV. Figure 6 shows the results of stepping electrodes previously swept down from 1157 to 927 mV back up to 1357 mV. Only a simple falling transient is seen, indicating the absence of a significant nucleation and growth process by comparison with the overlap of the growing centers. The oxidation centers for the conversion of $PbSO_4$ to PbO_2 appear to be fully developed because of the underlying PbO_2 which both readily conducts electricity and provides adequate centers for the growth of further PbO_2. The overlap of the growing regions must commence from the time the step is initiated. Increasing the step potential to 1484 mV and ultimately to 1500 mV similarly showed only a falling transient (Fig. 6). However, it was interesting to note that at the higher oxidation potentials evidence was obtained from subsequent cathodic sweeps that oxygen was present at the electrode. These are shown in Fig. 5 by peaks in the voltammogram.

The appearance of the "coup de fouet" in the charge and sometimes in the discharge behavior of batteries is well known. The form of a rising potential in a galvanostatic charging process charge curve is difficult to treat mathematically however. A potentiostatic charge process is more assessible. It is known that the early part of the recharge of a negative plate is quite efficient [the Pb(II)/Pb reaction is fast] and there are no crystallization effects to take into account. The main factor which will cause changes in the current passing through the battery is the positive plate, and this will

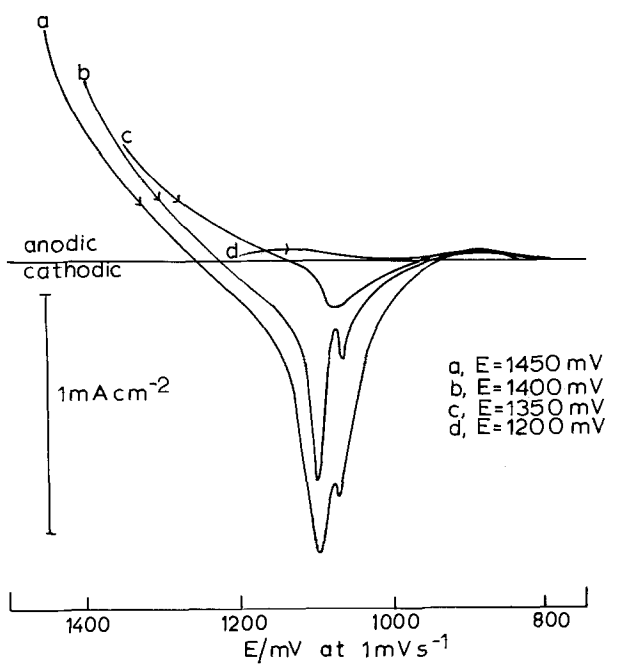

Fig. 5. Sweep to 700 mV from fixed potentials in 5M H$_2$SO$_4$

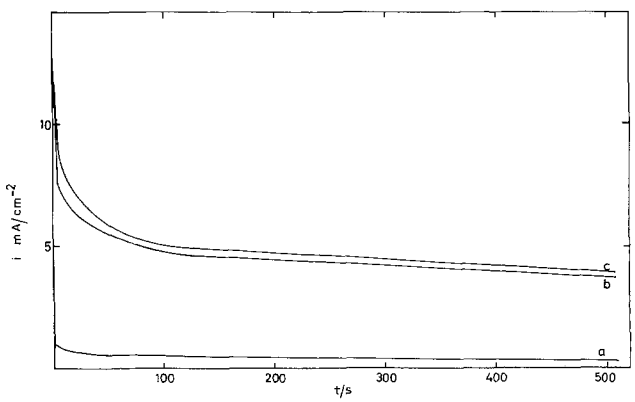

Fig. 6. Potential steps from 927 mV to higher potentials in the range (a) 1357 mV, (b) 1484 mV, (c) 1500 mV in 5M H$_2$SO$_4$.

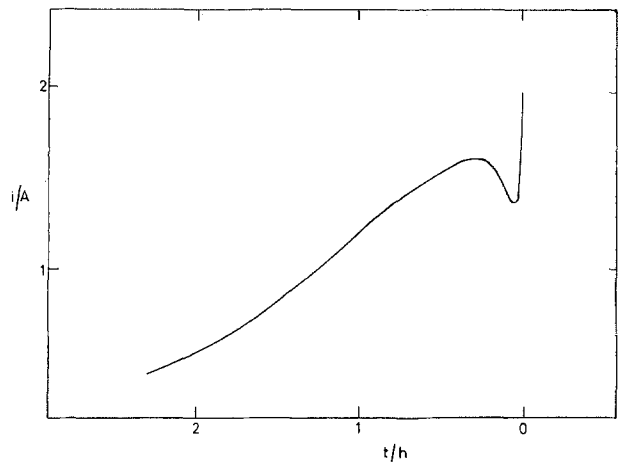

Fig. 7. Typical "coup de fouet" observed in a constant potential recharge of a 12V 40 A-hr lead acid battery at 13.9V.

be due to possible nucleation and growth effects. A relatively new 12V 40 A-hr battery was investigated using a constant potential charger to recharge from the fully discharged condition. Figure 7 shows the current response to a charge. A distinct "coup de fouet" is observed immediately the fall from the double layer charging peak is obtained. The current then falls away in the expected manner. The transient rises linearly at first which indicates that we are dealing with an instantaneous nucleation process. For two-dimensional growth and subsequent overlap the Eq. [1] describes the situation (6)

$$i = \frac{Z\mathbf{F}\pi M}{\rho} N_0 k^2 t \exp \frac{(-\pi M^2 N_0 k^2 t^2)}{\rho^2} \qquad [5]$$

where ρ = density, M = molecular weight, N_0 = number of nuclei/cm^2, k = rate constant for crystallization, Z = number of electrons transferred (2).

With a porous electrode the simple Eq. [5] characteristic of a compact deposit would not be expected to apply. However, by differentiating [5] and treating for the occurrence of a maximum many of these uncertainties of the present stochastic process may be removed. The results of this are shown in Fig. 8 which illustrates

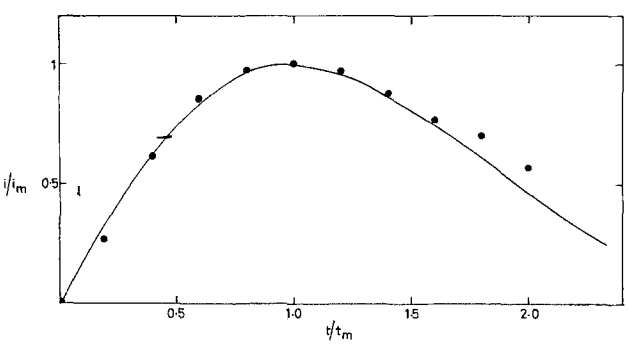

Fig. 8. Match of the rising and falling transient of Fig. 7 to the instantaneous nucleation with three-dimensional overlap model for electrocrystallization. Full cause, theoretical; ●, data points.

a reduced plate of the rising and falling part of Fig. 7 normalized in terms of t_m and i_m, the time and current co-ordinates of the maximum. The conformation of the data of Fig. 7 is very satisfactory. This is in complete agreement with earlier work using microelectrodes.

Recharging under conditions of galvanostatic control produced more complex responses as did the recharge of batteries which had received many cycles. These responses will be the subject of a subsequent paper.

Conclusions

1. An "induction period" in the potentiostatic oxidation of Pb|$PbSO_4$ is due to the thickening of the $PbSO_4$ film.
2. On Pb|$PbSO_4$ the development of a rising current indicates the onset of PbO_2 development.
3. At fast sweep rates the current peak for the formation of PbO_2 is buried in the oxygen wave.
4. The minimum overpotential for the development of PbO_2 from $PbSO_4$ is ~200 mV.
5. On Pb|PbO_2|$PbSO_4$ formed by partial reduction (passivating PbO_2 in H_2SO_4 aq) a rising transient is not obtained due to the presence of adequate PbO_2 growth areas on the electrode.
6. Using battery tests some theoretical aspects of electrocrystallization theory have been verified.

Superionic Conducting Glasses: Glass Formation and Conductivity in the AgI-Ag_2O-P_2O_5 System

Tsutomu Minami, Yakuni Takuma, and Masami Tanaka

Department of Applied Chemistry, University of Osaka Prefecture, Sakai City, Osaka-Fu 591, Japan

ABSTRACT

A glass-forming region was found in the AgI-Ag_2O-P_2O_5 system at a Ag_2O/P_2O_5 mole ratio $\leqq 3$. Glass transition temperatures and conductivities at 25°C for the glasses are, respectively, expressed by

$$T_g(°C) = 6.900[AgI] + 143.4[Ag_2O] + 98.24[P_2O_5]$$

$$-\log \sigma_{25}\ (\Omega^{-1}\,cm^{-1}) = 0.1952[AgI] + 5.067[Ag_2O] + 3.970[P_2O_5]$$

where [AgI], [Ag_2O], and [P_2O_5] are mole fractions of each component in the glass. These equations show that T_g and σ_{25} are primarily governed by the AgI content. From the results, it is speculated that a portion of the silver ions forms partially covalent bonds Ag-O-P. Conductivities at room temperature range from 10^{-3} to $10^{-2}\ \Omega^{-1}\,cm^{-1}$. The advantages of glass formation for obtaining solid electrolytes with higher ionic conductivity are shown. Transport numbers of silver ions are approximately unity in the glasses.

Solid electrolytes with high ionic conductivity at ambient temperature have been extensively studied for technological applications and/or fundamental interest (1-6). These electrolytes, however, are all crystalline solids. If glass formation of the electrolytes is possible, advantages can be expected, such as isotropic properties, ease of thin film formation, and the like. In addition, the electric conductivity of glasses with ion movement has been reported to be higher than that of crystals (7, 8). This is surprising for ionic conductors since, as is well known, electronically conducting glasses have several orders of magnitude lower conductivities than crystals because of high scattering and low carrier mobilities in the disordered structure (9, 10). Thus, in solid electrolytes, it is of interest to develop glass-forming systems with high ionic conductivities. In a previous paper (11), we reported the glass-forming region in the AgI-Ag_2O-MoO_3 system. In searching for other glass-forming systems with high ionic conductivity, the AgI-Ag_2O-P_2O_5 system appeared promising, since a composition with high AgI content in the AgI-$Ag_4P_2O_7$ system was reported to form a glassy product when cooled naturally (5).

In this paper, the glass-forming region is presented for the AgI-Ag_2O-P_2O_5 system, with emphasis on the composition range of high AgI and low P_2O_5 content. The glass transition temperature and the conductivity were determined as a function of composition.

Experimental

Sample preparation.—Silver iodide,[1] special grade Ag_2O, and special grade H_3PO_4 were used as raw materials for the sample preparation. For samples with a Ag_2O/P_2O_5 mole ratio of 2 or 3, $Ag_4P_2O_7$ [1] or Ag_3PO_4,[1] respectively, was also used as the raw material instead of Ag_2O and H_3PO_4, in order to compare the characteristics of glasses prepared from different raw materials. Glasses were prepared by melting the mixed raw materials in a Pyrex glass ampul at 500°C for 20 hr. The resultant melts were poured onto a stainless steel plate.

The x-ray powder diffraction measurements, using Cu-K_α radiation, were made for all the samples prepared to determine whether any crystalline phase was included.

Determination of glass transition temperature.—The glass transition temperature (T_g) of each glassy sample was determined by differential thermal analysis (DTA) using a Rigaku Denki thermal analyzer. The DTA was measured from room temperature to 500°C with a heating rate of 10°C/min and a nitrogen gas flow rate of about 60 ml/min.

Conductivity measurement.—Conductivities were measured at 1000 Hz in an electrically shielded chamber (made of brass) filled with dry nitrogen gas in the temperature range 200°-300°K by using a universal bridge (YHP, Model 4260A) and/or a G-C bridge (Ando Denki, Model TR-1C). Two types of samples were used for the conductivity measurement. In the first, evaporated silver electrodes were applied to the opposite sides of bulk glass samples whose diameter and thickness were 7-15 and 1-2 mm, respectively. In the second, pellets of pulverized glass were pressed using a mixture of 0.3g of glass and 0.9g of silver powder for the electrodes. About 1.2g of pulverized glass was stacked between the electrodes and pressed into a pellet 13 mm in diameter, using 2 tons/cm^2 with a hand press. The latter type of sample construction was reported to minimize the contact resistance in the conductivity measurement of silver ion conducting electrolytes (3, 5, 12).

Transport number measurement.—The transport number of silver ions in glassy electrolytes was measured by Tubandt's method (13) and by the emf method. In Tubandt's method, a cell of the type

$$\underset{(+)}{Ag/X_1/X_2/X_3/X_4/}\underset{(-)}{Ag} \qquad [I]$$

was used, where X's were pellets of glasses. The change in mass of the four cell parts was measured by a microbalance (Mettler, Model M5), and the total charge passed was measured with a coulometer (Nichia, Model N-CR_4). In the emf method, a cell of the type

$$Ag/\text{bulk glass}/I_2, C \qquad [II]$$

was used, where the cell reaction is

$$Ag(s) + \tfrac{1}{2}\, I_2(g) = AgI(\text{glass}) \qquad [1]$$

and the transport number of silver ions, t_r, can be determined by

$$t_r = \frac{V}{V_0} \qquad [2]$$

where V is the emf measured, and V_0 the standard emf for the formation of AgI (=687 mV) (5).

Key words: solid electrolytes, silver ion conducting glasses, superionic conductors, phosphate glasses.

[1] AgI, Ag_3PO_4, and $Ag_4P_2O_7$ were prepared according to Ref. (5) from special grade $AgNO_3$, KI, $Na_2HPO_4 \cdot 12H_2O$, and $Na_4P_2O_7$.

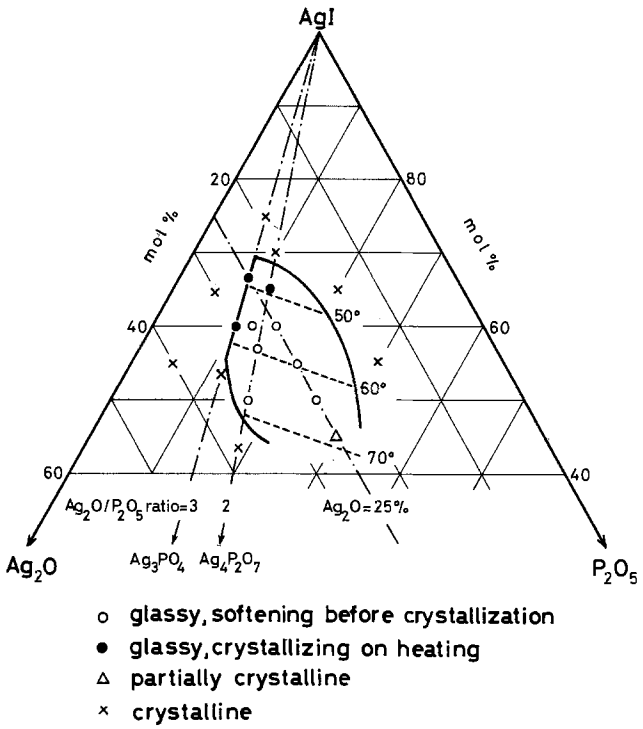

Fig. 1. Glass-forming region and iso-T_g lines in the AgI-Ag_2O-P_2O_5 system. The values in the figure are T_g(°C).

Results and Discussion

Glass-forming region and T_g.—Figure 1 shows the glass-forming region and iso-T_g lines in the AgI-Ag_2O-P_2O_5 system. In the figure open circles denote glassy samples which softened before crystallization; *i.e.*, only endothermic change at T_g was observed and no crystallization peaks were observed in DTA measurements. Shaded circles denote glassy samples which crystallized on heating; *i.e.*, exothermic peaks due to crystallization as well as endothermic changes at T_g were observed in DTA measurements. The triangle denotes a sample in which a small portion of crystallized inclusion was observed. For this sample, the transparent (glassy) part was used for T_g and conductivity measurements. Crosses denote crystalline samples. Glassy samples were transparent and yellow to brown in color, depending on the composition. The samples were somewhat sensitive to light, and thus were carefully handled under safe-lights.

The glass-forming region is limited to compositions with the Ag_2O/P_2O_5 ratio, $R \leqq 3$, and it is remarkable that glass formation was possible for the compositions with $R = 3$. This high value of R recalls the so-called "invert glass" (14) and means there are no condensed structural units of PO_4^{3-} group (15); in other words, these glasses can be classified as "ionic" glasses (16) as well as phosphate glasses. No appreciable difference was observed in the glass-forming ability of samples prepared from AgI, Ag_2O, and H_3PO_4 and from AgI and Ag_3PO_4 or $Ag_4P_2O_7$.

The iso-T_g lines are drawn by

$$T_g(°C) = 6.900[AgI] + 143.4[Ag_2O] + 98.24[P_2O_5] \quad [3]$$

or

$$T_g(°K) = 280.0[AgI] + 416.5[Ag_2O] + 371.3[P_2O_5] \quad [3']$$

where [AgI], [Ag_2O], and [P_2O_5] are mole fractions. Equations [3] and [3'] were determined by computer analysis based on least squares. In Table I, comparison between observed and calculated values of T_g is shown. The maximum deviation and the probable error are 4.1° and ± 1.9°.

The iso-T_g lines are roughly horizontal. This means that T_g is primarily determined by AgI content, rather than Ag_2O or P_2O_5 content. We can speculate from this result that a portion of silver ions, especially introduced in the form of Ag_2O, forms partially covalent bonds Ag-O-P. The formation of partially covalent bonds Ag-O-P was suggested in Ag_2O-P_2O_5 glasses from *IR* spectra (17).

Table I. Comparison of calculated and observed T_g in AgI-Ag_2O-P_2O_5 glasses

Glass No.	Composition (m/o) AgI	Ag_2O	P_2O_5	T_g(°C) Observed	Calculated*	Deviation
1	66.7	25.0	8.3	50	48.6	+1.4
2	60.0	30.0	10.0	55	57.0	−2.0
3	65.0	23.3	11.7	48	49.4	−1.4
4	57.1	28.6	14.3	59	59.0	0.0
5	50.0	33.3	16.7	70	67.6	+2.4
6	60.0	25.0	15.5	58	54.7	+3.3
7	55.0	25.0	20.0	62	59.3	+2.7
8	50.0	25.0	25.0	64	63.9	+0.1

10	60.0	28.0	12.0	52	56.1	−4.1

* Calculated by Eq. [3].

Figure 2 shows the composition dependence of density. The data are plotted against AgI content for a series of compositions on each tie line of $R = 3$, $R = 2$, and Ag_2O content = 25 mole percent (m/o). The density change with composition is linear in each series of compositions, but the slopes are quite different. This is in evident contrast with the composition dependence of T_g mentioned above, and of conductivity, shown later.

Dependence of conductivity on temperature and composition.—In Fig. 3, the comparison of conductivity between bulk glasses and pellets is shown for the samples with $R = 2$. The conductivities are expressed by

$$\sigma = \frac{C}{T} \exp\left(-\frac{E}{RT}\right) \quad [4]$$

where σ is the conductivity, T the absolute temperature, C a constant, R the gas constant, and E the acti-

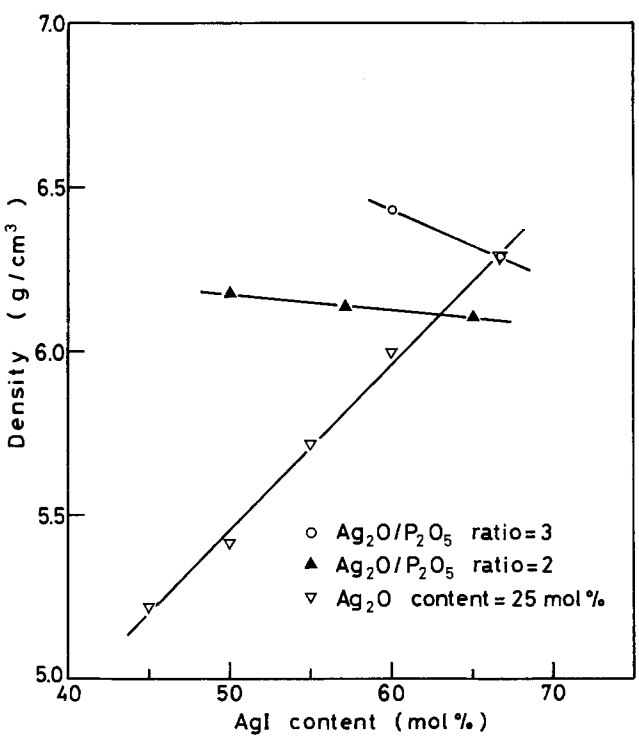

Fig. 2. Composition dependence of densities in the AgI-Ag_2O-P_2O_5 glasses.

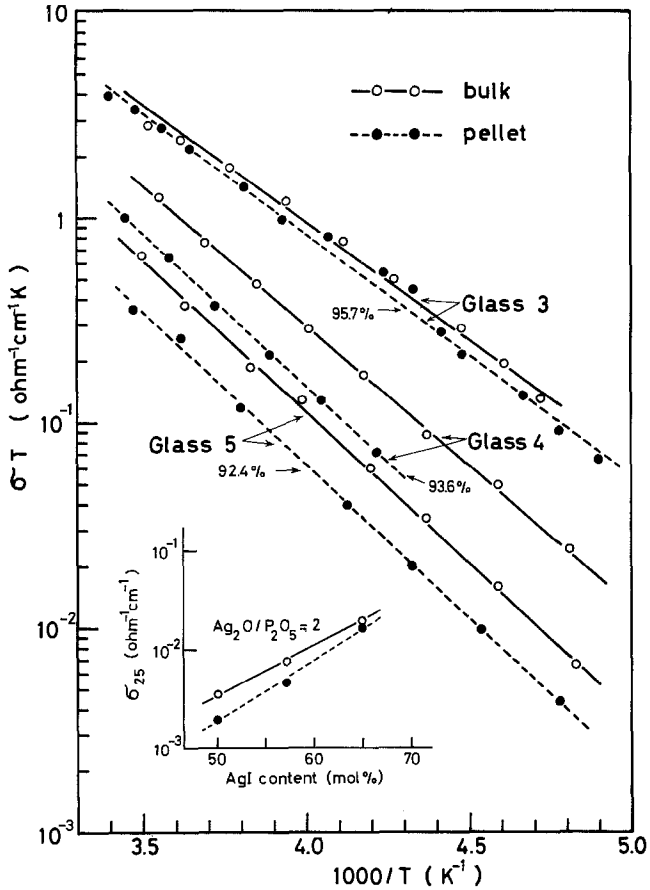

Fig. 3. Comparison of conductivities between bulk glasses and pellets. Percentages are packing densities of pellets.

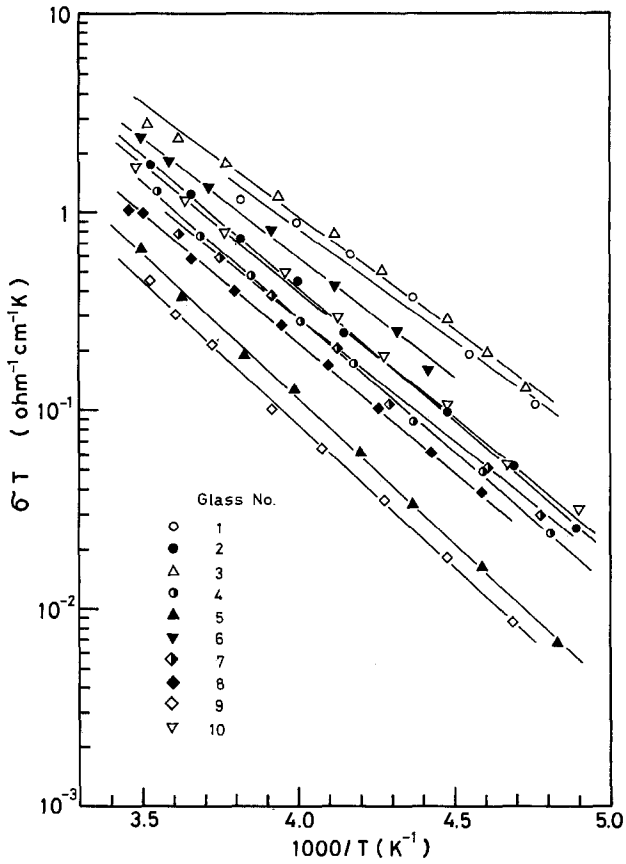

Fig. 4. Temperature dependence of conductivity in the AgI-Ag_2O-P_2O_5 glasses.

vation energy for conduction. The conductivities of pellets at a given temperature are slightly smaller than those of bulk glasses, and the E values are very similar between pellets and bulk samples. These results are reasonable, if the packing densities of the pellets (shown in the figure) are considered. In the inset of the figure, the composition dependence of bulk and pellet conductivities at 25°C, σ_{25}, determined from the temperature dependence, are also shown. The values of σ_{25} of pellets are smaller by 6-44% than those of bulk glasses. The difference becomes smaller with increasing AgI content, which is probably associated with the decrease in T_g with increasing AgI content.

Figure 4 shows the temperature dependence of conductivities for all the bulk glasses. The straight lines were drawn by least squares. The activation energies ranged from 5.2-6.7 kcal/mole and increased with the decrease in conductivity. It should be noted that the energies are larger by only 2-3 kcal/mole than those of crystals of similar compositions (5).

The values of σ_{25} determined from Fig. 4 are plotted against AgI content in Fig. 5. Those of crystals reported by Takahashi *et al.* (5) are shown for comparison, using a dotted curve. In Ref. (5), the composition dependence of σ_{25} was separately shown for AgI-Ag_3PO_4 and AgI-$Ag_4P_2O_7$ systems, but in Fig. 5, σ_{25} is plotted against AgI content within the composition range of glass formation, using the Ag_2O/P_2O_5 ratio as a parameter. It should be noted that σ_{25} of glasses is 5-10 times larger than that of crystals, and that σ_{25} of glasses increases almost linearly with increasing AgI content, irrespective of the position in the glass-forming region. The latter fact allows us to speculate again that a portion of silver ions introduced as Ag_2O forms partially covalent bonds Ag-O-P and thus makes a small contribution to the high conductivity of the glasses.

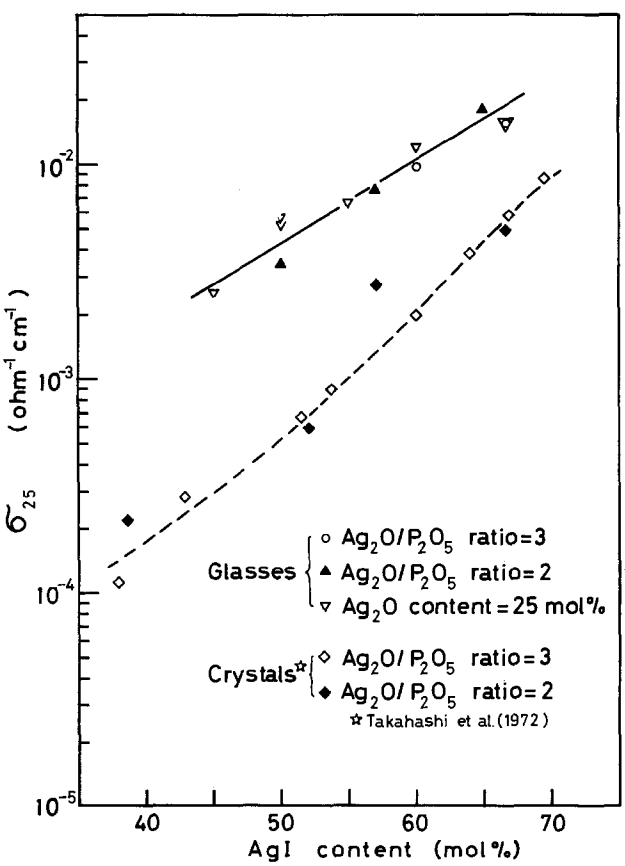

Fig. 5. Composition dependence of conductivity at 25°C, σ_{25}, in the AgI-Ag_2O-P_2O_5 glasses. The conductivities of crystals in the AgI-Ag_3PO_4 and AgI-$Ag_4P_2O_7$ systems reported in Ref. (5) are replotted for comparison.

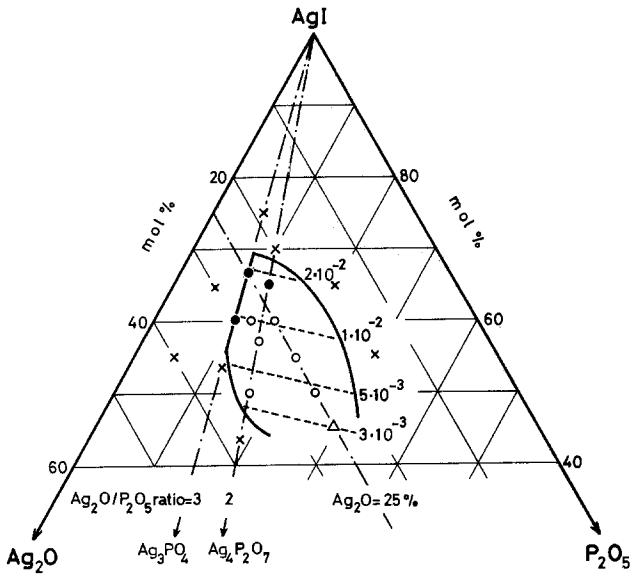

Fig. 6. Iso-σ_{25} lines in the AgI-Ag_2O-P_2O_5 glasses. The values in the figure are σ_{25} (Ω^{-1} cm^{-1}).

Figure 6 shows the iso-σ_{25} lines which were drawn by

$$-\log \sigma_{25} = 0.1952[AgI] + 5.067[Ag_2O] + 3.970[P_2O_5] \quad [5]$$

A small value of the factor for AgI and the nearly same value for Ag_2O and P_2O_5 are noticed.

Table II shows the comparison between observed and calculated values of σ_{25}. The agreement is very good, with the maximum deviation and probable error for log σ_{25} (Ω^{-1} cm^{-1}) being 0.09_2 and $\pm$ 0.04_1, respectively. In Table II, the activation energies are also shown for each glass.

Transport number of silver ions.—Table III shows the result of the transport number measured for glass 4 by Tubandt's method. The result indicates that the charge carriers of glass 4 are nearly 100% silver ions. Transport numbers determined by the emf method are listed in the last column of Table II. We can conclude that the predominant carriers in the glasses are silver ions and that the contribution of protons to the conduction is negligible, although water content was not determined.

Appreciable difference in properties was not detected between glasses prepared from different raw materials.

Conclusion

Glasses were prepared in the AgI-Ag_2O-P_2O_5 system in the composition range of Ag_2O/P_2O_5 ratio $\leqq 3$ and high AgI content. Glass transition temperatures and conductivities were primarily governed by the AgI content. From these results we speculate that some portions of silver ions, especially introduced in the form of Ag_2O, form partially covalent bonds Ag-O-P.

Conductivities of the glasses are higher than those of crystals of the same chemical composition, indication that glass formation has advantages for obtaining high conductivity solid electrolytes. Transport numbers of silver ions were approximately unity for the glasses. The influence of water content on glass-forming ability, glass transition temperature, conductivity, transport number, and so on, are now under study and will be published elsewhere.

Aspects of the Role of Lignin Additives in Pasted Lead Electrodes

B. K. Mahato*

Globe-Union Incorporated, Corporate Applied Research Group, Milwaukee, Wisconsin 53201

ABSTRACT

The effect of the cations of lignosulfonate salts on the physical and electrochemical characteristics of pasted-type lead electrodes has been studied. The cations studied were H^+, Na^+, NH_4^+, Zn^{++}, Ca^{++}, and Ba^{++}. The lignosulfonate anion concentration was held constant by maintaining constant u.v. absorption at 280 mμ wavelengths. The cations affected the hydrogen evolution potential at the end of formation and at the onset of passivation potential, and they affected the capacity retentive characteristics during cycling. Of all the lignosulfonates tested, the sodium salt imparted the best capacity retentive characteristics.

The high rate, low temperature performance of the lead-acid battery is recognized to be limited by the performance of its negative electrode (1). The inclusion of an expander material, particularly a sulfonate derivative of lignin, in the negative active material increases its capacity or the efficiency with which it is utilized. The lignosulfonates have been found to be adsorbed strongly on the metallic lead surface (2), to cause recrystallization and particle size growth of lead sulfate (3), to cause the formation of a porous passivating lead sulfate layer (4), delay onset of the solid-phase passivation reaction (5), and to beneficially influence the electroreduction process during formation (6). In brief, these prior observations qualitatively indicate that the lignin compound in the lead matrix modifies the microstructure of the negative active material produced during formation and delays the electrode passivation during high rate discharge. However quantitative characterization of the functioning of this type of additive has been difficult, particularly in pasted-type electrodes, due to the multitude of variables involved in preparation of the lead electrode, the ill-defined nature of the lignin and lignosulfonate molecules, and the lack of analytical means of monitoring the concentration and stability of these compounds in the lead-acid system.

The lignosulfonate obtained from bisulfite cooking of softwood is believed to be an ordered polymer containing 16 MeO groups, 8 sulfo groups, 9 phenolic OH groups, and 2 sulfide sulfur atoms per repeating unit (7). The molecular character of the product is influenced both by the raw material and process variables (8). Its physical and chemical properties are also influenced by the nature of the cations present in the molecule (9).

In this work it was attempted to understand the specific role of lignosulfonate in the lead-acid battery negative by determining the effects of the cations on the physical and electrochemical properties of the sponge lead electrode.

Experimental

The lignosulfonate samples tested are listed in Table I. These were obtained from American Can Company, Rothschild, Wisconsin. Anionic equivalent amounts of these samples were defined as those producing identical u.v. absorption in water solution at 280 mμ wavelengths. These amounts, used for paste preparation, are indicated in the table. The cation concentrations calculated from the organic sulfur content of these samples are also included in the table. The absorptivity of lignosulfonic acid at 280 mμ wavelength was found independent of cation concentrations at least in the range used in the present study.

Pastes of leady oxide and sulfuric acid solution were prepared by a Readco Laboratory Mixer using a dry-blended mixture of lignin compound with ball mill oxide, and 88-106 ml water plus 60 ml 1.325 sulfuric acid solution per kilogram of oxide. The oxide had 26.9 ± 1.4% free lead. Carbon black and barium sulfate additives were not used. SLI-type pasted electrodes measuring 14.50 cm long × 12.00 cm wide × 0.15 cm thick were prepared. The electrode grid was antimonial lead with 4.75% Sb, 0.275% Sn, and 0.275% As. Curing was carried out at ambient temperature for 3 days. The dry paste weight of the test electrode was controlled at 75 ± 1g per plate. The average geometric surface area of both sides of the electrode, excluding the area occupied by the grid members, was 312 cm^2 per electrode. A test cell had one test electrode and two dry-charged counterelectrodes at 0.64 cm separations. No separators were used. Electroformation was carried out in 1.250 sp gr sulfuric acid solution at 5 mA/cm^2 for 24 hr, at 21.5° ± 0.5°C. The electrode potential relative to a standard $Hg/Hg_2SO_4/4.685M\ H_2SO_4$ reference was measured at the end of formation. The electrolyte specific gravity was then adjusted to 1.270. The anodic behavior was determined by linear potential sweep, and the discharge capacity at 100 mA/cm^2 and −18°C (0°F). Test cells were also cycled in the scaled-down version of the SAE J 240 life test described in Table II.

All experiments were carried out in triplicate. Microstructures of the active material as formed and at

different stages of life cycling were examined by SEM. The specific surface of the active mass was determined by BET nitrogen adsorption using a Quantasorb analyzer.

Results and Discussion

The effect of lignosulfonate cation on the end-of-formation potential is shown in Table III. The relative hydrogen overvoltage at the formation current density used becomes increasingly cathodic for the following order of cations: Na^+, H^+, Ca^{++}, NH_4^+, Zn^{++}, and Ba^{++}. Maracell-E and Maracell-C are commercial varieties of sodium lignosulfonate. The latter is a desulfonated, purified product with average molecular weight 5-10 times larger than that of Maracell-E (10). The difference in their hydrogen overvoltages appears due to this difference of molecular structure. Of all the lignosulfonate samples tested, the barium salt exhibited the maximum cathodic potential. This is consistent with the reported stronger adsorption of barium lignosulfonate than sodium lignosulfonate by lead powder (9).

Anodic current *vs.* potential for negative electrodes containing different lignosulfonates is shown in Fig. 1. The test cells were at 21° ± 0.5°C; potential was anodically scanned at 2 mV/sec. The curve shapes are similar to those reported recently by Brennan and Hampson (5) for a stationary lead electrode. They attribute the nonlinearity in the high current region to the commencement of solid-phase reaction leading to electrode passivation. In this reaction, sulfate or bisulfate anions combine with the lead surface under the influence of potential to form a passivating film. Figure 1 indicates that for the control electrode, potentials more negative than −923 mV do not favor the formation of lead sulfate nuclei on the lead surface by direct anion attack; at potentials more positive than −923 mV the reaction commences. The cations of the lignosulfonate additive are seen to affect this potential in the order $Zn^{++} < Na^+ < Ba^{++} < NH_4^+ < Ca^+ < H^+$. This suggests a possible role of cation in controlling the reaction mechanism in some fashion. No direct correlation between this critical potential and hydrogen overvoltage at the end of formation is evident. It is, however, highly likely that the anionic attack of lead begins when the dissolution process is unable to sustain the anodic potential. The dissolution mechanism of lead as well as precipitation of lead sulfate is influenced by the structure of electrode/electrolyte interface, the coverage of interface by the additive, nature of additive, and the concentration of dissolving species at the liquid interface. During anodic dissolution, besides the concentration of dissolving species, the *p*H of the interfacial layer increases, bringing adsorbed additives into the solution. The *p*H-dependent solubility of the lignosulfonate compound is well known (11). The cation in the additive possibly controls *p*H-dependent dissolution behavior. The saturation concentration of Pb^{2+} ion at the interface is also possibly influenced by the lignosulfonate anion, which is known to be a strong sequestering agent (11) through formation of a transient "Pb-lignosulfonate complex." Such a transient complex formation could provide a mechanism for the formation of a large crystal noted in the literature (3), *i.e.*, the decomposition of the transient compound to feed crystal growth on the already formed lead sulfate crystals. Such a process might also be accompanied by the occlusion of additive in the discharge matrix, which would then come into play during subsequent charging and electrocrystallization. The inhibiting influence of a lignin compound (totatin FNA) on the nucleation and growth of passivating lead sulfate film has been considered by Brennan and Hampson (12).

Figure 2 shows the 100 mA/cm², −18°C (0°F) discharge characteristics of negative electrodes containing various lignosulfonates immediately after electroformation. All the additives irrespective of their cationic nature produced approximately the same discharge capacity—about three times that of the control. However, the effect of cation has been surfaced during repetitive charge-discharge cycling of the electrodes (to be discussed later). To avoid unnecessary presentation of similar results, the characteristic

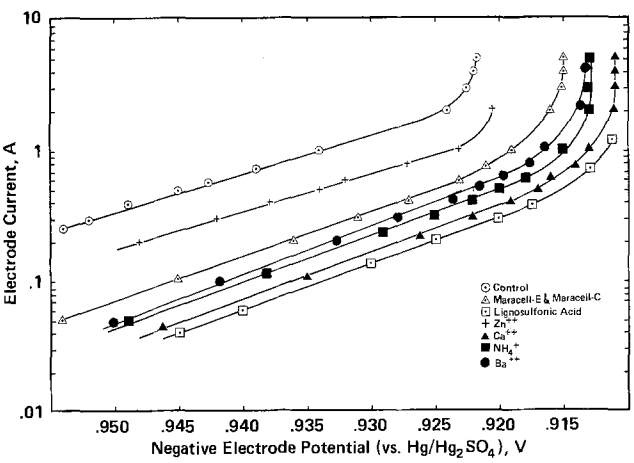

Fig. 1. Semilogarithmic representation of the linear potential sweep on freshly electroformed pasted negotive electrodes containing different lignosulfonate salts; 1.270 specific gravity H_2SO_4, 2 mV/scan rate.

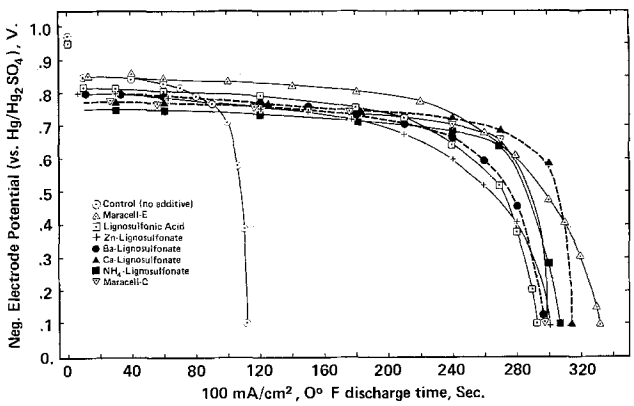

Fig. 2. Discharge characteristics of freshly formed negative electrodes as a function of lignosulfonate cations.

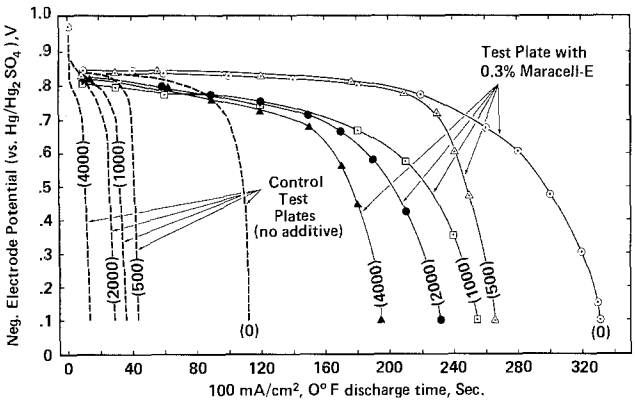

Fig. 3. Discharge behavior of control electrode (without additive) and test electrode with 0.3 w/o Maracell-E during SAE J 240-type cycling.

behavior of the electrode with 0.3 weight percent (w/o) Maracell-E is discussed in detail and summary results of the remaining test electrodes are reported. Figure 3 shows for an electrode with 0.3 w/o Maracell-E, relative to a control, the degradation of this initial discharge behavior during SAE J 240 cycling. The control electrode lost 60 and 88% of its initial capacity at 500 and 4000 cycles, respectively; the electrode with Maracell-E lost only 20 and 41%. Associated differences between the morphologies of the lignosulfonate-containing and the lignosulfonate-free electrodes, both initially and over the course of life cycling, are shown in the SEM micrographs of Fig. 4-7. These represent freshly exposed (by fracture) cross sections of charged electrodes, either about 0.50 mm from the electrode surface or at the center. The electrodes contained 0.0 or 0.3 w/o Maracell-E, and micrographs were made after 0, 500, 1000, 2000, and 4000 cycles following charging.

The complex electroformation process in the pasted negative electrode has been followed by Pavlov *et al.* (13) through analysis of the phases present in the active material during electroformation. No consideration was given to the role of additives. Pierson *et al.* (6) carried out optical microscopic studies of the active material. In the present work, the nodular structure (Fig. 4a) of the lead matrix is in agreement with

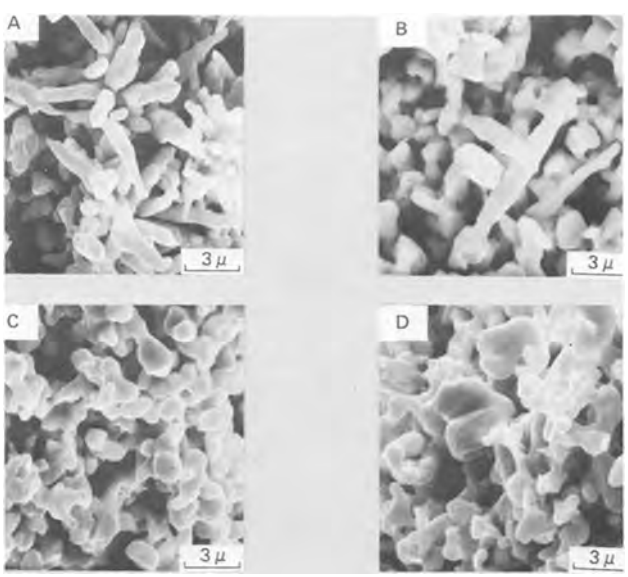

Fig. 4. Structure of charged negative electrode without lignosulfonate additive at: A, 0; B, 500; C, 1000; and D, 2000 cycle points.

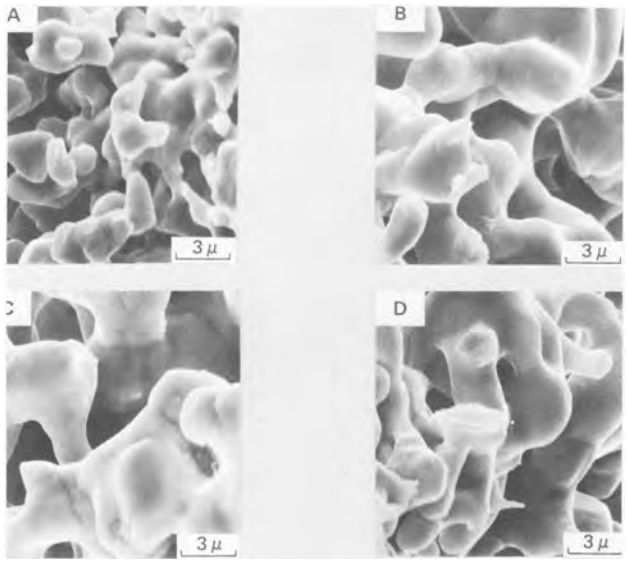

Fig. 5. Structure of charged negative electrode with lignosulfonate additive at; A, 0; B, 500; C, 1000; and D, 2000 cycle points.

the lead crystal morphology observed by Simon, Caulder, Gurlusky, and Pierson (6). The porous structure of the pasted electrode is the result of the conversion of low density lead compounds to higher density lead.

The influence of the additive on the initially electroformed material morphology is demonstrated in Fig. 4a and 5a. The lignosulfonate additive has caused to form, in place of an interconnected nodular lead mass (Fig. 4a), an interconnected network of acicular crystals (Fig. 5a). A degree of preferred orientation perpendicular to the electrode surface is also evident in Fig. 5a. It has been hypothesized (14) that the additive functions here similarly, as do the organic addi-

tives used in commercial electrodeposition processes. This does not seem likely, however, since in the latter application the additives' purpose is to increase the density of the deposit; in the pasted electrode it serves, adversely, to promote porosity and increased surface area and reactivity of the electrodeposit. That surface adsorption of the additive material by freshly formed metallic lead probably figures in the expander function is indicated by the increased hydrogen overpotential or end-of-formation potential (Table III) and the onset of passivation potential (Fig. 1).

Figures 4, 5, and 6 demonstrate the effect of repeated charge-discharge cycling on the crystal morphology, size and orientation, and the influence of the sodium lignosulfonate additive. The comparative structures of lead at the surface and at the center of the electrode cross section are shown in Fig. 6 and 7 after 4000 cycles, for the control and additive-containing electrodes, respectively. The greater densification of lead at the surface compared to that in the center demonstrates that in the cycling mode used the charge transfer reaction was largely localized at the surface. The initial as-formed lead deposit (Fig. 4, 5, and 6) is made finer grained and more acicular by the additive, and in spite of subsequent growth the differentiation from the control electrode is more than maintained during cycling. What agglomeration does subsequently occur in the lignosulfonate-containing active mass during cycling is hypothesized to be attributable to the loss of activity of the additive with cycling. The activity loss may result both from reduction of concentration as the material is dissolved out of the electrode matrix, as well as from its chemical degradation in the battery environment. A lack of analytical means for monitoring the concentration of additive in the electrode matrix does not permit quantitative substantiation of the hypothesis. However, the degradation of lignin polymer by a variety of displacement and cleavage reactions in acidic conditions have been acknowledged (15-17). The soluble fraction of the lignosulfonate is also expected to be ultimately oxidized at the lead-dioxide electrode during overcharge.

The morphologies of the active material for various lignosulfonate cations and as a function of cycling are reflected in the trend of specific surface reduction shown in Fig. 8. Maracell-C-type sodium lignosulfonate exhibited higher specific surface area during the test period than the others. The linear trend of loss of surface area for the electrode with zinc lignosulfonate additive with cycling is not understood, but indicates a possibly different degradation mechanism.

The trend of 100 mA/cm², −18°C (0°F) discharge capacity on cycling with varied lignosulfonate cations is shown in Fig. 9 to be approximately parallel to that of the specific surface area (Fig. 8). The change in

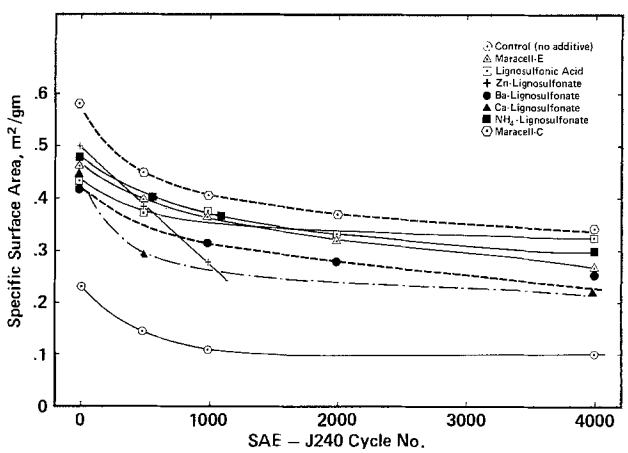

Fig. 8. Variation of specific surface area of negative electrode with different lignosulfonate additives, during SAE J 240 cycling.

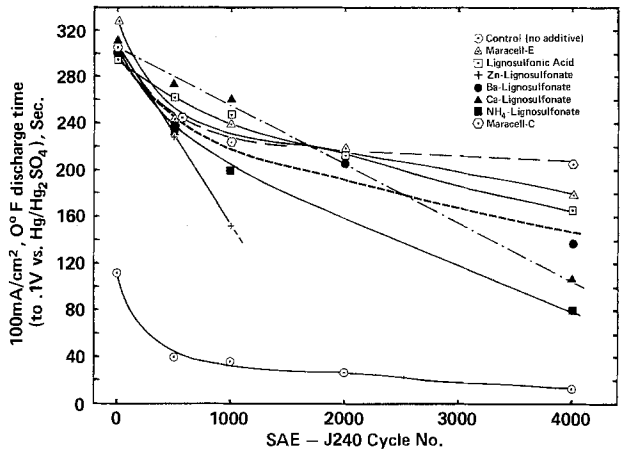

Fig. 9. High rate, low temperature discharge capacity of negative electrode in SAE J 240 cycling as a function of lignosulfonate cation.

high rate, low temperature capacity of the test electrodes during cycling is attributed to the cations associated with the lignosulfonate additive. The fact that inorganic cations tested here do not influence the discharge behavior of the lead electrode (18) indicates that the cationic effect noted here might be a result of their role on the stability, *i.e.*, dissolution and desorption characteristics of the additive. The desorption of a lignosulfonate (totatin FNA) from lead electrodes at high cathodic potential was noted by Brennan *et al.* (5) by differential capacity measurement. The role of cation on the adsorption and desorption characteristics of lignosulfonates is not known. Work in this area is needed for a thorough understanding of the role of additive on the characteristic properties of the lead electrode. Such an understanding might provide a means to improve the high rate performance of the lead electrode and its maintenance during cycling, a desirable long range objective of the lead-acid battery technology.

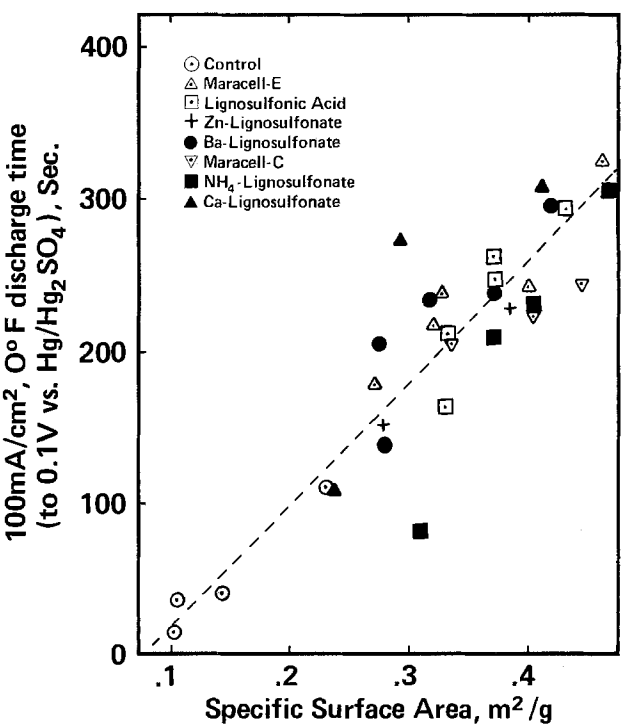

Fig. 10. Correlation between high rate, low temperature capacity and specific surface area of active material.

Figure 10 shows a linear relationship between the 100 mA/cm², 0°F discharge capacity and the BET-nitrogen adsorption surface area. Admittedly the deviation of the data is large, indicating a possibility of a secondary effect which could result from variables associated with the electrode preparation and/or the deviation of electrochemically active surface area from the BET-nitrogen adsorption surface area. Since, in fact, the high rate capacity is expected to be proportional to the electrochemically active surface area, a generally linear relationship between electrochemically active surface area and specific surface area is also to be expected.

Conclusions

1. The cations of lignosulfonate salt additives influence the hydrogen evolution potential at the end of formation and the potential for onset of the solid-phase reaction, but not the initial high rate, low temperature performance.
2. The lignosulfonate salt cation influences the extent and rate of loss of capacity during cycling.
3. The sodium salt of lignosulfonic acid imparted the best capacity retentive characteristics of all the lignosulfonate samples tested.
4. The high rate, low temperature capacity and specific surface area are linearly related.

Effect of Caffeine on the Anodic Dissolution of Copper (100) Plane in Acidic Copper Sulfate Solution

M. F. Ahmed, S. M. Mayanna, and F. Pushpanaden

Department of Chemistry, Central College, Bangalore University, Bangalore 560001 India

ABSTRACT

Anodic dissolution of copper (100) plane in acidic copper sulfate solution is inhibited by the addition of caffeine. Evidence to this effect is offered by the surface coverage data and by the topographical changes brought about by caffeine on the surface. The inhibition is attributed to the adsorption of caffeine on the surface of the crystal plane.

Several nitrogen-containing organic compounds have been used as corrosion inhibitors. The corrosion inhibition is a surface process which involves the specific adsorption of inhibitors on the metal surface (1). The extent of inhibition of metallic corrosion depends on the nature of metal surface and extent of adsorption of the inhibitor (2). The type of interaction of the inhibitor on the metal surface during corrosion has been deduced from its adsorption characteristics (3-5). Vermilyea (6) has emphasized the need for a careful study of metallic corrosion on single crystal substrates. Many attempts have been made in this direction using copper single crystal planes (7-10). In a similar attempt, the present investigation examines the effect of caffeine on the anodic dissolution of copper (100) plane in acidic copper sulfate solution.

Key words: surface coverage, inhibition, etch pattern.

Experimental

A solution of composition 0.25M $CuSO_4$ + 0.1M H_2SO_4 was prepared from freshly distilled, preelectrolyzed sulfuric acid (AR) and twice recrystallized copper sulfate (AR) subjected to preelectrolysis, using conductivity water. Copper (100) plane with a dislocation density of $10^6/cm^2$ was grown at the Oak Ridge National Laboratory, Tennessee. The copper (100) plane was fixed in Tygon tubing such that only the desired plane was exposed. The surface preparation applied prior to the anodic dissolution was similar to that suggested by Jacquet (11). The dissolution was carried out galvanostatically (0.1-25 mA/cm²) in stirred, deaerated acidic copper sulfate solution and in acid copper sulfate solution containing various concentrations (10^{-8}-10^{-2}M) of caffeine. Caffeine in these concentrations did not alter the *p*H of the acidic copper sulfate solution. The time of dissolution was chosen to dissolve the metal to a constant thickness equivalent to 5 C/cm² (1.8μ). A 90V battery in series with a variable resistance was used as a constant current source. The overpotentials were recorded with reference to a freshly prepared copper reference electrode using d-c VTVM with an accuracy of ± 1 mV. The dissolved surface was examined under a metallurgical microscope. All the microphotographs were prepared at a magnification of 600X. The experiments were repeated to ensure reproducibility.

Results

Overpotentials.—The overpotential recorded in the pure acid copper sulfate solution increases with time and attains a steady value. The presence of caffeine in the solution does not alter the trend in the variation of overpotential with time. However, the overpotential values in presence of caffeine are higher than the values recorded in pure solution at the corresponding current densities. For any given current density, the extent of increase in the overpotential is a function of the concentration of caffeine. The effect of caffeine on the overpotential is maximum at a concentration of 5×10^{-3}M.

Figure 1 is the Tafel plot for the dissolution of copper (100) plane in pure acidic copper sulfate solution and in acid copper sulfate solution containing various concentrations of caffeine. The Tafel plots for pure solution and for solutions containing caffeine are parallel to each other and have a slope of 40 ± 5 mV.

The values of i_o (exchange current density) both in pure solution and in solutions with various concentrations of caffeine were evaluated from the Tafel plots. It is found that the i_o value decreases with an increase in the concentration of caffeine. As the value of i_o is related to the rate of electrode reaction, the inhibitor efficiency (γ) at each concentration of caffeine used was calculated using the equation (12)

$$\%\gamma = \left(\frac{i_o - i_o^*}{i_o}\right) \times 100$$

where i_o^* and i_o are the exchange current density values with and without caffeine, respectively. The values of i_o and inhibitor efficiency at different concentrations of inhibitor are given in Table I.

The surface coverage (θ) at each concentration of caffeine was calculated using the equation (13)

$$(1 - \theta) = \left(\frac{i_o^*}{i_o}\right)$$

One could calculate the apparent free energy of adsorption of the inhibitor from θ-values using the equation (14)

$$\frac{\theta}{e^{(x-1)}(1-\theta)^x} = \frac{C_{org}}{55.5} e^{-\Delta G^\circ_{ads}/RT}$$

where C_{org} is the concentration of inhibitor in the bulk of the solution and x the size factor. Using the above equation, with $x = 9$ for the space filling model of adsorption of caffeine on the surface, the apparent free energies of adsorption (ΔG°_{ads}) were evaluated and they are recorded in Table I. Figure 3 is a plot of overpotential *vs.* θ at different current density values.

Surface topography.—The etch patterns that develop on copper (100) plane on dissolution at different current densities are distinguishable with respect to their features. They show predominantly serrated layers (Fig. 2a) at a current density of 0.1 mA/cm², spirals (Fig. 2b) at 0.25 mA/cm², and square concentric loops enclosing tiny pits (Fig. 2c) at 0.5 mA/cm². Occasional large pyramidal pits (Fig. 2d) develop at a current density of 2 mA/cm². On further increase in the current density, the same feature, *i.e.*, the square pyramidal pit, persists in the etch patterns. However, the density of the square pyramidal pits in the etch patterns increases with the increase in current density accompanied by a consequent diminution in their size. Figure 2e is the etch pattern showing a dense etch pit development at 25 mA/cm².

To investigate the effect of caffeine on the etch patterns, first the etch patterns developing at a constant current density of 2 mA/cm² with successively increasing concentrations of caffeine (10^{-8}-5×10^{-3}M) in the solution were examined. As described above, occasional large square pyramidal etch pits develop at 2 mA/cm² in pure solution (cf. Fig. 2d). No noticeable change is effected in this pattern by caffeine up to a concentration of 10^{-5}M in the solution. However, when the caffeine concentration reaches a value 10^{-4}M, there is a change in the etch pattern that develops at 2 mA/cm². This is shown in Fig. 2f which may be described as occasional etch pits with faceted slopes scattered in a background of smooth pits. Figure 2g showing pyramidal pits with very smooth slopes and Fig.

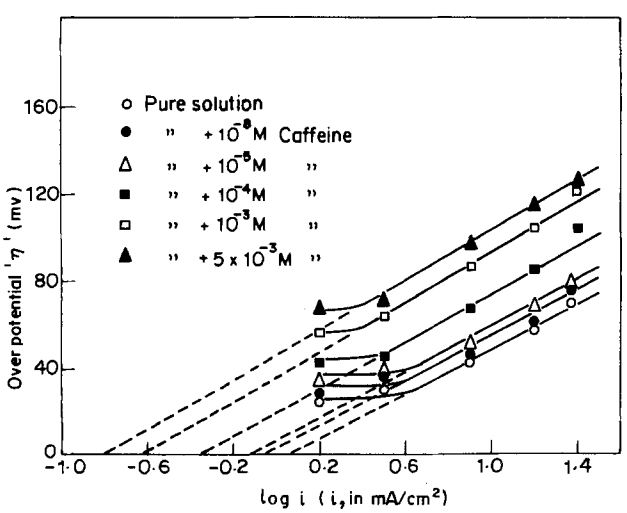

Fig. 1. Tafel plots for the dissolution of copper (100) plane in pure and caffeine-added acidic copper sulfate solution.

Table I. Surface coverage θ, percent inhibitor efficiency, and free energy of adsorption (ΔG°_{ads}) of caffeine on copper (100) plane during dissolution in acid copper sulfate solution containing various concentrations of caffeine

Conc. of caffeine (M)	Exchange current density (mA/cm²)	θ	Inhibitor efficiency, %	$-\Delta G^\circ_{ads}$ (kcal/mole)
0	1.2020	—	—	—
1×10^{-8}	0.8710	0.27	27	9.6
1×10^{-5}	0.7762	0.35	35	7.6
1×10^{-4}	0.4571	0.61	61	8.0
1×10^{-3}	0.2399	0.80	80	10.3
5×10^{-3}	0.1259	0.89	89	12.7

2h showing layers are similarly the etch patterns that develop at 2 mA/cm^2 with 1×10^{-3} and 5×10^{-3}M caffeine in the solution, respectively.

Caffeine is effective in causing changes in the etch patterns in concentrations starting from 10^{-4}M. Hence, the effect of current density on the etch patterns that develop in solutions containing 1×10^{-4}, 1×10^{-3}, and 5×10^{-3}M caffeine, respectively, was next examined by dissolving the crystal in the current density range 2-25 mA/cm^2. No noticeable variation of features is observed in the etch patterns produced between current densities 2-25 mA/cm^2 with 1×10^{-4} and 1×10^{-3}M caffeine in the solution, respectively. But the features that develop at low current densities (2 mA/cm^2) with the above concentrations of caffeine in the solution (Fig. 2f and g) decrease in size and increase in number as the current density is increased. However, in presence of 5×10^{-3}M caffeine in the solution, the spacing in between the layers observed in etch patterns produced at 2 mA/cm^2 (Fig. 2h) gradually decrease as the current density is raised to 10 and then to 15 mA/cm^2 and, when the current density finally reaches a value 25 mA/cm^2, square concentric loops enclosing tiny pits (Fig. 2i) and spirals develop in the etch patterns.

Table II summarizes the topographical results of dissolved copper (100) plane. It is found that the features in the etch patterns developing at low current densities (<1 mA/cm^2) in pure solution are similar

to those developing in solutions containing 5 × 10^{-3}M caffeine at higher current densities (>15 mA/cm²).

Discussion

The mechanism of dissolution of copper in acidic copper sulfate solution is (15)

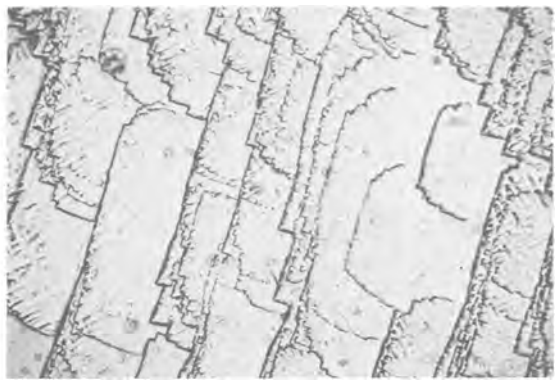

Fig. 2h. Layers on dissolved copper (100) plane in acidic copper sulfate solution + 5 × 10^{-3}M caffeine at 10 mA/cm². (X600).

$$Cu \rightarrow Cu^{+} + e$$

$$Cu^{+} \xrightarrow{rds} Cu^{++} + e$$

The experimental data in presence of caffeine show no change in Tafel slope (Fig. 1) consistent with the above mechanism. This suggests that caffeine does not interfere with the mechanism of dissolution. The observed decrease in the dissolution rate as evidenced by the decreasing exchange current density values with increasing concentration of caffeine in the solution are, however, attributed to the action of caffeine on the surface. It is known (16) that the dissolution process initiates at reaction sites (kinks in a step of dislocation) and the dissolution rate depends upon their number (17). A curtailment of these reaction sites would therefore lead to a reduction in the dissolution rate and this may be precisely how caffeine achieves inhibition, by being adsorbed on the surface at the reaction sites. In such a situation, the removal of copper atoms at reaction sites is rendered difficult and needs higher overpotentials. The experimentally observed linear increase in the anodic overpotential with surface coverage θ therefore supports the contention that caffeine inhibits dissolution by being adsorbed at the reaction sites. Further, the negative values for the free energy of adsorption evaluated, are also a characteristic of spontaneous adsorption of caffeine on the surface. However, the dependence of free energy of adsorption on surface coverage signifies an interaction between the adsorbed caffeine molecules (18).

The change of surface features produced in the etch patterns in presence of caffeine also demonstrate the adsorption of caffeine on the crystal surface. During dissolution, the movement of steps generated by the removal of atoms at reaction sites results in the appearance of different surface features which are related to the crystal structure (19). Screw dislocations provide steps for growth at small driving forces (6) in addition to the steps provided by misorientations.

Table II. Surface features in the etch patterns produced on copper (100) plane on dissolution in pure and caffeine-added acidic copper sulfate solution at different current densities

Pure solution current density (mA/cm²)	Solution + current density (mA/cm²)	Caffeine conc. (M)	Surface features in the etch patterns
0.10	2-15	5 × 10^{-3}	Layers
0.25	25	5 × 10^{-3}	Spiral pits
0.50	25	5 × 10^{-3}	Square concentric loops
—	2	1 × 10^{-3}	Square pyramidal pits with smooth slopes
—	2	1 × 10^{-4}	Square pyramidal pits with faceted slopes
2-25	2-25	1 × 10^{-5}-1 × 10^{-3}	Square pyramidal etch pits

Hence, in pure solution, spiral etch pits at lone screw dislocations (20) and square concentric loops enclosing tiny pits at two screw dislocations of opposite sign (20) appear at low current densities. Formation of layers at low current density could be due to the bunching of steps provided by misorientations (21). Large square pyramidal etch pits observed at a comparatively higher current density (2 mA/cm^2) form in accordance with Vermilyea's observation (22), wherein a pyramidal etch pit develops due to shortening of space between spiral turns at large undersaturations (overpotentials). Cabrera and Levine (23) proved theoretically that dislocations with large Burger's vector open up at small undersaturations and large undersaturations are necessary to open up dislocations of elementary Burger's vector. This may be the reason for an increase in the number of pyramidal pits per unit area with a resulting diminution in size at higher current densities.

Caffeine by being adsorbed at the reaction sites changes conditions for the step movement and, hence, is responsible for the surface changes. At 25 mA/cm^2, with a concentration of 5×10^{-3}M of caffeine in solution, the surface coverage is maximum and most of the reaction sites are covered by the adsorbed caffeine. The condition for the movement of steps generated from the exposed reaction sites seems to be similar to that at low current densities in the absence of caffeine. Hence, similar features, namely, spirals and square loops, are observed.

The Open-Circuit Transient Method of Analyzing Overpotential in Anodic Oxidation

J. L. Ord,* J. C. Clayton, and W. P. Wang*,[1]

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

ABSTRACT

The open-circuit technique and its application to studies of overpotential in anodic oxidation are described in detail. The digital circuitry which is used to record transients under program control can be operated either by a minicomputer or a microprocessor. Transients are written on magnetic tape for recall by analysis programs written in BASIC. Three approaches to data analysis are described and their advantages and disadvantages discussed. The anodic oxidation of tantalum in sulfuric acid is chosen to illustrate application of the technique both to facilitate comparison with results obtained by other techniques, and to illustrate how a nonlinear dependence of $\log(i)$ on E affects open-circuit analysis. A procedure for second-order analysis which accounts for $\log(i)$-E curvature through an effective-field model is described, and the significance of differences between first- and second-order results is discussed.

Although open-circuit transients were first used in overpotential studies over twenty year ago, they have seen only limited application in electrochemistry since that time, and are not widely used at present. The open-circuit technique did not become popular because the alternate techniques for studying overpotential were more direct and generally easier to apply. This

Key words: transient, anodic oxidation, tantalum.

situation has been changed considerably by recent advances in technology which have made it much easier to record and analyze open-circuit transients. There is still little to be gained by applying open-circuit transients in systems where it is possible to make direct measurements of current density as a function of potential, but wherever this is not possible, the open-circuit technique is now a more attractive alternative than it used to be.

Most of the recent applications of open-circuit transients have been in the field of anodic oxidation where the growth of a surface film introduces hysteresis into direct measurements of current density as a function of potential. Other techniques are more popular even in this field, but open-circuit transients have been used in studies of the anodic oxidation of several metals. The technique was first applied by Lake and Casey to the anodic oxidation of cadmium (1), and it has since been applied to the anodic oxidation of iron (2-5), tantalum (6), niobium (7), bismuth (8), vanadium (9, 10), zirconium (11), platinum (12, 13), and tungsten (14).

For a process as complex as anodic oxidation, it is somewhat misleading to refer to the various methods of studying overpotential as alternate techniques. Each technique involves its own special set of experimental conditions, and the expression relating current density to potential determined using a particular technique may not apply under other experimental conditions. The situation is somewhat analogous to using constant pressure and constant volume as alternate conditions for measuring the specific heat of gases without the aid of the first law of thermodynamics to explain the discrepancy between the results. At the present time there is no satisfactory theoretical expression for the relation between oxidation current density and potential in terms of fundamental quantities, hence parameter values obtained by different techniques provide complementary rather than redundant information, and the wider the range of techniques used to study a system, the more useful the results of the study. It can be argued (5, 13) that open-circuit transient results provide the most reasonable starting point for modeling the anodic oxidation process in some systems, but this is not our concern in this paper. Our objectives here are threefold: to describe modern circuitry for recording open-circuit transients, to evaluate alternate approaches to their analysis, and to show how the analysis can be carried to second order in a system where the dependence of $\log(i)$ on E is nonlinear. We use tantalum in sulfuric acid as our example both because it exhibits such nonlinear behavior, and because ample data are available from other types of measurement for comparison purposes.

Experimental

Open-circuit transients have been used in studies of anodic oxidation for over fifteen years in this laboratory. During that time many different techniques have been used to record and analyze the transients. We have found that analog techniques which use an oscilloscope or an oscillographic recorder to produce graphs of potential *vs.* time cannot match the resolution and accuracy of the digital technique we describe in this paper. When we began the digital recording and analysis of open-circuit transients ten years ago, few laboratories had comparable facilities, and the techniques we developed were not widely applicable. This is no longer the case, for advances in microprocessor technology have made digital recording circuitry less expensive and easier to use than analog circuitry.

Figure 1 is a schematic of the circuitry we use in anodic oxidation studies. Twelve-bit binary analog-to-digital and digital-to-analog converters with a resolution of one part in 4096 interface the HP2114B minicomputer to the analog circuitry which applies current to the cell and follows the potential of the reference electrode. All four operational amplifiers have FET inputs; the amplifiers used as the follower, A1, and the current source, A4, are high voltage models. Amplifier A2 conditions the output of A1 to suit the ± 10V range of converter AD1. The values of R1 and R2 may be switched to set the gain, and converter DA1 is used to offset the zero of potential. AD1 has a sample-and-hold amplifier on its input which holds the voltage constant during the 20 μsec conversion period.

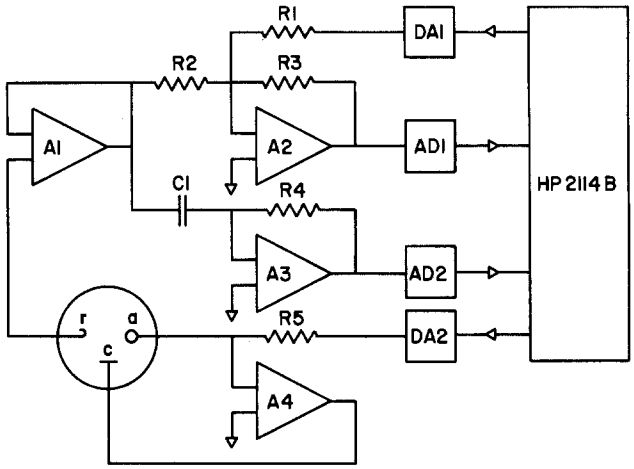

Fig. 1. Circuit schematic. The electrochemical cell contains a reference electrode, r, a working electrode whose oxidation is to be studied, a, and a platinum counterelectrode, c. Amplifier A1 follows the potential of the reference electrode, and amplifier A2 scales the output of A1 for analog-to-digital converter AD1. Digital-to-analog converters DA1 and DA2 are used to offset the output of A1 and to drive the current source amplifier, A4. Amplifier A3 is used as a differentiator whose output is digitized by AD2.

Amplifier A3, which acts as an analog differentiator, was added to the circuitry to enable the results of analog and digital differentiation to be compared. Nominal values of 1 μF for C1 and 100 kΩ for R4 were chosen to suit our experimental conditions. We found it more convenient to use a second converter, AD2, than to multiplex the input of AD1 in order to digitize the output of the differentiator.

Converter DA2 which drives the current source has a response time of 5 μsec, and is used as the "switch" which opens the circuit. When a transient is terminated by reapplying the current, the data acquired during the transient are written on magnetic tape. The 4 cartridge magnetic tape unit is one of several peripheral devices controlled by the computer which are not shown in Fig. 1. A video terminal and an X-Y point plotter are used for graphical output during analysis, and a teletype is used to list data.

The electrochemical cell used in this study has a tantalum working electrode, a platinum counterelectrode, and a mercurous sulfate reference electrode. It is filled with deaerated 0.1M H_2SO_4 held at room temperature, 22°C. Between experiments the oxide film is removed by dissolution in hydrofluoric acid saturated with ammonium fluoride. The cylindrical tantalum sample is then remounted between Teflon washers in a glass electrode holder, and the assembly is inserted into the cell through a standard taper joint.

Results and Discussion

Open-circuit transients are used to determine the dependence of current density on potential at selected points during anodic oxidation. They perturb most systems only slightly, and the dependence of current density on potential determined by analyzing a transient is assumed to apply also just before the circuit was opened. On opening the circuit, the external current drops suddenly to zero, but the oxidation current has

no discontinuity, and continues to flow as the capacitance discharges. The duration of the transient is usually chosen to suit the particular system being studied. For an ideal activation-controlled process, the circuit might well be kept open until the reverse current across the barrier becomes significant, but most systems do not reach this point before their behavior is dominated by processes other than anodic oxidation. In the high overpotential region, the relation between current density and potential for an ideal activation-controlled process can be written

$$i = i_0 \exp((V - V^*)/V) \quad [1]$$

where V^* is the zero of overpotential, i_0 is the exchange current density, and V_0 is the Tafel slope (defined in terms of natural logarithms). In open-circuit transient analysis, Eq. [1] is used as the first-order approximation for the dependence of current density on potential over the range of the transient, and least squares analysis is used to find the value of V_0 which gives the best fit to the experimental data.

The analysis is based on the equation expressing the current in the external circuit as the sum of the oxidation current, i, and the current charging the layer capacitance, i_c. Under anodic oxidation at constant field i_c is zero, but when the circuit is opened i_c becomes equal to $-i$, and the equation of the open-circuit transient may be written

$$C\,dV/dt = -i_0 \exp((V - V^*)/V_0) \quad [2]$$

provided the capacitance, C, can be considered constant over the course of the transient. This equation may be integrated, under the condition that $i = i_1$ and $V = V_1$ when the circuit is opened at $t = 0$, to give

$$V = V_1 - V_0 \ln(1 + t/T) \quad [3]$$

where $T = CV_0/i_1$, and Eq [3] may then be differentiated to give

$$dV/dt = -V_0/(t + T) \quad [4]$$

Equations [2]-[4] are the basic equations describing an open-circuit transient. Equation [2] is used to analyze V-dV/dt data, Eq. [3] to analyze V-t data, and Eq. [4] to analyze dV/dt-t data. We illustrate the application of all three of these approaches to the analysis of an open-circuit transient.

A typical open-circuit transient recorded during the anodic oxidation of tantalum at 40 μA/cm^2 in 0.1M H_2SO_4 is plotted in Fig. 2. The initial potential is 19V (relative to the mercurous sulfate electrode), and the duration of the transient is 0.734 sec. At points B, C, and D the slope of the curve has changed by factors of 8, 16, and 28 from its initial value at A, indicating that the current density through the oxide film has dropped from its initial value of 40 μA/cm^2 by corresponding factors at these points. The 37 points in the figure were selected from readings taken every millisecond by an algorithm designed to give approximately the same number of points for least squares analysis at all values of the initial potential and oxidation current density. The algorithm tests every reading to see whether the potential has changed from its last recorded value by a specified interval and whether or not dV/dt has reached the value at which the current is to be reapplied. The potential interval is calculated by taking the difference between the initial potential and an assumed zero of overpotential, and dividing by 128. This factor gives a convenient point density and simplifies the division process because it is a power of 2. We normally record transients until dV/dt has changed by a factor of 16, but we have found a factor of 8 to be more suitable in systems where processes other than anodic oxidation begin to dominate the behavior at low current density, and we prefer a factor of greater than 16 for second-order analysis. Under normal operating conditions, each point in Fig. 2 would be recorded as binary integers, giving the time the circuit has been open in milliseconds and the potential on a specified scale. In this study, the output of the analog differentiator is recorded at the same time that the potential is recorded, and 8 successive readings of each, taken over a 200 μsec interval, are recorded along with the time reading so that standard deviation estimates from least squares analysis can be checked.

An analysis of the transient in Fig. 2 using V-dV/dt data is illustrated in Fig. 3. The expression used in fitting the data is obtained by dividing both sides of Eq. [2] by their initial values to give dimensionless quantities, then taking logarithms. The dV/dt data obtained by digital differentiation of the V-t data are used in the analysis in order to make the three first-order analyses directly comparable treatments of the same set of V-t data. With the point spacing shown in Fig. 2, dV/dt at the midpoint of the potential interval is given with sufficient accuracy simply by $\Delta V/\Delta t$. The least squares line fitted to the data is shown in

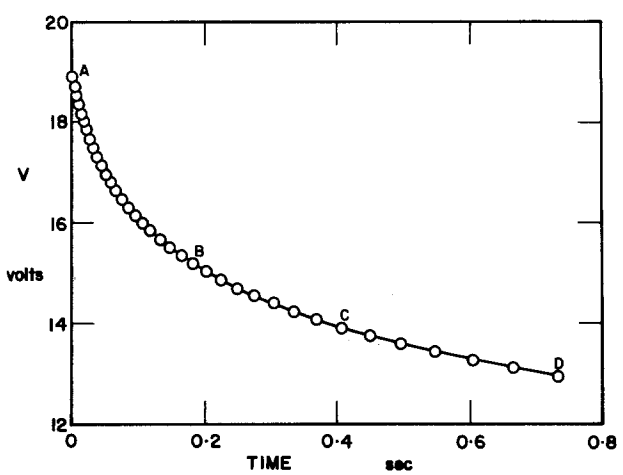

Fig. 2. Open-circuit transient recorded during the anodic oxidation of tantalum at 40 μA/cm^2 in 0.1M H_2SO_4. The circuit is opened at point A, and the slope of the transient changes from its initial value by factors of 8, 16, and 28 at points B, C, and D, respectively.

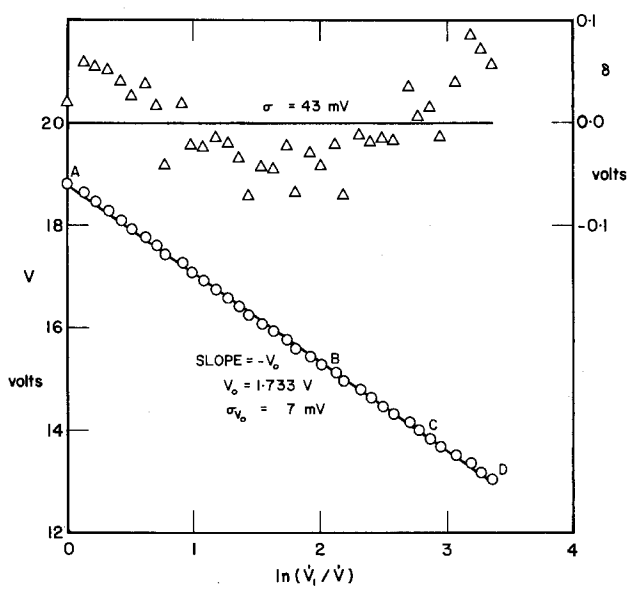

Fig. 3. First-order V-dV/dt analysis of the open-circuit transient plotted in Fig. 2. dV/dt and its initial value are designated $\dot{V}$ and $\dot{V}_1$, respectively. The deviation plot in the upper portion of the figure uses a 20 times expanded scale. The analysis gives $1/C$ = 1.858 cm^2/μF.

the lower portion of Fig. 3, along with the least squares values for V_0 and its standard deviation. The deviation from this line is plotted in the upper portion of the figure on a 20 times expanded scale. The least squares value for the standard deviation in V assumes that the values for dV/dt are known precisely, and this is not the case. The bulk of the deviation attributed to V is actually due to scatter in dV/dt. One can attempt to reduce the scatter in the dV/dt data by using analog dV/dt data in place of digital dV/dt data or by smoothing the digital dV/dt data, but we do not recommend either of these approaches. Although analog dV/dt data give a smoother deviation curve, they introduce a systematic error characteristic of analog differentiation, and do not reduce the apparent standard deviation in V appreciably. Smoothing of the dV/dt data can be accomplished most effectively in this application by using the V-t data and fitting to the integrated equation. In any event, a value of 1.733V with an estimated standard deviation of 7 mV is as accurate a first-order value for a Tafel slope as has any physical significance.

The least squares line enables dV/dt to be calculated at $t = 0$, and hence enables the reciprocal capacitance to be calculated using $1/C = -(dV/dt)_1/i_1$. (In anodic oxidation studies $1/C$ is commonly used in place of C because it is a more appropriate quantity to plot *vs.* film thickness.) The value calculated in this manner from the analysis in Fig. 3 is $1/C = 1.858$ cm^2 μF. Note that V_0 and $1/C$ are the only parameters determined by the analysis, and that an additional assumption will be needed before we can calculate i_0 and V^*.

A V-t analysis of the same data used for the analysis in Fig. 3 is illustrated in Fig. 4. Again the least squares line is plotted in the lower portion of the figure, and the deviation from the line is plotted on a 20 times expanded scale in the upper portion of the figure. The fitting procedure is somewhat more complicated than that used in Fig. 3 because T must be varied to minimize the standard deviation of the least squares fit. We first estimate T using either three equally spaced data points or the initial and final slopes, then we refine this estimate in three stages with progressively smaller T intervals by using a parabolic fit to find the minimum at each stage. The deviation of the data from the line is considerably smaller than it was in Fig. 3, and appears almost entirely systematic rather than random. The V_0 value of 1.738V with standard deviation of 2 mV differs from the value in Fig. 3 by only 5 mV, well within the error estimate. The value for $1/C$ calculated using $T = 22.8$ msec is 1.906 cm^2/μF, which differs from the previous value by 2.5%. The wider variation in $1/C$ than in V_0 values is characteristic of open-circuit analysis—although the technique depends for its existence on the discharge of a capacitor, it is better suited for determining the Tafel slope than it is for determining the capacitance.

From the form of Eq. [4] it appears that T must be varied in a dV/dt-t analysis in much the same way as it is in a V-t analysis, but this is not the case. If we follow a suggestion by Milner (15) and take reciprocals of both sides of Eq. [4] we can plot $(dV/dt)^{-1}$ as a linear function of t, in which case T is given by the intercept of the least squares line. Milner recommends this form of open-circuit transient analysis as preferable to V-t analysis under most circumstances. A $(dV/dt)^{-1}$ *vs.* t plot of the transient is shown in Fig. 5 in a format similar to that used in the previous two figures: the least squares line is shown in the lower portion of the figure, and the deviation from the line is shown on a 20 times expanded scale in the upper portion. Of necessity, the ordinate in Fig. 5 is expressed in units different from those used in the previous two figures, but the figures are scaled so that the magnitude of the plotted deviation has approximately the same significance in all three figures. The plot in Fig. 5 differs from the previous two in a number of important respects. The point spacing along the least squares line is highly nonuniform, with the points in the initial region overlapping to a greater extent than can be illustrated in the figure. The data in the initial region exhibit a systematic deviation from the line, but the increasing scatter in the data in the later portion of the transient obscure any systematic deviation. On the average, the scatter is no worse than in Fig. 3, as evidenced by the fact that the standard deviation in V_0 estimated by least squares is 7 mV for both. The V_0 value of 1.675V differs from the V-dV/dt value by 58 mV and from the V-t value by 63 mV, amounts totally inconsistent with the least squares estimates of the standard deviation in V_0. The T value of 18.4 msec differs from that in Fig. 4 by over 20%, and results in a value for $1/C$ of 2.271 cm^2/μF, considerably different from those obtained by the other two methods.

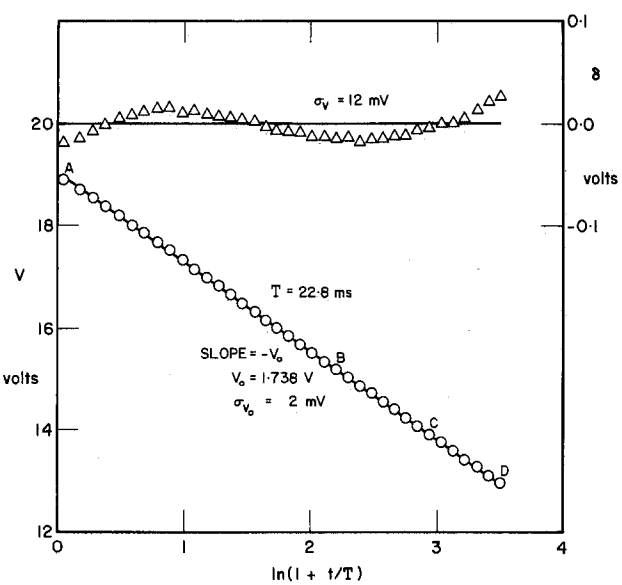

Fig. 4. First-order V-t analysis of the open-circuit transient plotted in Fig. 2. The deviation plot in the upper portion of the figure uses a 20 times expanded scale. The analysis gives $1/C$ = 1.906 cm^2/μF.

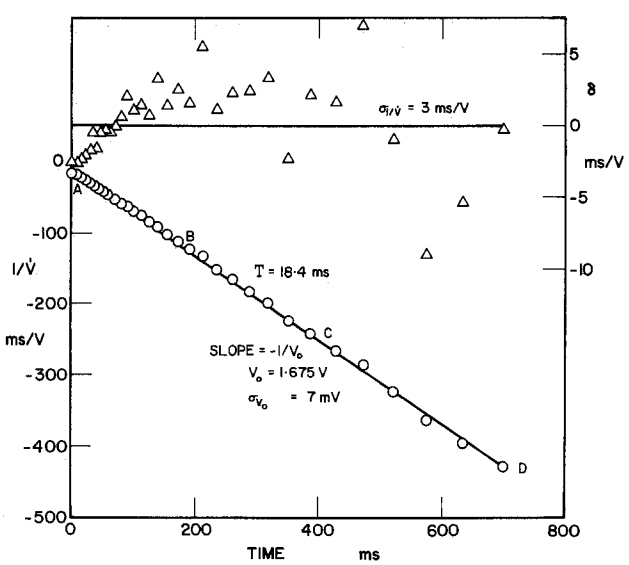

Fig. 5. First-order dV/dt-t analysis of the open-circuit transient plotted in Fig. 2. The deviation plot in the upper portion of the figure uses a 20 times expanded scale. The analysis gives $1/C$ = 2.271 cm^2/μF.

The surprisingly different values of V_0 and $1/C$ obtained by the third method of analysis force us to look more carefully at what is involved in fitting data using least squares. Certainly all three methods start with the same 37 tabulated values of V and t, and all three fit the data to a linear dependence of $\log(i)$ on V. The differences arise in the least squares minimization procedure in the third method. Two assumptions are implicit in least squares analysis: that the abscissa is known precisely, and that the ordinate has a standard deviation which does not vary from point to point. In our system, the nature of the program-controlled measurement process is such that t is known precisely, and the values of V read by the successive-approximation analog-to-digital converter have a standard deviation which is independent of V, so the V-t data are ideally suited for least squares analysis. This is not the case for the V-dV/dt data, but the logarithm in the fitting function compensates for this to a considerable extent. There is no such compensation in the dV/dt-t analysis, and the increasing scatter in the data is readily apparent in Fig. 5. The combination of increasing scatter in the data and separation between data points causes the high t data to dominate the least squares fitting in dV/dt-t analysis. This would be less serious if the dependence of log (i) on V were exactly linear, but in this case the systematic deviation plot in Fig. 4 shows that the high t data exhibit a lower Tafel slope than the least squares value, and their domination of the dV/dt-t analysis results in a lower least squares value for the Tafel slope.

Of the three methods we have used for first-order analysis of open-circuit transients, the V-t analysis is clearly the best, and is the only one suitable for carrying to second order, but the V-dV/dt analysis gives results which are not significantly different to first order without the necessity of carrying out a minimization with respect to T. The dV/dt-t analysis uses data which are poorly suited to least squares analysis, and can give misleading results under some circumstances.

In order to complete the first-order analysis we must determine values for the parameters i_0 and V^*. Although it is not possible to determine i_0 or V^* from the analysis of an individual open-circuit transient, it is usually possible to determine both parameters from a sequence of open-circuit transients applied during oxidation at constant current density. Anodic oxidation differs from most other electrochemical reactions in that the potential increases with time under constant current conditions. A linear increase of potential with time is usually interpreted as indicating control of the process by the field in the oxide film. The determination of i_0 and V^* for a sequence of transients with $i_1 = 40$ μA/cm^2 is illustrated graphically in Fig. 6, in which V_0 and $1/C$ are plotted *vs.* V_1. The transient shown in Fig. 2 is the $V_1 = 19$V transient in this sequence. The linear variation of V_0 with V_1 shown in the figure has occasionally been misinterpreted as implying that V_0 is an explicit function of potential. This is no more the case for V_0 than it is for $1/C$. For a field-limited process, both V_0 and $1/C$ are proportional to film thickness and have no first-order field or potential dependence. We can determine i_0 and V^* from the data in Fig. 6 provided we assume that neither vary with film thickness during oxidation at constant current density. If i_0 and V^* have common values for all of the transients with V_0 values on the line in Fig. 6, then the slope of the line is equal to $\ln(i_1/i_0)$, and its intercept on the V_1 axis is equal to V^*. The least squares values for the slope and intercept give $V^* = -1.12$V, and $i_0 = 4.2 \times 10^{-4}$ μA/cm^2. The $1/C$ data should have the same intercept as the V_0 data if both are proportional to film thickness. The least squares value for the $1/C$ intercept, -1.15V, is 30 mV lower than the V_0 intercept, but this is not significant in view

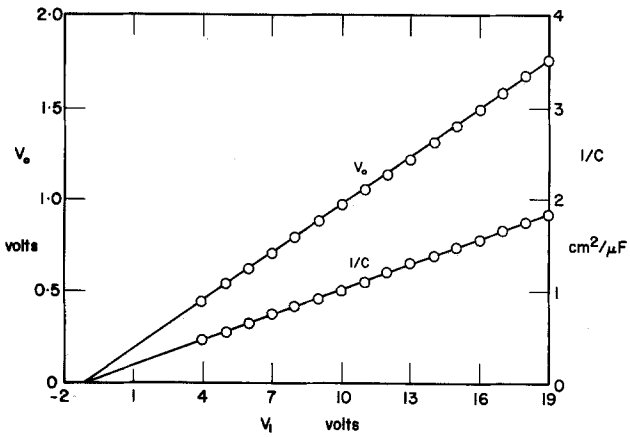

Fig. 6. Plot of V_0 and $1/C$ vs. initial potential for a sequence of open-circuit transients recorded at intervals during the anodic oxidation of tantalum at 40 μA/cm^2 in 0.1M H_2SO_4. The values of V_0 and $1/C$ were determined by first-order V-t analysis over a slope range of 16.

of the extrapolation involved in determining the intercepts.

A plot of V_0 and $1/C$ *vs.* V_1 can also be useful in less ideal systems. An early indication of film breakdown at high voltage is given by an upward deviation of V_0 from the linear dependence on V_1. In systems where oxygen evolution limits the potential range for anodic oxidation, a downward deviation in V_0 accompanies the onset of oxygen evolution. The most sensitive parameter for detecting the onset of oxygen evolution is $1/C$ which begins to curve downward before either the potential or V_0 show a detectable deviation from linearity. In systems such as platinum with a very narrow oxidation range before oxygen evolution begins, the $1/C$ values may show no meaningful dependence on film thickness although V_0 exhibits a clear dependence on thickness. In systems which show a complicated dependence of V_0 and $1/C$ on V_1, it is wise to test thickness dependence by plotting both V_0 and $1/C$ *vs.* an independent measurement of the oxide film thickness. In our laboratory, we use a self-nulling ellipsometer to follow the oxidation process and provide a nonelectrochemical measure of the film thickness.

So far we have based our analysis on a linear first-order approximation for the dependence of $\log(i)$ on V. The systematic S-shaped deviation left after first-order analysis shows that the dependence of $\log(i)$ on V is not exactly linear. For the data analyzed in Fig. 4, the nonlinearity is a property of the relation between ionic current and potential, but nonlinearity can also result from the presence of a superimposed electronic leakage current which varies more slowly with potential than the ionic current and becomes dominant in the low potential region of the transient. Electronic leakage leaves an S-shaped deviation after least squares analysis also, but the S is inverted and the data fall below the fitted line at low potentials. We normally test for leakage at the end of an experiment by switching the current down by successive factors of 2 until the potential shows an anomalous drop as the total current approaches the leakage current. On the basis of this test we select the appropriate slope range for use in the analysis.

An earlier paper from this laboratory (16) proposed an effective-field model to account for the nonlinear dependence of $\log(i)$ on E. In the model, $\log(i)$ depends linearly on the effective field which is assumed proportional to the product of the field and the dielectric constant, K, of the oxide film. This model results in a nonlinear relation between $\log(i)$ and E if the dielectric constant of the oxide film depends on the field

in it. The open-circuit transient equations can handle this type of nonlinearity because it enters symmetrically into the charge stored on the layer capacitance and into the dependence of current density on field. If we use the linear dependence of K on E reported in our earlier paper, we can write

$$K = K_0 (1 - \gamma(V - V^*)/(V_1 - V^*)) \quad [5]$$

where γ is a dimensionless parameter giving the fractional change in K between zero field and the oxidation field. If we then use the variable U defined by

$$U = (V - V^*) K/K_1 \quad [6]$$

in place of V, Eq. [2] can be written

$$C_1 dU/dt = -i_0 \exp(U/V_0) \quad [7]$$

which has the same form as Eq. [2], and hence has the same form of solution. The degree of nonlinearity of the transformation from V to U depends on the value of γ, but the transformation is such that $U = 0$ when $V = V^*$, and $U = V_1 - V^*$ when $V = V_1$ for all values of γ. In the equations, we use K_1 and C_1 to designate values at the oxidation field in the same way that we use i_1 and V_1.

The steps involved in using Eq. [7] to analyze a transient are as follows: (*i*) set V^* equal to its value from first-order analysis; (*ii*) choose a value for γ and transform the data from V to U; (*iii*) fit the transformed data using the process illustrated in Fig. 4, (*iv*) repeat for other values of γ until the value is found which minimizes the standard deviation in V, from the fitted line. (In the least squares analysis, the standard deviation in V is calculated using the appropriate value of dV/dU at each point.) The results of using this process to fit the transient plotted in Fig. 2 are shown in Fig. 7 for γ values between 0 and 0.4. The standard deviation in V is plotted as a function of γ in the lower portion of the figure, and the deviation in V is plotted as a function of V in the upper portion of the figure for $\gamma = 0$ and for $\gamma = 0.215$, the value at which the standard deviation minimizes. The standard deviation of 2 mV at $\gamma = 0.215$ is less than half a least significant bit of the analog-to-digital converter, and the only sign of any residual systematic deviation is an apparent tendency of the first point to lie a little above the line. The V_0 value at $\gamma = 0.215$ is 1.494V with a standard deviation 1/3 mV, and the corresponding value of $1/C_1$ is 1.275 cm^2/μF. The lack of a residual systematic deviation at $\gamma = 0.215$ can be used to test our earlier comments concerning first-order dV/dt-t analysis. If we carry out a second-order dV/dt-t analysis with $\gamma = 0.215$, we reduce the standard deviation in $(dV/dt)^{-1}$ by only 27% instead of the factor of 6 for V-t analysis, but we get rid of the systematic deviation and obtain a value for V_0 of 1.492 with a standard deviation of 6 mV and a value for $1/C_1$ of 1.280 cm^2/μF, both of which agree well with the values from V-t analysis. This result confirms our assertion that a small systematic deviation can have a serious effect on dV/dt-t analysis.

Although Fig. 7 is useful for discussing the details of the second-order fitting process, the physical significance of varying γ shows up best on a plot of $\log(i)$ *vs.* E. Up to this point we have written current as a function of potential rather than field, and the values we have determined for V_0 and $1/C$ have been proportional to film thickness. If we know the field in the oxide film under oxidation at current density i_1, found by ellipsometry to equal 5.68×10^6 V/cm in this instance, we can express our results more simply in terms of two thickness-independent parameters: the Tafel slope in field units, and the dielectric constant of the oxide film. We can then construct plots of $\log(i)$ or $\log(i/i_0)$ as a function of E and look graphically at what happens when we go from a first-order analysis with $\gamma = 0$ to a second-order analysis with $\gamma = 0.215$.

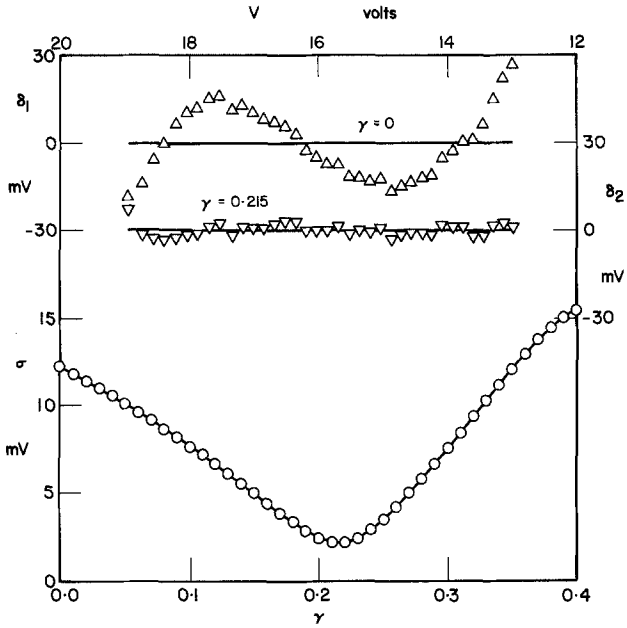

Fig. 7. Plot of standard deviation in V *vs.* γ, and deviation from the fitted line *vs.* V at $\gamma = 0$ and $\gamma = 0.215$, for second-order V-t analysis of the transient plotted in Fig. 2. The analysis gives $1/C_1 = 1.275$ cm^2/μF at $\gamma = 0.215$.

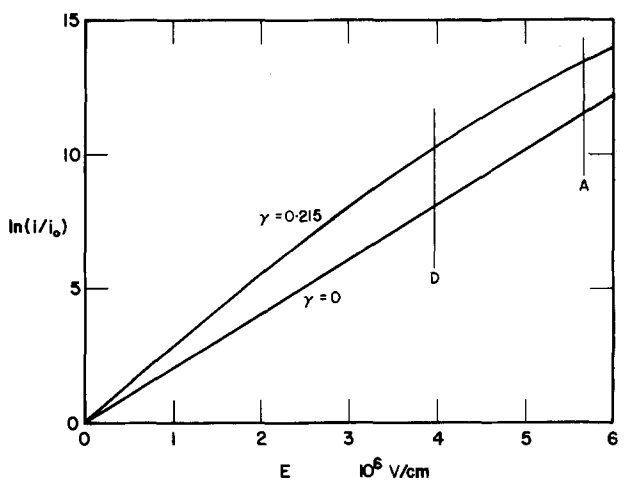

Fig. 8. Plot of $\ln(i/i_0)$ *vs.* E determined by first-order ($\gamma = 0$) and second-order ($\gamma = 0.215$) analysis of the open-circuit transient plotted in Fig. 2.

In Fig. 8 we plot $\log(i/i_0)$ *vs.* E for the expressions determined by first- and second-order analysis. This form of plot has no overlap and is more convenient than a $\log(i)$ plot for comparing shapes of curves. As can be seen in the figure, the two curves have similar slopes over the region of the open-circuit transient. The difference between first- and second-order V_0 values does not indicate a difference in Tafel slope in the region of the transient. In Fig. 8, V_0 is proportional to the reciprocal of the slope of the line from the origin to the point at the oxidation field, and since this slope is steeper for the second-order curve, V_0 is correspondingly lower. Although i_0 cannot be read directly from this type of plot, the displacement between the curves at the oxidation field gives a measure of the factor by which the i_0 values differ between first and second order. The over-all conclusion to be drawn from least squares analysis is that the second-order expression is a better approximation than the first-order expression for the dependence of $\log(i)$ on E in region A-D. The important feature of the second-order curve is its shape in region A-D, not the functional form used

to represent that shape. The physical significance of a parameter such as i_o, obtained by extrapolating the second-order expression to zero field, is certainly open to question.

The significance of second-order parameters is a question which has been dealt with in the case of steady-state measurements also. Young has fitted the dependence of $\log(i)$ on E under steady-growth conditions to a linear first-order expression (17), and to second-order expressions of the form $\alpha E + \beta E^2$ (18), and $\gamma E^{1/2}$ (19). He found that the $\alpha E + \beta E^2$ form gave a better second-order fit than the $\gamma E^{1/2}$ form, but concluded that this was due primarily to the extra fitting parameter. In Fig. 9 we show our first- and second-order expressions along with Young's three expressions on a plot of $\log(i)$ *vs.* E. In a plot of this type, all of the curves intersect at point A and separate at lower fields intersecting the current-density axis at their corresponding i_o values. On the scale used in this figure, our first- and second-order expressions appear indistinguishable across region A-D, but have i_o values which are clearly different. At point A, Young's three expressions all have similar slopes (the first-order expression having been corrected using 27.6 for the dielectric constant rather than the 23.2 value used in his 1954 measurements) but separate noticeably across region A-D and intersect the axis at widely different values of i_o. The magnitude of the difference between the open-circuit and steady-state Tafel slope values shows up clearly in Fig. 9: both are measures of the derivative of E with respect to $\log(i)$, but they differ in what is held constant as the derivative is taken. The significance of the difference in Tafel slope values is a subject of some controversy (6), and we do not discuss it further here.

The accuracy to which the dielectric constant of the oxide film can be calculated is limited by the accuracy to which the sample area can be determined. If we correct for the fact that the macroscopic surface area of the sample used here is 14% lower than the nominal 1.25 cm^2 on which current-density calculations are based, and if we assume a roughness factor of unity, we get values for the dielectric constant of 24.2 from our first-order analysis, and 36.2 at the oxidation field increasing to 46.1 at zero field from our second-order analysis. We can display the field-dependence of the dielectric constant graphically, but such a plot does not account for the magnitude of the difference between the first and second-order values at zero field. We can, however, use the equation for the capacitive discharge current in the effective model to predict the ratio of these quantities. This equation has an extra term due to the field-dependence of the capacitance

$$dQ/dt = C\,dV/dt + (V - V^*)\,dC/dt$$

$$= C_o\,(1 - 2\gamma)\,dV/dt \quad [8]$$

where C_o is the value of the capacitance at zero field. This equation predicts a value of $(1 - 2\gamma)$ for the ratio between the first- and second-order dielectric constant values at zero field. If we test this relation using a slope range of 4 in the first-order analysis to minimize the effect of the systematic deviation, the first-order value of 25.7 predicts a value of 45.1 for the zero-field dielectric constant at $\gamma = 0.215$. The fact that the measured second-order value is only 2% higher than the predicted value shows the consistency of the equations of the effective-field model. We will not attempt to discuss the physical significance of our dielectric constant results here, because to do so would require a discussion of the coupling between field and strain in anodic oxide films, a subject which goes beyond the scope of this paper.

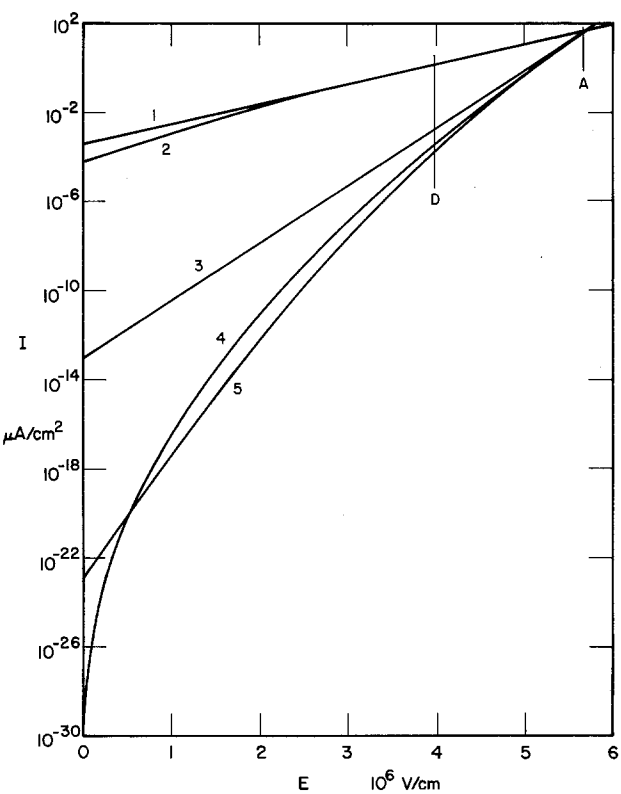

Fig. 9. Plot of $\log(i)$ *vs.* E from first-order (1) and second-order (2) open-circuit analysis, and from first-order (3) and second-order steady-state analysis with $\gamma E^{1/2}$ (4) and $\alpha E + \beta E^2$ (5) field dependence (see text).

The Effect of Stress Applied During Electrodeposition of Nickel Monocrystals on Their Structure

M. R. Chodkowski and R. Weil*

Department of Materials and Metallurgical Engineering, Stevens Institute of Technology, Hoboken, New Jersey 07030

ABSTRACT

The effect of stresses exceeding the yield strength on the structure of monocrystalline, nickel electrodeposits was investigated. A considerable refinement of the structural features due to the stress was observed and was attributed to a greater dislocation density on the growth surface. This refinement of the structure can affect how the stress varies with deposit thickness. Observations of the dislocation structures suggest that the cell structure developed in the near-surface regions under stress. The size of the cells appeared to be related to the structural features which constituted the surface. It was also demonstrated that it is possible to grow monocrystalline, nickel deposits to thicknesses in excess of 100 μm.

Electrodeposits are frequently in a state of internal, tensile stress which can momentarily exceed the yield strength. It has not been determined whether such a stress in a deposit, when acting as the substrate, affects the electrocrystallization processes and thereby the structure of subsequently plated layers. If the phenomenon of stress in electrodeposits is to be understood, this effect must also be considered. The effect of stress on the electrocrystallization is difficult to determine because the factors which are believed to cause the stress also change the structure (1). For example, changing the pH of a nickel-plating bath can increase the stress and simultaneously alter the size and orientation of the grains. In fact, the plating variables and bath composition probably affect the stress via changes in structure (1). However, a stress which exceeds the yield strength can also change the electrocrystallization processes because of alterations in the density and distribution of the dislocations and the creation of slip steps. It is to the study of this phenomenon that this investigation is addressed.

The purpose of this investigation was therefore to determine whether the structure of electrodeposits is altered because of the presence of a stress. In order to separate the influences of the other factors from the effects due to stress, it was applied externally in a tensile machine during deposition rather than causing it to have a high value by adjusting the plating variables or the bath composition. The plating conditions were therefore chosen so that the internal stress would be very small. While an externally applied stress does not act exactly like an internally produced one, the effects on the structure should be similar.

Experimental Considerations

A recent study of Souzis and Weil (2) showed that nickel monocrystals plated in additive-free, all-sulfate baths possess internal stresses which are initially high and tensile, decrease with increasing thickness, and then level off at about 5 μm. The structure at thicknesses exceeding 5 μm should therefore be representative of low stress deposits. Applying an external stress during the electrocrystallization of such a deposit should reveal its effect on the structure. An external stress differs from an internally produced one in that the former continues to strain the material which has already been deposited. Therefore, it was also necessary to determine the effect on the structure of straining after deposition.

Three structures produced under the same condition except for the stress had to be compared, namely: (*i*) with the external stress applied after plating; (*ii*) with the external stress applied during plating; and (*iii*) without the external stress. The first and second structure could be produced on the same substrate sample by plating first on one side only and then coating this deposit. Then, still without the external stress, the other side was plated to a thickness of 25 μm to be sure that the internal stress had leveled off. The external stress was then applied without interrupting the plating. In this way, the first coated deposit was stressed after plating. The deposit on the other side of the substrate at thicknesses in excess of 25 μm was deposited while being stressed. Pieces of the same substrate plated alongside had the structure produced without external stress or subsequent straining.

It was desirable to study monocrystalline samples because of the data available from previous work (2). Also the stresses which could develop in polycrystalline samples because of the variation in the yield strength of grains of different orientations had to be avoided. It was therefore necessary to develop means to deposit monocrystalline nickel deposits considerably thicker than 25 μm.

Experimental Procedure

The procedure which was found most often to yield thick, monocrystalline nickel deposits involved the use of melt-grown, single-crystal copper substrates having a {100} plane parallel to the surfaces to be plated. The substrates, which originally were lath shaped about 60 × 10 × 1.5 mm, were formed into the shape of a tensile specimen by plating polycrystalline copper on each end in an acid-sulfate bath. These copper deposits were about 10 mm long and resulted in a total sample thickness of about 7.5 mm. By withdrawing the sample during copper plating, the thickness became tapered, thereby avoiding sharp corners where fracture could occur during tensile straining. The substrates were electropolished in a 50% phosphoric acid solution for 2 min at an initial current density of 0.5 A/cm^2, rinsed in fresh 15% phosphoric acid, washed several times in water which was distilled thrice in the presence of oxidizing agents to remove organic impurities (3), and then dried. The reason for the drying is discussed later. After mounting in the appropriate fixtures for plating, the substrates were immersed in a 25% sulfuric acid solution for 10 min, rinsed again several times in the triple-distilled water, and quickly placed in the plating bath. The plating bath, which contained 0.43 moles/liter $NiSO_4 \times 6H_2O$ and 0.4 moles/liter H_3BO_3, had the same composition used by Souzis and Weil (2) and was purified in the same way. The current density was 20 mA/cm^2, the pH was 3.7, and the temperature 27°C. Three tensile-specimen-shaped substrates were avail-

Specimen II	100	25	50	2×10^{-3}	35%

* Plated without concurrent straining.

able. The nickel deposit on one became polycrystalline. Thus data from two experiments were useful.

The experiments consisted, as was already discussed, of plating one side (designated side A in Table I) of the substrate while the other was coated with a stop-off lacquer. The deposit thicknesses are also listed in Table I. Then the lacquer was removed and the nickel deposit was coated. For plating under an externally applied stress, the sample had to be placed in a special fixture. This fixture, which was made of a titanium alloy containing 2% palladium, consisted of two jaws held together by screws for gripping the copper-plated ends of the tensile-specimen-shaped substrate. There were also two guide bars to prevent bending or compressing of the substrates during mounting. The top grips were free to move in the tensile direction. All outer surfaces of the fixture were coated with stop-off lacquer. After the sample was mounted in the fixture, the top jaw was attached to the tensile machine (Instron Model TTCL M13). Then the lower jaw was attached by means of a pin to a lacquer-coated, titanium alloy rod protruding out of the plating bath which was contained in a Teflon beaker. After the attachment, the fixture was pulled into the bath by means of the rod. The current had previously been set so that it flowed as soon as the substrate was in the plating bath. The elapsed time between removal from the sulfuric acid solution and the start of plating had to be less than 15 sec, otherwise the deposit became polycrystalline. For this reason the substrate was dried to minimize oxidation during the necessarily long time interval while it was being mounted in the fixture. As already discussed, a 25 μm thick deposit was laid down without external stress on the as yet unplated side of the substrate (designated B in Table I). Then straining was begun while plating continued. The strain rates, which are also listed in Table I, were such that each layer of deposit was continuously stressed beyond its yield strength.

The structures of the samples plated under the three previously discussed conditions were studied. All deposit surfaces were examined by scanning electron microscopy. X-ray Laue patterns were taken to determine if the deposits were monocrystalline. Thin foil samples for examination by transmission electron microscopy were prepared by the Bollmann (4) method. The Bollmann electrolyte for thinning was modified in that it did not contain sulfuric acid. After dissolving the copper substrates, thin foil samples were prepared by electropolishing both sides of the deposit so that the resulting sample represented the structure at about half the total deposit thickness. Other thin foil samples were prepared by electropolishing only the side of the deposit which had been adjacent to the substrate. In this way, the foil represented the structure near the surface of the deposit.

Results

The surface structure of the ~100 μm thick monocrystalline nickel deposit which was neither stressed during nor subsequent to plating consisted primarily of ridges. At a thickness of 25 μm, the surface structure was similar except that the ridges were about half as long. The Laue x-ray pattern of the 100 μm thick plate which had sharp, unstreaked spots was indicative of a monocrystal of relatively high perfection.

The surface structure of the 100 μm thick deposit on side A of specimen II which was stressed after deposition is shown in Fig. 1. The structure only differs from that of the samples which were neither stressed during the plating nor afterward in that one set of parallel slip lines extends through the ridge structure. An arrow points to a slip line where, apparently, a displacement of part of a large ridge occurred. The ridges themselves experienced essentially no distortion due to the straining of the sample. The extended direction of the ridges makes an angle of 45° with the slip lines, which are along <110> directions. The extended ridge on a {100} plane must be of the <001> type. The structure of a thin foil sample representing the near-surface region of the 100 μm thick deposit is shown in Fig. 2. A well-developed dislocation-cell structure is evident. In the sample representing the interior of about half the total thickness, there was no well-defined dislocation-cell structure. The dislocations were more uniformly distributed and fewer in number than near the surface.

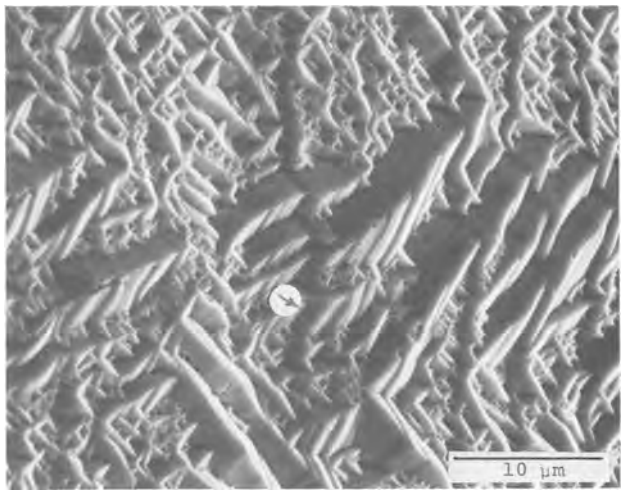

Fig. 1. Scanning electron micrograph of surface of nickel monocrystal strained after plating. Arrow shows displacement at slip step.

The surface structure of side B of specimen II, which was deposited while being strained, is shown in Fig. 3. The structure is much finer than that seen in Fig. 1. The grooves between the blocks again lie in <001> directions as they form an angle of 45° to the slip lines. The ridges at large slip steps are noteworthy. Well-defined dislocation-cell structures were observed halfway through the thickness and near the surface. The structure at half the thickness was similar to that seen in Fig. 2. The cell walls near the surface of the deposit had

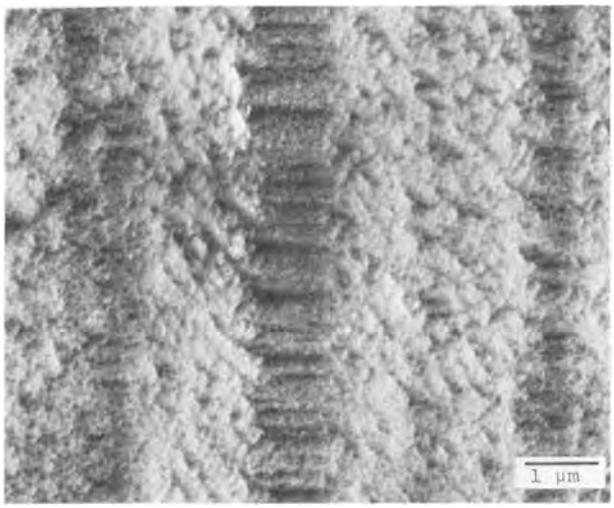

Fig. 3. Scanning electron micrograph of surface of nickel monocrystal. Strained during plating.

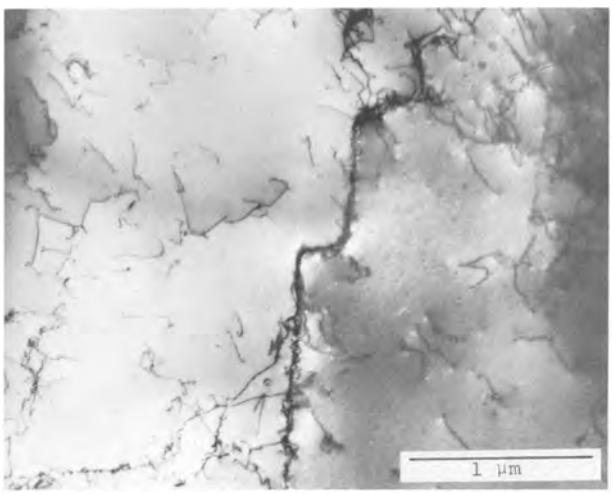

Fig. 4. Transmission electron micrograph of thin-foil sample from near-surface region of nickel monocrystal strained during plating.

a distinctly crystallographic character, as shown in Fig. 4. The cell walls were found to lie along <001> directions. It is also significant that none of the samples examined by transmission electron microscopy showed any twins. The Laue x-ray patterns of the samples strained during deposition, which consisted of streaked spots, were indicative of monocrystals of low perfection.

No significant differences were observed between the structures of specimens I and II. Apparently the thickness difference or the doubling of the strain rate had no effect. Specimen II was strained 35% in order to avoid the fracture which occurred in specimen I at 39%.

Discussion

By comparing Fig. 1 and 3 and noting the higher magnification of Fig. 3, it is evident that the stress applied during deposition resulted in a considerable refinement of the structural features which comprise the surface. As the size of the ridges at a thickness of 25 μm was about half that shown in Fig. 1, the structure obtained by deposition under an externally applied stress was also much finer than that of the initial 25 μm thick layer which was plated without straining. The refinement of the structure due to the applied stress was probably due to the higher dislocation density resulting from plastic deformation rather than the slip steps. If the slip steps created on the surface had served as sites for growth, a layer structure would have resulted. It is evident from Fig. 3 that such a structure was not formed. Rather, the block-shaped features probably grew on emerging dislocations. The growth of blocks on screw dislocations has been postulated (4). At a large slip step, the structural features are more ridge shaped probably because growth occurred on a different crystal plane, namely, of the {111} type, and because fewer dislocations would be expected to emerge on this growth surface.

The refinement of the structure due to straining beyond the yield strength could affect the magnitude of the internal stress which develops in subsequent layers. A cause of internal stress is believed to be the coalescence of crystallites (1, 5). The smaller the crystallites, the higher would be the stress. Thus a refinement in the structural features tends to maintain the stress at a higher value in subsequently deposited layers. This phenomenon could explain why the stress decreases rather slowly with increasing deposit thickness rather than dropping off sharply from a high initial value. This initial value in the case of epitaxial deposits would be expected to decrease sharply once the misfit between the initial substrate and deposit has been relieved.

It is interesting that the externally applied stress did not cause the deposit to become polycrystalline or result in the development of twins. As was previously observed by Lighty *et al.* (6), dislocations only result in polycrystallinity if foreign substances are associated with them. Twins, which are also believed to be due to codeposited foreign substances (7), are also not caused by stress as shown in this study.

The dislocation-cell structure apparently developed in the near-surface region under stress. Only in the samples which were stressed during deposition was a cell structure observed in the interior regions. These interior regions, however, were near-surface regions under stress at one time. The cell structure results from complex, irregular dislocation motion induced by stresses originating from dislocations already present, according to Sumino and Yamamoto (8). The dislocations already present could be sources for generating more dislocations. There are a number of studies (9-11) which have shown that such dislocation-generating sources are present in greater numbers in the near-surface regions. The surface roughness probably also affected the cell structure in that the areas under recessed regions between the blocks or the ridges were closer to the surface, and therefore would have more sources and develop more dislocations which would form the cell walls. The crystallographic nature of the cell walls in Fig. 4 was probably due to this phenomenon. It may be recalled that both the cell walls and the grooves between the blocks of Fig. 3 were parallel to <001> directions. In Fig. 2, there are also some larger and some smaller cells which correspond to the variation in the ridge size of Fig. 1.

The deposits produced for this study remained monocrystalline to thicknesses considerably greater than generally observed by others (12, 13), who reported that nickel deposits on {100} oriented substrates which are the most favorable for thick monocrystalline growth (12), become polycrystalline at thicknesses of 10-20 μm. However Leidheiser and Gwathmey (14) reported obtaining thick nickel monocrystals on {100} substrates. The fact that thicker monocrystals were obtained in this study is attributed to the purity of the electrolyte, selection of the proper plating conditions, careful maintenance of the substrate surface, *i.e.*, preventing contamination, oxidation, or dewetting, and the absence of twins in the copper basis metal. When vapor-deposited substrates which contained many twins were used, the plates became polycrystalline while still very thin. This result illustrates why a substrate with few, if any, twins was needed. It may be recalled that if the time between the immersion of the substrate in sulfuric acid and the start of plating was greater than 15 sec, the deposit became polycrystalline, showing the

need for substrate-surface maintenance. The purity of the plating bath was probably responsible for preventing the development of twins in the deposit (7). Multiple twinning is believed to be responsible for the transition to polycrystallinity (13). As only pH, current density, and bath-temperature values within a narrow range used in this study resulted in monocrystalline deposits, the necessity for maintaining the proper plating variables is evident.

Conclusions

1. Stresses exceeding the yield strength result in a refinement of the structure of monocrystalline nickel electrodeposits.
2. The stresses in a deposit can influence the value of this property in subsequent layers.
3. The dislocation-cell structure developed in the near-surface regions under stress and was related to the size of the structural feature on the surface.
4. It is possible to grow monocrystalline, nickel electrodeposits thicker than 100 μm.

Electroless Deposition of Cuprous Oxide

Charles B. Greenberg* and J. Shannon Breininger

PPG Industries, Incorporated, Glass Research Center, Pittsburgh, Pennsylvania 15238

ABSTRACT

It is generally well known that certain metals can be deposited on dielectric substrates at room temperature by aqueous, electroless chemistry following surface activation. Much less is known about electroless growth of oxides. One oxide, namely cuprous, has been deposited on glass as an adherent thin film of good quality. It was formed on a precursory electroless silver film from a highly alkaline solution containing Cu^{+2}, tartrate ion, and formaldehyde. Growth of cuprous oxide requires having Cu^{+2} highly coordinated with OH^- and also having the electroless silver, activating surface relatively free of its own oxide. Silver oxide, at least within our experimental conditions, seems to activate the codeposition of electroless Cu. Data are presented to confirm the identity of the Cu_2O film. Competing reactions for the deposition of Cu_2O and Cu are discussed in terms of hydroxide complexing and surface activation.

Electroless deposition of copper from alkaline, aqueous solutions containing cupric ion is well known (1, 2). The cupric ion is often complexed by tartrate and reduced by formaldehyde. Palladium and electroless silver, as well as copper itself, are well known as activators for otherwise noncatalytic, or perhaps only poorly catalytic, dielectrics such as glass. Sard (3) has discussed the nucleation and growth of copper on several substrates including glass. Schoenberg (4), by electron paramagnetic resonance with frozen solutions, has studied the complexing in solution as a function of pH. He has related this to the plating rate for deposition of electroless copper.

Perhaps because of the considerable interest in copper, and its excellent electrical conductivity, no one seems to have commented on what happens under certain conditions which are unfavorable for its deposition. In highly alkaline solutions which have only a low concentration of tartrate, an oxide deposits electrolessly. It has been identified as cuprous oxide. There are only a few oxides known to deposit electrolessly from previous work (5, 6). PbO_2, Tl_2O_3, and MnO_2 have been deposited autocatalytically using an oxidizing agent, ammonium persulfate. Cu_2O growth occurs by reduction of Cu^{+2} and can be initiated other than by Cu_2O itself. When steps are taken to provide a preferred activating site on electroless silver, the transparent cuprous oxide film is adherent, of good optical quality, and apparently free of codeposited metallic copper. It is also free of haze, exhibiting the specular reflectance which is required for its intended application in architectural glazing (7). The work described herein has meaning in light of what Schoenberg has written about complexing. It also provides some insight into what actually activates Cu_2O, in contrast to metallic copper, within the conditions of our work.

Experimental Procedures

Thin film preparations.—In Table I are shown the aqueous solutions used, unless otherwise indicated, and the sequence in which they were used for Cu_2O deposition. All steps were at room temperature. Procedures were similar to those previously described

Table I. Compositions of solutions in the sequence used

A. Sensitizer
0.5 g/liter $SnCl_2 \cdot 2H_2O$
0.5 cm^3/liter HCl (conc)

B. Silvering
1.1 g/liter $AgNO_3$
5.0 cm^3/liter NH_4OH (28-30% NH_3)
0.16 g/liter NaOH
1.3 g/liter dextrose

C. Silver rinse
0.1 g/liter $Na_2S_2O_3 \cdot 5H_2O$

D. Cu_2O growth
3.8 g/liter $CuSO_4 \cdot 5H_2O$
29.0 cm^3/liter HCHO solution (with methanol)
3.0 g/liter $NaKC_4H_4O_6 \cdot 4H_2O$
25.0 g/liter NaOH

(7). The coating was formed on one surface of commercially available flat glass by puddling solutions horizontally on a leveled surface. Substrate size was 50-60 cm^2, thickness 0.3-0.6 cm. Prior to coating, the glass was scrubbed with cerium oxide, followed by a detergent cleaning. A sensitization time of 1 min was typical; the tin chloride was dissolved in concentrated HCl and then diluted with water (8). For the silvering formulation, about 25-35 sec were required to attain a luminous transmittance of about 0.40-0.50, using the CIE standard C response. This was the usual target preceding deposition of the Cu_2O film. Less NH_4OH, longer times, and multiple applications were used for thicker silver films in supplemental experiments. Between sensitization and silvering was a water rinse. After silvering and prior to Cu_2O deposition, the rinse contained $S_2O_3^{-2}$ to inhibit codeposition of metallic copper; this is elaborated in a following section. The electroless silver was dried with N_2 when checking luminous transmittance. Otherwise the $S_2O_3^{-2}$ solution was drained off for best uniformity but was not dried off. The following deposition of Cu_2O required 2.5-3.5 min preferably; the solution was a fresh 1:1 mixture of two otherwise stable components. As is typical for the deposition of electroless copper, one component contained the Cu^{+2} and formaldehyde, the other the tartrate ion and NaOH. In normal storage the mixed solution is stable for at least 8 hr, longer with care to prevent contamination. The effect of contaminants on oxidation of liquid aldehydes has been discussed (9). Following the final rinse with water, the sample was dried with flowing N_2.

What is particularly noteworthy about the solution used for electroless deposition of the oxide is the relatively low concentration of tartrate ion and the high *p*H of about 13.9. Another formula previously used for electroless deposition of copper has about four times as much $KNaC_4H_4O_6 \cdot 4H_2O$ and 11.1 g/liter of NaOH instead of 25.0 (10); otherwise, the concentrations of $CuSO_4 \cdot 5H_2O$ and formaldehyde solution (37% HCHO) are the same. This formula is used here too for the purpose of forming a comparative, metallic copper film. It has a *p*H of 12.9 and also contains 1.3 g/liter of $NiSO_4 \cdot 6H_2O$ which insures adhesion but produces no detectable nickel in the film (7).

Spectrophotometric analysis.—Spectral characterization of samples from 0.3 to 2.1 μm, essentially the solar range at sea level, was done with a Beckman DK-2A spectrophotometer. This instrument was coupled to a Datex SDS-1 recording system which converts the signal to computer language. Using the CIE weighted ordinate method (11), color parameters are thereby also determined. It is easy to convert CIE data into the more familiar terminology of the NBS-ISSC system. Both data are presented instead of the corresponding visual perceptions of film color.

For supplemental information, luminous transmittance and luminous reflectance were measured, without obtaining full spectral curves, using the Gardner Hazemeter System HG-1200 and the modified Precision Glossmeter Model GG-9100 (10). They have, respectively, the CIE standard C response and the approximate standard C response. Supplemental data were also obtained in one case with a Diano/Hardy I spectrophotometer.

Film identification.—A sample of the oxide-containing film was analyzed directly using a Norelco x-ray diffractometer. The analysis was repeated several times while fine tuning the signal relative to background; identification of a thin film is not usually easy by x-ray diffraction. Presented here is a pattern which is definitive and typical. By interferometric measurement the oxide component was found to be about 700Å thick (12). Its deposition time was 3 min.

Results and Discussion

Spectral data.—For a film deposited by the sequence in Table I, using 2.5 min for the oxide growth, reflectance from the film-air surface and transmittance are plotted in Fig. 1(a). An electroless Ag-Cu film on glass is spectrally characterized in Fig. 1(b). The thicknesses of the precursory silver films are similar, as are the final luminous transmittances. The reflectance curve for the Ag-Cu film shows a sharply rising reflectance with increasing wavelength in the red, characteristic of metallic copper (13). This is also shown in Table II by the reflected dominant wavelength, and color designation in the NBS-ISCC system. In the infrared portion of the spectrum the reflectance is as high as 0.96. The infrared reflectance curve in Fig. 1(a), on the other hand, never exceeds 0.32. Also, there is a band whose minimum is at 0.7-0.8 μm; it appears to be the result of interference. This band contributes to the bluish green reflectance observed and shown in Table II. Hass, Schroeder, and Turner (13) have shown similar bands for mirror coatings of aluminum and

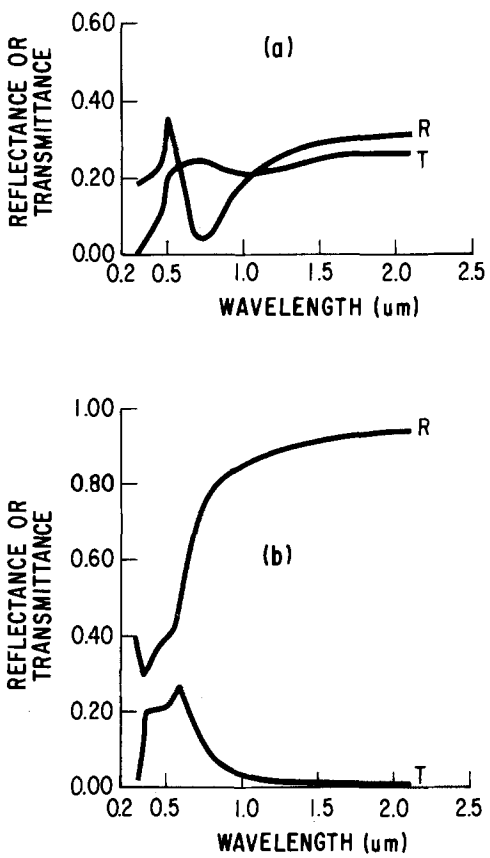

Fig. 1. Reflectance at 8° angle of incidence from the film-air surface (R) and normal transmittance (T) for two electroless thin films on glass: (a) Ag-Cu_2O and (b) Ag-Cu. Thicknesses of the precursory silver films are similar and estimated to be approximately 50-100Å; this is based on luminous transmittances of (a) 0.41 and (b) 0.45 for silver.

Table II. Comparative color in the CIE and NBS-ISCC systems for the electroless films in Fig. 1

	Transmission		Reflection	
	(a) Ag-Cu_2O	(b) Ag-Cu	(a) Ag-Cu_2O	(b) Ag-Cu
Dominant wavelength (nm)	572	572	497	593
Excitation purity (%)	33.6	8.5	16.8	12.8
Tristimulus Y	0.22	0.24	0.25	0.44
NBS-ISCC color	Light olive (106)	Light olive gray (112)	Light bluish green (163)	Grayish red (28)

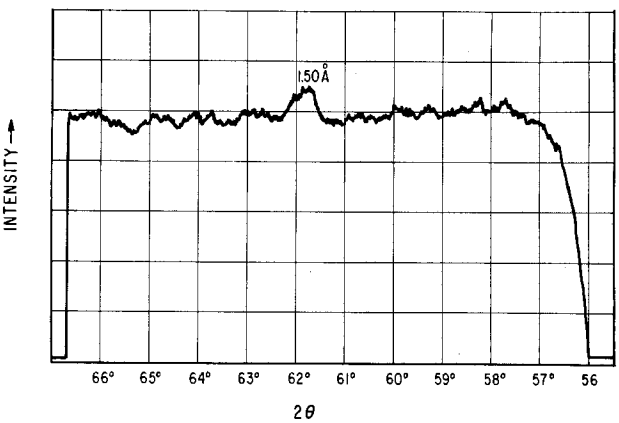
rhodium overcoated with nonabsorbing and absorbing films to quarter-wavelength optical path lengths. The reflectance can be effectively reduced especially when the refractive index of the oxide is relatively high. The refractive index of bulk Cu_2O is a very high 2.7. For a film of $CuO_{0.67}$, a gross defect structure of cuprous oxide, indexes of 3.0-2.2 from 0.5 to 0.8 μm have been reported (14, 15).

For Fig. 1(a) the very different infrared reflectance, the reflectance minimum, and the bluish green reflection, as well as an easily observed iridescence of the film when nonuniform, all are indications of an oxide, possibly cuprous. There is no evidence of metallic copper. The sharply declining reflectance and transmittance from about 0.5 to 0.3 μm, although not identified, could possibly be attributed to the fundamental absorption of cuprous oxide (14, 16). The dip in transmittance at about 1.0 μm, however, is from the substrate.

Identification by x-ray diffraction.—In Fig. 2 is an x-ray diffraction pattern. Two peaks are very clearly identified at 2.45 and 2.12Å. The two major peaks for cuprite, Miller indexes (111) and (200), are at 2.465 and 2.135Å; the relative intensities are known to be 100 and 37%, respectively. The major peaks for other possible substances, including Cu, Ag, CuO, Ag_2O, and Ag_2S, are quite different. The major constituent of the film, therefore, is cuprous oxide. The slight shift in lattice parameters is probably an indication of nonstoichiometry, not at all unlikely for a thin film in general and cuprous oxide in particular. Note that there are no peaks for the electroless silver component; it is probably too thin to be detected. The very high background at low angles is from the underlying glass.

In Fig. 3 is the diffraction pattern for a third peak corresponding to the third most intense for cuprite; it has been enhanced at ¼ the normal scanning rate. Its Miller index is (220) with an expected relative intensity of 27%. It is evident at 1.50Å and is similarly shifted from the given value of 1.51Å for cuprite. There is a small peak in Fig. 2 at $2\theta \cong 62°$ which recommended expanding detection sensitivity. Other Cu_2O lattice parameters in the 2θ range covered have known relative intensities less than 10% and therefore were assumed to be undetectable. The order of peak intensities in Fig. 2 does follow that for bulk cuprite.

Complexing and chemical reactions.—At the relatively high pH of 13.9, in Cu^{+2}-$C_4H_4O_6^{-2}$-OH^- solution, only four-coordinated complexing of Cu^{+2} by OH has been indicated by Schoenberg (4). At the usual pH for deposition of electroless copper, about 12.9, OH coordination may also be threefold; the fourth bond is to the COO^- of the tartrate. Schoenberg's configurations are shown schematically in Fig. 4. When formaldehyde is included, it may, in the form of the methylene glycol anion, displace the indicated tartrate complex as the initial step in electroless deposition (4). Also shown in Fig. 4 is a configuration which has been reported to be especially consistent with the exceptional stability against hydrolysis (17). The exact nature of Cu^{+2} complexing in alkaline solution is not to



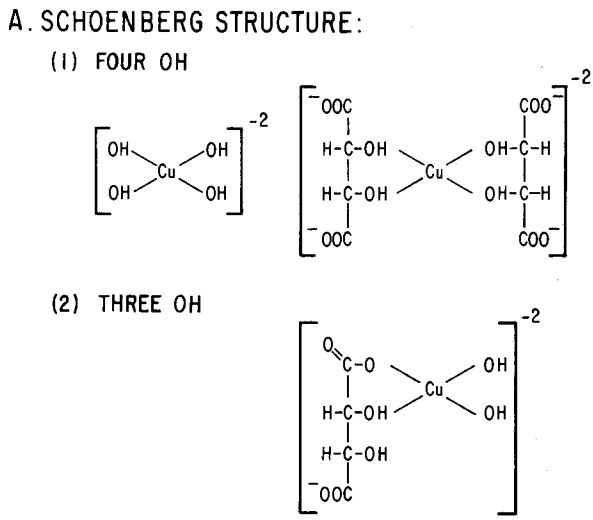


Fig. 3. X-ray diffraction pattern showing a third peak

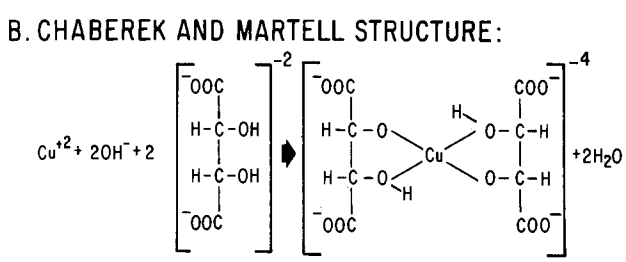

Fig. 4. Suggested complexing of Cu^{+2} by OH^- and $C_4H_4O_6^{-2}$ in alkaline solution, drawn schematically from the literature.

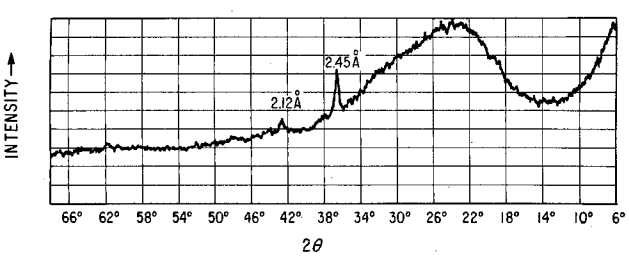

Fig. 2. X-ray diffraction pattern of a Ag-Cu_2O film. The radiation is $CuK_{\alpha 1}$.

be found with total agreement, perhaps, in part, because it varies with composition. Schoenberg's description is, however, reasonable for reference; moreover, it includes the *p*H range for usual electroless coppering solutions, as well as that for deposition of Cu_2O. What it suggests is that whether Cu_2O or Cu forms is likely to be a function, in part, of the concentrations of OH^- and tartrate, and the complexes formed therefrom. Pertinent oxidation-reduction reactions in alkaline solution have been reported. For the catalyzed deposition of copper metal (18)

$$Cu^{+2} + 2HCHO + 4\,OH^- \rightarrow Cu + 2HCOO^- + 2H_2O + H_2 \quad [1]$$

A reaction for the formation of Cu_2O has been written for the reduction of Fehling's solution by formaldehyde (19)

$$2Cu^{+2} + HCHO + 5\,OH^- \rightarrow Cu_2O + HCOO^- + 3H_2O \quad [2]$$

In the absence of the $C_4H_4O_6^{-2}$ from the solution in Table I, a Cu_2O film also formed rapidly, but the solution was decomposed after only a few minutes. The latter suggests that the tartrate ion is necessary in complexing for increasing the relative stability of this solution. On the other hand, because Cu_2O did form rapidly without $C_4H_4O_6^{-2}$, it is likely that, within limits set by stability, a maximum of OH^- bonding is desirable. Experiments were carried out with the $C_4H_4O_6^{-2}$-containing formula in Table I adjusted to lower *p*H's including 12.6, 12.8, and 13.2. Cuprous oxide begins to deposit, within a few minutes, at a *p*H of approximately 13. In the absence of $S_2O_3^{-2}$ treatment, the aforementioned codeposition with small amounts of Cu above *p*H $\cong$ 13, even without $C_4H_4O_6^{-2}$, suggests that both reactions [1] and [2] may be possible; their respective rates depend in part on complexing and in part on the catalytic surface. The solution in Table I is a reasonably good compromise for deposition of Cu_2O, having enough tartrate for stability while having considerable OH^- complexing.

Activation of Cu_2O growth.—When an electroless silver film is freshly prepared on glass, it almost certainly is not purely metallic. It must contain silver oxide. This is difficult to prove by x-ray diffraction for such a few molecular layers of oxide. It is, however, implied by the simple curve in Fig. 5. The reflectance decreases significantly during the time the film is exposed to demineralized water. The silver must be oxidized by dissolved O_2, perhaps to Ag_2O which dissolves then at its own rate; its reported solubility in H_2O is 0.013 g/liter at 20°C. Much the same thing occurs at least during the normal rinsing step. A similar oxidation of silver has been mentioned (20).

It was when working with solutions of Cu^{+2} similar to that in Table I, but at lower alkaline *p*H values and without the $S_2O_3^{-2}$ rinse, that it was first observed that Cu_2O and Cu codeposited on electroless silver. The latter formed in areas which suggested a pattern associated with the puddling techniques of film formation. This raised the question as to whether Cu_2O and Cu are differently activated. Several things were done to alter the uppermost surface of the electroless silver film. For example, a silver film was rinsed for 1 min with an aqueous solution of 1.0% by weight of $KMnO_4$ and then dried. It has been concluded from qualitative emission spectrographic analysis and the interference pattern in Fig. 6 that this film probably contains oxides of both silver and manganese. Deposition was attempted by dipping the treated sample in a Cu^{+2}-containing solution similar to that in Table I except for less NaOH. The *p*H was 13.2. After 5 min, there was a heavy deposit of copper but no visible Cu_2O. A similar, untreated, but dried, silver film which was dipped in a companion solution of the same formulation became coated with Cu_2O and spots of metallic copper. The edges were coated with Cu, where the electroless silver had been slow to dry. Gas evolution which was observed may have accompanied these Cu spots by Eq. [1]. The experiment demonstrates the very important effect which the activating site has,

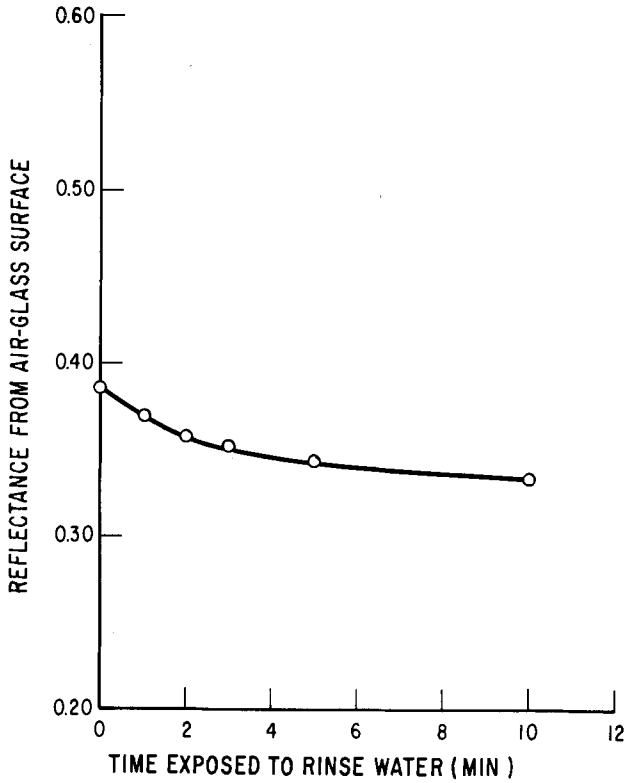

Fig. 5. Luminous reflectance with approximately the standard C response, when an electroless silver film is continuously exposed to demineralized water at room temperature. The film is approximately 200Å thick. Data are averaged for two experiments. Experiments were done horizontally as previously described (10).

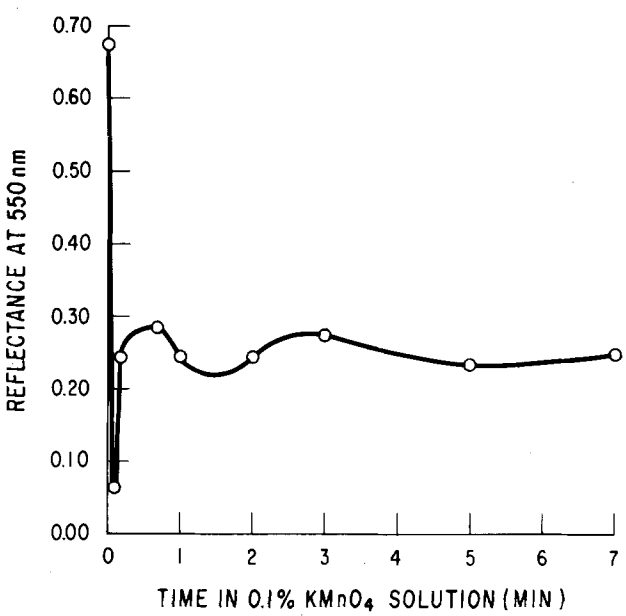

Fig. 6. Interference pattern plotted from the film-air reflectances of electroless silver films on glass after various oxidations in $KMnO_4$ solution at room temperature. The luminous transmittance of the initial silver film in each case was 0.08, thicker than usual so as to produce interference minima. Data are from Diano/Hardy spectral curves.

having had no intentional variation in the electroless solution. One film formed as Cu, the other predominantly as Cu_2O.

Codeposition of copper metal is inhibited by a precursory treatment of electroless silver with a sulfide-forming rinse, for example, a solution of ammonium sulfide. Using normal coating procedures and solutions from Table I other than $S_2O_3^{-2}$, codeposition was prevented by quickly rinsing the electroless silver with a 2.8×10^{-3}% by weight solution of $(NH_4)_2S$; at 2.2×10^{-3}% there was codeposition. At higher concentrations such as at 0.22 and 0.022% all film growth seemed to be inhibited. It is known that S^{-2} scavenges silver oxide (21)

$$Ag_2O + S^{-2} + H_2O \rightarrow Ag_2S + 2\,OH^- \qquad [3]$$

Ag_2S is practically insoluble. Growth of Cu_2O, with the $(NH_4)_2S$ rinse, was indicated by color and iridescence and marked by haziness. Haziness suggests the growth of fewer and relatively larger crystals of Cu_2O. For inhibiting haziness under otherwise similar conditions, the $S_2O_3^{-2}$ solution was found to be a better rinse. Ag_2O is also known to react with sodium thiosulfate to form Ag_2S and sodium sulfate (21). The presence of sulfur in an electroless silver film after exposure to a concentrated solution of $S_2O_3^{-2}$ (3.0 g/liter) has been confirmed qualitatively by comparative x-ray fluorescence analysis. In previous efforts with other silver- and sulfur-containing films, however, it was not possible to identify crystalline silver sulfide by electron diffraction (7).

Apparently, under our conditions, the formation of silver sulfide on Ag, to the extent of inhibiting the growth of silver oxide, favors silver activation of Cu_2O. Silver oxide is apparently favorable for Eq. [1] and the deposition of copper metal. It is possible that the well-known electroless deposition of copper is always activated by silver oxide and not metallic silver at all, although a contrary suggestion has been made (20). The physical and chemical properties which dictate the roles of silver and silver oxide as activators are, at this time, only matters of speculation. Perhaps it is significant that Ag_2O is readily reduced chemically (21) or that it is known to be photoconductive (22).

Summary

Cuprous oxide thin films of good quality, approximately 700Å thick, have been deposited on activated glass by aqueous, electroless chemistry at room temperature. Identification has been made from spectral data and by x-ray diffraction analysis. The films were grown from a highly alkaline solution, pH equal to 13.9, containing Cu^{+2}, tartrate ion, and formaldehyde. Apparently one factor which shifts electroless deposition kinetically, away from the familiar and prevailing copper metal of somewhat lower alkaline pH's, to cuprous oxide, is the highly hydroxide-coordinated Cu^{+2}. Complexing of Cu^{2+} has elsewhere been reported to shift, in the presence of tartrate ion, from three to four coordinated OH's in the pH range of 12.8-13.7. The oxidation-reduction reaction which produces cuprous oxide may be the Fehling reaction.

A second factor, which assures that cuprous oxide will form free of any detectable, codeposited, metallic copper, is the activating site. By prior treatment the glass was coated with electroless silver, care being taken to inhibit the usual formation of silver oxide. The latter seems to activate the electroless codeposition of copper, even when the solution is properly alkaline. Growth of silver oxide was inhibited by rinsing the electroless silver film with a dilute, aqueous solution containing $S_2O_3^{-2}$, thereby forming silver sulfide instead. Our experimental results indicate that metallic silver itself is probably the activator for Cu_2O growth.

As far as is known, this is the first description of electroless deposition of cuprous oxide as a potentially useful optical film. That it grows at all provides some clues about the significance of the Cu^{+2} complex in solution and the role of the activating surface. Each subject bears on the electroless deposition of both cuprous oxide and copper. Further research on either of these should be very useful indeed, relating not only to film deposition but relative bath stability as well.

The Reduction of SiO_2 with Carbon in a Plasma

D. M. Coldwell* and R. A. Roques*

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

The feasibility of a process for the reduction of low impurity silica (SiO_2) with carbon in a plasma heat source was investigated. An rf induction plasma reactor was fabricated and used to optimize process variables. Maximum silicon content of the product was 33% by weight. Emission spectrographic analysis of this product showed a reduction in some impurity levels of one to two orders of magnitude. While the plasma approach proved technically feasible, poor heat transfer from the plasma to the reactant and low yield make the process economically unattractive for large-scale use.

The reduction of a silicon-containing halide has long been the source of the electronics industry's elemental silicon. However, this process is far too expensive to fall within the goals of ERDA's Low-Cost Silicon Solar Array Program which demands solar-grade silicon costing less than $10 per kilogram.

One approach to obtain these goals is the reduction of naturally occurring silicon oxides with carbon in a high temperature induction plasma torch. Coldwell (1) has studied the thermodynamics of this reaction under plasma conditions with a computer model which utilized an iterative free energy minimization technique. A threshold temperature of 2500°K was predicted below which no silicon is formed, only silicon monoxide and silicon carbide. Above 2500°K, elemental silicon and carbon oxides should be produced. The yield of silicon and the type of carbon oxides are dependent on the initial ratio of carbon to silica (SiO_2). This analysis assumed equilibrium reaction conditions only to show that the proposed reaction was thermodynamically feasible.

While other investigators (2-4) have used induction plasmas, their work involved the reduction of processing of only a single reactant. This plasma reduction, on the other hand, required a chemical reaction between two components to occur above the threshold temperature in the plasma itself. A diagram of the process is shown in Fig. 1.

The plasma was formed in an induction torch described by Reed (5) and improved upon by Boumans *et al.* (6). It was used to reduce silicon dioxide yielding elemental silicon and carbon mono- or dioxide.

Experimental Procedure

Raw material preparation.—In order to maximize reactivity of the raw materials, fine grinding and intimate blending were first necessary. The naturally occurring silica was purchased as silica flour of less than 400 mesh ($<37\ \mu m$) particle size and the carbon, *i.e.*, carbon black, was available in a pelletized form of ultimate particle size in the millimicron range. The raw materials were further comminuted and blended in a rubber-lined ball mill using flint pebble grinding media to minimize contamination. The general approach taken was the upgrading of starting material quality and careful avoidance of contamination of the reactants and product through the process. Table I gives the results of emission spectrographic analysis of raw materials.

The initial emphasis of this study was on using powder or pelletized material but difficulties of reactant feed, penetration into the plasma, and sufficient residence time in the plasma for reaction to occur were experienced. An alternative approach was material formed into 6 mm diam rods. Binder additions of 5 weight percent (w/o) polyvinyl alcohol (PVA), and sufficient water to produce good extrudibility, improved the plasticity and strength of these extruded rods. The durability of the rods was sufficient to withstand the heat exposure on entering the plasma flame without fracturing or decrepitating before being vaporized.

Experimental reactor description.—An induction heating system unit was used to construct the rf plasma reactor. A two-turn coil around a 30 mm diam quartz tube had provisions for introducing and measuring gas flows. To prevent localized melting of the tube wall where the flame was in close proximity, the discharge was vortex-stabilized by introducing a sheath gas tangentially into the quartz tube. This plasma could be maintained on the axis of the tube even if the diameter of the flame (approximately 1.5 cm) was much greater than the skin depth of the plasma gas. The plasma reactor is shown diagramatically in Fig. 1.

The reactant material was fed to the flame by a continuous rod feed mechanism. This rate was controlled by a variable speed motor driving a threaded rod which moves the feed rod vertically into the reduction chamber. The rod was positioned to enter the plasma at its hottest point.

The temperature distribution within the plasma was determined spectroscopically (7). Peak temperature was found to be 15,000°K, decreasing to 1000°K downstream. The size of the region greater than the threshold temperature was large enough to be easily used as the rod feed target.

A tubular bundle was fabricated and placed downstream from the plasma to quench product gases. It was positioned so that its surface temperature was elevated ($>$ 600°K). After each run, the collected product was removed from the bundle and the bundle etched in dilute hydrofluoric acid to remove any traces of previous runs. Optimum collecting temperature was estimated by heating the cooling chamber wall and was found to be approximately 600°K.

Since the product obtained is amorphous and of millimicron size, further processing is necessary to quantitatively determine the amount of elemental silicon present. Wet analysis of the unsintered product gave erratic results which were reproducible only after the sintering step. Sintering at 1825°K for 1 min in argon consolidated the silicon and disproportionated approximately 70% of the silicon monoxide to silicon dioxide and silicon.

Results and Discussion

Experiments with feed rod composition of one mole SiO_2 to one mole carbon were made to determine optimum reactor conditions with respect to power, feed rate, and gas flow rate. Maximum and minimum values were used for each process variable. The experimental design can be represented by a cube with axes representing each of the three variables and individual experimental conditions by the center and corners (8). This is shown schematically in Fig. 2.

and minimum feed rate, run *GP/F*, which produced 23% silicon in the sintered product. Other reactor conditions led to results repeatable within 20%.

The amount of product collected as a percent of the amount of material fed to the reactor is indicative of the efficiency of heat transfer to the material in order to vaporize it. The theoretical amount of silicon which could be obtained at 100% reduction of the SiO_2 is $\approx$ 39% by weight of the starting material mixture. The *GP/F* run yielded product silicon that was 15% of theoretical. This low efficiency of heat transfer appears to be a significant problem in utilizing this plasma process.

Using the optimum reactor conditions, the raw material carbon to silica mole ratios were varied from 1 : 1 to 2.8 : 1. The addition of a binder such as methyl cellulose or polyvinyl alcohol, was necessary to extrude 6 mm diam rods but had little effect on reaction rate or silicon yield. Table III lists data and results of experimental runs made with the compositions investigated. The highest yield of silicon occurred at a carbon to silicon mole ratio between 1.5 :1 and 1.9 :1. It also appears that wet ballmilling of the carbon and silicon is more favorable for comminution and intimate mixing than is dry milling.

Chemical analyses of the sintered reaction product showed 28-33% of the material collected in the best runs was silicon. The silicon was visible after consolidation in globular form with the characterisic protrusions of a material which expands on freezing from the melt. Globules ranged from $\approx$ 25-250 μ, as shown in Fig. 4. Emission spectrographic analysis of the silicon indicated at least an order of magnitude reduction in content of some impurities from the starting materials with electrically active elements such as boron, arsenic, and phosphorus below the detection limits. Table IV shows a comparison between the analyses of the raw material batch and the silicon product.

These experiments were the first to demonstrate a chemical reaction between two reactant solids fed into an induction plasma. Despite the short residence time in the plasma, the silica was reduced to either elemental silicon or silicon monoxide.

Table IV. Emission spectrographic analysis of silicon product

Problems and Unknowns in Plasma Technology

A number of difficulties were identified in the use of a plasma heat source for a reversible chemical reaction, which are inherent in plasma technology and require solution before use of an induction plasma is practical. (*i*) The energy utilization is low due to the series of multiple steps (rf generation, plasma gas exitation, and gas to reactant solids), each of which is less than 50% efficient. The large volumes of inert gas required to sustain the plasma multiply the amount of heat required. (*ii*) The large volumes of gases cause the desired chemical concentration to be very low, which severely limits controlled collection of product condensate. Separation of unreacted material from product is complicated by the simultaneous quenching of both species. (*iii*) A molecular dynamics computer simulation showed that quenching rates higher than are physically possible are necessary to remove vaporized elemental silicon from the product before it reoxidizes (9). Even if this reaction and disproportionation to silicon are taken in account, the quench rate required is an order of magnitude too great to be achieved with current technology. (*iv*) Control over the reaction temperatures within the plasma is difficult. The exact reaction temperature was unknown, occupied a very small volume, and varied greatly because of the steep temperature gradient within the plasma. (*v*) The usage of argon gas is excessive.

Summary

The technical feasibility of producing silicon from the raw materials, silica and carbon black, was demonstrated using a laboratory-scale plasma reactor. Energy utilization was inefficient due to poor heat transfer characteristics of the plasma and yield of silicon in the product collected as condensate was never greater than 33% ($\approx$ 25% of the stoichiometric amount available). The problems related to inefficiency of energy utilization and product yield were not resolved.

The experimental results suggest that a reduction reaction likely occurs while reactants are in a condensed state. Further heating of the rod causes product silicon to vaporize simultaneously with carbon and oxygen-containing gases from additional reduction reaction. High yield recovery by quenching of the product silicon from a highly reactive gas stream, regardless of how the mixture was formed, is unlikely.

A Parametric Study and Computer-Based Simulation of an Undivided Sodium Hypochlorite Electrolyzer

G. R. Heal, A. T. Kuhn, and R. B. Lartey

Department of Chemistry and Applied Chemistry, University of Salford, Salford, Lancashire M5 4WT England

ABSTRACT

The electrolysis of brines has been carried out in an undivided cell under controlled hydrodynamic conditions and with simultaneous chemical analysis of all major products formed (ClO^-, O_2, H_2, ClO_3^-). The experimental data are compared with predictions made using a simple model and proven mass transfer relationships, and it is shown that a satisfactory fit obtains.

In recent years there has been a dramatic revival in the use of electrochemical hypochlorite cells. Unlike the earlier cells, which were unstirred and which used strong made-up brines to produce NaOCl for chemical production, the newer generation of electrolyzers operates with low strength (*ca.* 3%) NaCl, often using untreated seawater. This is pumped through a parallel plate cell at high velocity to give a large volume of low strength NaOCl which is used for disinfection or to prevent fouling. Details of the applications, the designs of such cells, and operating modes may be found in a recent paper by Bennett (1) or in Ref. (2, 3). Hypochlorite cells also feature in a number of patents, most of which are listed in the references cited above. There have also been valuable contributions to the subject from Soviet workers. Thus both Medrish (4) and Skripchenko *et al.* (5) describe extensive measurements of current efficiency and power consumption together with product analysis. Further additions to the patent literature include British Patents 1,399,898 (addition to 1,278,591). What is, however, lacking in the literature, is information relating to the performance of such cells. The older, nonpumped hypochlorite cells have been fully described in the textbooks of industrial electrochemistry. But the performance of the modern force-flow cells is either not described, or else information given omits important details such as channel dimensions. In such cases, electrochemical parameters, such as diffusion layer thickness, cannot be deduced. Lastly, some of the published data relate to experimental conditions in which one or more parameters were not held constant. In large cells, for example, a significant rise in temperature will occur during the passage of the brine through the cell, thereby making cell performance prediction difficult.

Chemistry and Electrochemistry of the System H_2O-NaCl-Cl_2

Because the subject has not been treated in the literature in the last decade, we should initially consider the chemistry and electrochemistry involved in an undivided hypochlorite cell. Thus the following equations may be written:

(*i*) Homogeneous system: When chlorine is dissolved in water, the following reactions can take place

$$H_2O + Cl_2 \rightarrow HOCl + Cl^- + H^+ \quad [1]$$

$$HOCl \rightarrow H^+ + OCl^- \quad [2]$$

$$OCl^- + 2HOCl \rightarrow ClO_3^- + 2Cl^- + 2H^+ \quad [3]$$

$$2\,OCl^- \rightarrow 2Cl^- + O_2 \quad [4]$$

Both reactions [1] and [2] are fast as Landolt and Ibl and others (6) have shown. The equilibrium position of [2] is pH dependent and Ref. (7) shows a typical curve. From simple equilibrium postulates, one can say that decrease in $[Cl^-]$ or $[H^+]$ concentrations will lead to increase in either HOCl or OCl^- (whichever is favored at the particular pH. Reaction [4] is catalyzed by heavy metal ions or active charcoal as well as other dissolved or suspended species.

(*ii*) Electrochemical reactions: Most of the species described above can undergo at least one electrode reaction, either at the anode or cathode. So too, can water and ions derived from it. We can list here:
at the anode

$$2Cl^- \rightarrow Cl_2 + 2e \quad [5]$$

$$6\,OCl^- + 3H_2O \rightarrow 2ClO_3^- + 4Cl^- + 6H^+ + 3/2\,O_2 + 6e^- \quad [6]$$

$$H_2O \rightarrow 2H^+ + \tfrac{1}{2}\,O_2 + 2e \quad [7]$$

$$ClO_3^- + H_2O \rightarrow ClO_4^- + 2H^+ + 2e \quad [8]$$

$$ClO_3^- + HClO \rightarrow ClO_4^- + Cl^- + H^+ \quad [8a]$$

at the cathode:

$$OCl^- + H_2O + 2e \rightarrow Cl^- + 2\,OH^- \quad [9]$$

$$2H^+ + 2e \rightarrow H_2 \quad [10]$$

$$2H_2O + 2e \rightarrow H_2 + 2\,OH^- \quad [11]$$

$$3H_2O + ClO_3^- + 6e \rightarrow Cl^- + 6\,OH^- \quad [12]$$

We can make certain assertions at the outset. Thus the homogeneous reaction [3] does not proceed fast below 50°C as shown by Ormerod (15) and also Jaksic (21) while the anode reaction [8] is scarcely significant above 10°C as shown in (15). But for further consideration of the over-all steady state, one must distinguish between those cells which are divided by a membrane or diaphragm into anode and cathode compartments (as in the chlorine industry) and those which are undivided. In the former, the anolyte reaches a pH value of 2-3 and gaseous chlorine is evolved while the electrolyte is saturated with hypochlorous acid as well as dissolved chlorine and additionally contains a given amount of ClO_3^-. The latter (9) is formed by oxidation of OCl^- ions arising from back-migration of OH^- ions from the catholyte. The catholyte is strongly alkaline with H_2 evolved at the cathode. Any chlorine seeping through the diaphragm is converted to OCl^- ion and this is immediately reduced at the cathode (reaction [9]) to Cl^- so that no trace of it is ever found. Of the chlorate formed in the anolyte, some diffuses to the catholyte and this too is reduced at the cathode, though incompletely so that measurable amounts (typically 0.07 g/liter) are found in the catholyte liquors leaving the cell.

In an undivided cell however, the pH is substantially uniform across the cell. H_2 is still evolved at the cathode and Cl_2 at the anode. However the pH being now much higher, this dissolves virtually to completion to form hypochlorite solutions. Some values for these

Key words: brine electrolysis, undivided cell, reactor modeling, electrochemical mass transfer.

equilibrium constants have been quoted in the literature. Thus for Eq. [2] Hammer and Wranglen (8) quote a mean value of 4.6×10^{-8} (at 20°C), while Hine and Yasuda (9) quote 1.33×10^{16} at 25°C for $Cl_2 + 2\,OH^- \rightarrow Cl^- + ClO^- + H_2O$.

Kinetic analysis of cell reactions.—Certain of the reactions discussed above have been extensively studied although not always under the precise conditions that obtain in hypochlorite cells.

Cathodic losses.—The reduction of the OCl^- ion, as well as its undissociated counterpart, is well understood. Wolf and Landsberg (10) studied this reduction in alkaline solutions on graphite electrode at OCl^- concentrations of up to 1.2×10^{-3} mole liter^{-1}, finding reduction currents of the order of 1 mA · cm^{-2} and a mechanism that agreed with their earlier work [Schwarzer and Landsberg (11)] as well as that of Mueller (12) on platinum cathodes. The latter author derives the expression

$$i = k\,[ClO^-] \exp\,[0.42\,\mathbf{F}E/RT]$$

for the rate of reduction on the metal surface which is seen to be first order in hypochlorite ion (at least up to 2.4×10^{-3} molar). No *p*H effects were determined in this work, although these are reported in the study by Schwarzer and Landsberg (11) who show the reductive behavior at *p*H = 5.3, 7.5, and 10.0. At the most negative potentials, there appears to be no *p*H effect and the current (at 5 mmole HClO) is diffusion limited although, at less cathodic potentials (+0.2 *vs.* SCE), separate plateaus due to the OCl^- and the HOCl reduction can be seen. Another recent paper by Harrison and Khan (13) supports the above findings and it is clear that oxides of Pt can catalyze the reaction. However, in the context of hypochlorite cell operation, the cathode will always be cathodic to this region. A recent paper by Hine and Yasuda (9) is noteworthy in that it reports measurements at higher ClO^- concentrations than the others cited here. At 0.09M OCl^- in 2*N* NaOH + 3*N* NaCl a limiting current for the OCl^- reduction of 10 A · dm^{-2} is reached and appears to be first order in OCl^- as evidenced by Mueller (12) at much lower concentrations. There does not appear to be any dependence in NaCl concentration (1.3 and 0.3*N* NaCl) nor on *p*H (2-0.2*N* NaOH) again supporting previous workers. In conclusion, it will be seen that especially at higher operating conditions of OCl^-, a significant loss of efficiency can occur. Hammer and Wranglen (8) have studied both anodic and cathodic losses, though mainly with an eye to the chlorate manufacturing process. From their results the additional parameters of temperature and ClO_3^- can be studied. Increase in temperature favors decomposition of OCl^- at the cathode while increased ClO_3^- concentration depresses it. Both effects are tied to viscosity changes in the electrolyte with resulting changes in diffusion limiting currents. At zero OCl^-/HOCl concentration and the very high (273 g/liter) concentration of ClO_3^-, a certain amount of reduction of the latter takes place and from 2-8% of the cathodic current could be so consumed (steel cathode, *p*H 10, 14-100 A · dm^{-2}, 25°C). Again it is true to say that under normal hypochlorite cell operating conditions, this source of loss will not be significant. Seen from the over-all cathodic operation viewpoint, it is probably true to say that reactions [9] and [10] are the dominant ones and that the aim in cell design should be to offer a cathode on which these reactions proceed with the lowest overpotential, thus minimizing this contribution to cell voltage. Reduction of hypochlorite on Fe cathodes has been studied (14).

Anodic loss reactions.—We are here mainly concerned with reactions [6] and [7] since it has been shown (15) that [8] is unimportant above 10°C. Reaction [7] is itself insignificant at normal operating potentials, provided the Cl^- concentration is reasonably high.

It will, of course, be seen that simple measurements of oxygen evolution from the cell will not elucidate the contributions of [6] and [7] since both are a source of this element. Thus Kuhn and Mortimer illustrate how, at high current densities (16), the amount of oxygen evolved increases as brine concentrations are lowered from 1 to 0.13M. Although they do not specifically attribute the contributions from the two different sources, the obvious importance of stirring and mass transport make it clear that it is [6] and not [7] which is the main source of oxygen inefficiency under these conditions since mass transport problems would not be anticipated for [7] at any normal operating current densities. Unpublished results (15) do throw light on this question. At 3% NaCl concentration 21-25% of the anodic current was lost in this way at 0°C (inlet temperature) though this dropped to 13% at 10°C. Using 1% brine at 10°C approximately 30% of the current loss was ascribable to this reaction. (Current density was believed to be *ca.* 300 mA · cm^{-2}.) From the same source, we see that current losses due to perchlorate formation were 13-30% (at 0°C) and essentially nil at 10°C. Finally, current loss due to reaction [5] was 11% at 10°C and 5% at 0°C all in 3% brine, with a 72% efficiency in OCl^- manufacture at the higher temperature, dropping to 50% at zero degrees. In the 1% brine at 10°C, the hypochlorite efficiency was 36-44% with chlorate losses around 25% and oxygen evolution, as listed above, rather higher. Though these results are reasonably accurate, they are made in cells with an appreciable entrance-exit temperature gradient. Furthermore, the hydrodynamics are ill-defined and on these, as has been seen, the loss rate of reaction [6] depends. The work of Hammar and Wranglen, cited above, is equally interesting in the information cited on the anodic side, although it should be stated that (*i*) the hydrodynamic conditions are ill-defined, and (*ii*) the brine concentrations are always so high that O_2 evolution is suppressed (Eq. [7]). Thus the rate of oxidation of (HOCl + OCl^-) is linearly related to its concentration, independent of *p*H in the region *p*H 6-11 as is the reductive loss, and increases by some 2%/°C. At 4 A · dm^{-2} and 100 mmole hypochlorite, 25°C, the loss is some 25%. A paper by Despic *et al.* (17) deals with the oxidation rate of OCl^- ions alone (no HOCl) and the mechanism even under these "simplified" conditions is most complex. Perchlorates can also be formed, and we have detected them analytically. The kinetics of reaction [8a] have been studied by D'Ans (40).

Mechanistic and kinetic conclusions.—The reactions of possible importance in the hypochlorite cell, both chemical and electrochemical, have been discussed. It will be seen that as a fixed quantity of brine (whether this be static or continuously stirred or recycled) is electrolyzed, a point is reached where the rate of destruction of hypochlorite (due to several of the processes described) matches the rate of formation. This situation results in a plateau in the concentration *vs.* time curve, as seen in Marshall and Millington (18). After further time, of course, the level of concentration will actually decrease due to losses of Cl^- from the system as ClO_3^-.

The relative importance of anodic and cathodic losses.—The question is sometimes raised whether losses of hypochlorite at the anode or cathode are more significant (ignoring losses in the bulk). This can be seen to be largely a matter of definition. Defining it in terms of molecules of OCl^- or HOCl lost per unit area in a given time, the cathodic losses are greater since under the diffusion-controlled regime that prevails in most cells, the small value of δ (diffusion layer thickness) at the cathode (due to the copious evolution of hydrogen gas there) assists in this respect. On the other hand while two electrons

serve to destroy one molecule of HOCl at the cathode; at the anode, from 0.3 to 3 electrons, by means of a reaction such as

$$7HClO + H_2O \rightarrow 2ClO_3^- + O_2 + 5Cl^- + 9H^+ + 2e$$

or Eq. [6] and Ref. (8) are used to destroy the HOCl.

The foregoing treatment suggests that while much excellent work has been done in the general area, there are no studies to describe accurately the modern undivided force-flow hypochlorite electrolyzer operating at high current density and, therefore, in the mass transport-controlled region, as far as many of the reactions listed above are concerned. The apparatus described below, being a recycling loop, approximates to an "infinitely long" cell, although the actual dimensions of the electrodes are comparatively small. In this it resembles the commercial reactors fitted with recycle and "bleed-off." A useful general treatment of such systems has been given by Pickett (19).

Experimental

The cell consisted of two polypropylene blocks, each 31 cm long, 9 cm wide, and 2.5 cm thick, which were bolted together. A cell cavity was created by machining a recessed area in each block, and the electrodes were further countersunk in each cavity. The effect of interelectrode gap was studied by introduction of a polypropylene spacer between two electrode blocks. Electrolyte entered and left the cell by means of a twin-branched manifold angled at approximately 20° to the plates and designed to reduce entry and exit turbulence to a minimum. In addition, the cell cavity was large enough to provide a smoothing section (17 cm from entry to leading edge of the electrodes) and an exit section (5 cm from electrode trailing edge to exit manifold). Electrodes were made of platinized titanium 2 cm wide × 10 cm long, supplied by Messrs. Marston Excelsior Limited, Wolverhampton. Brine was circulated through the cell by an Iwaki magnetically coupled all PTFE pump. The brine circulation circuit also incorporated a cooling/heating coil immersed in a constant temperature bath, and a Venturi system (previously calibrated) to measure brine velocity. Provision was made for circulating the brine through a gas-disengagement chamber and this was coupled to an Orsat gas analysis apparatus, in which H_2 and O_2 could be estimated. The cell itself was oriented with electrodes vertical and the angle of the cell at 45° to the vertical. This prevented accumulation of gas bubbles (gas-locking) at low brine velocities. Direct-current power was supplied to the cell from a power pack, current was measured using a Sangamao Weston S82 multirange precision ammeter. Cell voltage and half-cell voltage were measured with a Garrett-Normalair digital voltmeter of high impedance and using a back-entry Luggin probe connected to a saturated calomel reference.

Results and Discussion

The cell was operated under a range of current densities (from 25 to 450 mA · cm^{-2}) and brine flow rates (15-75 cm sec^{-1}) all obtained at 25°C. The buildup of hypochlorite, and chlorate concentrations was followed as a function of time, as were the rates of hydrogen and oxygen evolution. Too much data were gathered to present here, but are fully reported elsewhere (20). The buildup of hypochlorite concentration is shown in Fig. 2 and 3. The qualitative explanation of this is well known and lies in terms of the increasing rate of the back-reduction of hypochlorite at the cathode, until a point is reached where the rate of hypochlorite production at the anode is matched by its reduction at the cathode. Increasing brine flow rates aid this reductive destruction by decreasing the thickness of the boundary layer at the cathode, though this effect is least marked at high current densities where the co-evolution of gas bubbles at the cathode surface constitutes an extremely efficient means of enhancing mass transport of OCl^- ions to this surface.

The main purpose of the present work, however, is to show that, using a comparatively simple computer-based model, the results obtained experimentally in this work can be simulated or predicted.

Bennett (1) mentions the development of a computer-based model for prediction of hypochlorite cell performance. However no details are given and the impression is that his model is a largely empirical one. In the model described here, all in-built parameters are derived from the general literature describing the hydrodynamic behavior of electrochemical cells or relating to the chlorine-evolving reaction. The actual model should therefore be applicable to all parallel plate hypochlorite cells, not particularly to our own design.

The model has been built on a limited number of assumptions which suppose that the destruction of any hypochlorite formed, whether at the anode (chlorate formation) or at the cathode (reduction of chloride), is diffusion controlled. Second, these respective oxidation and reduction processes are assumed to take place in preference to the alternative oxidation/reduction processes of oxygen and hydrogen evolution, respectively. Thus the imposition of any current over and above the limiting current for the given hypochlorite destruction process will be taken up by gas evolution. We shall see, however, that this is an interactive situation in that an increase in gas evolution will increase the diffusion-limiting current of the concurrent hypochlorite destruction process, as shown by Janssen and Hoogland (23), Fouad and Sedhamed (24), and others. This situation, in which the mass transport is a function not only of the rate of flow of electrolyte through the cell, but also of the gas evolution current density (which itself is inversely related to the hypochlorite concentration), requires a computational solution, and, with this model, no internally generated data were used whatsoever. The constants used came entirely from the published literature. In the main, these related to values for diffusion layer thickness under various conditions. The treatment of Beck (25), which was independently confirmed by ourselves (26), enabled us to combine the effects of separate mass-transport enhancement effects by treating the mass-transfer coefficients or partial limiting currents additively so that

$$i_{lim(1)} + i_{lim(2)} = i_{lim(total)} \quad [13]$$

where $i_{lim(1)}$ is the diffusion-limiting current due to one hydrodynamic process, *e.g.*, forced convection, and $i_{lim(2)}$ is that due to co-evolution of gas.

The model finally adopted was based on the equation

$$\text{net rate of } OCl^- \text{ formation} = (\text{total } OCl^- \text{ formation rate}) - (OCl^- \text{ destruction rate}) \quad [14]$$

where the destruction processes considered were: (*i*) reduction of OCl^- at the cathode, and (*ii*) oxidation of OCl^- at the anode.

That all the significant processes for the destruction of hypochlorite both anodic and cathodic are essentially diffusion controlled under the present conditions has been evidenced by various workers (8, 9, 35-37). In dilute brines, Ibl and Landolt (6) suggest a mechanism of mass transfer with chemical reaction (Cl_2 hydrolysis) for the anodic oxidation process. However, one may note, as did Hammar and Wranglen (8), that in the anodic film the *p*H is apparently too low for Cl_2 hydrolysis to occur to any appreciable extent. Thus, it may be stated that in hypochlorite production Cl_2 hydrolysis may commence in the diffusion layer and be completed in the bulk electrolyte where alkaline conditions prevail. These same authors (8) showed the anodic and cathodic destruction of hypochlorite to be diffusion-controlled processes under both acidic and alkaline conditions. Unpublished calculations by us, using the constants evaluated by Wranglen (8) even

though these are not strictly applicable from one cell to another, confirm that chlorate formation was diffusion controlled in the present case as it was in his.

It can also be shown that the rate of chlorate formation by the homogeneous reaction is not significant at this temperature.

From Weiss (22), the following equation relating to the homogeneous ClO_3^- formation in alkaline solutions may be derived

$$[ClO_3^-] = t\{2.28 \times 10^{-9} f_1 + 1.39 \times 10^{-19} f_2 [H^+]\}[ClO^-]^2$$

where t is the time (seconds), and f_1 and f_2 are combinations of the activity coefficients of ClO^- ions. Assuming $f_1 = f_2 = 0.7$ for Cl^- ions (33) and also at $pH = 10$, *i.e.*, $[H^+] = 10^{-10}$ mole/liter, we obtain

$$[ClO_3^-] = t\{1.6 \times 10^{-10} + 9.7 \times 10^{-22.5}\}[ClO^-]^2$$

On substituting the observed values of $[ClO^-]$ and t gives

$$[ClO_3^-] = 44 \times 10^{-8} \text{ mole/liter}$$

which is a negligible contribution as compared to the experimentally determined total chlorate concentration (of the order of 10^{-3} mole/liter). Therefore heterogeneous chlorate formation, under the present conditions, is much faster than the homogeneous contribution and is also diffusion controlled, as shown by Hammar and Wranglen (8).

From Eq. [14] and knowing the total volume of electrolyte in the system, the rate of increase in OCl^- as a function of time was derived, and this was the function for which experimental data was matched against the model prediction. We shall discuss separately the terms on the right-hand side of Eq. [14].

For the diffusion-controlled anodic and cathodic destruction reactions, we can apply Ficks equation to obtain the corresponding limiting currents arising from such losses, namely

$$i_{anodic} = \frac{n_a \mathbf{F} D A_a}{\delta_{Ta}} [ClO^-] \quad [15]$$

$$i_{cathodic} = \frac{n_c \mathbf{F} D A_c}{\delta_{Tc}} [ClO^-] \quad [16]$$

Also, since the diffusion coefficients of most substances are of the same order of magnitude, namely, 10^{-5} cm^2/sec, we can, without introducing appreciable errors, assume the same diffusion coefficients D for the Cl^- ion as for ClO^- ions, as data on the former is lacking in the literature. From a plot of diffusion coefficient of Cl^- against brine concentration with data taken from Parsons (27) the following equation relating diffusion coefficient of hypochlorite in a given brine concentration is derived

$$D = (1.95 - 0.177\,[Cl^-]_o) \times 10^{-5} \text{ cm}^2/\text{sec} \quad [17]$$

where $[Cl^-]_o$ is initial brine concentration.

Furthermore, data on the diffusion layer thickness as functions of current density of gas (O_2 or H_2) evolution, for a nonflow system, have been provided by Janssen and Hoogland (23), as well as by Fouad and Sedahmed (24). By replotting data taken from these two sources on a log-log scale, a straight line is obtained from which a relation between the current density of H_2 evolution (i_{H_2}) and the corresponding diffusion layer thickness (δ_{H_2}) can be drawn. A similar relation between i_{O_2} and δ_{O_2} can also be obtained for oxygen evolution. Since the data from these two sources were not in complete agreement, the most consistent values were taken for this work, *i.e.*, data on H_2 evolution from Ref. (23) and data on O_2 evolution from Ref. (24). The general form of the equations obtained is

$$\delta_{gas} = \frac{K}{(i_{gas})^n} \quad [18]$$

where δ_{gas} = the resulting diffusion layer thickness (centimeters), i_{gas} = the current density of the gas evolution process (milliamperes per square centimeter), $K = 38.9 \times 10^{-3}$ for H_2 and 20.6×10^{-3} for O_2, and $n = 1/2$ for H_2 and $1/3$ for O_2.

Finally, for a pumped flow system the average thickness of the diffusion layer, δ_f, for a flat plate inserted into a laminar flow of fluid is given (28, 29) as

$$\delta = 3/2\ (\nu/D)^{-1/3}\ (\nu L/V)^{1/2} \quad [19]$$

where ν is the kinematic viscosity of the electrolyte (square centimeter per second), L is the length of the electrode, V is the electrolyte velocity (centimeters per second), D is the diffusion coefficient of the ion being discharged, ClO^- in this case (square centimeter per second).

By substituting literature values (27, 30) into Eq. [19] it is found that the term involving the Schmidt group, *i.e.*, $(\nu/D)^{-1/3}$ is approximately the same for practical brine concentrations (0.1-5M), with an average value of 0.11. In addition the kinematic viscosities ν are also close to each other, an average value being 0.011 cm^2/sec. With anode and cathode dimensions (L, as used in this work) of 6.6 and 7.6 cm, respectively, Eq. [19] therefore simplifies to

$$\delta_{fa} = 0.0444/\sqrt{V}\ \text{cm} \quad [20]$$

$$\delta_{fc} = 0.0494/\sqrt{V}\ \text{cm} \quad [21]$$

where δ_{fa} and δ_{fc} represent diffusion layer thicknesses at the anode and cathode, respectively, resulting from electrolyte flow.

From Eq. [13], we can write, for the effective diffusion layer thickness (δ_T) resulting from both flow and gas evolution

$$\frac{1}{\delta_T} = \frac{1}{\delta_f} + \frac{1}{\delta_{gas}} \quad [22]$$

The validity of this mode of addition has been confirmed by using data published in (31) and in a later more extensive study (26).

Applying Eq. [22] to the anode, we can write

$$\frac{1}{\delta_{Ta}} = \frac{1}{\delta_{fa}} + \frac{1}{\delta_{O_2}} \quad [23]$$

It will be appreciated that gaseous oxygen may be formed at the anode by one of two possible mechanisms. The first of these is discharge of OH^- to give O_2. The second is co-formation of ClO_3^- and O_2 (the well-known Foerster reaction). It is not possible to distinguish these two unless a simultaneous chlorate analysis is performed. Fortunately (32) this was the case. Knowing that the chlorate determined must inevitably result in an equivalent amount of oxygen, it was possible to compare total oxygen formed with that produced by the Foerster reaction. The two were found to be virtually identical and it followed that oxygen formation from water discharge was negligible. [In support of this the standard reversible potential for the Foerster reaction is lower ($E^\circ = 1.14$V) than that of water discharge ($E^\circ = 1.23$V) as derived from thermodynamic data (8, 33).] With this information, the rate of oxygen evolution could be predicted, as before, by inserting $[ClO^-]$ into Fick's equation to obtain this value, *i.e.*

$$i_{O_2} = \frac{10^3\, n_a' \mathbf{F} D\, [ClO^-]}{\delta_{Ta}} \quad [24]$$

where n_a' is the number of electrons involved in the formation of 1 mole $O_2 = 4$ (Eq. [6]). Substituting Eq. [18] for O_2 evolution, and Eq. [24] in Eq. [23] and rearranging gives

$$[ClO^-] = \frac{2.26 \times 10^{-9} \times \delta_{Ta}}{(1.95 - 0.177\,[Cl^-]_o)} \left(\frac{1}{\delta_{Ta}} - \frac{1}{\delta_{fa}}\right)^3 \quad [25]$$

Equation [25] can be solved for δ_{Ta} for a given hypochlorite concentration, all other values known.

Similarly, we can write, for the cathode

$$\frac{1}{\delta_{Tc}} = \frac{1}{\delta_{fc}} + \frac{1}{\delta_{H_2}} \quad [26]$$

and from the main cathodic reactions (Eq. [9] and [10]) the current available for H_2 formation (i_{H_2}) equals the total cathodic current minus the current for hypochlorite reduction, *i.e.*

$$i_{H_2} = i_{Tc} - i_{red} \quad [27]$$

where i_{Tc} = total cathodic current density (milliamperes per square centimeter) and i_{red} = current density for hypochlorite reduction (milliamperes per square centimeter).

From Fick's law

$$i_{red} = \frac{10^3 \times n_c F D\,[ClO^-]}{\delta_{Tc}} \quad mA/cm^2$$

so that

$$i_{H_2} = i_{Tc} = \frac{10^3\, n_c F D\,[ClO^-]}{\delta_{Tc}} \quad mA/cm^2 \quad [28]$$

Substituting Eq. [18] for H_2 evolution, and Eq. [28] in Eq. [26] and simplifying gives

$$[ClO^-] = \frac{\delta_{Tc}}{10^3 \times 1.93 \times (1.95 - 0.177\,[Cl^-]_o)} i_{Tc} - \frac{38.9 \times 10^{-3}\,\delta_{fc} - 38.9 \times 10^{-3}\,\delta_{Tc}}{\delta_{fc} \times \delta_{Tc}} \quad [29]$$

and Eq. [29] can be solved for δ_{Tc} for a given hypochlorite concentration, all other values known.

Substitution of the δ_{Ta} and δ_{Tc} values, calculated as shown above, in Eq. [15] and [16] will yield the anodic and cathodic current losses. The assumptions so far have been based on an initial Cl^- concentration $[Cl^-]_o$. Under the conditions used here, this initial value will slowly decrease. In the first place, a fraction of the initial Cl^- will be converted to ClO^- ions. However, as we have seen, the concentration of ClO^- ions reaches a limiting value (when the rate of their re-reduction to Cl^- matches their rate of formation from Cl^-). Moreover, under normal brine concentrations, the amount of depletion caused by this does not exceed 10%. There is, however, a second source of Cl^- loss, *i.e.*, the formation of chlorate ions. These are only slowly reduced at the cathode, and, as seen earlier, the result is a continuous buildup of ClO_3 and corresponding loss of Cl^-. The chlorate formation process can be either a homogeneous or an anodic one. However under the conditions of this work, the homogeneous process has been shown to be negligibly slow.

Data by Kuhn and Mortimer (34) relating drop in current efficiency of Cl_2 evolution, E_{Cl_2}, with decrease in brine concentration can be plotted to yield the empirical equation

$$E_{Cl_2} = 100\,([Cl^-])^{0.2}\ \% \text{ for } [Cl^-] < 1 \text{ mole} \quad [30]$$

At brine concentrations of 1 mole and above the data shows E_{Cl_2} to be nearly 100%. Since Cl^- ions are taken up both by ClO^- and ClO_3^- formation, the chloride ion concentration at any time $[Cl^-]$ is given by

$$[Cl^-] = [Cl^-]_o - 10^3 \times [ClO^-] - [ClO_3^-] \quad [31]$$

where $[Cl^-]_o$ is the initial brine concentration (mole/liter), $[ClO_3^-]$ the chlorate concentration (mole/liter), and $10^3 \times [ClO^-]$ the hypochlorite concentration (mole/liter). Substituting Eq. [31] in [30] and expressing in current yields

$$I_{Cl_2} = I_T \times \{([Cl^-]_o - 10^3 \times [ClO^-] - [ClO_3^-])^{0.2}\} \quad [32]$$

and I_T being the total current (amperes).

The instantaneous concentration of chlorate can be found in terms of hypochlorite concentration by considering the heterogeneous chlorate formation reaction and applying both the Faraday and Fick laws. For the present situation this gives $d[ClO_3^-] = 0.346 \frac{[ClO^-]}{\delta_{Ta}} dt$ mole/liter where t is the duration of electrolysis (hours). Integration gives the instantaneous chlorate concentration as

$$[ClO_3^-] = 0.346 \int_o^t \frac{[ClO^-]}{\delta_{Ta}} dt \text{ mole/liter} \quad [33]$$

Equation [14] can now be rewritten in terms of the "net" current for hypochlorite formation as follows

$$I_{net} = I_T \times \{([Cl^-]_o - 10^3 \times [ClO^-] - [ClO_3^-])^{0.2}\} - \frac{n_a F D A\,[ClO^-]}{\delta_{Ta}} - \frac{n_c F D A\,[ClO^-]}{\delta_{Tc}}$$

or, by substituting the various terms in the loss reactions

$$I_{net} = I_T \times \{([Cl^-]_o - 10^3 \times [ClO^-] - [ClO_3^-])^{0.2}\} - \frac{9.65\,(1.95 - 0.177\,[Cl^-]_o)\,[ClO^-]}{\delta_{Ta}} - \frac{25.09\,(1.95 - 0.177\,[Cl^1]_o)\,[ClO^-]}{\delta_{Tc}}$$

Also, an equation relating I_{net}, $[ClO^-]$ and time (from which plots of $[ClO^-]$ *vs.* time can be constructed) may be derived by application of Faraday's law to I_{net} and electrolyte volume of 1290 cm^3. This yields the rate of hypochlorite formation as

$$d[ClO^-] = \frac{I_{net}}{2F \times 1290 \times 3600} \cdot dt \quad [35]$$

where t is in hours. With the value of I_{net} known for a given $[ClO^-]$, Eq. [35] can be integrated, putting the boundary condition that at $t = 0$ $[ClO^-] = 0$, to give

$$t = \frac{6.92 \times 10^4\,[ClO^-]}{I_{net}} \text{ hours} \quad [36]$$

Thus, by specifying the current input I_T, the initial brine concentration $[Cl^-]_o$, the brine velocity V, and the cathodic current density i_{Tc}, the model Eq. [34] and [36] can be solved to generate theoretical values of $[ClO^-]$ as a function of time; the required values of δ_{Ta}, δ_{Tc}, and ClO_3 being given by Eq. [20], [21], [25], [32], and [33].

Computer Program

The flow diagram for the program is shown in Fig. 1. The program computed $[ClO^-]$ values at time intervals of ½ hr up to 30 hr. The value of $[ClO^-]$ was started at zero and incremented until the time calculated from the equations exceeded the chosen value. The incremental steps in $[ClO^-]$ were then reduced by a factor of 10 and the process continued. The step size was reduced by 10^{-7} in all. A new time was then chosen and the new $[ClO^-]$ value found in a similar manner. The initial value of $[ClO^-]$ was reset to zero for each time interval because later in some runs the calculated value rose to a maximum and then fell. To solve [25], δ_{Ta} was started at 10^{-3} as a guess value the first time but in subsequent evaluations the previous root was used as starting value.

The program was written in ANSI Fortran IV and was run on an ICL 1904S computer. The graph plotting package used was GINO-F with a CALCOMP offline plotter. The core used was about 28,000 word and running time 1 min per analysis. Copies of the program may be obtained from the authors.

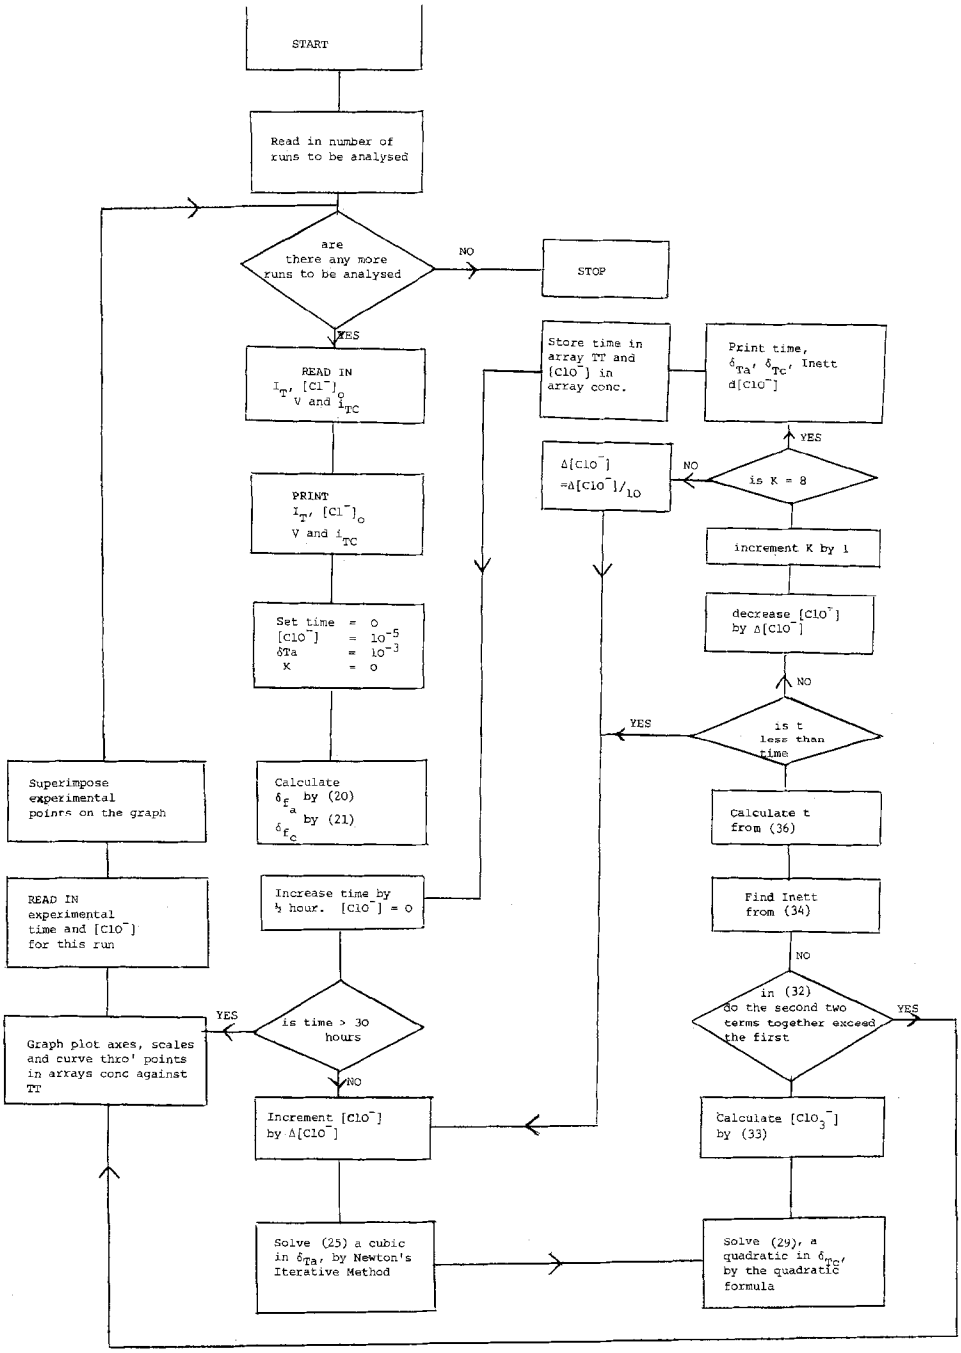

Fig. 1. Flow diagram of the computer program. The numbers in parentheses refer to equations in text.

Figures 2 and 3 show theoretically derived plots (continuous lines) together with the actual data points obtained from this work. It will be seen that good agreement exists between the two sets of data. In most cases agreement is within or better than 10%. The agreement so obtained shows that reaction modeling of this particular process might profitably be employed in the design and specification of this type of electrolyzer. Though the model relates to a parallel plate electrolyzer the same approach might equally well be used for the co-axial cylindrical cells marketed by several major corporations in this field.

We recognize two possible sources of error in our modeling approach. The first of these lies in our implicit assumption that ClO_3^- once formed is not cathodically reduced. Only one paper treating the kinetics of cathodic reduction of ClO_3^- appears to exist (38) and this confirms that, though small, a finite reduction does in fact take place.

The second source of uncertainty relates to the appropriate value of "n" in the anodic oxidation of OCl^- ions to ClO_3^-. We have seen that values from 0.3 to 3 have been suggested (8, 39) and it is clear from the literature that this remains an open question. Unpublished computer plots have shown us that the predicted $[OCl^-]$ values can be made to span the experimental prints by $\pm 10\%$ using limiting values or assumptions in these two respects.

Until these fundamental issues of kinetics and reaction mechanism have been clarified, no model could be expected to show a perfect fit. Nevertheless, the ± 10 concordance which we have shown here not only demonstrates the validity of our model, but also provides, it is felt, a useful prognosticatory tool, for cell designers.

Dynamic Interfacial Electrochemical Phenomena at Living Cell Membranes: Application to the Toad Urinary Bladder Membrane System

Arthur A. Pilla* and Gary S. Margules

Bioelectrochemistry Laboratory, Orthopaedic Research Laboratories, Columbia University, College of Physicians and Surgeons, New York, New York 10032

ABSTRACT

The concept of electrochemical information transfer *in vivo* has been studied using the isolated toad urinary bladder membrane system to evaluate a recently developed approach to membrane impedance which emphasized the coupling of interfacial processes to standard transport phenomena. Laplace plane analysis was utilized to examine frequency response from 1 Hz to 1 MHz. The results indicate that, under the linear conditions of this experiment, Na^+ ion is the predominant current carrier and that the rate-determining step is its penetration into the membrane phase from the aqueous phase. Thus, membrane transport appears to be a very rapid step, whereas the interfacial step of phase transfer regulates transport in this system. The implication of this result in terms of potential dependent interfacial steps in the control of cellular function is discussed.

It is becoming increasingly evident that many cellular functions involve a control or regulatory step occurring at the cell's cytoplasmic membrane (1-7). Often this involves the activation of certain membrane-bound enzymes by the specific interaction of charged species such as ions (8-10) and hormones (11, 12). Because of the type of over-all molecular structure of the protein-containing lipid membrane (13-18), it has been possible to postulate that these regulating interactions occur at interfaces or surfaces and that they are dynamic and potential dependent (19-23). This then constitutes the concept of electrochemical information transfer *in vivo*, in which it is supposed that a highly specific dynamic charge injection can cause a selective modification of, *e.g.*, enzyme and/or transport activity, which in turn may modify cellular and tissue function in a beneficial manner. This approach has guided recent studies in which inductively coupled pulsating currents have caused a selective modification of bone (osteocyte) and cartilage (chondrocyte) activity (24, 25). Thus it appears that either Ca^{2+} activity and/or protein synthesis may be selectively elicited by the proper choice of independently different pulse parameters. These parameters were predicted (22, 25, 26) on the basis of an analysis of the different time constants anticipated in either ion or hormone binding at the cell membrane and the subsequent steps to this trigger. It thus appears possible, for bone and cartilage at least, to selectively modify in a beneficial manner two different cellular functions. This approach has already been extended to the clinic wherein it has been possible to heal otherwise incurable bone fractures with approximately 85% success (25).

In order to establish a working hypothesis for the application of electrochemical information transfer *in vivo*, a detailed analysis of the transient electrical behavior of living cell membranes has recently been carried out (22, 23, 26). This approach focuses on the analogy between the electrode/solution interface and those occurring at the living cell's membranes and the intra- or extra-cellular fluid. Of particular importance

* Electrochemical Society Active Member.

Key words: living membranes, impedance, Laplace plane, adsorption, cellular regulation, epithelial cell, phase transfer.

is the addition of potential dependent specific adsorption (binding) and slow phase transfer (partitioning) as coupled steps in the response of the membrane to dynamic changes in interfacial potential. By allowing these to interact with membrane and aqueous transport along with dielectric and surface charge behavior, it has been possible to present a unified approach to membrane impedance (22, 26, 28). The significance of this approach lies in its capability to treat the highly heterogeneous and dynamic behavior of living membranes in a relatively rigorous manner so that theoretical models may be established and experimental tests may be carried out.

The present study involves such a test on the isolated toad urinary bladder membrane system. This system is uniquely suited to a living cell membrane impedance study since, as a membrane system, it consists of a supported single layer of epithelial (skin) cells in tight junction contact (29-31). These mucosal cells (so called because they border the inside surface of the bladder) are approximately 10μ thick and exhibit asymmetrical membranes with respect to both structure and function. Under physiological conditions these cells transport urea, water, and Na^+ (both actively and passively). Tight junctions between the mucosal cells severely limit under normal conditions, transepithelial transport and allow the membrane system to exhibit selective transport properties. The mucosal cells are supported on a loose sheet (electrically resistive only) of connective tissue (collagen) which is widely interspersed with blood vessels and smooth muscle fibers. There is also a discontinuous layer of cells bounding the serosal or external surface of the bladder. These would also not be expected to contribute to the over-all membrane response of this system. It was, therefore, expected that, under the transient electrical conditions of the present study, the bladder system would exhibit a relatively simple response related to passive Na^+ transport. This study will present the application of Laplace plane modeling and analysis to this living membrane system.

Theoretical

In order to construct an impedance model for the toad urinary bladder membrane system, it is necessary to briefly review the application of Laplace plane analysis to a generalized membrane. At the onset it must be pointed out that Laplace plane analysis, in the manner applied here, assumes linear conditions, *i.e.*, the impedance of the system may be defined. Linearity conditions can be established for this complex system, since the modeling may be performed using a piecewise linear approximation, *i.e.*, for any given steady-state behavior the superimposed time varying perturbation may be low enough so that changes from rest or steady state are linear (32). In addition, the very nature of Laplace plane analysis allows the transient impedance of the system to be evaluated (33). In this manner impedance can be obtained using a minimal number of perturbations (usually less than five) with presently available instrumentation, thereby "freezing" the behavior of the system in time.

To establish the impedance of a membrane it is considered that, in addition to the well-known dielectric properties of the lipid-protein system (34), the passage of transient current will satisfy specific adsorption and phase transfer properties which may be coupled to aqueous and membrane transport. This is illustrated in Fig. 1 where it can be seen that in addition to both intra- and extra-cellular diffusion (assumed planar) surface double-layer charging, specific adsorption, and phase transfer (partitioning) can take place. All of these processes can be coupled and are assumed in the first instance to take place at every interface (inner and outer) of each membrane.

Laplace plane analysis is performed in the complex frequency domain defined by the Laplace variable, s, a complex number with the dimensions of frequency and having a real, σ, and imaginary, $j\omega$, part such that $s = \sigma + j\omega$. This variable is utilized in the Laplace transformation wherein the transformed function $F(s)$ is obtained by operating on a time domain function $f(t)$ according to

$$F(s) = \int_0^\infty f(t)\exp(-st)\,dt \qquad [1]$$

All functions in this study will be described in the s plane. The basics of obtaining impedance models in this fashion has been extensively described elsewhere (33, 35).

When a transient current passes across a membrane, a portion of it will satisfy all of the interfacial charging (both specific and nonspecific) and dielectric requirements. This is termed the charging current, $i_c(s)$. Another portion of the total current, $i(s)$, will satisfy all phase transfer phenomena, *i.e.*, that portion of the current carried across the membrane. This is termed the phase transfer current $i_p(s)$. The total current is, therefore, given by

$$i(s) = i_c(s) + i_p(s) \qquad [2]$$

To describe $i_c(s)$ it is convenient to express it in terms of the change in charge, $q(s)$, which may occur as a result of a change in interfacial potential $\eta(s)$ as

$$i_c(s) = sq(s) = q_E s\,\eta(s) + q^e s c^e \Delta c^e(o,s) \qquad [3]$$

where $q_E = (\partial q/\partial E)_{c^e}$ and $q^e = (\partial q/\partial c^e)_E$ representing the variation of q with potential, E and with the concentration of a species c^e which specifically adsorbs at interface e (membrane/extracellular fluid). Note that more than one species may adsorb at this interface, and that specific adsorption may also occur at interface i (membrane/intracellular fluid). However, for

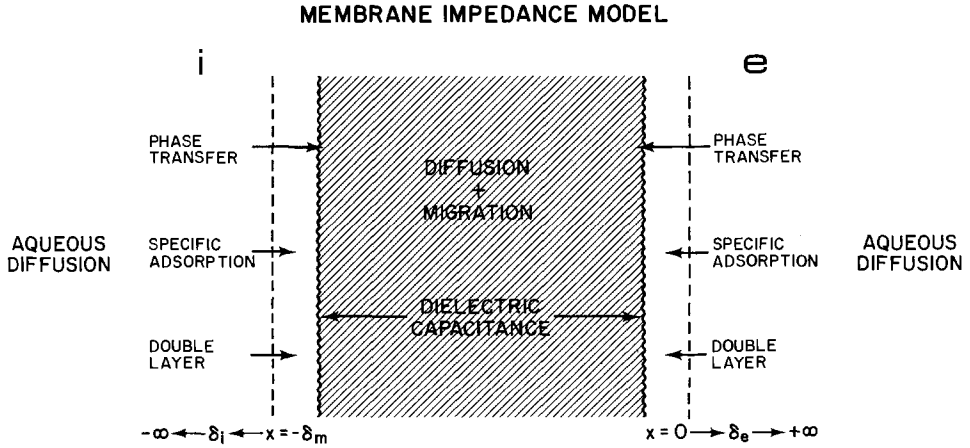

Fig. 1. Schematic diagram depicting the essential elements of the interfacial membrane impedance model described in this study. In addition to aqueous and membrane mass transport finite kinetics are allowed for specific adsorption (binding) and phase transfer (partitioning). All processes are coupled and may involve both the extracellular, *e*, and intracellular *i*, interfaces.

the sake of clarity only a single species at e will be considered. Extension to more complex systems has been described elsewhere (26, 28). Both q_E and q^e are constant coefficients representing the linear conditions of the model; they may change for different resting or steady-state conditions. In Eq. [3] $\Delta c^e(o,s)$ represents the change in concentration with time (frequency) of species c^e at the interfacial region ($x = 0$) as a result of specific adsorption. In other words this quantity represents the change in concentration c^e in the plane $x = 0$ while in the preadsorbed state (*i.e.*, before specific binding has taken place). $\Delta c^e(o,s)$ is defined by $\Delta c^e(o,s) = (c^e(o,s) - c^e)/c^e$, which makes it a relative change (to avoid carrying initial conditions throughout the derivation of the model), and is the reason why c^e appears in the second term on the right-hand side of Eq. [3].

Since specific adsorption has been invoked, it is necessary to establish a relation between the concentration of the specifically adsorbed species Γ_e and $\Delta c^e(o,s)$. This is readily done by assuming first order kinetics (35, 36) which gives

$$\Delta\Gamma_e(s) = v_e/\Gamma_e s[\Delta c^e(o,s) - \Delta\Gamma_e(s) + a\eta(s)] \quad [4]$$

where $\Delta\Gamma_e(s)$ is given by $\Delta\Gamma_e(s) = (\Gamma_e(s) - \Gamma_e)/\Gamma_e$, representing a change with respect to the initial concentration of adsorbed species, Γ_e; v_e is an exchange adsorption rate constant and, a, represents the potential dependence of adsorption (a constant coefficient) and that portion of the total potential change, $\eta(s)$, which acts at interface e. There is a similar relationship for each adsorbing species at each interface. Note that Eq. [4] allows adsorption kinetics to be finite thereby making the model somewhat more general than has previously been the case (37).

It is now necessary to obtain an expression for the phase transfer current, $i_p(s)$. Since $i_p(s)$ represents all of the total current which actually traverses the membrane, in addition to the expected concentration dependence, finite kinetics are also allowed for partitioning (*i.e.*, penetration of the transporting species from the aqueous phase into the membrane phase). Since this is expected to be potential dependent $i_p(s)$ can be written as

$$i_p(s) = I_E\eta(s) + I^{ce}\Delta c^e(o,s) + I^{cm}\Delta c^m(o,s) \quad [5]$$

in which $I_E = (\partial i_p/\partial E)_{c^e,c^m}$; $I^e = (\partial i_p/\partial c^e)_{E,c^m}$, and $I^m = (\partial i_p/\partial c^m)_{E,c^e}$ representing the variation of i_p with potential and with the aqueous and membrane concentrations of the transporting species, respectively. Again in this linear model these are constant coefficients. The relative concentration change $\Delta c^e(o,s)$ is as for Eq. [4], while $\Delta c^m(o,s)$ represents the relative concentration change of the same species in the membrane phase at the plane $x = 0$ (*i.e.*, after partitioning just inside the membrane). The first term on the right-hand side of [5] represents the finite phase transfer kinetics allowed in this model. The physical significance of this term may be related to the influence of surface charge upon transport (38-41) particularly in the context of specifically adsorbed charge.

Equations [3] and [5] may be employed to provide an expression for the total impedance of the model proposed. For this it is necessary to obtain explicit expressions for $\Delta c^e(o,s)$ and $\Delta c^m(o,s)$ taking into account finite specific adsorption kinetics as given by Eq. [4]. Mass transport in the aqueous phase can be represented by Fick's second law, since the supporting electrolyte in physiological solution is approximately 0.2M. The important quantity is the flux at the plane $x = 0$ which is given by, for finite planar diffusion

$$\left(\frac{d\Delta c^e}{dx}\right)_{x=0} = -\left[\left(\frac{s}{D_e}\right)^{1/2} \coth\left(\frac{s}{D_e}\right)^{1/2}\delta_e\right]\Delta c^e(o,s) \quad [6]$$

Where D_e is the aqueous diffusion coefficient and δ_e is the thickness of the diffusion layer in the extracellular fluid. This quantity reduces to the familiar square root of frequency (Warburg) behavior under semi-infinite conditions.

Membrane mass transport occurs under both concentration and electric field gradients thereby necessitating use of the Nernst-Planck equation which is written here for planar conditions as

$$\Delta c^m(x,s) = \frac{D_m}{s}\left[\frac{d^2\Delta c^m}{dx^2} + \frac{\mathbf{F}}{RT}\frac{d}{dx}\left(\Delta c^m\frac{dV}{dx}\right)\right] \quad [7]$$

where D_m is the diffusion coefficient in the membrane phase (not necessarily equal to D_e), dV/dx is the voltage field across the membrane and the other quantities have their usual significance. For most membranes the concentration of the transporting species within the membrane is relatively low (37). In addition, the linear conditions of this model (which are experimentally obtainable) suppose that the change in voltage field is constant through the membrane. For these two reasons, it appears possible to assume constant field conditions, so that $dV/dx = \text{const} = \bar{V}$. Under these conditions Eq. [7] can be solved analytically. Once again the flux at $x = 0$ is the desired quantity. This is given by, for a membrane of biological thickness

$$\left(\frac{d\Delta c^m}{dx} + \frac{\mathbf{F}\bar{V}}{RT}\Delta c^m\right)_{x=0} = \left[\frac{\mathbf{F}\bar{V}}{2RT} + \frac{1}{\delta_m} + \frac{1}{3}\left(\frac{\mathbf{F}^2\bar{V}^2}{4R^2T^2} + \frac{s}{D_m}\right)\delta_m\right]\Delta c^m(o,s) \quad [8]$$

where δ_m is the membrane thickness (usually 70-100Å), and the other terms have been defined previously.

The remaining requirement to solve for $\Delta c^e(o,s)$ and $\Delta c^m(o,s)$ in Eq. [3] and [5] is to provide a mass balance condition which will account for both aqueous and membrane mass transport in the presence of specific adsorption. This can be written as

$$D_e c^e\left(\frac{d\Delta c^e}{dx}\right)_{x=0} - \Gamma_e s\Delta\Gamma_e(s) = D_m c^m\left(\frac{d\Delta c^m}{dx} + \frac{\mathbf{F}\bar{V}}{RT}\Delta c^m\right)_{x=0} \quad [9]$$

which states that the actual flux through the membrane (right-hand side, Eq. [9]) is equal to the flux of the same species in the aqueous phase (first term, left-hand side, Eq. [9]) minus the amount specifically adsorbed. Physically this can be pictured by saying that only that quantity of transporting species actually gets through the membrane which does not accumulate at the plane $x = 0$ (the interface) via the process of specific adsorption.

All of the above relationships are sufficient to generate an expression for the impedance of a single membrane where partitioning and specific adsorption occur at one interface. The result is for the charging impedance $Z_c(s)$

$$Z_c(s) = 1/q_E s \quad [10]$$

when $\partial\Gamma_e/\partial E$ is negligible, a condition often applicable when the species undergoing phase transfer is itself specifically adsorbed. The phase transfer impedance $Z_p(s)$ is given by

$$Z_p(s) = \frac{1}{I_E}\left[1 + \frac{I^e}{n\mathbf{F}c^e(D_e s)^{1/2} + s\Gamma_e/(1 + s\Gamma/v_e)} + \frac{I^m}{n\mathbf{F}c^m D_m\left[\frac{\mathbf{F}\bar{V}}{2RT} + \frac{1}{\delta_m} + \frac{1}{3}\left(\frac{\mathbf{F}^2\bar{V}^2}{4R^2T^2} + \frac{s}{D_m}\right)\delta_m\right]}\right] \quad [11]$$

Both $Z_c(s)$ and $Z_p(s)$ are in parallel as is evident from Eq. [2]. As shown elsewhere (26, 28) $Z_c(s)$ would contain additional terms related to the specific adsorption process, particularly when several species contribute to the current response. For the purposes of this application $Z_c(s)$ is represented by a pure capacitor which is primarily due to the dielectric and double layer response of the membranes in the toad bladder system. On the other hand $Z_p(s)$ contains a phase transfer impedance ($1/I_E$) coupled with semi-infinite aqueous mass transport and specific adsorption (second term in brackets on right-hand side of Eq. [11]) in series with membrane transport which has a more physically meaningful form than reported elsewhere (37).

Inspection of Eq. [10] and [11] shows that it is possible to represent the impedance for this particular model by the aperiodic equivalent electric circuit shown in Fig. 2. The placement of elements in this circuit is directly related to the actual physical pathway (mechanism) which is proposed. No assumption other than the basic model is employed to establish this topology and the frequency behavior described by Eq. [10] and [11] and Fig. 2 can be used to diagnose mechanism and kinetics. Note that this modeling procedure would result in several variants of Fig. 2 if both sides of the membrane and more than one species is involved (22, 26, 28), thereby permitting extensive diagnosis to distinguish among several different proposed pathways.

It is useful to attach physical significance to each of the elements shown in Fig. 2 for the eventual evaluation of kinetic parameters. Referring to Eq. [10] it can be seen that

$$C_d = \partial q/\partial E = q_E \qquad [12]$$

as expected for the charging current pathway. Note that C_d contains (in a series arrangement) contributions from the electrical double layers present at the inner and outer membrane interfaces, as well as that due to the dielectric property of the membrane structure. Although it is in principle possible to isolate the dielectric from double-layer contributions using very high frequency measurements coupled with ion dependences (28, 42), it was not within the scope of the present study to pursue this. Examination of Eq. [11] allows the phase transfer impedance R_p to be defined as

$$R_p = 1/(\partial i_p/\partial E) = 1/I_E \qquad [13]$$

showing that phase transfer kinetics would be expected to exhibit purely resistive behavior corresponding remarkably to the form of the activation process involved in electron transfer at the electrode/solution interface (35). It might, therefore, be expected that ion penetration (partitioning) would involve simple rearrangement of the entry site by, *e.g.*, lipid polar head deformation or displacement (43). The specific

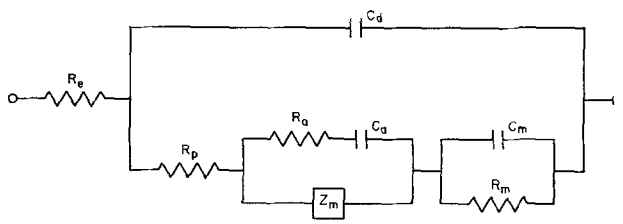

Fig. 2. Aperiodic equivalent electric circuit presented as a shorthand (but exact) notation of the Laplace plane behavior of a membrane (artificial or biological) at which a single species is involved in phase transfer. Note the topology of this circuit corresponds to the physical processes considered in the model and can be examined using the wide frequency range achievable via real axis Laplace transformation. The physical significance of each element is described in the text.

adsorption parameters R_a and C_a are given by

$$R_a = \frac{(\partial i_p/\partial c^e)}{(\partial i_p/\partial E)}\frac{1}{v_e} \qquad [14]$$

and

$$C_a = \frac{(\partial i_p/\partial E)}{(\partial i_p/\partial c^e)}\Gamma_e \qquad [15]$$

where it can be seen that R_a is inversely proportional to the exchange adsorption rate constant v_e and C_a is proportional to the initial concentration of adsorbed species Γ_e as expected. The aqueous transport impedance Z_D is in parallel with the adsorption pathway as required by the mass balance condition given in Eq. [9]. In this application to the isolated toad urinary bladder semi-infinite planar diffusion conditions can be assumed as indicated in Eq. [11]. In this case the movement of a concentration wave to or from the interface is exactly analogous to the propagation of a voltage signal along a semi-infinite R_DC_D transmission line (32). Z_D is therefore given by

$$Z_D(s) = \frac{(\partial i_p/\partial c^e)}{(\partial i_p/\partial E)}\frac{1}{n\mathbf{F}c^e(D_e s)^{1/2}} \qquad [16]$$

for which the R_DC_D array has the following physical significance

$$R_D = \frac{(\partial i_p/\partial c^e)}{(\partial i_p/\partial E)}\frac{1}{n\mathbf{F}c^e D_e} \qquad [17]$$

and

$$C_D = \frac{(\partial i_p/\partial E)}{(\partial i_p/\partial c^e)} n\mathbf{F}c^e \qquad [18]$$

in which R_D is inversely proportional to the diffusion coefficient, D^e, and C_D is directly proportional to the bulk concentration, c^e, of the diffusing species. Membrane mass transport is represented by the parallel combination of R_m and C_m in Fig. 2. Referring again to Eq. [11], these are given by

$$C_m = \frac{(\partial i_p/\partial c^m)}{(\partial i_p/\partial E)}\frac{n\mathbf{F}c^m\delta_m}{3} \qquad [19]$$

and

$$\frac{1}{R_m} = \frac{(\partial i_p/\partial c^m)}{(\partial i_p/\partial E)}\frac{n^2\mathbf{F}^2 D_m c^e \delta_m}{6RT}\left[3\bar{V} + \frac{6RT}{n\mathbf{F}\delta_m} + \frac{n\mathbf{F}\bar{V}^2}{2RT}\right] \qquad [20]$$

where it can be seen that C_m is proportional to the resting membrane concentration, and R_m is inversely proportional to the diffusion coefficient, D_m, and the voltage field to which the transporting species is subjected. Note that if $\bar{V} = 0$, Eq. [20] reduces to that which would be obtained in the absence of a significant electric field (32).

The above procedure illustrates the manner by which the potential dependent interfacial processes of specific adsorption and phase transfer can be coupled with both aqueous and membrane mass transport in a relatively quantitative manner. For the purposes of illustration a single interface has been modeled. However, it is to be realized that all of the interfaces and membranes in a living system may be treated in an analogous manner, generating equivalent electric circuits similar to that shown in Fig. 2 and added to it, in most cases in series.

In addition, for the interface treated only a single species has been considered. It is straightforward to consider the case of two or more species which may adsorb and/or transport across the same interface even if they act in a coupled manner. It is thus possible in principle to generate models using the above approach which can be employed to distinguish among the physi-

ologically meaningful pathways which can be proposed for a given system.

As mentioned above, the mucosal surface of the isolated toad urinary bladder is known physiologically to selectively transport Na^+ in a passive manner (44-46). In addition, steady-state measurements using microelectrodes have established that the mucosal (inside) membrane exhibits significantly higher resistance to ion transport than the serosal (outside) membrane (47). There is also some indication that the tight junction (cell to cell) contact exhibits a much higher resistance than the same serosal membrane (47). It can, therefore, be expected that current flow through this membrane system will essentially be straight through the mucosal cell (and not be deviated significantly in a parallel pathway across the cell layer). The isolated toad bladder can thus be expected to correspond relatively closely to those portions of the single interface model required for potential dependent Na^+ ion transport.

Experimental

In this study the urinary bladder of the toad (*Bufo marinus*) is subjected to low level current pulses and the voltage response is observed. To perform this type of measurement the bladder must first be isolated from the toad. This is performed using a rapid surgical procedure on a pithed (brain-dead) toad to minimize cellular damage (usually from drying, trauma, and autolysis). First the toad's abdominal cavity is opened in the usual manner exposing the viscera. At this point the bladder is exposed and when full (mostly water since the toad uses this organ for water balance) is seen to be a bilobed structure occupying almost the whole abdominal cavity. At this point the bladder can commence drying if precaution is not taken to maintain the exposed areas moist with amphibian Ringer's solution (an isotonic salt solution described below). The bladder is excised by first severing the dorsal facial layers of each lobe. These are then clamped close to the urinary sphincter region from which the bladder is severed and withdrawn usually while full. If the bladder is completely full, it is in a highly stretched condition and is transparent except in the area of an occasional blood vessel. It is in this stretched condition that the impedance measurements are made. To maintain this situation, the excised full bladder is placed in a petri dish containing aerated Ringer's solution and a cork template. The latter is utilized to hold the bladder in a stretched condition for mounting in a conductivity type chamber. This is achieved by pinning the bladder along one edge of the cork and opening a lobe along the center while pinning the remaining portions of bladder along the other three edges of the cork template. This is the most sensitive part of the isolation procedure since the mucosal cells are now directly exposed. These are fragile and care must be taken not to touch, in any way, that portion of the mucosal surface which will serve as the membrane system when mounted in the measurement chamber. Mounting on the cork template is carried out so as to provide a uniform stretch (monitored by observing for uniform transparency). The bladder is now relatively free of folds and will usually present a single supported mucosal cell layer for study. Great care is exercised during bladder mounting since nonuniform stretch and/or folded cell layers will affect transport properties (48, 49).

Once mounted, the wet bladder is rapidly transferred to the measurement vessel which is essentially a conductivity cell having two identical chambers separated by the bladder. In position between the two chambers, the bladder is then held in place by the pressure applied when the chambers are forced together. The bladder occupies a circular area of approximately 1 cm^2 bounded by O-rings on the face of either chamber. The pressure exerted by the O-rings prevents lateral leakage and minimizes edge damage (50, 51) particularly with the relatively large surface area of exposed bladder. The chambers are then filled simultaneously with Ringer's solution to avoid uneven hydrostatic pressure particularly from the serosal side which can cause morphologic changes such as intercellular space variation thereby modifying transport properties (31, 51).

The conductivity cell (see Fig. 3) consists of two identical chambers each provided with solution and gas inlets and outlets. In addition provision is made for current input and voltage measurement electrodes. These are sintered tantalum slugs providing high surface area for minimal faradaic effects under the experimental conditions employed. An important monitor of membrane integrity is the existence of a transepithelial resting potential due primarily to the active transport systems functioning to maintain intracellular ionic concentration levels. Generally this potential difference is between 10 and 100 mV, mucosal side negative. Provision is, therefore, made in each chamber to introduce a SCE reference electrode (Tacussel Type C-10) to assess membrane integrity, viability, and monitor possible base line changes during the experiment.

The physiological solution utilized to bathe the mucosal and serosal sides of the bladder in the measurement cell is isotonic for the amphibian. It is composed of (in mM/liter): NaCl 109; $CaCl_2$, 0.9; $NaHCO_3$, 2.4; KCl, 2.5; and $C_6H_{12}O_6$, 5.5. The bladder is allowed to stabilize in this solution (while aerated) until the resting potential is invariant (usually after 0.5-1 hr). Current pulses are then applied so that the transepithelial potential change (not including IR_e drop) is restricted to 1 mV or less. In this manner linear conditions are achieved and the active transport systems do not deviate significantly from base line since the net change in intracellular ionic concentration is negligible (<10 $\mu C/cm^2$ of total charge injection is utilized).

The circuit employed for these measurements is shown in block diagram form in Fig. 3. A current pulse (usually <1 $\mu A/cm^2$) is applied across the membrane system by driving the noninverting (+) input of a tunable fast potentiostat, A1, (Tacussel PIT-20-2X) with a pulse generator, SG, (Tektronix PG 405) equipped with an offset voltage source for base line current variations. Resistor, R_C (usually 100-300 kΩ) is

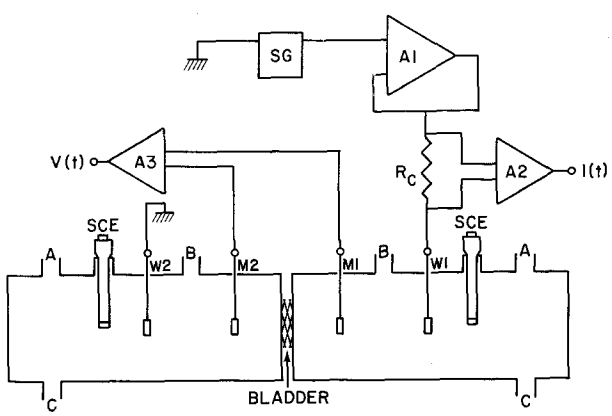

Fig. 3. Block diagram of the circuitry and measurement chamber employed for the transient impedance determination of the isolated toad urinary bladder membrane. The conductivity type chamber is shown in some detail and depicts perturbing (W1 and W2) and measurement (M1 and M2) electrodes along with the saturated calomel electrodes (SCE) employed for resting potential measurements. A, B, and C are solution/gas inlet, gas outlet, and solution outlet, respectively. A1 is the tunable amplifier utilized for current injection via signal generator, SG. R_C current limits and allows input current measurement via amplifier A2. Voltage response is obtained via amplifier A3.

current limiting and allows the input current pulse, $I(t)$, to be measured via amplifier, A2. The voltage response, $V(t)$, is measured using electrodes M1 and M2 into amplifier, A3. Both A2 and A3 are the vertical amplifiers (Tektronix 5A22N) of a dual beam oscilloscope (Tektronix 5103N) which is used to display $V(t)$ and $I(t)$ simultaneously. Records of these time domain signals are obtained photographically so that data points required for analysis via digital Laplace transformation (33, 52) are available. Presently the system is being equipped with a transient recorder to increase accuracy and manipulation speed (necessary for living system studies). The total relaxation time of the toad bladder membrane system has a duration of approximately 10-50 msec (with an apparent area of 1 cm^2). In order to obtain data points with sufficient time resolution (from <100 μsec to 50 msec) a series of four to five records in overlapping time ranges are usually obtained.

The experiments reported here have been carried out in isotonic amphibian Ringer's solution. However, it is to be noted that modifications in ionic concentration in either or both mucosal and serosal compartments which will not destroy the viability of the membrane system are in progress. These studies are designed to evaluate the effect of (particularly) Na^+ on the impedance parameters related to transport. In addition it is well known physiologically that antidiuretic hormones such as arginine-vasopressin or oxytocin have a profound influence upon Na^+ (53-55) (as well as urea and water) transport via membrane surface interactions (49, 56, 57). Experiments using the above conditions will be reported elsewhere.

Results and Discussion

In order to obtain the toad bladder membrane system impedance from the experimentally obtained time domain input and response curves the data was first transformed into the Laplace frequency domain. As in previous applications of this technique (58) real axis ($s = \sigma$) transformation was employed. The basics of this approach have been extensively described elsewhere (33, 52). Essentially, digital Laplace real axis transformation is carried out using an algorithm which assumes exponential behavior between successive data points in time. The highest obtainable frequency is limited only by the time at which experimental data is first available. The requirement therefore, is not that the input pulse, here $I(t)$, reach its constant value before data are useful, but that the detection instrumentation be capable of recording the initial rise from zero amplitude. The current pulse risetime in these experiments was approximately 1 μsec allowing the first data point at 100 nsec to be obtained relatively easily. Using the above approach the real axis impedance, $Z(\sigma)$, was evaluated over the frequency range 1 Hz to 1 MHz.

Once $Z(\sigma)$, which is a real function, was available, the next step was to apply diagnostic criteria to ascertain the applicability of the model proposed earlier. This was performed by first examining high and low limiting frequency regions. Referring to Eq. [10] and [11] and Fig. 2 it can be seen that, at high frequencies, the following functional relationship would be expected to hold

$$\underset{\sigma\to\infty}{Z(\sigma)} = R_e + \frac{1}{C_d\sigma} \qquad [21]$$

where R_e is now the electrolyte resistance between the measuring electrodes (M1 and M2, Fig. 3) and the bladder membrane, and C_d is defined in Eq. [12]. Inspection of Eq. [21] shows that at the highest accessible frequencies, a plot of $Z(\sigma)$ *vs.* $1/\sigma$ should be a straight line from which R_e and the dielectric (and double layer) membrane capacitance may be obtained. A typical plot of this type is shown in Fig. 4. It can be seen that indeed the membrane system responds as expected in this frequency range. C_d obtained in this

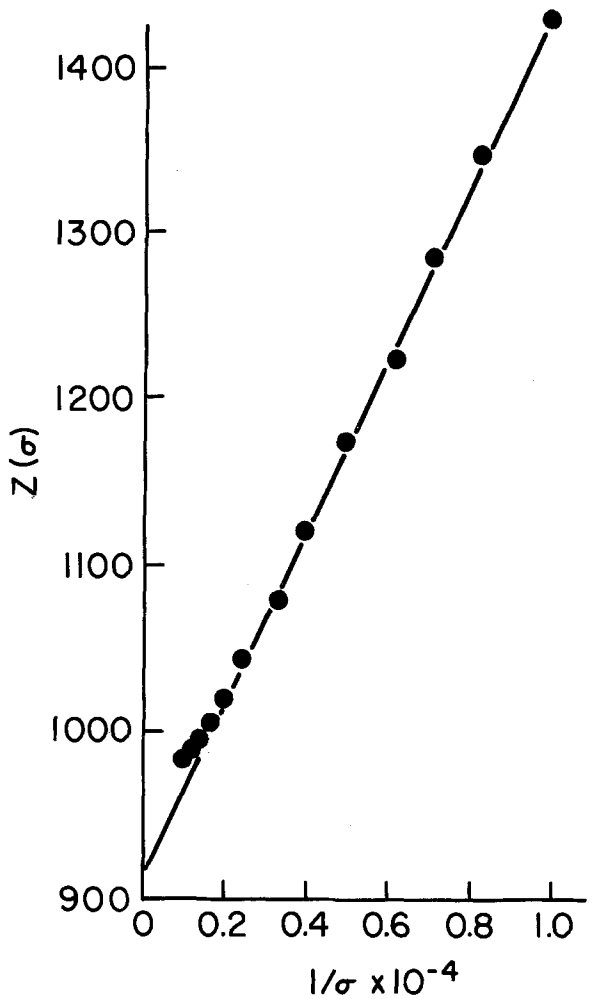

Fig. 4. High frequency diagnostic plot of the real axis impedance $Z(\sigma)$ *vs.* $1/\sigma$ allowing the determination of R_e and dielectric (and double layer) toad urinary bladder membrane capacitance, C_d. See text for details.

manner is approximately 1.7 ± 0.5 μF/cm^2. Note that the dielectric capacitance of the serosal (inner) membrane is in series with that of the mucosal membrane. An attempt to separate its contribution to the observed C_d was not the object of this preliminary study.

Referring again to Eq. [10] and [11] and Fig. 2, it can be seen that in the low frequency limit (prior to steady state conditions) $Z(\sigma)$ would be expected to exhibit the following behavior

$$Z(\sigma) = R_e + R_p + \left(\frac{R_D}{C_D\sigma}\right)^{1/2} \qquad [22]$$

where R_p is defined in Eq. [13], and R_D and C_D in Eq. [17] and [18], respectively. This relationship shows that in the lowest frequency ranges, compatible with that at which steady-state behavior occurs, a plot of $Z(\sigma)$ *vs.* $\sqrt{1/\sigma}$ should be a straight line. Plots of this type over the expected frequency range failed to reveal the anticipated functional behavior. This led to the preliminary conclusion that, under the linear conditions of this experiment, the response could indeed involve the Na^+ ion since its extracellular concentration (≃0.15M) is too high for significant aqueous diffusion polarization to exist.

Because of the above results and the fact that the bladder membrane exhibits steady-state current behavior it now had to be established whether the transporting species (Na^+) exhibits phase transfer polarization (slow partitioning kinetics) and whether it or another (high aqueous concentration) species exhibits

specific adsorption. Knowledge concerning these two possibilities would reveal whether (Na^+) partitioning depends upon its (or other species) specific interaction with the membrane penetration site, or whether this site undergoes structural (conformational ?) changes or rearrangements as a function of potential to allow (Na^+) entry and/or exit. It has, for example, been proposed (59) that Ca^{2+} adsorption (or binding) at the extracellular entry to the Na^+ pore regulates Na^+ permeability in epithelial cell systems. However, if this were the case, then the response of this membrane system to a linear perturbation should contain a potential dependent adsorption or binding contribution involving Ca^{2+}. This does not appear to be the case for the present study since Ca^{2+} adsorption kinetics would also lead to a limiting low frequency linear function of $Z(\sigma)$ *vs.* $1/\sqrt{\sigma}$ because of its low ($\simeq$ 1.5 mM) aqueous concentration.

It is now necessary to consider whether or not specific adsorption not coupled to aqueous diffusion is one of the kinetic steps in the transient response of the bladder membrane. Examination of the mass balance condition given in Eq. [9] shows that, if specific adsorption of the transporting species (Na^+) is present, then relaxation to steady state would necessitate a new equilibrium surface concentration, Γ'_e. At this point no further steady-state current could pass because this would involve the injection of much more charge than could be compensated by the adjustment in interfacial concentration of the transporting species. Since this is obviously not the case experimentally, it is necessary to invoke the specific adsorption of a species other than that which undergoes phase transfer. This is done by considering that specific adsorption, if present, in this case, contributes to the charging current, $i_c(s)$, only. Thus $i_c(s)$ is now given by

$$i_c(s) = sq(s) = q_E s\eta(s) + q'_e s c'_e \Delta c'_e(o,s) \quad [23]$$

where c'_e is the bulk concentration of the adsorbing species. The relative change in aqueous concentration of the adsorbing species at the plane $x = 0$, $\Delta c'_e(o,s)$, is related to its adsorbed surface concentration change by an equation similar to Eq. [4]. In addition mass balance is given by

$$\Gamma'_e s \Delta\Gamma'_e(s) = D'_e c'_e \left(\frac{d\Delta c'_e}{dx}\right)_{x=0} \quad [24]$$

which states that the flux in aqueous phase (right-hand side Eq. [24]) of the adsorbed species is equal to its change in surface concentration. Using all of the above, the charging admittance $Y_c(s) = 1/Z_c(s)$ is now written as

$$Y_c(s) = q_E s + \frac{q'_e s\Gamma'_e}{1 + (s\Gamma'/v'_e)} \quad [25]$$

where the second term on the right-hand side represents the contribution of finite adsorption (binding) kinetics to the over-all charge requirements of the interface.

In contrast to the charging impedance which has increased in complexity (compare with Eq. [10] because of a possible specific adsorption process, the phase transfer impedance $Z_p(s)$ becomes less complex because Na^+ does not appear to be involved in this process. Thus in the absence of specific adsorption and aqueous diffusion the phase transfer impedance becomes

$$Z_p(s) = \frac{1}{I_E}\left(1 + \frac{I^m}{n\mathbf{F}c^m D_m\left[\frac{\mathbf{F}V}{2RT} + \frac{1}{\delta_m} + \frac{1}{3}\left(\frac{\mathbf{F}^2\bar{V}}{4R^2T^2} + \frac{s}{D_m}\right)\delta_m\right]}\right) \quad [26]$$

in which all of the terms have been previously defined.

Inspection of Eq. [25] and [26] shows that, if the toad bladder membrane system responds in the manner just proposed to linear perturbation, then its aperiodic

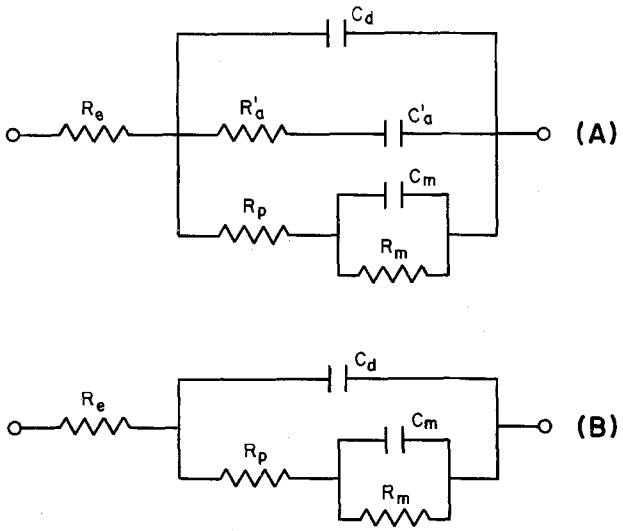

Fig. 5. Aperiodic equivalent electric circuits employed to analyze for the specific phase transfer behavior of the toad urinary bladder membrane system. The top circuit (A) shows a specific adsorption pathway coupled with phase transfer while the bottom circuit (B) shows only the phase transfer process. Finite adsorption was undetected in this study, and the frequency spectrum of $Z(\sigma)$ corresponds therefore, to (B) wherein R_p (partitioning) appears to be the rate-determining step.

equivalent electric circuit would be that given in Fig. 5a. Here all of the parameters have physical significance as defined previously. This model states that a specific adsorption (binding) process not involving phase transfer can occur (R'_a, C'_a) and that a certain quantity of charge can flow to readjust the surface concentration of the adsorbing species to its new resting value. This process does not involve the species undergoing phase transfer, but may, of course have an effect on its kinetics. The species contributing ultimately to the steady-state current through the membrane now follows the R_p, C_m, R_m (Fig. 5a) pathway in its relaxation to steady state. If specific adsorption is absent from the transient response of the bladder membrane to linear perturbation, it can readily be seen that its behavior would be that represented in Fig. 5b. Here the charging impedance is given by Eq. [10] and the phase transfer impedance by Eq. [26].

Analysis for either of the above types of behavior is carried out in a straightforward manner using real axis Laplace plane methods. First, advantage is taken of the fact that both R_e and C_d have been isolated in the high frequency range (Fig. 4). Next, if the adsorption time constant ($R'_aC'_a$) is sufficiently different from that of phase transfer (R_e, R_m, C_m) then R'_a and C'_a, can be isolated from the following

$$\frac{1}{1/(Z(\sigma) - R_e) - C_d\sigma} = R'_a + \frac{1}{C'_a\sigma} \quad [27]$$

which states that a plot of the experimentally known quantity on the left-hand side *vs.* $1/\sigma$ should be a straight line in the intermediate frequency range. This would then allow the evaluation of R'_a and C'_a. These parameters are then employed to determine the remaining quantities in the phase transfer pathway over a lower frequency region via

$$\frac{1}{1/(Z(\sigma) - R_e) - C_d\sigma - (1 + R'_aC'_a\sigma)/C'_a\sigma} = R_p + \frac{1}{C_m\sigma} \quad [28]$$

from which a plot of the left-hand side should be linear in $1/\sigma$. Finally the membrane transport parameter R_m is obtained from knowledge of the steady-state voltage response. If finite specific adsorption kinetics are not present Eq. [28] would no longer be valid. However, the behavior described in Eq. [27] would still obtain, R'_a and C'_a being substituted by R_p and C_m, respectively.

The above diagnostic procedures were employed in the lower and intermediate frequency ranges. As can be seen in Fig. 6 the functional behavior described by Eq. [27] exists over the intermediate frequency range. It was however, not possible to detect another frequency range over which Eq. [28] was obeyed. This appeared to indicate that the over-all transient impedance of the bladder membrane system would be given by Eq. [10] and [26] as depicted in Fig. 5b. In fact R_p and C_m were evaluated from plots such as Fig. 6 and R_m obtained from a knowledge of the steady-state voltage response. These values, along with those determined for R_e and C_d over the high frequency range (Fig. 4) could then be employed to reconstruct the entire $Z(\sigma)$ spectrum obtained experimentally. This was convincing evidence that the impedance of the toad urinary bladder membrane system could be represented by the aperiodic equivalent circuit shown in Fig. 5b. The values obtained in these preliminary experiments for the phase transfer parameters are $R_p = 400 \pm 125\ \Omega cm^2$, $C_m = 2.7 \pm 0.9 \times 10^{-3}$ F/cm^2 and $R_m = 30 \pm 10\ \Omega cm^2$. Note that, while finite specific adsorption kinetics were not observed (*i.e.*, Fig. 5a), this did not preclude the possibility of very rapid adsorption kinetics. Thus, referring to Fig. 5a, it can be seen that if $R_a \to 0$ (infinitely rapid kinetics) then the observed value of C_d would in fact be a sum $(C_d + C_a)$ representing electrostatic and adsorption effects. This possibility is presently under study by examination of the effect of various ions on "C_d."

As is common for biological systems the scatter in the data (from toad to toad) is relatively high. This does not preclude, however, analysis of the mechanistic pathway. Thus, for every bladder membrane examined, the behavior could be described by Eq. [10] and [26] as represented in Fig. 5b. This behavior persisted even when the transepithelial resting potential

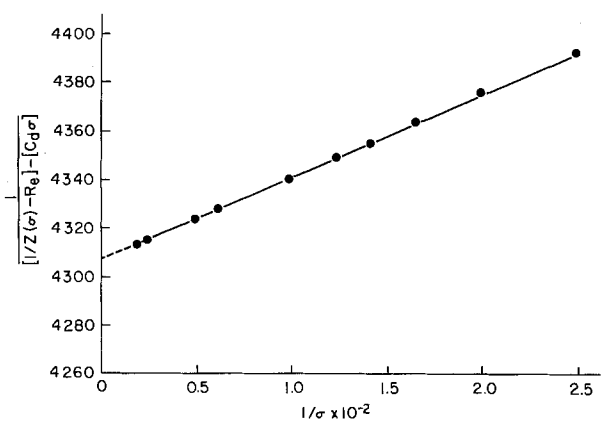

Fig. 6. Intermediate frequency plot of the real axis Laplace plane impedance data using the functional relationship described in Eq. [27] establishing, along with Fig. 3, that the toad urinary bladder membrane exhibited dielectric (and possible infinitely fast specific adsorption) behavior, and that the pathway for Na^+ transport involves slow phase transfer and fast membrane transport.

was lower (<20 mV) than would normally be accepted in biological studies of this membrane system. This is interpreted to mean that the species responsible (Na^+) for the phase transfer portion of the total response did not change its intracellular concentration enough to necessitate compensating action by an active transporting system. This was expected because of the low quantity of charge injected with each perturbation.

Examination of the data obtained reveals that the interfacial (potential dependent) phenomenon of phase transfer (partitioning) of Na^+ is by far the rate-limiting step for its memorane transport. The value of the phase transfer impedance, R_p, is significantly larger than its kinetically relevant counterpart for membrane transport, R_m. This result shows that the interfacial structure (in this case the mucosal interface) determines to a large extent, the passive transport properties of this cell system. Previous analyses using single (38) and bilayer artificial (39-41, 60) membrane systems have dealt with the effect of the diffuse double layer structure upon transport. Remarkably the simple Gouy-Chapman theory quantitatively predicts the shift in current-voltage relationships at steady state in many cases. However, this agreement may be fortuitous even in artificial systems since it is apparent that some divalent cations (*e.g.*, Ca^{2+}) have more specific structural effects than others (61). It is also not clear that the compact double layer, which must exist at interfaces of this type, has been adequately taken into account. Certainly steady-state measurements will not be revealing in this respect. Recent studies involving attempts to isolate the dielectric from double layer capacitance at membranes have been described (42) and may represent the most significant approach thus far in the elucidation of the structure of these interfaces.

The apparent rapidity of membrane transport for this system would appear to favor a pore rather than a carrier interpretation, in agreement with a recent study of membrane noise in a similar epithelial system (62). The determining factors of pore penetration are of course not discernible at this stage. It is not possible, for example, to preclude the involvement of a specific adsorption process which could cause a "gating" phenomenon for Na^+ transport. A suspicion that this may be taking place can be invoked to account for the somewhat high value of C_d observed. In the present study, the adsorption process (if present) appears infinitely fast, but could be separable from the dielectric response by analysis of the system while varying ionic concentration, or by careful high frequency measurements which are presently being carried out.

It is believed that this is the first study of this type on the toad bladder membrane system. Placed in the context of classical studies it is hoped that these results will shed further light on the highly complex transport function of this type of living cell. It is interesting to note that, while short-circuit steady-state studies reveal the existence of a significant intercellular (leak) pathway for current flow (46, 63), this was not detected in the present work. Most probably this is due to the fact that short-circuit conditions are highly nonlinear and usually result in a significant modification in the structure of the intercellular spaces (29). The present study may thus provide an experimental condition in which the bladder is as physiologically undisturbed (electrically) as possible.

Conclusion

This study has invoked the existence of dynamic interfacial electrochemical phenomena, which constitutes the basis of the electrochemical information transfer *in vivo* concept, to provide a model for the elucidation of living cell function. The use of finite kinetics for phase transfer and specific adsorption has allowed a unified approach to membrane impedance to

be applied to the toad urinary bladder membrane system. The modeling approach, which is carried out in the Laplace plane, allows the heterogeneous nature of biological membranes to be treated in a straightforward manner. In this application it has proved successful in a preliminary isolation of the mechanistic pathway for passive Na^+ transport by a careful functional analysis over the wide frequency range available through the use of real axis Laplace transformation. The data obtained reveals that phase transfer and not membrane transport is the rate-limiting step for Na^+ transport. The determining factor for Na^+ entry is not yet clear, but it is intriguing to consider the approach (43, 73) in which the polar groups blocking entry are deformed by the high electric fields present at the interfaces when the penetrating ions interact with, *e.g.*, the lipid structures. The transient injection of charge, as carried out in this study, would then act to provide a sufficient change in interfacial field to allow those Na^+ ions with sufficient energy to penetrate the membrane phase and be literally propelled through to the other side. The deformation of an entry site could of course be caused by a specific adsorption process and would simply constitute a logical extension of the basic premise.

This study has revealed that it is possible to employ modern bioelectrochemical approaches to the study of living membranes. It was begun with the conviction that dynamic interfacial electrochemical processes constitute basic biological steps in cell function. Here a small charge injection has resulted in the modification of a transport function by causing a potential dependent change in interfacial membrane structure. Other biochemical functions appear also to be dependent on similar effects. For example, specific adsorption can influence the activity of membrane bound enzymes (8, 9, 64-66). Transmembrane potential changes as a result of protein synthesis (67) suggest at least a modification in transport properties. The surface charge of differentiated *vs.* undifferentiated (68) and normal *vs.* malignant (69) cells is significantly different, allowing at least the possibility of different interfacial structures which could cause cellular function change. Cell-cell and cell-tissue interaction appears to be greatly dependent upon surface structure and charge (70-72, 74-76). It is hoped therefore, that studies such as this will aid in the elucidation of cellular mechanisms so that even more significant clinical applications will be forthcoming. Certainly, the current success in the healing of otherwise incurable bone fractures by very specifically encoded charge injection (25), the parameters for which were chosen by analyses similar to that given here, warrants significant efforts in this area of bioelectrochemistry.

Acknowledgments

The authors sincerely acknowledge C. A. L. Bassett, M.D. for many helpful discussions and for suggesting the use of the toad urinary bladder for these studies and NIH Grant #AM-07822, NSF Grant #NSF-APR-76-19469, and Electro-Biology, Incorporated for partial support of this work.

A portion of this work has been submitted by one of the authors (GSM) to the Department of Chemical Engineering and Applied Chemistry, Columbia University, as partial fulfillment of the requirement for the Master of Science Degree in Bioengineering.

Manuscript received March 28, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

Thermodynamic Potential for the Anodic Dissolution of n-Type Semiconductors

A Crucial Factor Controlling Durability and Efficiency in Photoelectrochemical Cells and an Important Criterion in the Selection of New Electrode/Electrolyte Systems

Allen J. Bard*

ABSTRACT

We show that the standard potential for anodic dissolution, $E_D°$, of n-type semiconductors (*e.g.*, $E_D°$ for $CdS \leftrightarrows Cd^{2+}(aq) + S + 2e^-$ is + 0.08V *vs* SCE) plays a key role in ultimate efficiency of thermodynamically stable n-type semiconductor-based photoelectrochemical cells. The selection of redox active substances that can be used for competitive capture of photogenerated holes is limited to those systems where the product does not have the potential to oxidize the semiconductor. Where E_{VB} and E_{CB} represent the position of the valence and conduction band positions at the interface, respectively, we must conclude that $E_D°$ is at a more negative potential (*vs.* a reference) than E_{VB}, if the semiconductor undergoes photoanodic dissolution. Quenching of the photoanodic dissolution by competitive hole capture by some electrolyte component, say A, is possible if $E_{redox}(A^+/A)$ lies at a potential more negative than E_{VB}. But additionally, if the A^+, the oxidation product, is to be incapable of oxidizing the semiconductor, $E_{redox}(A^+/A)$ must be more negative than $E_D°$. Consequently, for the semiconductor to be thermodynamically stable in the A/A^+ electrolyte the maximum photovoltage output, $(E_{CB}-E_{redox})$, can be no greater than $(E_{CB}-E_D°)$ for E_{CB} more negative than E_D.° Naturally, kinetic inertness of the semiconductor to an oxidant with E_{redox} more positive than $E_D°$ may allow its presence and/or use in a more efficient cell. N-type CdS and TiO_2 semiconductors in aqueous electrolytes are treated in detail. Some preliminary comments are made concerning p-type materials.

Much attention has been focused recently on the use of certain redox active electrolytes to "quench" the photoanodic dissolution of small bandgap, nonoxide, n-type semiconductors (1-6). Broadly interpreted, the success realized can be attributed to the ability of the redox active species to capture photogenerated holes before the holes participate in oxidation reactions of the semiconductor. At present there is no detailed understanding of the factors controlling the competi-

tion between the interfacial electron transfer and the photoanodic dissolution, although clearly certain energetic requirements (7) must be met for any photo-induced interfacial charge transfer to occur.

Power efficiencies of ~10% can be obtained for the conversion of monochromatic visible light to electricity with "stabilized" n-type semiconductor-based cells (1-6). Even cells employing polycrystalline photoelectrodes appear to give good efficiencies (2, 3, 8-10). It is appropriate to enunciate criteria which will aid in (*i*) the selection of new electrolyte/electrode combinations and (*ii*) the determination of durability and conversion efficiency under operating conditions. The aim of this note is to point out the importance of the standard potential for the anodic dissolution, $E_D°$, of n-type semiconductors. For semiconductors which undergo photoanodic dissolution, the position of $E_D°$ controls the ultimate efficiency and limits the redox active substances that can be used for competitive capture of photogenerated holes.

Theory and Discussion

According to Gerischer (7), the energetics of an n-type semiconductor/electrolyte interface at equilibrium in the dark are as sketched in Fig. 1, where the energy levels of importance, which can be expressed in volts *vs.* a reference electrode, are as follows: E_f is the Fermi level of the semiconductor, E_{CB} and E_{VB} are the conduction and valence band positions, respectively, at the interface, E_{BG} is the semiconductor bandgap, and E_{redox} is the actual redox potential of the chemical system ($A^+ + e = A$) in equilibrium with the semiconductor. In the following discussion we will generally assume that A^+ and A are at unit activity, so that $E_{redox} = E_{redox}°$. However, if the redox system involves H^+, *e.g.*, the O_2/H_2O system, E_{redox} will be a function of pH. Moreover, all energy levels (given on some absolute scale in electron volts) will be expressed relative to a saturated calomel electrode, *i.e.* in volts *vs.* SCE.

Absorption of light within the depletion region corresponding to a VB → CB electronic transition results in separated e^--h^+ (electron-hole) pairs such that h^+ goes to the interface and the e^- moves to the bulk of the semiconductor. The h^+ rises to the top of the valence band, and, in the absence of surface states, is at a potential equal to E_{VB}. Thus, if E_{redox} is more negative than E_{VB}, interfacial electron transfer can occur to fill h^+, thereby oxidizing some component of the electrolyte. However if the standard potential for the anodic dissolution of the semiconductor, $E_D°$, is more negative than E_{VB}, h^+ can also cause oxidation of the crystal. The primary oxidation product, then, will depend on the relative rate of the two competing h^+ reactions.

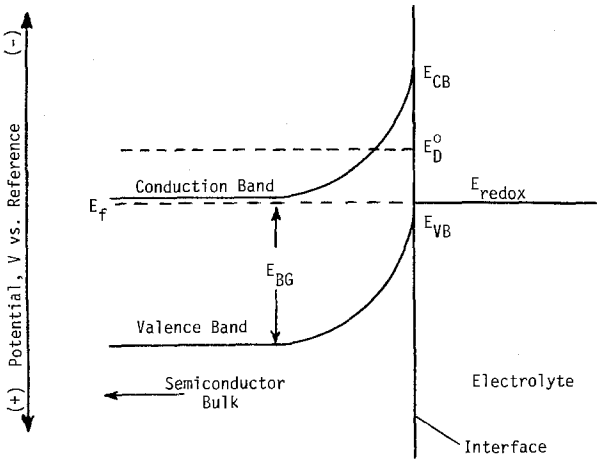

Fig. 2. E_{redox} more positive than $E_D°$

Significantly, though, the relative position of E_{redox} and $E_D°$ is crucial to whether prolonged stabilization of the semiconductor is expected. In Fig. 2, we show a situation where $E_{redox}°$ is more positive than $E_D°$. What is readily apparent is that the oxidized form of the redox couple with a potential $E_{redox}°$ is capable, energetically, of spontaneously oxidizing the semiconductor in the dark. If the redox system is represented by A/A^+ and one starts with only the reduced form, A, present, then the photogeneration of h^+ can lead to photoanodic dissolution and to interfacial transfer to give the oxidized form, A^+. But with the $E_{redox}°$ level of A/A^+ situated more positive than $E_D°$, A^+ is capable of chemically oxidizing the semiconductor. Thus, the use of A as a reductant to capture competitively photogenerated h^+ is not attractive, because the primary oxidation product may, thermodynamically, oxidize the semiconductor.

Figure 3, shows the situation for $E_{redox}°$ (A/A^+) more negative than $E_D°$. In this case the primary oxidation product, A^+ is not capable, thermodynamically, of oxidizing the semiconductor to an appreciable extent. Thus, if A can successfully capture 100% of the photogenerated h^+, then the semiconductor could be stabilized to anodic dissolution for an indefinite period.

A comparison, though, of Fig. 2 and 3 suggests several other important comments. First, the amount of band bending in the dark (E_{CB}-E_{redox}) is

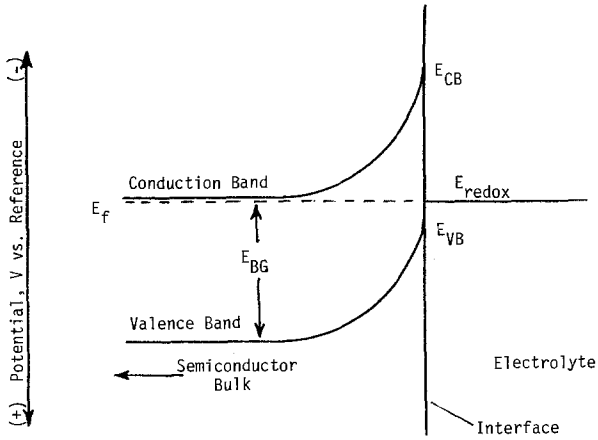

Fig. 1. N-type semiconductor at dark equilibrium

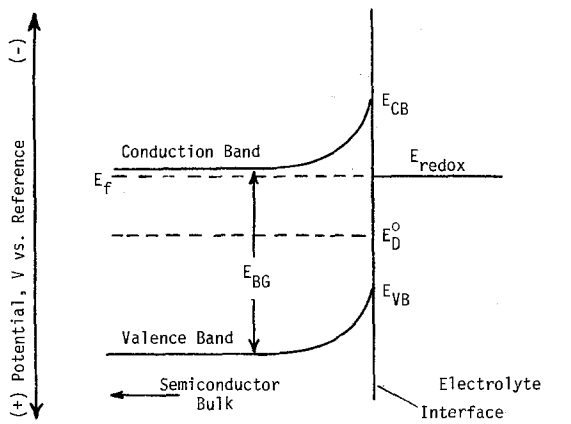

Fig. 3. E_{redox} more negative than $E_D°$

equal to the maximum open-circuit photopotential, and in Fig. 3 the amount of band bending is less than ideal. In fact, the position of $E_D°$ will limit the amount of band bending to E_{CB}-$E_D°$ for an electrolyte system which can stabilize the semiconductor. Thus, the maximum conversion efficiency with monochromatic light and for a thermodynamically stable system is just E_{CB}-$E_D°/E_{BG}$.

Second, the position of E_{redox} may be required to be significantly more negative than E_{VB}. This may preclude effective overlap of filled levels of the redox active A and the valence band (containing the primary photogenerated h^+) of the semiconductor. Indeed, if the h^+ position is, at best, at the top of the valence band, stabilization of the semiconductor to photoanodic dissolution may not be possible, owing to the slow oxidation of A because of this lack of overlap. This consideration suggests that surface states or intermediate levels may be of importance in the transfer of holes to solution species whose E_{redox} is located in the band-gap region, and there may be merit in the controlled introduction of such states or levels so that the photogenerated hole can rise to a level more negative than $E_D°$.

Third, when E_{redox} is required to be substantially more negative than E_{VB} there may be substantial overlap of the filled levels in A and the conduction band (unfilled) levels of the semiconductor. This will result in significant dark anodic currents.

Finally, since $E_D°$ must be closer to E_{VB} than E_{redox}, we can only be cautious about the prospects for finding a large number of redox active materials that will be capable of competing efficiently with photoanodic dissolution. The presence of surface states will alter the prospects considerably, and their role in the known cases of stabilization should be investigated in detail.

Consideration of a couple of examples will serve to reinforce the principles outlined here. Table I shows some pertinent information. Stabilization of CdS to photoanodic dissolution has been reasonably successful (1-6) and is a useful illustrative case. In aqueous electrolytes the energetics are as in Fig. 4, and are approximately independent of pH (6, 11). The value of $E_D°$ is for the reaction $Cd^{2+} + S + 2e^- =$ CdS and is based on the thermodynamic data given in Latimer (12). From the foregoing discussion, E_{redox} must be more negative than +0.08V *vs.* SCE. Consequently, and in retrospect, it is understandable that failure results in the attempted (13) use of I^- to capture competitively photogenerated h^+. The primary oxidation product, I_2, is capable of oxidizing CdS, since $E_{redox}°(I_2/I^-)$ is +0.25V *vs.* SCE (12). Indeed, it is well known that I_2 will oxidize CdS, and this reaction is used in an established analytical procedure (14). Since the oxidation of CdS by I_2 will occur at some finite rate, it may be possible to generate some reasonable concentration of I_2 at CdS. However, it is the long-term stability that is of importance here. Moreover, an axiom of inorganic photochemical systems is that, at the very least, the role of the light is to accelerate thermodynamically favorable chemical processes. Thus, irradiation of CdS in the presence of I_2 should increase its rate of spontaneous oxidation.

Table I. Calculated standard potentials for decomposition half-reactions of several semiconductors

Compound	Half-reaction	$E_D°$ (V *vs.* SCE)
TiO_2	$TiO^{2+} + ½\ O_2 + 2e^- \rightleftarrows TiO_2$	+1.18
ZnO	$Zn^{2+} + ½\ O_2 + 2e^- \rightleftarrows ZnO$	+0.65
	$Zn(OH)^+ + ½\ O_2 + 2e^- \rightleftarrows ZnO + OH^-$	+0.52
	$ZnO_2^{2-} + 2H_2O + ½\ O_2 + 2e^- \rightleftarrows ZnO + 4\ OH^-$	+0.19
Fe_2O_3	$2Fe^{3+} + 3/2\ O_2 + 6e^- \rightleftarrows Fe_2O_3$	+1.00
WO_3	$WO_4^{2-} + 4H^+ + ½\ O_2 + 2e^- \rightleftarrows WO_3 + 2H_2O$	+1.40
SnO_2	$Sn^{4+} + O_2 + 4e^- \rightleftarrows SnO_2$	+1.11
CdS	$Cd^{2+} + S + 2e^- \rightleftarrows CdS$	+0.08

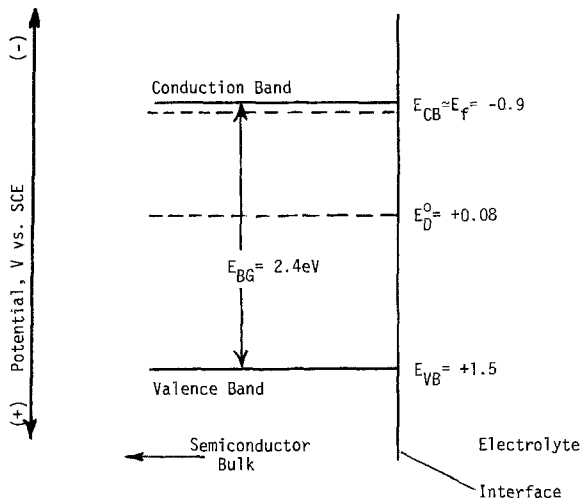

Fig. 4. CdS in aqueous solution

In the presence of X^{2-} (X = S, Se, Te) the positions of E_{CB} and E_{VB} for CdS are located at more negative potentials, but the E_{redox} values (12, 15) for X^{2-}/X_n^{2-} at −0.7, −0.9, and −1.1V *vs.* SCE for X = S, Se, and Te, respectively, are all sufficiently negative that the elemental chalcogen is incapable of oxidizing CdS. Thus, long-term stability can be expected provided the $X^{2-} \rightarrow X_n^{2-}$ oxidation is 100% efficient. Incidentally, it is worth noting that the lightest elemental chalcogen, O_2, is thermodynamically capable of oxidizing CdS, since in H_2O the E for the O_2/H_2O couple under 1 atm of O_2 ranges from +1.0 to +0.16V *vs.* SCE from pH = 0 to pH = 14 (12). Likely primary oxidation products from H_2O (such as ·OH or H_2O_2) are certainly capable of spontaneously oxidizing CdS. However, the slow rate of the reaction of CdS with O_2 may make it possible to use this material as the photoanode in a cell for the electrolysis of H_2O, provided intermediates like OH and H_2O_2 can be avoided.

The other n-type CdX photoelectrodes can be treated in the same way as CdS. At this time, the point to emphasize here is that the position of $E_D°$ for CdS is significantly more negative (~1.4V) than E_{VB} and, therefore, limits the immediately foreseeable output voltages in stable aqueous systems to about 1.0V. This projection is clearly altered if the band positions can be moved substantially more negative by specific interactions with the electrolyte; *e.g.*, in the presence of X^{2-} the bands move more negative by ~0.5V, while $E_D°$ is presumably constant (6).

For a stable oxide semiconductor the value of $E_D°$ lies at more positive potentials. For example, the energetics for TiO_2 (16) electrode immersed in a solution of pH = 0 are shown in Fig. 5, $E_D°$, calculated from available free energy data (12) for the half-reaction $TiO^{2+} + ½\ O_2 + 2e^- = TiO_2$, is + 1.18V *vs.* SCE, which is 0.18V positive of the E for the O_2/H_2O reaction at pH = 0. At more alkaline pH's both the flatband potential and the E_{redox} for O_2/H_2O shift toward more negative values by about 59 mV/pH unit, while $E_D°$ is independent of pH, as long as TiO^{2+} is the predominant Ti(IV) species in solution. Thus, the separation between $E_D°$ and $E(O_2/H_2O)$ increases with increasing pH, leading to greater stability of the material. The value of $E_D°$ is consistent with an equilibrium constant for the reaction $TiO_2 + 2H^+ \rightleftarrows TiO^{2+} + H_2O$ of 2×10^{-7}. In sufficiently acidic solutions some small amount of dissolution of the TiO_2 may occur. Indeed, the change observed in surface morphology of a TiO_2 single crystal immersed in 1.0*N* H_2SO_4 under irradiation (17) may represent this light-catalyzed dissolution. At higher pH's the TiO_2 electrode is stable, even

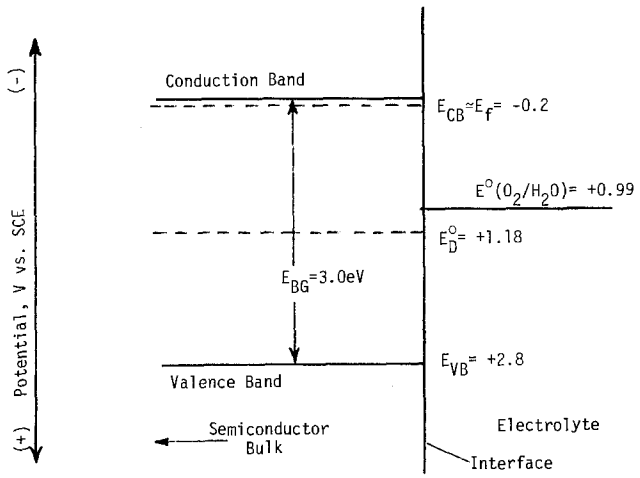

Fig. 5. TiO_2 in aqueous solution at $pH = 0$

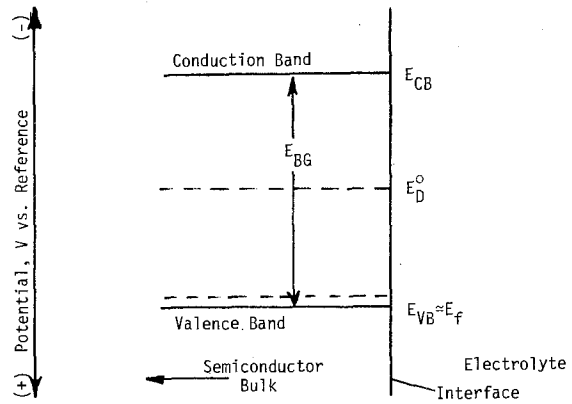

Fig. 6. P-type semiconductor at flatband potential

under prolonged irradiation, as predicted from the above discussion. Note, however, that $E_D°$ lies quite negative of E_{VB} and, as discussed for CdS, may limit how positive the potential of an added redox active electrolyte can be, for use in a photoelectrochemical cell without encountering stability problems with the electrode. It is also of interest to consider the behavior of the electrode in a nonaqueous solvent, *e.g.*, acetonitrile. $E_D°$ will become more positive in a solvent which complexes or solvates the lattice metal ion to a smaller extent, yielding a more stable semiconductor with respect to photo-oxidation.

The behavior of ZnO in aqueous electrolyes is also an interesting case. For the half-reaction $Zn^{2+} + \frac{1}{2} O_2 + 2e^- = ZnO$, $E_D°$ is +0.65V *vs.* SCE (12). This lies near or negative of $E(O_2/H_2O)$ at all *p*H's (when $E_D°$ is calculated for the appropriate Zn(II) species, *i.e.*, Zn^{2+}, $Zn(OH)^+$, or ZnO_2^{2-}) and is consistent with the known instability of ZnO under irradiation, even though E_{CB} and E_{VB} are located at about the same positions for ZnO and TiO_2 (16, 18, 19). Thus, it is $E_D°$ rather than E_{VB} which governs the long-term stability of the material. It is true that the position of E_{VB} is related to the bonding energy of the valence electrons and thus the stability of the lattice. However, in terms of half-reactions, E_{VB} represents the potential for the abstraction of one electron from the lattice (*e.g.*, $CdS^+ + e = CdS$), whereas $E_D°$ involves equilibrium constants and potentials involving the intermediate species which may be so thermodynamically favorable as to make $E_D°$ quite negative of E_{VB}. Thus, while redox couples with potentials near E_{VB} clearly will cause decomposition of the lattice (7), in fact couples at even more negative potentials are capable of oxidizing the semiconductor. Ideally, $E_D°$ should be at, or below E_{VB}. For the semiconductor materials investigated for which thermodynamic data are available, even the very stable ones (9), such as SnO_2, WO_3, and Fe_2O_3, $E_D°$ is negative of E_{VB} for an aqueous solution.

Though p-type semiconductors have received some attention as photocathodes, p-type semiconductor-based photoelectrochemical cells have not been found to be very efficient. We note that the systems studied, *e.g.*, p-GaP, GaAs, CdTe, (20-23) all have n-type counterparts which undergo photoanodic dissolution in aqueous solution (1, 6, 24-26). This allows us to conclude that the $E_D°$ in each case is situated at a potential which is more negative than E_{VB}. Since a heavily doped p-type material has $E_f \approx E_{VB}$ at the flatband potential, E_{FB}, the p-type material is thermodynamically unstable to anodic dissolution at E_{FB} in particular and at potentials more positive than $E_D°$. The flatband condition for a p-type electrode is shown in Fig. 6 and since the majority of charge carriers are holes, it is apparent that the anodic dissolution may occur. At least, the dissolution will occur until the E_f at the surface is approximately $E_D°$. Consequently, in practice, p-type semiconductors having a fairly negative $E_D°$ may give poor output photovoltages. Logically, other factors concerning p-type materials must be considered, including the standard potential for cathodic reaction, *e.g.*, $CdTe + 2e^- \rightarrow Cd + Te^{2-}$. For p-type materials such a reaction should be feasible for E_{CB} more negative than such a potential. And again, whether the semiconductor is stable may depend in large measure on relative rates of minority carrier (e^-) interfacial transfer *vs.* the cathodic decomposition of the semiconductor.

ABSTRACT

The basic electrochemical properties of WO_3 electrodes are described. The influence of the preparation techniques on the photoelectrochemical behavior of the electrodes is reported. The results are discussed in view of applications in solar energy conversion systems.

The tungsten oxide (WO_3) is a transition metal oxide with a number of interesting optical and electrical properties (1, 2). During the last years new interest arose in it because of its potential use in small area displays (3). The subject of our interest, however, is its use as light-sensitive electrodes in a semiconductor/electrolyte solar cell.

Semiconductor/electrolyte cells are considered as potential solar energy converters [for a review see (4)]. In principle they allow a direct conversion into electrical and/or chemical energy. Few self-regenerative solar cells have been realized (5-8), and direct photoelectrolysis has been reported (9, 10). Problems arise from the photocorrosion [see, *e.g.*, (11, 12)] of the semiconductor electrode. Most known semiconductor electrodes immersed in an aqueous electrolyte show this phenomenon, and other semiconductors (*e.g.*, TiO_2) which are known to be stable have energy gaps which are too large to be used efficiently for solar energy conversion. In order to find suitable electrodes, it seems to be necessary to investigate less known semiconductor materials with respect to their photoelectrochemical behavior. In this paper we present results obtained from some investigations with WO_3 electrodes.

Different values of the bandgap energy of WO_3 have been reported ranging from 2.5 to 3.65 eV (2, 13). This scattering is probably due to a strong influence of the preparation technique on the electrical and optical properties. Tungsten oxide can be obtained in different colors from lemon yellow to dark blue. The color can be changed also by electric charge injection [electro- and electrochemichromism, see, *e.g.*, (3)]. For the coloration mechanism several models have been proposed; in any case the degree of disorder due to lattice defects seems to play an important role. Electrochemical investigations in relation to display applications were performed already by Chang *et al.* (17), and preliminary experiments in connection with solar energy conversion were reported by Hodes *et al.* (18) and by Butler *et al.* (27).

Experimental

Tungsten oxide layers were prepared by two different techniques:

(*i*) By sputtering WO_3 powder on tungsten sheet, films of thicknesses 0.4-0.7 μm were obtained which were transparent and showed typical interference colors. X-ray analysis revealed a diffraction pattern typical for a crystalline structure of composition $WO_{2.98}$ (19). A heat-treatment in an oxygen atmosphere for only 10 min at 600°C effected a visible darkening of the films. The original greenish interference color turns into dark blue. Obviously the oxide reacts further with the tungsten substrate, leading to lower tungsten oxides.

(*ii*) By thermal oxidation of tungsten sheets (purity 99% in an oxygen atmosphere at 780°C) oxide layers of several μm thickness were obtained. If the oxidation time was shorter than *ca.* 15 min, the oxide layers assumed a dark blue color; for longer times a lemon yellow color was obtained. X-ray analysis also revealed here a diffraction pattern compatible with a

slightly substoichiometric tungsten oxide of about $WO_{2.98}$.

The electrochemical investigation has been performed in a 1 compartment cell. As electrolyte 0.1*N* Na_2SO_4 has been used, the *p*H has been adjusted by adding NaOH and H_2SO_4, respectively. The electrolyte was stirred by circulating it with a pump through the cell. The electrode potentials were measured under potentiostatic conditions using a calomel electrode as a reference electrode.

The photocurrent measurements were performed using a 450W xenon lamp and a grating monochromator. The light intensity was measured with a calibrated thermopile (Kipp and Zonen, Type CA1) having a flat response for wavelengths greater 150 nm. For low intensities a photometer equipped with a silicon n-p cell (UDT Type 80 × Optometer) was used. In some cases the light was chopped and then the photocurrent measured using lock-in technique.

The space charge capacity was measured by superimposing an a-c 50 kHz voltage of 25 mV on the externally applied voltage using a bridge circuit.

Results

The influence of the sample preparation on the space-charge capacity *C* is seen in Fig. 1, where $1/C^2$ is plotted *vs.* the electrode potential U_E for differently prepared oxide layers. Using the Mott-Schottky equation

$$\frac{1}{C^2} = \frac{2}{e \cdot \epsilon \cdot \epsilon_0 \cdot N_D}\left(U_E - U_{fb} - \frac{kT}{e}\right)$$

(N_D = donor density, U_E = electrode potential, U_{fb} = flatband potential, and the other constants have their usual meaning). N_D can be obtained from the slope of the plot. A straight line for the Mott-Schottky plot, however, has only been obtained for sputtered layers (curve 1) which were not heated in an O_2 atmosphere, resulting in $N_D = 10^{17}$ cm^{-3} [$\epsilon = 10$ for 50 kHz (20)]. A linear dependence has been obtained over a much larger potential range (up to 3V) which is not shown in Fig. 1. It is interesting to note that the donor density could be varied over several orders of magnitude by varying the oxygen pressure during the sputtering process (in all these cases linear $1/C^2$ *vs.* U_E curves have been obtained). Curves 2-4 of Fig. 1 have been obtained with sputtered layers which were annealed at 600°C in an oxygen atmosphere for different times. Curve 5 represents the result of a (lemon yellow colored) thermally grown oxide layer resulting into $N_D = 10^{20}$ cm^{-3} (calculated from the slope of the flat part of curve 5). It should be mentioned that our capacity curves are slightly frequency dependent, as it has been observed also with several other semiconductor electrode (21). The flat potential dependence is not influenced by this effect. The flatband potential, however, is slightly changed by the heat-treatment ($U_{fb} = +0.2$ *vs.* SCE for sputtered layer and -0.05V *vs.* SCE for thermally grown WO_3).

A typical current-potential curve (sweep rate 10 mV/sec) as obtained with a thermally grown yellow oxide layer is shown in Fig. 2. During anodic polarization the current is limited to a very low level which can be increased by light absorbed by the oxide, a behavior typical for n-type semiconductor electrodes. In this potential range the oxide is very stable. The anodic photocurrent caused by band-band excitation is due to oxygen evolution. This could be shown by analysis of the gas evolved at the semiconductor electrode with a quadrupole mass analyzer. During cathodic polarization the WO_3 electrode is reduced to a substoichiometric oxide (17) or to hydrogen bronze (3, 16) which can be reoxidized by a subsequent anodic sweep. During reduction the layer changes into a deep blue color, this being the electrochromic effect. The current potential curves obtained with the other oxide layers differed only with respect to the absolute value of the current density; untreated sputtered layers showed the smallest current densities and the yellow samples the highest.

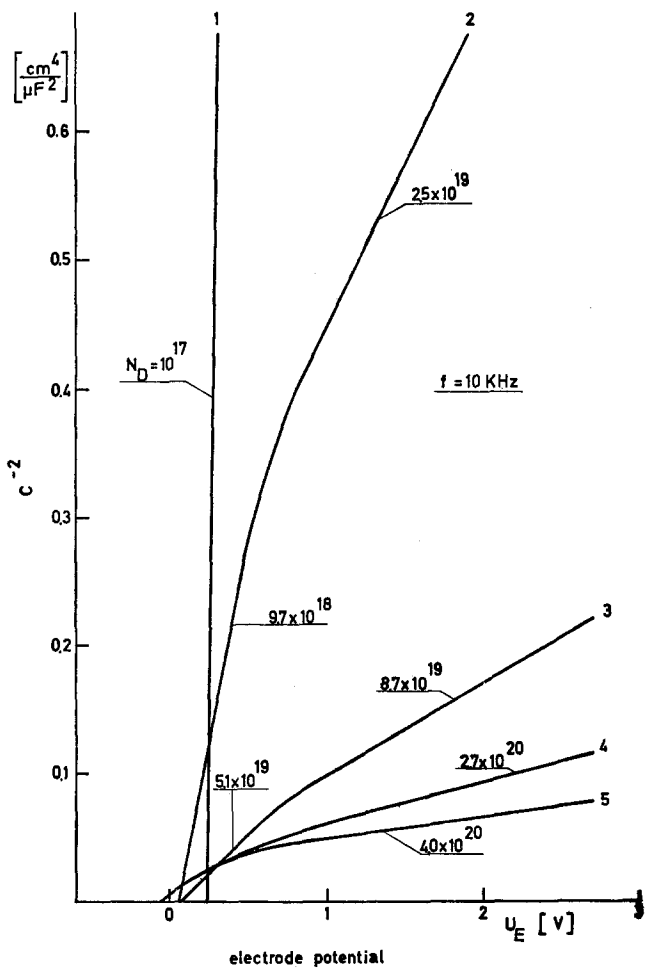

Fig. 1. Mott-Schottky curves of WO_3 layers in 0.1*N* H_2SO_4 (f = 50 kHz). 1, sputtered layer without heat-treatment; 2-4, sputtered layer, annealed at 600°C in O_2 for 10, 30, and 90 min; 5, thermally grown (yellow) layer at 760°C for 120 min.

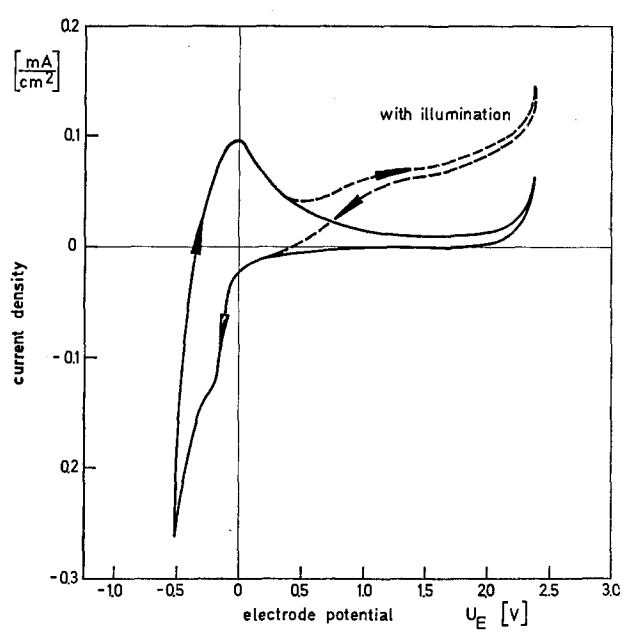

Fig. 2. Current-potential curve of thermally grown WO_3 layer in 0.1*N* H_2SO_4, sweep rate 10 mV/sec.

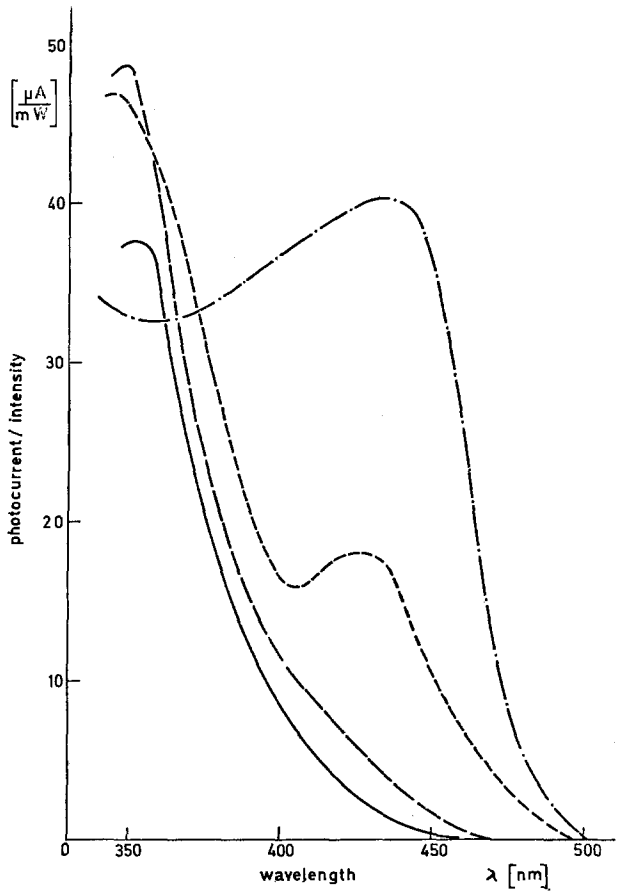

Fig. 3. Spectral distribution of the anodic photocurrent at U_E = 2V *vs.* SCE. Solid line, sputtered layer without heat-treatment; dashed lines, sputtered layer, annealed at 600°C in O_2 for 10 min and for 1.5 hr; dashed dotted line, thermally grown (yellow) layer at 760°C for 120 min.

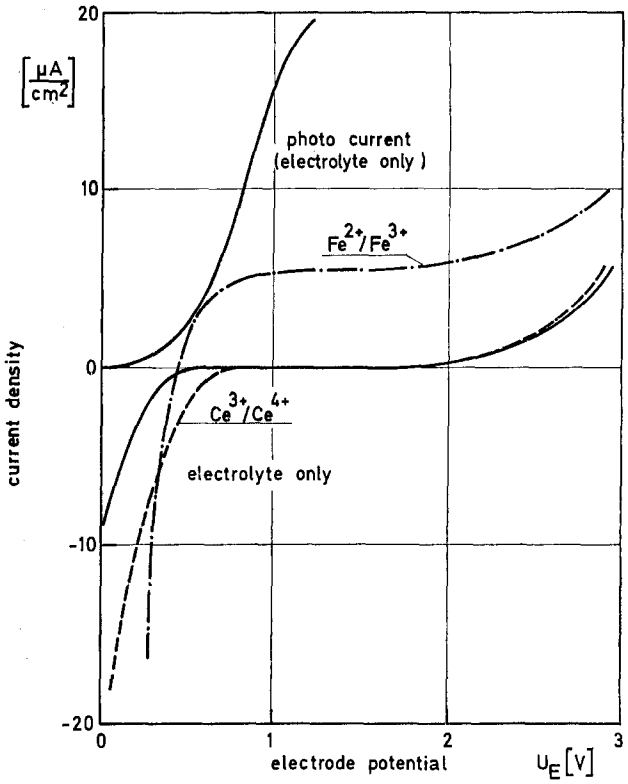

Fig. 4. Potentiostatic current-potential curve of sputtered untreated WO_3 with redox systems. Dashed, 10^{-2}M Fe^{2+}/Fe^{3+} in 0.1*N* H_2SO_4; dashed-dotted, 10^{-2}M Ce^{3+}/Ce^{4+} in 0.1*N* H_2SO_4; solid, 0.1*N* H_2SO_4.

Figure 3 shows the spectral distribution of the photocurrent which again depends strongly on the electrode preparation. With sputtered layers (solid line) the photocurrent raises mainly at wavelengths below 400 nm (3.1 eV), whereas annealed layers (dashed line) and the thermally grown yellow layer (dashed-dotted line) show photosensitivity also between 400 and 480 nm (2.6 eV). This effect is reversible: for instance after heating a thermally grown layer in vacuum at 780°C, the long wavelength peak disappears completely.

The potentiostatically measured current-potential curves of Fig. 4 show a typical behavior of a n-type semiconductor if a redox system is added to the electrolyte. In the case of Fe^{2+}/Fe^{3+} (dashed line), the cathodic current starts to rise at potentials slightly above the flatband potential, *i.e.*, the current is determined by electron transfer from the conduction band to the Fe^{3+} ions. During anodic polarization a small additional current of about 5 μA has been found due to electron transfer from Fe^{2+} ions into the conduction band. In the case of Ce^{3+}/Ce^{4+} (dashed-dotted line) similar results were obtained, only the anodic current was much smaller. Also, for comparison the i/U_E behavior without the added redox systems (solid line) is shown with and without illumination.

Discussion

The WO_3 electrodes show a typical electrochemical behavior of a n-type semiconductor electrode as far as the current-potential curves are concerned. It is interesting to note, however, that annealing of WO_3 layers in an O_2 atmosphere leads to a strong red shift of the photosensitivity. This shift is accompanied by a change of the electrical properties of the compound represented by the capacity curves which should be interpreted first.

As shown in Fig. 1 a simple Mott-Schottky curve has only been obtained with untreated sputtered layers. In all other cases the curves showed a lower slope, indicating a larger donor density and they are not straight. They may be described by two curves with a steep slope at lower potentials and a much lower slope at higher potentials. It is rather surprising that with the thermally grown layers of yellow color too a donor density (curve 5 in Fig. 1) has been obtained being larger than for freshly sputtered layers since the yellow color indicates nearly stoichiometric composition (19).

There are two possibilities to interpret the bent Mott-Schottky curves: (*i*) Such curves are bent if the density of donor states varies within the space charge region (12). In the case of the thermally grown yellow oxide we know that the composition of the WO_3 is not constant over the whole oxide layer. Near the metal substrate, for instance, the oxide shows a much darker color. (*ii*) The Mott-Schottky curves may be described by two curves. The lower slope can be interpreted by deeper donor levels which are not ionized within the bulk (22, 23). Accordingly this type of donor state is formed during the heat-treatment in an oxygen atmosphere, the number of states increasing considerably with increasing annealing times. It is difficult to test one of these assumptions experimentally. We prefer the latter interpretation because in the first case it is difficult to explain the linear slope, always found at higher anodic potentials.

The most interesting effect observed during the investigations is the additional photocurrent peak around 430 nm observed with annealed and thermally grown layers. This long wavelength sensitivity cannot be explained by assuming a corresponding shift of the bandgap due to some lattice changes. Such a change of bandgap could be ruled out by absorption measurements of a WO_3 layer deposited of a quartz substrate. Annealed layers only showed a very small shift of the

bandedge, probably due to the change of an amorphous to a crystalline structure.

The main sensitivity of untreated sputtered layers below 400 nm must be due to a direct band-band transition in WO_3. These results agree well with a bandgap of 3.2 eV, taken from Deb's paper (2) in which the absorption edge was analyzed very carefully. As forementioned, there are a number of lower values of bandgaps in the literature as, for example, in the paper of Butler *et al.* (27). According to an investigation on WO_3 Butler (28) could show also that an indirect transition exists in WO_3 corresponding to a bandgap of 2.7 eV. The spectral distribution obtained by Butler *et al.* (27) and that determined by ourselves with freshly sputtered WO_3 layers agree quantitatively. The presence of an indirect transition, however, does not explain the occurrence of the additional photocurrent peak we have observed with annealed and thermally grown layers.

We postulate therefore that this photocurrent is caused by a transition from the valence band to energy states being below the conduction band. These interband states are distributed over a relatively large energy range (Fig. 3). These states cannot be formed within the original sputtered layer during the heat-treatment because no additional photocurrent peak has been observed with layers sputtered on a quartz substrate covered by a conducting SnO_2. In the case of an oxide layer deposited on a tungsten substrate, however, the original oxide layer reacts with the substrate during the heat-treatment, leading to the formation of some substoichiometric oxide and a corresponding oxygen gradient existing throughout the whole layer. This process must be responsible for the formation of additional states within the bandgap.

The question arises whether the interband states correlated with the 430 nm-peak in the photocurrent spectrum are really bulk or perhaps surface states. Surface states, however, can be excluded because in this case the quantum yield should be very low (24) whereas we found photocurrents being comparable with those occurring by direct band-band excitation. On the other hand, if the 430 nm peak is due to excitation of electrons from the valence band into interband states in the bulk, then these electrons must be thermally excited into the conduction band or are transferred along these states toward the back side contact, whereas the holes are consumed for the oxygen evolution at the surface. Such an electron transfer via interband states is only possible, however, if the density of states is large so that sufficient interaction exists (interstate band).

Apart from the optical and electrical properties of WO_3 its applicability as a semiconductor electrode in a solar cell has been also investigated. In connection with this problem the relative position of the energy bands at the semiconductor surface is of importance, which can be derived from the flatband potential. Assuming the Fermi level in the bulk to be 0.1 eV below the conduction band, and taking for the flatband potential the value $U_{fb} = 0.55$ eV *vs.* NHE (+0.2V *vs.* SCE for sputtered layers, see Fig. 2) one obtains a position of the energy bands at the WO_3-surface as plotted in Fig. 5. For comparison the position of energy levels of SnO_2 (13, 25) and TiO_2 (22) are also shown. Since the flatband potential occurs at potentials more positive than the hydrogen potential, any direct conversion of solar energy into chemical energy by water decomposition is not possible with WO_3 electrodes. However, in principle it is also possible to use WO_3 as an electrode in a self-regenerating solar cell with a redox system as an electrolyte. In such a case solar energy is converted into electrical energy as has been demonstrated with CdS electrodes and $[Fe(CN)_6]^{4-/3-}$ or $S/S^=$ as redox systems (4, 5). In the case of WO_3 a redox system should be selected of which the energy levels (occupied levels O_{red})

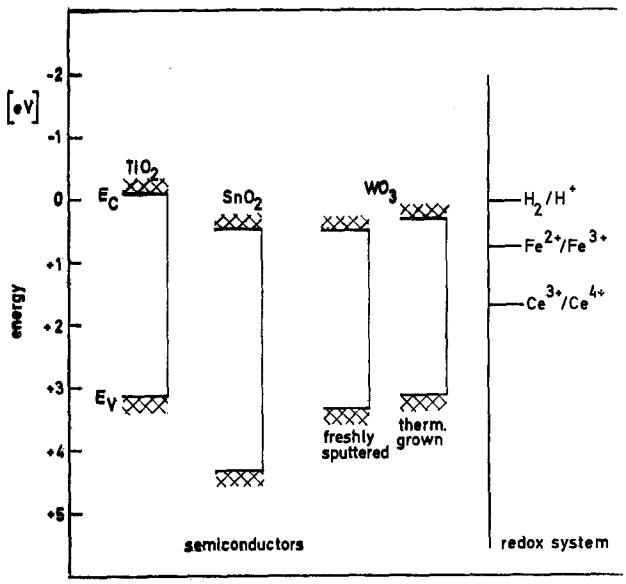

Fig. 5. Energy diagram

overlap with the valence band so that only electron transfer from the redox system to the valence band is possible if holes are produced by light excitation. Corresponding experiments with Ce^{3+} have shown, however, that no Ce^{3+} was oxidized during illumination. The corresponding anodic photocurrent leads only to oxygen evolution, although the valence band overlaps much better with the occupied energy levels of $Ce^{3+/4+}$ (Fig. 5) than with corresponding levels of the H_2O/O_2 system. This result can only be interpreted by assuming a much stronger interaction between the electrode surface and H_2O molecules, or by assuming a preferable charge transfer from H_2O into surface states. In other redox systems such as $Fe^{2+/3+}$ the occupied levels overlap better with the conduction band (Fig. 5), and a corresponding exchange current is visible as shown in Fig. 4. These results are very similar to those obtained with SnO_2 (25, 26).

Acknowledgment

The authors would like to express their gratitude to Dr. G. Pellegrini (Euratom) and Dr. B. Strocka (Philips) for their kindness in performing and evaluating the x-ray measurements, to R. D. Boehnke (Philips) for producing the sputtered layers, and to R. Schubert (Euratom) for valuable help during the work.

An Ellipsometric Study of the Anodic Oxidation of Nickel in Neutral Electrolyte

J. L. Ord,* J. C. Clayton, and D. J. DeSmet*,[1]

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

ABSTRACT

Ellipsometry is used to study alternate anodic and cathodic galvanostatic cycling of a nickel electrode in neutral sulfate and borate electrolyte. The removal of the electropolishing film under cathodic reduction, the anodic oxidation of the nickel substrate, and the deposition and conversion of films of $Ni(OH)_2$ and NiOOH can all be distinguished clearly on a plot of the optical data. The mechanism of anodic oxidation of the substrate is investigated using both optical and open-circuit transient measurements, and the field in the oxide film is concluded to limit the substrate oxidation process.

In recent years, a number of studies of the anodic oxidation of nickel have made use of ellipsometric as well as electrochemical measurements. Bockris, Reddy, and Rao (1) made extensive use of ellipsometric results in their study of the mechanism of passivation of nickel in sulfate electrolyte of pH 3.15. They interpreted the structure observed in their optical data during passivation as arising from a change in the refractive index of the film from 4.0 to 3.5 — 0.4i (at λ = 5461Å). They took the increase in absorption as indicating an increase in the electronic conductivity of the film, and concluded (*i*) that a 60Å prepassive film formed by a dissolution-precipitation mechanism, and (*ii*) that passivity resulted from the film becoming an electronic conductor. They assumed the prepassive film to be $Ni(OH)_2$ which oxidized to $NiO_{1.6}$ on passivation. They determined film thicknesses by correlating optical and coulometric measurements and found little further increase in film thickness as the potential was increased in steps across the passive region.

Chernykh and Yakovleva (2, 3) studied the anodic oxidation of nickel in KOH and used an approach similar to that of Bockris *et al.* in their analysis of optical data. They assumed that the index of the film lay between 2.8 and 3.3 (at λ = 5461Å) and concluded that the absorption coefficient of the film increased due to an increase in electronic conductivity. They found a greater variation of film thickness with potential, an increase from 20 to 60Å, than was reported in acid electrolyte.

Sato and Kudo (4) studied the anodic oxidation of nickel in a neutral borate buffer of pH 8.42. They chose an index for the oxide film of 2.7 — 0.25i at λ = 5461Å and concluded that the film thickness increases from 4 to 10Å linearly with potential across the passive region. They estimated the field in the film to be 1.6 $\times$ 10^7 V/cm after 1 hr of potentiostatic oxidation and measured current densities of less than 0.1 $\mu A/cm^2$ under these conditions.

DeSmet (5) studied the anodic oxidation of nickel in acid and neutral electrolyte using an automated ellipsometer with a nulling time of 1 sec and a resolution of 0.01°. He found considerable structure in the optical data, particularly in acid electrolyte, which would be very difficult to detect with a manual instrument. He concluded that a single-layer model in which the layer converted to a different form on reduction could account for his results in neutral electrolyte but failed to find any simple model which could account for his acid electrolyte data. The response time of the ellipsometer enabled him to follow film growth, and although he found some evidence for control of the process by the field in the film, he concluded that existing models for a field-limited process were inadequate to account for his data.

MacDougall and Cohen (6-9) have recently studied the anodic oxidation of nickel in acid and neutral electrolyte using coulometry, electron diffraction, and x-ray emission spectroscopy. From their measurements

Key words: anodic oxidation, ellipsometry, nickel.

they concluded that a film of NiO between 9 and 12Å thick is formed by 1 hr of potentiostatic oxidation at both pH 2.8 and 8.4, and they found little dependence of film thickness on potential. They stated that the discrepancy between their results in neutral sulfate electrolyte and the results of Sato and Kudo in neutral borate electrolyte is well beyond the error limit given for their measurements, ±1.5Å. They rejected a high field mechanism for film growth because of the high electronic conductivity of the film, and they stated that the growth process can be described by a place-exchange mechanism.

Okuyama and Haruyama (10) used coulometry to study the passive film formed on nickel in neutral borate electrolyte and concluded that a duplex film of NiO and Ni_3O_4 is formed by oxidation of nickel and that the Ni_3O_4 is oxidized to NiO_2 at higher potentials. They quote Tafel slopes for both the oxidation and the reduction of NiO and NiO_2, but they find Ni_3O_4 very difficult to reduce.

The contradictory nature of the recent work on the anodic oxidation of nickel makes it difficult to say very much about the basic processes involved. With opinion about equally divided on a question as fundamental as whether or not the film thickness varies with potential, it is not possible to say whether oxidation is limited by field-controlled transport of ions through the oxide film or by some other process. In this paper we attempt to clarify this situation by using ellipsometry to identify the various dissolution, oxidation, deposition, and conversion processes which take place when a nickel electrode is cycled galvanostatically in neutral electrolyte. We then investigate the mechanism by which an oxide film grows on a nickel surface by oxidation of the substrate. In interpreting our ellipsometric data we make extensive use of what we have learned from our studies of the deposition and oxidation of nickel hydroxide films in neutral electrolyte (11, 12). In these studies we followed the growth of nickel hydroxide films to thicknesses of over 2000Å, and this wide thickness range enabled us to determine the optical properties of $Ni(OH)_2$ and NiOOH films uniquely from our optical data. We found more than one phase of $Ni(OH)_2$ and NiOOH, and we assumed them to be the α- and β-$Ni(OH)_2$, and γ- and β-NiOOH phases identified by other workers (13, 14). The multiplicity of phases complicates the interpretation of optical data considerably, particularly because the phases are perhaps better thought of as a family of related compounds of variable composition rather than as distinct phases (15), but $Ni(OH)_2$ and NiOOH have such distinctive optical properties, the former being transparent and the latter strongly absorbing, that it is easy to identify even very thin films of each and to identify the reversible reaction which converts one into the other.

Experimental

The optical measurements were made with a self-nulling ellipsometer which has been described in detail elsewhere (16). The instrument uses a helium-neon laser as a light source, and all refractive indexes quoted in this paper are for $\lambda = 6328$Å. Under the optical conditions encountered in this study, the instrument has a nulling time of less than 1 sec with a resolution of 0.01°. The hollow equilateral glass prism used as a cell requires that the ellipsometer be set for an angle of incidence of 60°. The cell is fitted with standard-taper joints for mounting the nickel working electrode, a platinum counterelectrode, a mercurous sulfate reference electrode, and a gas dispersion tube used for saturating the electrolyte with argon. Measurements were made at room temperature (23°C), and all potentials quoted are relative to the mercurous sulfate reference electrode.

A cylindrical electrode with a flat on one side for optical measurements was prepared from a single crystal of nickel. When mounted between Teflon washers in the electrode holder, a surface area of 1.25 cm^2 is exposed to the electrolyte. The optical surface was prepared by diamond polishing, then the sample was chemically polished prior to a final electropolish in 50% H_2SO_4. This final treatment was chosen in order to make our work directly comparable to that of MacDougall and Cohen (6-9), but we found that we could reduce the film left after chemical polishing just as easily as we could the film left after electropolishing. Two electrolytes were used in this study: 0.15N Na_2SO_4, and an equivolume mixture of 0.15N sodium borate and 0.15N boric acid. The borate electrolyte has a pH of 8.4, but the sulfate electrolyte is unbuffered, and varying its nominal pH over the range from 6.1 to 9.1 had litle effect on the experimental results.

The circuitry used with the cell is controlled by a HP 2114B minicomputer which records optical and electrochemical data at 1 sec intervals and records open-circuit transients for overpotential analysis at programmed intervals. The technique we use to record and analyze open-circuit transients has been described in detail elsewhere (17).

Results and Discussion

The first two figures show the results obtained when a nickel electrode undergoes two sequential anodic-cathodic cycles at 80 $\mu A/cm^2$ in 0.15N Na_2SO_4. Figure 1 combines a plot of potential *vs.* time with a P-A plot of the optical data, where P and A are the null settings of the polarizer and analyzer prisms of the ellipsometer. Corresponding points are given the same label on the P-A and V-t plots in Fig. 1 on the P-t plot in Fig. 2, and on the theoretical optical model curves in Fig. 3. The optical data obtained during this simple experiment provide a great deal of information about the processes involved at the various stages of the experiment. In the following paragraphs we look at each stage in sequence and discuss the interpretation of the optical data obtained during that stage.

The experiment begins at point A just after the electropolished nickel electrode is inserted into the optical cell. The initial cathodic cycle is carried out galvanostatically until the potential reaches −1.350V, then the potential is held at this value for 60 sec. During the first 20 sec of the cathodic cycle, the optical data shift

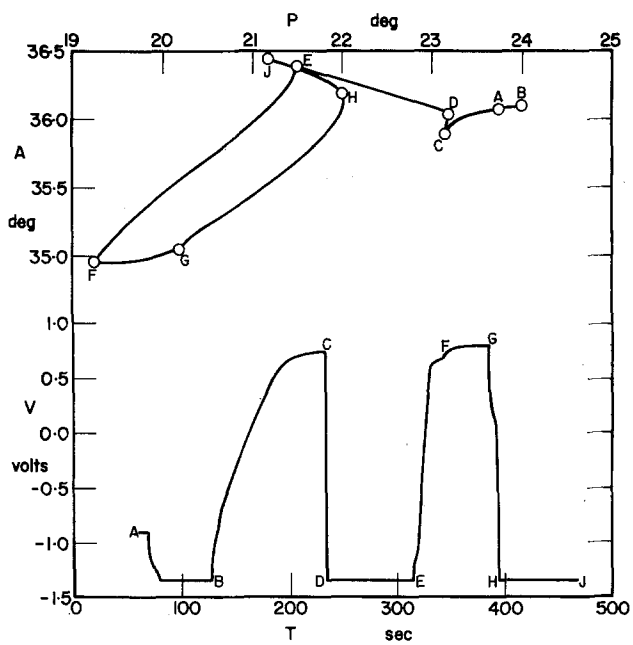

Fig. 1. Alternate cathodic (A-B, C-D-E, G-H-J) and anodic (B-C, E-F-G) cycling of a nickel electrode at 80 $\mu A/cm^2$ in 0.15N Na_2SO_4. The experiment begins at point A with the electropolished nickel electrode under open circuit in the optical cell.

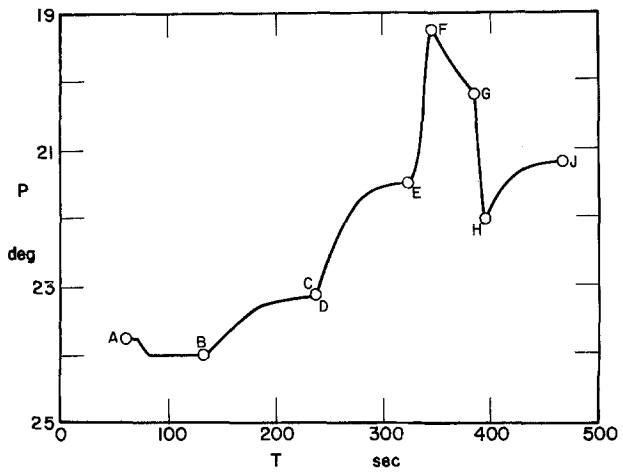

Fig. 2. Polarizer null position vs. time data for the experiment plotted in Fig. 1. Corresponding points have the same labels in the two figures.

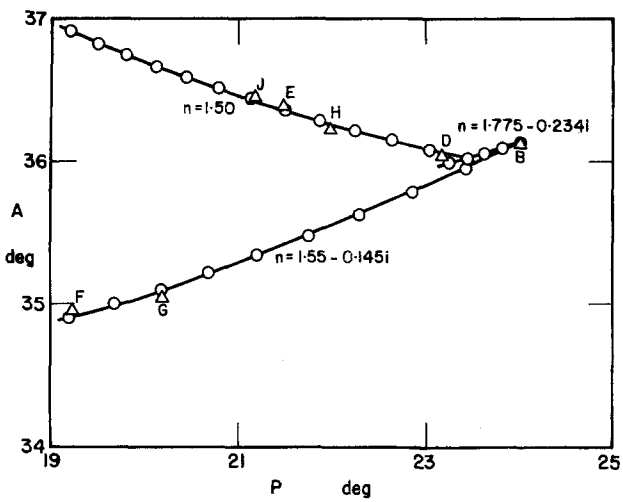

Fig. 3. Optical model for the experiment plotted in Fig. 1. The experimental points represented by triangles are the points with corresponding labels from Fig. 1. The thickness interval between plotted points is 4Å for the film with index 1.775 — 0.234i, and 20Å for the films with indices 1.50 and 1.55 — 0.145i.

toward higher P-values, indicating that a film is being removed from the surface. After this period, the optical data show no further change, implying that the nickel surface is film free. Similar results are obtained with nickel electrodes which have been chemically polished just prior to insertion in the optical cell. The reaction products resulting from film removal show no tendency to deposit on the nickel surface. Even if reaction products are allowed to build up in the electrolyte by performing several experiments in sequence, the only evidence for $Ni(OH)_2$ deposition during a 10 min cathodic cycle is a shift of 0.02° in P. If the concentration of nickel is increased still further by adding $NiSO_4$ to the electrolyte, it requires on the order of 3 min before deposition of $Ni(OH)_2$ begins. Once $Ni(OH)_2$ begins to deposit, the deposition rate increases with time. It appears that nucleation of a nickel hydroxide film on a bare nickel surface does not take place readily in neutral deaerated sulfate electrolyte. We have found that $Ni(OH)_2$ deposits readily on nickel in air-saturated nickel nitrate electrolyte (11), but deposition begins before the initial film is completely removed from the surface. We conclude that no significant thickness of surface film is present on the nickel electrode at point B in Fig. 1.

The first galvanostatic anodic cycle begins at point B and continues to point C. During the cycle, a series of open-circuit transients are recorded at 0.1V intervals from —0.6 to 0.7V. The optical data indicate that a thin film grows on the nickel surface during the anodic cycle. The P-t data in Fig. 2 show that the growth rate is constant over the region where the potential increases linearly with time and that the growth rate slows as the potential approaches a plateau. These features are characteristic of film growth by galvanostatic oxidation of the substrate. As point C is approached, the optical P-A data in Fig. 1 begin to deviate from the linear relation observed at lower potentials. Our optical model in Fig. 3 interprets the displacement in the optical data from B to C as resulting from the growth of a film of index 1.775 — 0.234i to a thickness of just under 18Å on a substrate of index 2.147 — 4.239i.

The layer-removal process which takes place during the first cathodic cycle is not observed on the second cathodic cycle. When the current is reversed at point C, the optical data trace out the curve C-D-E in the P-A plane. The initial jump to point D does not show up on the P-t plot in Fig. 2 because little P shift is involved. The displacement in the optical data from D to E is indicative of further film growth, and the slope of the P-A curve shows that the index of the additional film differs from the index of the film grown during the first anodic cycle. In our work on conversion reactions involving $Ni(OH)_2$ films (11, 12) we found that displacements in the optical data of the type observed between D and E result from the deposition of nonabsorbing films of $Ni(OH)_2$ with refractive index 1.50. The P-t data show that the deposition begins rapidly, then slows as the electrolyte adjacent to the working electrode becomes depleted of nickel ions. A minor variation of the experiment demonstrates this point very clearly. If the optical nulling is interrupted for 10 sec at point C to allow the working electrode assembly to be loosened in its standard taper joint and flicked once or twice to disperse reaction products into the bulk electrolyte, the optical displacement from D to E disappears completely from the subsequent cathodic cycle. Instead, the optical data continue to drift slowly in the C-D direction and tend toward a point on a curve through B parallel to D-E. From this we conclude that the oxide film formed on the first anodic cycle cannot be removed from the nickel surface by cathodic reduction and converts only slowly to $Ni(OH)_2$ under extended cathodic reduction. There is some evidence that this slow conversion takes place also under the deposited layer of $Ni(OH)_2$. In Fig. 3, the model assumes that deposition of $Ni(OH)_2$ takes place on top of a 12Å layer whose thickness does not change during the deposition. If we assume that the oxide film formed on the first anodic cycle is NiO and use x-ray data to estimate that conversion of NiO to $Ni(OH)_2$ results in a film 2.13 times as thick, we can estimate a value for the refractive index of the NiO film. This is the way in which the value 1.775 — 0.234i used in our model was obtained. The strength of our optical model lies more in its success in identifying the nature of the various processes involved than in the specific numbers it presents for film thicknesses and indexes.

The second anodic cycle has a much steeper V-t slope than the first, and it has an additional plateau at the high potential end. The optical data provide a clear picture of the processes involved on the second anodic cycle. Both the P-A data and the P-t data show a sharp inflection at the end of the first plateau, indicating that quite different processes are involved in regions E-F and F-G. The very rapid optical changes along E-F are characteristic of a layer conversion process. The reaction involved in this process, the oxidation of $Ni(OH)_2$ to form NiOOH, has been studied extensively in work on the nickel battery electrode.

We have studied the conversion of $Ni(OH)_2$ to NiOOH over a wide range of film thicknesses (11 12), and we have determined approximate refractive indexes of the various films involved in the process. We found that the index required to fit NiOOH films in the 1000-2000Å thickness range did not fit thin films of NiOOH very well, presumably because the structure and water content of NiOOH films formed under these conditions vary somewhat with film thickness. The index chosen in our optical model, 1.55 — 0.145i, is a compromise value which gives a NiOOH to $Ni(OH)_2$ film thickness ratio of approximately 1.5. In the model the NiOOH film is put directly on the substrate, implying that the underlying NiO film converts to NiOOH. Although our identification of the conversion process from $Ni(OH)_2$ to NiOOH relies on other work we have done, the process which takes place along F-G provides striking confirmation of our identification. At point F the optical *P-A* data inflect sharply and start to trace their way back along the theoretical curve representing the growth of NiOOH. According to our optical model, approximately 40Å of the NiOOH film dissolves between F and G. If we were to continue the anodic cycle the optical data would continue to work their way back along the curve toward point C as the NiOOH layer dissolves. With this background we interpret the dip in the optical data as the first anodic cycle approaches point C as resulting from the conversion of NiO to NiOOH which dissolves at a rate which balances its formation rate in the steady state. In unstirred electrolyte, we find a correlation between the time spent on the plateau at C and the thickness of $Ni(OH)_2$ film subsequently deposited. From this we conclude that the dissolution of NiOOH is the primary source of the nickel ions for the deposition of $Ni(OH)_2$ along D-E.

Once our understanding of the processes involved has reached this level, we can predict the results of further cycling. Provided we do not disperse the reaction products produced along F-G into the bulk electrolyte, a cathodic cycle initiated at point G will result first in a fast conversion reaction followed by a sharp inflection in the optical data as deposition of $Ni(OH)_2$ begins. The deposition of $Ni(OH)_2$ will begin rapidly and will slow in much the same way as it did at point E. This prediction is exactly what is observed experimentally. At this point we can say that our optical data have given us a fairly complete picture of the processes involved when a nickel electrode is cycled in neutral sulfate electrolyte.

We next deal with the question of whether the results we have obtained in sulfate electrolyte apply generally to the behavior of nickel in neutral electrolyte. We know from our optical work on the deposition of FeOOH films in neutral electrolyte (18) that deposition processes can be quite different in borate and sulfate electrolyte. The results of an experiment similar to the one described above but performed in neutral borate electrolyte are presented in *V-t* and *P-A* plots in Fig. 4 and in a *P-t* plot in Fig. 5. In this experiment we use a 10 min initial cathodic cycle instead of the 1 min cycle used in sulfate electrolyte, but this does not affect the results obtained on subsequent cycles. The initial anodic cycle starts off the same way as in sulfate electrolyte, but as the potential levels onto a plateau, the *P-t* curve shows an increase in slope, and the *P-A* data start to trace out the curve we used to represent the growth of NiOOH in the optical model. The rate of growth of NiOOH decreases with time, but if the anodic cycle is continued long enough several thousand angstroms of a film with the characteristic black appearance of NiOOH can be grown on the electrode. The NiOOH film can be converted to a transparent film of $Ni(OH)_2$ by cathodic reduction as is illustrated by cycle C-D-E, but there is no evidence of deposition of $Ni(OH)_2$. The second anodic cycle, E-F-G, converts the film back to NiOOH and causes it to continue growing slowly.

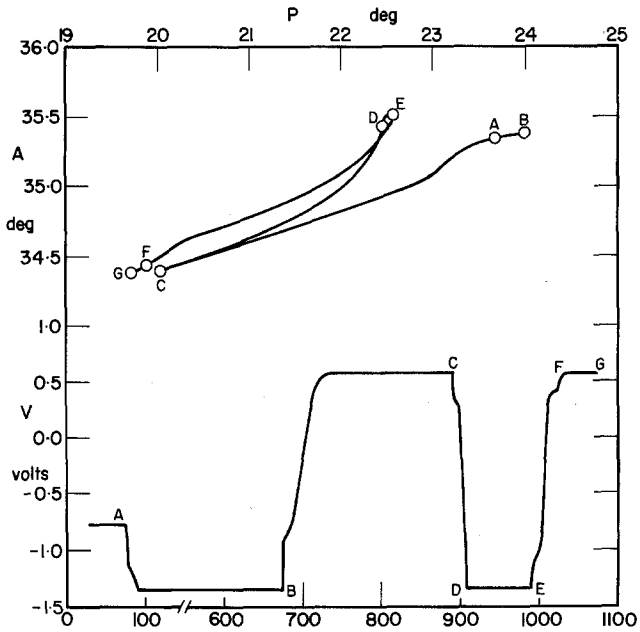

Fig. 4. Alternate cathodic (A-B, C-D-E) and anodic (B-C, E-F-G) cycling of a nickel electrode at 80 $\mu A/cm^2$ in a borate buffer of pH 8.4. The experiment begins at point A with the electropolished nickel electrode under open circuit in the optical cell.

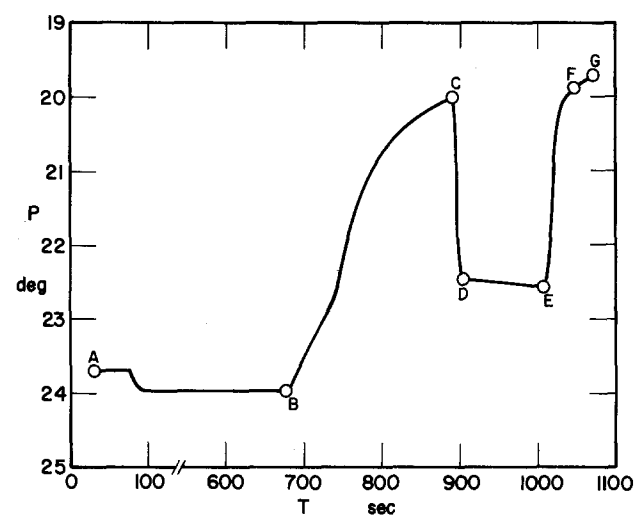

Fig. 5. Polarizer null position vs. time data for the experiment plotted in Fig. 4. Corresponding points have the same labels in the two figures.

Depending on our viewpoint, we can either regard the results obtained in borate as very different from or very similar to the results obtained in sulfate electrolyte. Certainly the results appear very different if one compares only the first anodic cycle in borate with the first anodic cycle in sulfate, but if an over-all comparison is made the basic processes involved are seen to be very similar. In fact the only significant difference between the electrolytes concerns what happens when NiOOH begins to dissolve. In sulfate electrolyte the reaction products remain in solution in the electrolyte adjacent to the electrode, but in borate electrolyte they deposit back on the surface. As a result, film growth occurs on the anodic cycle in borate and on the cathodic cycle in sulfate electrolyte. The optical model used to fit the sulfate data fits the data obtained in borate electrolyte equally well.

Now that we have determined the extent to which growth and conversion of nickel hydroxide films are

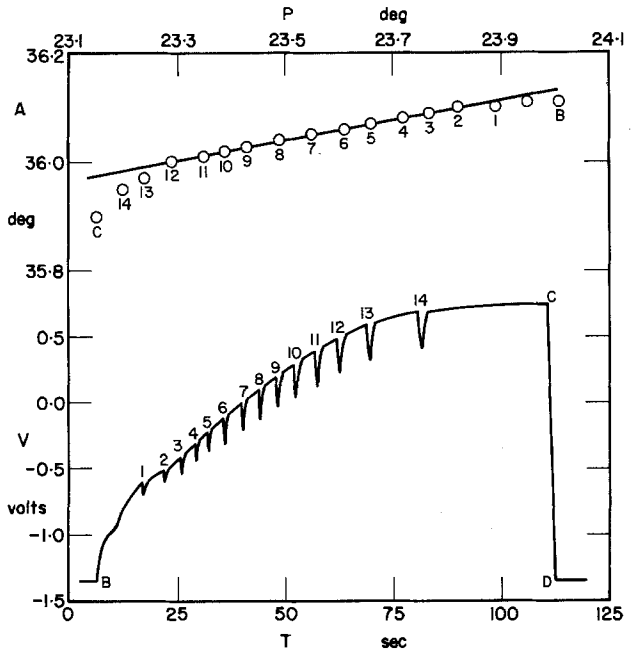

Fig. 6. Expanded scale plot of the first anodic cycle of the experiment plotted in Fig. 1. The open-circuit transients applied at 0.1V intervals from —0.6 to 0.7V are numbered sequentially.

involved in the first two anodic-cathodic cycles, we turn our attention to a more detailed study of the oxidation of the nickel substrate. The first anodic cycle from the experiment in Fig. 1 is replotted on an expanded scale in Fig. 6. Fourteen open-circuit transients are recorded at 0.1V intervals from —0.6 to 0.7V. The corresponding optical data are shown on a *P-A* plot in the upper portion of the figure. The line through the optical data is taken from the theoretical model in Fig. 3. In the model, the bare substrate point lies 0.025° higher in A than the experimental bare substrate point B. The optical data fall on the theoretical line between open-circuit points 2 and 12, then inflect downward toward point C.

Perhaps the most direct way to determine whether or not the substrate oxidation process is limited by the field in the oxide film is to plot potential *vs.* film thickness at constant current density. In Fig. 7, the data

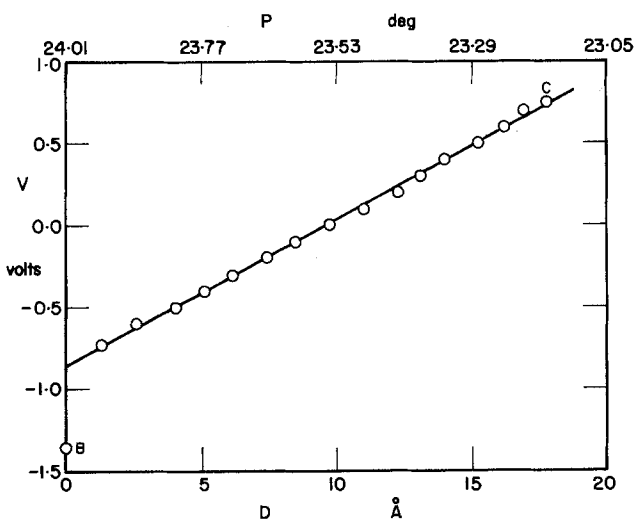

Fig. 7. Plot of potential *vs.* polarizer null position and film thickness for the data in Fig. 6. Film thicknesses are taken from the optical model in Fig. 3. The least squares line fitted to all the points except point B has a slope of 8.9 × 10^6 V/cm, and an intercept on the potential axis of —0.852V.

from Fig. 6 are replotted using two scales for the abscissa: the directly measured quantity *P* and the film thickness from the optical model for a film of index 1.775 — 0.234i. The three high potential points are projected onto the theoretical line along a line of slope 4 in the *P-A* plane which they trace out experimentally on open circuit. The line in Fig. 7 is a least squares line fitted to all of the data except the initial bare surface point. The least squares estimate of the deviation of the points from the line, 0.02V, over a potential range of almost 1.5V, shows that the voltage depends linearly on film thickness and, hence, that the field in the film is constant even on the potential plateau at C. The slope of the line gives the field in the film, 8.9 × 10^6 V/cm, and its intercept on the potential axis gives the zero of overpotential for substrate oxidation, —0.852V. Note that our value for the field depends on our choice of film index; had we chosen a higher film index more in line with that used by other workers, our field value would have been correspondingly higher.

Although the plot in Fig. 7 shows that the field is constant during oxidation at constant current density, it does not prove that the field in the oxide film controls the current density. To show that the field controls the current density we must determine the dependence of current density on potential and show that it is consistent with field control rather than potential control of the process. The dependence of current density on potential can be determined for the experiment plotted in Fig. 6 by analyzing the open-circuit transients. The dependence of potential on time is analyzed as the current density falls from 80 to 10 μA/cm^2 during the self-discharge of the layer capacitance. An exponential dependence of current density on overpotential is assumed in the form

$$i = i_0 \exp((V - V^*)/V_0) \qquad [1]$$

where i_0 is the exchange current density, V^* is the zero of overpotential, and V_0 is a Tafel slope defined in terms of natural logarithms. Analysis of a transient determines V_0 along with the layer capacitance *C*, but i_0 and V^* can only be determined by making further assumptions about data obtained from a set of open-circuit transients. The Tafel slope, V_0, is the critical parameter for distinguishing between field and overpotential control of a process: If V_0 is independent of film thickness, the process is overpotential limited, and if V_0 is proportional to film thickness, the process is limited by the field in the film. If V_0 turns out to be proportional to film thickness, we expect the reciprocal capacitance, 1/*C*, to be proportional to film thickness also.

V_0 and 1/*C* values determined by analyzing the open-circuit transients in Fig. 6 are plotted *vs.* film thickness in Fig. 8. The dependence of V_0 and 1/*C* on film thickness is not as simple as the dependence of potential of film thickness plotted in Fig. 7. The V_0 values show a monotonic increase approximately proportional to potential through transient 11, then decrease somewhat for the final three transients. The 1/*C* values, on the other hand, increase monotonically for only the first 5 transients before turning over. There is no question but what the V_0 values indicate field control of the process, increasing as they do by a factor of 4.5 between transients 1 and 11, but the 1/*C* values are certainly not proportional to film thickness. On the basis of these results and the fact that the optical data in this region do not fall on a straight line through the bare substrate point, we conclude that as the oxide film grows beyond monolayer thickness at a current density of 80 μA/cm^2, its oxidation state becomes progressively higher than that of NiO. The capacitance of an oxide film appears particularly sensitive to a progressive change in the oxidation state of the film (19).

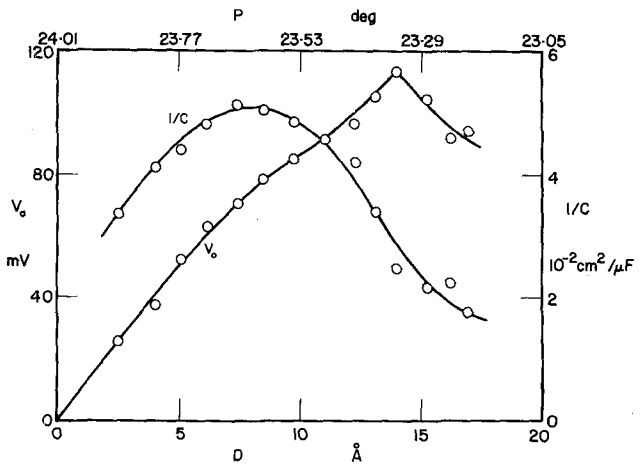

Fig. 8. V_o and 1/C determined from analysis of the open-circuit transients in Fig. 6 plotted vs. polarizer null position and film thickness from the optical model in Fig. 3.

Results similar in most respects to those plotted in Fig. 6, 7, and 8 are obtained when open-circuit transients are applied during the first anodic cycle in borate electrolyte. The potential-thickness plot indicates that the field in the film is constant up to the point where growth of NiOOH begins. The V_o values turn over a bit sooner in borate electrolyte, indicating that a single phase NiO oxidation model is less applicable than it is in sulfate electrolyte. All factors considered, the sulfate electrolyte appears to provide a bit "cleaner" system than borate electrolyte for studying the anodic oxidation of nickel.

Conclusions

1. The film left after chemical polishing or electropolishing is removed from the nickel surface within 30 sec under cathodic reduction at 80 $\mu A/cm^2$ in neutral electrolyte. $Ni(OH)_2$ does not deposit on the bare nickel surface even in contaminated electrolyte unless the nickel electrode is held cathodic longer than a nucleation time of over 100 sec.

2. The anodic oxidation of a nickel substrate is limited by the electric field in the oxide film. The film thickness increases uniformly with potential under galvanostatic oxidation, but the oxidation state of the film does not appear to remain constant under these conditions.

3. Formation of NiOOH occurs on the potential plateau at the end of an anodic cycle. It is soluble in sulfate electrolyte and does not build up on the surface as a film. If a film of NiOOH is formed in sulfate electrolyte by oxidation of $Ni(OH)_2$, the film thickness begins to decrease as soon as the film is converted to NiOOH. In borate electrolyte a film of NiOOH builds up on the potential plateau at the end of an anodic cycle. Under extended oxidation in borate electrolyte, the film will reach a thickness of several thousand angstroms.

4. On a cathodic cycle two processes take place at widely separated potentials: reduction of NiOOH to $Ni(OH)_2$ on a plateau at high potential and deposition of $Ni(OH)_2$ at low potential in competion with hydrogen evolution. Deposition of $Ni(OH)_2$ is appreciable only when dissolution of NiOOH has raised the nickel concentration in the electrolyte adjacent to the electrode just prior to the cathodic cycle.

Formation of Thick Layers of Iodine During the Anodic Oxidation of Iodide on a RDE

II. Open-Circuit Behavior

T. Bejerano

ABSTRACT

The open-circuit behavior of iodine layers formed on a RDE during the anodic oxidation of iodide was investigated. A plateau in potential was observed. Its value was found to depend on the concentration of free iodine in solution, and its length on the amount of iodine on the surface. It was shown that the sudden change in the nature of the iodine layer associated with the sharp decrease in current is not due to a phase transformation from supercooled liquid to solid iodine. The rate of decay of potential on open circuit from steady state can be used to estimate the average diffusion coefficient of NaI in the iodine layer. The experimental observations are consistent with a model in which I^- ions migrate or diffuse through the layer of I_2 and are oxidized at the metal/I_2 interface, while iodine is being dissolved at the I_2/solution interface. Steady state is reached when the rates of these two processes become equal.

Formation of thick layers of iodine during the oxidation of iodide in acid solutions has been observed by several investigators (1-7). In the first paper in this series (8) the phenomenon was studied on a rotating-disk electrode in acid and neutral solutions. It was observed that as the potential was stepped to a value in the limiting current region (+0.15V *vs.* mercury/mercurous sulfate electrode, MSE), the current first assumed its expected limiting value i_L, dropped suddenly after a few seconds to about 20% of this value, and then increased slowly to a steady-state value i_S. The ratio of i_S/i_L was found to be independent of the rate of rotation. An equation relating this quantity to the composition of the solution, the solubility of iodine in the supporting electrolyte, and the stability constant for the I_3^- ion was developed and tested. The thickness of the iodine layer was measured as a function of time during the anodic transient by determining the total cathodic charge, Q_c, required to reduce it. The film formed initially had very little effect on the current, although its thickness reached several hundred molecular layers. After a certain transition time a sudden change in the nature of the iodine layer occurred, which caused about a fivefold decrease in current. This was followed by slow dissolution of part of the film, accompanied by a corresponding increase in current until a steady state was reached. At steady state the current was typically 0.4-0.6 of the calculated limiting current, while the iodine film was 50-200 molecular layers thick.

The nature of the film formed initially and that existing at steady state is not known. It has been suggested by Gokhshtein (3-6) that iodine is first formed as supercooled liquid droplets which are suddenly solidified. In our previous work (8) the preliminary value of the specific resistance of the initially formed film was found to be $\rho_1 = 8 \times 10^4\ \Omega$ cm, and just after the transition the resistance rose to $\rho_2 = 2.4 \times 10^6\ \Omega$ cm, in a 0.02M NaI solution. The purpose of this paper is to investigate further the nature of the two films formed by observing the open-circuit behavior in different stages of formation of the film.

Experimental

The experimental procedure was exactly as described in the first paper in this series (8). Extensive use was made of the transient recorder, which allowed fast measurements of the open-circuit decay transients with slow recording on a strip chart recorded for maximum accuracy. All solutions used in this part of the work contained a certain amount of iodine, and a platinum wire dipping into the solution served as a reversible iodine reference electrode (RIE). All potentials reported are hence *vs.* a RIE in the same solution. The potential of this reversible electrode was measured against a SCE and calculated on the normal hydrogen scale. In a typical case of 9 mM NaI, 0.6 mM I_2, and 0.5M H_2SO_4 the measured value of the RIE was +0.629V NHE while the calculated value, neglecting activity coefficients, was 0.622V NHE.

Results

The potential of the plateau E_p and its length τ_p.— Following anodic oxidation for a desired length of time t_a, the potentiostatic circuit was rapidly opened with the aid of a mercury wetted switch, and the decay of potential with time was recorded. Three typical decay curves are shown in Fig. 1(a), taken at different times during the anodic oxidation transient. The length of the plateau τ_p is defined in this figure. The potential of the plateau E_p is the same, independent of the time t_a at which open-circuit measurement was started. Thus the low resistance film formed initially and the high resistance film formed after the transition time and maintained at steady state give rise to the same value of E_p. This behavior was reproduced independent of the composition of the solution or the angular velocity of the electrode.

Figure 1b shows the length of the plateau τ_p as a function of t_a in the same experiments. The variation of the cathodic charge required to reduce the iodine layer is also given in the same figure, together with the current/time transient. It is seen that the length of the plateau τ_p exhibits the same kind of variation with t_a as the thickness of the iodine layer, as expected. At the end of the plateau the potential rapidly

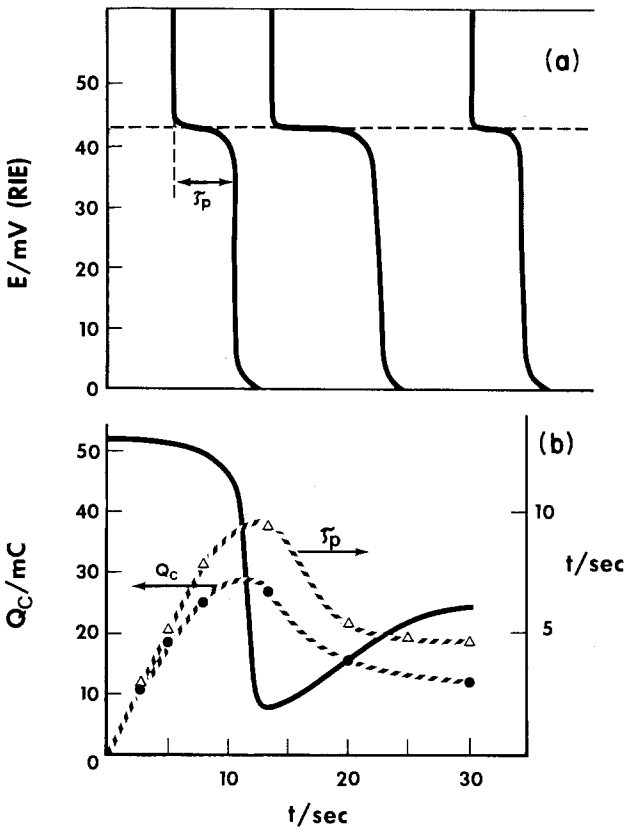

Fig. 1. (a) Open-circuit decay transients starting from +0.15V vs. RIE; (b) the length of the plateau τ_p and the cathodic charge Q_c required to reduce the iodine layer, as a function of time, for the same experiment, 9 mM NaI; 0.6 mM I_2, 0.5M H_2SO_4, 2500 rpm. Solid line shows variation of current with time.

decays to zero, *i.e.*, to the reversible I_2/I^- redox potential in the same solution. Open-circuit decay curves taken in a dilute solution where a film of iodine is not found (0.9 mM I^-, 0.06 mM I_2) were smooth and showed no plateau or inflection.

Values of Q_c and τ_p are shown in Table I for two different rates of rotation in a solution of 9 mM NaI, 0.6 mM I_2, and 0.5M H_2SO_4. Dividing Q_c by τ_p for each measurement gives the average rate of dissolution for the layer formed up to the time t_a at which open-circuit measurement was started.

The rate of decay to the plateau.—The rate of decay of open-circuit potential toward the plateau is shown in Fig. 2 as a function of t_a, for a solution of 18 mM NaI, 1.2 mM I_2; 0.5M H_2SO_4 at 400 rpm. The transition time in this experiment was t_c = 14.2 sec. It is noted that open-circuit decay is much slower at the early part of the anodic transient ($t_a < t_c$) than at longer times. The same behavior was observed in all

solutions and at all angular velocities. The lowest time to reach the plateau always occurred at the point where the anodic current had its minimum value, *i.e.*, for values of t_a slightly larger than t_c. As the angular velocity increases, the rate of open-circuit decay also increases, as is discussed below.

Discussion

The potential of the plateau.—The potential of the plateau observed in different solutions is given in Table II. To attempt to calculate this potential, two assumptions will be made: (*i*) the activity of iodine at the electrode surface is constant, and (*ii*) the concentration of iodide in the iodine phase is proportional to its concentration in the bulk of the solution. The potential of the plateau E_p (NHE) *vs.* the normal hydrogen electrode under these conditions will be

$$E_p(\text{NHE}) = E' - \frac{RT}{\mathbf{F}}\ln[I^-] \qquad [1]$$

where the constant E' includes the terms for the activity of iodine and the distribution coefficient of I^- between the iodine phase and the solution. The reversible potential for the I_2/I^- couple is given by

$$E_r = E^\circ + \frac{RT}{2\mathbf{F}}\ln[I_2] - \frac{RT}{\mathbf{F}}\ln[I^-] \qquad [2]$$

where $[I_2]$ represents the concentration of free I_2 molecules in solution. The potential of the plateau E_p(RIE), measured *vs.* a reversible iodine electrode in the same solution is hence

$$E_p(\text{RIE}) = E_p(\text{NHE}) - E_r = E'' - \frac{RT}{2\mathbf{F}}\ln[I_2] \qquad [3]$$

The concentration of free I_2 is calculated from the stoichiometric concentrations of I^- and I_2 and the

Table II. The potential of the plateau and the concentration of free iodine in solution 298°K, 0.5M H_2SO_4

Concentration (mM)			E_r (mV) (calculated)	E_p (mV)		E'' (mV)
NaI	I_2	Free I_2	NHE	NHE	RIE	RIE
9	0.6	0.0825	622	665	43	10.5
18	1.2	0.0889	605	649	43	12.5
45	3.0	0.0933	582	624	42	11.0
9.7	0.15	0.0186	600	662	62	10.1

known value ($K_1 = 740$ liter/M) of the equilibrium constant for the reaction

$$I_2 + I^- \rightleftarrows I_3^- \quad [4]$$

Examination of the data presented in Table II shows that for a given ratio of concentrations of I^- and I_2 the potentials E_p(NHE) and E_r vary significantly. On the other hand the concentration of free iodine, and the potential of the plateau measured *vs.* the RHE are essentially constant. Equation [3] and the assumptions leading to it are verified by the constancy of the quantity E'' shown in Table II.

It is of particular importance to note that the value of E_p observed at $t_a < t_c$ is equal to its value at $t_a > t_c$. The free energy of transformation of supercooled liquid to solid iodine at 25°C was calculated from thermodynamic data, and found to be −0.86 kcal/mole. Hence the potential of the plateau corresponding to a liquid layer of iodine should be 19 mV higher than that corresponding to a layer of solid iodine. Thus, our experimental observations are inconsistent with the contention of Gokhshtein (3-6) that liquid iodine is initially formed on the surface. One cannot exclude the possibility, though, that liquid iodine is indeed formed under the experimental conditions employed by Gokhshtein (stationary microelectrode), but not under our present experimental conditions (at the RDE). The fact that E_p is constant throughout the anodic transient would seem to be consistent with a transition from an amorphous to a crystalline layer at the transition time t_c or from one type of crystal structure or habit to another.

The rate of dissolution of iodine at open circuit.—The average rate of dissolution of iodine at open circuit is shown in Table I for two angular velocities. The film formed initially ($t_a < t_c$) is seen to dissolve faster than the film which exists at steady state. Thus, the lower specific resistance of the film seems to be correlated with a higher rate of dissolution. At steady state the rates of dissolution $i_d = 2.7$ and 5.3 mA compare well with the observed (and calculated, cf. Eq. [12] of Ref. (8)) values of the steady-state current $i_S = 2.6$ and 5.2 mA. This observation is consistent with the model of ionic transport through the iodine layer, discussed earlier (8). According to this model iodide ions migrate through the iodine layer and are discharged at the metal/iodine film interface. At steady state the rate of the electrochemical reaction equals the rate of dissolution. At open circuit the current falls to zero, but the rate of dissolution is not affected as long as the layer of iodine on the surface lasts. This is not the case in the early part of the anodic transient. For the conditions shown in Fig. 1, the initial current is $i_L = 5.2$ mA, and the rate of formation of the iodine layer (measured as the initial slope of Q_c *vs.* t_a) is 3.8 mA. Thus the rate of dissolution is only 1.4 mA, compared to the value of 3.9 mA given in Table I for the rate of dissolution at open circuit. The difference is due to the fact that during the early part of the transient the current is close to the limiting current, and the concentration of I^- at the surface is close to zero. The rate of dissolution is then controlled by the rate of diffusion of I_2 away from the surface. As the circuit is opened, the concentration of I^- quickly reaches a finite value at the surface, and dissolution of iodine is enhanced by the formation of I_3^- ions.

The rate of decay of potential toward the plateau.—A typical set of decay curves is shown in Fig. 2. In each case the electrode was polarized to +0.15V RIE, and the decay transient followed for about 0.3 sec. In Table III the length of the decay transient, defined as the time taken for the potential to reach +55 mV RIE (*i.e.*, 90% of the total change of potential from its initial value to the plateau) is given for three different rates of rotation. The thickness of the Nernst diffusion layer δ and the time of relaxation of this layer, are also given for comparison. The latter was calculated from the relationship

$$\delta = \sqrt{\pi D t} \quad [5]$$

where $D = 1.36 \times 10^{-5}$ cm²/sec is the average diffusion coefficient of I^- and I_2.

Table III. Rate of decay of potential on open-circuit toward the plateau

18 mM NaI; 1.2 mM I_2; 0.5M H_2SO_4

Angular velocity (rpm)	Diffusion layer thickness (cm)	Relaxation time of diffusion layer (m sec)	Decay time of transient (m sec)	
			$t_a < t_c$	$t_a > t_c$
400	3.0×10^{-3}	200	270	83
2,500	1.2×10^{-3}	33	30	8
10,000	0.6×10^{-3}	8	7	4

It is clearly seen that for $t_a < t_c$ the length of the decay transient is essentially equal to the relaxation time of the diffusion layer at all three rates of rotation. During this initial part of the anodic transient the current is close to the limiting current and the concentration of iodide at the electrode surface is therefore close to zero. Since at this stage the resistance of the film is low and iodide migrates through it readily, there will not be a significant concentration gradient in the film, and the concentration of I^- will be close to zero throughout the film. As the circuit is opened, the concentration of I^- at the film/solution interface will relax to the value corresponding to the rate of dissolution of iodine during the plateau. Since the concentration of I^- in the film, which affects the measured potential, is proportional to its concentration at the surface, the potential will relax at the same rate, which is the rate of relaxation of the diffusion layer.

At steady state the rate of dissolution is essentially the same during the transient and at open circuit, and there is no need for the diffusion layer to relax before the potential of the plateau can be reached. It is indeed seen in Table III that for $t_a > t_c$ the decay transient is much shorter than the relaxation time of the diffusion layer. On the other hand, a concentration gradient of Na^+ and I^- ions may exist in the film, due to the relatively high electric field in it. When the current is turned off this field disappears, and the concentration of NaI throughout the film becomes uniform. The relaxation time for this process, measured as the length of the open-circuit decay transient, is inherently independent of the rate of rotation of the electrode. The dependence observed experimentally is due to the variation of the thickness of the iodine film with rotation rate.

Combining these relaxation times with independent measurements of the thickness of the iodine layer under identical conditions allows us to estimate the average diffusion coefficient of NaI in the iodine layer, employing Eq. [5].[1] The results are shown in Table IV. It is seen that the average diffusion coefficient $\bar{D}$ is about five orders of magnitude lower in the film than in the aqueous phase.

The absolute mobility of the iodide ions is probably many times higher than that of the cation due to the possibility of transfer from I_3^- to I_2 species in a Grothius-type mechanism, as discussed earlier (8). The condition of electroneutrality, however, requires that both ions migrate together as the concentration throughout the layer becomes uniform. The average diffusion coefficient is related in this case to the diffusion coefficients of the two ions by the reciprocal relationship

[1] Since measurements were taken in 0.5M H_2SO_4 it is possible that the cation dissolved in the iodine phase is H^+ rather than Na^+, or that both cations are dissolved. Thus the value of $\bar{D}$ estimated above may apply to NaI, HI, or a mixture of both in the iodine phase.

Table IV. Average diffusion coefficient of NaI in the iodine layer

18 mM NaI; 1.2 mM I_2; 0.5M H_2SO_4

Angular velocity (rpm)	Specific conductivity (Mho cm^{-1})	Thickness of iodine layer (cm)	Decay time of transient (m sec)	Average diffusion coefficient (cm^2 sec^{-1})
400	4.0×10^{-7}	7.6×10^{-6}	83	2.2×10^{-10}
2,500	5.4×10^{-7}	3.9×10^{-6}	8	6.0×10^{-10}
10,000	6.3×10^{-7}	2.5×10^{-6}	4	5.0×10^{-10}

$$\frac{1}{D} = \frac{1}{D_+} + \frac{1}{D_-} \qquad [6]$$

and since $D_- >> D_+$, one has $\overline{D} \approx D_+$, *i.e.*, the average diffusion coefficients given in Table IV are essentially equal to the diffusion coefficient of the cation in the iodine layer. The specific conductivity depends on a simple sum of the diffusion coefficients or the absolute mobilities of the ions, and will hence be related to D_- in the present system. It may be said that for concentration changes in the film the movement of the ions is coupled in series while for ionic conductivity it is coupled in parallel. The slower moving ion controls the rate of the former process, while the faster moving ion controls the rate of the latter.

Conclusions

The purpose of this part of the work was to study the open-circuit behavior of rotating-disk electrodes upon which a layer of iodine had been formed. A plateau in potential was observed. Its length was related to the amount of iodine on the surface, but the value of the potential was independent of the time during the anodic transient when the circuit was opened. This excludes the possibility that the transition from one type of film to the other represents a phase transformation from liquid to solid iodine. A transition from amorphous to crystalline, or from one type of crystal structure to another is likely.

At steady state iodine is formed at the metal/film interface and dissolves away at the film/solution interface. This model is supported by the observations that the rate of dissolution at open circuit is equal to i_S, and the decay time of the potential to E_p is much shorter than the relaxation time of the diffusion layer. The potential of the plateau observed in different solutions was accounted for by assuming that I^- dissolved in the iodine film at a concentration proportional to its concentration in solution. The average diffusion coefficient of NaI in the iodine film was estimated. It is proposed that the values obtained are characteristic of the slower moving cation. The evidence presented in this and a previous publication (8) lends support to a model of ionic rather than electronic transport of charge through the iodine film.

Acknowledgments

The authors wish to thank Dr. E. Kirowa-Eisner of the Institute of Chemistry, Tel Aviv University for useful discussions and suggestions in the course of this work. One of us (T.B.) wishes to thank the Research and Development Authority, Ben Gurion University of the Negev for a six-month leave of absence during which most of the experimental work was done. Partial financial support for this work by the Ministry of Development is gratefully acknowledged.

This work was performed in partial fulfillment of the requirement for the degree of Ph.D. in electrochemistry by T. Bejerano at the Tel Aviv University.

Manuscript submitted May 2, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

Chemiluminescence from Step Experiments

An Analytical Treatment of Diffusion and Electron Transfer

Larry R. Faulkner*

Department of Chemistry, University of Illinois, Urbana, Illinois 61801

ABSTRACT

An analytical treatment of diffusion and electron transfer has been derived for the step technique that is employed frequently in the study of electrochemiluminescence (ECL). The two reactants leading to emission are generated sequentially in two steps, and reaction between them occurs during the second step. Each step lasts for a period t_f, and time into the second step is measured as t_r. Rigorous solutions for the concentration profiles, the current transient in the second step, and the homogeneous reaction rate have been obtained for systems in which all species have equal diffusion coefficients. Very good linear approximations for the current and the reaction rate apply to the experimentally important early part of the second step ($t_r/t_f < 0.2$). These linear formats also hold for mixed systems in which the two precursor/reactant pairs feature different diffusion coefficients. Such cases could not be treated rigorously, but they can be handled adequately via interpolation formulas that permit accurate predictions of the slopes and intercepts of the linear relations.

Since Feldberg's first suggestions in 1966 (1, 2), the analysis of luminescence transients stimulated electrochemically in step experiments has played an important role in the study of chemiluminescence from radical ion reactions (3, 4). In these experiments, one employs a planar microelectrode which is immersed in a quiescent solution containing a precursor for each reactant ion. In general, the two reactants are derived from different precursors but often both are derived from the same parent substance, *e.g.*, rubrene (R) in benzonitrile. Before the start, the electrode is held at a potential where no reaction takes place. At $t = 0$, a step is made to a potential where one reactant, *e.g.*, $R^{-\cdot}$, is electrogenerated at a diffusion-controlled rate. This process continues for a period t_f, then the potential is stepped to a value that causes electrogeneration of the second reactant, *e.g.*, $R^{+\cdot}$. This change in boundary condition at the electrode causes the first reactant to diffuse back to the interface. In so doing, it meets the outward flux of the second, and electron transfer takes place with the formation of excited states

$$R^{+\cdot} + R^{-\cdot} \rightarrow R^* + R \qquad [1]$$

Light can arise from the excited species R* by several mechanisms. Information about those mechanisms is obtained by comparing the rate of light emission I (einsteins/sec) to the rate of ion annihilation N (moles/sec) (1, 2, 5, 6). Both quantities decline as time proceeds because $R^{-\cdot}$ is consumed.

The light transient is directly measured, but the rate function N must be obtained from the theory of diffusion and reaction in the system. The problem is a complex one, and it has been treated only by digital simulation (1, 2, 4). There is evidence that simulation is a reliable approach (7, 8), but it has two serious drawbacks: It requires significant amounts of computer time; and, being a numerical technique, it offers no closed-form solutions and, consequently, it suggests no formats for analyzing experimental results.

Presented below is an analytical approach to this diffusion-kinetic problem. The results eliminate the need for digital simulation as a means for predicting either the rate function N, the faradaic current in the second step, or the concentration profiles of the reactants in solution. In addition, this treatment yields simple analytical forms for both the current and the reaction rate at earlier times in the second step, when experimental signals are greatest. These forms suggest important simplifications in the analysis of real data.

Key words: luminescence, excited state, electrogenerated chemiluminescence, Feldberg treatment.

Case I. Homomolecular Ion Annihilation

Let us consider first the experiment in which both reactant ions are generated from the same precursor, as in the example involving rubrene cited above. We designate the precursor as P, the first reactant as R_1, and the second as R_2. All three species are regarded as having equal diffusion coefficients, D. The Fick law equations are then

$$\frac{\partial C_P(x,t)}{\partial t} = D\frac{\partial^2 C_P(x,t)}{\partial x^2} + 2kC_{R_1}(x,t)C_{R_2}(x,t) \qquad [2]$$

$$\frac{\partial C_{R_1}(x,t)}{\partial t} = D\frac{\partial^2 C_{R_1}(x,t)}{\partial x^2} - kC_{R_1}(x,t)C_{R_2}(x,t) \qquad [3]$$

$$\frac{\partial C_{R_2}(x,t)}{\partial t} = D\frac{\partial^2 C_{R_2}(x,t)}{\partial x^2} - kC_{R_1}(x,t)C_{R_2}(x,t) \qquad [4]$$

where t is time measured from the start of the experiment and x is the distance into the solution from the electrode surface. The parameter k is the rate constant for the electron transfer

$$R_1 + R_2 \rightarrow 2P \qquad [5]$$

The nonlinear couplings among [2]-[4] make it difficult, and perhaps impossible, to achieve a general analytical solution. However, by adding the three equations one obtains

$$\frac{\partial \sigma(x,t)}{\partial t} = D\frac{\partial^2 \sigma(x,t)}{\partial x^2} \qquad [6]$$

where $\sigma(x,t) = C_P(x,t) + C_{R_1}(x,t) + C_{R_2}(x,t)$. Likewise, subtracting [4] from [3] gives

$$\frac{\partial \delta(x,t)}{\partial t} = D\frac{\partial^2 \delta(x,t)}{\partial x^2} \qquad [7]$$

where $\delta(x,t) = C_{R_1}(x,t) - C_{R_2}(x,t)$.

Equations [6] and [7], which were first presented by Schwartz *et al.* (9), are linear and can be solved easily to give the distributions of combined concentrations σ and δ, which must apply regardless of the rate constant k. The details are presented in the Ap-

pendix. The results are

$$\sigma(x,t) = C_P^* \quad [8]$$

$$\delta(x,t) = C_P^* \left[\operatorname{erfc}\left(\frac{x}{2(Dt)^{1/2}} \right) - 2S_{tf}(t) \operatorname{erfc}\left(\frac{x}{2(Dt_r)^{1/2}} \right) \right] \quad [9]$$

where C_P^* is the bulk concentration of the precursor, $S_{tf}(t)$ is the step function which rises from zero to unity at $t = t_f$, and t_r *is* time measured into the second step from its start, *i.e.*, $t_r = t - t_f$.

Current flow.—In the forward step, the current magnitude is simply given by the Cottrell equation for diffusion-controlled electrolysis of P

$$(t < t_f) \qquad i = \frac{FAD^{1/2}C_P^*}{\pi^{1/2}t^{1/2}} \quad [10]$$

In the second step, the current is opposite in sign. Its magnitude is given by

$$i = FAJ_P(0,t) + 2FAJ_{R_1}(0,t) \quad [11]$$

where the J's are fluxes at the electrode surface. Substitution from Fick's first law gives

$$i = FAD \left\{ \frac{\partial}{\partial x} [C_P(x,t) + 2C_{R_1}(x,t)] \right\}_{x=0} \quad [12]$$

which is

$$i = FAD \left\{ \frac{\partial}{\partial x} [\sigma(x,t) + \delta(x,t)] \right\}_{x=0} \quad [13]$$

or

$$i = FAD \left[\frac{\partial \delta(x,t)}{\partial x} \right]_{x=0} \quad [14]$$

Evaluation of the derivative gives the current in closed form

$$(t \geq t_f) \qquad i = \frac{FAD^{1/2}C_P^*}{\pi^{1/2}} \left[\frac{2}{t_r^{1/2}} - \frac{1}{t^{1/2}} \right] \quad [15]$$

or in terms of the dimensionless current parameter usually used in simulations

$$Z = \frac{it_f^{1/2}}{FAD^{1/2}C_P^*} = \frac{1}{\pi^{1/2}} \left[2\left(\frac{t_r}{t_f}\right)^{-1/2} - \left(1 + \frac{t_r}{t_f}\right)^{-1/2} \right] \quad [16]$$

The expressions [15] and [16] apply rigorously regardless of k. They were recognized empirically, but not derived, in earlier publications by Feldberg (1) and by Michael (7). Table I offers a comparison between exact Z values from [16] and simulated data taken from a model involving 1000 iterations/step and a dimensionless redox rate constant $kt_fC_P^*$ equal to 1000. That choice of rate constant implies essentially diffusion-controlled annihilation of R_1 and R_2 (1, 5, 10).

Concentration profiles.—The distributions of concentrations of P, R_1, and R_2 cannot be obtained analytically by this approach for the general case of arbitrary k. However, they can be obtained for the special case of infinite k. That limiting situation is of interest because simulation has demonstrated that the behavior of the system is virtually independent of k as long as $kt_fC_P^* \geq 1000$ (1, 11). This condition holds for nearly all experiments of the type considered here.

When $k \to \infty$, R_1 and R_2 cannot coexist (9), hence δ represents the concentration of R_1 wherever it is positive, and the concentration of R_2 wherever it is negative. The concentration of P is therefore $C_P^* - |\delta|$. Figure 1 displays these relationships.

The distance d where $\delta = 0$ marks the junction between the two reactant zones, R_1 and R_2 diffuse toward that plane from opposite directions, and they meet there and react to give light. The location of this plane is defined by

$$2\operatorname{erf}\left[\frac{d}{2(Dt_r)^{1/2}} \right] - \operatorname{erf}\left[\frac{d}{2(Dt)^{1/2}} \right] = 1 \quad [17]$$

For comparisons with simulated data, it is convenient to express d as a distance on a conventional dimensionless scale

$$X_r = d/2(Dt_f)^{1/2} \quad [18]$$

Thus, [17] can be reexpressed

$$2\operatorname{erf}\left[\frac{X_r}{(t_r/t_f)^{1/2}} \right] - \operatorname{erf}\left[\frac{X_r}{[1 + (t_r/t_f)]^{1/2}} \right] = 1 \quad [19]$$

For a given value of t_r/t_f, X_r must generally be evaluated numerically, but a very good approximation is available for small t_r/t_f, as described below.

Redox reaction rate.—The electron transfer reaction is controlled by the rates of diffusion of the reactants into the plane at d, hence

$$N = A \lim_{x \to d} J_{R_1}(x,t) = -A \lim_{x \to d} J_{R_2}(x,t) \quad [20]$$

or generally

$$N = AD \left. \frac{\partial \delta(x,t)}{\partial x} \right|_{x=d} \quad [21]$$

(Note that the equality of fluxes expressed in [20] is assured by the continuity of δ and its derivative.) The derivative is easily evaluated from [9], and one obtains

Table I. Analytical and simulated results for case I

	Z		ω_n	
t_r/t_f	Analytical	Simulated*	Analytical	Simulated*

* 1000 iterations/step, $kt_fC_P^* = 1000$.

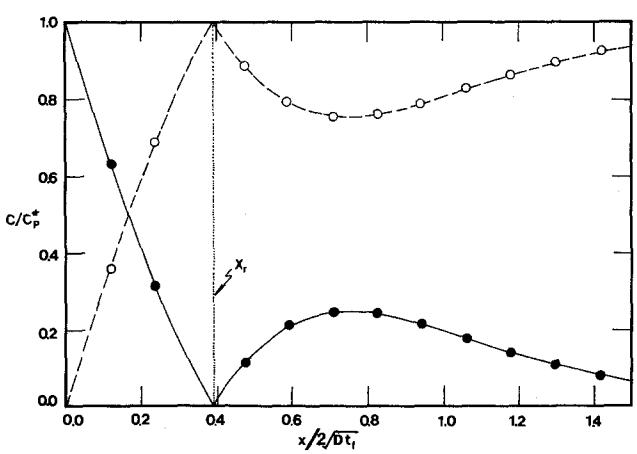

Fig. 1. Concentration profiles for $t_r/t_f = 0.3$. The reaction plane is at the dotted vertical line. Solid curve is $|\delta|/C_P^*$. To the right of the reaction plane it represents C_{R_1}/C_P^*, and to the left it is C_{R_2}/C_P^*. Dashed curve is $(\sigma - |\delta|)/C_P^*$. It represents C_P/C_P^* everywhere. Points are from a simulation involving 1000 iterations/step and $k \to \infty$.

$$N = \frac{AD^{1/2}C_P^*}{\pi^{1/2}} \left\{ \frac{2}{t_r^{1/2}} \exp\left[\frac{-d^2}{4Dt_r}\right] - \frac{1}{t^{1/2}} \exp\left[\frac{-d^2}{4Dt}\right] \right\} \quad [22]$$

This relation can be rearranged to give the familiar dimensionless reaction rate parameter

$$\omega_n = \frac{Nt_f^{1/2}}{AD^{1/2}C_P^*} = \frac{1}{\pi^{1/2}} \left\{ \frac{2}{(t_r/t_f)^{1/2}} \exp\left[\frac{-X_r^2}{(t_r/t_f)}\right] - \frac{1}{[1+(t_r/t_f)]^{1/2}} \exp\left[\frac{-X_r^2}{1+(t_r/t_f)}\right] \right\} \quad [23]$$

Table I shows a comparison between ω_n values calculated from [23] and corresponding data obtained from a simulation. The analytical results were generated in two steps. First, the value of X_r corresponding to a given t_r/t_f was calculated from [19] by the Newton-Raphson technique, then ω_n could be calculated by substitution into [23]. It is interesting that the simulated values are uniformly high by about 1.5%, despite the extreme accuracy in the Z values. Table I actually shows the first test that has been possible of the accuracy of ω_n values obtained by simulation, and it gives some feeling of the precision with which those numbers can be regarded.

Case II. Mixed System with Equal Diffusion Coefficients

Let us now examine the case in which R_1 and R_2 are derived from separate precursors P_1 and P_2, respectively, but all four species have the same diffusion coefficient, D. The diffusion-kinetic equations are then

$$\frac{\partial C_{P_1}(x,t)}{\partial t} = D\frac{\partial^2 C_{P_1}(x,t)}{\partial x^2} + kC_{R_1}(x,t)C_{R_2}(x,t) \quad [24]$$

$$\frac{\partial C_{P_2}(x,t)}{\partial t} = D\frac{\partial^2 C_{P_2}(x,t)}{\partial x^2} + kC_{R_1}(x,t)C_{R_2}(x,t) \quad [25]$$

$$\frac{\partial C_{R_1}(x,t)}{\partial t} = D\frac{\partial^2 C_{R_1}(x,t)}{\partial x^2} - kC_{R_1}(x,t)C_{R_2}(x,t) \quad [26]$$

$$\frac{\partial C_{R_2}(x,t)}{\partial t} = D\frac{\partial^2 C_{R_2}(x,t)}{\partial x^2} - kC_{R_1}(x,t)C_{R_2}(x,t) \quad [27]$$

where k is now the rate constant for

$$R_1 + R_2 \rightarrow P_1 + P_2 \quad [28]$$

The sum of [24] and [26] gives

$$\frac{\partial \sigma_1(x,t)}{\partial t} = D\frac{\partial^2 \sigma_1(x,t)}{\partial x^2} \quad [29]$$

where $\sigma_1 = C_{P_1}(x,t) + C_{R_1}(x,t)$. Likewise the sum of [25] and [27] gives

$$\frac{\partial \sigma_2(x,t)}{\partial t} = D\frac{\partial^2 \sigma_2(x,t)}{\partial x^2} \quad [30]$$

where $\sigma_2(x,t) = C_{P_2}(x,t) + C_{R_2}(x,t)$. Finally, the difference between [26] and [27] gives [7], where $\delta(x,t)$ is defined as before.

Solution of these equations by the methods used for case I shows that

$$\sigma_1(x,t) = C_{P_1}^* \quad [31]$$

$$\sigma_2(x,t) = C_{P_2}^* \quad [32]$$

$$\delta(x,t) = C_{P_1}^* \operatorname{erfc}\left[\frac{x}{2(Dt)^{1/2}}\right] - S_{t_f}(t)[C_{P_1}^* + C_{P_2}^*] \operatorname{erfc}\left[\frac{x}{2(Dt_r)^{1/2}}\right] \quad [33]$$

Similarly, we obtain the key results for $t \geq t_f$

$$Z = \frac{it_f^{1/2}}{FADC_{P_1}^*} = \frac{1}{\pi^{1/2}} \left[(1+r_C)\left(\frac{t_r}{t_f}\right)^{-1/2} - \left(1+\frac{t_r}{t_f}\right)^{-1/2} \right] \quad [34]$$

$$(1+r_C)\operatorname{erf}\left[\frac{X_r}{(t_r/t_f)^{1/2}}\right] - \operatorname{erf}\left[\frac{X_r}{[1+(t_r/t_f)]^{1/2}}\right] = r_C \quad [35]$$

$$\omega_n = \frac{Nt_f^{1/2}}{FAD^{1/2}C_{P_1}^*} = \frac{1}{\pi^{1/2}} \left\{ \frac{(1+r_C)}{(t_r/t_f)^{1/2}} \exp\left[\frac{-X_r^2}{(t_r/t_f)}\right] - \frac{1}{1+(t_r/t_f)^{1/2}} \exp\left[\frac{-X_r^2}{1+(t_r/t_f)}\right] \right\} \quad [36]$$

where $r_C = C_{P_2}^*/C_{P_1}^*$.

Comparisons between these analytical results and simulated values of Z and ω_n for mixed systems involving various values of r_C are as satisfactory as those given in Table I for case I.

It is interesting to note that relations [34]-[35] are actually general results that include [16], [19], and [23] as the special cases for $r_C = 1$. The dimensionless current and luminescence transients for a homomolecular system are therefore identical to those of a mixed system with precursors at equal concentrations. Since this is true, we will consider only mixed systems in the arguments below.

Behavior at Short Times

From an experimental standpoint the domain of greatest interest is $0 \leq t_r/t_f \leq 0.2$, because most of the signal appears there. Simple linear equations describing the behavior of ω_n and Z in that region would be particularly useful. We shall see in this section that they are readily available.

Reaction rate.—Equation [35] can be simplified to the form

$$(1+r_C)\operatorname{erf}(p) - \operatorname{erf}(q) = r_C \quad [37]$$

where $p = X_r/(t_r/t_f)^{1/2}$ and $q = X_r/(t/t_f)^{1/2}$. At very short times into the second step, the reaction plane at distance d is very near the electrode surface. As t_r approaches zero, q approaches zero, hence the second term of [37] vanishes. Thus we find

$$\lim_{t_r \to 0} \operatorname{erf}(p) = \operatorname{erf}(p_0) = \frac{r_C}{1+r_C} \quad [38]$$

$$p_0 = \operatorname{erf}^{-1}\left(\frac{r_C}{1+r_C}\right) \quad [39]$$

Now we expand the error functions in [37] as Taylor series about their limiting arguments, and we truncate after the linear terms

$$\operatorname{erf}(p) \cong \frac{r_C}{1+r_C} + \frac{2}{\pi^{1/2}} e^{-p_0^2}(p - p_0) \quad [40]$$

$$\operatorname{erf}(q) \cong \frac{2}{\pi^{1/2}} q \quad [41]$$

Substitution into [37] gives, after rearrangement

$$p - p_0 = \frac{q}{(1+r_C)e^{-p_0^2}} \quad [42]$$

Equation [36] can be rewritten as

$$\omega_n = \frac{1}{\pi^{1/2}}\left[(1+r_C)\left(\frac{t_r}{t_f}\right)^{-1/2} e^{-p^2} - \left(\frac{t}{t_f}\right)^{-1/2} e^{-q^2}\right] \quad [43]$$

Let us now expand the two exponentials in [43] as Taylor series about the limiting arguments, and truncate after the linear terms

$$e^{-p^2} \cong e^{-p_0^2} - e^{-p_0^2}(2p_0)(p-p_0) \quad [44]$$

$$e^{-q^2} \cong 1 \quad [45]$$

Substitution of [42] into [44] gives

$$e^{-p^2} = e^{-p_0^2} - 2p_0q/(1+r_C) \quad [46]$$

and substitution of [45] and [46] into [43] yields the essentially linear form

$$\omega_n \cong a\left(\frac{t_r}{t_f}\right)^{-1/2} - b \quad [47]$$

where

$$a = (1+r_C)e^{-p_0^2}/\pi^{1/2} \quad [48]$$

and

$$b = \frac{1}{\pi^{1/2}}\left[2p_0q\left(\frac{t_r}{t_f}\right)^{-1/2} + \left(\frac{t}{t_f}\right)^{-1/2}\right] \quad [49]$$

Recognizing that $q = p(t_r/t)^{1/2}$, one can use [42] to obtain an explicit expression for q in terms of (t_r/t_f). Substitution into [49] then permits an evaluation of the time dependence of b. In general, b varies only slightly over the domain of interest. For example, with $r_C = 1$, it takes on the values of 0.821, 0.812, and 0.789, for $t_r/t_f = 0$, 0.1, and 0.2, respectively. This variation is small compared to the magnitude of ω_n for $t_r/t_f \leq 0.2$, hence, it is convenient to regard b as a constant equal to the limiting value for $t_r/t_f = 0$, which is

$$b = (2p_0^2+1)/\pi^{1/2} \quad [50]$$

Equation [47] with a and b defined by [48] and [50], is a good linear representation of ω_n in the short time region. For $r_C = 1$ the approximate value exceeds the exact one by only 0.03, 2, and 2.8% at $t_r/t_f = 0.001$, 0.1, and 0.2.

The remaining discrepancy arises mainly because [50] is too low an estimate of the mean value of b over the time range of interest. A higher value should be used, but it is not convenient to assign one precisely, because information needed for that purpose was lost by the omission of higher order terms in the Taylor expansions. A pragmatic approach is to raise b by 5%, so that we reassign

$$b = (1.05)(2p_0^2+1)/\pi^{1/2} \quad [51]$$

This expedient gives approximate values of ω_n via [47] that underestimate the exact values for $r_C = 1$ by only 0.1, 0.05, and 0.8% at $t_r/t_f = 0.001$, 0.1, and 0.2. Obviously, such accuracy is entirely adequate for comparisons with experimental results.

Current.—Equation [34] shows that Z is precisely linear against the time parameter $(1+r_C)(t_r/t_f)^{-1/2} - (t/t_f)^{-1/2}$ for all t_r/t_f. The slope is $\pi^{-1/2}$ and the intercept is zero.

Case III. Mixed System with Different Diffusion Coefficients

Of more general experimental interest than either case I or case II is the mixed system in which the two couples have different diffusion coefficients; that is, R_1 and P_1 diffuse according to coefficient D_1, while R_2 and P_2 move according to D_2. Unfortunately this change means that the analogous equations to [24]-[27] do not all involve the same diffusion coefficient, hence linear differential equations like [7], [29], and [30] cannot be obtained. Exact solutions for ω_n and Z could not be derived for this case in the present work.

Nevertheless, a series of simulations revealed that ω_n and Z gave excellent linear plots in the formats derived above. The general relations can be expressed

$$Z = \frac{it_f^{1/2}}{FAD_1^{1/2}C_{P_1}^*} = \frac{f_Z}{\pi^{1/2}}\left[\frac{(1+r_C)}{(t_r/t_f)^{1/2}} - \frac{1}{(t/t_f)^{1/2}}\right] \quad [52]$$

$$\omega_n = \frac{Nt_f^{1/2}}{AD_1^{1/2}C_{P_1}^*} = f_\omega a\left(\frac{t_r}{t_f}\right)^{-1/2} - f_I b \quad [53]$$

where a and b are defined in Eq. [48] and [51].

The simulations used for this study involved 10,000 iterations/step and $kt_fC_{P_1}^* = 10{,}000$. For each simulation the concentration ratio r_C and the ratio of diffusion coefficients, $r_D = D_2/D_1$, were constants chosen from the ranges $0.75 \leq r_C \leq 2.0$ and $0.5 \leq r_D \leq 2.0$. Plots of Z *vs.* $(1+r_C)(t_r/t_f)^{-1/2} - (t/t_f)^{-1/2}$ and ω_n *vs.* $(t_r/t_f)^{-1/2}$ were examined over the range $0.01 \leq (t_r/t_f) \leq 0.1$. Linear correlation coefficients were always equal to unity within a few parts in 10^5.

The factors f_ω and f_Z can be interpreted as ratios $(D_{eff}/D_1)^{1/2}$, where D_{eff} is an effective diffusion coefficient. In general they are nearly equal and depend on both r_C and r_D. The squares of both are essentially perfectly linear with r_D at constant r_C

$$f_Z^2 = 1 + m_Z(r_D - 1) \quad [54]$$

$$f_\omega^2 = 1 + m_\omega(r_D - 1) \quad [55]$$

The slopes m_Z and m_ω are not linear with r_C, but can be precisely expressed as

$$m_Z = 0.300 + 0.545r_C - 0.149r_C^2 \quad [56]$$

$$m_\omega = 0.330 + 0.281r_C - 0.067r_C^2 \quad [57]$$

The intercept factor f_I in [53] is linear with r_D and depends negligibly on r_C

$$f_I = 1 + 0.418(r_D - 1) \quad [58]$$

Given r_C and r_D for an experimental system, one can use [48], [51], and [54]-[58] to calculate simply and precisely the parameters that define the linear Z and ω_n functions for $t_r/t_f \leq 0.2$. As an example of reliability consider the case for $r_C = r_D = 1.25$. We find $p_0 = 0.5407$, $a = 0.9476$, and $b = 0.939$. The predicted slope of the Z plot is $f_Z/\pi^{1/2} = 0.615$, whereas the simulated value is 0.617. The predicted ω_n function is

$$\omega_n = 1.014\left(\frac{t_r}{t_f}\right)^{-1/2} - 1.04 \quad [59]$$

and that from simulation is

$$\omega_n = 1.027\left(\frac{t_r}{t_f}\right)^{-1/2} - 1.085 \quad [60]$$

Equations [59] and [60] give ω_n values that agree to within 1.5% over the whole time domain of interest. Such agreement obviates the need for further simulations of these kinds of problems unless information is needed for $t_r/t_f > 0.2$.

Examining Experimental Results

We have seen above that simple linear forms describe both Z and ω_n at earlier times during the second step. This convenience makes it particularly attractive to confine an analysis of experimental results to this region. Is there a loss in ignoring data for the $t_r/t_f > 0.2$? Probably not. In fact it may be dangerous to rely on information from that region. Not only is the later signal very low in comparison to that from the earlier period, as Fig. 2 illustrates dramatically, but in addition the later times feature much lower reactant fluxes into the annihilation zone, hence side reactions with

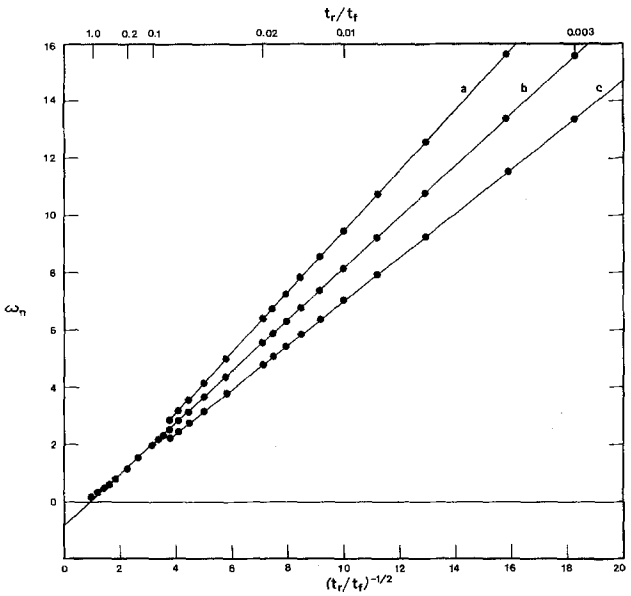

Fig. 2. Linear plots of reaction rate. (a) $r_C = 2$, (b) $r_C = 1$, (c) $r_C = 0.5$. Points are exact. Lines are the linear approximations indicated in Eq. [47], [48], and [51]. All t_r/t_f values covered here are readily accessible in typical experiments.

impurities (*e.g.*, oxygen) may compete significantly with the hoped-for electron transfer. The anomalously high slopes that are often observed in Feldberg plots may be due to this effect. One can have far greater confidence that the calculated redox rate actually holds in experimental systems at earlier times.

Is there any way to be sure it holds even there? The current transient bears importantly on this question, for it is the only observable aside from the emission decay. Its behavior can be predicted quantitatively, without adjustable parameters, on the basis of current flow in the forward step (7, 8). If the actual current in the second step matches the predicted decay, then the diffusion patterns in the system must correspond generally to those considered here. That is, $\delta(x,t)$ and $\sigma(x,t)$ would be verified. Since the current is insensitive to k, good agreement there does not guarantee that the actual ω_n is the predicted value. On the other hand, the real ω_n could be no greater than the predicted value at any time, and it could only be less if $kt_fC_{P1}^* < 1000$ (1, 11). For most experiments, $kt_fC_{P1}^*$ is probably greater than 1000 by several orders of magnitude (3, 4, 11), hence agreement between actual and predicted current transients would provide very strong evidence that the predicted ω_n applies to the real system and is a safe basis for correlating the light intensity.

APPENDIX

Equations [6] and [7] are subject to the initial conditions, $\sigma(x,0) = C_P^*$ and $\delta(x,0) = 0$, and the semi-infinite conditions, $\lim_{x\to\infty} \sigma(x,t) = C_P^*$ and $\lim_{x\to\infty} \delta(x,t) = 0$. Laplace transformation of [6] and [7] yields two ordinary differential equations that can be solved under these conditions to give the well-known forms

$$\bar{\sigma}(x,s) = C_P^*/s + A(s)e^{-(s/D)^{1/2}x} \qquad [A\text{-}1]$$

$$\bar{\delta}(x,s) = B(s)e^{-(s/D)^{1/2}x} \qquad [A\text{-}2]$$

where $\bar{\delta}(x,s)$ and $\bar{\sigma}(x,s)$ are the transforms of $\delta(x,t)$ and $\sigma(x,t)$. The functions $A(s)$ and $B(s)$ are as yet undetermined.

A consideration of flux balance at the electrode surface reveals that

$$J_P(0,t) + J_{R1}(0,t) + J_{R2}(0,t) = 0 \qquad [A\text{-}3]$$

at all times. This implies that

$$D\frac{\partial\bar{\sigma}(x,s)}{\partial x}\bigg|_{x=0} = 0 \qquad [A\text{-}4]$$

hence from [A-1] we find that $A(s) = 0$. Therefore

$$\bar{\sigma}(x,s) = C_P^*/s \qquad [A\text{-}5]$$

and inverse transformation gives [8].

During the forward step, $C_P(0,t)$ and $C_{R2}(0,t)$ are both zero, so from [8] we find that $C_{R1}(0,t) = C_P^*$. In the reversal step, $C_P(0,t) = C_{R1}(0,t) = 0$, hence $C_{R2}(0,t) = C_P^*$. Thus

$$\delta(0,t) = C_P^* - 2S_{tf}(t)C_P^* \qquad [A\text{-}6]$$

$$\bar{\delta}(0,s) = B(s) = \frac{C_P^*}{s}(1 - 2e^{-t_fs}) \qquad [A\text{-}7]$$

By substitution into [A-2], one obtains

$$\bar{\delta}(x,s) = \frac{C_P^*}{s}e^{-(s/D)^{1/2}x} - 2\frac{C_P^*}{s}e^{-t_fs}e^{-(s/D)^{1/2}x} \qquad [A\text{-}8]$$

Inverse transformation yields [9].

Technical Notes

New Cathodic Reactants for Lithium Batteries

A. A. Inocêncio*,[1]

Institute of Physical Chemistry, University of Bonn, Bonn, Germany

By studying the electrochemical behavior of substances such as water, methanol, formic acid, and formaldehyde in organic solvents, it was verified that they are cathodically reduced at a suitable potential, so that they can be combined with an anode of lithium in batteries operable at room temperature. Because of the low molecular weight of the anodic and cathodic materials these batteries have large energy density. Our experiments with cathodic half-cells show that high current densities and, therefore, high power densities are possible. The reduction mechanism of water in a one molar solution of lithium perchlorate in tetrahydrofuran has recently been reported by the author (1). Reports about the reduction mechanism of methanol and formic acid are being prepared. In this communication the results obtained for these cathodic reactants in half-cell experiments and in the preliminary tests of some prototype cells are discussed.

Experimental

The cyclic voltammograms were obtained using a Wenking electronic potentiostat, an Exact Electronics functions generator Type 250, and Hewlett Packard X-Y recorder. For getting the stationary current-potential curves a Rohde and Schwarze d-c power supply Type NGU BN 95140 and a Wenking precision potential meter Type PPT 67 were used. In the tests of the prototype lithium cells, a Rohde and Schwarze d-c power supply Type NGU BN 95140 and a Hartmann and Braun low speed recorder, arucomp 4902 were used.

Figure 1 shows the cross section of an assembled lithium cell in a 1:1 scale. The parts labeled with 2 in the figure are made of Teflon. By assembling the cell, the Teflon parts are pressed together by means of the nuts and the stainless steel rings labeled, 1. Stainless steel ring, labeled 3, are used between the Teflon parts to prevent leakage. Two types of cathodic catalysts, labeled 4, were tried: (*i*) a sintered nickel disk (s.Ni, in Table I); (*ii*) a disk made as follows: carbon and nickel powder (1:1) was mixed with PTFE, Type TF 5032 (0.6 $cm^3\ g^{-1}$ of the mixture) as a binder. This paste was extended on a nickel gauze and pressed (200 kg cm^{-2}). After pressing, the catalyst was heated at 200°C for ½ hr. On the side facing the anodic compartment a PVC membrane was pressed (150 kg cm^{-2}). In this case the separator, 6, was not used. This catalyst is referred to as C + Ni in Table I. The geometrical area in both cases was about 10 cm^2. The real area was not measured. The lithium anode, 5, was prepared by pressing pieces of lithium strips on a stainless steel gauze. The separator, 6, was a Teflon (or PVC) membrane.

The chemicals used were: tetrahydrofuran, Merck, dried p.a.; propylene carbonate, Merck, for synthesis; methanol, Merck, dried p.a.; formic acid, uvasol, for spectroscopy; formaldehyde, Merck, for histology; and lithium perchlorate, purified and dried Fluka A. G. They all were used without further purification.

Results and Discussion

Cyclic voltammograms.—The study of the electrochemical behavior of substances such as methanol, formic acid, formaldehyde, and water on platinum in electrolytic solutions of organic solvents such as tetrahydrofuran (THF), showed that they can be reduced at a potential much more positive than the potential at which the deposition of the alkali metals occurs in the same solvent. At the reduction potential of these substances, the solvent (THF) does not undergo any electrochemical reaction. Figure 2 shows two cyclic

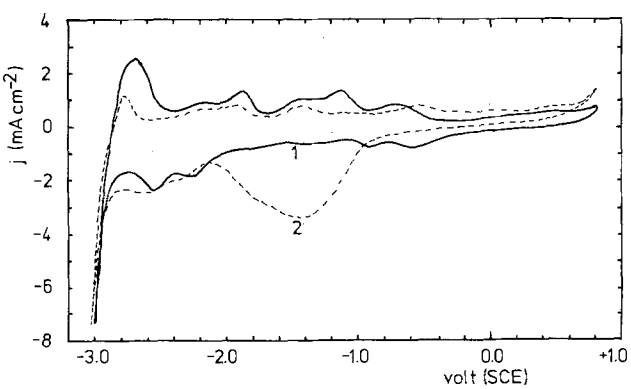

Fig. 2. Cyclic voltammograms on platinum in a 1M $LiClO_4$ solution in THF (curve 1) and in a 1M $LiClO_4$ solution in THF with 1% methanol (curve 2). Scan rate: 154 mV sec^{-1}.

voltammograms on platinum. Curve 1 was in a 1M lithium perchlorate solution in THF, with a scan rate of 154 mV sec^{-1}. The lithium deposition takes place at about −3.0V *vs.* the saturated calomel electrode (SCE). The reduction potential of the electrolytic solution is more negative than the potential of lithium deposition and therefore does not appear in the voltammogram. Curve 2 corresponds to the same solution as curve 1, with the addition of methanol, 1% in volume. Addition of methanol results in a reduction peak in the voltammogram.

Formic acid, formaldehyde, and water also undergo cathodic reduction in organic solutions. The reduction peak of water and formaldehyde begins at about −1.0V *vs.* SCE. The reduction peak of formic acid begins at about −300 mV *vs.* SCE.

Stationary current-potential curves.—The qualitative results reported above suggest the possibility of constructing lithium batteries using methanol, formic acid, formaldehyde, and water as cathodic reactants, since, considering the oxidation potential of lithium in organic solvents (about −3.0V *vs.* SCE), cells having a lithium anode and using the above-mentioned materials as cathodic reactants would have an electromotive force (emf) equal or greater than 2V.

To determine the current density obtainable from such cathodic reactants, stationary current-potential curves were measured in a 1M solution of lithium perchlorate in THF on different catalysts. Three such curves were registered for a 20 volume percent (v/o) methanol concentration on carbon containing 10% platinum, on sintered nickel, and on stainless steel.

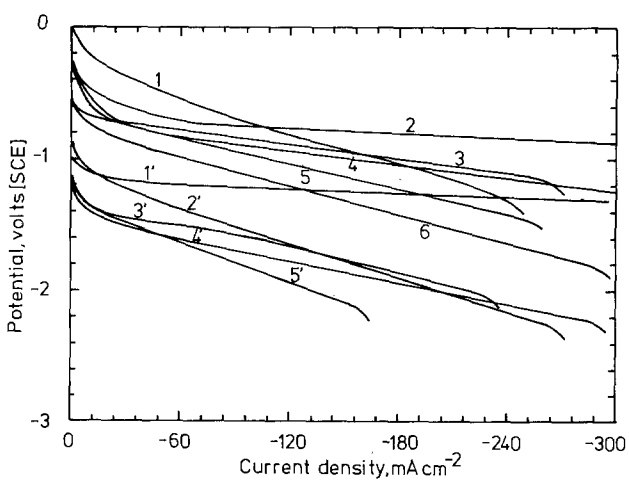

Fig. 3. Stationary current-potential curves for the cathodic reduction of formic acid at a concentration of 20%, in a 1M $LiClO_4$ solution in THF; on carbon with 10% platinum (curve 1), sintered nickel (curve 2), palladium-gold-gauze (curve 3), nickel-gauze (curve 4), and two different qualities of stainless steel (curves 5 and 6). Stationary current-potential curves for the cathodic reduction of formaldehyde at a concentration of 20% in a 1M $LiClO_4$ solution in THF; on sintered nickel (curve 1'), carbon with 10% platinum (curve 2'), two different qualities of stainless steel (curves 3' and 4'), and palladium-gold-gauze (curve 5').

With sintered nickel it is possible to get a current density greater than 200 mA cm^{-2} without a strong polarization of the electrode. On carbon with 10% platinum catalyst it is not possible to attain such a current density. In any case, up to about 70 mA cm^{-2} the potential has a higher value than for the curve on sintered nickel. With stainless steel we can obtain approximately 60 mA cm^{-2} at an acceptable potential of the electrode.

In Fig. 3 current-potential curves are shown for the cathodic reduction of formic acid in THF, registered at a concentration of about 20%, on carbon with 10% platinum (curve 1), sintered nickel (curve 2), palladium-gold-gauze (curve 3) nickel-gauze (curve 4), and stainless steel of different qualities (curves 5 and 6). On sintered nickel, current densities greater than H 300 mA cm^{-2} are possible without a strong polarization of the electrode. Up to about 100 mA cm^{-2} the reduction potential of the formic acid on carbon with 10% platinum is more positive than on sintered nickel. On other catalysts, *e.g.*, palladium-gold, current densities greater than 200 mA cm^{-2} are also obtainable.

As was pointed out earlier, formaldehyde undergoes cathodic reduction in THF on different catalysts. The curves in Fig. 3 were obtained for a formaldehyde concentration of about 20%, on sintered nickel (curve 1'), carbon with 10% platinum (curve 2'), two different types of stainless steel (curves 3' and 4'), and palladium-gold-gauze (curve 5').

The substances that have been discussed, such as methanol, formic acid, formaldehyde, and water, also undergo cathodic reduction in organic solvents other than THF. As an example, the curves obtained in a 1M solution of lithium perchlorate in propylene carbonate on different materials are mentioned. They are similar to those obtained in THF.

Half-cell experiments intended in the electrolytic solution without the above-discussed reactants, showed that when passing negligible current compared with those reported above the deposition potential of lithium (about −3.0V *vs.* SCE) and the oxidation potential of the electrolytic solution (about +1.5V *vs.* SCE) were reached almost instantly.

Preliminary results with some prototypes of lithium cells.—In Table II there are data for lithium cells employing water, methanol, formaldehyde, and formic acid as cathodic reactants. The open-circuit voltage (second column) is about 3.0V for all cells. The energy density was calculated with the open-circuit voltage, taking into account only the active materials (third

Table II. Some data for a new type of cell. The energy density was calculated with the OCV, taking into account only the active materials A, and with the operating voltage, taking into account the electrolyte solution B

and fourth columns), and with the operating voltages, taking into account the solvent and the supporting electrolyte (fifth and sixth columns). The operating voltage of the lithium-water cell was estimated from a half-cell experiment at a current drain of 100 mA cm^{-2}, assuming for the lithium electrode, at this current drain, a polarization of about 150 mV. For the other cells, the operating voltage was taken from the discharge curves. In each case one electron is assumed for every molecule of reactant consumed. The energy density in all cases is very high, especially for water.

In the first, second, third, and fourth rows of Table I there are results for cells whose cathodic reagent was formic acid. In cells 1 and 2 the cathodic catalyst was carbon and nickel (1:1). In cells 3 and 4 the cathodic catalyst was a sintered nickel plate. The separators were a PVC-membrane in cell 2 and a zitex-membrane in the other. These separators develop a high internal resistance, and therefore it is not possible to charge the cells very much. To obviate this inconvenience a Nafion membrane or lithium ion-conducting solid separators (4-7) should be used.

The capacity was 3.6 A-hr for cells 1 and 2, 2.5 A-hr for cell 3, and 6.7 A-hr for cell 4. In cells 1 and 2 the yield was not very high. In cells 3 and 4 the yield was better, 58% and 40%, respectively. The cells can function without interruption for a long period of time.

Figure 4 shows a voltage-time curve for the discharge of the fourth cell of this group. The different parts of the curve correspond to the different currents passed through the cell. This cell functioned for 700 hr.

Cell 5 in Table I has methanol as the cathodic reactant and carbon nickel (1:1) as the cathodic catalyst. In the table the capacity, yield, and duration are indicated. The yield was low, about 1%, because of some methanol passing through the separator to the anodic compartment and reacting with the anode (lithium). A lithium ion-conducting separator (4-7) or a selective membrane that does not permit the methanol going to the anodic compartment should be employed.

In the last two rows of Table I results are shown for a lithium-formaldehyde and for a lithium-water cell whose cathodic catalysts were carbon-nickel (1:1) and sintered nickel, respectively. The ohmic drop, in all cases, was not subtracted.

Conclusion

These results show the possibility of constructing batteries using water, methanol, formic acid, formaldehyde, etc., as cathodic reactants in organic solutions. The cathode of these batteries is essentially the hydrogen electrode, whose potential depends on the acidity of the material employed as the proton source and on the catalyst. The current densities that can be obtained from the cathode are very high, as the stationary current-potential curves show. In the preliminary tests of the prototypes it was not possible to obtain such current densities due to the high internal resistance caused by the separators. The separators which were used were more or less permeable to the cathodic reactants. In the cells with water (8, 9), formaldehyde (aqueous solution), and formic acid, a film of lithium hydroxide and of lithium formate was formed by chemical reaction of the cathodic reactant with the anode. This film prevents, to a certain extent, further chemical reaction, but causes some passivation. In the cells with methanol as the cathodic reactant, the lithium methanolate formed by chemical reaction on the anode does not form a protective film and, therefore, the life of the anode depends greatly on the diffusion coefficient of the methanol through the separator. Hydrogen is liberated in the cathodic compartment, and can be employed in fuel cells or stored for further applications. Experiments to improve this new type of cell are now being made in our laboratory at the University of Brazil.

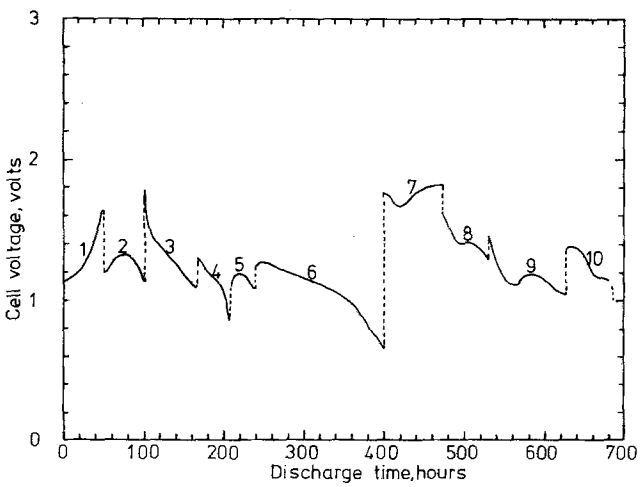

Fig. 4. Voltage-time curve for the discharge of cell 4 in Table I, with the charges of 5.5 (1), 10.0 (2), 7.2 (3), 6.0 (4), 5.0 (5), 4.0 (6), 1.5 (7 and 9), 2.0 (8), and 1.0 mA (10).

Summary

It was ascertained, using the cyclic voltammetry and by plotting stationary current-potential curves, that substances such as water, methanol, formic acid, and formaldehyde can be cathodically reduced in organic solvents such as tetrahydrofuran and propylene carbonate on catalysts such as platinum, sintered nickel, stainless steel, etc. There is a potential interval equal to or greater than 2V between the reduction potential of these substances and the oxidation potential of lithium. The stationary current-potential curves for experiments with cathodic half-cells showed that with all these cathodic reactants, current densities greater than 100 mA cm^{-2} can be obtained without the electrode becoming excessively polarized. Since the molecular weight of these substances is small it is possible to obtain great energy densities with them. Prototypes of lithium batteries using these cathodic materials were constructed and tested. An open-circuit voltage of about 3.1V was measured for all cases. Some prototypes worked without interruption for 700 hr. Depending on the cathodic material, energy densities between 1.7 and 3.2 kW-hr kg^{-1} can be obtained.

Acknowledgments

The Effects of Cations and Anions on Hydrogen Chemisorption at Pt

J. C. Huang,* W. E. O'Grady,* and Ernest Yeager*

Case Laboratories for Electrochemical Studies and the Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106

The adsorption of hydrogen on the platinum electrode has been the subject of extensive investigation [see. *e.g.*, Ref. (1-10)]. Many questions persist, however, as to the true nature of the multiple hydrogen adsorption peaks observed in linear sweep voltammetry studies of single crystal as well as polycrystalline platinum. Up to five peaks have been observed (10) in ultrapure dilute sulfuric acid electrolytes. Factors which have been proposed to account for these multiple peaks include different adsorption sites on a given crystallographic plane, a distribution of surface crystallographic orientations even with a given single crystal macro-orientation, induced heterogeneity associated with the perturbing of adjacent sites by the adsorbed hydrogen itself, and the adsorption of anions which create further surface heterogeneity by blocking some sites and perturbing adjacent sites. The situation is further complicated by the fact that in acid solutions the point of zero charge (pzc) for Pt falls within the hydrogen adsorption-desorption region. Thus the adsorption-desorption of anions can closely couple to the hydrogen adsorption-desorption process.

In considering the role of oxyanions Conway and his co-workers (10) have examined both their own linear sweep voltammetry data and that of others and conclude that anion adsorption changes the relative heights of the hydrogen adsorption peaks but has relatively little effect on the peak potentials, and hence, adsorption energies. On this basis they conclude that the anions principally affect the distribution of adsorbed hydrogen on the surface but do not disturb significantly the adsorption energy for a particular type of site. In examining the dependence of hydrogen adsorption on Pt on the electrolyte, however, we differ with this conclusion and find that ionic adsorption substantially shifts the potentials in addition to the relative heights of the peaks. These effects appear well beyond what can be explained on the basis of simple blocking of hydrogen adsorption sites.

The purpose of this note is to present experimental data to substantiate this view. Despite the relatively large amount of data on ion adsorption effects, we have found it necessary to obtain additional data to more clearly establish the trends. Much of the data in this literature has been obtained by adding various ionic components to sulfuric acid solutions. The HSO_4^- and/or $SO_4^=$ ions, however, are moderately strongly adsorbed on Pt in the hydrogen adsorption region as the present work indicates, and this complicates studies of the adsorption of other ions in this electrolyte. The present study shows that $HClO_4$ and HF are better reference electrolytes for anion studies. The measurements have also been extended to alkaline solutions. Relatively little data have been reported for hydrogen adsorption on Pt in alkaline solutions and even then much of this has been obtained by charging techniques (8, 9) which do not show up well the fine structure in this potential region.

Key words: hydrogen adsorption, platinum, electrosorption, voltammetry, hydrogen electrode.

Experimental

Conventional techniques were used to record the linear sweep voltammograms. For all work herein reported the sweep rate was 100 mV/sec and the voltammograms recorded after several cyclic sweeps. The measurements were made in an all-Teflon cell, consisting of a main working electrode compartment and two separate compartments for the reference and counterelectrodes. The working electrode was a 0.5 cm disk of reference grade Pt (99.999% pure) mounted in Teflon. The reference and counterelectrodes were β-Pd-H using Pd foils charged continuously with purified H_2 from the back side. O_2 was removed from the solution by bubbling purified helium through the cell prior to measurements. The cell was mounted in a N_2-atmosphere box to prevent CO_2 and dust contamination of the electrolyte in the filling of the cell and to eliminate any possible diffusion of O_2 into the cell.

The working electrode surface was first polished with alumina to a mirror finish, washed with distilled water, degreased with spectro grade isopropanol, cleaned with 1:1 volume ratio H_2SO_4-HNO_3 (reagent grade), rinsed with triply distilled water followed by pyrolyzed water, further cleaned with ultrasound in a solution of the same composition as the electrolyte to be used, and then either introduced into the cell or stored in pyrolyzed water. All of these operations were carried out in carefully cleaned Teflon vessels. This procedure was repeated for each new electrolyte.

The acid solutions were prepared with ultrapure acids (Ultrex H_2SO_4 from J. T. Baker, ultrapure 49% HF and 85% H_3PO_4 from Apache Chemicals, ultrapure 70% $HClO_4$ from Ventron Alfa Products) and pyrolyzed water. The latter was prepared according to the procedure described by Conway *et al.* (11). The H_2SO_4, $HClO_4$, and H_3PO_4 solutions were prepared in cleaned glassware and used without further chemical treatment. All HF solutions were prepared in Teflon bottles. The HF solution was first made up as 10*M* and subjected at this concentration to activated charcoal purification, principally to remove trace chloride. Omission of the activated charcoal purification had no significant effect on the results. The solution was then diluted down to desired concentration with pyrolyzed water.

Solutions of 0.1*M* NaOH were also prepared in Teflon bottles and subjected to the activated charcoal purification. A 50% stock solution of NaOH was first formulated from special low carbonate NaOH pellets (J. T. Baker) with triply distilled water. This solution was allowed to stand over several weeks and the solution

decanted many times to remove precipitated Na_2CO_3. The carbonate solubility in 50% NaOH is $\sim 10^{-4}M$ and the carbonate concentration in the 0.1*M* NaOH should be $\sim 5 \times 10^{-7}M$.

Before each measurement, the final solution was preelectrolyzed at a potential of 1.5V between two auxiliary Pt electrodes ($4 \times 2 \times 0.01$ cm) within the Teflon cell for at least 24 hr for acid solutions and 48 hr for the NaOH solutions.

Results

Figures 1 and 2 indicate the voltammetry curves for 0.1*M* HF and 0.1*M* $HClO_4$ as well as the effect of adding successively increasing amounts of H_2SO_4 to these electrolytes. Only the hydrogen region is shown for purposes of clarity, but the sweep in the anodic direction was continued out to 1.4V *vs.* RHE. The curves for the HF and $HClO_4$ solutions resemble each other closely. The addition of H_2SO_4 to either of these electrolytes has a substantial effect on the hydrogen adsorption region with respect to the position as well as relative height of the strongly adsorbed hydrogen peak IV [H_{A4}, using the notation of Conway *et al.* (10)]. The addition of up to 0.1*M* HF to 0.05*M* H_2SO_4, however, has virtually no effect on the hydrogen adsorption. This implies that undissociated HF as well as F^- are not adsorbed to any significant extent with the presence of SO_4^{2-}. Figure 3 compares the curves for 0.02*M* H_2SO_4 and 0.14*M* HF, both of which have essentially the same *p*H. The shift in potential and increment in height of peak IV is similar to that noted by Frumkin *et al.* (6) although Fig. 3 shows clearly four peaks for the H_2SO_4 solution while the earlier Soviet work indicated only two. This figure indicates that the principal differences between the HF and H_2SO_4 solution are not due to *p*H.

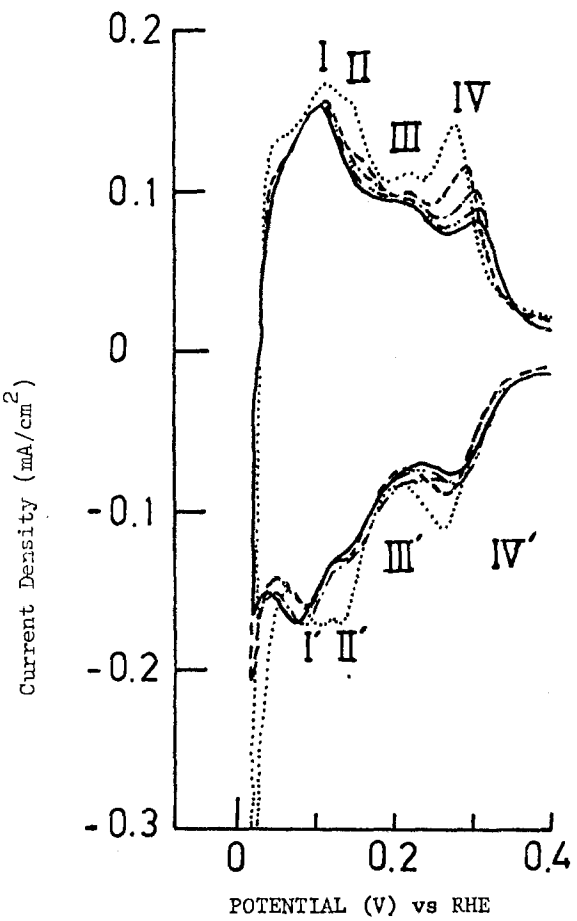

Fig. 1. Voltammograms for Pt in 0.1M HF with various concentrations of H_2SO_4 added. —— 0.1M HF, –·–· 0.1M HF + 5 × 10^{-5}M H_2SO_4, –·– 0.1M HF + 5 × 10^{-4}M H_2SO_4, – – – 0.1M HF + 5 × 10^{-3}M H_2SO_4, ... 0.1M HF + 5 × 10^{-2}M H_2SO_4.

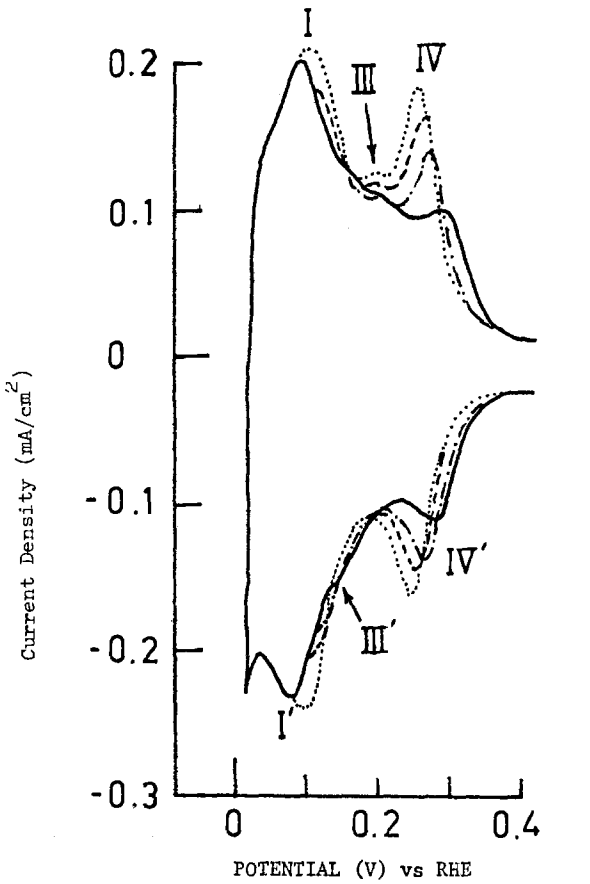

Fig. 2. Voltammograms for Pt in 0.1M $HClO_4$ with various concentrations of H_2SO_4 added. —— 0.1M $HClO_4$, –·– 0.1M $HClO_4$ + 5 × 10^{-4}M H_2SO_4, – – – 0.1M $HClO_4$ + 5 × 10^{-3}M H_2SO_4, ... 0.1M $HClO_4$ + 5 × 10^{-2}M H_2SO_4.

In voltammetry studies of the hydrogen peaks in H_2SO_4 solutions reported in the literature, peaks I, III, and IV have usually been observed in the anodic sweep but only peaks I and IV have shown up in the cathodic sweep. Various explanations have been proposed to explain peak III in the anodic sweep, and particularly why peak III is missing in the cathodic sweep (7, 10, 12-14). In the present work the counterpart of the anodic peak III is evident in the cathodic sweeps in 0.1*M* HF (Fig. 1) and 0.1*M* $HClO_4$ (Fig. 2) although not in the H_2SO_4 solutions (Fig. 3 and 6) or 0.033*M* H_3PO_4, (Fig. 4) which rather closely resembles H_2SO_4. The lack of peak III in the cathodic sweep in the H_2SO_4 and H_3PO_4 solutions is probably due principally to the strong overlap of the other more predominant peaks.

Figures 5 and 6 indicate the effects of HCl additions to 0.1*M* HF and 0.5*M* H_2SO_4. Peak IV in both the HF and H_2SO_4 is shifted substantially in the cathodic direction. The shift amounts to ~120 mV with $10^{-2}M$ HCl in the 0.1*M* HF solution. This shift is quite linear with the log concentration of H_2SO_4 or HCl added to the HF or $HClO_4$ solutions as shown in Fig. 7. Such linearity may arise because of the logarithmic nature of the anion adsorption isotherm.

Cations have much less effect on the hydrogen adsorption on Pt in acid solutions. The addition of chloride-free $(C_2H_5)_4NF$ to the HF solution shifts peak I in the anodic direction and peak IV in the cathodic direction (see Fig. 8), whereas the addition of Cs_2SO_4 to H_2SO_4 only slightly shifts the weak hydrogen adsorption peak I in the anodic direction (Fig. 9). The addition of either 5 × $10^{-3}M$ Na_2SO_4 or 5 × $10^{-3}M$ Li_2SO_4 to 0.05*M* H_2SO_4 has a negligible effect as is

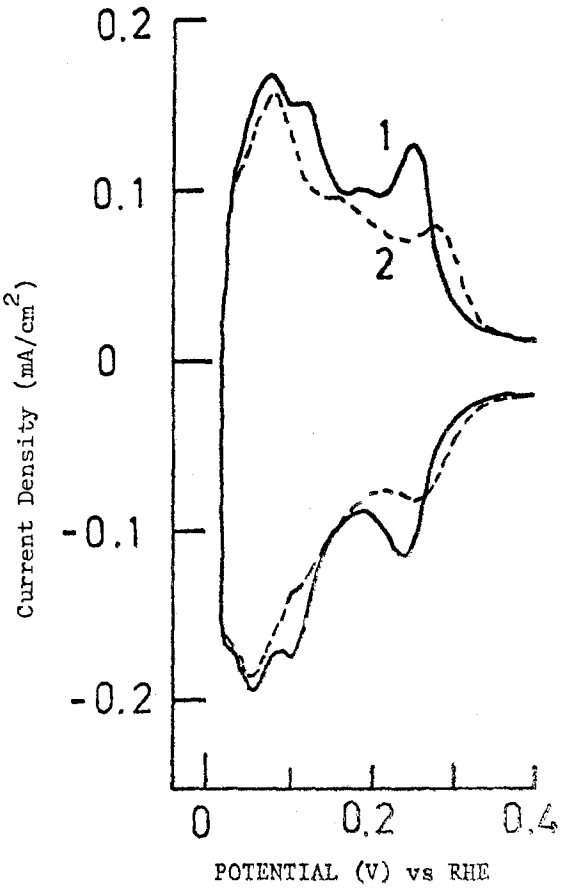

Fig. 3. Voltammograms for Pt in 0.02M H_2SO_4 and 0.14M HF. Curve 1, 0.02M H_2SO_4 and curve 2, 0.14M HF.

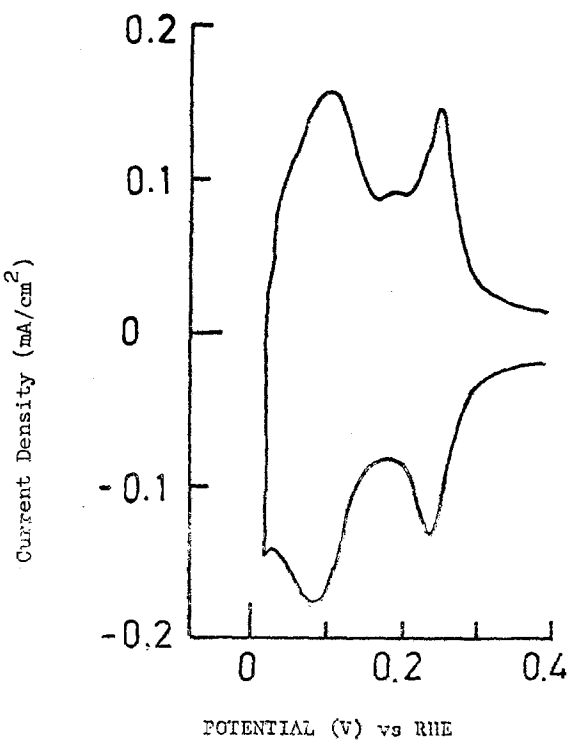

Fig. 4. Voltammogram for Pt in 0.033M H_3PO_4

also the case with the addition of $5 \times 10^{-4}M$ $Ba(ClO_4)_2$ or $5 \times 10^{-4}M$ $Sr(ClO_4)_2$ to the $0.1M$ $HClO_4$.

The hydrogen adsorption region is quite different in alkaline solutions (see Fig. 10 and 11). Only two peaks (A and B) are clearly observed. Peak C corresponds to

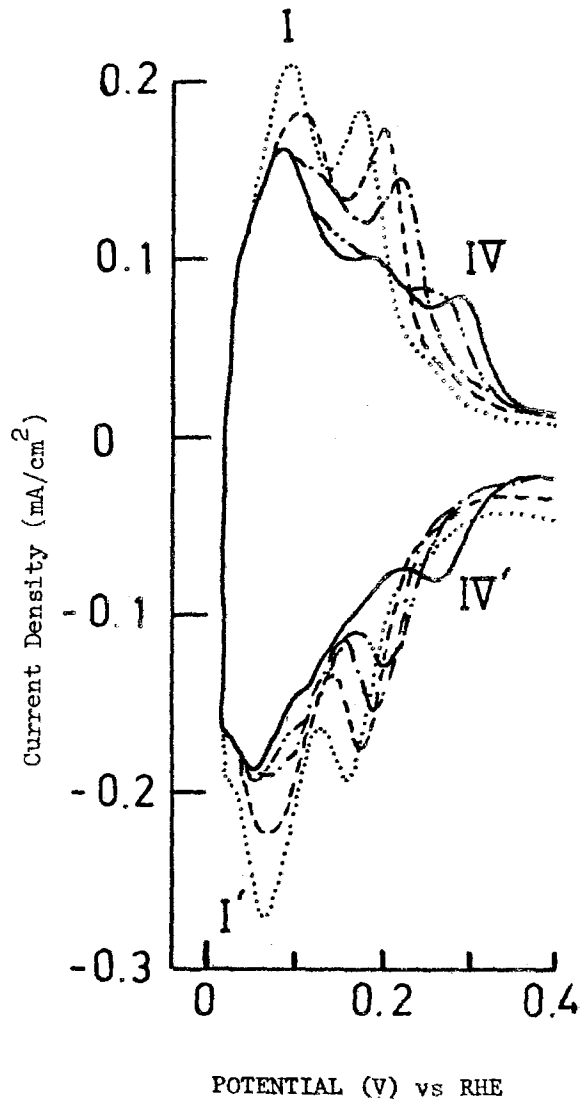

Fig. 5. Voltammograms for Pt in 0.01M HF with various concentrations of HCl added. —— 0.1M HF, -·-· 0.1M HF + 10^{-5}M HCl, -·- 0.1M HF + 10^{-4}M HCl, --- 0.1M HF + 10^{-3}M HCl, ... 0.1M HF + 10^{-2}M HCl.

the anodic oxidation of solution phase H_2 produced during the cathodic sweep. In contrast to the acid media, the positions and heights of both peaks A and B are substantially influenced by the addition of $Ba(OH)_2$ or $Ca(OH)_2$. The addition of Cl^-, F^-, ClO_4^-, PO_4^{-3}, SO_4^{-2}, or SiO_3^{-2} up to $10^{-3}M$ had no detectable effect and $10^{-3}M$ Br^- had only a slightly perceptible effect. The pzc in the alkaline solutions even in the presence of these various anions is probably still quite anodic to the hydrogen adsorption region, and thus specific adsorption of these anions is small in this region. With a strongly specifically adsorbed anion such as I^- in alkaline solution the effects on the hydrogen adsorption peaks are pronounced (see Fig. 12). Tracking of the peak shifts in position *vs.* height changes, however, is rather difficult with the data in Fig. 12.

Discussion

It is difficult to explain all of the anion and cation effects in acid and alkaline solutions on the basis of a single model for the interaction of the ions with the hydrogen adsorption. The situation is complicated by a lack of a clear understanding of the extent to which various structural features of the electrode surface are responsible for the several hydrogen peaks, *i.e.*, the importance of intrinsic *vs.* induced heterogeneity [see *e.g.*, Ref. (10)]. The addition of various cations and

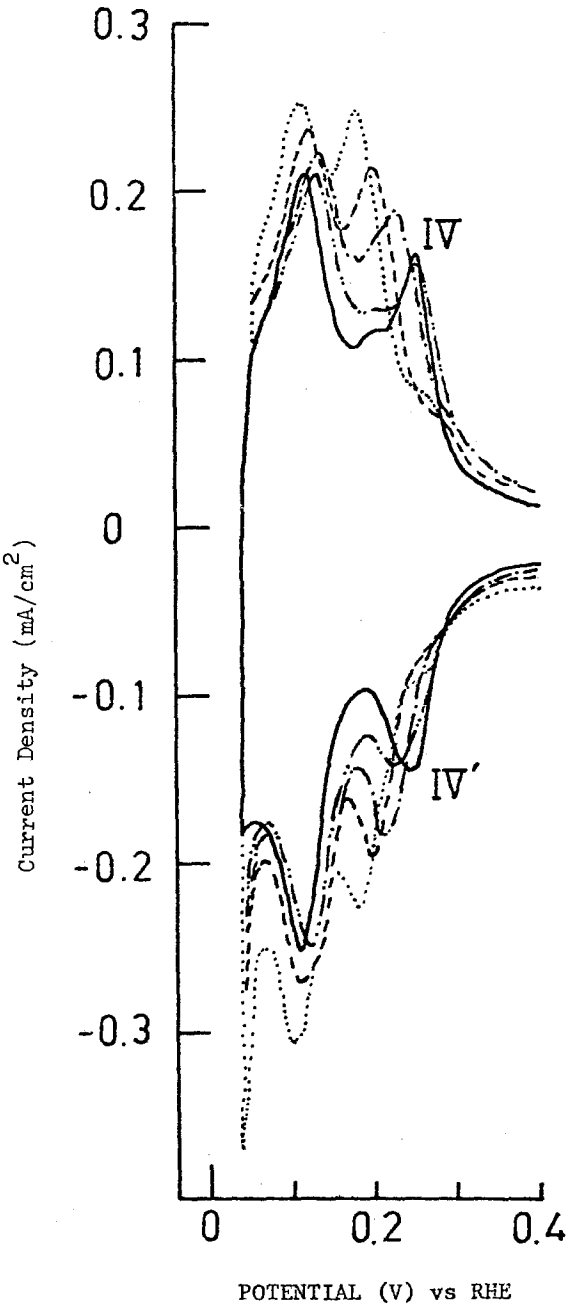

Fig. 6. Voltammograms for Pt in 0.5M H_2SO_4 with various concentrations of HCl added. ——0.5M H_2SO_4, –·–· 0.5M H_2SO_4 + 10^{-5}M HCl, –·– 0.5M H_2SO_4 + 10^{-4}M HCl, – – – 0.5M H_2SO_4 + 10^{-3}M HCl, ... 0.5M H_2SO_4 + 10^{-2}M HCl.

anions to electrolytes such as HF and $HClO_4$ can bring about changes in the structure of the hydrogen adsorption region in the voltammetry curves in a number of ways:

1. *Blocking of sites by anion adsorption and coupling of hydrogen adsorption and anion desorption.*—Specific adsorption of ions, particularly anions, can block sites on which hydrogen otherwise would be adsorbed. For hydrogen to adsorb on these sites requires the desorption of anions with the result that hydrogen adsorption and anion desorption are coupled. Such coupling can be expressed through the following equation

$$yH^+ + X_{ad}^{-(z-\sigma_x)} + (y\sigma_H + \sigma_x)e^- \rightarrow yH_{ad}^{(1-\sigma_H)} + X^{-z}$$

This effect can lead to a shift in the peak potential as well as peak area. Strong anion adsorption makes it more difficult to adsorb hydrogen and hence a shift to

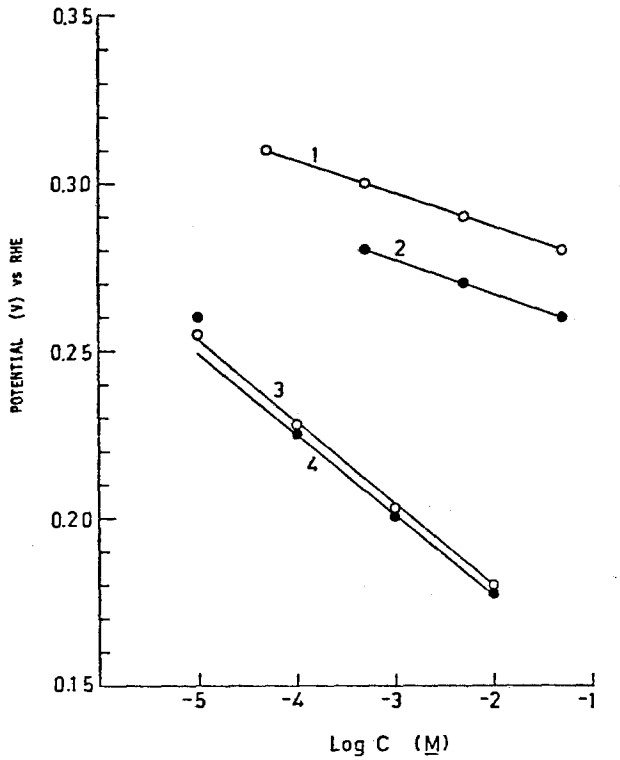

Fig. 7. The shift of strongly bound hydrogen peak potential as a function of the concentration of added anions. Curve 1, 0.1M HF + H_2SO_4; curve 2, 0.01M $HClO_4$ + H_2SO_4; curve 3, 0.1M HF + HCl; curve 4, 0.5M H_2SO_4 + HCl.

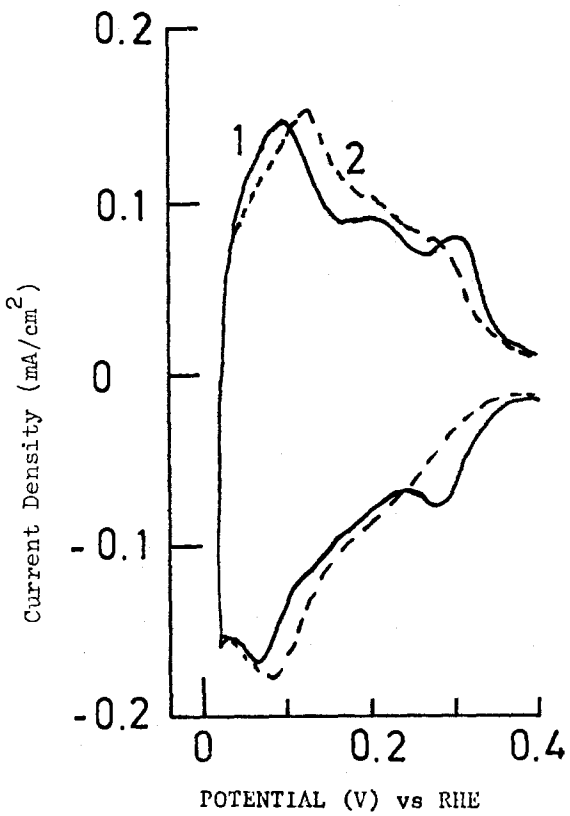

Fig. 8. Voltammograms for Pt in 0.1M HF with $(C_2H_5)_4N^+$ cations added. Curve 1, 0.1M HF and curve 2, 0.01M HF + 5 × 10^{-3}M $(C_2H_5)_4NF$.

more cathodic potentials should occur for the particular peak(s) involved with such coupling.

Evidence for this effect is to be found in Fig. 13, in which the ratio of the charge associated with the strong

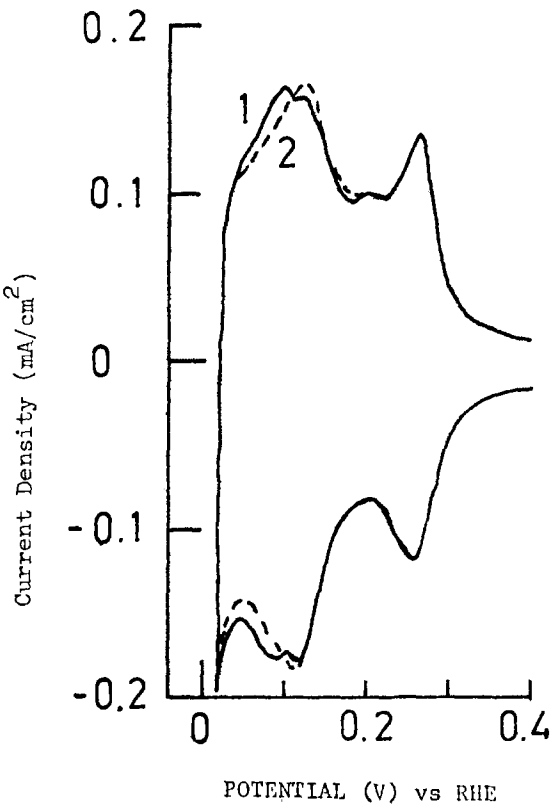

Fig. 9. Voltammograms for Pt in 0.05M H_2SO_4 with Cs^+ cations added. Curve 1, 0.05M H_2SO_4 and curve 2, 0.05M H_2SO_4 + 5 × 10^{-3}M Cs_2SO_4.

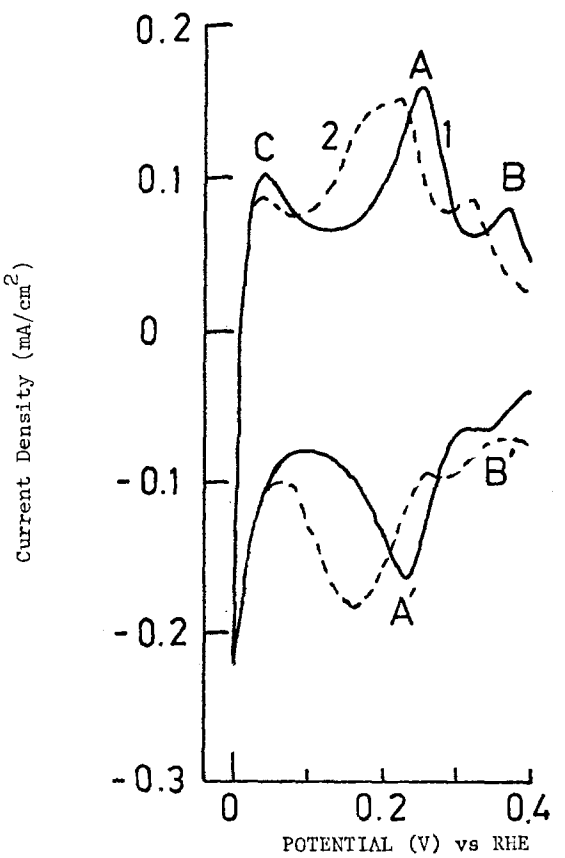

Fig. 10. Voltammograms for Pt in 0.1M NaOH with Ba^{2+} cations added. Curve 1, 0.01M NaOH and curve 2, 0.1M NaOH + 5 × 10^{-3}M $Ba(OH)_2$.

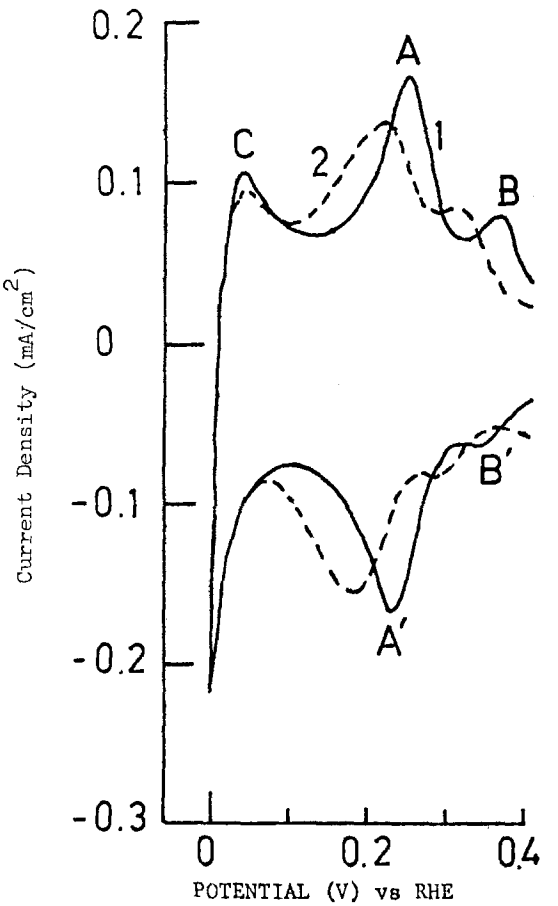

Fig. 11. Voltammograms for Pt in 0.1M NaOH with Ca^{2+} cations added. Curve 1, 0.1M NaOH and curve 2, 0.1M NaOH + 5 × 10^{-3}M $Ca(OH)_2$.

hydrogen adsorption peak to the total charge for hydrogen adsorption is shown to increase linearly with the log of the concentration of sulfate added to the 0.1*M* $HClO_4$ and HF electrolytes. The specific adsorption of the SO_4^{-2} should follow a Temkin isotherm over this concentration region, and hence the amount of specifically adsorbed sulfate is expected to be a linear function of the log of the concentration of this ion in solution. The linearity in Fig. 13 implies that the charge ratio is linearly dependent on the amount of specifically adsorbed SO_4^{-2}. In principle, the coupling mechanism proposed above should lead to a linear dependence of the charge Q_{IV} under the strong peak *IV* on log $C_{SO_4^{-2}}$ and not the charge ratio Q_{IV}/Q. It is difficult, however, to ensure that the ratio of true-to-apparent electrode area is constant between measurements and hence it has been preferable to plot Q_{IV}/Q. Since the Q_{IV}/Q is rather small compared to unity, a near linear relation is still observed in Fig. 13.

2. *Modification in the hydrogen adsorption energies for sites adjacent to adsorbed anions.*—The adsorption energies for hydrogen on sites adjacent to adsorbed anions are expected to be modified. This effect can occur through changes in the surface electronic structure as well as local changes within the compact double layer, particularly the water dipoles immediately adjacent to the electrode. Such electronic interactions of the anions with hydrogen adsorbed on adjacent sites are similar to those considered by Conway *et al.* (10) in regard to induced heterogeneity. The authors believe this effect to be small except for strongly adsorbed ions such as iodide where very substantial electronic interactions occur between metal surface orbitals and those of the iodide.

3. *Changes in the potential distribution across the interface.*—For ionic double layer effects to have a

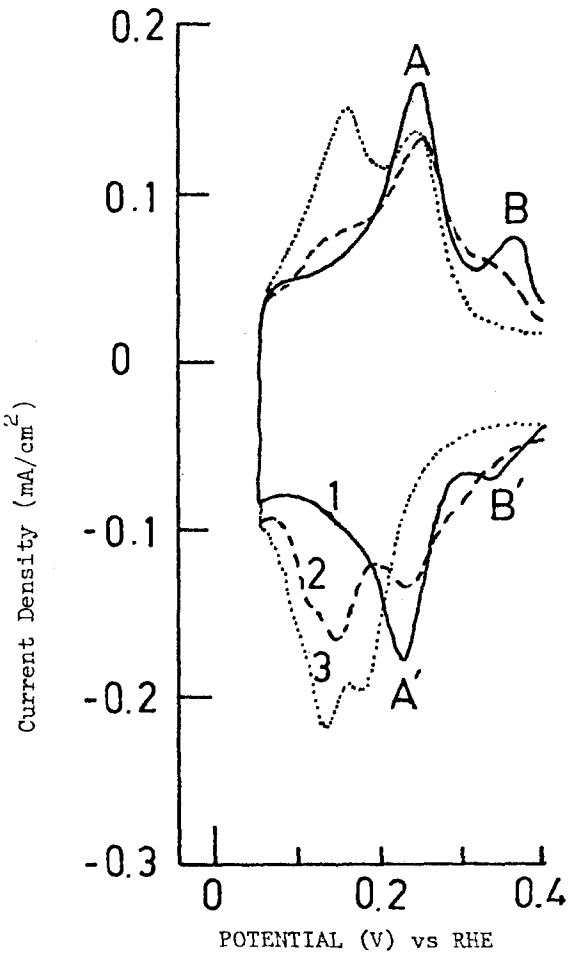

Fig. 12. Voltammograms for Pt in 0.1M NaOH with I^- anions added. Curve 1, 0.1M NaOH; curve 2, 0.1M NaOH + 10^{-5}M NaI; curve 3, 0.1M NaOH + 10^{-3}M NaI.

large influence on hydrogen adsorption requires that the H_{ad} have substantial positive or negative charge. Double layer effect may produce minor shifts in the peak potentials such as observed with some cations in alkaline solutions, but it is doubtful if the M-H dipoles are sufficiently strong to explain the large shifts in the peak potentials observed with anion adsorptions in acid electrolytes.

4. *Surface restructuring.*—During the sweep of the potential into the anodic film formation region, the ions adsorbed on the metal and the anodic film possibly can influence the surface restructuring which occurs during the oxidation and subsequent reduction of the platinum surface. Thus the microstructure and distribution of lattice sites prevailing in the hydrogen adsorption region are probably dependent on the electrolyte composition. This effect can result in changes in the relative peak heights, but should not result in significant shifts in the peak potentials.

Of these various mechanisms for accounting for anion and cation effects, the authors believe that the coupling of the ionic adsorption to the hydrogen adsorption (mechanism 1) is predominant for anion adsorption effects in acid media and that changes in the double layer-potential distributions (mechanism 3) is predominant for the cation adsorption effects on alkaline solutions.

Volatile Products in the Corrosion of Cr, Mo, Ti, and Four Superalloys Exposed to O_2 Containing H_2O and Gaseous NaCl

George C. Fryburg,* Robert A. Miller,[1] Fred J. Kohl, and Carl A. Stearns

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio 44135

ABSTRACT

Cooled target collection techniques were used to study the formation of volatile products when samples of Cr, Ti, IN-738, 713C, NASA-TRW VIA, and B-1900 were exposed at elevated temperatures to oxidizing environments containing $H_2O(g)$ and $NaCl(g)$. Samples were heated to 1050°C in 1 atm of slowly flowing oxygen, saturated with water at 21°C, and containing about 50 ppm $NaCl(g)$. Volatile products were detected for all materials except B-1900 and Ti. High pressure mass spectrometric sampling was used to directly identify volatile products emanating from samples of Cr and IN-738 subject to the above environments. Mo samples were also studied at 675°C with 4 ppm $NaCl(g)$ added to the $O_2 + H_2O$ environment. For Cr and IN-738 the volatile species were identified primarily as $(NaCl)_{1,2,3}CrO_3$, $(NaOH)_{1,2}$-CrO_3, $Na_2Cr_2O_7$, and $CrO_2(OH)_2$. These same species are deduced to prevail for 713C and NASA-TRW VIA. For Mo, the major species identified were $(NaCl)_{1,2}(MoO_3)_3$, $NaOH(MoO_3)_3$, $(MoO_3)_{3,4}$, and $MoO_2(OH)_2$.

Equilibrium thermodynamic calculations applied to gas turbine engines operating under conditions thought to be conducive to hot corrosion attack indicate that the engine hot section environment should be relatively rich in the contaminant gases $NaCl(g)$, $NaOH(g)$, and $HCl(g)$ (1). These chemical species are generally considered as highly reactive at high temperature, and therefore it seems reasonable to expect that they might play a significant role in the hot corrosion process. Previously it had been demonstrated that adverse effects could be associated with exposure of hot oxidizing metals to partial pressures of $NaCl(g)$ (2-4). Hancock *et al.* (2) have shown that additions of $NaCl(g)$ to the oxidizing environment can compromise the so-called protective oxide scale on certain alloys used in turbine engines. For the oxidation of chromium, Stearns *et al.* (3) presented evidence which indicates that additions of $NaCl(g)$ lead to increased rates of chromium transport from the sample. Their results indicated a first-order dependence of Cr-compound vaporization on $NaCl(g)$ partial pressure and on oxygen pressure. They identified the vapor species by high pressure mass spectrometry. Jones *et al.* (4) have presented evidence to show the $NaCl(g)$ can: (*i*) induce dissociation of $Na_2SO_4(c)$; (*ii*) promote spalling of Al_2O_3 surface oxide; (*iii*) remove Cr from samples as a volatile "chromchloride"; and, (*iv*) accelerate the degradation, by sulfidative oxidation, of certain CoCrAlY-coated alloys.

The phenomenology of interaction between oxidizing metals and the gaseous species $NaCl(g)$, $NaOH(g)$, and $HCl(g)$ is not well characterized and the operative mechanisms are not understood. To elucidate the kinetics and mechanisms of such interactions, we have been investigating various metal-oxygen-contaminant gas systems at elevated temperatures. Our previously reported studies of $Cr + O_2 + NaCl(g)$ yielded some kinetic information for this system and identified $(NaCl)_{1,2,3}CrO_3(g)$ as the major volatilizing species (3). The work reported here is a continuation of this effort and describes (*i*) the effect of adding water vapor to the $Cr + O_2 + NaCl(g)$ system, and (*ii*) interactions of $NaCl(g)$ and/or $H_2O(g)$ with Mo, Ti, and the superalloys NASA-TRW VIA, B-1900, IN-738, and 713C. The compositions of these alloys are presented in the Appendix.

Experimental

Two experimental techniques were used in the present atmospheric pressure investigations; cooled target collection and high pressure mass spectrometric sampling. Schematics of the respective apparatus are shown in Fig. 1. It can be seen that the furnace assembly apparatus was common to both techniques. The metal sample, measuring approximately 1 × 1 × 0.25 cm, was suspended on a platinum wire within a 2.2 cm ID quartz tube that was mounted in a 15 cm long tube furnace. The furnace temperature was controlled through a thermocouple by a precision set-point current proportionating controller coupled to a saturable core reactor power source. Temperatures could be maintained to ±2°C. Sample temperature was measured independently with a Pt-Pt 13% Rh thermocouple inside the quartz tube and contacting the side of the sample.

Partial pressures of $NaCl(g)$ were developed by heating $NaCl(c)$ in a platinum crucible that was situated below the sample in a 1.3 cm diam quartz tube. The crucible was 2 cm long by 0.6 cm in diameter and

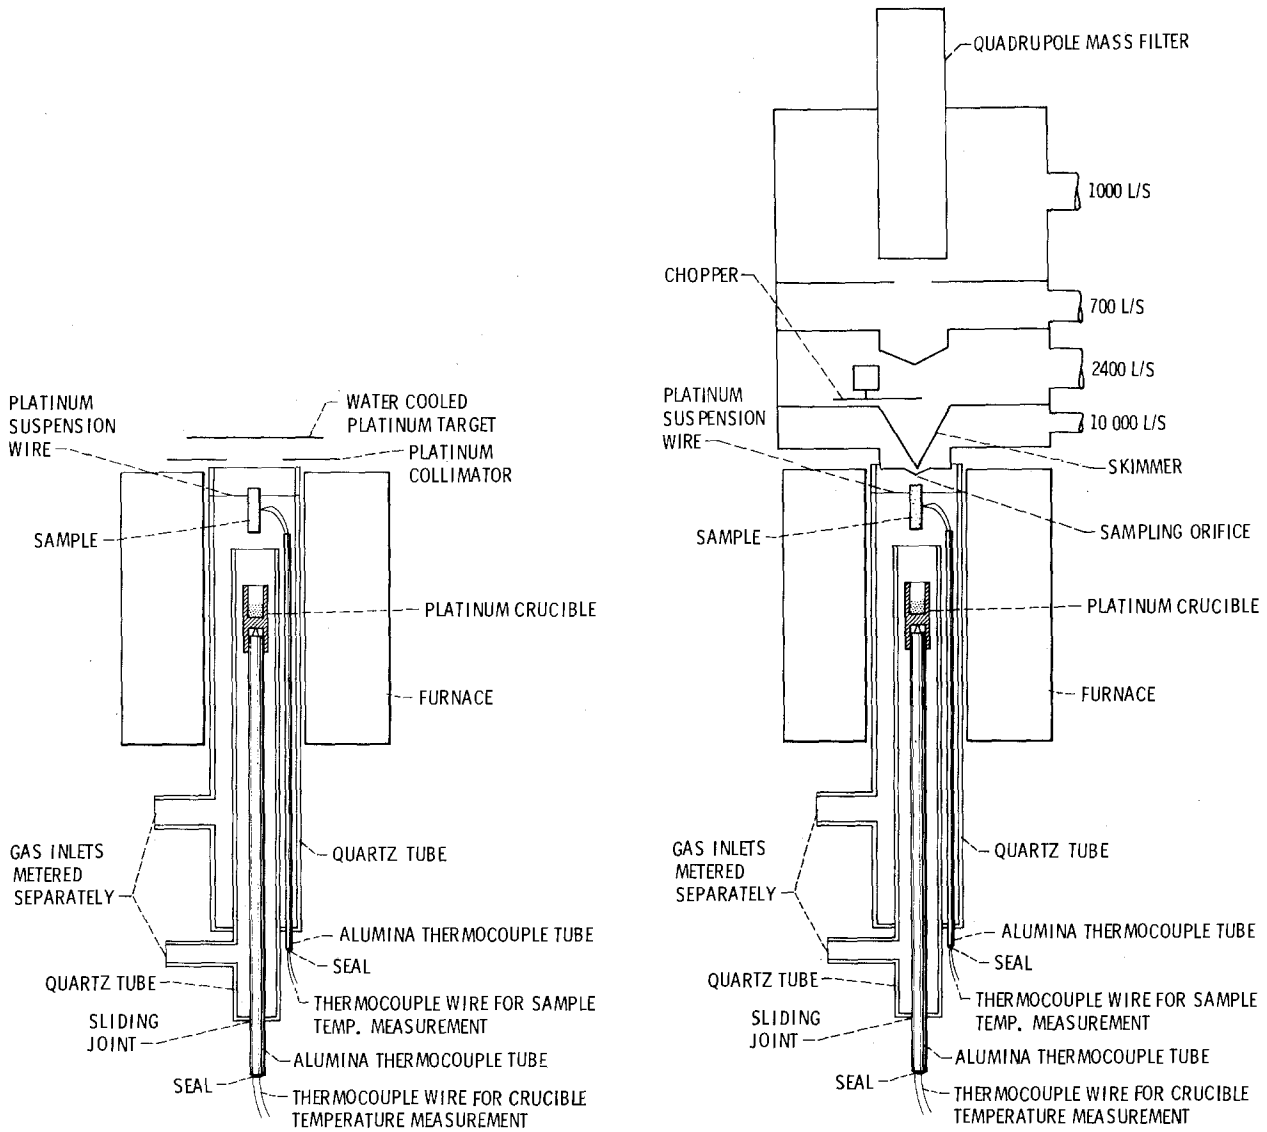

Fig. 1. Schematic of apparatus: (a, left) target collection, (b, right) high pressure mass spectrometric sampler

it was supported on a double bore alumina thermocouple tube. A Pt-Pt 13% Rh thermocouple in the alumina tube extended into the crucible base and facilitated continuous measurement of the crucible temperature. A slip-seal system allowed the crucible assembly to be moved vertically so that the crucible temperature could be varied by changing its position in the furnace. The crucible temperature was maintained considerably lower than the sample temperature to ensure no condensation of NaCl on the sample.

Metered oxygen flows were supplied independently to both concentric quartz tubes. Flows were adjusted to gas velocities of 0.7 and 2.5 cm sec^{-1} for the outer and inner quartz tubes, respectively. The oxygen supplied to the outer tube could be saturated with water vapor at room temperature by passing the gas through a fritted glass plug in the bottom of a 20 cm high column of water. The mass fraction of NaCl(g) in the apparatus was determined from the weight loss (per unit time) of NaCl(c) in the crucible and the volume flow rate of gas through the apparatus. No attempt was made to apply corrections to the NaCl(g) concentrations for collision and reactions with the quartz wall of the apparatus. In the target collection experiments a mass fraction of about 50 ppm NaCl(g) was used, and in the mass spectrometric sampling experiments NaCl(g) concentrations of 160 ppm were generally employed. Metal samples were always preoxidized for 4 hr at high temperature, usually 1000°C in pure oxygen. The experiment was then started by adding contaminant gases, and at least 5 min were allowed to elapse before measurements were begun.

In the target collection experiments, volatile products emanating from the sample were collected on polished platinum targets (5 × 5 × 0.04 cm) attached to a water-cooled copper plate [Fig.1(a)]. The target was positioned about 2 cm above the open end of the quartz tube. A platinum collimator (with a 2 cm diam opening) was located between the target and quartz tube opening. Deposits collected in measured times were dissolved in water. Resulting solutions were analyzed for metal cations by atomic absorption and/or emission spectroscopy.

Identification of volatile species emanating from samples was accomplished with the high pressure mass spectrometric sampler positioned at the quartz tube opening as shown in Fig. 1(b). The high pressure, free-jet expansion, modulated molecular beam, mass spectrometric sampler facilitates direct mass spectrometric analysis of atmospheric pressure sources. This technique preserves the dynamic and chemical integrity of sampled species. The theory and details of the free-jet expansion sampling technique are given in the literature (5-7).

For our sampler the inlet orifice was 0.022 cm in diameter, located at the apex of a 106° occluded angle cone fabricated from 0.025 cm thick Pt-10% Rh. The cone was welded on the end of a 1.5 cm long × 2.0 cm

diam stainless steel tube. The sampling cone protruded into the quartz tube about 1 cm and was heated to a temperature approaching that of the metal sample. Heating of the orifice was necessary to prevent condensation on and subsequent clogging of the orifice by NaCl and other condensible volatile species.

In the mass spectrometric sampling experiments, the furnace temperature was adjusted to produce a sample temperature of about 1050°C, except in the case of molybdenum. Molybdenum samples were heated to only 675°C because the high rate of vaporization of MoO_3 at higher temperatures resulted in rapid clogging of the sampling orifice. The lower temperature required for molybdenum samples necessitated lower concentrations of NaCl(g) because it was not possible to heat the crucible to higher temperatures without overheating the molybdenum. Generally the NaCl(g) mass fraction was around 4 ppm for molybdenum experiments.

Results and Discussion

Target collection experiments.—The effects of exposing hot oxidizing metals to partial pressures of NaCl(g), $H_2O(g)$, and NaCl(g) + $H_2O(g)$ was studied for the metal samples Ti, B-1900, Cr, IN-738, VIA, and 713C. For Ti and B-1900 samples no metals (other than Na) were detected in collected deposits. In experiments with the other metal samples, the only metal detected (other than Na) in collected deposits was Cr. The rate of collection of Cr per unit area of sample shall be designated R.

Values of R, obtained with a preoxidized Cr sample exposed to various gas phase compositions, are presented in Table I. These results show that R was increased markedly by additions of $H_2O(g)$ or NaCl(g) to the oxidizing environment. When both of these additions were present simultaneously an additional synergistic effect was obtained. In oxygen alone $R = 1$ $\mu g\ cm^{-2}\ hr^{-1}$; the transported Cr was undoubtedly derived from the oxidation of $Cr_2O_3(c)$ on the surface of the sample to $CrO_3(g)$ (8) according to the reaction

$$Cr_2O_3(c) + 3/2\ O_2(g) = 2CrO_3(g) \quad [1]$$

With the addition of $H_2O(g)$ to the oxygen, the value of R was increased by a factor of four. The increase may be attributed to the formation of a volatile hydrated oxide

$$\frac{1}{2}Cr_2O_3(c) + \frac{x+1}{4}O_2(g) + \frac{x}{2}H_2O(g) = CrO_2(OH)_x(g) \quad [2]$$

where $x = 1$ or 2. If it is assumed that reactions [1] and [2] occur independently, the value of R due only to reaction [2] was 3 $\mu g\ cm^{-2}\ hr^{-1}$.

When only NaCl(g) was added to the oxygen, the value of R increased by a factor of five compared with the case of oxygen alone. This observed increased rate was due to the formation of volatile species containing both Na and Cr (3). Again with the assumption of independent reactions, the rate attributable to the Na- and Cr-containing species was 4 $\mu g\ cm^{-2}\ hr^{-1}$.

Addition of both contaminants, NaCl(g) and $H_2O(g)$, to the oxygen yielded $R = 20$ $\mu g\ cm^{-2}\ hr^{-1}$. This is twice the sum of the rates of the three individual reactions just discussed. Apparently an additional reaction was occurring; this reaction probably involved NaOH and/or HCl which are expected to be formed by the hydrolysis of NaCl, *i.e.*

$$NaCl(g) + H_2O(g) = NaOH(g) + HCl(g) \quad [3]$$

The rate of collection of Cr from preoxidized alloy samples exposed to $O_2(g)$ + $H_2O(g)$ + NaCl(g) was compared with that from oxidized Cr. The results obtained for contaminant additions of 2.5 volume percent (v/o) $H_2O(g)$ and 50 ppm NaCl(g) are presented in Table II. Except for B-1900, all the alloys tested exhibited volatile Cr-containing species. For IN-738 the value of R was 80% of that found for pure Cr, for 713C it was 60%, and for VIA it was 50%. Measured values of R for 713C and VIA were found to decrease gradually with each one-half hour collection run. The values reported in Table II are the maximums obtained in the first one-half hour collection run. The observed decreases in R as a function of collection time were probably associated with the rate of diffusion of chromium to the surface and subsequent oxidation to Cr_2O_3. Evidently this process was slower than the reaction to form volatile chromium species at the surface.

Mass spectrometry experiments.—High pressure mass spectrometric sampling techniques were used to identify and measure volatile species emanating from preoxidized samples of Cr and IN-738 at temperatures above 1000°C in oxygen containing $H_2O(g)$ or NaCl(g) or $H_2O(g)$ + NaCl(g). Similar studies were made with Mo samples at 675°C. The main Cr-, Mo-, and Na-containing ions identified under the various experimental conditions are presented in Tables III, IV, and V together with their measured relative intensities and probable parent molecular species. In all cases, ions were identified by their m/e values; isotopic distribution and behavior when either NaCl(g), $H_2O(g)$, or the sample were removed from the system. The reported relative intensities can be converted to correct ratios of partial pressures only if reliable values are available for the relative ionization and fragmentation

Table I. Rate of collection of chromium volatilizing from chromium specimen exposed to 1 atm of slowly flowing oxygen containing different vapors

Chromium temerature, T_{Cr} (°C)	Mass fraction $H_2O(g)$* (%)	Mass fraction NaCl(g)** (ppm)	Rate of collection,† ($\mu g\ cm^{-2}\ hr^{-1}$)
1000	0	0	1
1000	1.4	0	4
1000	0	50	5
1000	1.4	50	20

* Oxygen was saturated with $H_2O(g)$ at 21°C by bubbling through fritted glass into a 20 cm column of water.
** The mass fraction of NaCl(g) was determined from weight loss of the platinum crucible and from the gas flow through the apparatus. No corrections were made for collision and reaction with the quartz walls.
† Measured collection rates were reproducible to ±20%.

Table II. Rate of collection of chromium volatilizing from chromium and chromium-containing alloys exposed to 1 atm of slowly flowing oxygen containing 2.5 v/o $H_2O(g)$ and 50 ppm NaCl(g)

Material	Temperature (°C)	Rate of collection ($\mu g\ cm^{-2}\ hr^{-1}$)
Chromium	1000	15
IN-738	1015	12
713C	1015	10*
B-1900	1015	0
NASA-TRW VIA	1015	7.5*

* Rates were falling slowly in time. Value given is maximum rate determined in first one-half hour run. It was not possible to assess the reproducibility of the rate.

Table III. Mass spectrum of vapors over the $Cr_2O_3(c)$-$O_2(g)$-$H_2O(g)$ system*

Ion	Relative intensity	Probable parent molecule
O_2^+	1.00	O_2
$CrO_2(OH)^+$	2×10^{-8}	$CrO_2(OH)$ and/or $CrO_2(OH)_2$
$CrO_2(OH)_2^+$	3×10^{-8}	$CrO_2(OH)_2$

* $Cr_2O_3(c)$ sample temperature = 1100°C; O_2 flow = 380 ml/min; H_2O saturated O_2 at 21°C.

$Na_2OHCrO_3^+$	2.0×10^{-3}	1.9×10^{-2}	$(NaOH)_2CrO_3$

* $Cr_2O_3(c)$ sample temperature = 1020°C; NaCl(c) temperature = 830°C (equivalent to 160 ppm); O_2 flow = 380 ml min^{-1}; H_2O-saturated O_2 at 21°C.

cross sections, multiplier gains for each ion, quadrupole mass filter transmission as a function of m/e, and Mach-number focusing factors for each species. At present, most of these quantities are unknown for the complex molecular species presented in the tables. Finally, parent molecular species were assigned on the basis of familiarity with the mass spectrum-molecular composition relationships for other inorganic halide molecular systems. It is well established (9) that halogen-containing molecules fragment upon electron impact ionization to yield molecular ions with the loss of a halogen atom, *e.g.*

$$Na_2Cl_2(g) + e^- \rightarrow Na_2Cl^+ + Cl + 2e^- \quad [4]$$

The results presented in Table III are for the $Cr_2O_3(c) + O_2(g) + H_2O(g)$ system; the ion intensities were normalized to a value of unity for the ion O_2^+. The only Cr-containing species identified were $CrO_2(OH)_2^+$ and $CrO_2(OH)^+$. While the ion $CrO_2(OH)_2^+$ could only originate from $CrO_2(OH)_2(g)$, the ion $CrO_2(OH)^+$ could be a fragment of $CrO_2(OH)_2(g)$ or it could originate from $CrO_2(OH)(g)$. On the basis of these results, it was not possible to determine if $CrO_2(OH)(g)$ was actually present. These results are in contrast to the transpiration results reported by Kim and Belton (10) for this system. They interpreted their measurements on the basis that $CrO_2(OH)$ was the only volatile oxide in this system.

In Table IV the results obtained for the $Cr_2O_3(c) + O_2(g) + NaCl(g)$ system, with and without added $H_2O(g)$, are presented. Both sets of ion intensities were normalized to $NaCl^+$ for the system without $H_2O(g)$ added. Such normalization puts the intensities in the proper perspective and shows that addition of $H_2O(g)$ reduces the NaCl(g). The observed Cr-containing species are seen to be mainly complexes of NaCl and CrO_3 with the general formula $(NaCl)_xCrO_3$ where $x = 1$, 2, and 3. As stated in our previous report (3), we believe that these species are the first observed examples of alkali halide-metal oxide complexes. In this regard, one point must be emphasized: The fact that the rate, R, was found to increase in the target experiments when NaCl(g) was added to the $Cr_2O_3(c) + O_2(g)$ system, indicates that R is not limited by the vaporization rate of $CrO_3(g)$ and therefore the Na- and Cr-containing species are not products of gas phase reactions. Furthermore, because species such as $(NaCl)_xCrO_3$ are not the product of gas phase reactions they likewise cannot be the product of sampling artifacts such as clustering (11).

Returning to Table IV, one sees that the main effects of adding $H_2O(g)$ to the $Cr_2O_3(g) + O_2(g) + NaCl(g)$ system were: (*i*) to reduce the $NaCl^+$ intensity, and (*ii*) to increase the prominence of NaOH-CrO_3 complexes. Both effects could result from the formation of NaOH in the hydrolysis of NaCl, either by reaction [3] or on the surface. The point emphasized above, precluding gas-phase formation, applies equally to the observed complex $(NaOH)_xCrO_3$ where $x = 1$ and 2. The fact that NaOH-containing species were observed even when $H_2O(g)$ was not added to the system indicates that the system was not completely free of water vapor. No special precautions were taken to dry the oxygen or sodium chloride used in these experiments. Parent ions corresponding to the species NaOH(g) and HCl(g) could not be measured because large in-phase background peaks were present at their respective m/e. These background peaks were due to the approximately 2300 ppm of argon impurity in the "missile" grade oxygen used.

An exhaustive search was made for the frequently proposed (2, 4, 12-17) vapor molecules CrO_2Cl_2, $CrCl_2$, $CrCl_3$, and Na_2CrO_4. This effort was unrewarding and only the species $Na_2Cr_2O_7(g)$ was detected in addition to the complexes. Therefore, we conclude that the main reactions responsible for the vapor transport of Cr are

$$1/2\,Cr_2O_3(c) + 3/4\,O_2(g) + xNaCl(g) = (NaCl)_xCrO_3(g) \quad [5]$$

$$1/2\,Cr_2O_3(c) + 3/4\,O_2(g) + xNaOH(g) = (NaOH)_xCrO_3(g) \quad [6]$$

where $x = 1$, 2, and 3 for reaction [5], and $x = 1$ and 2 for reaction [6].

Experiments were performed with samples of IN-738 at about 1050°C in $O_2(g) + NaCl(g)$. Mass spectral scans were made over the range from $m/e = 23$ to $m/e = 250$. All of the ions in this range listed in Table IV for the $Cr_2O_3(c) + O_2(g) + NaCl(g)$ system were detected with IN-738. Additional, as yet unidentified peaks of lesser intensity, were recorded at m/e values

Table V. Mass spectrometrically observed Mo-containing species over an oxidized Mo sample heated to 675°C in various flowing gas environments

System	Sample environment	Observed ions	Relative intensity*	Probable parent molecule
A	O_2 (380 cm^3/min)	O_2^+	$>10^5$	O_2
		$(MoO_3)_3^+$	1.0	$(MoO_3)_3$
		$(MoO_3)_4^+$	0.3	$(MoO_3)_4$

* Intensities are relative to $(MoO_3)_3^+$ measured in system A.

of 65, 66, 88, 89, 105 107, 146, and 147. That the main species observed with IN-738 correspond to those noted with Cr is not surprising because it is well established (18) that the main surface oxide constituent present on oxidized IN-738 is $Cr_2O_3(c)$.

Because Mo is a member of the same family as Cr, and because Mo has been identified near the surface in certain oxidized alloys (18), we investigated the Mo system to ascertain if the same type of complex molecules were formed as observed with the Cr system. Results obtained for the $MoO_3(c) + O_2(g)$ system, with and without additions of NaCl(g) and $H_2O(g)$, are presented in Table V. Without any contaminants added to the oxygen, the primary vaporizing species was $(MoO_3)_3$ as one would expect (19). The other ion intensities were normalized to a value of unity for the $(MoO_3)_3^+$ ion. The tetramer $(MoO_3)_4$ was also observed but at about 1/3 the intensity relative to the trimer. With NaCl(g) added to the oxygen, mixed alkali-halide-metal oxide complexes became prominent. These complexes are similar to those found for chromium and they can be represented by the general formula $(NaCl)_x(MoO_3)_3$ where $x = 1$ and 2. These complexes differed from the chromium ones in that the metal oxide was polymerized in keeping with the characteristic difference between Cr and Mo oxide systems at high temperatures (8, 19). Additions of $H_2O(g)$ alone to the oxygen resulted in the formation of the hydrated oxide molecule $MoO_2(OH)_2(g)$ postulated by Belton and Jordan (20). This species was quite abundant judging from the fact that the ion intensity was five times greater than the trimer ion. The ion $MoO_2(OH)^+$ was also observed but as with the chromium case it was not possible to decide whether this ion arose from ionization of $MoO_2(OH)(g)$ or from fragmentation of $MoO_2(OH)_2(g)$.

When both NaCl(g) and $H_2O(g)$ were added to the oxygen with Mo samples, the molecule $NaOH(MoO_3)_3$ was observed in addition to those noted for O_2 alone, NaCl(g) alone, and $H_2O(g)$ alone. In this case it was not possible to discern if the species $Na_2OH(MoO_3)_3^+$ was present because of interference from the species $NaCl(MoO_3)_3^+$.

Concluding Remarks

The mass spectrometric identification of the vapor species emanating from the metal samples studied under various conditions allows a better interpretation of the rates obtained for chromium vaporization (Table I) in the target collection experiments. For oxygen without any contaminant additions, the volatile chromium species was undoubtedly $CrO_3(g)$ formed by reaction [1]. This species was not identified in our mass spectrometric sampling because its concentration (at the highest temperatures we could achieve with our furnace) was just below the detection sensitivity of our sampling system. The concentration, as calculated from measured R values and gas flows, was about 0.03 ppm, and the detection limit at this mass was around 0.05 ppm.

With $H_2O(g)$ added, the rate increased because of the formation of $CrO_2(OH)_2(g)$, in addition to the $CrO_3(g)$, according to reaction [2] with $x = 2$. Additions of NaCl(g) yielded increased rates by the formation of $(NaCl)_xCrO_3(g)$ with $x = 1$, 2, and 3 according to reaction [5]. With the additions of $H_2O(g) + NaCl(g)$, the rate R was observed to increase more than expected from the sum of reactions [1], [2], and [5]. The difference must arise from the formation of $(NaOH)_xCrO_3(g)$ (with $x = 1$ and 2) by reaction [6]. Thus we can conclude that NaOH molecules are more reactive than NaCl molecules because the rate of Cr transport was higher when some of the NaCl was converted to NaOH. It should be mentioned that the other hydrolysis product of NaCl, namely, HCl, would also be expected to react with chromium at high temperatures. Nevertheless, we were unable to detect any adduct molecules of HCl and CrO_3 within the limit of our sensitivity. In addition, no chromium chlorides or oxychlorides were observed.

The rates of chromium vaporization from the alloys (Table II) can be interpreted on the basis of the same reactions as those described for chromium. It was somewhat surprising that no chromium was detected from B-1900. An extensive scale analysis has been made for these four alloys on samples oxidized for 100 hr in slowly flowing oxygen (18). This analysis showed that for samples oxidized at 1000°C, B-1900 contained the least amount of chromium in the scale surface of all four alloys. ESCA analysis indicated that there was about 3.8 atom percent (a/o) chromium in the outer layer. This was probably dissolved in the continuous layer of α-Al_2O_3 observed on the sample, and must have been unreactive with respect to the NaCl and H_2O. Another explanation could be based on the fact that the samples in this study were preoxidized for only 4 hr and the scale formed on B-1900 in this short time was entirely α-Al_2O_3.

With regard to the chromium system (and certain alloy systems also) it is important to reiterate that the observed enhanced vaporization of chromium precludes a gas phase reaction explanation of the formation of the complex molecular species reported here. A gas phase mechanism would be limited by the rate of formation of $CrO_3(g)$.

In the experiments involving molybdenum the observed vaporizing species were seen to be analogous to those found for the chromium system except that the Mo-containing species displayed the stronger tendency of molybdenum to form oxide polymers. The molybdenum results stimulate one to speculate about tungsten because it is in the same chemical family as Cr and Mo. One would expect that tungsten would form complex molecules identical to those formed by Mo in our experiments but probably at higher temperatures. Unfortunately, such W-containing molecules were beyond the mass range of our mass spectrometer.

A more quantitative correlation of these results is not possible at this time because we have not derived actual partial pressures for the various species from the measured ion intensities. Nevertheless, the qualitative description provided by our results provide valuable insights into the hot corrosion process. This is especially true for the "chromia-former" alloys (18) such as IN-738. While the chromia-former alloys are generally considered to be more resistant to hot corrosion[2] attack than the "alumina-formers," these alloys also appear to be most effected by exposure to NaCl(g) (2). The mechanism of NaCl(g) attack postulated by Hurst *et al.* (2(a)) involves NaCl(g) reaching the alloy surface below the oxide scale. Presumaby, the NaCl(g) penetrates through microcracks in the oxide and forms volatile chromium oxychlorides [*e.g.*, $CrO_2Cl_2(g)$] which cause scale lifting or cracking. Once the scale is compromised, $Na_2SO_4(c)$ on the surface can contact the alloy substrate and cause accelerated attack.

Our results show that attack by NaCl(g) results in the formation of adduct molecules rather than the oxychlorides postulated by others. Furthermore, the attack takes place, and the adduct molecules are formed, at the surface of the oxide scale. Thinning of the scale could result in the formation of regions of aggravated stress where cracking might occur, thus compromising the scale. Also, a thinned section of scale might be more readily fluxed by the $Na_2SO_4(c)$. In either case, the NaCl(g) attack compromises the oxide scale and thus promotes hot corrosion attack. It is important to emphasize that although the degree of attack by NaCl(g) is of a much smaller magnitude than the $Na_2SO_4(c)$ hot corrosion attack, the NaCl(g)

[2] Hot corrosion is considered here as the accelerated, sometimes catastrophic, oxidation of metals and alloys caused by deposits of Na_2SO_4.

attack may be of equal importance in the over-all hot corrosion process taking place in turbine engines.

A Comparison of the Mass and Resistance Change Techniques for Investigating Thin Film Corrosion Kinetics

Wen-Yaung Lee, Hans C. Siegmann,[1] and Jerome M. Eldridge*

IBM Research Laboratory, San Jose, California 95193

ABSTRACT

In situ quartz crystal oscillator microbalance (QCM) and electrical resistance change (RC) measurements were carried out simultaneously on identically prepared Permalloy films in order to establish the sensitivity and reproducibility of each technique for investigating atmospheric corrosion. Both techniques were found to be highly sensitive to thickness changes (better than 1Å) resulting from corrosion in a high humidity atmosphere containing trace quantities of acid-forming, gaseous pollutants. However, the QCM results were found to be an order of magnitude more reproducible than the RC data. Moreover, it was established from the QCM findings that the average mass increase due to corrosion was quite closely proportional to the square root of exposure time in the test chamber. Thus complex thin film corrosion kinetics can be determined with considerable accuracy provided reasonable experimental procedures are employed. The results of both measurements were compared also in an isochronal plot where it was found that the resistance change was proportional to the square of the mass increase arising from the formation of corrosion products. The origin of this relationship was investigated by carrying out simulated corrosion studies involving punching out holes in an aluminized Mylar structure while determining the effects of material loss on electrical resistance.

Thin Permalloy ($Ni_{0.80}Fe_{0.20}$) films corrode in high humidity atmospheres containing trace amounts of acid-forming gaseous pollutants (1). The magnetic characteristics of the films are degraded by corrosive processes, and device failure may then occur.

As part of an effort to improve our scientific understanding of the complex materials and environmental factors controlling thin film corrosion kinetics and mechanisms, we initiated this study to assess two quantitative techniques for measuring thin film corrosion rates. The rates of identically prepared 1000Å Permalloy films were studied *in situ* in a reactive atmosphere by quartz crystal oscillator microbalance (QCM) and electrical resistance change (RC) measurements. Simulation studies were suggested by the appearance of corroded Permalloy surfaces, showing that the chemical attack is quite localized across the film. In the simulation experiments, holes were punched out of conductive, aluminized Mylar strips in order to determine the effect of metal loss on resistance.

Experimental Procedure and Results

In order to establish the sensitivity and reproducibility of the microbalance and resistance methods for monitoring film corrosion, six Permalloy test structures were prepared for each technique during a single vacuum-deposition run. Considerable care was taken in preparing the structures in order to minimize film-to-film differences (metallurgy, surface contamination, etc.). Quartz wafer substrates (0.5 in. diam $\times$ 5 MHz frequency for the QCM and 1.0 in. diam for the RC measurements) were cleaned simultaneously. All processing and handling was done under Class 1000 clean room conditions to minimize potential particulate effects (*e.g.*, stabilization of water droplets during testing). One thousand angstrom thick films were deposited, through masks onto substrates held at 200°C, from an electron beam-heated Permalloy source. The QCM technique requires two electrodes: The Permalloy film serves as one and an inert gold film on the back side of the quartz functions as the other. The films were cooled to room temperature, removed from the deposition system, and the necessary current and potential contacts were made to each specimen (using a water impermeable polymer at each contact to eliminate possible galvanic reaction at the probe electrodes). The four-point probe, circular van der Pauw film geometry (2), was used for the RC measurements. All twelve structures were then loaded along the inside periphery of a cylindrical plexiglass test chamber (6.5 in. OD $\times$ 16 in. long). After ensuring the RC devices conducted ohmically and the base frequencies of the QCM structures were stable (to within $\pm$5 Hz/day) in dry air, a reactive atmosphere was introduced at 25.0°C. This filtered air had a relative humidity of 70% and contained trace quantities of SO_2, NO_2, O_3, H_2S, and Cl_2 (1). Changes in resistance and frequency were intermittently monitored over a period of 170 hr. Spurious galvanic effects were minimized by applying small (10 mA) electric currents only for the short times needed to obtain data points.

The corrosion-induced resistance changes increase monotonically with exposure time (t). This is shown in Fig. 1, where $[R(t) - R(o)]/R(t)$ is plotted against t for the six specimens. With these coordinates, the slopes are directly proportional to the corrosion rate, provided reaction occurs uniformly across the specimen surface. Although the attack is, in fact, highly localized. the films exhibit average corrosion rates of several angstroms per hour. The $\Delta R/R(t)$ values at any given time vary by as much as a factor of 8.

The sample-to-sample reproducibility of the QCM technique exceeds that of the RC approach by an order of magnitude, *i.e.*, the spread is less than a factor of 2. See Fig. 2, and note that a decrease in frequency of 1 Hz results from a mass increase (due to condensation of corrosive reactants) of 1.77×10^{-8} g/cm^2. The inflections in the Δf *vs.* t plots around 1300 $\pm$ 500 Hz are relatively insignificant; they probably arise from a temporary reduction in the relative humidity of the test environment. Whatever the origin of the inflection, deviation of the data from a smooth curve is relatively minor. This is clearly demonstrated

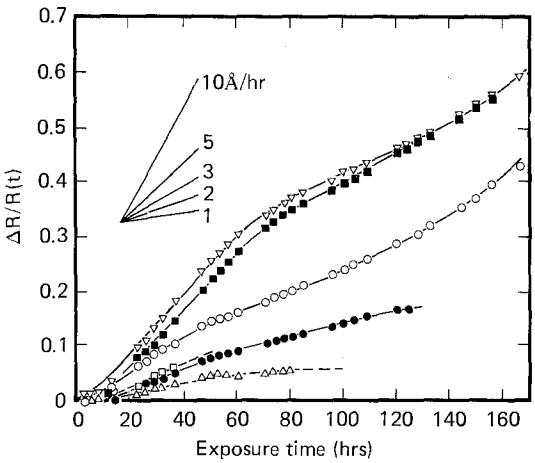

Fig. 1. Dependence of Permalloy film resistance change on exposure time to a corrosive atmosphere for six identical specimens.

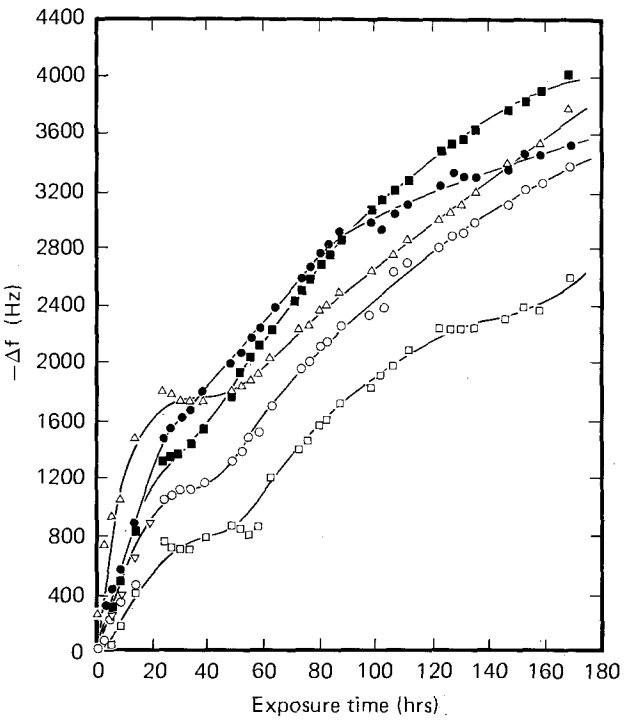

Fig. 2. Dependence of Permalloy film mass change on exposure time to a corrosive atmosphere for six identical specimens. (A frequency decrease of 1 Hz equals a mass uptake of 1.77 × 10^{-8} g/cm².)

by the fact that the average frequency shifts for these specimens is almost exactly proportional to the square root of exposure time, after an initial incubation period (τ) of 3-4 hr. See Fig. 3 in which the error bars indicate the standard deviation from the mean. The incubation period probably involves saturation of the surface with gaseous species. Accordingly, adjusting the time coordinate for a τ value of 4 hr shows that

$$-\Delta\bar{f} = 271\sqrt{t-\tau} \qquad [1]$$

with a correlation coefficient $r > 0.999$. For the films studied here, this time dependence suggests that the reaction is limited by the diffusion of reactants through a reasonably coherent layer of corrosion products. The value of the rate constant (−271 Hz/hr$^{1/2}$ in this case) clearly depends upon film and test conditions. We regard the finding of a well-defined rate law as significant because it convincingly demonstrates that complex phenomena involving the corrosion of

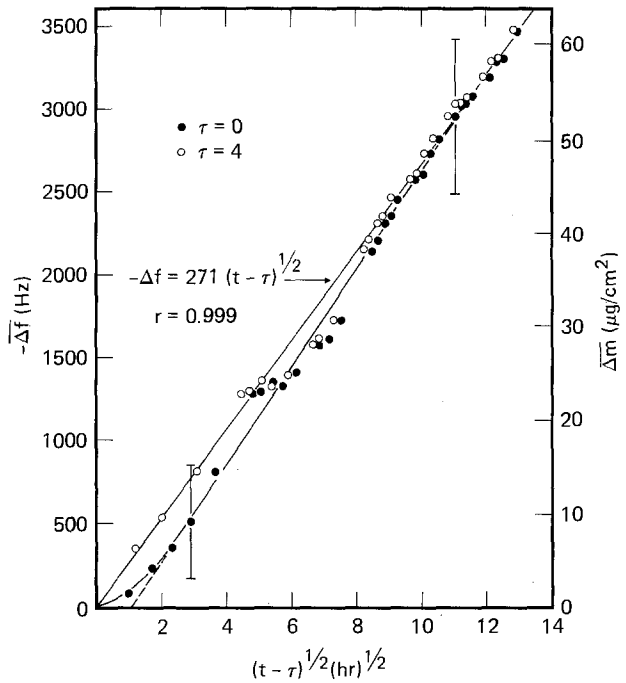

Fig. 3. Dependence of average mass uptake on the square root of exposure time to a corrosive atmosphere for Permalloy films.

multicomponent alloy films can be precisely measured, provided care is taken to minimize various artifacts (particulate, etc.) and a large enough sample size is used.

Microscopic examinations revealed that the corrosion products or active sites are not uniformly distributed across the surface. Thus, the large spread in the $\Delta R/R(t)$ *vs.* t curves can probably be attributed to minor variations in metallurgical properties and surface contamination across the specimens, as well as specimen-to-specimen differences.

In an effort to understand better the significance of the RC data, the relationship between resistance and mass change was explored by comparing the results in Fig. 1 and 2. The isochronal plot in Fig. 4 shows that the average $\Delta R/R(t)$ values increase approximately linearly with the square of the average mass uptake. The fit shown here is surprisingly good, considering the large spread in the resistance data.

We now consider the localized nature of corrosive attack on the films in order to gain some insight into the origin of the dependence shown in Fig. 4. Ideally, we would like to know the shapes, densities, and distributions of the corroded regions as a function of exposure time to the reactive environment. Since

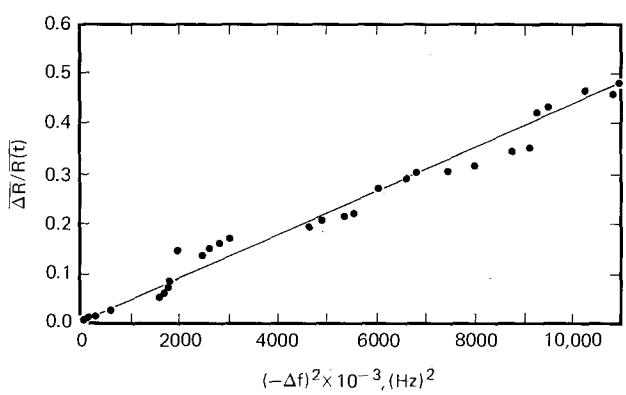

Fig. 4. Functional relationship between average resistance and mass changes of Permalloy films during atmospheric corrosion.

this information is quite tedious to establish, we have attempted to develop it in a rudimentary fashion by examining the surfaces of severely corroded Permalloy films using scanning electron and optical microscopy. The corroded parts of the film typically fall into two size categories and are more or less randomly distributed across the surface. See Fig. 4 of Ref. (1), for example, and note there are small elongated areas (~3 × 10 μm) and much larger, circular ones (~80-100 μm diam). Although the number of larger defects per square centimeter is only one-twentieth that of the smaller, the former comprise over 90% of the total corroded film area.

These observations lead us to believe that the smaller corroded regions form on nucleation sites with the introduction of the reactive atmosphere. The density of the nucleating centers is presumably dependent on film preparation conditions but will not be further discussed here. With continued exposure to the atmosphere, corrosion processes continue around a few of the small defects leading to the formation of the ~90 μm diam regions. We infer that this growth process is relatively rapid since the number of intermediate size defects is typically very low. Obviously, the larger regions contribute to most of the observed RC and QCM changes since they comprise >90% of the corrosion product.

To determine whether the above description is consistent with the observed resistance-mass change dependence shown in Fig. 4, a simple experiment was designed to simulate the effects of corrosion on film resistance. This involved punching out holes (0.125 in. diam) in a conductive aluminized-Mylar strip (1 in. wide by several inches long) while measuring the resistance-mass change dependence. The holes were confined to the central region and were well away from the electrical probes used to determine resistance by the standard four-point technique. The test structure treated is shown schematically in Fig. 5a, at the end of an experiment in which the hole positions were roughly random. The resistance increase $[\Delta R/R(o)]$ *vs.* mass loss $(\Delta m/m_o)$ curves are shown in Fig. 6 where m_o is the initial mass of the section of film being perforated. Variations in hole diameter by a factor of two or so had little effect on the results, provided the holes were more or less randomly positioned. However, note that the results are quite sensitive to the randomness of the hole positions. This can be seen from the results of a second experiment wherein a fixed number of holes were formed on an ordered lattice, and the hole diameter was increased in several steps. The scatter of the data

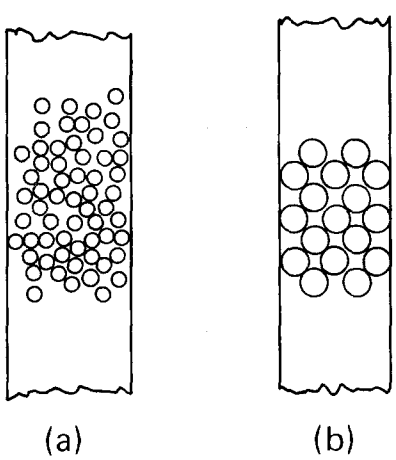

Fig. 5. Appearance of aluminized Mylar strips at conclusion of simulated corrosion experiments. (a) Random hole case; (b) ordered holes.

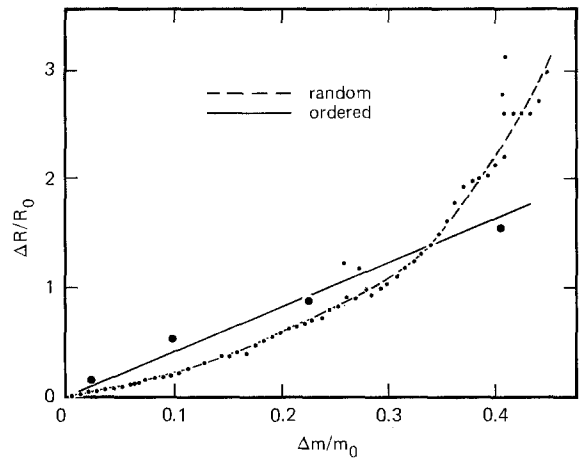

Fig. 6. Dependence of relative resistance change on mass of conducting material removed.

from a smooth curve for the random hole case is inherent in the experiment since $\Delta R/R(o)$ depends on the accidental distribution of holes, even with a fixed and relatively large number of holes; only the average of many experiments is expected to yield a smooth curve. Data from the randomized hole case are replotted in Fig. 7 and exhibit a similar quadratic dependence to that of Fig. 4. Clearly, the quantity $\Delta R/R(\Delta m/m_o)$ is the analog of $\Delta R/R(t)$. Hence we conclude that Permalloy film corrosion is initiated at randomly positioned active sites. It is also clear that the corroded regions penetrate the entire film thickness since the square law relationship in Fig. 4 holds up to quite large values of $\Delta R/R(t)$. Were the holes to penetrate uniformly only a fraction of the film thickness, the $\Delta R/R(t)$ *vs.* $|-\Delta f|^2$ plot would saturate at some constant value determined by the thickness of unreacted alloy.

The experimental resistance-mass change data of Last and Thouless (3) and percolation theory for transport in inhomogeneous conductors by Kirkpatrick

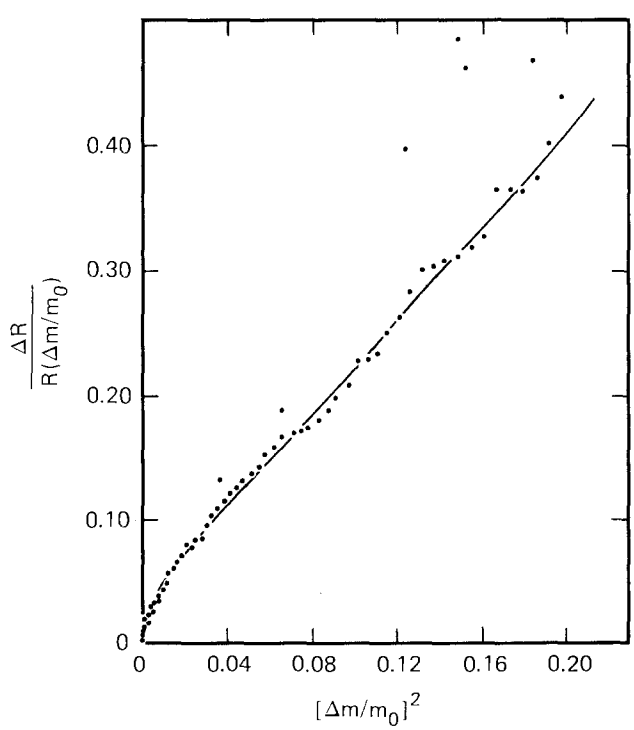

Fig. 7. Functional relationship between resistance and mass changes for the simulated, random-hole corrosion experiment.

(4) indicate an approximately linear dependence of resistance on mass change for a low (~10%) concentration of holes or defects. Although our findings (Fig. 6) also appear to be linear initially, they also fit a quadratic dependence quite well over the whole range of mass increase. Moreover, our $\Delta R/R_0$ *vs.* $\Delta m/m_0$ curve is concave upward whereas theirs (3, 4) are concave downward. The difference is not understood but our findings are intuitively reasonable.

The agreement between the results in Fig. 4 and 7 permits us to approximate the average molecular weight of the corrosion products. Note that the curve in Fig. 7 can be used to estimate the mass of Permalloy consumed in causing a given resistance increase. Likewise, the mass of condensed gases needed to cause the same resistance increase can be obtained from Fig. 4. On combining these estimates of the mass of gas condensed and Permalloy reacted, we estimate a molecular weight of roughly 200 ± 30 by the time the relative resistance change $\Delta R/R(t)$ has increased to 0.4. This value is consistent with ESCA examinations of the corroded Permalloy films which suggest that hydrated chlorides and sulfates (*e.g.*, $NiCl_2 \cdot 6H_2O$, $FeCl_2 \cdot 4H_2O$, and $FeSO_4 \cdot H_2O$) make up most of the corrosion products.

Oxidation Studies of Permalloy Films by Quartz Crystal Microbalance, AES, and XPS

Wen-Yaung Lee and Jerome Eldridge*

IBM Research Laboratory, San Jose, California 95193

ABSTRACT

The quartz crystal oscillator microbalance has been used in conjunction with Auger electron and x-ray photoelectron spectroscopies to study the oxidation at 185°C and 1 atm O_2, of air-exposed Permalloy films vacuum deposited at 200° and 350°C. Frequency shifts corresponding to weight gains of the films during oxidation combined with data obtained from AES, XPS, and ion sputter-etching showed: (*i*) the oxidation rate was diffusion controlled, (*ii*) Fe was preferentially oxidized with moderate Ni enrichment in the remaining alloy, and (*iii*) the average iron oxide composition is $FeO_{1.3}$. Reaction appears to be limited by iron diffusion through the alloy. Average iron diffusion coefficients estimated from the parabolic rate constants are in good agreement with that reported for iron in thin polycrystalline Ni films.

The quartz crystal microbalance (QCM) with its easily obtainable mass sensitivity of better than 10^{-9} g/cm^2 ($\simeq 10^{12}$ molecules/cm^2) has been extensively used in various mass-related measurements (1-6). However, in addition to measuring the net weight change of the film, it is desirable to determine the compositions of the reaction products, using such surface sensitive techniques as Auger electron spectroscopy (AES) and x-ray photoelectron spectroscopy (XPS). It is well known that the different chemical valence states for most elements can be determined by XPS (7), and that AES coupled with ion sputter-etching provides a tool for obtaining the depth distribution of various elemental species. But these two techniques have their intrinsic difficulties: *e.g.*, the destructive nature of either the excitation source used (8-10) and/or the ion-sputtering needed for in-depth profiling (11-14). Because of these and other uncertainties (viz., excitation cross section, electron escape depth, and the effects of diffraction, surface roughness, and backscattered electrons), AES and ESCA results are generally qualitative. It is the purpose of this paper to demonstrate that QCM can be used in conjunction with AES and XPS to obtain quantitative information on complex surface reactions involving the oxidation of alloy films.

We have chosen to study the oxidation of Permalloy ($Ni_{0.80}Fe_{0.20}$) films using these techniques, with the intent to establish a foundation for future studies of various thin film systems. The complicated surface composition and chemistry of air-exposed Permalloy films have been studied by Pollak and Bajorek using AES and XPS (15) and the oxidation (in the 350°-500°C range) of Permalloy films was carried out by Coren and Francombe (16) and by Bajorek *et al.* (17). However, to our knowledge no kinetic data have been reported for Permalloy film oxidation. To obtain a better insight into the stability of Permalloy in an oxygen atmosphere at intermediate temperatures, the oxidation kinetics of 1000Å films were investigated here with the QCM technique. Specimens were prepared at two temperatures (200° and 350°C) to assess potential microstructural effects on reactivity.

* Electrochemical Society Active Member.
Key words: alloy film reactivity, preferential oxidation, thin film diffusion.

AES, XPS, and ion sputter-etching were subsequently used to analyze the oxidized films. The results show that the oxidation rate is controlled by iron transport through the alloy and that Fe is preferentially oxidized, leading to a moderate Ni enrichment in the underlying alloy.

Experimental Procedures

Permalloy films were electron-beam deposited through masks from a single source [Fe 18 atom percent (a/o), Ni 82 a/o], under 10^{-7} Torr vacuum. The film thickness was 1100 ± 50Å as analyzed by an optical interferometer and 1160 ± 40Å by electron microprobe (EM) analysis, assuming a Permalloy density of 8.7 g/cm³. The film composition was also analyzed by EM and was found to be Fe 19.2 ± 0.2 and Ni 80.8 ± 0.2 a/o. These films were deposited directly onto optically polished, AT-cut quartz crystal substrates (0.5 in. diam). The patterned Permalloy film also served as one of the two excitation electrodes. The other excitation electrode was a 1000Å gold film vacuum-deposited, prior to the Permalloy, onto the other quartz crystal face at 200°C. To minimize frequency changes due to effects other than oxygen up-take, a double-resonator technique was employed, using gold as reference electrodes. The reaction chamber was held at 185° ± 0.4°C, leading to a frequency fluctuation of ±5 Hz over a typical 24 hr period. The quartz-crystal microbalance system is illustrated schematically in Fig. 1.

It has been shown (18) that, for a quartz crystal vibrating at its fundamental thickness-shear mode

$$\Delta m/m = -\Delta f/f \qquad [1]$$

where $-\Delta f$ is the frequency lowering due to a uniform mass addition (Δm) which is small compared to the initial mass of quartz (m); and, f is the initial frequency of the quartz device. For an AT-cut, 5 MHz crystal, the mass change corresponding to a 1 Hz shift is 1.77×10^{-8} g/cm². However, both the true film surface area and the oxide density must be known to convert this weight change into oxide thickness.

AES and XPS spectra were taken at room temperature with Physical Electronics Industries Auger and Hewlett-Packard 5650A spectrometers, respectively (19, 20). The peak-to-peak heights of the oxygen KLL Auger transition at 510, the Fe LMM at 650, and the Ni LMM at 850 eV were monitored during the Xe ion sputtering at 5×10^{-5} Torr pressure and 1 keV beam voltage. Aluminum K_α radiation was used for excitation to obtain all ESCA data and the binding energy was referred to the $Au4F_{7/2}$ line at 83.9 eV.

Experimental Results

Typical frequency shift-oxygen exposure time curves are shown in Fig. 2. It is seen that the total weight increase after 160 hr of O_2 exposure amounts to ~6 $\times 10^{-7}$g for an electrode area of 0.3 cm², showing the necessity of using an extremely sensitive technique such as QCM. The results are quite reproducible, with run-to-run variations being less than several percent of the total frequency changes. As seen in Fig. 3, the results fit well to a parabolic rate law, after an initial period of several hours. The parabolic rate constants (K_p) calculated from the slopes are 1.7×10^{-17} and 9.4×10^{-18} g/cm²·sec for films deposited at 200° and 350°C, respectively.

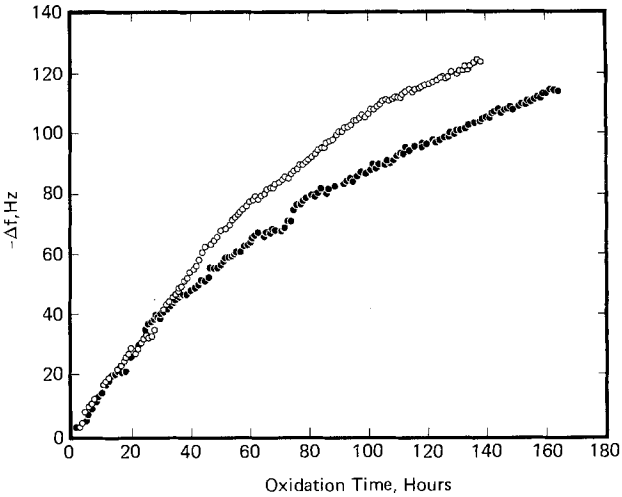

Fig. 2. QCM frequency changes of Permalloy films due to oxidation at 185°C and 1 atm O_2. Solid circles are for films deposited at 350°C and open circles at 200°C.

Typical AES spectrum for the surface of an air-exposed Permalloy film is shown in Fig. 4. In addition to Fe, Ni, and O, note that small amounts of C, S, and Cl are present. These are typical contaminants for air-exposed films (10). Except for oxygen, however, these contaminants appear to be limited only to the surface region because their signal intensities quickly decrease to the background noise upon sputtering. Figure 5 shows a similar spectrum for a heavily oxidized (~160 hr) specimen. It is seen that the Ni signal strength is relatively small compared to that for the air-exposed films. In certain runs, Ni could not be detected by AES on heavily oxidized surfaces. The very low Ni signal strength and the fact that the lower Fe LMM Auger transition at 44 eV splits into a

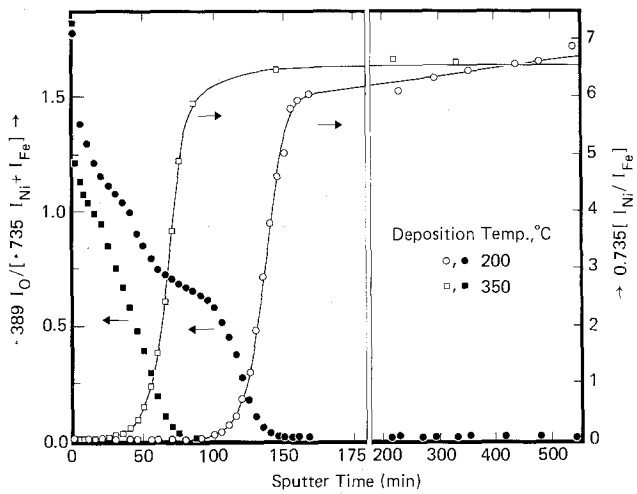

Fig. 7. AES sputter depth profiles of oxidized Permalloy films

doublet (at 41 and 48 eV) characteristic of oxidized Fe (21) indicate that the film surface is predominantly iron oxide.

The AES depth profiles of both the air-exposed and heavily oxidized films were obtained and analyzed according to the equation (13, 14)

$$\frac{I_{Ni}/I_{Ni}^{\circ}}{I_{Fe}/I_{Fe}^{\circ}} = \frac{S_{Fe}}{S_{Ni}} \cdot \frac{C_{Ni}}{C_{Fe}} \qquad [2]$$

where I_{Ni} and I_{Fe} are the peak-to-peak heights, obtained after a steady-state surface composition is reached by sufficient sputtering of the alloy with bulk concentrations of C_{Ni} and C_{Fe}, respectively; I_{Ni}° and I_{Fe}° are those for pure metals; and, S_{Fe} and S_{Ni} are the sputtering yields. It should be pointed out that this equation is correct strictly when the matrix dependence of electron escape depths and backscattering factors are small.

The normalized I_{Ni}/I_{Fe} and $I_O/(I_{Ni} + I_{Fe})$ signal strength ratios are plotted against sputter-etching time in Fig. 6 and 7 for the air-exposed and heavily oxidized films, respectively. The normalization constant $I_{Fe}^{\circ}/I_{Ni}^{\circ} = 0.735$ was obtained from pure Ni and Fe films and agrees well with that calculated from data reported by Palmberg *et al.* (22). The value of $I_{Fe}^{\circ}/I_O^{\circ} = 0.389$ was extracted directly from their data (22). From Fig. 6, it is seen that the normalized I_{Ni}/I_{Fe} ratio increased from ~2 at the air-oxide interface to a maximum of about 5.3 near the inner interface, before gradually leveling off to the bulk value of 4.0 ± 0.1. This is accompanied by a rapid decrease of the $I_O/(I_{Ni} + I_{Fe})$ ratio, which reaches a minimum approximately when I_{Ni}/I_{Fe} achieves a maximum. The findings indicate that iron is depleted from the alloy surface to form an iron-enriched oxide tarnishing layer, as reported earlier (10). Furthermore, since $(I_{Ni}/I_{Ni}^{\circ})/(I_{Fe}/I_{Fe}^{\circ}) = 4.0 \pm 0.1$ and $C_{Ni}/C_{Fe} = 4.2$ (as determined by EM) S_{Ni}/S_{Fe} calculated from Eq. [2] is found to be 1.05. Thus Ni sputters only slightly faster than Fe at the Permalloy composition, and the AES depth profiles for bulk Permalloy also represent approximate compositional profiles.

For the deliberately oxidized films, the I_{Ni}/I_{Fe} ratio increased sharply from nearly zero as the oxide-alloy interface was approached, reaching a steady-state value of about 6.6, as can be seen in Fig. 7. This value yields an iron concentration in the remaining bulk alloy of ~13%, indicating that Fe is depleted from the underlying alloy during the oxidation process. This finding, augmented by the essential absence of Ni in the oxide region, prove that Fe is preferentially oxidized in Permalloy under the conditions used here. Similar results have been reported also for Permalloy oxidized at temperatures between 350° and 500°C using x-ray diffraction (16) and nuclear backscattering and x-ray fluorescence (17) techniques. On the other hand, the $I_O/(I_{Ni} + I_{Fe})$ ratio decreases with increasing ion etching time, even within the oxide layer where the Ni concentration is almost zero. This

result implies that the iron oxide composition is changing. Unfortunately, these profiles cannot be used to calculate the oxide composition profile directly, because of the sputter-induced damage (preferential sputtering of O) (12, 23). However, the $I_O/(I_{Ni} + I_{Fe})$ ratios extrapolate to ~1.5 at the outer oxide surface, corresponding to the composition of Fe_2O_3.

In order to further identify the oxidation products, ESCA spectra were obtained also for companion films prepared and oxidized under the same conditions. Typical results for the $Ni2P_{1/2}$ and $Fe3P_{1/2}$ transitions are shown in Fig. 8 and 9, respectively. From the binding energy observed for $Fe3P_{1/2}$ (56.4 eV relative to metallic iron at 53.1 eV) in Fig. 8 it appears that the dominant oxidation products on the surface are Fe_2O_3 (24, 25), although there is also the possibility that Fe_3O_4 is present (23). The spectra in Fig. 8 indicate that small amounts of metallic (at 870.2 eV) and higher valence state (at 874.2 eV) Ni are also present on the surface.

Sputter profiling of the oxidized films reveals that the binding energy of the $Fe3P_{1/2}$ line gradually

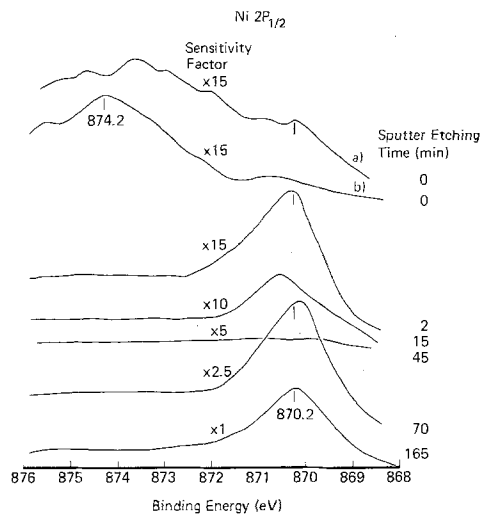

Fig. 8. XPS spectra for the $Ni2P_{1/2}$ transition of: (a) air-exposed, and (b) oxidized Permalloy films. The oxidized films have been sputter-etched with Ar ions at 1 kV, 5 × 10^{-5} Torr pressure and a filament current of 10 mA.

decreases from 56.4 eV at the surface to reach the metallic value of 53.1 eV on approaching the inner interface. Because this binding energy shift corresponds to a change of Fe oxidation state from +3 to 0, it appears that the average iron oxide composition is graded from Fe_2O_3 at the surface to FeO near the inner interface. However, this change in composition can also be due to the preferential sputtering of oxygen (12, 22), as mentioned earlier. On the other hand, Fig. 8b showed that the $Ni_2P_{1/2}$ transition quickly reached the metallic state value upon sputter profiling, remaining low in intensity throughout the oxide layer and did not increase in strength until the underlying alloy was reached. These results are quite consistent with those from AES profiling.

Discussion

If a reasonable average oxide composition and density are assumed, the total oxide thickness can be estimated from the QCM data. One can then estimate the corresponding reduction in iron concentration in the underlying alloy and compare this with the AES finding. Thus, we assume that the oxide layer is an equal mixture of Fe_2O_3, Fe_3O_4, and FeO with an average oxide composition of $FeO_{1.3}$ and a density of 5.4 g/cm³. The results are given in Table I, along with those based on the premise that the oxide is Fe_2O_3. The average $FeO_{1.3}$ composition clearly yields final alloy compositions that are in very good agreement with the AES-determined results. The oxide thicknesses were calculated by assuming that the true film surface area equals the geometrical area. For comparison, the oxide thicknesses (estimated from the products of the oxide sputter etching times and the Permalloy sputter etching rate) are 195 and 187Å for the 200° and 350°C films, respectively. Since the oxide sputtering rate is not likely to be constant throughout the oxide layer or the same as that of Permalloy, estimates like this should be viewed with caution.

Since the QCM data fit reasonably well to a parabolic rate law and the AES results show that Fe is preferentially oxidized with a moderate Ni enrichment in the underlying alloy, it appears that the diffusion of Fe is the rate-limiting step for reaction. If the oxidation step at the oxide-alloy surface is fast compared with the diffusion of Fe atoms in the alloy, the over-all diffusion coefficient (D) is related to the parabolic rate constant (K_p) through the following equation (26)

$$D = \frac{\pi}{(\rho C)^2} \cdot \left(\frac{M}{16Z}\right)^2 \cdot K_p \qquad [3]$$

where ρ = 7.86 g/cm³, C = 0.192, and M = 55.85 are the density, mole fraction in the alloy, and atomic weight of Fe, respectively; Z = 2.6 for the average oxide $FeO_{1.3}$. Hence, diffusion coefficients of 4.2 × 10^{-17} and 2.3 × 10^{-17} cm²/sec were calculated for films deposited at 200° and 350°C, respectively. These values are close to that (~5 × 10^{-18} cm²/sec) re-

Table I. Comparison of various estimates of iron oxide thicknesses and resulting alloy compositions

Film deposition temperature (°C)	Assumed oxidation product	Δf (Hz)	t (Å)	(Ni/Fe)$_{QCM}$*	(Ni/Fe)$_{AES}$**
200	Fe_2O_3	124	139	5.8	6.6
200	$FeO_{1.3}$	124	150	6.5	6.6
350	Fe_2O_3	114	128	5.5	6.6
350	$FeO_{1.3}$	114	138	6.2	6.6

* Composition of the underlying alloy layer after oxidation, as calculated from QCM data.

ported for Fe diffusion through polycrystalline Ni film at 185°C (27). Since these values are several orders of magnitude higher than those extrapolated for lattice diffusion, it seems that grain boundary and defect-enhanced lattice diffusion provide the dominant transport mechanisms (27). Furthermore, the larger diffusion coefficient for the 200°C films nicely reveals the dependence of film reactivities on film deposition temperatures in that the lower temperature formed ones are finer grained, and presumably have a much higher vacancy concentration. Thus, they are more accessible to grain-boundary and defect-enhanced lattice diffusion than films deposited at the higher temperature.

As mentioned earlier, XPS results indicate that very small amounts of metallic Ni and its compounds (probably hydroxide) are present near the iron oxide surface. According to Whittle *et al.* (28), the minimum mole fraction (X_{Ni}) of nickel at the alloy/oxide interface needed to form NiO can be estimated from

$$(1 - X_{Ni})/X_{Ni} = \exp\left[\frac{1}{RT}(\Delta F^\circ_{FeOx} - \Delta F^\circ_{NiO})\right] \quad [4]$$

where ΔF°_{FeOx} and ΔF°_{NiO} are the standard free energies of iron and nickel oxide formation, respectively. Since the difference in the standard free energy of iron oxide (Fe_2O_3 or Fe_3O_4) and nickel oxide formation is at least 30 kcal/mole (29), X_{Ni} is estimated to be very close to unity and thus is much larger than the bulk Ni concentration in the alloys. Therefore, iron oxide is expected to be formed exclusively because of thermodynamic considerations. Trace amounts of nickel near the surface and its absence inside the iron oxide region suggest that nickel is probably incorporated in the iron oxide during its nucleation and growth stages and sparsely dispersed near the surface (30). This interpretation is consistent with the observation that occasionally AES detected no Ni on the surfaces of heavily oxidized films, due to its small sampling area (~50 μm).

Finally, it should be pointed out that lateral stress build up (2) in the film during oxidation could also cause some frequency changes in addition to that caused by the mass loading effect. The frequency shifts caused by stress (Δf_s) are related to that of the mass effect (Δf_m) by

$$\Delta f_s/\Delta f_m \simeq K\,\Delta s/\tau_f \quad [5]$$

where $\Delta s/\tau_f$ is the averaged stress change of the film and K is 2.75×10^{-12} cm²/dyne for AT-cut quartz crystals. The isotropic stress of Permalloy films on glass or mica is on the order of 10^9 dyne/cm², and all the films used here contain an initial air-formed oxide of about 18Å (estimated from AES/depth profiling). Since the additional oxide grown is only several times larger, the net stress change of the film is not likely to be drastically larger than 10^9 dyne/cm². Accordingly, the stress effect appears to be quite negligible, *i.e.*, less than 1% of the mass loading effect.

Liquid Crystal Mixtures for Low Voltage Dynamic-Scattering Display

Yoshikazu Hori and Masakazu Fukai

Matsushita Electric Industrial Company, Limited, Central Research Laboratory
3-15 Yagumo Nakamachi, Moriguchi-shi, Osaka, 570 Japan

ABSTRACT

New liquid crystalline compounds with high negative dielectric anisotropy and wide temperature range have been prepared by using the double-Shiff's-base compounds of bis-(4'-n-alkylbenzylidene)-2-cyano-1,4-phenylenediamine. The effect of negative dielectric anisotropy on the dynamic scattering properties was studied. With the increasing value of negative dielectric anisotropy of the liquid crystal mixture, they gave the low threshold voltage of the instability followed by the rapid increase of dynamic scattering intensity, and a low voltage dynamic scattering display device has been achieved. The increase of the contrast ratio above threshold and the weak temperature-dependent threshold characteristic improved the matrix-addressing properties remarkably.

Since Heilmeier, Zanoni, and Barton (1) reported the electro-optical effect of nematic liquid crystals and the capability of application to flat display devices in 1968, a great deal of research and development in liquid crystal material has been carried out actively, and many electro-optical effects such as dynamic-scattering and twisted nematic have been reported. Research to lower the driving voltage of liquid crystal displays using the twisted-nematic effect has been carried out (2). But few studies to lower the driving voltage of the dynamic-scattering display have been reported, although the effect has been well investigated experimentally and theoretically by many researchers (3-6). Elliott (7) reported the effects of dielectric anisotropy on dynamic-scattering by using material with a high negative dielectric anisotropy ($\Delta\epsilon \sim -2.0$) and found that this type of material decreased the threshold voltage slightly.

In this paper, the relation between the characteristics of the dynamic-scattering effect and the dielectric anisotropy of nematic liquid crystal is dealt with.

Experimental Procedure

Material.—The double-Shiff's-base compounds of bis-(4'-n-alkylbenzylidene)-2-cyano-1,4-phenylenediamine with high negative dielectric anisotropy were prepared and added to a room temperature nematic mixture. The compounds are abbreviated as BACYP1 to BACYP4 according to the number of carbon atoms in the alkyl chains, and the formula and the mesomorphic temperature ranges are shown in Table I.

The compounds were synthesized from 2-cyano-1,4-phenylenediamine, and 4-n-alkylbenzaldehyde and purified by recrystallization in the mixture of n-hexane and benzene. The impurities of these compounds were confirmed to be less than 0.15 mole percent (m/o) by DSC.

A triple mixture of Shiff's-base compounds was used as a host material. The nematic temperature range was from −6° to 69°C. It consisted of 4-ethoxybenzylidene-4'-butylaniline, 4-propylbenzylidene-4'-pentylaniline, and 4-methoxybenzylidene-4'-heptylaniline. Each component of this mixture was purified by recrystallization in n-hexane and the purities were confirmed by gas chromatographic analysis.

Nematic mixtures for the experiments were prepared by mixing these substances in arbitrary ratios. 3.5-dinitrobenzoic acid and the other dopants of a small quantity for specific resistivity and the homeotropic alignment were added.

Key words: liquid crystal display, low voltage driving, dynamic scattering mode, double-Shiff's-base compounds, high negative dielectric anisotropy.

They were placed between indium oxide coated conductive glass plates of about 10 μm gap. The electrical field was applied to the liquid crystal layer through a transparent electrode.

Measurement of physical and electro-optical properties.—For the measurement of the nematic temperature ranges the crystal (or smectic)-to-nematic and nematic-to-isotropic transition temperatures were measured by observing the phase change of compounds on the temperature control stage of a polarizing microscope.

The dielectric anisotropies and conductivity anisotropies were obtained by the measurement of dielectric constants and conductances parallel and perpendicular to the molecular orientation with a capacitance bridge.

Electro-optical properties were measured in the conventional way. The incident light from a tungsten lamp was irradiated to the panel normally, and the light transmitted normally to the liquid crystal layer was detected by a photo sensor. The response time was measured by the definition as follows. The rise time is the time the transmission falls 90% to the final transmission after the electrical field (32 Hz square wave) has been applied. The decay time is the time the transmission recovers 90% to the initial transmission after the electrical field has been turned off.

Cutoff frequency was defined as the frequency which divides the conduction and dielectric region in the curve showing the frequency dependence of the threshold voltage of electrohydrodynamic instability (8).

Experimental Results

Nematic temperature ranges.—The nematic temperature ranges of the mixtures used in this study are shown in Table II.

By the addition of double-Shiff's-base compounds the nematic temperature range is widened in general and nematic mixtures with a temperature range of more than 100°C are obtained. In the case of the mixture containing 30 weight percent (w/o) of BACYP1, a nematic phase could not be observed clearly.

The properties of dielectric anisotropy.—Figure 1 shows the dependence of dielectric anisotropy ($\Delta\epsilon$) and dielectric constants parallel ($\epsilon_{\parallel}$) and perpendicular ($\epsilon_{\perp}$) to the molecular orientation on the concentration of BACYP. The negative dielectric anisotropy and dielectric constants increase proportionally to the increase of BACYP concentration. When the effect of the number of carbon atoms in the alkyl group is compared, BACYP with a smaller number of carbon atoms in the alkyl group is effective in increasing the negative dielectric anisotropy.

The dielectric anisotropy of double-Shiff's-base compounds themselves are estimated to be between −8 and −5 at room temperature from the figure. These are much greater than that of chloro compounds of these double-Shiff's-base types (7).

The properties of conductivity anisotropy.—Figure 2 shows the variation of the conductivity anisotropy as a function of BACYP2 concentration. It is defined as the ratio between the conductance parallel ($\sigma_{\parallel}$) and perpendicular ($\sigma_{\perp}$) to the molecular orientation. By the addition of BACYP2, the conductivity anisotropy is increased, and this is the important factor for producing the charge formation and causing dynamic-scattering when an electrical field is applied.

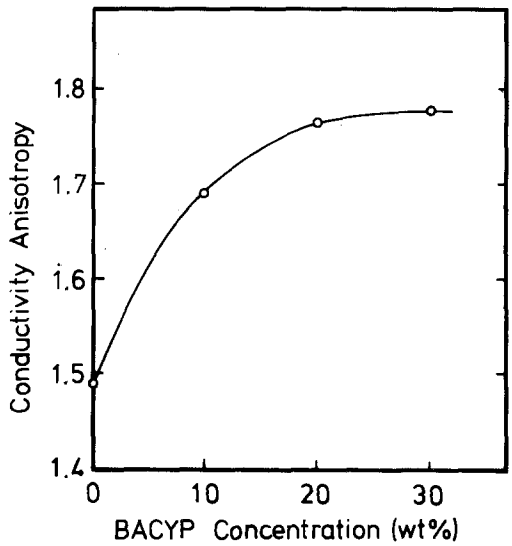

Fig. 2. The dependence of conductivity anisotropy ($\sigma_{\parallel}/\sigma_{\perp}$) on BACYP2 concentration.

Light scattering properties.—The properties of transmission as a function of applied voltage in nematic mixtures containing 0, 10, 20, and 30 w/o concentration of BACYP2 at 25°C is shown in Fig. 3. The threshold voltage of the host material is about 8V but accompanied by the increase of BACYP2 concentration it decreases to about 5V, and the voltage to give the same transmission also decreases. The same effect was con-

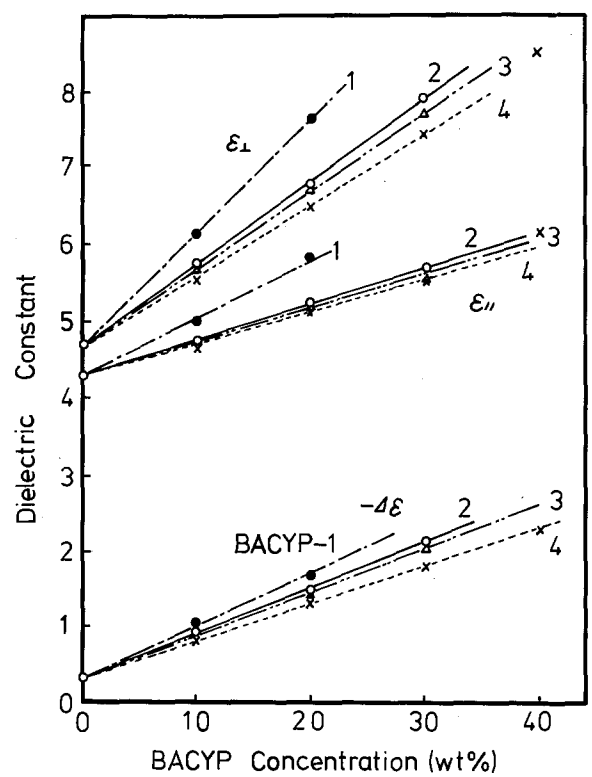

Fig. 1. The dependence dielectric constants ($\epsilon_{\parallel}$, $\epsilon_{\perp}$) and dielectric anisotropy on the concentration of BACYP.

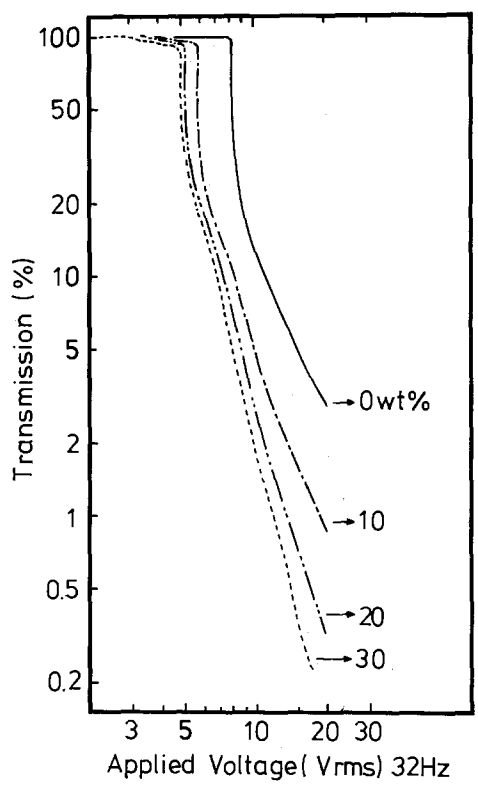

Fig. 3. The variation of transmission with the applied voltage when the concentration of BACYP2 is changed.

firmed in the mixtures containing the other double-Shiff's-base compounds except BACYP1.

The mixture containing 30 w/o BACYP1 did not have a nematic phase at room temperature, and it showed a quite different characteristic.

Figure 4 shows the properties of transmission as a function of applied voltage in nematic mixtures containing 10 w/o of BACYP1, BACYP2, BACYP3, and BACYP4 at 25°C and shows the effect of number of carbon atoms in the alkyl group of BACYP. The threshold voltage and the voltage to give the same contrast ratio are lower in the nematic mixtures containing the double-Shiff's-base compounds with fewer carbon atoms in the alkyl groups.

The same tendency was confirmed in the mixtures with other concentrations of double-Shiff's-base compounds except BACYP1. This means the double-Shiff's-base compounds with fewer carbon atoms in the alkyl groups and higher negative dielectric anisotropy have greater effect in decreasing the threshold voltage and the voltage to give a sufficient contrast ratio.

The effects of dielectric anisotropy.—Figure 5 shows the variation of the threshold voltage of light scattering (V_{th}), of Fredericksz transition (V_{fr}), and of the voltage to give the contrast ratio of 20:1 with negative dielectric anisotropy for the nematic mixtures containing BACYP2.

V_{fr} decreases linearly with increasing negative dielectric anisotropy as expected from the Leslie equation of $V_{fr} = \pi(K_{33}/|\Delta\epsilon|\epsilon_0)^{1/2}$ (9) where K_{33} is the elastic constant and ϵ_0 is the dielectric permittivity in a vacuum. The difference of the gradient from $-1/2$ is considered to be caused by the change of elastic constant due to the addition of double-Shiff's-base compounds.

V_{th} also decreases but the gradient is smaller than that of V_{fr} and has a slight tendency to saturate as the negative dielectric anisotropy increases.

The dependence of V_s on dielectric anisotropy has the same tendency as V_{th}, but the gradient is slightly greater than that, because the rate of increase of the dynamic-scattering intensity above threshold becomes as great as the increase of negative dielectric anisotropy. These characteristics are suitable for low voltage driving.

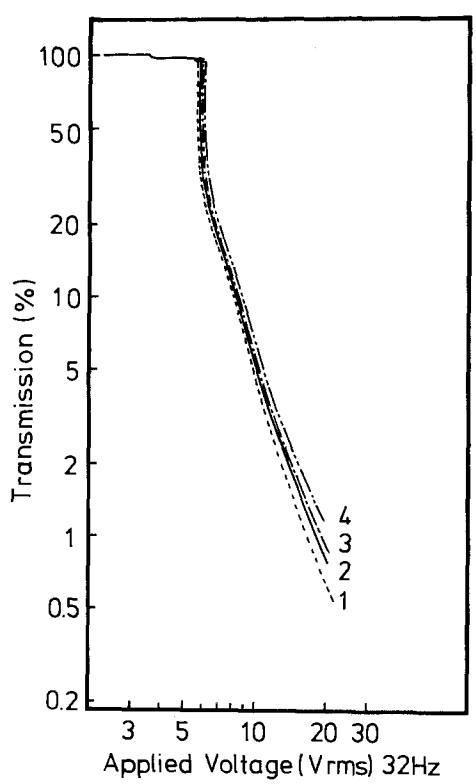

Fig. 4. The effect of the BACYP number on the transmission and voltage characteristics. 10 w/o of each BACYP is contained. The numbers denote BACYP numbers.

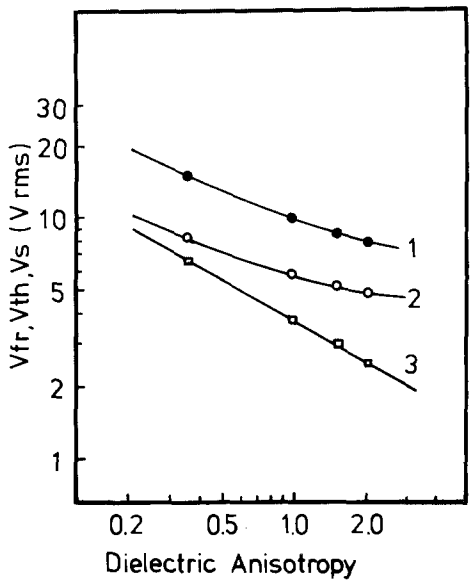

Fig. 5. The dependence of the threshold voltage of light scattering (V_{th}) (no. 2) and the Fredericksz transition (V_{fr}) no. 3) and the saturation voltage (V_s) (no. 1) on the negative dielectric anisotropy.

The higher negative dielectric anisotropy is considered to give improved dynamic-scattering due to greater interaction with the ion flow and higher anisotropy of the refractive index (7).

The anisotropy of the refractive index was confirmed to increase from 0.44 to 0.49 by the addition of BACYP2.

Cutoff frequency characteristics.—The variation of the threshold voltage with frequency was derived by the Orsay Liquid Crystal Group (10) and was written by using ω and ζ^2 as

$$V_{th}^2 = \frac{\pi^2 K_{33}}{|\Delta\epsilon|\epsilon_0} \frac{\epsilon_{||}}{\epsilon_{\perp}} \frac{1 + \omega^2\tau_D^2}{\zeta^2 - (1 + \omega^2\tau_D^2)} \quad [1]$$

$$\zeta^2 = \left(1 - \frac{\sigma_{\perp}}{\sigma_{||}} \frac{\epsilon_{||}}{\epsilon_{\perp}}\right)\left(1 + \frac{\epsilon_{||}}{|\Delta\epsilon|} \frac{1}{1 + \eta_0/\gamma_1}\right) \quad [2]$$

$$1/\tau_D = \sigma_{||}/\epsilon_{||}\epsilon_0 \quad [3]$$

ζ^2 is a nondimensional term and is a function of dielectric anisotropy, dielectric constants, conductivity anisotropy, and viscosity coefficients. τ_D is the dielectric relaxation time and η_0 and γ_1 are viscosity coefficients.

Cutoff frequency is described as a function of ζ^2 as

$$\omega_c = (\zeta^2 - 1)^{1/2} \sigma_{||}/\epsilon_{||} \quad [4]$$

and when $\omega = \omega_c$ the threshold voltage becomes infinite theoretically. Cutoff frequency is easily controlled by changing the conductance, but as ζ^2 decreases with the increase of negative dielectric anisotropy, the cutoff frequency also decreases if conductance is kept constant.

In order to maintain the properties for frequency and to satisfy the low temperature characteristics (11), conductance must be increased by adding a larger quantity of conductive dopants. In the case of a mixture containing 20 w/o concentration of BACYP2, the

conductance should be increased to be twice that of the host material to keep the same frequency characteristics. Because the driving voltage is decreased to be about one-half, the power consumption decreases to one-half as a result.

The decrease of ζ^2 with the increase of negative dielectric anisotropy restrains the decrease of threshold voltage of light scattering in comparison with the threshold voltage of Fredericksz transition as expected from Eq. [1] and shown in Fig. 5.

By obtaining the values of ζ^2 experimentally and inserting them into Eq. [1], the agreement between the experimental results and threshold voltage theory can be confirmed.

Figure 6 shows the variation of the value of ζ^2 and the threshold voltage of light scattering. The open circles denote the values of ζ^2 obtained experimentally from cutoff frequency by Eq. [4] and the solid line denotes the calculated value of ζ^2 obtained by inserting the experimentally estimated values into Eq. [2].

The full circles show the variation of experimental results of threshold voltage compared with the threshold voltage of the host material. The dashed line shows the calculated value based on theory. Good agreement is obtained and the characteristics of threshold voltage can be explained.

Response time.—Figure 7 shows the dependence of the decay time of light scattering on BACYP2 concentration in a nematic liquid crystal mixture after the electrical field of a 10V square wave is turned off. It increases exponentially to the BACYP2 concentration due to the increase of viscosity (12).

Figure 8 shows the dependence of rise time on the concentration of BACYP2 by the application of a 10V electrical field. Although the viscosity increases, negative dielectric anisotropy also increases, so rise time is shortened as a result. This is expected from the equation (13)

$$T = \eta[\Delta\epsilon \cdot \epsilon_0 E^2 - Kq^2]^{-1} \qquad [5]$$

where η is the proper fluid viscosity, q is the wave vector of the disturbance, E is the applied field, and K is the appropriate elastic constant.

Matrix addressing property.—Figure 9 shows the temperature dependence of the threshold voltage of light scattering. By the addition of BACYP, the temperature dependence of the threshold voltage becomes weak with a minimum near 40°C. This characteristic and the rapid increase of dynamic-scattering intensity above the threshold are advantageous for the matrix-addressing properties in a wide temperature range at a fixed driving voltage.

Figure 10 show the dependence of the contrast ratio on the duty ratio for matrix arrays by a one to two and one to three voltage selection method at 25°C. The bias voltages were set to the minimum threshold voltage between 0 and 60°C. The solid lines show the characteristics by the one-third voltage selection method and the dashed lines show the characteristics by the one-half voltage selection method.

The duty ratio to give the contrast ratio of 10:1 is reduced from 1/4 to 1/6-1/7 by the one-third voltage selection method, and a duty ratio of 1/3 by the one-half voltage selection method can give a sufficient contrast ratio by the addition of 30 w/o of BACYP.

Discussion

The threshold condition for the electrohydrodynamic instability in nematic liquid crystal is determined by the torque balance of elastic, dielectric, and viscous torque to give a steady-state angular momentum.

Under the simplest one-dimensional model, they are written as Eq. [6]

$$V_{th}^2 = \pi^2 K_{33}/\epsilon_0 \left\{ \epsilon_{\parallel} \left(1 - \frac{\sigma_{\perp}}{\sigma_{\parallel}}\right) \frac{K_1}{\eta_1} - \Delta\epsilon \left(\frac{K_1}{\eta_1} - \frac{\sigma_{\perp}}{\sigma_{\parallel}} \right) \right\} \quad [6]$$

This agrees with the Helfrich expression (14), and this also agrees with the expression of the Orsay Liquid Crystal Group in the case of $\omega = 0$ except for a different definition of the viscosity factors. Both ($\Gamma_{visc.}$) and ($\Gamma_{diel.}$) are dependent on dielectric anisotropy, and they increase as the negative dielectric anisotropy increases. If the rate of increase of ($\Gamma_{visc.}$) is larger than that of ($\Gamma_{diel.}$), the threshold voltage will decrease with an increase in the negative dielectric anisotropy.

The condition is described as in Eq. [7]

$$\left| \frac{\partial \Gamma_{visc.}}{\partial \Delta\epsilon} \right| > \left| \frac{\partial \Gamma_{diel.}}{\partial \Delta\epsilon} \right| \quad [7]$$

and the result becomes

$$\frac{K_1}{\eta_1} - \frac{\sigma_{\perp}}{\sigma_{\parallel}} > 0 \quad [8]$$

We determined the value of K_1/η_1 experimentally to be 1.0 or more, and the value of $\sigma_{\perp}/\sigma_{\parallel}$ is 0.67, so the condition was sufficiently valid for the nematic mixture used in this study.

In the case of MBBA (4-methoxybenzylidene-4'-butylaniline) the noticeable effects were not observed in these experiments. It is considered that the condition to reduce the threshold voltage is not sufficiently valid. The value of K_1/η_1 obtained was between 0.8 and 0.9 which fits fairly well with the reported value (15), and the value of $\sigma_{\perp}/\sigma_{\parallel}$ was 0.7. Moreover, referring to the effects of dielectric anisotropy on the threshold of MBBA, Penz (16) analyzed theoretically and estimated that threshold voltage of light scattering increases with the increase of the negative dielectric anisotropy.

Conclusion

Double-Shiff's-base compounds of bis-(4'-n-alkylbenzylidene)-2-cyano-1,4-phenylenediamine were prepared and added to the room temperature liquid crystal material to study the effects of negative dielectric anisotropy on dynamic-scattering properties. The results can be summarized as follows.

1. The negative dielectric anisotropy is the important factor that dominates the properties of dynamic-scattering.
2. By the addition of BACYP to the room temperature nematic mixture, liquid crystalline compounds with wider nematic temperature ranges of more than 100°C have been prepared.
3. The negative dielectric anisotropy increases with the increase of BACYP concentration, and the threshold voltage of the Fredericksz transition decreases as expected from Leslie's theory.
4. The threshold voltage of light scattering also decreases from 8 to 5V by the increase of dielectric anisotropy from 0.5 to 2.0 and conductivity anisotropy from 1.5 to 1.8 as expected from the theory of Helfrich and the Orsay Liquid Crystal Group.
5. The voltage to give sufficient contrast ratio in dynamic-scattering decreases more rapidly than the threshold voltage with the increase of negative dielectric anisotropy. A display device of low voltage driving between 7 and 8V has been achieved.
6. The cutoff frequency decreases by the addition of BACYP when the conductance is kept constant, because of the increase of dielectric constants and the decrease of the value of ξ^2 due to the increase of negative dielectric anisotropy.
7. Conductance should be increased to maintain the frequency characteristics and to complete the properties in low temperature. As a result a half-power consumptive device of less than 100 $\mu W/cm^2$ has been achieved.
8. The decay time becomes long by the addition of BACYP but the rise time is shortened because of the increase of negative dielectric anisotropy.
9. The matrix-addressing properties are also improved because of the rapid increase of dynamic-scat-

tering intensity above threshold and the weak temperature dependence of threshold voltage.

Silicon Oxidation Studies: The Role of H_2O

E. A. Irene* and R. Ghez*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The thermal oxidation of Si using H_2O-O_2 and H_2O-N_2 ambients has been studied with an automated ellipsometer which can observe the oxidation *in situ*. The oxidations were carried out in the temperature range of 780°-980°C on <100> oriented single crystal Si. The resulting SiO_2 film growth data was analyzed according to a linear-parabolic oxidation model. The parabolic rate constant was found to increase abruptly with small additions of H_2O to O_2 while the linear rate constant increased gradually over the range of added H_2O (0-2000 ppm). The over-all increase in the rate of oxidation due to H_2O in O_2 was found to be greater than predicted based on the independent diffusion and reaction of O_2 and H_2O related oxidant species. These effects of H_2O were found to be reversible. Therefore, the kinetic role of H_2O on the oxidation of silicon is essentially twofold. The H_2O acts both as an additional source of oxidant and as an accelerator for the oxidation process involving O_2. It is postulated that this latter effect occurs because the H_2O modifies the SiO_2 network thereby enhancing diffusion of the primary oxidant through the SiO_2 film.

The remarkably large effect of trace amounts (25 ppm) of H_2O in the O_2 ambient on the SiO_2 film growth kinetics has been previously reported (1). Based on a linear-parabolic model (2) the effect of 25 ppm H_2O in O_2 (1) on Si oxidation was found to be related both to surface kinetics through the linear rate constant, k_{LIN}, and to diffusional kinetics through the parabolic constant, k_{PAR}. It was therefore suggested (1) that the role of H_2O is manifold, including a catalytic effect, the effect of an additional oxidant, and a structural alteration of the growing SiO_2 film.

A previous analysis of Si oxidation thickness-time data for oxidation in pure O_2 (3) has shown that a linear-parabolic kinetic model provides a reasonably accurate representation of the oxidation phenomena, provided that sufficient data in the proper thickness ranges is used for the analysis. Therefore, this model will be utilized in the present study to analyze the role of H_2O in the SiO_2 film growth data obtained from an automated ellipsometer (4) which can measure SiO_2 film thickness *in situ* during oxidation.

The present study is an extension of previous work (1, 5, 6) on the effects of H_2O on Si oxidation kinetics. Two of the previous studies (5, 6) utilized relatively large amounts of H_2O (> 6000 ppm), and one of the studies (1) reported the effect of trace amounts of H_2O (25 ppm) on Si oxidation kinetics. The present investigation considers oxidation of Si in pure dry O_2 (<1 ppm H_2O), in controlled amounts of H_2O up to 2000 ppm in an N_2 ambient, and by controlled additions of H_2O to O_2 (up to 2000 ppm H_2O). The extensive SiO_2 film thickness-time data for oxidation temperatures of 780°, 893°, and 980°C are analyzed by the previously developed linear least squares technique (3) using the linear-parabolic model (2). The data and analysis of this study enable the mechanism for Si oxidation to be further elucidated.

Experimental Procedures

Sample preparation.—All substrates were <100> oriented chem-mechanically polished silicon wafers measuring 3.2 cm in diameter and 0.025 cm in thickness. All the wafers were p-type with a nominal resistivity of 2 Ω-cm. It was reported previously (1) that the resistivity type or value in the range 0.5-10 Ω-cm had no influence on the oxidation process. The wafers were cleaned as reported elsewhere (1) but an initial oxide thickness of from 3-6Å SiO_2 was observed

* Electrochemical Society Active Member.
Key words: insulating films, oxidation kinetics, rate constants.

in contrast to the previously reported thickness of 10-12Å for the initial oxide film (1). With the automated ellipsometer (to be described later) the cleaned Si wafers could be immediately placed in a dry N_2 ambient, whereas in previous studies the wafers were exposed to room air for about 10 min during the ellipsometric measurements. After the initial SiO_2 film measurement the samples were heated in dry N_2 (10-15 min) to the experimental oxidation temperature and the SiO_2 film thickness was remeasured. The SiO_2 film now measured 7-8Å. After continuous heating for 5 hr at 900°C in dry N_2 the total film thickness never exceeded 11Å. Apparently there is some small amount of oxidant either present in the N_2 or desorbing from the walls of the reaction vessel but the relative amount of SiO_2 growth is negligible for this study.

Gas ambients.—Both N_2 and O_2 were supplied from boil-off of liquid sources. Dew points of the gases were measured by means of a hygrometer (1, 3). As previously reported (1, 3), the O_2 was shown to contain trace amounts of methane ($\sim$ 17 ppm) which at the experimental oxidation temperature combusts to form H_2O. This trace H_2O substantially increases the rate of oxidation (1). For dry oxidations, the methane was removed by heating the oxygen to about 1000°C, in order to combust the methane to H_2O and CO_2, and then cold trapping at −80°C to reduce the H_2O concentration to less than 1 ppm H_2O in the O_2. To add H_2O to N_2 or O_2, the N_2 or the previously dried O_2 is flowed through a thoroughly cleaned fused silica vessel which contains deionized H_2O. By controlling the H_2O temperature with a variable temperature refrigeration unit the concentration of H_2O can be adjusted to any desired level from less than 1 ppm upward. The reported H_2O concentrations are steady-state values as measured with a hygrometer at the oxidation furnace exit under fixed flow conditions and with the furnace at the oxidation temperature.

Automated ellipsometer.—The instrument used for this study has been described in detail elsewhere (4). Basically, the ellipsometer uses a laser light source, polarizer, compensator, and an encoded rotating analyzer. The light intensity measurement after the analyzer is automated. The ellipsometry measurements are made with the sample in a fused silica rf-heated reaction tube. Therefore it is possible to collect and analyze the ellipsometric data as the SiO_2 film grows without interrupting the oxidation run. The optical constants characteristic of the Si surface as a function of temperature were previously measured (4). The film thickness accuracy of the ellipsometer is estimated to be better than 10% for very thin SiO_2 films (less than 20Å) and better than 3% for thicker films. The oxidation data to be shown are reproducible to within 2% total spread in film thickness and each reported data set is an average of at least two independent oxidation runs.

In order to determine whether there was any change in SiO_2 refractive index when H_2O was added to the O_2 ambient, ellipsometric measurements were made near half an ellipsometric period (about 1200-1400Å for 6328Å light) for greatest accuracy in film refractive index. No systematic trend in refractive index was observed which was greater than the estimated accuracy of the instrumentation of ±0.005 for the refractive index. This negative result was anticipated based on a report (7) of a decrease in refractive index of about 1.4×10^{-4} for 10^3 ppm H_2O in SiO_2. Therefore to cause a change of −0.005 in index, the SiO_2 must contain 5×10^4 ppm H_2O which is 30 times larger than the largest amount of H_2O in the ambient used for the present study.

SiO_2 quality.—In order to check on the charge levels in the SiO_2 films grown, capacitance-voltage (C-V) measurements were made. Evaporated aluminum counterelectrodes were used as electrical contacts. The C-V measurements (at 1 MHz) revealed an average fixed positive charge level of $\sim 5 \times 10^{10}$ charges/cm^2. Bias-temperature stressing ($\pm 10^6$ V/cm at 200°C for 15 min and subsequent cooling under bias) revealed an average mobile positive charge level of $\sim 7 \times 10^{10}$ charges/cm^2. These values are characteristic of MOS quality oxide.

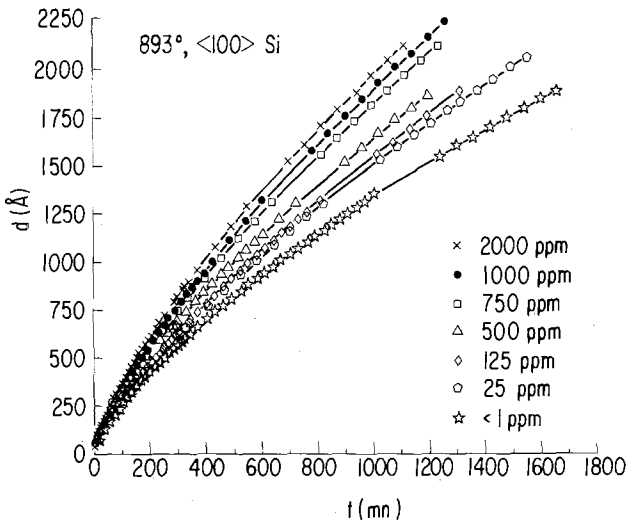
The density of fast surface states was measured by the low temperature C-V technique (8, 9). Fast state densities, N_{FS}, for dry oxides were found to be $\sim 2 \times 10^{11}$ cm^{-2} and this density decreased to $\sim 2 \times 10^{10}$ cm^{-2} for oxides prepared with 2000 ppm H_2O in O_2. These results are in qualitative agreement with previously published results (9) on the effect of H_2O on N_{FS} levels.

Data analysis.—The linear, k_{LIN}, and parabolic, k_{PAR}, rate constants are obtained by the iterative linear least squares (LLS) analysis described previously (3). Essentially, a linear-parabolic rate law (2) is used which has the following form

$$t - t_o = A(d - d_o) + B(d^2 - d_o^2) \qquad [1]$$

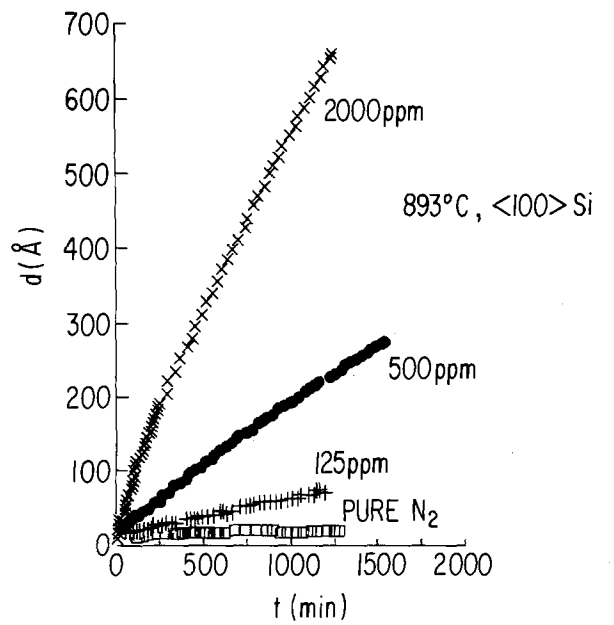
In this equation d is the SiO_2 film thickness for a time of oxidation, t; A and B are the reciprocals of k_{LIN} and k_{PAR}, respectively; and d_o and t_o are the parameters that define the limit of influence of the initially rapid oxidation regime which precedes the linear-parabolic mode of oxidation (1-3). The first iteration of the LLS analysis includes all the (d, t) data points for a given data set and considers the value for (d_o, t_o) to be $(0, 0)$. The second and all ensuing iterations drop the smallest value (d, t) data point and utilize this dropped point as the value for (d_o, t_o) in the iteration, thereby renormalizing the data to new axes, (d_o, t_o), with each iteration. For each iteration standard deviation values are calculated which enable an assessment of the quality of the fit of the data to the model. A region in (d, t) space of best fit is determined by the error analysis and the rate constants which best describe the data are calculated (3). From calculated standard deviation values, the errors associated with k_{LIN} and k_{PAR} values are less than ±10% and for d_o values the spread could be as large as ±50Å.

In order to quantitatively determine if the role of H_2O in O_2 is solely to supply an additional oxidant which diffuses through the SiO_2 film and reacts at the Si-SiO_2 interface, a rate equation has been derived which considers simultaneous but independent diffusion and reaction of two oxidant species, *i.e.*, species due to both O_2 and H_2O as has been done previously (10). However the previous work (10) does not include the (d_o, t_o) boundary condition and the constants are not defined in the same way as in our previous oxidation studies (1, 3). Therefore, details of our derivation are included in the Appendix and the resulting integrated rate equation has the form



$$t - t_o = A(d - d_o) + B(d^2 - d_o^2) + C \ln\left(\frac{d + \alpha}{d_o + \alpha}\right) \qquad [2]$$

The constants A, B, C and α, can all be expressed in terms of the linear and/or parabolic rate constants obtained from the oxidation of Si by H_2O and O_2 individually (see Appendix).



Experimental Results

Representative data for oxidation at 893°C in ambients composed of various concentrations of H_2O in O_2 are shown in Fig. 1a and for the H_2O-N_2 ambients in Fig. 1b. Calculated rate constants are shown in Table I.

Table I shows that the k_{LIN} values which correspond to the H_2O-O_2 ambients, increase smoothly as the concentration of H_2O in O_2 increases from less than 1 ppm ($\sim 10^{-6}$ atm H_2O) to 2000 ppm ($\sim 10^{-3}$ atm). Since the linear rate constant is associated with the chemical reaction between oxidant and Si at the Si-SiO_2 interface (2), the increase in k_{LIN} in a H_2O-containing

(a) In O_2 with various amounts of H_2O

(b) With various H_2O concentrations in N_2

Fig. 1. Thickness (Å) vs. time (min) data for oxidation of <100> Si at 893°C.

ambient can be attributed to the additional oxidant present at the Si-SiO_2 interface. However, the parabolic rate constant, k_{PAR}, increases sharply with the first traces of H_2O in O_2 up to 125 ppm followed by a smaller rate of increase for H_2O concentrations from 125 to 2000 ppm. The parabolic rate constant is related to the mechanism for diffusion of oxidant through the SiO_2 film to the Si-SiO_2 interface. Therefore, the large and initially sharp change in k_{PAR} with trace H_2O addition suggests that H_2O alters the diffusion of oxidant to the Si-SiO_2 interface.

Table I. Rate constants according to the linear-parabolic model

Ambient	k_{LIN} (A²/min			k_{PAR} (A²/min)			d_o (A)
ppm H_2O in O_2	T, °C			T, °C			T, °C
	780	893	980	780	893	980	893
<1	0.57	2.2	7.7	265	4350	14,000	340
25		2.2			6250		340
125	0.65	2.3	8.4	285	6500	19,300	330
500		2.6			7350		275
750		2.8			8000		275
1000		2.9			8400		270
2000	0.69	3.4	16.7	690	8500	23,700	235
2000 ppm H_2O in N_2	0.10	0.60	4.6	360	2000	2,530	~0

The values for d_o [d_o represents the upper thickness limit of the influence of the initially rapid oxidation regime (1-3)] decrease as the concentration of H_2O in O_2 increases. For oxidations in the H_2O-N_2 ambient, the initially rapid regime was not detected at all. Deal and Grove (2) have also reported that d_o was not observed for oxidation in large amounts of H_2O. They attributed this finding to the smaller Debye length expected for H_2O oxidation under the assumption that oxidation proceeds via diffusion of an ionic species (11, 12) and therefore the width of the space charge layer relative to the total oxide thickness is important. However, there exists reasonable doubt as to whether the oxidation of Si proceeds via an ionic diffusion mechanism (13, 14). Hence, the interpretation of the oxidation kinetics in the thickness range below about 400Å is in question and further discussion will be reserved for a future publication.

Figure 2 shows the comparison of dry O_2 data and 2000 ppm H_2O in O_2 data along with calculated data from Eq. [2] using the rate constants found in Table I. It is seen that the rate of oxidation actually observed for the H_2O-O_2 ambient is greater than the rate calculated based on the simultaneous but independent diffusion and reaction of the H_2O- and O_2-related oxidant species. Therefore, there exists an additional effect on oxidation kinetics due to the H_2O in O_2 other than the superposition of an additional independent oxidant.

In order to address the question whether the H_2O related kinetic effect on the SiO_2 network is reversible or whether the structural alteration is permanent, the following experiment was performed: First, a Si sample was oxidized at 980°C for ~ 100 min to a thickness of ~ 700Å in pure, dry O_2; then the oxidizing ambient was switched to 2000 ppm H_2O in O_2 and oxidation was continued for another ~ 100 min; finally the ambient was again switched to dry O_2 after the oxidation

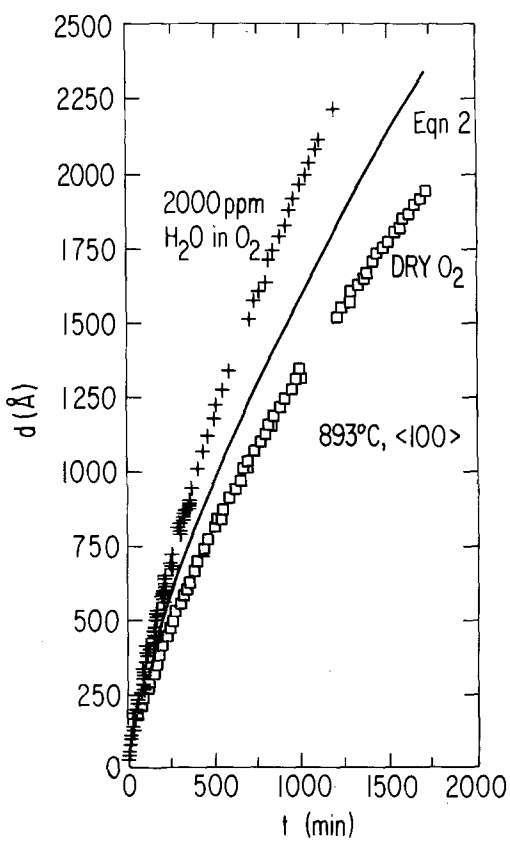


Fig. 2. Comparison of oxidation data for oxidation in dry O_2 and 2000 ppm H_2O in O_2 with thickness-time data calculated using Eq. [2].

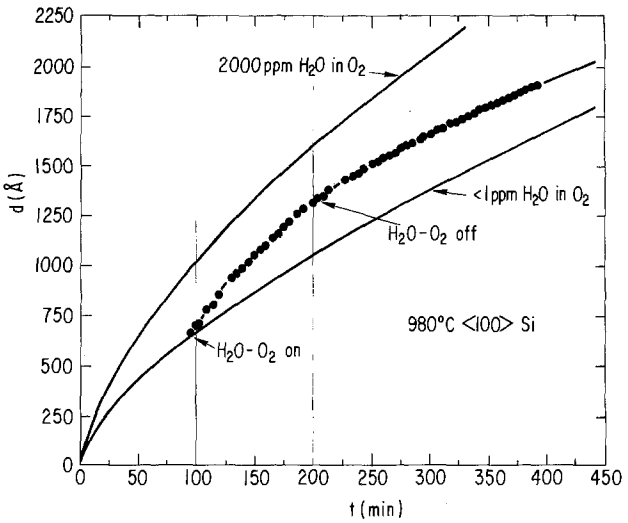

Fig. 3. The effect on Si oxidation of changing the ambient from dry O_2 to 2000 ppm H_2O in O_2 and back to dry O_2 (data points) with dry O_2 and 2000 ppm H_2O in O_2 data for comparison (solid curves).

tube was flushed for 10 min with dry N_2 at 980°C to remove 95% of the residual moisture and the oxidation was continued in dry O_2. In Fig. 3 the thickness-time data obtained in this experiment are plotted for comparison with the data sets for dry O_2 and 2000 ppm H_2O in O_2 data sets. It is seen that within several minutes after the ambient is switched from dry O_2 to H_2O in O_2 the growth behavior proceeds in parallel to the H_2O-O_2 curve. Similarly, when the ambient is returned to dry O_2, the rate quickly reverts to that for dry O_2. Therefore, the effect is reversible and must take place via a rather labile chemical species, possibly SiOH, which have been observed in SiO_2 and can be oxidized to SiO_2.

Discussion of Results

The experimental observations on the role of H_2O in O_2 on Si oxidation made in this study can be explained qualitatively by considering previously measured properties of bulk amorphous SiO_2.

It is well understood that H_2O reacts with bulk amorphous SiO_2 disrupting the SiO_2 network by forming nonbridging SiOH groups (see for example (7, 15-19)). This loosening of the SiO_2 network is evidenced by a decrease in the SiO_2 viscosity, density, acoustic velocity, and refractive index and an increase in the thermal expansion coefficient (7, 19). Also related to the loosening effect of H_2O on SiO_2 is the report (18) that the diffusion coefficient of O_2 in H_2O-treated bulk SiO_2 is greater than in dry O_2. Therefore, the large effect of relatively small amounts of H_2O on $\bar{k}_{PAR}$ for thin films of SiO_2 appears to be via the same network loosening mechanism as observed for bulk SiO_2. Previous results on the effects of H_2O on the properties of bulk SiO_2 (7, 15, 18) show that labile —OH species cause the loosening of the network and that the physical properties would revert to the dry SiO_2 values upon removal of the —OH by dry annealing. The experiment reported here in which the ambient was switched from dry to wet to dry O_2 showed that the kinetic effect is also reversible and therefore the same as the H_2O effect on bulk SiO_2.

Conclusions

The kinetic role of H_2O in the oxidation of Si is essentially twofold. First, H_2O itself is an oxidant source and thereby converts Si to SiO_2. Second, H_2O alters the SiO_2 by loosening the SiO_2 network and increasing the diffusion of other oxidant species. The loosening process is via formation of Si-OH groups and the reaction which forms these groups is reversible.

APPENDIX

In order to derive Eq. [2] we assume that O_2 and H_2O diffuse independently through an oxide film of thickness d, and that the two oxidant species react independently at the oxide-silicon interface. Let the quantities related to O_2 be denoted with subscript 1 and those related to H_2O with subscript 2. The flux, F_1, of O_2 through the film is given by

$$F_1 = D_1(C_1^* - C_{1,d})/d = k_1 C_{1,d} \qquad [A\text{-}1]$$

where D_1 is the diffusion coefficient, k_1 is the reaction rate constant, C_1^* is the concentration at the gas-oxide interface, and $C_{1,d}$ the concentration at the oxide-silicon interface. Eliminating $C_{1,d}$ yields

$$F_1 = k_1 C_1^*/(1 + k_1\, d/D_1) \qquad [A\text{-}2]$$

and a similar relation for F_2. If Ω is the volume of oxide formed per unit of oxidant, then the time rate of change of d is

$$\dot{d} = \Omega_1 F_1 + \Omega_2 F_2 = \frac{\Omega_1 k_1 C_1^*}{1 + k_1\, d/D_1} + \frac{\Omega_2 k_2 C_2^*}{1 + k_2\, d/D_2}$$

This relation can be easily integrated to give

$$t - t_o = A(d - d_o) + B(d^2 - d_o^2) + C \ln \frac{d + \alpha}{d_o + \alpha} \qquad [A\text{-}3]$$

in which the constants A, B, C, and α can be expressed in terms of the linear and parabolic rate constants for each of the oxidizing species, $k_{L1} = \Omega_1 k_1 C_1^*$, $k_{P1} = 2\Omega_1 C_1^* D_1$, $k_{L2} = \Omega_2 k_2 C_2^*$, $k_{P2} = 2\Omega_2 C_2^* D_2$

$$A = \frac{(k_{L1}/k_{P1}) + (k_{L2}/k_{P2}) - (k_{L1} + k_{L2})/(k_{P1} + k_{P2})}{k_{L1}k_{L2}\,(k_{P1}^{-1} + k_{P2}^{-1})}$$

$$B = (k_{P1} + k_{P2})^{-1} \qquad [A\text{-}4]$$

$$C = [2k_{L1}k_{L2}\,(k_{P1}^{-1} + k_{P2}^{-1})]^{-1} \left\{ 1 - \frac{k_{L1}^{-1} + k_{L2}^{-1}}{k_{P1}^{-1} + k_{P2}^{-1}} \left[(k_{L1}/k_{P1}) + (k_{L2}/k_{P2}) - \frac{k_{L1} + k_{L2}}{k_{P1} + k_{P2}} \right] \right\}$$

$$\alpha = \frac{1}{2} \frac{k_{L1}^{-1} + k_{L2}^{-1}}{k_{P1}^{-1} + k_{P2}^{-1}}$$

The rate law [A-3] is a linear-parabolic relation, with a logarithmic correction which accounts for only a few percent.

Conduction and Charging Behavior in MA(O)S-Systems

H. Kampshoff, F. Stephany, and P. Balk*

Institute of Semiconductor Electronics, Sonderforschungsbereich Festkörperelektronik, Technical University, D-5100 Aachen, Templergraben 55, Germany

ABSTRACT

Measurements were made of *I-V* and *C-V* characteristics of metal-Al_2O_3-silicon capacitors in the dark. The Al_2O_3 layers were deposited pyrolytically at temperatures between 700° and 950°C on substrates of both conductivity types; some of the samples were subjected to a final O_2 anneal. The observed dependence of the conduction on the electrode material indicates that the process is injection limited and that electrons are the major carriers. From the magnitude of the effective barrier heights and the relatively weak temperature dependence of the currents, it is concluded that in all cases the injection takes place via a trap-assisted tunneling mechanism. The buildup of space charge in the insulator has a pronounced effect on the magnitude of the conductivity. The same behavior was observed on MAOS capacitors with a purposely grown 2.5 nm SiO_2 film.

Storage of injected charge carriers is a phenomenon that may be expected to occur quite generally in metal-insulator-silicon structures with layered dielectrics. It has been explored thoroughly in only a few systems, notably in the metal-Si_3N_4-SiO_2-Si (MNOS) and metal-Al_2O_3-SiO_2-Si (MAOS) structures, where field effect transistors with such gate systems yield useful electrically alterable nonvolatile storage devices (1, 2).

In several respects the behavior of both systems is rather similar (3-5). However, MAOS devices with Al gates show a pronounced tendency toward negatively charging the layered dielectric not only for positive but also for negative gate voltages. Only for very large negative voltages the system reverts to "normal" behavior and starts acquiring positive charge. The "abnormal" charging effect may be suppressed by annealing the Al_2O_3 film in O_2 prior to metallization or by utilizing a Au electrode (3).

An important reason for the rapid development of MNOS storage devices is undoubtedly the extensive knowledge about the technology and characteristics of Si_3N_4 that already existed in the electronics industry. This facilitated optimization of material parameters for storage applications and allowed a study of the charging and discharging mechanism on well-defined samples. One of the at first surprising insights gained in these studies was that rapid charging only takes place under field conditions where considerable d-c currents flow through the system (6). Moreover, charge injected from the silicon extends over a relatively large depth into the nitride layer (7). These findings suggested that early models which take into account only tunneling of charges across the SiO_2 layer into traps near the insulator-insulator interface were at least an oversimplification of the true state of affairs. It was also discovered that not only electrons but also holes play a role in the conduction and charging of Si_3N_4 films (8). The conduction process is strongly affected by the accumulation of space charge in the layers (9, 10).

The amount of information available on the behavior of the MAOS system and the properties of Al_2O_3 layers is rather modest in comparison. Nevertheless, Al_2O_3 with its high dielectric constant and large bandgap is an interesting material for application in multilayer storage devices. Moreover, investigations on such alternate systems might be expected to contribute to a better understanding of the charging and discharging mechanisms operative in such devices in general. It was thus decided to study their *I-V* characteristics along with the charge storage in the system as obtained from *C-V* measurements. These studies were carried out on MAS capacitors without purposely grown SiO_2 films. Al_2O_3 films obtained by chemical vapor deposition at 700°C and above from an aluminum halide system were used because of the superior properties of the material prepared in this manner (1). Special attention was paid to the effect of fabrication parameters (deposition temperature and rate, annealing) and electrode materials on the sample properties.

This type of investigation appears to be also of interest since the information in the literature regarding conduction in MAS systems is rather contradictory. Whereas Tsujide *et al.* (11) found a bulk-limited Poole-Frenkel conduction mechanism for high temperature pyrolytic films, Walden and Strain (12) interpreted their measurements on a similar material using an injection-limited mechanism. Salama (13) concluded that in sputtered Al_2O_3 films the Poole-Frenkel effect predominates. It should be remarked that a pronounced effect of film preparation conditions on the conduction mechanism is also known to exist for SiO_2, where thermally grown films show injection-limited conduction (14, 15), whereas for sputtered films Poole-Frenkel conduction has been reported (16).

In the work described in this paper a distinct correlation between the physicochemical material properties and the electrical behavior of the samples was found. In all cases the data point to an injection limitation of the currents. A mutual dependence between current and insulator space charge was observed and the nature of the dominant charge carrier could be determined.

Experimental

Sample preparation.—Freshly etched 1 Ω cm (100)-oriented p- and n-type silicon wafers were used as substrates for deposition. Under our experimental conditions these had a layer of 1.0-1.5 nm of native oxide. The Al_2O_3 films (typically 100 nm thick) were obtained by pyrolysis of $AlBr_3$ in an $NO-H_2$ atmosphere at temperatures between 700° and 950°C. The volume fractions of the gases entering the reaction zone of the rf heated furnace were 0.0026 $AlBr_3$, 0.02 NO, and 0.1 H_2 with N_2 making up the balance. The rate of deposition was 10 nm min^{-1}.

In many cases the samples were cut into two parts, one of which was annealed for 1 hr in oxygen at the film deposition temperature. Since the film thickness determined by ellipsometry was the same before and after annealing we conclude that the amounts of SiO_2 formed at the interface during this process must be negligible. However, we cannot exclude the possibility that interdiffusion of the oxide layers takes place during deposition and annealing. Circular metal electrodes (diameter 0.8 mm) were deposited onto the oxide films by evaporation through a metal mask. The back sides of the samples were contacted using Ga-In alloy.

Film characteristics.—In agreement with earlier experience (17) films deposited below 800°C are amorphous, whereas those obtained above this temperature showed an electron diffraction pattern typical for γ-Al_2O_3. Transmission electron micrographs obtained on thin films of the polycrystalline material showed a crystallite size of approximately 10 nm. Somewhat surprisingly, increasing the deposition rate above the standard value of 10 nm min^{-1} by increasing the $AlBr_3$ concentration in the gas phase led to larger crystallite sizes. These and further characteristics of the Al_2O_3 layers are summarized in Table I, where data on 750° and 900°C films are presented as representative for both types of material.

Electrical measurements.—*I-V* characteristics were determined in the dark at room temperature using a Keithley 602 electrometer. As has been observed in measurements on other insulators, the currents decay with time under constant voltage. This phenomenon, related to space charge effects in the film, obeys an $I \sim t^{-a}$ law (a = 0.2-0.5), which was also found by Walden (12, 18). Although the current does not completely saturate even in 24 hr, it was found that satisfactory *I-V* characteristics could be obtained by raising the voltage in steps after waiting for 2 min. Figure 1 shows that the features of such a curve and one obtained after 10 min waiting time are essentially the same. Here and in the following figures the data are presented in the form I *vs.* V/d (d = film thickness). Other plotting methods, notably I *vs.* $(V/d)^{1/2}$, were tried but did not lead to a simpler (*i.e.*, straight line) representation. Essentially the same current-voltage characteristics were obtained on samples on which a 2.5 nm SiO_2 layer had been grown by oxidation in N_2 with 1% O_2 at the Al_2O_3 deposition temperature prior to deposition.

Table I. Characteristics of Al_2O_3 films, deposited at 750° and 900°C

Deposition temperature	750°C	900°C
Structure	Amorphous	γ-Al_2O_3
Grain size, nm	<1	≈10
ϵ	7	9
n (λ = 546.1 nm)	1.66 ± 0.01	1.75 ± 0.01
Breakdown strength,* mV/cm	8	8.5
Etch rate,† nm/min	400	0.1

* Maximum of final breakdown strength distribution, measured at ramp rate of 1 MV cm^{-1} sec^{-1}.
† In H_3PO_4 at 100°C.

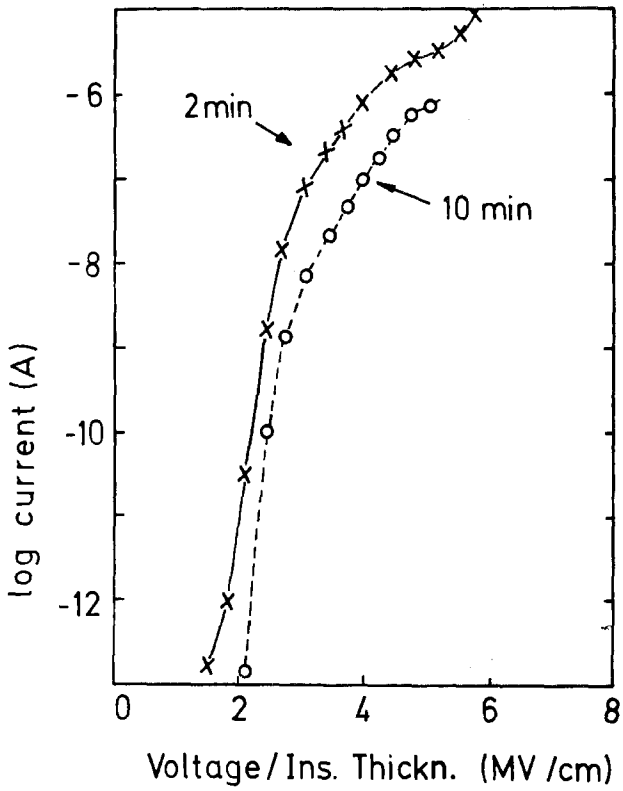

Fig. 1. Effect of waiting time on shape of *I-V* curves. Sample: 1 Ω cm n-Si substrate/amorphous Al_2O_3/Al (neg.).

A check of the minority carrier generation time using the Zerbst method (19) indicated that the generation rate would in most cases be sufficiently large to produce the measured current on inverted samples if the minority carrier in the silicon would be the major carrier in the oxide. Consequently illumination generally did not affect the measurements. However on samples with p-type substrates under positive bias the current would level off at approximately 10^{-10}A and only rise again upon illumination.

For each point on the *I-V* curves the flatband voltage V_{FB} was measured at 1 MHz using a Boonton capacitance-inductance meter (Model 71 A) in order to keep track of the charge in the insulator system. Our equipment permitted measurement of V_{FB} up to a value of ±35V.

Results

In this section we present the most important experimental results obtained in the present study. Figures 2 through 4 show the dependencies of the measured currents on the sample voltages normalized with respect to sample thickness. Along with these data for each voltage value the shift of the flatband voltage ΔV_{FB} has been plotted.

Figure 2 shows a comparison between films deposited at 750°C and films prepared at 900°C for both polarities of applied voltage. These layers are typical for the amorphous and polycrystalline range, respectively. The samples had Al electrodes. It may be seen that the 900°C samples exhibit the lower conductivity values. The polycrystalline sample yields a current-voltage plot of only slightly varying slope, along with a charging plot with constant positive slope for positive voltages. Positive ΔV_{FB} values are also obtained for moderately negative voltages, but for larger stresses the flatband shift reverses direction and eventually negative ΔV_{FB} values are reached. Here, as well as in all other cases, the same results were obtained on substrates of both conductivity types.

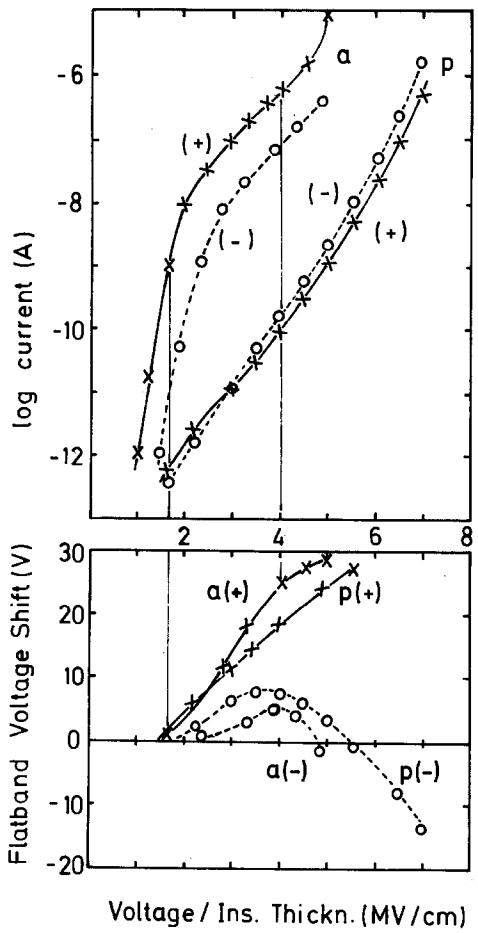

Fig. 2. Effect of deposition temperature [750°C (a) and 900°C (p)] on I-V and ΔV_{FB}-V characteristics of MAS structures. Al electrode (positive and negative); 1 Ω cm n-Si substrate.

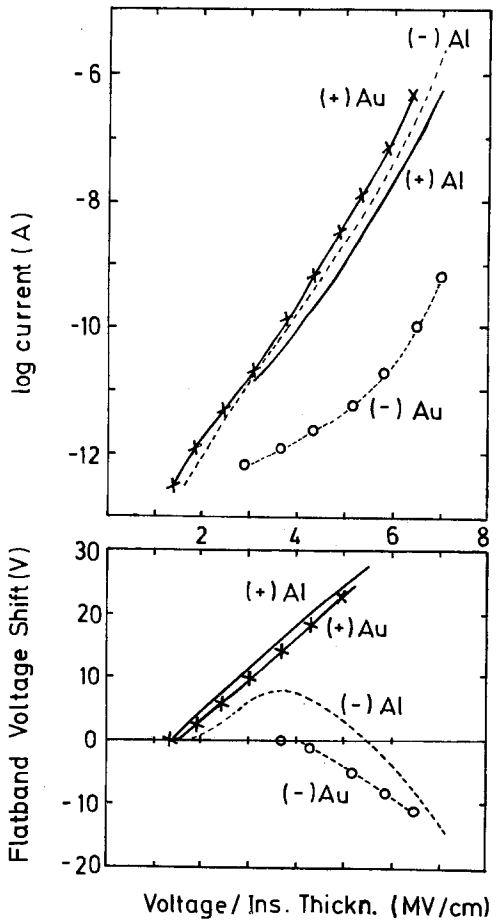

Fig. 3. Effect of metal electrode on I-V and ΔV_{FB}-V characteristics of MAS structures for positive and negative polarities. Electrode metals: Al and Au; Al_2O_3 (900°C); 1 Ω cm n-Si substrates.

The current-voltage curves for the amorphous layers are more structured and show three distinct regions. Starting at small voltages, the current first rises steeply, next a region of smaller slope follows, and at still higher voltages a second steep increase is observed. As indicated in the figure, the transition to the middle region coincides with the onset of a charge storage process which involves charges of the same sign for both positive and negative voltages. Upon reaching saturation of the charging the current starts its second steep rise. Under negative bias a reversal of the charging process sets in at the latter point. The currents measured for positive voltages are slightly larger than those for negative voltages.

The effect of the metal electrode is demonstrated in Fig. 3 on capacitors with polycrystalline films and Al and Au electrodes. Structures with amorphous layers show a similar behavior. The most striking feature of the results are the very low currents for Au electrodes under negative bias, paralleled by the absence of any indication of negative charge storage for this polarity. Under positive bias current and charging appear to be independent of the electrode material.

Figure 4 shows the changes in the characteristics of 900°C samples with an Al electrode brought about by O_2 annealing. The most obvious effects of this treatment are the reduced sample currents and the disappearance of the positive V_{FB} branch for negative sample voltages. The conductivity of the system is largely independent of polarity. However, the onset of negative charging moves out to larger voltages, and the amount of stored charge increases more rapidly with voltage. On the other hand, the positive charging process for the opposite polarity starts at smaller voltages.

The effect of the O_2 treatment on amorphous samples was quite similar to that described above. Unfortunately, the current and ΔV_{FB} curves could only be followed to much lower voltages since these specimens broke down at considerably reduced field values. This reduction was particularly pronounced for capacitors with a Au electrode.

In Fig. 5 current values at constant voltage, obtained on polycrystalline and amorphous samples, have been plotted against reciprocal temperature. Particularly in the range below room temperature the temperature dependence of the conductivity is modest; the current-voltage characteristics at different temperatures are obtained from each other by a small parallel shift.

Finally, it was found that structures with polycrystalline Al_2O_3 samples having larger crystallite size (30 nm) yield essentially the same conductivity curves as those with standard films (crystallite size 10 nm). However, as could also be observed from the pronounced looping of the C-V curves, charge storage starts at lower voltages than those measured for the standard material.

Discussion

The most outstanding features of the data presented in the preceding section are the following: The sample conductivities are dependent on the electrode material. There appears to be a correlation between I-V characteristics and charging effects. Particularly below room temperature the conductivity changes only moderately with temperature. The smaller conductivity of the MAS structures with polycrystalline films compared

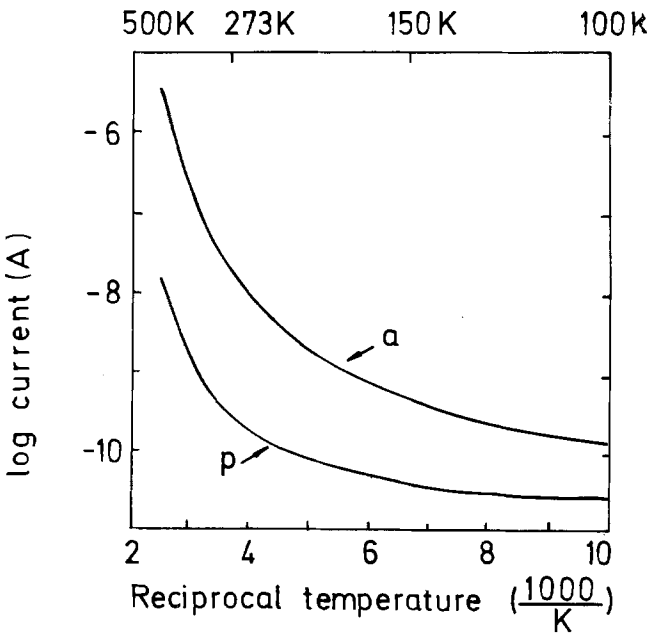

Fig. 5. Temperature dependence of sample currents for 750° (a) and 900°C (p) Al_2O_3 layers at 5.1 and 5.6 mV cm^{-1}, respectively.

to those with the amorphous layers and the effect of O_2 annealing suggest that imperfections play a major role in determining the electrical properties of the capacitors.

The electrode dependence of the current points to an injection-limited conduction mechanism. The relative insensitivity of the current to temperature changes is indicative of a tunneling process. This mechanism is apparently universal for high temperature Al_2O_3 films since all films investigated in this study showed the above-mentioned behavior.

The conduction process is dominated by electrons. This may be concluded from the fact that both current and negative charge injection for negative voltages are strongly suppressed by using instead of Al an electrode metal with larger work function and thus larger barrier for electron injection, *e.g.*, Au. On the other hand, for positive voltages the current is independent of the electrode material. This observation is incompatible with hole conduction. The comparable magnitude of the currents for both negative and positive Al electrodes suggests that in the latter case the electrons are being supplied from the Si conduction band. The model is further supported by the observed saturation of the current at high values on p-type substrates with positive voltages and the removal of this effect under illumination. It would also seem to follow from the energy band diagram (1) of the MAS system, even when using Powell's recent measurements on Al_2O_3, indicating that the bandgap is only approximately 8 eV (20).

A quantitative comparison between the measured *I-V* data and the trends shown by two conduction mechanisms which play a major role in other thin insulating films is shown in Fig. 6. The measured curves are for amorphous and polycrystalline layers under positive bias. Calculated curves (21) are given

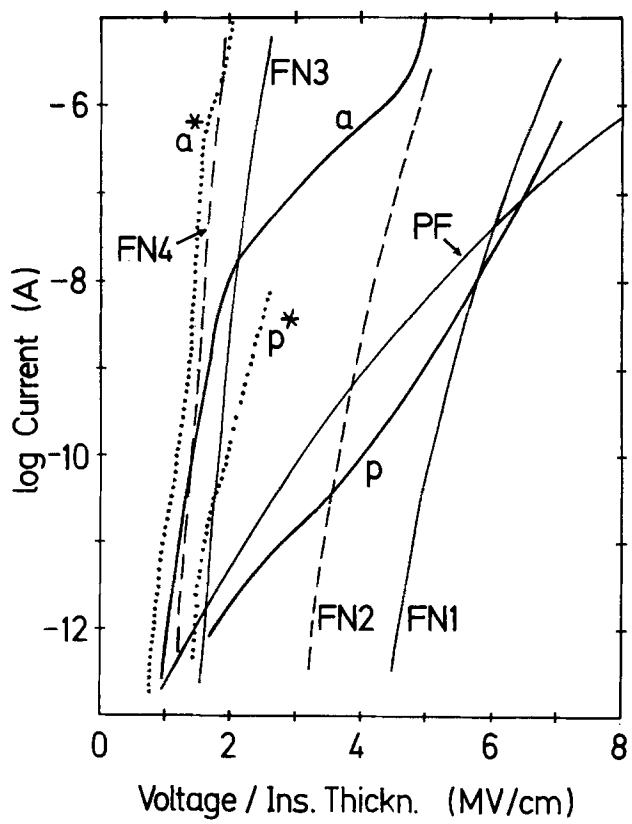

Fig. 6. Comparison between calculated and experimental *I-V* curves. a, p: experimental curves for amorphous and polycrystalline samples with 1 Ω cm n-Si substrate and Al electrode positive. a*, p*: experimental curves, corrected for space charge effect on contact field. FN 1, calculated Fowler-Nordheim curve for $\phi = 2$ eV, $m^* = 1m$; FN 2, the same for $m^* = 0.5m$; FN 3, calculated Fowler-Nordheim curve for $\phi = 1$ eV, $m^* = 1m$; FN 4, the same for $m^* = 0.5m$; PF, calculated Poole-Frenkel curve for $\phi = 1.2$ eV and $\epsilon = 3.1$.

for the same I-V range for Fowler-Nordheim tunneling through barriers of different heights, computed after

$$J = A_1 \frac{E^2}{\phi} \exp\left(-A_2 \frac{m^{*1/2}\phi^{3/2}}{E}\right)$$

taking for the effective mass m^* values of m and $0.5m$ (m = electronic mass). In the above expression ϕ is the barrier height and A_1 and A_2 are constants. There are indications in the literature that reduced effective mass values are to be expected for insulators (14, 15). The barrier height indeed appears to play a dominating role in determining the sample conductivity. The calculated curve for the Poole-Frenkel current (21)

$$J = A_3 E \exp\left(-\frac{E_t - A_4\epsilon^{-1/2}E^{1/2}}{kT}\right)$$

for a trap depth E_t of 1.2 eV exhibits a considerably smaller slope and was chosen to approximate the experimental curve for the polycrystalline sample. The dielectric constant ϵ was chosen as 3.1, *i.e.*, equal to the square of the refractive index. Somewhat surprisingly the over-all slopes of the experimental data seem more compatible with a Poole-Frenkel bulk mechanism than with an electrode-limited Fowler-Nordheim injection. Only the first and third regions of the curve for amorphous Al_2O_3 exhibit slopes compatible with the latter process.

At this point it should be realized that the field at the injecting contact is not given by V/d but has, in fact, a lower value due to the space charge stored in the insulator. The possible occurrence of such effect was first pointed out by Pittelli (22) and taken into account in Waldens work (18) on Al_2O_3 films. For Si_3N_4 it was discussed by Arnett and DiMaria (10). As may be seen from the example of the amorphous Al_2O_3 film in Fig. 6 the slope of the I-V curve is strongly reduced in the central region where the amount of stored charge is increasing. Only the steeply rising initial and third regions where the insulator charge remains constant show the immediate effect of the increase in V/d. By the same token, the curve in Fig. 6 for the polycrystalline sample shows too small a slope over the entire range. For this reason the true field at the injecting contact, $E(o)$, was calculated from V_{FB} after the expression (10)

$$E(o) = -(V - V_{FB} - \psi_s)d + Q_{ss}^{\circ}/\epsilon\epsilon_o$$

where ψ_s is the voltage drop over the semiconductor space charge region and Q_{ss}° the fast interface state charge density at the flatband condition. Since the terms with ψ_s and Q_{ss}° were relatively small they were neglected in the calculations. The corrected experimental values are shown as dotted lines for the voltage range for which V_{FB} values were available. Of course, since the field is increasing from the contact inward we have overcompensated for the space charge effect by equating the field in the tunneling region to its value at the injecting contact. This explains the nearly vertical sections of the corrected curves.

The unexpectedly low barrier energies which would follow from an interpretation of the conductivity data in terms of Fowler-Nordheim tunneling appear to indicate that this model does not apply. Even when using reduced effective mass values one arrives at barrier energies of only 1-1.5 eV instead of the expected value of approximately 3 eV for the Si-Al_2O_3 barrier. Similarly unsatisfactory results are obtained by explicitly allowing for the presence of a thin SiO_2 film between silicon and Al_2O_3. For a 1.5 nm SiO_2 film and $m^* = 0.5m$ for both oxides an I-V characteristic nearly coinciding with curve FN 1 in Fig. 6 was calculated for this case of modified Fowler-Nordheim tunneling. The similarity between the experimental results obtained on samples with and without purposely grown SiO_2 layer suggests that such a layer may dissolve into the Al_2O_3 film. It thus could not have the expected effect on the current-voltage characteristic.

The only tunneling mechanism which predicts sufficiently large currents at relatively small field is the resonance tunneling process (23). Such a process of trap-assisted tunneling exhibits the same characteristics as a Fowler-Nordheim process and has also been invoked to explain the low field hole injection in MNOS devices (24). In this process carriers from the metal or the semiconductor reach the conduction band of Al_2O_3 in two or more tunneling steps via trapping states in the forbidden gap of the insulator. For a monoenergetic trap level this mechanism should indeed yield a roughly linear change of V_{FB} with the field in the contact region and an exponentially decreasing current with increasing reciprocal field. The observed temperature dependence of the current would also seem to be compatible with this type of tunneling process.

So far the crystallographic nature of the samples was not explicitly invoked to explain their current conduction. This seems to be justified, since the differences measured between amorphous and polycrystalline material are only quantitative in nature. Furthermore, the conduction does not seem to depend to a considerable extend on crystallite size (and thus on grain boundaries). These findings, and the effect of O_2 annealing, are compatible with the proposed model in which defect centers play a critical role in the conduction process.

A final point to be discussed is the shape of the I-V curves for unannealed amorphous films, particularly the steeply rising section at low fields. It is surprising that in this field region charge storage does not take place and that only at higher voltage values a space charge layer is being built up. This behavior seems to be contrary to that expected on the basis of accepted models (9). An explanation based on the assumption that these films may have conductive channels which would not affect the over-all charging of the layers does not seem likely. Such inhomogeneities could possibly occur in polycrystalline films where one might expect enhanced conduction along grain boundaries. However, in the latter case this effect is not observed.

Conclusions

The results obtained in this study indicate that the conduction in MAS structures is an injection-limited process with electrons being the major charge carriers. However, the sample conductivity is not only dependent on the work function of the electrode material but also on the volume properties of the Al_2O_3, most likely its defect structure. Thus the trap-assisted tunneling mechanism suggests itself as the process dominating the conduction for all different types of Al_2O_3 films over the entire voltage range.

A natural consequence of this model is the formation of a space charge layer extending for considerable depth into the insulator. For this reason the absence of any effect of a thin SiO_2 layer on the I-V characteristics is not surprising, since interdiffusion of SiO_2 and Al_2O_3 will most likely occur.

For application in MAOS devices the use of polycrystalline Al_2O_3 films would seem preferable since in this case the undesirable injection of electrons from the metal electrode is greatly suppressed. Moreover, we have established that the charge retention in devices with such layers is better than in those with amorphous Al_2O_3. These advantages are to some extent offset by the larger threshold values for charge storage under positive bias. For this reason graded structures

with higher state densities near the silicon (2), structures with a metal doped insulator-insulator interface (25) or with a third layer [consisting of a lower band-gap insulator (26)] may be expected to yield charge storage devices with optimized properties.

Plasma Etching of Titanium for Application to the Patterning of Ti-Pd-Au Metallization

C. J. Mogab and T. A. Shankoff

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A study of plasma etching of filament evaporated Ti, in a radial flow reactor, using Pd (Au) as a mask is described. This work was prompted by recurrent problems with etch-out of Ti from contact windows during wet chemical patterning of Ti for the Ti-Pd-Au metallization process. CF_4, $CClF_3$, and $CBrF_3$ plasmas were investigated. Details of some of the plasma chemistry and interaction of these plasmas with Au are given. Only $CBrF_3$ plasmas were found to provide suitable selectivity for etching Ti in the presence of Au. $CBrF_3$ tends to produce an unstable plasma. However, a stable, uniform plasma can be formed by the addition of a sufficient quantity of He. Oxygen was also added to enhance the amount of atomic bromine formed in the plasma since this was thought to be the active species for Ti etching. The optimum gas mixture was determined to be 63% $CBrF_3$, 25% He, and 12% O_2. A relatively strong Arrhenius-type temperature dependence of the etch rate was measured with an activation energy of ~0.2 eV for this gas mixture. The range of process parameters (power, pressure, temperature) for which acceptable etching could be achieved was found to be quite broad and working conditions were chosen mainly on the basis of an arbitrary etch time of 4 min to clear 1000Å of Ti from a 3 in. wafer. These conditions are: 200W rf power, 0.35 Torr of the $CBrF_3$-He-O_2 mixture, 150°C wafer platen temperature, and a 4.4 cm electrode spacing. No measurable etching of Au or Pd occurs, using these conditions, while the etch rate for CVD Si_3N_4 is ~25 Å/min. Undercutting of Ti is negligible even with a 100% overetch. No change in MOS characteristics was observed after plasma exposure.

The standard process for patterning Ti-Pd-Au metallization using the beam lead technology (1) for silicon integrated circuit fabrication is as follows: (*i*) Ti and Pd are deposited sequentially by filament evaporation; (*ii*) the Pd is patterned using a photoresist mask and a wet chemical etch which does not attack Ti; (*iii*) thin Au is electroplated over exposed Pd through a second photoresist mask. Ti serves as the ground plane for this plating; (*iv*) a third photoresist mask is used to delineate the beam array and then thick Au is plated; and (*v*) the photoresist is stripped and Ti is etched using the Pd (Au) as a mask for the wet chemical etchant.

A schematic cross-sectional view of a metal-oxide-semiconductor (MOS) field effect transistor fabricated with polycrystalline silicon as the gate electrode and Ti-Pd-Au as the second level metal is shown in Fig. 1.

Inadvertent removal of Ti from contact windows can occur during Ti etching if any of the following conditions exist: (*i*) poor step coverage by Ti-Pd (caused, for example, by misalignment of contact windows through the silicon nitride with respect to contact win-

Key words: silicon integrated circuits, metallization, pattern generation.

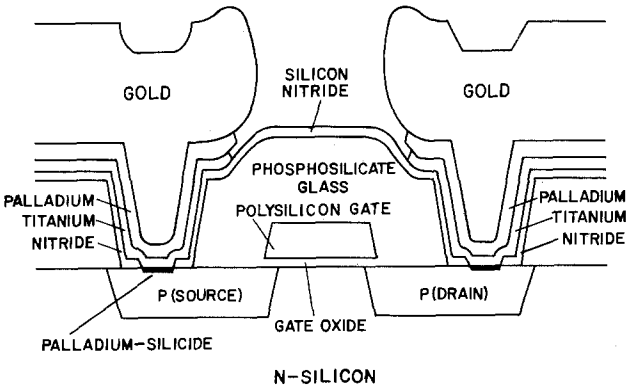

Fig. 1. Schematic cross section of MOS device structure after patterning of Ti-Pd-Au metallization.

dows through the phosphosilicate glass layer); (*ii*) misaligned Ti-Pd metallization over properly aligned contact windows; (*iii*) misaligned Au over marginally aligned Ti-Pd and/or marginally aligned windows; and/or (*iv*) poor dimensional control of window(s) and metallization features. All of the foregoing conditions encourage the formation of capillary channels which permit penetration of Ti etchant into the windows.

Etch-out of Ti in contact windows leads to oxidation of palladium-silicide contacts during subsequent annealing of the metallization with a resultant loss in yield, and even more serious, poor reliability of marginally good devices. As complete elimination of the aforementioned tolerance errors would require unrealistic process control, we have investigated plasma etching of Ti as an alternative patterning technique. The motivation for consideration of plasma etching lies in the expectation that the capillary channels allowing access of etchant to the windows should promote rapid recombination of the plasma active species and thus, in effect, preclude etching there. Plasma etching has an obvious advantage here in that the species which cause etching are not stable in the absence of the plasma and decay rapidly when collisions with a third body such as a solid surface can occur. In contrast, liquid etchant, once trapped in a capillary channel, continues to etch until all reactants are depleted to an equilibrium concentration.

There is no certain way to determine, by visual inspection prior to etching, whether Ti etch-out will occur. Thus, it is difficult to carry out controlled experiments which would allow a direct comparison of the extent of etch-out to be made between wet etching and plasma etching. A valid comparison would require split lot experiments and data from a large number of wafers. At this time the data available is not sufficient to permit an assessment of the effectiveness of plasma etching in preventing Ti etch-out in contact windows. Accordingly, we make no attempt to compare plasma etching to wet etching in terms of device yield or reliability. Rather, the intent of this paper is to discuss some problems encountered in plasma etching of Ti using Pd (Au) as a mask and the process conditions developed to overcome them.

Process Requirements

This investigation was stimulated by reliability problems which arose with MOS logic devices. Consequently, the requirements for the Ti etch process were dictated by the structure of these devices; a structure common to most MOS integrated circuits utilizing Ti-Pd-Au metallization.

The logic devices have poly-Si as the gate electrode and Ti-Pd-Au as the second level metal (see Fig. 1). The Ti is 1000Å thick, the Pd 2000Å thick, the thin Au $\sim$ 1.5 μm thick, and the beams are $\sim$ 15 μm thick. During Ti etching, Au and Pd are exposed. CVD silicon nitride which serves as a sodium ion barrier ($\sim$ 1200Å thick) is exposed upon removal of Ti. An acceptable etching process, therefore, must produce a high selectivity for Ti over Au, Pd, and Si_3N_4. In addition, no MOS damage should occur, to the extent of causing changes in device operating characteristics, and undercutting of Ti must be acceptable.

Experimental

A radial flow reactor similar to one described by Reinberg (2) was used in this study. In this type of apparatus the plasma is generated by rf energy (13.56 MHz) between two parallel, circular electrodes; the wafers to be etched rest on the grounded electrode. Gas is fed through a ring beneath the grounded electrode and pumped through a hole in its center; thus, gas flows radially across the electrode.

A differentially pumped quadrupole mass spectrometer was attached to the pumping line through an orifice in order to monitor the reactor effluent. A sapphire window on the Pyrex vacuum enclosure of the reactor chamber allowed the optical emission from the plasma to be monitored in the u.v.-visible region of the spectrum from $\sim$ 1800 to 8000Å. Substrate heating was accomplished by use of resistance heating coils embedded in the ground electrode.

Wafers used in this study were either test structures consisting of thermally oxidized Si-CVD Si_3N_4 (1200Å) and Ti-Pd-Au or device wafers, all receiving standard processing up to the Ti etch stage. In addition, Si wafers with 2500Å of Si_3N_4 and a photoresist pattern on them were used to measure the etch rates of Si_3N_4 in the various gases tested. Etch rate measurements were obtained with the aid of a Dektak surface profilometer.

Results

Gas selection.—The titanium halide binary compounds all have relatively high vapor pressures in comparison to other chemically simple titanium compounds. Consequently, only halogen-bearing gases were considered as potential etchants. Two gases which were known at the outset to etch Ti were tetrafluoromethane (CF_4) and chlorotrifluoromethane ($CClF_3$).

A CF_4-O_2 mixture was already in use to etch an ion milling mask in Ti on a bipolar microwave transistor device (3). In this process, the Ti is etched down to Au. In order to prevent Au staining, however, it was reported that conditions had to be carefully controlled, even though the Au is not exposed until Ti is removed. Indeed, previous experience with plasma etching of dielectrics deposited over Au had shown staining to be a persistent problem whenever Au is exposed, at elevated temperatures ($\gtrsim$ 50°C), to a plasma where both oxygen and fluorine are present (4). The stains are thought to be gold oxides whose formation is catalyzed by atomic fluorine. The presence of stains results in unsatisfactory thermocompression bonding to Au beams which is required for device packaging.

In principle, a pure CF_4 plasma could be used for Ti etching in the presence of Au, however, there is normally enough oxygen present due to residual water vapor and real leaks in the vacuum enclosure to render this an unsatisfactory solution. Moreover, the presence of oxygen is desirable because it enhances the amount of free fluorine in the plasma, thereby yielding higher etch rates. Also, CF_4 and CF_4-O_2 plasmas etch Si_3N_4 at relatively high rates and so are undesirable for etching down to a thin Si_3N_4 layer.

Chlorotrifluoromethane ($CClF_3$) plasmas were also known to etch Ti, although less data were available than for CF_4. Emission spectra taken for $CClF_3$ plasmas under various conditions of power and pressure revealed no emission from atomic fluorine in the plasma although a substantial amount of emission from atomic chlorine was observed. Figure 2 compares the emis-

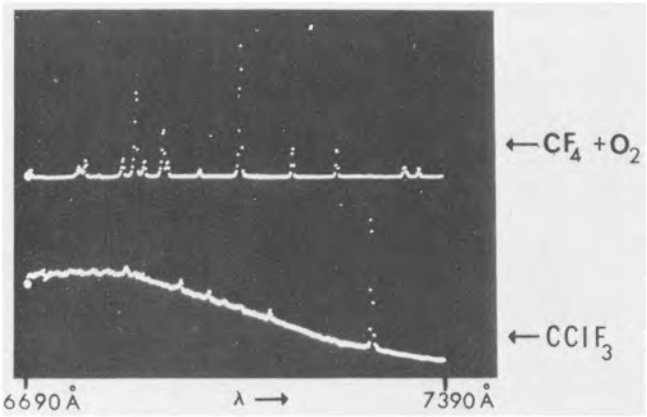

Fig. 2. Comparison of the emission spectrum of a CF_4-O_2 plasma to the spectrum for a $CClF_3$ plasma from 6690 to 7390Å. The observed lines are due to atomic fluorine and chlorine, respectively.

sion spectra of a $CClF_3$ plasma at 350W, 0.35 Torr, and a CF_4-O_2 plasma at 150W, 0.35 Torr for the spectral region from ~ 6690 to 7390Å. This frequency range was chosen for comparison because it includes several very intense emission lines from excited states of atomic fluorine. All of the lines seen in the upper spectrum of Fig. 2 are due to electronic transitions of F. Note that these lines do not appear in the lower spectrum corresponding to a $CClF_3$ plasma. The prominent line in this spectrum results from the $4s^4P$-$4p^4S^\circ$ transition of Cl at 7257Å. Numerous other lines, assignable to Cl transitions, were observed outside the frequency range of Fig. 2.

The absence of emission from F in the $CClF_3$ plasma provides necessary but insufficient evidence for concluding that F is not produced in this plasma. It is possible that F is present in the nonradiative ground state The CF_3-Cl bond strength is 3.7 eV (5) while the CF_3-F strength is 5.6 eV (6) and the CF_2-F strength is 4.2 eV (7). Thus, it is energetically more favorable to split off Cl than F. On the other hand, the first excited state of Cl is ~ 9 eV above the ground state while the first excited state of F is ~ 12.5 eV above its ground state. Thus, one might argue that the presence of the "softer" Cl modulates the energy distribution of the free electrons in the plasma to the extent that there are not enough electrons available with sufficient energy to excite F above its ground state once it has been freed. The latter argument can be shown to be invalid by a simple experiment, the results of which are illustrated in Fig. 3. When a few percent He are added to the $CClF_3$ plasma two lines appear, in the spectral range corresponding to Fig. 2, due to transitions between excited states of He as shown.[1] Since the first excited state of He lies 19.82 eV above the ground state it is clear that electrons with energy sufficient to excite F are indeed present in the plasma. Therefore, it is concluded that $CClF_3$ does not produce a significant F concentration under the plasma conditions used in these experiments.

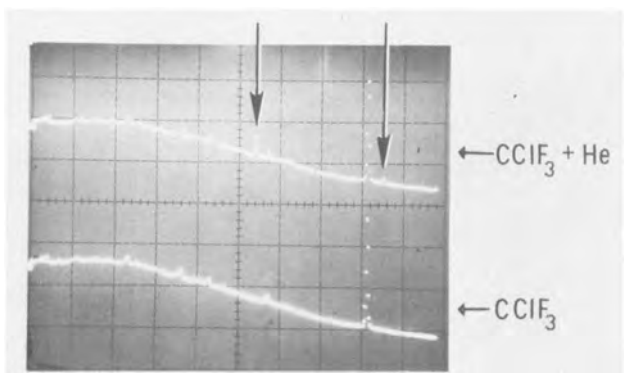

Fig. 3. Emission spectrum of a $CClF_3$ plasma with and without He present. The two lines marked with arrows (upper spectrum) are due to He transitions at 7065 and 7281Å. The frequency range in Fig. 3 is identical to that for Fig. 2.

Accordingly it was anticipated that in a $CClF_3$ plasma, etching of Ti would occur by the formation of volatile $TiCl_4$ and the absence of F would eliminate Au staining if oxygen was present in the plasma. Several attempts were made to determine what volatile Ti product results from etching. The intensity of emission from excited states of atomic chlorine was monitored with and without Ti etching in the $CClF_3$ plasma. A reproducible decrease in intensity resulted when Ti was placed in the plasma. For example, when the area of Ti exposed to the plasma was ~ 100 cm^2, the Cl line intensities decreased by ~ 20%. Mass spectra of the reactor effluent taken during etching showed no detectable Ti-containing product even when a substantial amount of Ti surface area (two 6 × 3 × 0.30 in. Ti sheets) was exposed to the plasma. However, a porous deposit was formed on the unheated rf electrode directly above the substrates. This deposit was analyzed by x-ray dispersive analysis and found to contain Ti. The vapor pressure of $TiCl_4$ is several Torr at room temperature (8); thus, it would be expected to appear in the effluent. The absence of mass spectral confirmation of $TiCl_4$ and the observed deposit therefore suggest that a more complex, less volatile reaction product is formed, probably involving atomic chlorine in the reaction.

As anticipated, Au staining did not occur with $CClF_3$; however, an erratic and often severe problem with Au "transport" was observed. Normally, $CClF_3$ plasmas etch Au at a rate comparable to Ti. At 85°C the etch rate for Au in a $CClF_3$ plasma at 200W, 0.35 Torr is ~ 250 Å/min. (This loss is tolerable and could be compensated by plating the Au slightly thicker if desired.) Often though, the Au was transported across the wafer surface rather than being removed by etching. The mechanism by which this occurs is not understood. Occasionally Au would be transported heavily enough to be quite obvious as shown in Fig. 4a. Note that a thin Au layer has covered almost the entire area shown. More frequently, Au was observed to transport in a more subtle fashion between closely spaced lines particularly where these lines crossed steps in the underlying dielectric as shown in Fig. 4b. Underplating also seemed to enhance the tendency for transport.

The occurrence of transport was not readily predictable nor was it clear from a limited number of experiments that it could be avoided entirely by some optimum choice of plasma parameters. Consequently, the use of $CClF_3$ was abandoned.

An alternative halogen-bearing gas for which no data were available concerning Ti etching was bromotrifluoromethane ($CBrF_3$). In earlier work with this gas we observed that atomic bromine is produced in a $CBrF_3$ plasma,[2] and it was anticipated that this would yield a volatile Ti product. It was also noted that $CBrF_3$ often forms an unstable plasma characterized by constrictions, *i.e.*, localized, very intense regions of plasma which would obviously hamper the attainment of uniform etching in a batch-type operation. This form of instability is probably related to the electronegative character of the halocarbon gases as our observation of the ease of maintaining a uniform stable plasma is: $CF_4 \gtrsim CClF_3 > CCl_2F_2 \gtrsim CBrF_3$. Presumably, a constriction occurs when a spatial fluctuation in electron density is stabilized by electron attachment outside the constricted region. The more conductive

[1] The He was added at constant total pressure, thus diluting the $CClF_3$, which accounts for the slight drop in intensity of the Cl line.

[2] As with $CClF_3$, this gas produces no significant amount of atomic fluorine. The CF_3—Br bond strength is 3.06 eV (9).

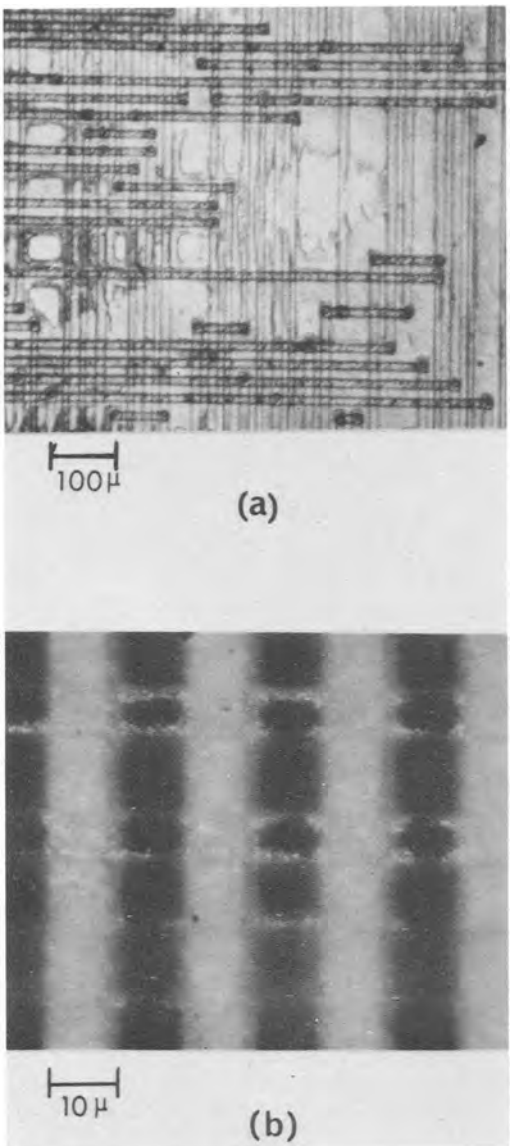

Fig. 4. (a) Optical micrograph illustrating unusually severe Au transport observed following etching in $CClF_3$ at 200W, 0.35 Torr. (b) Optical micrograph illustrating Au transport between closely spaced runners. Note that transport has occurred preferentially along steps.

constriction thereafter carries most of the current and the rf power is dissipated mainly in this region.

We have found that instabilities in $CBrF_3$ plasmas can be eliminated by the addition of He as a diluent. Whether the stabilizing effect of He is due to collisional detachment or some other mechanism is not known. Whatever the reason, this has proven to be a very reliable method of achieving a stable $CBrF_3$ plasma. Consequently, all of the Ti etching experiments in $CBrF_3$ were carried out using a He diluent.

As was the case with $CClF_3$, no Ti reaction product could be positively identified by mass or optical spectroscopy when etching Ti in $CBrF_3$ plasmas. However, as it was again suspected that Br played an important role in the etching reaction, we sought to maximize the Br content of the plasma by the addition of O_2. Additions of O_2 to a CF_4 plasma can produce an increase of several hundred percent in the amount of atomic F thereby enhancing the etch rate of materials such as Si which can react directly with F (10, 11). Similarly, the addition of oxygen to a $CClF_3$ plasma was found to produce a substantial increase in the intensity of emission from excited states of chlorine atoms presumably reflecting a similar increase in chlorine atom concentration. Thus, it seemed reasonable to expect that O_2 would perform the same feat when added to $CBrF_3$. Figure 5 illustrates the result of replacing He with O_2 in a $CBrF_3$-He plasma. As can be seen, the O_2 does increase the intensity of emission from excited Br atoms but by a maximum of only $\approx$ 10%. In fact, the intensity actually begins to decrease somewhat as the He content drops below $\sim$ 20%. Again assuming that the emission intensity is a measure of atom concentration, these results indicate that oxygen does not markedly influence the Br atom concentration. It should be noted that the replacement of He by O_2 showed no indication of affecting the stability of the plasma.

The addition of O_2 to $CBrF_3$ caused only a small increase in etch rate for Ti as might be expected from the data of Fig. 5. Nevertheless, oxygen was retained in the gas mixture because of its potential usefulness in removing traces of photoresist and hydrocarbon residues which are occasional contaminants on wafer surfaces.

Process parameters, etch rates, and uniformity.—As already discussed the gas mixture was optimized to produce plasma stability and maximize the concentration of Br. The optimum composition determined was 63% $CBrF_3$, 25% He, and 12% O_2. Detailed measurements of the dependence of etch rate on rf power

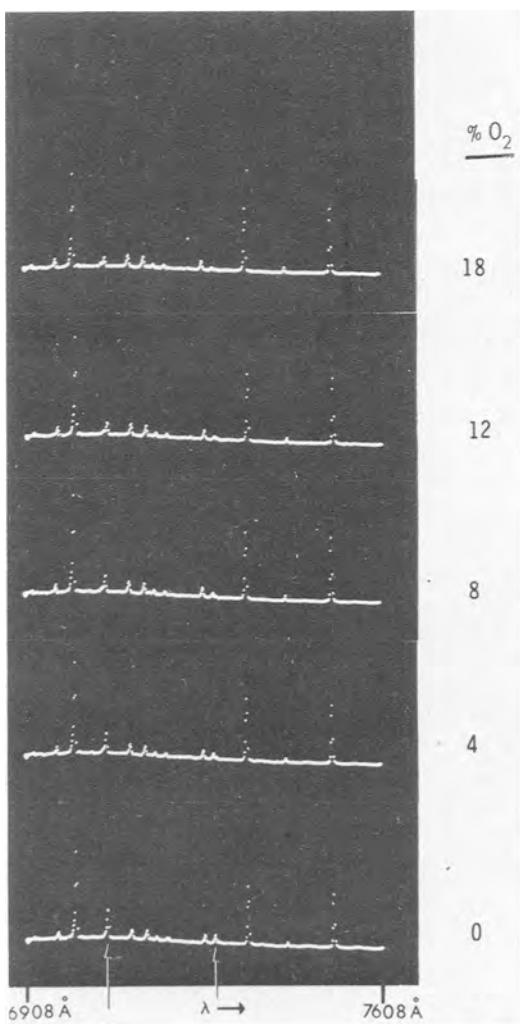

Fig. 5. Optical spectra illustrating the slight enhancement of Br emission accompanying the replacement of He by O_2 in a $CBrF_3$-He mixture. The $CBrF_3$ content was held constant at 63%. All lines seen are due to atomic bromine transitions except the two lines marked by arrows which are due to He.

and pressure were not made for two reasons. First, the Ti did not etch uniformly enough to obtain meaningful data; usually the Ti would clear first at the periphery of the wafer. For this reason it seemed more practical to measure the time to completely remove Ti from a wafer as a function of plasma parameters. Second, there were no evident problems in fulfilling the process requirements, outlined in that section above, over a wide range of plasma conditions tested (80-350W, 0.2-0.7 Torr, 60°-150°C). Hence conditions were established, empirically, which provided for a reasonably short cycle time.

Some indication of the effect of rf power on rate can be obtained by noting that at 125°C,[3] 0.35 Torr, the times to clear 1000Å Ti from 3 in. wafers are 10 and 6 min at 80 and 200W, respectively.[4]

The etch rate is a comparatively strong function of temperature as shown in Fig. 6 where the times to clear equisized pieces of a 3 in. wafer (1000Å Ti) are plotted as a function of reciprocal temperature. The apparent activation energy derived from the slope of the best fit line in Fig. 6 is ~ 0.2 eV.

For convenience, the plasma parameters were adjusted to give a total etch time, including ≈ 25% overetch, of 4 min to clear 1000Å Ti from a 3 in. wafer. Successful batch etching can be done using these conditions: 200W rf power, 0.35 Torr of 63% $CBrF_3$-25% He-12% O_2, a 150°C substrate table temperature, and an electrode separation of 4.4 cm. As will be indicated shortly, these conditions provide a high selectivity so that substantial overetching is permissible. Moreover there is no staining of the exposed Au nor any Au transported between closely spaced lines including regions where these lines cross steps.

Selectivity and undercutting.—No measurable Pd or Au etching was observed using the plasma conditions just outlined, although a thin, innocuous layer of palladium oxide is formed on prolonged exposure of Pd surfaces to the plasma, when O_2 is present in the gas mixture. The etch rate of Si_3N_4 was approximately 25 Å/min. Evidently, Au is substantially more inert toward Br and O than for F and O, Cl, or Cl and O. No undercutting could be measured (optical microscope) after the nominal etch time whereas a 100% overetch produced $\lesssim$ 0.2 μm undercut per edge (*i.e.*, the linewidth decreased by $\lesssim$ 4000Å). It is of interest to compare these figures with values typical of wet etching; etching for the nominal time (2 min) produces ~ 0.6 μm undercut per edge while a 100% overetch undercuts ~0.9 μm per edge. The fact that undercutting is reduced substantially with plasma etching supports our contention that plasma etching will suppress contact etch-out when processing errors produce channels which allow access of etchant into contact windows.

Effect of MOS parameters.—No adverse effects on MOS characteristics due to plasma exposure have been observed on device wafers etched in our experiments. Added assurance about potential MOS damage was gained by running a well-characterized test wafer for four times the normal etch time and then retesting. Again no significant change in any MOS parameter was observed.

Residual Pd.—Occasional problems arose with residual Pd due to incomplete removal during Pd etching. Wet etching of Ti which is accompanied by vigorous bubbling will normally remove these residues. For plasma etching, however, there is no mechanical agitation and Ti is simply etched out from beneath the residue making it easy to observe with an optical microscope.

[3] The temperature measurement was made using a thermocouple embedded in the large Al plate (the grounded electrode) on which the wafers rest.

[4] It is noteworthy that the etch rates reported here refer to filament evaporated Ti as we have found that rf-sputtered Ti etches more slowly.

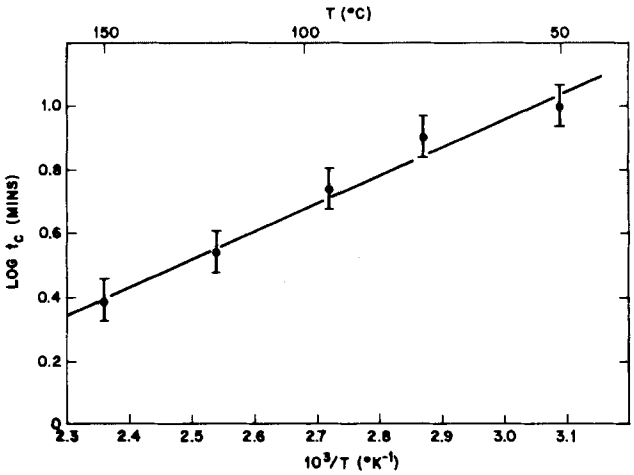

Fig. 6. Arrhenius plot of the time to clear 1000Å of Ti as a function of temperature for etching in a $CBrF_3$-O_2-He plasma.

Conclusions

Titanium can be etched by CF_4, $CClF_3$, or $CBrF_3$ plasmas or in plasmas containing mixtures of these gases with O_2. However, for etching Ti in the presence of Au, Pd, and Si_3N_4 only the $CBrF_3$ plasma offers the necessary selectivity and freedom from Au staining and transport to be of practical value.

A mixture of 63% $CBrF_3$, 25% He, and 12% O_2 was found to produce a uniform, stable plasma. Helium is useful in stabilizing the plasma while oxygen enhances the generation of atomic bromine which is thought to be a major etch-active species. This gas mixture provides excellent selectivity; the etch rate for Au and Pd is essentially zero, while Si_3N_4 is removed at ~ 25 Å/min using the nominal conditions: 200W rf power, 0.35 Torr, 150°C substrate carrier temperature, and a 4.4 cm electrode separation. Under these conditions a 1000Å thick Ti film can be removed from a 3 in. wafer in approximately 3 min. The choice of power, pressure, and temperature is not critical and is dictated mainly by the desired etch time.

The high selectivity for Ti over Pd and the absence of convective agitation in the plasma makes it imperative that Pd and/or Pd compounds be completely removed from the Ti surface during prior processing if plasma etching is to be successful.

SiO_2 Particulates Dispersed in CVD Reactor

I. Semi-*In Situ* Observation

A. Shintani,* K. Suda, M. Suzuki, M. Maki, and K. Takami

Hitachi, Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

The number of size variations with time of vitreous silicate particulates in a CVD reactor for SiO_2 film deposition are measured by observation of Mie scattering of a He-Ne laser light on the submicron particles (0.1-0.5 μm diam). The predominant particles are found to be 0.2-0.3 μm in diameter. The size distribution varies with time during the reaction period. Particulates greater than 0.3 μm diam decrease in number with time, whereas the number of smaller particles gradually increases or does not change except at reaction initiation. The size distributions are affected by substrate temperature and reactant and dopant concentrations. Generally, these parameters influence the number of large particles more than smaller particulates. Large particles greater than 0.3 μm diam decrease in number with O_2 flow rate at O_2/SiH_4 ratios greater than 100 and also with the PH_3 flow rate. However, the number of small particles does not vary radically with these gas flow rates. Lowering the substrate temperature results in a reduction in the large particle number. This large particle phenomenon is primarily caused by small particle coagulation. Furthermore, the small particles (0.1-0.2 μm diam) before coagulation reflect the particle nucleus number.

The low temperature chemical vapor deposition (CVD) technique has been usefully employed for the formation of vitreous silicate and phosphosilicate glass (PSG) in silicon device technology. In this CVD technique, SiH_4 and O_2 are generally used as the source reactants. It is well known that SiH_4 reacts violently with O_2, causing SiO_2 fog so that vitreous silicate particles are deposited on the cooled reactor wall. These SiO_2 particulates dispersed throughout the reactor are the cause of pin holes and/or flakes on SiO_2 films formed. Interest in SiO_2 fog centers not only on the characteristics of the SiO_2 films, but also on formation mechanism and kinetics of the film. The problem is: Whether or not there are differences in the formation mechanism and kinetics between SiO_2 particulates and films.

Many investigators, for instance Goldsmith and Kern (1), Baliga and Ghandi (2), Shibata and Sugawara (3, 4), Middelhoek and Klinkhamer (5), and Kern *et al.* (6), have dealt with the kinetics of SiO_2 film growth using SiH_4 and O_2. However, the exact mechanism of SiO_2 film formation has not been confirmed, since the reaction between SiH_4 and O_2 is quite complicated. With regard to SiO_2 particulates, there have been no reports even on particle size.

In this paper, part I of the study, an aerosol measuring technique (7) is applied to the SiO_2 CVD in order to evaluate particulate dispersion in the reactor. The estimation is carried out by measuring the size, number, and related distributions of submicron particles. The results obtained are compared with the SiO_2 film formation process using a basic aerosol theory. The present paper is the first report on exact measurements of SiO_2 particle dispersions in a CVD reactor.

Experimental

Laser particle monitor.—The laser particle monitor (LPM) used in this work consists of a laser light source (8 mW He-Ne laser), a light scattering cell, and a photomultiplier tube as shown in Fig. 1. The laser light is used so that the intensity of Mie scattering light on submicron particles is sufficient for photomultiplier sensitivity. A light scattering cell to which sample gas is introduced possesses optical traps. These optical traps absorb light scattered in directions other than to the photomultiplier. The photomultiplier changes the scattered light intensities into electric signals (pulses). The pulse height and number correspond to particle size and number, respectively. The LPM numerically indicates the number of the particles in individual diameter regions ranging in 0.1-0.2, 0.2-0.3, 0.3-0.4, and 0.4-0.5 μm. Further details

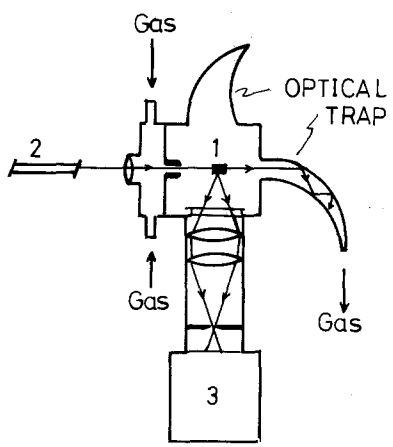

Fig. 1. Schematic diagram of the LPM. 1, Sensing zone; 2, He-Ne laser tube; 3, photomultiplier.

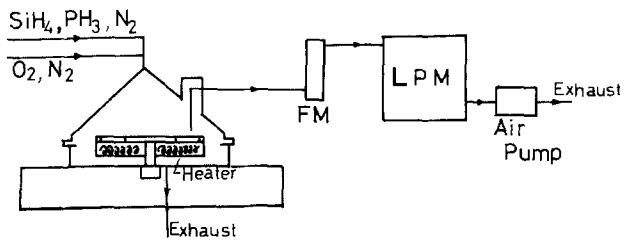

Fig. 2. Schematic diagram of the experimental setup

regarding LPM will be reported elsewhere at a later date (8).

CVD apparatus and experimental setup.—A bell-jar type reactor, as depicted in Fig. 2, was employed for growth of SiO_2 films. The sample holders were heated to 415° ± 5°C and were rotated in a planetary system. A sampling nozzle of 1/4 in. stainless tube was placed about 3 mm above the holders to pump up sample gas as close to the substrates as possible. The sample gas was introduced through this nozzle into the LPM by an air pump at the rate of 1 liter/min. The pipe length from the nozzle end to the LPM was fixed at 2m, because good reproducibility with less than 10% error in the measurement is obtained for pipe with length of 2.5m or less. Some particulates would be newly generated and the particles could grow in this pipe. A little amount of these unknown particles may be added in the measurements, though the reaction time in the sampling pipe was very short, less than 1.5 sec, compared with that in the reaction chamber. Accordingly, this measuring technique was not a complete "*in situ*," but a "semi-*in situ*" method.

Particle formation conditions.—It is well known that the deposition rate of SiO_2 film on a Si wafer varies with substrate temperature and reactant and dopant concentrations. The effects of these experimental parameters on particle size and distribution in SiO_2 dispersions were studied to investigate the correlation between SiO_2 particle formation and film deposition mechanisms. The measurements were carried out at temperatures of 210°-500°C in gas concentrations of 0.018-0.14 mole percent (m/o) for SiH_4, PH_3/SiH_4 ratios of 0.028-0.132, and O_2/SiH_4 ratios of 13.2-132.

Particle distribution measurements.—Each measurement was performed after a blank test in which no reactant was introduced. This test confirmed that no particles before the reaction were present in the apparatus within the LPM sensitivity (greater than 5×10^7 particles/m^3). The number of particles in individual size regions and the total number were recorded at intervals of about 20 sec during the reaction period.

Results

SiO_2 particle dispersions.—The thickness of both SiO_2 and PSG films grown on Si wafers were linearly proportional to deposition time (Fig. 3). These results reveal that both films grow at steady state. However, the size distribution of SiO_2 particles dispersed in the CVD reactor were generally varied at any time during the deposition period as shown in Fig. 4. Some characteristics can be noted from the figure: The particles of 0.1-0.3 μm diam steeply increased in number at the beginning of the reaction. After this increase, their number rapidly decreased within 3 min after the introduction of the gases and then tended to increase gradually with deposition time. On the other hand, the number of 0.3-0.5 μm diam particles increased relatively slowly within 4 min of the reaction start, and then they monotonously decreased with time. When the reactant gas supply was stopped, the particles of 0.1-0.2 μm diam immediately increased

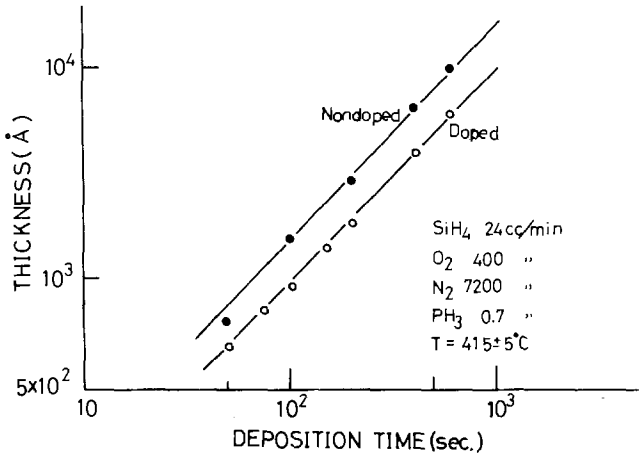

Fig. 3. Deposition time dependence of SiO_2 and PSG film thicknesses.

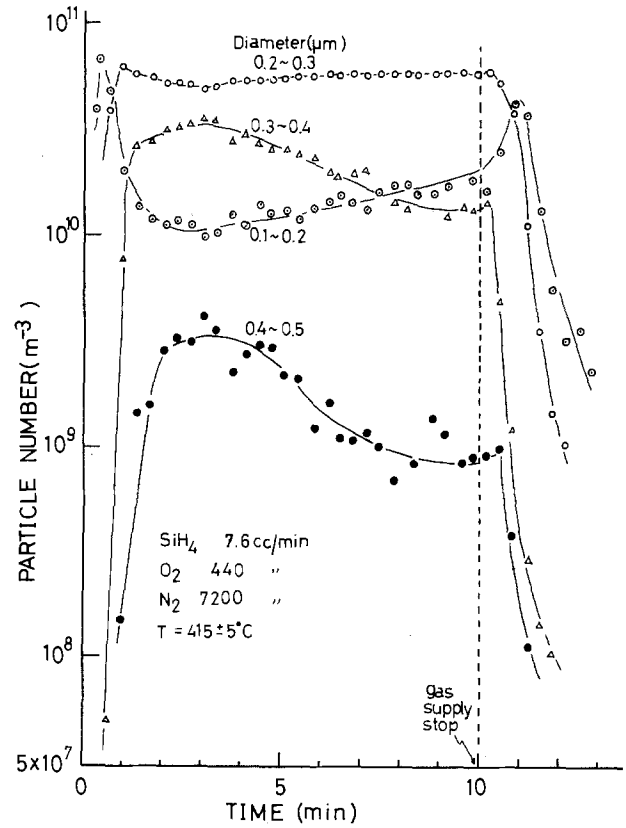

Fig. 4. Time variations of the individual particle sizes at 415°C

in number, then drastically reduced. The total particle number was independent of reaction time, contrary to the individual particle number distribution. The particles of 0.2-0.3 μm diam approximately dominate the total particle number. On the other hand, the larger particles contribute less to the total number.

Temperature dependence of particle distribution.—The substrate temperature was raised while maintaining the other experimental conditions at the same levels as those shown in Fig. 4. Then, the particles in regions above 0.3 μm diam numerically increased and the smaller particles decreased as depicted in Fig. 5. The total particle number also slightly increased under these conditions. The rate of each particle number variation with time was larger at 450° than 410°C.

This temperature dependence of particle distributions at temperatures between 210° and 500°C is illustrated in Fig. 6. The particles in the 0.4-0.5 μm

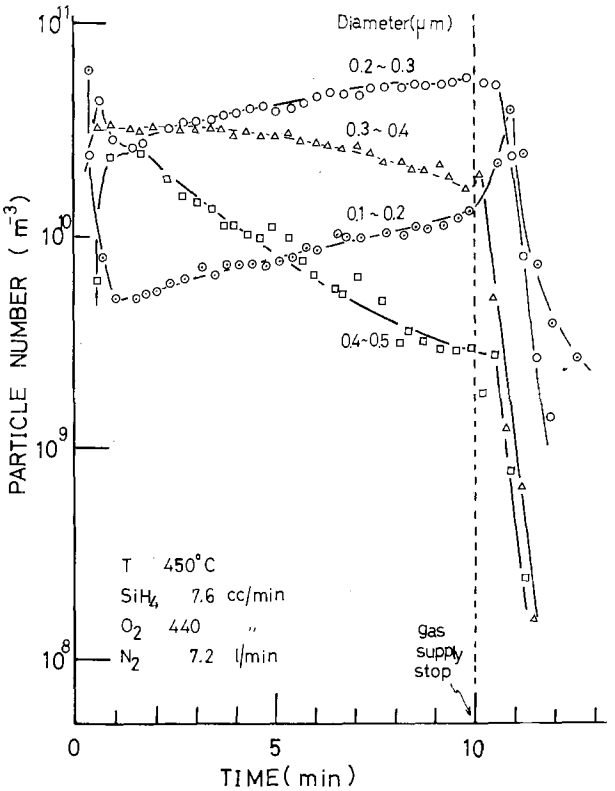

Fig. 5. Time variations of the individual particle sizes at 450°C

diam range were eliminated because their number at low temperatures were beyond the LPM sensitivity limit. The results for two points (3 and 9 min after the gas supply) are plotted in Fig. 6 to enable investigation of the time variation of the temperature dependence. No characteristic difference, however, was found between the two points. Small particles of 0.1-0.2 μm diam steadily increased in number with lowering temperature. The number of 0.2-0.3 μm diam particles showed no definite temperature dependence. The large particles in the 0.3-0.4 μm diam range also showed no large temperature dependence at temperatures higher than 400°C. However, at temperatures lower than 400°C, the number of the large particles was reduced with the lowering in temperature.

Reactant and dopant concentration dependences of particle distributions.—Baliga and Ghandi (2) reported that the deposition rate of SiO_2 films is proportional to the square root of O_2 flow rate at O_2/SiH_4 ratios less than 10. As this ratio is taken above 10, the deposition rate is lowered with the increase in O_2 flow rate. Recently, Shibata and Sugawara (3) made a detailed study of this phenomenon for PSG. It was found that the O_2 flow rate dependence of the deposition rate varies for different substrate temperatures. In order to investigate the influence of this reactant concentration on particle distributions, the O_2 flow rate was varied from 100 to 1000 cm^3/min while keeping the other conditions constant. As a result, the large particles of 0.3-0.5 μm diam decreased at a rapid rate with increasing the O_2 flow rate as shown in Fig. 7. This result resembled the case of the film formation, whereas the small particle number was almost constant or gradually increased with the O_2 flow rate.

When a small amount of PH_3 was added to the reactant gas as a dopant, the SiO_2 film deposition rate steeply decreased, as indicated by Shibata and Sugawara (4). The deposition rate gradually increased with the amount of PH_3 after the initial steep rate reduction. In the case of particles dispersed in the reactor, the large particles of 0.3-0.4 μm diameter also showed a tendency of a decrease-minimum-increase in number with the PH_3 flow rate (Fig. 8). The PH_3 concentration giving the minimum particle number was not the same as that for the minimum film deposition rate. The PH_3 concentration for the

minimum particle number was higher than that for the minimum film deposition rate. However, the small particles did not effectively change with the addition of PH_3 as shown in Fig. 8. The total number of particles was also almost completely independent of PH_3 concentration.

Discussion

SiO_2 particle formation.—The elementary processes determining the size distribution of particles are chemical reaction collision and sticking (coagulation) of each particle, and deposition of particles on the cooled reactor wall. Chemical reaction growth of particles proceeds at steady state, likewise the SiO_2 film formation on a Si wafer. This is because there is no basic difference in the chemical reaction between the particle growth and film formation. Accordingly, the chemical reaction growth cannot explain the time variation of particle number.

Consequently the coagulation and deposition of particles are taken into account for the particle variation in number with time. The coagulation is considered first. Under certain experimental conditions, the large particles diminished in number and then vanished as illustrated in Fig. 9. In the figure, the variation of 0.1-0.2 μm particle number with time is in contrast to that of 0.2-0.3 μm particles; when one increases in number, the other decreases. From this result, particle nucleation is considered assuming that 0.2-0.3 μm particles can be formed by the coagulation of two 0.1-0.2 μm diam particles. Therefore, the number of 0.1-0.2 μm particles before collision can be estimated by the sum of observed 0.1-0.2 μm particles and two times the number of 0.2-0.3 μm particles. This initial number of 0.1-0.2 μm particles does not change with

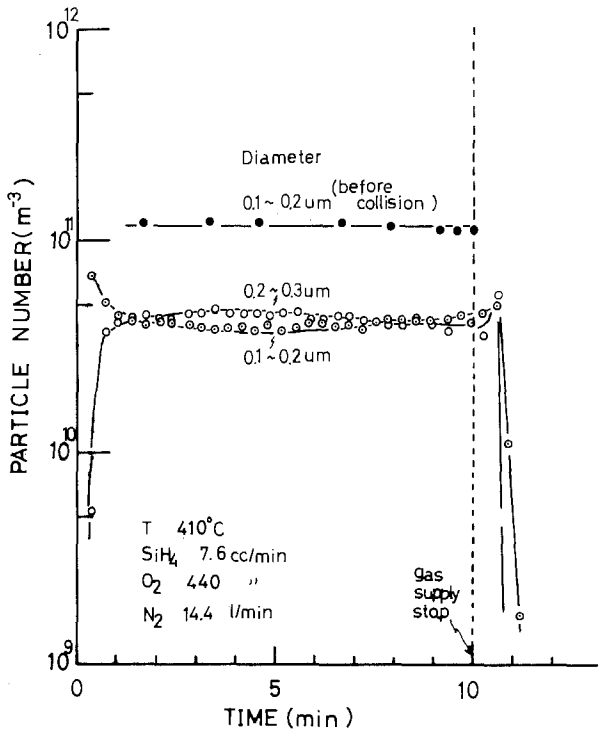

Fig. 9. The small particle size distribution under a selected experimental condition.

time as shown in Fig. 9. As previously noted in Fig. 4, only 0.1-0.2 μm particles are dominant in the reactor immediately after the reactant gases are introduced. Consequently the number of 0.1-0.2 μm particles before collision takes place is considered to represent particle nucleation. If this model approximates the actual conditions, 0.1-0.2 μm particles are dominant in the reactor under particular experimental conditions which result in few particle collisions. Thus, they do not change in number with time. In fact, this phenomenon occurred when the reactant gases were very diluted, as indicated in Fig. 10. This cor-

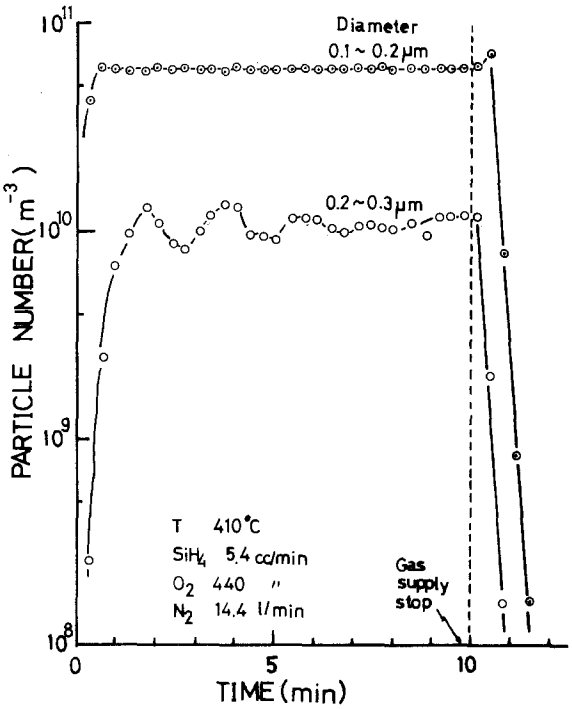

Fig. 10. Domination of the 0.1-0.2 μm diam particles

respondence between the number of 0.1-0.2 μm particles and particle nuclei is established on the assumption that these particles are single particles.

The radii of all particles generated at the reaction start would be the same and constant, R. These particles move along the laminar gas flow and come in contact with another particle and become bonded into one particle. The total number of encounters occurring per second, N, is expressed as

$$N \propto n^2 v R^3 \quad [1]$$

where n is the particle concentration and v the velocity gradient in the fluid (9). The gas flow used in this work is laminar, because the Reynolds number is roughly estimated to be on the order of 100. A distinctive feature of Eq. [1] is the rapid rise in number of encounters with increasing particle size. For the rate of change of n, the following expression is obtained

$$\frac{dn}{dt} \propto -n^2 v R^3 \quad [2]$$

Integration of Eq. [2] gives the reduction of particle number with time due to coagulation, which can be expressed as

$$n = \frac{n_0}{1 + (cn_0 v R^3)t} \quad [3]$$

where n is the initial concentration of the particles with R radius and c is the proportional constant in Eq. [2]. The integration is based on the assumption that v is constant with respect to time. Equation [3] indicates that the particle number decreases with time t. This qualitatively accounts for the reduction of 0.1-0.2 μm particles in number over the first 3 min after the reaction starts, as shown in Fig. 4. During this time, 0.2-0.5 μm particles are formed by coagulations of small particles. After this particle formation period, the large particles with 0.3-0.5 μm diam decrease in number according to a formula similar to Eq. [3].

The above discussion is based on the suppositions that the particles are spherical and that the particle collisions occur between the same size particles (Eq. [1]). However, the phenomena occurring in the reactor are more complicated. This complication results in the fact that 0.1-0.2 μm particles gradually increase in number after a drastic reduction at the beginning of the reaction, as seen in Fig. 4. This is partly because collisions occur among various sized particles.

Another reason for the complication is that the particles are deposited on the cooled wall of the reactor. Particular experimental conditions can maintain an equilibrium between formation and reduction processes of certain particles due to coagulation and deposition. This resulted in the fact that no variation in 0.2-0.3 μm particle number with time was noted in Fig. 4 and 9.

A more detailed theory and closer examination of particle behavior are necessary for a more detailed analysis and discussion. However, presently, both detailed theory and examination are not available because of theoretical difficulty and a lack of adequate measurement techniques.

Temperature effect on the particle formation.—Clarification of the effect of temperature on particle formation in the CVD reactor is extremely complicated, since the bell-jar wall is water cooled and then the gas temperature varies with the distance from the substrates. The sampling nozzle was placed as close to the substrates as possible so that the gas was pumped up around the substrates as mentioned previously. However, it remained unclear what region of the gas was sampled. From this view point, the real gas temperature was unknown, and therefore the data obtained did not show a definite or true temperature dependence of particle size distribution. Therefore, the data only indicate the particles generated when the sample holders are kept at some temperature. Gas temperature, however, goes up with holder temperature, indicating that particle distribution varies with substrate temperature.

Accordingly to Volmer and Weber (10) and Frenkel (11), the nucleation rate, Γ, for particle condensation from vapor is given in a formula similar to the rate constant in Eyring's absolute rate theory, $\Gamma = A \exp(-\Delta E/kT)$. If this equation is applicable to particle formation, the small particles, especially 0.1-0.2 μm particles, increase in number with increasing gas temperatures. However, the obtained results (Fig. 6) are apparently contrary to this prediction. This is due to neglecting the temperature dependence of particle coagulation. This is not taken into account because analysis of particle collision rates in the transition regime is accompanied by difficulties in specifying particle mobilities (9). Coagulation in a gas flow system would be activated by increasing gas temperature similarly to the case in a stagnant system. Then, if the increase in coagulation is greater than the particle nucleation, the small particles decrease in number with gas temperature; whereas the large particle number increases. The results shown in Fig. 6 are qualitatively consistent with this. Since medium size particles, 0.2-0.3 μm diam, are maintained in equilibrium between particle formation and reduction as described previously, their temperature dependence would be small in the temperature range studied.

Reactant and dopant effect.—From the viewpoint of chemical kinetics, the nucleation rate described above has a parameter, A, which includes a frequency factor, meaning a statistical collision probability of reactant gas molecules. Accordingly, particle nucleation is generally activated with increasing the O_2 flow rate. The increase in number of small particles with the O_2 flow rate is partly caused by this O_2 flow rate effect. On the other hand, the reason for the decrease of large particles in number with the O_2 flow rate is possibly that the O_2 gas inhibits the particle coagulation at high O_2/SiH_4 ratios.

The addition of PH_3 to the reactant gas also inhibits the coagulation of the particles. This effect induces a reduction of the large particles with the PH_3 flow rate in the low PH_3 concentration region. The small particle number before coagulation (not illustrated in Fig. 8) also changed slightly in a manner similar to the large particle variation. Although these particle behavior characteristics caused by PH_3 addition are similar to the effect of PH_3 on the SiO_2 film formation rate, the detailed effect and mechanism in SiO_2 formation is not well understood at present.

Summary and Conclusions

The SiO_2 particles generated in the CVD reactor are distributed in various sizes. The individual size particles vary in number with reaction time. Large particles, greater than 0.3 μm diam, decrease in number with time, while smaller particles increase or do not change in number. The particle size distribution is affected by substrate temperature (gas temperature) and the reactant and dopant concentrations. These experimental parameters have a greater effect on the 0.3-0.5 μm particles than on the 0.1-0.2 μm particles. Larger particles decrease in number with decreasing temperature and increasing in flow rates of O_2 and/or PH_3. These behavior characteristics in the CVD reactor appear to be caused by the nucleation and coagulation of particles.

In the present paper, only the particle distribution is discussed. The correlation between SiO_2 film characteristics and particles will be reported in the near future. In part II of this study, it is emphasized that

the pin holes in the films are caused, especially, by the 0.3-0.5 μm diam particles.

The Deformation of Polycrystalline-Silicon Deposited on Oxide-Covered Single Crystal Silicon Substrates

Takaya Suzuki, Akio Mimura, and Takuzo Ogawa

Hitachi, Limited, Hitachi Research Laboratory, Hitachi, Ibaraki 319-12, Japan

ABSTRACT

The cause of the bowing of wafers with thick polycrystalline-silicon layers deposited by the hydrogen reduction of trichlorosilane has been studied. High temperature dilatometer measurements show that the expansion coefficient of the polycrystalline-silicon layer in the temperature range 100°-900°C is 2.3-4.2 $\times$ 10^{-6}°C^{-1}, and that the polycrystalline-silicon layers contract perpendicularly to the direction of growth at temperatures higher than about 1000°C. The experimental data indicate that the bowing of wafers is caused by the intrinsic tensile stress generated by the contraction of the polycrystalline-silicon layer buried behind the advancing surface of the growing layer, and not by the the thermal stress generated by the difference in the thermal expansion coefficients between the grown layer and the substrate. This contraction of the polycrystalline layer may be induced by a mechanism similar to sintering.

The use of polycrystalline-silicon films for the fabrication of semiconductor devices has received considerable attention in recent years. Especially, thick films of 200-500 μm deposited by chemical vapor reaction have been used as mechanical supports in the fabrication of dielectrically isolated, silicon integrated circuits. However, when such thick films or layers of polycrystalline-silicon are deposited on wafers, bowing can be observed. This severe macroscopic deformation creates undesirable effects to further processing. The difference between the coefficients of thermal expansion of polycrystalline-silicon layers and of single-crystal silicon substrates has been considered the probable cause of the bowing (1). This has not been confirmed, however, because no data on the coefficient of thermal expansion of polycrystalline-silicon layers have been available. Recently, Kamins (2) reported that the incidence of degradation was sporadic, and that the bowing was related to the inclusion of trace quantities of oxygen in the structure of the polycrystalline-silicon layers. But, on the other hand, it has been reported that compensation for wafer bowing is possible through doping with a small amount of oxygen in the polycrystalline-silicon during deposition (3). As described above, a clear explanation has not been made yet as to the cause of the bowing observed in wafers with polycrystalline-silicon layers.

Key words: polycrystalline-silicon layer, bowing, expansion, contraction, sintering.

In this paper we report the results of an experimental study on the cause of the bowing, and show that the bowing is due to the contraction of the polycrystalline-silicon layers originating from a mechanism analogous to sintering. The sintering takes place at the high temperatures used for the growth reaction.

Experimental Method

Polycrystalline-silicon layers with a thickness between 60 and 500 μm were deposited in a conventional, vertical-type, rf-heated, epitaxial reactor by the hydrogen reduction of trichlorosilane ($SiHCl_3$) at 1100°-1260°C. No doping impurities were intentionally added during the deposition. Substrates (50 mm diam) on which the polycrystalline-silicon was deposited were thermally grown oxide-coated, n-type (10-15 Ω-cm), single crystal silicon wafers with a thickness of 300 $\pm$ 10 μm and with a surface orientation of <100>. The substrate silicon was coated with 1.7 μm thick thermally grown oxide.

Figure 1 shows an example of a polished and Sirtl-etched cross section of a thick (220 μm) polycrystalline-silicon layer grown at 1200°C. It can be seen that

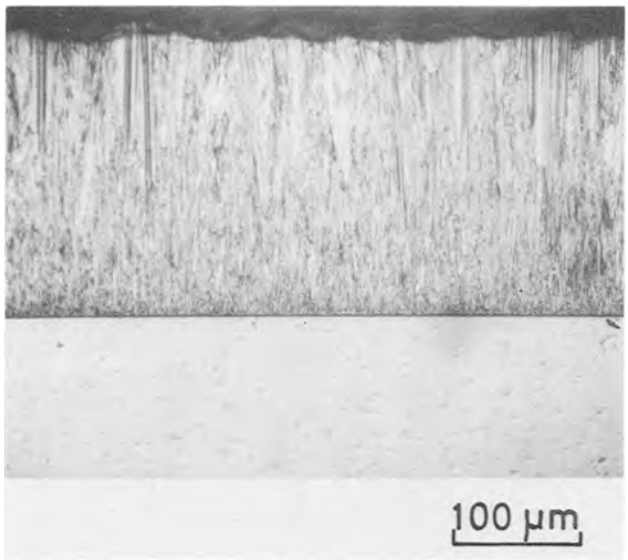

Fig. 1. Cross section of a thick polycrystalline-silicon layer grown on an oxide-covered single crystol substrate.

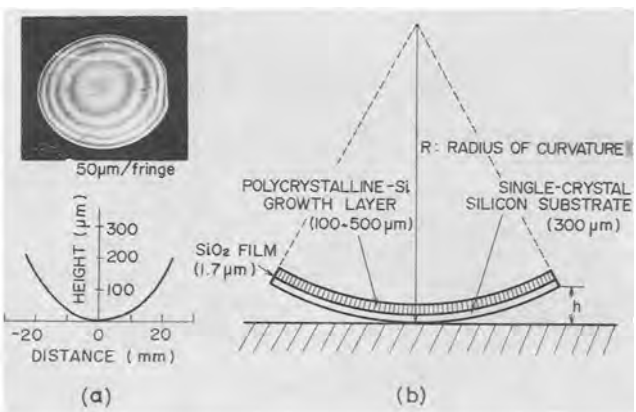

Fig. 2. Bowing of wafer with thick polycrystalline-silicon layer: (a) A typical interference pattern of the deformation; (b) Schematic illustration of the bowing.

the polycrystalline-silicon layer has a columnar grain structure. X-ray diffraction studies have shown that a <110> texture predominates.

Figure 2(a) shows a typical interference pattern of the deformation which was observed with a commercial flatness tester (Speedlap Check-Flat). The polycrystalline-silicon was deposited at 1200°C to a thickness of 400 μm. The polycrystalline-silicon layer side of a wafer is always concave, as is shown schematically is Fig. 2(b). In the following discussion, the degree of bowing will be expressed by the reciprocal of the radius of curvature R calculated from the deviation h from a flat plane 50 mm in length, assuming that the bowed wafer is one part of the surface of a sphere. The deviation h was measured with a surface measuring instrument (DEKTAK).

In an effort to identify the cause of wafer deformation, bowing was examined by measuring small changes in the length of the polycrystalline-silicon layer due to expansion or contraction at temperatures which ranged from 100° to 1260°C. The small changes in length at high temperatures were measured with a dilatometer (Rigaku Denki, Type 8003H) with a differential transformer. Measured samples of the polycrystalline-silicon layer were prepared by etching off both the single crystal silicon substrate and the silicon oxide film. They were cut to the size shown in Fig. 3. The amount of expansion or contraction perpendicular

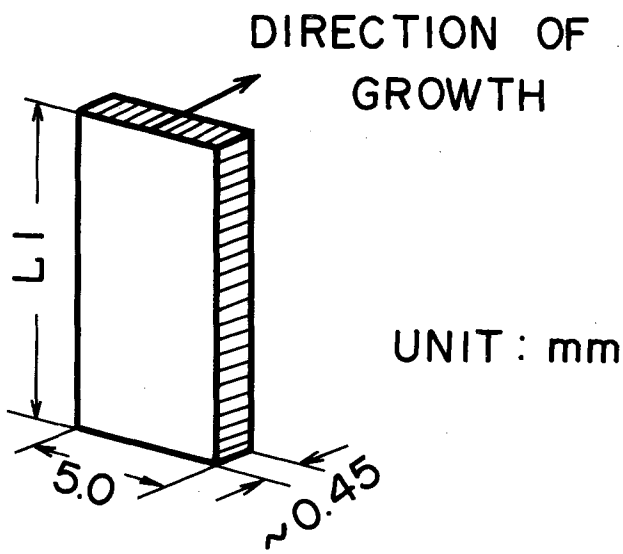

Fig. 3. Polycrystalline-silicon sample used for measuring the amount of expansion or contraction at high temperatures.

to the growth direction was measured. A high purity transparent quartz was used as a reference sample. The thermal expansion coefficient of the quartz is about one order of magnitude smaller than that of single crystal silicon. The load for holding the samples was less than 10 g/mm² which is much smaller than either the yield stress or nucleation stress of dislocation in single crystal silicon (4). The oxygen content of the high purity (99.999%) nitrogen or argon which was used as the ambient gas in these measurements was monitored, and was always less than 2.0 ppm.

Results and Discussion

Bowing of wafers with polycrystalline-silicon layers. —The incidence of degradation was not sporadic. Figure 4 shows the influence of the thickness of the polycrystalline-silicon layers on the bowing. The degree of bowing, $1/R$, increases monotonically with the thickness of the polycrystalline-silicon layers. The tendency of the monotonic increase in the degree of bowing $1/R$ cannot be explained by mismatches of the thermal expansion coefficients. Figure 5 shows the influence of growth temperature on the bowing. As the growth temperature decreases, the degree of bowing $1/R$ shows

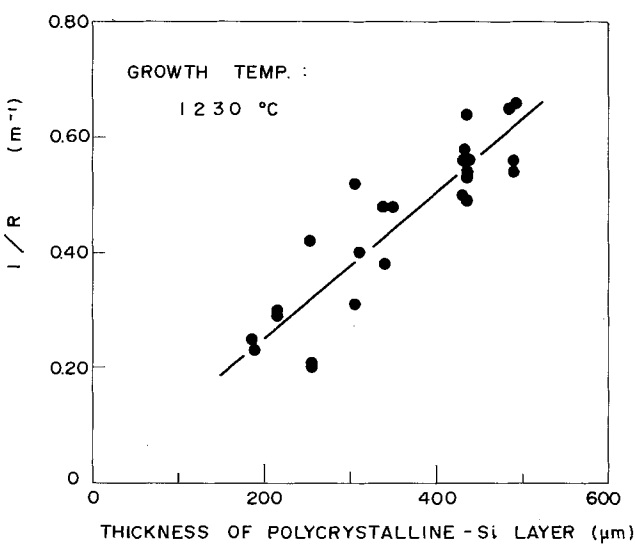

Fig. 4. Influence of thickness of polycrystalline-silicon layer on wafer curvature.

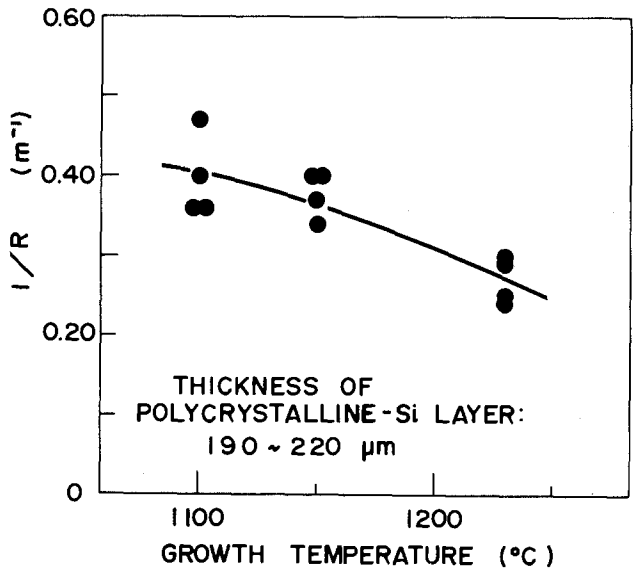

Fig. 5. Influence of growth temperature on wafer curvature.

a gradual increase. This tendency cannot be explained by mismatches of the thermal expansion coefficients either. In addition, it is found that the bowing of wafers with polycrystalline-silicon layers increased monotonically when the thickness of the single crystal silicon substrate is reduced by successive etching, and that the degree of bowing reached a maximum when all of the single crystal silicon substrate and the silicon oxide layer are removed and only a polycrystalline-silicon layer remains. The bowing seems to be caused by some internal stress arising from an intrinsic property of the polycrystalline-silicon layer itself.

It was observed after the growth of polycrystalline-silicon that the amount of silicon deposited on the periphery of the back surface of a wafer placed on the susceptor increases as the degree of bowing of the wafer increases. In addition, it was also observed during the growth of polycrystalline-silicon layers that the temperature near the outer edge of the wafer is lower than the temperature near the center of the wafer. These observations indicate that the edges of wafers are already lifting from the susceptor during the growth reaction. Occurrence of bowing during growth was also observed by Kamins (2). Thus, it seems that the layers contract by some internal stress during growth at high temperatures. To test this assumption, the amount of expansion and contraction of the layers perpendicular to the direction of growth at high temperatures was measured using a dilatometer.

Expansion and contraction at high temperatures.— Figure 6 shows a typical example of the measured results of the amount of expansion and contraction of a polycrystalline-silicon sample heat-treated in nitrogen and oxygen atmospheres. The time interval from 0 to 112 min corresponds to the rise in temperature from room temperature to 1200°C at a rate of about 10°C/min, and the time over 112 min corresponds to the heat-treatment process at the constant temperature of 1200°C. As can be seen from this figure, the polycrystalline-silicon sample expands with increases in temperature. However, the progress of the expansion slows and contraction begins to occur in the case of the nitrogen atmosphere when the temperature exceeds about 1000°C. When the temperature reaches 1200°C, contraction continues to proceed even when the temperature is held constant. Heat-treatments in an argon gas atmosphere have given the same results. In the case of the oxygen atmosphere, however, such contractions are not observed.

Figure 7 shows the linear thermal expansion coefficients of polycrystalline-silicon layers in the high temperature region between 100° and 1000°C obtained from expansion curves, such as those shown in Fig. 6, for samples in a nitrogen atmosphere. Although the two curves were both obtained from measurements of samples grown under identical conditions (growth temperature = 1230°C, growth rate = 6 μm/min), there were some differences between them. The measured data for single crystal silicon using the same method of measurement are also shown for comparison. The data for the single crystal silicon agree with the data reported by others (5-7) which were obtained by different methods. The expansion coefficient of the polycrystalline-silicon layer, which is perpendicular to the growth direction, is 2.3-4.2 $\times$ 10^{-6}°C^{-1} in the temperature range 100°-900°C. This is not so different from the values of 2.9-4.5 $\times$ 10^{-6}°C^{-1} for the single crystal silicon. Therefore, it is clear that the main cause of the bowing in wafers with polycrystalline-silicon layers is not the mismatch of the thermal expansion coefficients. It seems that the contraction occurring at temperatures higher than about 1000°C is closely related to the bowing. Therefore, contraction phenomena were examined in more detail.

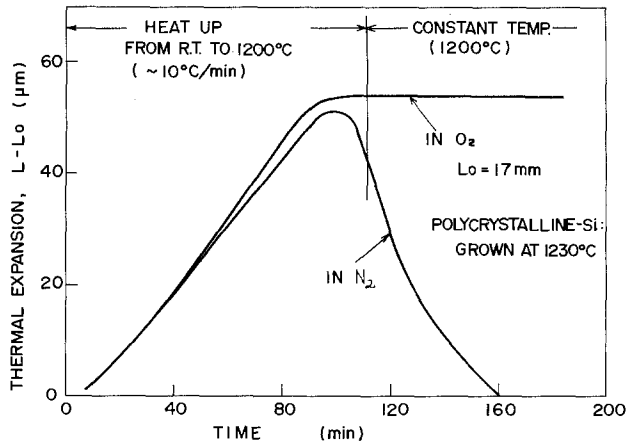

Fig. 6. An example of thermal expansion and contraction of polycrystalline-silicon layers at high temperatures.

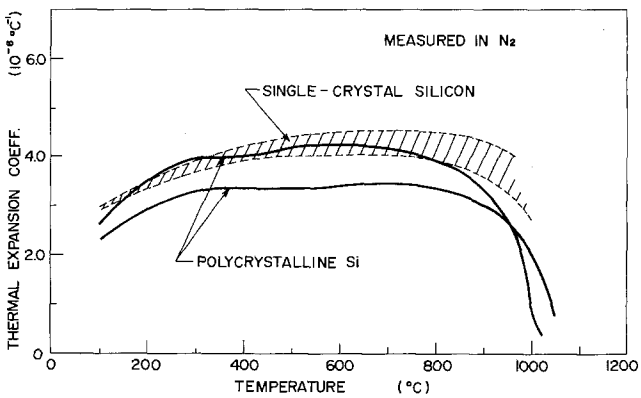

Fig. 7. Thermal expansion coefficient of polycrystalline-silicon layer and single crystal silicon at high temperatures.

Figure 8 shows the influence of the growth temperature of polycrystalline-silicon samples on contraction when heat-treated at 1200°C in an argon atmosphere. The heat-treatment starting point (t = 0) in this experiment was defined as the time when the temperature of the sample, rising at a rate of about 10°C/min, reached 1200°C. The amount of contraction of the sample ΔL was obtained by subtracting the length at each time L from the initial length L_i at t = 0. The contraction of the polycrystalline-silicon layers has a tendency to increase with decreases in growth temperature.

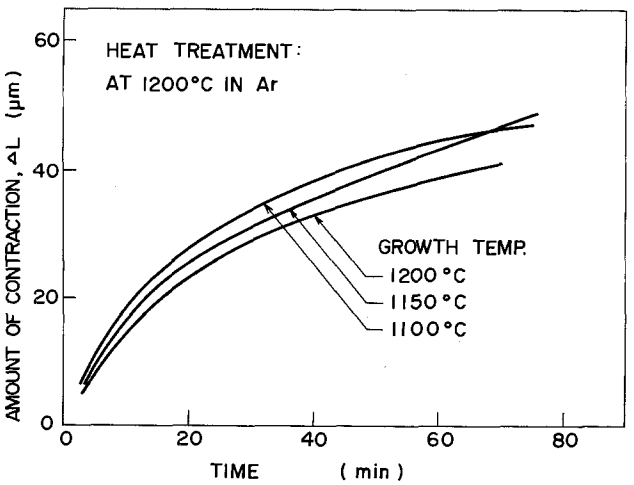

Fig. 8. Influence of growth temperature of polycrystalline-silicon layer on contraction.

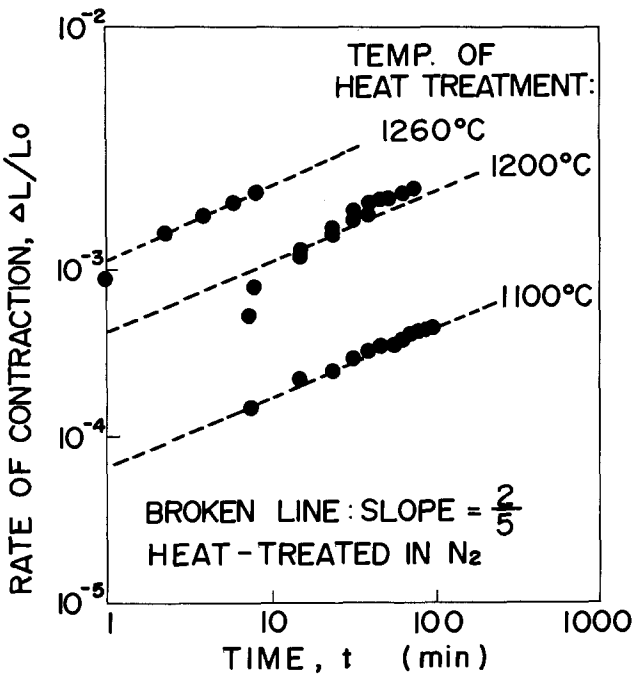

Fig. 9. Time dependence of the rate of contraction at various heat-treatment temperatures.

Figure 9 shows the time dependence of the rate of contraction at different heat-treatment temperatures. The polycrystalline-silicon samples were grown at 1200°C. The measured points fall approximately on the straight broken lines, with slope of 2/5, indicating that the relationship $L/L_0 \propto t^{2/5}$ holds. The rate of contraction increases as the heat-treatment temperature increases.

As described above, polycrystalline-silicon layers contract during heat-treatment in an inert gas atmosphere in a direction perpendicular to the growth direction. This seems to be a phenomenon similar to the sintering process which occurs in metals and ceramics. The rate of sintering is closely related to the mechanism of material transport at grain boundaries. Several types of models and theories of material transport have been reported. Kingery (8) interpreted the contraction during sintering as the decrease of distance between the centers of two neighbor grains in contact. According to his model, substantial material transport into the contact region of the grains occurs and the grains approach one another, because the grain boundary acts as a sink for vacancy diffusion. The rate of decrease in center-center distance l of grains with radius r is expressed as follows

$$\frac{\Delta l}{l} = \left[\frac{20\gamma a^3 D_v}{\sqrt{2}\, r^3 kT}\right]^{2/5} \cdot t^{2/5} \qquad [1]$$

where γ is the surface tension at the contact point, a is the interatomic distance, r is the initial radius of a grain, k is the Boltzmann constant, T is the sintering temperature, t is the sintering time, and D_v is the self-diffusion coefficient. The self-diffusion coefficient D_v is given as

$$D_v = D_0 \exp(-E/kT) \qquad [2]$$

where E is the activation energy.

The relation $\Delta L/L_0 \propto t^{2/5}$ was also observed to hold in the contraction phenomena observed in this experiment, as shown in Fig. 9. Therefore, the contraction of the polycrystalline-silicon layers observed in the heat-treatments in this experiment seems to be induced by a mechanism similar to the sintering considered by Kingery. If the temperature dependence of γ and a is ignored and t is assumed constant, Eq. [1] gives the relation

$$D_v \propto T \cdot \left(\frac{\Delta l}{l}\right)^{5/2}_{t=\text{const}} \qquad [3]$$

Figure 10 indicates a plot of $T(\Delta L/L_0)^{5/2}_{t=\text{const}}$ at $t = 1$ min *vs.* $1/T$. From the slope of this straight line, the activation energy $E = 190$ kcal/mole $= 8.2$ eV is obtained. This value is quite large compared to the activation energy of self-diffusion of Si ($= 112$ kcal/mole $= 4.9$ eV), which was obtained in single crystal silicon (9). Therefore, the mechanism of material transport in the case of the contraction of polycrystalline-silicon is not so simple as to be elucidated only by vacancy diffusion. It is probable that small amounts of impurities in polycrystalline-silicon affect the material transport. For example, as seen in Fig. 6, the presence of oxygen prevents the contraction of polycrystalline-silicon.

On the cause of bowing.—From the experimental results described above, the cause of the bowing of

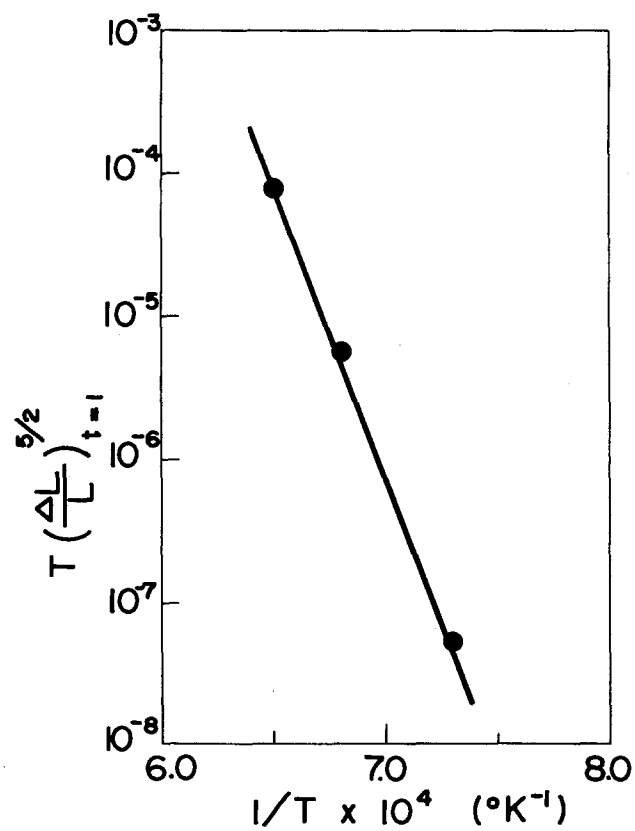

Fig. 10. $T(\Delta L/L_0)^{5/2}_{t=\text{const}}$ at $t = 1$ min *vs.* $1/T$

wafers with a polycrystalline-silicon layer can be considered as follows. The internal stress which causes the bowing of the wafer consists of two terms (10): one of these is a thermal stress due to the difference in the thermal expansion of the layer and the substrate, and the other is an intrinsic stress due to the manner of the growth of the layer. However, it is clear from Fig. 7 that thermal stress is not the dominant cause of bowing, since the expansion coefficient of the polycrystalline-silicon layer is scarcely different from the expansion coefficient of the single crystal silicon substrate. It was observed that the bowing was generated during the growth reaction of the polycrystalline-silicon layer rather than during the cooling process.

The experimental data showed that the polycrystalline-silicon layers contract at temperatures higher than about 1000°C. Therefore, at the high temperatures obtained during the growth reaction, it is believed that the polycrystalline-silicon layer already buried behind the advancing surface of the growing layer is contracting. This contraction may be induced by a mechanism similar to the sintering proposed by Kingery (8). That is, as a result of material transport at the grain boundaries of polycrystalline-silicon, tensile stress, which is thought to be a kind of so-called growth stress (10), is generated within the layer. Since the grain structure of the layers deposited by chemical vapor growth is columnar, such an internal stress is most probably large in a direction perpendicular to the growth direction. The polycrystalline-silicon layer side of the growing wafer is thought to be bowed concavely by this tensile stress during the high temperature growth reaction. Therefore, it would appear that the degree of bowing increases as the growth layer becomes thicker or the growth time longer.

The tendency that the bowing decreases with increasing growth temperature of the polycrystalline-silicon (Fig. 8) can be understood from the following explanation. When the growth temperature increases, the crystal structure of the polycrystalline-silicon layer buried behind the advancing surface of the growing layer becomes more perfect and the grains become larger. This results in a significant reduction in the rate of contraction during growth.

Summary

The degree of bowing of wafers with a thick polycrystalline-silicon layer increases monotonically with the thickness of the polycrystalline-silicon layers and with decreases in growth temperature. This bowing is generated during the growth of the polycrystalline-silicon layer rather than during the cooling process. The amount of expansion and contraction of the layers perpendicular to the direction of growth at high temperatures was measured. It was found that the expansion coefficient of the polycrystalline-silicon layer in the temperature range 100°-900°C is 2.3-4.2 $\times$ 10^{-6} $°C^{-1}$, which is scarcely different from the values for single crystal silicon. It was observed that the polycrystalline-silicon layers contract in a direction perpendicular to the direction of growth at temperatures higher than about 1000°C. From these experimental results, it is concluded that the bowing of wafers is caused by the tensile stress generated by the contraction of the polycrystalline-silicon layer already buried behind the advancing surface of the growing layer, rather than by the thermal stress generated by the difference in the thermal expansion coefficients of the growth layer and the substrate.

ABSTRACT

Low temperature photoluminescence and Auger electron spectroscopy have been used to study chemical-vapor deposited SiO_2 and Si_3N_4 layers as encapsulants for high temperature annealing of GaAs. Silicon dioxide or silicon oxynitride layers allow out-diffusion of Ga, while suitably prepared rf plasma deposited Si_3N_4 layers can be used to anneal GaAs with negligible Ga out-diffusion.

Ion implantation is a versatile method of doping semiconductors and is an established fabrication step for many silicon devices (1). Although the use of implantation in the III-V compounds is less widespread, important device applications have emerged. These include the fabrication of light emitting diodes (2), GaAs field-effect transistors, optical waveguides, and detectors (3). Because of the difficulties of selectively doping GaAs or other compound semiconductors by standard diffusion processes as compared with Si, it now appears that implantation will play an increasing role in future device applications of compound semiconductors.

In view of the potential for this doping method, it is important to develop reliable procedures for implantation and annealing in these materials. Ion implantation produces considerable lattice damage which must be annealed out in order to restructure the lattice and activate the implanted impurities. While this procedure is relatively straightforward in Si, annealing a compound semiconductor such as GaAs is more difficult. The incongruent evaporation of Ga and As from GaAs at temperatures in excess of 600°C (4) makes it impossible to anneal bare GaAs samples without surface degradation. It is thus necessary to encapsulate the sample with a suitable dielectric layer or to perform the anneal in a carefully controlled ambient (5, 6). There have been numerous discussions of implantation and annealing in GaAs using encapsulants such as sputtered or chemical-vapor deposited SiO_2 (7), thermally or reactively deposited or sputtered Si_3N_4 (8-10), or sputtered AlN (11). In the present work we have used low temperature photoluminescence (PL) and Auger electron spectroscopy (AES) to investigate the annealing-encapsulation properties of chemical vapor deposited SiO_2 and rf plasma deposited Si_3N_4 layers on GaAs.

It is well known from diffusion experiments in Si that Ga has a very high diffusion coefficient in SiO_2 (12). Gyulai *et al.* (13) have used proton backscattering spectrometry to show that SiO_2 layers on GaAs permit out-diffusion of Ga. Previous low temperature photoluminescence studies have demonstrated the growth of emission bands from GaAs annealed under various conditions. A broad band with a peak near 1.356 eV has been correlated with the outdiffusion of Ga (14). There is other evidence to suggest that this band is related to the incorporation of Cu on Ga sites (15, 16) as Ga atoms are lost due to out-diffusion. In either case, this band can be directly or indirectly attributed to Ga loss. In this work the 1.356 eV photoluminescence band is monitored after annealing with three types of encapsulation, and the encapsulant films are examined for Ga outdiffusion using AES. The three encapsulants studied are silicon dioxide, silicon nitride, and oxygen-contaminated silicon nitride.

Experimental Procedures

The SiO_2 layers used in this study were deposited by thermal oxidation of silane, with the sample maintained at ~450°C (17). All Si_3N_4 layers were prepared by rf plasma deposition from reaction of silane with nitrogen, with samples maintained at ~450°C. Those nitrides labeled A were deposited in a system where silane and nitrogen were mixed prior to initiation of the rf plasma. Those labeled B were prepared by first initiating a nitrogen plasma and then introducing the silane. For type B, the silane is introduced separately from the plasma region, over the surface of the sample. All the anneals were performed in an open tube furnace with a silica liner, in the presence of flowing forming gas (N_2 with 4% H_2).

The photoluminescence samples were pressed into indium-wetted copper heat sinks (18) after removing the encapsulating layer. The sample/heat sink assembly was held at 5°K in a Janis Super-Varitemp gas exchange cryostat. Photoluminescence was excited by the 5145Å line from an Ar-Kr laser. Spectra were recorded using a 0.5m scanning spectrometer and a cooled (77°K) photomultiplier with S-1 response.

Auger electron spectra (AES) and depth profiles were obtained using either a conventional Physical Electronics Industries Model 545 scanning Auger microprobe (SAM) or a custom-built thin film analyzer (TFA) (19). Incident electron beam energies were 6 keV (SAM) or 5 keV (TFA) with typical beam currents of 5 and 70 μA, respectively. In both systems ion sputtering was performed with 2 keV Ar^+ using either stationary beams from two ion guns in lateral opposition (SAM) or an electrically rastered beam from one ion gun (TFA). Both systems were optimized for maximum depth resolution. Comparative studies on the two instruments gave statistically insignificant differences, and they are therefore considered essentially equivalent. Some of the analysis techniques used in this study have been described in detail elsewhere (19). First, an Auger spectrum of the sample surface

is taken prior to sputtering. A second complete spectrum is recorded after an "ion dusting," removing ~20Å, for comparison with the unsputtered surface. Finally, conventional multiplexer depth profiling is performed for the specific elements of interest.

To avoid charging of the dielectric layers during analysis, samples were mounted at grazing incidence to the electron beam (30°). However, in some cases severe charging was observed and no useful analytical information could be obtained. Subsequent examination of such encapsulants by scanning electron microscopy showed a high degree of surface roughness. Data presented here are from samples which did not exhibit charging phenomena.

Results and Discussion

Figure 1 shows the 5°K photoluminescence spectra obtained from GaAs samples annealed at 900°C with various encapsulants. Figures 2-4 illustrate the Auger depth profiles for these encapsulants after the heat-treatment.

Figure 1(a) illustrates that when a sample is annealed with SiO_2 encapsulation, a broad luminescence band is observed with a peak at 1.356 eV. This defect band is related to Ga out-diffusion, as discussed above. Although the SiO_2 films used in this work are considerably better than those studied previously (14), Ga out-diffusion is still evident as shown in Fig. 1(a). This observation is substantiated by the AES depth profile of the oxide on a similarly treated sample (Fig. 2). A detectable Ga signal is observed in the surface Auger spectrum (see inset). Since the sample was encapsulated on all sides during the anneal, the presence of Ga at the surface clearly indicates diffusion of Ga from the substrate through the SiO_2 layer. However, no Ga was detected within the SiO_2 layer itself. Presumably, this is due to a solid solubility of

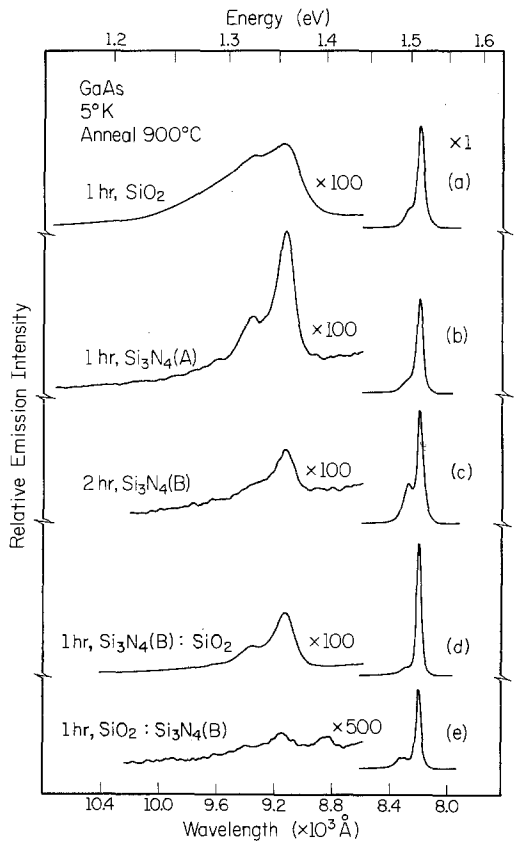

Fig. 1. Photoluminescence spectra from GaAs samples annealed with various encapsulants. The scale factors are indicated relative to the 1.52 eV band-edge peak for each sample.

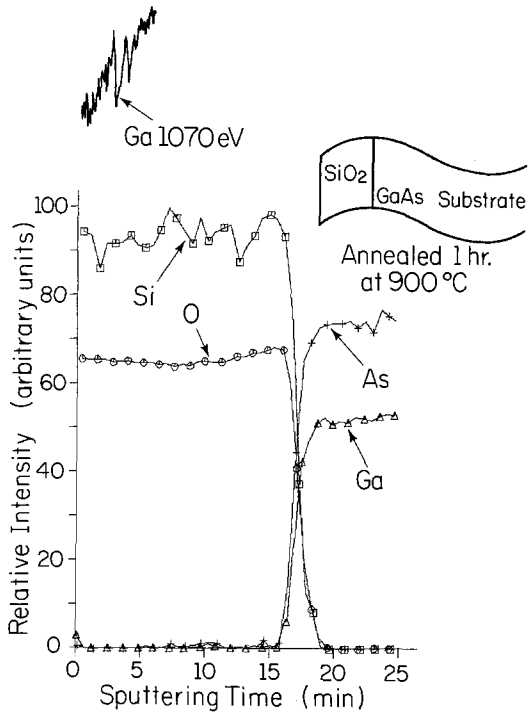

Fig. 2. Auger depth profile obtained from a GaAs sample encapsulated with SiO_2 and annealed at 900°C for 1 hr. The inset illustrates the Ga Auger spectrum observed at the SiO_2 surface prior to sputtering.

Ga in SiO_2 below the Auger detection limit [~0.5 atomic percent (a/o)].

The PL spectrum from a sample annealed with Si_3N_4(A) is presented in Fig. 1(b). This spectrum also clearly indicates Ga loss from the GaAs. The lower energy peaks associated with the 1.356 eV band in Fig. 1 are phonon replicas of the main zero-phonon peak. These peaks are separated by ~36 meV, the LO phonon energy in GaAs (20). Figure 3(a) shows an AES depth profile for a similar sample annealed with Si_3N_4(A) encapsulation. A relatively strong Ga signal is observed at the Si_3N_4 surface and a uniform Ga level is seen throughout the encapsulant. As discussed earlier, Si_3N_4(A) was prepared by premixing silane and nitrogen prior to the formation of the plasma. The AES data also shows the presence of a uniformly high level of oxygen within the film. Both PL and AES data clearly show the out-diffusion of Ga through such nitride layers.

Figure 1(c) displays the PL spectrum obtained from a sample with Si_3N_4(B) encapsulation, annealed at 900°C for 2 hr. A weak 1.356 eV band is seen. In a sample annealed with such an encapsulant for 1 hr, the intensity of the 1.356 eV band was very weak. The absence of a strong defect PL band even after the 2 hr anneal suggests that Si_3N_4(B) effectively suppresses Ga out-diffusion. In AES studies, no Ga signal could be detected either in the surface spectrum or in the depth profile of this nitride (Fig. 3b). It is also interesting to note that the oxygen level in Si_3N_4(B) was low, barely above the detection limit of ~0.1 a/o. This is at least an order of magnitude lower than the oxygen level observed in Si_3N_4(A).

Anneal studies were also carried out using a multilayered dielectric sandwich as the encapsulant. Figure 1(d) shows the PL spectrum obtained when a Si_3N_4(B)/SiO_2 dielectric layer (with SiO_2 in contact with the GaAs) was used as the encapsulant. The 1.356 eV band is observed, although the intensity of this band is weaker than in spectrum 1(a). The AES data (Fig. 4b) failed to show any Ga either at the

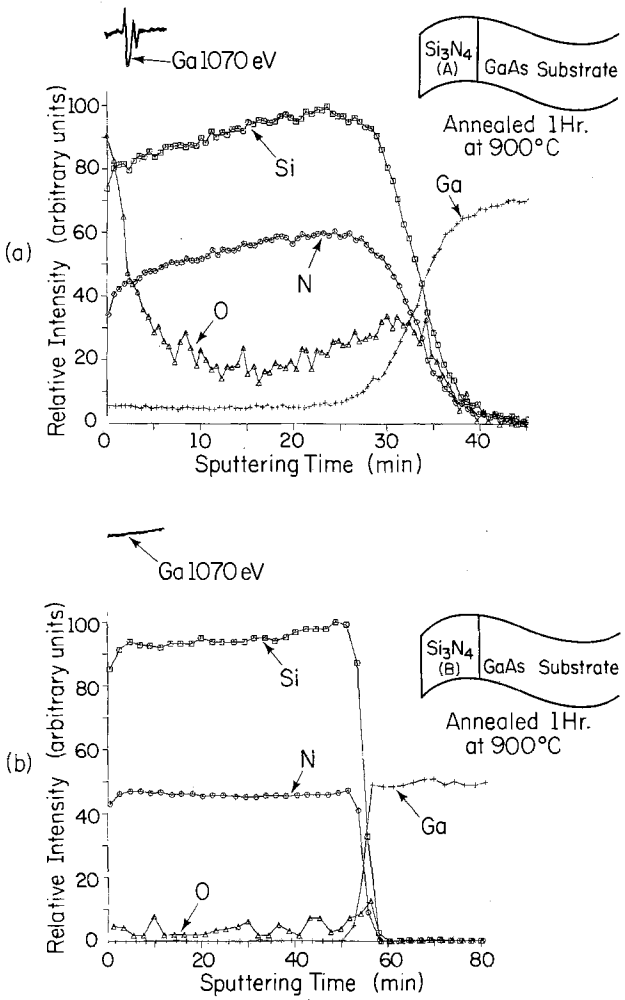

Fig. 3. Auger depth profiles obtained from GaAs samples encapsulated with (a) Si_3N_4(A), and (b) Si_3N_4(B) layers and annealed at 900° for 1 hr. The insets illustrate the Ga Auger spectra at the Si_3N_4 surfaces prior to sputtering.

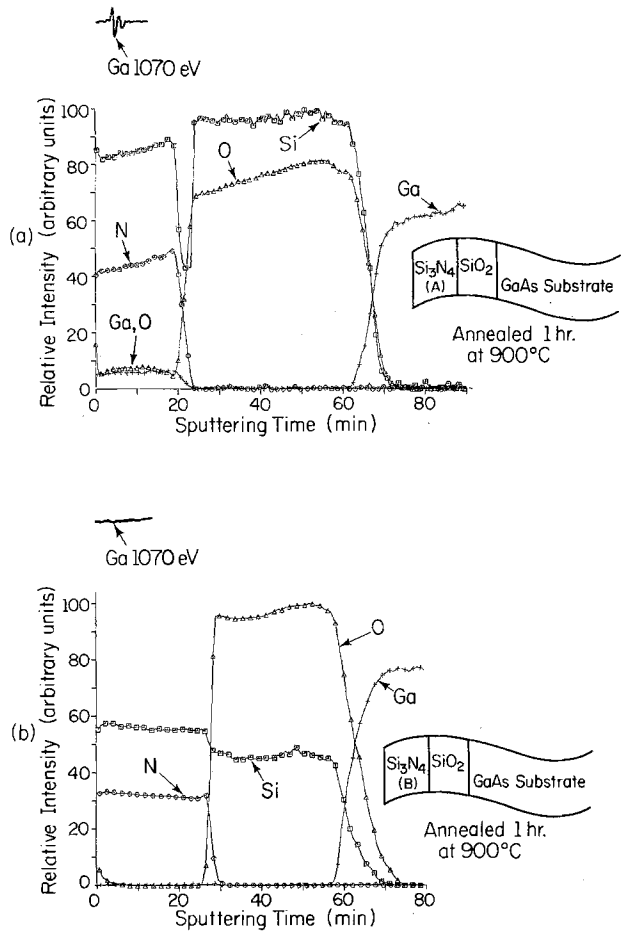

Fig. 4. Auger depth profiles obtained from GaAs samples encapsulated with (a) Si_3N_4(A)/SiO_2, and (b) Si_3N_4(B)/SiO_2 layered dielectrics and annealed at 900°C for 1 hr. The insets illustrate the Ga Auger spectra at the Si_3N_4 surfaces prior to sputtering.

surface or within the dielectric layer. However, when the anneal was repeated with a Si_3N_4(A)/SiO_2 layered encapsulant, AES depth profiles clearly showed the presence of Ga both at the surface and within the nitride layer (Fig. 4a). GaAs samples encapsulated with SiO_2/Si_3N_4(B) were also annealed. As expected, PL (Fig. 1e) and AES data indicated negligible out-diffusion of gallium from the substrate. No Ga pile-up was observed at the oxide-nitride interfaces in any of the cases studied.

These PL and AES studies show that Ga is lost when SiO_2 is used as an encapsulant. Moreover, out-diffusion of Ga is observed when Si_3N_4 layers contain a high oxygen level. We have concluded that oxygen contamination of the nitride film is responsible for the pronounced Ga out-diffusion. The oxygen impurity is distributed throughout the type A nitride layer and is apparently introduced by reaction of silane with the residual oxygen or water vapor in the system. In deposition procedure B, much of the residual oxygen and water vapor reacts with the nitrogen to form oxides of nitrogen and is therefore unavailable for reaction with the silane when it is introduced. The affinity of silane for oxygen is orders of magnitude higher than its affinity for nitrogen. It is thus very unlikely that the oxygen observed in Si_3N_4(A) is free oxygen. The Si_3N_4(A) film is best described as silicon oxynitride. This description is consistent with the fact that the refractive index measured for type A films is ~1.85, which lies between the refractive index of SiO_2 (1.46) and that of the Si_3N_4(B) films (2.18). Differences were also observed in the etch rates of the two types of films. Nitride A etches at a rate of ~3000Å/min in 48% HF, compared with $\lesssim$ 200Å/min for Si_3N_4(B).

Conclusion

In conclusion, it has been shown from low temperature photoluminescence and AES studies that:

1. SiO_2 encapsulant on GaAs permits Ga loss during annealing at 900°C.
2. Attempts to deposit Si_3N_4 layers by premixing silane and nitrogen result in silicon oxynitride films which also permit Ga out-diffusion during annealing.
3. Si_3N_4 layers prepared by introducing silane separately from the nitrogen plasma region allow negligible Ga out-diffusion. Such films can be successfully used to encapsulate GaAs for postimplant annealing.

Influence of Temperature on Anodically Grown Native Oxides on Gallium Arsenide

T. Ishii*,[1] and B. Jeppsson

Microwave Institute Foundation, S-10044 Stockholm 70, Sweden

ABSTRACT

A native oxide film is grown on GaAs by anodically oxidizing GaAs in a mixed solution consisting of aqueous tartaric acid and ethylene glycol. A homogeneous oxide film up to 8000Å thick is obtained with a linear thickness-voltage dependence of 19.5 Å/V. The as-grown oxide is highly transparent in the near infrared and the visible light regions. The refractive index is almost constant in the near infrared region, and it weakly depends on the wavelength in the visible light region changing from 1.7 to 1.9. In the u.v. region, the oxide becomes less transparent and is completely opaque for wavelengths shorter than 0.22 μm. The oxide is very stable and almost no detectable changes regarding oxide properties, structure, and composition occur below 350°C. However, the oxide begins to decompose above 350°C first by releasing water. The oxide decomposition most rapidly proceeds around 450°C mainly by vaporizing water and arsenic oxide. It continues up to 700°C, resulting in a pure gallium oxide. The refractive index of the decomposed oxide is fairly constant around 1.5 over the wide wavelength region from visible light to near infrared. The decomposed oxide is believed to be β-Ga_2O_3. By heat-treatment above 650°C, the surface of GaAs becomes rough and a new layer is formed at the oxide-GaAs interface. This interface layer is completely arsenic depleted and has a Ga:O ratio of 2:1. The highest temperature to which the anodically oxidized GaAs can be heat-treated is approximately 650°C. As a means for increasing this temperature limit, a double oxide structure consisting of the anodic oxide film and a SiO_2 film is investigated. By coating GaAs with double oxide films consisting of a 500Å thick anodic oxide film and a 2000Å thick SiO_2 film, GaAs can be heat-treated at 800°C for 2 hr without degradation of the GaAs surface.

With the rapid progress of material and process technology, GaAs is now supplementing Si in the electronic field and is extensively used in microwave, optical, and various functional devices. For many applications, a good native oxide on the semiconductor surface is indispensable, and consequently SiO_2 on Si is the major factor behind the success of Si as an electronic material. For the same reason, a good native oxide on GaAs has long been required.

To obtain a native GaAs oxide, several methods have been suggested such as thermal oxidation (1-4), plasma oxidation (5, 6), galvanic oxidation (7, 8), and anodic oxidation (9-22). As GaAs begins to vaporize the volatile component at rather low temperatures, the anodic oxidation is an interesting low temperature process to obtain the native oxide without dissociating the GaAs.

Key words: anodic oxidation, spectrophotometry, He backscattering, mass spectrometry.

One of the disadvantages of the anodic oxidation has been the difficulty to grow a thick oxide film. Hasegawa *et al.*, however, succeeded in growing a thick oxide film by anodically oxidizing GaAs in a suitable mixture of a weak carboxylic acid, water, and a polyhydric alcohol (17-19), thereby making this technique of great interest for several applications. This anodic oxidation process is also very interesting because it is highly stable and reproducible.

Several interesting applications of the anodically grown native GaAs oxide have been suggested. The oxide has been used in MOS devices and in several low temperature processes for material and device fabrication (12, 15, 16, 18-21). Although the use of the oxide in high temperature processes has been suggested (14) and some properties of the oxide have been studied (9, 13, 22), the influence of temperature on the structure and the properties of the oxide are at present not fully understood. Detailed knowledge of the temperature characteristics of the oxide is required both when the oxide is used in a process involving elevated temperatures, and when the oxide is an integral part of a device operated at elevated temperatures.

In this paper, we describe the temperature characteristics of the anodically grown native GaAs oxide heat-treated in a N_2 atmosphere up to 800°C. The thickness and the optical properties of the oxide are evaluated using a spectrophotometer. By analyzing the oxide structure using He backscattering techniques, He-induced x-rays, and mass spectrometry, a model for the decomposition of the oxide occurring during heat-treatment is proposed. Because of the sublimation of arsenic from the GaAs surface, heat-treatment of a naked or an anodically oxidized GaAs has so far been limited to below 650°C. Means of increasing this temperature limit to 800°C are investigated.

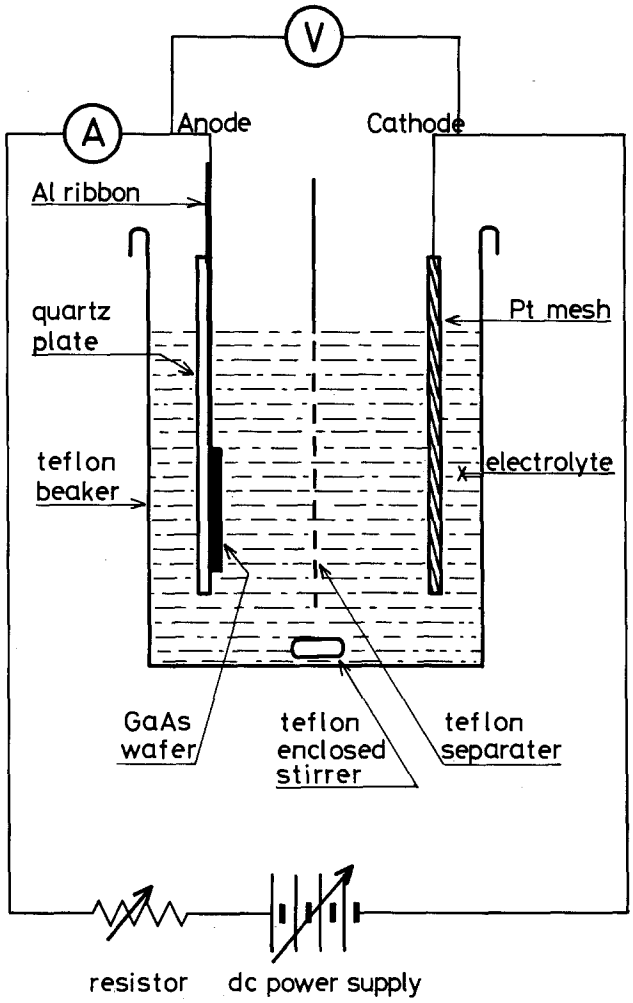
Anodic Oxidation of GaAs and Characteristics of As-Grown Native GaAs Oxide

Anodic oxidation of GaAs.—Figure 1 shows the experimental setup for the anodic oxidation. A Teflon beaker and a platinum cathode were used. A Teflon separator was inserted between the anode (GaAs specimen) and the cathode. The electrolyte was magnetically stirred during the anodic oxidation.

n-type GaAs wafers of (100) orientation and tin doped with a net donor concentration of (7-10) $\times$ 10^{17} cm^{-3} were used for the experiments. The wafers were thoroughly degreased in trichloroethylene and acetone. An aluminum ribbon was contacted to the back surface of the wafer, which then was fixed on a quartz plate with wax such that the polished surface was exposed to the electrolyte, paying attention not to make any shunt path. Samples were etched chemically in a mixed solution of 3 H_2SO_4:1 H_2O_2:1 H_2O to remove a 20-30 μm thick surface layer. Samples were then dipped in HCl to remove the natural uncontrolled oxide on the surface and were rinsed thoroughly in water prior to anodic oxidation.

GaAs was anodically oxidized in an electrolyte consisting of water, tartaric acid, and ethylene glycol (17-19). The electrolyte consisted of one part of the aqueous solution of tartaric acid and two parts of ethylene glycol. The *p*H adjustment of the electrolyte by a weak base, which is a commonly used technique, was avoided so as not to contaminate the electrolyte. The logarithmic concentration of tartaric acid and the logarithmic resistivity of the electrolyte were linearly proportional to the *p*H value of the electrolyte as shown in Fig. 2(a) and (b), respectively. The aqueous solution of ethylene glycol without tartaric acid showed a *p*H value of 5.45 and a resistivity of 1.78 $\times$ 10^4 Ω-cm.

The anodic oxidation was performed using a constant current method. By controlling the output of a d-c power supply and the resistance of a variable resistor, the bias current was kept constant during the anodic oxidation. The applied voltage was measured between the anode and the cathode. It increased with the growth of the oxide, and the current bias was terminated immediately upon reaching a predetermined voltage. A constant voltage method was avoided because inhomogeneity in the current density and thereby locally high current density on the wafer caused local breakdown in the grown oxide in the very early stage of the anodic oxidation. Current density was determined by dividing the bias current by the exposed sample area.



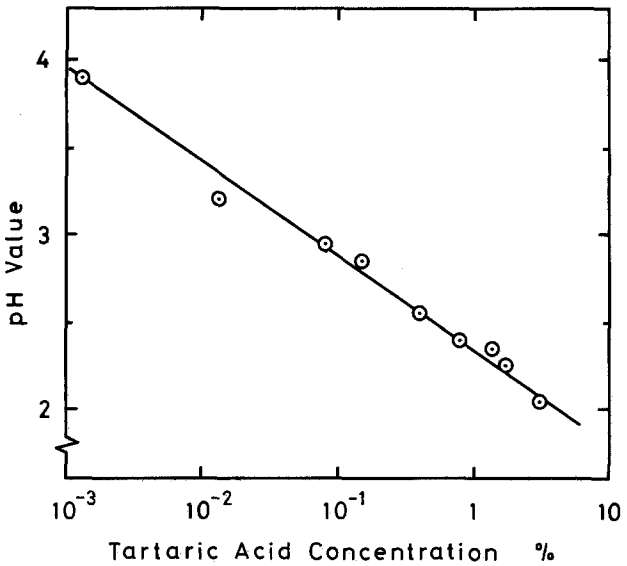


Fig. 1. Experimental setup for anodic oxidation. The anodic oxidation was performed using a constant current method by controlling the output of the d-c power supply and the resistance of the variable resistor. The current bias was terminated immediately upon reaching a predetermined voltage.

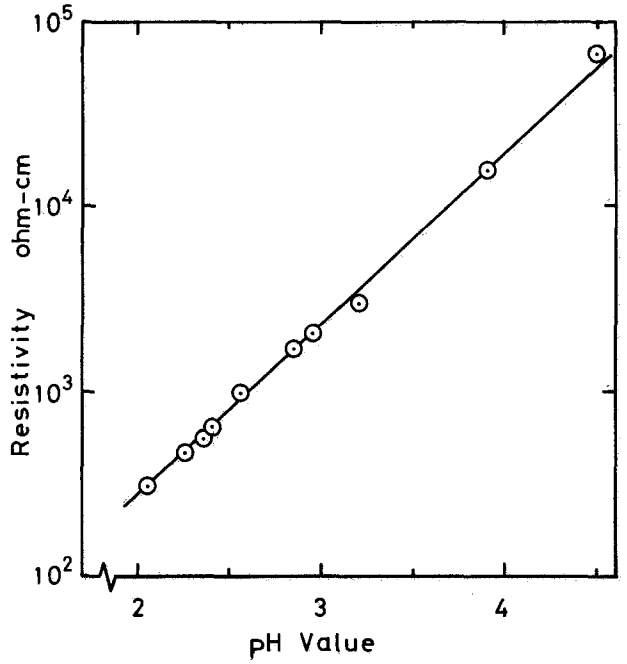
Thickness of the oxide was linearly related to the applied voltage as described later. Figure 3(a) shows the relation between the thickness-voltage constant and the concentration of the tartaric acid. The thickness-voltage constant becomes saturated for tartaric acid concentrations above 0.01%. The thickness-voltage constant is also shown as a function of the current density in Fig. 3(b). Except at very low or high current densities, it is almost constant as a function of current density in the range from 0.75 to 3.0 mA/cm^2. The fact that the thickness-voltage constant is almost independent of the composition of the electrolyte and the current density means that excellent stability and reproducibility can be achieved in this process. The change of the current density due to error in measuring the sample area, and the change of the electrolyte composition due to continuous use do not, therefore, seriously affect the thickness of the grown oxide films.

The anodic oxidation became unstable above 150V, accompanied by frequent current spikes when the tartaric acid concentration was more than 3% and/or the current density was higher than 10 mA/cm^2. This



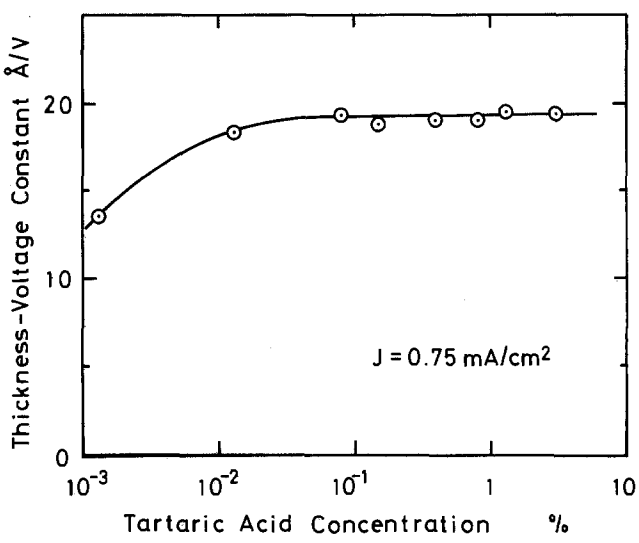


Fig. 2. Plots of logarithmic tartaric acid concentration vs. pH value (a) and logarithmic resistivity vs. pH value (b) of the electrolyte for anodic oxidation. The electrolyte consisted of one part of an aqueous solution of tartaric acid and two parts of ethylene glycol.

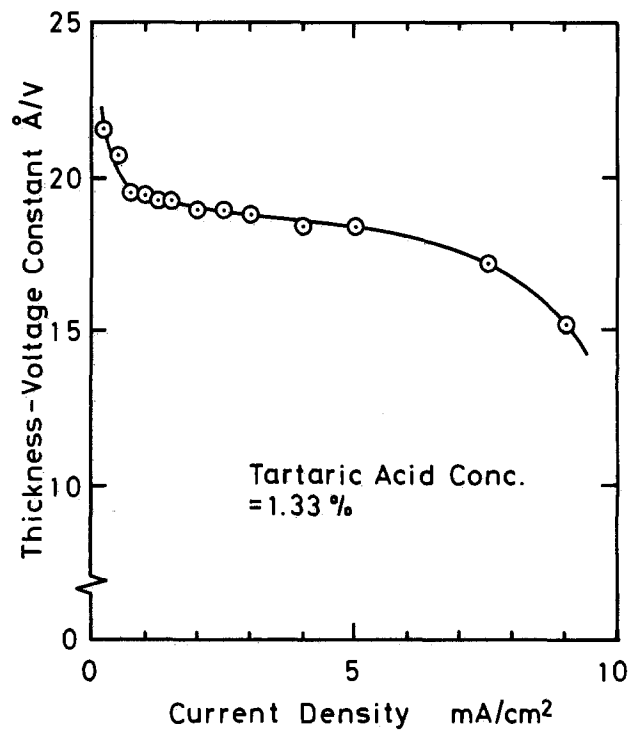

Fig. 3. Thickness-voltage constant as a function of the tartaric acid concentration in the electrolyte (a) and the current density for the anodic oxidation (b).

instability was due to the local breakdown in the grown oxide, which was found to be very similar to the crystal defects in the GaAs in our other experiments.

Figure 4 shows the relation between the applied voltage and the thickness of the grown oxide films. The thickness increased linearly with the applied voltage as already mentioned in other papers (11-13, 17, 21), and the thickness-voltage constant, corrected for by the voltage drop in the bath, was 19.5 Å/V. Anodic oxidation at as high as 380V was possible, and an 8000Å thick oxide film could be obtained when high quality GaAs was used. The homogeneity of the 8000Å thick oxide film was excellent judging from the interference color.

Above 380V the oxides broke down electrically and the anodic oxidation became seriously unstable. At the breakdown points, a salt was formed, which could be removed easily by a strong acid or base leaving, however, deep pits on the GaAs surface.

Optical properties of the as-grown native GaAs oxide.—Optical index and thickness of the anodically grown native GaAs oxides were mainly determined by an optical method using a spectrophotometer. A Perkin-Elmer Spectrophotometer Model 350 covering the wavelength region from 0.195 to 2.7 μm was used. The absolute reflectivity of the virgin surface of GaAs (R_{GaAs}) was measured in the wavelength region from 0.195 to 2.7 μm. The refractive index of the GaAs (n_{GaAs}) was calculated from the reflectivity using the equation

$$n_{GaAs} = \left(\frac{1+\sqrt{R_{GaAs}}}{1-\sqrt{R_{GaAs}}}\right) \quad [1]$$

The output of the spectrophotometer was adjusted such that the reflectivity of the GaAs was kept constant at 100% over the whole wavelength region. Thus, the interference by the light reflected from the oxide surface and the light reflected from the oxide-GaAs interface occurred between 0 and 100%. The refractive index of the oxide (n_{ox}) could be determined from the mini-

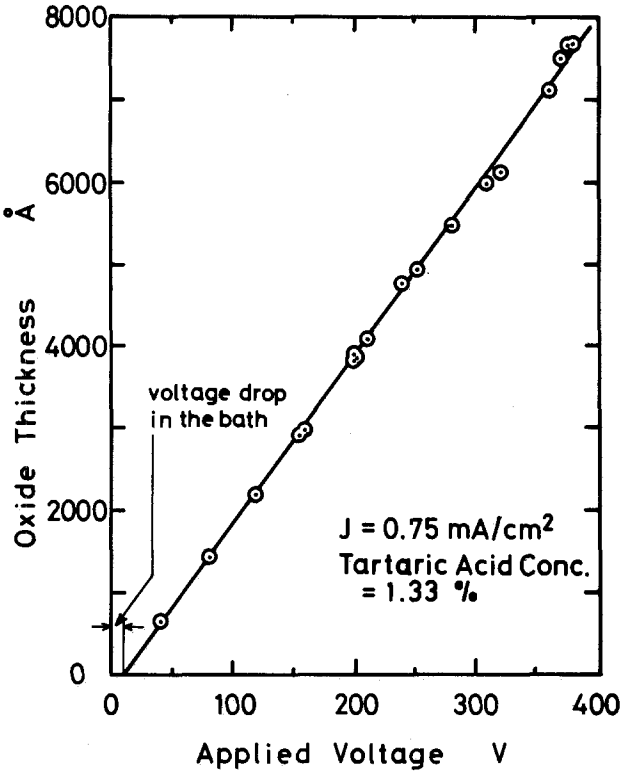

Fig. 4. Oxide thickness as a function of the applied voltage. The anodic oxidation was performed in the electrolyte having 1.33% tartaric acid concentration at the constant current density of 0.75 mA/cm². The voltage drop in the bath was 5V.

mum reflection ratio (R_{min}) for the wavelength where the interference minimum occurred using the equation

$$n_{ox} = \sqrt{n_{GaAs}} \cdot \sqrt{\frac{1 - \sqrt{R_{GaAs} \cdot R_{min}}}{1 + \sqrt{R_{GaAs} \cdot R_{min}}}} \qquad [2]$$

As long as the absorption of the oxide film can be neglected, Eq. [1] and [2] are very accurate. The thickness of the oxide film (d_{ox}) is given by the equation

$$d_{ox} = \frac{1}{2} \cdot \frac{1}{n_{ox}} \cdot \left(N + \frac{1}{2}\right) \lambda \qquad [3]$$

where λ is the wavelength of the interference minimum and N is the order of the interference.

The oxide thickness was also measured by a mechanical method using a Perthometer Type C3A to control the accuracy of the optical method when the optical index changed by heat-treatment of the oxide film. Since a good agreement with an accuracy of about ± 30Å was obtained, only the optical method is discussed in this paper.

Figure 5 shows the typical interference spectrum obtained from a 3000Å thick oxide film on GaAs. The interference maxima occurred at 100% for wavelengths longer than 0.3 μm, because the light reflected from the GaAs surface was transmitted through the oxide film without loss. As the oxides were highly transparent in this wavelength region, the refractive index is determined from Eq. [1] and [2] with high accuracy. The oxide became increasingly less transparent in the u.v. region, showing decreasing reflection ratios at the interference maxima, and it became perfectly opaque for wavelengths shorter than 0.22 μm. Only the reflection from the oxide surface could then be observed.

Until the present, the refractive index of the native oxide on GaAs has mainly been determined by ellipsometry (10-13, 19). The refractive index obtained by ellipsometry is very accurate, but the measurement only takes place at the operating wavelength of the ellipsometer. By spectrophotometry, on the other hand, an oxide film gives several interference minima at different wavelengths, and refractive index is determined from each interference minimum. When oxide films having different thicknesses are measured, there are many interference minima at various different wavelengths. By connecting refractive indexes at different wavelengths with a smooth curve, the wavelength dependence of the refractive index can be obtained.

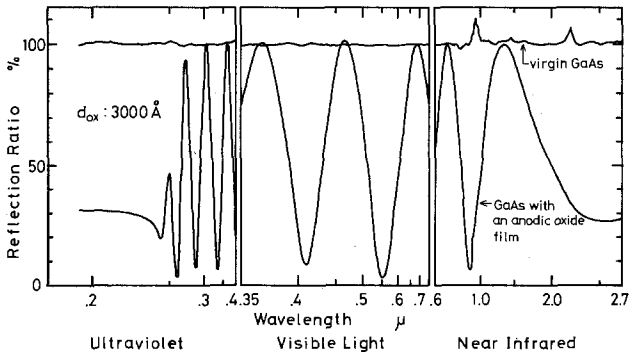

Fig. 5. Interference spectrum from a 3000Å thick as-grown oxide film on GaAs over the wavelength region from 0.195 to 2.7 μm.

Figure 6 was thus obtained for the as-grown oxides. The refractive index was almost constant in the near infrared region, weakly dependent on the wavelength in the visible light region, being higher at shorter wavelengths, and changed rapidly in the u.v. region. The total dependence of the refractive index on the wavelength showed the general characteristics of a glassy dielectric (23). From the previous ellipsometric study, the measured value of the refractive index of the anodically grown GaAs oxide was 1.82 at 5461Å according to Dell'Oca *et al.* (11) and 1.8 according to Spitzer *et al.* (12, 13) and 1.815 according to Müller *et al.* (21), the latter two having been measured at around 6000Å. In good agreement with these results, the values obtained by spectrophotometry in the present investigation were 1.82 and 1.80 at the corresponding wavelengths.

Influence of Temperature on Oxide Properties

Thickness change by heat-treatment.—Figures 7(a) and (b) show the absolute and the relative changes of the oxide thickness caused by heat-treatment, respectively. Four samples having different thicknesses were heat-treated successively in a dry purified N_2 atmosphere for 1 hr at each temperature. From the shape of the thickness change, it seemed to be convenient to consider the change by dividing the temperature into four regions.

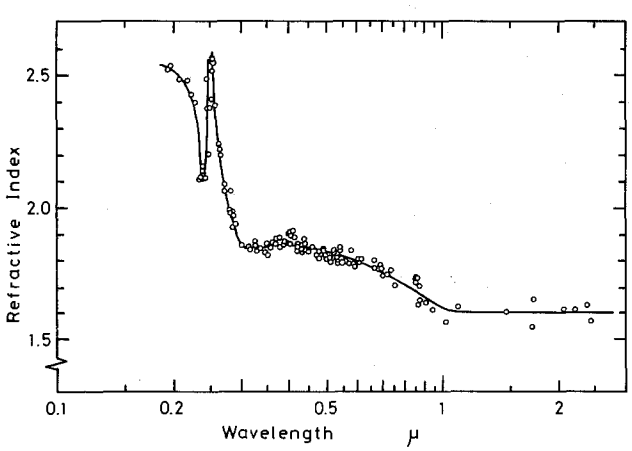

Fig. 6. Wavelength dependence of the refractive index of the as-grown oxide on GaAs measured by spectrophotometry.

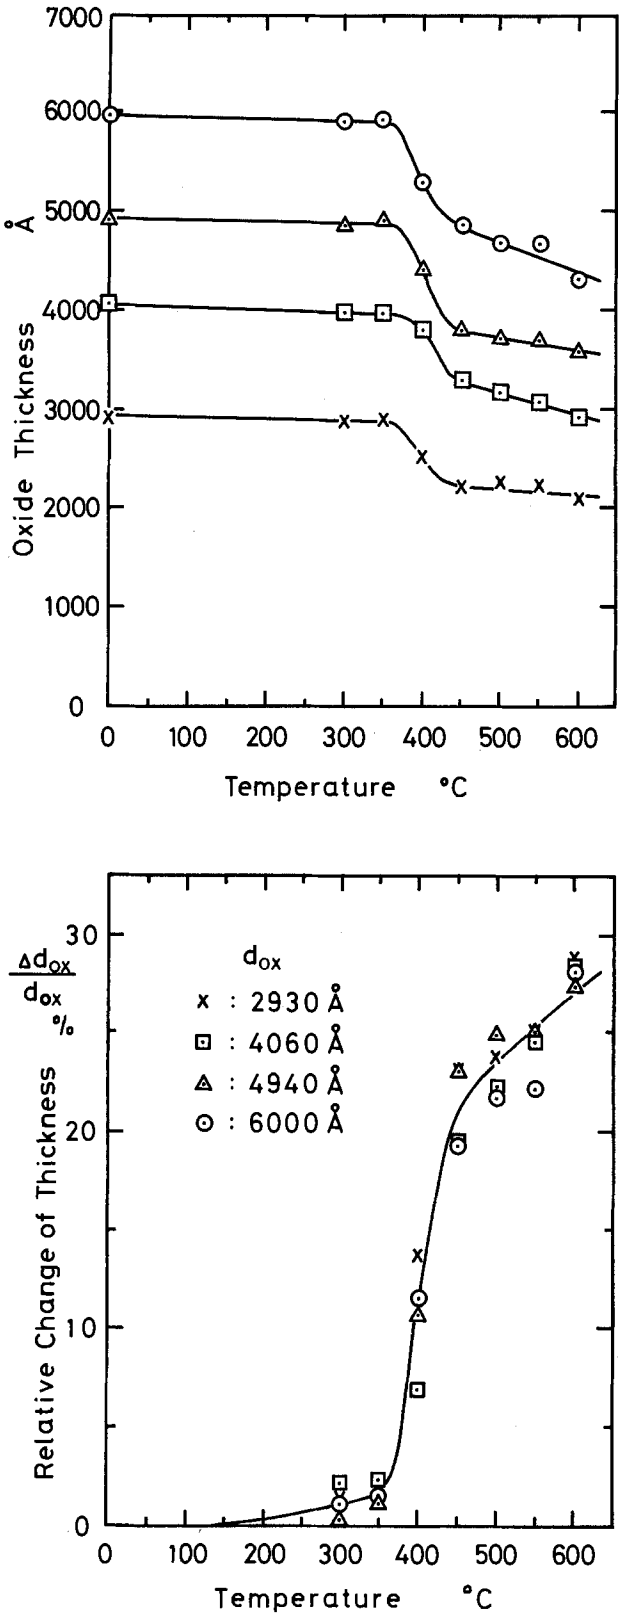

Fig. 7. Absolute (a) and relative thickness changes (b) of the anodic oxide films caused by heat-treatment. Oxide films were heat-treated successively for 1 hr at each temperature.

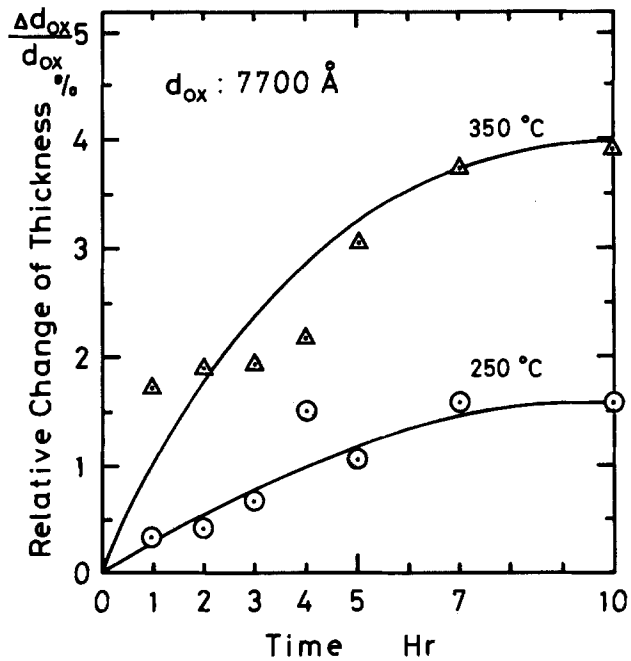

Fig. 8. Relative thickness changes of oxide films heat-treated at 250° and 350°C as a function of the time of heat-treatment.

Region 1: $T < 350$°C.—The thickness change was very small. This is more clearly shown by Fig. 8 where relative change in oxide film thickness is plotted *vs* time. The 7700Å thick oxide films were totally heat-treated for 10 hr at 250° and 350°C, respectively. The thickness change became saturated after a few hours' heat-treatment, and was less than 5% even at 350°C.

Region 2: 350°C $< T < 450$°C.—Drastic changes of the oxide thickness and the interference color were observed. The oxide thickness decreased by as much as 25% of the initial value after heat-treatment at 450°C. The change occurred in an early stage of heat-treatment, indicating an apparent decomposition of the oxide.

Region 3: 450°C $< T < 650$°C.—The changes of the oxide thickness and the interference color were gradual.

Region. 4: $T > 650$°C.—This region is not shown in Fig. 7 because the samples became too pitted and discolored for accurate optical measurements.

Change of optical properties by heat-treatment.—No changes in the optical properties of the oxides and the GaAs could be observed by heat-treatment in Region 1. The interference color and the refractive index did not change. By spectrophotometry, no difference was found between the reflectivity of the oxide-removed GaAs surface and the one of the unanodized GaAs surface.

The optical properties of the oxides changed remarkably by heat-treatment in Region 2. Although the oxides apparently remained glassy and transparent, their interference color changed completely because of the thickness decrease and the refractive index change. Figure 9 shows the change of the refractive index with heat-treatment. After heat-treatment, the refractive index became more weakly dependent on the wavelength in the visible light region. The wavelength dependence of the refractive index disappeared after heat-treatment in Region 3. The refractive index became almost constant around 1.5 over the wide region from visible light to near infrared.

Etching properties of heat-treated oxides.—Etching properties of as-grown oxides and oxides heat-treated below 350°C were almost identical. Oxides could be etched in a common acid or base with a high etch rate. As an example, a 7000Å thick oxide was completely removed in less than a few seconds in a cold HCl or a cold 48% HF solution. The etch rate of the oxides decreased with heat-treatment temperatures above 350°C. Oxides, however, could be etched without difficulty in a strong cold acid or base. Typical etch rates of a few hundred angstroms per second were obtained using a cold 48% HF solution after heat-treatment at 650°C.

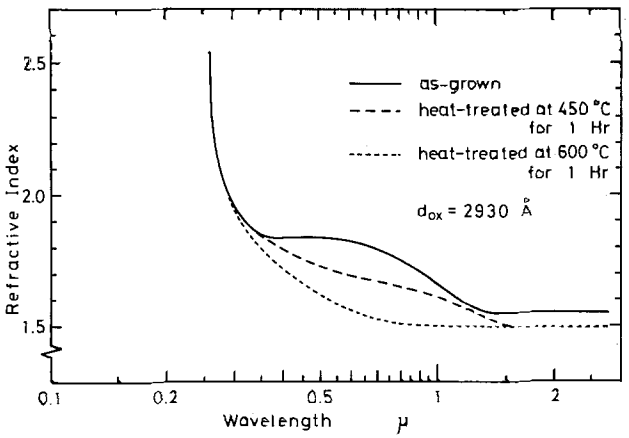

Fig. 9. Wavelength dependence of the refractive index of a heat-treated oxide. The oxide was kept for 1 hr at each temperature.

During these experiments it was found that a thin layer difficult to etch with either a cold acid or a cold base was formed at the oxide-GaAs interface. The thickness of the interface layer increased with the time and temperature of heat-treatment. From the interference spectra shown in Fig. 10, the interface layer was measured to be 500Å thick after heat-treatment at 800°C for 1 hr and to be 250Å thick after heat-treatment at 600°C for 1 hr. An indication of a very thin interface layer was noted in Fig. 10 after heat-treatment at only 400°C. It was, however, impossible to measure the thickness by spectrophotometry.

The interface layer left after the cold etching discussed above could be successfully removed using a warm (60°C) HF or a hot (120°C) H_3PO_4 etch. After this warm acid etching, samples heat-treated above 600°C showed a pitted surface which was believed to originate from arsenic sublimation from the GaAs surface.

Oxide Structure and Decomposition Mechanism

Composition and structure of the anodically grown native GaAs oxide before and after heat-treatment were investigated using Rutherford backscattering He-ions, He-ion-induced x-ray emission, and mass spectrometry. By combining the excellent thickness resolution of the backscattering technique and the excellent mass resolution of the ion-induced x-ray analysis, the oxide structure was analyzed (22). By mass analysis of vaporized materials from the oxide at different temperatures, the process of the oxide decomposition caused by heat-treatment was investigated.

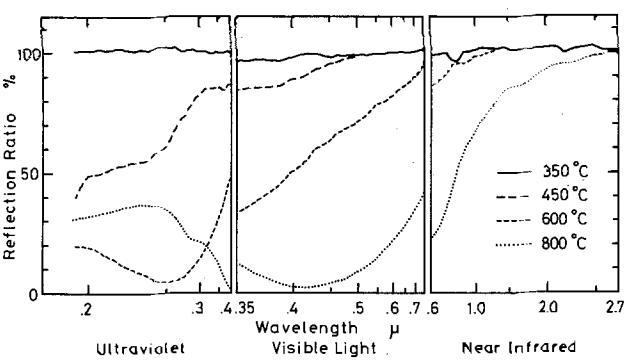

Fig. 10. Reflection spectra from the oxide-removed GaAs after heat-treatment. GaAs wafers were anodically oxidized to give 3000Å thick oxide films, heat-treated for 1 hr at each temperature, and then etched in a cold 48% HF solution.

Experimental procedures.—GaAs was anodically oxidized at 300V, and a 6000Å thick oxide film was grown on the surface. Thus prepared, a number of oxides were heat-treated in a dry purified N_2 atmosphere at different temperatures between room temperature and 650°C for periods ranging from 15 min to 5 hr.

A 1.8 MeV He-ion beam was used, and the backscattering spectra were obtained using a surface barrier solid-state detector, for which the system resolution was 20 keV. The characteristic x-rays for a 1.0 MeV He-ion beam were detected by a Si(Li) x-ray detector which had a resolution of 175 eV, an area of 30 mm^2, a 12.5 μm Be absorber, and a 50 μm Mylar window. Specimens were inclined by 20° to the incident He beam.

For mass spectrometry, a Micromass Type 1 from Vacuum Generators Limited was used. This spectrometer had a minimum detectable partial pressure of 3×10^{-12} Torr nitrogen equivalent, and a resolving power of 22. The GaAs samples which were completely covered by a 6000Å thick oxide film were put in a vacuum furnace with vacuum better than 4×10^{-6} Torr, and were then heated up. Vaporized materials from the oxide-coated GaAs were analyzed by the mass spectrometer. Two heat-treatment procedures were used. In one procedure, the samples were heated up successively from room temperature to 700°C with 50°C steps, and were kept for 1 hr at each temperature. In the other procedure, the samples were directly introduced into the furnace at a given temperature and were then kept at this temperature. Naked GaAs pieces were also heat-treated using the same procedures.

Change of oxide structure by heat-treatment.—Figure 11 shows typical random backscattering spectra

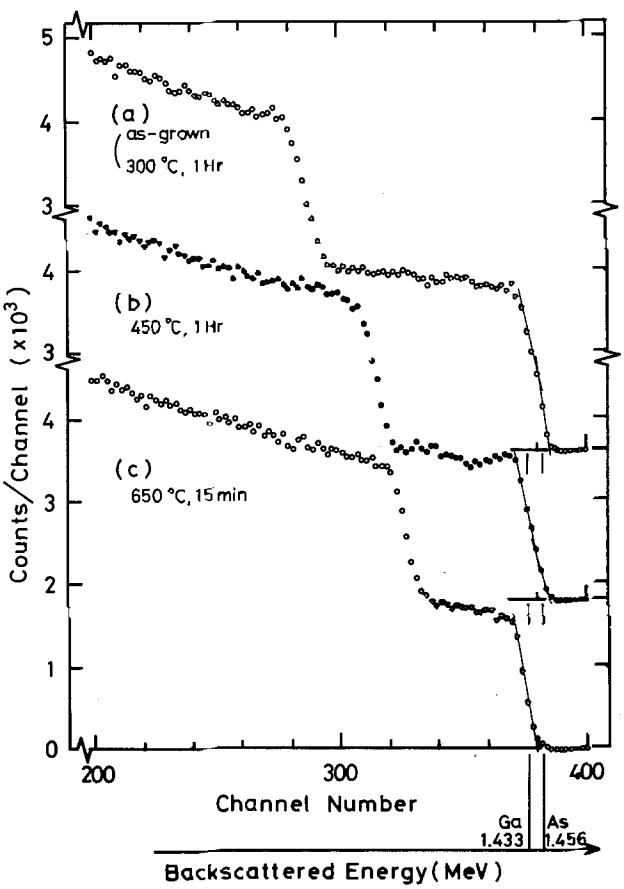

Fig. 11. Typical random backscattering spectra for 1.8 MeV He ion incidence. Curve (a) shows scattering from a 6000Å thick as-grown oxide film. The oxide film heat-treated at 300°C is identical with the as-grown one. Curves (b) and (c) show scattering from identical films after heat-treatment at 450° and 650°C, respectively.

obtained from several samples. Curve (a) is the spectrum from an unheat-treated sample. The leading edge lines up with the arsenic edge and consists of two slopes of almost the same height. This means that the Ga:As ratio in the oxide is nearly 1:1. No peaking due to excess gallium at the oxide surface, which was pointed out by Feldman *et al.* in the oxide made by a H_2O_2 process (22), is observed. The flat plateau indicates that the oxide structure is homogeneous, and that the Ga:As ratio is constant throughout the oxide layer. No change of the backscattering spectrum was observed by heat-treatment at 300°C.

Curve (b) is the spectrum from a sample heat-treated at 450°C for 1 hr. The oxide thickness has decreased to 75% of the initial thickness well in agreement with the results obtained by the optical and the mechanical methods. The leading edge still lines up with the arsenic edge, and it consists of two different slopes. However, the height of the first slope due to arsenic has remarkably decreased, showing a depletion of arsenic in the oxide. From the wavy shape of the curve in the plateau region and the fact that the shape varied across the wafer and also from wafer to wafer, it is believed that the oxide structure is nonuniform. For samples heat-treated longer than 15 min no differences in the obtained spectra were observed.

Curve (c) is the spectrum from a sample heat-treated at 650°C for 15 min. The oxide thickness has further decreased. The leading edge now lines up with the gallium edge, which means complete depletion of arsenic in the oxide. The flat plateau again shows the homogeneous structure consisting of gallium oxide. Heat-treatment longer than 15 min at 650°C did not seem to introduce any conclusive difference regarding oxide thickness and structure, but some inhomogeneity was introduced at the oxide-GaAs interface by heat-treatment longer than 1 hr.

This inhomogeneity was carefully examined by a channeling technique using a sample where the oxide was removed by a cold 48% HF solution after heat-treatment. Using this sample, curves (a) and (b) in Fig. 12 show the random and channeled spectra, respectively. As in the previous etching study, the interface layer not removed by the cold etching is clearly seen in the spectra. From the facts that the leading edge of the random spectrum lines up with the gallium edge (a) and that the clear peaking due to random scattering appears in the channeled spectrum (b), the interface layer is assumed to be an amorphous or a polycrystalline layer containing a negligible amount of arsenic. By detailed experiments, the Ga:O ratio in the interface layer was found to be 2:1 within an error of 20%. The thickness of the interface layer depends on the time of heat-treatment. From channeled backscattering spectra, the thicknesses were calculated to be 180Å for 15 min, 235Å for 1 hr, and 325Å for 5 hr. These values are in good agreement with the results obtained by the optical method (see Fig. 10). The occurrence of the interface layer and its dependence on heat-treatment seem to be connected with the sublimation of arsenic from the GaAs surface and thereby the accumulation of the free gallium at the GaAs surface. This is discussed later.

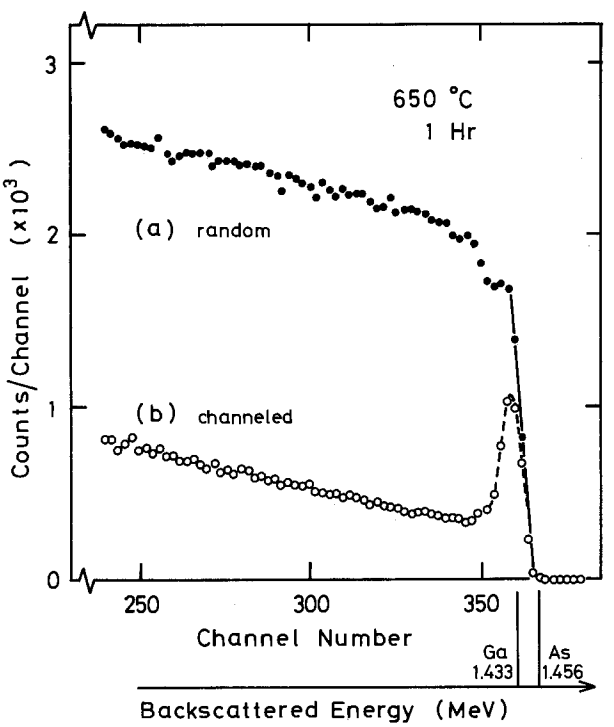

Fig. 12. Random and channeled backscattering spectra obtained from the oxide-removed GaAs using a cold 48% HF solution after heat-treatment at 650°C for 1 hr. A new amorphous or polycrystalline layer is formed at the oxide-GaAs interface, which is completely arsenic depleted and is difficult to remove by the cold etching technique.

Oxide composition.—He-ion-induced x-ray spectra of the samples discussed in the previous section are shown in Fig. 13. As the penetration of the He-ions into the oxide is expected to be 2500Å (22) and the oxide thickness is more than 3500Å even after the heat-treatment at 650°C for 5 hr, the x-ray spectra well represent the feature of the oxide composition.

No difference can be observed between the as-grown oxide and the oxide heat-treated at 300°C [Fig. 13(a) and (b)]. Thus the oxide composition essentially does not change in Region 1 ($T < 350$°C).

The depletion of arsenic in the oxide that occurs in Region 2, (350°C $< T <$ 450°C), is illustrated in Fig. 13(c) by the remarkable decrease of the arsenic K_α

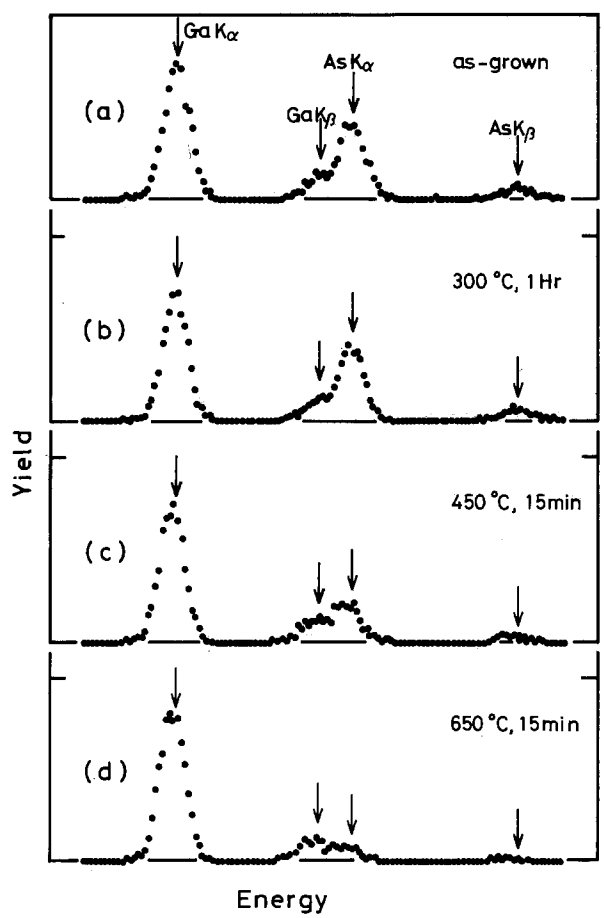

Fig. 13. X-ray spectra for an as-grown 6000Å thick oxide film (a) and for identical oxide films heat-treated at different elevated temperatures (b, c, and d). The 1.0 MeV He beam was incidented on the samples with an angle of 20°.

and K_β yields for a sample heat-treated at 450°C. In Region 3 ($450°C < T < 650°C$), the oxide gradually changes to a more gallium oxide-rich structure illustrated in Fig. 13(d), where the heat-treatment at 650°C has resulted in an almost pure gallium oxide. In these experiments it was further noted that at each temperature the change of the oxide composition was almost completed within the first 15 min of heat-treatment.

Oxide decomposition.—Changes of the partial pressure of H_2O, OH, O, AsO, As, and As_2 by heat-treatment of the oxide-coated GaAs were observed by mass spectrometry. Figures 14 and 15 show the relative changes of the partial pressure of these materials as a function of temperature and of time, respectively.

Logan *et al.* report that the as-grown oxide is supposed to be a mixed structure of Ga_2O_3, As_2O_3, and H_2O (12). From their investigation and our present experiments concerning the sorts of the vaporized materials, the oxide is believed to decompose by vaporizing water and arsenic oxide at elevated temperatures. In Fig. 14 water begins to vaporize at 350°C. The water vaporization rapidly increases and becomes maximum around 450°C. From the shapes of the temperature-pressure relation in Fig. 14 and the time-pressure relation regarding H_2O, OH, and O in Fig. 15, OH and O are believed to be derived from the dissociation of H_2O, possibly due to the ionization-induced dissociation by mass spectrometer.

Rapid increase of the partial pressure of AsO, As, and As_2 at around 400°C is noted in Fig. 14. The maximum vaporization of these materials also occur at around 450°C. Because of the high vapor pressure of As_2O_3 above 350°C (24) and the good correlations among the temperature-pressure relations for AsO, As, and As_2 corrected for by the direct sublimation of arsenic from GaAs shown in Fig. 14 and the time-pressure relations for the identical materials shown in Fig. 15, AsO, As, and As_2 are also supposed to be derived from the dissociation of As_2O_3 due to ionization.

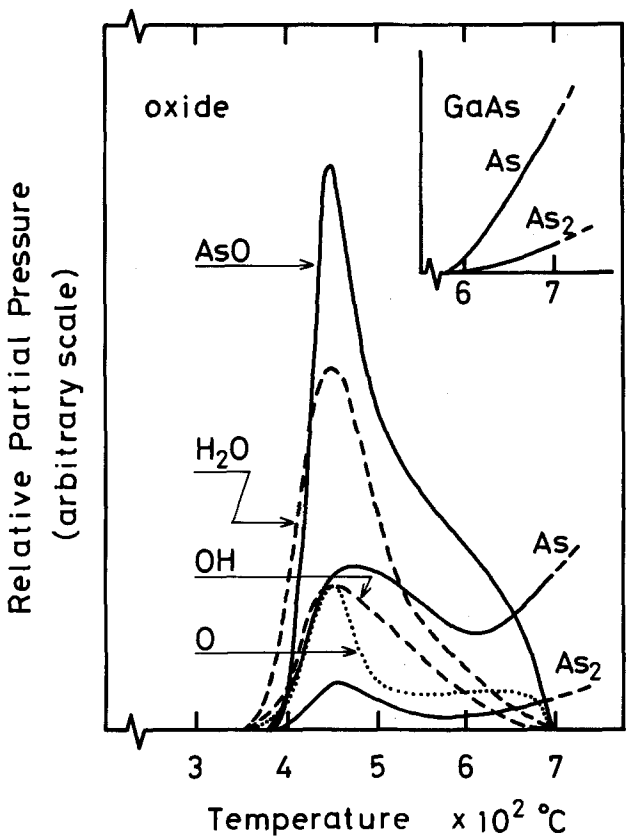

Fig. 14. Relative changes of partial pressures of vaporized materials from an anodically oxidized GaAs and a naked GaAs (inserted figure) during heat-treatment as a function of temperature. GaAs completely covered with a 6000Å thick anodic oxide film was successively heated up to 700°C with a 50°C step.

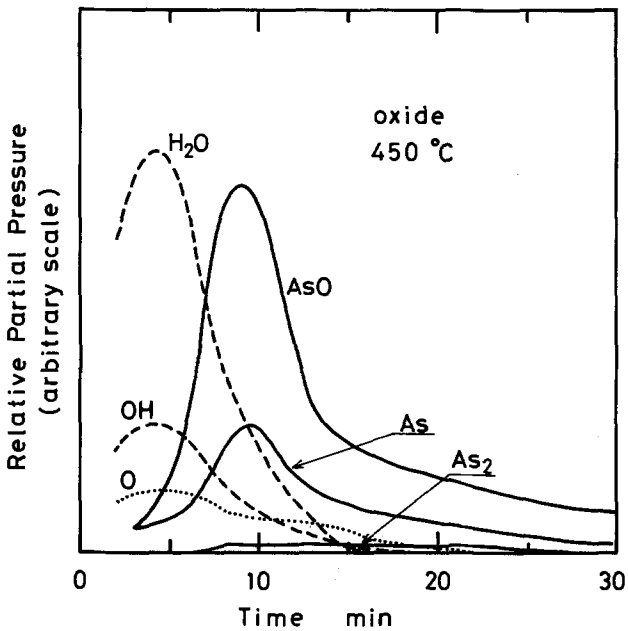

Fig. 15. Relative change of partial pressures of vaporized materials from an anodically oxidized GaAs during heat-treatment as a function of time. GaAs completely covered with a 6000Å thick anodic oxide film was directly heated up and kept at 450°C.

As the partial pressure of oxygen is still high even after the H_2O and OH partial pressures have become low enough in Fig. 14 and the second peak of the oxygen partial pressure correlates well to the peaks of AsO and As partial pressures in Fig. 15, oxygen due to the dissociation of As_2O_3 also contributes to the measured oxygen partial pressure. Below 600°C, vaporization of As and As_2 from the oxide is believed to be dominant. However, it is at present not clear whether the As and As_2 are due to the sublimation from the oxide or the decomposition of As_2O_3. On the other hand, the increase of As and As_2 partial pressures above 600°C is attributed to the sublimation from GaAs judging from the figure inserted in Fig. 14, where the partial pressures of As and As_2 from a naked GaAs wafer are illustrated as a function of temperature. At 700°C vaporization from the oxide becomes negligible, which means that the oxide decomposition is completed. The oxide is now expected to have become a stable and pure structure consisting of gallium oxide. Drastic vaporizations of water and As_2O_3 during the first 15 min are noted in Fig. 15. In the figure, first water and then As_2O_3 vaporize, and the rapid progress of the oxide decomposition in the early stage of heat-treatment is clearly shown. The time required to complete this rapid decomposition is shortened at higher temperatures. Heat-treatment in N_2 atmosphere or in vacuum is identical, judging from the starting temperature of the oxide decomposition and the changes of various oxide properties such as thickness, optical index, interference color, and etching characteristics.

Summarizing the experiments described above, it is possible to outline the basic features of the decomposition mechanism of the anodically grown native GaAs oxide during heat-treatment. The oxide decomposition is triggered by the vaporization of water at 350°C, and it rapidly proceeds at around 450°C by the combined effect of water and arsenic trioxide vaporizations. With the oxide decomposition, the oxide remarkably decreases its thickness and converts to a more and more gallium oxide-rich structure. Only a small amount of arsenic oxide remains in the oxide at 650°C and the

oxide decomposition is completed at 700C, resulting in a pure gallium oxide structure. The gallium oxide is believed to be β-Ga_2O_3, judging from the refractive index and etching characteristics (2-4).

The anodically grown native GaAs oxide is useless to mask the arsenic vaporization. Above 650°C appreciable sublimation of arsenic from the GaAs surface takes place resulting in a pitted surface. It is furthermore believed to lead to the formation of an intermediate layer at the oxide-GaAs interface consisting of gallium oxide and free gallium having a Ga:O ratio of 2:1, and during the fast cooling at the end of the heat-treatment cycle forming an amorphous or a polycrystalline layer.

High Temperature Heat-Treatment of Double Oxide Structure

In the previous sections, it has been shown that heat-treating the anodically oxidized GaAs above 650°C severely degrades the GaAs surface, and an undesired interface layer is formed. The oxide, regardless of thickness, is apparently unable to prevent the sublimation of arsenic from the GaAs surface. It is, however, clear that for processes involving temperatures above 650°C the possibility of using the oxide in intimate contact with the GaAs is of great importance. Several papers have reported that the use of SiO_2 (25), Si_3N_4 (26, 27), or AlN (26) as the annealing encapsulant of an ion-implanted GaAs successfully suppresses the sublimation of arsenic at temperatures as high as 800°C. This section therefore describes means of using the anodic oxide up to 800°C by depositing a SiO_2 film on top of the anodic oxide film in order to prevent the arsenic sublimation.

Double oxide structure.—The double oxide structure in the present investigation was made by depositing a SiO_2 film on top of the anodically grown native GaAs oxide film, using the conventional CVD technique (28, 29). Thicknesses of the anodic oxide films ranging from 500 to 3000Å were examined. Silane was decomposed in N_2 + O_2 atmosphere at 450°C, and a 2000Å thick SiO_2 film was deposited on the anodic oxide film. The period of heat-treatment associated with the deposition of the SiO_2 film was 15 min. As the deposition temperature of SiO_2 was higher than 350°C, the decomposition of the anodic oxide was unfortunately unavoidable. Though the anodic oxide had largely changed to the gallium oxide-rich structure after the SiO_2 deposition (see Fig. 11 and 13-15), the SiO_2 film was expected to readily prevent the sublimation of arsenic from GaAs above 650°C, having improved adherence to GaAs through the anodic oxide film.

Heat-treatment of GaAs coated with the double oxide films.—GaAs coated with the double oxide films was heat-treated at temperatures between 650° and 800°C in a dry purified N_2 atmosphere. For comparison, GaAs coated with only a 3000Å thick anodic oxide film was heat-treated in the same manner. Figure 16 shows the highest temperature at which the samples could be heat-treated for at least 1 hr as a function of the initial thickness of the anodic oxide film. For the same thickness of the SiO_2 film (2000Å), the temperature decreases with increasing thickness of the anodic oxide film. This thickness dependence of the heat-treatment temperature can be caused when the arsenic-depleted anodic oxide film absorbs arsenic from GaAs or when the anodic oxide film and the SiO_2 film are intermixed, making a single oxide film. A thick anodic oxide film can absorb more arsenic from GaAs in the former case, and the thinner the anodic oxide film is the more dominant the effect of the SiO_2 film becomes in the latter case. When the initial thickness of the anodic oxide film was 500Å, heat-treatment at 800°C for 2 hr was possible. Figure 17(a) shows the result from the double oxide structure consisting of a 500Å thick anodic oxide film and a 2000Å thick SiO_2 film after heat-treatment at 800°C for 2 hr, and Fig. 17(b) shows the result from

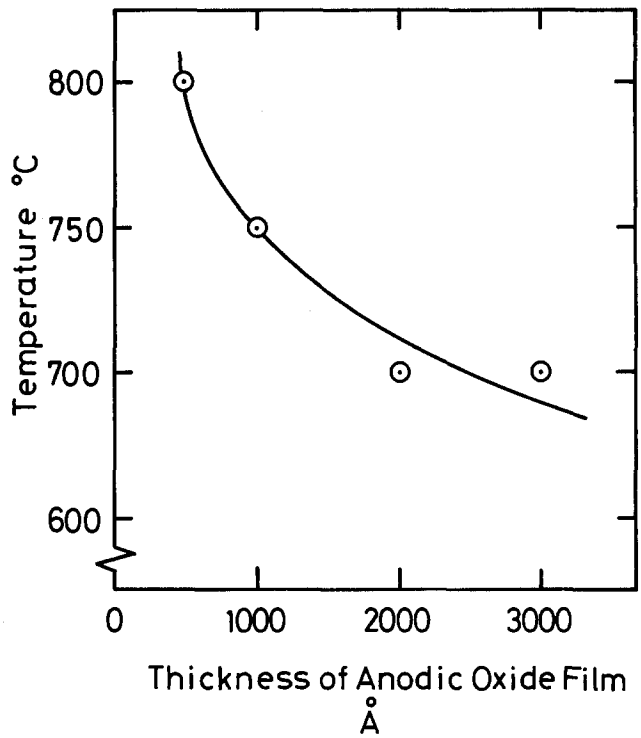

Fig. 16. Relation between the highest temperature to be able to heat-treat GaAs as a function of the initial thickness of the anodic oxide film in the double oxide structure. The SiO_2 film on top of the anodic oxide film was 2000Å thick.

a 3000Å thick anodic oxide film after heat-treatment at 700°C for 1 hr. In contrast to the degraded GaAs surface shown in Fig. 17(b), no degradation can be observed for GaAs coated with the double oxide films [Fig. 17(a)].

The advantage of the double oxide structure is further shown in Fig. 18. GaAs wafers coated with double oxide films consisting of a 500Å thick anodic oxide film and a 2000Å thick SiO_2 film are compared to GaAs coated simply with a 3000Å thick anodic oxide film as a function of heat-treatment at different temperatures for 1 hr. The surface roughness (or degradation) is shown in the form of the reflectivity of the oxide-removed GaAs surface measured at a wavelength of 6000Å. The reflectivity for GaAs coated with just the anodic oxide film rapidly decreases by heat-treatment above 650°C, while the reflectivity for GaAs protected by the double oxide films and heat-treated up to 800°C remains unchanged compared to that of virgin GaAs.

It was very difficult to remove only the SiO_2 film without removing the anodic oxide film, and it was therefore very difficult to separately examine the change of properties of the individual oxide film after heat-treatment. However, the properties of the anodic oxide film after heat-treatment were believed to be quite different depending on whether the anodic oxide film was covered with the SiO_2 film or not. For example, the double oxide films could be removed without difficulty by an HF solution after heat-treatment above 650°C. However, for samples without the SiO_2 coating, the anodic oxide film was very difficult to remove by common etching techniques. Though an inhomogeneous layer was introduced at the oxide-GaAs interface for GaAs simply coated with an anodic oxide film after heat-treatment above 650°C, such an inhomogeneous interface layer has not been observed for GaAs coated with double oxide films.

Summary and Concluding Remarks

The anodic oxidation of GaAs in an electrolyte consisting of water, tartaric acid, and ethylene glycol results in highly uniform native oxide films with con-

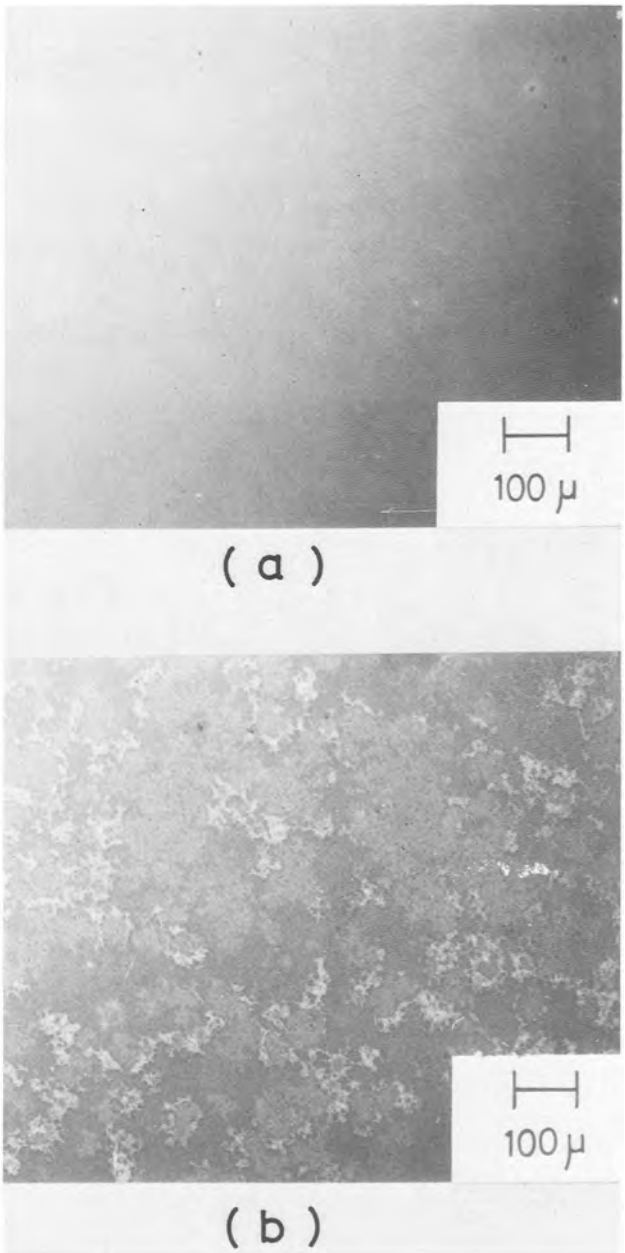

Fig. 17. Comparison of the surface roughness of GaAs after heat-treatment. In sample (a), GaAs was covered with double oxide films consisting of a 500Å thick anodic oxide film and a 2000Å thick SiO_2 film, and was heat-treated at 800°C for 2 hr. In sample (b), GaAs was covered only with a 3000Å thick anodic oxide film, and was heat-treated at 700°C for 1 hr.

trolled thicknesses up to 8000Å. The properties of the oxide essentially do not change below 350°C. The observed slight change of less than a few percent is understood to be due to the densification of the oxide. The as-grown oxide or the oxide stabilized below 350°C has a homogeneous structure consisting of As_2O_3, Ga_2O_3, and H_2O, where the Ga:As ratio is almost 1:1. The oxide is transparent in the visible light and the near infrared region, but becomes increasingly less transparent in the u.v. region, and is perfectly opaque for wavelengths shorter than 2000Å. The refractive index of the oxide is almost constant independent of wavelength in the near infrared region, weakly dependent on wavelength in the visible light region, and it changes rapidly in the u.v. region. The oxide can be etched easily by a common cold acid or base, and the virgin GaAs surface is recovered. Therefore the anodic oxidation-etching cycle is an excellent cleaning method

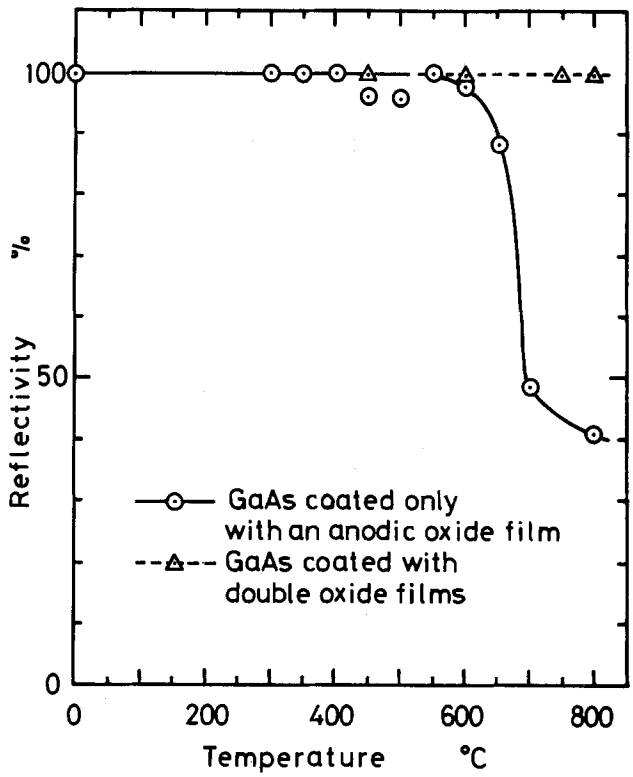

Fig. 18. Reflectivity of the oxide-removed GaAs surface after heat-treatment. GaAs was covered with a 3000Å thick anodic oxide film or double oxide films consisting of a 500Å thick anodic oxide film and a 2000Å thick SiO_2 film. After heat-treatment at the indicated temperatures, samples were etched in a warm 48% HF solution and the reflectivity measured for a 6000Å light.

for GaAs surfaces and is also a useful technique in material analysis, as controlled parallel layers can be removed from the surface.

Drastic changes of the oxide properties are observed by heat-treatment from 350° to 450°C. This low temperature decomposition is initiated by the release of water. The most drastic decomposition appears at around 450°C, associated with vaporizing water and arsenic trioxide. The decomposition is very fast and almost all changes are completed during the early period of the heat-treatment, for example, in less than 15 min at 450°C. As a result, the oxide changes to an inhomogeneous and a gallium oxide-rich structure. These aspects of decomposition are important when device stability and reliability are considered. When the anodic oxide is used as an integral part of a device and temperatures above 350°C are required, or when the oxide is used in a high temperature device processing step, the oxide must be stabilized. The required anneal time is, however, very short. The oxide is for instance stabilized in less than 15 min at 450°C, resulting in a quasistable oxide. Prolonged annealing results in only minor changes.

The oxide further decomposes vaporizing water and arsenic trioxide. However, the oxide decomposition becomes gradual and the oxide becomes a more and more gallium oxide-rich structure in the temperature region ranging from 450° to 650°C. The refractive index becomes almost constant at around 1.5 over the wide wavelength region from visible light to near infrared, which is quite similar to the value of a thermally grown oxide. Judging from the wavelength dependence of the refractive index, the etching properties and the analysis of the composition and the structure of the oxide, the oxide seems to approach pure β-Ga_2O_3.

Above 650°C, appreciable sublimation of arsenic from the GaAs surface takes place, resulting in a pitted surface. It is furthermore believed to lead to the formation of an intermediate layer at the oxide-GaAs interface,

which is at present not fully identified but is supposed to consist of gallium oxide and free gallium. During cooling, an amorphous or a polycrystalline interface layer is formed, having a Ga:O ratio of 2:1. The oxide itself is still glassy and can be removed by a strong cold acid like HF or a strong base. The interface layer, however, is difficult to etch by a common cold acid or base, and only a warm HF or a hot H_3PO_4 can successfully remove the layer. The decomposition of the oxide is complete at 700°C resulting in pure gallium oxide, β-Ga_2O_3. The degraded GaAs surface after long heat-treatment above 650°C makes it difficult to use the oxide in a high temperature processing. The high temperature limit for GaAs coated with only an anodic oxide film is therefore approximately 650°C.

The temperature limit can be improved by depositing a CVD SiO_2 film on top of the anodic oxide film. GaAs covered with such double oxide films, consisting of a 500Å thick anodic oxide film and a 2000Å thick SiO_2 film, can be heat-treated at 800°C for 2 hr with no degradation of the GaAs surface. This result demonstrates the important possibility of using the anodic oxide in intimate contact with the GaAs material in high temperature processes, for example as the annealing encapsulent of ion-implanted GaAs or as a diffusion mask.

Acknowledgments

The authors wish to thank Prof. P. Weissglas for valuable discussions, and Drs. L. Stensland and L-E. Flordal for their assistance with the optical measurements and useful suggestions. The helpful cooperation of Dr. D. Sigurd regarding the structure analysis of the oxide is highly appreciated. They also wish to acknowledge their colleagues for their helpful cooperation.

Manuscript submitted April 19, 1976; revised manuscript received June 6, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

Publication costs of this article were assisted by the Microwave Institute Foundation and Mitsubishi Electric Corporation.

Si Molecular Beam Epitaxy (n on n^+) with Wide Range Doping Control

Yusuke Ota

Bell Laboratories, Reading, Pennsylvania 19604

ABSTRACT

Silicon single crystal films were made by molecular beam epitaxy (MBE) technique in an ultrahigh vacuum (UHV). Sb-doped epitaxial films were grown on Czochralski (CZ) grown n^+ ($\rho \leq 0.003$ Ω-cm), (111) or (100) substrates at temperatures ranging from 600° to 1050°C. The doping density of the films was controlled from high 10^{13} to high $10^{17}/cm^3$. p-type epitaxial films on n^+ substrate were also grown from a boron-doped source. TEM and preferential dislocation etching revealed that the epitaxial films are high quality single crystal with low dislocation density. The electrical properties of the epitaxial films were found to be bulklike. p^+-n-n^+ diodes were fabricated on these films and they showed low reverse leakage current and sharp breakdown. These diodes operated excellently at millimeter wave frequencies.

For many silicon devices, especially microwave diodes and transistors, very abrupt profiles across the epitaxy-substrate interface are important. Most of these devices require a heavily doped substrate ($>10^{18}/cm^3$) and lightly doped epitaxial layer ($<10^{16}/cm^3$). In chemical vapor deposition (CVD), such as hydrogen reduction of $SiCl_4$ or pyrolysis of SiH_4, outdiffusion and autodoping are very difficult to avoid because of the high temperature processing and the existence of halogen and hydrogen gases which transport dopant atoms during epitaxial growth. It is difficult to grow thin epitaxial films with resistivity $\rho \geq 50$ Ω-cm on a highly doped substrate. Si molecular beam epitaxy (Si MBE) has been studied by many authors (1-13). However, to my knowledge there is no report about successful growth of device quality n-type epitaxial films with a wide range doping control by MBE. Although Schewman and King have grown n-type epitaxial films at doping concentrations between 5×10^{17} and $4 \times 10^{18}/cm^3$ by the MBE technique at temperatures below 800°C, they have not reported the quality and the electrical characteristics of these films (12).

Experimental

Growth system.—Figure 1 shows the growth system inside a 12 in. bakable stainless steel bell jar. It consisted of the following major parts: an e-gun system to create a Si molecular beam, a substrate heating system, an effusion furnace for Sb doping, a viewing port for monitoring the substrate temperature and steering of the electron beam, cold shrouds to shield the bell jar walls from heat radiation from both the heated source silicon and Si substrate, and a radiation reflector located behind the Si substrate. The source silicon was located 23 cm from the substrate and the silicon beam was evaporated upward. A thermocouple was attached to the reflector which monitors and controls the substrate temperature. For substrate temperature below 750°C at which the pyrometeric measurement is not accurate, the thermocouple reading was used. The silicon source was built on an Airco Temescal deep crucible e-gun unit with a 270° electron beam deflection. In a 270° deflection system, the tungsten filament is hidden from the Si substrate, which avoided tungsten contamination of the epitaxial film. Since the crucible was made of copper, the area adjacent to the source silicon was protected by high purity silicon to avoid Cu contamination.

The silicon source consisted of three sections. They were made of either high purity floating zone (FZ) single crystal p-type, 5 kΩ-cm silicon or high purity polysilicon (impurity <0.4 ppb). A cross-sectional view of the source assembly is shown in Fig. 2. The center portion of the source section was a truncated cone of shaped silicon (part A). During film growth, the e-beam impinged only on the center of this section. For an e-beam current of 140 mA, the molten area was less than 13 mm in diameter. The doughnut-shaped silicon (part B) protected the copper crucible surface from bombardment by stray electrons. Since the main beam did not strike outside of part A and a small gap existed between parts A and B, the region B remained at low temperature. With this arrangement, Cu contamination was avoided. Another possible source of contamination was sputtering of the stainless steel parts surrounding the e-gun system by the electrons reflected from the silicon surface, mainly from part A. This source of contamination was eliminated by placing a semicircular silicon wall (part C) around the side opposite to the incoming direction of the e-beam. The focusing capability of the e-beam was improved by the addition of magnetic field poles. They are not shown in Fig. 2.

With this source design and modifications, stacking fault-free films were grown at a growth rate of 1.4 μm/hr using a beam current of 250 mA at 4.5 kV.

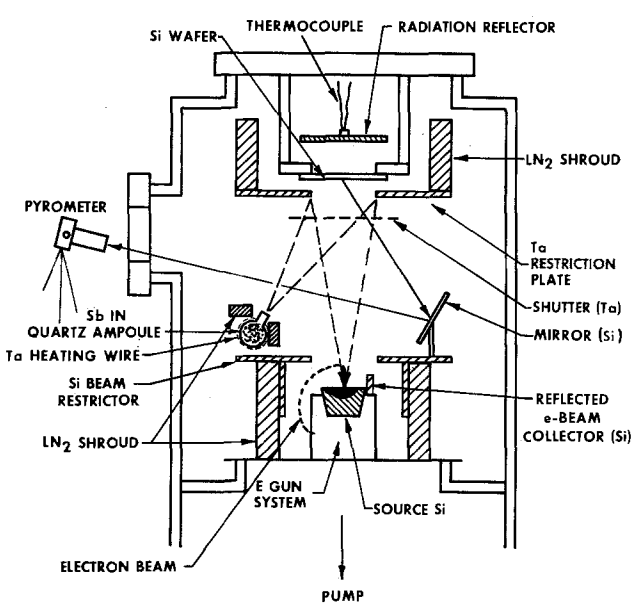

Fig. 1. Si MBE growth system

Key words: silicon, molecular beam epitaxy, doping, ultrahigh vacuum.

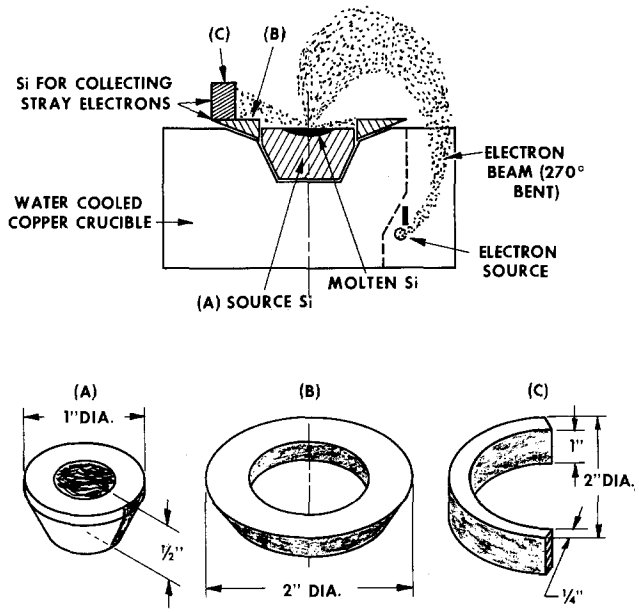

Fig. 2. Si molecular beam source system

Without such modifications, stacking fault-free films could be grown only at a very low beam current, *i.e.*, at a low growth rate (<2000 Å/hr). This problem was more severe for (111) substrates than for (100) substrates.

A cross-sectional view of the resistive substrate heater is shown in Fig. 3. Rectangular silicon substrate (45 × 13 × 0.5 mm) was clamped with tantalum clamps at both ends of the sample. Ta shims were inserted between the clamp and the sample. These shims provided uniform contact to the silicon substrate and prevented the Si sample and Ta clamps from fusing together. The Ta clamp at one end was fixed to a Mo end block, and the other was fixed to a slidable Mo piston. This prevented the silicon sample from warping when it was heated. Mechanical bending of silicon at high temperature ($\gtrsim$ 900°C) would generate dislocations which affect the quality of the epitaxial layer. Using this sliding sample holder, there was no warping in the samples.

A Ta radiation reflector (7.5 cm × 6 cm × 0.25 mm) was placed 6 mm behind the silicon sample. It served three functions. First, it acted as a silicon beam collector which shielded the insulators and other fixtures.

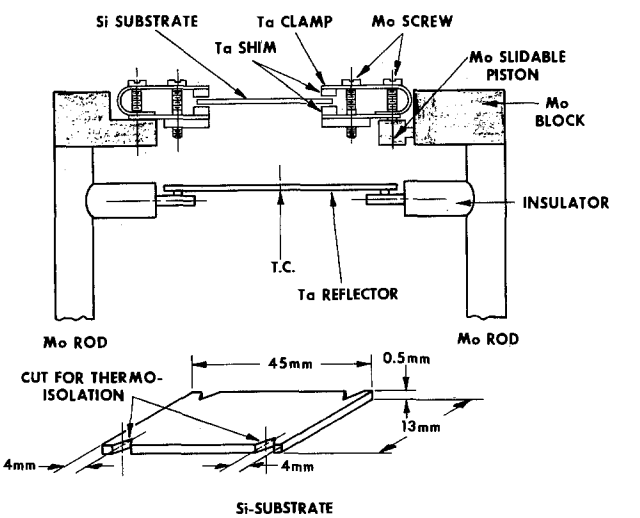

Fig. 3. Substrate heating system

This reflector was cleaned after 4-5 deposition runs. Second, it acted as a radiation shield. This reduced outgassing from the fixtures such as the ceramic insulators and copper lead wires. This added further assurances for contamination-free epitaxial films. Third, a Chromel-Alumel thermocouple was attached to the back side of this reflector to control the substrate temperature. It was also used to monitor the growth temperature below 820°C. The control of the growth was adequately achieved by using a combination of programmable power supply and proportional-type temperature controller. A relationship between the thermocouple reading and the silicon surface temperature was determined from an optical pyrometer measurement for the temperatures above 820°C (pyrometer reading, 790°C) with the emissivity correction. Silicon surface temperatures in the range between 500° and 800°C were estimated by extrapolating the high temperature data.

For the sample size shown in Fig. 3, the temperature uniformity was checked visually and by an optical pyrometer for temperatures above 820°C. When the substrate temperature was ~900°C, a temperature gradient was visually observed near the Ta clamp to approximately 3 mm away from the clamp. Our observations showed that this region was narrowed to less than 3 mm for growth temperatures above 1000°C. When the center of the sample was at 900°C, the pyrometer readings indicated a temperature drop of 30°-50°C in the dark regions near the Ta clamps.

Pyrometer readings were taken at a few points in the visually uniform regions. The variation of the readings was within the resolution of the pyrometer ±5°C. For film growth temperatures below 900°C, the sample had to be shaped to improve the temperature uniformity of the sample. Four notches were cut from the sample as shown in Fig. 3. The depth of the cuts depended on the substrate temperature for film growth and they were determined empirically. For the sample size shown in Fig. 3, 2 mm deep cuts were used to grow films at ~800°C. The doping uniformity for two samples with and without the cuts were compared with spreading resistance measurements. Both samples had n-type ~1.5 Ω-cm and 5 μm epitaxial films grown at 770°C. For the sample without the cuts, the surface spreading resistance at 6 mm from the clamp was 50% lower than that at the center and a 10% variation was observed in the center region. However, the sample with the cuts showed a uniform resistivity over almost the entire length (3.8 mm) of the sample. The spreading resistance readings were ~4.5 kΩ. We found that the film resistivity is a sensitive function of the growth temperature. From the spreading resistance data, we inferred that this setup provided a uniform growth temperature across the sample. The relationship between the film resistivity and the sample temperature is discussed further in a later section.

Antimony dopant vapor was generated with a simple effusion furnace. It consisted of a quartz ampul with a 6 mm diameter opening, a tantalum heating wire, a Chromel-Alumel thermocouple, and a liquid nitrogen-cooled shroud. This effusion furnace system was capable of generating a well-controlled flux of Sb vapor. The furnace temperature was controlled by a proportional-type thermocouple temperature controller to within ±0.1°C of the set temperature. The controller and the programmable power supply were isolated by an optical isolator. This effusion furnace could also be used for arsenic doping. However, we felt that antimony is easier to use in this system because of its chemical stability and lower vapor pressure as compared to As.

All three major heated sections, *i.e.*, the Si source, the substrate, and the effusion furnace, were sur-

rounded by liquid nitrogen cold shrouds to prevent radiation heating of the surrounding fixtures and walls. Without these shrouds, stray dopants could cause difficulty of doping control as electrically active contaminants.

Sample preparation and growth procedures.—One side of the Si substrate was Syton-polished and etched in 0.05 mole CrO_3-HF mixture to remove possible surface damages from polishing. This etchant did not destroy the mirror surface of the sample. After rinsing in DI water, the sample was cleaned in a HCl-H_2O_2 mixture to remove the absorbed chrome on the sample surface. ~40Å thick oxide was grown on the Si surface during this cleaning procedure and it was removed in 15:1 diluted HF. Finally, the sample was boiled in an NH_4OH-H_2O_2 mixture for 20 min. This operation formed a protective oxide of ~50Å in thickness. The sample was mounted onto the heater assembly and the system was evacuated.

The vacuum system was baked at 150°C overnight and ready for film growth when the vacuum was at 10^{-11} Torr. With the shutter closed, the source Si and the effusion furnace were heated for 30 min. Once the vacuum recovered to low 10^{-9} Torr, the substrate was heated at 1240°C for 45-60 sec and slowly cooled to the growth temperature. This preheating step was optimized for vaporizing the thin oxide layer and producing an atomically clean surface for epitaxial film growth. The growth started by opening the shutter. Typical growth conditions were as following: e-beam was at 140 mA and 4.5 kV which produced a ~6000 Å/hr growth rate, the Sb source was at 300°C which generated ~10^{-7} Torr Sb vapor pressure in the ampul and the typical vacuum during the growth was between 1 and 5 × 10^{-9} Torr.

Results

Crystalline quality.—The crystalline quality of the films was examined with transmission electron microscope (TEM) and preferential defect etching, and the surface texture was examined with SEM and optical microscope. The surface texture observed by an interference contrast microscope at 750× and SEM at 5000× were usually featureless. When the film thickness was less than several hundred angstroms, the texture of the film surface provided information on the growth mechanism. A featureless surface in this thickness range would indicate that the film growth was by a two-dimensional nucleation mechanism (7). This was different from the film growth via a three-dimensional nucleation where single crystal island formation was observed. The presence of islands caused poor crystalline quality. We found that a featureless surface is essential for good quality film growth. The TEM measurement showed excellent crystallinity and no stacking faults or dislocations. Figure 4 shows the transmission electron diffraction pattern from the epitaxial film grown on an (100) substrate at 600°C. In spite of the TEM results, when this sample was examined by Secco etch, it revealed a dislocation density of 200/cm² but no evidence of stacking faults.

The dislocation density in most of the epitaxial films was less than 10^3/cm² and close to that observed on the substrate surface, where Secco etch and Sirtl etch were used for (100) and (111) films, respectively. It is important to note that the dislocation density was independent of the film growth rates (0.2-1.4 μm/hr), the growth temperatures (600°-1050°C) or the film thicknesses (0.3-9.0 μm).

Thickness and doping concentration control.—*Thickness.*—The growth rate was controlled by varying the e-beam current at a fixed acceleration voltage. For the present system, the beam current was adjusted manually. Since the growth rates were shown in the range of a few thousand angstroms per hour, a reasonable control of e-beam current could be made. With this manual control the thickness reproducibility was ±10%. The film thickness *vs.* growth time is shown in Fig. 5, where the e-beam current was at 140 mA. The substrate temperatures were from 600° to 1050°C as indicated in Fig. 5, and for both (100) (□) and (111) (○). The (△) is for amorphous Si films deposited at room temperature. These data indicated that the growth rate is independent of either the Si substrate temperatures or the surface orientations.

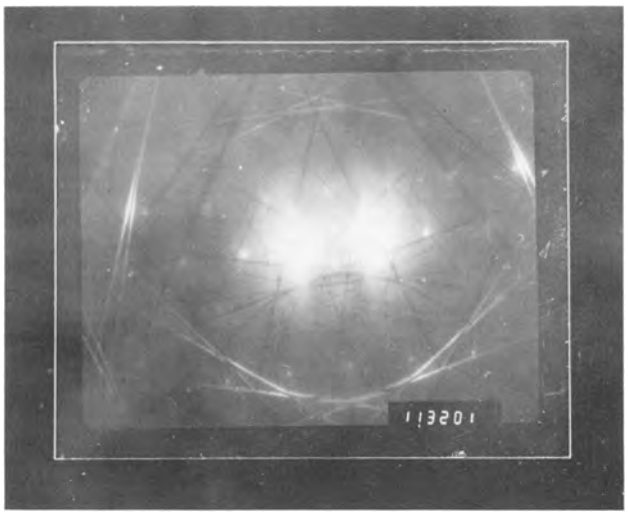

Fig. 4. Transmission electron diffraction pattern from a (100) epitaxial film grown at 600°C.

Most of the film thicknesses were determined by observing the step formed at the Ta clamped area with an interferometer. Several samples were also measured by *IR* multiple reflection technique. These

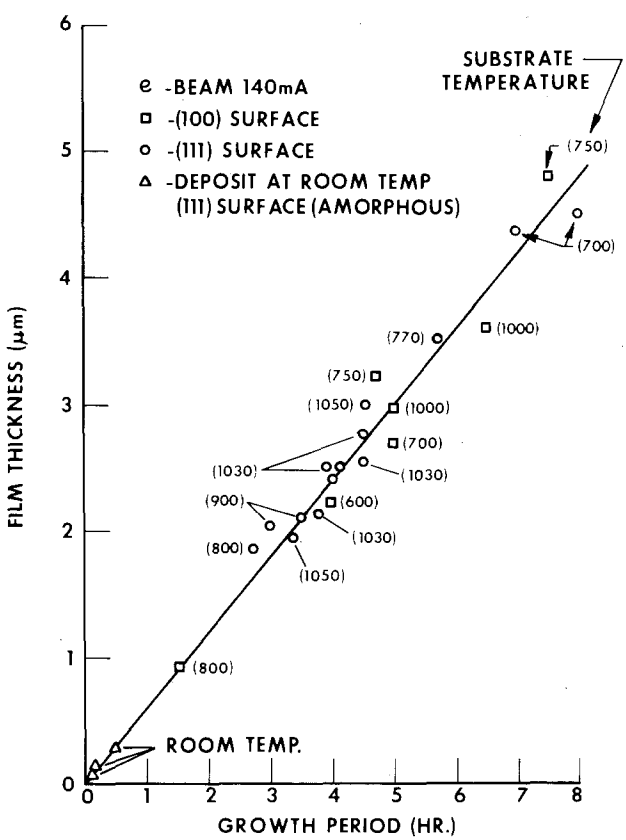

Fig. 5. Film thickness *vs.* growth period relationship.

results agreed with those by the interferometer to within ±10%.

Doping.—With the antimony effusion furnace, a simple way to vary the doping concentration in the film was to change the effusion furnace temperature. However, due to the sensitivity of vapor pressure of Sb with temperature, it was rather difficult to control the Sb concentration in the film by changing only the effusion furnace temperature. A convenient method for doping epitaxial films was to change the silicon substrate temperature T_S, while keeping the Sb source temperature constant. Figure 6 shows the relationship between the film resistivity and the growth temperature T_S for Sb source heated at 300°C (●) and 260°C (▲). The data are for a film growth rate of 0.6 μm/hr. By this method the resistivities of the films could be reproducibly varied over three orders of magnitude. Epitaxial films with resistivities higher than 20 Ω-cm were grown in this fashion. With the conventional CVD method, it is usually difficult to grow epitaxial films with $\rho > 50$ Ω-cm, especially on n^+ substrates. If the epitaxial films were thin, say, less than 3 μm, it was extremely difficult to grow such high resistivity films on highly doped substrates by the CVD method. The datum point (□) was obtained from a special run to investigate the system capability to create high resistivity films. The growth rate was 1.2 μm/hr and the effusion furnace temperature was 260°C. The film resistivity was 150 Ω-cm as measured by spreading resistance measurements. The dependence of the doping concentration on the substrate temperature is believed to be due to the dependence of the sticking coefficient of Sb on the surface temperature of Si. Figure 6 shows that the scattering of the film resistivity increases as the substrate temperature decreases. This effect could be explained by the fact that the residual Sb on the shutter and other parts which were not cooled with liquid nitrogen contributed to the main Sb source and the sticking coefficient of Sb on Si was a strong function of temperature. However, we have not investigated this question further.

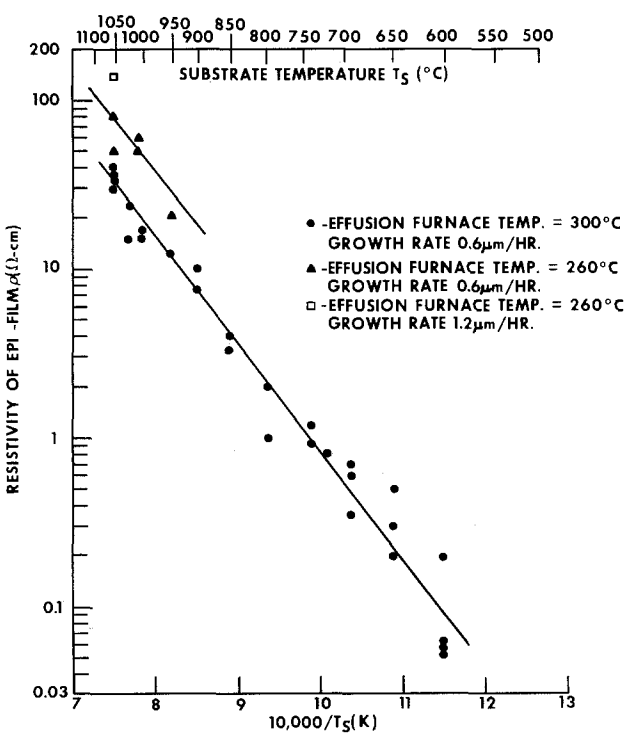

Fig. 6. Dependence of doping density on the growth temperature, where dopant is Sb.

Spreading resistance measurements.—Spreading resistance measurements were used to evaluate the resistivity of the film. While the spreading resistance measurements do not give a direct reading of the resistivity profile (14), this technique is still a convenient method for determining the approximate resistivity and the location of the epitaxy substrate interface of a p-n junction. Figure 7 shows the uncorrected spreading resistance data for an Sb-doped 2.9 μm thick film grown at 1000°C on an As-doped 0.002 Ω-cm (111) substrate. The resistivity from the spreading resistance measurements was approximately 15 Ω-cm. Spreading resistance measurements near the interface of two layers of different conductivities are subject to uncertainties. In spreading resistance measurements, the probe penetration depths are extremely difficult to determine and influence the resolution of the profile. Therefore, the spreading resistance technique was used mainly to determine the resistivity of the films in the plateau region where the influence from the substrate can be neglected. The lateral doping uniformity was also examined at eight locations on this sample as shown in Fig. 8. The result indicated that lateral doping uniformity is excellent.

Film resistivity vs. carrier concentration.—Resistivities ρ *vs.* doping concentrations N_D of films were de-

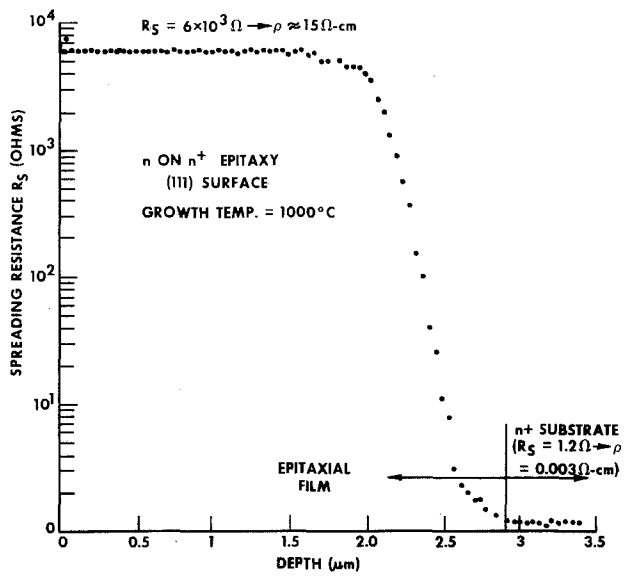

Fig. 7. Spreading resistance vs. depth profile on n on n^+ epitaxy

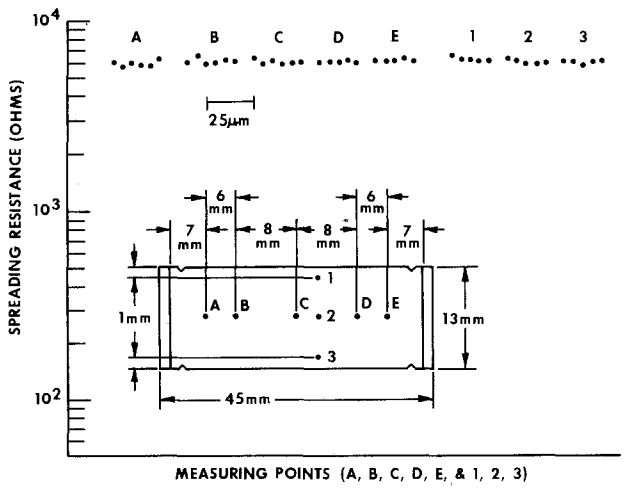

Fig. 8. Lateral spreading resistance profile

termined by two methods: (*i*) Hall effect measurement was made on a few n-type layers on p^+ substrates. Due to difficulties in making good contacts to the samples which were lightly doped ($<10^{16}/cm^3$), only one datum point was obtained as shown by (HALL) in Fig. 9. (*ii*) A combination of MOS C-V and spreading resistance measurements were used to determine the resistivity *vs.* concentration for n-type layers on n^+ substrates. The results are shown by (MOS-SPREAD) in Fig. 9. MOS capacitors were fabricated with 2000Å thermal oxide. The doping concentrations were determined from the high frequency C-V plots at 1 MHz. The film resistivities were determined by converting the spreading resistances into resistivities in the region where constant readings were observed. Good agreements with bulk Si data (15) (the solid line) were observed. Hence, we concluded that the epitaxial films had the same quality as bulk single crystals.

Diode characteristics.—Using the millimeter wave diode processing technique, p^+-n-n^+ mesa diodes were fabricated with a sample of 15 Ω-cm and 2.9 μm film (this sample is the same as that shown in Fig. 7). The diode was formed by diffusing boron from a BN source to 0.5 μm depth, mesa etched, passivated, and metallized (16). Figure 10 shows a typical *I-V* characteristic for a diode made with this material. From Fig. 10, the breakdown voltage was approximately 72V (at 10 μA). The theoretical breakdown voltage was 66V (17). The calculation assumed error function distributions for boron (p^+) and arsenic (n^+) and an active layer width of 2.1 μm. The breakdown voltages for other diodes (68 ± 5V) from the same epitaxial film agreed with the calculation.

Trap measurements.—Pt Schottky diodes on n-type film were fabricated for deep trap measurement by the DLTS technique (deep level transient spectroscopy) (18). The epitaxial film was 5 Ω-cm, 5 μm thick, Sb doped on an (100) oriented substrate. No deep trap was detected in the as-grown film for trap energies over a range between 0.08 and 0.3 eV from the conduction band at reverse bias voltages from 1 to 10V, as shown in Fig. 11. For the film resistivity of this sample, the sensitivity of the DLTS measurement was around $2 \times 10^{12}/cm^3$, this strongly suggests that no major electrically active contamination was introduced in the epitaxial growth process.

Doping profile.—In order to investigate the doping profile near the film-substrate interface, As profiles were measured by the SIMS technique (secondary ion mass spectroscopy) for substrates with As concentrations $\simeq 5 \times 10^{19}/cm^3$. Figure 12 shows the results of SIMS analysis. Curves (a) and (b) are for samples grown at 1050° and 800°C, respectively. The out-diffusion of As from the substrate into the film was less than 300Å for a 3 hr growth at 800°C and less than 2000Å for a 2 hr growth at 1050°C. Curve (c) shows the doping profile near the film-substrate

interface of a conventional CVD epitaxial film.[1] This film was 1.2 μm thick grown at 1200°C using $SiCl_4$. This curve indicated that the out-diffusion of As was significantly larger than that in MBE films grown at lower temperatures. For the MBE films, evaporation of As the highly doped substrate during the initial cleaning steps at 1240°C was investigated. Figure 13 shows the SIMS data for a substrate (As = 5×10^{19}/cm³) which was thermally treated at 1240°C for 1.5 min in an UHV. The surface depletion of As was close to 300Å.

Discussion

Epitaxial film can grow in a form of discrete three-dimensional islands, two-dimensional layers, or a combination of both (7). Many factors can contribute to the three-dimensional growth. For defect-free films, the environment should promote the two-dimensional growth. Three major factors are essential for the two-dimensional growth and hence for the growth of defect-free silicon films by the MBE technique. These are discussed in this section.

Ultrahigh vacuum (UHV).—Several researchers studied the growth mechanisms of silicon crystal in an UHV (7, 8). They recognized that a clean environment is very important to grow epitaxial films by the two-dimensional mechanism (7). For the present growth system, a clean environment was provided in a bakable UHV system. This was capable of obtaining a vacuum of middle 10^{-11} Torr after overnight baking and with liquid nitrogen in a cryogenic panel and cooling of the shrouds. The importance of an ultrahigh vacuum was observed in the following experiment.

When the system was not baked and the sublimation pump and the cryogenic panel were not used, the system had an initial vacuum of 10^{-9} Torr. During the film growth, in a very short time the vacuum was in the high 10^{-6} Torr region and remained at this pressure for longer than a few hours. The high background pressure was due to outgassing from the vacuum chamber by the heat radiation from the silicon source and the substrate heater, and the excess gas release had caused saturation of the ion-pumps. Silicon films grown in this environment often showed the presence of discrete three-dimensional growth centers. In the early stage of the growth, the film showed island formation and when the film was a few thousand angstroms thick it appeared milky. This milky appearance of the surface became noticeable when the growth temperature was above 800°C. [This is different from the thermal etching of silicon during the film growth as suggested by Schewman and King (12).] This experiment confirmed the necessity of UHV system with proper baking and cooling during film growth for growing defect-free silicon epitaxial films. The vacuum during the growth should be below the 10^{-8} Torr range.

Silicon source.—The basic requirements for the silicon source were a high purity Si and a controllable constant sublimation rate. In an earlier design, silicon vapor was created in an ultrahigh purity graphite crucible (99.9999% pure), heated at 1450°C to vaporize Si (19). Three-dimensional islands were observed for films grown with this source on (111) substrates at growth temperatures ranging from 670° to 1050°C. These films contained high densities of stacking faults and twin structures (>10^9/cm²). This was believed to be due to the carbon contamination. The graphite silicon source was changed to an electron beam heating system to avoid the presence of carbon in the sublimation source. High purity, high resistivity floating zone p-type silicon ($\rho > 5$ kΩ-cm) or high purity polysilicon (impurity level >0.4 ppb) was used as the source material. After the source structures were shaped, they were etched in CP-4 and cleaned with e-beam in the UHV system before the film growth. This system was successful for generating a clean Si molecular beam.

In situ cleaning.—Joyce *et al.* (7) did a careful study relating three-dimensional nucleation and the substrate surface preparation. They found that an atomically clean surface was necessary to avoid island formation in the film growth and that such a surface could be generated if the final step in the surface cleaning constituted a 1200°C heating under high vacuum conditions for 10 min prior to film growth. Allen *et al.* (20) also reported that heating silicon to about 1200°C was necessary to obtain atomically clean silicon surfaces. Kimura and Lee (11) also used sublimation to try to clean their substrate surfaces but found that prolonged thermal treatment in vacuum actually led to excessive surface concentration of silicon carbide particles which, in turn, were responsible for generating stacking faults. They showed that this was especially true for CZ crystals but that there was sufficient carbon in FZ crystals to also be important.

Recognizing the importance of the substrate surface cleanliness, we also studied the sample surface preparation for substrates used in this deposition system. CZ substrate heated at 1200°C for 10 min in vacuum were observed to have a high density of thermal pits on the substrate surface. These results were different from the observations of Joyce *et al.* and agreed with those of Kimura and Lee. Epitaxial films grown on this pitted surface were not smooth.

Heating silicon at temperatures higher than 900°C in vacuum usually causes nonuniform sublimation resulting in thermal pits. These pits occurred in less than 1 hr at 900°C and less than 5 min at 1200°C. The formation and size of these pits depended on the length of heating, the temperature, the initial crystalline perfection, the thermal history of the crystal, and probably other factors still unknown. We observed more thermal pitting on FZ silicon than on CZ silicon. This is in disagreement with the postulation of Gates and Lavin (21) who claimed that the increased oxygen in CZ silicon was responsible for the greater thermal pitting. We also observed that most of the (100) surfaces showed more severe pitting than (111) surfaces. This agreed with the results of Batdorf and Smits (22).

We found that the shortest possible heating time should be used to produce the atomically clean surface. This was enhanced by using a final chemical cleaning step of boiling NH_4OH-H_2O_2 which leaves about 50Å

[1] The imolantation effect during SIMS analysis is not considered in these profiles.

of SiO_2 on the surface. These thinly oxidized substrates were preheated to 1240°C for less than 1 min prior to film deposition. Using this cleaning method, low dislocation density films were obtained (less than 1000 cm^{-2} which was close to the dislocation density in the substrates).[2] No stacking faults were observed in these films. As the thermal evaporation cleaning period is extended prior to film deposition, the dislocation count in the deposited films increases and stacking faults are sometimes generated as reported by Kimura and Lee, most probably because of an increase in silicon carbide particles at the growth interface although we were unsuccessful in identifying this phase. Figure 14 shows results of Sirtl etchings on epitaxial films grown on (111) As doped (As $> 5 \times 10^{19}/cm^3$) substrates at 900°C. Figure 14(a) is for a film grown by the recommended preheating procedure after Sirtl etching for 1 min. Figure 14(b) is for a film grown by using a prolonged preheating procedure, 10 min at 1240°C and Sirtl etched for 30 sec. The film represented by (a) had an average dislocation density less than $100/cm^2$ and the one represented by (b) had an average stacking fault and dislocation density of $2 \times 10^5/cm^2$.

Atomically clean silicon surfaces can also be obtained by sputter cleaning with ionized inert gases (He or Ar) (23-25). For the conditions used, the silicon surface damaged by sputtering could not be annealed to the original surface conditions for the moderate annealing temperatures used. Furthermore, Ar penetrated the silicon surface which was very difficult to remove (23, 24) and the sputtering process could cause additional contamination (24). Hence, the sputter cleaning by inert gas ions for surface preparation for Si MBE was not pursued further.

Unvala (6) and Thomas and Francomb used doped silicon for growing doped epitaxial films in vacuum with some success (1, 6). We investigated this technique in the present system. Phosphorus-doped FZ silicon crystals with resistivities ranging from 1 to 150 Ω-cm were used as silicon and dopant sources. Films grown with these sources had unpredictable and nonuniform resistivity and conductivity type. Both p and n regions were sometimes observed in the same sample. This was due to a rapid initial evaporation of phosphorus from the molten silicon and also possibly compensation from the background boron which is always present in the silicon crystals. Hence, this approach was discarded for n-type film growth. Tannenbaum and Povilonis (3) obtained p-type doping films with good reproducible results using boron-doped silicon source. However, the film resistivity decreased as the source was repeatedly used due to accumulation of boron near the surface. They used a source temperature of 1350°-1380°C which was below the silicon melting temperature. Boron-doped silicon crystals were used for growing p-type films in the present system. The source was heated to >1600°C with an electron beam. A few p-type films were grown on n^+ substrates at 950°C. For the few runs done to date, resistivities of the films were 0.5-0.7 Ω-cm from a 0.1 Ω-cm source, 5-10 Ω-cm from a 2 Ω-cm source, and 15-20 Ω-cm from 10 Ω-cm source, respectively.

As stated above, for n-type doping a separate Sb source effusion furnace was used. The Sb source temperature could be varied from 50° to 700°C. Typically, it was set at 300°C. The use of high purity elemental Sb provided a contamination-free doping source. The relatively low vapor pressure of Sb (less than that of P and As) minimized reevaporation of the dopant from surrounding fixtures where some parts are radiatively heated by the heated silicon source and substrate. This reduced the possibility of spurious doping in successive film growths. We also found that the film resistivity could be controlled readily by changing the film growth temperature with a constant Sb vapor pressure. Doping concentrations from 2×10^{14} to $4 \times 10^{17}/cm^3$ were grown reproducibly with this effusion furnace at 300°C and a growth rate of 0.6 μm/hr. One film was Sb doped to $6 \times 10^{13}/cm^3$ with the effusion source heated at 260°C and the growth rate of 1.2 μm/hr. The film resistivity could also be adjusted with the growth rate for a given effusion furnace temperature and a film growth temperature.

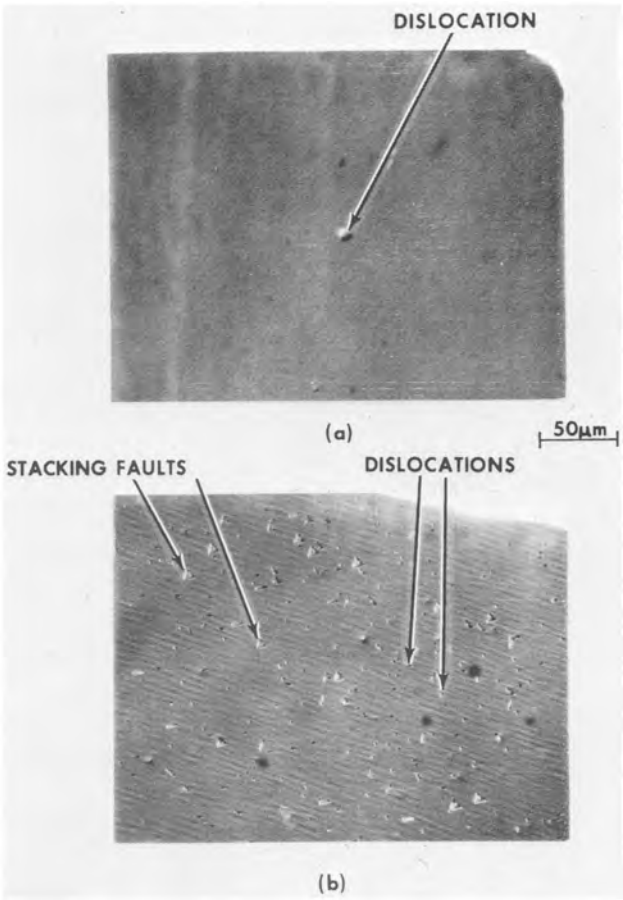

Fig. 14. (111) epitaxial film surface after Sirtl etching. (a) Epitaxial film grown by normal procedure (1 min Sirtl etching). (b) Epitaxial film grown by using a prolonged preheating period, 1240°C, 10 min (30 sec Sirtl etching).

The outdiffusion of As from n^+ substrate into the epitaxial film was remarkably smaller than that of the conventional CVD method. It was believed to be due not only to the lower growth temperature but also to the absence of other dopant transport mechanisms in the present system. No autodoping of As into the epitaxial film was observed. This was proved by the capability of growing high resistivity thin p-type films (>15 Ω-cm) on n^+ substrate (~0.002 Ω-cm). High quality epitaxy films with both well-controlled doping and sharp doping profiles near the film-substrate interface produced high quality, millimeter wave PIN diodes.

Conclusion

In order to grow high quality epitaxial films by MBE, three factors must be present, namely:

1. A bakable ultrahigh vacuum system with liquid nitrogen cold shrouds capable of achieving a vacuum lower than 10^{-8} Torr during the film growth.
2. A high purity silicon source with e-gun heating.
3. An atomically clean silicon surface free of thermally induced damage.

[2] Most of the low resistivity substrates (<0.01 Ω-cm) used in this study were CZ grown crystals and contained dislocation densities <1000/cm^2.

For n-type doping of the film in the MBE system, Sb is recommended. The film doping concentration can be controlled by varying the silicon growth temperature. For p-type film, boron-doped silicon source can be used. The quality of the substrate affects the quality of the epitaxial film.

Acknowledgment

I take pleasure in acknowledging the able technical assistance of R. Jimski on this project. I would also like to thank W. L. Buchanan and O. G. Petersen for fabricating and analyzing p^+-n-n^+ switching diodes, P. M. Petroff for performing TEM measurements, and G. E. Becker and J. C. Bean for exchanging valuable information. Valuable assistance from J. H. Mattes of the BTL machine shop is also acknowledged.

Manuscript submitted May 23, 1977; revised manuscript received July 26, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

Publication costs of this article were assisted by Bell Laboratories.

Argon Implantation Gettering of Bipolar Devices

M. R. Poponiak, T. Nagasaki, and T. H. Yeh*

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

The effectiveness of impurity gettering of bipolar devices by argon implantation is described. The excess BV_{CEO} leakage and "piped" device improvement are used as the criteria for evaluation. Implantation gettering when done at the preemitter step is found to be more effective than at the prebase step of the total processing sequence. The significantly higher yield obtained by the preemitter gettering supports the model of enhanced diffusion along dislocations for the formation of pipes in the bipolar devices.

Recently, gettering has been receiving renewed attention throughout the semiconductor industry. This is due to the advancements made in device technology, which not only demands lower leakage characteristics for logic or memory devices than before, but also makes it imperative to have a very high percentage of operational devices in the large integrated circuit chip. With this criteria in mind, an improvement definitely is needed to achieve higher final chip yields.

Extensive work on the effectiveness of various diffusion gettering schemes (1-9) for reducing junction leakage has been well established. Mechanical damage (2) produced by sandblasting or lapping has also been demonstrated to be an effective getter. Damage created by ion implantation (10-15) clearly demonstrated its ability to getter metallic impurities and reduce excessive leakage. A comparison of various species of implant *vs.* a standard phosphorus diffusion for gettering of Au, clearly demonstrated the effectiveness of implant damage (15).

In this paper, we are going to address the effectiveness of impurity gettering by argon implantation. The results to be presented here utilize a bipolar test structure composed of several different sizes, single and multiemitter transistors. Standard electrical testing and the aluminum anodization method (16) were utilized to determine yields and defect density. Gettering was done at two different processing steps, *i.e.*, prebase and preemitter, to determine which step is more effective in curing the excessive BV_{CEO} leakages or "piped" devices in the integrated circuits.

Experiments

A block flow diagram of the processing sequence is illustrated in Fig. 1. A total of sixteen Czochralski-grown p-type wafers, of <100> orientation and 10-20 Ω-cm resistivity, were utilized in the experiment. Both sides of the wafer were chem-mechanically polished.

* Electrochemical Society Active Member.
Key words: impurity gettering, device yield improvement.

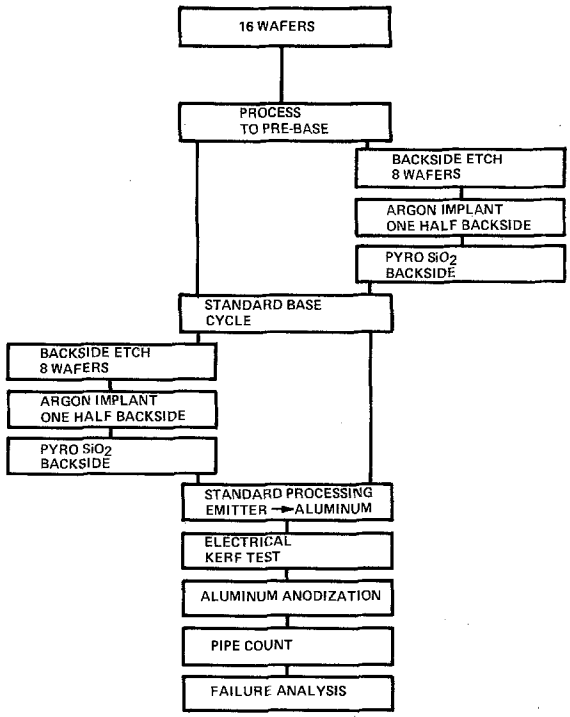

Fig. 1. Block diagram of the processing sequences

Conventional bipolar processing, which included an arsenic capsule subcollector and a 2 μm, n-type, 2 $\times$ 10^{16} cm^{-3} epitaxial layer, was used until the prebase step. The back side of eight wafers was stripped clean just prior to the base diffusion. Half the back side of each wafer was then implanted with 6 $\times$ 10^{15} cm^{-2} argon at 70 keV according to Fig. 2.

An aluminum mask was used to prevent implantation into the control half of the wafers. The half-wafer concept reduced the number of wafers required for good statistical results. A 1000Å pyrolytic SiO_2 layer was deposited onto the back side of the wafers at 1000°C for 5 min, after the implantation for the prebase portion of the experiment. This layer served two purposes. First, it provided a 15 min, 1000°C heat cycle which included the heating up, deposition, and cooldown times in order to accomplish part of the gettering prior to the actual base diffusion. Second, it served as a diffusion mask for the boron and arsenic which may compete with the process of gettering by argon implantation for some impurities, such as Cu, Fe, Ni, and Au, in the active device areas. After these modifications to the process the wafers proceeded through the BBr_3 base deposition at 875°C and a drive-in cycle of 925°C and resulted in a sheet resistance of 440 $\Omega/\square$. Then followed by an arsenic capsule emitter diffusion at 1000°C for 115 min, a sheet resistance of 14 $\Omega/\square$ resulted. Aluminum metallization then followed.

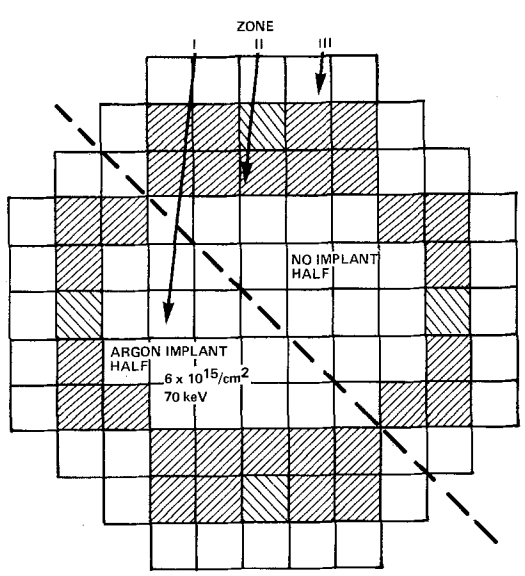

Fig. 2. Map of argon implant and zones on wafer

For the preemitter portion of the experiment, the wafers received standard processing through postbase drive-in. The back side of the wafers were stripped and implanted with argon as previously described. The preemitter wafers also received the pyrolytic SiO_2 layer on the back sides of the wafers. The wafers were then processed with arsenic capsule emitter diffusion and metallization as described before.

Results

The pipe densities to be discussed in this paper were calculated according to the relationship of

$$Y = 1 - P = e^{-\lambda A} \qquad [1]$$

where P is the probability that a device is piped, A is the total emitter area, λ is the defect density, and Y is the over-all yield of the devices.

Two different device structures were utilized in the experiments: a multiemitter transistor (MET), which contains 316 emitters in a common base of ~210 mil^2 with each individual emitter area of 0.2925 mil^2 (0.45 mil $\times$ 0.65 mil); an array of 1800 small single transistors, each having 0.0525 mil^2 of emitter area (0.15 mil $\times$ 0.35 mil) distributed in an array structure of ~35,000 mil^2.

The MET structures were electrically probed first. The criteria for a piped device is defined as BV_{CEO} equal to or less than 3V at 100 μA. The 316 emitters were tied together with common aluminum metallurgy. After the electrical testing, the MET structures and the array of small transistors (since they were too small for electrical testings) were anodized at 2.5V for 45 min in an electrolyte of 8% H_2SO_4 to decorate the aluminum on devices which are piped. One bad emitter in any of the 316 or 1800 emitters of the MET or array structure, respectively, was counted as a failed device for that particular structure. The over-all yield of the wafer is measured directly by counting the good devices, and the λ's are calculated according to Eq. [1].

All the data plots have the average values and are separated into three equal wafer zones as illustrated in Fig. 2.

Table I summarizes the results of the MET with the average λ's and yields. The preemitter gettering improves the defect density approximately by a factor of 3, from 11.90 to 3.76 $\times$ 10^{-3} defects per mil^2, whereas the prebase improves it by a factor of approximately 2, from 10.50 to 4.36 $\times$ 10^{-3} defects per mil^2. The overall yield on a whole wafer can be improved from 42.9 to 72.2% by the preemitter gettering process and from 44.9 to 63.4% by the prebase gettering process. The detailed improvement of the yield on three different zones of the wafer due to the two gettering processes is plotted in Fig. 3. The average yields for the wafers without gettering in zones I, II, and III are 76, 43, and 12 ~ 17%, respectively. This zonal dependency of yield indicates the susceptibility of wafers to dislocation generation at the periphery caused by handling at the various processing steps. These dislocations, in turn, tend to induce impurity precipitation or to cause enhanced diffusion to form pipes. The detailed aspect on the possible mechanism of pipe formation is given in the discussion section. According to Fig. 3, the prebase or preemitter gettering improved the yield by only about 2-10% to a final level of 75-84%, respectively, in zone I of the wafer. However, in zone II, the yield is improved by 30-37% to a final level of 73 and 80%, respectively. Likewise, in zone III, the yield is increased by 28-36% to a final level of 40 and 53%, respectively.

Table I. Yield and defect density of MET

Wafer zone	Preemitter Gettered Y (%)	Preemitter Gettered λ (10^{-3})	Preemitter Control Y (%)	Preemitter Control λ (10^{-3})	Prebase Gettered Y (%)	Prebase Gettered λ (10^{-3})	Prebase Control Y (%)	Prebase Control λ (10^{-3})
I	83.6	1.95	74.4	3.21	75.2	3.10	73.4	3.36
II	79.9	2.44	42.4	9.33	74.2	3.24	44.5	8.80
III	53.1	6.88	11.9	23.10	40.8	9.74	16.8	19.40
Avg	72.2	3.76	42.9	11.90	63.4	5.36	44.9	10.50

λ = Defect density, number of defects per mil².
Y = Yield of the devices in percent.

Table II. Yield and defect density of small transistors

Wafer zone	Preemitter Gettered Y (%)	Preemitter Gettered λ (10^{-3})	Preemitter Control Y (%)	Preemitter Control λ (10^{-3})	Prebase Gettered Y (%)	Prebase Gettered λ (10^{-3})	Prebase Control Y (%)	Prebase Control λ (10^{-3})
I	60.2	5.70	38.4	10.80	39.4	10.5	37.2	11.10
II	34.2	12.10	14.6	21.60	28.9	14.0	14.4	21.70
III	13.0	22.90	3.74	36.90	10.2	25.7	3.14	38.90
Avg	35.8	13.60	18.9	23.10	26.2	16.7	18.2	23.90

λ = Defect density, number of defects per mil².
Y = Yield of the devices in percent.

The larger improvement in zone II and III signifies that the pipe-forming defects are more numerous in these two zones than the one in the center and can be drastically reduced by the implantation gettering.

Table II summarizes results obtained on the small transistor structures. As previously shown for the MET, a significant improvement of defect density can also be realized by gettering. Preemitter achieves 1.7 times improvement on the average, *vs.* only 1.4 for the prebase. The over-all leakage limited yield on a whole wafer can be improved from 18.9 to 35.8% due to preemitter gettering process, and from 18.2 to 26.2% due to prebase gettering process. The detailed improvement of the yield on three different zones of the wafer due to the two gettering processes is plotted in Fig. 4. The average yield of the wafers without gettering in zone I, II, and III is only 37, 14, and 3%, respectively. They are much lower than those yields corresponding to the MET structure. This zonal dependency of yield for the small transistor structure points out once more the wafers' susceptibility to pipe formation at the peripheral area, even to a more significant degree as compared to the MET structure. But, nevertheless, after the prebase gettering, the yields are improved to 39.4, 28.9, and 10.2%, respectively, in zone I, II, and III of the wafers, and after the preemitter gettering, the yields are improved even more to 60.2, 34.2, and 13%, respectively, in zone I, II, and III of the wafers.

Although both the prebase and preemitter implantation gettering improve the yields of the small transistor structure considerably, they are still much lower than the yields of the MET structure. Searching some parameters to explain this phenomenon, Fig. 5 may offer something for contemplation. It illustrates the effect of the emitter perimeter to its area's ratio, *P/A*, on the leakage limited yield, and clearly indicates that the yield decreases as the ratio of the *P/A* increases. The work of Hu *et al.* (17) on dislocation propagation and emitter edge defects which are generated under

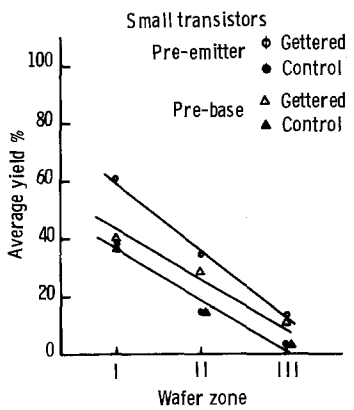

Fig. 4. Yield improvement and zone dependency on preemitter or prebase implanted wafers for small transistors.

appropriate condition, cast off small dislocation half-loops. These half-loops which straddle the edges, may offer some explanation why the over-all yield is still low for the smaller transistors as compared to the MET, even after its improvement by either the preemitter or prebase gettering process.

Discussion

It is clearly demonstrated from the obtained results that the argon implant damage gettering is an effective method to improve the leakage-limited yield of the bipolar devices. The implantation gettering applied at the preemitter step appears to be more effective than when applied at the prebase step.

The lower gettering efficiency of the prebase process perhaps can be explained by the following. The prebase argon implanted wafer has to go through two more high temperature steps, namely, the base diffusion and drive-in, than the preemitter argon implanted wafers. These two high temperature processes anneal out some of the implantation damage, thus releasing some of the impurities associated with them. Once the impurities are redissolved, they can be redistributed toward those defects which were originally in the active device area or toward those new defects being created during the emitter diffusion to cause the formation of pipes or leaky junctions. Consequently, the efficiency of the prebase argon implantation gettering process cannot be as high as the preemitter process. Because preemitter gettering gives a higher yield than the prebase gettering, it not only renders further support to the pipe formation model caused by the enhanced diffusion along dislocations (4, 18, 19), but also rules out one of the other possible models (18) caused strictly by the impurity precipitates alone, as proposed by Lawrence (20). In his model, the pipes are claimed to be formed at the locally retarded base diffusion, *i.e.*, the base-collector junction, and the subsequently diffused emitter-base junction. However, the locally retarded base-collector junction is caused mainly by the copper or precipitates of other metals which are formed near the wafer surface before the base diffusion is carried out. Therefore if this model of impurity precipitation is thought to be responsible for the pipe formation, then the prebase implantation should be able to getter the precipitates, thus minimizing the retarded base diffusion and reducing the pipe formation. It should give higher yield than the preemitter gettered ones, since such a defect caused by the retarded base diffusion would already be formed by the time the preemitter gettering is given to the wafers.

On the other hand, Barson *et al.* (4) proposed that an enhanced emitter (phosphorus) diffusion along the stacking faults or dislocations is responsible for the pipe formation. The pipe densities are markedly increased when gold is being introduced before the emitter diffusions. Work by Campbell *et al.* has also shown an enhanced arsenic diffusion along epitaxial defects (21). In this study, although we did not purposely introduce any metal contaminants (such as gold or copper, etc.) during the process and used arsenic instead of phosphorus for the emitter, we feel that the enhanced diffusion model holds true here also. The argon implant damage sites in the back of the wafers are able to compete with the few crystalline defects in the active areas of the devices for the impurities, which were unintentionally introduced into the wafer during the processes. In other words, the argon implanted damage sites in the back of the wafers are the preferred sites for precipitation. When the arsenic emitter is introduced to the preemitter gettered wafers, the few dislocations in the base and collector regions have very few precipitates on them and thus much less enhancement of arsenic diffusion occurs. Consequently, a reduction of pipes and leaky junctions is realized.

Summary

Argon implantation has been successfully demonstrated in this paper to be an effective getter of impurities for the bipolar devices. It can reduce the excessive BV_{CEO} leakages, or "piped" devices, and thus increase the over-all yield of the integrated circuits. Although both the prebase and preemitter implantation are found to be useful, the latter is more effective. The significantly higher yield obtained by the preemitter gettering supports the model of enhanced diffusion along dislocations for the formation of pipes in the bipolar devices.

Hydride VPE Growth of GaAs for FET's

G. B. Stringfellow* and G. Hom

Hewlett-Packard Laboratories, Palo Alto, California 94304

ABSTRACT

Epitaxial layers of GaAs suitable for fabrication of MESFET devices have been grown by the hydride VPE technique (AsH_3 + HCl + Ga + H_2). The materials properties and FET characteristics of devices fabricated in this material are similar to those for LPE, and the more common $AsCl_3$ VPE growth techniques. The uniformity of sheet resistance of this material over a substrate area of ~6.5 cm^2 is typically ~5% (standard deviation from the mean). A new technique has been developed for the growth of buffer layers. The background doping level of 4-9 × 10^{15} cm^{-3} is found to be reduced to $<10^{14}$ cm^{-3} by the addition of NH_3 to the AsH_3 stream. More complex $n^+/n/$ buffer layer structures have been grown in a single operation by simply programming gas flow rates during the run.

GaAs epitaxial layers for microwave devices are usually grown by either LPE from a Ga-rich melt (1, 2) or by VPE using the $AsCl_3$ technique (3-5). Less extensive work has been performed on the hydride (AsH_3 + HCl + Ga) VPE technique (6-8) and recently molecular beam epitaxy (MBE) has been shown to be suitable for GaAs FET devices (9). The reason for the limited utilization of the hydride VPE process which has been highly developed for $GaAs_{1-x}P_x$ LED applications lies in the fact that the residual impurity level of GaAs grown by this technique is relatively high, typically 10^{15}-10^{16} cm^{-3} (6, 8, 10). LPE and $AsCl_3$ VPE processes routinely produce material with $N_D - N_A < 10^{14}$ cm^{-3} and $\mu_{77} > 10^5$ cm^2/V sec (1-5, 11). For Gunn effect devices, such low doping levels are required. For FET's, the active layer is doped to ~10^{17} cm^{-3} and low carrier concentrations are necessary only for the buffer layer separating the active layer from the Cr doped semi-insulating substrate. The buffer layer is necessary since the substrate may produce undesirable effects near the substrate/epilayer interface. On the other hand, the highly developed hydride VPE technique offers distinct advantages over both LPE and $AsCl_3$ VPE techniques. It offers maximum flexibility of operation. For example, in the hydride technique, the Ga sees only HCl and H_2 and need not be saturated with As as is necessary in LPE and the trichloride technique. This saves a step in the growth process and facilitates rapid change of composition during alloy growth. Furthermore, the III/V ratio in the vapor phase and hence solid stoichiometry is an independent variable only in the hydride system. Another advantage of the hydride system is its suitability for commercial applications, since it has been developed to large-scale production capacity for GaAsP growth. This contrasts with $AsCl_3$ and LPE systems which are typically laboratory scale. LPE has the additional drawback of typically providing inadequate control of growth morphology and thickness uniformity (12, 13).

The purpose of the present paper is to describe the application of a standard hydride process to the production of GaAs for FET applications. Particular emphasis will be placed on a new technique for the production of layers with low residual doping levels ($<10^{14}$ cm^{-3}).

Experimental

The rf heated reactor used in this work was developed for GaAsP growth (9) but a modified version used for GaAs is shown in Fig. 1. The modifications include the addition of four-way valves in close proximity to provide a short residence time of the reactants in the gas lines and thus allow the rapid, well-controlled initiation and termination of growth necessary for precise control of the thickness of submicron layers. The gases used are hydrogen purified by diffusion through a Pd-Ag membrane and electronic grade AsH_3, HCl, and H_2S (used for n-type doping).

The growth conditions were selected to give (*i*) a growth rate of ~0.1 μ/min which yields the necessary control of thickness for submicron layers; (*ii*) good morphology (III/V ratio ~6); and (*iii*) insensitivity to temperature gradients of ~15° existing across the graphite pedestal. The latter is accomplished by growing at a substrate temperature of ~750°C, near the maximum of the growth rate *vs.* temperature curve where the growth rate is least sensitive to temperature (14). The flow rates used are: f_{HCl} = 2.0 scc/min, f_{AsH_3} (1%) = 30 scc/min, f_{H_2} = 300 scc/min.

All substrates were Cr-doped semi-insulating ($\rho > 10^6$ Ω-cm) GaAs oriented 2.5° ± 0.5° off the (100) plane toward (110). Substrates were prepared directly

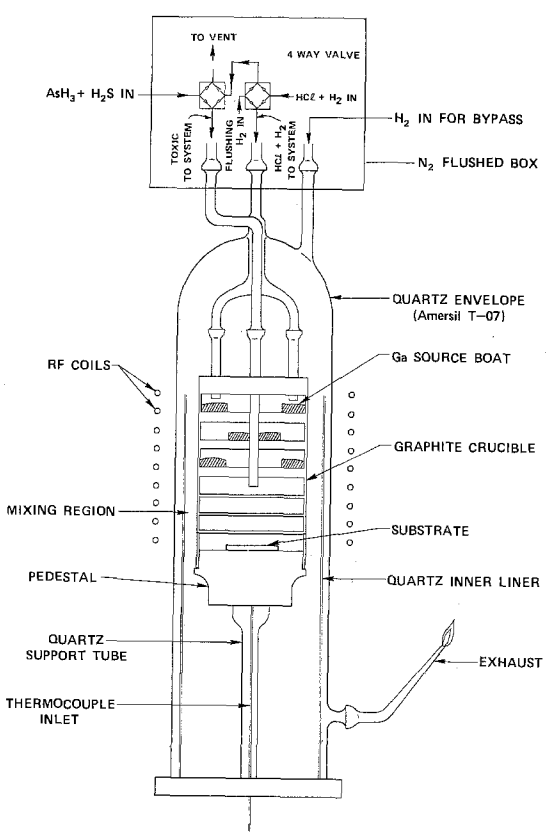

Fig. 1. Schematic diagram of VPE reactor used for GaAs growth

* Electrochemical Society Active Member.

Key words: vapor phase epitaxy, GaAs, buffer layers, FET material.

before placing them in the reactor using standard Br-methanol polishing techniques.

During heat-up the substrate is maintained in a $AsH_3 + H_2$ ambient, $P_{AsH_3} \sim 10^{-3}$, to avoid deleterious surface decomposition. Growth is initiated by turning the four-way HCl valve near the entrance to the reactor. The same valve is used to terminate growth and the sample is cooled in $AsH_3 + H_2$.

Measurements were made to determine thickness uniformity and carrier concentration and mobility. The latter were performed using standard van der Pauw techniques. The thickness and doping uniformity were monitored using groove and stain techniques, standard *C-V* profile measurements, and a new contactless technique for conductance measurements (15). The technique consists of placing the resistive layer (on a dielectric substrate) in a waveguide, perpendicular to its axis. The loss at 18 GHz is then measured to determine the sheet resistance of the epitaxial GaAs layer. The sheet resistance of an entire wafer could be rapidly sampled at 3 mm intervals using this technique.

Results

Single layer structures.—With appropriate care in substrate preparation and proper substrate orientation, the morphology of submicron layers is perfectly specular with no visible morphological defects such as hillocks, pyramids, or terraces even when viewed using the Nomarski interference technique. Small pits associated with particles left on the surface after substrate preparation are frequently observed.

For FET structures, the layers are S-doped to $\sim 1 \times 10^{17}$ cm^{-3} using H_2S. In Fig. 2, the carrier concentration is plotted *vs.* H_2S partial pressure. The results plotted on a log-log scale follow a linear relationship with a slope of ~1.1, similar to previous results reported by Enstrom *et al.* (8). The residual doping level with no intentional doping was found to be in the range of $4\text{-}9 \times 10^{15}$ cm^{-3}. A plot of room temperature mobility *vs.* $N_D - N_A$ is shown in Fig. 3. The mobilities fall on the solid line calculated after Rode and Knight (16) for a constant acceptor concentration of 5×10^{15} cm^{-3}. For $n = 1 \times 10^{17}$ cm^{-3}, values of room temperature mobility of 4500 cm^2/V sec are consistently observed. *C-V* profiles of $N_D - N_A$ *vs.* depth from the epilayer surface were obtained as illustrated in Fig. 4. In general, the doping in the epilayer is constant with an abrupt decrease at the substrate/epilayer interface.

The uniformity of sheet conductance (doping level × thickness) is shown for a representative sample in Fig. 5. The data obtained using a contactless microwave loss technique (15) indicate that the thickness gradually increases toward the outside of the substrate. The values at the very edge are unreliable because of inaccuracies in the measurement technique. Eliminating these data labeled A, B, and C in the figure results in a standard deviation from the mean of <5%. Values of ~5% for a 6.5 cm^2 substrate area are routinely observed. Thus the hydride VPE system can be used to grow uniform layers well suited for FET fabrication.

Multiple layer structures.—FET's fabricated in VPE material grown directly on Cr-doped substrates were found to have back-biasing problems, *i.e.*, the transconductance of one FET under a given bias was found to be affected by the bias on an adjacent device or by the application of a bias to the substrate. This effect is occasionally observed in LPE material also and is thought to be due to states, possibly acceptors, at the substrate/epilayer interface (4, 17, 18). To avoid this and to effectively isolate the active region from the substrate, it is desirable to grow a buffer layer between the n epilayer and the substrate.

In LPE and $AsCl_3$ VPE systems, the buffer layer is usually simply an undoped layer. Values of $N_D - N_A$ of $<5 \times 10^{13}$ cm^{-3} have been reported by many workers for both the $AsCl_3$ system (3, 4, 11) and the LPE system (1, 2, 11). The hydride system is typically characterized by much larger residual doping levels in the range 10^{15}-10^{16} cm^{-3} although doping levels in the 5×10^{14} cm^{-3} range have been claimed for specially selected AsH_3 and HCl cylinders (7).

Several approaches have been taken to reduce the doping level of GaAs for use as buffer layers. Cr doping is used to make melt-grown GaAs semi-insulating and has been used successfully as a dopant for semi-insulating VPE material (19), but is less successful in LPE systems(20). A better approach is to attempt to reduce the concentration of contaminants, rather than over doping with a deep-lying impurity. Since Si is believed to be a major contributor to the contamination, the addition of H_2O to the system to form SiO_2 has been successfully used to control residual doping (21, 22); however, O itself is an undesirable deep donor which limits the usefulness of this approach. A similar approach using NH_3 to remove Si from the system as Si_3N_4 has been effective in reducing the background doping level of GaP grown in similar systems from $\sim 10^{17}$ cm^{-3} to $<10^{15}$ cm^{-3} (23).

For our VPE system using electronic grade AsH_3 and HCl, the residual doping level of 4-9 $\times 10^{15}$ cm^{-3} is much too high for buffer layer growth. Attempts were made to reduce this doping level by intentional introduction of NH_3 and, alternatively, H_2O into the system. The H_2O approach was abandoned at an early stage because it resulted in very poor morphology, even though it did act to reduce n to $\sim 10^{14}$ cm^{-3}.

To test the effect of NH_3, partial pressures of up to 6×10^{-2} Torr were introduced during the growth of otherwise undoped epilayers. The morphology was found to be excellent, at least as good as without NH_3 present. The presence of NH_3 also dramatically reduced the background doping level to below 10^{13} cm^{-3} in some cases. Unexpectedly, the residual doping level was observed to begin to increase after $\sim 3\mu$ of growth had occurred, as demonstrated in Fig. 6-8, where the doping profiles for buffer layers grown with three different NH_3 partial pressures of 0.06, 0.04, and 0.02 are plotted. Clearly the value of $N_D - N_A$ is reduced by the presence of NH_3, but the total thickness over which $N_D - N_A$ is reduced and the magnitude of the reduction are dependent on the NH_3 partial pressure. In Fig. 9, the value of $N_D - N_A$ observed is plotted *vs.* NH_3 partial pressure.

To make useful FET structures, it is necessary to introduce H_2S to form an abrupt n/buffer layer interface. It was found that simply turning on the H_2S during the growth results in a gradual increase in doping level, the resulting n/buffer layer interface not being abrupt enough for FET applications. By turning off the HCl flow for ~ 5 min while the H_2S concentration is being equilibrated and then continuing growth, abrupt profiles are obtained. An example is shown in Fig. 10.

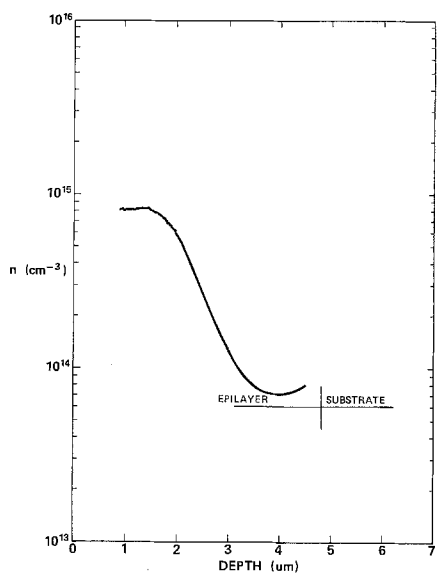

Fig. 7. Doping profile obtained from C-V measurements on a buffer layer grown with $p_{NH_3} = 4 \times 10^{-2}$.

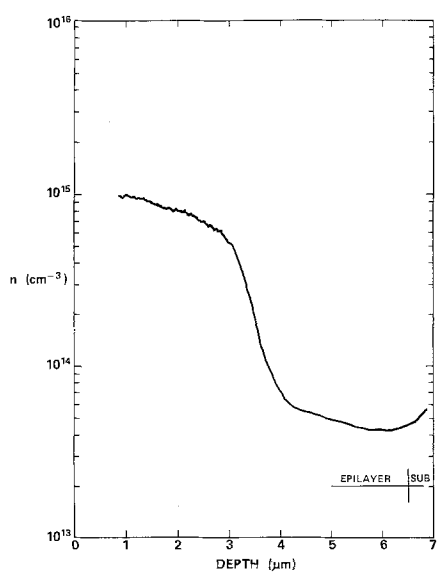

Fig. 6. Doping profile obtained from C-V measurement on buffer layers grown with $p_{NH_3} = 6 \times 10^{-2}$. The epilayer thickness was determined by the cleave and stain technique at the Schottky barrier.

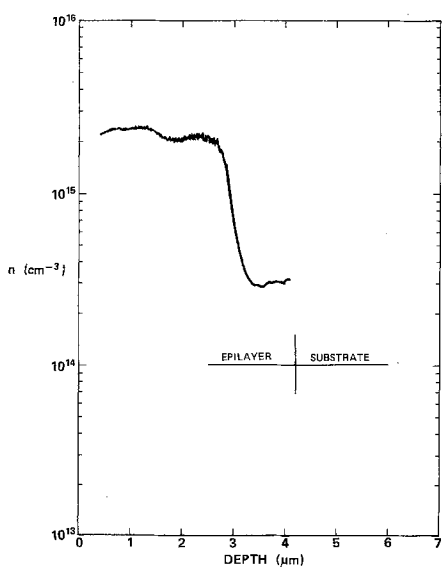

Fig. 8. Doping profile obtained from C-V measurements on a buffer layer grown with $p_{NH_3} = 2 \times 10^{-2}$.

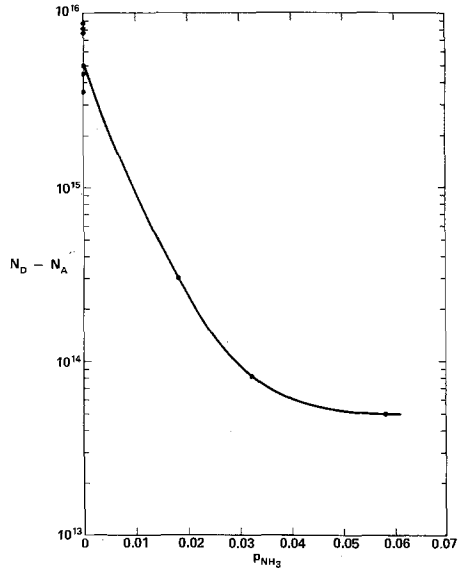

Fig. 9. Carrier concentration, measured at a position 1-2 μm from the buffer layer/substrate interface, vs. NH_3 partial pressure in the system during growth.

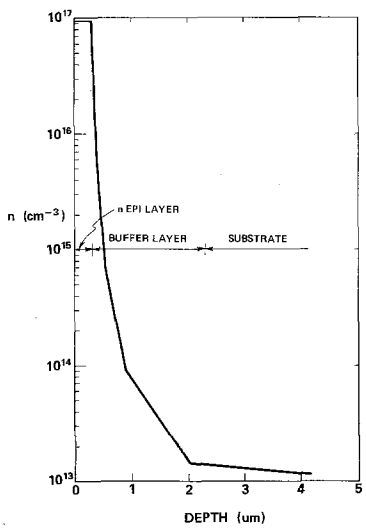

Fig. 10. Doping profile obtained from C-V measurements of n/buffer/substrate structure. The n-layer thickness is ~0.3μ, calculated knowing growth rate and time of growth and the buffer layer thickness is 2μ obtained by staining a cleaved cross section near the Schottky barrier.

The steepness of the profile can be characterized by the slope in micrometers/decade. This number is typically 0.05 μm/decade for n/buffer layer structures and 0.05-0.1 μm/decade for n/substrate structures. Another important characteristic of the profile is the absence of evidence for states at the substrate/buffer layer interface. Measurements on FET's fabricated in n layers with the buffer layer present indicate that the backbiasing effect is essentially eliminated. Furthermore, no looping in the low frequency *I-V* characteristics was observed (24).

The reproducibility of growing the n/buffer/substrate structures is excellent with run-to-run deviation in layer conductance being ~10%. The uniformity of the n-layer sheet resistance for the n/buffer layer structures is similar to n layers grown directly on the substrate. Typically, the standard deviation is ~5%.

Recently, n^+/n/buffer layer structures have proven to be superior for high power FET's (25). Such structures can be readily grown using the present system by simply increasing the H_2S flow rate after the 0.3μ thick 10^{17} cm^{-3} active layer growth is completed. The doping profile obtained by successively thinning such a structure is shown in Fig. 11.

Discussion

A potential problem with NH_3 additions to the system to produce buffer layers is that it might introduce N into the GaAs layer and adversely affect its electron mobility (23). Experimentally, the doping level cannot be determined since the layer of interest is <3 μm thick with n $<10^{14}$ cm^{-3}. For such a layer, surface states would cause depletion of the entire layer in a Hall effect or van der Pauw specimen. An idea of the effect of N doping can be obtained by comparison with GaP results. In GaP, the nitrogen is introduced intentionally because it acts as a radiative recombination center to improve the efficiency of green LED's. However, the concentration of N expected to be incorporated into the GaAs solid is small because of the large difference in size between N and As. A quantitative estimate of the solid solubility and distribution coefficient of N in GaAs can be made using thermodynamic calculations which correctly predict these quantities in GaP. The solid solubility is simply given by the expression

$$x = \exp(-\Delta H_D^*/RT)$$

with ΔH_D^* calculated from the DLP model (26) using the expression

$$\Delta H_D^* = \Omega^s = 4.375 \times 1.15 \times 10^7 \, \Delta a_0^2/a^{4.5}$$

to yield $\Omega = 4.55 \times 10^4$ cal/mole and $x^* = 5 \times 10^{12}$ cm^{-3}. The actual concentration may be somewhat larger than this due to kinetic effects, as observed for GaP (27), however, an upper limit is given by the NH_3 partial pressure times the nitrogen distribution coefficient. The distribution coefficient may be calculated again using the DLP model

$$k = \frac{x_{GaN^s}}{p_{NH3}} = \frac{p_{GaCl}}{p_{HCl}p_{H_2}} \exp\left(\frac{-\Delta G^\circ}{RT}\right) \frac{1}{\gamma_{GaN^s}}$$

ΔG° for GaN formation was obtained from Thurmond and Logan (28) and the activity coefficient of GaN in solid GaAs-rich phase is given by the expression

$$RT \ln \gamma_s = \Omega^s$$

with $\Omega = 4.55 \times 10^4$ cal/mole as calculated above. The values of p_{HCl} and p_{GaCl} are the partial pressures at the growth interface and hence must be calculated. Using standard thermochemical techniques (27), we obtain values of 9.25×10^{-4} and 4.76×10^{-3} for p_{HCl} and

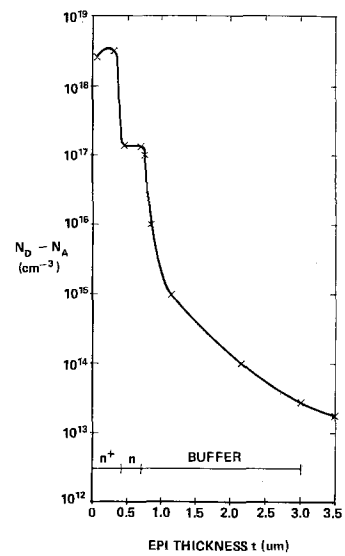

Fig. 11. Doping profile for n^+/n/buffer layer structure obtained by successive etching and C-V profile measurements.

p_{GaCl}, respectively. Multiplying the distribution coefficient by the highest NH_3 partial pressure used, 6×10^{-2}, yields the highest N concentration expected, 10^{14} cm^{-3}. Thus, thermochemical calculations indicate the nitrogen concentration in the solid should be between 5×10^{12} and 10^{14} cm^{-3}. Even at 10^{14} cm^{-3} the effect on the mobility would be small. A calculation of the mobility limited by N scattering at this doping level (27) yields a mobility many orders of magnitude larger than the polar optical mode scattering limited mobility.

The reason for the increase in $N_D - N_A$ after the first few microns of growth is unclear. Three possible mechanisms were tested and found untenable. (*i*) The possibility of NH_3 decomposition during the run was tested by quantitative analysis of the NH_3 content of exhaust gases collected from the cold reactor, hot reactor before growth, and hot reactor immediately after the termination of growth. Less than 3% decomposition was detected in all cases. (*ii*) A similar increase of doping level in buffer layers grown by the $AsCl_3$ VPE technique has been reported (4, 18). The effect was attributed to the out-diffusion of an acceptor from the substrate to compensate the adjacent section of the buffer layer. Thus slower growth rates which give longer times for the diffusion to take place were intentionally adopted to maximize the effect (18). This mechanism was tested by simply growing several microns of undoped GaAs before introducing NH_3 into the reactor. The results, as shown in Fig. 12, indicate that the NH_3 is fully as effective when the growing layer is isolated from the substrate. (*iii*) Since impurities may well be released from the graphite during growth, the effect may be due to either acceptors being released during the initial 20-30 min of growth or donors being released after 30 min due to diffusion through a skin purified by a high temperature HCl cleaning of the graphite between runs. This hypothesis was disproved by noting that the same phenomenon is observed with no clean-up between runs. To date, we do not understand the cause of the increase in doping after 2-3μ of growth but since we need only 2μ buffer layers, the technique is practical. Our experience with more than 100 runs indicates that the effect is reproducible. Similar profiles are measured for all runs investigated.

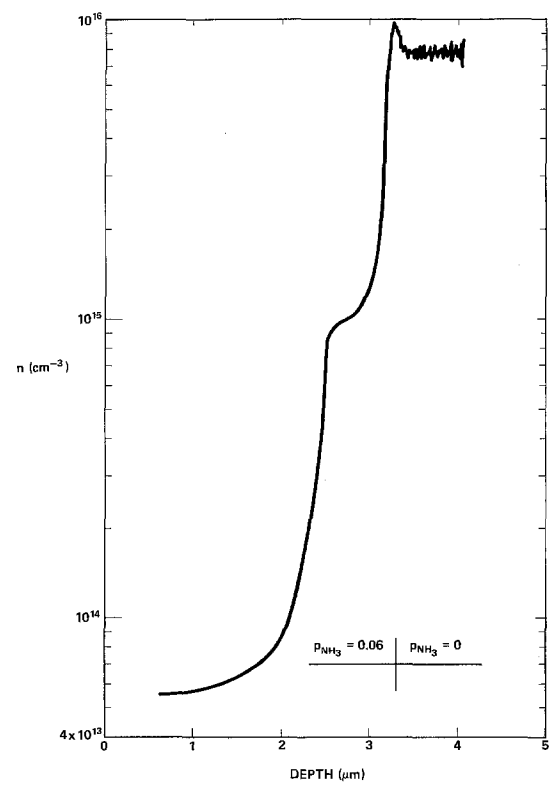

Fig. 12. Doping profile (from C-V measurements) on an epitaxial layer for which the first 3.0μ were grown undoped without NH_3 after which NH_3 ($p = 6 \times 10^{-2}$) was introduced for the remainder of the growth cycle.

Summary

The standard $AsH_3 + HCl + Ga + H_2$ VPE system widely used for large scale commercial $GaAs_{1-x}P_x$ and GaP growth has been demonstrated to be suitable for the growth of GaAs for FET applications. The material properties and FET characteristics of devices fabricated in this material are similar to those for $AsCl_3$ VPE and LPE material. The uniformity of sheet resistance is typically 5% (standard deviation from the mean).

A technique has been developed for the growth of buffer layers with $n < 10^{14}$ cm^{-3} by adding NH_3 to the gas stream. This makes the system versatile and flexible to the extent that multiple layers can be grown with nearly any desired profile from abrupt to gradually increasing, with doping levels between 10^{14} and $> 10^{18}$ cm^{-3}. Furthermore, this can be done in a single operation by simply programming gas flow rates.

The hydride VPE system has clear advantages in that it is more flexible and has been scaled up for large-scale commercial production and hence may ultimately be the most useful technique for commercial production of GaAs for FET applications.

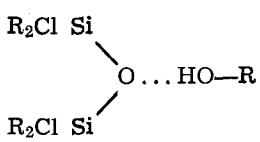
Technical Note

On SiOH and SiH Groups in SiO_2 Films on Silicon

A. G. Revesz

COMSAT Laboratories, Clarksburg, Maryland 20734



There is increasing evidence that hydrogen in various forms plays a very important role in almost all aspects of Si/SiO_2 interface structures; most of the evidence has been inferred from very sensitive but nonspecific electrical measurements.[1] Various aspects of incorporation of hydrogen into the SiO_2 film during its growth and postoxidation treatments have also been studied with radioactive tracer techniques (3-6). These techniques are sufficiently sensitive, but they cannot distinguish between the various forms of hydrogen. This information can be obtained by internal reflection infrared absorption spectroscopy, as was demonstrated by Beckmann and Harrick (7). Subsequently, the same technique was also applied by Hughes and Pankey to Si/SiO_2 structures prepared under well-defined conditions with the intention of gaining insight into their irradiation behavior (8).

The purpose of this note is to enhance our understanding of the complex role of hydrogen in thermally grown SiO_2 films on silicon by putting the results of Ref. (7) and (8) into proper perspective, particularly by comparing them with *IR* spectroscopic data of fused silica, silicate glasses, and various organosilicon compounds.

The most pertinent *IR* spectroscopic data of Ref. (7) and (8) are summarized in Table I. It should be noted that the "dry" and "wet" oxidization methods as described in Ref. (7) refer to an oxidizing ambient of oxygen with 60 ppm H_2O and oxygen saturated with H_2O at 85°C, respectively. The assignment of the various absorption peaks was discussed in detail (7), but this can be put into a better perspective by the following comparison. Fused silica may contain SiOH (silanol) groups which are isolated. That is, the H does not form a hydrogen bond with oxygen; the OH bond of these silanol groups absorbs at 3600 cm^{-1} (9). The OH bond in silanol groups formed by H_2O adsorption on the silica surface absorbs at 3750 cm^{-1} if there is no H-bond between adjacent SiOH groups, and at 3607 cm^{-1} if there is H-bonding between them. Adsorbed H_2O molecules which are H-bonded to surface SiOH groups absorb at 3480 cm^{-1} (10). Further comparison can be made with the absorption peaks of OH groups in organosilanols, which are around 3680 cm^{-1} (11). Although H-bonded silanol groups have not been observed in fused SiO_2, they occur in silicate glasses where they absorb in the range of 2600-3000 cm^{-1} (medium interaction), or at 2350 cm^{-1} (strong interaction) (9). The SiH bonds in SiH_4 and its derivatives absorb in the range of 2180-2260 cm^{-1} (12), and those present in chemically or electrochemically produced stain films on silicon surfaces absorb between 2000 and 2300 cm^{-1} (13).

Based on this comparison, some data in Table I warrant discussion. First, the absorption peak at 3700 cm^{-1} may indicate that the SiOH groups in that particular sample behave somewhat differently from silanol groups in fused SiO_2. Also, the 2800 cm^{-1} peak is unexpectedly high for SiH. The observation that these absorption peaks shifted to lower values (to 3600 cm^{-1} for OH and 2400 cm^{-1} for SiH) as a result of irradiation indicates that the bonds were considerably strained in the as-grown oxide film, and then relaxed during irradiation. There is additional evidence that this oxide film is structurally strained; its density increased by ~13% during irradiation (14). This increase is much higher than that observed with irradiated fused SiO_2 (~3%) (15). In the irradiation-induced relaxed state, both OH and SiH bonds absorb at wave numbers which are comparable with those given in Ref. (7).

The absorption peaks at 3375 and 3200 cm^{-1} were attributed to H-bonded OH groups in Ref. (7) and (8), respectively. This assignment is not so obvious, because it is known that silanol groups in fused silica do not form H-bonds (9). The shifts in the absorption peaks due to H-bonding (relative to isolated OH groups) are 225 and 500 cm^{-1}. These values are larger than those characteristic of

(where R is an organic group), or similar configurations: 45-85 cm^{-1} (16). In SiO_2 the oxygen atoms attached to the Si atoms are more electronegative than chlorine or organic groups; hence, the effective nega-

Key words: SiO_2 films, hydrogen and thermal growth, *IR* spectroscopic data.

[1] In addition to electrical measurements, some more specific and/or structure-sensitive methods (EPR, cathode-luminescence, electron injection, etc.) have also demonstrated the effects of hydrogen. These results and other chemical and structural aspects of the Si/SiO_2 interface are summarized in Ref. (1).
The effects of low temperature hydrogen treatment are summarized in Ref. (2).

Table I. Average concentration (cm^{-3}) of Si-OH and Si-H groups in SiO_2 films

Oxidation	Annealing method	Irradiation, 10^8 rad (Si) (no field)	Observed absorption peak (cm^{-1}) and assignment: ~3700 OH	3600 OH	3375 OH...O	3200 OH...O	2800 SiH	2400 SiH	~2350 SiH	2250 SiH...O

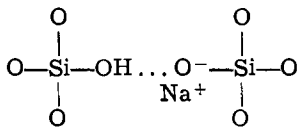
Thermal (8) (dry O_2, Si tube)	1000°C, N_2, 30 min	Yes				2.9×10^{20}			1.8×10^{21}	

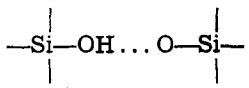
The thermal oxidation and heat-treatments in Ref. (7) were performed in SiO_2 tube furnaces.
• Could not be resolved.



tive charge on the bridging oxygen between two Si atoms is even less [due to increased $d\pi$-$p\pi$ bonding between silicon and oxygen (16)], and the shift resulting from H-bonding would be smaller yet. Therefore the extent of shift indicates that H-bonding in these SiO_2 films does not involve bridging oxygen.

The 225 cm^{-1} shift (from 3600 to 3375 cm^{-1}) (7) is comparable to that characteristic of H-bonding in organo-silanols

$$R_3Si—OH \ldots {}_H O—SiR_3$$



which ranges from 185 to 223 cm^{-1} (11). However, since the density of the SiOH groups in that particular SiO_2 film is $\sim 5 \times 10^{20}$ cm^{-3} (corresponding to 1/40 for the OH/Si ratio), it is unlikely that the silanol groups would form H-bonds with each other provided that their distribution is more or less uniform. On the other hand, if the silanol groups were aligned preferentially along structural channels (1), then H-bonding between them might be possible. It was shown that large concentrations of hydroxyl (6) and water (5) can be injected into SiO_2 films; it was suggested in both cases that structural channels are responsible for the effect. It is conceivable that SiOH groups along these channels are more similar to those adsorbed on SiO_2 surfaces than to those present in bulk-fused silica. Another possibility is that the hydrogen-bonded silanol groups are confined to a relatively small region in the SiO_2 film rather than being distributed uniformly along channels, so that the local OH/Si ratio there is much higher than 1/40.

The larger shift attributed to H-bonding, 500 cm^{-1} (from 3700 to 3200 cm^{-1}) (8), is more comparable to those characteristic of silicate glasses: 640-800 cm^{-1} (9). In the case of glasses, the H-bond forms in the following manner

In this configuration the oxygen adjacent to the sodium is more ionic than in the silanol-silanol configuration; consequently, the H-bond is stronger and the shift in the OH absorption peak is larger. It is known that, depending on preparation conditions, the Na concentration in thermally grown SiO_2 films can be between 10^{15} and 10^{19} cm^{-3}. The upper limit is ten times less than the concentration of OH groups exhibiting the large shift. Thus, it is possible that Na present in the SiO_2 film is partially responsible for the effect.

Another, and even more likely, possibility is that the OH groups form H-bonds with nonbridging oxygen atoms which are not associated with a Na^+ ion

These nonbridging O atoms probably arise from defect reactions associated with the growth of the SiO_2 film (1). Since this nonbridging oxygen is considerably less ionic than that associated with Na^+ but is more ionic than the bridging oxygen, it is expected that the shift in the OH absorption is less than 640-800 cm^{-1}. It is very possible that the 100 cm^{-1} shift attributed to SiH...O bond formation (7) also involves nonbridging oxygen. The nonbridging oxygen may capture a hole

$$\equiv Si—O \rightleftarrows \equiv Si—O^- + h^+$$

In this case it is more ionic; the ionicity depends on the interaction with the hole. With increasing ionicity, the H-bonding could approach that involving a nonbridging oxygen associated with Na^+.

From the viewpoint of gross structural features such as optical properties, etc. (as obtained by x-ray and electron diffraction), noncrystalline SiO_2 films on silicon are very simliar to fused silica; however, some transport properties exhibit significant differences which have been attributed to the presence of structural channels in thermally or anodically grown SiO_2 films (1). The above considerations on the nature of hydrogen-related bonds in these films supply the first evidence that some important chemical bonds are also different from those occurring in fused silica. It is evident from Table I that the detailed nature of these bonds and their density depend on the preparation technique. In this respect, it is particularly interesting to note the effect of postoxidation annealing in N_2 on the SiH groups: The 300°C treatment eliminated these groups from the anodically grown oxide, whereas the 1000°C treatment increased their density by a factor of five in the case of thermally grown film. This increase, as well as the increase in the OH concentration during N_2-anneal at 1000°C, can be attributed to unintentional "hydrogen doping" which results from the diffusion of hydrogen-bearing species (originating from water vapor in the ambient) through the hot SiO_2 tube (1). (Although SiO_2 tube furnaces were used in both cases, the two sets of experiments were performed in different laboratories.) Another effect related to the furnace tube is manifested in the order of magnitude lower OH and SiH concentrations

in N_2-annealed SiO_2 films prepared in a silicon tube furnace as compared with those prepared in a SiO_2 tube furnace (8). The results in Table I are not yet sufficient to fully characterize the various processing steps, but they indicate that the *IR* absorption technique could very well be used for this purpose. Thus, a well-planned combination of this analytical technique and careful sample preparation could lead to a much better control of Si/SiO_2 interface technology.

Recent application of this technique to chemically deposited Si_3N_4 films demonstrates this point: The density of Si-H and N-H groups present in these films depends on various process parameters, and many important properties of these films as used in memory devices are, in turn, determined by these hydrogen-bearing groups (17).

Brief Communications

Preparation of Magnetic and Dielectric Emulsion

S. Yamaguchi

National Institute for Researches in Inorganic Materials, Sakura-mura Niihari-gun Ibaraki-ken, 300-31, Japan

The phenomenon where a surface of austenitic stainless steel undergoes a strain-induced martensitic transformation when polished mechanically (1) is significant when preparing a magnetic and dielectric emulsion. An aqueous suspension of alumina was employed as the abrasive for rubbing the alloy surface. The rubbing sludge obtained behaved itself as a dielectric magnet, which contained the martensite particles.

Starting materials for the preparation were powdered gamma-alumina, water, and a plate of stainless steel (Cr: 18, Ni: 8). The surface of this malleable alloy was polished mechanically with an aqueous suspension of alumina. During this rubbing process, the abrasive became gray, indicating that fine particles of alloy were dispersed evenly in it. The dark paste prepared in this way reacted to a hand magnet. The alloy content of the sludge could be controlled by controlling the polishing duration with a given quantity of alumina.

Various types of stainless steel are known which contain Ti, Mo, W, etc., as the retarders against the martensitic transformation (2). Using one of them, thus, enables us to produce a magnetic pasty matter with the remanence we want. A smooth surface of metal substrate was smeared with the emulsion that contains the ferromagnetic alloy particles by about 50 weight percent (w/o). The surface has been investigated in terms of electron reflection (see Fig. 1). The diffraction pattern observed here is shown in Fig. 2. The mean size of the particles in the specimen is estimated to be about 50Å from the half-width value of the reflections. Figure 2 differs from Fig. 3, where the specimen has been observed with the intact gamma-Al_2O_3 employed as the abrasive. The (220) and (311) reflections from alumina appear weaker in Fig. 2 than in Fig. 3. This demonstrates that from the reflection

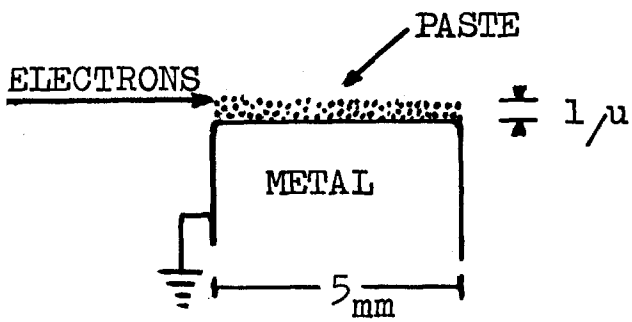

Fig. 1. Disposition for scanning the specimen layer by electron reflection.

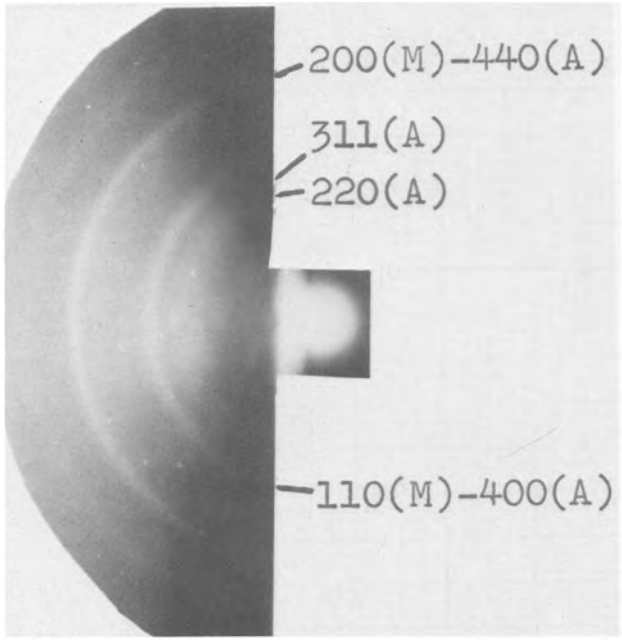

Fig. 2. Electron diffraction pattern observed from the emulsion composed of martensite (M) and alumina particles (A). Wavelength of the electrons is 0.0347Å. Distance between the object and the screen is 50 cm. Positive enlarged 2.3 times.

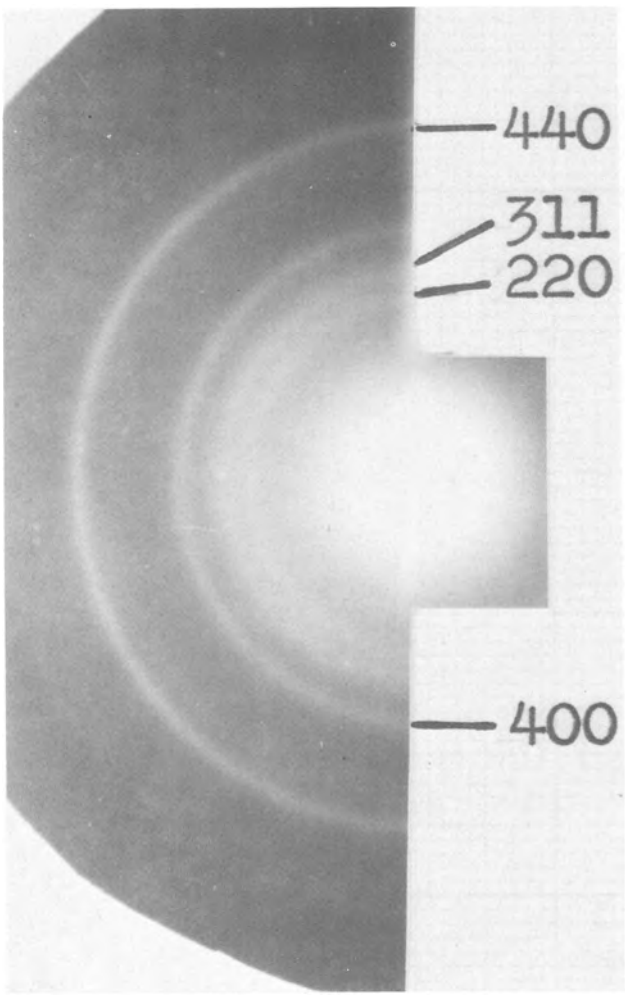

Fig. 3. Alumina employed as the abrasive. Compare this pattern with Fig. 2.

intensities observed, one can estimate roughly the alloy content of the emulsion to be about 50 w/o.

Magnetic and dielectric analysis of the specimen has been carried out by means of electron diffraction (3). An undisturbed reference pattern from a gold foil has been superimposed onto Fig. 2 in order to reveal the magnetic and dielectric influence which the reflections underwent. The double exposure obtained in this way is shown in Fig. 4, in which there is found eccentricity between the diffraction rings of the two different objects. This ring eccentricity is expressed as the resultant $\vec{\Delta R}$ of two vectors, *i.e.*

$$\vec{\Delta R} = \vec{\Delta Z} + \vec{\Delta X} \qquad [1]$$

where $\vec{\Delta Z}$ and $\vec{\Delta X}$ denote the magnetic and the dielectric displacement of the reflection, respectively. The following two equations apply to the disposition of the object relative to the screen

$$|\vec{\Delta Z}| = \frac{eLl\lambda}{h} \cdot |\vec{B}| \qquad [2]$$

$$\vec{\Delta Z} \perp \vec{B}$$

and

$$\vec{\Delta X} = \frac{Ll}{2V} \cdot \vec{E} \qquad [3]$$

$$\vec{\Delta X} \parallel \vec{E}$$

In these equations, $\vec{B}$ denotes the remanence of the martensitic particles, $\vec{E}$ the electrostatic field strength which is produced by the electrons charged at the dielectric object during the diffraction experiment, e electron charge in emu (1.6×10^{-20}), L the distance between the object and the screen (50 cm), l the effective magnetic or dielectric path traveled by electrons (about 0.1 mm), λ the wavelength of the electrons applied (0.0347Å), h Planck's constant (6.6×10^{-27} erg · sec), and V is the potential difference for accelerating the electrons (140 kV).

One measures $\vec{\Delta R} = 0.7$ mm in Fig. 4. Hence, one can calculate $\vec{B} \approx 100$G according to Eq. [1], [2], and [3], if one assumes that $\vec{\Delta Z}$ is nearly parallel to $\vec{\Delta X}$ and that $\vec{E}$ is about 20 kV/cm (4). The value of $\vec{B}$ estimated in this way is plausible as the remanence of the mar-

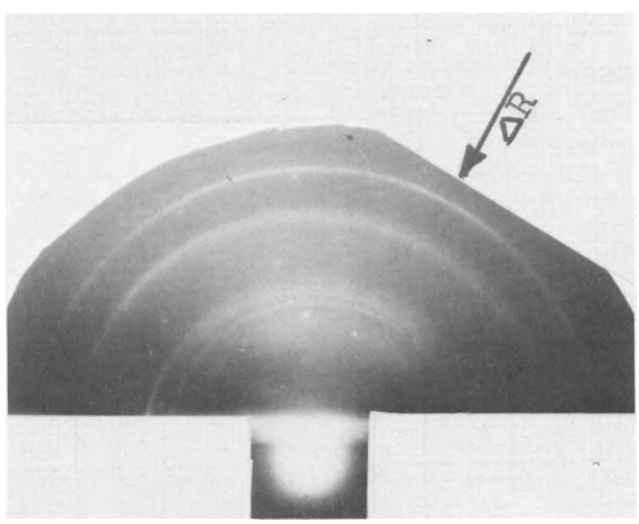

Fig. 4. Double exposure in which Fig. 2 is superimposed on the reference pattern from a gold foil. The diffraction ring eccentricity as denoted by $\vec{\Delta R}$ is due to the magnetic and dielectric effect arising from the specimen.

tensite particles in question. It was possible here to detect the rather weak remanence, since l in Eq. [2] was sufficiently long in the case of RHEED procedure (see Fig. 1).

A rubbing sludge was produced by mechanically polishing the surface of a soft iron plate with an aqueous suspension of synthetic hematite. Figure 5 was observed from the sludge whose iron content was about 50 w/o. This figure should be compared with Fig. 6, which shows the intact hematite powder. It follows from these observations that in the sludge there are scattered iron particles. The rather high background around the (110) and (214) reflections in Fig. 5 implies the tribochemical formation of the cubic Fe_3O_4 particles which give the (311) and (440) reflections corresponding to the spacings of 2.53 and 1.48Å, respectively (4).

Figure 7 is a double exposure in which Fig. 5 is superimposed onto the reference pattern of gold. The diffraction ring eccentricity here appears small compared with that in Fig. 4. This means that the Fe-Fe_2O_3 emulsion is not only nearly free from remanence, but this is also conductive. This preparation has begun to succumb to weathering on exposure to air for several weeks. This differed thus from the martensite-alumina emulsion, insofar as the physical and chemical properties are concerned.

The powdered oxide used in the present study plays a dual role, to wit, it is the support for the metal particles as well as the abrasive for the metal substrate. The magnetic and simultaneously dielectric emulsion as produced with the alloy and the appropriately selected abrasive can be utilized as a memory store material which is free from the eddy current effect.

Electromigration in Ion Bombardment

William Primak and Emmet Monahan

Argonne National Laboratory, Argonne, Illinois 60439

Determination of the charge incident on insulators subjected to ion bombardment had been a troublesome matter in this laboratory (1). In a recent investigation (2) it was concluded that the cause was the voltage bias produced by charging of the insulator affecting the secondary emission contribution to the ion current. In our target chambers most of the electric current from the ion-bombarded insulating specimen appeared to flow to the metal plate on which it was set by secondary emission from surrounding areas. It was found that the results could be made much more reproducible by suitable application of external bias to the target plate and target chamber apertures and components. These results were obtained in room temperature bombardments of vitreous silica and were applied to studies of various glasses and ceramic materials (3,4). Currently we are investigating the behavior of these materials when they are subjected to ion bombardment at elevated temperatures, the glasses at various temperatures up to the strain point, and high temperature ceramic materials up to 600°C. It has become evident that charge incident on some of these specimens is being conducted to the metal support by ionic conductivity through the specimen resulting in electromigration of alkali ion. There may also be oxygen release, but this is yet conjectural.

Ion bombardment at room temperature of many of the materials we have investigated causes a change in the index of refraction in a layer approximately the thickness of the range of the ion. Among the causes which have been identified are introduction of centers, change of composition, implantation of gas, compaction, and structural change (4). The thickness can be calculated from the index of refraction and the fringes seen in a spectrophotometer tracing of the reflected or transmitted light. These fringes will be referred to here as chromatic fringes. It is also possible, although much more difficult, to deduce the refractive index changes. However, these are relatively small and would not affect the determination of the thickness of the layer by 10-20%, even less when the effects are studied as a function of incident charge (or dose) (4). The behavior of Pyrex glass when bombarded at elevated temperature has made it evident that other effects are occurring.

In Fig. 1 is a photomicrograph taken in reflection with 0.55μ light of one corner of a 2 × 2 1/2 mm area bombarded with 120 mC/cm^2 of 140 keV He^+ at 350°C. The edge of the bombarded area (depressed, *V.I.*) formed a step which could be seen in an interferometer and lay in the midst of the fringe pattern seen in Fig. 1. If these monochromatic fringes are counted from the edge to the center, a depth of about 3.5μ is calculated for index of refraction 1.47. The reality of this thickness was demonstrated by determining the depth from the chromatic fringes seen in a spectrophotometer tracing of light reflected from the center of this area, 3.6μ. This is the thickness which contains approximately the quantity of alkali equivalent to the charge incident in the bombardment. The thickness is so great in Pyrex glass because of its low alkali concentration, 4 weight percent (w/o). The effect was sought in other cases, and the results are assembled in Table I.

Key words: glasses, ion-depletion, radiation damage.

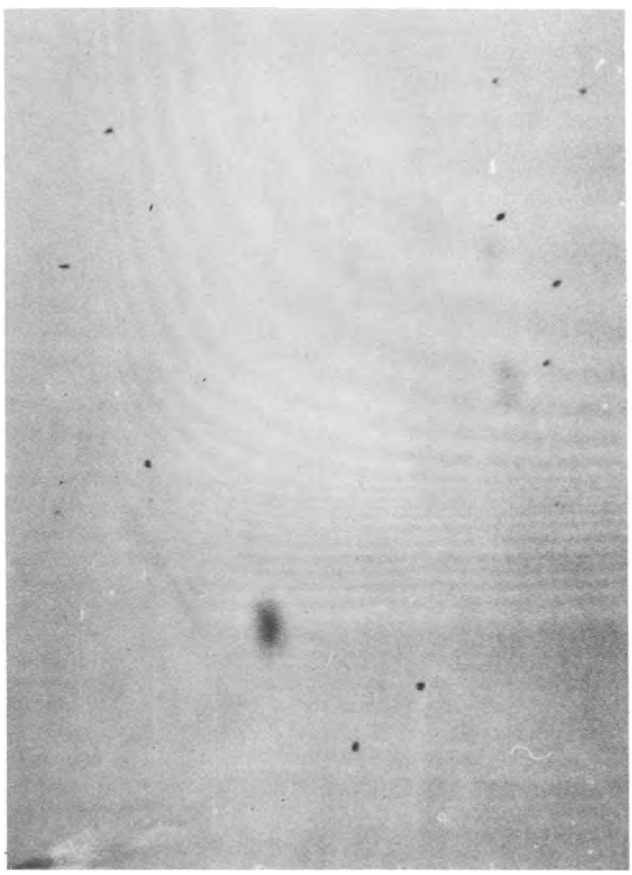

Fig. 1. Pyrex glass, photomicrograph, in reflection, wavelength 0.55μ, one corner of 2 × 2½ mm area bombarded at 350°C with 120 mC/cm^2 He^+ 140 keV. Edge of the bombarded area is in the midst of the fringe pattern.

The results for the lithium niobate (5) are curious. They could be explained by part of the charge being conducted ionically and part electronically. However, in view of the dose equivalent alkali thickness being so

Table I. Alkali migration layers

Material	Ion, dose (mC/cm^2)	Temperature (°C)	Range (μ)	Layer thickness (μ)	Dose equivalent alkali thickness (μ)
Pyrex	H^+ 120	425	1.39	4.38	4.23
Pyrex	He^+ 120	350	0.97	3.60	4.23
BK-7	D^+ 108	375	1.62	1.00	1.04
C-1	He^+ 108	275	0.84	0.89	0.88
$LiNbO_3$	D^+ 72	600	0.5	0.11	0.20

nearly twice the incident charge, it seems more likely that, concomitant with the migration of the lithium ion, the charge of the niobium is reduced by one.

When Pyrex glass is bombarded at room temperature, there is little change in contour at the edge of the bombarded area. However, at these temperatures there is a marked depression. This is in accord with the collapse which has been reported (6) for the electrolysis of glasses.

The glass C-1 appears to be pervious to helium in room temperature bombardment. However, at 200°C, where increased permeability would be expected, dense protuberances appeared, as seen in Fig. 2. These do not have the typical appearance of the radiation blistering seen on other materials. We speculate this may be caused by oxygen formed in electromigration.

Electromigration is another mechanism for the deterioration of glasses and ceramic materials in radiation environments. This effect is apt to be variable and depend on material and target base configuration, and on plasma condition, electron emission, and voltage bias in the region. All of the cases cited here involve migration of alkali ion. The alkali ions have long been known to be the most mobile ions in these materials (7) and there are many reports of this mobility (8).

We are currently looking for evidence of other effects associated with ionic conduction in the ion bombardment of ceramic materials.

Addendum in revision.—The altered surface formed on heated Pyrex and C-1 glass cathodes of a glow discharge tube have now been studied and give the same result described above for ion bombarded cathodes, that the volume of altered glass is closely that containing the alkali equivalent to the cathode charge. The electrical characteristics of a glow discharge tube with a heated soda-lime glass cathode or anode have been reported (9).

A Static Sodium-Water Cell

B. D. Goldberg and F. R. Foulkes*

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A4.

A "dynamic" sodium-water cell with a rotating cathode was described in a previous report (1). In this report we describe a mechanically simplified "static" cell.

CELL DESCRIPTION

The cell (Fig. 1) consisted of a glass tube (A) housed in a Lucite block (B), containing a stainless steel tube (C) to which a 100-mesh type 304 stainless steel wire screen cathode (D) having a geometric area of 0.5 cm^2 was attached by means of two spot-welded stainless steel posts (E). The sodium was contained in a glass tube (F) which was attached to a pressure plate (G) with a clamp (H). Water, sodium hydroxide, hydrogen, and nitrogen exited via drain (I). Attached to the bottom of the stainless steel tube was a carburetor (J) which rendered the water used in the cell into a mist. Nitrogen gas and water were admitted through control valves (K) and (L), respectively. Current was gathered from the sodium anode by means of a series of copper pins (M) imbedded in the sodium (N). The stainless steel tube acted as the cathode current collector (O). The sodium was pressed onto the stainless steel mesh with a pressure of from 4 to 5 kg/cm^2 by a compressed air piston arrangement connected to the cell pressure plate.

EXPERIMENTAL DETAILS

Cell operation.--Before operation the cell was purged with nitrogen. The cell was started by turning on the water at a constant flow rate of about 5 cm^3/min. Since the feeding of the sodium involved no shearing of the sodium, the cell operated smoothly with no undue mechanical stress.

Electrical measurements.--A Keithley 610C solid state electrometer and model 370 recorder were used to measure and monitor cell output voltage. Current was measured and monitored via a Honeywell Electronik 194 chart recorder (50 mV full scale) connected across a shunt resistor (50 mV = 10 A) in series with the cell.

RESULTS AND DISCUSSION

Fig. 2 shows the steady state cell polarization characteristics obtained over several runs, the current

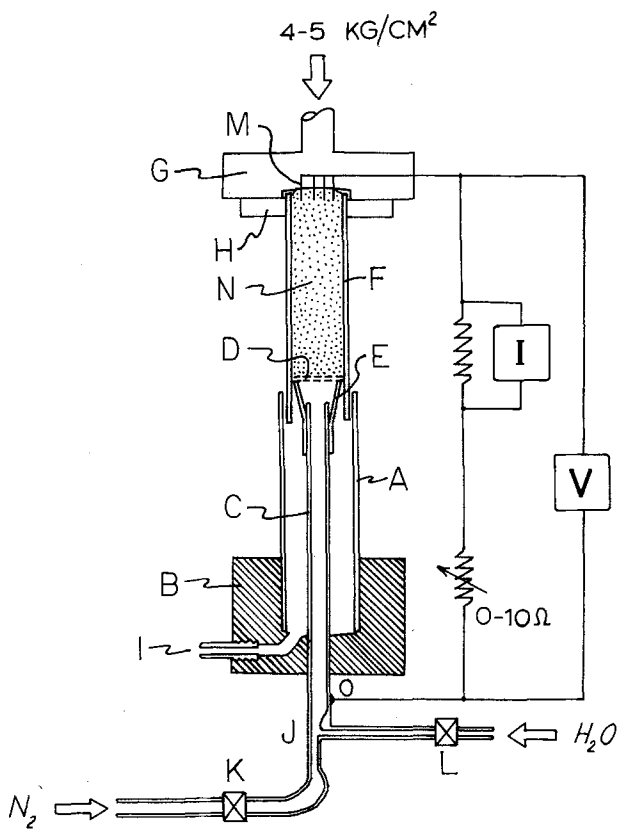

Fig.1. Sodium-Water Static Cell.

* Electrochemical Society Active Member.

Key words: primary cell, high power battery, sodium-water cell.

density being based on a geometric cathode area of 0.5 cm^2. Open circuit voltages of about 2.0 V were consistently obtained, which were in reasonable agreement with the calculated standard reversible value of 1.89 V for the reaction

$$Na + H_2O \rightarrow NaOH + \tfrac{1}{2}H_2. \quad [1]$$

From the shape of the polarization curve it can be seen that the cell output was strongly activation controlled. Linear regression analysis using 51 data points over 4 orders of magnitude of current yielded the following relationship between cell voltage and current density (correlation coefficient r = 0.801):

$$V = 0.7542 - 0.2002 \log i \quad [2]$$

The Tafel slope of -0.2002 V/decade very strongly suggested the presence of *mixed* activation control involving activation polarization of both the anodic reaction

$$Na \rightarrow Na^+ + e^- \quad [3]$$

and the cathodic reaction

$$H_2O + e^- \rightarrow OH^- + \tfrac{1}{2}H_2. \quad [4]$$

It is readily shown that the Tafel slope under mixed activation control is given by

$$\frac{dV}{d \log i} = - \frac{2.3\ RT}{F} \left\{ \frac{1}{\alpha_H} + \frac{1}{\alpha_{Na}} \right\} \quad [5]$$

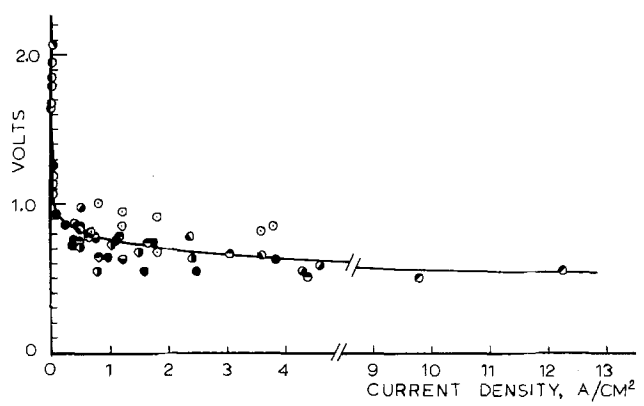

Fig. 2 Steady State Cell Polarization Curve.

The transfer coefficient for the hydrogen evolution reaction on steel in alkaline media is known to be $\alpha_H = 0.5$ (2). If we assume that α_{Na} is between 0.75 and 1 (3) and substitute these values plus $\alpha_H = 0.5$ into Eq. [5], then Eq. [5] yields the observed Tafel slope of -0.2002 V/decade in the temperature range from 30°C to 60°C, values which are consistent with the occurrence of some local overheating at the sodium/water interface. If one were to assume only cathodic activation control ($\alpha_H = 0.5$) or only anodic activation control ($\alpha_{Na} = 1$), temperatures of 231°C and 737°C, respectively, would be required to yield the observed Tafel slope using Eq. [5]. These temperatures are highly unlikely in view of the facts that the m.p. of sodium is 97.8°C and that the presence of molten sodium was not observed visually.

This mixed activation control of the output of the static cell contrasted strongly with the behaviour of the dynamic cell, the polarization of which was controlled by a combination of cathodic activation polarization and cell internal resistance (1). Unlike in the dynamic cell, the thickness of the oxide film in the static cell was not amenable to control. Since the film was visibly non-uniform in thickness, it appears likely that the effective electrode area was much smaller than the assumed 0.5 cm^2, so that even the large exchange current density for the sodium half-reaction was exceeded, resulting in anodic polarization in addition to cathodic polarization.

Although the activation polarization of the static cell was much more severe than that of the dynamic cell, the static cell offers the clear-cut advantages of an essentially flat discharge curve and greater mechanical simplicity than the dynamic cell. As was stressed in the case of the dynamic cell, control of the

thickness of the oxide film is the key to exploiting the sodium/water system. Work is now being carried out to construct a static cell with an oxide film of thin but controllable and uniform thickness.

Stress Corrosion Cracking of Admiralty Brass in Nonammoniacal Sulfate Solutions

A. Kawashima, A. K. Agrawal,* and R. W. Staehle*

Department of Metallurgical Engineering, Ohio State University, Columbus, Ohio 43210

Stress corrosion cracking (SCC) of CDA 443 admiralty brass has been studied in sodium sulfate solution over a pH range of 1.3 to 12.7, at open circuit and controlled potentials using a slow strain rate technique. All the tests were conducted in a 200 ml glass cell at room temperature in 1N Na_2SO_4 solution whose pH was adjusted with either H_2SO_4 or NaOH to the desired value. Potential of specimens was controlled with a Wenking potentiostat model ST72, against a mercury-mercurous sulfate reference electrode; the counter electrode used was of platinum.

Test specimens were hour-glass type, with gauge dimensions 1.25 x 0.5 cm^2 and 0.25 cm thick. Specimens were annealed for one hour at 550°C under a blanket of argon and furnace cooled, this gave an average grain diameter of 0.05mm. After heat treatment specimens were polished longitudinally with 600 grade SiC paper. The specimen length exposed to the test solution beyond the gauge section was carefully covered with an epoxy cement. The straining, at a rate of 1.5 x 10^{-5} sec^{-1}, was started after a specimen had attained a steady corrosion potential or a quasi steady state current in the case of controlled potential tests. During the tests load (tension) on a specimen was monitored with a load cell; the fracture stress in a solution was compared with a reference value obtained in air. Fractured specimens were metallographically examined; the crack velocity, $v = L/t_f$, was calculated from the maximum crack penetration, L, observed near the fractured tip and the failure time, t_f.

Results are summarized in Figure 1, where the ratio of fracture stress in a test solution to that in air is plotted against the pH of the solution. Results in the figure are grouped in bands according to the test potential. The crack velocity scale is shown on the right ordinate, with the scale placed in such a way that all data points fall within ± 0.3 decade of the measured value. Such a small difference in crack velocity is not considered serious where the values vary over several orders of magnitude. The cracking in all instances was transgranular with considerable branching, especially at high anodic potentials. In such cases the calculated values give only an idea of the magnitude and not the true velocity.

SCC was not observed in any of the specimens tested at open circuit potential, which was 180 ±20 mV_H in all cases up to pH 10.1, but ∿90 mV_H for 11.6 and ∿-40 mV_H for pH 12.7. In these cases, < 200 mV_H, it is possible that the crack velocity is so small that no detectable penetration occurred in approximately 30 hours of exposure. A slower strain rate might have allowed more time for crack penetration, especially in the pH range 4 to 10. SCC occurred at anodic potentials; the overpotential, $\eta = E-E_{cor}$, varied with the pH. The η was ∿20 mV in the pH range 4 to 10, but increased to ∿100 mV or more at either end of the forementioned range. It is clear from Figure 1 that in admiralty brass: a) SCC severity increases with an increase in potential at any pH between 2 and 12; b) at a fixed potential it increases with an increase in pH in the pH range 2 to 4; c) it stays relatively constant up to a certain pH (∿10) and decreases thereafter; d) the pH where the decreasing trend starts broadens with an increase in potential.

The concentration of sulfate ions in the solution also plays an important role in promoting SCC. Preliminary data in pH 8 solution at 300 mV_H show that cracking severity decreases with a decrease in sulfate ion concentration; no cracking occurred with the concentration dropped to 10^{-4}N.

Pickering and Byrne (1) have reported intergranular SCC of 70/30 brass in 1N Na_2SO_4 solution of pH ∿2 at 240 mV_H. It appears that 70/30 brass is more susceptible to SCC than admiralty brass which showed no cracking under the above condition in the present work. Pinchback et al (2) have reported transgranular SCC in admiralty brass in 0.05 to 0.5M $CuSO_4$ solutions at open circuit conditions. They have, however, neither reported the pH of the solutions nor the corrosion potential of the

*Electrochemical Society Active Member.

specimens. We measured the pH and the corrosion potential of admiralty brass in 0.05 and 0.5M $CuSO_4$ solutions; pH's were 4.2 and 3.5 whereas potentials were 280 and 300 mV_H, respectively. Figure 1 suggests that admiralty brass should suffer SCC in the above conditions and thus supports the results of Pinchback et al.

A generally held view, till recently, has been that SCC of brasses does not occur without the presence of ammonia or its derivatives in the test environment (3). The present work negates this view and conclusively shows that SCC of admiralty brass occurs in nonammoniacal solutions over a wide range of pH depending upon the oxidizing condition, as represented by the anodic potential in Figure 1. The fact that below pH 2 and above pH ∿12, where Cu_2O is unstable, no SCC was observed points to an active role of Cu_2O in crack propagation, which has been suggested before by many workers (4). The increase in severity with increasing potential favors anodic dissolution, rather than hydrogen embrittlement, as the cause of SCC.

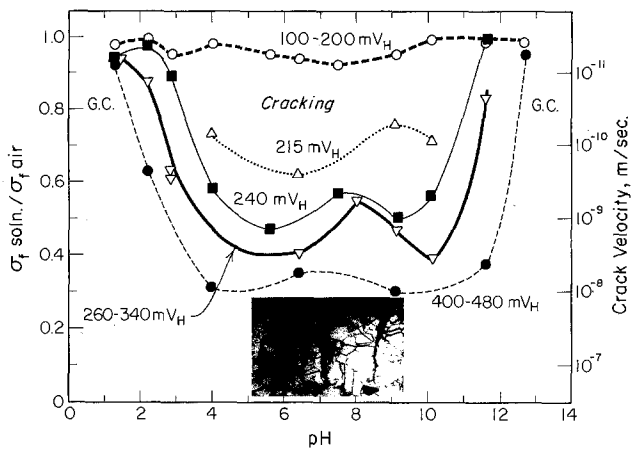

Fig. 1 Fracture stress ratio of admiralty brass in 1N Na_2SO_4 solution to that in air and crack velocity vs. pH at different potentials.

Epitaxial Pattern Shift Comparison in Vertical, Horizontal, and Cylindrical Reactor Geometries

P. H. Lee,* M. T. Wauk, R. S. Rosler,* and W. C. Benzing*

Applied Materials, Incorporated, Santa Clara, California 95051

Bipolar IC fabrication requires a predictable amount of epitaxial pattern shift in determining design rules for minimum device spacing. These design rules compensate for the amount and direction of pattern shift to correct the subsequent masking operations to the buried layer mask. One purpose of this work is to establish the dependence of pattern shift on growth conditions and substrate orientation. Another purpose is to compare pattern shift in three commercial reactor geometries.

Work in pattern shift has been reported by several authors (1-5). It is the general experience of most workers that pattern shift is minimized at higher growth temperatures (1200°C for $SiCl_4$) and lower growth rates (less than 0.6 micron/min). Workers (3,4) have investigated the role of HCl etching in pattern shift and washout. The degree of pattern shift and washout is due, in part, to the epitaxial growth on the pattern sidewalls formed from the buried layer diffusion. The differences in growth rate (6) contribute to the pattern shift and washout. The present authors believe that growth temperatures, growth rates, substrate orientation, HCl etch, and pattern depression are interrelated parameters to be considered in minimizing pattern shift and washout.

Epitaxial depositions were made in commercially available reactors in vertical, horizontal, and cylindrical geometries.* Single crystal epitaxial depositions were made with silicon tetrachloride at four deposition rates and four deposition temperatures. The $SiCl_4$ concentration was controlled to achieve the desired growth rate and the optical deposition temperature was corrected to true temperature using silicon emissivity (7) and quartz absorbtivity. There was no HCl etch prior to deposition and the depositions were undoped. The two inch boron P- doped substrates have the following orientation; ⟨111⟩ off + 3-1/2 to + 4-1/2° towards the ⟨110⟩, ⟨100⟩ off + 3° to +5° towards the ⟨110⟩, and ⟨100⟩ ± 1/2°. An antimony buried layer was diffused into the substrates. A square grid line pattern which has a 10 mil line width spaced 200 mils apart was aligned parallel and perpendicular to the substrate flat. The diffusion concentration after drive-in was approximately 25 ohm per square and the diffusion oxide thickness was approx. 7000 Angstroms. After an approximately 10 micron deposition was made, the substrates were angle lapped, Sirtl etched, and the pattern shift was measured optically at 125X with interference contrast. Approximately five measurements for each deposition condition were made. The deposition thickness was measured with the sodium fringe count method. The shift ratio was calculated by dividing the pattern shift by the deposition thickness on each wafer. Statistical methods were used on the meas-

Cylindrical geometry - Applied Materials AMC-7000

urement techniques and estimates to experimental error were determined.

The estimated experimental error is approximately ± 20% with the optical shift measurement being the major contributor. Statistical methods were employed to determine the deviation and confidence limits on at least 6 measurements for the experimental data. This work confirms previous work done by Drum and Clark (2) as the pattern shift was primarily non-symmetrical and the pattern shift was calculated by the shift in the centerline of the pattern. Pattern washout with the on-orientation substrates was especially evident on the lower temperatures using the vertical and cylindrical geometries. The pattern washout was probably caused by the enhanced ⟨111⟩ "slanting face" growth as reported by Enomoto (3).

The only pattern shift observed was towards the right and parallel to the substrate flat. For the ⟨111⟩ and ⟨100⟩ off-orientation substrates, the amount of pattern shift was comparable for each reactor geometry. The shift ratios for the two off-orientation substrates is shown in Fig. 1 and Fig. 2. The graphs indicate that the amount of pattern shift is independent of reactor geometry when corrected deposition temperatures are used. Shift ratios of less than 1.0 can be produced with silicon tetrachloride using growth temperatures above 1150°C (corrected) and growth rates below approximately 0.6 micron/min.

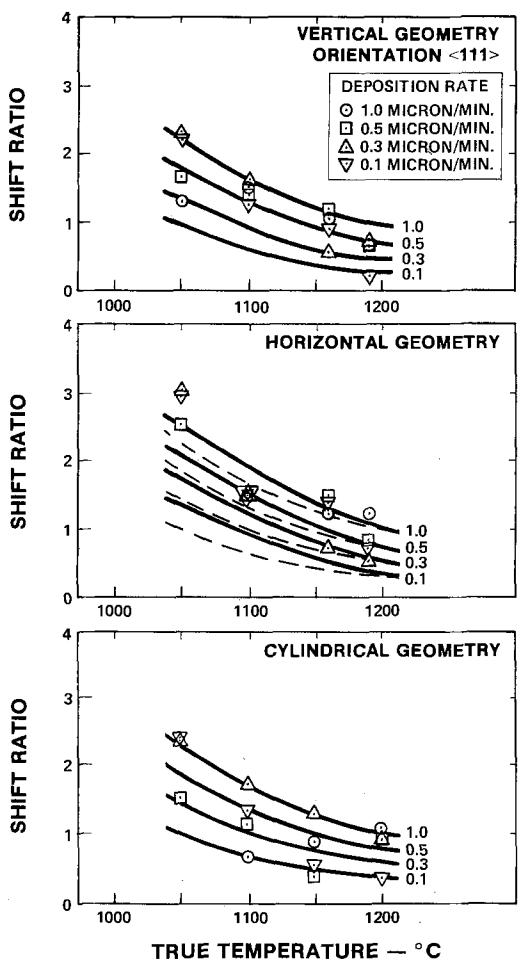

Fig. 1. Pattern shift on ⟨111⟩ substrates in vertical, horizontal, and cylindrical geometries. The dashed lines are the superimposing of the cylindrical curves upon the vertical and horizontal curves.

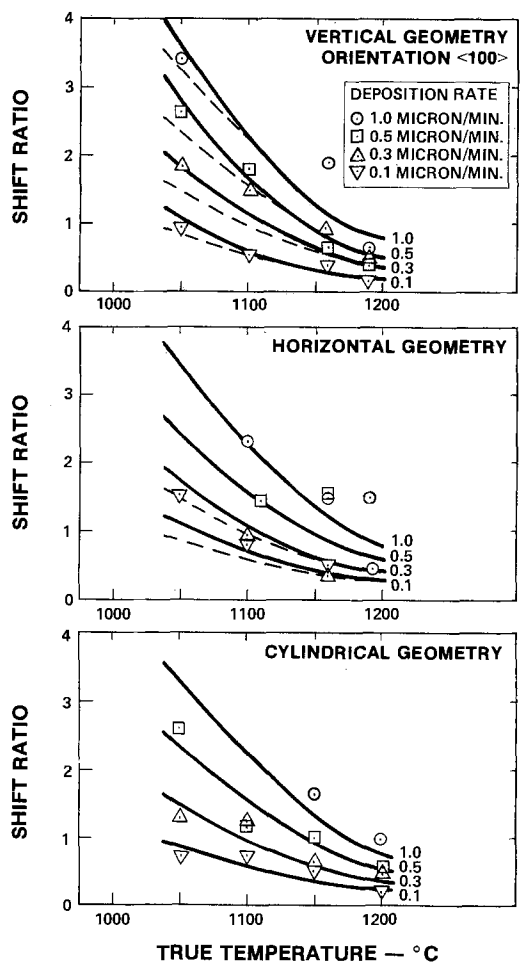

Fig. 2. Pattern shift on ⟨100⟩ substrates in vertical, horizontal, and cylindrical geometries. The dashed lines are the superimposing of the cylindrical curves upon the vertical and horizontal curves.

It has been the belief of several workers that a cylindrical reactor has greater pattern shift compared to the vertical and horizontal geometries (8). The present authors have found that observation to be not correct. Instead, when one compares each reactor geometry on an equal (true) temperature basis, the pattern shift curves coincide within experimental error. The primary difference in the comparison is the method of temperature measurement. Temperatures in vertical and horizontal geometries are typically measured by infrared optical pyrometry. The indicated temperatures need to be corrected upwards due to the silicon emissivity and quartz absorbtivity. For example, an indicated pyrometer reading of 1150°C is actually 1225° (emissivity correction is +65°C (7) and quartz absorbtivity correction is +10°C (9)). In the case of a radiantly heated cylindrical reactor, the indicated temperature equals the true temperature. A radiantly heated cylindrical reactor is typically calibrated with a thermocouple that is inserted in the graphite susceptor. Under comparable conditions, the present data shows that the amount of pattern shift is independent of reactor geometry.

The observed behavior of pattern shift with respect to temperature and growth rate is believed to be a crystal growth mechanism. From Figs. 1 and 2, the amount of pattern shift is lower at higher temperatures and slower growth rates. The magnitude of pattern shift at differing growth conditions is dependent upon the surface energy for crystal growth. Anisotropic growth rates for the different crystal planes is the major cause for shift (10). A discontinuous surface is exposed at the buried layer pattern edge. Due to atomic surface diffusion or surface migration effects at this edge (11), a competition of atomic capture takes place and leads to differing growth rates along the ⟨110⟩ plane. At lower temperatures, the growth rate ratios are higher between the ⟨110⟩ plane (substrate flat) and the substrate planes. It is reasonable that anisotropic growth is independent of reactor geometry. This anisotropic growth mechanism confirms the present data that pattern shift is lower at higher temperatures and slower growth rates.

ACKNOWLEDGMENTS

The authors wish to thank Ms. B.D. Mell for making the depositions, Ms. T. P. Boblet for making the shift measurements, and E. Fleck for the experimental design.

Potentiometric Determination of the Gibbs Free Energy of Formation of Cadmium and Magnesium Chromites

K. T. Jacob

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada, M5S 1A4

ABSTRACT

The standard Gibbs free energy of formation of magnesium and cadmium chromites have been determined by potentiometric measurements on reversible solid-state electrochemical cells

$$\text{Pt, } \begin{matrix}\text{Au-5\%Cd}\\+\\\text{CdO}\end{matrix} \;\Big|\; \text{CaO-ZrO}_2 \;\Big|\; \begin{matrix}\text{Au-5\%Cd}\\+\\\text{CdCr}_2\text{O}_4 + \text{Cr}_2\text{O}_3\end{matrix} \text{, Pt}$$

in the temperature range 500°-730°C, and

$$\text{Pt, Cr} + \text{Cr}_2\text{O}_3/\text{Y}_2\text{O}_3\text{-ThO}_2/\text{Cr} + \text{MgCr}_2\text{O}_4 + \text{MgO, Pt}$$

in the temperature range 800°-1200°C. The temperature dependence of the free energies of formation of the ternary compounds can be represented by the equations

$$\text{CdO(r.s.)} + \text{Cr}_2\text{O}_3\text{(cor)} \rightarrow \text{CdCr}_2\text{O}_4\text{(sp)}$$

$$\Delta G^\circ = -42{,}260 + 7.53T\ (\pm 400)\ \text{J}$$

and

$$\text{MgO(r.s.)} + \text{Cr}_2\text{O}_3\text{(cor)} \rightarrow \text{MgCr}_2\text{O}_4\text{(sp)}$$

$$\Delta G^\circ = -45{,}200 + 5.36T\ (\pm 400)\ \text{J}$$

The entropies of formation of these spinels are discussed in terms of cation disorder and extent of reduction of Cr^{3+} ions to Cr^{2+} ions. Thermodynamic data on the chromates of cadmium and magnesium are derived by combining the results obtained in this study with information available in the literature on high temperature, high pressure phase equilibria in the systems CdO-Cr_2O_3-O_2 and MgO-Cr_2O_3-O_2.

Recent thermodynamic studies (1-3) on the aluminates chromites, and vanadites of iron, nickel, cobalt, and manganese have shown that the entropy of formation of cubic spinel phases from component oxides with rock-salt and corundum structures can be expressed as $-7.25 + \Delta S^M + \Delta S_{rand}$ J deg^{-1} mol^{-1}, where ΔS^M is the entropy of cation mixing on the tetrahedral and octahedral sites of the spinel, and $\Delta S_{rand} = n$Rln3 is the entropy change associated with randomizing the direction of Jahn-Teller distortions. The Jahn-Teller term applies only for spinel phases that have ions with $3d^4$ or $3d^9$ electronic configuration in octahedral site or $3d^3$, $3d^4$, $3d^8$, or $3d^9$ configuration in tetrahedral site. The ΔS^M term can have values ranging from 0 for normal spinels to 11.5 J deg^{-1} mol^{-1} for spinels with random distribution of cations. The ΔS_{rand} term can have values ranging from 0 to 18.3 J deg^{-1} mol^{-1}. Because of the large octahedral site preference energy of Cr^{3+} ion compared to those of Cd^{2+} and Mg^{2+} ions, the chromites of cadmium and magnesium are expected to be normal spinels even at high temperatures with no significant entropy contribution from the mixing of cations. Their entropies of formation from oxides can therefore be expected to have a value close to -7.25 cal deg^{-1} mol^{-1}. However, chromium ion can exist in different oxidation states and the entropy arising from the mixing of these multivalent chromium ions can effect the accuracy of the semiempirical correlation for the entropy of formation of spinel phases.

Chromium exhibits all valency states from Cr^{2+} ($3d^4$) through Cr^{6+} ($3d^0$). Although no binary oxide of Cr^{2+} has yet been synthesized, it exists in ternary compounds formed under extremely reducing conditions. Much the same is apparently true of Cr^{5+}, which exists only in compounds that are stabilized by a very favorable host structure (*e.g.*, apatites and spodiosites). Stubican and Greskovich (4) have shown that, although there is no significant solubility of Cr_2O_3 in $MgCr_2O_4$ at 1700°C in oxidizing atmospheres, approximately 33% of Cr^{2+} ions can substitute for Mg^{2+} ions on the tetrahedral sites in reducing atmospheres between 1800° and 2000°C. The reducing atmospheres were obtained by admitting some air into the system and allowing it to react with a graphite susceptor. Assuming that equilibrium between graphite and carbon monoxide was achieved in their apparatus, the oxygen partial pressure could have been as low as 10^{-15} atm, approximately five orders of magnitude below that corresponding to the reduction of pure chromium

Key words: cadmium, magnesium, chromites, chromates, free energy, entropy, thermodynamics, solid-state galvanic cell.

sequioxide. The interest in $MgCr_2O_4$ and its solid solutions arises from their use as important constituents of steel plant refractories.

The entropy of formation of $MgCr_2O_4$ at low oxygen potentials can be deduced from the temperature dependence of the oxygen potential corresponding to the reduction of $MgCr_2O_4$ to MgO and Cr, and compared with that predicted by the semiempirical correlation. Any differences between the values may be indicative of the presence of Cr^{2+} ions. In $CdCr_2O_4$ in equilibrium with Cr_2O_3 and a cadmium alloy the oxygen potential is sufficiently high to ensure that no Cr^{2+} ions are present.

The heats of formation of $MgCr_2O_4$ and $CdCr_2O_4$ have been measured by Müller and Kleppa (5) as -46.3 (± 0.8) kJ mol^{-1}, and -42.3 (± 0.8) kJ mol^{-1}, respectively, by high temperature solution calorimetry. The free energy of formation of $MgCr_2O_4$ was measured by Tretjakov and Schmalzried (6) with a solid oxide cell in which calcia-stabilized zirconia was employed as a solid electrolyte. The author is unaware of any previous study on the free energy of formation of $CdCr_2O_4$. Muller *et al.* (8) have reported on phase equilibria in MgO-Cr_2O_3-O_2 and CdO-Cr_2O_3-O_2 systems between 450° and 850°C and at high oxygen pressures (up to 3500 atm). They identified two magnesium chromates, the low temperature α-$MgCrO_4$ and the high temperature β-$MgCrO_4$, and three chromates of cadmium, the low temperature α-$CdCrO_4$, the high temperature β-$CdCrO_4$, and a new phase Cd_2CrO_5. Approximate values for the free energies of formation of some of these chromates can be obtained from data on chromites and phase relations at high pressures.

Experimental Methods

Materials.—Fine powders of Cr, CdO, MgO, and Cr_2O_3, each 99.99% pure, were obtained from Alfa Inorganics. The cadmium chromite was prepared by heating pellets containing an intimate mixture of the component oxides in air at 1000°C for 4 days. The magnesium chromite was prepared by heating the component oxides under argon gas at 1300°C for 2 days. The formation of the chromites was confirmed by x-ray diffraction analysis. The chromite was ground, pelletized, and reheated until no extra x-ray lines were visible. A gold alloy containing 5 atom percent (a/o) cadmium was prepared by melting a mixture of gold and cadmium, each 99.999+ purity, in closed zirconia crucibles under argon gas and quenching in liquid nitrogen. A fine powder of the alloy was prepared by filing. The iron particles in the powder were removed magnetically. Impervious calcia-stabilized zirconia tubes supplied by the Zirconia Corporation of America contained 15 mole percent (m/o) CaO. Thoria pellets containing 7.5 m/o Y_2O_3 were prepared from mixed nitrate solution by evaporation and subsequent decomposition as described earlier (9). The argon gas used as the atmosphere for the potentiometric experiments was 99.99% pure and was dried and then deoxidized by passing through a column of titanium granules at 900°C. The electrodes were prepared by mixing the component metal and oxide powders, compacting the mixture into 1 cm diameter pellets, and sintering at high temperature in an inert gas atmosphere at 1000°C for 2 days. An x-ray examination of the pellet revealed that there was no change in the composition of the pellet during sintering.

Apparatus.—The design of the apparatus for the study of the free energy of formation of $CdCr_2O_4$ is similar to those used earlier in the study of $ZnAl_2O_4$, $ZnCr_2O_4$ (10), $ZnTiO_3$, and Zn_2TiO_4 (11). Because of the high vapor pressure of cadmium, it was necessary to have it at low activity as an alloy with gold. In order to minimize the change in composition of the alloy, the electrode pellets composed of mixtures of alloy and oxides in equimolar ratios were contained in two CaO-ZrO_2 crucibles covered with lids. The flat closed ends of the two CaO-ZrO_2 crucibles were polished and pressed against each other by a system of alumina rods and a spring loading arrangement.

A schematic diagram of the apparatus used for the study of the free energy of formation of $MgCr_2O_4$ is shown in Fig. 1. Since the oxides were equilibrated with metallic chromium, the oxygen potential of the ambient argon atmosphere had to be maintained below 10^{-13} atm to prevent significant oxidation of chromium under the experimental conditions. A large number of titanium internal "getters" had to be introduced into the high temperature system in order to remove the residual oxygen from the inert gas and to deoxidize any oxygen bearing gases that desorb from

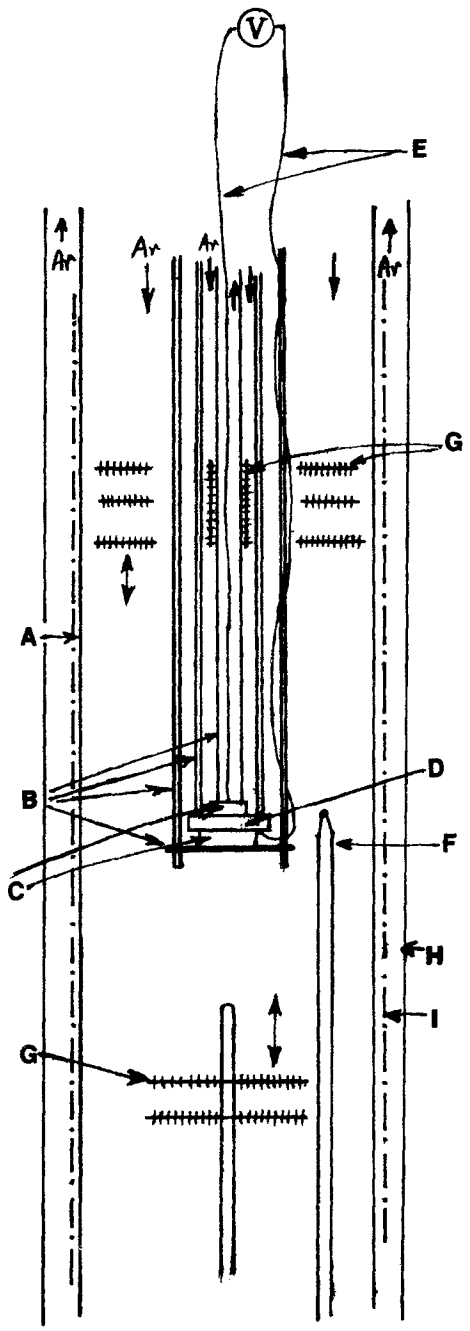

Fig. 1. Schematic diagram of the apparatus used to measure the free energy of formation of $MgCr_2O_4$. A, Alumina reaction tube; B, alumina rods and slabs used for spring loading the electrodes against the electrolyte; C, electrode pellets; D, Y_2O_3-ThO_2 electrolyte pellet; E, platinum leads; F, Pt-Pt (13% Rh) thermocouple; G, titanium internal "getters;" H, outer coaxial alumina tube; I, electrical shield (earthed platinum foil).

the alumina tubes and supports. The alumina reaction tube was surrounded by another longer coaxial alumina tube and the space between the two tubes was flushed with prepurified argon gas. With this construction the oxygen gradient across the alumina reaction tube is greatly reduced, so that the contamination of the inert gas atmosphere around the cell by oxygen diffusing through the alumina tube is minimized. An open stacked pellet assembly, where the reference and test electrodes were spring loaded against the two polished sides of a Y_2O_3-ThO_2 electrolyte pellet, was employed in cells containing Cr + Cr_2O_3 electrodes, since at the low oxygen potentials oxygen transport via the gas phase between the electrodes would not be significant.

Procedure.—The reversible potential of the following cells was measured as a function of temperature using a Keithley electrometer with a minimum impedance of $10^{12}\Omega$

$$\text{Pt, } \begin{matrix}\text{Au-5\%Cd} \\ + \\ \text{CdO}\end{matrix} \Big/ \text{CaO-ZrO}_2 \Big/ \begin{matrix}\text{Au-5\%Cd} \\ + \\ \text{CdCr}_2\text{O}_4\text{Cr}_2\text{O}_3\end{matrix} \qquad \begin{matrix}\text{Pt - - - I} \\ (500°\text{-}730°\text{C})\end{matrix}$$

$$\text{Pt, Cr} + \text{Cr}_2\text{O}_3/\text{Y}_2\text{O}_3\text{-ThO}_2/\text{Co-CoO}, \qquad \begin{matrix}\text{Pt - - - II} \\ (800°\text{-}1200°\text{C})\end{matrix}$$

and

$$\text{Pt, Cr} + \text{Cr}_2\text{O}_3/\text{Y}_2\text{O}_3\text{-ThO}_2/\text{Cr} + \text{MgCr}_2\text{O}_4 + \text{MgO}, \qquad \begin{matrix}\text{Pt - - - III} \\ (800°\text{-}1200°\text{C})\end{matrix}$$

Steady potentials (±2 mV) were obtained with cell I approximately 4 hr after attaining thermal equilibrium, while with cells II and III approximately 10 hr were required. Presence of a volatile component (cadmium) in cell I probably facilitated the more rapid attainment of equilibrium at the electrode-electrolyte interface. Reproducible potentials could not be measured with cell I above 800°C. Also once the cell was heated above 850°C, the low temperature measurements could not be repeated without replacing the electrode pellets. Although the cell was designed to minimize composition changes in the alloy at the two electrodes by the volatilization of cadmium, some differential vaporization was probably responsible for the irreversible damage of electrode pellets at the higher temperatures.

After assembling cells II and III, the reaction tube was evacuated to a pressure of 10^{-4} mm Hg, and then refilled with prepurified argon gas. This procedure was repeated after heating the furnace to 600°C, to remove the oxygen bearing gas species that desorb from the refractories. Despite these precautions, preliminary experiments indicated slight oxidation of chromium metal in the pellets. It was found by trial and error that most satisfactory measurements could be performed when the Cr+Cr_2O_3 and Cr+$MgCr_2O_4$+MgO electrodes were prepared by compacting a mixture of metal and oxide powders in the molar ratios 1.5:1 or 1.5:1:1. With cells II and III reproducible emf's could not be measured below 800°C. This is probably related to the sluggish reaction between Cr and Cr_2O_3 to establish the equilibrium oxygen potential. It was also observed that in order to yield reproducible emf's the cells had to be heated initially to 1100°C.

The reversibility of the cells was checked by passing small currents (≈50 μA) through the cells for approximately 1 min in either direction, and it was found that the cell potential returned to its initial value within 1 hr, after which it remained constant for up to 6 hr. The cell potentials were also independent of the flow rate of the inert gas around the cell.

Results

The reversible cell potentials (emf's) are plotted as a function of temperature in Fig. 2 and 3. The following equations were obtained by least mean squares regression analysis of the emf data

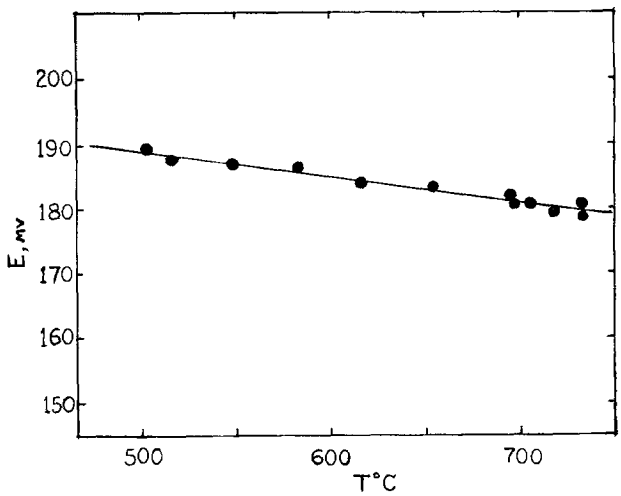

Fig. 2. The variation of the potential (emf) of cell I with temperature.

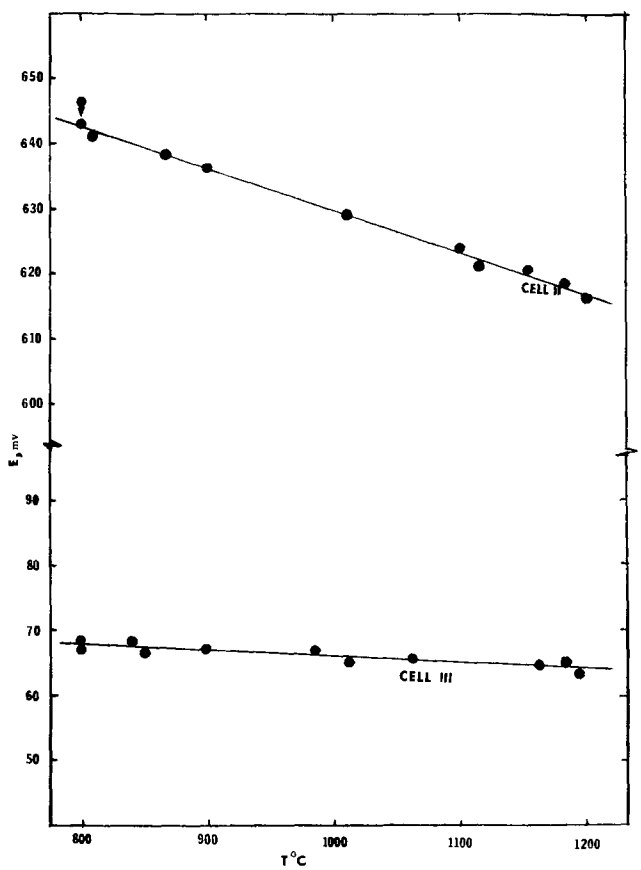

Fig. 3. The temperature dependence of the emf of cells II and III.

$$E_I = 219 - 3.9 \times 10^{-2}T\ (\pm 1.8)\text{mV} \qquad [1]$$

$$E_{II} = 712 - 6.45 \times 10^{-2}T\ (\pm 2)\text{mV} \qquad [2]$$

$$E_{III} = 78.0 - 9.25 \times 10^{-3}T\ (\pm 2)\text{mV} \qquad [3]$$

The standard free energy of formation of $CdCr_2O_4$ is directly related to the emf of cell I. For the reaction

$$\text{CdO(r.s.)} + \text{Cr}_2\text{O}_3\text{(cor)} \rightarrow \text{CdCr}_2\text{O}_4\text{(sp)} \qquad [4]$$

$$\Delta G° = -2FE_I$$

$$= -42{,}260 + 7.53T\ (\pm 400)\text{J} \qquad [5]$$

where **F** is the Faraday constant and E is the emf in volts. The emf of cell II is a measure of the difference in the oxygen potential of the Co+CoO and $Cr+Cr_2O_3$ mixtures. The oxygen potential of the Co+CoO electrode has been measured independently (3) as

$$\Delta\mu_{O_2}\,(Co+CoO) = -469{,}240 + 142.04T\ (\pm 400)J \quad [6]$$

The oxygen potential of the $Cr+Cr_2O_3$ electrode obtained from the above equation and the emf of cell II is

$$\Delta\mu_{O_2}\,(Cr+Cr_2O_3) = -743{,}960 + 166.9T\ (\pm 600)J \quad [7]$$

This value is in good agreement (±500J) with the data of Mazandarany and Pehlke (7) obtained from a solid oxide cell with Y_2O_3-ThO_2 electrolyte, and Jeannin *et al.* (12) obtained by a gas equilibrium technique, indicating that the emf apparatus was functioning satisfactorily at the low oxygen potentials associated with the $Cr+Cr_2O_3$ mixture.

The emf of cell III is directly related to the free energy of formation of magnesium chromite from the component oxides

$$MgO\,(r.s.) + Cr_2O_3\,(cor) \rightarrow MgCr_2O_4\,(sp) \quad [8]$$

$$\Delta G^\circ = -6FE_{III}$$

$$= -45{,}200 + 5.36T\ (\pm 400)J \quad [9]$$

Discussion

The Gibbs free energy of formation of $MgCr_2O_4$ obtained in this study is −38.38 kJ mol^{-1} at a mean temperature of 1000°C. The corresponding value obtained by Tretjakov and Schmalzried (6) is −33.89 kJ mol^{-1}. The smaller value obtained by them (6) is almost certainly due to electronic conduction in their CaO-ZrO_2 electrolyte at the low oxygen potentials corresponding to the $Cr+MgCr_2O_4+MgO$ electrode. The values for the standard free energy of formation of Cr_2O_3 obtained by Tretjakov and Schmalzried (6) are also significantly less negative than those obtained in this study and in the earlier study of Mazandarany and Pehlke (7) using Y_2O_3-doped ThO_2 as the electrolyte. The "second law" heat of formation of $MgCr_2O_4$ obtained in this study (−45.2 ± 1.2 kJ mol^{-1}) is in good agreement with the value of −46.3 (±0.8) kJ mol^{-1} reported by Müller and Kleppa (5) at 700°C. The "second law" heat of formation of $CdCr_2O_4$ (−42.26 ± 1.2 kJ mol^{-1}) obtained by the electrochemical measurements is almost identical to that obtained by high temperature solution calorimetry (−42.3 ± 0.8 kJ mol^{-1}) (5).

The entropy of formation of $CdCr_2O_4$ from its component oxides obtained in this study (−7.53 ± 1.0 J K^{-1} mol^{-1}) is in excellent agreement with that predicted by the semiempirical correlations (−7.5 J K^{-1} mol^{-1}) for the entropy of formation of 2-3 spinels. However, the measured entropy of formation of $MgCr_2O_4$ is approximately 2 J K^{-1} mol^{-1} more positive than the estimated value, the difference being larger than the combined statistical uncertainty in both the measured and estimated values. It is likely that the higher entropy of $MgCr_2O_4$ is due to the presence of divalent chromium ions in the spinel and the consequent mixing of cations. The Cr^{2+} ion has the same electronic structure (d^4) as the Mn^{3+} ion, and may be expected to have strong octahedral site preference. The Cr^{3+} and Cr^{2+} ions would therefore mix on the octahedral sites. The presence of d^4 ions on the octahedral site would also give rise to Jahn-Teller entropy associated with the randomization of the direction of the distortions in the cubic phase. The difference between the measured and estimated entropies is suggestive of the presence of 2(±1) ionic percent Cr^{2+} ions on the octahedral site of the spinel structure.

Thermodynamic data on cadmium and magnesium chromates.—Muller *et al.* (8) have determined the phase equilibria for the systems MgO-Cr_2O_3-O_2 and CdO-Cr_2O_3-O_2 from 450° to 850°C and oxygen pressures from 2 to 3500 atm. There are indications that thermodynamic equilibrium was not attained in their studies at the lower temperatures. For example, the temperature corresponding to the dissociation of α-$MgCrO_4$ according to the reaction

$$4\alpha\text{-}MgCrO_4 \rightarrow 2MgCr_2O_4(s) + 2MgO(s) + 3\,O_2(g) \quad [10]$$

and the temperature corresponding to the oxidation of the spinel $MgCr_2O_4$ according to the scheme

$$4MgCr_2O_4(s) + 3\,O_2(g) \rightarrow 4\alpha\text{-}MgCrO_4 + 2Cr_2O_3(s) \quad [11]$$

are both given as 553°C at an oxygen pressure of 4 atm. This can only be true if the standard free energy of formation of the spinel $MgCr_2O_4$ from its component oxides is zero, contrary to the evidence from both galvanic cell and calorimetric studies. Since thermodynamic equilibrium would be achieved more closely at the higher temperature, the phase equilibrium data of Muller *et al.* (8) at the highest temperatures may be used in conjunction with the data on the spinel phase obtained in this study to estimate the free energies of formation of β-$MgCrO_4$, β-$CdCrO_4$, and Cd_2CrO_5 from the oxides MgO, CdO, or Cr_2O_3 and gaseous oxygen.

For β-$MgCr_2O_4$ the standard free energy of formation at 707°C calculated from the dissociation pressure is 5000J more negative than the value obtained from the reverse oxidation reaction. Whenever small hysteresis effects of this nature were observed in the measured equilibrium oxygen pressures, average values have been used in computing the values shown in Table I. The entropies of formation of the chromates have been estimated as 180 (±12) J K^{-1} mol^{-1} oxygen gas, assuming that entropies of the condensed phases on the two sides of the chemical reaction for the formation of the chromates are approximately equal, and therefore the major entropy change arises from the conversion of oxygen gas into a condensed phase. In the absence of any direct thermodynamic studies on the chromates of magnesium and cadmium, the values presented in Table I provide the best information now available.

Manuscript submitted May 6, 1977; revised manuscript received Aug. 2, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

Table I. Standard free energies of formation of the chromates of magnesium and cadmium

Reaction	ΔG°, J
$MgO(s) + \frac{1}{2}Cr_2O_3(s) + \frac{3}{4}\,O_2(g) \rightarrow \beta\text{-}MgCrO_4(s)$	−127,500 + 135T (±4000)
$2CdO(s) + \frac{1}{2}Cr_2O_3(s) + \frac{3}{4}\,O_2(g) \rightarrow Cd_2CrO_5(s)$	−138,100 + 135T (±4000)
$CdO(s) + \frac{1}{2}CrO_2O_3(s) + \frac{3}{4}\,O_2(g) \rightarrow \beta\text{-}CdCrO_4(s)$	−133,400 + 135T (±4000)

ABSTRACT

A novel use of solid-state galvanic cells for the determination of thermodynamic properties of oxides by employing mg amounts of powder instead of presintered pellets is described. The oxides which were investigated all belong to the rare earths and actinide family, and present enhanced ionic and electronic mobilities which are essential for performing these kind of measurements. The advantage of this method is to allow a fast and direct sampling of oxide fuel rods which is normally carried out by chemical methods. Some examples of this technique are given.

Solid-state electrochemical cells have been so widely used for the determination of thermodynamic properties of oxides at high temperatures (1, 2) that this method can be considered to be a standard thermochemical method. However, while in most cases the potentiometric determination of oxygen activity in solid oxide samples could be straightforwardly performed when keeping the oxygen potential constant (at constant temperature) by the presence of a second phase, the same determination could be very difficult when one has to measure the dependence of the oxygen chemical potential of nonstoichiometric oxides on the oxide composition. Here the problem is to have small (and possibly fast) compositional changes of the oxide phase (obtained by suitably injecting oxygen in the sample chamber) and to measure both the amount of oxygen injected and the change of oxygen potential of the oxide. It has already been shown that in order to obtain reliable results, one of the requirements is to avoid oxygen permeation across the cell walls by a suitable choice of the operation conditions (3, 4) or by the use of a double wall chamber and to reduce the amount of oxygen outgassed from the inside of the cell (walls, electrodes) by suitably baking out the cell before operation. Also, the choice of the volume of the sample chamber has a straightforward influence on the reliability of the measurements, especially when coulometric determinations are carried out on (small size) samples having high (10^{-3}-10^{-8} atm) equilibrium pressures. In this case, in fact, the residual oxygen in the gas phase could significantly affect the composition of the oxide sample.

Examples of this use of the electrochemical technique have been given by Tretyakow and Rapp (5) and Riccardi (6), but their cells are relatively difficult to use and utilization of small size and large surface area (powder) samples that allow faster equilibration with the gaseous atmosphere is easier. We have designed various types of cells which at least in principle fulfill all the aforementioned criteria and permit an extension of the electrochemical method to the microanalysis of oxide powder sample. As an example, these cells have recently been used in our laboratories to measure the oxygen potential profiles in irradiated (U, Pu)$O_{2\pm x}$ fuels.

This investigation has succeeded in showing the feasibility of a reliable oxygen potential determination in milligram amount samples in synthetic fuels, irradiated, and nonirradiated fuels (7). We report and discuss in a rather general fashion the results obtained, which provide further proof of the usefulness of the electrochemical method as well as a guideline for new applications.

Experimental

Single compartment cell.—The first type of cell used (Fig. 1) is a single wall cell, which consists of a (4 mm ID) YSZ[1] tube closed at one end and electrolytically sealed to a UHV copper adapter. This is fitted to an ultrahigh vacuum valve attached to a Varian ion-getter pump (2 liters/sec) and to the HV system

* Electrochemical Society Active Member.

Key words: solid electrochemical cells, cerium oxide, (Pu-U) mixed oxides, oxygen chemical potential determination.

[1] Yttria stabilized zirconia.

(see Fig. 2). The inner volume of the cell (tube, valve, and pump) is about 30 ml. All connections are made by means of UHV miniconflat valves. The cell is designed to operate as a gas concentration cell

$$\text{Pt, } (P_{O_2}') \text{ } MeO_x/YSZ \text{ } (t_{o=} = 1)/(P_{O_2}'')/\text{Pt} \quad \text{(I)}$$

where on the left side compartment MeO_x could also serve as the electrode (in this case MeO_x is an electronically conducting oxide), and thus Pt serves to close the electrochemical circuit, whose open-circuit voltage is given by the Nernst equation

$$E_I = \frac{RT}{4F} \ln \frac{P_{O_2}''}{P_{O_2}'} \quad [1]$$

when the electronic transport number of the electrolyte is zero or negligible with respect to the ionic transport number of the electrolyte. It has already been shown that a cell of this type, equipped with porous Pt electrodes, could be operated at a pressure as low as 10^{-8} atm (8).

Preliminary experiments carried out with a cell consisting of a YSZ tube which was platinized[2] inside and outside and filled with a CeO_{2-x} sample [previously equilibrated with a CO/CO_2 mixture of known ratio to fix its composition (9)] resulted in erratic behavior. It is apparent that the presence of a solid phase which buffers the oxygen pressure in the outer atmosphere is not sufficient to attain the same equilibrium pressure value for the three-phase electrolyte-gas phase (in the pores of the porous Pt layer) metal contact. Subsequently, the cell geometry shown in Fig. 3 was used and since the oxide powder is poured from the bottom of the electrolyte tube, it is possible to form a two-phase oxide-electrolyte contact. The electrical circuit is completed with Pt wire leads and a Pt/Pt-Rh 10% thermocouple, which is gently pressed onto the powder by the collar-spring combination. The reference electrode is a porous Pt electrode suitably deposited on the outer surface of the YSZ tube.

After having introduced the sample, the whole system, including the ion-getter pump, is baked under vacuum at 570°K. The sample is then brought to a known composition by equilibration with CO/CO_2 mixtures of known oxygen fugacity at 1173°K by using the data of Hampson (10). After equilibration and before proceeding with the measurements, the system is held for 30 min under vacuum until a pressure of less than 10^{-8} Torr (as read with the ion-getter pump) is reached in the system. The hot zone of the cell at 970°K and the leak rate of the cell is about 10^{-10} Torr 1 sec^{-1}.

Double wall cell.—In order to reduce the oxygen permeation from the atmosphere through the wall of the electrolyte tube [which is significant at temperatures higher than 1300°K (4)], a double wall cell has been developed (Fig. 4). It consists of a solid-state galvanic cell of the type

$$\text{Pt, } (P_{O_2}') \text{ } MeO_x/YSZ/CeO_{2-x}/YSZ/(P_{O_2}'')/\text{Pt} \quad \text{(II)}$$

The emf of cell II is again proportional to the ratio of the oxygen partial pressure in the right and in the left side cell compartments, according to the equation

$$E_{II} = E_I = \frac{RT}{4F} \ln \frac{P_{O_2}''}{P_{O_2}'} \quad [2]$$

and the over-all cell equation is O_2 (P") → O_2 (P'). The inner part of the cell consists of a 4 mm ID, 6 mm OD YSZ tube containing the oxide sample which is electrolytically sealed onto a copper tube. This is done by baking at 570°K, and cold sealing by crimping under a vacuum. The outer part of the cell consists of a 12 mm OD, 8 mm ID YSZ tube. A porous Pt reference electrode is deposited on the outer wall of the tube. The CeO_{2-x} powder in the bottom of the outer tube serves both as an oxygen getter in the annular chamber between the outer and inner YSZ tube, and to produce electrochemical continuity between the two electrolyte tubes. The annular chamber itself is under UHV conditions by means of a rotary diffusion pump (100 liters/sec) and details are shown in Fig. 4. Under these conditions, the CeO_{2-x} powder operates as a reversible oxygen electrode whose cell emf in cell II is

[2] The procedure consists of firing a Pt paste to obtain a porous Pt layer.

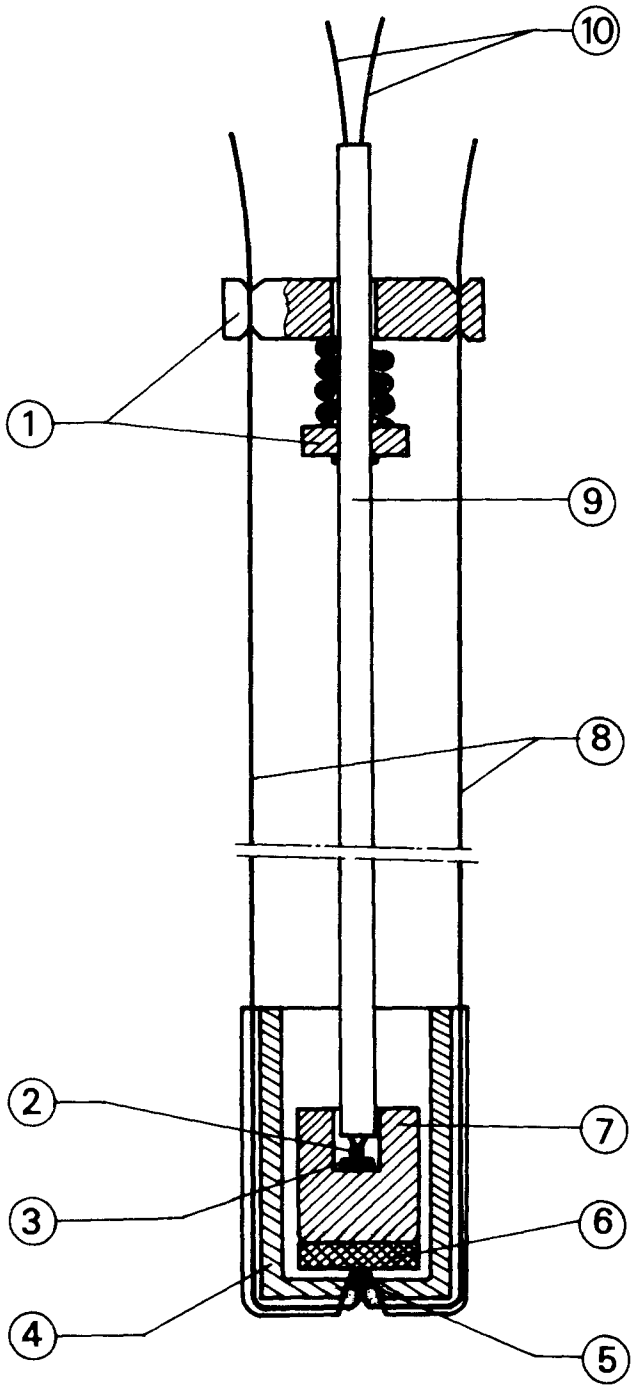

Fig. 3. Schematic drawing of the single compartment emf cell using yttria stabilized thoria electrolyte: (1) Al_2O_3 collar and ring; (2) and (5) thermocouple and electrical contact; (3) $(U\ Pu)O_{2-x}$ sample; (4) Al_2O_3 crucible; (6) reference electrode; (7) yttria-doped thoria crucible (electrolyte); (8) and (10) Pt-Pt 10% wire; (9) Al_2O_3 capillary.

independent of the oxygen partial pressure in the annular chamber, and corresponds to the emf in cell I.

Thoria-electrolyte cell.—In order to extend the operation of the cell to oxygen potentials less than $\simeq$100 kcal/mole, the YSZ must be substituted by thoria-base electrolytes in order to avoid the excessive electronic conduction. This would make it difficult to evaluate the unknown oxygen potential by integration of the Wagner equation

$$E = \frac{1}{2\mathbf{F}} \int_{\mu' O_2}^{\mu'' O_2} t_{O^=} d\mu O_2$$

which substitutes for the Nernst equation for E when $t_{O^=}$ is not unity.

Fig. 4. Because YST[3] tubes have poor mechanical stability during thermal cycling, are much more expensive than YSZ, and could eventually still exhibit electronic conductivity due to their impurity content, a cell design that does not involve the use of such a tube has been chosen. The cell consists of an alumina tube (see Fig. 3) which is restrained by a support wire acting also as thermocouple and electrical conductor for the cell. The reference electrode and the (YST) electrolyte pellet are mounted inside this crucible. The specimen for analysis is placed in the cavity, and electrical contact to the specimen is made by another thermocouple which is spring loaded in order to maintain contact during the experiment. The complete assembly is fitted inside an alumina tube which is connected to the UHV system. This cell has been tested by measuring the oxygen potential over Fe/FeO against the Ni/NiO reference electrode. This cell emf (Fig. 5) was found to be within the limits of accuracy reported in literature.

Results

Measurements on CeO_{2-x}.—A single wall cell has been used for these measurements, and this has been thoroughly described in a previous paper (7). The results of these experiments are given in Fig. 6 in terms of their dependence on the temperature of the chemical potential of oxygen in equilibrium with a sample of known and constant composition. One can observe that they display the same temperature dependence as reported by Hampson (10) and they compare well with analogous results of Bevan and Kordis (11).

The oxygen potentials determined from the experimental emf values are reported in Fig. 7 (for a single value, at 905°K) and Fig. 8. For comparison purposes, the Rand and

Markin results (12) are reported for same compositions. There is remarkably good agreement in both cases.

Measurements on hypostoichiometric uranium-plutonium $(U_{0.80}Pu_{0.20})O_{2-x}$ *fuels.*—A batch of uranium-20% plutonium oxide was prepared by a coprecipitation method. Small (500 mg) samples from this batch

were reduced in various H_2/H_2O gas ratios at 1473°, 1573°, and 1673°K for 6 hr. The reduction was performed in a glove box which contained the galvanic cell so that specimens could be transferred directly to the cell. After the measurements, the specimens were transferred to another box where the oxygen-to-metal ratio (O/M) was determined by a gravimetric technique involving oxidation to $MO_{2.00}$ with CO/CO_2 and by x-ray analysis. Both methods agreed to within 0.006 O/M units. Three sets of oxygen potential measurements were carried out at temperatures between 800° and 1300°K and O/M values of 1.995, 1.985, and 1.964. The results are shown in Fig. 9 together with the results of Woodley (13) and Markin (14). The results of Markin are adjusted to $U_{0.8}Pu_{0.2}$ oxide following Woodley's method. The results obtained compare better with the extrapolated Woodley data than with those of Markin. This is also clear from the entropy data shown in Table I.

Inadvertent oxidation of the specimen of O/M = 1.99 due to the transfer of hypostoichiometric oxide between boxes during analysis could give rise to the difference in $\Delta G(O_2)$ between the above results and those of Woodley. At this O/M ratio the chemical potential of oxygen strongly depends on the stoichiometry, and a small oxidation could cause a large change in oxygen potential. To eliminate the above-mentioned uncertainty due to the specimen oxidation, research is now underway for a method of quantitative coulometric titration using a solid-state galvanic cell.

Conclusions

The experimental results given above demonstrate that in the case of oxides exhibiting high ionic and electronic mobility (like most of the oxides with the fluorite structure), a loose contact between the electrolyte walls and the oxide powder (which works at the electrode) is sufficient to obtain reliable thermodynamic data with a solid galvanic cell. These results should be discussed in the context of the theory of the oxygen electrode at high temperature and have a rather wide significance which goes beyond the achievement of an accurate measurement of oxygen profiles in irradiated fuels. It is in fact known that the erratic behavior of (porous) Pt electrodes at very low partial pressures of oxygen is essentially due to the kinetic hindering of the reaction

$$\tfrac{1}{2}\,O_2\ (\text{gas}) + 2e\ (\text{Pt}) \rightleftarrows O^{=}\ (\text{into the electrolyte}) \quad [3]$$

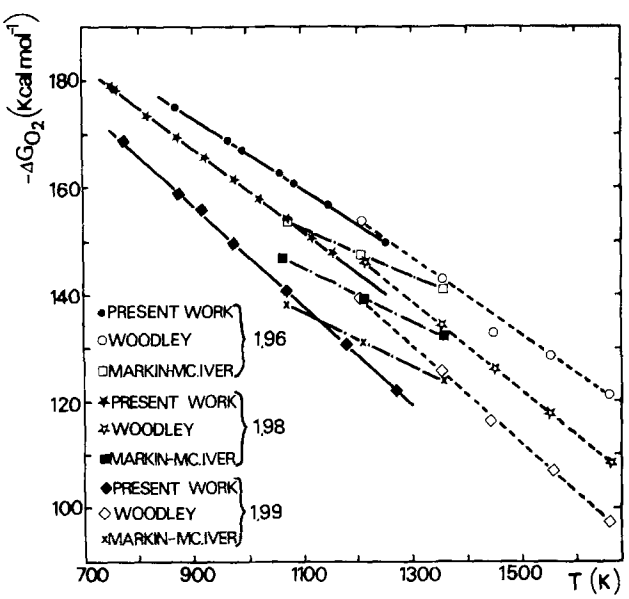

Fig. 9. Comparison of experimental and literature data of partial molar-free energy of oxygen vs. temperature on microsamples of $(U_{0.08}Pu_{0.2})O_{2-x}$ at different oxygen-to-metal ratios.

Table I. Entropy values (eu) of hypostoichiometric U-Pu oxides

Markin	44	47	48
Woodley	73	82	93
Present work	67	77	93

which occurs at the three-phase contact between the atmosphere, the electrolyte, and the metal.

Under these conditions, other reactions which behave like parasitic processes at high oxygen partial pressures take place such as the direct exchange of dissolved oxygen in Pt

$$O\ (\text{Pt}) + 2e \rightleftarrows O^{=}\ (\text{into the electrolyte}) \quad [4]$$

or the redox reactions involving adsorbed gases, like CO_2 and H_2

$$CO_2 + 2e \rightleftarrows CO + O^{=}\ (\text{into the electrolyte}) \quad [5]$$

and

$$H_2O + 2e \rightleftarrows H_2 + O^{=}\ (\text{into the electrolyte}) \quad [6]$$

become potential determining.

Incidentally, it is recalled that the oxygen diffusion in Pt is known to be a very slow process (15) and that both H_2 and CO are strongly chemisorbed on Pt.

By considering that the oxides used in the present work display high oxygen diffusivity in conjunction with good electronic conductivity and, moreover, a fast equilibration rate with the atmosphere, their use does maintain oxygen pressure at the interface between the oxide, the atmosphere, and the electrolyte corresponding to the thermodynamic equilibrium value, so that the reactions

$$\tfrac{1}{2}\,O_2\ (\text{gas}) + 2e\ (\text{oxide}) \rightleftarrows O^{=}\ (\text{into the electrolyte}) \quad [7]$$

and

$$O\ (\text{oxide}) + 2e\ (\text{oxide}) \rightleftarrows O^{=}\ (\text{into the electrolyte}) \quad [8]$$

occur at the same potential.

Since reactions [4] or [8] are potential determining at very low partial pressures of oxygen, it is an obvious conclusion that the condition which should be fulfilled to determine very low partial pressures of oxygen is to use a solid electrode. This type of electrode exchanges oxygen with the gas phase at a very fast rate, and behaves like a virtually unpolarizable electrode (16).

Standard Free Energy of Formation of Alumina

D. Ghosh* and D. A. R. Kay

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4L7

ABSTRACT

The standard free energy of formation of alumina, $\Delta G°_f(Al_2O_3)$, has been determined in the temperature range 1350°-1550°C, by studying the reaction

$$2Al_{(l)} + 3/2\ O_{2(g)} = Al_2O_{3(\alpha)}$$

using electrochemical cells of the type

$$Pt_{(s)} - Al_2O_{3(s)}, Al_{(l)}|Al_2O_3 \text{ in liquid slag}|O_{2(g)}, Pt_{(s)}$$

and

$$C_{(s)}, Al_{(l)}|Al_2O_{3(s)}|\text{ionic oxide slag}|Al_2O_{3(s)}|Fe\text{-}C_{(l)}, CO_{(g)}, C_{(s)}$$

Evaluation of the experimental data gives

$$\Delta G°_f(Al_2O_3) = -394{,}680 + 77.8T \text{ cal/mole } (1640°\text{-}1830°K)$$
$$= -1652.45 + 0.3257T \text{ kJ/mole } (1640°\text{-}1830°K)$$

and a value of the standard enthalpy of formation of alumina, $\Delta H°_{298}(Al_2O_3)$, of −392.60 kcal/mole (−1643.7 kJ/mole) which is about 8 kcal/mole more positive than the generally accepted thermochemical value of −400.40 kcal/mole (−1676.4 kJ/mole). A value for $\Delta H°_{298}(Al_2O_3)$ of about −393 kcal/mole is consistent with data in the literature from low temperature formation cell measurements at ~1000°C and from mineralogical studies.

The reaction

$$3[O]_{1w/o} + 2[Al]_{1w/o} = Al_2O_{3(\alpha)} \quad [1]$$

where [ ] represents a component in solution in liquid iron and 1 w/o refers to the 1 weight percent (w/o) solution standard state, is of importance in steel deoxidation and electroslag remelting.

Under equilibrium conditions, the soluble oxygen content of the steel is controlled by the soluble aluminum content and the activity of alumina in the deoxidation product or slag, through the equilibrium constant, K_1

$$K_1 = a_{Al_2O_3}/h_{Al}{}^2 \cdot h_O{}^3 \quad [2]$$

where $a_{Al_2O_3}$ is the Raoultian activity of α-alumina and h_i is the Henrian activity of component i in solution in steel. In order to be able to use Eq. [2] to control the soluble oxygen content in liquid steel, the solution thermodynamics of the Fe-Al-O system and the standard free energy of formation of alumina must be accurately known at steel-making temperatures of about 1600°C. In practice, there is a discrepancy between the experimental and thermodynamically predicted values for the solubility product of alumina, the thermodynamically predicted values being smaller than the experimental values. Although there are sampling and analytical difficulties associated with the experimental determinations, it is possible that the presently accepted free energy data for alumina are in error.

* Electrochemical Society Active Member.

Key words: electrochemical cells, thermochemistry, alumina.

The highest temperatures at which the standard free energy of formation of alumina has been determined directly are those of aluminum extraction (1-6), *i.e.*, about 1000°C. There have been no direct determinations at steel-making temperatures.

The work presented in this paper describes experiments with high temperature electrochemical cells designed to determine the standard free energy of formation of alumina at steel-making temperatures.

Electrochemical Cells

Two types of electrochemical cell were used in the present work. The first cell, cell I, may be represented by

$$Pt_{(s)} - Al_2O_{3(s)}, Al_{(l)}|Al_2O_3 \text{ in liquid ionic slag}|O_{2(g)}, Pt_{(s)}$$

and the following reactions may be considered:
The anode reaction

$$3(O^{2-}) + 2Al_{(l)} = Al_2O_{3(s)} + 6e \quad [3]$$

The cathode reaction

$$3/2\ O_{2(g)} + 6e = 3(O^{2-}) \quad [4]$$

The cell reaction

$$2Al_{(l)} + 3/2\ O_{2(g)} = Al_2O_{3(s)} \quad [5]$$

The free energy change for the cell reaction and the cell emf are then given by the relationships

$$\Delta G_{cell} = \Delta G^\circ_{cell} + RT \ln (a_{Al_2O_3}/a_{Al}^2 \cdot p^{3/2}O_2) \quad [6]$$

and

$$E_{cell} = E^\circ_{cell} - (RT/6F) \ln (a_{Al_2O_3}/a_{Al}^2 \cdot p^{3/2}O_2) \quad [7]$$

respectively.

When the reactants and products of the cell reaction are in their respective Raoultian standard states of pure gases at 1 atm pressure and pure condensed phases, *i.e.*, the slag is alumina saturated

$$\Delta G_{cell} = \Delta G^\circ_{cell} = -6FE^\circ_{cell} \quad [8]$$

The determination of the cell emf then gives the standard free energy of formation of alumina at the experimental temperature. The second cell, cell II, may be represented by

$$C_{(gr)}, Al_{(l)} | Al_2O_{3(s)} | \text{ionic oxide slag} | Al_2O_{3(s)} | Fe\text{-}C_{(l)}, CO_{(g)}, C_{(gr)}$$

and the corresponding anodic, cathodic, and cell reactions are

$$2Al_{(l)} + 3(O^{2-}) = Al_2O_{3(s)} + 6e \quad [9]$$

$$3CO_{(g)} + 6e = 3(O^{2-}) + 3C_{(gr)} \quad [10]$$

and

$$2Al_{(l)} + 3CO_{(g)} = Al_2O_{3(s)} + 3C_{(gr)} \quad [11]$$

respectively.

The cell emf is given by the relationship

$$E_{cell} = E^\circ_{cell} - \frac{RT}{6F} \ln (a_C^3 \cdot a_{Al_2O_{3(s)}}/p_{CO}^3 \cdot a_{Al}^2) \quad [12]$$

and Eq. [8] again holds when the reactants and products of the cell reaction are in their Raoultian standard states. The standard free energy of formation of alumina in this case is obtained from the measured cell emf and the known standard free energy of formation of carbon monoxide.

Cell Design

The design of the cell

$$Pt_{(s)} - Al_2O_{3(s)}, Al_{(l)} | Al_2O_3 \text{ in slag} | O_{2(g)}, Pt_{(s)}$$

is largely governed by the choice of the liquid slag electrolyte. Electrolytic studies of slag in the CaF_2-Al_2O_3 system (7) indicate that they conduct ionically at steel-making temperatures. Three current versions of the CaF_2-Al_2O_3 phase diagram (8-10) are shown in Fig. 1 and the recent version of Mitchell and Burel (10) was used in this work. The relevant properties of aluminum and the electrolyte are given in Table I. Graphite is one of the few materials which may be used to contain both aluminum and the electrolyte, but since the system must be alumina saturated, alumina itself may be used.

The cell assembly, consisting of a container, an Al/Al_2O_3 electrode, and an oxygen electrode, is shown diagrammatically in Fig. 2.

The Al/Al_2O_3 electrode.—The two types of Al/Al_2O_3 electrode design used in this work are shown diagrammatically in Fig. 3. These designs were chosen to satisfy the following conditions: (*i*) aluminum will float on the liquid slag, see Table I; (*ii*) aluminum melts at a lower temperature than the electrolyte; (*iii*) electrical contact has to be made with liquid aluminum; and (*iv*) aluminum must be protected against excessive oxidation. Conditions (*i*) and (*ii*) are satisfied by plac-

ing the outer alumina tube of the electrode in the well at the bottom of the graphite container and surrounding it with crushed prefused electrolyte. Aluminum, placed inside this tube, melts first and, when the electrolyte becomes molten, the tube is raised out of the well in order to allow the aluminum to float on top of the electrolyte inside the tube.

Graphite was used to make electrical contact with liquid aluminum in the initial experiments, Fig. 3a, but since this introduced a thermal emf with the platinum contact of the oxygen electrode, a $Pt-Al_2O_3$ cermet contact was developed, Fig. 3b.

The oxygen electrode.—The main requirement of the oxygen electrode is that oxygen gas of known partial pressure must contact the electrolyte and a platinum lead. Sridhar and Jeffes (16) have critically reviewed the design of oxygen electrodes and the one used in the present study, shown in Fig. 4, is based on their assessment.

Oxygen gas is passed through the inner of two concentric recrystallized alumina tubes and returned through the outer tube. Contact is made with the slag by a platinum wire passing down the inner tube, the end of the wire being retracted about 0.1 in. (0.25 cm) from the end. The two tubes were held in a brass head using an O-ring seal and a Swagelok fitting.

Cell II.—The design of the cell

$$C_{(gr)},Al_{(l)}|Al_2O_{3(s)}|\text{ionic oxide slag}|Al_2O_{3(s)}|$$

$$Fe\text{-}C_{(l)}, CO_{(g)}, C_{(gr)}$$

which consists of a container, an Al/Al_2O_3 electrode, and a C/CO electrode, is shown diagrammatically in Fig. 5. Although alumina shows considerable electronic conductivity at ~1600°C, it can be used to separate the individual electrodes, as long as a fully ionic electrolyte is interposed between them, the fully ionic electrolyte preventing the electronic short circuiting of the cell. Separation of the anode and cathode removes two of the restrictions on the electrolyte, *i.e.*, it must be saturated with alumina and it must not be reduced by aluminum.

Except for the absence of the well in the bottom, the graphite container is identical to that used for cell I.

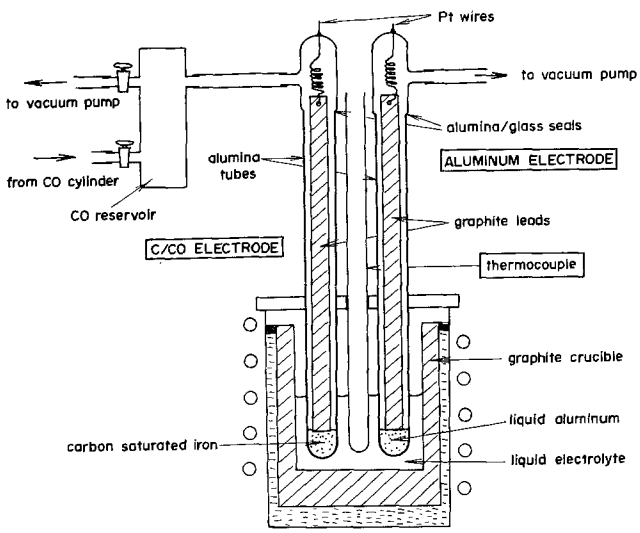

Fig. 5. Cell II assembly

The electrodes.—As shown in Fig. 5, both the Al/Al_2O_3 and C/CO electrodes are of similar construction, consisting of closed-end recrystallized alumina tubes which contain aluminum and graphite-saturated iron, respectively. Contact with the metal phase is made by a graphite rod in each case.

A glass head was joined to the top of each alumina tube by a glass/alumina seal (Corning No. 7056) and electrical contact with the graphite rods was made through platinum wires sealed into each head.

A 200 ml gas reservoir was connected to the head of the C/CO electrode and both the electrode and the reservoir were filled with CO gas at 1 atm pressure before an experiment. The glass head of the Al/Al_2O_3 electrode was connected to a mechanical vacuum pump and a pressure of $\sim 10^{-2}$ Torr (~ 1 N/m^2) was maintained throughout an experiment.

Experimental

Temperature measurement.—A Pt/Pt-13%Rh thermocouple, contained in a recrystallized alumina sheath, was used to measure the temperature of both cells.

In initial experiments, the alumina sheath was placed inside a graphite tube to protect it from slag attack. This protection proved unnecessary as slag attack was not excessive.

Thermocouples were calibrated against a National Research Council standard thermocouple.

Temperature control.—A 25 kW, 450 kHz Taylor Winfield "Thermionic" induction unit was used to heat the graphite cell to the required temperature. The power from this unit was manually controlled by fine adjustment of the coil current. High temperature thermal stability was achieved in about 45-60 min using this method of control. Over-all temperature control is estimated at ±5°C.

Emf measurement.—A Type P3 Croydon potentiometer and a Keithley Model 616 high impedance electrometer ($2 \times 10^{14}\Omega$) were connected in parallel through a double-pole, double-throw switch and were used to measure the cell and thermocouple emf's.

The emf of cell I (~2V at 1500°C) was outside the range of the potentiometer (0-1.8V) and could be read by the electrometer to only ±10 mV. For this reason a Weston (Eppley) Standard cell (1.0183V at 20°C) was introduced into the measuring circuit, in opposition to the formation cell, so that the resultant emf could be measured within ±1 mV on both instruments. High frequency pickup from the induction unit in cell I was eliminated by grounding all thermocouple and cell leads through 0.1 μF capacitors. In cell II, grounding the leads through capacitors did not remove all high frequency pickup. Cell emf and thermocouple readings were taken only when power to the induction unit was momentarily switched off.

Materials.—The source and type of materials used in this investigation are summarized in Table II.

Platinum-graphite thermal emf.—The use of a graphite lead in the initial Al/Al_2O_3 electrode design, Fig. 3a, introduced a platinum-graphite thermoelectric emf into the measured emf. Values of this platinum-graphite thermal emf were determined directly at experimental temperatures, the emf being measured between a $Pt\text{-}Al_2O_3$ cermet and a graphite rod set within a graphite block heated by the 450 kHz induction unit. The platinum-graphite emf obtained is shown as a function of temperature in Fig. 6, which was used to determine the true cell emf when using the graphite contact. This problem was overcome by using a $Pt\text{-}Al_2O_3$ cermet contact (Fig. 3b).

Cermet preparation.—Platinum and alumina powders in a 70:30 proportion by weight were mixed thoroughly and about 0.6g of the mixture pressed into a 3/16 in. diam (~0.5 cm diam) cermet. A platinum wire lead was passed through a hole in the base plate and bottom plunger of the cermet die before pressing and formed an integral part of the cermet. The "green" cermet was sintered in air at 1500°C for 12 hr. Typical cermet contacts, before and after use, are shown in Fig. 7. The cermet was sealed into a recrystallized alumina tube with Alundum cement, Fig. 3b, the top of the cermet being machined to fit the inside diameter.

Table II. Materials

Material	Source and type
Calcium fluoride	BDH, Extra Pure
Calcium carbonate	Fisher Scientific, Reagent Grade
Silica powder	Fisher Scientific, Reagent Grade
Alumina powder	Fisher Scientific, Certified
Alundum cement	Fisher Scientific
Graphite	Union Carbide, CS and ECV
Aluminum	Alcan, 99.995%
Platinum sponge	Johnson, Matthey & Mallory, Grade I
Oxygen	Canadian Liquid Air, Extra Dry
Carbon monoxide	Matheson, Technical
Recrystallized alumina	McDanel, 99.8%
Silica tubes	Quartz Scientific

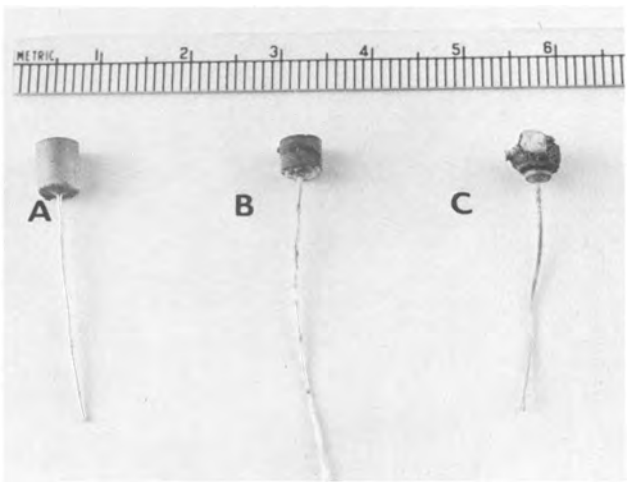

Fig. 7. Platinum-alumina cermets; (a) before use, (b) after 30 min at 1448°C, and (c) after 25 min at 1551°C.

Slag preparation.—The compositions of the $CaF_2\text{-}Al_2O_3$ slags used in cell I are shown in Fig. 1. Compositions close to the alumina saturated liquidus of Mitchell and Burel (10) were chosen to give maximum slag fluidity. Crushed and ground premelted calcium fluoride was mixed with alumina powder to give the required slag mixture.

The crushed and ground $CaO\text{-}SiO_2\text{-}Al_2O_3$ slag used in cell II was obtained from the required mixture of reagent grade powders, premelted in a graphite crucible. This starting slag, containing 38% CaO, 42% SiO_2, and 20% Al_2O_3, picked up alumina from the C/CO and Al/Al_2O_3 electrodes during the course of an experiment.

Procedure.—Cell I was set up by placing a cylindrical piece of high purity aluminum in the alumina tube of the Al/Al_2O_3 electrode, the bottom of which was sealed in the well of the graphite container. A slag mixture of predetermined composition was then poured into the container, with the thermocouple sheath in

position and the oxygen electrode positioned above the slag using the water-cooled brass electrode holder, Fig. 2. After placing refractory brick shields below and around the cell assembly in order to prevent excessive heat losses, the induction unit was switched on and the temperature raised to approximately that of the experiment in about 45-60 min. The melt was equilibrated for a further 15-20 min by which time a thermal steady state, with negligible thermal drift, was achieved. The aluminum electrode was then raised and the oxygen electrode lowered into the melt until the outer alumina tube was below the surface of the slag. The inner alumina tube was lowered into the slag with the oxygen flowing at 20-40 ml/min until a reading was obtained on the electrometer. When the inner tube was pushed too far into the melt the "sawtooth" emf associated with oxygen bubbling through the melt (16) was obtained. The inner tube was then pulled up until the sawtooth variation of the emf disappeared. When the electrodes were in position, time zero, the cell and thermocouple emf's were alternately monitored on the electrometer and check measurements made at convenient intervals with the potentiometer. Measurements made on both the potentiometer and electrometer agreed to within ±2 mV.

Cell II was set up in the induction coil as in the case of cell I. The slag mixture was then poured into the crucible and the electrodes positioned above the slag. The C/CO electrode was evacuated and filled with carbon monoxide at 1 atm pressure, and the Al/Al_2O_3 electrode was evacuated continuously. The cell was raised to the experimental temperature in 45-60 min and held for a further 10-15 min. The electrodes were then lowered and the cell and thermocouple emf's monitored at convenient intervals with the induction unit momentarily switched off.

After an experiment the electrodes were sectioned and checked for slag attack. The Al/Al_2O_3 electrode was also checked for the presence of aluminum and the cermet condition recorded. Finally, aluminum samples from cell I were analyzed gravimetrically for platinum (17).

Results

Cell I.—The type of cell emf *vs.* time relationship obtained experimentally is shown in Figure 8, which also shows the effects of imposing an external emf on the cell and discharging it momentarily through an external circuit in order to check its reversibility. Reversible plateau emf's of between 6 and 15 min duration were typically obtained. The initial decrease in cell emf is caused by the electrodes attaining thermal equilibrium with the electrolyte, and the final decrease is probably caused by failure of the oxygen electrode.

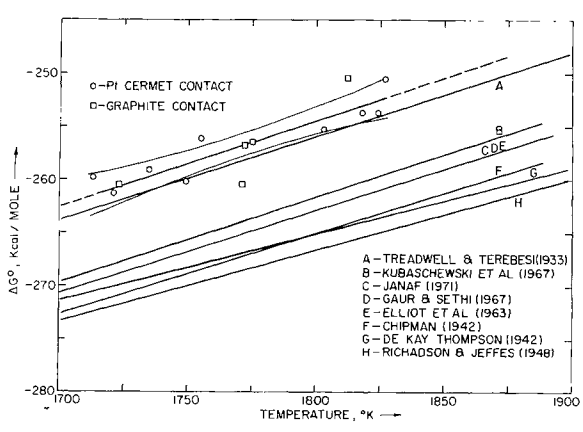
* G = graphite; C = cermet.



The raw data from cell I are given in Table III together with the calculated standard free energies of formation of alumina, $\Delta G°_f(Al_2O_3)$. These values of $\Delta G°_f(Al_2O_3)$ are also shown as linear function of temperature in Fig. 9, together with the relationships of other workers (1, 11, 13, 14, 18-21). A linear regression analysis of this data gives

$$\Delta G° = -398{,}560 + 80.02T \text{ cal/mole } (1713°\text{-}1827°\text{K}) \quad [13]$$

$$= -1668.70 + 0.3350T \text{ kJ/mole}$$

The 95% confidence limit at 1773°K is ±1.0 kcal (±4.187 kJ). These values are substantially more positive than those based on thermochemical data (11, 13, 14, 18-21) with the exception of the early work of Treadwell and Terebesi (1).

The standard free energy of formation of alumina has also been determined directly at aluminum extraction temperatures (~1000°C) using formation cells with alumina-saturated cryolite as the liquid electrolyte (1-6). These results are shown in Fig. 10, together with the results of the present investigation and the generally accepted thermochemical data (11, 14, 18). With the exception of the work of Thonstad (6), the low and high temperature formation cell determinations are generally consistent with each other and both these sets of results are at variance with those obtained from thermochemical data.

STANDARD FREE ENERGY OF FORMATION OF ALUMINA IN TEMP RANGE 1700-1900°K

Cell II.—Stable cell voltages were obtained for periods of over 2 hr once thermal equilibrium had been attained. Cell failure was usually caused by slag attack of the alumina refractories. Cell reversibility was checked by the same technique used for cell I.

Experimental data obtained from cell II are given in Table IV which also gives the standard free energy change for the cell reaction, the standard free energy of formation of carbon monoxide (11), and the calculated standard free energies of formation of alumina. Values of $\Delta G°_f(Al_2O_3)$ obtained from both cell I and cell II are shown as a function of temperature in Fig. 11, which also includes the generally accepted thermochemical relationship for comparison.

Third law analysis.—A third law analysis of the standard free energy data from cell I and cell II given in Tables III and IV, using values of Gibbs energy functions, gef_T, calculated from relevant enthalpy and specific heat data for alumina (22), aluminum (23, 24), and oxygen (25), yielded the values for the standard enthalpy of formation of alumina at 298°K, $\Delta H°_{298}(Al_2O_3)$ given in Table V. These values are also shown as a function of experimental temperature in Fig. 12, together with the results obtained from oxygen bomb calorimetry. The average value of $\Delta H°_{298}(Al_2O_3)$ from cell I data is −392.55 kcal/mole (−1643.5 kJ/mole) with 95% confidence limits of ±1.0 kcal/mole and that from cell II data is −392.71 kcal/mole (−1644.2 kJ/mole) with 95% confidence limits of ±2.3 kcal/mole.

Discussion

As indicated in Fig. 9, 10, and 11, the values of $\Delta G°_f(Al_2O_3)$ obtained in this work are substantially more positive than those based on thermochemical data, the only exception being the early work of Treadwell and Terebesi (1). The value of −254.42 kcal/mole (−1065.2 kJ/mole) at 1800°K determined from cell I data compares with the presently accepted best value of −262.92 kcal/mole (−1100.8 kJ/mole) at 1800°K, taken from JANAF Tables (11). It is therefore necessary to examine the possible sources of error in the present work.

II	1785	256.81	136.79	393.60

* $(\Delta H°_{298})_{Avg}$ = − 392.55 kcal/mole Al_2O_3 (cell I)
= − 392.71 kcal/mole Al_2O_3 (cell II)
= − 392.60 kcal/mole Al_2O_3 (cell I and cell II).

Cell I.—Standard conditions.—As shown in Eq. [7]

$$E_{cell} = E°_{cell} - (RT/n\mathbf{F}) \ln a_{Al_2O_3}/a_{Al}^2 \cdot pO_2^{3/2}$$

the standard cell emf, $E°_{cell}$, can only be obtained from cell I if the activities of alumina and aluminum and the partial pressure of oxygen are close to unity.

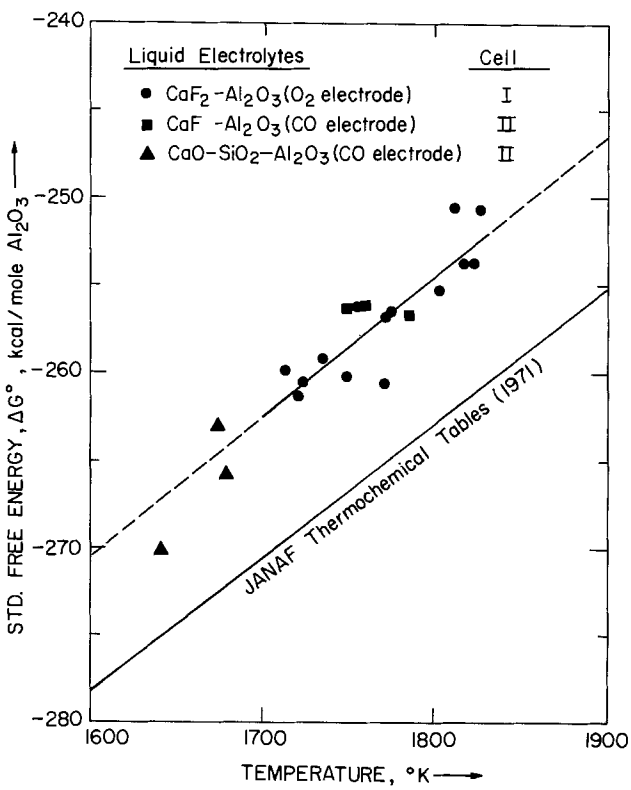

Fig. 11. $\Delta G°_f(Al_2O_3)$ data from cells I and II in comparison with the thermochemical relationship.

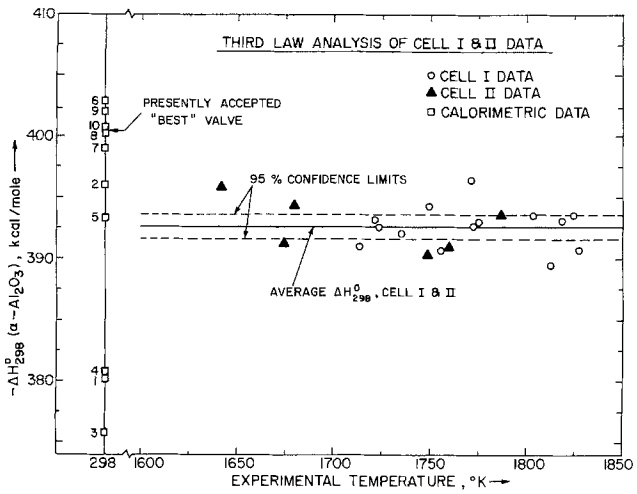

Fig. 12. The standard heat of formation of alumina, ΔH°_{298}, from cell I and II data and from bomb calorimetry. 1, Berthelot (63); 2, Wartenberg and Witsel (64); 3, Moose and Parr (65); 4, Roth and Muller (66); 5, Meichsner and Roth (67); 6, Roth, Wolf, and Fritz (68); 7, Snyder and Seltz (69); 8, Holley and Huber (70); 9, Schneider and Gattow (71); 10, Mah (72).

Despite inconsistencies in the three versions of the "CaF_2"-Al_2O_3 phase diagram reported in the literature (8-10), alumina saturation of cell I slags is virtually assured by the presence of solid alumina refractories in the cell. In any event, an alumina activity of less than unity, say 0.9, would introduce an error in E°_{cell} of +2.7 mV at 1800°K and give an apparent ΔG°_f (Al_2O_3) some 375 cal/mole (1.57 kJ/mole) more negative than the true value.

The solubility of carbon in molten aluminum is small (26, 27) and under the experimental conditions of the present investigation the effect of carbon on the activity of aluminum may be neglected. The aluminum-platinum phase diagram of Huch and Klemm (28), however, indicates extensive solubility of platinum in liquid aluminum at 1500°C. The maximum platinum content of anode aluminum at the end of an experiment with cell I was 2.54 w/o (0.0036 mole fraction) at 1551°C. Although Huch and Klemm report the presence of nine intermetallic phases in the platinum-aluminum system in the platinum-rich region of the diagram (Pt > 60 w/o), which indicates a very strong deviation from ideality in this region, there is a eutectic at 9 w/o platinum and 657°C. Under these conditions the deviation from ideality of aluminum solutions of >0.9964 mole fraction is not expected to be large. Calculations using Eq. [6] show that an aluminum activity of 0.90 at 1800°K would give an apparent $\Delta G^{\circ}_f(Al_2O_3)$ some 745 cal/mole (3.12 kJ/mole) more positive than the true value.

At the cathode, high purity oxygen gas, at slightly greater than atmospheric pressure, flows past a platinum wire in contact with the slag electrolyte. In principle, corrections are required for dilution of the oxygen by CaF_2 vapor, 0.7 mm Hg at 1500°C, for the excess pressure of oxygen caused by the immersion of the electrode tip under the electrolyte melt, and changes in barometric pressure. These corrections are extremely small, however, and well within the experimental precision of this investigation.

High experimental temperatures and the use of a high impedance electrometer and a potentiometer with a step-down resistance box minimized electrode polarization during measurement of the cell emf. A sawtooth cell emf was observed which varied with the frequency of gas bubbling when the oxygen electrode was pushed too far down into the slag electrolyte. This effect has been observed by Sridhar and Jeffes (16, 29) who solved the problem by retracting the platinum wire inside the inner alumina tube so that oxygen gas was in contact with the whole length of platinum wire, while contact with the electrolyte was made through the thin film wetting the inside of the tube. This effect is caused by the limited solubility of oxygen in the electrolyte setting up a "mixed" potential along that part of the platinum wire which is immersed in the slag.

Errors introduced by a radial temperature gradient in the cell, <5°C, are expected to be small and although the platinum-graphite thermal emf was only determined experimentally up to 1400°C with a reproducibility of ±0.2 mV, the error in the extrapolated values in the range 1400°-1600°C is estimated to be ~±0.5 mV.

Cell reaction.—In the present work it is assumed that the cell reaction represents the formation of alumina from its constituent elements. This assumption is only valid if the oxidation state of aluminum is single valued and can be represented by solid alumina. Other species, representing different oxidation states of aluminum, are $Al_2O_{(g)}$, $AlO_{(g)}$, $Al_2O_{2(g)}$, and $AlO_{2(g)}$. The standard free energies of formation of those oxides at 1700° and 1800°K (11) are given in Table VI. It is apparent that $Al_2O_{3(s)}$ is substantially more stable than the other oxides and that the cell emf must represent the formation of alumina from its constituent elements.

Cell reversibility.—Cell reversibility was checked by momentarily imposing a greater emf than the equilibrium value or by discharging the cell through an external circuit. In each case, the emf returned to its "open-circuit" equilibrium value within a few seconds, as shown in Fig. 8. Variations in oxygen flow rate had no significant effect on the cell emf except when the oxygen supply was cut off completely. Under these circumstances the cell emf decreased rapidly.

Individual electrode reversibility is implied in overall cell reversibility. The aluminum electrode is reported to behave reversibly (6, 31), and the behavior of the oxygen electrode has been reviewed by many workers (16, 32-35). It has been found to behave reversibly in molten carbonates (36), borates (37, 38), sulfates (39, 40), phosphates (39), silicates (16, 38, 41, 42) sulfate/carbonate mixtures (43), and in molten cryolite melts (4, 5) similar to those of the present investigation.

Electrolyte conductivity.—The difference between the standard free energies of formation obtained in the present work and those obtained from thermochemical data could be caused by mixed ionic and electronic conduction in the slag electrolyte. A 3% electronic conductivity would result in the present values being about 7.5 kcal/mole too positive and make them consistent with the generally accepted thermochemical data (11, 14).

There is, however, considerable evidence in the literature (44) which indicates that the ionic transport number of the electrolyte is sufficiently close to unity to preclude the possibility of any large systematic error. Solid CaF_2 is reported to be an ionic conductor (45, 46) and its successful use as a solid electrolyte has been reviewed (47). Literature on the conductivity of solid Al_2O_3 has been reviewed (48) and substantial electronic conductivity in the temperature range 900°-

Table VI. The standard free energy of formation, ΔG°_f, of aluminum oxides at 1700° and 1800°K (11)

Species	ΔG°_f (kcal/mole) 1700°K	1800°K
α-$Al_2O_{3(s)}$	−270.61	−262.92
$Al_2O_{(g)}$	−60.77	−61.80
$AlO_{(g)}$	−9.83	−11.23
$Al_2O_{2(g)}$	−87.43	−86.22
$AlO_{2(g)}$	−45.23	−45.03

1750°C has been reported (49-51). In the present work we are therefore concerned with the conductivity of an electrolyte formed by the addition of a semiconducting solid to a molten ionic liquid. Since the conductivity of CaF_2 (52) in the temperature range 1500°-1600°C are about five to six orders of magnitude larger than alumina (49), negligible electronic conductivities of the slags used in cell I are expected. In addition Mitchell and Benyon (7) report faradaic efficiencies of 100% in the CaF_2-Al_2O_3 system.

Finally, the good agreement of the present results with those at 1300°K (1-6) is also indicative of the electrolyte behaving ionically, since the probability of substantial electronic conduction is less at these lower temperatures. Nevertheless, the desirability of obtaining an experimental verification of this conclusion led to the design of cell II.

Electrode solution.—The design of cell I is such that anode oxygen and cathode aluminum could dissolve in the slag electrolyte, although the existence of a sawtooth variation of the cell emf with oxygen bubble formation at the anode indicates that the solubility of oxygen in the electrolyte must be small. Nevertheless, aluminum in solution could give rise to significant electronic conductivity in the electrolyte. The design of cell II, however, precludes this possibility.

Cell II.—Cell II was designed to eliminate some of the possible sources of systematic error in the operation of cell I outlined above. It is again an oxygen concentration cell, only in this case the oxygen potential of the cathode is controlled by the C/CO equilibrium. The separation of the electrode compartments from the electrolyte allows the replacement of alumina-saturated CaF_2-Al_2O_3 electrolytes by those in the CaO-Al_2O_3-SiO_2 system, unsaturated with alumina.

The electrolysis of CaO-SiO_2 slags (53) and the determination of transference numbers in the CaO-SiO_2 and CaO-SiO_2-Al_2O_3 systems (54) show that these slags are predominantly ionic conductors. For this reason CaO-SiO_2 (55, 56) and CaO-SiO_2-Al_2O_3 (57-62) electrolytes have been used in a number of high temperature cells to determine the thermodynamic properties of alloys or the electrolyte system itself. Reasonable agreement is obtained with determinations by other methods confirming the highly ionic nature of these slags.

In addition to the 38 w/o CaO, 42 w/o SiO_2, and 20 w/o Al_2O_3 electrolyte, unsaturated CaF_2-Al_2O_3 electrolytes containing only 10 and 15 w/o Al_2O_3 were used in cell II Here the possibility of significant electronic conductivity at these low alumina concentrations is small.

Steady plateau emf's of about 2 hr duration were obtained with cell II, cell failure being caused by solution of the anode and cathode alumina refractories in the slag electrolyte. The separation of electrode compartments also eliminated the possibility of the physical solution of anode aluminum and cathode gas in the electrolyte, thus precluding chemical interference with the cell reaction. Since identical electrode leads were used no thermal emf corrections were necessary, and with graphite contacts, possible problems associated with the solution of platinum in aluminum were eliminated.

The good agreement between cell I and cell II data, as shown in Fig. 11, and the general agreement with similar electrochemical work at ~ 1000°C, Fig. 10, indicate an error in the generally accepted thermochemical data for alumina.

Standard enthalpy of formation of alumina.—Values of $\Delta H°_{298}(Al_2O_3)$ from the third law analysis of cell I and cell II data have been presented in Fig. 12. These results are summarized in Table VII together with those from the third law analysis of the low temperature cell data and the average value of $\Delta H°_{298}(Al_2O_3)$ obtained from oxygen bomb calorimetry (63-72). These

(b) All data	10	393.08	10.23	7.32

results are again summarized in Fig. 13. Although the presently accepted value (70, 72) of $\Delta H°_{298}(Al_2O_3)$ of −400.40 kcal/mole is 7.8 kcal/mole more negative than the average value obtained from the present study, the average of all the calorimetric determinations is, by coincidence, in excellent agreement with the present data. It is clear from Table VII that a value of $\Delta H°_{298}(Al_2O_3)$ which is some 7 kcal more positive than the presently accepted thermochemical value would be consistent with the results from both high and low temperature electrochemical studies.

Assuming a value of $\Delta H°_{298}(Al_2O_3)$ of −392.60 kcal from the combined data of cell I and II, see Table VII, the following standard free energy of formation of alumina in the temperature range 1350°-1550°C

$$\Delta G° = -394{,}680 + 77.8T \text{ cal/mole} = -1652.45 + 0.3257T \text{ kJ/mole} \quad [14]$$

can be calculated using the Gibbs energy functions employed previously.

Independent evidence in support of this free energy data has been presented by Zen (73, 74) and Waldbaum (75) based on mineralogical studies. Reversed hydrothermal equilibrium data for the reaction

$$Al_2Si_2O_5(OH)_4 + 2SiO_2 = Al_2Si_4O_{10}(OH)_2 + H_2O \quad [15]$$

kaolinite quartz pyrophyllite vapor

yields a standard free energy of formation of pyrophyllite at 298°K, which is some 7 kcal more positive than the value derived from similar studies of the reactions

$$Al_2Si_4O_{10}(OH)_2 = Al_2SiO_5 + 3SiO_2 + H_2O \quad [16]$$

pyrophyllite andalusite quartz vapor

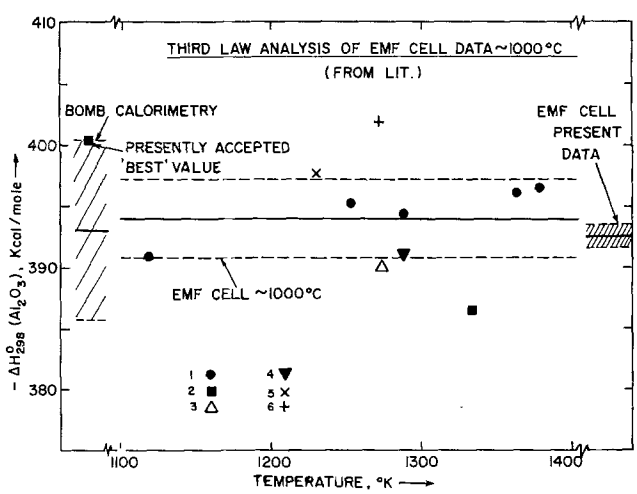

Fig. 13. The standard heat of formation of alumina, $\Delta H°_{298}$, from high and low temperature cell data, ~1000°C (from literature).

and

$$Al_2Si_4O_{10}(OH)_2 + 3Al_2O_3 = 4Al_2SiO_5 + H_2O \quad [17]$$

pyrophyllite corundum kyanite vapor

The calculations for reaction [15] were based on the well-established free energy data for kaolinite (76-79). The free energy data for andalusite and kyanite, reactions [16] and [17], respectively, were based on the solution calorimetric data of Holm and Kleppa (80) and were taken from Robie and Waldbaum (76). Since the free energy data for andalusite, sillimanite, and kyanite are dependent on the free energy data of corundum through the solution calorimetry of Holm and Kleppa (80), these discrepancies can be resolved if the presently accepted value of $\Delta H°_{298}(Al_2O_3)$ is some 7 kcal/mole too negative; a conclusion consistent with the results of the present work.

Zen (73, 74) has also discussed a discrepancy of about 10 kcal/mole between the free energy data for muscovite based on calorimetry (81) and solubility data (82) and those based on reversed hydrothermal equilibria measurements (83, 84) and has suggested that an error of 7 kcal/mole in $\Delta H°_{298}(Al_2O_3)$ would again eliminate the discrepancy.

There is therefore a considerable body of evidence which suggests that there is an error of about 7 kcal/mole in the presently accepted value of $\Delta H°_{298}(Al_2O_3)$ and in view of the important metallurgical and mineralogical consequences of such an error, $\Delta H°_{298}(Al_2O_3)$ should be redetermined by a technique other than that of oxygen bomb calorimetry.

Localized Corrosion of Aluminum: Blister Formation as a Precursor of Pitting

C. B. Bargeron and R. B. Givens

Applied Physics Laboratory, The Johns Hopkins University, Laurel, Maryland 20810

ABSTRACT

Blisters have been observed in the oxide film of aluminum in aqueous chloride solutions. They can be initiated by short duration ($\lesssim$ 1 msec), low voltage pulses. Such blisters grow only if the steady-state potential of the specimen is above the pitting potential. The growth proceeds laterally along the oxide-metal interface. Upon breaking, as a result of gas pressure from within, pitting corrosion begins. Thus, in this instance, blisters are experimentally demonstrable precursors of pits.

This paper contains a preliminary account of blister growth during the potentiostatic polarization of anodized aluminum. Although blisters have been observed at higher steady-state potentials during the anodization process with chloride ions in the solution (1), our observations indicate that blisters can be initiated by short duration ($\lesssim$ 1 msec), low voltage (2-5V) pulses. Such transients are extremely easily generated in an electrochemical experiment, by design or otherwise. Indeed the phenomenon of blister formation was first observed in our laboratory by accident. Our observations regarding blister growth and subsequent pitting, which are described in detail below, demonstrate that voltage transients can play an important role in pitting investigations, thus implying that such transients may have been a hidden variable in some studies.

A significant feature of blister growth is that the stressed oxide eventually ruptures, at which point pitting corrosion begins. Thus blistering is an experimentally demonstrable precursor of pitting. As such it is of importance to those interested in initiation mechanisms in localized corrosion, a topic which has received considerable attention in the literature (2-3).

Experimental Procedures

The aluminum used in this investigation had a purity of 99.999% and was obtained from the Alfa Products Division of the Ventron Corporation. A typical impurity analysis supplied with the 0.25 mm foil was 3 ppm Si, 2 ppm Fe, 1 ppm Cu, and others less than 1 ppm. Disks of this foil were degreased in acetone and placed in a Teflon holder with 0.46 cm^2 exposed to the electrolyte. They were then electropolished in a 10% perchloric acid-ethanol mixture for 4 min at +15V at about 24°C. After a thorough rinse with deionized water the electropolished surfaces were anodized galvanostatically at 1 mA/cm^2 in 3% ammonium tartrate solution to a voltage dependent on the oxide thickness desired (4). The counterelectrode was Type 304 stainless steel. The specimens were again washed abundantly in deionized H_2O and placed in a second Teflon holder with an exposed area of about 0.044 cm^2. The electrode was then mounted face up in a stainless steel beaker. The beaker served as the auxiliary electrode. A saturated calomel electrode (SCE) was employed as the reference electrode. Using a water-immersible objective, a light microscope was focused on the specimen. The entire exposed Al surface was in the field of view.

Precautions were taken to minimize the noise in the potentiostat circuitry. The anode current was amplified and then both recorded on magnetic tape and made audible via a loudspeaker system. (Listening to the current over a speaker is a definite asset.) Voltage pulses from a Tektronix pulse generator were used to initiate blisters. Such pulses were tailored in rise and fall time (~80 μsec), so that the frequency response of the potentiostat was not exceeded during the pulse. The pulse amplitude and duration were read on an oscilloscope. The pulse was superimposed on the potential set on the potentiostat.

The electrolyte used in the cell was 0.5M KCl unless otherwise noted. The pitting potential of Al in this solution is about −0.76V (SCE) (5). The potentiostat was generally set at −1.00V (SCE) when the specimen was first connected.

After the specimens were tested electrochemically, they were rinsed with copious amounts of deionized water to remove all soluble material. Specimens were then placed in a desiccator for at least 1 day before in-

Key words: pit initiation, breakdown mechanism, voltage pulses.

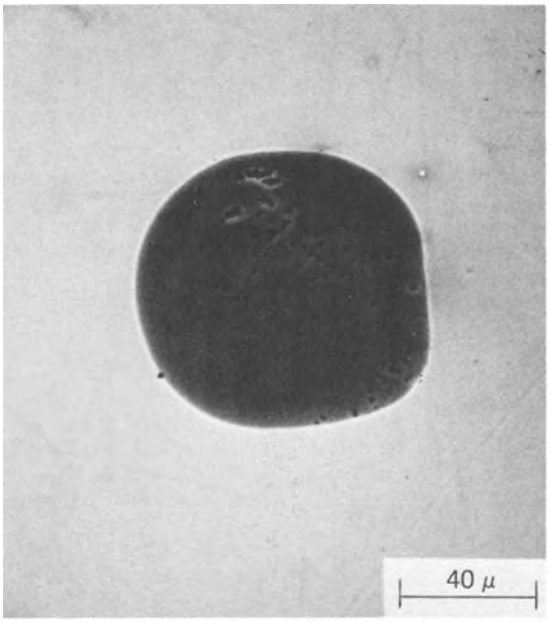

Fig. 1. A typical unbroken blister. The beam voltage was 20 keV and the stage tilt angle 30°.

vestigating them in a scanning electron microscope (SEM) with an energy dispersive x-ray analysis accessory system.

Results

A typical unbroken blister is shown in Fig. 1. As the dimensions indicate it has grown to a diameter of about 80μ. This blister was formed by setting the potential at −0.50V (SCE) and pulsing once with a pulse of amplitude 5.0V and a width less than 1 msec. The specimen had been anodized to +60V and thus had an oxide layer thickness of 800Å (4). Blisters generally have a circular shape, although their morphology can be influenced by grain boundaries and other topographical features. They appear under the low power light microscope a few seconds after the voltage pulse. Blister growth is typically somewhat jerky; that is the blister boundary does not move steadily outward, but rather increases by irregular increments with pauses in the boundary motion. During growth there is an observable frontal region extending outside the blister periphery in which there appears to be activity or stress of some type. In the SEM, the circumference of the blister frequently shows signs of stress. The shape, manner of growth, and stressed regions are all indicative of pressurized gas under the blistering oxide. The gas is apparently formed by a chemical reaction which attacks laterally along the oxide-metal interface as opposed to penetrating into the metal, although the dark spots seen in the blister are etch marks caused by a minor penetrating attack. The micrograph shown in Fig. 1 was taken at 20 keV beam voltage. Micrographs taken at 2.5 keV do not reveal the etch marks; thus, they are in the aluminum substrate under the oxide, the oxide itself being intact. The light colored ring about the blister periphery contains much larger amounts of chloride (as determined by the x-ray analysis system attached to the SEM) than either inside the blister where Cl is occasionally detectable or outside the blister where it is usually not detectable in our apparatus. Close examination of the 800Å oxide over the blister in Fig. 1 revealed no detectable cracks or holes. The SEM has resolution of 70Å, but the nonconducting oxide spoils this resolution somewhat.

There are several conditions which must be met if one wishes to observe growing blisters initiated by a single pulse of duration of 1 msec or less. A smooth surface is favorable. On rough surfaces, the oxide more frequently breaks soon after pulsing. The anodized layer thickness also plays a role as might be expected. The thinner layers break more easily; thus, blisters usually break at smaller diameters. The working electrode potential maintained by the potentiostat must be above the pitting potential. For example, in 0.5M KCl solutions, pulsing with the potential set below −0.76V (SCE) yielded no blisters. Since pitting potentials are dependent on the concentration of aggressive anions, the threshold potential for blister growth is also dependent on this factor. Also the pulse amplitude must be large enough. This amplitude is dependent on oxide thickness and is somewhat variable from specimen to specimen. In general 2-3V amplitudes are required for 200Å oxides; 4-5V amplitudes, for 800Å oxides; and greater than 10V amplitudes, for 2000Å oxides. If amplitudes much greater than those indicated are employed the oxide generally breaks immediately. Most of our tests have been made with 800Å oxides. Using the 4V amplitude for this oxide, the field strength required for blister formation with short pulses is about 5×10^5 V/cm, which is more than an order of magnitude lower than dielectric breakdown of anodized Al_2O_3 layers (6). Pulse duration is a variable which was not varied much in our tests; however, if the potentiostat is set at 2V (SCE) for a period of few seconds, many blisters form and grow under 800Å films. Some of these blisters break thus becoming pits. Wood *et al.* (7, 8) have reported experiments using "brief" pulses of approximate amplitude 2.0V (SCE) to pit aluminum with a 240Å oxide. The micrographs of pits they present as results of such tests (7, 8) appear to us to be very similar to many pits we have observed to have been formed from broken blisters.

Both intragranular as well as grain boundary sites have been observed as points of blister initiation on the aluminum surface.

Although blisters can grow to sizes on the order of 100μ on smooth surfaces they eventually rupture. Upon breaking there is a considerable increase in the current as illustrated in Fig. 2. The time at which the specimen was pulsed is also indicated. The shape of the current-time plot is reminiscent of some of those already in the literature (8, 9). The cause of the current increase in the case of a breaking blister is an increased area of unpassivated aluminum exposed to the electrolyte. A micrograph of a broken blister is shown in Fig. 3. The blister broke along its lower edge as shown. Under the break in the oxide, pitting has begun. The experiment was terminated shortly after the blister ruptured. If the blistered oxide cover is removed after the specimen has been taken from the pitting solution, then one ob-

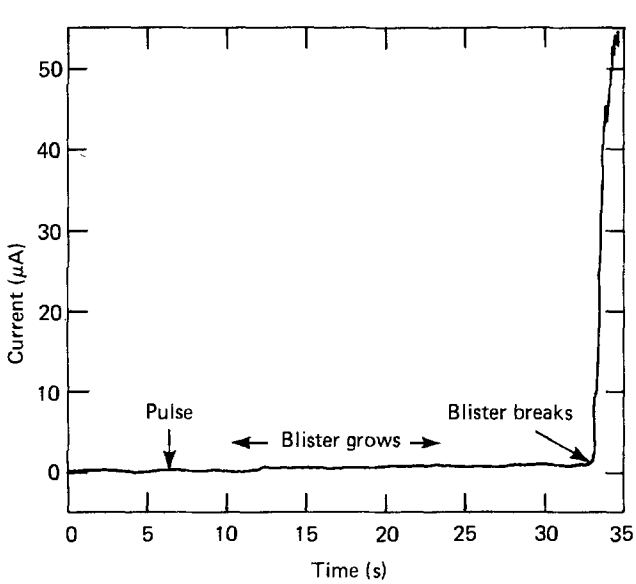

Fig. 2. A current-time plot showing the time of pulsation, the growth period, and the time of rupture.

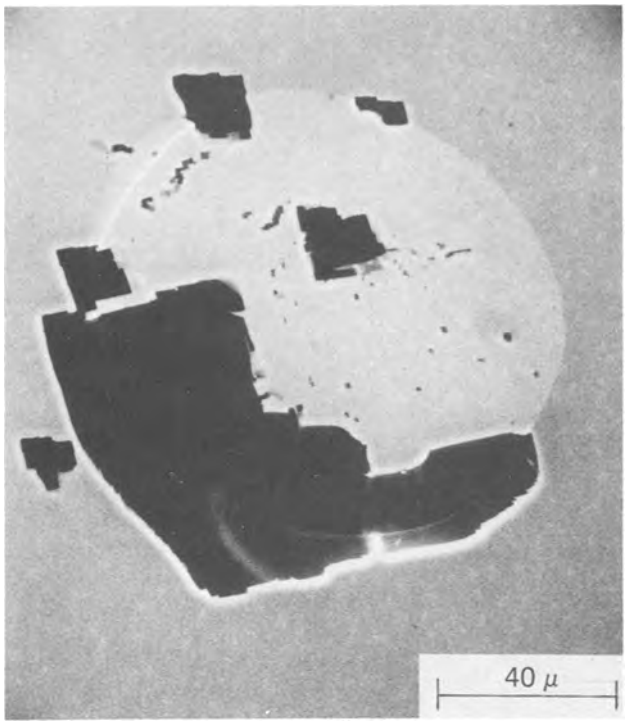

Fig. 3. A broken blister. The experiment was terminated shortly after the blister burst. The SEM conditions were as in Fig. 1.

serves more clearly that the blistering reaction proceeds laterally as opposed to penetrating, a point which was mentioned earlier. To illustrate, Fig. 4a shows a blister which broke near the end of the polarization period; a large portion of blistered oxide has been removed. Although subsequent pitting removed some aluminum, an appreciable fraction of the surface formerly under blistered oxide shows very little damage. For the sake of clarity a schematic drawing depicting the main features accompanies the micrograph in Fig. 4b.

Discussion

The brief description of blistering given above raises several questions of fundamental importance, most of which must necessarily wait for complete clarification and experimental verification. Nevertheless, the following paragraphs contain a hypothesis which might explain the observations.

A question of considerable significance is that of the transport of materials across the oxide to the aluminum. No cracks or holes could be found in blistered oxide which had not broken catastrophically. A possibility is that such defects are below the resolution of our SEM. The oxide over a growing blister supports pressurized gas which would probably favor crack propagation. This does not usually happen immediately and, when it finally does occur, such breaks are frequently outside of the perimeter within which the blister was confined most of its lifetime. Therefore, suppose that the voltage pulse has created (opened) some holes of rather circular cross section in the oxide. Now the oxide is reasonably hydrophilic; therefore, the following relationship holds

$$p = 4T_s/d \qquad [1]$$

where p is the gas pressure in the blister, T_s is the surface tension of the solution against the gas, and d is the hole diameter. Using $T_s = 75$ dynes/cm, if $d \lesssim 200$Å, then p must exceed about 150 atm to force gas bubbles through the holes into the bulk electrolyte. Thus the gas remains trapped in the blister until the oxide itself ruptures at which time many bubbles appear. Now there is evidence that the same reactions which occur during pitting corrosion also proceed during blistering. Recall that blisters will not grow unless the working electrode potential is greater than the pitting potential. During the course of many pitting experiments, it was often noted that gas bubble formation, which was invariably confined to the pits, seemed to stop at potentials very close to the pitting potentials for the solutions being used. Parenthetically, gas bubble formation was observed at all potentials above the pitting potential including the 2-5V range. This elementary connection between blistering and pitting leads one to suppose that all the necessary reactants for the pitting reaction reach the bare metal during blister growth. An important step in pitting is considered to be the acidification of the pit electrolyte due to the hydrolysis of the metal ion (10) or the hydrolysis of a metal-halide ion complex (9); both processes require water. In addition to lowering the pH, the H^+, which results from the hy-

drolysis, is probably a prime reactant in the gas-producing reaction according to one of the mechanisms discussed by Bockris and Reddy (11). The pathway of the reactants to the reaction site in this hypothesis must be through the holes and along the inside of the oxide to the periphery of the blister, which then becomes the reaction site because elsewhere the film and the electrolyte are separated from the metal. Although capillary forces likely play a role in transporting materials along the inside of the film to the reaction site, electrical forces could also be effective in this regard because the blister growth rate increases with increasing working electrode potential. The pressure within the blister may also be a factor in breaking open new holes near the periphery as the blister grows. As a result of the reaction occurring around the perimeter, the adhesion of the oxide to metal in that region is reduced, which allows the blister to grow. It does so in an irregular incremental fashion because the detachment proceeds in a nonuniform spatial manner until the adhesion weakens sufficiently, at which time the gas pressure finishes the separation and thus reestablishes the roughly circular morphology.

Regarding the spatially well-defined chloride ring pointed out in Fig. 1, its existence indicates that Cl^- plays a role in the blistering process. The chloride is more than a supporting electrolyte because no blisters form if Cl^- is absent from the electrolyte. For example, in 0.1M Na_2SO_4 with a working electrode potential of 0.18V (SCE), pulsing repeatedly with 5V pulses resulted in no blisters. [It is noteworthy that Al does not pit in SO_4^{2-}, at least below 1.6V (SCE) (12).] One has the feeling that Cl^- is important in both blistering and pitting; perhaps its role is in the formation aluminum chloride complexes which subsequently hydrolyze and free the Cl^- in the process (9). This catalytic behavior would help explain the well-defined accumulation of Cl^- in what appears to be the primary reaction region of the blistering process. Another possibility is that Cl^- is effective in attacking the oxide-metal interface Recent photoelectron spectroscopy studies have identified an intermediate compound, probably AlO, in the transition region between aluminum and the Al_2O_3 (13). Although the oxide in this case was formed in an oxygen atmosphere, such a transitional oxide likely exists between anodized films and metal also and may react with Cl^-.

Conclusions

The following conclusions have been reached for the experimental conditions described above:

1. Short duration, low voltage pulses are capable of initiating blisters in the oxide film of aluminum. Such blisters only grow at potentials above the pitting potential. The growth proceeds laterally along the oxide-metal interface.

2. Blisters ultimately break as a result of gas pressure from within, at which time pitting corrosion begins. Thus blisters are experimentally demonstrable forerunners of pits in this instance.

The sensitive nature of the oxide to transient voltage pulses implies the experimental necessity of being aware of and controlling the existence of such pulses.

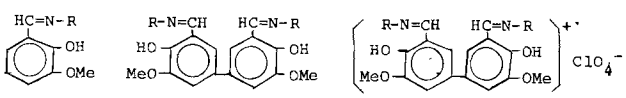
ABSTRACT



Electrochemical oxidation of Schiff bases derived from 2-hydroxy-3-methoxybenzaldehyde and various primary amines was investigated at a glassy carbon electrode in acetonitrile. On cyclic voltammetry all the compounds exhibited two anodic peaks below 1.5V *vs.* SCE. Controlled potential electrolysis of the Schiff bases at the potential of the first peaks gave cation radical salts from ring-coupled dimers. Possible sequences of the formation of the radical salts are discussed.

Electrochemical oxidation of benzylideneanilines has been studied by several workers, and the initial oxidation step has been proposed to be formation of a cation radical (I) (1-5).

$$Ar—CH=\overset{+\cdot}{N}—Ar' \qquad (I)$$

When an electroactive group such as —NMe_2 or —OH is present in the C-phenyl ring para to the azomethine group, the initial electron transfer is thought to occur from this group (1). However, in the anodic oxidation of salicylaldehydeaniles in acetonitrile it was suggested that a cation radical of type (I) was formed by the initial electron transfer, and that this then lost a proton to form a neutral radical (6).

To examine this discrepancy and as a continuation of our studies on the anodic oxidation of Schiff bases, we studied the oxidation of title compounds (MSB). In controlled potential electrolysis of MSB, cation radical salts (DSBR) were obtained from ring-coupled dimers (DSB). This paper reports the results of cyclic voltammetry and controlled potential electrolysis of MSB and related compounds in acetonitrile at a glassy carbon electrode.

MSB[1] DSB[1] DSBR[1]

Experimental

Materials.—MSB's were prepared by condensation of o-vaniline with appropriate primary amines in absolute ethanol or benzene under reflux for 2-5 hr. The crude products were purified by distillation, recrystallization, or column chromatography on silica gel. Analytical values for MSB's are summarized in Table I together with their mp or bp. Other Schiff bases were prepared by a similar method and gave the expected analytical values. Acetonitrile was distilled first from calcium hydride and then from phosphorus pentoxide after treatment by the method of Mann *et al.* (7). Sodium perchlorate, used as supporting electrolyte, was recrystallized from aqueous ethanol and stored over phosphorus pentoxide under reduced pressure. Pyridine was purified by distillation. All other chemicals were of reagent grade and were used without further purification.

* Electrochemical Society Active Member.

Key words: cyclic voltammetry, controlled potential electrolysis, cation radical salts.

[1] When —R is the *t*-butyl group, for example, these compounds will be represented as MSB*t*-butylamine, DSB*t*-butylamine, etc.

Apparatus.—Cyclic voltammetry and controlled potential electrolysis were carried out as described previously (5, 8). All voltammetric measurements were carried out at 25° ± 0.1°. Controlled potential electrolysis was done at room temperature unless otherwise specified. U.v., infrared, NMR, and mass spectra were obtained using Hitachi 124, EPI-2, R20-A, and RMU-6E spectrometers ,respectively. ESR spectra were recorded in a JEOL JES-P10 spectrometer, with 100 kHz modulation and X-band klystron.

Analysis of products obtained on controlled potential electrolysis and preparation of DSB.—Typical examples of the procedures are described.

(*i*) MSB*t*-butylamine (110.5 mg) was subjected to electrolysis in acetonitrile (50 ml) containing 0.1M sodium perchlorate at +0.8V *vs.* SCE at room temperature until the current decreased to less than 1% of the initial value (140 min). During this period 40.4C were consumed, which correspond to $n = 0.76$. The electricity consumed was estimated from the area below the current-time curve. A dark green precipitate (DSBR) began to be deposited at the electrode when electrolysis was started. This material was collected on a sintered glass disk and was washed repeatedly with cold methanol and acetonitrile. The yield of DSBR*t*-butylamine was 63.9 mg (50%) mp 240° decomp. Calculated for $C_{24}H_{32}N_2O_8Cl$: C, 56.3; H, 6.30; N, 5.47; Cl, 6.92. Found: C, 56.1; H, 6.33 N, 5.43; Cl, 6.38. DSBR*i*-propylamine was obtained similarly, mp 240° decomp. Calculated for $C_{22}H_{28}N_2O_8Cl$: C, 54.6; H, 5.83; N, 5.79; Cl, 7.33. Found: C, 54.6; H, 6.00; N, 5.86; Cl, 7.31. The DSBR's were in general poorly soluble in various solvents, including water, and when dissolved in some solvents they decomposed

* Bp, others are mp's.

fairly rapidly. Hence the only DSBR's obtained in pure form were those two described above.

After the DSBR*t*-butylamine had been filtered off, the solution from electrolysis showed a cyclic voltammogram which coincided with that of the starting MSB in the presence of excess perchloric acid, and on addition of excess pyridine the solution showed a cyclic voltammogram which coincided with that of the starting MSB under the same conditions (see Results). The absorption spectra of the solution from electrolysis coincided with those of the MSB in the presence of perchloric acid. Thus protonated MSB*t*-butylamine had been formed. The amount of the protonated MSB was determined by measuring the peak height of the voltammogram after adding excess pyridine, and by measuring the absorbance of the solution from electrolysis. The two measurements agreed well. In this case 50% of the MSB was recovered.

(*ii*) MSB*t*-butylamine (37.7 mg) was subjected to electrolysis in the presence of 0.20 mmole of pyridine at +0.8V. A total of 25C of electricity was consumed, which corresponds to $n = 1.4$. The yield of DSBR*t*-butylamine was 55.4 mg (*ca.* 100%). The solution after electrolysis showed no appreciable voltammetric peak.

The structure of DSBR*t*-butylamine was confirmed by the following observations. DSBR*t*-butylamine showed an ESR signal in the solid state (see Results). The infrared spectra of DSBR*t*-butylamine showed a characteristic absorption around 1100 cm^{-1} due to the perchlorate anion. DSBR*t*-butylamine was reduced by sodium dithionite in a manner similar to that reported for cation radical salts derived from carbazoles (9). A suspension of the DSBR (386 mg) and sodium dithionite (3g) in acetonitrile (50 ml) was refluxed for 10 hr with stirring. The DSBR gradually dissolved to give a brown solution. Excess sodium dithionite was filtered off, the solution was evaporated to dryness, and the residue (A) (242 mg) was hydrolyzed in 10% hydrochloric acid for 24 hr. The reaction mixture was extracted with chloroform and the extract was washed and dried. Evaporation of the extract gave 4,4′-dihydroxy-5,5′-dimethoxybiphenyl-3,3′-dicarbaldehyde (DOV) (100 mg) which was recrystallized from acetone-petroleum ether, mp 212°. Calculated for $C_{16}H_{14}O_6$: C, 63.6; H, 4.67. Found: C, 63.1; H, 4.64. Mass: M^+; *m/e* 302. NMR ($CDCl_3$): δ(ppm), 4.02 (s, 6H), 7.27 (d, 2H, J = 2 Hz), 7.31 (d, 2H, J = 2 Hz), 10.00 (s, 2H), 10.98 (s, 2H) (disappeared on D_2O treatment). Infrared (KBr disk): ν_{max} (cm^{-1}), 3450, 1660, 1250. The above residue (A) was dissolved in chloroform-benzene containing excess *t*-butylamine[2] and refluxed for 1 hr. On evaporation of the solvent, 5,5′-bis[*N*-(2-hydroxy-3-methoxybenzylidene)-*t*-butylamine] (DBS*t*-butylamine) was obtained and this was recrystallized from benzene-hexane, mp 235° Calculated for $C_{24}H_{32}N_2O_4$: C, 69.9; H, 7.82; N, 6.78. Found: C, 69.1; H, 7.81; N, 6.60. DSB*i*-propylamine was obtained similarly, mp 126°. Calculated for $C_{22}H_{28}N_2O_4$: C, 68.7; H, 7.34; N, 7.28. Found: C, 68.6; H, 7.33; N, 7.33.

Results

Cyclic voltammetry.—All the MSB examined showed three or four anodic peaks; no extra anodic peak was observed in a multiple sweep. The MSB's derived from aliphatic amines showed no appreciable cathodic peak even when the voltage scan direction was reversed at any potential, while MSB's derived from aromatic amines showed a small cathodic peak around 0.12V, possibly due to reduction of the partially soluble DSBR (see below). A typical cyclic voltammogram of MSB*t*-butylamine is shown in Fig. 1. Voltammetric data on MSB are summarized in Table II. The third and fourth waves were not studied further.

The first-oxidation peak potentials of various Schiff bases including MSB are compared in Table III. Among

[2] When residue (A) was recrystallized from benzene-hexane without excess *t*-butylamine, a mixture of DSB*t*-butylamine, DOV, and the mono-Schiff base of DOV was obtained.

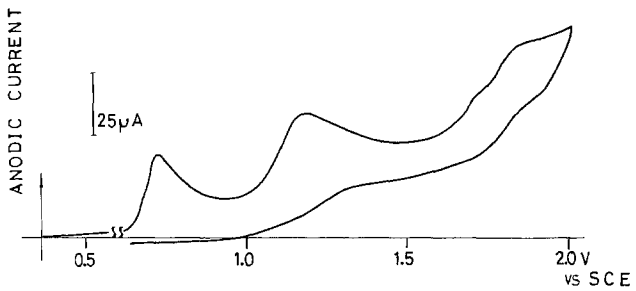

Fig. 1. Cyclic voltammogram of 2.0 mM MSB*t*-butylamine in MeCN/0.1M $NaClO_4$, sweep rate = 50 mV/sec, area = 0.071 cm^2.

the Schiff bases with a hydroxy group on the benzylidene ring, those derived from aliphatic amines were oxidized more easily than those derived from aromatic amines. Conversely, among the Schiff bases without a hydroxy group, those derived from aromatic amines were oxidized more easily.

Typical examples of the effects of added acids and bases on the cyclic voltammetry of MSB are illustrated in Fig. 2 and 3. In the presence of perchloric acid or sulfuric acid the first wave decreased while the second wave increased. In the presence of excess of acid, the first wave completely disappeared. The weaker acid, acetic acid, had no appreciable effect. When pyridine was added the first wave increased and the second wave decreased. With excess pyridine the peak current of the first wave almost doubled and the second wave disappeared. The effect of the stronger base, the methoxide ion, was examined in methanol[3]

[3] The voltammograms of MSB in acetonitrile and in methanol without methoxide ion were similar. The effects of pyridine were also similar.

(Fig. 3); a new peak appeared at a less positive potential and the peak height increased with increase in the concentration of methoxide ion, but this increase did not exceed the peak height of the first wave in the absence of methoxide ion.

Controlled potential electrolysis.—Detailed experiments were mainly carried out on MSBt-butylamine and MSBi-propylamine, but results with other MSB's were essentially similar. Typical results are summarized in Table IV.

Electrolysis in acetonitrile at the potential of the first wave gave a coulometric n-value of 0.7-0.8, and DSBR and protonated MSB ($MSBH^+$) were both formed in almost 50% yield. On electrolysis in the presence of an equimolar amount of pyridine, the n value was 1.3-1.8 and DSBR was formed almost quantitatively. Similar results were obtained with methanol as solvent, but on electrolysis in methanol in the presence of excess methoxide ion, no DSBR was formed.

Typical examples of ESR spectra of DSBRt-butylamine in the solid state and in concentrated sulfuric acid are shown in Fig. 4 and 5, but the exact nature of the species giving the latter spectrum (Fig. 5) is unknown: it must be due to some secondary radical formed from the DSBR.

Electrolysis of 2-hydroxy-3-methoxybenzaldehyde (o-vaniline) under similar conditions did not give a cation radical salt, although cyclic voltammetry of o-vaniline in the presence of pyridine suggested the formation of DOV: in acetonitrile containing 1% pyridine, o-vaniline showed an anodic peak at 0.85V and a cathodic peak at 0.40V, and an extra anodic peak at 0.46V on the subsequent anodic sweep; DOV gave an anodic peak at 0.47V and a cathodic peak at 0.41V under the same conditions (figures not shown).

Table IV. Results of controlled potential electrolysis

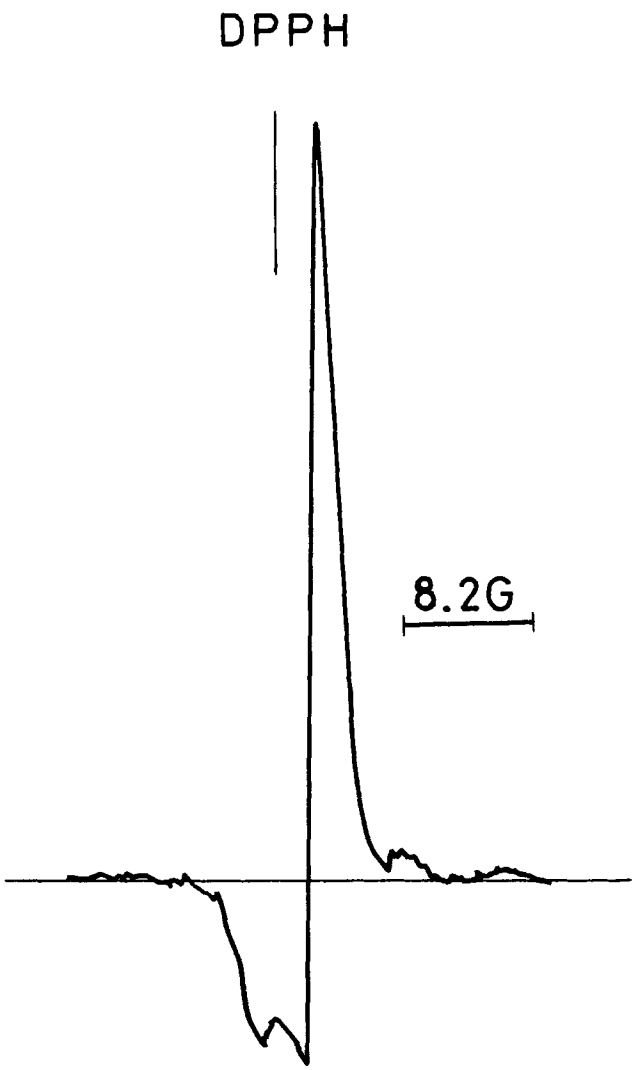
[a] The concentration of substrate was 1-5 mM.
[b] V *vs.* SCE.
[c] Unless otherwise indicated, runs were carried out in acetonitrile containing 0.1M sodium perchlorate at room temperature.
[d] Runs were carried out in the presence of an equimolar to 1.5M amount of pyridine.
[e] The determination of DSBR or $MSBR^+$ was not performed, though the formation of them was recognized.
[f] Calculated on the basis of the weight of green precipitate obtained by a similar treatment to that described in the experimental section.
[g] When electrolysis was carried out at room temperature, the DSBR was soluble in acetonitrile and the nature of the solution from electrolysis was complex.

Electrochemistry of DSB.—Typical cyclic voltammograms of DSBt-butylamine under various conditions are illustrated in Fig. 6 and 7. DSBt-butylamine showed two anodic peaks at 0.35 and 0.78V. The second peak seems to be due to the oxidation of an adsorbed species. On sweep reversal, a small ill-defined cathodic peak was observed at around 0.15V [Fig. 6(a)]. However, when the cathodic sweep was stopped at a potential distance intermediate between the first and second anodic peaks for a short period, a well-defined cathodic peak appeared at 0.15V on the subsequent further cathodic sweep [Fig. 6(b)]. The cathodic peak must be due to reduction of the adsorbed species as shown by a potential step experiment [Fig. 6(c)]. Figure 6(c) also shows the presence of second cathodic peak at around 0.05V when the voltage sweep was limited to the potential of the first anodic peak. The second cathodic peak did not appear with voltage sweep rates of less than 50 mV/sec. Upon multiple sweep, neither a new anodic nor an extra cathodic peak was observed regardless of the voltage sweep range. The E_p of the first anodic wave shifted *ca.* 50 mV cathodic for a tenfold decrease in the sweep rate (200 → 20 mV/sec), while that of the first cathodic wave remained unchanged.

Pyridine had little effect on the voltammograms of DSB. The voltammogram in the presence of perchloric acid suggests that the second anodic peak of DSB is not due to oxidation of protonated DSB, in contrast to results with MSB (Fig. 7).

Electrolysis of DSB in acetonitrile at the potential of the first wave gave an n value of almost unity, and DSBR was formed almost quantitatively (Table IV). Similar results were obtained on electrolysis at the potential of the second peak, in the former case most of the DSBR was formed on the electrode surface whereas in the latter case most of DSBR was formed in the solution. The presence of an equimolar amount of pyridine did not affect the results. The physical properties (mp, infrared, and ESR spectra) of DSBRt-butylamine and DSBRi-propylamine obtained on electrolysis of the corresponding DSB coincided with those of DSBR's obtained on electrolysis of the corresponding MSB. These findings together with the yields of



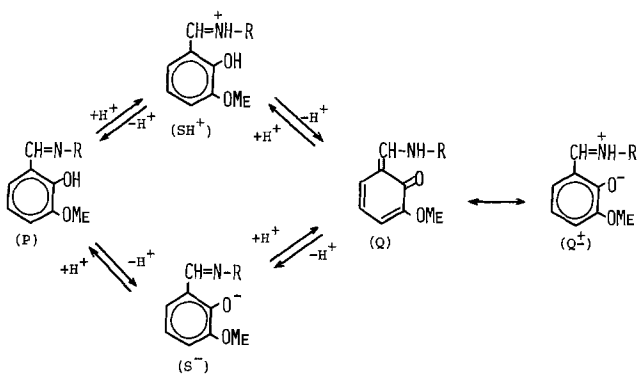


Fig. 4. ESR spectrum of DSBRt-butylamine in the solid state.

DSBR's cited in Table IV support the theory that MSB dimerizes exclusively in the position para to the hydroxy group.[4]

Discussion

In analogy with *N*-salicylidene-2-aminopropane, protonation equilibria in Scheme I can be considered

Scheme I

for MSB, and in the present solvent system the contribution of the quinoneamine form (Q) will be small (10). Then, the first peak observed on cyclic voltammetry of MSB will be ascribed to oxidation of P, the second peak to that of SH^+, and the new peak in the presence of methoxide ion to that of S^-. The results in Table III strongly suggest that the initial electron transfer in P involves the aromatic pi system including the hydroxy group, that is, oxidation of a phenol takes place. If the initial oxidation involves the lone pair electrons on the nitrogen atom, Schiff bases derived from aromatic amines would be oxidized more easily than those derived from aliphatic amines, regardless of the presence of a hydroxy group on the benzylidene ring.

A mechanism for the formation of DSBR consistent with the results can be described by Scheme II.

[4] In a preliminary electrolysis of 2-hydroxy-3-methoxy-5-methylbenzylidene-t-butylamine, no DSBR was formed.

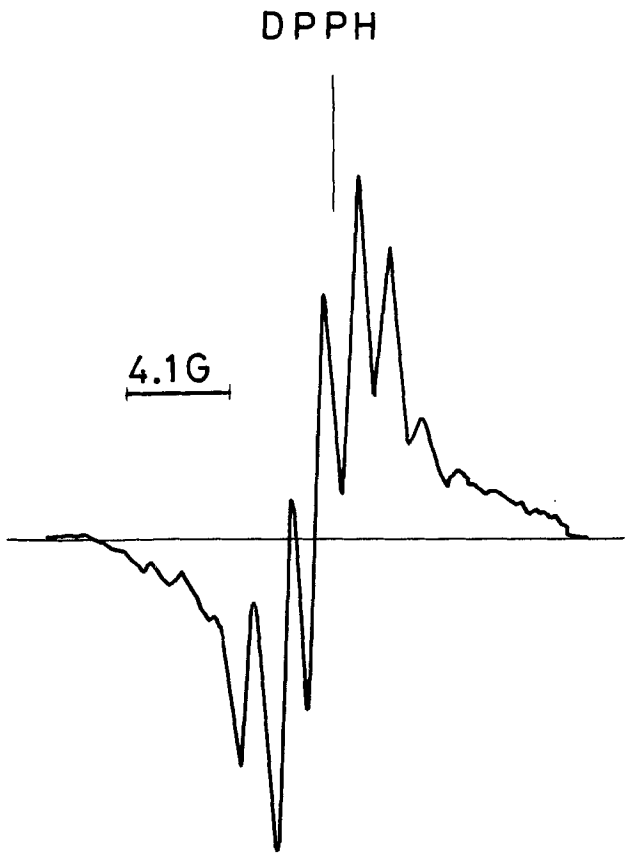

Fig. 5. ESR spectrum of DSBRt-butylamine in concentrated sulfuric acid.

$$MSB \underset{\longleftarrow\!\!-\!\!-\!\!-}{\xrightarrow{-e}} MSB^{+\cdot} \quad [1]^5$$

$$2MSB^{+\cdot} + 2MSB \rightarrow DSB + 2MSBH^{+} \quad [2]$$

$$DSB \underset{\longleftarrow\!\!-\!\!-\!\!-}{\xrightarrow{-e}} DSB^{+\cdot} \quad [3]^5$$

$$DSB^{+\cdot} + ClO_4^{-} \longrightarrow DSBR \quad [4]$$

$$DSB^{+\cdot} \xrightarrow{-e} DSB^{2+} \quad [5]$$

$$DSB^{2+} + DSB \longrightarrow 2DSB^{+\cdot} \quad [6]$$

$$DSB^{2+} + MSB \longrightarrow DSB^{+\cdot} + MSB^{+\cdot} \quad [7]$$

Scheme II

Electrolysis of MSB at the potential of the first wave will mainly proceed through reactions [1]-[4]. In reaction [2] it is not clear whether dimerization occurs before or after the loss of a proton from $MSB^{+\cdot}$. If the proton transfer precedes the dimerization, the proton will be removed from the hydroxy group to give MSB·. In methanol containing the methoxide ion, S^- in Scheme I will be oxidized to give MSB·. In this case DSBR was not formed at all. Though this observation does not necessarily exclude the possibility that MSB· dimerizes, it may support the dimerization of $MSB^{+\cdot}$. Reactions [8] and [9] are alternatives to reaction [2] which is similar to those suggested for anodic substitution reactions (11). However, these reactions seem less probable

$$MSB^{+\cdot} + MSB \longrightarrow [MSB\text{-}MSB]^{+\cdot} \quad [8]$$

$$[MSB\text{-}MSB]^{+\cdot} + 2MSB \longrightarrow DSB + 2MSBH^{+} + e \quad [9]$$

because similar processes to reaction [2] have been proposed for many phenol coupling reactions (12) and for oxidation of carbazoles and related compounds (13-15) where exclusive dimerization reactions have been observed. Exclusive DSBR formation on electrolysis of MSB in the presence of pyridine can support this view. If reactions [8] and [9] were operative, formation of pyridinated MSB would also be expected as observed in the oxidation of benzylidene-*p*-anisidines (5).

[5] This process may be reversible, but on cyclic voltammetry of MSB no corresponding cathodic peak was observed under the experimental conditions (see Results).

Irrespective of which process occurs in formation of DSB, a total of 0.75 electrons will be consumed per molecule of MSB, and half of the starting MSB will form DSBR, the rest being converted to protonated MSB. When pyridine is present in the system, it will act as a proton acceptor in place of MSB itself, and all the MSB will be oxidized to form DSBR. The *n* value should then be 1.5.

Since the oxidation potentials of $DSB^{+\cdot}$ and the starting MSB are similar, the $DSB^{+\cdot}$ can be further oxidized in part to form DSB^{2+} (reaction [5]). However, the results obtained on controlled potential electrolysis of DSB strongly suggest that DSB^{2+} will react with DSB to give $DSB^{+\cdot}$ again (reaction [6]). Similarly, reaction [7] can be considered and regardless of the extent to which reaction [5] occurs the over-all results on electrolysis of MSB will be the same.

A complete explanation for the voltammetric behavior of DSB cannot be offered from the present experimental results alone. However, the shifts of the first anodic peak of DSBt-butylamine with voltage sweep rate suggest that reaction [4] is very fast, fast enough to make reaction [3] apparently irreversible. The second anodic peak and the cathodic peak (Fig. 6) must be due to the oxidation and the reduction of adsorbed DSBRt-butylamine, respectively. Reactions [4] and [5], then, will be better represented as reactions [10] and [11]

$$DSB^{+\cdot} + ClO_4^{-} \longrightarrow DSBR_{adsorbed} \quad [10]^6$$

$$DSBR_{adsorbed} \xrightarrow{-e} DSB^{2+} + ClO_4^{-} \quad [11]$$

The absence of a well-defined cathodic peak when the voltage sweep was extended beyond the second anodic peak [Fig. 6(a)] may be ascribed to the lack of DSB near the electrode surface to reproduce $DSB^{+\cdot}$ by reaction [6]. No plausible assignment can be made for the second cathodic peak [Fig. 6(c)] at the present stage. We are now studying the exact nature of the products of electrolysis of MSB in methanol in the presence of methoxide ion.

Manuscript submitted April 5, 1977; revised manuscript received Aug. 11, 1977. This was Paper 324 presented at the Washington, D.C., Meeting of the Society, May 2-7, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

[6] To explain the observation that controlled potential electrolysis of DSB actually proceeded to completion in spite of the adsorption of DSBR at the electrode surface, the following reactions should also be considered

$$DSBR_{adsorbed} + DSB_s \rightarrow DSB_e + ClO_4^{-} + DSB_s^{+\cdot}$$

$$DSB_s^{+\cdot} + ClO_4^{-} \rightarrow DSBR_{precipitated}$$

where subscripts s and e denote a species in the solution and at the electrode surface, respectivly.

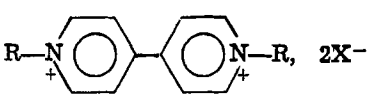
Modified Viologens with Improved Electrochemical Properties for Display Applications



J. Bruinink, C. G. A. Kregting, and J. J. Ponjeé

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

The redox reaction of 1,1'-diheptyl-4,4'-dipyridinium dibromide in water was investigated by means of linear potential sweep voltammetry. It was found that aging of the radical salt film or the occurrence of the second reduction step results in an additional oxidation peak. This additional oxidation peak is accompanied by a decrease of charge efficiency, leading to display failure. It was demonstrated that these problems can be largely avoided by use of modified viologens in combination with tin dioxide electrodes. The influence of the electrode material was also investigated.

The electrochemical reduction and oxidation of 4,4'-dipyridinium salts, better known as viologens, find application in redox-chromic displays (1). The general formula of these salts is

where R is the substituent and X^- the anion. From previous investigations (2-6) it is known that the reduction of the viologen ion A^{2+} proceeds as follows

$$A^{2+} + e \rightleftarrows A^{\cdot +}$$

$$A^{\cdot +} + e \rightleftarrows A$$

When R is CH_3 the first reduction step is a reversible one-electron reduction, which yields a stable blue radical ion in water as well as in various organic solvents. For R is CH_3 the second reduction step at more negative potential was reported to be reversible in non-aqueous solutions and irreversible in aqueous solutions in which the yellow brown product A is insoluble.

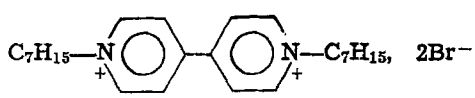
Further investigations have shown that if substituent R and anion X^- are properly chosen (*e.g.*, 1,1'-diheptyl-4,4'-dipyridinium dibromide), the first reduction step in aqueous solution is followed by a chemical reaction

$$A^+ + X^- \rightleftarrows AX\downarrow$$

The reaction product AX is deposited as a purple film on the electrode (7).

In an earlier paper, 1,1'-diheptyl-4,4'-dipyridinium dibromide with a platinum electrode was proposed as a suitable system for use in redox-chromic displays (1). This combination showed however, an irreproducible display behavior when used at long memory times and at high negative potentials (8). In this study linear potential sweep voltammetry is used to investigate the electrochemical properties of several viologens in order to evaluate their applicability in redox-chromic displays.

Experimental

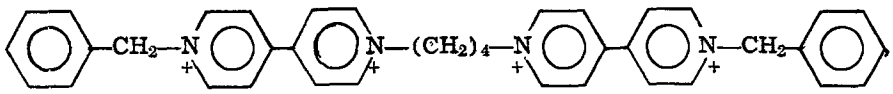


The synthesis of the viologens and modified viologens was carried out as described in the Appendix. The voltammetric measurements were performed using a PAR 173 potentiostat system. The recording intrument was either a Hewlett Packard 7000 AM recorder or a Philips oscilloscope PM 3330 with polaroid camera. If necessary electronic *IR*-compensation was applied.

The electrolyte solutions under investigation were deoxygenated by passing argon (oxygen content 5 ppm) through them. As reference and counterelectrodes we used Ag/AgCl electrodes separated from the cell solution by a Luggin capillary and glass frit, respectively. In some experiments, Ag/AgBr wire electrodes were used as a reference in order to exclude the disturbing influence of chloride ions. The electrochemical cell consisted of a standard double-wall Metrohm vessel, thermostated at 25°C. The working electrodes were homemade tin dioxide conductive glass (8 Ω/□) and Beckman platinum inlay electrodes.

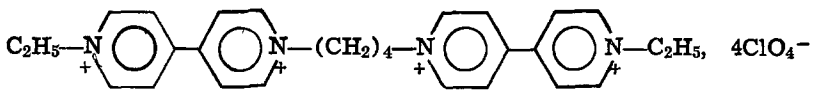
Results and Discussion

Stability of the electrodeposited film.—After electrodeposition, most of the viologen radical salt films show aging effects. Immediately after formation, the appearance of the film is very smooth with a homogeneous color, but after some time aging causes an inhomogeneous coloration of the film followed by formation of polycrystalline conglomerates. At this moment it is thought that during aging reorientation of the molecules is followed by recrystallization. The result of this recrystallization is a poor erasure behavior in redox-chromic displays, since the recrystallized layer is not completely available for a direct electrochemical oxidation. The effect of aging was found to be very sensitive to experimental conditions, such as the occurrence of the second reduction step during deposition of the film, electrode material, solvent, and smoothness of the electrode surface. Moreover the molecular structure of viologens was observed to have a striking influence on the effect of aging.



We found that the viologen radical salt films of dialkyl-dipyridinium compounds, with halide ions as anions, generally show these visible changes only about 10 sec after deposition. A typical example is 1,1'-diheptyl-4-4'-dipyridinium dibromide denoted further as HV-Br

With some other modified viologens, macroscopic



Key words: electrochromic, redox, displays, viologen.

changes of the film can be observed only after several minutes. A typical example of these modified viologens is tetramethylene bis-[4(1-benzylpyridine-4'-yl)pyridinium] tetrafluoroborate, denoted as BD-BF_4

The difference between the unstable HV-Br radical salt film and the more stable BD-BF_4 radical salt film can be illustrated by observing the potential of the film after deposition (compared with some reference electrode) as a function of time (Fig. 1). It can be seen that the potential of the BD-BF_4 film, starting at $t = 0$, shows only a minor change which is due to restoration of the concentration gradient after deposition. On the other hand, radical salt films of HV-Br show a change in electrode potential after formation, in correspondence with the aging effect.

Stable films are formed with tetramethylene [bis-4(1-ethylpyridine-4'-yl) pyridinium] perchlorate, denoted further as ED-ClO_4

No macroscopic recrystallization was observed, even after 100 hr. As can be seen from Fig. 1 radical salt films of this viologen show a stable potential. Combinations of modified viologens with smaller anions, *e.g.*, BD-Br and ED-Br, form soluble radical ions as can be seen from the appearance of a blue haze at the electrode during reduction.

Background potential limits.—Only measurements below $pH = 8$ are reported since in alkaline medium ($pH > 8$) a disturbing reaction of viologens has been reported (9).

Before discussing the voltammetric experiments, we first consider the suitability of two solid electrodes, namely, platinum and tin dioxide. Platinum was chosen since it was used in the prototype of a redox-chromic display (1), while tin dioxide was chosen since it was expected to be a good inert transparent electrode material for potential use in display devices.

The background potential limits for platinum electrodes are known for several electrolyte solutions. In the cathodic region hydrogen is evolved at nearly the theoretical limit, being about −0.5V (SCE) at $pH = 5$ (10). In our experiments we found an anodic limit of about 0.8V (SCE) for a solution of 0.3M potassium bromide at $pH = 5$ (10% citrate-sodium hydroxide buffer) corresponding with the bromide oxidation. The current density at that potential was about 5 $\mu A/cm^2$.

The background potential limit for tin dioxide in 0.3M potassium bromide at $pH = 5$ can be deduced from Fig. 2. It is clear that hydrogen evolution, as well as bromide oxidation, in the case of tin dioxide needs a higher overvoltage than in the comparable case of platinum. At a current density of 5 $\mu A/cm^2$, the cathodic and anodic potential limits are, respectively, −0.8 and 1.3V (Ag/AgCl). It follows from the same figure that the bromide/bromine redox reaction is irreversible on SnO_2. These values are different from those given by Zellmer (11), his values being −0.25 and 0.8V (SCE), respectively. The observed difference may be explained by differences in the tin dioxide surface as discussed by Yoneyama (12).

The effect of the observed very low background current level in the cathodic region more positive than −0.8V was investigated in experiments where the potential of a tin dioxide electrode in 0.3M potassium bromide solution ($pH = 5$) was maintained at, respectively, −0.5, −0.6, and −0.7V (Ag/AgCl). At −0.5V no visible changes of the electrode were observed, not even after 100 hr of electrolysis. At −0.6 and −0.7V the electrolysis resulted in a destruction of the electrode after 24 hr.

These results are in good agreement with Pourbaix diagrams yielding a decomposition potential of about −0.6V (Ag/AgCl) for tin dioxide at $pH = 5$ (13). Decomposition of tin dioxide electrodes during redox-chromic display operation has not been observed at $pH = 5$. This is confirmed by the fact that tin dioxide electrodes in 0.3M potassium bromide at $pH = 5$ exposed to 500 msec pulses between −0.9 and 0.3V (Ag/AgCl) for several days did not show any alterations, whereas in a similar experiment with Pt electrodes hydrogen evolution was observed. On the basis of the observations mentioned above, it is expected that interference of the hydrogen evolution will disturb the viologen reduction ($E \approx -0.5$V *vs.* Ag/AgCl) when platinum electrodes are used. The decomposition in the case of tin dioxide is expected to be negligible when pulsing at not too negative voltages (not less than −0.9V Ag/AgCl) and at a pH of about 5. For this rea-

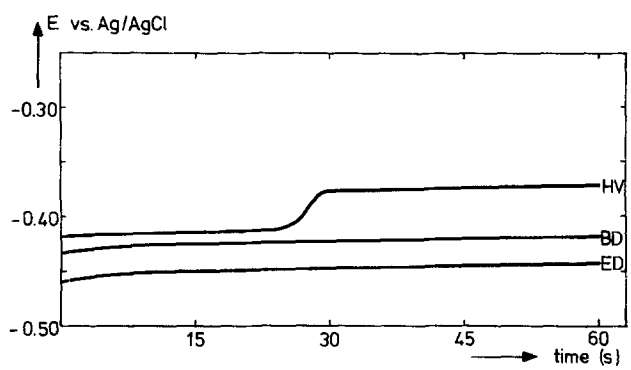


Fig. 1. The behavior of the potential E of a tin dioxide electrode covered with a viologen radical salt film as function of time. HV 10^{-2}M HV-Br, 3M KBr; BD 5×10^{-3}M BD-BF_4, 0.03M TEAB; ED 5×10^{-3}M ED-ClO_4, 10^{-2}M $LiClO_4$. The radical salt films were deposited during the cathodic sweep of a voltammogram. The total charge involved in their formation was about 1 mC/cm².

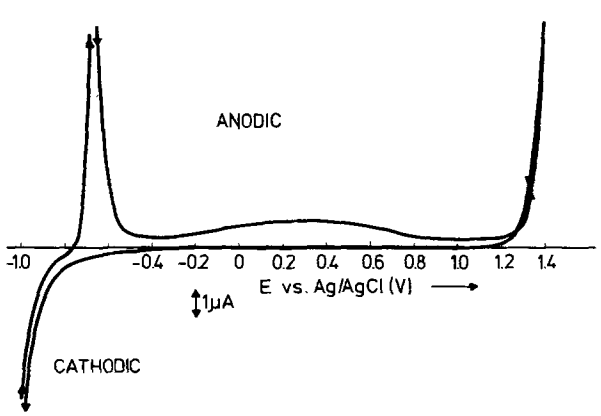

Fig. 2. Linear potential sweep voltammogram of an aqueous solution of 0.3M KBr and 10% citrate-NaOH buffer, $pH = 5$. SnO_2 electrode. Geometric electrode area, 0.2 cm². Scan speed, 0.020 V/sec.

son tin dioxide was chosen as the electrode for voltammetric investigations in order to investigate its suitability as the electrode in redox-chromic displays.

Voltammetric experiments.—The voltammetric behavior of an aqueous solution of HV-Br at SnO_2 is represented in Fig. 3 and 4. Figure 3A represents the voltammetric behavior which is found when the cathodic scan limit is chosen in such a way that only the first reduction and oxidation steps occur. The result is a very steep reduction peak a at −0.51V (Ag/AgCl) together with an oxidation peak a' at −0.45V (Ag/AgCl), which shows minor tailing. The observed behavior is very similar to that found with deposition and dissolution of thin metal films (14, 15).

If the potential sweep is extended to more cathodic potentials so as to include the second reduction step, a voltammogram with more than two reduction and oxidation peaks is obtained. The number of peaks depends on experimental circumstances such as scan speed and aging time (Fig. 3B). The peaks observed in the various experiments are summarized in Table I.

With relatively fast scans (> 0.1 V/sec), a voltammogram with four main peaks (a, a', c, c') is obtained (Fig. 4). Peaks a and a' are assigned to the formation and dissolution of the viologen radical salt film. Peak c at −0.84V is due to the second reduction step, which causes the formation of a yellow brown deposit. The corresponding oxidation peak c' is usually found at about −0.75V and is not visible at relatively low scan speed, because of the reaction $A^{2+} + A + 2X^- \rightleftarrows 2AX\downarrow$. The influence of this chemical reaction can be seen very clearly when Fig. 3B and 4 are compared.

Low scan speeds (< 0.1 V/sec), however, yield a more complicated voltammogram, as shown in Fig. 3B, in which the scan was reversed at −0.9V in order to avoid hydrogen evolution. In this voltammogram, too, an extra shoulder b connected with the second step reduction can also be seen. Further, two additional peaks d and b' (at −0.69 and −0.56V, respectively) corresponding to oxidation into the radical film are observed. Finally it is clear that the oxidation of the radical salt film is accompanied by the appearance of an extra peak f at −0.42V. By varying the scan range it has been estimated that b and b' are related. No pH dependence of d and b' has been observed. Their origin might be ascribable to the oxidation of charge-transfer complexes between A and $A^{\cdot+}$. If current and scan were interrupted at −0.9V during 1 min, all oxidation peaks c', b', d disappeared completely due to the reaction $A^{2+} + A + 2X^- \rightleftarrows 2AX\downarrow$ as was confirmed by spectral investigations. In that case only a' and f are observed. The correspondence of the appearance of f due to either the second reduction step or aging is demonstrated in Fig. 5, in which a linear sweep voltammogram of HV-Br is compared with an identical voltammogram, except for the fact that, with the latter, current and scan were interrupted for 1 min at the potential of current reversal. During this interruption the potential of the radical layer changes because of aging as already shown in Fig. 1. After the aging period the reverse scan is started at the potential of that moment (−0.37V). As a result it can be seen that only the peak f corresponding to the oxidation of the aged layer is observed, while without aging the normal dissolution peak a' is seen. It should be noted that this behavior is only found with viologens that form unstable radical salt films.

Table I. Survey of the observed voltammetric peaks with HV-Br

Reduction	Fast scan (Fig. 4)	0.1 V/sec	a,b,c
Oxidation			a',b',c',d
Reduction	Slow scan (Fig. 3B	0.1 V/sec	a,b,c
Oxidation			a',b',d,f
Oxidation	(After interruption)		a',f

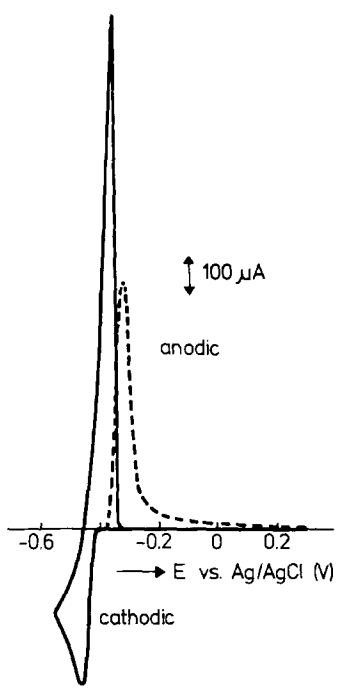

Fig. 5. Linear sweep voltammogram of 10^{-2}M HV-Br in an aqueous solution of 3M KBr. Dotted line: anodic sweep after interruption for 1 min. Geometric electrode area, 0.2 cm^2. Scan speed, 0.1 V/sec.

From microscopic observations it may be concluded that the peak f is due to the oxidation of reoriented parts of the radical salt film. This phenomenon is the subject of current investigations; results will be published elsewhere.

Since peak f shows a large tailing one can expect differences in charges involved in the cathodic (Q_c) and anodic (Q_a) scans. In order to evaluate this behavior, Q_a/Q_c of a more concentrated solution was measured as a function of the potential at which the sweep was reversed. From Fig. 6 it is obvious as a result that Q_a/Q_c of 10^{-2}M HV-Br approaches unity only if the first reduction step proceeds. These results differ from those reported by others (16), who found substantially lower values for the first reduction step. The discrepancy can be explained only by the presence of oxygen and/or impurities on the electrode surface, which, as we found, cause lower values of Q_a/Q_c. Scanning into the second reduction step region leads to the occurrence of peak f, which causes a decrease of Q_a/Q_c. An identical decrease was found after an interruption of the scan.

As already mentioned, some viologens such as ED-ClO_4 give stable films. In this respect it is interesting to look at a linear sweep voltammogram of ED-ClO_4 (Fig. 7). In this case a very simple voltammogram is obtained with only four peaks (a,a',c,c') present. The oxidation peak f is absent when scanning into the second reduction step region and also after interruption. It can be concluded that both first and second reduction steps proceed with ED-ClO_4 without complications and that aging effects are absent. The BD-BF_4 viologen voltammogram (Fig. 8) is somewhat more complicated than that of ED-ClO_4; here again a peak is observed which is believed to be due to C-T complexes. The observed influence of aging and second reduction step in terms of peak f, however, is very slight. The corresponding Q_a/Q_c of both BD-BF_4 and ED-ClO_4 is equal to unity within the experimental error, as can be seen in Fig. 6. Since above −1.0V (Ag/AgCl) hydrogen evolution was observed to have a strong influence, no data are presented for the highly cathodic potentials.

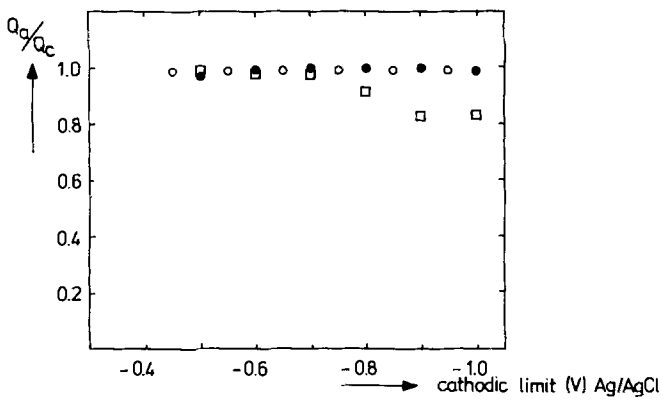

Fig. 6. Plot of Q_a/Q_c as a function of the cathodic scan limit of a linear sweep voltammogram. Q_a and Q_c are the respective charges of the anodic and cathodic parts of the scan. ○, 1.5 × 10^{-2}M BD-BF_4 in an aqueous solution of 0.03M TEAB; ●, 5 × 10^{-3}M ED-ClO_4 in an aqueous solution of 0.05M NaBr and 0.05M $NaClO_4$; □, 10^{-2}M HV-Br in an aqueous solution of 0.3M KBr. Fig. 8. Linear potential sweep voltammogram of 5 × 10^{-4}M BD-BF_4 in an aqueous solution of 0.04M TEAB. Scan speed, 0.005 V/sec. Tin dioxide electrode, 0.2 cm^2.

Conclusions

It has been shown that the oxidation behavior of viologen radical salt films is largely determined by aging effects, which were observed to be quite pronounced with HV-Br radical salt films. The same behavior can also be initiated by the occurrence of the second reduction step. As a result of aging or the occurrence of the second reduction step of HV-Br, Q_a/Q_c is less than unity. On the other hand, it was found that Q_a/Q_c equals unity if only the first reduction step of HV-Br is involved. Moreover it was shown that with modified viologens such as BD-BF_4 and ED-ClO_4, Q_a/Q_c is equal to unity within experimental error in a potential region down to −1.0V (Ag/AgCl) and with tin dioxide electrodes. It was shown that these tin dioxide electrodes should be used in preference to platinum. Especially with ED-ClO_4, aging effects were not observed. Thus it may be concluded that modified viologens are more promising materials for successful application in redox-chromic displays than HV-Br.

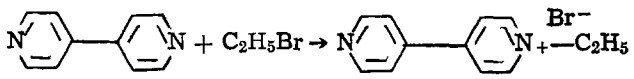
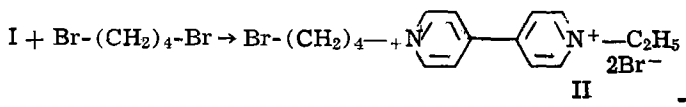
APPENDIX



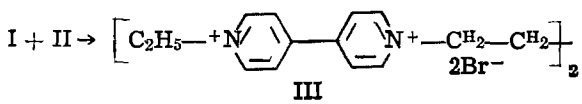
Synthesis of the Redox-Chromic Materials

1,1'-Diheptyl-4.4'-bipyridinium dibromide (HV-Br). —A mixture of 40g 4,4'-bipyridine, 200g 1-bromohep-

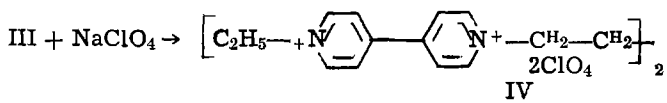


tane, and 250 ml dimethylformamide is refluxed while stirring for 3 hr. The precipitate is filtered off. Yield 93%. The crude product is purified by recrystallizations from ethanol-water and from acetonitrile.

The ^{1}H-NMR spectrum in D_2O of HV-Br relative to 2,2,3,3,- tetradeutero-3-(trimethylsilyl)-propionic acid-sodium salt was found to be: δ 0.89 ppm (t CH_3), δ 1.1-2.4 ppm (m CH_2), δ 4.79 ppm (t N-CH_2), δ 8.61 ppm (dβ-arom.-H), δ 9.18 ppm (dα-arom.-H).



Tetramethylene bis-[4(1-ethylpyridine-4'-yl)pyridinium] perchlorate (ED-ClO_4).—The synthesis is carried out according to the following scheme



I

II

III

IV

A mixture of 100g 4,4'-bipyridine and 500 ml 1-bromoethane is kept at room temperature for 5 days. The precipitate is filtered off and washed with ether. The main impurity, 4,4'-bipyridine, is removed by extraction with toluene. The crude product contains a few percent 1,1'-diethyldipyridinium-dibromide, which is removed by extraction with acetonitrile. The diquaternized product is filtered off and after evaporation of the solvent pure I is obtained.

A mixture of 30g I, 95 ml 1,4-dibromoethane, and 250 ml acetonitrile is refluxed for 8 hr. The precipitate is collected and washed with toluene. The product II is dried *in vacuo*. Yield 97%.

34.5g I, 60g II, and 500 ml dimethylformamide is heated for 16 hr while stirring at 120°C. After cooling III is filtered off and recrystallized from ethanol-water. Yield 44%. III is converted to IV by treatment with an aqueous solution of $NaClO_4$. IV is recrystallized from water.

The ^{1}H-NMR spectrum in DMSO-D_6 of ED-ClO_4 relative to 2,2.3,3,-tetradeutero-3-(trimethylsilyl)-propionic acid-sodium salt was found to be: δ 1.64 ppm (t CH_3), δ 2.11 ppm (broad CH_2 bridge), δ 4.6-5.0 ppm (m N-CH_2), δ 8.71-8.82 ppm (two pairs of doublets arom. protons β to N), δ 9.30-9.41 ppm (two pairs of doublets arom. protons α to N).

The ^{1}NMR spectra were run on a Varian-XL100 NMR spectrometer. Anal. Calcd. for $C_{28}H_{34}N_4Cl_4O_{16}$: C, 40.79; H, 4.15; N, 6.80. Cl, 17.20; O, 31.06. Found: C, 40.78; H, 4.15; N, 6.80; Cl, 17.12; O, 31.17.

Tetramethylene bis-[4(1-benzylpyridine-4'-yl)pyridinium] tetrafluoroborate (BD-BF_4).—The synthesis of this compound was analogous to that of ED-ClO_4.

The ^{1}H-NMR spectrum in DMSO-D_6 of BD-BF_4 relative to 2,2,3,3,-tetradeutero-3-(trimethylsilyl)-propionic acid-sodium salt was found to be: δ 2.10 ppm (broad CH_2 bridge), δ 4.77 ppm (broad N-CH_2 bridge), δ 5.97 ppm (s N-CH_2-phenyl), δ 7.4-7.8 ppm (m phenyl), δ 8.75 ppm (d arom. protons β to N), δ 9.33 ppm (d arom. protons α to N-bridge side), δ 9.48 ppm (d arom. protons α to N-benzyl side).

Anal. Calcd. for $C_{38}H_{38}N_4B_4F_{16}$. C, 50.83; H, 4.27; N, 6.24; B, 4.81; F, 33.85. Found: C, 50.65; H, 4.34; N, 6.25; B, 4.20; F, 34.23.

Electrochemical and Electrogenerated Chemiluminescence Studies of Substituted Olefin-Cyanophenanthrene Mixed Systems

Su-Moon Park*

Department of Chemistry, The University of New Mexico, Albuquerque, New Mexico 87131

and Richard A. Caldwell

Department of Chemistry, University of Texas at Dallas, Richardson, Texas 75080

ABSTRACT

Several mixed systems containing substituted olefins such as transanethole and substituted 9-cyanophenanthrenes were investigated by electrochemical and electrogenerated chemiluminescence (ECL)) techniques. The difference in the electrochemical behaviors of similarly structured cyanophenanthrenes is explained by the substituent effects on resonance stabilization of the electrogenerated species. The ECL of mixed systems mostly consists of the shorter wavelength emission from cyanophenanthrenes and the longer wavelength emission originated from an exciplex. Energy of exciplex emissions in the acetonitrile solution is linearly correlated with the reaction enthalpy of the electron transfer reactions between radical anions of cyanophenanthrenes and cation radicals of olefins studied.

Some organic photochemical reactions, *e.g.*, (2 + 2) cycloaddition reactions, have recently been shown to occur via an exciplex intermediate, which finally leads to the products. Caldwell and his co-workers (1-5) have shown exciplex intermediacy of several (2 + 2) cycloaddition reaction systems between cyanophenanthrenes and substituted olefins, resulting in a cyclobutane structure. They (1-5) and other investigators (6-8) have been able to identify the longer wavelength emissions, which do not correspond either to the phenanthrenes or olefins, when the reaction mixture was irradiated under reaction conditions. Multiplicity, lifetimes, and other properties of this intermediate species, an exciplex, have been determined and reported by these investigators.

We thought it would be very interesting to compare these photochemical observations with electrogenerated chemiluminescence (ECL) results of the corresponding photochemical systems, since the exciplex has been shown to be an intermediate species in the light-producing process of ECL (9-11).

Electrogenerated chemiluminescence is a process in which the energetic electron transfer reaction leads to the excited states (12-19). The reactants of the electron transfer reactions of interests are generated electrochemically at the anode or cathode, *i.e.*

$$D \rightarrow D^+ + e \quad \text{at the anode}$$

and [1]

$$A + e \rightarrow A^{\cdot -} \quad \text{at the cathode}$$

The resultant radical species react to give the excited state of either D or A (triplet or singlet) depending on the energetics involved in reaction [1]

$$D^{\cdot +} + A^{\cdot -} \rightarrow D^* + A,\ D + A^*,\ \text{or}\ A^* + D^* \quad [2]$$

In the light-producing step of reaction [2], an exciplex was shown to be involved, as already pointed out, which decomposes to an individual excited state, if the energy contained in the solvent-separated ion pair is greater than the one of the individual excited states (9-11), *i.e.*

$$A^{\cdot -} + D^{\cdot +} \rightarrow \underset{\text{exciplex}}{(A^- D^+)^*} \rightarrow A^* + D \text{ or } A + D^* \quad [3]$$

Thus, one observes the emitting excited states of either A or D. or both, plus an exciplex band, which does not correspond to A or D, in some cases. There are, however, many systems where the exciplex band is not observed.

In this paper, we describe experiments where the substituted olefins are used as D molecules, whereas substituted cyanophenanthrenes are used for A molecules. Results indicate that ECL techniques can be used for studying such reactions as is demonstrated later. ECL systems studied are those containing E-3,4-dianisyl-3-hexene (DAH), dimethoxystyrene (DMS), β-anisyl-iso-butylene (β-AIB), and anethole as olefinic donor molecules, and 9-cyanophenanthrene (9-CP), 3,9-dicyanophenanthrene (3,9-DCP), 3,10-dicyanophenanthrene (3,10-DCP), 3-methoxy-10-cyanophenanthrene (3,10-MCP), 3-methoxy-9-cyanophenanthrene (3,9-MCP) as substituted cyanophenanthrene acceptor molecules. Structures of these compounds are shown in Fig. 1.

Experimental

Cyanophenanthrenes and olefins were synthesized and purified in the laboratory of one of the authors (R.A.C.). Eastman Organic's ethanol recrystallized naphthalene was used after triple sublimation. Tri-p-

Key words: electrogenerated chemiluminescence, excited state, exciplex, cycloaddition.

tolylamine (TPTA) was kindly provided by Professor Ralph N. Adams of the University of Kansas, and used as received. Polarographic grade tetra-n-butylammonium perchlorate (TBAP) of Southwestern Analytical Chemicals, Inc., Austin, Texas, was used as a supporting electrolyte after drying in a vacuum desiccator at 120°C for more than 24 hr. Matheson, Coleman, and Bell's spectrograde acetonitrile (ACN) and benzonitrile (BzCN) were used as solvents after drying and purification according to the procedures described previously (9).

Solutions were prepared by weighing appropriate amounts of the donor and acceptor molecules into the ECL cell, followed by addition of solvents in a dry atmosphere glove box, but the measurements were made outside the box. The concentration of TBAP was always approximately 0.1*M* in all measurements.

Cyclic voltammograms were recorded with a Princeton Applied Research (PAR) Model 170 electrochemistry system, using either a three-electrode ECL cell of conventional design or a cell designed for the magnetic field measurements described by Faulkner *et al.* (20) in cases where the redox potentials were measured against the aqueous saturated calomel electrode (SCE). The conventional three wire electrode cell was used for the ECL measurements (21). ECL was generated by applying symmetrical square waves generated by the PAR 170 and detected with an Aminco-Bowman spectrophotofluorometer employing a Hammamatsu TV Corporation R-456 photomultiplier tube.

Results and Discussion

Electrochemical and ECL results obtained are summarized in Tables I and II, and typical results are reproduced in Fig. 2-4. Substituted cyanophenanthrenes are readily reduced as shown in Table I, but they are not oxidized within +2.0V *vs.* SCE. Substituted olefins, on the other hand, are oxidized from about +1.0 to +1.4V against SCE but are not reduced within the potential limit of interest. ECL's are observed from all systems studied in acetonitrile and benzonitrile solutions, as shown in Table II. More detailed discussions on the results follow.

Table I. Electrochemical data

Compounds‡	$E_{p,ox.}$* (V *vs.* SCE)	$E_{p,red.}$* (V)	i_{pa}/i_{pc} or i_{pc}/i_{pa}†	ΔE (mV)
DAH*	1.20, 1.28	n.r.**	0.74	~240
DMS	1.03, 1.37	n.r.	0.65	75
Anethole	1.28	n.r.	~0	—
β AIB	1.16	n.r.	0.58	~225
9-CP	n.o.**	−1.92 −2.66	1.03, 0.55	57
3,10-MCP	n.o.	−2.00, −2.72	1.00	62
3,9-MCP	n.o.	−2.05, −2.7	0.49	~180
3,10-DCP	n.o.	−1.57 —	0.47	~140
3,9-DCP	n.o.	−1.51, −2.11, −2.6	1.08, ~1.0	60, ~102

* Oxidation potentials of these compounds were measured against a Ag wire pseudoreference electrode and calibrated against an internal reference, TPTA ($E_{p,o}$ = 0.84 V *vs.* SCE). Reduction potentials were measured against an aqueous saturated calomel electrode (SCE).

** n.r. = not reduced, n.o. = not oxidized, within the potential of interest.

† i_{pa}/i_{pc} for reduction waves, i_{pc}/i_{pa} for oxidation waves. This parameter and ΔE were measured for the first and second waves where possible.

‡ For nomenclature of compounds, see Fig. 1 and text.

Table II. Emission in ECL

No.	Systems	ΔH* (eV)	ECL emissions, $h\nu_{max}$ (nm) In ACN	In BzCN
1	9-CP*-DAH**	2.97	389, 520	400,† 510

* Triplet energy level of 9-CP is 2.51 eV. Singlet energy level of 9-CP is about 3.3 eV.

** Fluorescence maximum of DAH in cyclohexane was: 0-0 band = 314 nm, 0-1 band = 338 nm (maximum intensity).

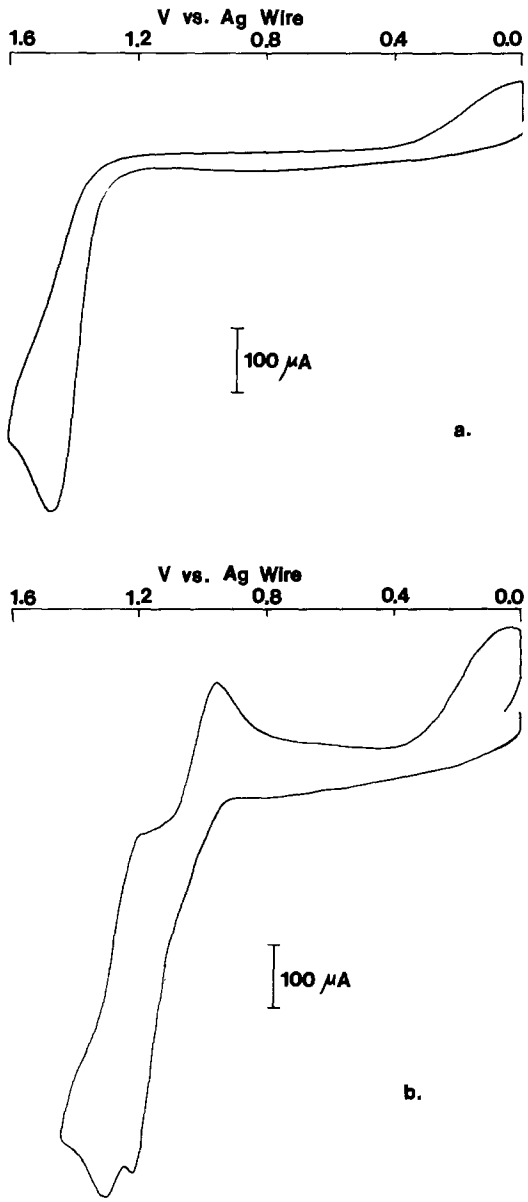
*** Exciplex emission was observed from this system but the emission peak could not be determined from the ECL spectrum.

† This was on the shoulder of exciplex emission and the correct wavelength could not be measured.

‡ Experiments were not performed in benzonitrile solution.

Electrochemical results.—Electrochemical data for oxidation and reduction potentials in acetonitrile as a solvent using 0.1*M* TBAP as a supporting electrolyte are collected in Table I.

Cyclic voltammetry of these compounds shows that the cation radicals generated upon oxidation at the platinum electrode are generally unstable, as evidenced by the absence of reversal current (Fig. 2). This is readily expected from the structure of the compounds due to the lack of stabilization through delocalization and resonance of the positive charge of oxidized product (cation radical). Losing a proton after the compound is oxidized will lead to the free radical, resulting in dimer or polymer formation. Two olefins, *i.e.*, DAH and DMS, show some stability as



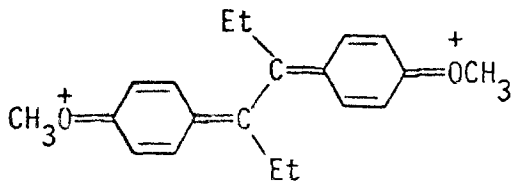


Fig. 2. Oxidation of olefins; (a) cyclic voltammogram of trans-anethole (2.2 mmole) and (b) cyclic voltammogram of DAH (1.2 mmole) in ACN at the Pt wire electrode. Scan rates were 200 mV/sec.

shown in Fig. 2. The first and second oxidation waves of DAH are very close, because the dication produced may be stabilized by the following quinonoid structure through resonance

and this is probably why even the dication of DAH shows stability on the reversal scan of the cyclic voltammogram (Fig. 2b). The second oxidation wave could have been that of the product derived from the radical cation. Most of the olefins except DAH that were used in this study are expected to polymerize (or dimerize) after losing protons upon oxidation. DAH is expected to be more stable, since it does not have a proton to lose, because of steric hindrance in forming the dimer. Detailed studies on the electrode processes of these compounds were not performed in this report.

The anion radicals of substituted cyanophenanthrenes are generally stable with the exception of 3,10-DCP and 3,9-MCP. Anion radicals of 9-CP and 3,10-MCP are stable, while their dianions are not stable, as shown in Fig. 3. 3,9-DCP forms an extremely stable anion radical at −1.51V *vs.* SCE and a stable dianion at −2.11V *vs.* SCE upon further reduction. This is further reduced at −2.6V *vs.* SCE, probably with formation of an unstable trianion radical. These compounds are not oxidized up to +2.0V *vs.* SCE in acetonitrile.

This interesting behavior (stability or instability of anion radicals) shown by this set of compounds can be explained by resonance stabilization-destabilization. In 3,9-DCP, where even the dianion is stable, one sees a high electron affinity due to two strongly electron-withdrawing cyano groups, which are located in such a way that the resonance structure stabilizes the anion radical produced by the addition of an electron, *i.e.*, the added electron is "shared" by two strongly electrophilic cyano groups by resonating structures. Since the electron is right on the electron-deficient center, the anion radical is expected to be stabilized. In 3,10-DCP, however, the corresponding resonance structure is such that an electron added on one cyanide group exerts a strong repulsion through resonance against the other cyanide group. This repulsion should contribute toward the instability of the radical anion produced. In 3,9-MCP and 3,10-MCP, the electron-donating methoxy group plays an impotrant role in deciding the electrochemical behavior. The partial charge generated through the resonance by a strongly electron-donating methoxy group is located such that either a strong repulsion (3,9-MCP) or no significant effect (3,10-MCP) will result from the addition of an electron to the electronegative cyano group of the molecule. Thus, in 3,10-MCP the addition of one electron to the cyano group does not seem to be affected very much by the presence of the methoxy group, whereas in 3,9-MCP two negative charges should be very repulsive after another electron has been added.

ECL results.—Upon generating both cation and anion radicals by applying square wave pulses, ECL spectra of the systems listed in Table II were obtained. ECL spectra obtained from 9-CP-β-AIB and 9-CP-DAH systems are shown in Fig. 4(a) and (b). Available system characteristics, *i.e.*, $\Delta H°$ for the homogeneous electron transfer reaction [3], are calculated from electrochemical data listed in Table I by the equation (20)

$$-\Delta H°\,(\text{eV}) = E_{p,ox} - E_{p,red.} - 0.16\,(\text{eV}) \qquad [4]$$

where $E_{p,ox}$ is the cyclic voltammetric peak potential for the oxidation of olefins and $E_{p,red.}$ is the reduction potential of cyanophenanthrenes. These are listed in Table II.

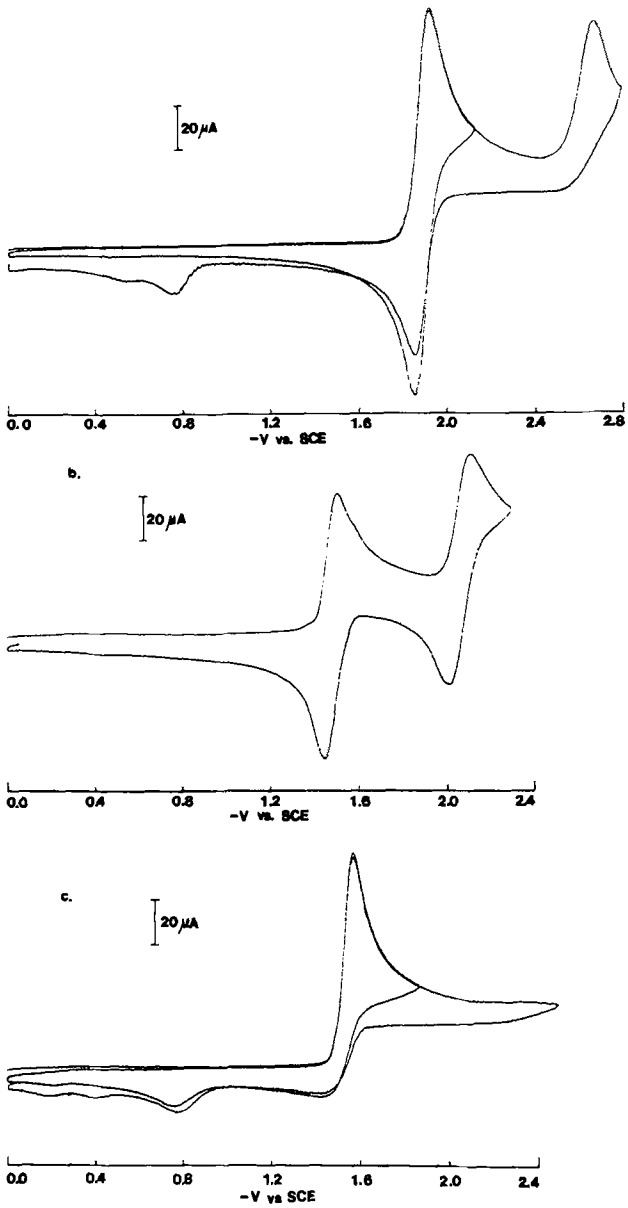

Fig. 3. Reduction of cyanophenanthrenes; cyclic voltammogram of (a) 9-CP (0.97 mmole), (b) 3,9-DCP (0.85 mmole), and (c) 3,10-DCP (0.91 mmole) in ACN with a scan rate of 200 mV/sec at a platinum wire electrode.

In all spectra shown in Fig. 4 and listed in Table II, the ECL spectra consists of monomer emissions derived from cyanophenanthrenes and longer wavelength emissions. The ECL intensities of almost all systems studied here in ACN decayed fairly rapidly. This is due to the instability of cation radicals produced upon oxidation. In most cases, a slow pulsation gives a side product, which blocks the working electrode and reduces the available electrode surface area, resulting in reduction in the number of photons (light) emitted. Also, after fast pulsation the ECL intensity dropped and it could not be restored on standing for some time or scanning only one direction. In several cases, the deteriorated electrode surface could be restored by scanning to one direction. This experimental observation indicates that a decomposition product forms on the working electrode, resulting in film formation on the surface of the electrode. These phenomena, however, can be avoided by pulsing the electrode slowly (1 sec pulse duration is usually satisfactory).

As has already been suggested above, the shorter wavelength emission of all ECL spectra is undoubtedly from the cyanophenanthrenes, which is readily identified by the comparison with fluorescence spectra of

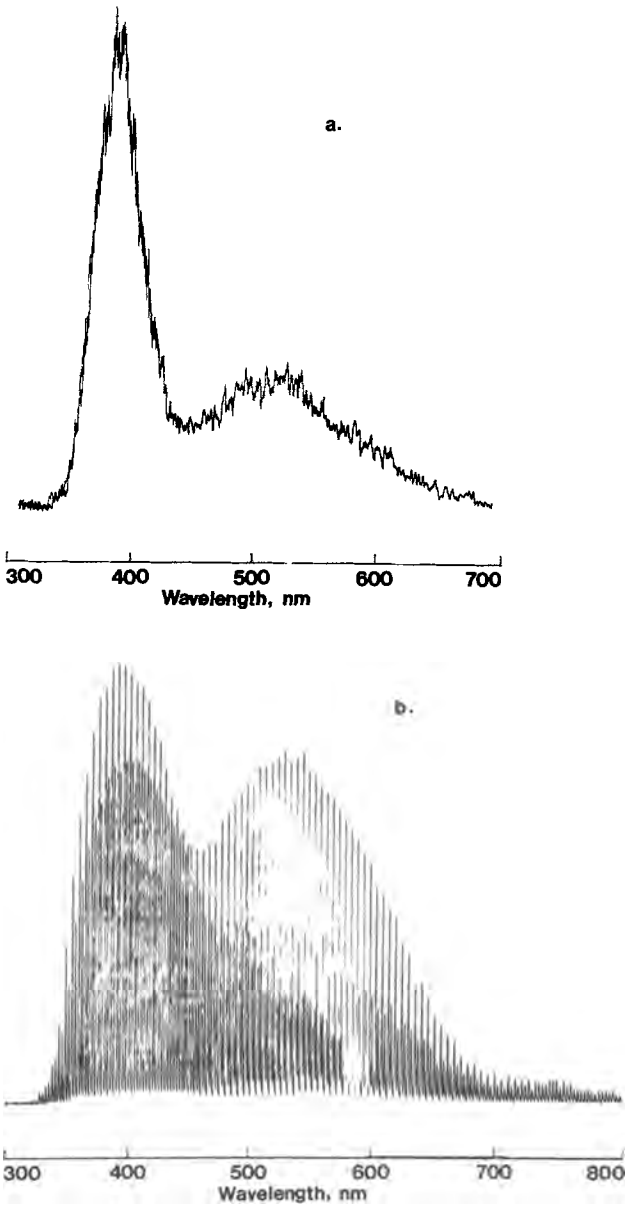

Fig. 4. ECL spectrum of (a) p-CP-β-AlB system in ACN; solution contained 1.9 mmole 9-CP and 1.5 mmole β-AlB; pulse duration was 50 msec, and (b) 9-CP-DAH system in ACN; solution contained 0.96 mmole 9-CP and 1.2 mmole DAH; pulse duration, 1 sec.

corresponding phenanthrenes. The possibility of having emissions from olefins is easily ruled out, since their excitation energy is high (see footnote **, Table II). Longer wavelength emission of these ECL spectra is assigned to be an exciplex for the following reasons.

Since the cation radicals of these systems are generally unstable in almost all cases, one has a good chance of having emissions from decomposition product of electrolyzed solution, which could have been excited by energy transfer from an excited cyanophenanthrene molecule produced by homogeneous electron transfer reaction (22). To see whether or not the luminescent products are being accumulated during the ECL experiment, a solution containing 1.3 m*M* 3,9-DCP and 2.2 m*M* β-AlB in 3.0 ml (system 11 in Table II) was pulsed for 6 hr with a frequency of 10 Hz between the first reduction potential of 3,9-DCP and the oxidation potential of β-AlB, and no detectable luminescent product was observed by the spectrophotofluorometer. Cyclic voltammograms recorded after the pulsation indicate that the concentration of β-AlB was considerably reduced, in that the peak current fell from 590 to 0.446 μA, but there were no new oxidation or reduction waves observed within the potential range of interest. Indeed, should the longer wavelength emission be originated from the decomposition products, one must observe them at the same wavelengths from systems containing the common donor or acceptor molecules, *e.g.*, from systems 3 and 11, or 1 and 8, which is not the case here. For the above system, the ECL spectrum remained constant, independent of the pulse frequency. Intensity, however, was a function of the pulse frequency.

In order to see the solvent effect on the longer wavelength bands, experiments on several systems were performed in benzonitrile. The results are summarized in Table II and show that most of the longer wavelength emission is blue-shifted by changing the solvent from acetonitrile, while the shorter wavelength emission is not shifted. The ratio of the intensity of the longer wavelength emission to that of the monomer emission was increased upon changing to the less polar solvent. Experiments in a solvent of a very low dielectric constant such as THF could not be done, because the anodic background appeared before the olefins were oxidized. With the above results alone, one can extrapolate the predicted result in a low dielectric constant solvent. That is, the large spectral shift upon changing solvent from ACN ($\epsilon = 37.5$) to BzCN ($\epsilon = 25.5$) reflects the charge-transfer nature of the spectrum observed and the fact that the relative intensity of longer wavelength emission increases in lower dielectric solvent medium is in agreement with the property of an exciplex (2, 3, 9, 10, 23). More experiments along this line are desirable but no solvents suitable for this study were available due to the limited anodic background potentials. More extensive description of solvent effects on exciplex emissions in ECL is found in the literature (9, 10).

One more convincing piece of evidence is that the energy of exciplex is related linearly with the $\Delta H°$ values listed in Table II. This plot is shown in Fig. 5. To interpret this plot, we start with the equation (23, 24)

$$E(A^-D^+) = IP_D - EA_A - C + \Delta H_s(A^-D^+) - \delta E_{FC} \quad [5]$$

where IP_D is the ionization potential of the donor, EA_A is the electron affinity of the acceptor, C is the coulombic energy, $\Delta H_s(A^-D^+)$ is the enthalpy of solvation of the exciplex, and δE_{FC} is the energy difference between the product molecules after the Frank-Condon transition and their equilibrium states. The IP_D and EA_A terms can be replaced with electrode potentials in such a way that

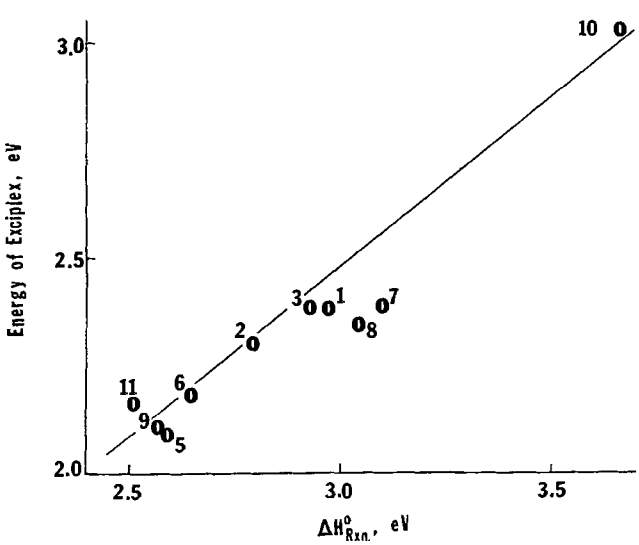

Fig. 5. Relationship between energy of exciplexes and $\Delta H°$. See Table II for names of compounds.

$$IP_D = kE_{p,ox.} + K'$$

$$EA_A = k'E_{p,red.} + K''$$

where k, k', K', and K'' are the constants. Assuming that $k = k' = 1.0$, we can rewrite Eq. [5] as follows

$$E(A^-D^+) = \Delta H^\circ + K$$

where K combines all constant terms derived from relations of ionization potential and electron affinity with electrode potentials plus other residual terms in Eq. [5]. We, therefore, expect the energy of exciplex emissions to be related linearly with reaction enthalpy of the systems from the above equation. The slope should be unity, since we have assumed $k = k' = 1$. The slope here was 0.78, excluding points 7 and 8. Considering that some of the electrochemical data are from irreversible electrode processes, the plot has a good correlation. An interesting fact found in Fig. 5 is that two systems containing compounds 3,9-MCP and 3,10-MCP show deviations from linearity. This might be attributed to the strongly electron-donating methoxy group on the phenanthrene, which can change the electron affinity property.

Systems 9 and 10 were studied and listed in Table II because of their proven ability to form an exciplex with many other organic counterions in ECL (9, 10, 26, 27).

Finally, the possibility that the longer wavelength emission might have been originated from an excimer, as a referee pointed out, may be ruled out by the fact that the bands have a charge-transfer character, as discussed above, and that the excimer bands were not observed by photoexcitation experiments in the benzene solution.

Because the reaction enthalpy ($-\Delta H^\circ$) of the systems are mostly lower than the singlet excited energy level of phenanthrenes, the emissive singlet excited states of monomers are probably produced through a triplet-triplet annihilation (TTA) mechanism (20, 25), although there is not clear-cut evidence for this. The triplets should be generated from decomposition of the exciplex as indicated in reaction [3]. In several systems, one can assume that thermal excitation from the cation-anion reaction potential surface to the singlet excited-state phenanthrene molecules can occur (26, 27).

The exciplex is thought to be formed directly from cation and anion radicals (9, 10). A triplet-quenching route for the formation of exciplex is very questionable, because the triplet population of both phenanthrenes and olefins is expected to be very low. While exciplex emission was observed from most systems described here in benzene solutions by the photoexcitation methods (1-8, 28), it was not observed in ACN solutions, probably because of the high dielectric constant of the medium. This indicates again that the direct formation of exciplexes by the ionic recombination reaction according to reaction [3] is more efficient than by photoexcitation. Observations of exciplex emissions in the polar medium by ECL techniques have been reported by several authors (9-11). From these experimental observations, the exciplex is considered to be formed directly from electrogenerated ions. In summary, we have

$$\dot{R}^- + \dot{R'}^+ \rightarrow {}^3R^* + R' \quad \text{or} \quad R + {}^3R'^*$$

$${}^3R^* + {}^3R^* \rightarrow {}^1R^* + R$$

$${}^1R^* \rightarrow R + h\nu$$

and $${}^3R'^* \rightarrow \text{photochemical product (?)} \qquad [7]$$

$$\dot{R}^- + \dot{R'}^+ \rightarrow {}^1(R^-R'^+)^*$$

$${}^1(R^-R'^+)^* \rightarrow R + R' + h\nu$$

where R = phenanthrenes and R' = olefins. Although production of the triplet excited state of olefin is possible, the yield should be very low due to the short lifetime of the radical cation produced at the electrode surface and, therefore, the efficiency of triplet-triplet annihilation should be low. Further, most of the triplet excited states of olefins, if there are any, are expected to undergo a photochemical reaction instead of emission through TTA (29).

In conclusion, ECL results also indicate that the exciplex is an intermediate species in (2 + 2) cycloaddition reaction systems studied here. There are, however, a few difficulties encountered in the electrochemical techniques. Solvent polarity, which is required for the electrical conductivity, prevents the reaction intermediate, *i.e.*, an exciplex, from proceeding toward the photochemical product, since the exciplex will be dissociated into the solvent-separated ion pair, which subsequently collapse to some other products. To support this argument, we should mention that most of the photochemical products were obtained in benzene solutions by photoexcitation but not in acetonitrile solutions (1-7, 28). The electrochemical products will, therefore, most probably be the ones derived from the radical species, although the transient exciplex emission can be observed by ECL techniques. The stability of the radical species gives an additional problem. The radical cation obtained at the electrode surface by oxidation of olefinic compounds is very unstable and decays to other products rapidly as shown by the absence of the reversal current in the cyclic voltammograms in Fig. 2. The products could be the ones derived from the free radical after losing a proton. Indeed, no detectable photochemical products were observed in the alternating current electrolysis. Thin layer chromatographic methods aided by the u.v.-viewing equipment were used to detect the products. Yet the ECL technique is an excellent alternative for studying some photochemical processes as demonstrated here.

Systems where the stable cation radical can be obtained from olefins, if available, can provide a good example for the product analysis, provided the steric hindrance is not severe. Further studies on such systems are in progress in our laboratory.

Radially Dependent Convective Warburg Problem for a Rotating Disk

Peter Appel and John Newman*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The oscillating concentration distribution of a reacting species in excess supporting electrolyte is calculated for a rotating disk system where a step change in the amplitude of the concentration fluctuation at the surface of the disk occurs at an arbitrary distance from the center of the disk. The response of a product species and of the supporting electrolyte to this step change is presented also.

Analysis of the current response of an electrochemical cell to an applied oscillating potential requires knowledge of the interplay of many factors. In addition to the faradaic impedance of the electrode reaction in parallel with the double-layer capacity, it was found necessary to describe concentration variations and the transient concentration overpotential. In the original Warburg problem of 1899, the diffusion layer was taken to be stagnant and one dimensional, and the surface concentration was found to lag behind the current by 45 degrees.

A finite thickness of the stagnant diffusion layer gives an approximate account of convection. On the other hand, Levart and Schuhmann (1) used the velocity profile of a rotating disk to calculate the concentration impedance, and later they extended the calculation to include homogeneous, first-order chemical reactions by means of a series expansion in $Sc^{-1/3}$ and a dimensionless parameter involving reaction kinetics and the oscillation frequency (2). This expansion, valid for high frequencies and any practical Schmidt number, is shown by these authors (3) to include as a special case the expansion of Homsy and Newman (4), valid for large Schmidt numbers and high frequencies.

However, the nonuniform ohmic potential drop in the solution leads to an inherently nonuniform current distribution (5), and this should be accentuated under alternating-current conditions (6). Our aim is to solve this problem for the rotating disk system, but in this paper we report only how a prescribed distribution of concentration variations at the surface influences the concentration gradients normal to the surface of the disk. In a subsequent paper, it will be necessary to show how this element of the problem interacts with the potential distribution in the bulk of the solution, the double-layer response to changes in composition and potential, and the reaction kinetics to produce the over-all impedance behavior of the disk electrode.

This decomposition of a complex problem into simpler parts is possible because the differential equations describing the concentration profiles are linear. These partial differential equations can thus be solved for a standard boundary condition where the concentration of one of the species makes a step change at a specified position on the surface. Superposition (7) of such standard solutions then permits one to calculate the normal gradients for an arbitrary surface concentration distribution, without solving repeatedly the partial differential equations.

Because of the complexity of the diffusion-layer equations for the alternating-current case, the bulk of this paper deals with the development and results for these standard solutions. The superposition integrals needed for the subsequent calculation of the impedance are stated toward the end of the paper (see Eq. [31] and [32]).

Deslouis *et al.* (8) investigated experimentally the frequency dispersion of a rotating disk, operated below the limiting current. The reaction used was the reduction of ferricyanide in excess supporting electrolyte. Their results are in surprisingly good agreement with the theoretical results of Levart and Schuhmann in view of our finding that both the oscillating current distribution (9) and the time-average current distri-

* Electrochemical Society Active Member.
Key words: supporting electrolyte, impedance, adsorption, alternating current, current distribution, effect of migration.

bution for this reaction (10) below the limiting current are nonuniform on the surface of the disk. Also, the concentration fluctuations of the product (ferrocyanide) influence the concentration overpotential to the same extent as the reactant [see Newman (11) Chapter 20].

Finally, the change in the double-layer capacity is caused by the fluctuations in the potential and the fluctuations of all ionic species in the solution just outside the double layer—including the supporting electrolyte. The latter fluctuations are caused by the influence of migration on the supporting electrolyte and the condition of electroneutrality outside the double layer. Therefore, we have included the effect of the supporting electrolyte in our calculations.

Mathematical Formulation

In our treatment we assume constant transport properties of the ionic species and neglect the influence of migration on the minor, reacting species. In addition, the cation of the supporting electrolyte is also the cation of the reacting species. This situation arises, for instance, if we reduce sodium ferricyanide to sodium ferrocyanide in excess sodium fluoride.

Since all transport equations used are linear, we may separate the equations into a time-dependent and a time-independent part. The time-independent part has been treated before, and since all time dependent quantities fluctuate with a frequency ω, we may write

$$\Delta c_i = \mathrm{Re}\{\tilde{c}_i \exp(j\omega t)\} \quad [1]$$

where Re denotes the real part of the expression and

$$\tilde{c}_i = |\Delta c_i(r,y)| \exp[j\phi(r,y)] \quad [2]$$

Δc_i is the local magnitude and ϕ, the phase angle of the oscillating concentration. Radial diffusion is small compared to radial convection, so that the conservation equation in cylindrical coordinates for the minor species becomes

$$j\omega\tilde{c}_i + v_r\frac{\partial\tilde{c}_i}{\partial r} + v_y\frac{\partial\tilde{c}_i}{\partial y} = D_i\frac{\partial^2\tilde{c}_i}{\partial y^2} \quad [3]$$

with the boundary conditions

$$\tilde{c}_i = 0 \text{ at } y = 0,\ r < r' \quad [4]$$

$$\tilde{c}_i = 1 \text{ at } y = 0,\ r \geq r' \quad [5]$$

$$\tilde{c}_i \to 0 \text{ as } y \to \infty \quad [6]$$

For high Schmidt numbers we may use the expression for the velocity distribution close to the disk surface. If we introduce subsequently the dimensionless variables

$$x = \left(\frac{r^3 - r'^3}{r^3}\right)^{1/3} \quad [7]$$

$$\eta_i = y\left(\frac{a\nu}{3D_i}\right)^{1/3}\left(\frac{\Omega}{\nu}\right)^{1/2} \Big/ x \quad [8]$$

the conservation equation becomes

$$\frac{\partial^2\tilde{c}_i}{\partial\eta_i^2} + 3\eta_i^2\frac{\partial\tilde{c}_i}{\partial\eta_i} = jK_ix^2\tilde{c}_i + 3\eta_ix(1-x^3)\frac{\partial\tilde{c}_i}{\partial x} \quad [9]$$

where K_i is a dimensionless frequency, given by

$$K_i = \frac{\omega}{\Omega}\mathrm{Sc}_i^{1/3}\left(\frac{3}{a}\right)^{2/3} \quad [10]$$

In this new coordinate system, the boundary conditions given by Eq. [4]-[6] are transformed into

$$\tilde{c}_i = 1 \text{ at } \eta_i = 0 \quad [11]$$

$$\tilde{c}_i \to 0 \text{ as } \eta_i \to \infty \quad [12]$$

$$\tilde{c}_i = F_0(\eta_i) \text{ at } x = 0 \quad [13]$$

The function $F_0(\eta_i)$ is obtained by solving Eq. [9] at $x = 0$ with boundary conditions [11] and [12]. The result is

$$F_0(\eta_i) = \frac{1}{\Gamma(4/3)}\int_{\eta_i}^{\infty} e^{-z^3}dz \quad [14]$$

The finite-difference form of Eq. [9] has to take into account the behavior of $\tilde{c}_i$ near $x = 0$ since this is a singular point of this equation. Therefore, an asymptotic solution was sought for small values of x. This solution also serves as a check on the values obtained numerically. For this purpose, we expand $\tilde{c}_i$ in a power series in x

$$\tilde{c}_i(\eta_i, x) = F_0(\eta_i) + F_1(\eta_i)x^m + F_2(\eta_i)x^n + O(x^p) \quad [15]$$

Substitution of this expression into Eq. [9] gives a set of coupled ordinary differential equations, and in addition we find that $m = 2$, $n = 4$, and $p = 5$. All these equations for $F_k(\eta_i)$, where $k > 0$, are subject to the boundary conditions

$$F_k = 0 \text{ at } \eta_i = 0,\ F_k \to 0 \text{ as } \eta_i \to \infty \quad [16]$$

since $\tilde{c}_i$ evaluated from the series expansion must also satisfy boundary conditions [11]-[13]. The equation for F_1 is

$$\frac{d^2F_1}{d\eta_i^2} + 3\eta_i^2\frac{dF_1}{d\eta_i} - \eta_iF_1 = jK_iF_0 \quad [17]$$

The solution to this equation satisfying boundary conditions [16] is

$$F_1 = \frac{jK_i}{2\Gamma(4/3)}\eta_i^2\int_{\eta_i}^{\infty} e^{-z^3}dz - \frac{jK_i}{6\Gamma(4/3)}e^{-\eta_i^3} + \frac{2jK_i}{6(\Gamma(4/3))^2}\int_0^1 X\int_{\eta_i/(1-X^3)^{1/3}}^{\infty} e^{-z^3}dz\,dX \quad [18]$$

The differential equation for F_2 is

$$\frac{d^2F_2}{d\eta_i^2} + 3\eta_i^2\frac{dF_2}{d\eta_i} - 12\eta_iF_2 = jK_iF_1 \quad [19]$$

which has been solved numerically since no analytic solution could be obtained. As mentioned before, we are interested in the flux at the surface of the disk as a function of x, the dimensionless distance from the step change at $r = r'$. Using the analytic solution for F_0 and F_1 and the numerical solution for F_2, we obtain the following expression, valid for small values of x

$$\left.\frac{\partial\tilde{c}_i}{\partial\eta_i}\right|_{\eta_i=0} = -\frac{1}{\Gamma(4/3)} - \frac{jK_i}{4\Gamma(4/3)}\left[\frac{\Gamma(5/3)}{\Gamma(4/3)}\right]^2x^2 - 0.01250457\,K_i^2x^4 + O(x^5) \quad [20]$$

Another singular point of Eq. [9] occurs at $x = 1$ (infinitely far away from the step change at $r = r'$). Proceeding in the same manner as before, we can show that the asymptotic expansion of $\tilde{c}_i$ valid for values of x close to 1 is

$$\tilde{c}_i = G_0 + G_1(1-x) + G_2(1-x)^2 + O[(1-x)^3] \quad [21]$$

The equation for G_0 is identical to the equation describing the uniform distribution and has been calculated

by Levart and Schuhmann (1) and by Mohr (as reported by Homsy) (4)

$$\frac{d^2G_o}{d\eta_i^2} + 3\eta_i^2\frac{dG_o}{d\eta_i} = jK_iG_o \qquad [22]$$

with boundary conditions [11] and [12]. Since the equations for G_o, G_1, and G_2 do not permit us to obtain an explicit dependence of K_i similar to Eq. [20], we calculated G_1 and G_2 only for $K_i = 50$. The solution of Eq. [22] has been obtained for all values of K_i investigated.

The linearization procedure for the convective diffusion equation for the supporting electrolyte, including the effect of migration, has been described elsewhere (9, 11). Basically, it involves the elimination of the migration term by applying the electroneutrality condition, resulting in the appearance of terms in the equation accounting for the interaction of each major component with all minor components in the solution. The analysis will be given for the cation of the supporting electrolyte. Using the same notation as in Eq. [9] with the effective diffusion coefficient D_e for the supporting electrolyte, where

$$D_e = \frac{z_+u_+D_- - z_-u_-D_+}{z_+u_+ - z_-u_-} \qquad [23]$$

we arrive at the following equation

$$\frac{\partial^2\tilde{c}_+}{\partial\eta_e^2} + 3\eta_e^2\frac{\partial\tilde{c}_+}{\partial\eta_e} = jK_ex^2\tilde{c}_+ + 3\eta_ex(1-x^3)\frac{\partial\tilde{c}_+}{\partial x} - \frac{z_Ru_+(D_- - D_R)}{z_+u_+D_- - z_-u_-D_+}\frac{\partial^2\tilde{c}_R}{\partial\eta_e^2} - \frac{z_Pu_+(D_- - D_P)}{z_+u_+D_- - z_-u_-D_+}\frac{\partial^2\tilde{c}_P}{\partial\eta_e^2} \qquad [24]$$

In order to take separately into account the concentration changes of supporting electrolyte, reactant, and product, we first solve the above equation with neglect of the last two terms with boundary conditions [11]-[13] and let its solution be denoted by $\tilde{\alpha}$. This solution is identical to the solution of Eq. [9] with D_e instead of D_i. Similarly, we solve Eq. [24], neglecting the interaction with the product species, but with $\partial^2\tilde{c}_R/\partial\eta_e^2$ evaluated from the solution to Eq. [9], with the boundary conditions

$$\tilde{c}_+ = 0 \text{ at } \eta_e = 0,\ \tilde{c}_+ \to 0 \text{ as } \eta_e \to \infty \qquad [25]$$

Let the solution be given by $\tilde{\beta}$; the solution to Eq. [24] due to interaction with the product species only is given by $\tilde{\delta}$. It is evident that both solutions are identical, except that $\tilde{\beta}$ involves the diffusion coefficient of the reactant and $\tilde{\delta}$ that of the product.

The asymptotic expansion of $\tilde{\beta}$ (and of $\tilde{\delta}$) near $x = 0$ proceeds along the same lines as before. Because the resulting equations are all linear, it is easy to show that

$$\tilde{\beta} = \tilde{\beta}_o(\eta_e) + jK_e\tilde{\beta}_1(\eta_e)x^2 + K_e^2\tilde{\beta}_2(\eta_e)x^4 + O(x^5) \qquad [26]$$

where $\tilde{\beta}_o$, $\tilde{\beta}_1$, and $\tilde{\beta}_2$ are independent of K_e and real. It is possible to obtain an analytic expression for $\tilde{\beta}_o$, but not for $\tilde{\beta}_1$ and $\tilde{\beta}_2$

$$\tilde{\beta}_o = \frac{z_Ru_+D_e}{\Gamma(4/3)(z_+u_+D_- - z_-u_-D_+)}\left(\frac{D_- - D_R}{D_e - D_R}\right)\int_{(D_e/D_R)^{1/3}\eta_e}^{\eta_e} e^{-z^3}dz \qquad [27]$$

Numerical solutions for $\tilde{\beta}_1$ and $\tilde{\beta}_2$ were not attempted; with the results obtained so far we are able to check the numerical solution of $\tilde{\beta}$ by evaluating both $\tilde{\beta}(0)$ and $\partial\tilde{\beta}/\partial\eta_e$ (at $\eta_e = 0$ and $x = 0$) and compare these values with the values obtained by using Eq. [26] at $x = 0$

$$\tilde{\beta}(0) = 0;\ \left.\frac{\partial\tilde{\beta}}{\partial\eta_e}\right|_{\eta_e=0} = \frac{z_Ru_+D_e}{\Gamma(4/3)(z_+u_+D_- - z_-u_-D_+)}\left(\frac{D_- - D_R}{D_e - D_R}\right)\left[\left(\frac{D_e}{D_R}\right)^{1/3} - 1\right] \qquad [28]$$

Results and Discussion

A comparison between the asymptotic solutions (Eq. [15] and [21]) and the numerical solution of Eq. [9] near $x = 0$ and $x = 1$ shows that the values and certain derivatives are identical within 0.1%.

Figures 1 and 2 show the derivatives of the real part and imaginary part of the reactant concentration, respectively, evaluated at $\eta_i = 0$. The real part is plotted against x^4, the imaginary part against x^2. This choice, as well as the form of the respective expressions on the ordinates, is suggested by the asymptotic solution for small values of x. Figures 3 and 4 show the concentration derivative of the cation of the supporting electrolyte due to a step change in the reactant concentration at the surface of the disk ($\partial\tilde{\beta}/\partial\eta_e(\eta_e = 0)$). Here again, the difference between the values of $\tilde{\beta}(0)$ and

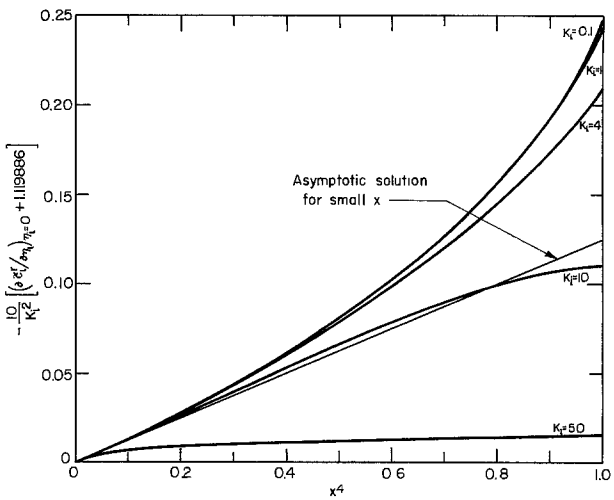

Fig. 1. Derivative of the real part of the concentration at $\eta_i = 0$, as a function of x^4.

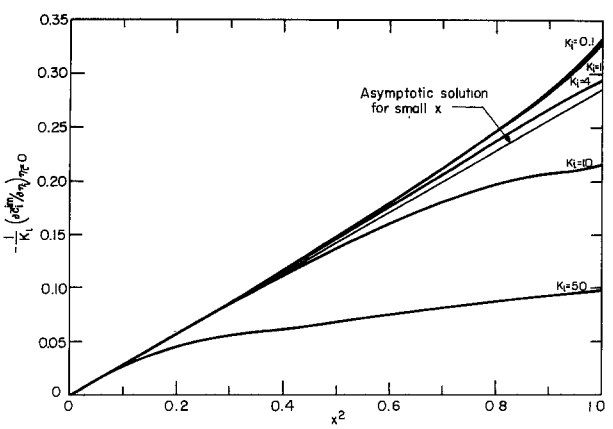

Fig. 2. Derivative of the imaginary part of the concentration at $\eta_i = 0$, as a function of x^2.

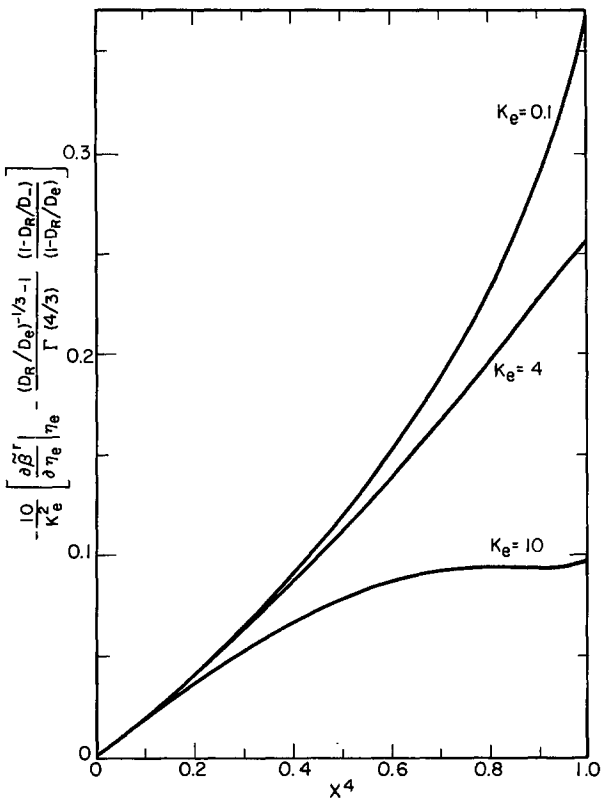

Fig. 3. Derivative of the real part of the concentration fluctuations at the disk surface of the cation of the supporting electrolyte due to a step change in the amplitude of reactant fluctuation.

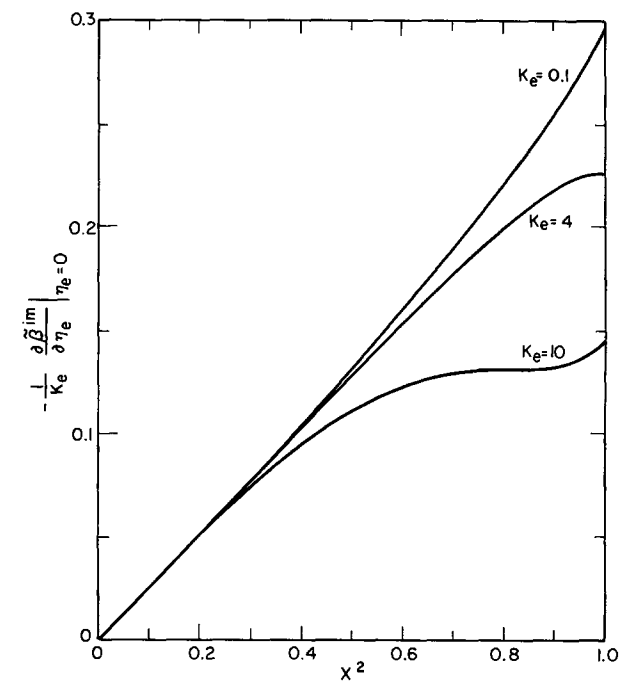

Fig. 4. Derivative of the imaginary part of the concentration fluctuations at the surface of the disk of the cation of the supporting electrolyte due to a step change in the amplitude of reactant fluctuation.

$\partial\tilde{\beta}/\partial\eta_e(\eta_e = 0)$ at $x = 0$ calculated from the numerical evaluation of $\tilde{\beta}$ and these values as obtained from Eq. [28] was less than 0.1%. The Nernst-Einstein relation was assumed to be applicable.

We shall now proceed to show how one can obtain the oscillating flux distribution at the disk surface for all ionic species from the results obtained so far, once the concentration distribution of these species at the surface of the disk is known. The dimensionless flux is defined as (4)

$$\frac{\partial\tilde{c}_i}{\partial\zeta_i}\Big|_{\zeta_i=0} = \frac{1}{x}\frac{\partial\tilde{c}_i}{\partial\eta_i}\Big|_{\eta_i=0} \quad [29]$$

since

$$\zeta_i = x\eta_i \quad [30]$$

The right side of Eq. [29] has been calculated as a function of x for a step change at $r = r'$. Therefore, for arbitrary surface concentration $\tilde{c}_{i,o}$, we obtain the corresponding flux distribution by superposition, which for the reactant becomes

$$\frac{\partial\tilde{c}_R}{\partial\zeta_i}\Big|_{\zeta_i=0} = \int_0^r \frac{d\tilde{c}_{R,o}}{dr}\Big|_{r=r'} \frac{\partial\tilde{c}_i}{\partial\eta_i}\Big|_{\eta_i=0} \left(\frac{r^3}{r^3 - r'^3}\right)^{1/3} dr' \quad [31]$$

The same expression holds for the product species, but the subscript R will then be replaced by P. For the cation of the supporting electrolyte we have shown how to take separately into account the contribution of reactant and product species. Because of the linearity of Eq. [24] we may add these contributions in the expression under the integral sign

$$\frac{\partial\tilde{c}_+}{\partial\zeta_e}\Big|_{\eta_e=0} = \int_0^r \left(\frac{d\tilde{c}_{+,o}}{dr}\Big|_{r=r'} \frac{\partial\tilde{\alpha}}{\partial\eta_e}\Big|_{\eta_e=0} + \frac{d\tilde{c}_{R,o}}{dr}\Big|_{r=r'} \frac{\partial\tilde{\beta}}{\partial\eta_e}\Big|_{\eta_e=0} + \frac{d\tilde{c}_{P,o}}{dr}\Big|_{r=r'} \frac{\partial\tilde{\delta}}{\partial\eta_e}\Big|_{\eta_e=0}\right)\left(\frac{r^3}{r^3 - r'^3}\right)^{1/3} dr' \quad [32]$$

Finally, the anion concentration can be calculated from the electroneutrality equation

$$\sum_i z_i\tilde{c}_i = 0 \quad [33]$$

and the anion flux by taking the first derivative of this equation.

Perhaps we should remind ourselves of the context in which these results are to be utilized. First, the steady distributions of current, potential, and concentrations should be obtained as in Ref. (10). This steady-state situation is to be perturbed by a small, superimposed alternating current, and the resulting alternating potential is to be assessed. This involves, first of all, perturbation of all the factors that go into the steady problem. These are principally Laplace's equation for the potential in the bulk solution, the mass-transfer behavior of the minor species in the diffusion layer, and the electrode kinetics. In addition, there are factors not present in the steady problem. These center around the double-layer capacity, which depends on the local time-average composition and potential, but they also involve a more general dependence of double-layer structure on composition and potential. The computation of the oscillating behavior is a linear problem, in contrast to the steady behavior, but it is still quite complex. The three regions—bulk solution, diffusion layer, and interface—must be treated simultaneously because of their rather strong coupling. In this treatment, it is an advantage to have the original partial differential Eq. [3] and [24] replaced by the superposition integrals in Eq. [31] and [32]. These latter are equivalent to the former in terms of the coupling with the bulk solution and the interface since the coupling can be phrased in terms of

concentrations in the bulk and at the surface and concentration derivatives at the surface.

Summary

The conservation equations of minor and major species have been solved for a rotating disk system where a step change in the amplitude of the concentration fluctuations at the surface of the disk occurs at an arbitrary distance from the center of the disk. The effect of migration on the supporting electrolyte was included in the analysis. Results were presented in the form of the flux of each species at the surface of the disk as a function of distance from the place where the step change occurs. The results obtained by the numerical solution of the complete equations were compared with asymptotic solutions valid for short or for very large distances from the step change. The differences were less than 0.1%.

It was shown that through the use of superposition integrals these results can be applied to the calculation of the oscillating flux distribution of each ionic species for arbitrary concentration distributions of these species at the surface of the disk.

Distribution of Potential and Current in Circular Corrosion Cells Having Unequal Polarization Parameters

E. McCafferty*

Naval Research Laboratory, Washington, D.C. 20375

ABSTRACT

A mathematical model has been developed to describe the distribution of potential and current across concentric circular corrosion cells having unequal anodic and cathodic polarizabilities. This theory is essentially an extension of the Wagner-Waber model to circular systems and is applicable to galvanic couples, metal matrix composites, and localized corrosion effects. The potential distribution in systems having unequal Wagner polarization parameters is not related in a simple way to the separate distribution curves for the two cases where the polarization parameters are equal. In thin-layer electrolytes, there is a geometry effect in which the electrode polarization and current flow are concentrated near the anode/cathode juncture. The theory is applied satisfactorily to Pt/Fe model systems in dilute sodium chloride and to earlier results of Rosenfeld and Pavlutskaya with circular electrodes.

Many corrosion systems can be described by a coplanar circular geometry. Examples include some instances of pitting (1), crevice corrosion under O-rings or washers (2), corrosion under barnacles (3), under tubercules of corrosion products (4), or under dust particles in condensed moisture films (5).

Gal-Or, Raz, and Yahalom (6) have mathematically treated systems of coplanar, concentric circular corrosion cells having linear corrosion kinetics and equal anodic and cathodic slopes. These authors analyzed the effect of various system parameters on the total anodic current, and more recently the distribution of potential and current across such cells has been evaluated (7, 8). These treatments essentially extended to cylindrical geometries the model developed by Waber and co-workers (9-12) in a series of publications on semi-infinite parallel electrodes with anode and cathode having linear and equal corrosion kinetics.

Smyrl and Newman (13) have recently presented an analysis for an array of corroding disks in a cathodic plane assuming Tafel kinetics but with equal anodic and cathodic slopes.

While the assumption of linear polarization over an extended potential range is often a reasonable approximation (as is discussed later), the assumption that anodic and cathodic slopes are equal seldom holds because the anode is generally far less polarizable than the cathode.

The case of unequal anodic and cathodic linear polarization has been solved by Kennard and Waber (14) for semi-infinite strips of parallel electrodes under bulk electrolyte.

The purpose of this paper is to extend the Waber model of linear corrosion kinetics to circular systems with unequal polarization parameters. Equations are derived for potential and current distribution and for the total anodic current, and generalized numerical calculations are made. This paper is largely mathematical, but comparisons are made with some preliminary experiments and also with the published work of Rosenfeld and Pavlutskaya (15, 16) for iron/copper disk electrodes under bulk and thin-layer electrolytes.

Mathematical Analysis

The cell geometry is shown in Fig. 1. The anode and cathode edges are coplanar, concentric, circles of radii a and c, respectively. The electrolyte thickness b is allowed to approach infinity for bulk electrolyte. The cell potentials and stylized polarization curves are show in Fig. 2. As pointed out by Kennard and Waber (14), if the plots are linear over only a portion of the curves, tangent approximations can be drawn and the open-circuit potentials E_a° and E_c° replaced by the intersections $E_a^{\circ\prime}$ and $E_c^{\circ\prime}$, respectively, of the tangent lines with the potential axis.

The electrostatic potential $P(x, y, z)$ at any point in the electrolyte is given by Laplace's equation

$$\nabla^2 P(x, y, z) = 0 \qquad [1]$$

provided that: (*i*) there are no concentration gradients in solution, (*ii*) the solution is electroneutral, and (*iii*) there are no sources or sinks of ions in the electrolyte (17). In cylindrical coordinates, Laplace's equation is

$$\frac{\partial^2 P(r,z)}{\partial r^2} + \frac{1}{r} \cdot \frac{\partial P(r,z)}{\partial r} + \frac{\partial^2 P(r,z)}{\partial z^2} = 0 \qquad [2]$$

with the term in $\partial^2 P(r, z)/\partial\theta^2$ deleted because the potential is not dependent on the angle θ. The general approach is to solve for $P(r, z)$ subject to appropriate boundary conditions and then to evaluate the local current density $i(r, 0)$ from Ohm's law for electrolytes

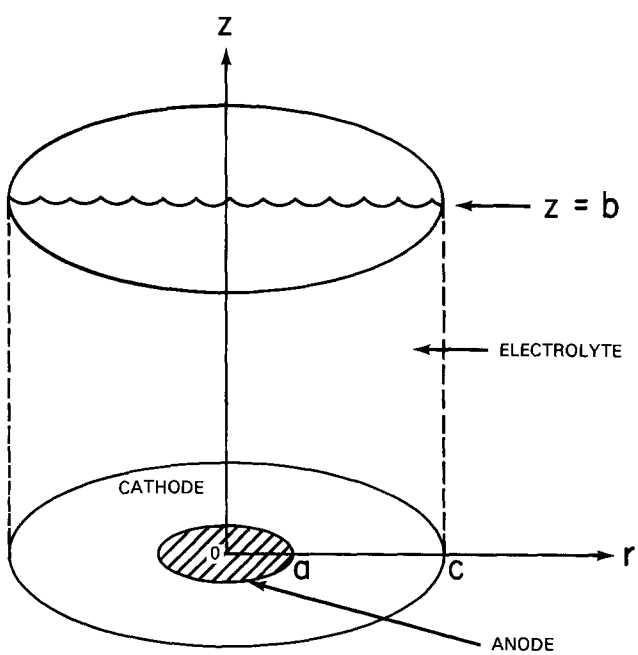

Fig. 1. Cell geometry

* Electrochemical Society Active Member.

Key words: current distribution, potential distribution, circular electrodes, galvanic couples, thin-layer electrolyte.

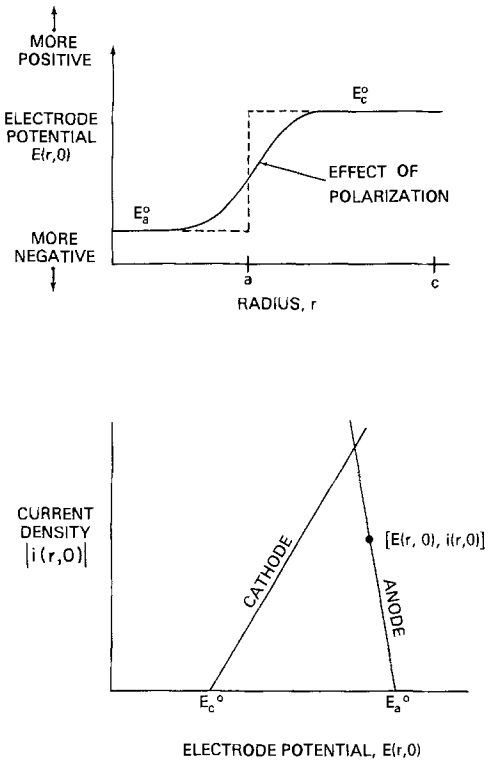

Fig. 2. Electrode potentials and idealized linear polarization curves. E_a° and E_c° refer to the open-circuit potentials of anode and cathode, respectively.

$$i(r,0) = -\sigma\left[\frac{\partial P(r,z)}{\partial z}\right]_{z=0} \qquad [3]$$

where σ is the electrolyte conductivity.

The potential $P(r,z)$ must satisfy the boundary conditions of no current flow across the planes $r = 0$ and $r = c$. Thus

$$\left[\frac{\partial P(r,z)}{\partial r}\right]_{r=0} = \left[\frac{\partial P(r,z)}{\partial r}\right]_{r=c} = 0 \qquad [4]$$

For bulk electrolyte, $P(r,z)$ must be bounded for large z. For bulk electrolyte, the general solution to Laplace's equation subject to these conditions is

$$P(r,z) = B_0 + \sum_{n=1}^{\infty} B_n J_0(\lambda_n r)\, e^{-\lambda_n z} \qquad [5]$$

where B_0 and B_n are coefficients to be determined, J_0 is the Bessel function of order zero, $\lambda_n = x_n/c$, and x_n are the zeroes of $J_1(x) = 0$.

Linear polarization model.—The remaining boundary condition relates the electrode potential $E(r,0)$ along the metal surface *vs.* some standard reference electrode to the electrostatic potential $P(r,0)$ within the electrolyte but "just outside" (18) the electrode surface. That is

$$V' - P(r,0) = E(r,0) \qquad [6]$$

where V' is a constant which includes the various differences in electrostatic potential across the extra interfaces which are introduced in the measurement of a potential difference across the metal/solution interface of interest (19).

Following Wagner (20) and Waber (9-12), it is assumed that there is a linear dependence over an extended range between the electrode potential E and current density i. As mentioned earlier, this is a reasonable approximation in a number of experimental cases.

The recent literature contains a number of examples of polarization plots which are linear or approximately so over an extended potential range. For example, steels in aerated neutral to basic solutions, with or without chloride, displayed both anodic and cathodic plots which were approximately linear over an extended range (21). Additional examples include the corrosion of tin in citrate solutions (22) and of bare and coated aluminum in chloride solutions (23). Other examples involve specialized geometries, such as the pitting of aluminum (24), or specialized conditions, such as the dissolution of mild steel at high anodic overpotentials in concentrated electrolytes (25). On the cathodic side, the reduction of oxygen on nickel in dilute H_2SO_4 (26) and on silver in KOH (27) display linear regions. Polarization curves for a variety of metals in thin-layer electrolytes (15) display linear regions over at least part of the potential ranges for both anodic and cathodic processes.

As pointed out by Stern and Geary (28), the combined effects of concentration polarization plus ohmic drops interfere with activation polarization processes so that sometimes a very short Tafel region is observed. Such cases often give straight line segments in E *vs.* i.

At this point, it should be clear that the model invokes linearity over an extended potential range and not merely in the pre-Tafel region near the corrosion potential where the familiar Stern and Geary (28) linear relation is valid.

Thus, the anodic and cathodic Wagner polarization parameters are defined as

$$\mathcal{L}_a = \sigma \left|\frac{dE}{di}\right|_a, \quad 0 \leq r < a \qquad [7a]$$

and

$$\mathcal{L}_c = \sigma \left|\frac{dE}{di}\right|_c, \quad a < r \leq c \qquad [7b]$$

where $\mathcal{L}_a$ and $\mathcal{L}_c$ have the dimensions of length, and $\mathcal{L}_a \neq \mathcal{L}_c$. For the anodic branch in Fig. 2, $di/dE = i(r,0)/[E(r,0) - E_a^\circ]$. This expression combines with Eq. [7a], [6], and [3] to give the final boundary condition for the anode surface

$$P(r,0) - \mathcal{L}_a\left[\frac{\partial P(r,z)}{\partial z}\right]_{z=0} = V' - E_a^\circ, \quad 0 \leq r < a \qquad [8a]$$

Similarly for the cathode

$$P(r,0) - \mathcal{L}_c\left[\frac{\partial P(r,z)}{\partial z}\right]_{z=0} = V' - E_c^\circ, \quad a < r \leq c \qquad [8b]$$

Equations for bulk electrolyte.—The boundary conditions in Eq. [8a] and [8b] are used to determine the coefficients B_0 and B_n. The method of solution is outlined in the Appendix, which notes the differences between the present analysis and the earlier work of Gal-Or and co-workers (6) for $\mathcal{L}_a = \mathcal{L}_c$. More detail is available elsewhere (29). The result for B_0 is

$$B_0 = V' - \left(\frac{a}{c}\right)^2 E_a^\circ - \left(\frac{c^2 - a^2}{c^2}\right) E_c^\circ - \frac{2a}{c^2}(\mathcal{L}_a - \mathcal{L}_c) \sum_{n=1}^{\infty} B_n J_1\left(x_n \frac{a}{c}\right) \qquad [9]$$

The coefficients B_n are given by

$$B_m\left[\left(1 + \mathcal{L}_c \frac{x_m}{c}\right)\frac{J_0^2(x_m)}{2} + (\mathcal{L}_a - \mathcal{L}_c)\left(\frac{x_m}{c}\right)\left(\frac{a}{c}\right)^2 A_m\right] + \frac{a}{c^2}(\mathcal{L}_a - \mathcal{L}_c) \sum_{\substack{n=1 \\ n \neq m}}^{\infty} B_n W_{nm} = -\frac{(E_a^\circ - E_c^\circ)}{x_m}\left(\frac{a}{c}\right) J_1\left(x_m \frac{a}{c}\right) \qquad [10]$$

where A_m and W_{nm} are defined by

$$A_m = \frac{1}{2}\left[J_0^2\left(x_m\frac{a}{c}\right) + J_1^2\left(x_m\frac{a}{c}\right)\right] \quad [11]$$

and

$$W_{nm} = \frac{x_n^2}{x_n^2 - x_m^2}\left[J_1\left(x_n\frac{a}{c}\right)J_0\left(x_m\frac{a}{c}\right) - \frac{x_m}{x_n}J_0\left(x_n\frac{a}{c}\right)J_1\left(x_m\frac{a}{c}\right)\right] \quad [12]$$

Equation [10] thus generates a series of equations, say k of them, where m is fixed in turn from 1 through k. These k equations are solved simultaneously to give the coefficients B_n from $n = 1$ to k.

Equations [5], [6], and [9] combine to give the electrode potential along the metal surface

$$E(r,0) = \left(\frac{a}{c}\right)^2 E_a^\circ + \left(\frac{c^2-a^2}{c^2}\right)E_c^\circ + \frac{2a}{c^2}(\mathcal{L}_a - \mathcal{L}_c)\sum_{n=1}^{\infty} B_n J_1\left(x_n\frac{a}{c}\right) - \sum_{n=1}^{\infty} B_n J_0\left(x_n\frac{r}{c}\right) \quad [13]$$

where the B_n are determined from the system of equations generated by Eq. [10]. It should be noted that the indeterminate constant V' vanishes in the final expression for $E(r,0)$.

Differentiation of Eq. [5] as in Eq. [3] gives the local current density

$$\frac{i(r,0)}{\sigma} = \frac{1}{c}\sum_{n=1}^{\infty} B_n x_n J_0\left(x_n\frac{r}{c}\right) \quad [14]$$

where again the set of B_n is determined from Eq. [10].

The total anodic current I_{anodic} is related to the local current density by

$$I_{anodic} = \int_{r=0}^{a}\int_{\theta=0}^{2\pi} i(r,0)\,r\,dr\,d\theta \quad [15]$$

Use of Eq. [14] in Eq. [15] gives the result

$$\frac{I_{anodic}}{\sigma} = 2\pi a\sum_{n=1}^{\infty} B_n J_1\left(x_n\frac{a}{c}\right) \quad [16]$$

Thin-layer electrolyte.—For a thin layer of electrolyte, it is required that no current flows across the upper boundary of the electrolyte. Thus, $[\partial P(r,z)/\partial z] = 0$ at $z = b$ .The solution of Laplace's equation subject to this requirement and to Eq. [4] is

$$P(r,z) = C_0 + \sum_{n=1}^{\infty} C_n J_0(\lambda_n r)\cosh[\lambda_n(b-z)] \quad [17]$$

The resulting expressions for thin-layer electrolytes are

$$E(r,0) = \left(\frac{a}{c}\right)^2 E_a^\circ + \left(\frac{c^2-a^2}{c^2}\right)E_c^\circ + \frac{2a}{c^2}(\mathcal{L}_a - \mathcal{L}_c)\sum_{n=1}^{\infty} C_n \sinh\left(x_n\frac{b}{c}\right)J_1\left(x_n\frac{a}{c}\right) - \sum_{n=1}^{\infty} C_n\cosh\left(x_n\frac{b}{c}\right)J_0\left(x_n\frac{r}{c}\right) \quad [18]$$

$$\frac{i(r,0)}{\sigma} = \frac{1}{c}\sum_{n=1}^{\infty} C_n x_n \sinh\left(x_n\frac{b}{c}\right)J_0\left(x_n\frac{r}{c}\right) \quad [19]$$

and

$$\frac{I_{anodic}}{\sigma} = 2\pi a\sum_{n=1}^{\infty} C_n \sinh\left(x_n\frac{b}{c}\right)J_1\left(x_n\frac{a}{c}\right) \quad [20]$$

where the coefficients C_n are generated by the system of equations

$$C_m\left\{\left[1 + \mathcal{L}_c\frac{x_m}{c}\tanh\left(x_m\frac{b}{c}\right)\right]\frac{J_0^2(x_m)}{2} + (\mathcal{L}_a - \mathcal{L}_c)\frac{x_m}{c}\left(\frac{a}{c}\right)^2\tanh\left(x_m\frac{b}{c}\right)A_m\right\} + \frac{a}{c^2}\frac{(\mathcal{L}_a - \mathcal{L}_c)}{\cosh\left(x_m\frac{b}{c}\right)}\sum_{\substack{n=1\\ n\neq m}}^{\infty} C_n W_{nm}\sinh\left(x_n\frac{b}{c}\right) = -\frac{1}{\cosh\left(x_m\frac{b}{c}\right)}\cdot\frac{(E_a^\circ - E_c^\circ)}{x_m}\left(\frac{a}{c}\right)J_1\left(x_m\frac{a}{c}\right) \quad [21]$$

The relationship between the two sets of coefficients C_n and B_n is that $C_n \sinh (x_n\, b/c) \to B_n$ for large b. Thus, the above expressions for thin layers reduce to the results for bulk electrolyte for large b.

Comparison with Previous Case of $\mathcal{L}_a = \mathcal{L}_c$

When $\mathcal{L}_a = \mathcal{L}_c = \mathcal{L}$, the above results for bulk and thin-layer electrolytes reduce to the following

$$E(r,0) = \left(\frac{a}{c}\right)^2 E_a^\circ + \left(\frac{c^2-a^2}{c^2}\right)E_c^\circ + 2\left(\frac{a}{c}\right)(E_a^\circ - E_c)\times \sum_{n=1}^{\infty}\frac{J_1\left(x_n\frac{a}{c}\right)}{x_n\left[1 + \mathcal{L}\frac{x_n}{c}Q\right]J_0^2(x_n)}J_0\left(x_n\frac{r}{c}\right) \quad [22]$$

$$\frac{i(r,0)}{\sigma} = -2\frac{a}{c^2}(E_a^\circ - E_c)\times \sum_{n=1}^{\infty}\frac{J_1\left(x_n\frac{a}{c}\right)\cdot Q}{\left[1 + \mathcal{L}\frac{x_n}{c}Q\right]J_0^2(x_n)}J_0\left(x_n\frac{r}{c}\right) \quad [23]$$

and

$$\frac{I_{anodic}}{\sigma} = -4\pi\frac{a^2}{c}(E_a^\circ - E_c)\times \sum_{n=1}^{\infty}\frac{J_1^2\left(x_n\frac{a}{c}\right)Q}{x_n\left[1 + \mathcal{L}\frac{x_n}{c}Q\right]J_0^2(x_n)} \quad [24]$$

where in each of the above

$$Q = \begin{cases} 1, & \text{bulk electrolyte} \\ \tanh\left(x_n\frac{b}{c}\right), & \text{thin layer} \end{cases} \quad [25]$$

These equations are the same as previously reported (6-8) except that the signs of electrode potentials in Eq. [22]-[24] now conform to the convention that the noble direction is the more positive.

Numerical Evaluation

Values for $\mathcal{L}_a$ and $\mathcal{L}_c$.—As mentioned earlier, the anode is generally less polarizable than the cathode. This fact is illustrated by many electrode kinetic studies carried out under carefully controlled condi-

tions. With iron, for example, in a variety of deaerated electrolytes, anodic Tafel slopes of 30 to 80 mV/decade have been observed while the cathodic slopes for hydrogen evolution were 120 mV/decade (30-33). To cite two more examples, cadmium and indium undergo consecutive single electron transfers to Cd^{+2} and In^{+3}, respectively, and display Tafel slopes of 40-50 mV/decade (0°C) and 22 mV/decade, respectively, while the hydrogen evolution reaction on both surfaces is again 115-120 mV/decade, characteristic of a single electron transfer reaction (34, 35).

In more practical situations where conditions are not as well defined, Tafel behavior is less seldom observed and instead polarization curves sometimes display segments which are approximately linear in current (rather than logarithm of current) over a considerable potential range, as discussed earlier. In this instance, the cathode again is often the more polarizable.

Values of linear polarization parameters compiled earlier (7) indicate that $\mathcal{L}_a$ is generally of the order 1-10 cm while $\mathcal{L}_c$ is usually 10-100 cm although there are exceptions. In data tabulated by Gouda and Mourad (21) for steel in a variety of neutral to basic solutions both with and without added chloride, the cathodic slope $|dE/di|$ varied from 1.5 times to approximately 20 times the anodic slope but with most ratios in the range of 5-10. Specific conductivities were listed for only three solutions for which values of $\mathcal{L}_a$ are calculated to be 0.9, 1.9, and 48 cm, with corresponding $\mathcal{L}_c$ values of 7.5, 12.2, and 193, respectively.

Bulk electrolyte.—For the computations in this section, $\mathcal{L}_a$ is fixed at 1 cm. Figure 3 shows the potential distribution $E(r,0)$ for $\mathcal{L}_a = 1$ cm and $\mathcal{L}_c = 10$ cm for fixed values of $E_a° = 0.00$V and $E_c° = 1.00$V. The coefficients B_n were calculated up to B_{100} using the system of simultaneous equations generated by Eq. [10]. These simultaneous equations were solved using the computer, and the coefficients were then substituted in Eq. [13] to obtain the electrode potential distribution. Convergence was assessed by numerical evaluation.

Figure 3 also shows potential distribution plots for $\mathcal{L}_a = \mathcal{L}_c = 1$ and $\mathcal{L}_a = \mathcal{L}_c = 10$, calculated from Eq. [22]. It is evident that the potential behavior of the electrodes with unequal anodic and cathodic polarization parameters cannot be deduced from the two separate curves for the equal polarization parameters.

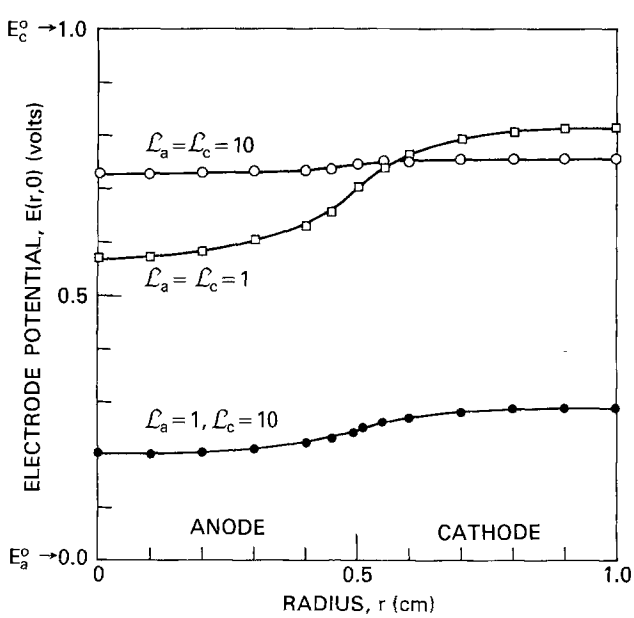

Fig. 3. Comparison of electrode potential distributions for equal and unequal polarization parameters with bulk electrolyte. (Anode radius $a = 0.5$ cm, cathode radius $c = 1.0$ cm; $E_a° = 0.00$V, $E_c° = 1.00$V.)

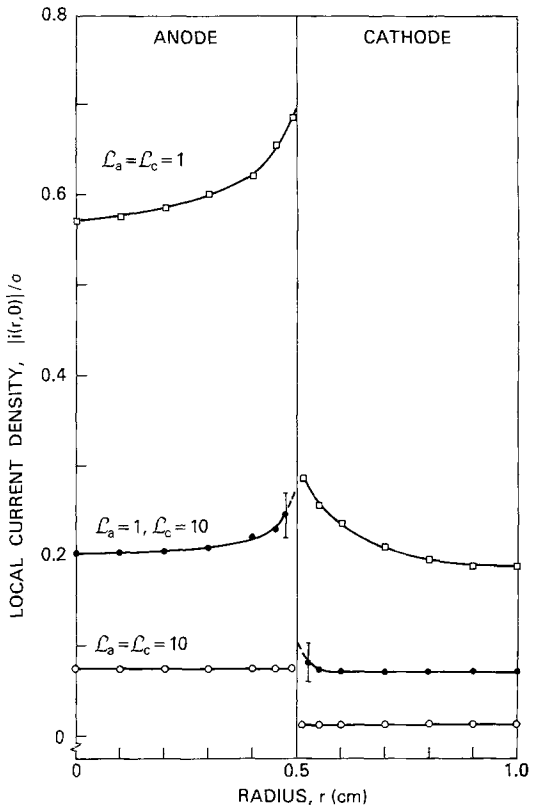

Fig. 4. Current distributions corresponding to the electrode potential distributions in Fig. 3.

The corresponding current density curves for the three systems are shown in Fig. 4. It is seen that the values for the case of unequal parameters are intermediate between the two cases where $\mathcal{L}_a = \mathcal{L}_c = 1$ and $\mathcal{L}_a = \mathcal{L}_c = 10$.

Figure 5 shows the potential distribution calculated from Eq. [13] with $n = 100$ for a fixed value of $\mathcal{L}_a = 1$ but with variable $\mathcal{L}_c$. Corresponding cur-

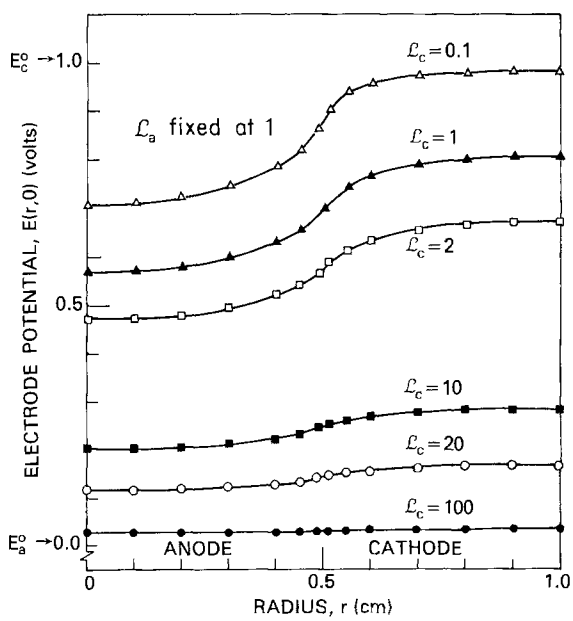

Fig. 5. Distribution of electrode potential across circular cells under bulk electrolyte with $\mathcal{L}_a$ fixed at 1 cm, combined with various values of $\mathcal{L}_c$. (Anode radius $a = 0.5$ cm, cathode radius $c = 1.0$ cm; $E_a° = 0.00$V; $E_c° = 1.00$V.)

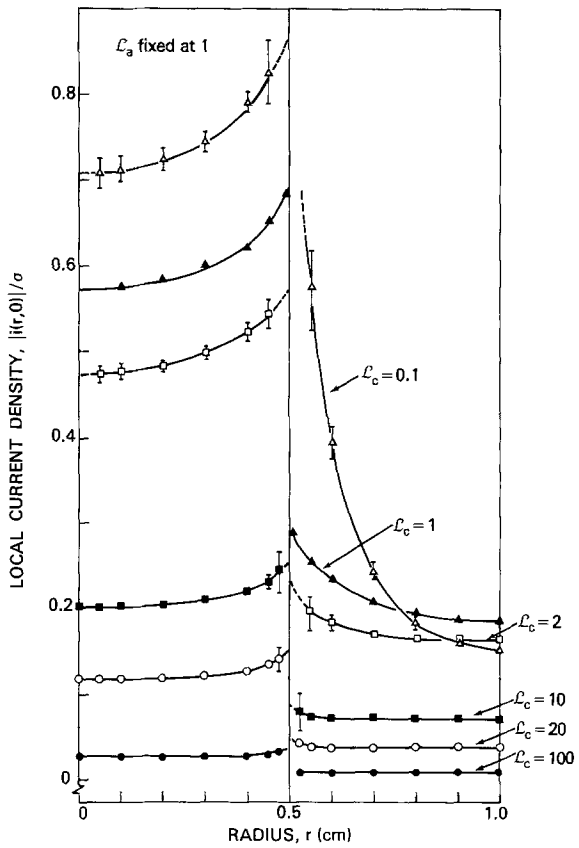

Fig. 6. Distribution of current across circular cells under bulk electrolyte with $\mathcal{L}_a$ fixed at 1 cm and combined with various values of $\mathcal{L}_c$. (Anode radius a = 0.5 cm, cathode radius c = 1.0 cm; E_a° = 0.00V, E_c° = 1.00V.)

rent distribution curves calculated from Eq. [14] are shown in Fig. 6. When $\mathcal{L}_a = 1$ and $\mathcal{L}_c = 0.1$, the galvanic couple is under anodic control, as shown in Fig. 7, and the electrode potentials across the metal surface of both components are polarized up near the potential of the uncoupled cathode.

When $\mathcal{L}_c >> \mathcal{L}_a$, *e.g.*, $\mathcal{L}_c = 100$ and $\mathcal{L}_a = 1$, the system is under cathodic control, as illustrated schematically in Fig. 7. For this case, Fig. 7 predicts that the electrode potential would approach the values of the open-circuit potential of the anode, and the current would be much less than for the case of anodic control (for fixed $\mathcal{L}_a$). These expected trends are verified in the results of the numerical analysis shown in Fig. 5 and 6.

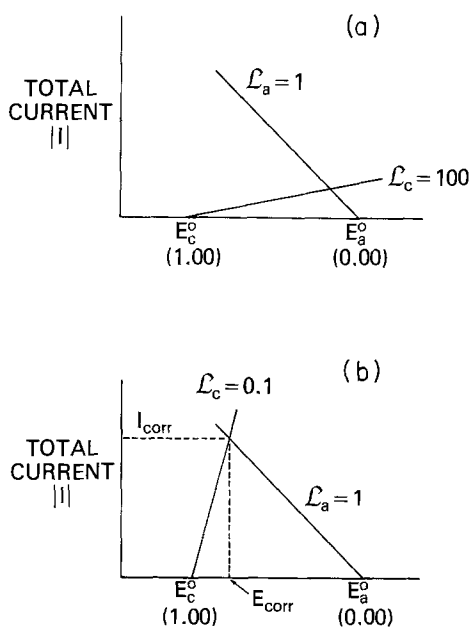

Fig. 7. Schematic representation of (a) cathodic control and (b) anodic control. Previous treatments of $\mathcal{L}_a = \mathcal{L}_c$ (6-8) correspond to the case of mixed control.

The results in Fig. 5 and 6 for $\mathcal{L}_a = \mathcal{L}_c = 1$ also provide a check on the consistency of the present method with the previous relationships for equal polarization parameters. Both potential and current distributions calculated from the set of B_n resulting from Eq. [10] with $\mathcal{L}_a$ and $\mathcal{L}_c$ both equal to 1 agree with the results obtained with Eq. [22] and [23].

One additional trend can be seen in Fig. 5 and 6. For this system of fixed $\mathcal{L}_a$, the more polarizable the cathode (*i.e.*, the larger $\mathcal{L}_c$), the more uniform the potential and current distribution.

The total anodic current was calculated from Eq. [16] for the systems with $\mathcal{L}_a$ fixed at 1 with variable $\mathcal{L}_c$. Results are listed in Table I. The total anodic current can also be calculated from the schematic Evans diagrams shown in Fig. 7. For the anodic branch

$$\left|\frac{dE}{dI}\right|_a = \frac{E_{corr} - E_a^\circ}{I_{corr}} \qquad [26]$$

and for the cathodic branch

$$\left|\frac{dE}{dI}\right|_c = -\frac{E_{corr} - E_c^\circ}{I_{corr}} \qquad [27]$$

where I_{corr} is the corrosion current, *i.e.*, the total anodic current referred to earlier as I_{anodic}. With $I_a = i_a A_a$ and $I_c = i_c A_c$, where A_a and A_c are the area of anode and cathode, respectively, use of Eq. [7a] and [7b] in Eq. [26] and [27] gives

$$\frac{I_{corr}}{\sigma} = \frac{E_c^\circ - E_a^\circ}{\frac{\mathcal{L}_a}{A_a} + \frac{\mathcal{L}_c}{A_c}} \qquad [28]$$

where again I_{corr} has the same meaning of I_{anodic} in in Eq. [15].

Values of I_{corr}/σ calculated from Eq. [28] are also listed in Table I. These calculated values agree with the results from the computer analysis for $\mathcal{L}_a = 1$ coupled with cathodic values of $\mathcal{L}_c = 50$ and $\mathcal{L}_c = 100$, where the current distribution is uniform. There is disagreement between the results of the Evans diagram analysis and the computer analysis for those systems where there is a nonuniform distribution of current, and this divergence is greater the more pronounced the localized attack at the anode/cathode juncture.

Results for $\mathcal{L}_a = \mathcal{L}_c = 10$ and $\mathcal{L}_a = \mathcal{L}_c = 100$ are also included in Table I. Current distribution plots

Table I. Comparison of total current calculated from Evans diagrams and from summation of current distribution curves for couples with unequal polarizabilities in bulk electrolyte. (Anode radius a = 0.5 cm, cathode radius c = 1.0 cm, E_a° = 0.00V, E_c° = 1.00V.)

$\mathcal{L}_a$ (cm)	$\mathcal{L}_c$ (cm)	I_{corr}/σ (Calculated from Evans diagrams, Eq. [28])	I_{anodic}/σ (Calculated from Eq. [10] and [16])
1	0.1	0.760	0.607
	1	0.589	0.485
	2	0.471	0.401
	10	0.181	0.169
	20	0.103	0.099
	50	0.0445	0.0437
	100	0.0228	0.0227
10	10	0.0589	0.0576
10	100	0.0181	0.0179
100	100	0.00589	0.00587

published in an earlier report (8) were nearly uniform for the former system and exactly so for the latter. The current distribution for $\mathcal{L}_a = 10$ and $\mathcal{L}_c = 100$ was calculated from Eq. [14] and was observed to be uniform although the plot is not shown here. Thus, there is good agreement between Evans diagram analyses and computed calculations for systems where there is a uniform current distribution.

Hence, the classical Evans polarization diagrams cannot be used to calculate accurately the value of the galvanic current in all instances without consideration of the matter of current distribution.

Thin-layer electrolyte.—Figure 8 shows the electrode potential $E(r, 0)$ for $\mathcal{L}_a = 1$ cm and $\mathcal{L}_c = 10$ cm for different electrolyte thicknesses. The coefficients C_n were computed up to C_{100} from Eq. [21] and were used in Eq. [18] to obtain the potential distributions.

The corresponding current distributions are shown in Fig. 9. The local current densities were calculated from Eq. [19] and [21] with $n = 100$, except near $r = 0.0$ and $r = 0.5$ where 125 terms were used. For the thin layers, there is a geometry effect in which the corrosion attack is concentrated near the anode/cathode boundary.

Figure 10 shows the total anodic current calculated from Eq. [20] for two different combinations of $\mathcal{L}_a$ and $\mathcal{L}_c$. In both cases, the total current approaches values for the bulk for electrolyte thicknesses of approximately 0.1-0.3 cm.

Figure 11 compares the potential distribution for $\mathcal{L}_a = 1$ and $\mathcal{L}_c = 10$ to the cases of equal polarization parameters, $\mathcal{L}_a = \mathcal{L}_c = 1$ and $\mathcal{L}_a = \mathcal{L}_c = 10$ for an electrolyte thickness of 0.001 cm. As with the bulk, the potential distribution for the system of an electrolyte thickness of 0.001 cm. As with the bulk, the potential distribution for the system of unequal parameters is not related in a simple manner to the individual distribution curves for each of the two equal parameters.

Comparison with Experiment

Procedure.—Experiments were performed with Pt/Fe couples in bulk 0.05M NaCl open to the air for both stirred and quiescent conditions. In each of the experiments, the iron anode was a circular electrode of radius $a = 1$ cm, and the platinum cathode was annular shaped with dimension $c = 2.5$. Both metals were 99.99% pure. The platinum was cleaned by flaming and was kept in a dessicator until use; the iron was abraded down to 3/0 emery paper immediately before use. Extraneous surfaces were masked with an alkyd varnish.

In a given experiment, both parts of the galvanic cell were initially uncoupled so that each electrode

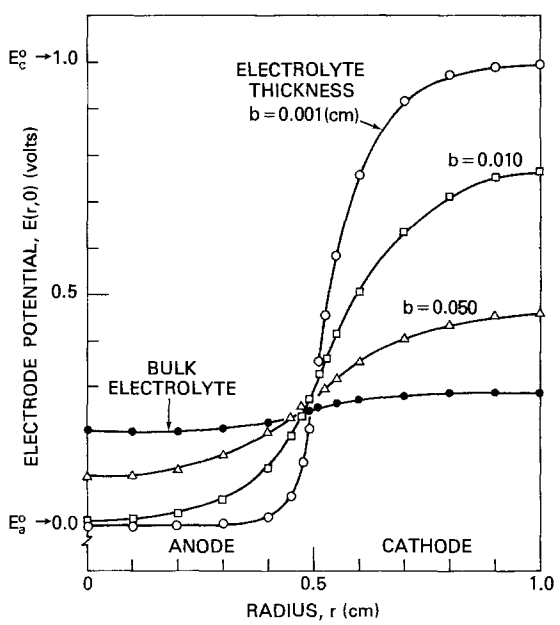

Fig. 8. Distribution of electrode potential for $\mathcal{L}_a = 1$ cm and $\mathcal{L}_c = 10$ cm for different electrolyte thicknesses. (Anode radius $a = 0.5$ cm, cathode radius $c = 1.0$ cm; $E_a^\circ = 0.00$V, $E_c^\circ = 1.00$V.)

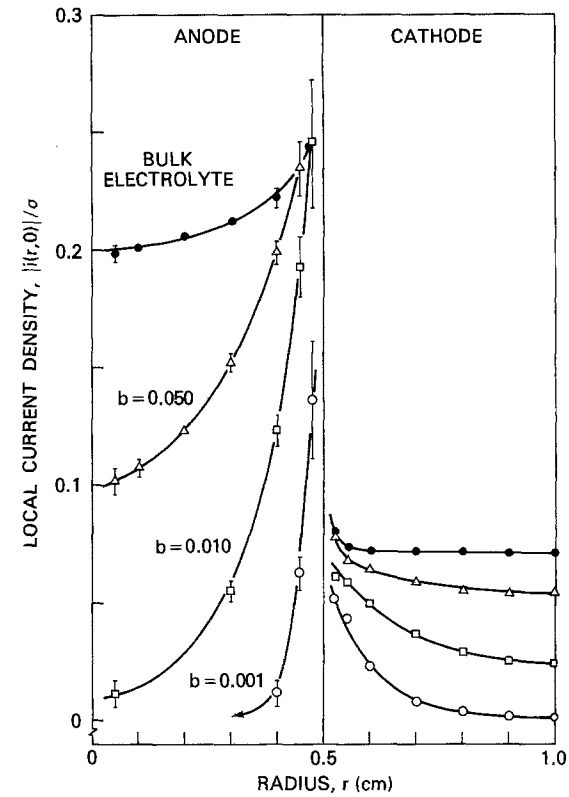

Fig. 9. Current distribution for $\mathcal{L}_a = 1$ cm and $\mathcal{L}_c = 10$ cm for different electrolyte thicknesses. Cell parameters are the same as in Fig. 8. (Limits between which the local current densities oscillate are indicated for the anodic points. Error limits for the cathode are smaller.)

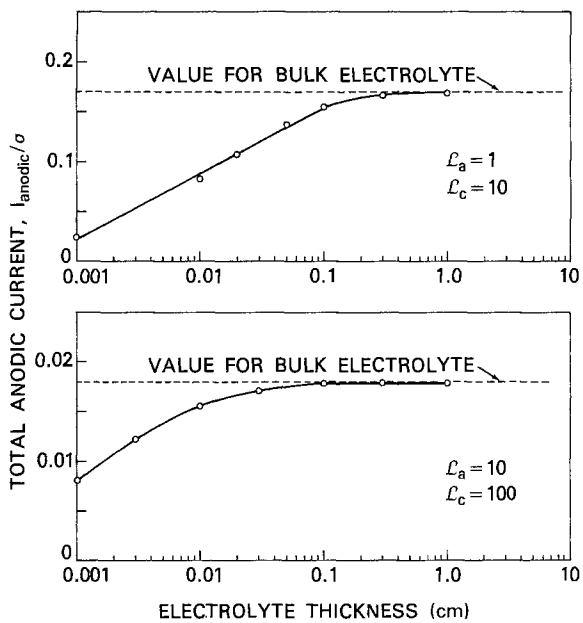

Fig. 10. Total anodic current computed as a function of electrolyte thickness for two different combinations of $\mathcal{L}_a$ and $\mathcal{L}_c$. (Anode radius $a = 0.5$ cm, cathode radius $c = 1.0$ cm; $E_a^\circ = 0.00$V, $E_c^\circ = 1.00$V.)

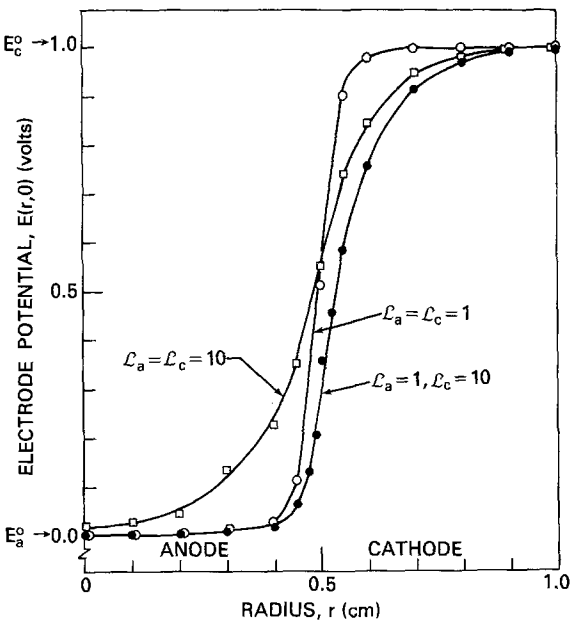

Fig. 11. Comparison of electrode potential distribution for equal and unequal polarization parameters for a thin-layer electrolyte of thickness b = 0.001 cm. (Anode radius a = 0.5 cm; cathode radius c = 1.0 cm; $E_a°$ = 0.00V, $E_c°$ = 1.00V.)

could reach its own open-circuit steady-state potential. Approximately 8 hr were required for the quiescent solution and 6 hr for the stirred solution. Reference electrodes were chlorodized silver wires described previously (36) and immersed directly into the electrolyte near the surface at the center of the anode and the center of the cathode. Measured electrode potentials were always converted to potentials *vs.* the conventional Ag/AgCl electrode.

Evans polarization diagrams were determined using a Wenking potentiostat in a two-electrode configuration (37) so that it acted as a zero-resistance ammeter. In this mode, the auxiliary electrode terminal is connected directly to the reference electrode terminal, so that a constant potential difference is set between the working electrode (anode) and the auxiliary electrode (cathode). For a constant potential difference, a constant current and constant individual electrode potentials were observed in 10-20 min for the quiescent solution and in 5 min for the stirred solution. With increased current, electrode potentials of the anode and cathode approached each other. At zero potential difference set between the two electrodes, the measured current was the short-circuit current, or the total anodic current, I_{anodic}.

Results and discussion.—Polarization curves for the two cases are plotted in the usual manner, as well as linearly, in Fig. 12 and 13. In both cases, the couples are under cathodic control. Each cathodic plot in Fig. 13 is linear over only a portion of the curve, and the extrapolated value $E_c°'$ of the open-circuit potential is quite different from the observed value $E_c°$.

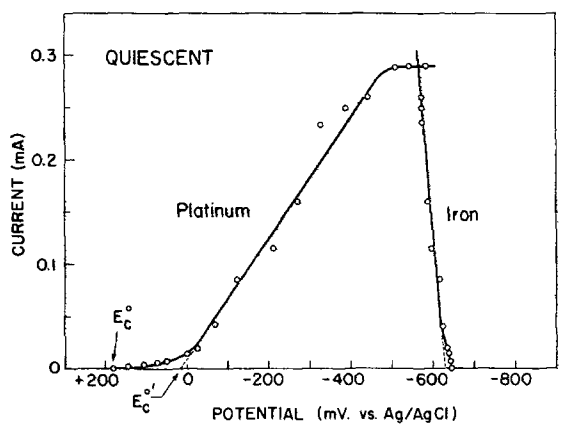

Fig. 13. Polarization curves plotted linearly for platinum and iron in 0.05M NaCl open to the air.

Table II lists values for the total anodic current calculated from Eq. [20] with n = 100. The electrode

Table II. Summary of data for Pt/Fe couples in bulk 0.05M NaCl open to the air. (Anode radius a = 1.0 cm, cathode radius c = 2.5 cm, electrolyte thickness b = 3.0 cm, σ = 5.5 × 10^{-3} Ω^{-1} cm^{-1})

Condition	Experimental parameters	Potential at center of anode Calculated (V)	Measured (V)	Potential at center of cathode Calculated (V)	Measured (V)	Total anodic current Calculated (mA)	Measured (mA)
Stirred	$E_a°'$ = −0.595V $E_c°'$ = −0.322V $\mathcal{L}_a$ = 0.59 cm $\mathcal{L}_c$ = 5.23 cm	−0.535	−0.506	−0.445	−0.477	2.2	2.7
Quiescent	$E_a°'$ = −0.635V $E_c°'$ = +0.020V $\mathcal{L}_a$ = 3.7 cm $\mathcal{L}_c$ = 155 cm	−0.565	−0.584	−0.550	−0.577	0.33	0.29

potentials at the center of the anode and center of the cathode calculated from Eq. [18] (with $n = 100$) are also given in Table II. Agreement between experiment and theory is satisfactory.

In the strictest sense, the present model does not apply exactly to the unstirred electrolyte where the cathodic reaction is diffusion controlled. The problem is that the requirement of uniform concentration will not hold within the thin diffusion layer near the surface. Nevertheless, it is instructive to make the calculations because in many practical cases of corrosion the cathodic reaction does involve oxygen reduction under diffusion control. Table II shows that the calculated corrosion current is slightly too high, because the calculated potential lies in the limiting current range.

For the stirred solution, where Tafel behavior is observed, the linear approximation calculates a value of the short-circuit current which is lower than the observed value. This result is in general agreement with the results for other systems where current distributions have been compared for Tafel and linear kinetics. For a cathode having a narrow slot, the current density down the lateral face of the slot falls off more rapidly with distance for linear than for logarithmic polarization (38). For a planar cathode opposite a remote anode, the current density across the cathode breadth is also smaller for linear than for Tafel kinetics (39).

The results for the stirred electrolyte are also in general agreement with the recent analysis of Smyrl and Newman (13), who treated the case of a corroding disk in an infinite plane assuming Tafel kinetics for the disk and the linear approximation for the plane. These authors characterize linear or Tafel polarization through two parameters (called J and δ, respectively) derived from the dimensionless quantity $\lambda/[\sigma(d\eta/di)]$, first introduced by Hoar and Agar (40), in which λ is a "characteristic length" of the geometrical system. From the definition of the Wagner polarization parameter

$$J = \frac{\lambda}{\mathcal{L}} \qquad [29]$$

for linear kinetics. For Tafel kinetics, $d\eta/di = (1/i)(RT/\alpha n\mathbf{F})$, so that

$$\delta = i_{avg}\frac{2.303}{b\sigma}\lambda \qquad [30]$$

where b is the Tafel slope. Thus for Tafel polarization, δ plays the role of J but depends on the current density.

For the stirred electrolyte, the anodic Tafel slope in Fig. 12 is 80 mV/decade, which gives $\delta = 4.50$ at the observed corrosion current, using the disk radius as λ. The value of J for the cathode corresponding to $\mathcal{L}_c = 5.23$ cm is 0.29, using $(c\text{-}a)$ as the characteristic length. (Smyrl and Newman use the disk radius for the characteristic length for their infinite cathode, but there is little difference between using $(c\text{-}a)$ or a in the present case). From Fig. 5 in Ref. (13), the potential difference between the center and edge of the disk for $\delta = 4.50$ and $J = 0.29$ is between 25 and 50 mV, in agreement with the value 38 mV calculated from Eq. [13] of the present analysis.

The current distribution across the iron disk calculated from Eq. [14] also agrees qualitatively with the analysis of Smyrl and Newman (13) who plot results for a slightly different value of δ (1.14 rather than 4.50) coupled with various values of J.

Application to the experiments of Pavlutskaya and Rosenfeld.—Few detailed experiments have been carried out with circular coplanar electrodes. However, Rosenfeld and Pavlutskaya (15, 16) have measured the potential distribution across an iron circular anode in contact with a copper disk cathode in 0.1*N* NaCl of

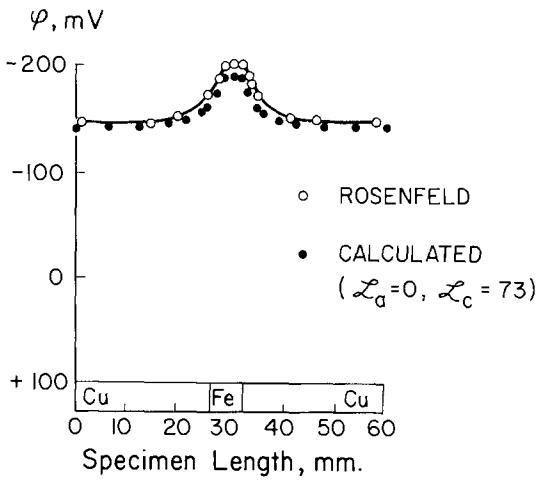

Fig. 14. Comparison of calculated potential distribution with experimental data of Rosenfeld for circular electrodes in bulk 0.1*N* NaCl. The experimental data are redrawn from Ref. (15).

both bulk and 165μ thickness. Their experimental data are shown in Fig. 14 and 15 which are redrawn from photographic enlargements of their published results.

Rosenfeld (15) has also published polarization curves for a variety of metals in bulk and thin-layer electrolyte in which the data have been presented linearly. In order to apply the present theory to the Rosenfeld results, photographic enlargements were made of the published cathodic polarization curves for copper and anodic polarization curves for iron in 0.1 NaCl.

For copper in bulk 0.1 NaCl, the cathodic curve was nearly linear for an appreciably large overvoltage of about 1V, after which the curve shifted considerably, presumably as the reaction moved from the region of oxygen reduction into that of hydrogen evolution. A tangent approximation was drawn to the linear portion of the curve; and, as explained earlier, the value of E_c° was replaced by the value $E_c^{\circ\prime}$ at the intersection of the tangent approximation and the potential axis. For copper in 165μ 0.1*N* NaCl, the cathodic polarization curve was linear over the entire range shown. Values of $\mathcal{L}_c$ were calculated from the slopes of the cathodic polarization curves and the handbook value of the electrolyte conductivity and are listed in Table III.

The anodic curves for iron reported by Rosenfeld are somewhat curious in that the polarized potentials start out in the active (more negative) direction be-

† Ref. (41) (for 200μ thickness).

fore turning toward the more noble (positive) direction.

This behavior is not the usual for an anodic polarization curve and is not consistent with this author's observations for iron in the bulk as reported here or in thin-layer electrolyte (36). Thus, for the purposes of these calculations, the open-circuit potential of the anode was taken to be that as observed by Rosenfeld, with the $\mathcal{L}_a$ value determined from the "normal" part of the curve, where the anode was practically nonpolarizable, as per the behavior in Fig. 12.

A complete listing of the various parameters extracted from the Rosenfeld data is given in Table III.

The potential distributions calculated from Eq. [13] for the bulk and from Eq. [18] for thin-layer electrolyte are shown in Fig. 14 and 15. In both cases, there is good agreement between the calculations and the experimental data.

In addition, Rosenfeld and Pavlutskaya have shown the effect of cathode area on the total anodic current for both bulk and thin-layer electrolyte. These experimental results are shown in Fig. 16, which again is redrawn from a photographic enlargement from the Rosenfeld text (15). The total anodic current for variable cathode area was calculated using Eq. [16] for the bulk and Eq. [20] for thin-layer electrolyte. Results are superimposed on the Rosenfeld data in Fig. 16. In general, the calculations are in good agreement with the experimental data, although for thin-layers, the calculated currents are somewhat high for the smaller area cathodes. Nevertheless, the agreement is much better than for the extreme cases where $\mathcal{L}_a$ and $\mathcal{L}_c$ are taken to be equal, as shown in Fig. 16.

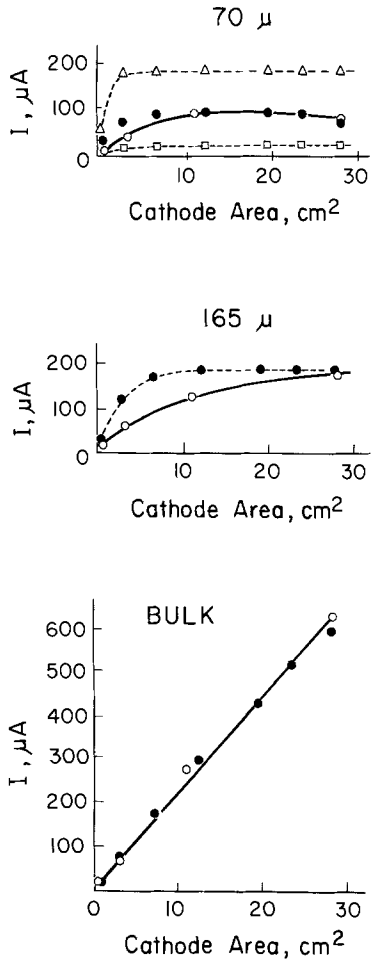

Fig. 16. Comparison of calculated anodic current with experimental data for varying cathode size. —O— Experimental data of Rosenfeld redrawn from Ref. (15). 70μ: Δ $\mathcal{L}_a = \mathcal{L}_c = 1$, □ $\mathcal{L}_a = \mathcal{L}_c = 30$, • $\mathcal{L}_a = 1$, $\mathcal{L}_c = 30$; 165μ: • $\mathcal{L}_a = 0$, $\mathcal{L}_c = 46$; Bulk: • $\mathcal{L}_a = 0$, $\mathcal{L}_c = 73$.

Summary

A mathematical model has been developed to describe the distribution of potential and current across circular corrosion cells having unequal anodic and cathodic linear polarization parameters. This analysis is applicable to systems of bimetallic galvanic couples or to systems where there is a localized geometry effect, as in pitting corrosion.

The potential distribution in a system having unequal anodic and cathodic polarization parameters is not related in a simple manner to the separate distribution curves for the two cases where the polarization parameters are equal.

For bulk electrolyte, the value of the electrode potentials depends on whether the system is under anodic, cathodic, or mixed control. Current distribution is more uniform for the more polarizable combinations of electrodes. Thus, the total corrosion current calculated from Evans diagrams may be in error if the individual current distributions are not uniform.

In thin-layer electrolytes, there is a geometry effect in which the electrode polarization and current flow is concentrated near the anode/cathode juncture. In a typical system, the tendency toward bulk behavior occurs at about 0.1-0.3 cm, *i.e.*, 1000-3000μ.

APPENDIX

The solution to Laplace's equation subject to the boundary conditions of: (*i*) no current flow across the planes $r = 0$ or $r = c$, and (*ii*) that the electrostatic potential be bounded for large values of z is

$$P(r,z) = B_0 + \sum_{n=1}^{\infty} B_n J_0(\lambda_n r) e^{-\lambda_n z} \qquad [A\text{-}1]$$

At the metal surface

$$P(r,0) - \mathcal{L}_a \left[\frac{\partial P(r,z)}{\partial z} \right]_{z=0} = V' - E_a° \qquad [A\text{-}2]$$

for the anode $(0 < r \leq a)$; and

$$P(r,0) - \mathcal{L}_c \left[\frac{\partial P(r,z)}{\partial z} \right]_{z=0} = V' - E_c° \qquad [A\text{-}3]$$

for the cathode $(a < r \leq c)$. Use of Eq. [A-1] in Eq. [A-2] and [A-3] gives the pair of equations

$$B_0 + \sum_{n=1}^{\infty} B_n(1 + \mathcal{L}_a\lambda_n) J_0(\lambda_n r) = V' - E_a°, \quad 0 \leq r < a \qquad [A\text{-}4]$$

and

$$B_0 + \sum_{n=1}^{\infty} B_n(1 + \mathcal{L}_c\lambda_n)J_0(\lambda_n r) = V' - E_c^\circ, \quad a < r \leq c \qquad [A\text{-}5]$$

Each equation is multiplied by $rJ_0(\lambda_m r)\,dr$ and integrated over the appropriate limits. Equation [A-4] becomes

$$\frac{B_0}{\lambda_m} aJ_1(\lambda_m a) + B_m(1 + \mathcal{L}_a\lambda_m)\int_{r=0}^{a} rJ_0^2(\lambda_m r)\,dr + \sum_{\substack{n=1 \\ n\neq m}}^{\infty} B_n(1 + \mathcal{L}_a\lambda_n)\int_{r=0}^{a} rJ_0(\lambda_n r)J_0(\lambda_m r)\,dr = \frac{(V' - E_a^\circ)}{\lambda_m} aJ_1(\lambda_m a) \qquad [A\text{-}6]$$

where the summation in Eq. [A-4] has been split into two cases: $n = m$, and $n \neq m$. In the previous case (6) where $\mathcal{L}_a = \mathcal{L}_c = \mathcal{L}$ applied over the entire interval from $r = 0$ to $r = c$, the integrals in Eq. [A-6] were the usual orthogonality relations. Here, instead, the second integral in Eq. [A-6] is a Lommel integral (42) which is evaluated as

$$\int_0^a rJ_0(\lambda_n r)J_0(\lambda_m r)\,dr = \frac{a}{\lambda_n^2 - \lambda_m^2} \times [\lambda_n J_1(\lambda_n a)J_0(\lambda_m a) - \lambda_m J_0(\lambda_n a)J_1(\lambda_m a)] \quad (n \neq m) \qquad [A\text{-}7]$$

When $n = m$, the right-hand side of Eq. [A-7] is evaluated from l'Hospital's rule to be $(a^2/2)[J_0^2(\lambda_m a) + J_1^2(\lambda_m a)]$. Evaluation of the two integrals in Eq. [A-6] then yields one of the two simultaneous equations in B_0 and B_n. The second equation follows from multiplication of Eq. [A-5] by $rJ_0(\lambda_m r)\,dr$ and integration from $r = a$ to $r = c$. The two simultaneous equations are solved to give Eq. [10] in the text.

The constant B_0 is also evaluated from Eq. [A-4] and [A-5]. Both equations are multiplied through by rdr, integrated over the appropriate limits, and solved simultaneously to give Eq. [9] in the text.

Techniques for Characterizing Porous Electrodes

I: Determination of the Double Layer Capacity

B. V. Tilak and C. G. Rader

ABSTRACT

Two relaxation techniques are examined for determining the double layer capacity of porous electrodes of finite length. In the presence of a faradaic reaction, under near equilibrium conditions, analytical expressions are derived for the transient potential response to current perturbations of the form $i(t) = \Delta i \exp(-t/\tau)$ and $i(t) = \Delta i(1 - t/\tau)$. The ease with which the system parameters (R_T and C_T) can be deduced by employing these two techniques is analyzed. Experimental support for the exponential relaxation technique is provided by examining three electrochemical systems: sintered nickel plaque/NaOH; Teflon-bonded Pt on Pt screen/NaOH; and $TiO_2 + RuO_2$ coatings on Ti/NaCl aq.

Porous bodies are unique in that they offer high specific surface area, thereby enabling one to carry out otherwise slow reactions at an enhanced rate. Operating with a high specific area porous medium, however, creates its own problems via the associated phenomena such as mass transport, charge transport, finite conductivity of the electrolyte, etc.

Characterization of porous electrode operations requires a knowledge of the structural details of the internal surface of a porous body and operational details within the porous matrix. The resulting equations describing mass transport and potential variations are not only nonlinear and multidimensional, but they also require simultaneous solution. Solution of the system equations may be facilitated by idealizations (simplifications) of various phenomena, as reflected in several published models for describing the operation of, for example, gas diffusion electrodes. The results, however, are valid only for a given set of conditions and not for a random choice of variables. These various models may be classified into three groups—homogeneous, quasihomogeneous, and statistical or discrete models (1).

"Surface area" is one of the parameters which characterizes a porous electrode, and double layer capacitance is known to provide a reliable estimate of the surface area effective for participation in electrochemical reactions, as opposed to physical or geometric area measured, for example, by standard BET adsorption techniques.

The theoretical treatment of double layer charging was first presented by Ksenzhek and Stender (2). Posey and Morozumi (3), assuming double layer charging to be the only significant interfacial process, presented solutions to the boundary value problems of potentiostatic and galvanostatic charging of finite porous electrodes. It will be shown that the present treatment reduces, in the limit, to the analytical expression presented by Posey and Morozumi for the potential response to a galvanostatic step function.

In 1969, Rangarajan (4) presented a comprehensive treatment of the transient behavior of flooded porous electrodes under galvanostatic and sinusoidal perturbations. In this work, ohmic activation, and concentration polarizations were treated as a generalized impedance, along with a detailed discussion of the possible pitfalls of a naive data interpretation in a region of coupled (mixed) phenomena. Response to other forms of input (*e.g.* potentiostatic) can also be deduced, under linear perturbation conditions, from the formalism outlined in Ref. (4).

In 1973, Austin and Gagnon (5) introduced a triangular voltage sweep method for determination of the double layer capacity of a porous electrode. Under limited conditions, approximate correction can be made for faradaic current interference by this technique. Tiedemann and Newman (6) have described a method for double layer capacity determination by exploring the current response to a voltage step input function. This method, which requires estimation of the intrapore resistance, has yielded values of the double layer capacity for Pb and PbO_2 electrodes in sulfuric acid which are in agreement with literature values. Universal applicability of this technique is doubtful, however, due to the disregard of faradaic reaction. McHardy *et al.* (7) have employed a low frequency a-c technique for determination of differential capacitance. While the reported results are internally consistent, the experimentally measured impedance may reflect complex phenomena which are not uniquely related to double layer charging.

Thus, various limitations are seen to exist in most treatments of double layer capacity determination, and these may be generalized in terms of either lack of experimental accessibility or theoretical tractability to deduce the parameter(s) of interest.

Relaxation Techniques and the Parametric Approach

A critical analysis of various perturbation techniques (8)—transient or steady-state (periodic)—carried out in a time or frequency axis (parametric domain) showed that the role of input parameters, occurring through the input current or voltage profile, lies in the ability to "force" specific features; *e.g.*, maximum, inflection point, change of polarity, etc., in the output response profile. Thus, in the case of linear relaxation methods (8), two-parameter current (or potential) controlled input functions were found to offer response characteristics unique in the ease of data analysis and in experimental design.

Two new methods.—The theory of the overpotential transient resulting from the application of an exponentially decaying current ($i = \Delta i \exp(-t/\tau)$) was introduced by Rangarajan (9) in 1973. This discourse on relaxation processes was concerned with the interplay of activation, linear diffusion, and a following or preceding chemical reaction in the bulk. The usefulness

[1] Present address: The University of Newcastle upon Tyne, Newcastle, NE1 7RU England.

Key words: double layer capacity, porous electrodes, exponential relaxation technique, Ni plaque, Cl_2 evolution.

of a "parametric approach" as regards providing a unified picture of relaxation techniques has recently been demonstrated again by Rao *et al.* (10). A "decreasing current ramp technique" (dcrt), $i = \Delta i\,(1 - t/\tau)$, was used for measuring the rate constant and transfer coefficient in the study of a fast electrode reaction ($K_4Fe(CN)_6 + K_3Fe(CN)_6$/Pt). In the present communication, these two-parameter current-controlled input functions are examined (theoretically and experimentally) for determining the double layer capacitance of porous electrodes.

It may be noted here that the single-pulse galvanostatic method and the coulostatic case can be viewed as special cases of the exponential technique when $t << \tau$ (where t = time and τ, the input time constant) and when Δi is large and equal to $\Delta q/\tau$; *i.e.*, $\tau \to 0$ and Δq finite. The double pulse method and the a-c techniques also come under the exponential relaxation type perturbation in a general sense, since τ in the exponential input plays a role analogous to the frequency, ω, in the a-c techniques. In the impedance measurements we employ "ω" as a probe to obtain the fingerprints of the dynamics of the (porous) system, *viz.*, its spectra of relaxation times. We do the same in the proposed methods via τ. There is yet another difference. Whereas in the impedance approach average responses are measured, the entire time variation during τ can be exploited in the exponential technique.

Theoretical Considerations

The multidimensional difficulties associated with the quantitative description of gas diffusion or two-phase porous electrodes can be solved by assuming a homogeneous model wherein the interconnected multiphase system is treated as a homogeneous phase. This, in essence, replaces the distributed heterogeneous sources/sinks by appropriate homogeneous or volume entities.

Homogenization is achieved in the elementary flooded pore model by transformation of surface sources (or sinks) to volume sources by introducing the parameter S, signifying the specific surface of a matrix in cm^2/cm^3. This can be justified since the electrochemical reaction takes place, though at different rates, along the entire surface of the porous medium. S can be identified as the total internal surface for flooded porous electrodes. However, its precise meaning depends on the reaction mechanism. Thus, for gas-filled electrodes, S can be equal to the total internal surface (up to 80% gas content), and it reflects macroporosity if wetting of macropores is possible.

In the case of three-phase systems, S may be calculated in terms of the common area between the gas and liquid, provided the pore distribution statistics are calculable (11).

Following the elementary flooded model defined previously (3, 4), the system of equations defining the time variant potential in a pore of finite length may be expressed as follows

$$\frac{\partial^2\eta}{\partial\xi^2} - \alpha\eta - \beta\frac{\partial\eta}{\partial t} = 0 \qquad [1]$$

where $\alpha = \dfrac{R_o S l n \mathbf{F} i_o}{RT} = \dfrac{R_o}{R_T}$ (ratio of the electrolyte resistance in the pores to the charge transfer resistance); $\beta = R_o C_T$ (time constant associated with the charging of the double layer); $R_o = l/\sigma A$; A = cross-sectional area (cm^2); l = pore length; σ = specific conductance of the solution phase (Ω^{-1} cm^{-1}); $C_T = Scl$ = total differential capacity; S = surface area of porous electrode/unit length; c = differential capacity/cm^2; $I = iSl$ = total current; $\xi = x/l$; x = distance coordinate; and i = microkinetic current density = $i_o n\mathbf{F}\eta/RT$. The initial condition is $\eta(t = 0) = 0$, and boundary conditions are $(\partial\eta/\partial\xi)_{\xi=1} = 0$; $(\partial\eta/\partial\xi)_{\xi=0} = -R_o i(t)$; and $i(t)$: two-parameter current-controlled input function. Equation [1] actually expresses the fact that, at any instant, the impressed current is a sum of double layer charging and faradaic currents.

The salient features of the present formulation are as follows:

(*i*) The specific structure of the porous material is ignored and its behavior is assumed to be equivalent to that of an isotropic, macroscopically homogeneous medium which restricts the space variations along one dimension; *i.e.*, the depth of the electrode. (This hypothesis transforms the sources and sinks distributed over the pore walls to volume sources and sinks.)

(*ii*) Diffusion and migration are not considered. [See Ref. (4) where diffusion coupling has been analyzed under galvanostatic conditions.]

(*iii*) Potential distribution is given by a simple equation as insured by the hypothesis that the solution + matrix conductivity is constant.

(*iv*) Only small perturbations from equilibrium conditions are examined by using a linear i-η relationship.[2] [Under these restrictions, the porous electrode can be viewed as equivalent to a transmission line of finite length with electrolyte resistance in series shunted by a parallel combination of double layer and faradaic impedances. See Ref. (12).]

The boundary value problem stated above was solved (using Laplace transforms) for two, two-parameter current-controlled input functions: (*i*) $i(t) = \Delta i \exp(-t/\tau)$, (exponential current decay); and (*ii*) $i(t) = \Delta i\,(1 - t/\tau)$, (decreasing current ramp).

Alternately, the potential response to the exponentially decaying current input can also be derived following the theorems developed by Rangarajan (9), according to which

$$\eta(t) = i(t)\,\gamma^3(t,\tau)$$

where

$$\gamma^3(t,\tau) = \mathcal{L}^{-1}[Z(P - 1/\tau)],\ i(t) = \Delta i \exp(-t/\tau)$$

$\mathcal{L}^{-1}$ refers to the inverse transform in Heaviside's notation[3] and $Z(P)$ the generalized impedance of the porous matrix-electrolyte interface in the Laplace domain, as deduced earlier (4).

Thus, the transient response to the above two current-controlled input functions appears as follows:

Exponential relaxation technique ($i(t) = \Delta i \exp(-t/\tau)$)

$$\eta = -R_o i(t)\left\{\left[\frac{\exp\left(-t\left(B - \frac{1}{\tau}\right)\right) - 1}{\beta\left(B - \frac{1}{\tau}\right)}\right] + \left[\frac{2}{\beta}\sum_{n=1}^{\infty}\frac{(-1)^n \cos n\pi(1-\xi)}{\left(A - \frac{1}{\tau}\right)}\right.\right.$$
$$\left.\left.\cdot\left\{\exp\left(-t\left(A - \frac{1}{\tau}\right)\right) - 1\right\}\right]\right\} \qquad [2]$$

Decreasing current ramp technique ($i(t) = \Delta i(1 - t/\tau)$)

[2] How small the perturbation should be to validate linear laws as observed experimentally (cell current *vs.* half-cell voltage) has not been discussed clearly to date. It is interesting to note that one may expect the linearity to hold up to higher amplitudes than expected, as shown in Table II of Ref. (4), where the analytical, linear expressions are compared with those arising from the numerical, nonlinear model of Grens II and Tobias (13). Further work on this aspect is in progress.

[3] In Heaviside notation, $\mathcal{L}[f(t)] = P\int_0^\infty \exp(-Pt)\cdot f(t)\cdot dt$.

$$\frac{\eta}{\Delta i R_o} = \frac{1}{\beta}\left[\left\{ \left[\frac{1}{B} - \frac{t}{\tau B} + \frac{1}{B^2\tau} \right] - \exp(-Bt)\left(\frac{1}{B} + \frac{1}{\tau B^2} \right) \right\} + 2\sum_{n=1}^{\infty} (-1)^n \cos n\pi(1-\xi) \left[\left(\frac{1-\exp(-At)}{A} \right) - \left(\frac{At-1}{A^2\tau} \right) - \left(\frac{\exp(-At)}{A^2\tau} \right) \right] \right] \quad [3]$$

where

$$A = \frac{n^2\pi^2 + \alpha}{\beta}$$

$$B = \alpha/\beta$$

General Features of the Potential Response

Exponential relaxation technique.—Figure 1 shows that there exists a maximum (η_m) in the potential transient. The origin of this maximum can easily be understood in terms of the initial increase in η arising from the imposed current and the decreasing nature of the input current function with time. It is obvious that this is due to a time lag in following i and will be absent if the double layer charging is instantaneous. This rationale can be further extended to qualitatively understand the position (t_m) and the magnitude of η_m as related to the relative magnitude of the time constant of the input function, τ (see Fig. 2).

The situation shown in Fig. 1 for $\tau = \infty$ corresponds to the galvanostatic perturbation previously examined by Posey and Morozumi in 1966 (3).

While the observed maxima are attributed solely to the input function time constant τ, α (the ratio of electrolyte resistance in the pores to the charge transfer resistance) and β (related to the intrinsic electrode/electrolyte properties) will also influence the position and the magnitude of the observed η_m as seen in Fig. 3 and 4.

Decreasing current ramp technique (dcrt).—For reasons identical to those presented above for the exponential relaxation technique, the dcr input function will also exhibit a maximum in the potential transient which is dependent on the relative values of α, β, and input τ, as shown in Fig. 5, 6, and 7. The uniqueness of the observed maximum in the potential-time profile can now be exploited to characterize the system in terms of the relevant parameters, *e.g.*, C_T and R_T. Differentiation of the general η-t relations presented previously leads to the following expressions for η_m and t_m—the experimentally accessible quantities.

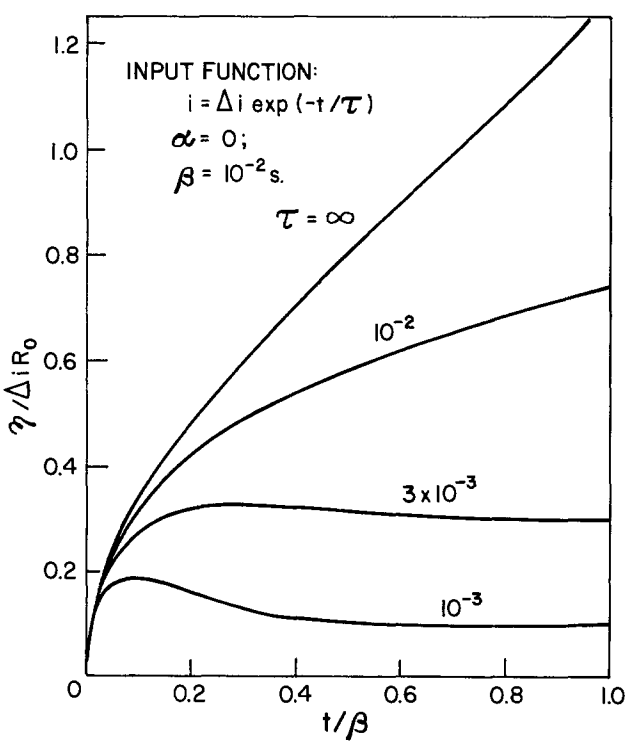

Fig. 1. Influence of τ on the potential-time profile for the exponentially decaying current input, when $\alpha = 0$.

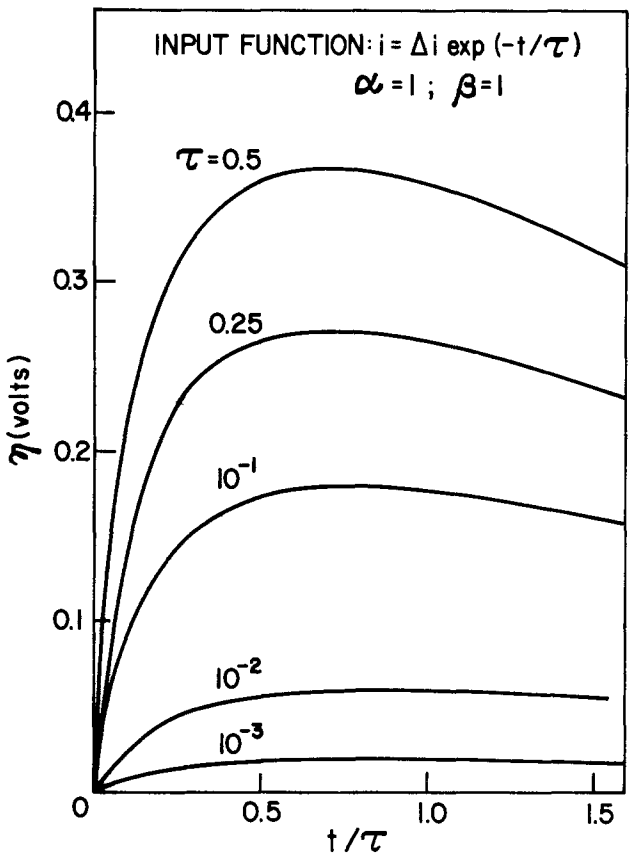

Fig. 2. Influence of τ on the potential-time profile for the exponentially decaying current input, when $\alpha = 1$.

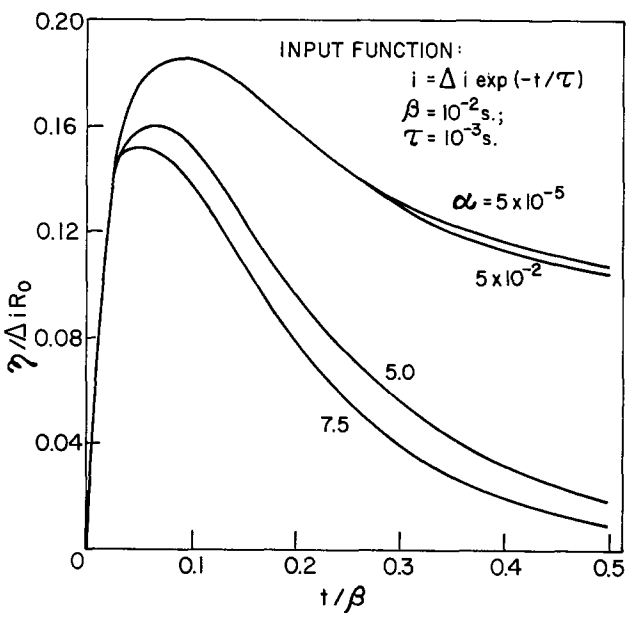

Fig. 3. Influence of α on the potential-time profile for the exponentially decaying current input function.

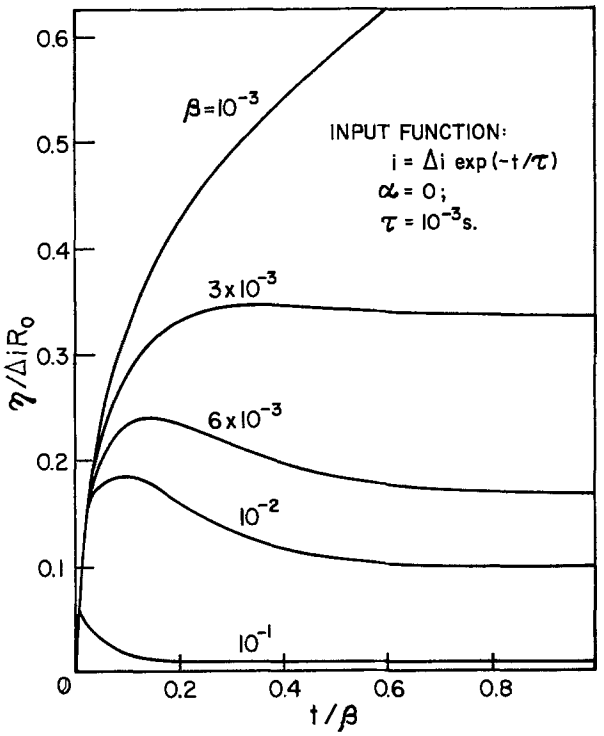

Fig. 4. Influence of β on the potential-time profile for the exponentially decaying current input function.

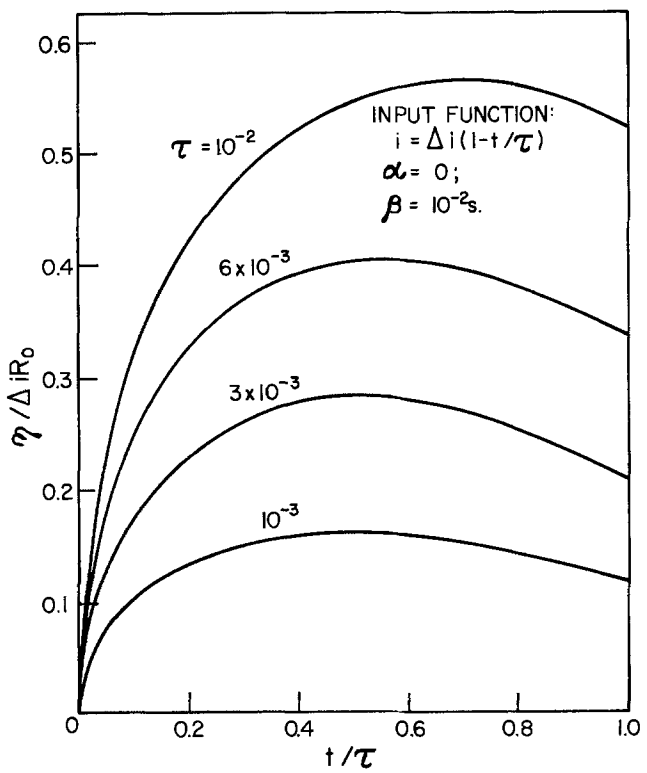

Fig. 5. Influence of τ on the potential-time profile for the decreasing current ramp input, when $\alpha = 0$.

Exponential relaxation technique ($\xi = 0$)

$$\frac{\eta_m}{\Delta i \tau} = \frac{1}{C_T} \cdot \exp\left(\frac{-\alpha t_m}{\beta}\right) \cdot \theta_3\left[\exp\left(\frac{-\pi^2 t_m}{\beta}\right)\right] \quad [4]$$

Where θ_3 (X) is the Jacobian θ function defined as $\sum_{n=0}^{\infty} \epsilon_n X^{n^2}$ ($\epsilon_n = 1$ for $n = 0$, $\epsilon_n = 2$ for $n > 0$).

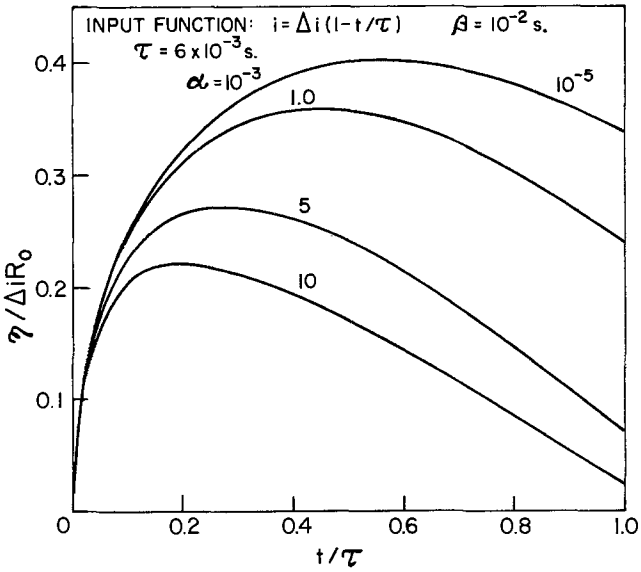

Fig. 6. Influence of α on the potential-time profile when the input function is $i = \Delta i\ (1 - t/\tau)$.

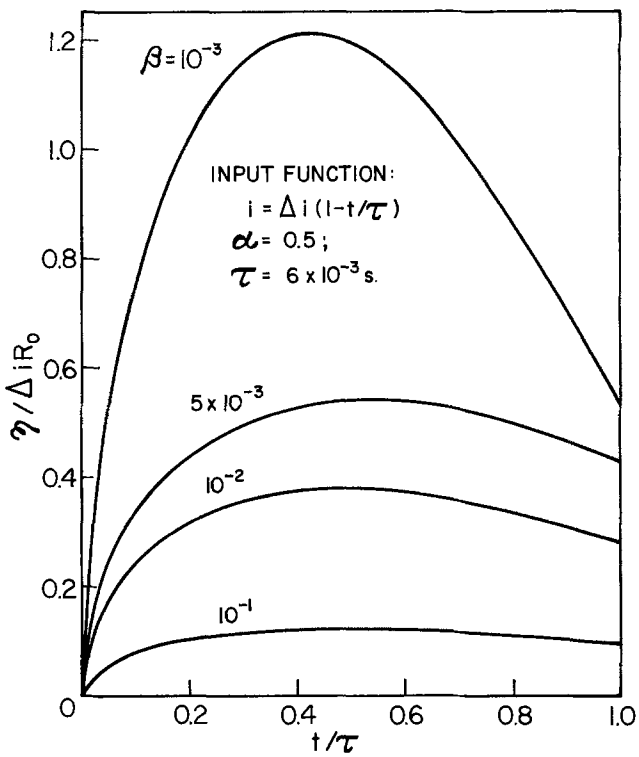

Fig. 7. Influence of β on the potential-time profile for the input function $i = \Delta i\ (1 - t/\tau)$.

dcrt ($\xi = 0$)

$$\frac{\eta_m}{\Delta i \tau} = \frac{1}{C_T}\left\{\left(\frac{1 - Bt_m}{B^2\tau^2}\right) + \exp(-Bt_m)\left(\frac{B^2\tau^2 - 1}{B^2\tau^2}\right) + 2\left[\sum_{n=1}^{\infty}\left(\frac{1 - At_m}{A^2\tau^2}\right) + \exp(-At_m)\left(\frac{A^2\tau^2 - 1}{A^2\tau^2}\right)\right]\right\} \quad [5]$$

where

$$A = \frac{n^2\pi^2 + \alpha}{\beta}$$

$$B = \alpha/\beta$$

Equation [4] can also be directly deduced from the generalized impedance $Z(P)$ using the following theorem derived in Ref. (9)

$$\frac{\eta_m}{\Delta i\tau} = \gamma'(T_m); \quad T_m = \frac{t_m}{\tau}$$

where

$$\gamma(t) = \mathcal{L}^{-1}[Z(P) - Z(\infty)]$$

and

$$\gamma'(t) = \frac{d\gamma}{dt} = \mathcal{L}^{-1}[P(Z(P) - Z(\infty))]$$

It should be noted from the above equations that the η_m-t_m relationship for the exponential perturbation is seemingly less complicated than the analogous expression for dcrt. This is not at all surprising, since dcrt has been shown to possess interesting features for "lumped parameter" systems, wherein it is possible to find times when η is wholly activation or diffusion controlled. Since the porous electrode system is a distributed system, η is no longer separable as "activation" and "diffusion" overpotentials. Nor is "the *IR*-drop" separable as for nonporous systems. The parameters characterizing these phenomenological components occur in a mixed position in the impedance for $Z(P)$ (4).

We now examine the behavior of the η_m-t_m relationship for the exponential relaxation technique under limiting conditions.

$\beta \to 0$.—This corresponds to a shift in control from R_o (electrolyte resistance in the pores) to R_T (charge transfer resistance) and double layer capacitance, C_T. The mathematical representation of this situation appears as

$$\frac{\eta_m}{\Delta i\tau} = \frac{1}{C_T}\exp\left(\frac{-\alpha t_m}{\beta}\right) \qquad [6]$$

Thus a plot of ln $\eta_m/\Delta i\tau$ *vs.* t_m under these conditions, should yield a straight line of slope α/β $(= 1/R_TC_T)$ and intercept $1/C_T$.

$\beta \to \infty$.—

$$\frac{\eta_m}{\Delta i\tau} = \sqrt{\frac{R_o}{\pi t_m C_T}}\exp\left(\frac{-\alpha t_m}{\beta}\right) \qquad [7]$$

Analogous to the $\beta \to 0$ case, a plot of ln $\eta_m t_m^{1/2}\pi^{1/2}/\Delta i\tau$ *vs.* t_m should yield a straight line of slope α/β and intercept $\sqrt{R_o/C_T}$. The $\beta \to 0$ approximation will apply when $t_m > \beta/\pi^2$, and this condition reduces the total expression relating η_m and t_m to the simple relationship corresponding to $\beta \to 0$. We shall examine here this possibility in greater detail.

In a practical system, the limiting approximation for η_m-t_m will be approximately obeyed, even for $t_m\pi^2/\beta \sim$ 2-5, which can be easily ensured by an appropriate choice of the input time constant τ. This is illustrated in Fig. 8, wherein the nonlinearity in η_m-t_m relationship is seen to prevail only at very low t_m values.

Experimental

All experiments were carried out in an all-glass, three-compartment cell, which was thoroughly cleaned in a hot HNO_3 + H_2SO_4 mixture and rinsed with triple distilled water. A large platinum gauze was used as the counterelectrode and the potential of the working electrode was measured with respect to a hydrogen electrode in the same solution. While studying the chlorine electrode reactions, a Cl_2/Cl^- electrode (14) and a SCE were employed.

The porous electrodes examined in this study were a sintered nickel plaque and a Teflon-bonded platinum electrode on a Pt screen (kindly supplied by Energy Research Corporation). The TiO_2 + RuO_2 electrode was prepared following the procedure described in Ref. (15). All solutions were deaerated with purified (16) H_2 (and N_2), and the studies were carried out at 25°C. The exponentially decaying current pulses were generated using the circuit described in Ref. (17), wherein the *IR* drop across the resistance in an *R-C* circuit during charging conditions is fed to a fast-rise Wenking potentiostat (70 HVI/90) operating in a galvanostatic mode. Potential-time transients were recorded on a Tektronix 564B oscilloscope with Type D plug-in amplifier and camera attachment. The transients were enlarged for the analysis of the data. The potentiodynamic experiments were performed using the standard circuitry (16).

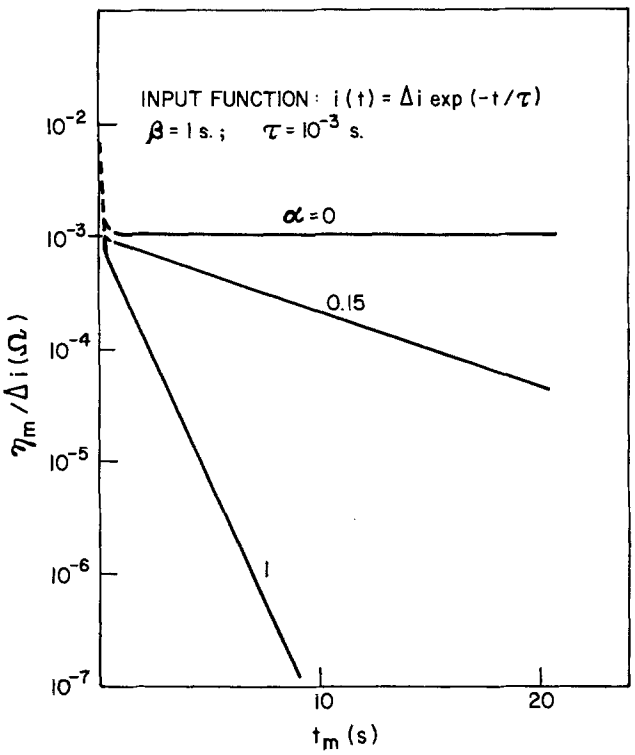

Fig. 8. η_m-t_m variation for various values of α when the input function is $i = \Delta i$ (exp $-$ t/τ).

Results and Discussion

"Ni plaque" electrode.—The initial system chosen for examining the application of theory to the objective of determining experimental parameters was nickel plaque-sintered Ni sheet in 4M NaOH at 25°C. In this system, the faradaic process is the hydrogen evolution reaction.

Figure 9 depicts actual potential/time profiles at different values of the input parameters τ and Δi. As predicted by the present theory, a maximum is observed in the potential transient, the locus of which is dictated by the input parameters and electrode properties (c.f. Fig. 1 and 4).

Following the $\beta \to 0$ approximation, the experimentally determined η_m-t_m pairs are plotted as ln $\eta_m/\Delta i\tau$ *vs.* t_m. The results for the Ni-plaque electrode system are shown in Fig. 10. The linearity predicted by the theory is apparent for values of $t_m > 50$ msec. From the intercept of Fig. 10, C_T is estimated to be 6.7 mF. The slope yields a value of the charge transfer resistance, $R_T = 63.9\Omega$. This R_T value corresponds to an exchange current density of $\sim$ 1 μA/cm^2, in general agreement with the published data (18).

In order to test the self-consistency of the present results with the limiting expression, the value of R_o is required. This may be evaluated from the galvanostatic charging transients at $t \to 0$. From the slope of the η *vs.* $2i\ t^{1/2}/\pi^{1/2}$ plot, which yields $\sqrt{R_o/C_T}$ (see Fig. 11), R_o is calculated to be 10.8Ω. Hence, $\beta = R_oC_T = 72$ msec. Therefore, the $\beta \to 0$ approximation should be valid for values of $t_m \geq 50$ msec, as observed in Fig. 10.

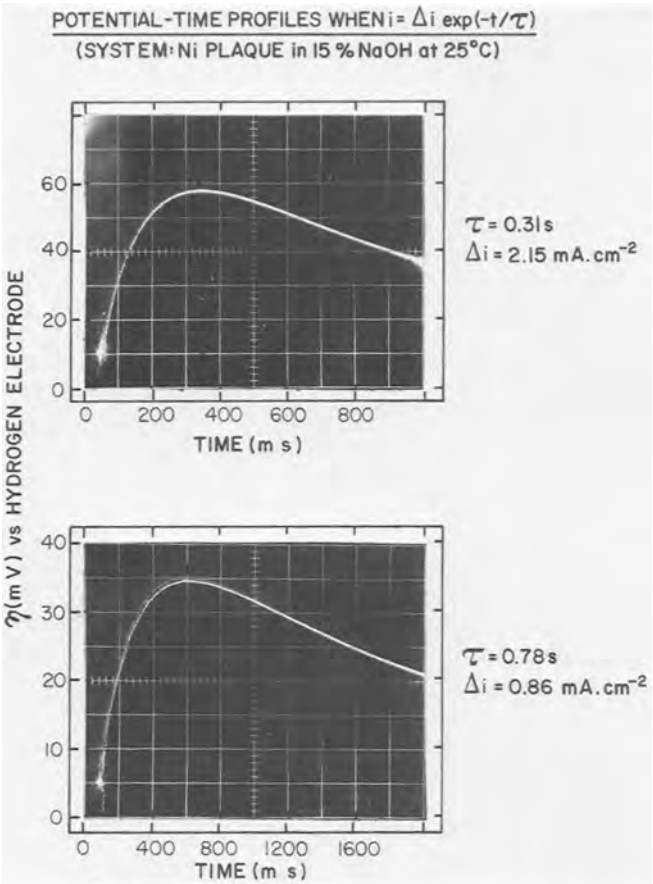

Fig. 9. Experimentally observed potential-time profile for the Ni plaque/NaOH system when the input function is $i = \Delta i \exp(-t/\tau)$.

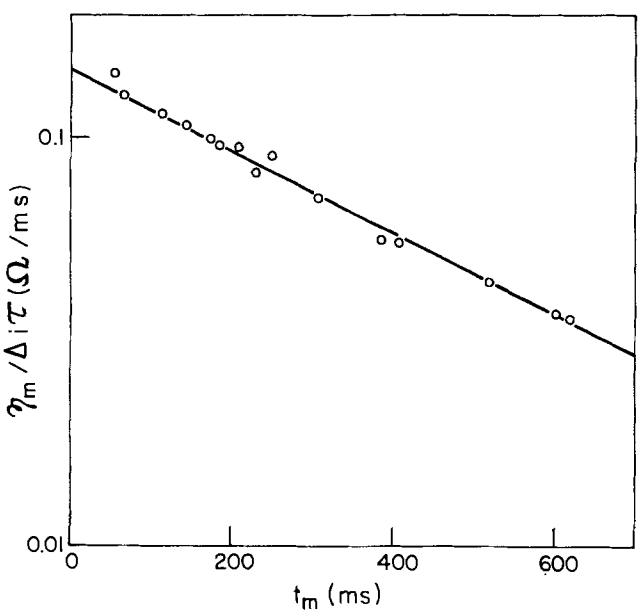

Fig. 10. Plot of ln $(\eta_m/\Delta i\tau)$ *vs.* t_m for the Ni plaque/NaOH system.

The self-consistency of the parameters derived from the $\beta \rightarrow 0$ approximation can be further tested by theoretically constructing the potential-time profiles and comparing with the experimental profiles. As seen in Fig. 12, the agreement is excellent.

Teflon-bonded Pt on Pt screen.—Figure 13 shows the experimental data for the Teflon-bonded Pt on Pt screen (supplied by Energy Research Corporation) in

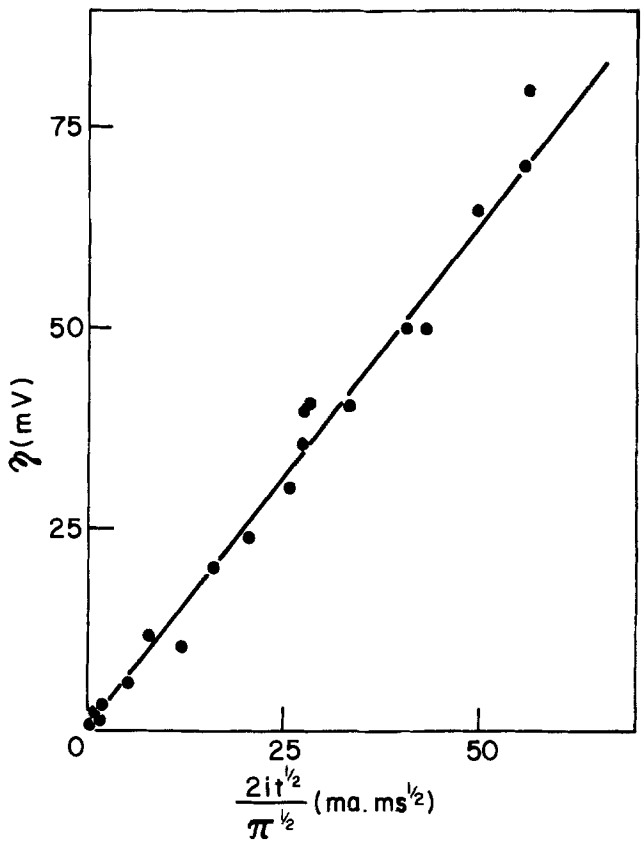

Fig. 11. Plot of η *vs.* $2it^{1/2}/\pi^{1/2}$ for the Ni plaque/NaOH system

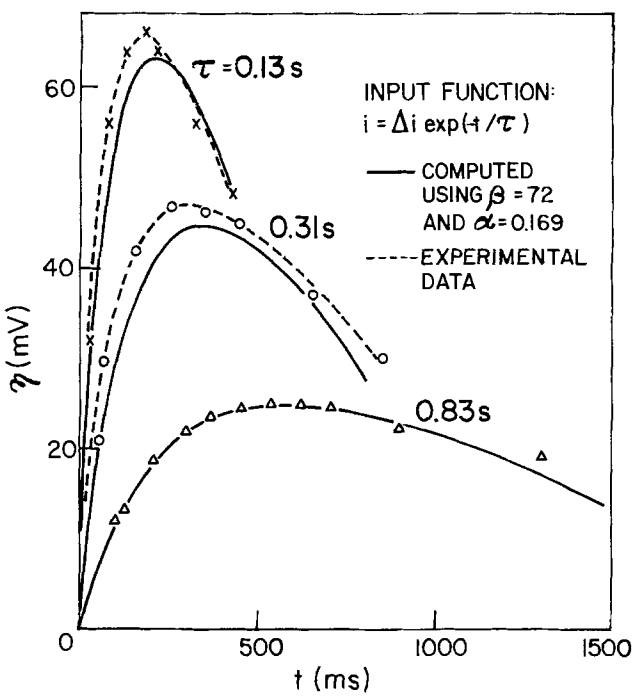

Fig. 12. Comparison of the experimentally observed potential-time profiles with the computer η-t profile, when $i = \Delta i \exp(-t/\tau)$.

4M NaOH at ~25°C. The η_m-t_m data pairs, plotted as $\ln(\eta_m/\Delta i\tau)$ *vs.* t_m, follow the linear trend at $t_m >>$ ~15 msec, as predicted by the $\beta \rightarrow 0$ approximation.

From the intercept and the slope of the line in Fig. 13, $C_T = 454$ mF and $R_T = 0.18\Omega$. This C_T value may be compared with the roughness factor of 2×10^4 cm²/cm² estimated from the BET measurements assuming $C_{ideal} \approx 20$ μF/cm².

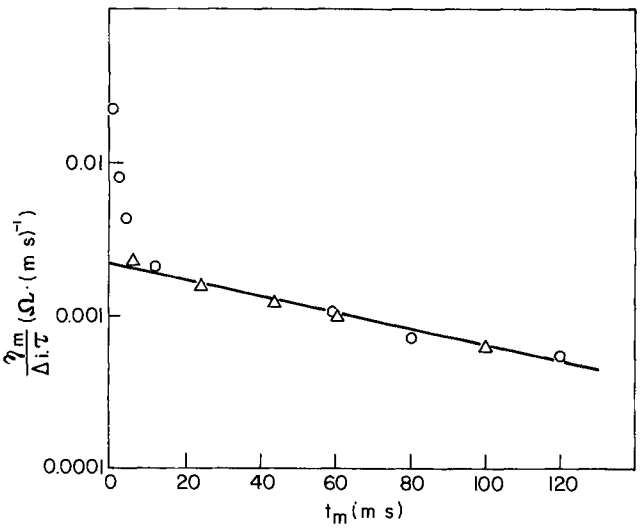

Fig. 13. Plot of ln ($\eta_m/\Delta i\tau$) *vs.* t_m for the Teflon-bonded Pt on Pt screen/NaOH system (the circles and triangles represent data acquired in independent experiments).

Planar electrodes.—It is of interest at this stage to examine the exponential relaxation technique for estimating the surface area of planar electrodes. For this purpose, a TiO_2 + RuO_2 electrode, used extensively as an anode in chloralkali cells, was chosen, since BET measurements have indicated roughness factors in the range of 180-230 (19).

From the potential-time and current-time transients at a potential of 680 mV *vs.* SCE in 5M NaCl solutions, ln $\eta_m/\Delta i\tau$ was estimated and plotted *vs.* t_m (see Fig. 14). These results show an over-all capacitance of 8.2 m**F**/cm^2 from the intercept, and infinite charge-transfer resistance, indicating the absence of faradaic processes in this potential region.

In order to confirm these results, linear-sweep voltammetric studies were carried out. The current-voltage profiles at various sweep-rates (see Fig. 15) show almost a flat current plateau over a significant potential range, which is suggestive of the absence of faradaic reactions in the potential region of 100-800 mV *vs.* SCE. The current *vs.* sweep-rate (s*) curve at E = 680 mV *vs.* SCE (see Fig. 16) is linear, and from the slope of the plot, the capacitance is estimated to be 8.4 m**F**/cm^2, which is in excellent agreement with the capacity value deduced from the exponential relaxation technique.

The potential response to the exponentially decaying anodic current pulse was also examined near the reversible potential for the Cl_2/Cl^- reaction in 5M NaCl aq. at 95°C. The ln ($\eta_m/\Delta i\tau$) *vs.* t_m plot is shown in Fig. 17. From the slope and the intercept, the charge-transfer resistance is calculated and found to be 9.87Ω. This value may be compared with the R_T value of 11.5Ω estimated from the linear i-η plot (Fig. 18) near the reversible potential.

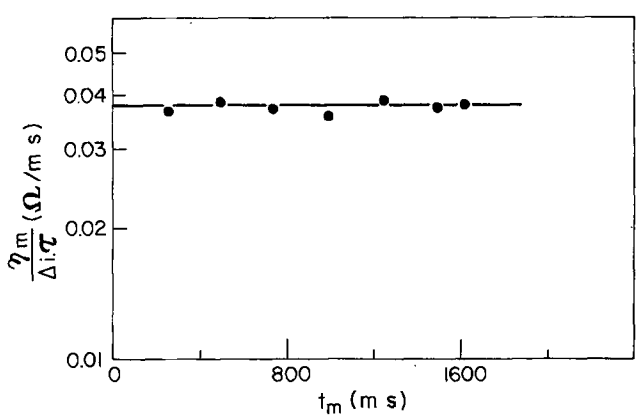

Fig. 14. Plot of ln ($\eta_m/\Delta i\tau$) *vs.* t_m for TiO_2 + RuO_2 electrode in 5M NaCl aq. at 25°C (the potential of the test electrode was 680 mV *vs.* SCE).

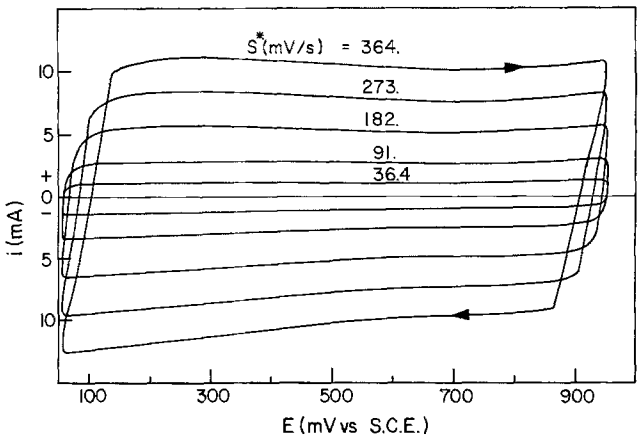

Fig. 15. Linear sweep voltammograms for TiO_2 + RuO_2 electrode in 5M NaCl at 25°C (area of the test electrode ~3.2 cm^2).

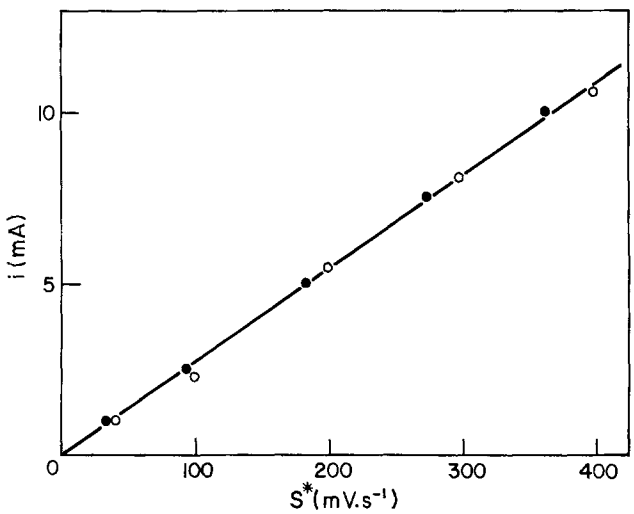

Fig. 16. Plot of i *vs.* sweep rate at E = 680 mV (data taken from Fig. 15); the closed and open circles represent data acquired in independent experiments).

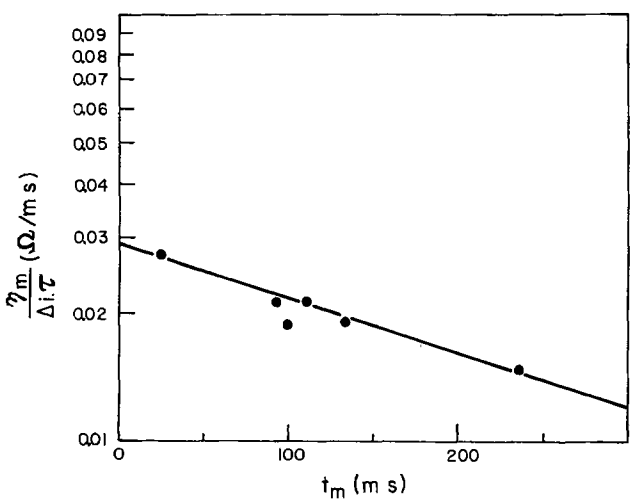

Fig. 17. ln($\eta_m/\Delta i\tau$) *vs.* t_m for TiO_2 + RuO_2 electrode in 5M NaCl aq. (*p*H ~3.5) at 95°C.

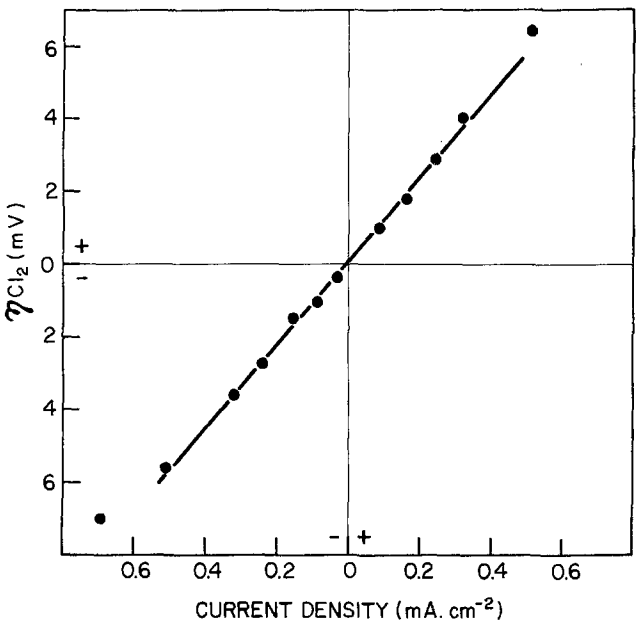

Fig. 18. Current-overpotential curve at low overpotentials for TiO_2 + RuO_2 electrode in 5M NaCl aq. (pH ~3.5) at 95°C.

It may be noted, however, that the C_T value deduced from the data obtained at the reversible potential of the Cl_2/Cl^- reaction is much higher than the C_T value in the nonfaradaic region. An explanation of this discrepancy may be sought in terms of adsorption pseudocapacitance, neglected in the present treatment. The presence of a finite adsorption pseudocapacity near the reversible potential is evident from the low Tafel slopes (20) and the fractional stoichiometric numbers (21) observed during the chlorine evolution reaction, which could arise only when adsorbed intermediates participate (21) in the rate-determining steps, *e.g.*, recombination and/or electrochemical desorption.

The examples cited above suggest the versatility of the exponential relaxation technique in providing a reliable estimate of the surface area of either a planar or a porous electrode, although a strong interference from the faradaic reaction is present and acknowledged. The obvious advantage of this method lies in the simplicity of experimental design and accessibility and theoretical tractability. However, in the case of systems where adsorbed intermediates participate in the rate-determining step, the present theory is inadequate and, hence, it is necessary to choose a system or a potential region for estimating the electrode surface area, in which the role of adsorbed intermediates is either absent or minimal. Studies to incorporate pseudocapacitance variations within the porous body and evaluate the diffusion-coupling are in progress.

Conclusions

The exponential relaxation technique provides a reliable means for determining the effective surface area of a planar or porous electrode in the presence of a faradaic reaction.

The present method permits simultaneous determination of R_T and C_T with the proviso that the influence of adsorption pseudocapacitance is negligible (*i.e.*, reaction intermediates do not participate in the rate-determining steps of the over-all charge transfer reaction) and diffusion within the porous body is absent.

Acknowledgments

The authors are grateful to Dr. K. V. N. Rao for supplying Ni plaque, Dr. B. S. Baker of Energy Research Corporation for the Teflon-bonded Pt screen, and Mrs. U. I. Keller for carrying out the experiments with meticulous care and devotion. Our thanks are also to the Hooker Chemicals & Plastics Corporation for permission to publish this paper. One of us (S.K.R.) thanks the Science Research Council, U.K., for financial support and the Indian Institute of Science, Bangalore, for leave of absence.

Manuscript submitted June 3, 1977; revised manuscript received Aug. 14, 1977. This was Paper 39 presented at the Las Vegas Nevada, Meeting of the Society, Oct. 17-22, 1976.

Publication costs of this article were assisted by Hooker Chemicals & Plastics Corporation.

Corrosion Resistance of Types 316 and 317 Stainless Steels in Simulated SO_2 Scrubber Environment

E. A. Lizlovs*

Climax Molybdenum Company of Michigan, Research Laboratory, Ann Arbor, Michigan 48105

Pollution control has necessitated the installation of wet scrubbers to remove SO_2 from exhaust gases of power plants and smelters. The operational principles of these scrubbers have been described in several excellent articles (1-2). The scrubbing systems, however, have confronted the industry with severe and complex corrosion problems and the necessity of evaluating different construction materials. A considerable amount of corrosion testing has been carried out in actual operating scrubbers (3-6). A simple bench test simulating some important parameters involved in corrosion in wet scrubber environments has been developed at this laboratory (7). The results of these tests were in general agreement with the results of industrial testing. Furthermore, the laboratory tests indicated the influence of molybdenum content on the corrosion resistance of stainless steels in the scrubber environment. Even variations of molybdenum content within specification limits had a large impact on the corrosion behavior of T316 stainless steel which is widely used in scrubber construction. This investigation is concerned with the effect of variations in molybdenum content on the corrosion resistance of T316 and T317 stainless steel in simulated scrubber environments. Type 304 samples were also included in the tests primarily to check the severity of the test solution, since T304 is known to have inadequate corrosion resistance in scrubber environments (3).

Experimental

Material.—The chemical compositions of the steels are shown in Table I. The steels were prepared by induction melting in argon and casting in air using a split-heat technique. The ingots were hot-forged, hot-rolled into an 8 mm (0.30 in.) thick sheet, and finally cold-rolled to 4 mm (0.15 in.) thickness. The steels were then solution annealed at 1095°C (2000°F) for 24 hr in a hydrogen atmosphere and water quenched. The heat-treatment gave homogeneous alloys with no observable delta ferrite even at the highest molybdenum content. The molybdenum content of the alloys was varied between 2 and 4.2% in about ½% increments.

* Electrochemical Society Active Member.
Key words: crevice, chlorides, molybdenum, passivity, pH.

Corrosion test.—Probably the most important parameters governing the corrosion of stainless steels in scrubbers employing limestone slurry for SO_2 absorption are the pH of the liquid and slurry, temperature, chloride content, oxygen, and crevices. The slurry pH in many cases is reported to be 5-6 or higher (6), however, excursions to lower values can occur, and at certain scrubber locations, a lower pH value also can be expected. The chlorides in the presence of oxidizing agents (oxygen) could cause pitting and crevice corrosion and, at low pH values would also lead to the loss of passivity and the onset of general corrosion. The accumulation of chloride ions will take place in the case of recirculating systems. The presence of oxygen (and possibly other oxidizing agents) on one hand will promote localized chloride attack, while on the other hand will help in maintaining the passivity of stainless steel at low pH values. The ionic species expected in the scrubbing liquid upon the absorption of SO_2 are H^+, HSO_3^-, $SO_3^=$, and some $SO_4^=$. Based on the above considerations, the following test solution was compounded: 2000 ppm $NaHSO_3$ and 3000 or 30,000 ppm Cl^-, added as NaCl. Experiments were performed at pH's 2, 3, and 5.3. The pH values were adjusted with NaOH. Most of the tests were conducted at 80°C (180°F) and some of the tests were conducted at pH 5.3 at 90°C (195°F). The tests were run for one week and the test solution was purged continuously with oxygen to ensure that the solution was always saturated with oxygen. The corrosion coupons were 25 × 20 × 2-4 mm (1 × 0.75 × 0.01-0.015 in.) thick. The surface was polished with 600 grit SiC paper. The samples were immersed in a test solution with crevices applied by rubber bands and Teflon cylinders pressed against each of the major faces. The evaluation of corrosion attack was by weight loss determination and visual inspection.

Results and Discussion

Experimental results are summarized in Tables II-IV. The corrosion rates are expressed in terms of weight loss over the entire geometric area of the coupons. A corrosion rate of less than 1 mg/dm²/day

* Interference films indicating borderline passivity.

(mdd) usually corresponded to slight crevice attack, or discoloration under the rubber band, or some very small pits. Corrosion rates in the range of 1 to about 10 mdd corresponded, in most cases, to well-defined crevice corrosion, usually under the rubber band, but in a number of cases also under the Teflon cylinder. The severity of crevice corrosion was reflected in the numerical value of the corrosion rate, the higher number corresponding to a more severe case of crevice corrosion. Occasionally there was also evidence of borderline passivity and the corrosion coupons showed interference films, indicating a loss of passivity followed by repassivation. Corrosion rates in excess of 10 mdd usually corresponded to severe corrosion both by crevice attack and by general attack due to loss of passivity.

The corrosion resistance of the T304 was inadequate under all experimental conditions, and all samples were severely damaged by crevice corrosion and by general etching. At the 3000 ppm Cl^- level the corrosion rates were quite low for all molybdenum-containing alloys at all three pH values and also at 90°C (195°F) with the exception of one 2.9% Mo sample which corroded at the rate of 24 mdd (Table III). Furthermore, above the molybdenum level of 3.4%, only a slight crevice corrosion was observable in the worst cases, and corrosion rates were either nil or less than 1 mdd.

More severe corrosion problems were encountered at the 30,000 ppm Cl^- level. Corrosion rates for some samples were widely different between the two runs (Table IV). Such widely different rates undoubtedly were caused by some samples becoming active and failing to repassivate, while in the other test, samples of the same material either remained passive or repassivated after an initial loss of passivity. In many cases, especially at pH 2, the corrosion coupons were covered with a surface film showing interference colors indicating borderline passivity.

The experimental results from the laboratory tests in general show considerable scatter of data, the same as the results from on-site testing (3). Considering the complexity of corrosion processes involved even in a simple laboratory test, such scatter should be anticipated. Comparison of all of the experimental data in Tables II-IV shows that only above the molybdenum content of 3.4% did the corrosion rate remain at consistently low rates reflecting a relatively small degree of crevice attack under all pH and chloride concentrations tested. It should be noted here that the test temperature was somewhat higher than normal for scrubber operation. At normal scrubber operations [pH of about 5.3, chlorides around 3000 ppm, and temperature of 60°-70°C (140°-160°F)] most probably all of the T316 samples, even those of the lowest molybdenum content (2%), would have sufficient corrosion resistance. However, operational departures into a higher temperature region, fluctuations in pH, and accumulation of chlorides in scrubbing liquids, conditions which to some extent are reflected in the series of tests presented here, will most likely cause serious corrosion problems unless T317 steel with at least 3.5% Mo is used. This conclusion is in agreement with INCO *in situ* test results (3).

It is of importance to note here that in previous experiments at this laboratory, alloys containing more than 3.4% Mo did not fail due to stress corrosion cracking in the wick test (8).

Conclusions

In SO_2-scrubber construction in locations where T316 stainless steel is normally used, T317 with at least 3.5% Mo should be used to withstand corrosion problems arising from pH and temperature fluctuations and chloride accumulation in the scrubbing liquid. The best corrosion resistance in the laboratory tests was shown by an experimental T317 steel with 4.2% Mo.

Cytochrome c_3 is an electron carrier present in the redox system of sulfate-reducing bacteria, *desulfovibrio* (1). It has been isolated from *d. vulgaris*, Hildenborough (2, 3). *d. vulgaris*, Miyazaki (4-6), *d. desulfuricans* (7), *d. salexigens* (8), and *d. gigas* (9). The physicochemical properties of cytochrome c_3 extracted from *d. vulgaris*, Miyazaki, have been studied extensively in our laboratory (6). Its molecular weight is nearly 14,000. The heme content of cytochrome c_3 has been believed to be two or more (3, 7, 10-12), and we confirmed that it contains four hemes by chemical analysis (6). Later Meyer *et al.* also reported four hemes in the molecule (13). Cytochrome c_3 is a natural electron acceptor for *desulfovibrio* hydrogenase (hydrogen:ferricytochrome c_3 oxidoreductase, EC 1.12.2.1), and is reversibly reduced by molecular hydrogen in the presence of hydrogenase (14). It has been demonstrated by Yagi *et al.* (15) that cytochrome c_3 is electrochemically active and interacts directly with a glassy carbon electrode as an electron carrier for hydrogenase. The redox potential of cytochrome c_3 was calculated from the measurements of the equilibrium between hydrogen and cytochrome c_3 (3, 6, 7).

The electrochemical methods have been applied in studying the electron transfer reactions of model systems for the prosthetic group in the heme proteins (16). The electrochemical reduction of ferricytochrome c on platinum (17) and mercury electrodes (18) has been studied. The mechanism of charge transfer was proposed to be a superposition of electron transport through adsorbed molecules and exchange of already reduced molecules (19).

In the present paper, the electrochemical behavior of cytochrome c_3 on mercury electrode has been studied by polarography, cyclic voltammetry and potentiometry.

Experimental

Cytochrome c_3.—Cytochrome c_3 was isolated from *d. vulgaris*, Miyazaki, and was purified as described by Yagi and Maruyama (6). The purity of the cytochrome c_3 used in the present experiments was over 80% as estimated from the purity index of the preparation (6). The concentration of cytochrome c_3 determined from the absorbance at 552 nm of the ferro-form was $5.2^4 \times 10^{-5}$ mole dm^{-3} (6). The base solution was 0.03M phosphate buffer of *p*H 7.0. Hydrogenase was isolated from *d. vulgaris*, Miyazaki, and purified as described elsewhere (20).

Polarography and cyclic voltammetry.—Polarographic and cyclic voltammetry studies of cytochrome c_3 were carried out on a mercury electrode with a PAR polarographic analyzer Model 174. In the polarographic study a normal pulse mode was used and the drop time of the dropping mercury electrode was 5 sec. In the cyclic voltammetry, a Metrohm hanging mercury drop electrode with the surface area of 4.11×10^{-2} cm^2 was used.

Redox potential measurement.—In the potentiometric study, ferricytochrome c_3 was reduced by hydrogen gas in the presence of a small amount of the purified hydrogenase, and the concentrations of ferri-form and ferro-form were determined polarographically. The ratio of ferri-form to ferro-form varied by introducing oxygen gas step by step. A large mercury pool electrode was used as a working electrode. All potentials shown in this work are given with respect to the saturated calomel electrode and all experiments were carried out at 25.0°C.

Results

Polarography.—A well-defined reduction wave of cytochrome c_3 was obtained as shown in Fig. 1. The

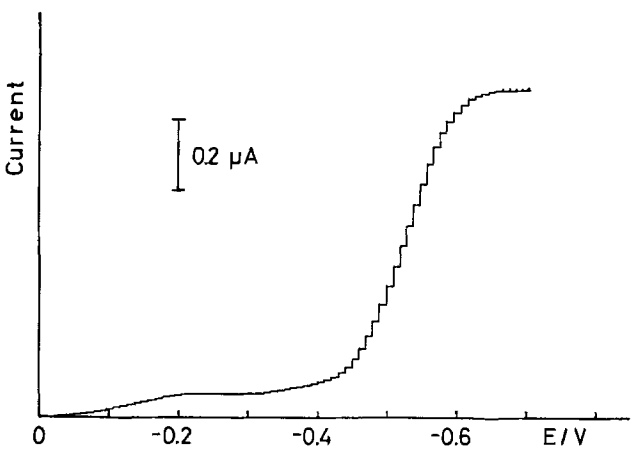

Fig. 1. Reduction of cytochrome c_3 on DME by pulse polarography. Concentration of cytochrome c_3 is $5.2^4 \times 10^{-5}$ mole dm^{-3} in 0.03M prosphate buffer at *p*H 7.0.

* Electrochemical Society Active Member.

Key words: cytochrome c_3, pulse polarography, cyclic voltammetry, potentiometry.

small preceding wave is due to the trace of oxygen in the solution. The half-wave potential is −0.527V (−0.281V *vs.* NHE), and the plot of log $[i/(i_d - i)]$ *vs.* electrode potential produces a straight line with an inverse slope of 0.085V from which the apparent number of electrons involved in the electrode process is calculated to be less than unity. In the case of the polarograms for the mixed ferri- and ferro-cytochrome c_3 system, the polarogram is symmetrical with respect to the current at $(i_{dc} + i_{da})/2$, where i_{dc} is the diffusion current for the reduction of the ferri-form and i_{da} is that for the oxidation of the ferro-form. The electrode potential corresponding to the current at $(i_{dc} + i_{da})/2$ is independent of the ratio of ferri-form to ferro-form and is the same as $E_{1/2} = -0.527$V for the reduction of the ferri-form. From these results it may be concluded that the electrode reaction of cytochrome c_3 is reversible even in the presence of strong adsorption of cytochrome c_3 on mercury electrode. The strong adsorption of the reactant is evidenced from the fact that the mercury drop formed in the cytochrome c_3 solution stayed on a mercury pool as a droplet at least for 30 min.

The diffusion coefficients of ferri- and ferro-cytochrome c_3 calculated from the pulse polarographic data were 1.2×10^{-6} cm^2 sec^{-1} for both forms. This value is in correspondence with that of horse-heart ferricytochrome c (MW = 12,350) determined by hydrodynamic techniques, 0.95×10^{-6} cm^2 sec^{-1} (20).

Cyclic voltammetry.—The cyclic voltammograms of cytochrome c_3 with various scan rates are shown in Fig. 2. The electrode potential at the current peak does not shift on the potential axis as a function of the scan rate. The current function $i_p v^{-1/2}$ is independent of the rate of voltage scan over a wide range, and the i_p *vs.* $v^{1/2}$ plot passes through the origin, where i_p is the peak current and v is the rate of voltage scan. The ratio of the cathodic to anodic peak currents is almost unity. The difference between the peak potential, E_p, and half-peak potential, $E_{p/2}$ was about 73 mV (the peak-to-peak separation is about 90 mV), which is much larger than 14.1 mV as expected for the reversible four-electron electrode process.

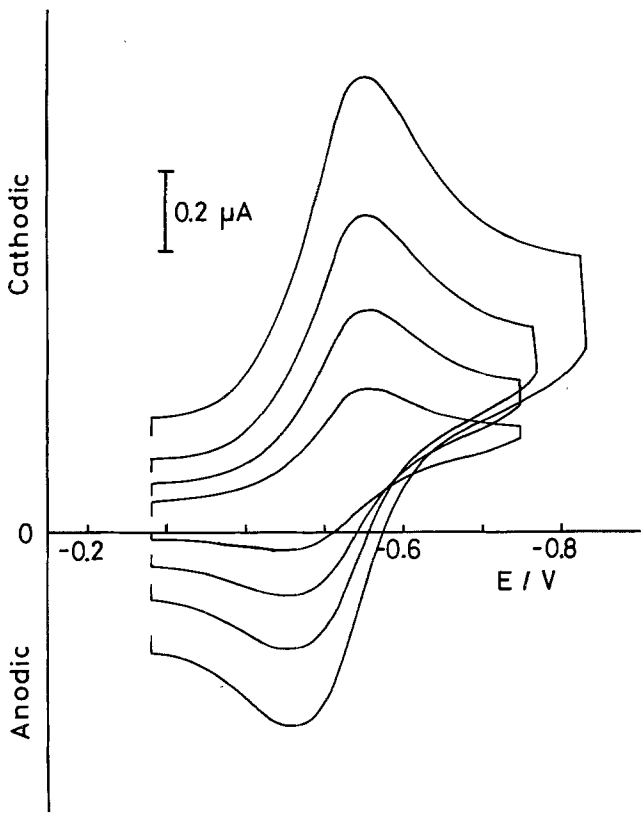

Fig. 2. Cyclic voltammogram of cytochrome c_3 on HMDE. Scan rate, 30, 50, 100, and 200 mV sec^{-1}. Concentration of cytochrome c_3 is $5.2^4 \times 10^{-5}$ mole dm^{-3} in 0.03M phosphate buffer at pH 7.0.

The peak current expected from the four-electron reversible process with the diffusion coefficient of 1.2×10^{-6} cm^2 sec^{-1} is about three times larger than that of the measured values in the present experiment. The apparent number of electrons involved in the electrode reaction of cytochrome c_3 is calculated to be about two.

Potentiometry.—The formal potential of the ferro- and ferri-cytochrome c_3 couple is −0.516 ± 0.001V (−0.270 ± 0.001V *vs.* NHE) and the Nernst slope of the plot of log (C_O/C_R) *vs.* electrode potential is 88 mV. That is, the apparent number of electrons involved in the electrode reaction calculated from the Nernst slope is less than unity. The redox potential determined in the present experiment (−0.516V) agrees with our previous measurement [−0.536V (6)], and 100 mV is different from other measurements [−0.415V (2, 7)] determined from the equilibrium pressure measurement of hydrogen over cytochrome c_3.

Discussion

It is concluded from the polarographic and voltammetric results that the electrochemical kinetics for the reaction

$$\text{ferricytochrome } c_3 + 4e \rightleftharpoons \text{ferrocytochrome } c_3$$

is diffusion controlled, and the reaction rate constant is the order of 0.1 cm sec^{-1} or greater. The electron transport in the electrode reaction takes place through the strongly adsorbed layer of cytochrome c_3 on mercury electrode.

The broad distorted voltammograms—both $(E_{p/2} - E_p)$ and i_p values are different from those expected from the four-electron reversible reaction—suggest that the electrochemical reaction of cytochrome c_3 is a reversible multistep process, and broadening is attributed to a small difference in the formal potential of these processes (22).

A large Nernst slope, 88 mV, can be explained in terms of the combination of the Nernst plots for the multistep processes with a small difference in the formal potentials (the difference is at most 70 mV in the present case).

These results are probably due to the fact that ferricytochrome c_3 accepts four electrons stepwise as a single entity. That is, the four hemes in cytochrome c_3 are not independent but constitute an interlocked heme cluster. A small difference in the formal potentials is attributable to the existence of intramolecular heme-heme interaction. These experimental findings are also expected from the results of Mössbauer spectroscopic (23) and electron paramagnetic resonance spectroscopic (24) studies on cytochrome c_3, in which the heme-heme interaction was observed.

Technique for Continuous High Resolution Long-Term Recording of Signals with High Levels

G. Edwall and A. Olofsson

Department of Applied Physics, Royal Institute of Technology, S-100 44 Stockholm, Sweden

For survey purposes, *e.g.*, in potentiometric long-term measurements, permanent long-term recording on strip-chart recorders is often used. The resolution and accuracy is generally limited to 3 decimal digits owing to the normally encountered poor characteristics of such recorders. In many cases, *e.g.*, with slowly varying signals, a higher resolution is needed. The signals are then usually fed to accurate digital instruments for display, and permanent records may be obtained from printers or signal processing computers connected to these instruments. Alternatively, a known bias signal is applied, bucking out the d-c part of the signal to be recorded, thus allowing only the varying part to be seen.

A long-term record is usually used to extract significant variations and/or trends such as drift in the signal being measured. For this purpose, the printer presenting only a sequence of digits is of limited value due to lack of human comprehension of data in that form. The use of a computer for signal processing may, in many cases, be too expensive, thereby leaving only the buck-out technique for consideration. However, if a highly accurate measurement ranging over four or more decimal digits is needed, considerable restrictions regarding accuracy and long-term stability are placed on the buck-out signal. The permissible signal variation is also restricted, by recorder end-point deflection, to one chart-width at the recorder setting used. In special situations, it may even be prohibitive to apply a buck-out signal. This is the case, for instance, in medical *in vivo* applications due to the patient safety problems and similarly in continuous electrochemical measurements due to the potential risk of electrode polarization.

In our case we needed a solution to the problems encountered in long-term monitoring of the stability of metal-metal oxide *p*H electrode potentials. From a permanent record we wanted to accurately reconstruct both the absolute level and the variations of the electrode potential. The signal range covered 5½ decimal digits with short-term variations in the last two places only, and long-term drift typically corresponding to less than two decimal digits per hour.

Key words: dynamic zero suppression, potential measurement technique, buck-out signal.

A varactor amplifier, used as a unity gain voltage follower, acts as an impedance buffer for the electrodes, providing an output voltage equal to the electrode zero current potential to within $5 \cdot 10^{-4}$. This voltage is measured and displayed on an accurate 5½ digit DVM (Model 190, Keithley Instruments Incorporated) (1). A digital-to-analog (D/A) converter (8 bits = 2 BCD-coded digits) acts as an interface between the DVM and a strip-chart recorder. It provides a means for recording variations in any two consecutive digits on the DVM, while all more significant digits are suppressed. The block diagram of the converter is shown in Fig. 1. With a mechanical selector, the BCD-coded output signals from two digits on the DVM are preselected. The signals from each digit are fed to a four-bit D/A converter generating an output current proportional to the input digit. The current from the least significant digit is divided by ten and added to the current from the more significant digit. By means of a current-to-voltage converter (adder), an analog output voltage directly proportional to the input value is generated. The output voltage span is adjusted with a potentiometer to fit the input range of the recorder. In our case the 1V range was used.

The D/A converter described enables flexible zero suppression of the d-c part of the input voltage, while the significant variations are displayed in analog form in 100 steps on the recorder. For instance, a signal symbolized by abc.de mV can be recorded as cd units on the recorder. Moreover, with this technique, the recorder need not be supervised for off-scale deflections,

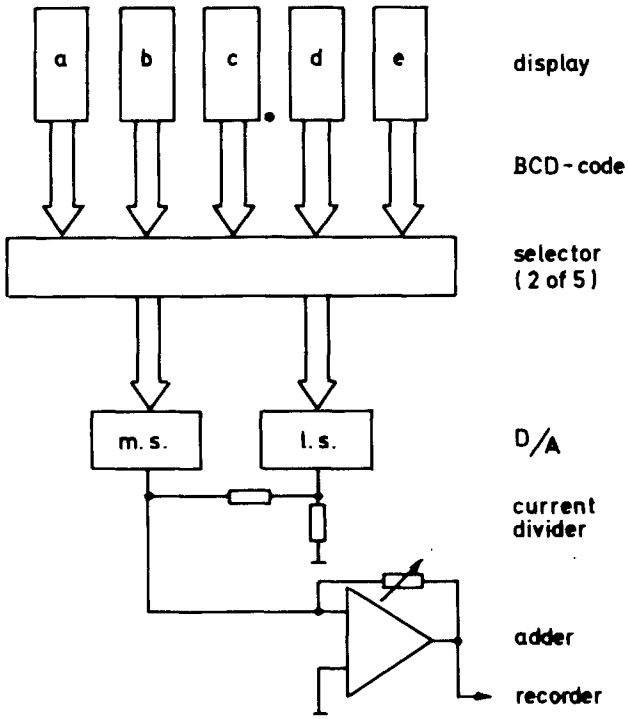

Fig. 1. The D/A converter

as it automatically changes from 99 to 00 or vice versa when the end points (*i.e.*, when b changes ±1 unit in the aforementioned example) are exceeded. Such changes are readily observed from the recording itself, and the actual signal magnitude is easily reconstructed. This is the case if the changes are not too frequent. Otherwise, a less sensitive setting or a higher recorder speed should be employed.

The above-described recording technique has now been extensively used by us. In our case, the input voltage level has not been found to be affected to any measurable extent (*i.e.*, <30 μV). Nonlinearity and drift in the recording equipment and its interface including the D/A converter has not posed any problem. However, there is a slow drift of the D/A converter output voltage (Zener stabilized) corresponding to approximately 1 digit (1% ≡ 10 mV) per week, which might cause misinterpretation if the equipment is left unattended for longer periods of time.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 124, No. 2 and 3, February and March 1977.

Electrochemical Characterization and Modification of Cadmium Sulfide Composition at 25°C

J. Vedel, M. Soubeyrand, and E. Castel
(pp. 177-180, Vol. 124, No. 2)

C. Gutierrez:[1] In their work, Vedel *et al.* oxidized anodically a ~1 μm layer of CdS in 10^{-2}M $CdSO_4$. After current interruption, 6-8 hr were needed for CdS to attain a stable potential. This rest potential increased with increasing previous anodization, from that corresponding to pure Cd (for Cd-saturated CdS) to that corresponding to pure S (for S-saturated CdS) and even higher. We would like to raise the following points in consideration of that work:

1. According to Vedel *et al.*, "... cadmium activity in Cd_xS, [is] a thermodynamical quantity that may be related to the activity of a defect, for example, the noncharged interstitial cadmium represented by Cd_i*. Then one has

$$\mu_{Cd}(Cd_xS) = \mu^o_{Cd_i^*} + RT \ln a_{Cd_i^*}" \qquad [1]$$

The above assumption of interstitial cadmium atoms (which, besides, are ionized[2]) is unnecessary. The correct equation is simply

$$\mu_{Cd}(Cd_xS) = \mu^o_{Cd}(Cd) + RT \ln a_{Cd}(Cd_xS) \qquad [2]$$

because if the CdS layer is in thermodynamic equilibrium, there is only one chemical potential of Cd in the whole CdS phase, irrespective of its microscopic structure.

2. The CdS layer was obtained by anodic oxidation of Cd in 0.5M Na_2S, pH = 9 at −0.9V *vs.* SCE. In principle, no anodization should be necessary, as the reaction

$$Cd + HS^- + H^+ \rightarrow CdS + H_2 \qquad [3]$$

is thermodynamically highly favored (ΔG° = −40.28 kcal/mole; log K = 29.52).

It is very interesting that the initial potential of Cd in 0.5M Na_2S was that of pure Cd, and not that corresponding to pure sulfur. In the case of lead, the potential values in Na_2S or NaHS solutions found by several workers in air[3-5] and N_2[5] coincide with that calculated for pure sulfur

$$S + H^+ + 2e \rightarrow HS^-$$

$$E^\circ_h = -0.062V \qquad [4]$$

which is 0.5V more positive than that corresponding to pure lead

$$PbS + H^+ + 2e \rightarrow Pb + HS^-$$

$$E^\circ_h = -0.564V \qquad [5]$$

Only in one case[6] and in a rather dilute Na_2S solution was the potential of natural galena sensibly more negative (~140 mV) than that corresponding to pure sulfur. It may be concluded that perhaps a more thor-

[1] Instituto de Química Física "Rocasolano," C.S.I.C., Serrano, 119, Madrid — 6, Spain.
[2] F. A. Kröger, H. J. Vink, and J. van den Boomgaard, *Z. Phys. Chem. (Leipzig)*, 203, 1 (1954).
[3] P. P. Lebedew, *Z. Elektrochem.*, 18, 891 (1912).
[4] G. Trümpler, *Z. Phys. Chem.*, 99, 9 (1921).
[5] R. Tolun and J. A. Kitchener, *Trans. Instn. Min. Metall.*, 73, 313 (1964).
[6] E. Baumgarten, *Chem.-Ing.-Tech.*, 44, 613 (1972).

ough exclusion of oxygen is necessary to observe the potential of pure lead corresponding to reaction [5].

3. In one case the $E°_h$ of anodized CdS was found to be + 0.470V, far higher than that of $E°_h = +0.31$V corresponding to pure sulfur in equilibrium with cadmium sulfide, according to

$$Cd^{2+} + S + 2e \rightarrow CdS \quad [6]$$

Vedel *et al.* state that in the anodization of CdS "One must be careful lest the emf Emax should ever be less than the emf corresponding to the oxidation of cadmium sulfide into sulfur (Emax $\lesssim$0.7V)" [presumably *vs.* a Cd electrode in the same solution]. If this applies also to the CdS with $E°_h = +0.470$V, it is clear that some oxygen inadvertently introduced in the system reacted with the CdS. In any case, the potential must correspond to some oxidized form of CdS, such as CdO: a possible reaction could be

$$Cd^{2+} + \tfrac{1}{2}\,O_2 + 2e \rightarrow CdO_c \quad [7]$$

with $E°_h = +0.781$V. However, the observed potential of 0.470V would correspond to $\log p(O_2) \approx 10^{-21}$ atm, while the residual oxygen pressure is probably much higher.[7]

Vedel *et al.* claim that the observed potential $E°_h = +0.470$ does correspond to pure sulfur, with $E°_h = +0.31$V, and that "this deviation may be attributed to the formation of sulfur in a state different from the standard state of the element." They suggest that gaseous sulfur is formed. This suggestion is best ignored, as (*i*) Evolution of gaseous sulfur at a pressure higher than the vapor pressure of pure sulfur requires a more positive potential than that for deposition of solid sulfur. Therefore, the element would be produced as a gas only if deposition of the solid were strongly impeded. We know no case in which this phenomenon occurs; and (*ii*) More importantly, any gaseous sulfur evolved on anodization would be swept away by the argon flow.

4. In Fig. 2 of the article being discussed, a change in the composition of Cd_xS of $\Delta x = 0.01$ appears. This range of compositions is probably too high. The highest level of Cd excess in CdS reached by Kröger *et al.*[2] produced $\sim 10^{18}$ electrons cm^{-3}, corresponding to $\Delta x \sim 5 \cdot 10^{-5}$. For other chalcogenidse it is $\Delta x \sim 10^{-3}$.[8] In general, "... the calculated equilibrium concentration of point defects, particularly in the metallic oxides but also in the sulfides etc. is extremely small, even at high relative temperatures $\theta = T/Tm$ (Tm = the melting point of the crystal)."[9] Therefore, it seems clear that oxidation of impurities accounts for most of the anodization current.

5. The authors state that "In order to plot the two [E *vs.* Δx] curves on the same diagram, it was first observed that both their left parts showed a sigmoidal shape recalling that of titration curves." As a matter of fact, these curves are known as coulometric titrations in solid-state electrochemistry, and Valverde[9] has found experimentally and justified theoretically that for the silver chalcogenides they should be sigmoidal in shape.

6. The authors try to justify the experimental slope of 0.090V in the region *hi* of their titration curve (Fig. 2) by means of an incorrect derivation. As said above in paragraph 3 the region *hi* does not correspond to CdS, but to some oxidation product, perhaps CdO. Therefore CdS plays no role in this region. It is stated that "When the x value is equal to x_H, the vacancy concentration $|V_{Cd}''|$ is very low ($|V_{Cd}''|_{x=x_H} \sim 0$)." Although not clearly stated, x_H corresponds to Cd_xS in equilibrium with pure sulfur, which has a potential (*vs.* a Cd electrode in the same solution) of 0.31 + 0.408 = +0.718V. This potential corresponds to the highest possible concentration of sulfur in homogeneous Cd_xS, *i.e.* to the highest possible concentration of cadmium vacancies, which is just the opposite situation to that postulated by Vedel *et al.* It is further stated that "The cadmium vacancies are assumed to be in equilibrium with metallic cadmium . . . The equilibrium is

$$Cd + V_{Cd''} + 2h \rightarrow Cd_{Cd} \quad [8]$$

together with the relation

$$K = a(Cd) \cdot |h|^2 \cdot f(V_{Cd''}) \cdot |V_{Cd''}|_x" \quad [9]$$

Equations [8] and [9] are totally incorrect. An excellent treatment of these equilibria has been given by Kröger and Vink.[10] In the system under consideration gaseous cadmium is in equilibrium with sulfur vacancies, V_s, according to

$$Cd_g \rightarrow Cd_{Cd} + V_s \quad [10]$$

(Cd_{Cd} = cadmium atom in a lattice-cadmium site). The corresponding equation is

$$[V_s] = K_r \cdot p_{Cd} \quad [11]$$

These are the correct equations to be applied, and not Eq. [8] and [9]. It is clear that if only Schottky defects are present in the crystal, an excess of metal may only be accommodated by the formation of nonmetal vacancies, and vice versa.

J. Vedel, M. Soubeyrand, and E. Castel:[11] 1. The convenient equation relating the activity of cadmium to its chemical potential is effectively

$$\mu_{Cd}(Cd_xS) = \mu°_{Cd}(Cd) + RT \ln a_{Cd}(Cd_xS)$$

2. Anodic oxidation increases the thickness of the sulfide layer by setting up an electrostatic field in the solid that favors the movement of the ions through the layer.

3. The value 0.31V (*vs.* NHE) corresponding to reaction

$$Cd^{2+} + S + 2e \rightarrow CdS$$

is calculated by assuming that sulfur is present in its standard state, *i.e.*, solid rhombic sulfur S_{rh}. In order to explain the difference between the calculated value and the observed one (0.470V), we assumed that sulfur was formed in an allotropic form, different from S_{rh}. As an example, the observed difference of free energy and some free energies of other forms of sulfur were compared (we never supposed the formation of gaseous sulfur). This hypothesis seems more realistic than the intervention of an equilibrium reaction involving gaseous oxygen at $p(O_2)$ less than 10^{-21} atm.

4 and 5. These remarks appear already in the original paper (in a different form) and we agree fully with them.

6. The part of the diagram in question corresponds to a cadmium-poor sulfide. Consequently, it is not incorrect to assume the formation of metal vacancies.

A New Niobium Selenide Cathode for Nonaqueous Lithium Batteries

D. W. Murphy, F. A. Trumbore, and J. N. Carides
(pp. 325-329, Vol. 124, No. 3)

M. S. Whittingham:[12] In their article, Murphy *et al.* suggest that in the original discharge curves of $NbSe_2 \cdot I_2$[13] which exhibited two plateaus, one might be due to iodine and the other to the niobium diselenide. It had been thought that the "$NbSe_2$ served as

inert host for the electrochemically active iodine;"[14] subsequently, it was discovered[15,16] that the layered dichalcogenides themselves are electrochemically active. These discharge/charge curves are shown in Fig. 1, and the two-step discharge behavior is clearly visible. However, Carides and Murphy[17] have also recently measured the open-circuit behavior of the Li/$NbSe_2$ couple, which was found to vary continuously from 2.28 to 1.66V as x increased from 0 to 1 in Li_x-$NbSe_2$. This emf regime is shown as the hatched area in the figure, and falls well below the step in the discharge curves particularly when it is noted that the cycling curves are showing marked polarization. Hence, neither of these discharge steps can be associated with the intercalation of lithium into the lattice of the selenide. The chemical form of the iodine in the "$NbSe_2 \cdot I_2$" complexes is not understood, but it is possible that the two discharge steps can be associated with different states of adsorption of the iodine on the selenide.

D. W. Murphy, F. A. Trumbore, and J. N. Carides:[18] The point raised by Dr. Whittingham, although not the subject of our paper, warrants discussion because of its relevance to other solid-solution electrodes of the layered transition metal dichalcogenides.

As to our interpretation of Broadhead's results,[19] Whittingham is correct that at the start of cycling the cell voltage is too high to correspond to intercalation. However, if subsequent cycles presented by Broadhead in that same figure (Fig. 2) are subjected to the same test, we see that later cycles are within the voltage range of lithium intercalation in $NbSe_2$.[20] This decrease in voltage on cycling occurs quite rapidly.[21] Figure 6 in ftn.[19] reproduced here as Fig. 3, more clearly fits our reference of two plateaus for a thin film cell. The initial portion of the 50th charge and the latter portion of that discharge clearly occur in the range of lithium intercalation. The discharge portion may have a higher capacity than the charge since iodine in the electrolyte may remove lithium from Li_xNbSe_2 in an "electrodeless" reaction.[22] While these data do not prove intercalation, they do not preclude such a mechanism from playing an important role. Based on the well-documented lithium intercalation in $NbSe_2$, intercalation must be the mechanism of choice.

In retrospect, it seems quite plausible that the commercial $NbSe_2$ used in the pellet cells described by Broadhead[19] was niobium-rich and/or contaminated on the surface. Iodine could be acting to clean up the $NbSe_2$. The marked difference in the pellet data, Fig. 2, (from commercial $NbSe_2$) and "thin film" data, Fig. 3, indicates important differences in these materials as might be expected from surface contamination or additional phases. No evidence has been published to substantiate intercalation or adsorption complexes of iodine with metal dichalcogenides. There is a compound of formula $NbSe_2I_2$,[23] but this is not readily related structurally to $NbSe_2$ and no evidence of its formation in this system has been presented.

ments down to low frequencies and a radiotracer technique to evaluate the exchange current.[25,26]

The first subject for discussion concerns the exploitation of the impedance measurements performed between 20 kHz and 20 Hz. From the values of the two components R_R and $1/\omega C_R$ of the faradaic impedance given in Fig. 2 of the paper under discussion, and from the value of the frequency-independent capacitive component C_L given in Fig. 3, the untreated values of the measured impedance can be restored, except for the frequency-independent resistive component R_L which is not indicated in the paper. For example, at pH 2.4 and for Ag^+ concentration = 0.033M and C_L = 105 μF/cm^2 (*i.e.*, 0.42 μF for an electrode area = $4 \cdot 10^{-3}$ cm^2), the impedance diagram $Z = R - jG$ has been reconstituted in a complex plane (see Fig. 1 of this discussion) where the R-axis origin corresponds to the unknown electrolyte resistance R_L. This resistance can be calculated from the electrolyte resistivity ρ and from the electrode radius r using Newman's relationship $R_L = \rho/4\ r$.[27] So doing with an electrolyte (a mixture of 1M KNO_3 and 1M HNO_3 with pH = 2.4) the composition of which is very similar, we measure 10.8 Ω-cm at 25°C for the resistivity and deduce $R_L = 77\Omega$. In reality the presence of a frit between the test electrode and the counterelectrode probably leads to a higher value of R_L. Consequently, it seems that the transfer resistance $R_D = 4\Omega$ is very low compared with R_L. In addition to such an R_D value, the circuit formed by R_D and C_L in parallel has a characteristic frequency close to 95 kHz. The diagram in Fig. 1 shows clearly that frequencies lower than 4140 Hz are on the outside of the range in which the impedance depends on the capacity C_L. So it appears impossible to reach C_L from impedance measurements only performed in the frequency range 4140-203 Hz corresponding to the results of Fig. 2 of the paper under discussion. That is why it would have been useful to mention the results of the measurements performed between 4140 Hz and 20 kHz where the impedance may begin to be dependent on C_L. This comment raises the following question: Is the accuracy of impedance measurements sufficient, and is the confidence interval on the computer-fitted values of R_L and C_L narrow enough to obtain a meaningful value for C_L and to pull a transfer resistance $R_D = 4\Omega$ out of a measured resistance higher than $R_D + R_L \sim 80\Omega$?

The second point is related to the influence of pH on the exchange current i_o. Our impedance measurements performed down to very low frequency show that the transfer $Ag^+ + e \rightleftarrows Ag$ is not the only process taking place at the interface. As a matter of fact, in Fig. 2 (from Fig. 7 in ftn.[26]) a capacitive loop between 1 kHz and 0.003 Hz can be seen which does not correspond to the electron transfer and which precludes obtaining the transfer resistance R_D. This loop, which cannot be explained in terms of surface diffusion, strongly depends on the anions' adsorption. The study of such impedance diagrams, corroborated by the exchange current values obtained from our radiotracer measurements, has led us to conclude that the adsorption of OH^- ions blocks the electrode. There seems to be a discrepancy between this result and the conclusions given in the paper under discussion which were deduced from R_D values leading to a diminishing exchange current when pH decreases. Can you provide direct evaluations of the exchange current, for example obtained by a radiotracer technique, confirming that this exchange current is an increasing function of pH?

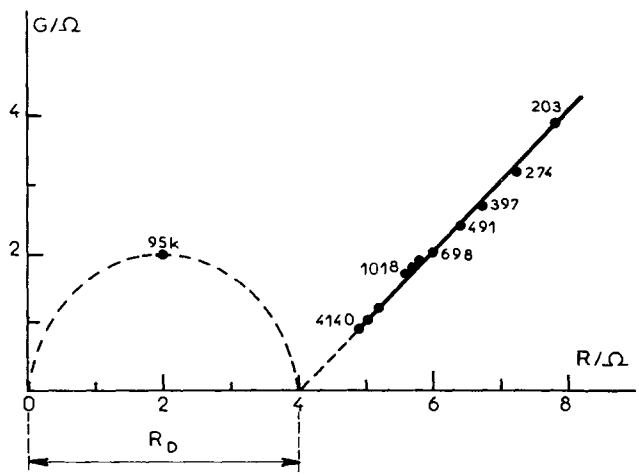

Fig. 1. Impedance diagram $Z = R - jG$ reconstituted from the volues of R_R and $1/\omega C_R$ given in Fig. 2 (Ag^+ = 0.033M) of the paper under discussion and with C_L = 105 μF/cm^2. The frequencies are indicated in Hz.

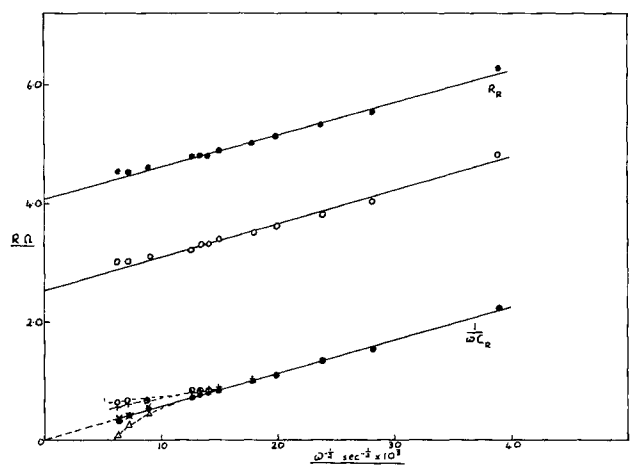

Fig. 3. R_R and $1/\omega C_R$ *vs.* $\omega^{-1/2}$ plots: ●, x, best fit plots for C_L and R_E; +, △, plots where best fit R_E constant C_L varied; ○, plot where best fit C_L constant R_E varied.

pedance plots vary as C_L and R_E are varied for a randomly selected data set. It is quite obvious which set of values gives the best fit of the data. It is of interest to note, as Wiart *et al.* point out, that at lower frequencies the data are very insensitive to changes in C_L and R_E and incidently are also less sensitive to C_L than they are to R_E. In addition, the many separate R_D values for each $[Ag^+]$ concentration and pH were calculated using values of C_L and R_E which were obtained without prejudice as the computer was told to search for the values of C_L and R_E over a wide range of values to give the best fit for each data set. Thus, in answer to the first question, we believe that the values of C_L and R_D obtained are valid.

The different conclusions reached in our respective papers on the role of $[H_3O^+]$ and $[OH^-]$ in the Ag^+-Ag reaction is more difficult to resolve. There are, however, a number of points which should be raised:

1. The pH range of our results lie between the pH ranges where Wiart *et al.* indicate a transition for $[OH^-]$ inhibition and its absence.

2. The value of our exchange reaction is much larger than reported elsewhere and we attribute this to our stringent purification procedures.

3. Radiotracer studies are an interesting method of investigating electrode reactions. However, the conclusion that the electrode surface is blocked does not distinguish between the electrode surface blocked by pretreatment or after immersion in the solution. The use of chromic acid in this electrode preparation is disturbing as we have found this material to affect electrode reactions adversely (ftn.[26]). Also, it is not clear to us what meaningful information one can obtain from scanning electron microscope studies as to the state of the electrode surface in solution (ftn.[26]).

4. While $[OH^-]$ may block the electrode surface, its kinetic dependence may not be a simple function of $[OH^-]$ but could be more complex, *e.g.*, $1/[OH^-]$. This would of course masquerade as a linear dependence on $[H_3O^+]$.

5. It is not clear whether in our study we are looking at the same reaction as Wiart *et al.* The impedance method used in both investigations is a perturbation technique; however, the time scale where Wiart *et al.* find $[OH^-]$ inhibition is at least 100 fold slower than our measurements. It may well be, therefore, that we are both looking at different kinetic steps of the overall process.

In conclusion, we believe that our results and those of Wiart *et al.* may not be as contradictory as they first appear. However, it is obvious that this system still needs extensive study, especially in regard to effects of electrode pretreatment.

Stability of MOSFET Devices with Phosphorus-Doped Oxide as Gate Dielectric

P. K. Chaudhari,* R. A. Michaud,* and R. M. Quinn
IBM Corporation, Poughkeepsie, New York 12602

ABSTRACT

An experimental technique of phosphorus doping into oxide is described. Evaluation of the effectiveness of these films is made by studying bias, temperature, and time dependence of the threshold voltage stability of MOSFET devices fabricated using this phosphorus-doped oxide as gate dielectric. Experimental data is analyzed in the light of two mechanisms known to exist in such phosphosilicate glass (PSG) layers and is shown to be in good agreement with them. It is shown that the threshold voltage stability can be maintained to within 0.03V under device operating conditions with realistic contamination levels (generally $<5 \times 10^{10}$ cm^{-2}). Results also indicate that the polarizability obeys $1/(T - T_c)$ with $T_c = 330$°K.

In the beginning of the IGFET technology, one of the more formidable obstacles blocking the development of practical MOS transistors was the migration of charge within the gate insulator under conditions of high electric field and temperature. A thin phosphosilicate glass (PSG) film on top of a thermally grown SiO_2 layer resulted in improved device behavior (1). PSG film containing approximately 4 mole percent (m/o) P_2O_5 and of the order of 125Å thick has been found to be very effective in blocking Na^+ ion contaminations as high as 10^{12} cm^{-2} (2). However, a drawback of utilizing PSG films for stabilization is that they are polarizable and can therefore contribute to the shift in the threshold voltage of the device (3). Another drawback is that the technological trend towards higher densities and micropower operation points to the necessity of thinner insulators in the gate area of an IGFET device. Since it is very difficult to produce sodium-free SiO_2 films in device production, and in view of the above demands, an experimental technique of phosphorus doping into SiO_2 films during thermal oxidation is described here. The effectiveness of these films is evaluated by studying bias, temperature, and time dependence of polarizing effects in FET devices, and by performing threshold voltage measurements. A two-mechanism model for PSG polarization instability is briefly reviewed here (4). The experimental results of phosphorus-doped oxide gate IGFET's are then analyzed in the context of these two mechanisms. Consistent with the data, the temperature dependence of the polarizability χ is also established and is discussed in the Appendix.

Experimental Details

Preparation of the oxide layer.—The silicon dioxide was grown onto the p-type 2 Ωcm silicon substrates utilizing an HCl-cleaned dry oxidation process. The oxidation temperature was 1050°C. Phosphorus was incorporated into the silicon dioxide films during the thermal oxidation process. At first pure oxygen is introduced; approximately 80% of the desired thickness of the oxide layer is grown, followed by a second growth utilizing dry oxygen and 1-2% volume of PH_3 to bring the total oxide thickness to its final value. This procedure prevents the diffusion of phosphorus into the silicon substrate. The films are annealed in nitrogen at 1050°C for 15 min. This is the final high temperature anneal, and it determines the value of the insulator charge and fast surface state density, both of which strongly affect the device threshold voltage. The oxidation rate is not affected by the addition of PH_3, but is similar to that in the ordinary thermal oxidation. Step etching techniques characterize the phosphorus to be uniformly distributed throughout the film and observed to be similar in composition to a conventional phosphosilicate glass, with a concentration of about 1.5 mole percent and a thickness of about 50Å. The dielectric permittivity is nearly constant.

Device fabrication.—A number of experimental MOSFET devices were fabricated using p-type 2 Ωcm silicon wafers. First source and drain regions were formed. Phosphorus-doped oxide was then grown immediately after cleaning as described above. Aluminum was used as the gate metal. After aluminum evaporation, devices were treated with forming gas anneal at 450°C for 15 min. Conventional photolithography was used throughout the fabrication. Mobile ion contamination checked by the high temperature quasistatic technique (5) using a control wafer was found to be consistently less than 5×10^{10} cm^{-2}. Devices thus fabricated had a threshold voltage range of approximately 1V.

Measurements.—The aging experiments were performed in the following manner. Discrete IGFET's were stressed in air at different temperatures with varying gate bias values applied with respect to the commonly connected substrate, source, and drain. After a given period at the elevated temperature, the devices were cooled to room temperature with the bias applied. Measurements were made of drain junction leakage, gate-to-substrate leakage, and drain current at a drain voltage of +10V. The MOSFET device threshold voltage was calculated by a least squares fit to the linear portion of the curve of the square root of the drain current as a function of gate voltage.

* Electrochemical Society Active Member.
Key words: phosphorus-doped oxide gate dielectric, polarization, threshold voltage stability.

A data listing was developed showing drain junction leakage current, gate leakage current, and threshold voltage shift (ΔV_{th}) from the initial value on each device throughout each experiment. The parameter that exhibited a consistent long-term drift problem was the threshold voltage of the device. The long-term changes observed in substrate leakage and drain junction leakage were negligible. The results presented in the next section will deal with time dependence of the threshold voltage shift. The values are averages obtained from 20-40 devices.

Theory

Phosphosilicate glass films grown on thermally oxidized silicon can be polarized by an electric field. The PSG polarization has two components which may be distinguished by determining the time response of the total polarization as a function of temperature (4). The pertinent features of this model are briefly reviewed here and will be used to verify the experimental characteristics of phosphorus-doped oxide gate IGFET devices.

Application of an electric field across a metal/PSG-SiO_2/Si structure will cause polarization of the glass layer (3). Under a stressing voltage V_G, this polarization will saturate while changing the threshold voltage V_{th} of the FET device by the amount

$$\Delta V_{th} = -\frac{\chi x_g}{\epsilon_g x_o} V_G \quad (\text{for } x_g << x_o) \quad \text{and} \quad (\chi << x_g) \qquad [1]$$

Here χ is the polarizability of the medium, x_g the glass thickness, ϵ_g is the dielectric constant of the glass, and x_o is the thickness of the oxide.

When χ becomes very large, the threshold shift saturates according to

$$\Delta V_{th}^{SAT} = -\frac{\epsilon_o x_g}{\epsilon_g x_o} V_G \qquad [2]$$

Both cases have been observed for PSG films. The first polarization component saturates relatively rapidly. A larger but much slower polarization process begins to occur at a significant rate above about 100°C. A very large effective value of χ characterizes this process, and its saturation value follows (2).

Experimental Results and Discussion

Figure 1 shows the threshold voltage shift *vs.* stress time with the field as the parameter plotted on a linear scale. Similar data, but with temperature as a parameter, is also shown in Fig. 2. It is clear from both figures that the instability observed is in general qualitative agreement with the model described above. That is, there is an initial component which saturates relatively rapidly (in 10^3 sec) followed by a larger but much slower polarization process which begins to occur at a significant rate above 100°C, eventually approaching a saturation value ΔV_{th}^{SAT} (see Fig. 2).

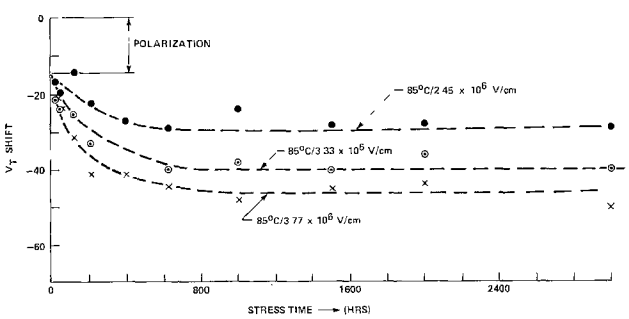

Fig. 1. Threshold voltage shift as a function of time of phosphorus-doped SiO_2 IGFET's.

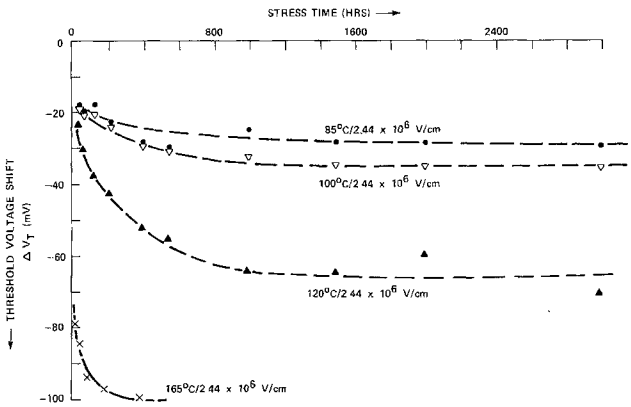

Fig. 2. Threshold voltage shift as a function of time of phosphorus-doped SiO_2 IGFET's.

The threshold shift data of these phosphorus-doped SiO_2 gate IGFET's will therefore be quantitatively analyzed in the context of the above model.

Fast polarization.—In order to obtain ΔV_{th}^{SAT} for the low temperature, fast polarization process, structures were stressed at 2.44×10^6 V/cm and at 165°C for several minutes. The value of the saturated shift ΔV_{th}^{SAT} thus obtained when substituted in Eq. [1] yielded the PSG glass thickness of ~60Å. In this evaluation, ϵ_g was taken as 4 and the polarizability $\chi = 0.05$ (4). Step etching techniques characterize the phosphorus-doped gate oxide in the present study to be similar in composition to a conventional phosphosilicate glass with a concentration of <1.5 m/o and a thickness of ~50Å. Extremely small values of polarization shift also support such a small concentration of P_2O_5. Furthermore, even though $\Delta V_{th}^{SAT} \sim V_G$, its magnitude was found to be $<<V_G$ that is also consistent with Eq. [1]. These experimental results conform to the data of Fig. 1 and 2 as analyzed above. Thus the fast polarization instability observed in the phosphorus-doped SiO_2 gate IGFET's studied here fits the oxygen ion transfer model as described for PSG-SiO_2 IGFET devices (4).

Slow polarization.—From Fig. 2 it is clear that a larger but much slower polarization process begins to occur at a significant rate above 100°C. The amount of the shift ΔV_{th} increases with the length of time the bias is applied, and its saturation value follows Eq. [2]. ΔV_{th}^{SAT} values obtained from Fig. 2 plotted on a linear scale in Fig. 3 as a function of polarizing V_G do indeed agree well with Eq. [2]. Here again the saturation value is simply proportional to V_G, and does not reach a value of V_G as predicted by Eq. [2], *e.g.*, with $x_g = 50$Å, $x_o = 450$Å, and $K_o = K_g = 4$ yields, $\Delta V_{th}^{SAT} = 1.22$V for $V_G = 11$V as against an observed value of ~25 mV (see Fig. 1). This discrepancy is due to the fact that the formula [2] is valid for large values of dipole concentration N (6). For very small values of N (10^{16} cm^{-3}) the shift V_{th}^{SAT} is found to be (6)

$$\Delta V_{th}^{SAT} = \frac{N q x_g^2}{\epsilon_o \epsilon_g} \qquad [2']$$

where N will be a function of bias. The data of Fig. 1 and 3 do conform to Eq. [2'] and further support the low concentration of P_2O_5 content as found here. Thus the slow polarization phenomenon is caused by the drifting of oxygen ions over many atomic distances, as Eq. [2] is based on the long-range ion drifting (4). The presence of such negatively charged nonbridging oxygen ions may also provide a trapping site for otherwise mobile Na^+ impurity ions, thereby accounting for the stabilizing effect of the phosphorus-doped oxide layer. However on a longer time scale,

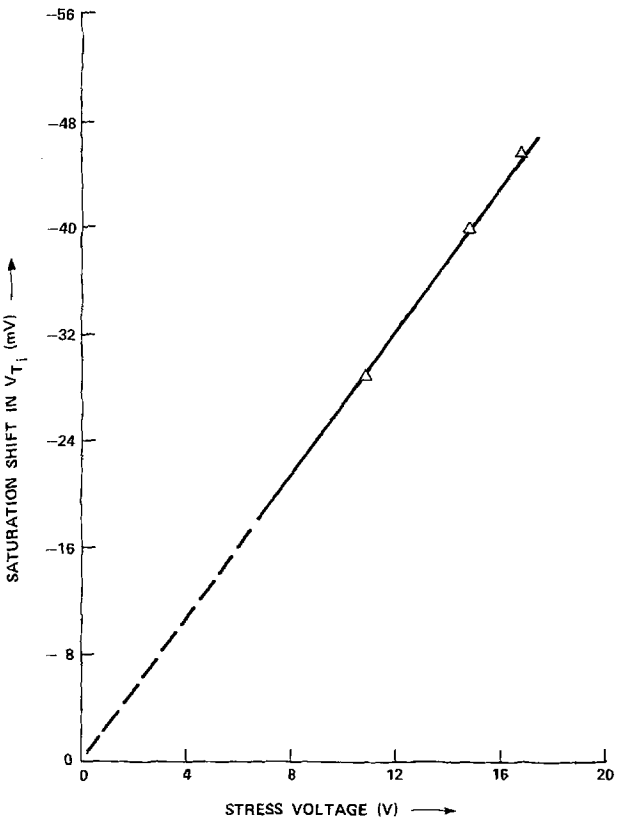

Fig. 3. Saturation shift in $V_{T_i}^{SAT}$ vs. stress voltage at 85°C.

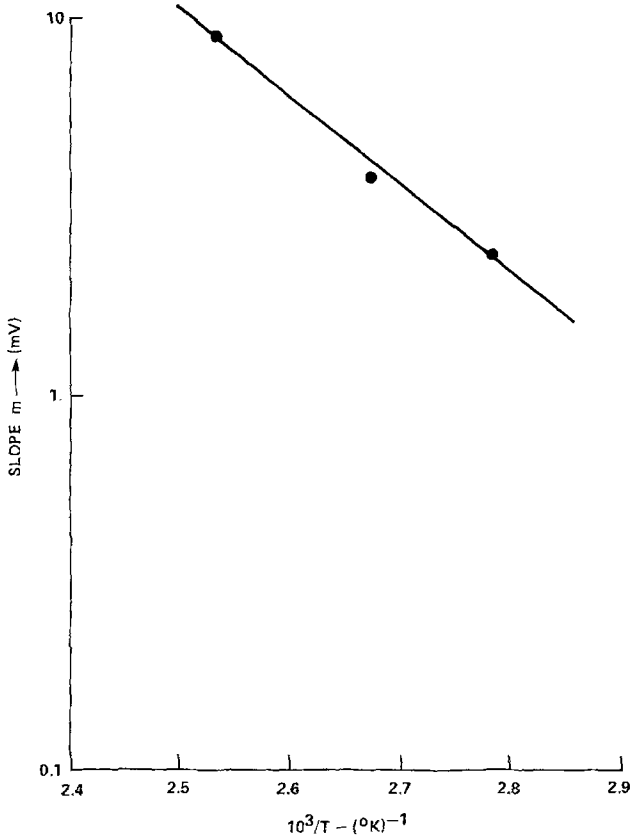

Fig. 4. Dependence of slope $m = d(\Delta V_T)/d(\log t)$ on temperature.

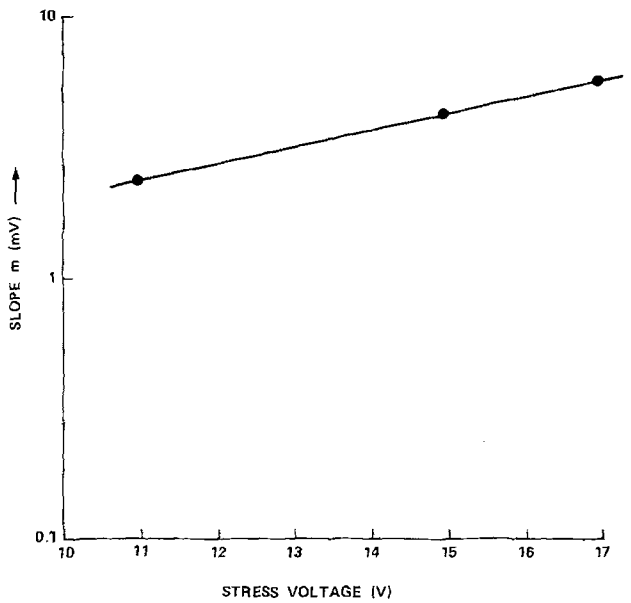

Fig. 5. Dependence of slope $m = d(\Delta V_T)/d(\log t)$ on stress at 85°C.

mobile ion drift such as Na^+ could also cause such a behavior as described by Eq. [2'] (2). In order to differentiate these similar phenomena some information might be gained if the SiO_2 thickness was varied systematically, with a constant m/o PH_3 in conjunction with negative field stressing. Now from Fig. 2 it is also seen that the rate at which saturation is approached is strongly dependent on temperature. This temperature dependence is further shown in Fig. 4, where the slopes m of the curves of Fig. 2 are plotted as a function of the inverse of temperature. Using this data, the temperature dependence of the polarizability is also discussed in the Appendix.

Reliability projections of the threshold voltage stability of these IGFET devices can now be estimated. Lumping the fast polarization contribution in the threshold voltage shift ΔV_{th} at $t = 1$ hr, the total threshold voltage shift for $t \geq 1$ hr may then be expressed by the empirical equation

$$\Delta V_{th} = \Delta V_{th}(1\,\text{hr}) + m \log t \qquad [3]$$

where m is a function of temperature and voltage and is expressed as (see Fig. 4 and 5)

$$m = \exp\left(-\frac{\Phi}{KT} + \beta V_G\right) \qquad [4]$$

with $\Phi = 0.495$ eV.

These results allow the stability of the IGFET devices to be estimated. From the data of Fig. 1, the threshold shift at 2.44×10^6 V/cm for operating conditions under 85°C is $\leq$30 mV for times as long as 10 years. It is also evident that the low temperature polarization results in a maximum of only 0.015V threshold shift. Thus the data of Fig. 1 indicate that the phosphorus-doped oxide films fabricated in this study are similar in composition to 1.5 m/o P_2O_5, 50Å (approximately) to conventional PSG-SiO_2 films and will furnish protection against Na^+ contamination levels in the low 10^{11} ions cm^{-2} region for realizing ΔV_{th} of only 30 mV for 450Å doped gate oxide under a field of 2.44×10^6 V/cm and at 85°C for the lifetime of the device. For each practical case, however, a proper amount of phosphorus doping must be individually selected for its Na^+ gettering capabilities and it must still maintain the negligible polarization behavior.

Conclusions

The experimental technique of phosphorus doping into silicon dioxide films during thermal oxidation is presented. Threshold instability of IGFET's fabricated

using this phosphorus-doped oxide as gate dielectric was analyzed and found to be consistent with the existing two polarization process models. The fast polarization component is found to be ≤0.015V, while the slow polarization component data indicate that 1-2 m/o PH_3-doped SiO_2 will effectively stabilize the threshold voltage of IGFET's under operating conditions of temperature and field. Temperature behavior of the saturation values of the threshold voltage shift has led to the polarizability dependence on temperature.

APPENDIX

Temperature Dependence of Polarizability

When the polarizability χ becomes very large compared to $\epsilon_g{}^u$ and ϵ_o (due to long-range ion drifting), the threshold voltage shift $\Delta V_{th}{}^{SAT}$ will saturate according to (4)

$$\Delta V_{th}{}^{SAT} = -\frac{\epsilon_o x_g}{\epsilon_g{}^u x_o} V_G \qquad [A\text{-}1]$$

The unrelaxed value of the high frequency dielectric constant $\epsilon_g{}^u$ is defined in terms of the relaxation strength Δ_ϵ by (7)

$$\epsilon_g{}^u = \chi/\Delta_\epsilon \qquad [A\text{-}2]$$

Combining [A-1] and [A-2], we get

$$\chi = -\epsilon_o \chi_g \Delta_\epsilon / \chi_o (\Delta V_{th}{}^{SAT}/V_G) \qquad [A\text{-}3]$$

Now values of $\Delta V_{th}{}^{SAT}$ obtained from the data of Fig. 2 are plotted in Fig. 6 as a function of the inverse of temperature. Consistent with the behavior observed in Fig. 6, $\Delta V_{th}{}^{SAT}$ may be expressed by the empirical relationship

$$\Delta V_{th}{}^{SAT}/V_G = C - \frac{T_c}{T} \qquad [A\text{-}4]$$

The data of Fig. 6 plotted on a compressed temperature scale as shown in Fig. 7 yield the value of $C = 1$. Thus with $\Delta_\epsilon = B/T$ (4) and [A-4], the temperature dependence of polarizability can be expressed from [A-3] as

$$\chi = \frac{\epsilon_o \chi_g B}{\chi_o (T - T_c)} \sim 1/T - T_c,\ T_c = 330°K \qquad [A\text{-}5]$$

Such a behavior was speculated by Eldridge, Laibowitz, and Balk (4).

LIST OF SYMBOLS

B	a constant in reciprocal temperature
C	dimensionless constant
m	slope defined by $d(\Delta V_{th})/d(\log t)$
t	time in hours
T	temperature in °K
T_c	a constant in units of temperature
V_G	gate voltage in volts
ΔV_{th}	threshold voltage shift in volts
$\Delta V_{th}{}^{SAT}$	saturation value of threshold voltage in volts
χ	polarizability of the medium
x_g	PSG thickness in Å
x_o	oxide thickness in Å
β	a constant in units of (volts)$^{-1}$
ϵ_g	dielectric constant of PSG
ϵ_o	dielectric constant of oxide
$\epsilon_g{}^u$	unrelaxed value of the high frequency dielectric constant of PSG
Δ_ϵ	relaxation strength of the medium
Φ	activation energy in eV

The Effect of Gamma Irradiation on the Low Temperature Properties of Amphoterically Si-Doped GaAs LED's

C. E. Barnes

Sandia Laboratories, Albuquerque, New Mexico 87115

ABSTRACT

The effects of gamma irradiation on the light intensity, total current, spectral characteristics, and radiative decay time as a function of applied voltage at 76°K have been studied in amphoterically Si-doped GaAs light-emitting diodes (LED's). At low voltages, both the total current, I, and radiative current are due to space charge recombination with the result that, at constant voltage, I increases with gamma dose, Φ, while the light intensity, L, remains constant. At higher voltages, where the radiative current is due to recombination in the neutral p-region, L decreases sharply with Φ at constant voltage. This rapid decrease is due, in part, to the presence of space-charge limited current (SCLC) flow which also leads to a decrease in I with Φ at constant high voltage. Spectral measurements show that the emission peak energy is proportional to junction voltage at low currents suggesting radiative tunneling of carriers in deep tail states. In accordance with the "wavy band" model for these diodes, tail states are also responsible for the observed inverse dependence of radiative decay time on diode current and emitted photon energy. The long lifetimes in the localized deep tail states lead to a radiation damage effect contrary to that observed for diffusion length-associated lifetimes; that is, the longest lifetimes are least affected by gamma irradiation.

Amphoterically Si-doped GaAs light-emitting diodes (LED's) have become commercially important devices because they possess higher efficiencies than many conventional Zn-diffused LED's. Among the wide variety of optoelectronic applications in which GaAs:Si LED's can be used are those in which the devices may be exposed to nuclear radiation. Therefore, it is important to know how the operating characteristics of these LED's will change following exposure to radiation. In this paper, it is shown that the unique properties of these devices at low temperatures significantly affect the GaAs:Si LED's response to gamma irradiation.

Previous studies in our laboratory (1, 2) and elsewhere (3, 4) have shown that the GaAs:Si LED's are quite sensitive to irradiation, primarily because of their relatively long preirradiation electron lifetimes. Our examination (2) of the effects of gamma irradiation on the room temperature light output of these devices showed that additional degradation results from the presence of radiative space-charge limited current (SCLC) flow at high currents. In this paper, we show that results taken at 76°K confirm this high current behavior and, also, support the "wavy band" model used to explain the LED properties at low currents.

Experimental Procedure

The amphoterically Si-doped LED's used in this study were obtained from Texas Instruments Incorporated. They are designated as TIL-26 emitters and constitute the emitter portion of the TIL-107 optical isolator studied previously (3). The TIL-26 consists of a single epitaxial layer in which the n- and p-type regions are grown by varying the growth temperature over a wide range. The substrate is n-type GaAs doped with approximately 10^{17} Si/cm^3. The device is mounted with the n-type side up and has a junction area of $A = 1.45 \times 10^{-3}$ cm^2.

The light output and total current of the GaAs:Si LED's were measured as a function of voltage and gamma dose. At low currents, the LED's were driven in the d-c mode, while pulsed techniques were used at high currents to avoid heating problems and bias-induced annealing. In both cases, phase sensitive detection was used to process the signal from a cooled S-1 response photomultiplier. For spectral measurements, a Spex 1 meter monochromator was used and the results were corrected for the wavelength response of the monochromator-photomultiplier combination. Radiative time decay measurements were made with a Si pin photodiode having a response time of a few nanoseconds. All measurements were made in a cryostat with the LED held at 76°K by immersing the bottom of the LED holder in liquid nitrogen.

Irradiations were performed at room temperature in the Sandia Co^{60} Gamma Irradiation Facility (GIF). Doses were determined with established dose mapping of the GIF cell performed previously with cobalt glass and 4-chlorostyrene dosimeters. All irradiations were performed with devices in the passive, open-circuit state.

Experimental Results

Typical current-voltage (I-V) curves at 76°K are shown in Fig. 1 for a GaAs:Si LED prior to irradiation and following successive doses to 1×10^8 rad. At lower voltages, where the applied voltage, V, equals the junction voltage, V_j, the slope of the I-V curves is given by $m = 1.7$ in exp $[qV/mkT]$ indicating that the total current flow is dominated by space-charge recombination (SCR) at low voltages. This result is often observed in GaAs LED's (1, 3, 5) as is the irradiation-induced increase in SCR current at constant voltage (6), shown in Fig. 1. The increase in current is a result of the introduction of additional nonradiative recombination centers by the irradiation.

At large voltages, the opposite is observed; that is, gamma irradiation causes a decrease in I at constant V. This decrease is approximately a factor of 10 smaller than the increase in I at small V. The gamma-induced decrease in current occurs over a voltage range where there is significant deviation from the junction-controlled exponential behavior observed at low voltages. It will be shown that the existence of a voltage drop across the neutral region leads to the irradiation-induced decrease in I.

Light intensity-voltage (L-V) curves at 76°K are shown in Fig. 2 for the same diode used to obtain the I-V curves in Fig. 1. At low voltages, L varies exponentially with V with a slope given by $m = 1.4$,

Key words: defects, LED's, radiation, semiconductors, electroluminescence, optoelectronics.

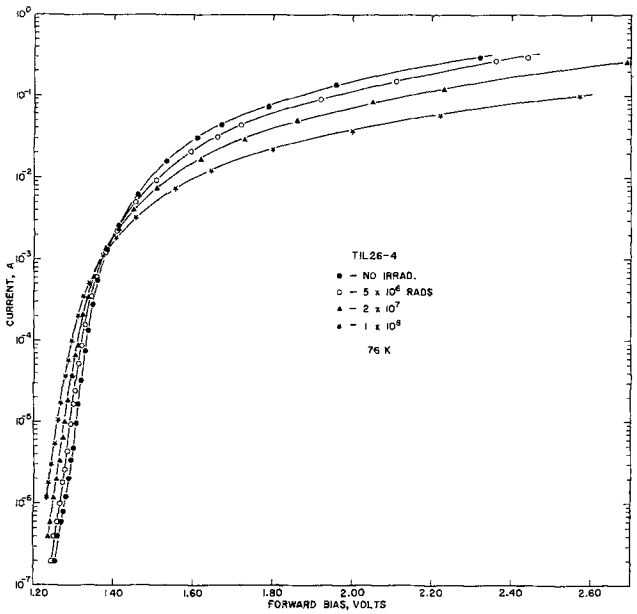

Fig. 1. Typical total current-voltage characteristics for an amphoterically Si-doped GaAs LED at 76°K. Note that gamma irradiation increases *I* at low voltage, but decreases *I* at high voltage.

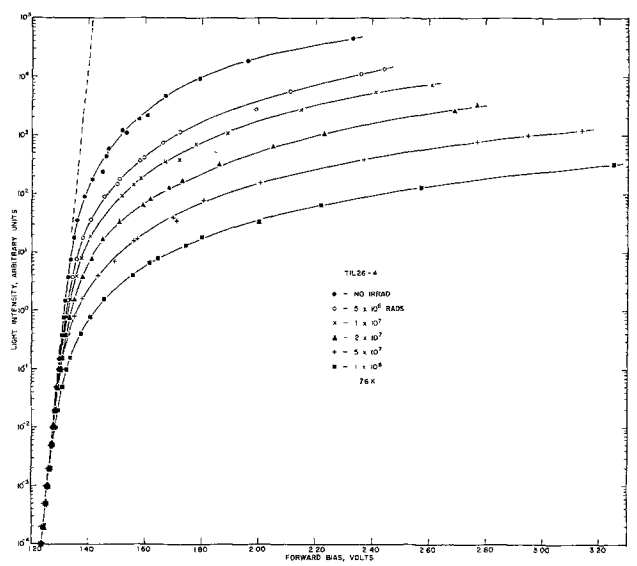

Fig. 2. Light output, *L*, vs. applied voltage for a typical GaAs:Si LED at 76°K. While L is insensitive to irradiation at low voltages, the gamma-induced degradation at large voltage is severe. The dashed line is used to determine junction voltage, V_J, at large applied bias.

indicating that the light output is also due to recombination within the space-charge region, a common observation in GaAs LED's at low temperatures (6). The existence of a radiative SCR current is further confirmed by the lack of any significant gamma-induced change in *L* at constant low voltage. This follows from the fact that, for a particular recombination process, the recombination rate in the space-charge region depends on the quasi-Fermi levels which, in turn, are determined by the majority-carrier concentrations. If the gamma dose is below that required for significant carrier removal, and if the defect centers are nonradiative recombination centers, then the total space-charge current due to recombination at all centers should increase, as shown in Fig. 1, but the radiative current should be unaffected following irradiation. In agreement with this reasoning, capacitance-reverse-bias measurements performed at 300°K demonstrated that the carrier-concentration profile did not change following irradiation (2).

As in the case of the *I-V* data, the light intensity-voltage characteristic is affected quite differently at large voltages. In contrast with the lack of any change at low voltages, the light intensity decreases strongly for constant voltages large enough to cause a deviation from the purely exponential junction-controlled SCR behavior observed at low voltages. The onset of a gamma-induced reduction in *L* indicates that the light output is the result of radiative recombination in the neutral p-region due to radiative diffusion currents near the junction and other radiative current flow mechanisms occurring across the entire p-region. As we will show, these latter processes account for a significant portion of the reduction in *L* at large voltages.

Spectral measurements indicate that the electroluminescence spectrum of the GaAs:Si LED's is dominated by a single broad band which does not change shape with irradiation. However, as shown in Fig. 3, the peak photon energy is a function of both applied voltage and gamma dose. The proportionality between peak energy and voltage suggests that radiative tunneling is occurring as observed previously for GaAs LED's at low temperatures (6-9). For this process, "shifting peak" spectra are seen because the tunneling probability is highest for carriers near their respective quasi-Fermi levels, the separation of which is determined by the junction voltage. Consequently, the peak photon energy shifts to higher energy with increasing junction bias. This result, in combination with the results shown in Fig. 2, indicates that the light output at 76°K and low voltages is due to carriers tunneling into the space-charge region with subsequent radiative recombination in that region.

At large, constant applied bias Fig. 3 shows that the peak energy decreases significantly with gamma dose. It should be emphasized that, for radiative tunneling, the peak energy is proportional to the junction voltage, V_J, rather than the total applied voltage. As will be shown later, much of the apparent reduction in peak energy with increasing dose, shown in Fig. 3, can be accounted for by the fact that the junction voltage changes with dose at constant, large applied voltage.

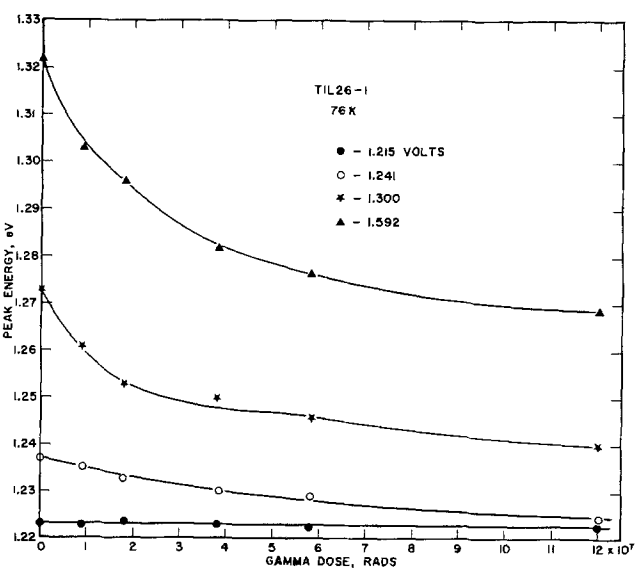

Fig. 3. Peak photon energy from spectral measurements as a function of applied voltage and gamma dose for a typical GaAs:Si LED at 76°K.

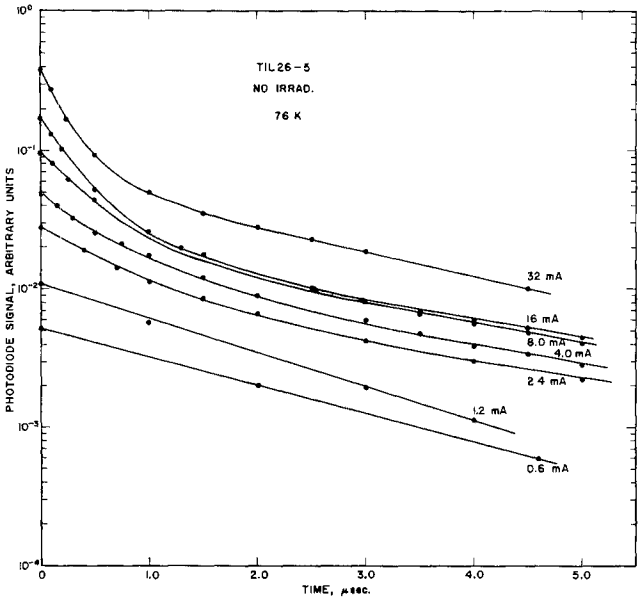

Fig. 4. Decay of the light output from a GaAs:Si LED following the application of a 10 μsec wide pulse at several current levels prior to irradiation. Note that the initial decay is more rapid at larger currents.

Turning our attention to the radiative time decay data, Fig. 4 illustrates the variation of the LED output with time following the application of a 10 μsec wide pulse for a variety of LED pulse current levels. At large currents, there is an initial rapid decay of light output followed by a long tail lasting several microseconds. With decreasing current, the initial decay becomes slower until at about 1 mA, the decay time can be approximately described by a single exponential within the time interval shown in Fig. 4. It is also interesting to note that at long times the decay curves are all approximately parallel, independent of LED pulse current level. These curves are to be contrasted with GaAs LED's containing Zn-diffused regions in which the radiative rise and decay times are typically tens of nanoseconds.

The effect of gamma irradiation on the radiative decay for a constant, relatively large pulse current of 16 mA is shown in Fig. 5. As irradiation proceeds,

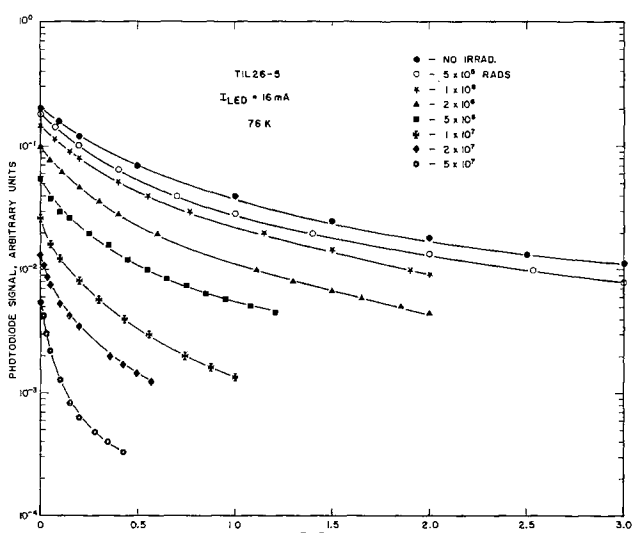

Fig. 5. Light output decay after application of a 16 mA pulse to a GaAs:Si LED at 76°K as a function of gamma dose. The initial decay becomes more rapid with Φ, but the long-time portions of the curves tend to remain parallel.

the initial radiative decay becomes more rapid, but the curves at long times are approximately parallel so that the slow decay is relatively unaffected by irradiation. This is an important result because it is just the opposite of what one would expect for the usual effect of radiation on minority carrier lifetime; that is, the longer the minority carrier lifetime, the more sensitive it is to irradiation. However, as we will show, the results in Fig. 5 are satisfactorily explained by the model developed for the amphoterically Si-doped GaAs LED's.

Device Theory

Prior to further analysis of the effects of gamma irradiation on the low temperature properties of GaAs:Si LED's, we will provide a brief description of the theory used to explain the properties of these devices. In agreement with the data shown in Fig. 4, previous authors (10-13) have observed unusually long radiative rise and decay times which were inversely proportional to LED current and emitted photon energy. In addition, it has been found that the peak photon energy can be varied by changing the Si doping level (14). A typical commercial device has a room temperature peak wavelength of 930-940 nm, 30-40 nm above that for a Zn-diffused LED. Further, at large currents, light emission from the entire p-region has been observed (10, 12). Explanation of these properties is based on a model developed through studies of photoluminescence in n- and p-type bulk GaAs:Si material (15-18) and of the amphoteric LED's themselves (10-14). During the growth of the epitaxial p-layer of the device, a lower growth temperature is used so that Si will substitute for As and act as an acceptor rather than for Ga which produces the donor activity in the n-layer. However, even at lower temperature, Si continues to substitute for Ga to a certain degree so that the end result is a compensated p-region containing 10^{18}-10^{19} Si atoms/cm^3 but only 10^{16}-10^{17} holes/cm^3 (10). The high concentration of Si leads to a merging of the Si shallow donor and acceptor states with conduction and valence bands resulting in the creation of deep band "tails." Because the Si atoms are randomly distributed, there are localized fluctuations in the potential resulting in perturbations of the energy band tails. Since the deepest conduction band tails occur in regions of low potential and the highest valence band states are in regions of high potential, the localized deep valence and conduction band tails are, by necessity, spatially separated from each other. In addition to the shallow donor and acceptor levels, Si introduces deeper levels, and the radiative recombination in these devices is generally thought to occur through a Si acceptor level at $E_V + 0.1$ eV (14). This level is assumed to follow the fluctuations in the valence band. This "wavy band" model has been used successfully by Byer (10, 11) and Redfield *et al.* (18) to explain the properties of amphoterically Si-doped GaAs LED's. At low currents, only the deepest tail states in the conduction and valence bands are filled. Since these states are spatially separated, recombination requires long-range tunneling which leads to long recombination times. In addition, recombination through the deepest states produces low energy photons with energies significantly less than the energy gap so that the peak photon energy is at a lower energy than in uncompensated, Zn-diffused LED's. Consequently, the recombination times are long at low photon energies. As the current is increased, the deepest tails are saturated and the electrons and holes occupy normal delocalized band states leading to vertical nontunneling recombination which is characterized by shorter recombination times and higher photon energies.

Byer (10) has used the space charge-limited current (SCLC) theory of Ashley and Milnes (19) and Lampert (20) to explain the observed wide-emitting

region at high currents. At lower currents, where the voltage drop across the p-region, $V - V_j$, first appears, one observes an Ohm's law range where the current, I, is proportional to $V - V_j$. As the current is increased, significant numbers of electrons begin to drift into the p-region resulting in the buildup of a space charge. In this range, Byer (10) observed a square law dependence, $I \propto (V - V_j)^2$, as predicted by the SCLC theory. Because the electron concentration is significant over the entire p-region, radiative recombination occurs across this whole region. In the SCLC range, Byer (10) found a sublinear dependence of the light intensity, L, on current in correspondence with the $L \propto I^{1/2}$ dependence predicted by the theory. The sublinear dependence occurs because many of the electrons reach the p-region electrode before they can recombine, resulting in a decreasing quantum efficiency as I is increased. In a later examination of GaAs:Mn LED's, Ashley (21) and Ashley *et al.* (22) showed that L can vary linearly with I and, hence, as $(V - V_j)^2$ in the SCLC range. This dependence agrees with the theory if one assumes that double injection is occurring in the p-region. In this case, the reduction in quantum efficiency due to the loss of electrons at the electrode is compensated for by hole injection.

In our previous study (2) of gamma irradiation effects on the room temperature properties of these amphoterically Si-doped GaAs LED's, the primary concern was with the rapid gamma-induced light output degradation at high currents. In agreement with previous work (10, 21, 22), a major component of the radiative current was found to be due to SCLC flow. Further, it was shown that this component degraded more rapidly with irradiation than the radiative diffusion current which dominates at low currents at room temperature. In the next section, it is shown that similar behavior occurs at 76°K.

Analysis and Discussion

We begin our analysis of the results in terms of the model outlined in the previous section by examining the effects of gamma irradiation on the radiative decay time. Figure 2 shows that the radiative current begins to deviate from an SCR current at about 1.30V indicating that electron injection into the neutral p-region is occurring above 1.30V with subsequent radiative recombination in this region. Figure 1, in turn, shows that this voltage corresponds to a current range of approximately 0.01-0.1 mA for the pre- and postirradiation I-V curves. The smallest current used in obtaining the radiative decay data shown in Fig. 4 and 5 is 0.6 mA. In particular, we are interested in analyzing the data in Fig. 5 taken at 16 mA. Therefore, it can be assumed that we are essentially dealing with radiative recombination in the neutral p-region in analyzing the radiative decay data. For the lowest currents in Fig. 4, and for long times following the 16 mA pulse in Fig. 5, only the deepest tail states are occupied and, as indicated in the previous section, the long decay time is due to the long-range tunneling required for recombination. It is important to realize that these recombination events are two-step processes. That is, in the first step, the electron is injected into the p-region and diffuses through this region for an average time given by the minority carrier lifetime associated with the diffusion length. At the end of this time, the carrier can be captured at a gamma-induced nonradiative recombination center or trapped in a spatially localized deep tail state. Here, it is assumed that the thermal equilibration time into the deepest states is very short. That is, as in a "band filling" model, the band tails essentially have their lowest states occupied first. The second step in the process is then the radiative recombination via long-range tunneling from the localized tail state. As we have pointed out, the time associated with this step can be very long.

The effect of irradiation-induced recombination centers on the time required for the first step, that is, the minority carrier lifetime, can be expressed by the equation

$$\frac{\tau_o}{\tau} = 1 + \tau_o K_\gamma \Phi \qquad [1]$$

where τ_o is the preirradiation lifetime and K_γ is the damage constant. Lifetime degradation will occur when the product of $\tau_o K_\gamma$ and Φ is significant compared to 1.0. Hence, the lifetime will begin to decrease at lower values of Φ for larger values of τ_o.

The time associated with the second step, recombination from the deep tail states, can be viewed as a localized lifetime since the deepest tail states are spatially localized. The alternative of capture of the mobile carrier at an irradiation-induced center is no longer available to the carrier once it is trapped in a localized band tail state. Therefore, irradiation should not have a strong effect on this lifetime except to possibly alter the tunneling probability if a nonradiative center is nearby.

The data in Fig. 5 conform with this model of the recombination process since the decay curves after long times tend to be parallel, suggesting that irradiation has less effect on the longer decay times which are primarily associated with carriers recombining from the deepest tail states. This can be more graphically illustrated by defining an initial lifetime, τ_i, which is given by the slope of the decay curve at time $t = 0$. In Fig. 6, τ_i is plotted as a function of pulse current and gamma dose. Note that at low currents, where τ_i is large and more nearly determined by the localized lifetime in the tail states, gamma irradiation has less of an effect, in a multiplicative sense appropriate to the ratio of (τ_o/τ) in Eq. [1], than it has at large currents where τ_i is small. At the largest currents, τ_i is determined by the diffusion length, which is associated with minority carrier lifetime since the deep states are saturated, especially at $t = 0$. We conclude, then, that while the inverse effect of irradiation on radiative decay time is unusual, it can be satisfactorily explained within the framework of the wavy-band model for highly compensated GaAs:Si LED's.

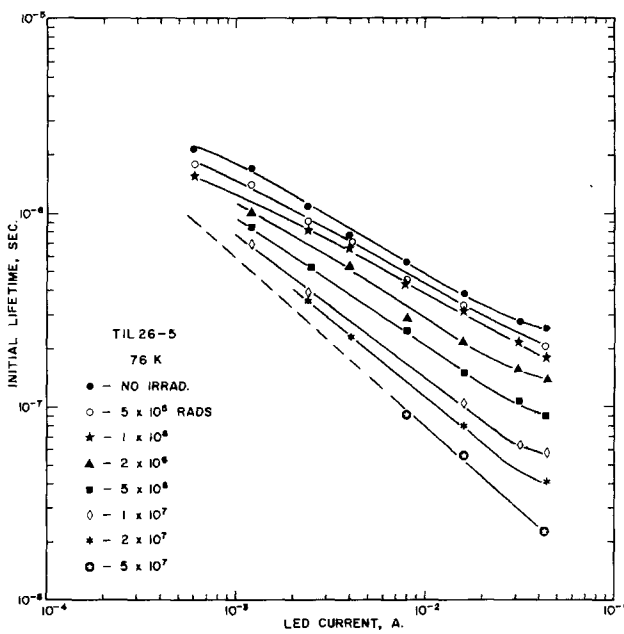

Fig. 6. Initial lifetime, calculated from the slope of the radiative decay curves at $t = 0$, *vs.* diode pulse current before and after successive gamma irradiation of a typical GaAs:Si LED. Note that gamma irradiation has a greater effect, in a multiplicative sense, on the shorter lifetimes at large currents.

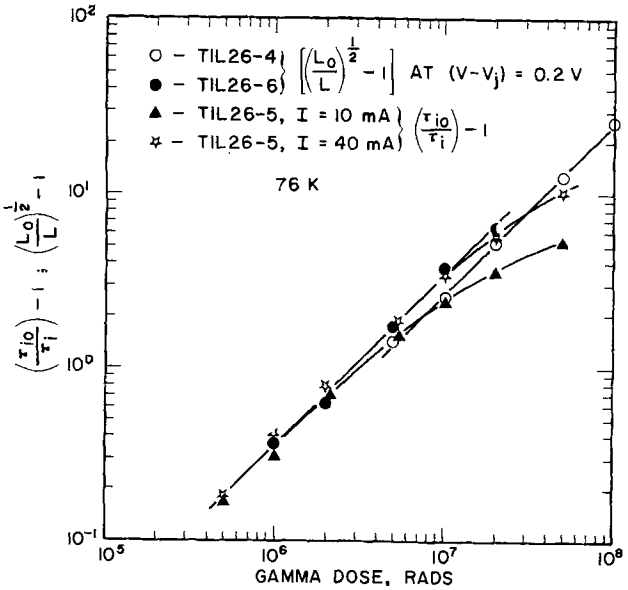

Fig. 7. Tests of Eq. [1] for the high current initial lifetime data and of Eq. [5] for the radiative SCLC component of the light output. Both types of data give approximately the same values of $\tau_0 K_\gamma$.

Since τ_i at large currents is associated with the minority carrier lifetime, one can use Eq. [1] to determine $\tau_0 K_\gamma$ from the high current data in Fig. 6. The validity of Eq. [1] is tested in Fig. 7 where $(\tau_{io}/\tau_i) - 1$ is plotted *vs.* Φ. Here, τ_{io} is the initial lifetime prior to irradiation. At $I = 40$ mA, a line with slope $= 1.0$ can be drawn through the points with deviation occurring only at the largest doses, indicating that Eq. [1] provides a satisfactory description of the lifetime degradation over most of the dose range. However, for a lower current, $I = 10$ mA, the deviation begins at a lower dose. This is to be expected since as the current is reduced and the dose is increased, the instantaneous carrier density during the current pulse is reduced so that the tail states are no longer saturated and the localized deep tail state lifetime becomes influential. The line drawn through the data gives a $\tau_0 K_\gamma$ value of 3.5×10^{-7} rad^{-1}.

Turning our attention to the light output degradation shown in Fig. 2, we wish to reemphasize the large difference in gamma effects between low and high voltages. As has been pointed out, the insensitivity to irradiation at low voltages arises from the fact that the radiative current is due to tunneling into the space-charge region and recombination there. As the voltage is increased, electrons traverse the space-charge region and are injected into the p-region. While a diffusion-limited radiative current is susceptible to degradation (2), it will be shown that the presence of radiative SCLC at high voltages is primarily responsible for the strong light output degradation in this range. To provide an indication of the importance of SCLC flow, we must study the variation of light intensity with the voltage drop across the neutral p-region, $V - V_J$, as a function of Φ. This is accomplished by extending the straight line, exponential portion of the L-V curves as shown by the dashed line in Fig. 2. One then subtracts the value of V_J, as given on the dashed line, from the applied voltage, V, at the same L. When this procedure is applied to the L-V data, the curves shown in Fig. 8 are obtained. In agreement with previous work (21, 22) and our room temperature study (2) of these diodes, a definite square law behavior is exhibited by all the curves. Using the standard equation for SCLC (19, 20)

$$I = \frac{9}{8} q \tau \mu_n \mu_p p_o A \frac{(V - V_J)^2}{l^3}, \text{ amperes} \qquad [2]$$

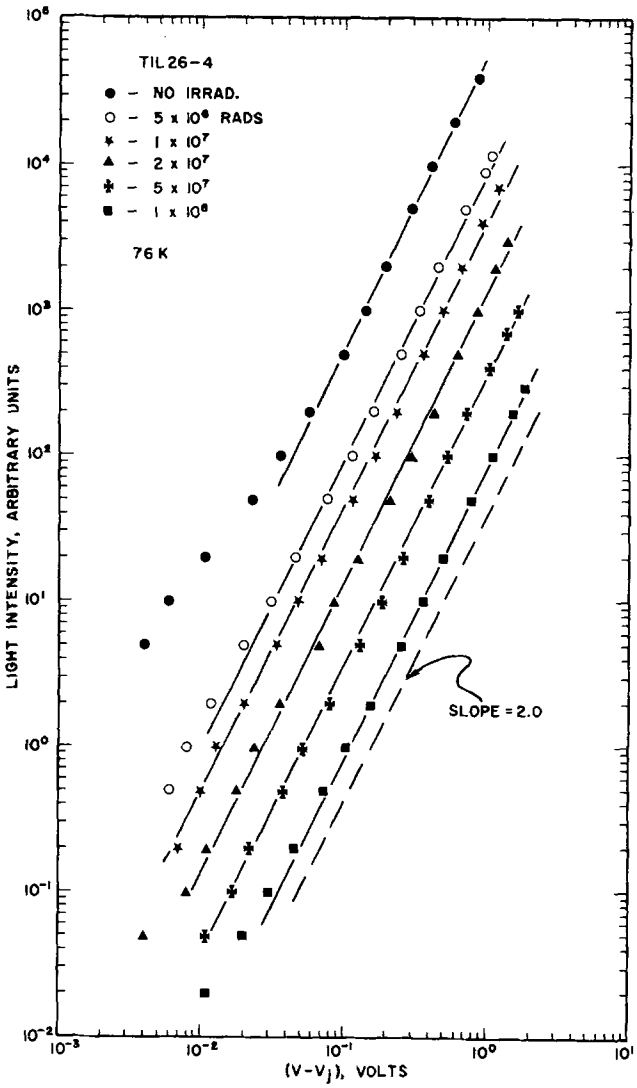

Fig. 8. Light intensity at 76°K *vs.* the voltage drop across the p-region prior to and following gamma irradiation of GaAs:Si LED. Note that all the curves exhibit square law behavior.

and the results of Ashley *et al.* (22) study of radiative double injection SCLC, it was shown, in our previous study (2), that

$$L = C_L \tau^2 (V - V_J)^2, \text{ arbitrary units} \qquad [3]$$

where

$$C_L = \frac{9}{8} C \frac{\mu_n p_o}{\tau_R l^3} (\mu_n + \mu_p), \text{ arbitrary units} \qquad [4]$$

In these equations, μ_n and μ_p are the electron and hole mobilities, respectively, p_o is the equilibrium hole density in the p-region, l is the thickness of the p-region, C_L and C are constants, and τ_R is the radiative lifetime. Equation [3] illustrates the square law variation of L with p-region voltage drop, shown in Fig. 8, and, also, the fact that L varies as the square of the electron lifetime. As noted in our earlier study (2), it is this latter dependence, relative to the linear variation of L with τ for a radiative diffusion current, that leads to the strong degradation at high voltages.

The degradation rate of L at constant $V - V_J$ is obtained by substituting Eq. [1] in Eq. [3]

$$\left(\frac{L_o}{L}\right)^{1/2} - 1 = \tau_0 K_\gamma \Phi \qquad [5]$$

Employing the data for TIL-26-4 shown in Fig. 8 and also data for LED TIL-26-6, one obtains the curves in Fig. 7 for $(V - V_J) = 0.2$V which have a slope of 1.0

indicating that Eq. [5] provides a valid fit to the data. This agreement extends over two orders of magnitude in gamma dose. The curves drawn through the points give an average value of $\tau_0 K_\gamma = 3.1 \times 10^{-7}$ rad^{-1} in good agreement with the value of 3.5×10^{-7} rad^{-1} obtained from the degradation of τ_i at large currents, also shown in Fig. 7.

The presence of SCLC flow at large voltages is also responsible for the gamma-induced decrease in total current, I, at constant high voltage shown in Fig. 1. This follows from Eq. [2] in which I is proportional to τ. This is to be contrasted with the SCR current which varies as $1/\tau$ (23), resulting in the increase in I with Φ at low voltages. A procedure similar to that used to obtain the L *vs.* $(V - V_J)$ data can be followed to obtain I as a function of $(V - V_J)$ from the results in Fig. 1. However, when this is done, one finds that $I \propto (V - V_J)^n$ where $2 > n > 1$ rather than the square law behavior shown in Fig. 8 for L. This result suggests that a significant component of the total current is due to ohmic current flow, carried by holes in the p-region, which is proportional to $(V - V_J)$. A majority carrier current component also agrees with the relatively small gamma-induced decrease in I at constant high voltage since the gamma dose is too small to cause significant majority carrier removal. At a constant voltage of 2.20V, I decreases by a factor of 4.7 after $\Phi = 1.0 \times 10^8$ rad and by a factor of 4.2 at a constant $V - V_J = 0.2$V. In contrast, L decreases by factors of 567 and 686, respectively, for the same constant values of V and $V - V_J$. In addition, at a constant low voltage of 1.26V in the SCR range, I increases by a factor of 25 after 1×10^8 rad. According to Eq. [3], L varies as τ^2 while, as we have noted, the SCR current is proportional to $1/\tau$. Therefore, assuming that the lifetime in the space-charge region is about the same as the lifetime in the p-region, the decrease in L in the SCLC range should approximately equal the square of the increase in I in the SCR range. This does appear to be the case since L decreases by a factor of 686 which is approximately the same as the square of the increase in I: $(25)^2 = 625$.

The fact that L at large voltages is dominated by radiative SCLC while the total current, I, has a significant ohmic component is not surprising since the radiative current will selectively favor an SCLC component over an ohmic current. This follows from the fact that a significant electron density must be present for there to be a significant light output. The comparison of the radiative and total currents is somewhat analogous to the frequent observation at room temperature of a radiative diffusion current in the presence of a total SCR current (1, 3, 5, 6).

We conclude the analysis of the data with a further examination of the "shifting peak" data shown in Fig. 3. The large variation in peak energy, E_p, with Φ at large constant voltage is difficult to explain because the radiative SCLC dominates at large voltages and the radiative tunneling current is relatively minor. One would expect that the sensitivity of E_p to voltage and also gamma dose would be a maximum at low voltages where radiative tunneling is the dominant radiative current mechanism. This difficulty can be resolved by noting that for radiative tunneling, E_p is proportional to V_J and not the applied voltage. We have seen that $V - V_J$ becomes significant at large voltages and so the curves in Fig. 3 are distorted by the variation of V_J with V as Φ increases. To construct a plot of E_p *vs.* V_J, we follow the same procedure for obtaining V_J for diode TIL-26-1 as was followed for TIL-26-4 in Fig. 2 and 8. The results, given in Fig. 9, show a definite linear variation of E_p with V_J, before and after irradiation, as one would expect for radiative tunneling (6-9). Note, however, that above $V_J = 1.29$-1.31V, the curves deviate from the set of parallel lines at lower voltages. Further, with respect to gamma dose, this deviation is random in both magnitude of E_p and slopes of the lines connecting the points. Comparison with Fig. 2 indicates that at $V = V_J \approx 1.30$V, the curves begin to show significant deviation from the purely exponential behavior. Therefore, at the highest voltages where radiative SCLC dominates, as one might expect, there is no significant trend in the variation of E_p with Φ. Indeed, when viewed in this more appropriate manner, the shifting peak data do not show large variations of E_p with Φ at any voltage. Over the entire range in Fig. 9, the decrease in E_p at constant V_J is less than 10 meV for a dose of 1.2×10^8 rad. This relatively minor variation agrees with the observation that the localized lifetime for long-range tunneling is not strongly affected by gamma irradiation and also with the fact that the separation of Fermi levels, which determines E_p, is relatively insensitive to Φ until majority carrier removal begins.

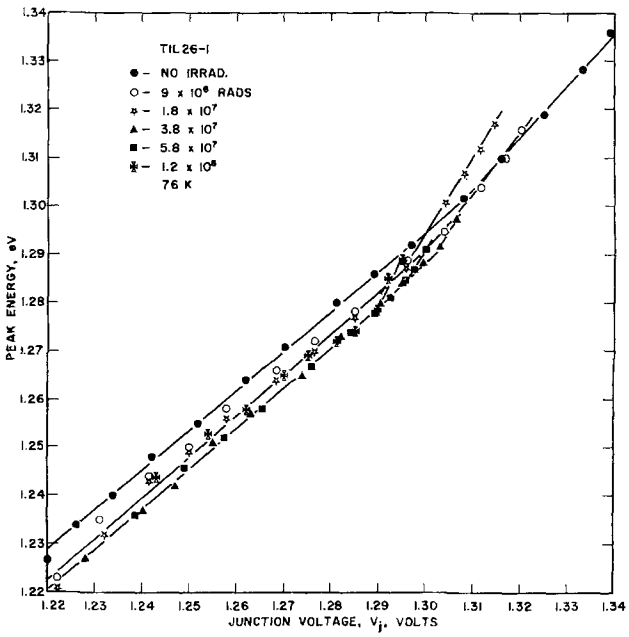

Fig. 9. Peak photon energy of the emitted light *vs.* junction voltage, V_J, for a GaAs:Si LED. The linear behavior is characteristic of radiative tunneling.

Conclusions

We wish to summarize this study of gamma irradiation effects in amphoterically Si-doped GaAs LED's by emphasizing the value of radiation effects studies in providing information about the preirradiation physics of the device in question. The data has shown that the effects of irradiation depend critically on the modes of radiative and total current flow and also on the region of the device where these currents are generated. At low voltages, the radiative current is due to tunneling into the space-charge region from band tail states and subsequent recombination in this region. As a result, gamma irradiation has no effect on the light intensity. The total current is also due to SCR, but, since this current includes all recombination paths, the gamma-induced nonradiative centers in the space-charge region contribute to an increase in I. In addition, gamma irradiation has a relatively small effect on the long radiative decay times observed at low voltages. This result is taken as further evidence for the correctness of the wavy band model in which the long decay times are due to the long lifetimes of carriers in deep localized band tail states.

At large voltages, the effects of irradiation are quite different, which serves to more clearly elucidate the changing modes of current flow. The results suggest that the light output at large voltages is dominated by radiative SCLC flow which is quite sensitive to irradi-

ation. The decrease in I with Φ at large voltages, just the opposite effect from that at low voltage, indicates that the total current also possesses an SCLC component. The lifetime damage constant product, $\tau_0 K_\gamma$, derived from the degradation of the SCLC component agrees with that determined from the radiative decay time data lending further credibility to both the SCLC model and the association of high current decay times with a diffusion-limited minority carrier lifetime.

The Effect of Substrate Preparations on the Surface Morphologies of the Epitaxial Layers of GaAs

Mutsuyuki Otsubo, Takao Oda, Shigeru Mitsui, and Hidejiro Miki

Mitsubishi Electric Corporation, Central Research Laboratories, Itami, Hyogo, 664 Japan

ABSTRACT

The effect of substrate preparations on the surface morphologies of the epitaxial layers of GaAs was studied using the open-tube $AsCl_3$ transport technique. It was found that the surface morphologies were closely related to the delta values of the substrates, which were obtained from an ellipsometric measurement. The higher delta values give the surfaces which are specular, smooth, and free from protrusions, while the lower delta values give the textured surfaces. Electrical properties of the grown layers depend strongly on the surface morphologies.

Epitaxial growth of GaAs is a considerably important technology for fabrication of microwave and optoelectronic devices. A necessary condition for fabrication of these devices, in particular Schottky barrier gate field effect transistors, is the ability to deposit smooth surfaces. The macroscopic surface imperfections which are a major problem to the attainment of such surfaces are pits and hillocks. The origin of these defects has been investigated by a number of workers using the $Ga/AsCl_3/H_2$ (1-4) and $Ga/AsH_3/HCl$ (5-11) growth systems in relation to growth parameters. It has been reported that the surface morphologies depend strongly on the deposition temperature (4, 10), the gas phase stoichiometry (7, 9-11), the substrate orientation (1, 6), the oxygen contamination of gas stream and the dirt (2, 5), and the substrate preparation (5). However, the surface morphologies of GaAs layers are not too well under control.

We have found that the surface morphologies of the epitaxial layers of GaAs depend also on the chemical etchant used for cleaning the substrates. This paper describes the effect of the substrate preparations, in particular chemical etching, on the surface morphologies and the electrical properties of the epitaxial layers of GaAs.

Key words: compound semiconductors, cleaning, ellipsometry.

Experimental

The deposition apparatus used in this investigation is the $Ga/AsCl_3/H_2/N_2$ flow system with a vertical reactor. The reactor tube, the Ga reservoir, the substrate holder, and the inner tube were made of synthetic quartz glass, and they were heated in a vacuum at 1000°C for 12 hr before using. The substrate holder was designed to rotate with $0 \sim 10$ rpm and to charge

with 4 ~ 5 wafers of 6 ~ 7 cm^2 in a given run. The additional Ga was introduced by filling the Ga reservoir with 99.99999% Ga, and the $AsCl_3$ gas diluted with a purified N_2 gas was introduced from small holes in an annular ring arranged above the Ga reservoir. The H_2S diluted with a Pd-diffused H_2 gas was used as a donor impurity. In the early stages of this investigation, when an H_2 gas was used as a carrier gas for $AsCl_3$, the arsenic flowed backward and could not be transported to the deposition zone. Therefore, the purified H_2 and N_2 gases were used and the $AsCl_3$ was bubbled by an N_2 gas. Four to five substrates with different surface preparations were simultaneously subjected to deposition in a given run. Normally 1 μm thick epitaxial layers of GaAs were deposited on the substrates and the epitaxial layer surfaces were observed by an interference optical microscope. No thickness dependence of the surface morphologies was observed provided that the epitaxial layers were 0.2-6 μm thick. The growth conditions normally used to produce smooth and flat layers are listed in Table I.

The substrates used in this investigation were normally obtained from Cr-doped semi-insulating, and sometimes from Si- or Te-doped n^+ boat-grown GaAs ingots. These were misoriented 2° off (100) toward the <110> direction. The slices were mechanically lapped with 4000 mesh Al_2O_3 abrasive and then were chemically etched by a 10 volume percent (v/o) bromine-methanol solution followed by a $3H_2SO_4$-$1H_2O_2$-$1H_2O$ solution at 60°C. These wafers were etched in various solutions listed in Table II just prior to use and then were placed on the substrate holder. Surface preparations used in this investigation are listed in Table II.

The substrate surfaces were estimated by ellipsometry. Two quantities of Δ and ψ are obtained. The Δ is the change in the relative phase between the parallel and perpendicular component of the polarized light on reflection, and ψ, the factor by which the amplitude ratio of the parallel and perpendicular components changes on reflection. The Δ and ψ are determined by measuring the polarizer and analyzer angles which give a null in the reflected light signal (14). The ellipsometric measurement has been done at an angle of 70° of the incident beam with a wavelength of 5461Å. The measurement was carried out within 10 min after etching the substrates.

Each substrate prepared in a particular manner is cut into two pieces. One is subjected to epitaxial growth and the other is used for an ellipsometric measurement. The average Δ value for five wafers is listed in Table II for each preparation. Deviation in Δ value for each preparation was within ± 1°. The epitaxial layers were observed by an interference optical microscope. Therefore the surface morphologies illustrated in the figures were taken with interference contrast.

The layers were also evaluated by a photoluminescence spectra and *I-V* curves of Schottky barrier diodes formed on the epitaxial layers. The photoluminescence spectra were obtained with a JE-25 spectrometer and a cooled RCA 7102 photomultiplier. An Ar ion laser was used as an excitation source which was filtered with a CS-2-64 Corning glass filter to eliminate laser background light. No correction for the photomultiplier and the spectrometer response was made. The measurement was done at 77°K.

Results and Discussion

Effect of surface preparations on the surface morphologies of the epitaxial layers of GaAs.—Figure 1 shows typical surface morphologies of the epitaxial layers of GaAs. Figure 1(a) shows a surface morphology of the epitaxial layer deposited on the substrate which is mechanically polished with a Mirrolite solution (Materials Development Corporation, US) on a rotating Pellon cloth after having been lapped off with 4000 mesh Al_2O_3 abrasive by approximately 100 μm to eliminate the work damage introduced in the crystal sawing process. The wafer was rinsed with deionized water and methanol, and then served for epitaxial growth. The epitaxial layer surface consists of an array of hillocks. When the epi-

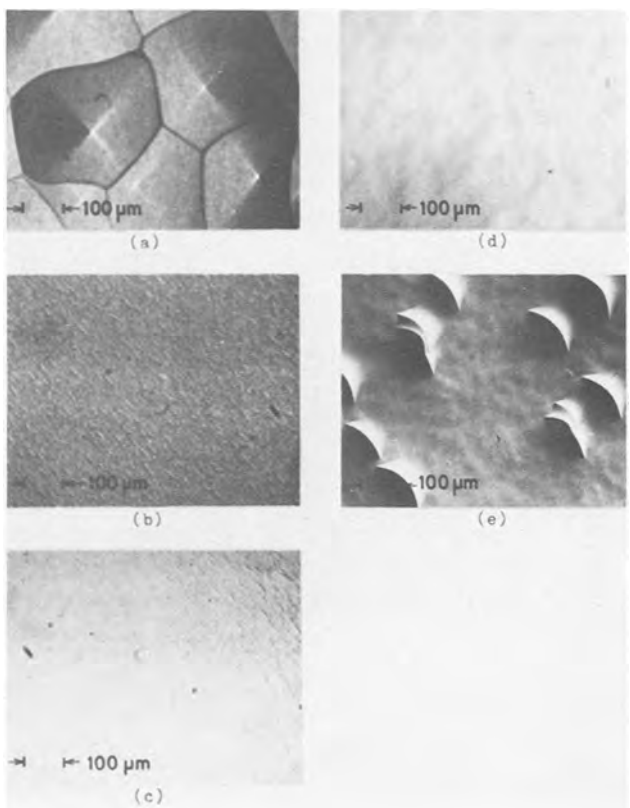

Fig. 1. Surface morphologies of the epitaxial layers deposited on the substrates which were etched with (a) a Mirrolite solution; (b) a 10 v/o bromine in methanol solution; (c) a citric acid-hydrogen peroxide-water solution; (d) a $3H_2SO_4$-$1H_2O_2$-$1H_2O$ solution; and (e) a 1HF-$3HNO_3$-$2H_2O$ solution.

taxial layer was deposited on the substrate prepared by this means, after etching with a $3H_2SO_4$-$1H_2O_2$-$1H_2O$ solution by approximately 30 μm, the surface of the layer was highly specular and smooth. Hence, the surface shown in Fig. 1(a) is thought to have originated in the mosaic structure at the substrate surface introduced by the mechanical polishing procedure (12).

Figure 1(b) shows a surface morphology of the layer deposited on the substrate etched with a solution of 10 v/o bromine in methanol. The surface was a straw-matted texture of fine grooves oriented in the <111> direction. The same surface texture was obtained in the layers deposited on the substrate etched with a solution of the citric acid-hydrogen peroxide-water system [Fig. 1(c)].

Figure 1(d) shows a surface morphology of the layer deposited on the substrate etched with a $3H_2SO_4$-$1H_2O_2$-$1H_2O$ solution at 60°C. The surface was highly specular, smooth and free from protrusions. When the substrate was etched at higher temperatures, the epitaxial layer surface contained with fine grooves oriented to the <111> direction were ready to obtain.

Figure 1(e) shows a surface morphology of the layer deposited on the substrate etched with a $1HF$-$3HNO_3$-$2H_2O$ solution. The surface shows a considerable number of protrusions on a specular background, which were closely related to etch hillocks formed on the substrate by the etching process. It is known that the etch hillocks on the substrate surface are covered with oxide (13).

In order to study the effect of the sulfuric acid content of the sulfuric acid-hydrogen peroxide-water solutions on the surface morphologies, the epitaxial layers were deposited on the substrate etched with $3H_2SO_4$-$1H_2O_2$-$1H_2O$, $5H_2SO_4$-$1H_2O_2$-$1H_2O$, and $18H_2SO_4$-$1H_2O_2$-$1H_2O$ solutions. The result is shown in Fig. 2. Increase in the sulfuric acid content in the solutions results in the textured surfaces, consisting of an array of fine grooves oriented to the <111> direction, whose density increases with increasing sulfuric acid content.

Figure 3 shows the effect of exposing the substrate to air on the surface morphologies of the epitaxial layers. The substrates, etched with a $3H_2SO_4$-$1H_2O_2$-$1H_2O$ solution at 60°C, were exposed to air for periods of 0, 80, 220, and 315 min. Exposure to air results in the textured surfaces consisting of fine grooves oriented in the <111> direction with a wavy background.

It is found from these investigations that the surface morphologies of the epitaxial layers are closely related to Δ values obtained from an ellipsometric measurement of the substrate surfaces. The higher Δ values result in the surfaces which are specular, as well as smooth and free from protrusions, while the lower Δ values result in the textured surfaces with fine grooves oriented to the <111> direction. Density of the fine grooves increases with a decrease in the Δ values. Therefore, it is important to select the etching solutions which give higher Δ values in order to obtain the epitaxial layers with specular surfaces which are smooth and free from protrusions.

It is confirmed using a microbalance that inadvertent gas etching, thicker than several tens of angstroms, did not occur in our experimental conditions. However, it is possible that slight thermal etching, within several tens of angstroms, occurs. Since the substrates with different preparation were simultaneously subjected to deposition in a given run, surface morphologies observed in this experiment are not caused by thermal and/or gas etching, but are due to substrate preparations. When an intentional gas etching, about 1 μm thick, was performed, the epitaxial layer surface was fairly smooth and no particular surface morphologies were observed.

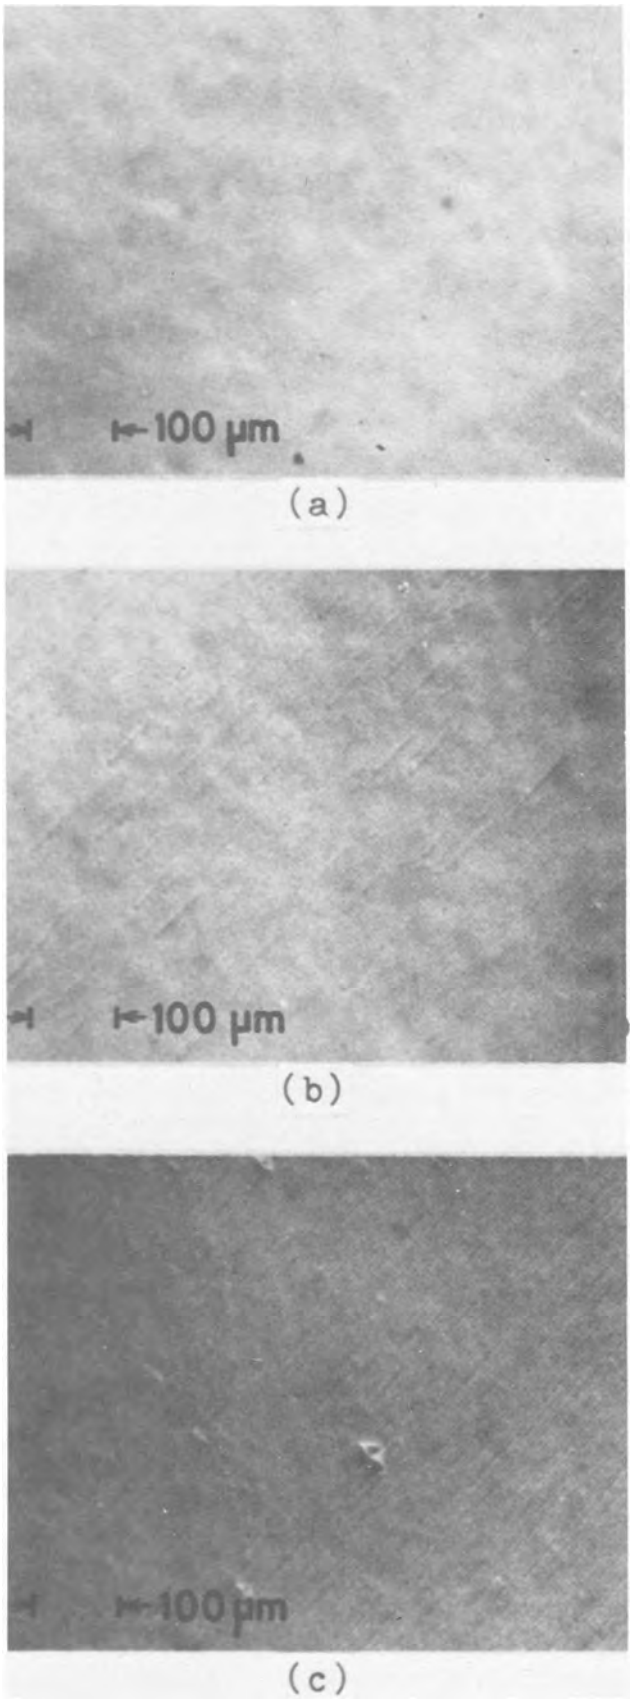

Fig. 2. The effect of sulfuric acid content in the sulfuric acid-hydrogen peroxide-water system on the surface morphologies of the epitaxial layers. The substrates were etched with (a) a $3H_2SO_4$ $1H_2O_2$-$1H_2O$; (b) a $5H_2SO_4$-$1H_2O_2$-$1H_2O$; and (c) a $18H_2SO_4$-$1H_2O_2$-$1H_2O$ solutions. The etching was performed at 60°C.

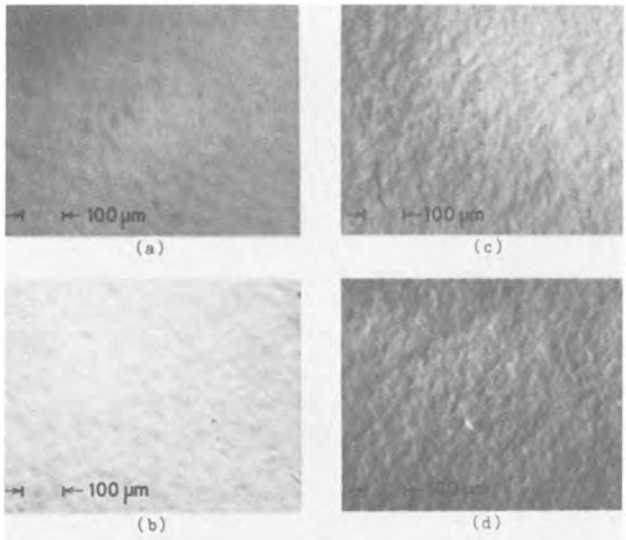

Fig. 3. The effect of exposing the substrates to air on the surface morphologies of the epitaxial layers. The substrates etched with a $3H_2SO_4$-$1H_2O_2$-$1H_2O$ solution were exposed for (a) 0; (b) 80; (c) 220; and (d) 315 min.

In order to determine the effect of changing the distance between the Ga surface and the outlet of $AsCl_3$ gas on the surface morphologies, the epitaxial layers were deposited on the substrates etched with a $3H_2SO_4$-$1H_2O_2$-$1H_2O$ solution at 60°C. The result is shown in Fig. 4. Increase in the distance results in the textured surfaces with fine grooves oriented to the <111> direction. This indicates that the surfaces shown in Fig. 4(b) and 4(c) have been obtained under lower concentrations of GaCl at the deposition zone because the reaction efficiency between the GaAs crust formed on the Ga surface and the HCl gas decreases with increasing the distance. From a resemblance in the surface morphologies between the layers deposited on the substrates with lower Δ values and the layers deposited with the larger Ga-$AsCl_3$ outlet distance, it must be concluded that the textured surfaces with fine grooves oriented to the <111> direction are produced by the deficiency of Ga at the substrate surfaces.

It has been reported that the oxide layer was formed on the substrate surfaces by chemical etching (14, 15) as well as the existence of the Ga deficient layer between the oxide layer-GaAs interface by the study of an Auger electron spectroscopy of etched GaAs crystals (15). It is possible that decrease in Δ values of the substrates, namely, increase in the oxide layer thickness, results in increase in the Ga-deficient layer thickness. When the substrates prepared by various treatments listed in Table II were heat-treated at the deposition temperature of 695°C for 5 min, the Δ values of these substrates were all 166°-167° regardless of substrate preparations. This indicates that the oxide layer formed on the substrate surfaces was almost evaporated and the Ga-deficient layer was exposed at the beginning of epitaxial growth. From these considerations, it must be concluded that the epitaxial layers with textured surfaces were produced by the presence of the Ga-deficient layer on the substrate surface at the beginning of epitaxial growth. Vapor etching of the substrate in the deposition apparatus just prior to deposition is the most suitable technique for eliminating the Ga-deficient layer.

Effect of the surface morphologies on the electrical properties of the epitaxial layers of GaAs.—In order to study the effect of the surface morphologies on the electrical properties of the epitaxial layers, *I-V* curves of Schottky barrier diodes formed on the layers and photoluminescence spectra were measured. The epi-

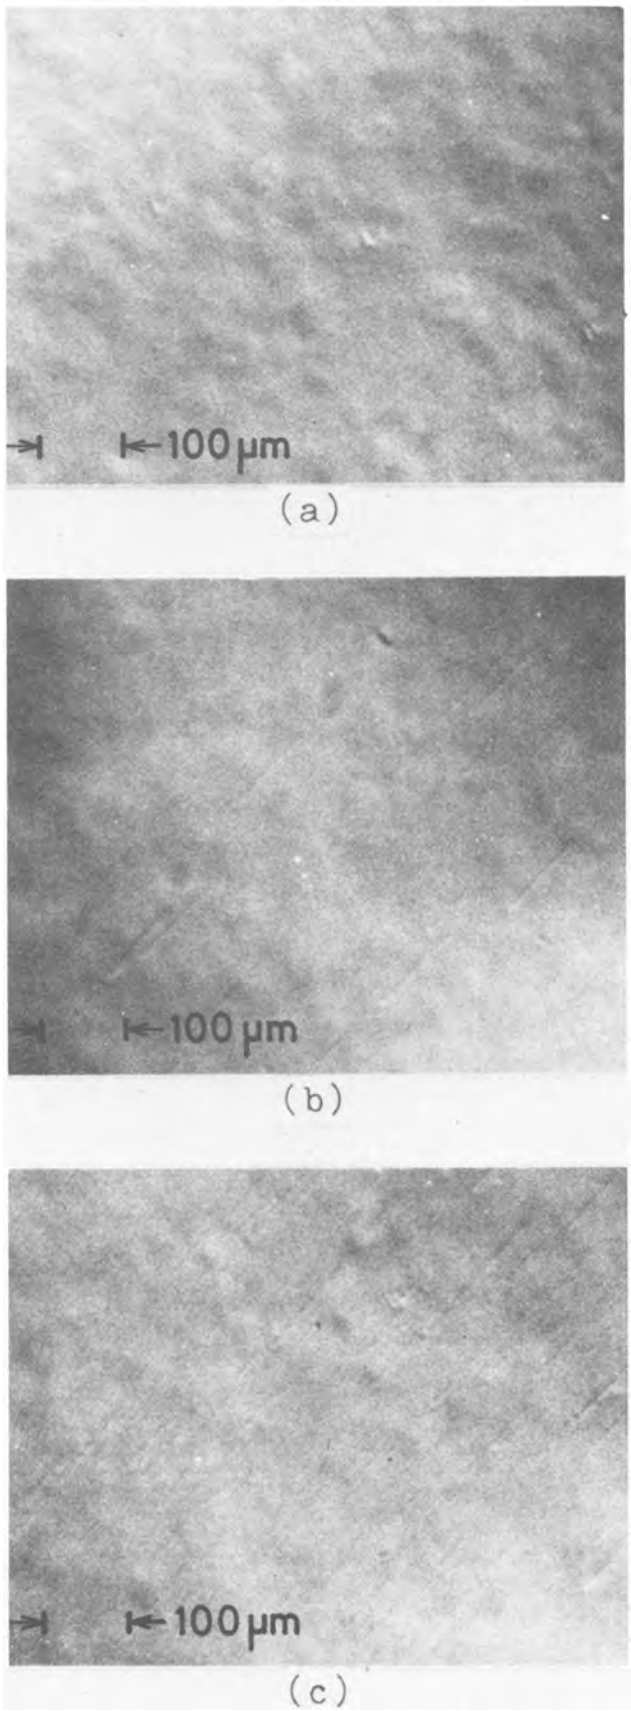

Fig. 4. The effect of changing the distance between the GaAs crust formed on the Ga source and the outlet of $AsCl_3$ gas on the surface morphologies of the epitaxial layers.

taxial layers deposited on the substrates which were prepared by various treatments listed in Table II were classified into three groups. Group (a) is the layers with the surfaces which are specular, smooth, and free of protrusions [Fig. 1(d), 2(a), 3(a), and 4(a)]. Group (b) is the layers with textured surfaces of a lower density of fine grooves [Fig. 2(b), 3(b), and 4(b)]. And group (c) is the layers with the higher density of fine grooves and a wavy background [Fig. 1(b) and 1(c), 2(c), and 3(c) and (d)].

Figure 5 shows the relation between the surface morphologies and *I-V* curves for Schottky barrier diodes formed on the three kinds of layers with carrier concentrations of 7-8 $\times$ 10^{16} cm^{-3} and 0.3 μm thick. It is apparent that the surface morphologies of the epitaxial layers are closely related to the backward characteristics of the diodes. Higher breakdown voltages with hard breakdown were obtained on the samples which belong to group (a), while in groups (b) and (c), the the higher leakage currents and lower breakdown voltages were observed, where the leakage current increases with an increase in the roughness of the epitaxial layer surfaces [Fig. 5(b) and 5(c)].

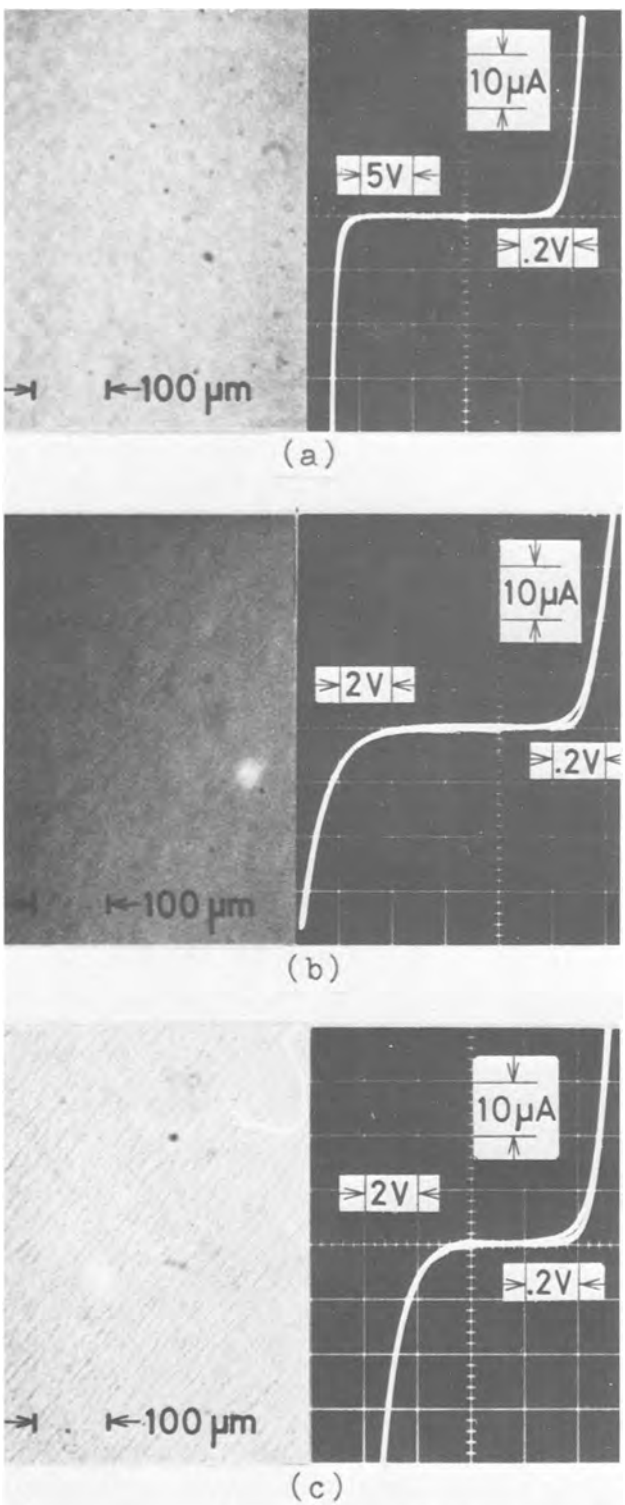

Fig. 5. *I-V* curves for Schottky barrier diodes formed on three kinds of layers.

Figure 6 shows photoluminescence spectra at 77°K on three kinds of layers. Two dominant emissions at 1.51 and 1.36 eV were observed. The emission at 1.51 eV is due to a band-to-band recombination and/or a shallow donor-to-valence band recombination (16), and the emission at 1.36 eV is due to Cu at Ga site (17). The intensity of the emission at 1.51 eV is higher in the layers of group (a), while the intensity of the emission at 1.36 eV is higher in groups (b) and (c). It is possible that the epitaxial layers with textured surfaces contain higher concentrations of Ga vacancies, resulting in lower intensity of a near band emission and higher intensity of 1.36 eV emission. This results in an increase in higher leakage currents of Schottky diodes and lower breakdown voltages.

Conclusions

The effect of substrate surface preparations, in particular chemical etching, on the surface morphologies of the epitaxial layers of GaAs were investigated. It is found that the surface morphologies are closely related to the Δ values of the substrate surfaces, and the electrical properties of the grown layers depend strongly on the surface morphologies. The surfaces of the layers grown on the substrates with higher Δ values were specular, smooth, and free from protrusions, while the surfaces grown on the substrates

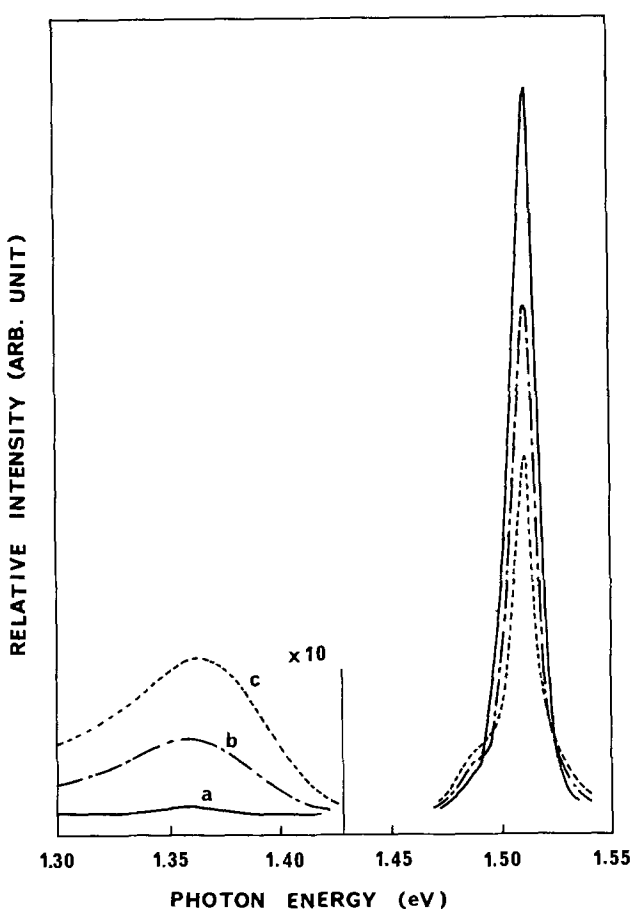

Fig. 6. Photoluminescence spectra at 77°K on three kinds of layers

with lower Δ values were textured and had a wavy background. It is presumed that the textured surfaces were obtained due to the deficiency of Ga on the substrate surfaces. Decrease in the Δ values results in an increase in leakage current of the Schottky barrier diode formed on the epitaxial layers.

Errors in Calculations of Predeposition Diffusion Profiles by Iterative Numerical Methods

Jakob H. Hohl

and Douglas J. Hamilton

University of Arizona, Tucson, Arizona 85717

ABSTRACT

The errors in numerical calculations of one-dimensional predeposition profiles have been determined for the direct method of finite differences and for the finite element method. These errors can be calculated because the exact solution of this linear diffusion problem is known to be the complementary error function. The relative errors at the nodes of the depth-time lattice are illustrated. The results are useful for assessing the errors of calculations of multidimensional profiles by these iterative methods, where no exact solutions are known. The results indicate that accurate calculations of such profiles will require such fine lattices and large numbers of time steps that the usefulness of the iterative methods becomes doubtful.

The progressing perfection of the integrated circuit technology to smaller and smaller geometries and the high degree of sophistication of contemporary circuit analysis programs pose increasingly exacting requirements on the device modeling techniques. An important aspect of the latter is the calculation of impurity profiles resulting from diffusions through rectangular or line-shaped windows. Such profiles cannot be described by closed form analytic solutions, and one must resort to numerical techniques for their calculation.

The methods of finite differences and of finite elements suggest themselves foremost for such computations because they are quite versatile and can be implemented without unduly complex analytic mathematical preparations. The potential difficulties lie in the numerical stability and in the estimation of the accuracy of the results.

For the direct method of finite differences the stability criteria and a formula for the error can be determined analytically. In the second section of this paper, the results for the one-dimensional diffusion problems, as derived by Carnahan, Luther, and Wilkes (1), are summarized. These results demonstrate the inherent problems with error estimation: a meaningful estimate can only be obtained when the solution of the problem is known for all steps and when the lattice of nodal points is fine with respect to the features of the solution. Neither condition is satisfied for multidimensional predeposition diffusion profiles. The one-dimensional profile satisfies the former condition but not the latter because it evolves from a step function. The error in an iterative calculation of this problem can only be determined by actually performing the computation.

The second section specifies the one-dimensional diffusion problem under consideration and defines all the parameters of the computations. In the third section, the finite difference calculation of the profile is outlined and the errors of the calculation are illustrated. The fourth section is devoted to the calculation of the same profile by the finite element method and to the presentation of its errors. Some conclu-

Key words: semiconductor, impurity, profile, computation.

sions, which also apply to calculations of multidimensional profiles are discussed in the fifth section.

Outline of the Diffusion Problem

The diffusion of impurities from a constant concentration condition at the surface of a half-space with unity diffusivity is considered. At the time instant $t = 0$, the volume concentration is zero and the surface concentration is discontinuously changed from $C_o = 0$ to $C_o = 1$. Under the usual assumptions, as, *e.g.*, constant diffusivity and absence of electrostatic fields, the diffusion process is governed by the linear one-dimensional diffusion equation. Normalizing the diffusivity to unity, the equation is

$$\partial^2 C/\partial x^2 - \partial C/\partial t = 0 \qquad [1]$$

and the given initial and boundary conditions lead to the well-known analytical solution

$$C(x, t) = \operatorname{erfc}(x/\sqrt{4t}) \qquad [2]$$

where x is the distance from the surface into the half-space in question.

For calculating the profile by an iterative method, the continuous variables x and t need to be replaced by a lattice of points

$$i, j \equiv (x_i, t_j) = (i\Delta x, j\Delta t); \quad i, j = 0, 1, 2, \ldots \qquad [3]$$

at which the values $u_{i,j}$ of the numerical solution will be calculated. The corresponding values of the exact solution will be denoted by $c_{i,j}$. The relative errors are defined as the deviation of the numerical solution from the exact solution divided by the exact solution

$$\epsilon_{i,j} = (u_{i,j} - c_{i,j})/c_{i,j} \qquad [4]$$

The numerical calculations proceed from time step to time step; the solution at the jth time step representing the initial condition for calculating the solution at the time t_{j+1}.

Direct Method of Finite Differences

Replacement of the derivatives in the diffusion Eq. [1] by ratios of differences between variables at adjacent points of the (x, t) lattice leads to the finite differences algorithm

$$u_{i,j+1} = u_{i,j} + \lambda(u_{i-1,j} + u_{i+1,j} - 2u_{i,j}) \qquad [5]$$

where $\lambda = \Delta t/(\Delta x)^2$ is called the mesh ratio. The boundary and initial conditions of the previous section translate into

$$u_{0,j} = 1; \quad u_{i\neq 0,0} = 0 \qquad [6]$$

The algorithm becomes numerically unstable when the mesh ratio exceeds ½.[1] For small mesh ratios, a first order estimate (1) reveals that the errors of the iteration, $e_{i,j}$, are bounded by

$$e_{i,j+1} \leq e_{i,j} + \lambda(e_{i-1,j} + e_{i+1,j} - 2e_{i,j}) + z_{i,j} \qquad [7]$$

$$z_{i,j} = (\Delta t/2)\partial^2 c/\partial t^2 - [(\Delta x)^2/12]\partial^4 c/\partial x^4 + O[(\Delta t)^2] + O[(\Delta x)^4] \qquad [8]$$

The derivatives are to be evaluated at the point i, j and O denotes "on the order of." To estimate the error $e_{i,j}$, one needs to know a pyramid of errors of all previous steps as well as the derivatives of the exact solution at the points of the space-time-lattice. However, in a general problem an iterative calculation is performed because the solution is not known, and hence the error cannot be estimated with much confidence.

Since $\partial^2 c/\partial t^2 = \partial^4 c/\partial x^4$, Eq. [8] indicates that for $\lambda = 1/6$, the errors will be on the order of $(\Delta t)^2$ rather than Δt. This mesh ratio has been used in the calculations described below. One notes, then, that the lattice points for the first time step, $j = 1$, correspond to the arguments $x_i/\sqrt{4t} = i\sqrt{3}/2 = 1.22i$ in the complementary error function [2]. There is less than one point per diffusion length which leads to an extremely coarse approximation of the function. Only after a considerable number of time steps will the lattice become fine with respect to the features of the solution. Therefore, the iteration starts with large inaccuracies and a reliable *a priori* error estimate is impossible.

Figure 1 illustrates the relative errors, $\epsilon_{i,j}$, of the first 50 iterations of the finite difference calculation of the function [2]. Since the errors are displayed *vs.* $x/\sqrt{4t}$ rather than x, the points corresponding to the same x_i migrate toward the left with consecutive steps. These points are connected by line segments. The points corresponding to the time steps 5, 10, 15, . . . are marked with black dots, and intervening points are indicated by circles.

The figure demonstrates the large spacing of the points of the early time steps with respect to the diffusion length. The maximum errors in the range of the first three diffusion lengths from the surface after 25 and 50 iterations are 15 and 8%, respectively.

Method of Finite Elements

The finite element method is based on a variational formulation of the problem at hand (2). The solution is again calculated at the points (x_i, t_j), but for the purpose of deriving the algorithm, the solution between these points is linearly interpolated (3). This parametrizes the functional in terms of the node values, $u_{i,j}$, of the solution. The extremization of the functional then requires that all its partial derivatives with respect to the node values vanish simultaneously, leading to a system of linear equations for the $u_{i,j}$.

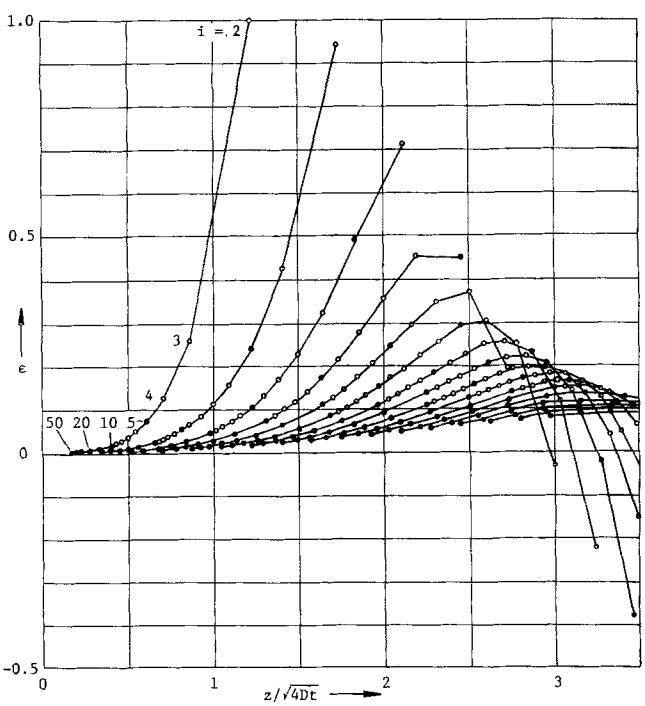

Fig. 1. Relative errors, ϵ, at the nodal points of a finite difference calculation of the complementary error function as the solution of a diffusion problem at time step i.

[1] To see this, consider an error, d, *e.g.*, a round-off error, introduced into the value $u_{i,j}$. This error will propagate to $u_{i,j+1}$, which will be in error by $(1 - 2\lambda)d$ and to $u_{i\pm1,j+1}$, which will be in error by λd. For $\lambda > ½$, the sum of the magnitudes of these errors will become $(4\lambda - 1)d > d$, and the effect of the disturbance grows from time step to time step.

The variational formulation of transient diffusion problems must explicitly reflect the causal character of the physical process (4). A formulation by Gurtin (5) has this property and leads to an algorithm which calculates the solution at the time t_{j+1} from that at the time t_j and the boundary conditions.

A formal analysis of the error of this method, like the one for the finite difference method, is not possible. It is said that the finite element method is more stable numerically and that it can be formulated for unequal lattice spacings more easily than the finite difference method. From a number of calculations with uniform lattices, but various mesh ratios, the optimum performance of the finite element method was again found to be around $\lambda = 1/6$. The variations of the errors for mesh ratios between 0.1 and 1 are insignificant, indicating the better numerical stability of the method. Calculations with unequal Δx_i lead to inferior results with either steps increasing or decreasing with depth. A calculation starting with a mesh ratio of 0.26 which from step to step decreased by 2%, using uniform Δx_i, showed marginally smaller errors than the calculation with $\lambda = 1/6$.

Figure 2 displays the relative errors of the calculation with the mesh ratio 1/6, using the same format as Fig. 1. One notes that the errors in the range up to 1.6 diffusion lengths are comparatively smaller, but that they increase rapidly beyond this point, soon exceeding those of Fig. 1.

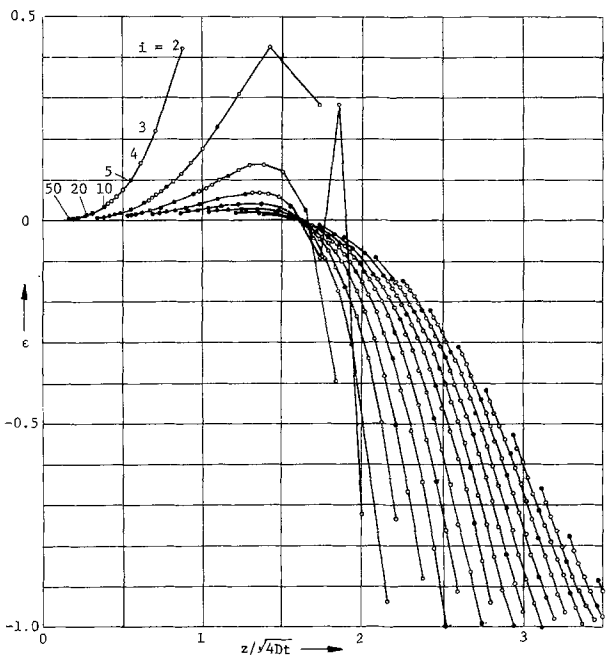

Fig. 2. Relative errors, ϵ, at the nodal points of a finite element calculation of the complementary error function as the solution of a diffusion problem at time step i.

Conclusions

The results of the two calculations demonstrate that both algorithms require at least five lattice points per diffusion length of the solution in order to yield a reasonable accuracy over a distance of three diffusion lengths from the source. In this range the solution varies over about five orders of magnitude, which encompasses the variations of concentrations of impurities encountered in semiconductor devices in practice.

If one now conjectures that the errors of two- and three-dimensional calculations behave similarly because of comparable characteristics of the solutions, one can estimate the expense of numerical calculations of such profiles. To this end, consider a predeposition diffusion through a square window eight diffusion lengths in size. Modeling one quadrant of the structure, three diffusion lengths beyond the window edges and to a depth of three diffusion lengths, using a space lattice with five nodes per diffusion length, thus requires 20,000 nodes and 40-50 time steps. In the finite element method, the computation entails the inversion of a matrix of dimension 20,000. Such an endeavor requires considerable computing power and is not inexpensive, particularly if one considers that numerous impurity profiles must be computed for devices of integrated circuits.

The finite element method which is often praised for superior computation efficiency is found to be, in fact, inferior to the finite difference method for the calculation of impurity profiles.

The idealization in using a linear diffusion process is appropriate for the comparison of the two computation methods. Both methods can accommodate the complication of concentration dependent diffusivity occurring at high concentrations due to internal electrostatic fields by updating the diffusivities after each time step. In a finite element calculation it becomes necessary, however, to invert a matrix at each time step, which makes it very inefficient.

Effects of Impurity Redistribution on the Short-Circuit Current of n^+-p Silicon Solar Cells

E. Y. Wang and L. Hsu

and H. W. Brandhorst, Jr.*

NASA-Lewis Center, Cleveland, Ohio 44135

ABSTRACT

The effect of impurity redistribution on the n^+-diffused layer of silicon solar cells has been studied. The impurity concentration was profiled by four-point-probe differential Hall and resistivity measurements. The electric field gradient and the mobility gradient in the diffused region were obtained from the impurity profiles. Short-circuit current was calculated from the effective recombination lifetime deduced from electric field gradient and mobility gradient results. The calculated short-circuit current was compared with measured values as a function of wavelengths and found to be in reasonably good agreement.

In recent calculations of the short-circuit current for silicon solar cells (1), we have found that this current is sensitive not only to the junction depth and the depletion region width (2) but also to the impurity distribution in the diffused and base regions. In order to verify these theoretical results, we have experimentally investigated the impurity profile and sheet resistance of the diffused layers of n^+-p silicon solar cells fabricated by normal diffusion processes with various lengths of drive-in times. We have also measured the short-circuit current on these "identical" solar cells. Experimental results obtained on these cells are in good agreement with the theoretical calculations.

Fifteen cells were fabricated from the (111) orientation of 10 Ω-cm p-type silicon. The chemically etched material was diffused in $POCl_3$ at 850°C for 30 min, the normal diffusion process for conventional n on p silicon solar cells at NASA-Lewis Center. The drive-in process at 850°C was performed for different lengths of time with nitrogen present as the carrier gas. After the diffusion and drive-in processes, cells were coated with Apiezen in the front; the back and edges of cells were etched away in a 2:3:1 (HNO_3:acetic:HF) solution for 1 min. The cells were then chemically treated in concentrated HF solution for 3 min, and subsequently went through the normal cleaning process for contact metallization (Al and Ag). For better ohmic contacts cells were sintered at 600°C for 20 min. At least three identical "cells" were made for the impurity profile and for the short-circuit current studies.

Impurity Profile by Differential Hall and Resistivity Measurements

The experimental technique for determining the impurity and resistivity profiles of the diffused layer is as follows (3): An oxide layer was grown by the electrolytic process of anodization of the diffused region of the cell. The oxide's thickness was estimated by electrolytic potential as well as by ellipsometry. Photoetching techniques were empoyed to obtain a Van der Pauw pattern of the n^+-layer of the silicon solar cells.

The method of Corbino images is applied to a circular isotropic Hall plate in order to determine its resistivity, ρ, and Hall coefficient, R_H. For a thin sheet in the Y-Z plane with a fixed magnetic field of arbitrary magnitude applied perpendicular to the surface of the sheet (x direction), the plate-oriented 4 fold symmetry axis is parallel to the magnetic field. Currents in the plate are constant in time and are linear functions of the electric fields. Currents in the plate produce negligible magnetic fields compared with the applied field.

In our experiment the Hall plate is isotropic but inhomogeneous. The measured conductivity σ and Hall coefficient R_H are related to the x dependent conductivity σ and Hall coefficient R_H as follows

$$\frac{1}{\rho} = \sigma = \frac{1}{t}\int_0^t \sigma(x)\,dx \qquad [1]$$

$$R_H = \frac{t\int_0^t \sigma^2(x)\,R_H(x)\,dx}{\left[\int \sigma(x)\,dx\right]^2} \qquad [2]$$

where the Hall factor has been taken as unity. For one carrier system, we can simplify Eq. [2] by

$$R_H(x) = \frac{1}{qn(x)} = \frac{\mu(x)}{\sigma(x)} = \rho(x)\,\mu(x) \qquad [3]$$

The $n(x)$ is the carrier concentration and t is the thickness of the Hall plate. Surface sheet resistivity and surface Hall coefficient are defined as

$$\frac{1}{\rho_s} = \sigma_s = \sigma t = \int_0^t \sigma(x)\,dx \qquad [4]$$

$$R_{Hs} = \frac{R_H}{t} = \frac{1}{\sigma_s}\int_0^t \sigma(x)\,R_H(x)\,dx \qquad [5]$$

Equation [5] is derived from Eq. [1], [2], and [4]. In differential form, $\sigma(x)$, $n(x)$, $\mu(x)$ become

$$\sigma(x) = \frac{d}{dx}\sigma_s \qquad [6]$$

$$n(x) = \sigma(x)/q\,\frac{d(R_{Hs}\,\sigma_s^2)}{dx} \qquad [7]$$

$$\mu(x) = \frac{1}{\sigma(x)}\,\frac{d}{dx}(R_{Hs}\,\sigma_s^2) \qquad [8]$$

Thus, the method for experimentally determining carrier concentration, resistivity, and mobility throughout the diffused layer is to measure σ_s and R_{Hs} successively after the removal of the surface layer (20.0 nm). The values of difference in σ_s and R_{Hs} for a

* Electrochemical Society Active Member.

Key words: silicon solar cell, impurity profile, short-circuit current.

consecutive measurement substituted in Eq. [6]-[8] give the values of $n(x)$, $\sigma(x)$, and $\mu(x)$.

Short-Circuit Current Calculation of the Silicon Solar Cells

The photoexcited minority carriers are created at a distance x from the junction, where L is the minority carrier diffusion length. The general expression for the short-circuit is given by (4)

$$\int_{0.4\ \mu m}^{1.1\ \mu m} \frac{dJ}{d\lambda} d\lambda = \sum_{\lambda = 0.4\ \mu m}^{\lambda = 1.1\ \mu m} J_{sc}(\Delta\lambda)$$

$$= q \sum_{\lambda = 0.4\ \mu m}^{\lambda = 1.1\ \mu m} \int \alpha\phi_o(\lambda) \exp^{-\alpha(\lambda)x} \exp \frac{-|x' - x|}{L} dx \qquad [9]$$

where q is the electronic charge and $\phi_o(\lambda)$ is photon flux density at wavelength λ; its values are taken from Ref. (5) and negligible reflection is assumed. Average values of α, the optical absorption coefficient, are taken from Ref. (6) and (7) and are taken as 50 nm for calculation purposes. The position where the excess minority carriers are collected is denoted as x'. For practical purposes, the total short-circuit current is just summed over the wavelength region from 0.4 to 1.1 μm.

Since minority carrier lifetime in the n^+-diffused region is known to be dependent on electric field gradient and mobility gradient, the L value is not a constant and the integration in Eq. [9] can simply be replaced by summation over small spatial regions. The notation J_{sc1} is used for the short-circuit contribution of the n^+-diffused region. By using Eq. [9] we can also calculate the short-circuit current contribution from both sides of the depletion region (J_{sc2} and J_{sc3}) and of the base region (J_{sc4}).The total short-circuit current is the sum of all four parts, *i.e.*

$$J_{sc}(\text{total}) = J_{sc1} + J_{sc2} + J_{sc3} + J_{sc4} \qquad [10]$$

Results and Discussion

Figure 1 shows an impurity profile of a typical solar cell. Sample R-1 has a drive-in time of 3 min; R-3, 10 min; and R-5, 60 min. These samples showed no significant change of surface concentration and have a deeper metallurgical junction (x_j) as the drive-in time increases; all the impurity profiles resemble an erfc distribution. The results of constant surface concentration for these cells suggest that the P_2O_5 layer on the silicon surface still acts as an infinite source during the drive-in process. The thickness of the grown oxide layer was measured by ellipsometry and the error was found to be around 5%. An accuracy of 2% in the Hall coefficient and sheet resistivity can safely be claimed. Therefore, the combined experimental data error should not exceed 10% for the first three or four measurements.

Figure 2 shows the hole mobility profile in the n^+-layer; it is obtained through a relationship with the experimental Hall electron mobility result (8). From Fig. 1 and 2, the electric field $E(x)$, the electric field gradient $dE(x)/dx$ (9, 10), and the mobility gradient $d\mu_p/dx$, can be calculated. The effective recombination lifetime τ_{eff} in the n^+ region is defined as

$$\frac{1}{\tau_{eff}} = \frac{1}{\tau_E} + \frac{1}{\tau_\mu} + \frac{1}{\tau_o} \qquad [11]$$

where $\tau_E = \left(-\mu_p \frac{dE}{dx}\right)^{-1}$, $\tau_\mu = \left(-E \frac{d\mu_p}{dx}\right)^{-1}$, and τ_o is the bulk recombination lifetime (values of τ_o are probably in the range of 10^{-7} sec) (11).

Figure 3 shows the spatial dependence of the effective lifetime for the R-3 cell. The solid curve is the theoretical calculation based on $x_j = 0.22$ μm, erfc distribution. The points based on the experimental differential Hall and resistivity measurements were superimposed on the same plot.

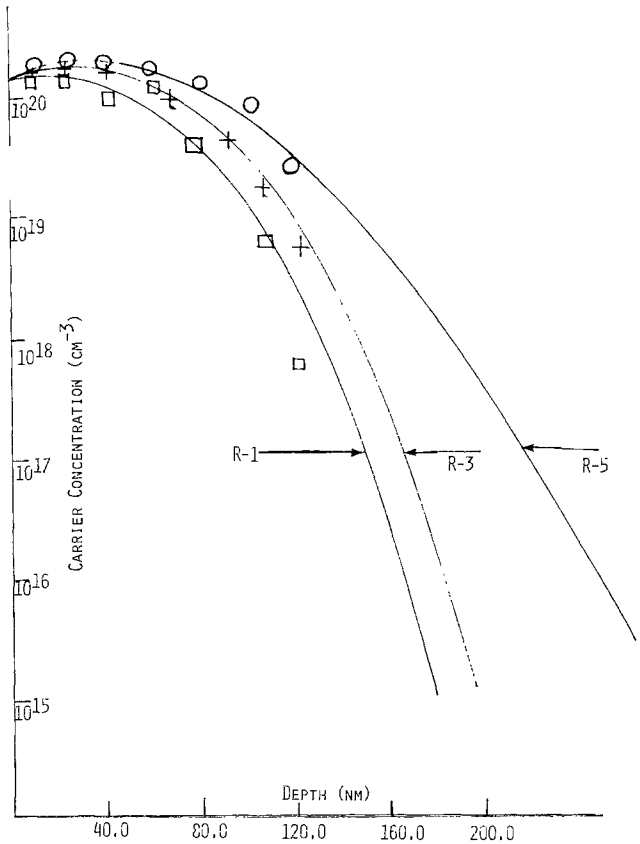

Fig. 1. Impurity profile of typical n^+-p silicon solar cells

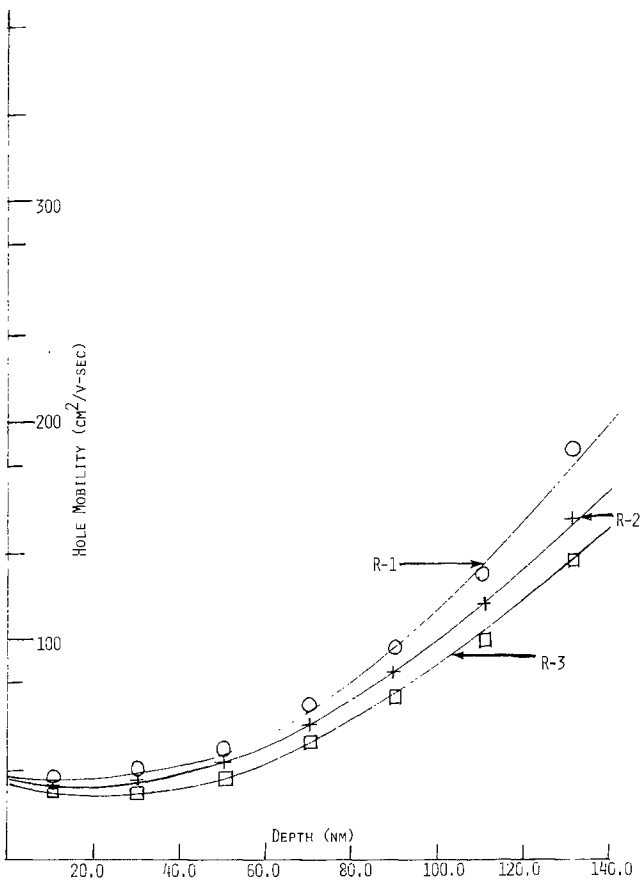

Fig. 2. Hole mobility profile of typical n^+-p silicon solar cells

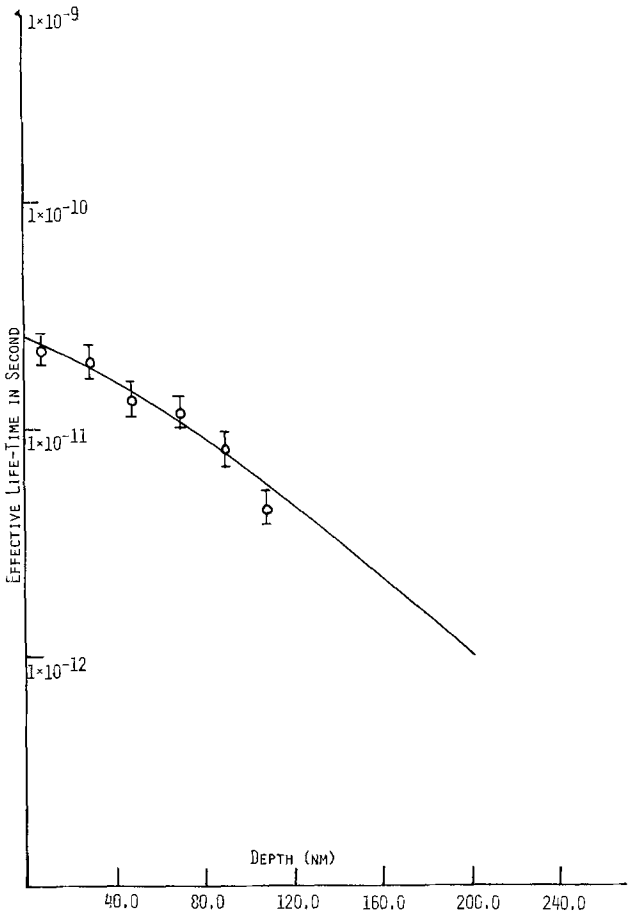

Fig. 3. Spatial dependence of the effective lifetime of n^+-region

Figure 4 shows the spectral response of these cells. The decrease in red response can be attributed to the decrease in the electron diffusion lengths, (L_n), of the base region as a result of longer drive-in times. The measurement of the L_n value through surface photovoltage (SPV) method (12) shows a maximum of a 10% decrease of its original value (about 200 μm) and thus confirms the result. As expected, the blue response is better for smaller x_j values.

Figure 5 shows the short-circuit current as a function of wavelengths. The solid lines are the theoretical calculations; experimental points are superimposed on the plot. The values of the parameters used in the calculations are listed in Table I. To determine whether or not the "drive-in" process changed the junction properties, junction capacitance was measured as a function of bias voltages. The results show that the junction still behaves as a one-side step junction, and that junction capacitance is independent of drive-in times. A built-in potential of 0.72V is obtained from a $1/C^2$ *vs.* V plot. The slope of this plot is related to the acceptor concentration in the base region and found to be 1.4×10^{15} cm^{-3} which corresponds to 10 Ω-cm base materials. A slight difference in slope values can be attributed to the variance (± 5%) in resistivity of the base material.

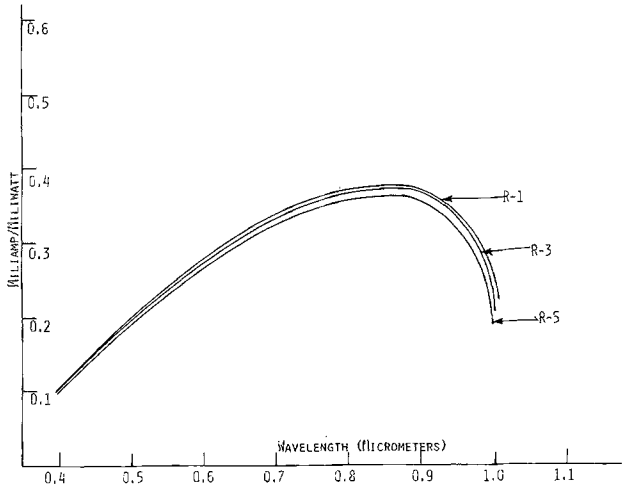

Fig. 4. Spectral response of n^+-p silicon cells with different drive-in times

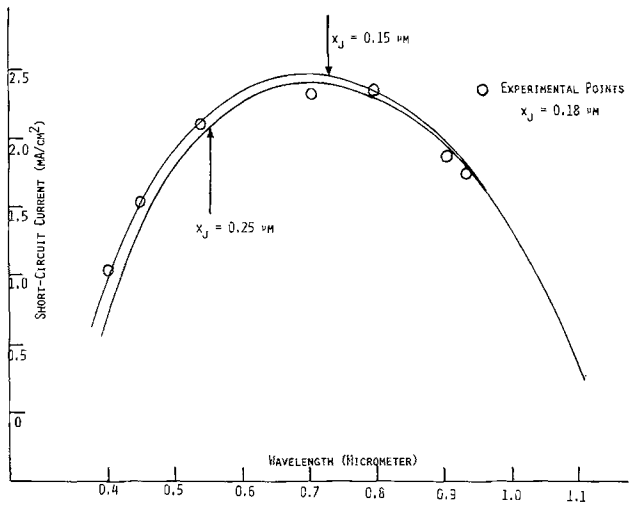

Fig. 5. Short-circuit current *vs.* wavelengths

In summary, the base layer of a silicon solar cell is the dominant factor in determining short-circuit current output. Through the four-point probe differential Hall and resistivity measurements used in our study, we have obtained the electric field gradient and the mobility gradient for a group of "identical" silicon solar cells with various lengths of drive-in times. Based on these values we have calculated the short-circuit current as a function of wavelength. The measured short-circuit is in good agreement with the calculated values.

A New Method for Calculating Background Dopant Density from p-n Junction Capacitance-Voltage Measurements

Richard L. Mattis and Martin G. Buehler*

Electronic Technology Division, Institute for Applied Technology, National Bureau of Standards, Washington, D.C. 20234

ABSTRACT

A new method is presented for calculating the average background dopant density within the depletion layer of a planar diffused p-n junction using capacitance-voltage (C-V) measurements. The method has been successfully applied to specimens having a background dopant density as high as 10^{18} cm^{-3}, and ideal data studies indicate that the method may be applicable to specimens having a background dopant density up to about 10^{19} cm^{-3}. The average background dopant density is calculated by finding the Gaussian diffused layer as characterized by an effective surface dopant density, background dopant density, and junction depth which can best be fitted to all the C-V data. It is not necessary to know the actual surface dopant density. The method is illustrated by calculations on both real and idealized C-V data.

The capacitance-voltage (C-V) method is widely used to measure dopant density *vs.* depth profiles of semiconductor specimens (1-4). Equations have been developed to correct for the peripheral capacitance (5-8) and for back-depletion into the diffused layer (8) for the case of Gaussian diffused planar p-n junctions, and the consequences of neglecting these corrections have been illustrated (8-10). A computer program has been written which incorporates both of these corrections (11). In order to measure the background dopant density with the use of a diffused p-n junction by these profiling C-V methods, it is necessary to force the space-charge or depletion region out of the region which is partly compensated by the diffused layer. In junctions where the dopant density profile does not level off at a steady background value, an accurate determination of the background dopant density is not possible. This problem is particularly acute in heavily doped specimens because, for a given reverse bias, the depletion width is smaller than for lightly doped specimens and the maximum reverse bias which can be applied (the reverse breakdown voltage) decreases as the background dopant density increases. Furthermore, in heavily doped specimens, the correction for back-depletion into the diffused layer makes a significant contribution to the calculation (9). If the surface dopant density has been calculated from the diffused layer sheet resistance and junction depth assuming a Gaussian diffused layer (12, 13) and if the diffused layer does not have a Gaussian profile, then errors in the diffused layer correction lead to errors in the calculated dopant density profile.

In this new method, the average background dopant density is calculated by finding the best Gaussian shape for the diffused layer that can be fitted to all C-V data. In essence, the problem is to find the parameters of the diffused layer within the depletion region which allow a proper back-depletion correction. The parameters of the Gaussian diffused layer are the junction depth, X_j, the effective surface dopant density, N_{0e}, and the background dopant density, N_b, which is also the quantity of primary interest in this measurement method. Assuming that X_j can be determined by lap and stain techniques, only N_{0e} and N_b are unknown. As is shown below, N_{0e} and N_b can both be determined if N_b is treated as a pseudo-variable which is constrained to be independent of depth.

An example of dopant densities calculated by the profiling method and by the new method to be described is given in Fig. 1. The test specimen was a 17 mil diameter planar diffused p-n junction diode fabricated on a 0.0216 Ω-cm n-type silicon wafer. The four profiles were calculated using four forms of the profiling method; namely, with no correction, with peripheral correction only, with back-depletion correction only, and with both peripheral and back-depletion corrections. Note that in this example the peripheral correction has a relatively small effect. Assuming a Gaussian diffused layer, the back-depletion correction was calculated using a junction depth of 1.52 μm as measured by the angle lap and stain

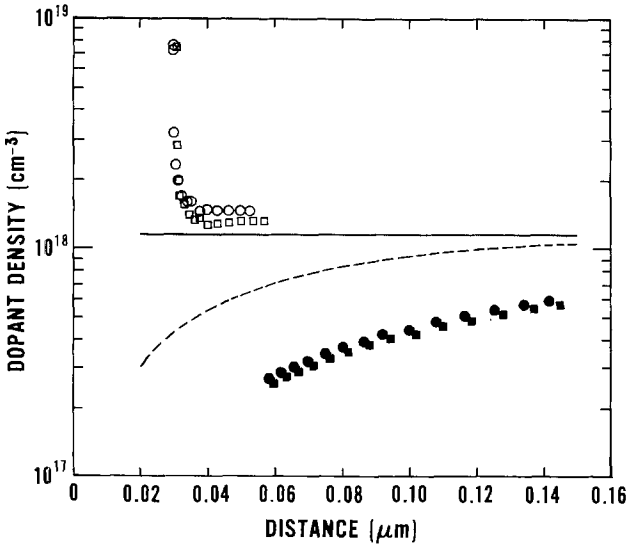

Fig. 1. Dopant densities calculated by the profiling method and the new method from C-V data taken on a p-n junction fabricated on a 0.0216 Ω · cm n-type silicon wafer. Four profiles calculated by the profiling method are shown representing no correction to the C-V data (●), peripheral correction only (■), back-depletion correction only (○), and both peripheral and back-depletion corrections (□). The uppermost point for the case of back-depletion correction only was negative as calculated; the magnitude is indicated in the plot. The solid line represents the average background dopant density calculated by the new method, and the dashed line represents the net dopant density calculated from the Gaussian fit.

method and a surface dopant density of 2.44×10^{20} cm^{-3} which was calculated from the junction depth and the measured diffused layer sheet resistance of 8.73 Ω/[] (12, 13). Note that the profiles for which the back-depletion correction was not applied do not approach a steady background level, and that the shapes of the profiles obtained by applying that correction are not realistic. Similar back-depletion corrected profiles, which sometimes include negative dopant density values,[1] have been calculated for other heavily doped specimens. The cause of this calculated profile shape lies in the assumed Gaussian shape of the entire diffused layer. When the new method is used, the average background dopant density is calculated to be 1.15×10^{18} cm^{-3} as indicated by the solid line in the figure. The Gaussian fit to the C-V data, when extrapolated to the surface gives an effective surface dopant density of 1.46×10^{23} cm^{-3}. The net dopant density calculated from the Gaussian fit is shown by the dashed curve in the figure. The large difference between the values of the surface dopant density calculated by the two methods indicates that the over-all diffused layer is non-Gaussian and falls more abruptly in the depletion region than a Gaussian diffused layer having the same sheet resistance and junction depth. The profiling method is thus not suitable for this specimen whereas the new method is.

The mathematical formulation of the new method is given in the Equations section. A brief description of how the equations are implemented is given in Calculation Procedure. Some examples of the method are reported in Ideal Data Studies and Real Data Studies sections which then leads to a discussion in the Evaluation and Limitations section and finally to the Conclusion. The method does not work when a Gaussian fit cannot be made, and this can be sensed and indicated. The method is based on the depletion approximation where the space-charge region is assumed to be free of holes and electrons and where the transition from the space-charge region to the depletion region is abrupt.

[1] A negative dopant density is calculated in Eq. [8] below if $N(W)$ is greater than $N(A)$. This can occur if the estimates of junction depth, effective surface dopant density, or background dopant density, which are all needed in the profiling method (8, 11), differ significantly from the correct values.

Equations

The equations and symbols used to present the new method may be understood with the help of Fig. 2. In the figure, A and B are the depletion widths on the heavily doped and lightly doped sides of the junction, respectively, $N(A)$ and $N(B)$ are the net dopant densities at A and B, X_j is the junction depth, N_b is the average background dopant density within the depletion region, N_{0e} is the effective surface dopant density representing the extrapolation of the Gaussian fit to the surface, and N_0 is the actual surface dopant density. Note that N_b is assumed constant within the depletion region and that N_{0e} may be vastly different from N_0.

In the absence of a correction for back-depletion, the depletion width, $W = A + B$, and the apparent dopant density, $N(W)$, can be calculated from the capacitance corrected for peripheral effects, C, and the reverse bias, V, by use of the following equations (14)

$$W = \frac{\kappa\epsilon_0 A_j}{C} \qquad [1]$$

$$N(W) = \frac{2}{q\kappa\epsilon_0 A_j^2}\left[\frac{d}{dV}\left(\frac{1}{C^2}\right)\right]^{-1} \qquad [2]$$

where $\kappa\epsilon_0$ is the dielectric constant of the test specimen, q is the electronic charge, and A_j is the active junction area. Equations [1] and [2] are in practice applied to a set of n C *vs.* V data pairs to produce a

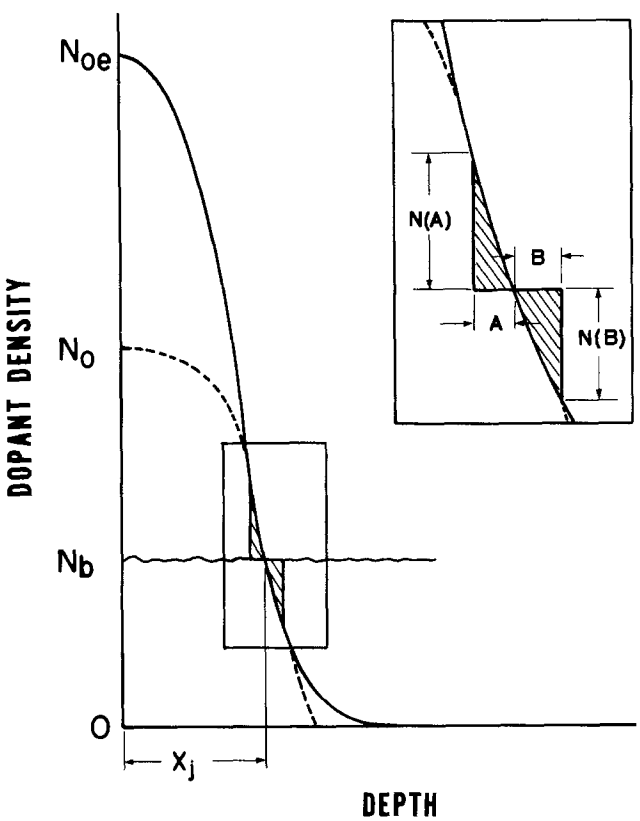

Fig. 2. Dopant density profile of a p-n junction showing a hypothetical diffused layer (dotted curve beginning at N_0) and the Gaussian fit to that layer (solid curve beginning at N_{0e}). The background dopant density is shown to vary with distance but is assumed constant within the depletion layer. The depletion region is shown enlarged in the inset.

set of $(n-1)$ $N(W)$ *vs.* W data pairs. The $N(W)$ and W values are known measured quantities.

For a Gaussian layer diffused into uniformly doped background material, the net dopant densities $N(A)$ and $N(B)$ are given by (8, 11)

$$N(A) = N_{0e}\exp\left[-\left(\frac{X_j - A}{L}\right)^2\right] - N_b \quad [3]$$

$$N(B) = N_b - N_{0e}\exp\left[-\left(\frac{X_j + B}{L}\right)^2\right] \quad [4]$$

where the parameter L is given by

$$L = \frac{X_j}{\sqrt{\ln\frac{N_{0e}}{N_b}}} \quad [5]$$

If values are assigned to X_j, N_{0e}, and N_b, then the quantities A and B can be calculated by simultaneously solving Eq. [6] and [7] (8)

$$W = A + B \quad [6]$$

$$\text{erfc}\left(\frac{X_j - A}{L}\right) - \text{erfc}\left(\frac{X_j + B}{L}\right) = \frac{2}{\sqrt{\pi}}\frac{N_b W}{N_{0e} L} \quad [7]$$

where Eq. [7] satisfies the charge neutrality requirement. The parameters $N(A)$ and $N(B)$ sum as follows (8, 15)

$$\frac{1}{N(W)} = \frac{1}{N(A)} + \frac{1}{N(B)} \quad [8]$$

The six equations listed above, Eq. [3] to [8], have seven unknown quantities: A, B, $N(A)$, $N(B)$, N_{0e}, N_b, and L, assuming that X_j can be determined by independent measurement. A seventh equation can be written if, for a set of $(n-1)$ $N(W)$ *vs.* W data pairs, N_b is constrained to be a constant such that

$$\frac{dN_b}{dW} = 0 \quad [9]$$

The above system of seven equations in seven unknowns can now be solved.

The computation is simplified by introducing the ratio R as defined by

$$R = \frac{N_{0e}}{N_b} \quad [10]$$

and by redefining L as

$$L = \frac{X_j}{\sqrt{\ln R}} \quad [11]$$

Substitution of these equations into Eq. [3], [4], and [8] leads to a new expression for the dopant density

$$N_b = N(W)\left\{\left[R\exp\left[-\left(\frac{X_j - A}{L}\right)^2\right] - 1\right]^{-1} + \left[1 - R\exp\left[-\left(\frac{X_j + B}{L}\right)^2\right]\right]^{-1}\right\} \quad [12]$$

For a properly chosen value of R, the condition given in Eq. [9] is satisfied and N_b is the average background dopant density of interest. For this condition, the best Gaussian fit to the C-V data has been found. The means by which a proper value of R is chosen is discussed in the next section.

Calculation Procedure

Given a set of C-V data in which the capacitances have been corrected for peripheral effects, a set of $N(W)$ and W values are first calculated using Eq. [1] and [2]. A first estimate of R is then made (10,000 has been found to be a good first estimate). For this value of R, L is calculated using Eq. [11] and a set of A and B values are calculated using Eq. [6] and [7]. A set of N_b values is then calculated using Eq. [12]. If the estimate for R has given the correct Gaussian fit, all of the N_b values [corresponding to the individual $N(W)$ values] are equal. The criterion for determining when R has been estimated correctly is based on the slope of N_b *vs.* W. More precisely, the N_b values are normalized with respect to the N_b corresponding to the maximum W, and the W values are normalized with respect to the maximum W. A least squares linear fit is then made to the normalized N_b *vs.* W values. If the absolute value of the slope is less than some value (usually 10^{-3}) the estimate of R is judged to be correct and the average background dopant density is given by the average of the unnormalized N_b values. If the above fit results in a positive slope, R is reestimated at a smaller value and the calculation is rerun. If the slope is negative, R is reestimated at a larger value. A rapidly convergent method for finding R is described in the Appendix.

It may be argued that N_b, originally defined as a constant parameter of the Gaussian fit, has been used also as a variable, thereby producing an inconsistency. However, the calculation procedure as described is designed to search for that value of R for which N_b is a constant, and it is judged to be a constant when a normalized plot of N_b *vs.* W has nearly zero slope.

The computer calculations to be described were performed using a BASIC interpreter having six-digit precision. The calculation of A in Eq. [6] and [7] was performed using an iterative algorithm which was terminated when the relative difference between two successive estimates of A was 10^{-4} or less (11).

Ideal Data Studies

Ideal C-V data for a Gaussian diffused p-n junction 17 mil in diameter and with a 1.5 μm junction depth were generated for 40 combinations of N_{0e} and N_b. The N_{0e} values were 10^{18}, 10^{20}, 10^{23}, and 10^{26} cm^{-3}, and the N_b values ranged from 10^{14} to 10^{20} cm^{-3} in half-decade steps (11). The C-V data were limited to practical values in that forward bias did not exceed 0.3V and reverse bias did not exceed the breakdown voltage which would be expected for a particular background dopant density. Peripheral capacitance was not included. The estimate of R was judged to be correct when the slope of the normalized N_b *vs.* W values was less than 10^{-3}. The first estimate of R in each case was 13,542. The results of these calculations are shown in Table I. For each N_{0e} value, those N_b values for which the absolute value of the error

was less than 0.10% are represented on a single line with the percent error given as $<\pm 0.10$. Those entries indicated as "no fit" could not be fitted to a Gaussian. This is discussed further in the Evaluation and Limitations section.

A second but similar ideal data study was carried but using 24 combinations of N_{0e} and N_b with X_j equal to 0.5 μm. These results are shown in Table II. Note that the shallower junction depth serves to reduce the measurement error of the various combinations of N_{0e} and N_b and also permits measurement in situations where a fit could not previously be made.

A third ideal data study was concerned with the consequences of errors in the junction depth and diameter, two needed input parameters. Using 15 sets of the previously discussed ideal data, X_j was entered 20% higher and 20% lower than the correct value. The resulting average background dopant densities were compared with the values previously calculated with no offsets (column 3 of Table I and II). For the junction depth study, the error exceeded 0.2% in only five of the 15 cases tried. In each of these five cases it was the underestimate of X_j which caused the error greater than 0.2%. These five cases are given in Table III. Note that these are cases of large N_b or cases of N_b approaching N_{0e}. With X_j entered correctly, the diameter was then offset by $\pm 1\%$. For these diameter offsets, the percent error in average background dopant density was in each case approximately minus four times the percent error in the diameter relative to the case of no error in the diameter. In this respect it follows the same pattern as in the profiling C-V method.

A fourth ideal data study was concerned with the repeatability of the average background dopant density in the presence of capacitance values which include random measurement error. Such sets of capacitance data were produced by modulating the previously calculated idealized capacitance values with a normally distributed random error having a standard deviation of 0.05%. This thus simulated a $\pm 0.1\%$ random measurement error. For each ideal data set. this procedure was repeated five times using five different sets of random numbers to generate the error. Each of the five sets of C-V data were then processed by the new method to produce five values of average background dopant density. The percent standard deviation of these five dopant density values was calculated. The results are shown in Table IV.

Real Data Studies

Capacitance-voltage data from 23 silicon specimens were processed by the new method. Fourteen of the specimens were n-type having nominal resistivity ranging from 100 to 0.009 Ω·cm and junction depth ranging from 0.44 to 1.84 μm. The method was successful on eleven specimens having average background dopant density in the range 4.64×10^{13} to 1.16×10^{18} cm^{-3} inclusive. The method gave somewhat erratic results on a specimen having an average background dopant density of approximately 2.7×10^{18} cm^{-3}. Attempts to apply the method to two more heavily doped specimens produced a "no fit" condition as described in the section Evaluation and Limitations. The nine p-type specimens had nominal resistivity ranging from 20 to 0.025 Ω·cm and junction depth ranging from 0.92 to 1.79 μm. The method was successful on eight specimens having average background dopant density in the range 6.21×10^{14} to 3.38×10^{17} cm^{-3} inclusive. The method produced a "no fit" condition when applied to the most heavily doped p-type specimen. The average background dopant density of that specimen is believed to be between 2 and 3×10^{18} cm^{-3}.

Evaluation and Limitations

The new method has been shown to work using idealized and real C-V data representing a wide range of practical conditions. The maximum measurable N_b appears to lie in the range 10^{18} to 10^{19} cm^{-3} depending on the shape of the diffused layer within the depletion region and also on the error which can be tolerated in a given application. The data in Tables I, II, and IV indicate that the error in N_b can be reduced in most instances by increasing N_{0e} or decreasing X_j. It may be possible to decrease X_j by using shorter diffusion times during junction fabrication. However, it may be difficult to produce junctions which are sufficiently abrupt as to have an N_{0e} of 10^{23} cm^{-3} or greater.

Regardless of the measurement error which can be tolerated, the method does not work if the C-V data cannot be fitted to a Gaussian. For the studies discussed thus far this "no fit" condition is manifest by successively smaller estimates of R until the lower limit 2 is reached. This limit is somewhat arbitrary, whereas R less than 1 corresponds to N_{0e} less than N_b, an unmeaningful case. It is uncertain what causes a "no fit" condition, however, it would seem that such might occur if the net dopant density within

the depletion region were linearly graded (for which a background dopant density is not defined) or if the net dopant density within the depletion layer were concave downward. The errors inherent in performing calculations with only six significant figures could conceivably lead to a "no fit" condition in some instances but this has not been verified. It is also possible that the assumption of abrupt depletion region boundaries is sufficiently invalid at such high background dopant densities as to make the model unworkable.

Another class of measurements for which a suitable fit cannot always be made is that in which an actual gradient in N_b exists. For heavily doped specimens having a gradient in N_b, R can be adjusted to be artificially high or low to force the set of calculated normalized N_b values to have a near-zero slope. Studies have indicated that when a measurement is made in the presence of a gradient the result is very nearly the average background dopant density within the depletion layer. In such a situation, the gradient is not detected as it is in a discrete point dopant density *vs.* depth calculation. For some lightly doped specimens having a gradient in N_b, there is no value of R in the range 2 to 10^{12} inclusive which gives a slope of the normalized N_b *vs.* W values sufficiently near zero. Such C-V data must be processed by the profiling method.

Conclusion

A method has been described for calculating the average background dopant density of a semiconductor specimen from C-V measurements made on a diffused p-n junction fabricated on the specimen. The method is particularly suited to relatively heavily doped specimens where profiling C-V calculations do not work. The method requires no knowledge of the actual surface dopant density of the diffused layer, and the junction depth is not a critical input parameter. The method has been tested with both ideal and real C-V data. The method is suitable for measurement of dopant densities up to 10^{18} cm^{-3}, however, above 10^{18} cm^{-3} errors become more probable and caution should be exercised in interpreting results.

APPENDIX

Procedure for Making Converging Estimates of R

A mathematical method for determining the correct value of R has been developed. The principle of this method can be explained with the help of Fig. 3. The figure shows how the slope of a plot of N_b *vs.* W behaves as a function of R and how this behavior can be used to converge on the final value of R. Represented in the figure are three sets of ideal C-V data for which the slope of the plot of normalized N_b *vs.* W values is plotted as a function of an estimate of R, designated R_e given as some coefficient times R_a the actual value of R for which the ideal C-V data

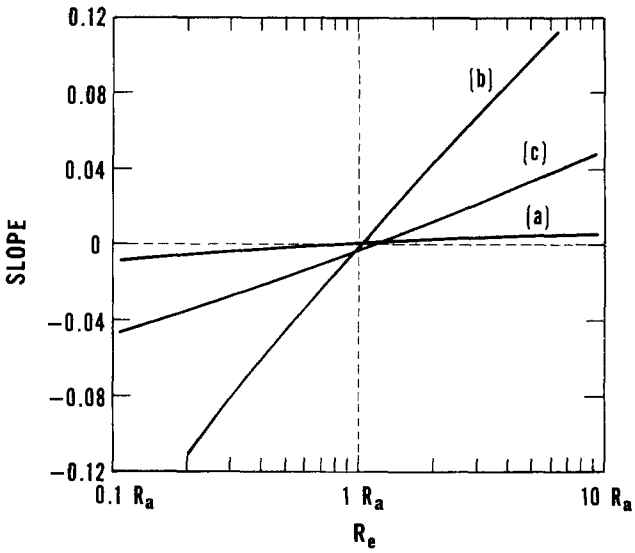

Fig. 3. Plot of the slope of the normalized N_b vs. W values as a function of R_e where R_e is the current estimate of R and R_a was the value of R used to calculate the ideal C-V data. Curves are shown for N_b equal to (a) 10^{16} cm^{-3}, (b) 10^{18} cm^{-3}, and (c) 10^{19} cm^{-3}. In each case N_{0e} was 10^{23} cm^{-3} and X_j was 0.5 μm.

were calculated. The plotted curves are all monotonically increasing from left to right and all pass through zero slope on the vertical axis at R_e approximately equal to R_a. (Deviations from R_e equal to R_a when the slope is zero may be a reflection of the error in Tables I and II.) Similar behavior was observed for other ideal data sets as well. Therefore for a set of real C-V data, if the slope of the plot of normalized N_b *vs.* W values is positive, it means that R_e is greater than R; if the slope is negative, then R_e is less than R.

In the first phase of the calculation to determine R, the parameter R_e (the estimate of R) is increased or decreased by decades depending on the sign of the slope of the normalized N_b *vs.* W values. This phase continues until a change in the sign of the slope is detected. The second phase consists of a succession of interpolations based on

$$R_e = \exp\left[\ln(R_1) - \frac{M_1}{M_2 - M_1}(\ln(R_2) - \ln(R_1))\right] \quad \text{[A-1]}$$

In Eq. [A-1], R_e is the new estimate of R, M_1 is the most recently calculated negative slope, calculated for R_e equal to R_1, and M_2 is the most recently calculated positive slope, calculated for R_e equal to R_2. The successive interpolations continue until the slope is sufficiently near zero at which time R is set equal to R_e.

Spray Deposition of Cadmium Stannate Films

G. Haacke, H. Ando, and W. E. Mealmaker

American Cyanamid Company, Chemical Research Division, Stamford, Connecticut 06904

ABSTRACT

The feasibility of spray coating transparent cadmium stannate electrodes onto glass has been demonstrated. Both cadmium stannate phases, Cd_2SnO_4 and $CdSnO_3$, can be deposited. The lowest electrical sheet resistances (10-20 $\Omega/\square$) and good optical transparency were obtained in $CdSnO_3$ films. With Cd_2SnO_4, clear films having 80-100 $\Omega/\square$ were achieved.

Thin films of cadmium (ortho) stannate (Cd_2SnO_4) are known to have high electrical conductivities and low visible absorption when prepared by rf sputtering under well-chosen conditions (1). The transparent electrode properties of these films suggest a wide range of applications where they would equal or surpass the performance of other transparent conductor materials (2, 3).

The practical utilization of cadmium stannate requires not only superior electrical and optical characteristics but also cost-effective preparation methods. When films having moderate electrical sheet resistances in the 10-100 $\Omega/\square$ range are needed sputter coating may be acceptable since the deposition time is short. For example, we can sputter in a 45 cm laboratory vacuum system Cd_2SnO_4 films from a 12.5 cm target plate within 5 min at 8μ plasma pressure and consistently obtain 15-20 $\Omega/\square$ sheet resistance after heat-treatment. The luminous transmittances of these coatings on Corning 7059 glass exceed 85% and in most cases reach 88-89% (substrate losses included). Films having lower sheet resistances require longer deposition times. 20 min are needed to achieve 2.5-3.0 $\Omega/\square$ and 82-83% luminous transmittance with coatings on Corning 7059 substrates. The sputter time increases to approximately 1 hr for 1 $\Omega/\square$ films. Such deposition times are rarely justifiable on economic grounds, so that a need exists to find more efficient preparation techniques for low sheet resistance cadmium stannate. Spray deposition appears to be one promising method since it has been successfully used to deposit transparent tin oxide (4) and indium oxide (5) electrodes. We have applied this technology to cadmium stannate and report the results of our investigations below.

Key words: transparent electrodes, pyrolysis, electrical sheet resistance, optical transmission.

Deposition Technique

The principle of spray deposition is based on the pyrolysis of a fine mist of a metal salt solution on a hot substrate. Binary oxide films, such as SnO_2 or In_2O_3, form quite readily and conditions for the deposition of optically clear coatings can be established without major difficulties. More stringent requirements have to be met when cadmium stannate is spray deposited since formation of the ternary stannate phase, instead of binary CdO/SnO_2 mixtures, occurs only within a narrow range of experimental parameters. A complicating feature arises from the existence of two cadmium stannate phases, Cd_2SnO_4 and $CdSnO_3$. Although both compounds are transparent conductors, good transparent electrode properties are achieved only in single phase films (6).

The experiments were carried out with a setup outlined in Fig. 1. A spray nozzle is located at a fixed position above the heated substrate. The substrate (2.5 $\times$ 2.5 cm) rests on a 0.6 cm thick carbon plate (EH grade, C.E. Chapin Company, East Rutherford, New Jersey) which provides good heat transfer and has a low burn rate even at high temperatures. Ceramic fire bricks (Thermolyne JR 11X2A) support the carbon plate which is directly heated by a regulated propane burner. This arrangement allows fast heat-up of the substrate to the desired deposition temperature and rapid removal of the coated samples during quenching experiments. The temperature is measured by a thermocouple

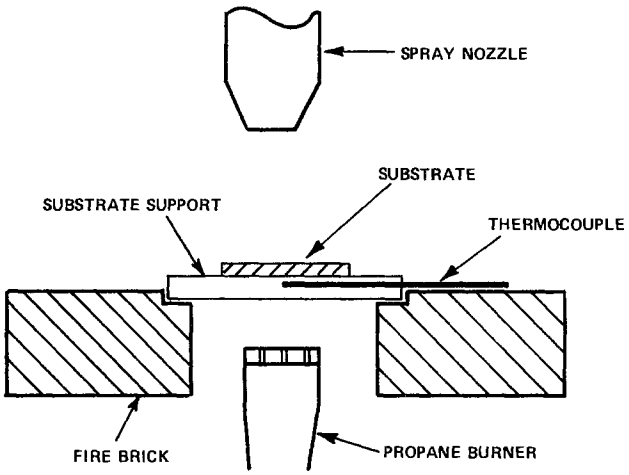

Fig. 1. Principal arrangement of spray equipment

inside the carbon plate and is monitored with a strip chart recorder. All "substrate" temperatures reported in this paper refer to the readings of this thermocouple; the actual substrate surface temperatures are lower than the values quoted here.

Critical parameters for the spray deposition of cadmium stannate are substrate temperature, composition of the spray solution, rate of deposition, and the spray characteristics, *i.e.*, size, velocity, and distribution of the droplets. The substrate temperature is important for two reasons. If it is too low (<400°-500°C) translucent or opaque coatings result. The optical transparency improves with increasing temperature but depending on the temperature range either one of the two cadmium stannate phases or mixtures of both develop. At high temperatures (>800°C) the Cd_2SnO_4 phase forms while $CdSnO_3$ is observed in films deposited below 800°C. Films containing both phases frequently occur if the required deposition conditions are not maintained. The composition of the films was determined by x-ray diffraction analysis (7).

Rate of deposition and composition of the spray solution are to a certain degree interdependent. The determining factor is the cadmium/tin ratio in the solution. For example, $CdSnO_3$ films with a sheet resistance $R_s \sim 20\ \Omega/\square$ can be prepared within 1.5 min when the Cd/Sn weight ratio is 5:1. It takes 5 min at a reduced spray rate to achieve the same R_s when the spray solution contains cadmium and tin in a 20:1 weight ratio. The higher Cd/Sn ratio has given better reproducibility of the electrical and optical film properties but for economic reasons the 5:1 ratio, requiring shorter deposition time, is preferable. Formation of either cadmium stannate phase becomes difficult when the Cd/Sn ratio drops below 5:1. Evidence also suggests that during prolonged spraying the electrical conductivity of the initial cadmium stannate layers deteriorates. It appears that this effect is caused by long exposure of the films to high temperatures. As a matter of fact the lowest R_s is obtained by fast deposition and immediate quenching of the sample.

A large number of cadmium and tin compounds and different solvents were investigated as components of the spray solution but none equaled aqueous solutions of $CdCl_2$ and $SnCl_4$. The influence of additives was also studied and hydrochloric acid was found to promote low sheet resistances and high transparencies. Small concentrations of indium or lead tend to improve the clarity of films of a given sheet resistance. In general, the concentration of each component in the solution can be changed within limits if other deposition parameters are adjusted accordingly. As an example the composition of a solution is given below which yields clear $CdSnO_3$ films with 10-20 $\Omega/\square$ sheet resistance at 700°-750°C substrate temperature: 100g 45.7% aqueous solution of $CdCl_2 \cdot 2.5H_2O$; 10g 35.1% aqueous solution of $SnCl_4 \cdot 5H_2O$; 3g 22.1% aqueous solution of $InCl_3$; 10g conc. HCl.

The spray characteristics are determined by the design of the spray nozzle, the oxygen gas pressure applied to operate the nozzle, and the flow rate of the metal salt solution. Conditions favoring the formation of cadmium stannate and resulting in optically clear films were found to require the smallest possible droplet size and a spray which arrives as a fine mist at the substrate. Care should be taken, however, that the spray is not heated excessively before it hits the hot substrate, otherwise the coatings are opaque. Good results were obtained with Sonicore® nozzles No. 035M-B from the Sonic Development Corporation, Upper Saddle River, New Jersey. These nozzles can be operated at low flow rates (5-130 cm^3/min) and produce droplets only a few microns in diameter.

A note of caution should be added. Although the nozzles are made of 316 stainless steel the highly acidic salt solutions cause gradual corrosion within the nozzles and a change of the spray characteristics. This change develops slowly and barely affects the film properties as long as R_s remains near 100 $\Omega/\square$ or higher. The changing spray characteristics become more critical in lower sheet resistance films and presumably are one of the causes of poor optical properties in samples with sheet resistances smaller than 10 $\Omega/\square$.

Substrate Materials

Silica appears to be a convenient substrate material for spray coating since its low coefficient of thermal expansion provides protection from thermal shocks occurring at the beginning and end of the deposition process. However, during attempts to produce Cd_2SnO_4 or $CdSnO_3$ films on silica with sheet resistances below ~100 $\Omega/\square$, it was observed that R_s decreased substantially less with increasing thickness t than one would have expected from $R_s \sim 1/t$. The cause of this result was traced to the formation of fine hairline cracks when the coatings exceeded a certain thickness (~0.5 μm). In most samples these cracks can be seen only with a scanning electron microscope; an example is shown in Fig. 2. This figure also demonstrates that a smooth film surface can be achieved by the spray coating technique.

Examination of the hairline crack structure revealed that they were induced by tensile stress indicating a poor match of the coefficients of thermal expansion β between the cadmium stannate and silica. Glasses with higher β's were explored and thicker films could be deposited without the formation of hairline cracks. A summary of these experiments is given in Table I. Corning 0211-type borosilicate glass appears to be the most suitable substrate material if β were the only parameter of concern. However, the low strain point (508°C) of this glass induces substrate distortions during spraying leading to unacceptable products. For this reason Corning 7059 or an equivalent glass is better suited, at least for $CdSnO_3$. The higher temperatures required for Cd_2SnO_4 restrict the choice of substrate material for this phase to alumino silicate or silica.

Electrical and Optical Film Properties

Transparent electrode applications of cadmium stannate films require optimized electrical sheet resistance

Table I. Critical film thickness resulting in hairline cracks for different substrate materials

Substrate material	Coef. thermal expansion ($°C^{-1}$)	Critical film thickness (μm)
Silica	$5 \cdot 10^{-7}$	~0.5
Aluminosilicate Corning 1720	$42 \cdot 10^{-7}$	~1.0
Borosilicate Corning 7059	$46 \cdot 10^{-7}$	1.0-2.0
Borosilicate Corning 0211	$74 \cdot 10^{-7}$	>2.0

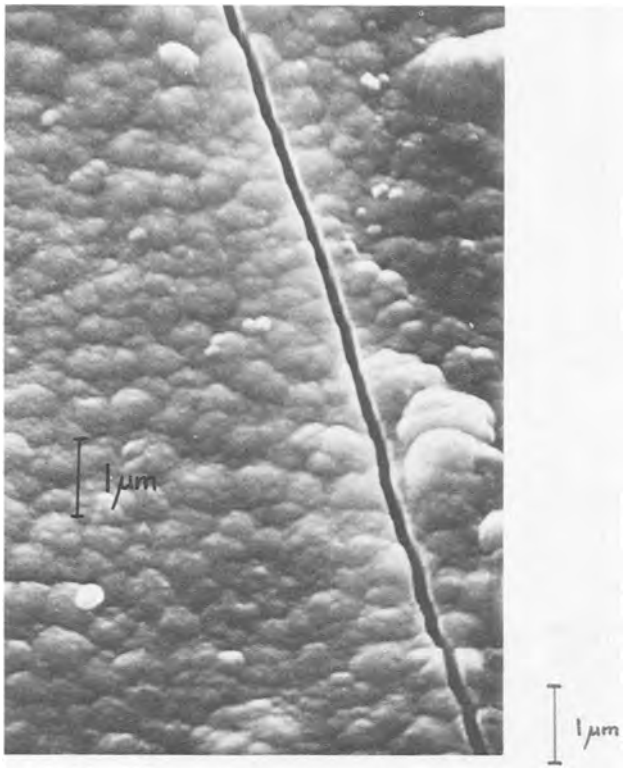

Fig. 2. Scanning electron micrograph of spray-deposited $CdSnO_3$ showing hairline crack caused by mismatch of coefficients of thermal expansion of film and substrate.

and optical transmission T. In general, R_s should be small and T should be as large as possible, but the relationships

$$R_s = 1/\sigma \cdot t$$

and

$$T = \exp(-\alpha t)$$

where σ is the electrical conductivity and α is the optical absorption coefficient, set forth that R_s and T are not independent of each other. Their common dependence on t stipulates that σ/α need to be maximized (8).

In sputter-coated Cd_2SnO_4 films electrical conductivities up to 6500 Ω^{-1} cm^{-1} have been achieved (1). The conductivities observed in spray-coated Cd_2SnO_4 do not reach these high values. Here, the best values are in the 500-1000 $\Omega^{-1}cm^{-1}$ range. Hall measurements with spray-coated Cd_2SnO_4 yielded mobilities of only 1-5 cm^2/V sec, which are approximately one order of magnitude lower than the mobilities measured in sputtered coatings (1). Presumably, the reduced mobilities are a consequence of the spray technique which creates lattice defects and grain boundary imperfections. Improvements in the deposition technique could lead to higher mobilities and consequently higher σ values. Impurities may also be present, but their influence on σ has not yet been studied sufficiently.

In view of the complications arising from the high substrate temperatures required for the formation of Cd_2SnO_4 only a limited amount of work was spent with this phase. On silica sheet resistivities of approximately 80-100 $\Omega/\square$ were achieved. Attempts to obtain lower R_s values by increasing the film thickness were only marginally successful because of developing hairline cracks (Fig. 2).

The optical properties of our spray-coated Cd_2SnO_4 are best characterized by Fig. 3. In this figure the transmission spectrum (measured with a CARY 14 spectrophotometer with a blank substrate in the reference beam) of a 120 $\Omega/\square$ coating is plotted. The film was sprayed onto silica at 850°C and required 10 sec

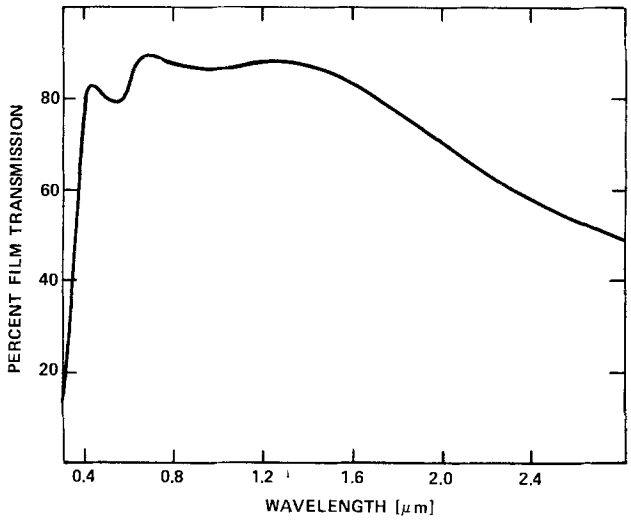

Fig. 3. Optical transmission spectrum of spray-deposited Cd_2SnO_4 film with 120 $\Omega/\square$ sheet resistance; substrate losses excluded (blank substrate in reference beam).

deposition time. It did not receive the postdeposition heat-treatment needed for sputtered Cd_2SnO_4 (1).

The lowest sheet resistivities were obtained in spray-deposited $CdSnO_3$ films. Although the conductivities in these films are approximately equal to those in Cd_2SnO_4, thicker layers could be prepared on Corning 7059 without crack formation. Hall mobilities and electron concentrations of the $CdSnO_3$ films do not differ significantly from those found in spray-coated Cd_2SnO_4, indicating that the same type of imperfections may cause the low mobilities.

Clear $CdSnO_3$ films attaining 10-20 $\Omega/\square$ sheet resistance have been spray deposited using solutions quoted above. Values as low as 3 $\Omega/\square$ were achieved with the same solutions but the optical properties of films with $R_s < 10$ $\Omega/\square$ are not yet acceptable; their transmission is less than 50% throughout the visible spectrum. Two examples of the transmission spectra of sprayed $CdSnO_3$ are presented in Fig. 4. Both films were prepared at 700°-750°C substrate temperature; the deposition time was 5 min. Again, no postdeposition heat-treatment was required. The existence of well-developed interference maxima and minima in the transmission curves is proof of a uniform film thickness.

Conclusions

We have confirmed that the spray deposition technique is suitable for the preparation of transparent

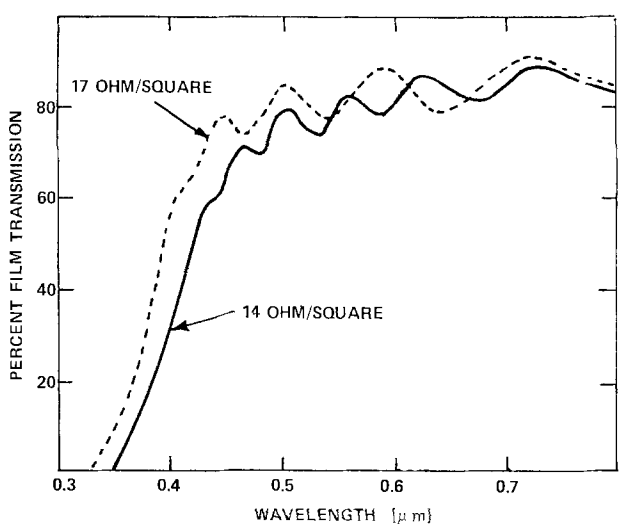

Fig. 4. Optical transmission spectrum of spray-deposited $CdSnO_3$ films; substrate losses excluded (blank substrate in reference beam).

conducting cadmium stannate films. Depending on the experimental conditions either Cd_2SnO_4 or $CdSnO_3$ can be deposited. Lowest sheet resistivities were obtained in $CdSnO_3$, and clear films with $R_s \sim$ 10-20 $\Omega/\square$ have been prepared. The feasibility of achieving sheet resistivities in the 1-10 $\Omega/\square$ range has been demonstrated but further refinements of the spray technology are needed to achieve useful optical properties. The superior transparent electrode properties of sputtered Cd_2SnO_4 films cannot yet be duplicated by spray deposition. Our investigations, however, have established that the postdeposition heat-treatment needed for sputtered Cd_2SnO_4 (6) is not an intrinsic requirement for the preparation of cadmium stannate films. Rather, the heat-treatment is specific for sputtered films to create large free electron concentrations and to reduce or remove the CdO phase which is initially present in these films.

The Ultimate By-Products of Stripping Photoresist in an Oxygen Plasma

R. F. Reichelderfer,* J. M. Welty, and J. F. Battey*

International Plasma Corporation, Hayward, California 94544

ABSTRACT

Evidence is presented that the final products of stripping an isoprene photoresist in an oxygen plasma are primarily oxides of carbon and water. The by-product gases are trapped in the exhaust of the reactor and weighed. The results are consistent with the conclusion that essentially all of the hydrogen in the photoresist becomes water and roughly half of the carbon becomes carbon dioxide. Presumably the other half becomes carbon monoxide which passed through the liquid nitrogen trap as a vapor.

The physically simplest of the plasma systems for processing silicon wafers is the stripping of photoresist with an oxygen plasma, as reported by Irving (1) and Bersin (2). The present work, as well as prior work, was undertaken in the expectation that a better understanding of this system would lead to improved reactor design and optimized operating conditions.

It has been shown (3) that the addition of both water vapor and carbon monoxide or carbon dioxide to the incoming oxygen flow reduces the photoresist stripping rate in an oxygen plasma without substantially reducing the atomic oxygen concentration. The implication is that these molecules are by-products of the stripping reaction. It has also been shown (4) that the photoresist stripping rate of a single silicon wafer is linear in atomic oxygen concentration for pressures in the order of 1 Torr and molecular oxygen conversion rates of 10% or less. The strip rates at the center of two closely spaced silicon wafers (5) suggests that about 550 CH_2 groups are stripped with the disappearance of each atomic oxygen atom. However, the fact that the ratio of the strip rates at the edge and center of closely spaced wafers varies approximately as the cube of the wafer diameter rather than the square suggests that the primary method of atomic oxygen consumption in the inter-wafer region is not linear and is probably quadratic in atomic oxygen concentration. This in turn suggests that most of the atomic oxygen is consumed by wall recombination at the wafer surface and a chemical reaction of a single oxygen atom is responsible for removing on the order of 5000 or more CH_2 groups from photoresist.

An experiment was planned wherein the exhaust gases from the stripping reaction would be trapped at liquid nitrogen temperature. It is assumed that any large molecular weight photoresist fragments would have very small vapor pressures at these temperatures and be effectively trapped. It was thought that the temperature could be raised in increments, the mass lost from the trap found by weighing, the number of molecules lost found by measuring the pressure rise in a known volume, and the molecular weight of the by-products of the stripping reaction calculated.

What in fact was found is consistent with the hypothesis that most of the hydrogen in the photoresist is turned into water and the carbon into carbon monoxide and carbon dioxide. Apparently the photoresist leaves the wafers in large molecular weight fragments which then continue to interact with the oxygen plasma until they are broken down into H_2O and CO and CO_2 by the time they get to the exhaust of the reactor.

Experimental Arrangement

A single 2 in. diameter silicon wafer was stripped of photoresist in an 8 in. diameter 13 in. long quartz reactor. The wafer was weighed before and after the application of the photoresist. The experimental arrangement is substantially the same as in (3). There was a quartz elbow about ¾ in. in diameter and about 12 in. in total length attached to the exhaust manifold through which all the exhaust gases pass. This was

* Electrochemical Society Active Member.

Key words: semiconductor processing, atomic oxidation of hydrocarbons, sequential oxidation of solid hydrocarbons.

joined by a ground-glass joint to a quartz cold finger about 1⅛ in. in diameter and 6 in. long. An inner tube in the cold finger forced the exhaust gases to flow down to the bottom of the cold finger and up the outer wall to get to the pump. The cold finger was immersed in liquid nitrogen.

After stripping was completed, the rf power and oxygen were shut off, after which the pump was shut off. Nitrogen was then slowly bled into the cold finger to a pressure of approximately an atmosphere to provide a blanket over the reaction products. With nitrogen still flowing, the ground glass joint on the pump end of the cold finger was disconnected and capped off. The ground glass joint on the reactor end was then disconnected and capped off. The cold finger was too heavy to weigh on the scales, so the cold finger was then connected to another quartz trap immersed in liquid nitrogen. The cold finger was then warmed up with a heat gun, and the trapped by-products of the stripping reaction transferred to the trap. The trap was then evacuated with the pump, shut off with a stop cock, and weighed. Since the evacuated trap had been weighed before receiving the trapped reaction by-products, their total weight can now be obtained.

At liquid nitrogen temperatures of 77°K, CO_2 and H_2O are virtually completely trapped, but CO is not trapped to any appreciable extent. A second Dewar was then filled with acetone which was chilled to a temperature of 203°K with an aluminum bar which had been immersed in liquid nitrogen. A second trap was immersed in liquid nitrogen and connected to the first trap which had been moved to the acetone bath. At 203°K the CO_2 becomes volatile and moves into the second trap. However, the water remains in the first trap. The mass of CO_2 and H_2O can now be obtained individually.

Experimental Results

The basic unit of Waycoat photoresist is isoprene or C_5H_8 which has molecular weight of 68.13.

The photoresist on the first wafer stripped had a mass of 2.0 mg which corresponds to 2.94×10^{-5} moles. If all the hydrogen is converted to water vapor 1.18×10^{-4} moles or 2.12 mg are to be expected. The actual mass trapped was 1.9 mg. If all the carbon is converted to CO_2 there should be 1.47×10^{-4} moles or 6.47 mg. The actual mass trapped was 2.5 mg.

A second wafer had a mass of 1.7 mg of photoresist. From this 1.80 mg of H_2O and 5.50 mg of CO_2 are to be expected. The actual mass trapped was 1.7 mg of H_2O and 3.9 mg of CO_2. The conclusion would seem to be that virtually all of the hydrogen is converted to water, and about half of the carbon is converted to carbon dioxide. With nothing but carbon and oxygen to work with it seems probable that the remaining carbon was present in the form of carbon monoxide which would not have been trapped.

Forty wafers were then stripped and the exhaust gases that were trapped at liquid nitrogen temperature were examined with an infrared adsorption spectrophotometer. The gases were transferred to the infrared adsorption cell at room temperature so the CO_2 would be essentially a gas whereas the water would be primarily a liquid. A colorless liquid was visible in the trap at room temperature. The spectrum of the gas showed strong, broad adsorption at 667 cm^{-1} and 2350 cm^{-1} and sharp doublets at 3600 and 3630 cm^{-1} and 3730 cm^{-1}, characteristic of CO_2.

There was no sign of the carbonyl stretch which would have been indicative of formaldehyde or formic acid.

Conclusion

In the vaporization of an isoprene (C_5H_8) photoresist with an oxygen plasma prior evidence suggests that the by-products of the reaction leave the photoresist surface in molecular weight groupings in excess of 5000. The present work shows that by the time the by-products leave the exhaust manifold the hydrogen is converted to water vapor and roughly half the carbon is present as carbon dioxide. It seems probable that the rest of the carbon escaped undetected as carbon monoxide.

Hot-Electron Trapping in CVD PSG Films

R. A. Gdula and P. C. Li

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Large-scale integration requires small geometry insulated-gate field effect transistors (IGFET's) with thin gate insulators. Contamination protection traditionally provided by $POCl_3$-generated phosphosilicate glass (PSG) is too difficult to control for 250Å gate insulators. A chemical vapor deposition (CVD) process capable of producing 50Å PSG layers has been developed by Li as an alternative. This paper describes the hot-electron trapping behavior of these CVD PSG/SiO_2 composites, which were found to be much superior to Si_3N_4/SiO_2 composites. The parameters of CVD PSG layer thickness, P_2O_5 concentration, and thermal anneal were evaluated. Electron trapping occurs at network imperfections inherent in CVD SiO_2 and, to a lesser degree, at sites containing phosphorus atoms. The first can be reduced by thermal annealing.

Large-scale integration (LSI) has forced silicon insulated-gate field effect transistor (IGFET) technology to provide smaller geometry devices, with a concomitant reduction in gate insulator thickness. Future devices may well employ the equivalent of only 250Å of SiO_2. Meanwhile, contamination is still a problem and

Key words: electron trapping, phosphosilicate glass, insulator, film, CVD.

protection of the gate area from intrusion by mobile impurities during processing and subsequent packaging of the chips is still necessary. Traditionally, phosphosilicate glass (PSG) passivation produced by the pyrolysis and diffusion of $POCl_3$ has been used (1-6), but the poor controllability of this process makes it unsuitable for very thin gate insulators.

A chemical vapor deposition (CVD) process to produce PSG through the reaction

$$SiBr_4 + PH_3 + O_2 \xrightarrow[N_2 \text{ carrier}]{600°\text{-}1000°C} PSG + \text{gaseous by-products} \quad [1]$$

has been developed by one of the authors (Li). This process, he has shown, controllably produces PSG layers as thin as 50Å with excellent quality (7).

With the progression towards smaller devices, hot-carrier injection was found to degrade the performance of planar transistors (8, 9) and to produce instabilities in metal oxide semiconductor field effect transistors (MOSFET's) (10-12). It has become important to understand trapping in thin-film insulators and to gauge the effects of processing on this trapping (13).

This paper characterizes the trapping of hot electrons in thin CVD PSG/SiO_2 composite dielectrics. The electrons were produced by avalanche injection of simple MOS and metal glass oxide semiconductor (MGOS) capacitors, after Nicollian and co-workers (14-17). The technique is more completely described in a previous paper (13).

Experimental Procedures

Sample preparation.—Silicon wafers (5.7 cm diam, boron doped, p-type, <100> orientation of 0.4 Ωcm resistivity) were quartered, stripped in concentrated HF, and given an inorganic cleaning (18) in hot aqueous solutions of $NH_4OH + H_2O_2$ and $HCL + H_2O_2$ finished by copious rinsing in deionized water. Films of SiO_2 were formed by thermal oxidation at 925°C in dry O_2 or in dry O_2 + 2% HCl and were well annealed in inert ambients at the same temperature; PSG films were produced by CVD at 900°C using reaction [1]. The total film thickness was ≤ 300Å in all cases. Pure aluminum was evaporated through metal masks to form capacitors whose field plates had an area of 2×10^{-3} cm^2. Aluminum was also deposited on the wafer back sides and annealed in N_2 at 400°C for 20 min to provide ohmic contacts to the silicon. Mobile charge levels were checked by the *I-V* loop technique (19) after biasing of the capacitors at $+2 \times 10^6$ V/cm, 200 C, for 10 min. Mobile charge levels, in all cases, were found to be $< 3 \times 10^{10}$ charges/cm^2. Film thickness was measured with an ellipsometer.

Trapping measurement technique.—Starting with a virgin capacitor, the high frequency (1 MHz) and low frequency (quasistatic) *C-V* characteristics were determined. Then the capacitor was avalanched by impressing a train of square positive pulses (amplitude = 25V, pulse width = 0.1 μsec). Repetition rates of 10 pulses/sec increasing to 1×10^6 pulses/sec were used to control the quantity of injected electrons during any avalanching period. With a measuring circuit similar to that in Ref. (17), the number of electrons flowing through the sample was counted on a coulometer. The sample was reconnected to the *C-V* measuring apparatus, and the high frequency *C-V* characteristics was retraced. A measure of the number of electrons trapped in the insulator was inferred from the shift, ΔV, between the high frequency *C-V* traces measured at midgap. The entire process was then repeated over and over for ever-increasing numbers of injected electrons. All measurements were made with the sample in darkness. Typical results for undoped SiO_2 films are described in a previous paper (13).

Results and Discussion

Preliminary evaluation.—Composite films consisting of 50Å of 4 mole percent (m/o) P_2O_5 CVD PSG over 200Å of thermal SiO_2 were prepared and annealed at 1000°C for 10 min in argon. The trapping behavior of such a film is compared in Fig. 1 with that of 250Å thermal SiO_2 and of a composite of 100Å of Si_3N_4 over 200Å of thermal SiO_2. It is seen that the CVD PSG/SiO_2 composite film traps far fewer of the injected electrons than the Si_3N_4/SiO_2 composite film, but still somewhat more than straight thermal SiO_2. If a hot electron shift, ΔV, of 100 mV end of life is allowed, the nitride/oxide composite will have reached that point after only 2.5×10^{12} e/cm^2 have been injected, or 480 times sooner than the CVD PSG/SiO_2, which required 1.2×10^{15} e/cm^2 injected to shift 100 mV.

Effect of PSG layer thickness.—Since previous work had shown that hot-electron trapping in thermal SiO_2 decreased drastically as the film thickness decreased below 250Å (Fig. 2), for such structures as 100Å CVD PSG over 100Å of thermal SiO_2 we expected the trapping to be dominated by the PSG layer. Figure 3 quite vividly shows this to be true. The as-deposited composite shifts ~100 times more, and the annealed composite ~10 times more than the thermal SiO_2 film, even though they are only about twice as thick. In Fig. 4, the trapping contribution of the underlying 100Å of SiO_2 is subtracted from the curve of the annealed composite, showing that almost all the trapping is in the PSG layer.

Utilizing this fact that for thin composites the PSG layer dominates the trapping behavior, we constructed a series of samples, varying the PSG thickness from

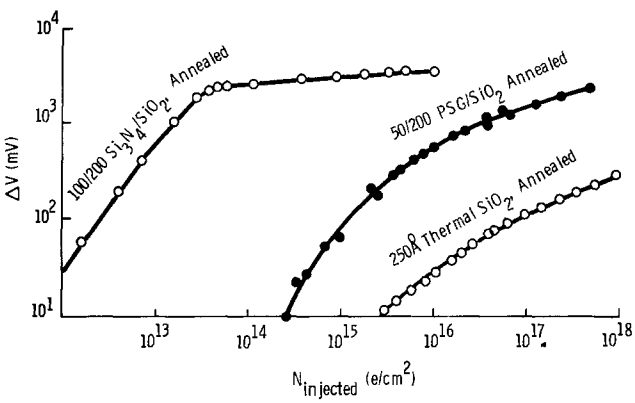

Fig. 1. Electron trapping in CVD PSG/SiO_2 compared with Si_3N_4/SiO_2 and thermal SiO_2 of equivalent thickness. The lateral shift, ΔV, of the high frequency *C-V* curve (measured at midgap) is a function of the number of electrons trapped in the insulator films.

~50 to ~200Å with total composite thickness = 250Å. The P_2O_5 concentration was ~4 m/o, and all samples were annealed after CVD for 10 min at 1000°C in argon. Their virgin C-V properties are presented in Table I. Their trapping behavior is shown in Fig. 5, where it is seen that the C-V shift caused by captured electrons is roughly proportional to the PSG layer

* Silicon became n-type because of diffusion of phosphorus from PSG. No measurements were taken on these samples.

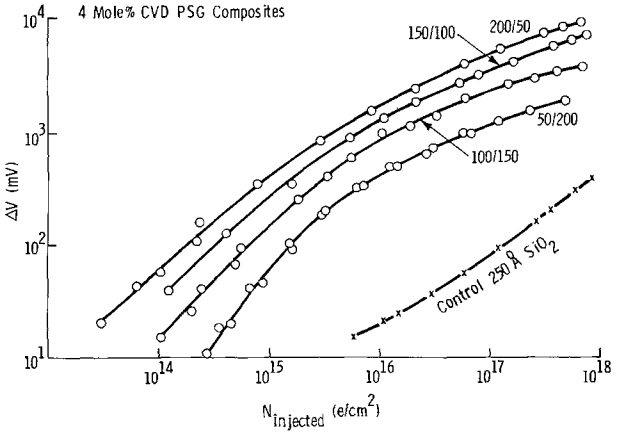

Fig. 5. Electron trapping in 4 m/o P_2O_5 × CVD PSG/250 × SiO_2 (nominal).

thickness. This is the behavior that would be expected if most of the electrons were trapped uniformly throughout the PSG layer thickness.

Effect of P_2O_5 concentration.—Composite films with a nominal 100Å of CVD PSG over 150Å of thermal SiO_2 were constructed with P_2O_5 concentrations of 0, 1, 4, and 10 m/o. We annealed these samples for 10 min at 1000°C in argon. Their virgin C-V properties are given in Table I. Since the PSG layer thicknesses of these samples varied from 80 to 168Å, their trapping behavior could not be compared directly on the basis of C-V shifts. The data were normalized for comparison by assuming that all the electrons were trapped uniformly throughout the volume of the CVD layer, and the number of electrons trapped, $N_{trapped}$, was calculated from the equation

$$N_{trapped} = \frac{\Delta V \epsilon_0 \epsilon_{ox}}{\bar{x} q} \quad [2]$$

where ΔV is the lateral C-V shift measured at midgap and referenced to the virgin C-V curve, ϵ_0 is the permittivity of free space = 8.85×10^{-14} f/cm, ϵ_{ox} is the dielectric constant of SiO_2 = 3.85, $\bar{x}$ is the centroid of the trapped charge = CVD layer thickness/2, and q is the charge on the electron = 1.6×10^{-19} coulombs. The thus normalized trapping curves are presented in Fig. 6. From this it is seen that, after about 5×10^{15} e/cm² are injected, the trapping does depend somewhat on the P_2O_5 concentration, but the 10 m/o film does not trap 10 times the number of electrons that the 1 m/o film traps. Curve 5 is calculated from

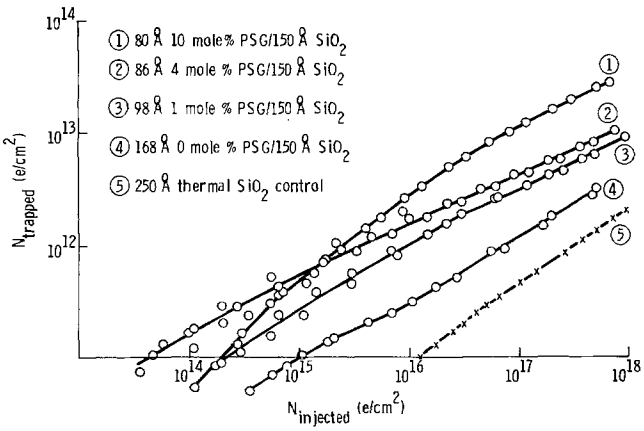

Fig. 6. Electron trapping in annealed CVD PSG layers as a function of P_2O_5 concentration. $N_{trapped}$ was calculated from the C-V shifts, assuming all electrons were uniformly trapped throughout the CVD layer.

the raw data of a 250Å thermal SiO_2 sample, with the assumptions outlined above. In the early parts of the curves, their positions bear no relation to P_2O_5 concentrations, as the behavior is dominated by large traps which are remnant from the deposition and unrelated to phosphorus.

Effect of thermal anneal.—In the preliminary experiments, electron trapping in CVD PSG films decreased substantially after a short anneal at 1000°C (Fig. 3). Two experiments were designed to gauge the effectiveness of annealing for reducing electron trapping in CVD PSG films. A set of samples of 4 m/o P_2O_5 120Å (nominal) PSG over 180Å of thermal SiO_2 was produced. In the first experiment, part of these samples were annealed at 1000°C in argon for times of 15-480 min. In the second, the remainder of the samples were annealed for 15 min at 900°, 1000°, 1050°, and 1100°C. The *C-V* data of these samples are given in Table I; the electron trapping behavior is presented in Fig. 7 and 8 and compared with a typical 250Å film of thermal SiO_2. Because of differences in the PSG layer thicknesses, the trapping data were normalized as described in the section on P_2O_5 concentration. In both experiments, the best results were obtained after a 15 min anneal at 1000°C. This also coincides with minimization of oxide charge and fast surface states as revealed by the *C-V* data taken prior to electron injection. At 1000°C for times longer than 15 min, V_{FB} became more negative, N_{FS} increased, and electron trapping increased. After 240 min at 1000°C, the silicon substrate was found to be n-type because of phosphorus diffusion from the PSG layer. For anneals of 120 min or less, no change in the substrate doping level was noticed from the *C-V* curves, with the boron ranging from 3 to 6 × 10^{16} atoms/cm^3 in a random fashion. For the 15 min anneals at different temperatures, the same behavior was seen, with optimum properties achieved in the 1000°C treatment. After 15 min at 1100°C, the silicon substrate was n-type. Although this investigation did not encompass all conceivable anneal conditions, it should be recognized that good results may be achieved with longer anneals at lower temperatures and with shorter anneals at higher temperatures.

Conclusions

1. As a composite dielectric for small IGFET's, CVD PSG/SiO_2 is much superior to Si_3N_4/SiO_2. The latter has a severe hot electron problem because of the high trapping efficiency of the nitride layer. For an allowed end-of-life V_T shift of a hundred or so millivolts, the CVD PSG/SiO_2 composite is expected to last 250-500 times longer.

2. In CVD PSG/SiO_2 composites, the electron trapping is dominated by the CVD PSG layer. Thus, trapping is proportional to CVD PSG layer thickness.

3. In CVD PSG layers, electrons are trapped by imperfections in the Si-O network inherent in the CVD process and, to a lesser extent, at sites that contain phosphorus atoms. The inherent CVD traps are larger and can be reduced by thermal annealing, during which rearrangements of the Si-O network can occur. This reduces the incidence of unsatisfied or strained bonds. The phosphorus-related traps cannot be eliminated by annealing, and the hot electron V_T shift can even be increased if the PSG layer thickness increases markedly because of diffusion. Best results are obtained from a short anneal at 1000°C.

Mass Transfer, Equilibrium, and Kinetics in the Chemical Vapor Deposition of Boron from Impinging Jets

L. Vandenbulcke and G. Vuillard

Centre de Recherches sur la Chimie de la Combustion et des Hautes Températures et Faculté des Sciences d'Orléans, 45045 Orléans Cedex, France

ABSTRACT

The deposition mechanisms of boron from boron trichloride and hydrogen vapors are investigated by a stagnation flow technique. The characteristics of gas flow are first deduced from experimental deposition rates. Then, using the Stefan-Maxwell equations for diffusion, the interfacial conditions of deposition, equilibrium, or supersaturation are inferred from experimental rates of deposition in the stagnation zone. Three mechanisms of deposition are deduced, mass transfer-interfacial equilibrium, mass-transfer-surface kinetics, and surface kinetics. They occur as a function of three experimental parameters; temperature, mass flow rate, and inlet composition BCl_3/H_2. A correlation for mass transfer in impinging jets is obtained.

The deposition of boron from boron trichloride and hydrogen vapors is a complex process which has been studied in detail (1-4), but which is still a matter of controversy (4). The reaction is heterogeneous and the deposition rate likely to be limited by the surface reactions or diffusion, or by a combination of these two steps. The relative importance of kinetics and diffusion factors were studied in the case of a flow perpendicular to a horizontal or vertical filament (1-2), and in the case of a flow parallel to a horizontal (1) or vertical (4) one.

Gruber (1) and Mehalso and Diefendorf (4) have neglected the production of the intermediate $HBCl_2$ which is detected in significant proportions in boron filament production (5) and in the gas phase at equilibrium (2). They compute the rate of mass transport, assuming thermodynamic equilibrium between boron and the gas phase calculated from the inlet $BCl_3 + H_2$ composition. The work of Carlton *et al.* (2) is based on a description of fluxes and concentrations of all the principal components (BCl_3, H_2, HCl, and $HBCl_2$). The deposition rate is shown to be governed by a combination of diffusion and kinetics considerations.

In the present work we confirm that the mechanism of Carlton *et al.* well describes the system in various experimental conditions, especially when the vapor phase is supersaturated. In addition to this mass transfer-kinetics mechanism, two others, mass transfer-equilibrium and surface kinetics, independent of mass transfer, arise. The three models are found to represent most accurately all possible experimental conditions. These deposition mechanisms were studied by a stagnation flow technique where the reactive BCl_3/H_2 mixture streamed through a cylindrical nozzle and was blown perpendicularly onto a cylindrical disk.

Experimental Techniques

The deposition equipment and experimental procedure have been described elsewhere (6). The deposition cell is represented schematically in Fig. 1. The stream of reactants is introduced in a 0.8 cm diam cylindrical nozzle normal to the substrate. The substrate is a disk of 1-3 cm diam, 0.2-1 cm thick. It is heated by a high frequency generator regulated by a thermocouple fitted at 0.05 cm under the surface to be coated.

In all experiments the pressure was equal to 1 atm, the temperature was varied from 1050° to 1250°C, and the BCl_3/H_2 flow rate ratio ranged from 5/95 to 70/30. The reactants mass flow rate was varied from 0.02 to 0.44 g/cm²/sec. The deposit thickness was measured with a microscope on polished transverse cross sections of the substrate, and deposition rate was deduced from experiments at 5 or 6 different deposition times.

Key words: gas flow, interface, diffusion, boundary layer, deposition mechanisms.

Characteristics of Gas Flow

Heat and mass transfer between an impinging axisymmetric turbulent jet and a flat surface have been studied by many authors. In the laminar case which is encountered in CVD, studies are more limited. Therefore, it is necessary to study directly or indirectly the characteristics of gas flow.

Deposit thickness profiles.—Figure 2 shows the thickness of boron deposits as a function of the radial distance on the substrate with varying mass flow rates of reactants. The thickness is constant in the stagnation zone and presents a bell shape for greater radial distances than the radius of the nozzle. This profile is characteristic of a deposition rate limited in part at least by diffusion, and this is confirmed by the influence of the mass flow rate on the deposition rate in the stagnation zone. The deposition rate in the stagnation zone appears as a parameter which makes deduction of the principal characteristics of gas flow in the jet possible.

Influence of natural convection.—In chemical vapor deposition, temperature and concentration gradients near the substrate introduce a secondary flow which is eventually not negligible as compared with the forced flow in the jet. The influence of free convection

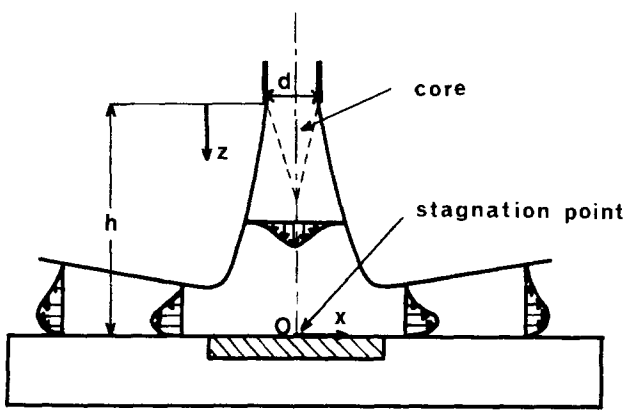

Fig. 1. Axisymmetric jet impinging on a flat plate

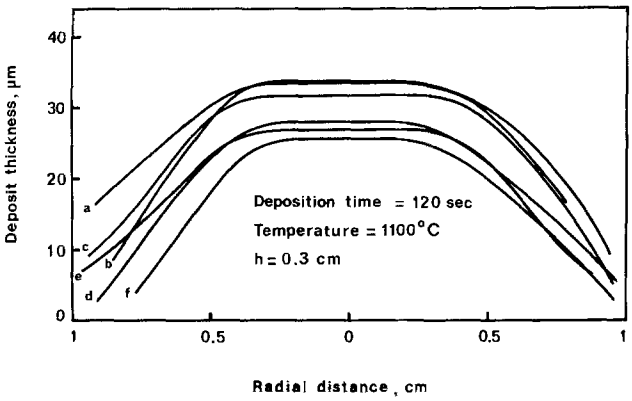

Fig. 2. Deposit thickness profile as a function of mass flow rate: a = 0.214, b = 0.178, c = 0.143, d = 0.119, e = 0.095, f = 0.071 g/cm²/sec; BCl_3/H_2 = 2/3.

depends on the ratio N_{Gr}/N_{Re}^2 (7-8) and the angle α between the directions of the forced flow and the buoyancy force (9). Free convection increases the transfer in assisting flow ($\alpha = 0°$). In opposing flow ($\alpha = 180°$), the buoyancy forces initially decrease the transfer below the corresponding forced-flow values. At low values of N_{Re}, the transfer tends to its purely free convective value. It passes through a minimum and then rises above the forced-flow values. In normal flow ($\alpha = 90°$), free convection increases the transfer but only when N_{Re} is very low (high values of N_{Gr}/N_{Re}^2). Therefore, the influence of free convection is often negligible with this geometry.

In our study, the effect of free convection is limited to the influence on transfer in the stagnation zone, 0.8-1 cm diam. Figure 3 presents the influence of the mass flow rate of reagents on the deposition rate for $\alpha = 90°$ (horizontal jet) and $\alpha = 180°$ (vertical downward jet). For mass flow rates greater than 0.05 g/cm²/sec, there is no significant difference with orientation of the reactor. For mass flow rates lower than 0.05 g/cm²/sec, the deposition rate decreases in the case of opposing flow. Calculation stated later shows that this limit corresponds to a ratio $N_{Gr}/N_{Re}^2 \simeq 0.1$. Because of the change in gas density in the film, due to both temperature gradient and composition changes induced by reaction, N_{Gr} was calculated to account for both temperature and composition gradients in the system. With constant mass flow rates, the influence of natural convection has been studied as a function of inlet compositions. N_{Gr} varies from 150 to 5500 when the inlet mole fraction of BCl_3 increases from 0.1 to 0.7.

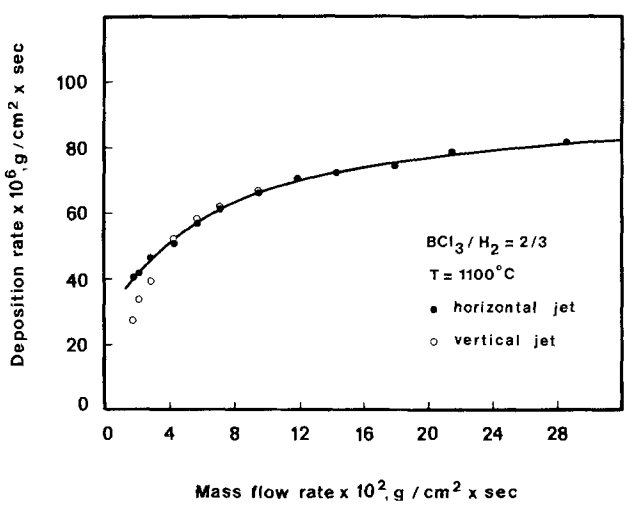

Fig. 3. Deposition rate as a function of reactants mass flow rates.

For a mass flow rate of 0.07 g/cm²/sec, the ratio N_{Gr}/N_{Re}^2 increases from 0.004 to 0.16. Orientation of the reactor is sensitive for $N_{Gr}/N_{Re}^2 > 0.08$. For a mass flow rate of 0.021 g/cm²/sec, orientation of the reactor is insensitive (N_{Gr}/N_{Re}^2 is always lower than 0.02). Then, natural convection can be neglected when $N_{Gr}/N_{Re}^2 < 0.1$. According to Oosthuizen and Madan (9), this value of 0.1 involves a decrease of 10% of the heat transfer, in the case of forced opposing flow of air on a cylinder compared with the pure forced case. In the normal flow case, they show that natural convection is negligible for $N_{Gr}/N_{Re}^2 < 0.53$. In our experiments, this value is never reached. Also we consider that natural convection is always negligible in the horizontal case. This assumption is confirmed by the following studies.

Influence of the distance h between the nozzle and the substrate.—Figure 4 presents the influence of h on the deposit thickness in the stagnation zone ($N_{Re} \simeq 180$). Mass transfer remains constant when h is lower than a critical value $h_c = 4$ (h is always greater than 0.2 to avoid the case of high mass transfer in a "wall jet" in which the opening between the plate and nozzle is smaller than the aperture of the nozzle). Figure 5 shows that h_c is a function of N_{Re} (experiments were performed in horizontal position for mass

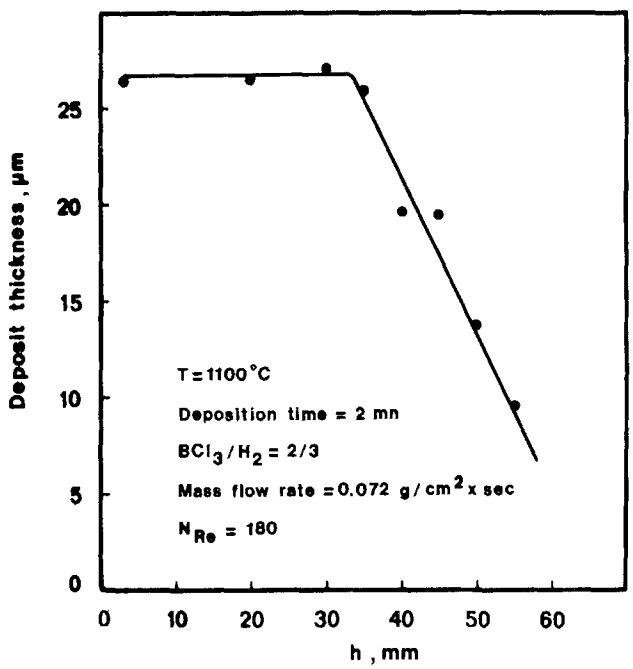

Fig. 4. Deposit thickness as a function of h

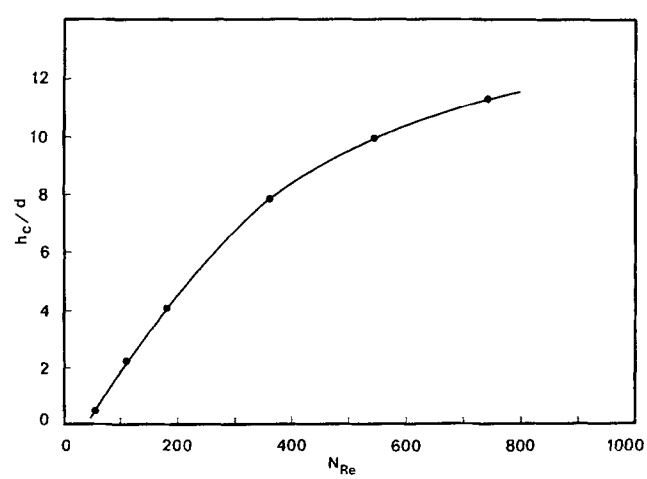

Fig. 5. Variation of potential core length with N_{Re}

flow rates lower than 0.05 g/cm²/sec). This figure leads us to conclude that for $N_{Re} \geq 50$, experiments can always be performed with a substrate placed in the core of the jet where mass transfer is independent of the distance h. The study of the influence of h on the deposit thickness in the stagnation zone is limited to values of $N_{Re} < 740$ because the limit of h in our reactor is 10 cm. Hrycak *et al.* (10) have studied the variation of the potential core length for $N_{Re} \geq 620$. This length reaches a maximum at a value of about 1200. For values greater than 2000, the dimensionless potential core length is $h_c/d \simeq 6$.

Influence of the substrate diameter d_o.—With a vertical reactor, the substrate diameter has no influence on the deposition rate in the stagnation zone when $N_{Gr}/N_{Re}^2 < 0.1$ and $h < h_c$. For $N_{Gr}/N_{Re}^2 = 0.1$, the potential core length decreases when the substrate diameter is greater than 2 cm. In the horizontal case, there is no influence when $N_{Gr}/N_{Re}^2 < 0.5$. Out of the stagnation zone, mass transfer increases logically in the upper part of the substrate.

All the above results permit us to conclude that in the range $50 < N_{Re} < 1000$ and appropriate experimental conditions (substrate placed in the core of the jet; $h > 0.2$ cm; $\alpha = 90°$ when mass flow rate is low), the mass transfer in the stagnation zone is independent of natural convection. It should be essentially studied as a function of forced flow. Thus the stagnation flow technique is of particular technical and theoretical interest.

Physicochemical Mechanisms of Deposition

Theoretical analysis and calculation.—Thermodynamical studies of the B-H-Cl system were used by Carlton *et al.* (2) to postulate a kinetic model taking into account the intermediate species $HBCl_2$. Table I gives the equilibrium composition obtained with more recent thermodynamical data for $HBCl_2$ (11) from a stoichiometric mixture of $BCl_3 + H_2$. These results confirm that $HBCl_2$ is the only important intermediate species at equilibrium. $HBCl_2$ is also a product of boron filament production (5) in conditions clearly out of equilibrium. Therefore, without any hypothesis on the interfacial conditions, equilibrium between boron and the vapor phase or supersaturation of the vapor phase, the deposition process is assumed to proceed as follows: (*i*) BCl_3 and H_2 diffuse to the deposition surface; (*ii*) BCl_3 and H_2 react, depositing boron and releasing $HBCl_2$ and HCl; and (*iii*) $HBCl_2$ and HCl diffuse away from the surface. Reactants and products diffuse through a boundary layer of thickness δ (Fig. 6). The Stefan-Maxwell equations are generally used for diffusion of ideal gases. For a 4 component mixture, there are 3 equations of the form

$$\frac{dX_1}{dz} = -(J_1X_2 - J_2X_1)\frac{RT}{PD_{12}} - (J_1X_3 - J_3X_1)\frac{RT}{PD_{13}} - (J_1X_4 - J_4X_1)\frac{RT}{PD_{14}}$$

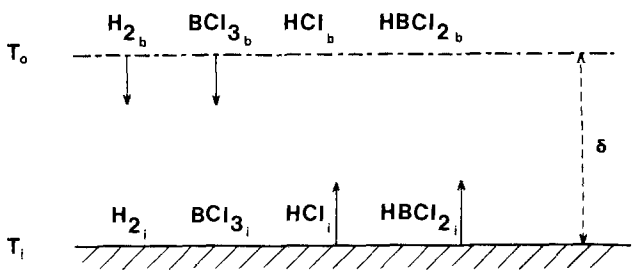

Fig. 6. Diffusion model for boron deposition

and one relationship between the 4 molar fractions

$$X_4 = 1 - X_1 - X_2 - X_3$$

The bulk stream compositions are known. They are assumed constant throughout the reactor, and are calculated from the arithmetic average of inlet and outlet compositions. On the other hand, the individual diffusion fluxes are not independent; they are related to each other by reaction stoichiometries. Finally, the interfacial composition is defined by kinetic or thermodynamical considerations. However, as pointed out by Carlton *et al.* (2), the H-B-Cl system is more complicated because at least two reactions proceed concurrently

$$2BCl_3 + 3H_2 \rightarrow 2<B> + 6HCl$$

$$BCl_3 + H_2 \rightarrow HBCl_2 + HCl$$

and there is no relationship between their rates. Therefore a trial and error method was employed to determine the value of J_{HBCl_2} which permits integration of the Stefan-Maxwell equations. The Runge-Kutta method, as modified by Gill, was selected for integrating this system of first order differential equations, and the interfacial reacting mixture at any δ was tested for kinetic or thermodynamical resistances. When a good fit was obtained, the computer program was completed by calculation of the mass transfer parameters N_{Sh}, N_{Sc}, N_{Re}, N_{Gr}.

In the case of interfacial kinetic resistance, the deposition rate, which is the difference between the diffusion rates of BCl_3 and $HBCl_2$, is calculated by the following relationship derived by Carlton *et al.* from their kinetic model

$$V = k_o \left[\frac{k'_{eq} \cdot P_{BCl_3}{}^i \cdot P_{H_2}{}^i}{P_{HCl}{}^i} - \frac{(P_{HCl}{}^i)^2}{k''_{eq} \cdot P_{H_2}{}^i} \right] \Big/ (1 + k_{HCl} \cdot P_{HCl}{}^i)$$

where k_o, k_{HCl}, k'_{eq}, k''_{eq} are exponential functions of reciprocal temperature. This kinetic model assumes that $HBCl_2$ is in equilibrium in the vapor phase. The value of k''_{eq} is the equilibrium constant for the reaction

$$BCl_3 + H_2 \leftrightarrows HBCl_2 + HCl$$

For consistency, we used the value of k''_{eq} from the Carlton *et al.* work which is slightly different from the actual value cited in Ref. (11).

In the case of interfacial thermodynamic resistance the deposition rate is calculated as the difference between the diffusion rates of BCl_3 and $HBCl_2$. The following reactions are in equilibrium

$$BCl_3 + H_2 \leftrightarrows HBCl_2 + HCl$$

$$2BCl_3 + 3H_2 \leftrightarrows 2<B> + 6HCl$$

The values of the equilibrium constants have been calculated from data of Ref. (11).

All the calculations depend on the values of the physical parameters. Some of them, the binary diffusion coefficients, are independent of composition. Physical film properties, the average diffusivity, and

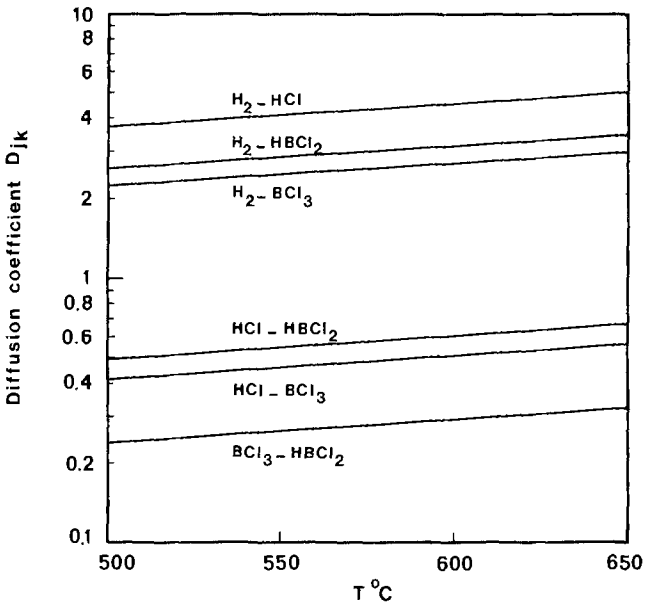

Fig. 7. Binary diffusion coefficients

the mixture viscosity were calculated from the arithmetic average composition and temperature of the bulk stream and the interface. The binary diffusion coefficients were calculated from the force constants given by Hirshfelder *et al.* (12) and Reid and Sherwood (13) by the method recommended by these authors. In Fig. 7 the coefficient values are presented as a function of temperature. The diffusivity of the mixture was obtained from the following definition successfully tested for quaternary transport data (14)

$$D_f = \frac{\Pi_j(1 - w_j)}{\sum_{j \neq k} \frac{w_j w_k}{D_{jk}}}$$

Viscosities of the pure gases were calculated by the procedure recommended by Reid and Sherwood (13). Viscosity of the film mixture was estimated from those of the pure components by the method of Bromley and Wilke (15).

Experimental results.—The boron deposit thickness in the stagnation zone is measured on transverse cross sections. These measurements are limited to smooth amorphous or slightly crystallized deposits, except in the case of tetragonal boron. In the other cases, the deposit becomes too irregular to get a correct thickness. Deposition rate is directly proportional to the reaction time. It is measured as the slope of the straight line [thickness = f (reaction time)] obtained from 5 or 6 different times.

Figure 8 shows the influence of mass flow rate on deposition rate at four temperatures and a constant inlet composition. Figure 9 shows the influence of inlet composition at 1100°C and two mass flow rates. The maximum efficiency is obtained for 15% BCl_3-85% H_2.

Calculation results and discussion.—Nondimensional parameters for heat or mass transfer in impinging jets are correlated by relationships where N_{Pr} and N_{Sc} occur with a power of 1/3 normal strength. We have therefore looked for a correlation of the form

$$N_{Sh}/N_{Sc}^{1/3} = f(N_{Re})^n$$

which implies that mass transfer is equal to its purely forced flow values, as justified in the precedent section.

Figure 10 presents the results obtained when the deposition rate is assumed to be limited by a combination of mass transfer and surface kinetics. The results are correlated as follows

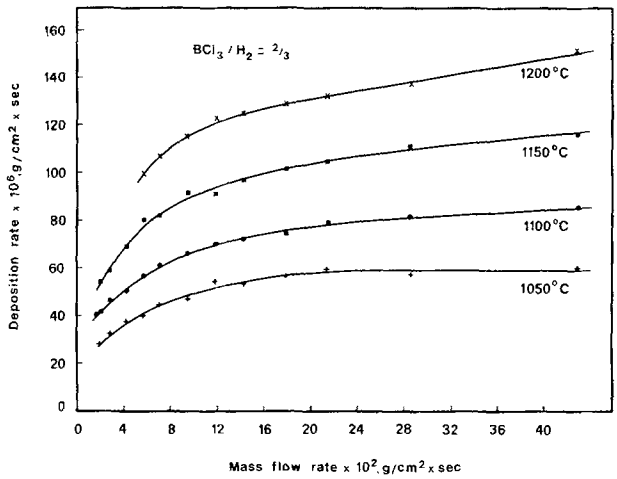

Fig. 8. Experimental deposition rate as a function of reactants mass flow rates.

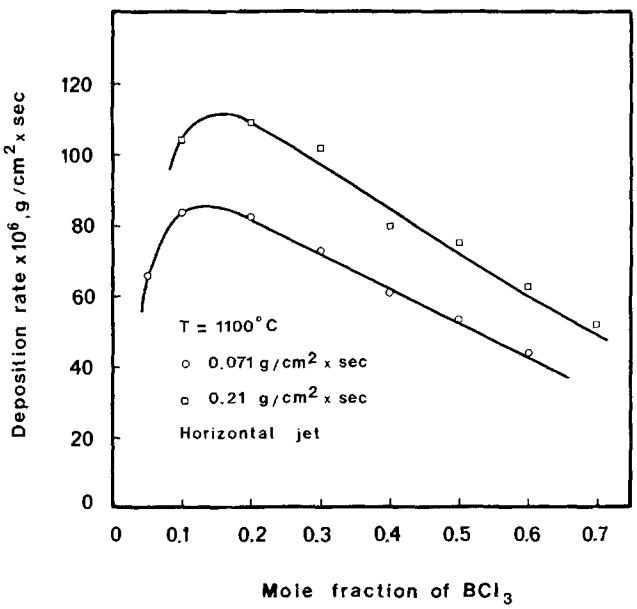

Fig. 9. Experimental deposition rate as a function of inlet gas composition.

$$N_{Sh}/N_{Sc}^{1/3} = 0.76\, N_{Re}^{0.43}$$

with a maximum deviation of about 15%. The mass transfer coefficient is lower than those derived by Coeuret (16) in the case of submerged liquid jets impinging on a flat plate ($N_{Sh_z}/N_{Sc}^{1/3} = 0.69\ N_{Re_z}^{0.5}$). The value 0.43 is greater than those obtained by Gardon and Akfirat (17) for heat transfer at low N_{Re} (<2000) in an impinging two-dimensional air jet [$N_{Nu} = f\ (N_{Re})^{0.32}$].

Figure 11 presents results calculated with a deposition rate limited by a combination of mass transfer and interfacial equilibrium with a constant inlet composition. We can show that this mechanism does not give a unique correlation for the mass transfer. However, at each temperature (except 1050°C), there is a critical Reynolds number $N_{Re,c}$ where the above correlation is accurately verified. We can note that for $N_{Re} < N_{Re,c}$, crystallization occurs very quickly and prevents determining correct values for the deposition rate. For $N_{Re} = N_{Re,c}$, the deposition rate is fixed at the same value by the two different deposition mechanisms involving kinetic or thermodynamic resistances at the interface. For $N_{Re} > N_{Re,c}$, mass transfers calculated with the mass transfer-equilibrium mechanism are too low because interface equilibrium is not main-

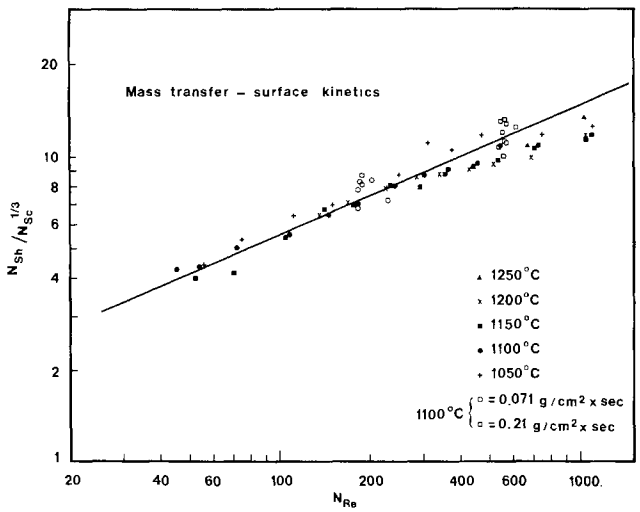

Fig. 10. Correlation of experimental results for mass transfer combined with surface kinetics.

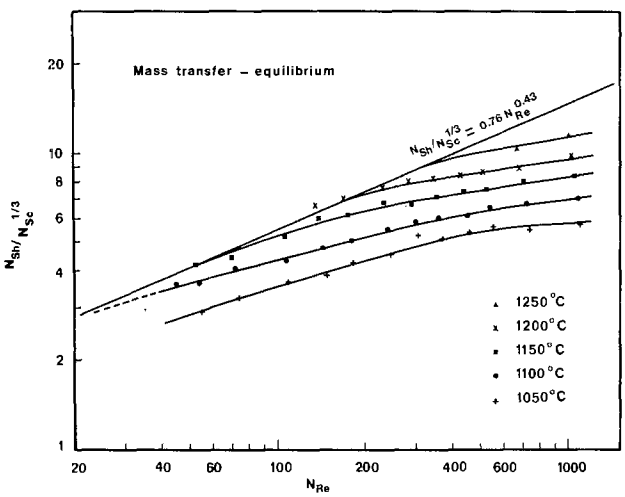

Fig. 11. Correlation of experimental results for mass transfer combined with interfacial equilibrium.

tained; hence, experimental deposition rates do not reach the maximum value for a given N_{Re}. We conclude therefore, that at low N_{Re}, the mechanism of deposition is a mass transfer-equilibrium one. In this case, the conversion of reactants to products and the deposition rate are maximum for a given mass transfer. This is a general result, and such a mass transfer-equilibrium approach can be used to calculate the maximum possible deposition rate if the mass transfer characteristics of the geometric system are known. If the equilibrium is quite favorable, one obtains the case of a total interfacial conversion of the reactants where the process is purely diffusionally controlled.

Figure 12 compares the theoretical deposition rates, calculated with this mass transfer-equilibrium approach, to the experimental ones (mass transfer is correlated by the equation $N_{Sh}/N_{Sc}^{1/3} = 0.76\ N_{Re}^{0.43}$). These curves confirm that at low N_{Re} the deposition rate reaches a maximum. Interfacial equilibrium is maintained for higher N_{Re} when temperature increases, as expected from the fact that the kinetic rate of the opposing reactions at equilibrium increases with temperature. When this rate becomes too low (N_{Re} too high), the vapor phase is supersaturated and the deposition rate is limited by a combination of mass transfer and surface kinetics.

At 1050°C the experimental rate becomes constant when $N_{Re} > 500$. The deposition rate is therefore only limited by surface kinetics, and the excess reactants

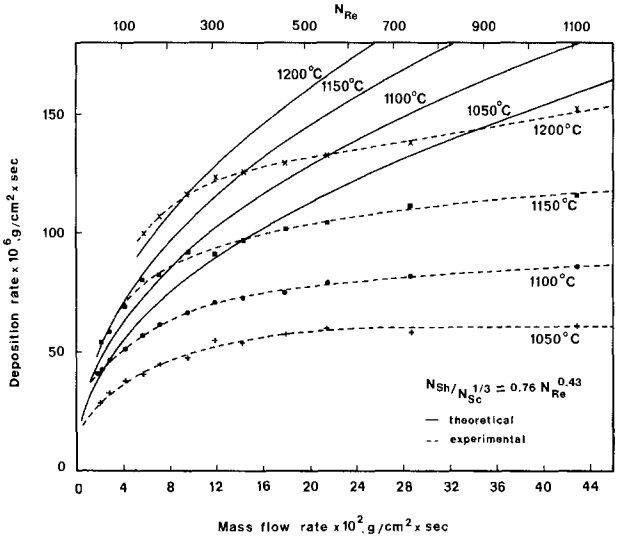

Fig. 12. Comparison between experimental and theoretical deposition rate calculated from mass transfer-interfacial equilibrium considerations.

are converted to $HBCl_2$ and HCl by the homogeneous reaction

$$BCl_3 + H_2 \leftrightarrows HBCl_2 + HCl$$

This second boundary in the deposition process is only found for $T = 1050°C$, because our experimental conditions are limited to $N_{Re} < 1000$. Figure 13 summarizes the above results and discussion, and shows the range of conditions where the different mechanisms occur.

Figure 14 presents the results calculated with a deposition rate limited by a combination of mass transfer and equilibrium as a function of the mole fraction of BCl_3 (X_{BCl_3}) in the inlet mixture. We deduce that the interfacial conditions are close to equilibrium as X_{BCl_3} increases. When $X_{BCl_3} > 0.6$, deposits are very thin and irregular, and natural convection becomes important. Tentatively, we set up Fig. 15 as a schematic representation of the influence of the inlet composition on the deposition mechanism.

Conclusions

In a jet impinging normally on a flat plate, mass transfer is nearly constant in the stagnation zone when the substrate is set within the core of the jet. The size of the potential core is essentially a function of N_{Re}. When $N_{Re} < 50$ it is reduced to zero, and mass transfer

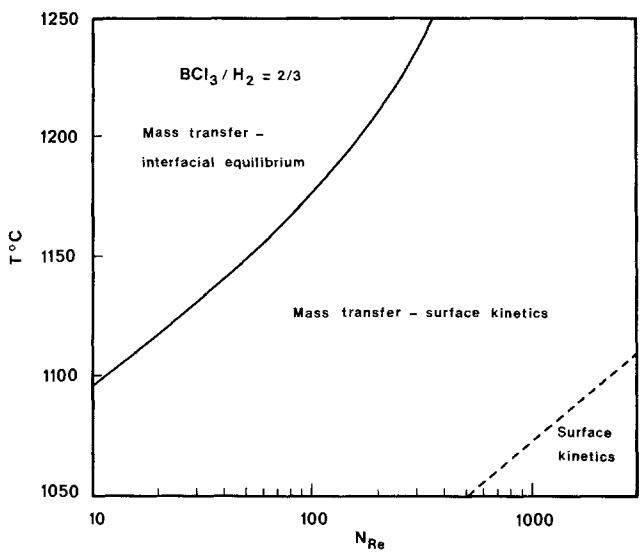

Fig. 13. Effects of T and N_{Re} on the deposition mechanism

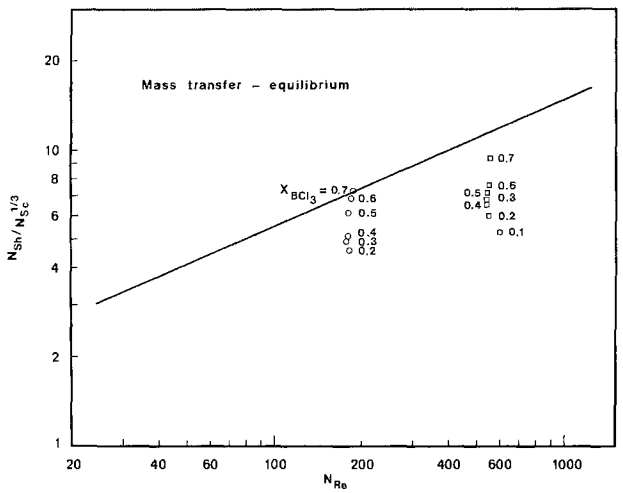

Fig. 14. Correlation of experimental results for mass transfer combined with interfacial equilibrium at various X_{BCl_3}.

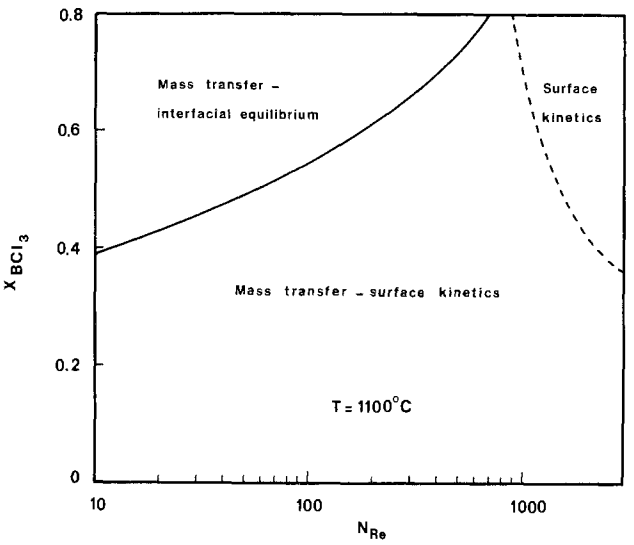

Fig. 15. Effects of X_{BCl_3} and N_{Re} on the deposition mechanism

at the stagnation point is everywhere a function of the distance between the nozzle and the substrate. In vertical downward jets, mass transfer is independent of free convection when $N_{Gr}/N_{Re}^2 < 0.1$. In the horizontal case, free convection appears always negligible when $N_{Gr}/N_{Re}^2 < 0.5$.

Over a large range of experimental conditions, the boron deposition mechanism is complex. For low N_{Re} and high temperatures, the deposition rate is limited by a mass transfer-equilibrium process. We can note that the interfacial equilibrium is influenced by diffusion. Particularly the H/Cl ratio which determines the equilibrium at given pressure and temperature is increased by diffusion as expected from the diffusivities of H_2 and BCl_3. For high N_{Re} and low temperature, the deposition rate is only limited by surface kinetics. For intermediate N_{Re}, the deposition rate is limited by a mass transfer-kinetics process. This is the case currently encountered in amorphous boron deposition. It allows us to infer a correlation for mass transfer in laminar impinging jets as follows

$$N_{Sh}/N_{Sc}^{1/3} = 0.76\, N_{Re}^{0.43}$$

The influence of inlet mixture composition is important. At constant N_{Re}, the interfacial conditions are farther from equilibrium when hydrogen inlet concentration increases. The influence of the deposition mechanism on the deposits structure is presented in the following paper.

Structure of Deposits–Process Relationships in the Chemical Vapor Deposition of Boron

L. Vandenbulcke and G. Vuillard

Centre de Recherches sur la Chimie de la Combustion et des Hautes Températures et Faculté des Sciences d'Orléans, 45045 Orléans Cedex, France

ABSTRACT

Chemical vapor deposition of boron is capable of yielding a wide variety of structures. They are studied using the deposition mechanisms proposed in a previous paper (1) and the effect of temperature, interfacial equilibrium, or effective supersaturation of the vapor phase is deduced. The experimental parameters which control the interfacial conditions are inlet gas phase composition, mass flow rate of reactants, and temperature. The full range of variation of boron structure, amorphous, α rhombohedral, β rhombohedral, and β tetragonal is followed by observing the material under these various conditions of growth. β rhombohedral appears as the thermodynamically stable form and α rhombohedral and β tetragonal as metastable crystalline forms occurring at low and high temperatures, respectively.

Both physical (PVD) and chemical vapor deposition (CVD) are capable of yielding materials in a wide variety of structures ranging from amorphous to polycrystalline, needlelike, single crystals, and epitaxial films. It is well known (2-4) that the major factors which control the nucleation and growth process, and ultimately, the final structure of the deposited material, are supersaturation and temperature. A large body of theory has been developed, and substantial verifications have been obtained in the physical process which involves the adsorption of monomers on the substrate, their migration to constitute stable nuclei which grow and coalesce. In the case of the condensation of one component, the supersaturation is defined as the ratio of the actual pressure of monomer to the vapor pressure in equilibrium with the condensed phase. It refers to the concentration of adsorbed monomers on the surface; the temperature relates to their mobility.

In CVD which inherently involves a multicomponent system, the theories of heterogeneous nucleation and crystal growth can be treated on the basis of a quantitatively defined supersaturation as in the simple case of molecular dissociation (5). This treatment is difficult to extend but the concept of supersaturation is retained as the excess of available reaction vapors relative to the concentration in equilibrium with the solid surface. Generally, CVD is effected in a flow system that may employ a carrier or a reduction gas; then the interfacial composition is affected by diffusion in the boundary layer. To achieve quantitative results on supersaturation, it is therefore necessary to calculate the interfacial composition in the real system.

In the CVD of boron from impinging jets of boron trichloride and hydrogen on a flat surface, the interfacial composition is constant in the stagnation zone: it has been calculated in a previous paper (1). Boron presents a polymorphism which has been extensively studied, but our knowledge of the crystal chemistry of boron as well as the mechanisms of vapor growth is, even now, incomplete. This paper attempts to correlate the mechanisms of CVD with the resulting deposit structures.

Key words: mass transfer, surface kinetics, equilibrium, supersaturation, boron polymorphism.

Experimental Techniques

The experimental equipment, materials, and procedure have been described elsewhere (1).

Boron was deposited from impinging axisymmetric jets (0.8 cm diam) of BCl_3 and H_2 on flat surfaces. Substrate materials were graphite and refractory metals (Ta, Mo, W) heated by a high frequency generator. Deposition rates were deduced from deposit thickness in the stagnation zone obtained with different deposition times. The influence of temperature, inlet gas composition, and mass flow rate of reactants has been presented in a previous paper (1). The same experiments permit us to study the influence of various parameters on the deposit structures in the stagnation zone. Structure of deposits was deduced from morphological and x-ray diffraction studies.

Supersaturation Study

Analysis and calculation.—In a previous paper (1), different composition mechanisms are examined as a function of inlet gas composition, temperature, and forced convection. For a constant composition of inlet gas ($BCl_3/H_2 = 2/3$), a boundary between two deposition processes, mass transfer-interfacial equilibrium and mass transfer-surface kinetics are drawn as a function of temperature and Reynolds number (N_{Re}). The boundary position is also a function of the inlet gas composition. In all cases the gas phase is essentially composed of H_2, BCl_3, HCl, and $HBCl_2$; other intermediates than $HBCl_2$ can be neglected.

For low N_{Re} and high temperature, the deposition is governed by a mass transfer-equilibrium process. The interfacial vapors are in equilibrium with solid boron and the system is saturated with respect to each component.

For high N_{Re} and low temperature, the deposition is governed by a mass transfer-surface kinetics process and the system is supersaturated in various components. This system is complicated because two reactions proceed concurrently and no simple relationship exists between their rates. The real interfacial system is defined by the sum of Eq. [1] and [2]

$$(1-a)BCl_3 + 3(1-a)/2H_2 \rightarrow (1-a)\langle B\rangle + 3(1-a)HCl \quad [1]$$

$$aBCl_3 + aH_2 \rightarrow aHBCl_2 + aHCl \quad [2]$$

$$BCl_3 + (3-a)/2H_2 \rightarrow (1-a)\langle B\rangle + aHBCl_2 + (3-2a)HCl \quad [3]$$

The interfacial partial pressures of H_2, BCl_3, $HBCl_2$, and HCl were calculated from the mass transfer-kinetics consideration (1). The value of a is obtained from diffusional fluxes of $HBCl_2$ and BCl_3 through the boundary layer determined by adding the additional restraint of vapor phase chemical equilibrium at the deposition surface.

This real system is compared to the corresponding system in equilibrium with solid boron. The corresponding equilibrium composition is calculated with the same H/Cl ratio which exists in the interfacial vapor of the real system. The equilibrium calculation is based on the values of the free energies of formation of the compounds given in Ref. (6). It is carried out by a simple iteration method. It can be noted that the H/Cl ratio calculated previously by mass transfer-equilibrium considerations is different from the ratio which exists in the real supersaturated vapor phase except at the boundary dividing the two domains of mass transfer-equilibrium and mass transfer-kinetics processes. The corresponding equilibrium system is written as

$$BCl_3 + (3-b)/2H_2 \leftrightarrows (1-b)\langle B\rangle + bHBCl_2 + (3-2b)HCl \quad [4]$$

$$(1-b)\langle B\rangle \leftrightarrows (1-b)B \quad [5]$$

Supersaturation of gaseous reagents H_2 and BCl_3 are calculated according to

$$\Sigma_j = P_j/P_{j,eq} \quad [6]$$

A total supersaturation of the gas mixture is defined as

$$\Sigma_t = \frac{(P_{H_2})^{(3-a)/2}\cdot(P_{BCl_3})\cdot(P_{HBCl_2,eq})^{b}\cdot(P_{HCl,eq})^{(3-2b)}}{(P_{HBCl_2})^{a}\cdot(P_{HCl})^{(3-2a)}\cdot(P_{BCl_3,eq})\cdot(P_{H_2,eq})^{(3-b)/2}} \quad [7]$$

By analogy with the condensation of one component in the PVD process, it is possible to calculate the supersaturation in the boron monomer. However, this gaseous monomer is unimportant relative to the deposition mechanism in CVD of boron. The effective pressure of boron in the supersaturated vapor phase is defined as the pressure in equilibrium in the vapor phase

$$BCl_3 + (3-b)/2H_2 \leftrightarrows (1-b)B + bHBCl_2 + (3-2b)HCl \quad [8]$$

Then, boron supersaturation which is defined as $\Sigma_B = P_B/P_{B,eq}$ is calculated as follows

$$\Sigma_B = \left[\frac{(P_{BCl_3})\cdot(P_{H_2})^{(3-b)/2}\cdot(P_{HBCl_2,eq})^{b}\cdot(P_{HCl,eq})^{(3-2b)}}{(P_{HBCl_2})^{b}\cdot(P_{HCl})^{(3-2b)}\cdot(P_{BCl_3,eq})\cdot(P_{H_2,eq})^{(3-b)/2}}\right]^{1/(1-b)} \quad [9]$$

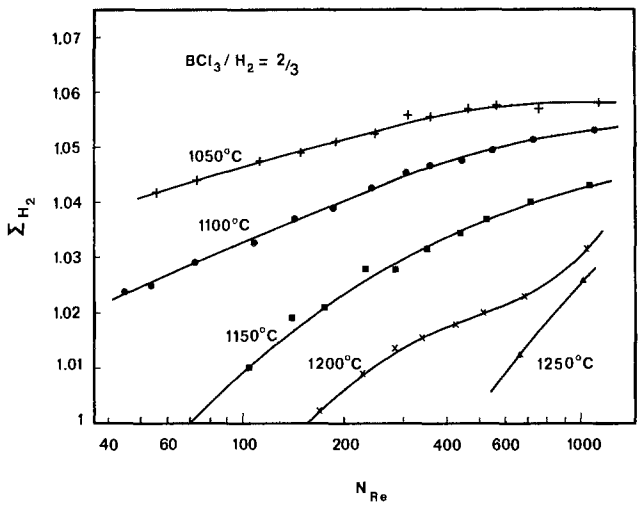

Fig. 1. Supersaturation of H_2 as a function of N_{Re}

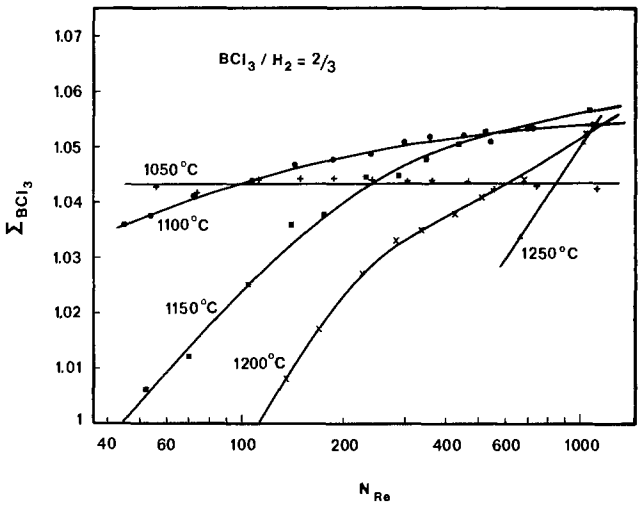

Fig. 2. Supersaturation of BCl_3 as a function of N_{Re}

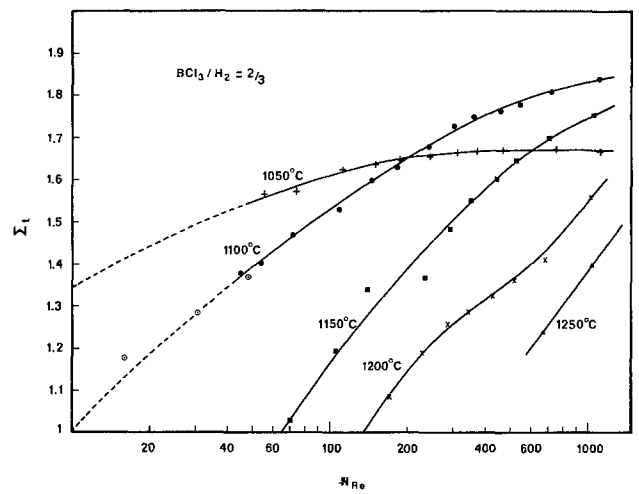

Fig. 3. Total supersaturation as a function of N_{Re}

Results and discussion.—The supersaturations Σ_{H_2}, Σ_{BCl_3}, Σ_t, and Σ_B *vs.* N_{Re} are reported in Fig. 1-4. These results are for five temperatures (T = 1050°, 1100°, 1150°, 1200°, and 1250°C) and a constant composition in the inlet gas mixture (BCl_3/H_2 = 2/3).

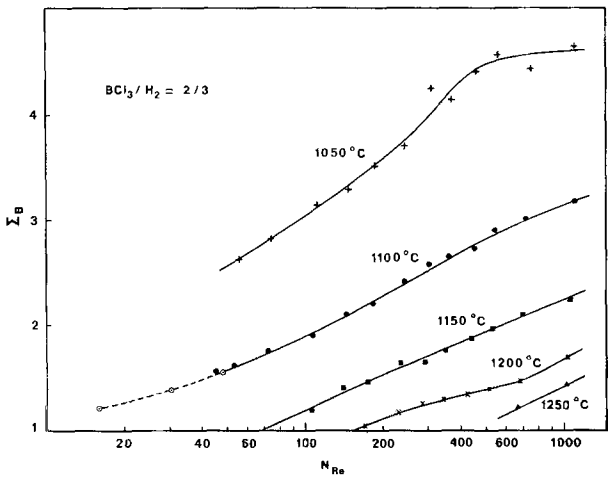

Fig. 4. Boron monomer supersaturation as a function of N_{Re}

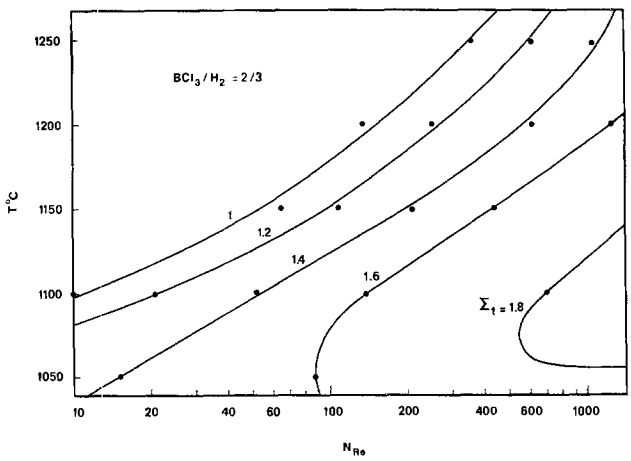

Fig. 5. Effects of T and N_{Re} on saturation and supersaturation

The dotted circles at 1100°C (Fig. 3) were obtained from vertical downward jet experiments where free convection diminishes the forced one (1); therefore the mass transfer corresponds to a hypothetical value of N_{Re} calculated by using the pure forced convection equation ($N_{Sh}/N_{Sc}^{1/3} = 0.76\, N_{Re}^{0.43}$).

We can conclude from these figures that, for each temperature, the vapor phase is saturated when N_{Re} is lower than a critical Reynolds number $N_{Re,c}$. The value of $N_{Re,c}$ increases with temperature. For $N_{Re} > N_{Re,c}$, the vapor phase is supersaturated. We find again the transition between two deposition processes where the interfacial vapors are either in equilibrium with B_{solid} or out of equilibrium.

At a temperature of 1050°C, we note that all the supersaturations reach maximum values when $N_{Re} > 500$. In that case, the excess of reactants BCl_3 and H_2 is converted more and more through vapor phase equilibrium into the gaseous by-products, $HBCl_2$ and HCl, which diffuse outside the boundary layer, and the deposition rate of boron remains constant for any mass flow rates. We find the second transition in the boron deposition process where the deposition rate becomes dependent only on surface kinetics. For temperatures greater than 1050°C, this second transition should occur greater than our experimental limit of 1000 for N_{Re}. We also note that the N_{Re} value at which Σ_{BCl_3} and Σ_t equal one is greater when the temperature increases in accordance with the fact that the conversion of BCl_3 into B_{solid} is favored by surface kinetics when temperature increases.

For a constant N_{Re} and in conditions far from a pure surface kinetics process, the supersaturations in reactants, Σ_{BCl_3}, Σ_{H_2}, and Σ_t increase with decreasing temperatures. Likewise, the supersaturation in boron monomer Σ_B increases logically with decreasing temperature, whatever the value of N_{Re}.

If we produce the supersaturations *vs.* N_{Re} curves drawn for $T = 1050$°C, we can see that saturation will be reached when $N_{Re} < 1$, hence at a very low mass transfer which is nearly always achieved in CVD, either by free or forced convection. At $T < 1050$°C, boron is therefore often deposited out of equilibrium.

All the above statements are summarized in Fig. 5 which presents the saturation and isosupersaturation curves for Σ_t on a single diagram $T = f(N_{Re})$. The isosupersaturation curves for Σ_B present the same trends, but their slope is always positive and decreases when Σ_B increases. In accordance with a previous paper (1), it can be concluded that the interfacial conditions depart from equilibrium when N_{Re} increases and T decreases.

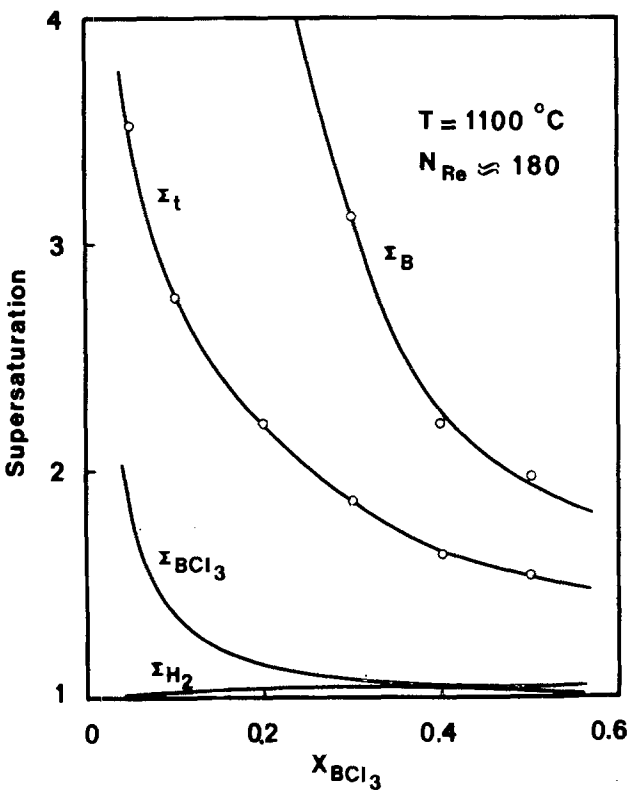

Fig. 6. Supersaturation as a function of inlet gas composition

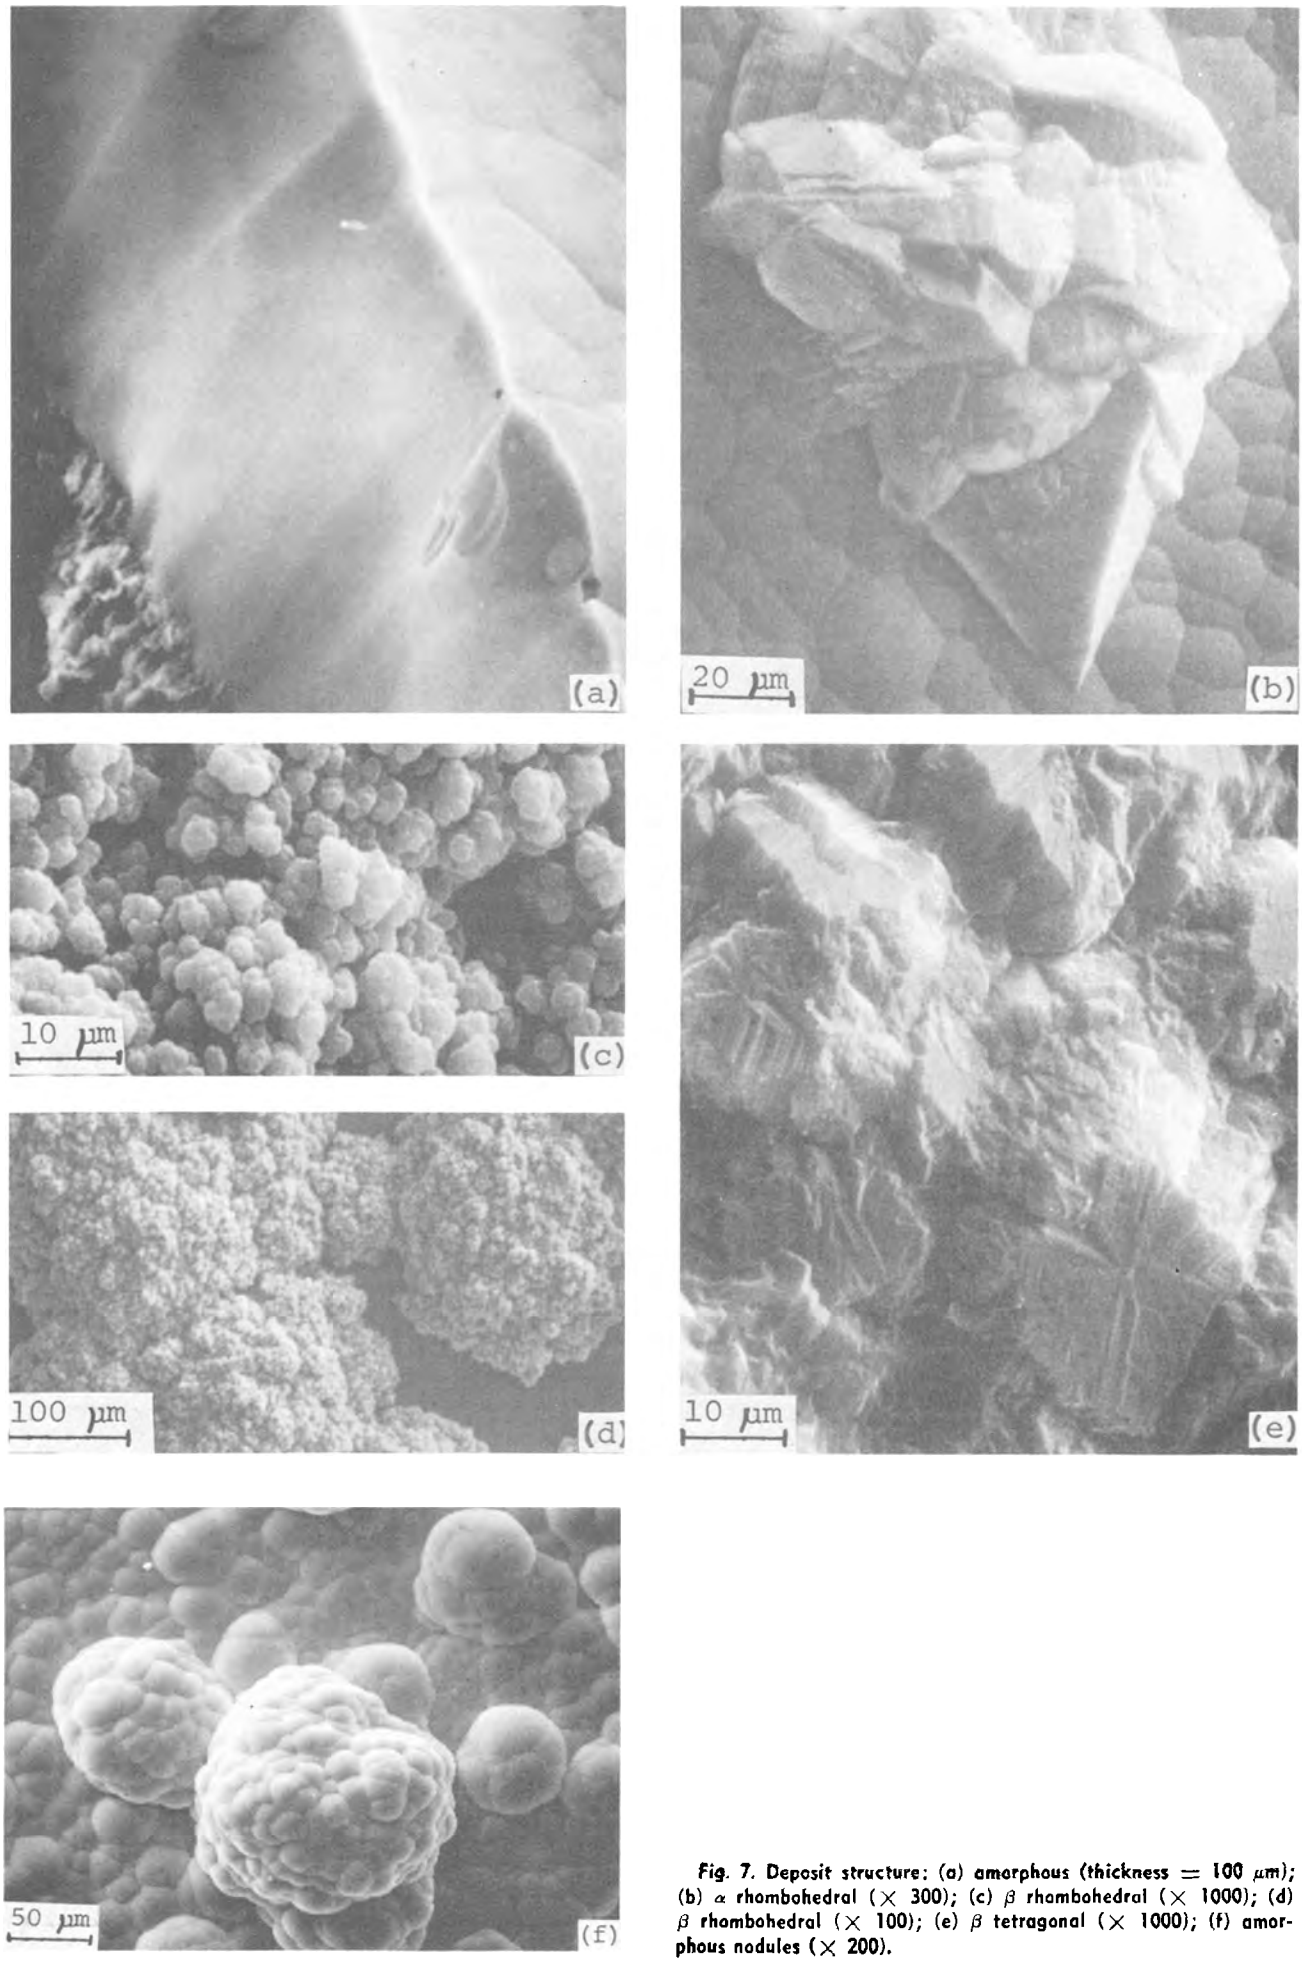
Figure 6 shows the influence of the inlet gas composition on the supersaturations for $T = 1100$°C and a mass flow rate of 0.071 g/cm²/sec ($N_{Re} \simeq 180$). The supersaturation in H_2 is low and varies only slightly with the molar fraction of BCl_3 (X_{BCl_3}). On the other hand, Σ_{BCl_3}, Σ_t, and Σ_B increase significantly when X_{BCl_3} decreases. According to the previous paper (1), the interfacial conditions are farther from equilibrium when X_{BlC_3} decreases.

Structure of Deposits

Results.—X-ray diffraction studies have enabled us to identify four crystallographic structures which are consistent with the four morphologies presented in Fig. 7. The amorphous boron forms the typically continuous coating (Fig. 7a). The α rhombohedral boron occurs as heaps of crystals which present some sharp facets (Fig. 7b). The β rhombohedral boron arises as heaps of very small crystals which conglomerate thereafter to cover all the surface (Fig. 7c-7d). The β



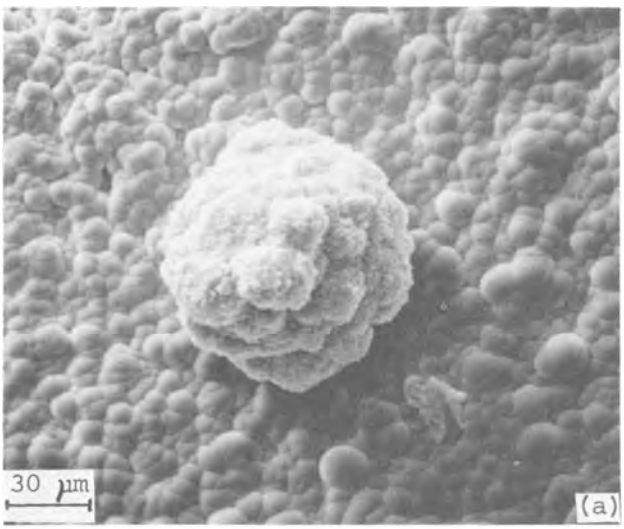


Fig. 7. Deposit structure: (a) amorphous (thickness = 100 μm); (b) α rhombohedral (× 300); (c) β rhombohedral (× 1000); (d) β rhombohedral (× 100); (e) β tetragonal (× 1000); (f) amorphous nodules (× 200).

tetragonal boron forms a polycrystalline continuous layer (Fig. 7e).

In all cases, boron grows initially with an amorphous structure. Thereafter, nucleation of crystalline forms of boron arises at different deposition times as a function of saturation or amount of supersaturation and temperature. These times vary from less than 1 min, in the case of saturation and $T \geqslant 1100°C$, to 20 or 30 min in the case of high supersaturation and $T < 1100°C$. There are some intermediate morphologies like the big amorphous nodules (Fig. 7f) which constitute preferred sites for crystal nucleation or transformation. Figure 8a shows the transformation of amorphous nodules into β rhombohedral boron. Figure 8b shows the growth of β rhombohedral on α rhombohedral crystals.

The advent of these different structures is connected with the deposition process. It is studied first as a function of T and N_{Re} for a constant inlet composition of reactants ($BCl_3/H_2 = 2/3$). Figure 9 presents the results obtained for a deposition time of 3 min. Curves of saturation and total isosupersaturation Σ_t are drawn on the same diagram. When the vapor phase is in equilibrium with B_{solid}, boron crystallizes in the β rhombohedral form as demonstrated at $T > 1100°C$. At $T \leqslant 1100°C$, boron crystallizes as β rhombohedral in the periphery of the substrates (out of the stagnation zone) where mass transfer is very low

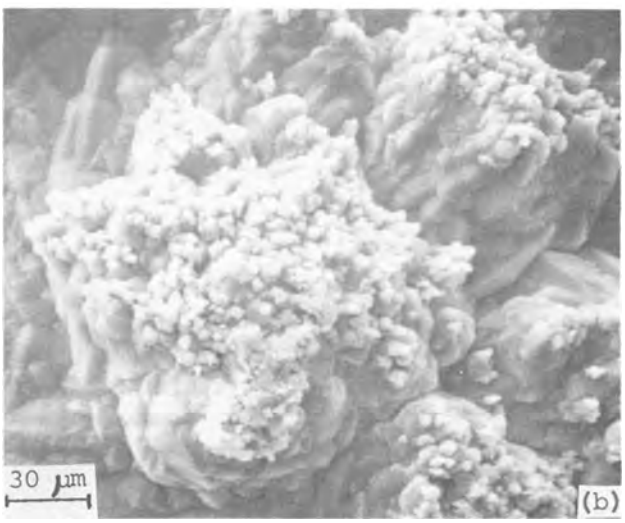

Fig. 8. Intermediate morphologies: (a) β rhombohedral growth on amorphous nodules (× 300); (b) β rhombohedral growth on α crystals (× 300).

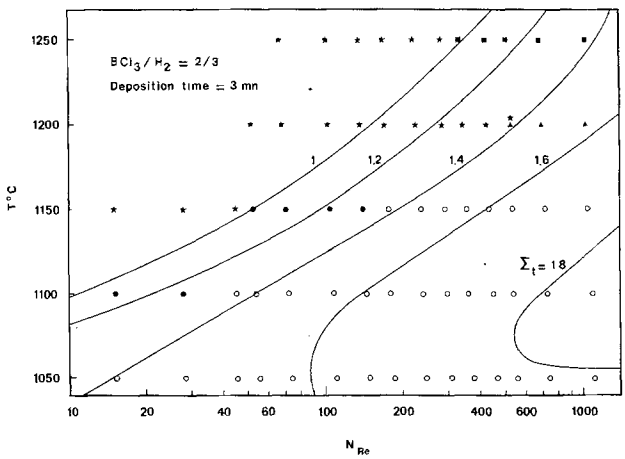

Fig. 9. Effects of T and N_{Re} on deposit structure (deposition time = 3 min): ○ = amorphous; ● = big nodules; ▲ = α rhombohedral; ★ = β rhombohedral; ■ = β tetragonal.

(1) and interfacial equilibrium accordingly maintained. In the supersaturated region, the structure depends on temperature and supersaturation. At $T \leqslant 1150°C$, boron remains amorphous in spite of the formation of big nodules when the supersaturation is low ($\Sigma_t < 1.4$). At $T = 1200°C$, boron is always crystallized in the conditions studied ($N_{Re} \leqslant 1000$), as β rhombohedral when $\Sigma_t < 1.4$ and as α rhombohedral when $\Sigma_t > 1.4$. At $T = 1250°C$, boron deposits consist of a continuous layer of the β tetragonal type.

Figure 10 presents the results obtained for $T < 1250°C$ with a deposition time of 10 min. β rhombohedral boron appears at all temperatures in the equilibrium region. It appears at $T = 1150°C$ when $\Sigma_t < 1.4$ and in all conditions at $T = 1200°C$. Boron is amorphous when $T \leqslant 1150°C$ and $\Sigma_t \geqslant 1.5$. At $T = 1150°C$, the α rhombohedral type is formed when Σ_t is equal to about 1.4 and at $T = 1100°C$ when $1 < \Sigma_t < 1.5$. At $T = 1250°C$ a complete scaling of the deposits occurs after a deposition time of 7 min. At $T = 1050°C$, a deposition time of 20 min is possible. Appearance of α rhombohedral crystals is then observed when $\Sigma_t < 1.5$.

The influence of the inlet gas composition has been studied only at $T = 1100°C$ and $N_{Re} \simeq 180$ and 550. When $N_{Re} \simeq 180$, a formation of big amorphous nodules is observed after 5 min of deposition when $X_{BCl_3} \geqslant 0.6$. In the other cases studied, the deposit is amorphous without nodules.

Discussion.—All the results show that in the range of temperatures 1050°-1250°C, the equilibrium solid

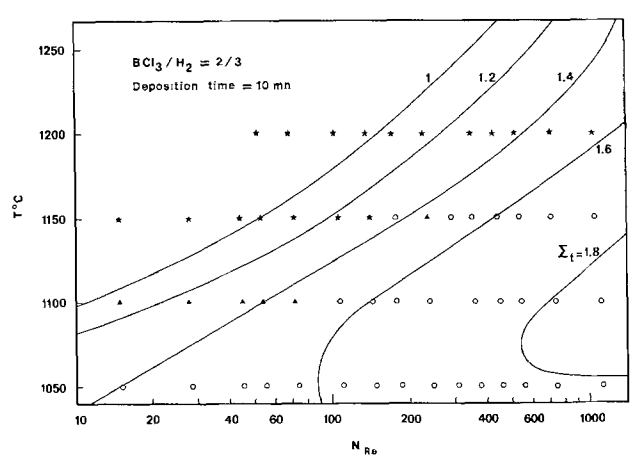

Fig. 10. Effects of T and N_{Re} on deposit structure (deposition time = 10 min).

phase is the β rhombohedral form. Below 1050°C, it is difficult to maintain the equilibrium between solid boron and the vapor phase. However, we think that this condition has been achieved by Naslain *et al.* (7) in the preparation of pure boron in quartz tube. They observed a β rhombohedral nucleation in interstices between α granules at temperature as low as 800°C, also by Luque and Augustin (8-9) who observed its deposition at $T = 850$°C in using very low mass flow rates ($5 \cdot 10^{-5}$ g/cm²/sec) of ($BCl_3 + H_2$) mixtures. Above 1250°C, equilibrium is likely to be reached and the β rhombohedral type is generally observed. Therefore, our results provide new evidence in support of β rhombohedral being the thermodynamically stable form at all temperatures (7-10).

Conversely, the other boron varieties appear as metastable forms whose formation is kinetically favored under various conditions. The different parameters which control their formation are temperature, supersaturation of the vapor phase, and deposition time. Boron remains amorphous for longer deposition times as temperature remains low and supersaturation high. At $T < 1200$°C, nucleation of α rhombohedral boron occurs when the supersaturation is low. The β nucleation and $\alpha \rightarrow \beta$ rhombohedral transformation occur rapidly in the range of 1150°-1200°C. At $T \leq 1100$°C, the solid-state transformation is kinetically improbable, and was not observed as it had been by Naslain *et al.* (7). The α rhombohedral type is the "metastable crystalline form of low temperature."

On account of the solid-state transformations of amorphous and $\alpha \rightarrow \beta$ rhombohedral, these two forms cannot be prepared at $T > 1200$°C. As α rhombohedral in the low temperature range, the β tetragonal form is "the metastable crystalline form of high temperature." Our experiments being limited to $T \leq 1250$°C, we have not observed the β tetragonal $\rightarrow \beta$ rhombohedral irreversible transformation. Moreover, we have not studied if this transformation is kinetically probable or not at the lower temperature of formation 1250°C.

Conclusion

The basic prediction of the importance of supersaturation and temperature in the development of morphological feature is clearly confirmed. Both supersaturation and temperature control the structure of boron deposits. Interaction between the deposit and the substrate does not seem to have any influence. The full range of boron structures has been found by observing the material under various conditions of growth.

Amorphous structure is maintained in conditions of high supersaturation and low temperature. Obtaining a pure thick layer of this form is limited to $T \leq 1200$°C. β rhombohedral boron appears as the thermodynamically stable form, and α rhombohedral and β tetragonal as metastable crystalline forms of respectively low and high temperatures. The $\alpha \rightarrow \beta$ rhombohedral transformation is observed in the range of 1150°-1200°C. The β tetragonal $\rightarrow \beta$ rhombohedral transformation has not been studied.

Technical Notes

An Attempt at the AES Evaluation of the Composition of Off-Stoichiometric Silicon Nitride

Simon Thomas

Burroughs Corporation, San Diego, California 92127

and Robert J. Mattox

Motorola Semiconductor Group, Phoenix, Arizona 85008

The use of silicon nitride as a passivation layer in silicon devices is gaining widespread acceptance. The nitride passivation has a variety of advantages over the conventional silicon dioxide or phosphosilicate glass layer. One of the most widely recognized advantages of the nitride passivation is its low permeability

Key words: plasma silicon nitride, Auger analysis, nitride passivation layer.

to the alkali ions, especially sodium (1). Although phosphosilicate glass (PSG) can effectively getter the mobile ions, it suffers from the adverse effects of corrosion of the aluminum metallization in the presence of humidity (2). Silicon nitride is an excellent alternative to the PSG as a final passivation over the metallization. The rather rigorous temperatures (~700°-1000°C) at which the silicon nitride is deposited by chemical vapor deposition (CVD) hitherto precluded the use of the nitride as a practical passivation layer over the metallization. The recent emergence of silicon nitride as a practical passivation layer is primarily due to the development of the new deposition method where the nitride can be deposited at a relatively low temperature (~200°-400°C) by the reaction of silane and ammonia and/or nitrogen in a glow discharge—the so-called plasma nitride (3).

Although plasma deposited silicon nitride offers excellent properties as a passivation layer in silicon device technology, the inability to consistently reproduce the physical and electrical properties such as the stoichiometry, density, etch rate, refractive index, dielectric constant, etc., has been a problem. On the other hand the silicon nitride layers deposited by the high temperature CVD method using proper ratios of NH_3/SiH_4 are shown to be stoichiometric with a composition Si_3N_4 (4, 5). However, the composition cannot be presumed to be stoichiometric in the case of the plasma-deposited silicon nitride, being strongly dependent on a variety of deposition parameters.

One of the physical properties of the silicon nitride most widely employed to characterize the composition and to evaluate the process of deposition is the refractive index of the film, with an acceptable value in the range 2-2.05 for passivation applications. A higher value for the refractive index is usually considered to be an indication of a silicon-rich film. In view of the possible diversity in the nitride composition, it would be essential to characterize the composition in order to optimize the deposition process. We have used Auger electron spectroscopy (AES) coupled with Ar^+ ion sputtering in our attempt to evaluate the composition of the plasma-deposited nitride layers. The main purpose of this paper is threefold: (*i*) to establish the main features in the Auger spectrum genuinely characteristic of silicon nitride; (*ii*) to point out the existence of preferential sputtering effect in Ar^+ ion sputtered silicon nitride; and (*iii*) to try to evaluate the composition of the plasma nitride films differing in refractive index, with a view to better control the deposition process.

The capacitively coupled plasma reactor design was employed in the deposition of the silicon nitride films. The reactor consisted of basically two parallel plates with the top plate being the cathode and the bottom plate being the grounded wafer plate. The reactant gases flow radially, being introduced at the center and exhausted from the bell jar through a mechanical pump. The deposition temperature was controlled by heating elements attached to the lower plate. The detailed description of this type of deposition technique is available in the literature (6-8). The conventional ammonia-silane-nitrogen chemical system was the reactant gas. By varying the ammonia/silane gas ratios along with other process variables such as rf power, pressure, plate spacing, etc., the refractive index of the resultant deposited films could be varied over a wide range of values. Ten such plasma nitride samples with refractive indexes ranging from 1.88 to 3.57 as measured by ellipsometry at 5461Å were selected for the Auger analysis together with a high temperature CVD nitride as a reference. The Auger analysis was performed using a single stage cylindrical mirror analyzer (Physical Electronics Industries, Incorporated) with an energy resolution of 0.6%. The electron beam parameters were Ep = 3 keV and Ip = 10 μA. Sputtering was performed at 4×10^{-3} Pa using 2 keV Ar^+ ions.

Before attempting to characterize the composition of the nitride by AES, it is essential to establish the salient features in the Auger spectrum from Si_3N_4. Many authors have studied the features in the Auger spectrum from stoichiometric CVD nitride (9-11). The Si LVV Auger spectrum is supposedly characterized by a very strong peak reported at 85 (9), 87 (10), and 92 eV (11). A shoulder peak (82 eV) is also observed at the low energy side of this main peak (10). All these features were observed from "sputter-cleaned" silicon nitride samples. The Auger spectra from our as-deposited samples always showed the presence of oxygen and relatively small amounts of carbon as surface impurities. The spectra from the as-received samples are similar to those already published and will not be presented here.

The surface layer of a nitride has been identified by Raider *et al.* (12) as a graded oxynitride resulting from the room temperature oxidation of the silicon nitride. In our samples, the surface oxygen content bears an inverse relationship to the nitrogen content in the film. The thickness of this oxynitride layer in most samples is typically <30Å. The presence of this oxynitride layer necessitates the argon ion sputtering before the bulk composition can be evaluated by AES. The tacit assumption is that the ion sputtering does not alter the composition significantly. We believe, from the present study, that the ion beam does alter the composition significantly, and the spectra reported are really from such an altered layer.

Typical Auger spectra from two samples with refractive indexes $n = 2.01$ and $n = 3.57$ are shown in Fig. 1, after sputter cleaning the surfaces with a 2 keV Ar^+ ion beam. Spectrum I is similar in shape to that reported by Holloway (10) for stoichiometric Si_3N_4. In this spectrum the "main" Si Auger peak occurs at ~88 eV, with the characteristic shoulder at ~83 eV. These are labeled peak A and B for convenience.

In Spectrum II, the ratio of peak heights A/B is much larger, and the nitrogen peak height smaller than in Spectrum I. The peak A has changed in energy to ~91 eV. In all the other samples analyzed, the ratio A/B and the energy of the peak A are dependent on the nitrogen peak height. Generally, it is believed that the characteristic silicon peak in silicon nitride is the peak A. We believe that the peak A is really an indication of the presence of "free" silicon in the surface layer and the Auger peak truly characteristic of the nitride is the "shoulder" peak at ~83 eV. In truly stoichiometric Si_3N_4, the occurrence of the 88 eV peak is an artifact and is a consequence of the preferential sputter removal of nitrogen making the surface silicon-rich. This conclusion was further strengthened by the absence of the 88 eV peak from the surface of a hot-pressed bulk silicon nitride sample fractured in air. While fully rec-

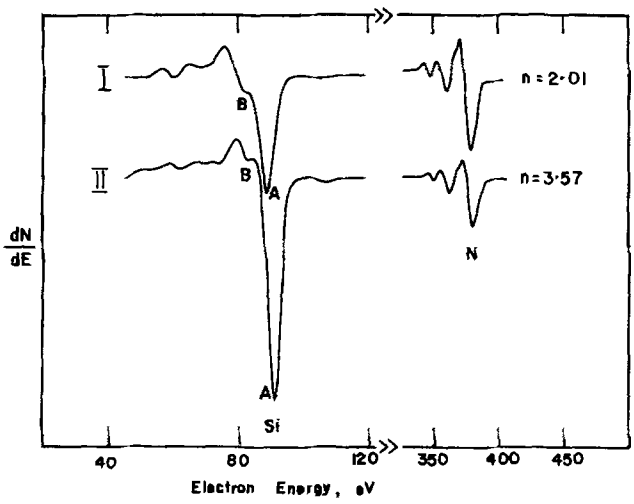

Fig. 1. Portions of the Auger spectra from sputter-cleaned plasma nitride samples with refractive indexes 2.01 (I) and 3.57 (II). Peak A is an indication of the presence of "free" silicon at the surface.

ognizing the profound influence of the small amount of oxygen impurity present on this sample in attenuating the 88 eV peak, the absence of the 88 eV cannot be explained solely by the oxygen contamination. In the CVD nitride, even with a comparable amount of oxygen present at the surface, the 88 eV was pronounced. The argument that the high temperature CVD nitride is significantly off stoichiometric, is invalid, in view of the results from other analytical techniques such as Rutherford backscattering (4, 5).

Another factor affecting the Auger peak shape and heights is the ion beam energy. After sputter cleaning the CVD nitride surface, it was bombarded alternately with 2 keV and 500 eV Ar^+ ions for 1 min durations (equivalent thickness removed 30Å, at 2 keV). The nitrogen and argon (imbedded) Auger peak heights and the height of peak A (measured from the maximum negative excursion to the shoulder at 83 eV) are shown in Fig. 2. As is evident, changing the ion beam parameters can drastically alter the preferential sputtering effects and hence the Auger peak heights. The same peak heights can be reestablished if the same ion beam parameters are used.

An attempt was made to determine the composition of the various plasma nitride samples differing in the refractive index. In Fig. 3, the nitrogen Auger peak height (sputter cleaned using identical ion beam parameters) is plotted against the refractive index of the film (curve 1). The true Auger peak heights should be

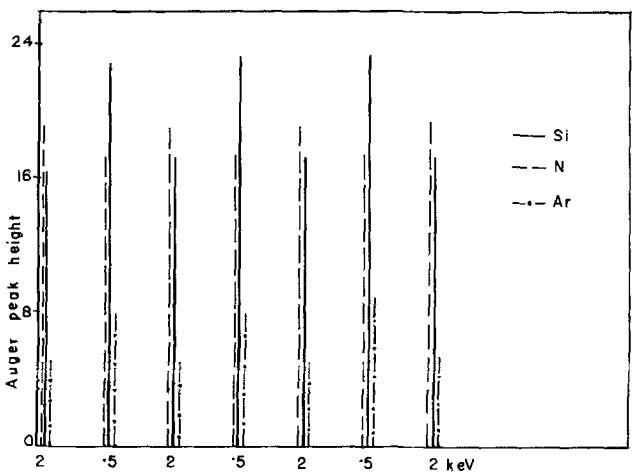

Fig. 2. The Auger peak heights from Si (peak A in Fig. 1), N, and Ar after the alternate bombardment with 2 and 0.5 keV Ar^+ ions for 1 min durations.

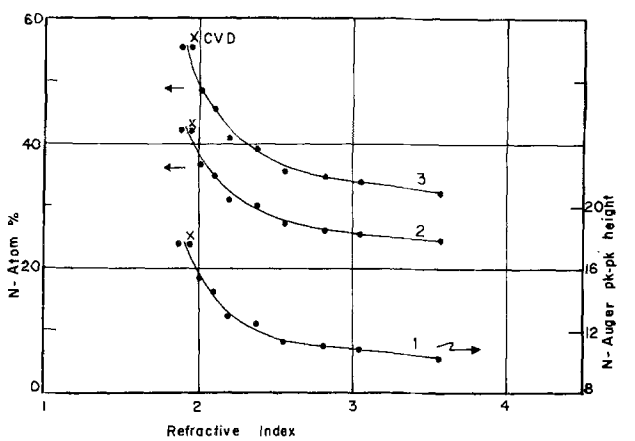

Fig. 3. Variation of the refractive index of the silicon nitride films with nitrogen concentration: 1. measured nitrogen Auger peak height; 2. N atom percent calculated from the measured nitrogen Auger peak height; and 3. N atom percent normalized to the high temperature CVD nitride film.

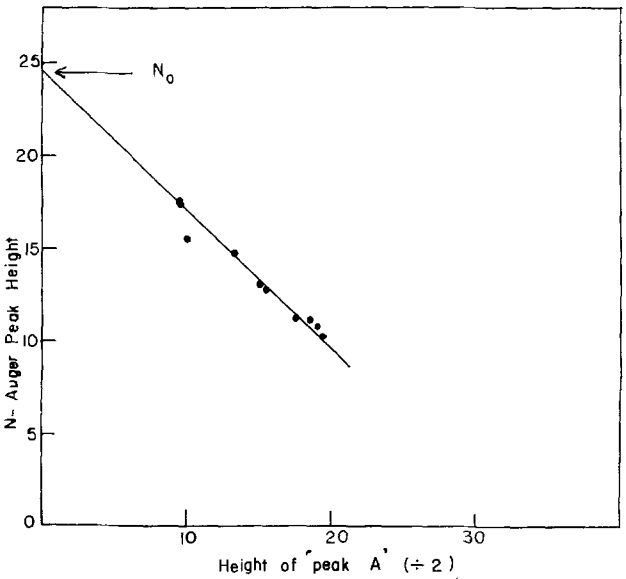

Fig. 4. Plot of nitrogen Auger peak height vs. height of peak A characteristic of "free" silicon.

larger than the measured values, for reasons discussed previously.

A graph plotted between the measured nitrogen peak height and the corresponding peak height of peak A (measured from the maximum negative excursion to the shoulder at 83 eV) in the silicon spectrum was found to be linear (Fig. 4) and was extrapolated to A = 0. This yielded a value for the nitrogen Auger peak height (N_0) if preferential sputtering was not present and the film was truly stoichiometric. Based on this value of N_0 for Si_3N_4, the atom percent of nitrogen was calculated corresponding to the measured peak heights and is shown in curve 2 (Fig. 3). Using this method of evaluation, the CVD film which was expected to be stoichiometric Si_3N_4 yielded a composition $Si_{58}N_{42}$—a significant deviation. Calculation based on the Si-KLL Auger peak height and the nitrogen peak height does not apparently eliminate this difference (13). The above deviation from stoichiometry is not due to the inherent nonstoichiometry of our CVD film, but rather to a consequence of the preferential sputtering effect. Based on the assumption that the CVD film was indeed stoichiometric, the atom percent of nitrogen in the plasma nitride films were calculated by normalizing to the measured peak height from this sample, and they are shown in curve 3 (Fig. 3).

It is evident from the above discussion that if the preferential sputtering is not recognized, the composition of the silicon nitride films will always be found to be silicon-rich using the AES-ion sputtering analysis. As can be seen from Fig. 3, the effect of the lower nitrogen content (silicon-rich) is to increase the refractive index from the expected value of 2. There are other parameters which influence the refractive index. The surface oxynitride and the interfacial oxide (detected on all samples by profiling) tend to lower the index, though the effect is relatively small for thick films. The presence of oxygen in the bulk of the film has a profound influence in lowering the refractive index, with a linear dependence on the atom percent of oxygen (14). Another very important factor especially in the plasma nitrides is the hydrogen content, which of course cannot be detected by the Auger technique. Preliminary studies on the above samples using *IR* spectroscopy have shown the presence of bonded hydrogen (both Si-H and N-H) in these films.

Mass Spectrometric Detection of Intermediates in Chemical Vapor Deposition of Si_3N_4

Sin-Shong Lin

Army Materials and Mechanics Research Center, Watertown, Massachusetts 02172

Silicon nitride has been widely used as an insulator and diffusion mask in semiconductor industries (1-3). Moreover because of superior physical properties at high temperatures, *e.g.*, good thermal shock resistance, extreme hardness, creep resistance, and chemical inertness, the material has been considered in the fabrication of gas turbine stator blades (4).

Si_3N_4 can be prepared from $SiCl_4$ and NH_3, using two different procedures. In the low temperature method (5-7), NH_3 is bubbled into cool $SiCl_4$ to form amorphous powders. The subsequent heating of the powders at 1200°C yields the crystalline form of alpha-phase Si_3N_4. In the second method (1-3, 8), commonly known as chemical vapor deposition (CVD), these two gases react in the temperature range 800°-1400°C. The product of the reaction is an adherent film and often consists of amorphous and crystalline Si_3N_4. The complete conversion of the amorphous matter to crystalline Si_3N_4 is difficult to accomplish unless the reaction is carried out at temperatures near 1400°C. This is explained by the high thermal stability of N-H bonds formed during the interaction of gases (9). The inclusions of NH and NH_2 groups in the Si_3N_4 lattice structure contribute to the formation of amorphous matter.

The previous attempt (10) to detect intermediates and condensates in the CVD process of alumina from aluminum chlorides and water was unsuccessful because the interaction of gases was believed to occur dominantly on surfaces instead in the vapor phase. In the CVD of Si_3N_4, the formation (11) of Si_3N_4 from $SiCl_4$ and NH_3 is expected to proceed through numerous reaction steps involving a series of intermediates and active complex molecules. It may be possible to detect some of these molecular intermediates by the present combined technique of atmospheric sampling and mass spectrometry. The knowledge that could be obtained might provide better understanding of the CVD process and also illustrate a new technique for the study of nucleation and condensation processes.

Figure 1 shows a block diagram of the sampling device for the CVD of Si_3N_4. The experimental apparatus includes gas inlet lines, a miniature CVD reactor, and a three-stage differential pumping vacuum system. The details have been described previously (10, 12, 13) and only features unique and pertinent to this work will be presented here.

The miniature CVD reactor was made of two high purity closed end alumina combustion tubes of ½ and ¼ in. OD in a concentric configuration as shown in Fig. 2. On the tip of each tube, an orifice varying from 6 to 50 mil was drilled along the axial line. A spacer or collar, cut from a ⅜ in. OD alumina tube up to 1 in. long, was placed between these two tips to serve as a reaction zone. Since the reactants pass rapidly through the reaction chamber into vacuum via the outer orifice, the extent of the interaction depends on the number of collisions between molecules in the reactor, which in turn is dependent on the time of molecular transit through the reactor. Thus the formation of intermediate molecular species depends not only on the pressure and the temperature of the reactor, but also on the degree of intermixing. The intermixing is related to the geometry of the reaction chamber, namely, sizes and spacing of the two orifices,

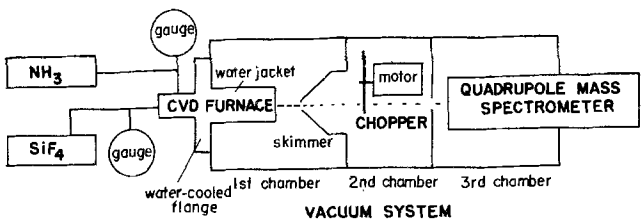

Fig. 1. Block diagram of experimental apparatus. The apparatus consisted of gas inlet lines, a miniature chemical vapor deposition furnace, and a three-stage differential pumping system. The quadrupole mass spectrometer, modulated beam mechanism, and expansion chamber are integral parts of the vacuum system.

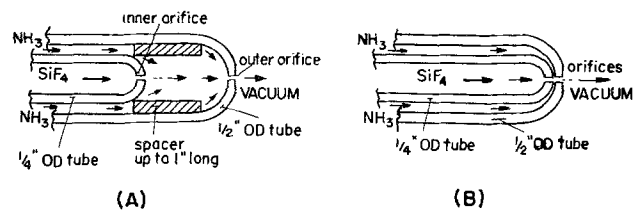

Fig. 2. Configuration of chemical vapor deposition reactor. The reactor is made of ¼ and ½ in. OD alumina tubes, and a spacer of varying lengths up to 1 in. as shown in (A). Without the spacer (B), the orifices are in the intimate contact position, and the interaction of gases is at minimum (almost null).

and the gas flow pattern. The interaction is minimal when the inner and the outer orifices are at the position of intimate contact as shown in Fig. 2(B).

SiF_4, instead of $SiCl_4$, was chosen because of the low atomic weight of fluorine which would enable us to monitor the complex intermediates within the limited mass range of the quadrupole mass filter. Also the monoisotopic nature of fluorine atoms facilitates the interpretation of ion peaks observed in mass spectra. The reagents SiF_4 and NH_3 were metered and introduced into the reactor individually through the core of the inner tube and the annular space between the two reactor tubes, respectively. The gas flows were initially set at 10 ml/min, and the pressure of the reactor, which was roughly equal to the NH_3 pressure because of the high conductance from the annulus to the reactor, was in the range 50-200 Torr depending on the sizes of the orifices. The heating was accomplished by the molybdenum winding around the reactor tube, and the temperature was recorded by a Pt-10%Rh/Pt thermocouple placed near the orifice of the inner tube. Prior to the CVD runs, mass spectra of each reactant were obtained so that the ions resulting from impurities present in the system could be distinguished from those ions resulting from the interaction. In some configurations of the CVD reactor, the gas flows could be adjusted so that ion peaks derived from one reactant would disappear from spectra. The intermediate ion species were observed only under the partial interaction of gases and were always accompanied by large amounts of the reactant ions. The vapor depositions were found to occur at all temperatures providing that the orifices were not in intimate contact. The deposits, white to translucent in appearance, were observed on the reactor wall, which tended to gradually clog the orifices during the run. No chemical analysis was made on these deposits due to the minute amounts available.

The experiments were performed with 15 different configurations of the reactor. The mass spectrometer was operated with the ionizing electron beam at 40 eV under varying resolution, sensitivity, and focusing conditions. Due to the corrosive atmosphere, the spectrometer was found to deteriorate considerably with time. Thus the detailed identification of trace intermediate ions in the CVD experiments became difficult. Furthermore due to the irreproducible geometry of the reactor, it was impossible to obtain systematic information concerning the CVD process.

In Table I, the observed ion species from mass spectra of SiF_4 and NH_3 are tabulated. At all temperatures, the most important ion species from SiF_4 is SiF_3^+, followed by SiF_4^+, SiF_2^+, SiF^+, $Si_2F_6^+$, and $Si_2F_7^+$. The origin of $Si_2F_7^+$ ion is not clear but it probably comes from the fragmentation of $(SiF_4)_2$. The major ions in NH_3 spectra at low temperatures are NH_3^+ and NH_2^+ with minor amounts of NH^+, N_2^+, and H_2^+. Due to extensive thermal dissociation, the abundances of N_2^+ and H_2^+ increase significantly while those of NH_3^+ and NH_2^+ decrease above 800°C.

Table I. Ion species observed in mass spectra of SiF_4 and NH_3 gases

Gas	Ion species	Neutral precursor	Abundances: Room temperature	T = 800°C	T = 1200°C
SiF_4	SiF_4	SiF_4	4	2	2
	SiF_3		100	100	100
	SiF_2	SiF_4/SiF_2	0.1	0.2	0.2
	SiF		0.1	0.2	0.2
	Si_2F_6	Si_2F_6	0.2	0.2	0.2
	Si_2F_7	$(SiF_4)_2$	0.1	0.05	0.05
NH_3	NH_3	NH_3	100	100	100
	NH_2		28	30	22
	NH		1	2	1
	N_2	N_2	—	2	280
	N		—	0.3	26
	H_2	H_2	—	—	15

Note: Abundances of SiF_4^+ and NH_3^+ are arbitrarily taken as 100, and listed data are only for comparison purposes.

Table II. Intermediate ion species observed in chemical vapor deposition of Si_3N_4 from SiF_4 and NH_3

Mass[a]	Ion species	Suggested neutral precursor	Abundances (SiF_3^+ as 100)[b]: Room temperature	T = 400°-1000°C	T = 1186°C[c]

556	$(Si(NH)_2)_6Si_2F_8$	Unknown	—	—	1

[a] Mass number is subjected to error of ±1 amu for polymeric ions over 286, and ±2 amu for polymeric ions over 479.
[b] Intensity data are taken directly from scan spectra for comparison only. SiF_3^+ is arbitrarily taken as 100.
[c] Data are taken from the run; P = 87 Torr, flow = 10 ± 1 ml/min for both gases, T = 1186°C, size of reactor: outer orifice = 1 mm diam, inner orifice = 0.2 mm diam, length of reactor chamber or spacer = 1.3 cm.

In Table II, the intermediate ion species observed in the CVD runs are listed. The most abundant ion species observed are $SiF_2NH_2^+$ and $SiF_3NH_2^+$. These two ions are observed in all CVD runs except in runs made with the intimate contact configuration and in runs below 400°C. The identities of these two ions have been confirmed from their isotopic distributions. The intensities of these ions are about one-hundredth of the most abundant reactant ion SiF_3^+ in the system, and are strongly influenced by pressure and flow of the reactants NH_3 and SiF_4. The majority of these two ions seem to derive from the neutral precursor SiF_3NH_2 which is the first intermediate molecule from the interaction. The reaction product HF in the form of HF^+ at mass 20 amu is observed mostly above 400°C, and $(HF)_4^+$ is found to dominate the mass spectra at low temperatures.

The remaining intermediate ions of complex molecular compositions listed in the table are detected at temperatures above 1000°C in some specific runs. The abundances listed in the last column are the highest observable intensities. The intensities of these ions diminish with increasing mass number and complexity, and are generally two or three orders of magnitude less than the most abundant intermediate ions $SiF_2NH_2^+$ and $SiF_3NH_2^+$. Due to low abundances, their identities are deduced only from mass numbers and relative positions in mass spectra. These ion peaks are found to occur in mass spectra separated by intervals of 19 and 58 amu units corresponding to composition differences of one F and $Si(NH)_2$ units. Also due to poor resolution at higher mass numbers, the molecular weights of these large intermediate ions are not established within one mass unit (one hydrogen atom). Based on a general fragmentation pattern of simple inorganic fluorides (14), in which neutral species upon electron impact preferentially yield an ion with one fluorine atom less than the neutral, the precursors of these small ions are suggested in the table. However, the fragmentation patterns of high polymeric molecules are not known at this time.

The over-all chemical reaction for the CVD of Si_3N_4 can be written as

$$3SiF_4(g) + 4NH_3(g) = Si_3N_4(s) + 12HF(g) \quad [1]$$

The stepwise processes leading to the formation of Si_3N_4 are suggested to occur through series of additive intermediates followed by elimination of hydrogen

fluoride molecule such as

$$SiF_4 + NH_3 = [F_3SiF\cdots HNH_2] = F_3SiNH_2 + HF \quad [2]$$

$$F_3SiNH_2 + SiF_4 = [F_3SiNH_2\cdots FSiF_3] = F_3SiNHSiF_3 + HF \quad [3]$$

and

$$F_3SiNH_2 + NH_3 = [H_2NSiF_3\cdots HNH_2] = H_2NSiF_2NH_2 + HF \quad [4]$$

Reactions [2] and [3] can be repeated and proceeded to form higher intermediate molecules of the general form

$$F(SiF_2NH)_nH + SiF_4 = F(SiF_2NH)_nSiF_3 + HF \quad [5]$$

$$F(SiF_2NH)_nSiF_3 + NH_3 = F(SiF_2NH)_{n+1}H + HF \quad [6]$$

where $n \geq 1$. Eventually all Si—F bonds are replaced by Si—NH and Si—NH_2 bonds with excessive N and H in the structure

$$a\ SiF_4(g) + b\ NH_3(g) = Si_aN_bH_{3b-4a}(s) + 4a\ HF(g) \quad [7]$$

where $4a > b \geq 4/3a$. And when $b = 4/3a$, reaction [7] is reduced to reaction [1], the complete formation to Si_3N_4.

The experimentally observed ion species are in good agreement with the above proposed mechanism since the formations of NH and NH_2 groups are major processes leading to the CVD of Si_3N_4. The ions $SiF_2NH_2^+$ and $SiF_3NH_2^+$ are presumably derived from SiF_3NH_2 which is the first intermediate molecule. This is an excellent indication that the proposed reaction [2] has actually taken place. The observed ion $Si_2F_5NH^+$ possibly originating from Si_2F_6NH agrees with reaction [3]. The remaining polymeric intermediate ions with an approximate formula, $(Si(NH)_2)_nSi_2F_m$ where n = 1-6, and m = 6-8, suggest that successive reactions [5] and [6] might have occurred. Moreover in these earlier stages of polymerization and nucleation, the reactions seem to proceed not only through chain-like additives such as in reactions [5] and [6], but also through cross-linkages to form two- and three-dimensional clusters. This is suggested by more NH units than Si in the composition of higher polymeric ions. Since the electron impact ionization behavior of these high polymeric species and nuclei are not available, detailed analyses of the stepwise mechanisms could not be reached.

The observed intermediate ion species could be used to explain the onset of the vapor phase nucleation in the CVD of Si_3N_4. At temperatures below 400°C, the reactions between SiF_4 and NH_3 gases take place primarily on surfaces. Consequently no intermediate molecule could be detected. Between 400° and 1000°C, the interaction is believed to occur both in the vapor and on the surface. The existence of only the first intermediate species SiF_3NH_2 suggests that the vapor phase reaction and nucleation are limited to the first few stages of condensation, and successive reactions probably occur on surfaces. Thus the resulting product, containing amorphous material, could not be entirely converted to crystalline Si_3N_4 at 1200°C. At temperatures above 1000°C, the vapor phase interaction and nucleation are found to proceed to a large extent. This is evidenced by the presence of polymeric intermediate molecules. The incomplete conversion to Si_3N_4 during the vapor phase interaction probably produces irregular lattice structures in the product containing NH groups.

The chemical reactions occurring in the SiF_4-NH_3 system are probably similar to those in the $SiCl_4$-NH_3 system widely employed in the industry. The substitution of fluorine by chlorine presumably yields similar reaction steps leading to the deposition of nitride films as described in preceding paragraphs. The difference in chemical nature of these two halogens will appear on the life times of the polymeric intermediates, which may result in different reaction rates and reaction temperatures. The sharp increase in the deposition rate in the $SiCl_4$-NH_3 system (8) above 1300°C (attributed to vapor phase nucleation) as compared to the observed presence of polymeric species near 1200°C may be attributed to this difference.

In summary, the presence of the intermediate molecular species reveals that vapor phase nucleation and interaction occurs during the CVD of Si_3N_4 at elevated temperatures. The interaction and nucleation on surfaces are found to become less important as the temperature increases. The proposed reaction mechanism leading to the formation of Si_3N_4 is in good agreement with the present experimental observation. Further analyses of these intermediate ion species should provide detailed mechanisms of the vapor phase nucleation.

Brief Communication

Alloy Composition Profile of Heterogeneous Structure in $GaAs_{1-x}P_x$ Determined by the Anodization-Electroreflectance Technique

S. Tachi, A. Moritani, and J. Nakai

Department of Electronics, Faculty of Engineering, Osaka University, Suita, Osaka 565, Japan

A graded bandgap structure in semiconductor alloys is often found in electronic devices such as solar cells, epitaxial wafers, and heterojunction interfaces. In fabrication of $Al_xGa_{1-x}As$-GaAs solar cells, the graded composition structure provides a potential increase of power conversion efficiency (1). It has been well known that a $GaAs_{1-x}P_x$ epi-wafer layer with continuously graded composition is grown beneath the thick epi-layer with uniform composition to minimize strain and crystal imperfections due to lattice mismatch between the $GaAs_{1-x}P_x$ epi-layer and the GaAs substrate (for $x < 0.45$) and/or GaP (for $x > 0.45$) (2). It is of vital importance for development of these devices to know the depth profile of the bandgap energy, *i.e.*, the alloy composition in a heterogeneous system easily and accurately up to a depth of 50 μm or more.

In this paper we propose a newly combined technique of the successive anodization and layer removal and the electrolytic electroreflectance measurement (AE technique), and we report, as an example of its application, the depth profile of the alloy composition x in the graded bandgap region of one of $GaAs_{1-x}P_x$ epi-wafer on the basis of the experimental data about the anodization of $GaAs_{1-x}P_x$ (3). Anodization has been used for sectioning to obtain the carrier concentration profile (4), and has been known to provide a strain-free, planar, reproducible sample surface as well as accurately controllable thickness of the anodized film. Electrolytic electroreflectance (ER) under the low field condition has been used to obtain a great amount of information about electronic energy band structures of solids such as values of the energy bandgap and types of the critical points, effective masses, etc., and it gives not only the energy value of the fundamental energy bandgap, but also those of higher interband transitions named E_1, E_2, and so on in energy band structure (5). The present AE technique has the advantage that the same electrolyte and the electrolytic cell can be used for anodization and ER.

The sample used was n-type $GaAs_{0.63}P_{0.37}$ with carrier concentration $N_d = 1 \times 10^{16} \sim 2 \times 10^{17}$ cm^{-3} and thickness of 30 $\sim$ 60 μm, epitaxially grown on n-type (100)-oriented GaAs substrate with $N_d \approx 1 \times 10^{18}$ cm^{-3}. The electrolyte used in this investigation was a mixture of one part of 3% aqueous solution of tartaric acid and two parts of propylene glycol (6). Anodization was carried out by the constant current method in the magnetically stirred electrolyte under illumination in order to accelerate the reproducible and uniform growth. The current density was kept at 3.0 mA/cm^2. After each anodization the sample was boiled in concentrated HCl for a while to remove the oxide completely from the surface. Then the sample was rinsed in deionized H_2O and immersed quickly in methanol to prevent its being oxidized in air. The cleaned sample was then immersed in the same electrolyte for ER measurement. The square wave modulation was adopted to deplete sample surface. With a sufficiently low field, ER spectrum can be represented in terms varying linearly and quadratically with the modulating electric field in zincblende-type crystals such as GaAs, $GaAs_{1-x}P_x$, and GaP, so that we have used [011] polarized light to eliminate the linear term and obtain the energy value of the energy bandgap from the analysis of ER signal (5). As the low field condition is achieved more easily at the E_1 transition than at the fundamental gap, the ER measurements were carried out near the E_1 transition, and the spectra obtained were analyzed by the use of the three-point method which gave the energy value of the E_1 transition using the value of the amplitude and the energy at the peaks and the base line in ER spectra. The corresponding alloy composition was derived from the energy value and the bowing parameter (340 $\pm$ 30 meV) of the E_1 transition. The bowing parameter used was determined by ER measurements of $GaAs_{1-x}P_x$ with $x = 0$, 0.01, 0.12, 0.37, 0.39, 0.41, 0.65, 0.85, and 1. It indicates intermediate value between those reported by Aspnes *et al.* (400 meV) (7) and Thompson *et al.* (310 meV) (8). The penetration depth of the light was estimated to be about 75Å for GaAs and about 80Å for GaP which was small enough to give the well-resolved depth profile of epi-layer with thickness of more than 30 μm.

Figure 1 shows the depth profile of the alloy composition of $GaAs_{0.63}P_{0.37}$ epi-wafer obtained by the present AE technique. The depth in horizontal scale was derived from the result of anodization (3). To obtain these data, 167 cycles of anodization were performed, and the stripped thickness of this epi-wafer was 52 μm. As seen in Fig. 1, the graded composition region is 32 μm and the alloy composition varies linearly from $GaAs_{0.63}P_{0.37}$ epi-wafer to the GaAs substrate.

In conclusion, we have reported and demonstrated the applicability of the present AE technique to the depth profile of the alloy composition in heterogeneous system, and have shown that, as an example, $GaAs_{1-x}P_x$ can be dug and treated up to 52 μm or more by the successive anodization and layer removal.

Key words: depth profile, heterogeneous structure, anodization, electroreflectance, $GaAs_{1-x}P_x$.

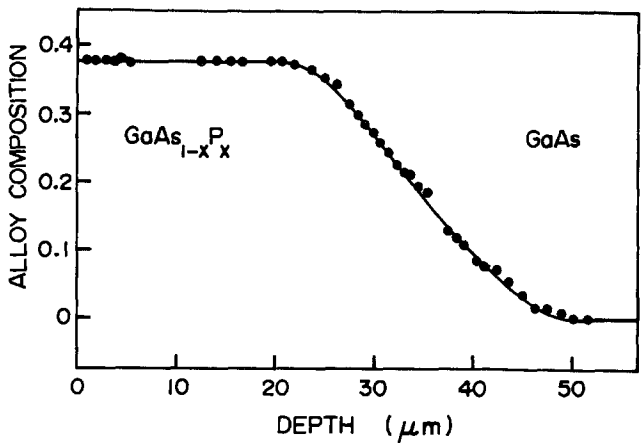

Fig. 1. Depth profile of the alloy composition of $GaAs_{0.63}P_{0.37}$ epi-wafer obtained by the AE technique.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 123, No. 10; October 1976; and Vol. 124, No. 2, 3, and 6; February, March, and June 1977.

The Dielectric Breakdown in Anodic Aluminum Oxide

H. J. de Wit, Ch. Wijenberg, and C. Crevecoeur (pp. 1479-1486, Vol. 123, No. 10)

J. M. Albella, J. M. Martinez-Duart, M. J. Puente, and J. Baonza:[1] The electrical breakdown of anodic oxides is still a controversial subject among researchers. The results obtained in anodic Ta_2O_5 thin films in our laboratory are in good agreement with the theory recently put forward by Wit *et al.* for anodic Al_2O_3 thin films.

Tantalum foil was anodized in a 0.01% PO_4H_3 electrolyte at a constant current density of 3 mA/cm^2. When the preset voltage was reached, the current was let to decay to a value about one thousand times smaller than the initial value. Before anodization, the tantalum samples were subjected to the following treatments: (*i*) degreasing by rinsing in carbon tetrachloride, acetone, and methanol; (*ii*) chemical etching in a 5:2:2 solution of commercial sulfuric, nitric, and hydrofluoric acids; and (*iii*) same treatment as before followed by an immersion in a solution of NH_4F-HF as it was used by Maurel *et al.*[2] As suggested in this work we have observed by scanning electron microscopy that treatment (*iii*) produces crystalline grains free of heterogeneities and with very well-defined boundaries.[3] We have also checked by Auger spectroscopy[3] that this treatment leaves a very clean surface by eliminating to undetectable limits the large fluorine contamination left after treatment (*ii*).

The breakdown voltage V_b was measured in samples anodized at a voltage V_f ranging from 25 to 200V which corresponds to a thickness from 432 to 3460Å. A ramp voltage of 1 V/sec was applied to the oxide by means of a copper-tipped probe with a contact area of about 5×10^{-4} cm^2. At least fifty determinations of V_b were made for each sample.

Several experimental results observed in our laboratory in the breakdown of Ta_2O_5 films strongly support the theory given by Wit *et al.* for Al_2O_3. These results are: (*i*) the shape of the breakdown voltage distribution curves are similar to those obtained by Wit *et al.* and P. Solomon *et al.*[4] in Al_2O_3; (*ii*) for a given surface treatment and in the voltage range studied, the ratio V_b/V_f is approximately equal to 0.3 and 1.1 for treatments (*i*) and (*ii*), respectively, the breakdown dispersion curves showing a large scattering in the measurements. On the other hand, treatment (*iii*) gives the largest breakdown voltage, $V_b = 1.2V_f$, and the least scattering in the measurements. The fact that V_b/V_f is practically independent of formation voltage, and therefore of oxide thickness and electric field, is qualitatively in agreement with Eq. [3] and [4] in the paper of Wit *et al.*, since the variation of V_b/V_f with the logarithm of the thickness is relatively small.

We therefore think that the above results strongly support the ionic mechanism postulated by Wit *et al.* and by Shousha,[5] at least for tantalum surfaces that are clean and free of inhomogeneities. According to this mechanism the breakdown is started by an ionic movement. This theory also confirms our preliminary observations[6] that V_b is very high for clean tantalum surface heated to 2500°K in ultrahigh vacuum. All these facts point out that the probabilistic nature of the breakdown phenomenon is very much affected by the state of the metal surface. In this sense, the smaller

V_b observed in samples subjected to treatment (*ii*) in comparison to treatment (*iii*) might be related to the fluorine contamination on the surface as it has been observed in silicon oxide by Croset and Dieumegard.[7] At present we are conducting research to elucidate if the breakdown and the scintillation is initiated at localized regions with a large impurity concentration such as, for instance, grain boundaries.

Origin of the Fixed Charge in Thermally Oxidized Silicon

H. Goronkin (pp. 314-317, Vol. 124, No. 2)

S. I. Raider:[8] The author of the paper under discussion presents experimental MOS data showing the variation in Q_{ss}/q with change in time of annealing SiO_2-Si structures in N_2 gas at 1100°C (Fig. 2 of paper). The Q_{ss}/q data represent the total calculated charge derived from flatband voltage C-V measurements of MOS capacitors formed with a 1300Å oxide film thermally grown on a <111> oriented, n-type Si substrate. These data were analyzed in terms of solid-state diffusion to determine whether they support the model[9] in which Si atoms (or ions) diffuse into an SiO_2-Si interfacial region to generate fixed oxide charge.

It was experimentally observed that an increase in the N_2 gas annealing time results in an initial decrease, followed by a gradual increase, in Q_{ss}/q. Similar variations in Q_{ss}/q were previously reported[10-12] after annealing SiO_2-Si structures in N_2 gas. Although Lamb and Babcock's data[10] are obtained from variations in anneal temperature rather than variations in anneal time, the interfacial process leading to an increase in Q_{ss}/q appears to be thermally activated.[12,13] Data that were obtained at the shorter anneal times at higher temperatures[10] presumably correspond to data obtained at longer anneal times at a lower temperature.

Only the decrease, but not the subsequent increase in Q_{ss}/q, is detected after annealing similar structures in either Ar or in He gas at temperatures greater than 1000°C.[10,13,14] The increase in Q_{ss}/q appears to be uniquely associated with annealing in N_2 gas. Si diffusion at the transition region should be independent of annealing ambient if the annealing gases are chemically inert. Lamb and Babcock[10] had suggested that this increase in Q_{ss}/q is related to the chemical interaction of N_2 gas with Si at the SiO_2-Si interface. Direct evidence has been presented indicating that N_2 does interact with Si at an SiO_2-Si interface during high temperature annealing.[14,15] In addition, the observed saturation in Q_{ss}/q with anneal time correlates with a saturation in N_2 concentration at the SiO_2-Si interface.[14] No increase in Q_{ss}/q is detected after annealing in Ar gas and no Ar is detected at the SiO_2-Si interface.[14,15]

SiO_2-Si structures annealed in N_2 at elevated temperatures apparently exhibit two electrical instability effects. Fixed oxide charge densities are minimized and primarily surface states[11,13,14] are generated. Surface states are detected after annealing in N_2 gas at temperatures greater than 1000°C with[13,14] and without[11] a 400°C postmetallization anneal. High temperature annealing in Ar exhibits only the first of these electrical instability changes. Fixed oxide charge formed during the oxidation reaction is minimized by a thermally activated process that is independent of the annealing ambient.[16] The observed increase in Q_{ss}/q is more properly associated with a chemical interaction between N_2 and Si within the SiO_2-Si transition region than with Si atom (or ion) diffusion at this interfacial region.

The Identification of the Mobile Ion during the Anodic Oxidation of Silicon

W. D. Mackintosh and H. H. Plattner (pp. 396-400, Vol. 124, No. 3)

P. F. Schmidt:[17] The conclusions drawn by Mackintosh and Plattner from their very interesting work,[18] for which I was privileged to act as one of the reviewers, are fully self-consistent if one accepts their premise that the noble gas markers are immobile also in anodic SiO_2. This interpretation of their experimental results appears to me, however, to be at variance with other results obtained by different techniques, and it is the purpose of this communication to point out the areas of disagreement and to suggest possible explanations.

The two main conclusions of their paper are: (*i*) The noble gas atoms stay near the outer surface of the oxide film during additional oxide growth, implying that the ionic current is carried almost exclusively by oxygen ions; and (*ii*) Phosphate ions, incorporated into a preexisting anodic SiO_2 film, appear to drift at least as fast as the oxygen ions during additional anodization, thus leading to the encapsulation of the phosphate-doped oxide by a layer of newly formed oxide. Both results were obtained by Rutherford backscattering, which allows very little error in the determination of the position of the noble gas markers. Determination of the position of the phosphate ions is more difficult because of the small mass difference between silicon and phosphorus; however the exact velocity of the phosphate *vs.* the oxide ions is not really a major point of the discussion (see below).

Before describing the older results which, in my opinion, are not readily compatible with the oxide ion migration model, I should like to first quote the unambiguous evidence given in ftn.[19] that silicon ions can be the mobile species, albeit in Si_3N_4 rather than in SiO_2. If a preexisting amorphous Si_3N_4 film is subjected to anodization, hydroxyl ions penetrate into the film and convert it into anodic SiO_2, starting from the outside. If, on the other hand, a crystalline Si_3N_4 film is anodized under otherwise identical conditions, anodic SiO_2 forms on top of the Si_3N_4 layer without change in the composition of the latter. Thus Si ions can be the mobile species; their tetrahedral bond angles do not constitute a fundamental difficulty.

Anodic SiO_2 films, even those grown in nearly anhydrous organic media, are very hygroscopic, to my knowledge more so than the anodic oxide films on any other element. The surface layer of a freshly grown anodic SiO_2 film is strongly hydrated respectively hydroxylated. A thin anodic SiO_2 film is under compressive stress, with increasing anodic-forming voltage the (compressive) stress first diminished, and it eventually becomes tensive.[20] If the film is now exposed to room air, the tensive stress gradually diminishes and can even become compressive again, but the tensive stress can be reestablished by reanodization to the same or very slightly higher voltage. These changes in stress are clearly indicative of absorption and desorption of moisture. The hydroxyl content of an anodic SiO_2 film, grown to different thicknesses at the same constant current density and in the same tritium-tagged electrolyte, is found to be nearly independent of

[16] S. I. Raider and A. Berman, Submitted to *This Journal*.
[17] Bell Laboratories, Allentown, Pennsylvania 18103.
[18] W. D. Mackintosh and H. H. Plattner, *This Journal*, 124, 396 (1977).
[19] P. F. Schmidt and D. R. Wonsidler, *ibid*, 114, 603 (1967).

the anodization voltage. In fact, it decreases slightly with increasing forming voltage. Only the surface layer of the oxide film is strongly hydroxylated, and the thickness of this hydroxylated region is nearly independent of the forming voltage.[20]

If a thermally grown SiO_2 film is subjected to anodic bias below the voltage at which additional film growth occurs, then hydroxyls—or possibly water—is injected into the film, eventually throughout its entire thickness if the bias is maintained long enough.[20] These hydroxyls—or water—can again be expelled by anodization to a higher voltage, only the surface layer remaining strongly hydroxylated or hydrated. The injection of the hydroxyls under low anodic bias required incubation periods of several minutes, in full analogy with the incubation periods observed by Dreiner[21] by means of capacitance measurements, suggesting that hydration of the oxide surface by a chemical step is required for the subsequent field-aided injection of hydroxyls; in other words, the hydroxyls in the solution do not simply pass into the oxide as current carrying carriers in the oxide.

In the past I have interpreted the dehydration of the oxide at full-forming field strength as a reaction between hydroxyls in the film and silicon ions in transit through the film. I am still at a loss to think of a fully satisfactory alternate mechanism. This explanation, however, presupposes the existence of mobile silicon ions.

I have dwelt on this description of the hydration and dehydration effects at such length because dehydration of a strongly hydroxylated SiO_2 must of necessity result in a shrinkage of the lattice. It seems conceivable to me that the shrinkage front, which is known to progress outwards from the Si/SiO_2 interface, could push ahead of it any interstitial atoms, especially if they are of larger size. The net effect during anodization to higher voltages would be to keep the noble gas markers near the outer surface of the oxide film.

Mackintosh and Plattner seem to imply that the phosphate ion as an entity, PO_4''', is migrating under bias in anodic SiO_2 films. PO_4''' is a tetrahedral ion with a "diameter" of about 3.92Å.

During thermal oxidation of silicon, oxygen gas is known to permeate the oxide lattice, and to cause additional oxide growth at the Si/SiO_2 interface. Mackintosh and Plattner therefore compare the anodic oxidation of silicon, with oxide ions mobile, to the thermal oxidation of silicon. Since they find that phosphate ions are at least as mobile as the lattice oxide ions, this implies a kind of "interstitial" migration of the phosphate ions as well.

The O_2 molecule, however, is dumbbell shaped, and can orient itself to pass through the constrictions in the SiO_2 lattice with its small dimension, not with its long dimension of 3.2Å. In addition, it is known that the larger alkali ions, such as Rb+ or Cs+ are too large to fit into the open spaces of the most widely spaced SiO_2 lattice (crystobalite), let alone to migrate freely through the constrictions of that lattice. Implanted Cs ions have indeed been used as immobile charges (at temperatures of 430°C and at fields of 1×10^6 V/cm) to control the surface potential of silicon in MOS structures.[22] Thus it appears exceedingly unlikely to me that PO_4''' could be a freely migrating species even in anodic SiO_2 films.

If the phosphate is indeed mobile, as claimed in ftn.[18], then, in my opinion, this mobility should be a consequence of the oxygen ions of the PO_4''' complex forming a component of the oxygen sublattice. If the oxide sublattice moved in a coherent way, it would simply take the phosphorus atoms along with it. This picture requires that the order of the oxygen ions during anodization be maintained. It has, in fact been found in all instances where the sequence of the oxide ions during anodization was monitored by means of O^{16}-O^{18} measurements, that the order of the oxide ions is indeed maintained; such is not necessarily the case for the cations.[23,24] If the phosphate ion is indeed tied to the anion sublattice, then it must become buried deeper during additional anodization, irrespective of whether anions or cations are the mobile species. Similarly, a species somehow tied to the cation sublattice must remain near the outer surface of the oxide, again irrespective of which species is mobile. This consideration implies that the position of the phosphate ion upon additional anodization may not be used at all in trying to determine the mobile lattice species. Thus my own earlier conclusions,[25] based upon its location, are certainly also invalidated. It would appear that a possible tie-in with one of the sublattices should be considered whenever markers are used.

According to ftn.[18], the motion of the phosphate during anodization is actually somewhat faster than that of the lattice oxygen. This is one experimental detail I have some reservations about in view of another observation. A n-type silicon electrode of somewhat higher resistivity (1 Ω-cm or higher) blocks the current flow in darkness up to high voltages. This current blocking immediately disappears if a very thin oxide film is formed on the bare Si surface in solutions of concentrated phosphoric or polyhedral borane acids, apparently due to a high surface recombination-regeneration velocity caused by the acid molecules incorporated[25,26] into the oxide film.

On the other hand, if a very thin oxide ($V_{form} = 10V$) is first formed in an inert electrolyte (such as KNO_2 in tetrahydrofurfuryl alcohol, or ammonium-pentaborate in water), then several hundred angstroms of acid-doped oxide can be grown on top of the "pure" oxide without causing excessive surface regeneration of minority carriers.[27] The discrepancy between this observation and that in ftn.[18], however, is marginal because current blocking of n-type Si anodes also disappears if a "pure" anodic oxide is grown to thicknesses larger than about 400Å (about 3.8 Å/V). If the migration velocity of the phosphate were only 10% higher than that of the oxide ions, no phosphate would yet have reached the Si/SiO_2 interface in the "cations immobile" model.

It should be possible to unambiguously clarify the question of the mobility of cations or anions in the anodization of silicon by monitoring the sequence of the cations before and after anodization. If only the anions are mobile, the sequence of the cations must, of course, be maintained. The experiment can be carried out by epitaxial deposition of a very thin silicon layer isotopically enriched in Si-30 on top of a normal silicon substrate. Since Si-30 is the only silicon isotope to become radioactive upon irradiation with thermal neutrons, anodization through the substrate/epitaxial interface, followed by stepwise dissolution of the oxide and determination of the specific activity of each oxide layer, would permit determination of the cation sequence.

In conjunction with the mechanism of phosphate migration (if indeed the phosphate migrates), it would also be of interest to determine the sequence of the oxide ions (O^{16}, O^{18}) before and after anodization, an experiment fully feasible with Rutherford backscattering or nuclear techniques. One would, however, have to look at a O^{16}-O^{18} transition somewhat deeper in the preexisting oxide film, in view of the known rapid exchange between the two oxygen isotopes at the oxide surface during additional anodization.[28] This exchange

is caused by the injection of hydroxyls or water discussed above, and is not necessarily evidence for the absence of cation migration.

Control of Al_2O_3 Position in Anodic GaAs Native Oxide

B. Bayraktaroglu, S. J. Hannah, and H. L. Hartnagel
(pp. 958-959, Vol. 124, No. 6)

J. P. S. Pringle:[29] Twice have I commented[30,31] on the inadequacy of the reviewing procedures used by *This Journal*, and the brief communication by Bayraktaroglu, Hannah, and Hartnagel provides a splendid illustration of my theme.

Their communication is indeed brief, since it is only eight paragraphs long. It opens with a statement of claim:

"It is shown that by careful control of kinetic growth parameters, it is possible to anodically position a thin Al_2O_3 layer in a native GaAs-oxide film either near the oxide-semiconductor interface or on the surface of the GaAs oxide." That claim is specific and unambiguous; nowhere is it substantiated. And that may not be obvious to the reader owing to the way the article has been written.

Consider first its organization. After stating their claim, the authors use the rest of the first paragraph to describe several "interesting" advantages that their claim "promises." In the next paragraph, they put forward a hypothesis that interprets their claim in terms of the differing mobilities of anions and cations at high and low electric fields across the oxide film. This leads naturally to paragraph three, where the "kinetic growth parameters" of the claim are identified as current density, and to paragraph four, where numbers are placed on this parameter; paragraph five notes "a limit to the thickness of Al_2O_3 on the GaAs surface." Only after the claim and the hypothesis interpreting it have been well and truly described is the experimental evidence presented in paragraphs six and seven. By placing their evidence after the discussion, the authors suppress consideration of possible alternatives, both by themselves and by their readers.

Next consider the style of the article. This is extremely positive throughout, as illustrated by these statements at the beginning of paragraph two.

"Due to the difference in the threshold fields required for the activation of different anions and cations, it is possible to influence the growth mechanism of anodic oxide films, and therefore shift the effective oxide formation region anywhere from the metal-oxide interface to the oxide-electrolyte interface." Note the decisive "Due to . . . it is possible . . . and therefore" construction here, and that none of these statements have been supported by any references. While such a style makes for easy reading, it does so at the expense of oversimplification. Everything is focused toward the claim; even the experimental evidence is presented, not in terms of what was actually observed, but in terms of the interpretation required by the claim! This combination of organization and style is most persuasive in suggesting that the authors have established their claim, but examination of the content of their article will show that they most certainly have not.

What did the authors actually observe? That is uncertain. When a sample of GaAs covered with a layer of Al of unspecified thickness was anodized at unspecified constant current density to an unspecified final voltage for an unspecified length of time in an unspecified electrolyte at an unspecified temperature, an etching of "some" of the "composite" oxide was observed when the formation current density was "high" "(> 2 mA/cm^2)", but not when it was "low" "(~ 20 μA/cm^2)."

The criteria for observing "etching" are not specified, nor is the strength, time, and temperature of the tartaric acid used. No evidence is presented that the tartaric acid will dissolve all of the "GaAs native oxide," nor is it explained in what way this differs from the "anodic GaAs native oxide" of the title. "The thickness of the oxide left behind was measured with a Dektak profile plotter" which implies the formation of an oxide step; that would require removal of the "oxide left behind" from part of the surface, but there is no discussion as to how this was done. "Measured values" unspecified "were compared with the expected thickness" unspecified "of Al_2O_3," but it is not specified whether they agreed or not, and to within what experimental error. When reporting their overpotential *vs.* time evidence in paragraph seven, the authors write (present author's comments in parentheses):

"After all the Al is converted into Al_2O_3 (unsupported statement), the overpotential exhibits a temporary (unspecified) steep (unspecified) increase for the high current density case, whereas a constant (how constant?) potential is maintained over a short (unspecified) period for the low current density case." No doubt the authors will claim they have at least specified the "electrolyte first suggested by Hasegawa and Hartnagel (2)," a tactic that forces the reader to look up the reference[32]—in which he finds a number of different electrolytes mentioned."

Evidence as indefinite as this neither confirms nor denies the claim, and it but remains to consider the hypothesis advanced in the second paragraph. This rests largely on the following statement:

"For anodic Al_2O_3 films, it is known (1) that the threshold field required for the activation of cations is larger than that for anions." That statement greatly surprised the present writer. Well it might, since he was responsible for the final draft of the reference (1)[33] cited, and no such conclusion was reached by him. How the authors reached that conclusion is up to them to explain; presumably—repeat presumably—they derived it in some way from the reported[33] variation of t_m, the transport number for the aluminum, with current density. If so, they have two questions to answer. First, how can they be so sure in paragraph four that:

"If low current densities are used, *i.e.*, ~ 20 μA/cm^2, after the Al_2O_3 is formed, there are only anions moving across the oxide to the GaAs-Al_2O_3 interface." When the reference[33] reports that the transport number of the aluminum was 0.33-0.41 at 100 μA/cm^2 (the lowest current density investigated), 0.44 at 300 μA/cm^2, 0.56 at 1 mA/cm^2 and 0.72 at 10 mA/cm^2? And second, how can they justify applying these results in 3% aqueous ammonium citrate electrolyte in preference to those obtained with solution A, a glycol-based electrolyte similar to some of those mentioned in their reference (2),[32] where t_m remained constant at approximately 0.6 for all current densities between 100 μA/cm^2 and 10 mA/cm^2?

The purpose of a scientific communication is not to convince the reader that a claim is valid, but to let the reader convince himself by providing enough evidence for him to do so. That the authors have not done; they have merely stated their claim, and then asked the reader to accept on trust that they have enough evidence in support, even though they are not going to specify exactly what it is. Not good enough! An effective reviewing procedure should protect the reader from misleading impressions, the publisher from wasting money, and authors and editors from subsequent embarrassment by curmudgeons such as the present writer. If I had been the reviewer for this article, its many and obvious deficiencies would have left me with only one recommendation: do not publish. Yet it has been published and apparently after review too—why?

B. Bayraktaroglu, S. J. Hannah, and H. L. Hartnagel:[34] The authors are disappointed that Dr. Pringle has failed to appreciate the main purpose of their short letter. It was a "brief communication" intended "to report information of technological importance . . . which warrants rapid dissemination, even though not necessarily a completed research."[35] The points presented there are felt to be an important development of anodic oxides on GaAs for device applications such as charge storage devices which in fact can now be produced successfully[36] with the low current growth scheme reported in the communication. Unfortunately, concise experimental parameters had to be omitted due to the limited space available for such a communication. Dr. Pringle has chosen to criticize the positive style which we used in compiling the letter. We admit that we were perhaps overenthusiastic in our presentation. We are, however, convinced that the conclusions we stated are correct and important. Indeed we now have further experimental evidence to support our understanding, namely Auger profile results in collaboration with the United Kingdom Post Office Laboratories. These new results are to be published shortly.[37] In our letter we state (admittedly without clear justification) that the threshold field for the activation of cations is larger than that for anions in an Al:Al_2O_3 system, because we interpreted the experimental results of Dr. Pringle and his co-authors[38] as being caused by the operation near the activation energy of the relevant ions rather than by their field-dependent mobilities. Regarding the first more specific question of Dr. Pringle, we clearly saw no indication of any oxide of GaAs on top of our Al_2O_3 for low current growth conditions, and thus had to conclude that only anions move to the GaAs-Al_2O_3 interface. Regarding his second specific question; we employ one part of aqueous solution of tartaric acid (30g of tartaric acid per liter of water) and two parts of propylene glycol. This is most likely nearer to his aqueous-based electrolyte. The experimental observation by Dr. Pringle and his co-workers of a constant t_m for strongly glycol-based electrolytes is explained by us on the basis of space-charge fields being more strongly responsible for the activation of metal ions than in our case. Finally, the authors feel that neither the referees nor the Editor are to be blamed as Dr. Pringle suggests. Indeed they seem to be more familiar with the recent developments of native oxidation of compound semiconductors such as GaAs than Dr. Pringle is, and thus were able to appreciate the interpretations of the data of the relatively simple chemical tests reported.

Editor's Note: Dr. Pringle's criticism of the Brief Communication itself is a matter into which I will not go. As to the review process, certainly, I do grant that unsubstantiated claims should not be published, whether in a Brief Communication or in other forms of publication in this JOURNAL. The question which has to be answered from the JOURNAL'S point of view is the suitability of the review process to minimize that possibility. The review system requires that we depend on our reviewers, who are certainly not without shortcomings. On the whole though, they do an effective, and indeed admirable, job and we must rely on what they say. It follows that not all papers, let alone Brief Communications, will be as "correct" as we would wish them to be. It does mean, I believe, that our system minimizes the shortcomings. In the long run, it is readers and users who weed out those things which are of little or no value. The job of any journal is to make the latter task as small as possible. Again, this note does not pertain specifically to any item published in this JOURNAL, but to the principle of review by peers.

The Rate Controlling Process in the Oxidation of Hot Pressed Silicon Nitride

D. Cubicciotti,* K. H. Lau, and R. L. Jones

SRI International, Menlo Park, California 94025

The high temperature oxidation of hot pressed silicon nitride has been found to follow a parabolic rate law (1, 2). The rate limiting step in the process has been presumed to be the diffusion of some species through the growing oxide layer as is generally the case in the parabolic oxidation of metals. We report below some critical experiments that show that processes occurring in the oxide scale do not control the rate of oxidation of hot pressed Si_3N_4 and that the diffusion of magnesium in the unoxidized ceramic is probably the rate limiting step.

The oxide scale formed during the high temperature oxidation of hot pressed Si_3N_4 is very porous, the pores presumably containing N_2 formed by the oxidation. In oxidations at temperatures near 1400°C the scale appeared to be fluid and sagged under the action of gravity. Therefore we suspected that the scale was not protective even though the oxidation rate law was parabolic.

To test the protectiveness of the oxide scale, we performed the following experiment. A piece of NC-132 (Norton Co. Si_3N_4 hot pressed with ~ 1% MgO) was cut and surface ground with diamond tools to 40 x 15 x 1.4 mm. The rate of oxidation was measured as a function of time at 1370°C in dry oxygen. The apparatus used was a constant volume system in which the total gas pressure and N_2 content were monitored as a function of time. The system was made of high purity alumina and the sample rested on platinum pads to prevent reaction with the alumina. The oxidation data obtained for the first 18 hours of oxidation are plotted as open points in Figure 1 and the solid curve is the best fit parabola. The parabolic rate constant is 1.4×10^{-9} kg^2/m^4 sec which is in reasonable agreement with literature values (1, 2). Following the initial 18-hour oxidation, the sample was taken from the apparatus, the corrosion scale was removed by diamond surface grinding, and the sample was reoxidized for a further 20 hours. The solid points in Figure 1 show the weight gain data obtained during the reoxidation.

The dotted curve in Figure 1 indicates the reoxidation curve that would be expected if the oxide scale was protective and controlled the rate of oxidation. The dashed curve is an extrapolation of the first oxidation curve. The reoxidation data fall very close to the dashed curve, which indicates that the process controlling the rate of oxidation must have been occurring in the bulk of the sample rather than in the oxide scale.

Concentration profiles for several elements were determined on the cross sections of oxidized samples using electron microprobe analysis. It was found that the concentration of magnesium in the body of oxidized samples decreased from the center to the oxidized surface in a profile typical of a diffusion process. The magnesium concentration in the oxide scale was small except at the outside surface where it was very large. We therefore believe that the diffusion of magnesium through the body of the unoxidized silicon nitride controlled the oxidation rate.

We propose the following mechanism for the oxidation of hot pressed Si_3N_4. The rate controlling step is the diffusion of magnesium through the silicate material in the grain boundaries of the ceramic. (Singhal (2) has already noted that the activation energy for oxidation (~ 100 kcal/mole) is comparable to that for diffusion of cations in silicates).

*Electrochemical Society Active Member.

The oxidation process occurs in the oxide layer. Silicon nitride dissolves in the oxide which is largely a silica-silicate slag. The N^{-3} ions dissolved in the oxide are oxidized to N_2 which generates the bubbles observed in the corrosion layer. At the gas/oxide scale interface, O_2 gas reacts with electrons released from the oxidizing N^{-3} to form O^{-2}. The key to the role of magnesium is that the solubility of Si_3N_4 in the silicate slag is increased by the presence of MgO. (An increase of the solubility of Si_3N_4 in silicate slags due to the addition of alkaline oxides has been observed by Dancy and Janssen (3).) In the oxidation of Si_3N_4, magnesium silicate apparently precipitates at the gas/oxide scale interface and the magnesium concentration in the oxide scale does not build up as oxidation proceeds. The net magnesium concentration at the Si_3N_4 interface, which sets the solubility of the Si_3N_4 in the oxide, is determined by the balance between the rates of arrival and removal of magnesium. The evidence suggests that a sufficient supply of oxygen is available; thus, the oxidation rate is controlled by the rate at which the Si_3N_4 dissolves.

The surface of the silicon nitride beneath the oxide layer becomes pitted during the corrosion process. It is important to understand why pitting occurs because the increasing surface roughness associated with the formation of the pits is probably responsible for the significant degradation of the room temperature bend strength of hot pressed silicon nitride that is observed following high temperature oxidation (4). The formation of pits can be explained by noting that the solubility of Si_3N_4 in the oxide slag is enhanced by Mg and the concentration of Mg in the unoxidized Si_3N_4 increases with depth. A planar interface between the scale and the bulk will not be stable under these circumstances. Local incursions by the scale into the bulk at sites of higher-than-average Mg concentration will encounter an increasing Mg content because of the Mg concentration profile that exists in the bulk Si_3N_4. Thus the ability to dissolve Si_3N_4 will be enhanced at the local incursions, leading to accelerated penetration of the oxide scale into the bulk Si_3N_4 at the same sites and eventually to the formation of pits.

The Precipitation of K $Co[Au(CN)_2]_3$ and Similar Cyanoaurate Complexes

E. T. Eisenmann

Bell Laboratories, Columbus, Ohio 43213

Hard gold baths, which use cyanoaurate (I) in combination with cobalt or nickel ions, operate close to the solubility limits of heretofore unknown coordination compounds. This condition became evident, earlier, when a pink precipitate was formed after cobalt ions were added to a solution of potassium dicyanoaurate (I) (1). From the ratio of Co:Au = 1:3, it was conjectured erroneously, though in agreement with other authors, that the precipitate contained the cyanides of both gold and cobalt (2). A more elaborate analysis showed, however, that the compound contained potassium, yielding approximately the ratio K:Co:Au = 1:1:3. The compound was consequently subjected to an X-ray diffraction analysis and found to exhibit a pattern of lines which is not in agreement with the individual cyanides of cobalt and gold nor with any other catalogued compound. The d-spacings are listed in Table 1.

Table I

Comparison of d-Spacings*

Unknown	AuCN	$Co(CN)_2$
7.55	5.05	5.1
3.85	2.92	3.55

* For most intensive lines, only.

The original precipitate was found to be readily soluble in cyanide or ammonia solutions and to some extent in water at high temperature. With this aqueous solution various reactions can be carried out. Addition of a strong acid leads to the precipitation of AuCN. Addition of S^{2-} precipitates black CoS. Thiocyanate produces a blue and diacetyldioxime a brown coloration. These reactions prove that the cobalt exists in the hydrated state, and not as a cyanocomplex. However, boiling the solution for an extended period results in the precipitation of $Co(CN)_2$ and AuCN. It is concluded, therefore, that the formula $KCo[Au(CN)_2]_3$ descibes properly the original precipitate. In solution, this compound dissociates into its components K^+, Co^{2+} and $Au(CN)_2^-$, yielding a solubility product of 5.10^{-9}. The precipitate $KCo[Au(CN)_2]_3$ forms hexagonal platelets up to 50 µm across and about 1 µm thick. Recrystallization from water, however, results in hexagonal prisms, which show a different X-ray diffraction pattern.

The recrystallized compound was qualitatively analysed by means of the electron microprobe and found to contain no potassium. Additional analyses with spectrophotometric methods yielded an Au:Co ratio of 2, hence the compound seems to have the formula $Co[Au(CN)_2]_2$.

Coordination complexes of cyanoaurate (I) with other transition elements (Mn, Ni, Cu) have been prepared by similar procedures, and Na^+, NH_4^+, Mg^{2+}, and Ba^{2+} have been substituted for potassium.

If $KCo[Au(CN)_2]_3$ is heated to about 120°C for several days, an intense purple discoloration of the material is observed, which is, however, not accompanied by any visible disintegration of the crystallites. The discoloration is similar to that caused by color-centers in alkali and silver halides. Recrystallization yields an admixture of pink crystals and a dark brown powder, presumably gold metal. Complete thermal decomposition of the compound occurs above 400°C.

Storage of the recrystallized, potassium-free material in a desiccator produces a color change from pink to lavender, apparently due to the loss of water. There is, however, no evidence of disintegration of the crystals. Reversal to the pink form can be achieved by contact with water. Heating this material leads to color changes, first to deep blue, then to metallic gold. These color changes are not accompanied by changes of the crystal shapes, unless the temperature exceeds 400°C, or a somewhat lower temperature is maintained for a long time.

The transition from the lavender to the blue modification involves a weight loss of 15%. Heating the lavender compound to 350°C for 2 hours results in a weight loss of 30%. These weight loss measurements, combined with the analysis for cobalt and gold, suggest the following formulas: $Co[Au(CN)_2]_2 \cdot 10\ H_2O$ for the lavender compound, $Co[Au(CN)_2]_2 \cdot 4\ H_2O$ for the blue compound, and $Co(CN)_2 + Au$ for the material with the appearance of gold.

It is noted that certain characteristics of electroplated cobalt-hardened gold are most favorably developed under conditions which are prerequisites for the precipitation of $KCo[Au(CN)_2]_3$. For example, high pH precludes the precipitation of $KCo[Au(CN)_2]_3$, and also leads to dull, relatively soft gold deposits. Similarly, dull deposits may result from high temperature, corresponding to an increase in the solubility of $KCo[Au(CN)_2]_3$. This temperature effect can be compensated by increasing the concentrations of the reactants, as practiced in the high-speed gold baths (such as Sel-Rex 55 GV). Cyanocobaltate is known to accumulate in extensively used hard gold baths; yet this compound has no effect on the brightness and hardness of the gold deposits. The brightening effect of cobalt can be obtained only with aquo or other weak cobalt complexes, which do not preclude the precipitation of $KCo[Au(CN)_2]_3$.

Analyses of gold deposits plated from a Technic Orosene 999 bath yielded amounts of the elements K, Co, C, and N in a ratio which is consistent with 2% by weight of $KCo[Au(CN)_2]_3$ in gold.

All hard gold deposits from acid electrolytes have a tendency to blister at temperatures above 400°C. This effect corresponds to the decomposition of $KCo[Au(CN)_2]_3$ and $Co[Au(CN)_2]_2$ at the same temperature.

These correlations suggest that coordination compounds of the hardening metal with dicyanoaurate are responsible for the special properties of hard gold deposits. Work is in progress to further investigate the involvement of $KCo[Au(CN)_2]_3$ in the deposition process of cobalt-hardened golds.

ACKNOWLEDGMENT

Thanks are due to N. H. Winquist for carrying out the electron probe analyses, and to N. R. Stalica for his assistance in their interpretation.

REVIEWS AND NEWS

DECEMBER 1977

Developments in Electrolytic Capacitors

Walter J. Bernard*

Sprague Electric Company, North Adams, Massachusetts 01247

In 1952 the total production of all types of electrolytic capacitors in the United States amounted to less than 60 million pieces; by 1976 the number of capacitors produced exceeded 700 million. The distribution by capacitor type at the beginning and end of this twenty-five year period is shown in Table I.[1] This enormous increase is not only a measure of the voracious appetite of the electronics industry during this period, but also reflects the technological advances within the electrolytic capacitor segment of the industry, advances made in all aspects of research and development, engineering, design, and manufacturing skills. At the beginning of this period the aluminum electrolytic capacitor was already a well-established and important electronic component, and two forms of tantalum capacitors—the foil counterpart of the aluminum electrolytic and the liquid electrolyte sintered pellet type—were showing a significant impact. Of these three types, the aluminum foil continued its dominance in both total number and rate of growth, but the most important major development in the industry was that of the solid electrolyte tantalum capacitor which appeared in the mid 1950's and has grown to a point where, in numbers at least, it has surpassed the position of the aluminum foil capacitor.

Aluminum Foil Capacitors

This construction represents the original electrolytic capacitor, which by 1952 had achieved an important position in circuit applications through its unsurpassed volumetric efficiency of capacitance and low cost per unit of capacitance. Advances of great significance have since been made in this device through research and development on its two principal components—the foil electrodes and the operating electrolyte. This progress has been demonstrated by a marked reduction in size, extension of the operating temperature range, improved electrical characteristics, increased reliability, and longer life, both on storage and in operation.

Electrodes

Etching.—The large capacitance of electrolytic capacitors is achieved by the presence of an extremely thin dielectric oxide film on the anode, and it is further enhanced by the creation of a high surface area of the anode foil through chemical or electrochemical etching. Furthermore, if the capacitance of the device is to be utilized with high efficiency, it is necessary that the cathode foil be etched also since it acts as a capacitance in series with the anode. This requirement is especially critical at low operating voltages, but it can also have a significant effect in the higher voltage ranges as well. Consequently, much effort has been expended in developing processes to maximize the active surface areas of both electrodes, consistent with other requirements of the device.

Electrochemical etching lends itself to easier control, but chemical procedures have also been used; in one instance the use of hydrochloric acid was reported to give a surface enhancement of a factor of ten (1). In electrochemical processes a chloride solution (2) is the most common electrolyte, and numerous compositional modifications have been reported, the most important of which is the addition of sodium sulfate (3,4).

The high surface area increase of aluminum through electrochemical etching is the consequence of the remarkable etch structures that may be developed with this metal. It has been demonstrated through electron microscopy that under certain conditions (5) the morphology of the etch consists of cylindrical channels, or tunnels, of exceptionally uniform diameter growing in the three mutually perpendicular (100) planes. The capacitance of foil etched in this fashion, based on a 25V oxide film measurement, can be as much as 65 times greater than the unetched metal.

The mechanical condition of the foil has a pronounced effect on the etching behavior and on the resulting surface increase. Procedures for etching hard cold-worked foil, as opposed to annealed aluminum, have been developed to give a significant improvement in the surface area; as measured by capacitance increase, the cold-worked foil has been shown to give an advantage of as much as 75% (6). The effect has been attributed to the presence of a high density of dislocations on the unannealed foil surface (7), presenting a large number of active sites for electrochemical attack and facilitating the development of an extremely fine etch structure. In general, therefore, the use of hard foil is most advantageous when the foil is to be anodized to relatively low voltages, say 100V, for as the oxide thickness increases, the consumption of metal tends to have a smoothing effect on the etch structure. Nevertheless, it has been reported that by the proper selection of etch conditions, particularly current density and electrolyte composition, the advantage of hard foil can be extended to 250V (8).

Generally, the purer the aluminum the more difficult it becomes to etch. The more common impurities, Si, Fe, and Cu, tend to facilitate electrochemical attack, but their continued presence is undesirable in the oxide film if capacitors of low leakage current and long life are to be constructed (9). When the impurity concentrations are maintained within the solid solubility limits the harmful effect on the oxide is largely eliminated, but even in that range slight variations in con-

Table I

	Capacitors manufactured (millions) 1952	1976
Aluminum foil	57.4	195.0
Tantalum foil	0.5	1.2
Tantalum-wet pellet	0.5	13.2
Tantalum-solid electrolyte	0	511.2
Total	58.4	720.6

centration can have a marked effect on the etching behavior of different foils (10).

The oxide film.—A dielectric or "barrier" aluminum oxide film may be electrochemically formed on the surface of aluminum in a variety of electrolytic solutions, as has been shown by much experimental work, but the necessities of large-scale manufacturing processes limit the choice to aqueous solutions of relatively simple composition. The most common are solutions of inorganic phosphates and borates, the former finding application principally at the lower end of the anodizing voltage range. The film thickness is controlled by several parameters, the most important being the temperature of the electrolyte, the applied voltage, and the current. The thickness is usually in the range of 12-14 Å/V of applied anodic potential, and corresponds to fields of nearly 10^7 V/cm (11). It is this factor of extremely thin films of controllable thickness and the capability of sustaining such high fields that give the electrolytic capacitor its unique characteristics.

Although most of the limitations of the capacitor are determined by the operating electrolyte, *i.e.*, temperature range of operation, temperature coefficient of capacitance, and frequency behavior, the oxide film quality will determine the leakage current and contribute significantly to the dissipation factor. Furthermore, the oxide may well be the limiting factor in regard to the ability of the capacitor to withstand an extended storage period without unacceptable deterioration of its fundamental electrical properties. Thus, much of the gain made in capacitor quality during the past twenty-five years stems from improvement in oxide quality.

The electrochemical sensitivity of aluminum to chlorides and sulfates (at concentrations as low as 1 ppm) (12) has made it necessary to introduce more rigorous manufacturing procedures both in the anodizing step and in the assembly of the component parts, thus leading to improved capacitor reliability and longer operating life. The use of higher purity aluminum, in which potentially harmful impurities are kept in solid solution, has probably made the greatest contribution to the reduction of the oxide leakage current (13, 14).

The most significant development in the formation of films on aluminum has been the discovery of the advantages to be gained by forming a layer of porous and nondielectric hydrated oxide on the surface prior to the formation of the barrier oxide film (15-19). The hydrous layer is itself partially converted to barrier oxide during the electrochemical step and creates a film of higher dielectric strength and thus of higher capacitance (20, 21). The structure of the resulting film has been shown to consist of a barrier layer at the metal-oxide interface, with the residual hydrous layer remaining at the oxide-electrolyte interface (22, 23).

Operating electrolytes.—In the early 1950's virtually all foil capacitors utilized as the operating electrolyte some variation on the conducting system composed of the reaction product of ammonium borate and ethylene glycol, and with excess glycol as the solvent. This electrolyte, developed twenty years earlier, had supplanted the wholly aqueous solutions then in use, and made it possible for the electrolytic capacitor to attain its widespread use and great commercial importance. Because of the elimination of water as the solvent these capacitors were termed "dry electrolytics," but the electrolytes are distinctly not anhydrous; they contain a significant amount of water which arises from the esterification reaction between its two principal components. In any event, the use of this electrolyte allowed the construction of capacitors that were capable of being operated over a wider temperature range than those with aqueous electrolytes and were, in general, superior in all other respects.

However, the increased demands of electronic equipment manufacturers for more rigorous service conditions revealed that the glycol-borate electrolyte systems also had serious limitations. These demands led both to important modifications of the glycol-borate solutions and to the development of entirely new electrolyte systems. The most important in the latter category are electrolytes using dimethyl formamide (DMF) as the solvent (24, 25). This substance, which has served as the basis of scores of patented formulations, has a liquid range from −61° to 153°C, and a dielectric constant of 36.7, making it an excellent solvent for a large number of compounds that give highly conducting solutions suitable for capacitor application. The important advantage this property has over the conventional glycol-borate electrolytes is illustrated by the comparison of temperature-specific resistivity values at low temperatures. It has been shown (26) that at −55°C a DMF-based electrolyte will increase its room temperature resistivity by a factor of only ten or twenty, while a typical glycol-borate solution will have a value that is several hundred times greater. It is clear that this characteristic permits the application of the new electrolytes to regions inaccessible to glycol borates. Further, as was pointed out above, the presence of water in glycol borates restricts its operation to about 100°C, whereas DMF electrolytes can be used in properly designed capacitors at 125°C.

Proper capacitor design, in this case, involves not only a seal capable of withstanding the vapor pressure of the liquid electrolyte components, but one that is chemically resistant to DMF. The powerful solvent action of DMF which enables it to be such an effective component in aluminum capacitors, is at the same time the cause of its principal limitation. Many of the conventional organic materials used in the construction of electrolytic capacitors are incompatible with DMF, and special seals and closures have been developed to exploit the useful properties of this substance. One example that has been successfully developed uses a polytetrafluoroethylene (PTFE) seal with a butyl rubber gasket (26).

In addition to DMF, a number of other solvents have found application. Among the most important are methyl cellosolve (27), dimethyl acetamide (28), and butyrolactone (29), but there are numerous others that have been reported and which may yet prove to be useful. These compounds share with DMF a wider liquid range than water and can be used as either the sole solvent or as one component in a mixture of solvents. In many instances ethylene glycol is the preferred cosolvent.

Concurrent with the introduction of new solvents, the development of an extensive number of solutes has occurred. The search for specific materials has centered on those compounds that will dissolve to form conducting solutions with the solvents of preference and will, at the same time, exhibit the requisite electrochemical characteristics, *i.e.*, have at least a limited ability to form barrier oxide films when dielectric repair is needed, and to withstand the high fields that are imposed upon the electrolyte. A great many substances have been found to meet these requirements, and the patent literature teems with illustrations. Among this large number, mention should be made of the salts of adipic acid (30, 31) trifluoracetic acid (32), maleic acid (33), salicylic acid (34), citric and tartaric acids (35), and formic acid (36). Boric acid also continues to play a role in this new generation of electrolytes in the form of organoboron complex ions (37, 38). In a separate category is the highly conducting azeotropic mixture of acetic acid and triethyl amine (39) which in itself is a liquid over a wide temperature range, and requires no solvent. Organic compounds dominate this field, but at least one class of inorganic compounds, soluble in DMF, has found application. These are the ammonium salts of heteropoly acids, specifically ammonium phosphotungstate (40).

The particular choice of electrolyte among this bewildering array of possibilities is determined by many factors, not the least of which are the economic consideration of materials of construction and manufac-

turing constraints. The emergence of many alternative systems has, however, permitted capacitors to be more closely tailored to specific applications as diverse as those relatively costly components designed to operate at 125° to exacting military specifications, and low cost miniature devices for use in inexpensive consumer products.

Tantalum Foil Capacitors

Capacitors constructed from tantalum foil have from the start occupied a special position. The high cost of tantalum foil precludes its use except in those instances where its distinctive properties as a capacitor anode material overshadow the obvious economies which are realized with aluminum. Tantalum electrolytics, like those of aluminum, offer high capacitance in a small space because of the properties of its dielectric film, and to an even greater extent. The dielectric constant of tantalum oxide is about 27, while that of anodic aluminum oxide is only 8.5. Tantalum oxide has, however, a somewhat greater oxide thickness than aluminum oxide at the same applied potential and, consequently, its capacitance advantage is not a factor of three but about two. In addition, however, the considerably greater mechanical strength of tantalum permits the use of thinner foils for both anode and cathode, further enhancing its volumetric capacitance efficiency. Although these factors introduce a substantial advantage, they only partially compensate for the enormous difference in foil costs. Justification for the use of tantalum lies therefore in a combination of properties of which high capacitance per unit volume is only one.

From the early days of its introduction to the capacitor market, the tantalum foil device was noted for its high reliability, a property that made it attractive for military applications and in the avionics industry, where the concept of reliability has a compelling value. This reliability is directly related to the inherent chemical stability of both the metal and its oxide. Unlike aluminum, which is readily attacked by many common ionic substances, tantalum is inert to nearly the whole spectrum of chemicals; and whereas aluminum oxide is susceptible to dielectric damage by a wide variety of materials, tantalum oxide is stable in all acid media with the exception of fluoride solutions. This extraordinary chemical stability therefore confers a pronounced advantage upon tantalum foil capacitors, permitting the employment of a wide choice of operating electrolytes of desirable properties, electrolytes which are wholly incompatible with aluminum capacitors. These electrolytes allow a wider temperature range of operation, and impart low dissipation factors to the capacitors in which they are used. Some of these electrolytes are discussed below.

Still another important characteristic of the tantalum foil device is its inherently low leakage current. This is also related to its electrochemical and chemical stability, conditions which, unlike the situation with aluminum, tend to make the leakage current a function only of the electronic conductivity of the oxide. Since the capacitor is designed to operate at a voltage somewhat less than that at which the oxide was formed, typically 75% of the formation voltage, the ionic current is virtually zero and the only significant contribution to leakage current is the low electronic component.

Nevertheless, because of material costs, these advantages extend to tantalum foil only the opportunity to be used as a specialty premium device, and the number of capacitors constructed of this metal is small in comparison to those manufactured with aluminum. The growth in usage during the past twenty-five years might yet have been significant in its own special area had it not been for the advances made in aluminum foil technology, for a great deal of important research has been carried on with tantalum during this period and impressive progress has been made.

Foil Developments

Etching.—The resistance of tantalum to chemical attack makes it a difficult metal to etch for capacitor use. It is particularly difficult to accomplish electrochemically because of the ease with which it becomes anodically oxidized in aqueous solution. The most successful etching media are consequently those in which a nonaqueous solvent is used and in which the concentration of water is restricted to an empirically determined low level. For example, NH_4HF_2 dissolved in formamide with the water content maintained at about 1% (41), and solutions of sodium salts of fluorinated aliphatic acids in DMF containing no more than 4% water (42) have been successfully used for this purpose. Apparently the only way aqueous solutions can be used is when a very high concentration of HF is the principal active component (43).

Oxide film formation.—A high quality oxide film is dependent on the purity of the anode foil, and in particular on the purity of the surface. This is especially significant in the case of tantalum, for if the full potential of its oxide is to be realized the phenomenon referred to as "recrystallization" must be avoided. This unusual effect involves the secondary growth of a crystalline oxide of poor dielectric properties in the place of the amorphous anodic oxide (44) and occurs only upon the application of voltage, either during the original anodization step or upon polarization of the completed capacitor. Once initiated, the growth of crystalline oxide may continue unchecked. When it is extensive in growth, the new oxide appears as dull gray patches on the foil surface, in marked contrast to the bright interference colors characteristic of the amorphous oxide. The amorphous oxide, when ruptured by the thicker crystalline film, ceases to serve as the dielectric and the leakage current of the capacitor rises to unacceptable levels.

In recent years this has ceased to be a serious failure mode. Avoidance of this problem is achieved by the use of very high purity tantalum and the employment of rigorous foil surface cleaning procedures. The etching of anode foil can serve as an effective cleaning step when proper precautions are taken to remove etch solution residues. Unetched foil may be chemically treated in various acid solutions containing HF (45, 46) to insure a clean surface for anodization.

The electrolytes used to form the oxide film usually contain phosphoric acid as one of the constituents; this is because the film composition becomes altered through the inclusion of phosphorus (47) which imparts increased stability to the oxide. Modification of the usual aqueous electrolyte to those containing ethylene glycol has been found to give electrolytes that anodize tantalum to substantially higher voltages (48).

Operating electrolytes.—The emergence of DMF as a solvent that extended the operating range of aluminum electrolytes was paralleled by its use in foil tantalums. Once again, however, the relative chemical inertness of the tantalum-tantalum oxide system permits the use of highly conducting electrolytes that are incompatible with aluminum foil capacitors. In the very low voltage range, for example, NH_4NO_3 in DMF imparts low temperature properties as yet unchallenged by aluminum capacitors (25). Some high voltage electrolytes are also based on DMF, including solutions of polyphosphates (49) and ammonium pentaborate (50).

Cathodes.—Efforts have been made to extend the commercial usefulness of tantalum foil capacitors by replacement of the cathode with a less costly material. The coincidence of DMF-based electrolytes in both tantalum and aluminum electrolytics makes it feasible to use aluminum cathodes at least for some applications (51).

Tantalum-Sintered Pellet-Type Liquid Electrolyte

Although the tantalum foil capacitor is limited in application because of its cost, the metal can be more

economically competitive with aluminum when anodes are constructed from sintered powder. In this form the surface area per unit weight is far greater than with etched foil. This more efficient use of metal is reflected in the continued growth of the "wet pellet" type, but its effect is far more dramatic in the case of the solid electrolyte capacitor, discussed below. For both types of capacitors the anode fabrication principles are identical, and the progress made in tantalum powder technology applies to both.

The liquid electrolyte pellet structure develops the highest volumetric efficiency of capacitance of all types of capacitors through its use of tantalum powder. Even though the solid electrolyte capacitor uses the same powder it is inferior in this regard because its dielectric cannot be safely subjected to the high fields that are applied to an anode using a liquid electrolyte.

Sintered anodes.—The pellet anode is prepared by compacting high purity tantalum powder mixed with an appropriate binder. The binder is later removed by decomposition and evaporation during vacuum heat-treatment, and a further heating step is used to sinter the powder particles into a compact, porous mass. The porosity of the finished pellet may be varied widely by controlling the process conditions, and it can exceed 60%. Since the final sintering temperature may be as high as 2000°C, carbon residues from the binder, as well as other impurities, are lost during this treatment and the anode metal undergoes significant purification. Much effort has gone into the design of the special furnaces needed for this process (52).

It has been shown (53) that a carbon content greater than 20 ppm can seriously affect capacitor life, and that the total of other metallic impurities should not exceed 50 ppm. Thus the sintering process is essential since it accomplishes the removal of the carbon that remains in high concentrations from decomposed organic binders. The mechanism by which this occurs is through the reaction with dissolved oxygen to form carbon monoxide (54).

The quality of tantalum powder has been further improved by the introduction of an electron-beam melting process (55). When the original powder is so melted (at temperatures well above 3000°C) most of its impurities are lost through evaporation, and the low concentrations of the remaining elements are rendered virtually innocuous by entering into permanent solid solution. The metal is subsequently reconverted to powder and is superior to conventional material for capacitor anodes. Its use enables oxides of higher dielectric strength to be formed, giving lower leakage currents and better high voltage properties.

In addition to purity, the powder particle morphology plays a significant role in capacitor characteristics. Particle size and shape determine the surface area, and hence the capacitance to be achieved, of the tantalum anode. A great deal of technology has been developed, therefore, in efforts to exploit these characteristics, and since 1960 there has been about a five-fold improvement in the surface area of powder (56) as measured by specific capacitance per gram, a convenient quantity that is directly related to the surface area. The maximum value of specific capacitance is now about 10,000, and is expected to increase even further as greater control over the roughness and particle size distribution of fine powders also increases.

Powders of high specific capacitance are clearly economically desirable, but their use is not universal in capacitor designs. Other factors frequently impose demands that cannot be met by such powders and as a result a large number of powders with a wide range of characteristics are used in the industry. One class that is finding important application is that consisting of agglomerated powders with superior flow characteristics (57).

Electrolytes.—The structure of a capacitor using a porous pellet as the anode requires an electrolyte that is radically different from those used in foil capacitors. In all electrolytic capacitors the electrolyte resistance is a significant, and often the chief, contributor to the dissipation factor; in foil types this resistance is minimized by maintaining the smallest spacing feasible (0.001-0.003 in.) between the electrodes and by the use of low resistivity electrolytes. However the anode-cathode spacing in a pellet type is inherently greater, and electrolytes with a specific resistivity at ordinary temperatures of a few hundred ohms/cm, typical of foil capacitors, cannot be used. The only electrolytes which are feasible are those with a specific resistivity of a few ohms/cm or less. Only a few such electrolytes, including aqueous sulfuric acid and concentrated solutions of lithium chloride and potassium formate, have found general application from the early days of this device, but improvements and modifications have been made over the years.

The addition of silica to sulfuric acid (58) reduces the danger of electrolyte leakage, as does the gelling of lithium chloride (59). Potassium formate, by virtue of its alkaline nature, can degrade the oxide film at high temperature and this can be prevented by the addition of silica or a silicate (60). Among other electrolytes that have been proposed and which may be useful are concentrated phosphoric acid and saturated potassium iodide (61).

Cathode.—The interior of the metal can used as a container for the anode and the electrolyte acts as the cathode for the capacitor. Silver has long been the metal used for this purpose because of its chemical compatibility with the electrolyte and its excellent mechanical properties in producing a well-sealed capacitor. The interior silver surface is chemically roughened and coated with finely divided platinum to provide a high cathode capacitance, permitting the full capacitance of the anode to be realized.

In combination with specially constructed outer enclosures, these capacitors can be designed to operate at temperatures up to 200°C. It is desirable under such conditions to minimize the cathodic evolution of hydrogen generated as a consequence of the leakage current. This may be accomplished by the addition of a substance that undergoes cathodic reduction more easily than hydrogen ion. Silver sulfate and copper sulfate are examples of solid compounds that may accomplish this (62), and ferric halides at least partially in solution will also function in this manner (63, 64). Cupric chloride has been recommended for use in chloride electrolytes (65).

Silver cathodes, however, suffer from three disadvantages: the costly construction severely limits its use; in some circuit applications silver may be deposited on the anode surface and lead to failure (66); and true hermetically sealed devices cannot be designed with silver cans. One approach that eliminates these disadvantages is the use of a tantalum can (67). The interior can surface must be given a very fine electrochemical etch in order to provide a cathode capacitance approaching that of platinized silver. A stainless steel can, if it were resistant to sulfuric acid at high temperatures, could also supplant silver. It has been claimed that this may be achieved by the addition of titanyl sulfate to the electrolyte (68).

Tantalum Pellet Capacitor—Solid Electrolyte

The first publications describing this device appeared in 1956 (69-71) and the dominant patents were issued in the early 1960's (72, 73). In a period of only two decades the annual production of this capacitor has grown to greater than a half-billion units in the United States alone, accounting for over two-thirds of all electrolytic capacitors.

The feature that distinguishes the solid electrolyte tantalum capacitor from other electrolytic capacitors, and which provides its special character, is the solid manganese dioxide conductor in contact with the anodic oxide. MnO_2, an electronic conductor, is referred to as a solid electrolyte, even though it does not

function in precisely the same way as operating electrolytes in other electrolytic capacitors. An anode of sintered powder is used in this capacitor, just as in the wet-pellet type, but the presence of a solid conductor rather than a liquid leads to a quite different capacitor structure with electrical characteristics that were previously unattainable. It is, for example, possible to operate the capacitor at −55°C with only a 2-3% loss in capacitance from the 25°C value. In addition, because of the high conductivity of MnO_2 throughout this temperature range, the dissipation factor at the low temperature extreme is much lower than any liquid electrolyte capacitor.

Sealing problems are much reduced and allow the use of simpler enclosures of more economical design, especially in comparison with the wet-pellet capacitor. Contact to the cathode lead from the MnO_2 layer is accomplished by coating the MnO_2 with graphite ("Aquadag"), followed by a metal layer to which a tinned lead may be soldered (72). This structure readily lends itself to a hermetically sealed container since nonanodizable metal lead wires may be tolerated within the enclosure and thereby simplify the requirements of a glass-to-metal seal.

Anode preparation.—The first steps in manufacturing the solid electrolyte capacitor are the same as those used in the wet-pellet type: a pressed pellet is sintered and then anodized to the desired formation voltage. The tantalum lead wire may be imbedded in the powder compact before sintering, or welded in place on the sintered anode, in which case an additional high temperature sintering period is needed in order to repurify the welded region. The significant developments in powder technology affecting the capacitor have been dealt with in the previous section on liquid electrolyte capacitors.

Deposition of manganese dioxide.—After anodization the pellet is impregnated with an aqueous solution of manganous nitrate, and then is heated to temperatures in excess of 300°C to convert the nitrate to manganese dioxide (72). The steps of impregnation and thermal decomposition may be repeated several times to fill completely the pores of the pellet with the conducting oxide and give a good external coating as well. Manganous nitrate has proved to be nearly unique in its suitability as an intermediate in this process. It has an unusually high solubility in water (>70 weight percent at 0°C), and therefore minimizes the number of deposition steps required to fill the pellet pores, and it decomposes at temperatures low enough to form highly conducting MnO_2. Its principal disadvantage lies in the need to subject the tantalum oxide/tantalum system to temperatures high enough to cause dielectric damage, and a solid-conducting system that could be deposited at lower temperatures would be a desirable development. Many alternatives have been proposed to replace manganous nitrate, but its use remains as yet unchallenged.

The numerous deposition steps required to give complete filling of the pellet pores can at the same time cause an undesirably heavy and nonuniform coating to build up on the pellet exterior. A mechanical method of shaping such pellets without damage to the dielectric has been described (74). Surface roughness of the final coating can also be controlled by the addition of a small amount of silica to the impregnating solution (75). In some instances the number of deposition steps can be reduced by incorporating a paste or slurry of MnO_2 in the manganous nitrate solution (76).

Under ordinary conditions the decomposition temperature may be in the range of 300°-450°C. The higher temperature has the advantage of reducing the reaction time but has the undesirable effect of causing thermal damage to the film, as discussed further below. Temperatures lower than 300° may be employed, however, when pyrolysis is carried out in an atmosphere of high relative humidity (77, 78). This is accomplished by the introduction of steam to the pyrolysis furnace, and results in MnO_2 coatings of excellent physical and electrical characteristics.

Reanodization.—The dielectric film in contact with tantalum undergoes a form of degradation when subjected to temperatures in excess of 250°C, the degree of damage being a function of the time of exposure at a given temperature. During the deposition of MnO_2 the extent to which the oxide is degraded can be significant, and it is therefore necessary to return the coated pellets to an anodizing bath to repair the dielectric.

The mechanism by which the oxide becomes damaged is through the diffusion of oxygen into the tantalum substrate, resulting in the formation of an oxygen-deficient region at the metal-oxide interface (79, 80). When this process occurs, the capacitance, leakage current, and dissipation factor are increased, and perturbations occur in the dependence of electrical properties on temperature, frequency, and applied d-c bias. When the anode is reanodized to the initial formation voltage the film is restored to its original condition. These solid-state reactions between tantalum and its oxide are complex and have been the object of an extensive and detailed study (81).

However, the presence of MnO_2 on the oxide surface prevents the application of the full anodizing voltage, and consequently the dielectric properties of the capacitor may be only partially corrected by a conventional reformation step. A procedure has been disclosed (82) that utilizes a high temperature polarization treatment to correct the damage done during heat-treatment. Another approach to the problem is through the formation of a modified tantalum oxide dielectric that is stable during the MnO_2 deposition process. This has been reported (83) to be achieved by the doping of tantalum powder with as much as 2% of molybdenum, resulting in an anodic film of high thermal stability. Other important properties have been attributed to this material when used for solid electrolyte capacitors, including the ability to withstand substantial cathodic bias without significant current flow (84).

Unlike liquid electrolytes, MnO_2 does not have the ability to repair or heal the oxide film except in a very limited sense. The phenomenon of "current flickering" in which a momentary high current occurs has been attributed to the healing of a small defect by the thermal contribution of oxygen from MnO_2 (85). It has been proposed that the current flow is further impeded by virtue of a vastly increased resistance of the manganese dioxide at that point (86, 87). It is this limitation in healing dielectric defects that reduces the volumetric efficiency of capacitance of the solid electrolyte capacitor. The need for a considerable margin of safety in dielectric stress requires that the operating voltage be as little as 25% of the formation voltage, compared to 75% in a liquid electrolyte type. The maximum operating voltage is therefore also more severely limited by the MnO_2. Since the practical limit of porous pellet anodization is about 400V, the present working voltage limitation is 125V. This present upper limit, however, represents a very impressive advance over the early years of this device when the maximum working voltage was 35V.

Other Developments

Solid Electrolyte Aluminum Capacitor

The development of the solid electrolyte tantalum capacitor has inevitably encouraged efforts to duplicate its success with aluminum as the anode material. Some progress has been made in this direction, but the solid electrolyte aluminum capacitor has not yet been shown to be a serious competitor to tantalum despite its inherently lower anode cost. The reasons are complex, but the most significant involve the marked differences in the chemical and physical properties of the metals. The low melting point of aluminum (659°C) restricts powder sintering temperatures to levels that preclude that process from acting as a surface purification step; the susceptibility of aluminum to chemical attack by

nitrates introduces obvious hazards in the MnO_2 deposition process, and the limitations in the choice of anodizing electrolytes impose difficulties in forming uniform oxide films within porous structures (88). As a consequence the electrical properties of aluminum pellet devices compare unfavorably to those of tantalum capacitors (89), and the commercial impact of those capacitors in the United States has so far been slight.

Capacitors using the MnO_2 electrolyte have also been constructed of etched foil (90) rather than pellets, obviating the difficulties of sintering and anodizing, but resulting in low capacitance values. The size disadvantage, compared to tantalum, has been reported to be a factor of five (91); this was in the case of an etched aluminum plate, folded in a corrugated pattern to increase its volume efficiency, and sprayed with zinc as a cathode contact. Another interesting structural modification uses a wound foil design with a glass-cloth separator, coated with MnO_2, between the anode windings (92). It is claimed that this construction has many electrical characteristics which are superior to solid electrolyte tantalum capacitors (93).

Tantalum Thin Film Capacitors

Tantalum electrolytic capacitor technology has been extended to applications in hybrid microcircuitry through the use of thin films of the metal (94). Tantalum may be prepared in thin form by chemical deposition or by electron beam evaporation, but the most satisfactory procedure for obtaining high quality films of controlled thicknesses is by d-c sputtering. Combined with an electrolytic anodizing procedure, the technologies of photolithography and vacuum deposition can produce discrete, solid-state, high capacitance devices. Capacitors with gold beam-leads are manufactured in this way for use primarily for the telecommunications industry (95).

Films of tantalum only a few thousand angstroms thick are usually deposited in the form of β-Ta, an allotropic form of the metal first reported in 1965 (96) and later described as a superior thin film capacitor material (97). This form of tantalum differs from the normal body-centered cubic form principally in its specific resistivity and temperature coefficient of resistivity. It transforms irreversibly to bcc tantalum when heated in vacuum to beyond 755°C (96).

Thin film capacitors incorporating MnO_2 as the cathode contact have also been developed (98). These capacitors suffer from the disadvantage of higher dissipation factor than those using only a deposited metal cathode, but the valuable property of "self-healing" permits larger capacitors of higher voltage to be produced.

Niobium Electrolytic Capacitors

The use of this metal as an anode material has long been an attractive possibility because of the high dielectric constant of its oxide and, through its great natural abundance, of a probable lower cost. The advantage over tantalum oxide of a dielectric constant of about 41 is not as large as it might seem because of a correspondingly greater film thickness (99), but it is still sufficient to give about a 15-20% greater capacitance. Chemically, the metal and its compounds are nearly identical to tantalum, and it would be expected that as a capacitor material niobium would behave much as tantalum does. In fact the anodic properties are similar but the quality of the oxide film is substantially poorer than Ta_2O_5. It shares with Ta_2O_5—but to a more serious extent—the tendency to undergo field recrystallization (100) and to react with its substrate (101).

These properties have been used to explain its limitations in capacitors, although it has been reported (102) that higher purity material permits 35V rated devices to operate at 85°C for long periods. In any event, there appears to be some fundamentally serious deficiencies with niobium that have not yet been resolved in a manner that encourages its commercial acceptance.

Other Metals and Alloys

Several pure metals and a large number of alloys can be anodized to produce oxide films. Many of the studies of these materials have been of a theoretical nature and have made important contributions to the understanding of oxide films, but there has also been a continuing interest in exploiting other anode materials either because of the higher dielectric constants of their oxides or as a less costly substitute for tantalum.

Among the several possibilities titanium has received the greatest attention. It is a low density (4.5) metal, relatively inexpensive and, since one of its allotropic oxides, rutile, has a dielectric constant greater than 100, its application as a capacitor oxide would represent an important advance. In spite of some promising reports (103, 104) no commercial device has yet been successfully produced. Anodic oxide films can be generated on the surface of titanium and—in the forming electrolyte at least—high voltages may be sustained under certain conditions (103). However, the films do not have good properties: electronic and ionic conductivities are high, giving rise to oxygen evolution at relatively low voltages and to low capacitance because of the resulting greater film thickness (99). The usual form of oxide obtained is probably anatase, and has a dielectric constant of about 40 (104). Rutile has been reported to form when the metal is oxidized using AC in barium hydroxide solution (105).

Both zirconium and hafnium have been studied, and of the two only hafnium in the thin film form seems to produce anodic oxides with good dielectric properties (106, 107). It is not clear, however, what commercial impact can be expected from this metal since it appears to have neither a technical nor economic advantage over tantalum.

The search for alloys of better film-forming properties has covered a very wide range of metals and compositions. A great deal of work has centered on additions to titanium with the hope of improving its dielectric properties; these additions include boron and tin (108), chromium and vanadium (109), palladium (110), and antimony (111). Various combinations of film-forming metals, including ternary alloys (112) have also been investigated. Although a large patent literature has emerged from this body of work, commercial applications have yet to appear.

Acknowledgments

The author wishes to express his thanks for helpful criticism and suggestions to Mr. E. J. Fresia, Mr. K. Meyer, Mr. R. J. Millard, Dr. J. J. Randall, and Mr. D. G. Rogers.

A Profile of Electrode Kinetics over the Past Twenty-Five Years

B. E. Conway

Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada

Significance of Electrode Kinetics

Many electrode processes of practical significance, *e.g.*, H_2 and Cl_2 evolution, metal plating, metal winning, and some organic electrode reactions, must be made to occur at reasonable rates if they are to be of preparative value, especially for large-scale operations. Normally, this involves substantial departures from electrochemical equilibrium conditions which apply only at the thermodynamic reversible potential for the process, so that appreciable current densities (i) can normally be achieved only by operating at considerable overpotentials (η). The relation between overpotentials η and associated current densities i is one of the main aspects of the kinetics of electrode processes. Practical electrochemical processes must be conducted with minimum overpotential. Other aspects of electrode processes enter into the performance of an electrochemical system, especially mass-transport limitations, ohmic resistance of solutions and cells, and reaction mechanisms.

The relations between η and i, or more usually $\log i$, are of rather special and fundamental interest in kinetics because electrode reactions are a class of processes where the free energy of activation is directly controllable in an experimentally easy way by adjusting the potential of a working electrode relative to that of some other reference. Mechanisms of reactions may also be potential dependent and in certain cases, relative yields of products, *e.g.*, Cl_2 and O_2 in anodic Cl_2 evolution, phenyl-hydroxylamine and aniline in reduction of nitrobenzene, hydrocarbon evolution in the Kolbe reaction, are dependent on potential, a useful feature of electrochemical preparative techniques. The potential dependence of electrode reaction rates is also of basic importance in interpretation of corrosion processes and in controlling morphology of electrodeposits of metals.

Electrode reaction kinetics depend also in important ways on (*i*) the solvent and (*ii*) the ions of the electrolyte or supporting electrolyte. In the first case, solvation effects are of prime importance as these determine the facility with which ions in solution are electrochemically discharged and the extent to which they are adsorbed at electrode interfaces. In the second case, (*ii*), the nature of ions in solution and the structure of the solvent determine the properties of the double layer at the electrode interface in important ways, and thence, the kinetics of electrode reactions which occur within or across this double layer. Both these effects have important connections with the properties and structure of electrolyte solutions, especially in aqueous media, *e.g.*, through hydration energies of ions and ion-pairing phenomena. Developments in theories and models of electrolyte solutions have had important influences on advances in electrode kinetics, especially with regard to theoretical aspects of this field concerned with the mechanism of activation and solvation-shell reorganization in electron-transfer processes involving ions in solution.

In the material which follows, the author gives a brief historical introduction and then an account of developments in selected topics of general interest in electrode kinetics over the past 25 years.

Background to the Twenty-Five Year Retrospect

The twenty-five year period extends back almost to the 1947 Faraday Society Discussion on Electrode Processes (1) which the present author recollects in some detail. In many ways, this was an outstanding meeting which served as a milestone in the development of electrode kinetics. On the one hand, it ended a period in which polarization effects in electrode processes had been treated in a quasithermodynamic fashion by a number of workers and such antiquated concepts as "bubble overvoltage" and "transfer resistance" of Ferguson were still debated. On the other hand, it marked the beginning of the period when basic kinetic limitations to the rate of an electrode process, on account of a potential-dependent free energy of activation (2, 3), became more widely recognized, based on "absolute rate theory" concepts which had been formulated earlier but not very widely adopted by most electrochemists at that time. A third point, of great significance for the development of electrode kinetics in the Western world, was the submission of three papers from the Russian School of electrochemistry, one by Ershler (4) concerning the same topic as that of Randles (5), presented at the same Faraday discussion (1) on the experimental study of the kinetics of reactions under partial diffusion control by a-c impedance analysis (5, 6), and others by Levich and by Frumkin.

It must be stressed that although the Faraday Discussion of 1947 marked a point in time at which the more quantitative and correctly represented treatments of electrode kinetics, originated by Erdey-Gruz and Volmer (7) and by Butler (3), became common in Western countries, such treatments had existed in the Russian literature since the early 1930's, especially with regard to the work of Frumkin's school on double-layer effects on electrode kinetics (8, 9) and the study of processes involving absorbed H at Pt electrodes [Frumkin, Dolin, and Ershler (10)]. It is of historical interest that the latter work was the earliest in which a "relaxation" technique (based on kinetic response of a two-step reaction to a-c modulation at various frequencies) had been applied to the evaluation of rate constants. The later "relaxation techniques" of Eigen and co-workers were based on observation of effects following a pulse perturbation (by changing temperature or pressure) of a process initially at equilibrium. This technique was applied in electrode kinetics [*e.g.*, by Gerischer *et al.* (11)] using fast potentiostats developed in the 1950's and it is still an important method, especially for evaluation of nucleation-controlled electrode reactions involving deposition or stripping of a surface phase, *e.g.*, as studied by Fleischmann and Thirsk (129, 130).

In addition to the Russian work in this background period must be specially mentioned the work of Butler in England in 1936 (3) regarding the formulation of rate equations for electrode processes in which a potential-energy curve representation of the course of the reaction was given more quantitatively than that of Horiuti and Polanyi (12) in the previous year, and which dealt, among other things, with the role of chemisorption of H in the H_2-evolution reaction and the behavior of the reversible H_2 electrode. A number of the principles of electrocatalysis, insofar as chemisorption of intermediates is involved, were developed later on the basis of this work by Butler. Secondly, the work of Bowden and Rideal (13) and of Agar (14) in this background period must be mentioned with regard to such matters as double-layer capacitance and charging curves, the significance of transfer coefficients, and that of activation energies in kinetics of electrode processes.

Difficulties of communication between 1939 and 1946 caused by the war made an unnatural gap in the development of the field of electrode kinetics as it did, of course, in other fields as well. Hence it took some time for the leading and newest ideas in 1939 to be reiterated after 1945 and to exert the influence they deserved in the postwar development of electrode kinetics. For example, Butler had changed his field of interest to biophysics of proteins and nucleic acids and it took some years after the war for the Russian work to reestablish its influence, a problem that was exacerbated by the termination of the Russian international journal *Acta Physicochimica* (in which a lot of electrochemical work was published) soon after the end of the war.

An important feature of experimental work on kinetics of electrode processes in this period arose from the recognition that the rates can be "programmed" through the applied potential with great facility, more so than in the case of other types of reactions where temperature or pressure must be modulated.[1] Various types of potential programs, *e.g.*, potential-step, repetitive-step (square-wave), single, and repetitive linear-potential sweep and alternating voltage can conveniently be used, with repetition rates, sweep rates, or frequencies varied over a wide range of values. Techniques of this kind, facilitated by contemporary advances in electronics, enabled many fast electrochemical reactions to be studied, while theoretical analysis of the coupled diffusion situation which then arises enabled the required equations to be developed (4, 5, 15) for quantitative evalution of the kinetics.

Progress in the treatment of the kinetics of single- and multi-step reactions under diffusion control was greatly stimulated by the appearance of Delahay's monograph "New Instrumental Methods in Electrochemistry" (1954), and by the many important papers by him in which various kinds of cases were studied and treated by exact mathematical analysis. This work had an important influence in the development of electroanalytical chemistry, both in instrumentation and the quantitative interpretation of experimental results in that field, *e.g.*, in the work of Reilley and of Anson.

Some Characteristic Aspects of Advances in Electrode Kinetics in the Period 1952-1977

The main areas in which a subject advances are often determined by (*i*) the influence of theoretical developments in the field (some of which go ahead of experiment); (*ii*) the development of new experimental techniques, especially where new instrumentation is involved; and (*iii*) the demands of applications for new or improved developments in (*i*) and (*ii*). Some particular areas in which important advances in these aspects of the subject have been made in the past 25 years are summarized in Table I.

In electrode kinetics, these influences have played a major role in developing the subject to a high level of sophistication in both instrumentation and the variety of theoretical treatments which are now available for interpretation of experimental results. It must be stated, however, that as in other aspects of chemical kinetics, a satisfactory *a priori* theoretical evaluation of rate constants of electrode reactions is as elusive a goal as it is for nonelectrochemical, even quite simple reactions. It is in the evaluation of characteristic types of kinetic behavior that the theoretical treatments of electrode kinetics (for complex reaction sequences) have been most successful.

In the material which follows, a selection of the topics in Table I which have constituted main stream areas of research in electrode kinetics over the past 25 years will be considered in more detail. A number of them, it is to be noted, formed the subjects of lively discussion and important papers in the 1959 Electrochemical Society Symposium on Electrode Processes at Philadelphia.

[1] The rates of nonelectrochemical reactions can be modulated only by change of temperature or pressure, assuming concentration is excluded. Techniques of this kind were developed by Eigen. While it was implicit, since the correct formulation of equations for rates of electrode processes, that rates depended on potential, modulation of the potential as the "independent variable" was not possible until the advent of reliable fast-rise potentiostats.

Table I. Principal advances in electrode kinetics over the past 25 years

Theoretical

1. Evaluation of electrode-kinetic equations for complex sequential reactions under activation control including significance of reaction orders, coverage effects, etc.
2. Evaluation of electrode-kinetic behavior for complex sequential reactions where solution-soluble intermediates and diffusion control are involved, especially for cyclic-voltammetry conditions.
3. Evaluation of behavior of chemisorbed intermediates at electrodes in terms of pseudocapacitance behavior and properties of adsorption isotherms, etc.
4. Evaluation of electrode-kinetic behavior for simple and complex surface reactions at electrodes under linear potential-sweep control.
5. Theory of a-c impedance for complex reactions and its representation in the complex plane.
6. Theory of open-circuit decay of potential at electrodes where complex mechanisms are involved.
7. Development of theories of electron transfer, including quantum-mechanical treatments.
8. Development of theories of proton transfer and electrochemical proton tunneling
9. Treatment of photoelectrode kinetics; 5/2 power law, and the behavior of cathodically generated solvated electrons.
10. Theory of semiconductor electrode processes and photoeffects on the kinetics of such reactions.
11. Kinetics and electrocatalysis: coupling of dissociative chemisorption with electrochemical processes.
12. Theories of behavior of porous electrodes and current distribution.
13. Evaluation of kinetics of formation of surface phases at electrodes by nucleation and growth mechanisms.
14. Evaluation of the kinetics of metal deposition including the elementary microscopic processes.
15. Kinetics of anodic oxide film growth.
16. Development of structural theories of the double layer and specific adsorption of ions in relation to ion adsorption effects in electrode kinetics; role of solvent adsorption and orientation.

Experimental

1. Studies of kinetics over a wide range of temperatures.
2. Kinetic studies at high pressures.
3. Development of techniques for study of reactions with solution-soluble intermediates (cyclic voltammetry, thin layer, rotating ring disk).
4. Study of the kinetics of photoelectrochemical reactions.
5. Study of electrocatalysis.
6. Study of kinetics of porous electrode and flow-through electrode materials.
7. Study of electroorganic reactions (reviewed by M. Baizer).
8. Study of electrochemiluminescent reactions.
9. Kinetic studies in electrochemical surface science: underpotential deposition of monolayers.
10. Kinetic studies of growth of anodic oxide and other films on electrode metals.
11. Kinetic studies of metal electrocrystallization.
12. Kinetic studies on film formation by optical reflectance and surface conductivity changes.
13. Study of electrodes on which an electroactive species is irreversibly chemisorbed.
14. Experimental study of kinetics of battery electrode reactions and development of high energy-density systems in nonaqueous media.
15. Study of the kinetics of periodic or oscillatory electrode reactions.

Instrumental

1. Development of fast-rise potentiostats.
2. Development of sequential function generators.
3. Development of phase-sensitive amplifiers.
4. Development of automatic ellipsometers.
5. Development of rotating-disk, ring-disk, and split ring-disk electrodes.
6. Development of techniques for Faradaic rectification and for advanced polarography.

Mechanism and Kinetics of Electron and Atom Transfer Reactions in the Steady State

The fundamental act of electron transfer in electrochemical processes has been of major interest since Gurney and Fowler's work, and Gurney's representation of it, in quantum-mechanical terms in 1931/1932 (16, 17). Butler's treatment (3) of this kind of problem in 1936 for an atom (H) transfer step coupled with electron transfer provided the basis for a number of more quantitative potential-energy profile theoretical treatments for the proton discharge and atom/ion desorption steps, as well as for the elementary steps in metal deposition, which were published (18-21) between 1951 and 1960. These treatments were most valuable for the relative rather than absolute (very difficult to obtain reliably for any process) values of en-

ergies of activation and exchange current-densities for various processes and conditions which they gave rise to. However, they were some of the first numerically evaluated calculations on kinetics of electrode processes that had been made and also involved detailed treatments (19-21) of ion-solvent interaction (based on electrostatic models) in the activation process, an important area that had been earlier treated experimentally in papers by Bockris (22, 23).

In the late 1950's and early 1960's, continuing until the present time, a major thrust in interpretation of the molecular dynamics of electron transfer reactions was made by Marcus (24, 25), Levich (26), Dogonadze and Kuznetzov (27) following the important treatments of Hush (28) in 1957/1958, and of Weiss in 1947 (29), 1951, and 1959 (30).

These theories represented the activation process in terms of a so-called "reorganization energy" associated with a change of ion-solvent interaction which in previous theories, *e.g.*, of Butler (3), Bockris and Parsons (18) and Bockris and Conway (19-21), had been treated in terms of an effective potential-energy profile for short-range H^+/H_2O or metal ion/H_2O interactions. These treatments differed in an important way from those of Butler, Bockris, Parsons, and Conway in that the activation process was attributed to long-range, nonspecific fluctuations of dielectric polarization in the solvent fluid according to Born's equation (based on analogies with polaron theory for creation of charges in a solid medium) rather than to change of configuration and short-range polarization in the ion solvate complex or in the inner coordination shell of Werner complex ions. This viewpoint had its origin in Hush's paper in 1958 (28).

These treatments also became associated with the view that a quadratic dependence of log i on overpotential should arise, and this question was examined experimentally by a number of authors (31, 32). However, this matter is quite distinct from the question of how "solvent reorganization" occurs and originates simply on any model [*cf.* Ref. (21, 33)] if harmonic approximations are employed for the potential functions corresponding to the energy barrier. It should be mentioned that while some evidence exists (31, 32) for potential-dependent Tafel slopes b (quadratic term effect) of some redox reactions, this could arise for other reasons (*e.g.*, ion adsorption), for the case of the H_2-evolution reaction on Hg which has been studied over many decades of current density, the b values are quite independent of potential.

The nature of the activation step in electrochemical proton transfer was taken up by Levich *et al.* (26, 27) in various papers. These authors pointed out that there would be a "double-adiabatic" adjustment of charge in the activation process associated with electron and with proton transfer, subject to quantitatively different quantum restrictions. They also argued that thermal activation of the OH bond in H_3O^+ (or H_2O) could not be significant at ordinary temperatures due to the large vibrational quantum ($h\nu \simeq 10$ kcal mole^{-1}) and therefore attributed the activation process in proton transfer at electrodes to long-range librational fluctuations in the solvent polarization. Appelby, Bockris, Sen, and Conway (33) argued that this was an unnecessary restriction since the work of Ackermann (34) had demonstrated, on the basis of a model of hydration of H^+ as $H_9O_4^+$ that appreciable room-temperature partial molar heat capacity of H_{aq}^+ arises and can be accounted for in terms of low frequency modes due to coupling with the solvent in the hydration shell of H^+. It is noteworthy that proton transfer processes in solution, where solvation effects can arise, always occur with much smaller activation energies than "atom" transfer reactions, *e.g.*, as in the gas phase, but the quanta involved are similar due to the fact that bonds to H normally have frequencies of around 10^{14} sec^{-1} in both the gas and liquid phase.

More recently, following the work of Hills and Kinnibrugh (134), studies (35) on the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ redox reaction at Au as a function of pressure showed that the volume of activation is (and must be) large. It could not be accounted for (by a factor of 4) by long-range fluctuation in the solvent polarization which, it can be shown (35), gives rise to only a small electrostriction volume change. Were the situation otherwise, a major change in volume of the ionic redox system would have to occur after the transition state is reached. This cannot be so, however, since the transition state at Au is almost symmetrical (in terms of its volume) with respect to the volumes of $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ in water, when the reaction is at equilibrium.

In the case of the H_2-evolution reaction, the interesting possibility that the proton itself tunnels to the electrode rather than being transferred by chemical activation was considered theoretically by Christov (36), Conway (37) [*cf.* Bawn and Ogden (38)] and both theoretically and experimentally by Conway and Salomon (39). Theoretically, appreciable proton tunneling rates are predicted (37) and a potential-dependent H/D separation factor should arise (37). Experimentally, working down to −110°C in cooled or supercooled alcoholic HCl solutions, Conway and Salomon (39) were unable to find any evidence for anomalous proton transfer behavior (*e.g.*, deviations from linearity in Arrhenius plots and anomalies in the Tafel plots).

Moreover, analysis of the temperature dependence of Tafel slopes for H_2-evolution at Hg and Ni down to low temperatures enabled Conway *et al.* (40) to demonstrate that the temperature dependence of the Tafel slope parameter b is not $b = RT/\beta\mathbf{F}$, but rather $b = (RT/\beta\mathbf{F}) + C$, *i.e.*, with a temperature-independent constant. The results were not represented by an equation of the form $b = RT/(\gamma T + \delta)\mathbf{F}$, *i.e.*, with a temperature-dependent β. In fact, the slopes db/dT are constant with temperature. Interpretations in terms of halide ion adsorption and proton tunneling were considered; *e.g.*, the residual constant C could correspond to participation of a temperature-independent but potential-dependent proton tunneling contribution at very low temperatures, below those where proton tunneling could be more directly detected.

Important advances were also made in the 25 year period in understanding the over-all kinetic behavior of complex (multistep) electrode reactions using steady-state kinetic treatments with various equations for the potential-dependent coverage of electrode surfaces with adsorbed intermediates. These lead to a series of characteristic criteria for reaction mechanisms in terms of reaction orders, Tafel slopes, etc. Applications were made to kinetics of H_2, O_2, Cl_2 evolution reactions and a number of organic fuel-cell oxidation processes, especially by Bockris and his school (41, 44, 103, 104). The illustrative paper (41) on O_2 is to be noted in particular.

For reactions involving solution-soluble intermediates, the development and application of rotating-disk (99, 100) and especially ring-disk electrode systems (96-98) by Levich *et al.*, by Alberry, and by Bruckenstein, has been invaluable, as both mechanisms of reactions and lifetimes of intermediates can be deduced. Rotation modulation is a new development.

With regard to interpretation of nonsteady-state kinetics of various types of processes, attention must be directed to the important generalized treatment of Rangarajan (95); this provides a unified approach to the effects of modulation of the kinetics of an electrode process by various means, and includes the role of coupled diffusion processes that often must be considered. Full mathematical development was given for a variety of cases commonly encountered in electrode kinetics. For the particular case of linear potential-sweep modulation, useful analytical and numerical simulation calculations have been given by Laviron (58) and by Kozlowska *et al.* (59) for complex reaction sequences.

Potential-Energy Barrier Effects in Discharge

The effect of potential on the rates of electrode processes has for many years [cf. Ref. (3, 12, 18-21)] been represented in terms of a two-dimensional potential-energy profile along a one-dimensional reaction coordinate. While, in reality, most processes require a multidimensional energy diagram for the potential surface, this approach is useful (3) as a basis for discussing effects of potential and effects of changing chemisorption energy of an intermediate, or activation energy. In particular, the potential-energy profile conveniently represents the symmetry factor β in terms of the fraction of the change of electrical energy VF applied at the initial state that causes an increase or decrease of free energy of activation: $\Delta G_V^{\pm} = \Delta G_0^{\pm} \pm \beta \Delta VF$. In electrochemical reactions, ΔV directly modifies the Fermi level, so that the electronic work function Φ of the metal is modulated: $\Phi_V = \Phi_0 \pm \beta \Delta V$. ΔV does not, however, significantly change the shape of the potential energy profile of the initial state, but it may have some effect on solvent orientation and ion adsorption at the electrode surface.

In terms of the above representation, it is useful to note (42) that β has a significance analogous to that of Brønsted's factor, α, relating changes of proton-transfer rate constants to changes of equilibrium constants for protonation in acid/base pairs. In terms of models of adiabatic electron transfer [e.g., of Hush (28)], $\pm\beta e$ represents the fractional average charge residing on the transition state.

A number of interesting cases were discussed by Krishtalik in various papers (43) where β may be 1 or 0, corresponding to "barrierless"[2] or "activationless discharge." These cases arise as shown in Fig. 1a and 1b where the conditions $\beta = 1$ or 0 depend on whether the initial-state potential-energy profile intersects the final-state profile at or below its zero-point energy level, or vice versa. In the case of an electrochemical reaction, the possibility of experimentally attaining either of these situations arises because the barrier height can be modified by $\pm\Delta VF$. Krishtalik has argued that the barrierless discharge case can be observed, e.g., at Hg, at low enough potentials, though the results then correspond to very low current densities where experimental difficulties arise and ion adsorption double-layer effects complicate interpretation of the results. The transition from regular ($\beta \simeq 0.5$ to barrierless ($\beta = 1$) discharge corresponds to a change of Tafel slope from $RT/\beta\mathbf{F}$ to $RT/\mathbf{F}$.

Under intermediate conditions, before the zero-point energy level is approached, β will be expected to be potential-dependent (but still near 0.5) due to the parabolic curvature (harmonic oscillator behavior) of the energy profile near the ground state (33, 44).

[2] Strictly, there is still a "barrier," equal to the endothermicity of the reaction, but there is no col in the potential surface. The terms above are Krishtalik's.

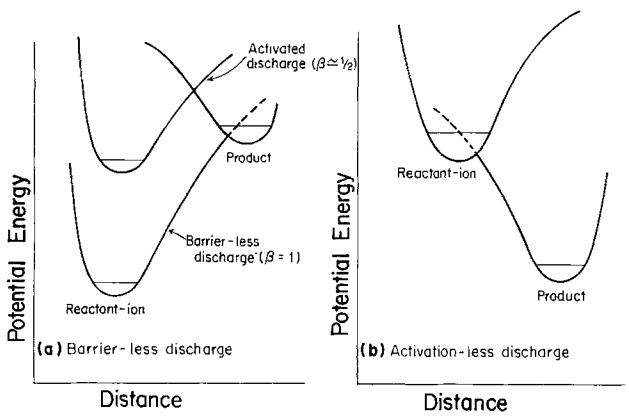

Fig. 1. Illustrating the significance of (a) "barrierless"; and (b) "activationless" discharge in electrode processes [after Krishtalik (43)].

Activationless conditions do not seem to have been observed, presumably because other factors then limit the rate.

The shapes of energy barriers such as those in Fig. 1a and 1b also give some idea of the relation of the configuration and charge of the activated complex to that of the initial state [cf. Ref. (28)]. Obviously, in the situation of Fig. 1a, the transition state is almost like the final state, while in Fig. 1b it is like the initial state.

Oscillatory Kinetics in Electrode Processes—Spontaneously Nonsteady Reactions

While oscillatory processes in homogeneous reactions are rare, but known, they are quite common in electrode processes and are of some general interest. A number of cases have been discovered in the past 25 years and are usually associated with S-shaped current-potential curves which arise in anodic reactions by passivation of an electrode or in cathodic ones by double-layer effects, e.g., in reduction of an anion (46) which tends to be repelled from the surface with increasing negative potential but reacts exponentially faster in this direction.

A S-shaped i-V profile has a negative resistance characteristic in the inverted part of the curve that can give rise to oscillation either coupled with double-layer and pseudocapacitance elements of the equivalent circuit, or with external circuit elements, as found by Hunger (52).

Periodic passivation and depassivation of Fe and Cu were investigated by Bonhoeffer and Gerischer (47) and the general behavior of such systems has been treated by Franck in various papers (48). Conway *et al.* (49) and Wojtowicz and Conway (50) studied the periodic oxidation of formic acid and ethylene at Pt in some detail, and identified the role of buildup and stripping of the surface oxide film at Pt, and of coupled diffusion. In fact, most periodic electrode processes are associated with periodical diffusion fluxes (50) due to the on-off nature of the rate of the electrode process (51). The requirement of a coupling with a diffusion process in order that an unstable steady-state condition arises can be demonstrated theoretically (50).

Most periodic electrode reactions exhibit nonlinear oscillatory behavior, *i.e.*, the "restoring force" is not linearly proportional to the displacement (here, the electrochemical affinity change in the reaction). In recent work, it was found that H_2-oxidation at Pt in trifluoroacetic acid containing traces of water (to give a small oxide film coverage at anodic potentials) was periodic, and that transition from linear (sinusoidal) to nonlinear (spike-pulses) oscillatory kinetics occurred, depending on the magnitude of current excursions, *i.e.*, on the potential involved. Two or more characteristic frequencies were observed, as can arise in nonlinear cases.

Mechanisms of oscillatory behavior are difficult to formulate but usually involve autocatalytic breakdown of an oxide film (47, 48), e.g., through film stripping by "lake" growth in the film (49), and a process (e.g., potential-dependent oxide-film formation) that gives rise to a S-shaped i-V profile (53). The kinetics give rise to a second-order differential equation that has a periodic rather than a steady-state solution (54); then the current and the concentration of intermediates (and the diffusion flux) which are each periodic in time, follow each other in a phase-plane plot (not the same as the complex-plane plots referred to above) rather than converge to definite steady-state values.

Kinetics in Electrocatalysis

While some of the principles involved in electrocatalysis, e.g., the role of the energy of chemisorption of an adsorbed intermediate in determining the activation energy of an electrode process involving a chemisorption step [Butler (3), Horiuti and Polanyi (12)], were enunciated in the 1930's, the main advances in the field have been made since *ca* 1955. However, a meeting at Leningrad must be noted since it was at

that conference that Frumkin, already in 1940, described electrochemical studies of catalyst surfaces (55). The useful term "electrocatalysis," originating with Grubb (56) in 1963, is now common.

A semantic question arises with the term electrocatalysis and associated kinetic representations of the phenomenon. While it is useful to consider reactions such as those of anodic O_2 or Cl_2 evolution, or cathodic H_2 production, in terms of "electrocatalysis," there is strictly no real pathway with which the rate of the "electrode-catalytic" reaction can be compared, since the necessary coupled electron-transfer steps that precede or follow any chemical step (*e.g.*, recombination of H, Cl, or O species) in the over-all electrode reaction can only occur at the electrodes. The recombination steps which arise in some pathways in these reactions can, however, be legitimately considered in terms of catalysis.

More particularly, the concept of electrocatalysis can be usefully applied to those reactions that require an initial dissociative chemisorption or rearrangement step that requires involvement of the electrode surface in order that it proceed at a reasonable rate. The electron-transfer steps that correspond to production of a current then follow such "catalytic" steps involving chemical production of an electrochemically reactive intermediate at the surface. The coupling of such electrochemical with chemical steps at a surface gives rise to complex kinetic behavior which has been worked out in some detail theoretically by Conway and Gileadi (57), Laviron (58, 121), and Kozlowska *et al.* (59) with special attention to the behavior which arises when electrode surface processes are studied by the potentiodynamic sweep method (discussed below).

In the area of experimental studies on kinetics and mechanisms of reactions involving a catalyzed dissociative chemisorption step at the electrode surface, *e.g.*

$$CH_3OH + 6Pt \rightarrow 3Pt{\equiv}C{-}OH + 3PtH$$

there must be specially mentioned the work of Bagotskii and Vasilev (101), Frumkin and Petrii (102), Bockris and co-workers (103, 104), Brummer and co-workers (109, 110), Breiter (105-107), and of Gilman (108) on the behavior of small molecules such as H_2, HCOOH, CH_3OH, C_2H_4, and C_3H_8. In this work, characterization of the chemisorbed intermediates was deduced from cathodic and anodic transients after adsorption of the reactant, using potentiodynamic sweep or galvanostatic pulses.

The work of Gilman (108), Breiter (105-107), Parsons (122), and of Brummer and co-workers (109, 110), as well as that of Bagotskii and his co-workers (101) in the USSR, led in this period to an understanding of the oxidation of chemisorbable organic substances at catalytically active noble metals, *e.g.*, Pt, Ir, and Rh, in terms of a rather general mechanism: the kinetics of oxidation are determined by a primary dissociative chemisorption step (or steps), coupled with H-ionization, together with oxidation of chemisorbed C-containing intermediates by O species discharged from water or OH^-. The latter processes depend on the potential for onset of surface oxidation of the noble metal anode which varies from 0.2-0.3V for Ru or Ir to 0.6-0.75V for Pt and Rh, depending on the pH and the anion of the electrolyte.

The work with hydrocarbons is particularly significant since the over-all reaction produces, in most cases, only H_2O and CO_2 with no solution-soluble intermediates except in the case of some olefins. The rate-controlling step for some hydrocarbon reactions was deduced, using steady-state kinetic and isotope-labeling methods by Bockris *et al.* (103) for propane and by Kuhn *et al.* (104) for olefins. The importance of "Temkin adsorption" (linear dependence of free energy of adsorption on coverage) in the kinetics of these types of processes was stressed by the Russian workers.

The kinetics of electrochemical reduction of O_2 has received much attention owing to its importance in fuel cell and air-depolarized battery systems. Leading work in this area was initiated and developed by Yeager (111, 112), who investigated O_2 scission in relation to peroxide pathways in the reduction reaction. More recently, the possibility of catalyzing the reduction of O_2 by paramagnetic La-Sr cobaltites and other structures with which (triplet-state) O_2 interacts magnetically was investigated by Tseung and co-workers (113-115).

Electrocatalysis and other aspects of the H_2-evolution process were extensively studied in the 25 year period on the noble metals, especially Pt, by Schuldiner and co-workers (123, 124) and by Breiter (125). In a series of papers describing very careful work in ultra-clean solutions, these authors were able to establish the mechanism of both H_2-evolution and H_2-oxidation by cathodic and anodic measurements down to potentials close to the H_2-reversible potential. Work on Pd showed the importance of coupled diffusion of H. The work on Pt provided rather important information for concurrent and later evaluation of Pt for fuel cell oxidation of H_2. In the latter field, the role of microcrystallite size and morphology of fine Pt deposits for H_2-oxidation has been examined in elegant electrochemical and scanning-electron microscopy work by Stonehart (126). The surface-to-volume and edge-to-surface ratios are important in electrocatalysis by fine particles; but the finer the particles, the more they tend to sinter at low temperatures, well below the Tammann temperature, giving rise to time-dependence of the real surface area and hence the catalytic activity of Pt electrode preparations.

An important field of investigation of a general type was the study of the dependence of electrochemical rate constants (or exchange current densities, i_0) on properties of the electrode metal, *e.g.*, the electronic work function, Φ (116-119). In the case of the H_2-evolution reaction, linear relations between log i_0 and Φ were found for several families of metals, depending on the mechanism (Fig. 2). Since log i, at a given potential, cannot directly depend on Φ, the observed relations are interpreted (116) in terms of the dependence of heat of activation on the energy of chemisorption of H. The experimental behavior can be simulated theoretically (120). This area of work in kinetics stimulated

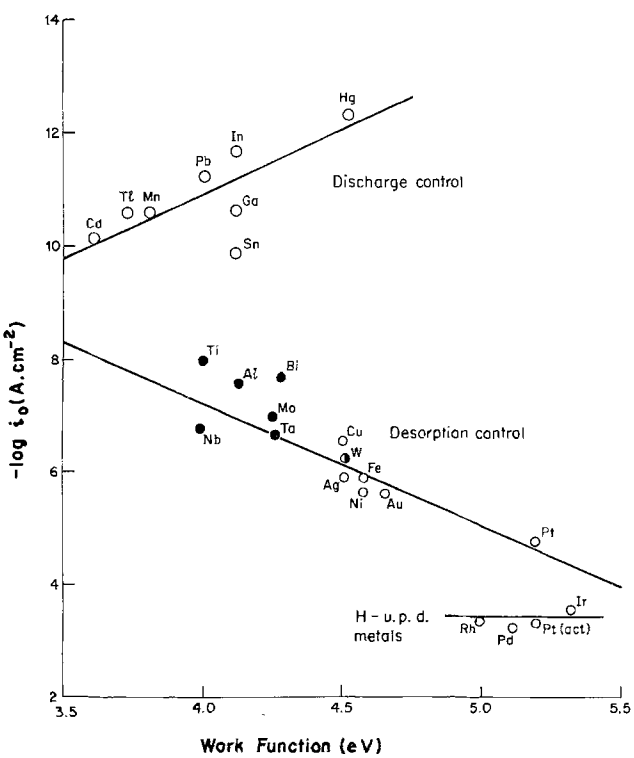

Fig. 2. Dependence of log i_0 on work function Φ for various series of metals [based on Ref. (116-119)].

many attempts to improve electrocatalytic performance by use of alloy electrodes. In general, the results are disappointing because binary alloy compositions rarely have properties better than those corresponding to one component or the other and *a priori* predictions of electrocatalytic activity have usually been unsuccessful except Tseung's (113-115) regarding activation of O_2 through paramagnetic interactions. However, submonolayers of deposited metal atoms such as Ru or Pb on Pt have been found to promote catalytic activity for certain reactions. Competitive and bifunctional mechanisms involving participation of surface oxide species are involved in these effects.

Kinetic Studies in Electrochemical Surface Science

Principles and methods.—Although studies of chemisorption of oxygen and hydrogen species at noble metal electrodes were initiated many years ago by Bowden and Rideal (13), Butler and Pearson (60), and by Frumkin and various co-workers (61), kinetic aspects of surface processes have only been quantitatively examined in recent years (*e.g.*, 57-59, 62, 92). In early work as well as in some more recent work, coverage of electrodes by O and H^- species was usually determined by means of galvanostatic charging curves (60, 61). As in regular electrode processes, kinetic information on surface processes can be derived from current-potential relations derived from charging curves by observing the displacement of potential V for given coverages θ to be attained at various rates of charging, *i.e.*, the current densities. Alternatively, potential-step charging curves [*cf.* Ref. (11)] can be recorded and the time-dependent current transient analyzed in terms of the kinetic equation(s) for the electrochemisorption process at the electrode surface. Both these procedures are in a sense "single pulse" techniques.

Some advantages accrue if an impulse of varying frequency or rate can be imposed on the electrode so that its kinetic relaxation characteristics can be immediately observed and kinetic information derived. Two important methods fall into this category: (*i*) a-c impedance measurements on electrochemical surface processes (10, 63, 64); and (*ii*) potential-sweep or repetitive potential-sweep measurements (cyclic voltametry) on electrodeposition and desorption processes at electrode surfaces (65).

As in the study of regular Faradaic processes, *e.g.*, the kinetics of a redox reaction (6), the a-c impedance method may be employed to elucidate the kinetics of surface processes at electrodes, *e.g.*, the electrosorption of H and oxygen species (OH and O) and metal atoms at noble-metal electrodes.

The first studies of this kind were made by Dolin and Ershler (10) and by Eucken and Weblus (64), who recognized that an electrosorption process of the kind

$$Pt + H_3O^+ \rightleftharpoons PtH_{ads} + H_2O \qquad I$$

was associated with a pseudocapacitance corresponding to the potential dependence of coverage of the electrode, *e.g.*, by H, and a reaction resistance corresponding to the reciprocal of the exchange current density or standard rate constant for the surface process.

More recently, capacitative and ohmic behavior of surface reactions such as that above have been studied by a-c techniques by Breiter (63) and by Bagotskii *et al.* (66).

Kinetic information derives from the fact that as frequency of the alternating modulating voltage applied to the electrode is increased, a condition eventually arises where the forward and backward processes of I can no longer keep up with the alternating driving potential. Thus the coverage of H can no longer follow electrode potential in the way it does at sufficiently low frequencies where equilibrium is almost maintained in I. This results in a "dispersion" of the pseudocapacitance C_ϕ due to the electrosorbed species, and eventually $C_\phi \to 0$, so that the measured capacity simply falls to the double-layer capacity at sufficiently high frequencies.

Kinetic analysis for processes in monolayers.—Transient electrochemical techniques give a sensitive means of following chemisorption or desorption processes at metals that proceed with charge transfer, *e.g.*

$$H_{aq}^+ + Pt + e \rightarrow PtH_{ads}$$
$$H_2O + Pt \rightarrow PtOH + H^+ + e$$
$$\hookrightarrow PtO + H^+ + e$$

Also, the changes of H adsorption brought about by adsorbed electroinactive species can also be measured accurately so that their adsorption can be studied. In "underpotential deposition" reactions, such as those above, multiple states of chemisorption arise below a monolayer (65, 90, 91) and are of great interest in electrochemical surface science. Here we shall briefly mention the kinetic aspects of studies in this field.

Because of the noncontinuous nature of a process in which a monolayer is formed or desorbed (the rate is limited by $\theta = 0$ or 1), steady-state kinetic methods are inapplicable. Kinetic studies on surface processes involving monolayers must therefore utilize transient procedures such as potential step, potential sweep, galvanostatic charging, or a-c modulation. For kinetic information to be derived, the "charging" of the surface must be conducted over a range of rates, or in a-c modulation over a range of frequencies (63, 66) sufficient to reach the "relaxation" frequency of the electrochemical surface process.

Normally, *e.g.*, in galvanostatic charging experiments (92), charging curves (i-V profiles) must be taken at various values of i, and the potential for a given coverage plotted against log i for sufficiently high i that the process is driven to irreversibility. However, the kinetics of the process of deposition in a particular submonolayer state are not easily evaluated due to the poor resolution of this method unless the curves are differentiated (93).

The linear potential sweep, by comparison, is a superior method for deriving kinetic information on surface processes, on account of its excellent resolution of various states of electrosorption below a monolayer (65, 91). In the linear potential sweep method, a given current peak for deposition into a chemisorption state at the electrode surface will retain a characteristic, constant peak potential, V_p, so long as the process remains reversible. When irreversibility sets in, V_p becomes displaced logarithmically in the peak current, i_p, (Tafel relation); but, for a surface process i_p is proportional to sweep rate s, so that V_p becomes dependent on log s.

The required kinetic equations for deposition of a monolayer under potential-sweep control were first derived by Srinivasan and Gileadi (95). Their treatment can be developed (94) to give equations which enable the experimentally observed kinetics of a surface reaction to be characterized by a critical sweep-rate parameter, s_0, as is a regular reaction by i_o, the exchange current density.

The current densities for deposition or removal of an electrosorbed species A of coverage θ_A in a reaction such as

$$A^- + M \rightarrow MA_{ads} + e$$

are

$$\vec{i} = zFk_1(1 - \theta_A)C_{A^-} \cdot \exp \beta VF/RT \qquad [1]$$

$$\overleftarrow{i} = zFk_{-1}\theta_A \exp -(1 - \beta)VF/RT \qquad [2]$$

In the sweep method, V is modulated linearly in time, so that $V = V_{initial} \pm st$ where s is the sweep rate dV/dt. Then (94)

$$V_{p,irrev} = V_{p,rev} + \frac{RT}{\beta F} \ln \frac{\beta F}{k_o RT} + \frac{RT}{\beta F} \ln s \qquad [3]$$

where $RT/\beta F$ ($= b$) is the Naperian Tafel slope and k_o is a standard rate constant {$k_o = k_1 \exp(\beta V^\circ F/ER)$

$= k_{-1} \exp[-(1-\beta)]V^{\circ}\mathbf{F}/RT$ for the standard potential V° for the surface process defined as the peak potential ($\theta_A = 1/2$) when the process behaves reversibly}. Equation [3] leads to the useful relation for the kinetic behavior of a reaction under potential-sweep control

$$V_{p,irrev} - V_{p,rev} = b \ln s_o + b \ln s \qquad [4]$$

which is similar to the Tafel equation $\eta = -b \ln i_o + b \ln i$. In Eq. [4], s_o has been defined from Eq. [3] as

$$s_o = \beta\mathbf{F}/k_oRT \qquad [5]$$

It is seen that s_o characterizes the kinetics of a surface process just as the exchange current density i_o does for a regular continuous Faradaic process. It has the advantage (contrast i_o) for kinetic evaluations in electrocatalysis that the real area of the electrode is not a required parameter. Hence the general problem in evaluation of electrocatalysis of separating the real-area factor from the intrinsic catalytic effectiveness of a surface is conveniently avoided in this approach. Also the problem that i_o is not a unique characteristic parameter for a surface process, since it depends on the coverage for which it is measured, does not arise with s_o, which applies to any point on the i-V profile.

When lateral interactions on the surface are significant ($g \neq 0$), a more complex result is obtained, but it is still possible (94) to evaluate s_o and hence characterize the kinetics. The electrochemical kinetics of surface processes, including those for resolved submonolayer states, can hence be completely characterized since b and s_o, as well as the coverage and relative energy of the states, can be measured. Exemplification of the method is given schematically in Fig. 3 and with respect to experimental results for one of the states of H adsorption at Pt, in Fig. 4. Accompanying the change of slope of the V_p *vs.* log s relation of Fig. 3, is a change of shape of the i-V profiles as demonstrated by Srinivasan and Gileadi (95). The general characteristic features of such reversible and irreversible i-V profiles were treated by Angerstein-Kozlowska *et al.* (96) for simple and complex surface processes, including nucleation.

Development of very thin layers of surface oxide on noble metals and of thick layers on baser metals has been studied by many workers, especially with regard to passivation in corrosion and anodization. Kinetic aspects of film formation and inhibited metal dissolution were studied in an important series of papers by Vetter (127) using galvanostatic techniques, and by Epelboin (79, 128), with a-c impedance methods. Initial stages of passivation are established by submonolayer quantities of surface oxide (indicating that dissolution commences at active sites), but a stable condition of passivity usually requires substantially thicker layers. Recent advances in this field have been made using techniques of surface physics, LEED, HEED, with Auger and ESCA photoelectron spectroscopy, and by using methods based on changes of optical reflectivity. Thus studies on surface processes at electrodes have been greatly clarified by the simultaneous use of *in situ* ellipsometric and direct reflectivity measurements, *e.g.*, in the various works of Yeager and Cahan and of Bockris and his co-workers.

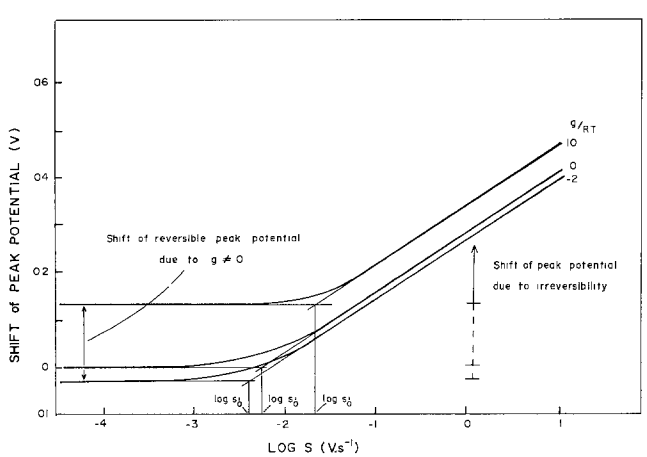

Fig. 3. Principle of evaluation of s_o from a plot of peak potential V_p, *vs.* log s from a series of cyclic-voltammetric i-V profiles taken at various sweep-rates s [Ref. (91, 94)].

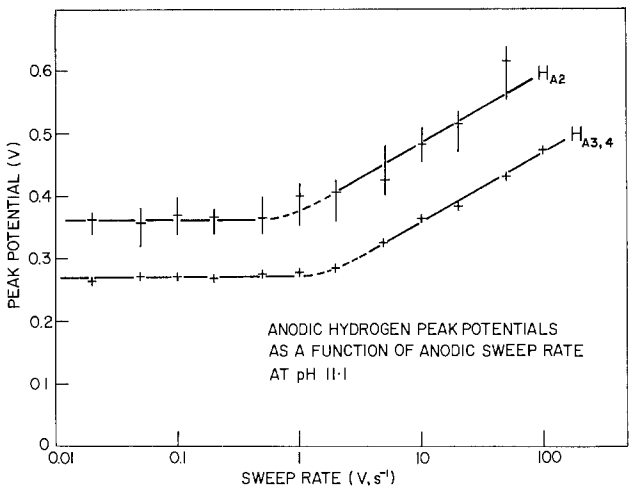

Fig. 4. Example of the application of the method illustrated in Fig. 3 and discussed in Ref. (91, 94) to the process of H deposition/ionization at Pt in two of the states of H-chemisorption (aq. 0.1M Na_2CO_3).

In conclusion, many important studies of the kinetics of multilayer growth where a new phase is formed should be mentioned. Here dissolution-precipitation processes are often involved with some metals while high-field film growth occurs at others. Nucleation-and-growth mechanisms are commonly the basis of electrochemical phase growth. They are often of importance in corrosion and battery electrode reactions. The main developments were in the kinetics of formation and growth of halides (Hg_2Cl_2), sulfate ($PbSO_4$), and oxide films by dissolution-precipitation and nucleation mechanisms, studied by Fleischmann and Thirsk and their co-workers (129, 130), and in the field of metal deposition, through nucleation mechanisms, studied by Budewski and Kaischew (131), and by Bockris and his school [*e.g.*, see Ref. (20, 44)].

Theoretical kinetic equations were developed from the treatments of Avrami (132) and of Evans (133) for the representation of nucleation-controlled phase growth in two-dimensional monolayers and in three-dimensional thicker deposits. Elegant experimental demonstrations of successive growth of monolayers, both of halide and oxide films (129, 130) and of metal layers (131), were given. The observed kinetics agree with theory under potentiostatic conditions.

"Electrosorption Valency" and the State of Electrochemisorbed Species

In the previous section, work on the kinetics of processes involving deposition or desorption of electrodeposited monolayers was described. In addition to the thermodynamic and kinetic problems associated with processes of this kind, recent work has been concerned with the electrical state of electrodeposited atomic species, *i.e.*, to what extent does a deposited species have ionic character or, conversely, to what extent do ions, upon specific adsorption, lose their charge? This type of problem was first addressed by Lorenz (70), Gerischer (71), and by Conway and Bockris (20) with regard to elementary steps in metal deposition, and in some ways by Grahame (72) for specifically adsorbed ions. Essentially the possibilities

are: (*i*) $A^{z+} + M + \lambda(ze) \rightarrow MA_{ads}^{z(1-\lambda)+}$ for electrodeposition of a species A at a metal M with partial charge transfer; or (*ii*) $A^{z-} + M \rightarrow MA_{ads}^{z(1-\lambda)-} + \lambda ze$ (in M) for specific adsorption of an ion A^{z-}.

Evaluations of λ have been made for various examples of electrosorption by Schulze and Vetter (73), who find most atom deposition reactions, *e.g.*, of H and metal atoms at noble metals, have λ close to 1. $\lambda < 1$ arises in a number of cases of specific adsorption of ions. The relative values of λ can be interpreted in terms of polarity of ligand-to-metal bonds by regarding deposited or adsorbed species as acting as ligands of the adsorbate. The thermodynamic significance of λ was discussed in various papers by Frumkin *et al.* (74) and its chemical significance by Conway *et al.* [see also in Ref. (74)].

The significance of λ for kinetic representation of surface processes is of interest because rate equations have to be modified to the form

$$i = \lambda z\mathbf{F}kC_{Az+} \exp \beta\lambda z\mathbf{F}V/RT$$

to include the λ factor when $\lambda < 1$.

A-C "Relaxation" Studies and Representation of Electrode Kinetics in the "Complex-Plane"

The a-c impedance method is of general interest in kinetics of electrode processes since it provides a convenient method for evaluating rate constants for fast reactions and dealing in an exact way with the problem of coupled diffusion processes. Apart from diffusion effects, at high enough frequencies, ω, where $1/\omega$ becomes comparable to the relaxation time of the reaction determined by the reciprocal of its rate constant, the potential-dependent reaction process ceases to be able to keep up with the applied frequency, so that a "lossy" situation arises as was mentioned with regard to adsorption pseudocapacitance.

The situation is exactly analogous to that in other relaxation processes, *e.g.*, in dielectric polarization in a polar medium where, at sufficiently high frequencies, dipole orientation cannot keep up with the rate of alternation of the applied field so that a "dispersion" of the dielectric constant arises.

The relaxation or dispersion effects were treated for dielectric polarization by Cole and Cole (75) in terms of a plot of the real *vs.* the imaginary component of the dielectric constant, giving a so-called Argand diagram or a representation of the kinetic behavior in the "complex-plane." It was recognized by Rehbach and Sluyters (76) in 1961 that a similar representation could be applied to the kinetic behavior of electrode processes where a "real" (ohmic) component corresponding to the reciprocal of the rate constant (as mentioned earlier) arises, together with an "imaginary" (capacitative) one dependent on frequency. In general, the capacitative component is a compound one, being comprised of a double-layer contribution C_{dl}, an adsorption pseudocapacitance in cases such as reaction *I*, and a diffusional pseudocapacitance and resistance (elements of the Warburg impedance) dependent on square root of frequency (4, 5).

It must be stated that the complex-plane method of analysis has been very fruitful in the treatment of the kinetics of surface and other processes at electrodes, and has given new insights into the relation between kinetic processes occurring over various frequency ranges or time domains. The analysis is closely connected with the representation of electrode processes in terms of equivalent circuits of varying complexity, depending on the distinguishable types of kinetic processes involved including solution resistance (ohmic transport of ions) and double-layer capacitance. It is generally applicable whenever there is a kinetic restriction on the rate of some process (as is usually the case) in a sequence of processes.

Experimental studies on a-c frequency effects and corresponding complex-plane analyses have been greatly facilitated in recent years by the availability of well-engineered phase-sensitive amplifier systems [*cf.* Ref. (77, 78)] which enable the ohmic and capacitative currents to be directly read out with the appropriate phase-angle setting. A similar system can be applied in the study of a-c modulated reflectivity of electrode surfaces at which some electrode process can occur and be modulated with an alternating voltage. The "in-phase" and "out-of-phase" components of relative reflectivity can then be directly recorded and represented in terms of complex-plane plots from which the relaxation characteristics of the surface processes can be derived.

A-c impedance studies, with analysis of the results in the complex plane, have recently been made for quite complex electrode processes by Armstrong *et al.* (78), and by Epelbein *et al.* (79). In film-forming processes leading to passivation, interesting negative resistance components enter into the equivalent circuit together with behavior corresponding to negative capacitance which has electrical analogue characteristics of an inductance. Such complex systems can give rise to oscillatory phenomena (47-51) where no real steady-state in the kinetics of the electrode process can exist.

In the complex-plane representation of the a-c behavior, the capacitative contribution $1/\omega C$ to the impedance Z is plotted against the ohmic one for various frequencies ω. Regular simple kinetic processes give a semicircular arc lying on the ohmic resistance axis (Fig. 5a) while complex processes with more than one characteristic rate constant give two or more arcs (Fig. 5b). Similar behavior is found for processes in aqueous solution which exhibit several relaxation times, *e.g.*, contact ion-pair dissociation, solvent-shared ion-pair dissociation, and solvation shell relaxation; in these cases, ultrasonic or dielectric absorption experiments are involved.

Processes coupled with diffusion which give rise to a Warburg impedance (5) generate a straight line of 45° slope in the complex-plane plot since the capacitative and ohmic contributions arising from diffusion are both linearly dependent on $\omega^{-1/2}$. Their relation to the kinetically controlled arc in the complex plane is illustrated in Fig. 5c.

For processes that involve generation of a surface film, the equivalent circuit becomes very complex and will include a pseudocapacitance corresponding to potential dependence of coverage of a species electrodeposited in a mono- or multi-layer. The film formation can influence some other Faradaic process such as oxidation of the metal itself or of an organic reactant in solution, giving rise to passivation. Such reactions often exhibit a Σ-shaped current-potential profile giving rise to negative resistance and negative capacitance which corresponds to a pseudoinductance. In the complex plane, such processes give [*cf.*, Ref. (79)] curves such as that in Fig. 5d, with a loop. Such equivalent circuits often give rise to oscillatory currents at constant potential or oscillating potentials at constant current.

Complex-plane representations of the impedance behavior of various types of reactions have been treated by Armstrong *et al.* (78), for processes such as cadmium oxidation in alkaline solutions which show active dissolution followed by passivation with diffusion in the pores of the film, and by Epelbein *et al.* (79) for passivation of Ni and Fe where oscillatory phenomena arise. Armstrong (78) has also treated the interesting case of metal/solid electrolyte interfaces where blocking or nonblocking behavior can arise, and in powdered solids (78) where interparticle resistance can be significant.

Kinetics of Photoemission of Electrons at Electrodes

While photovoltaic effects have been known for a long time, in fact since Becquerel's observations (80)

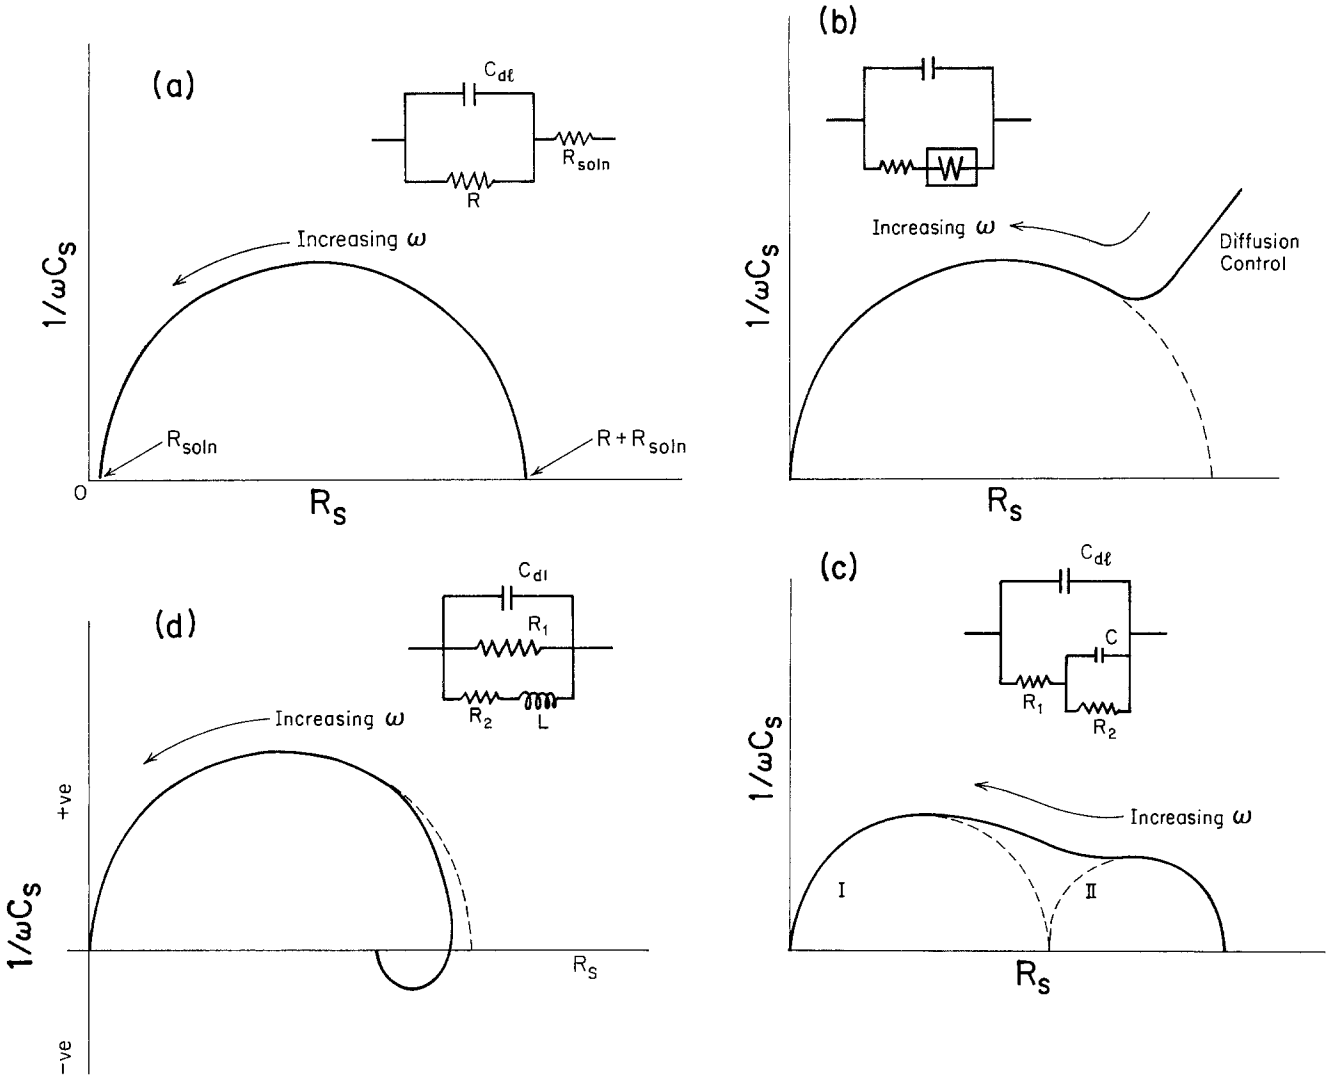

Fig. 5. Plots of capacitative *vs.* ohmic impedance components in the complex plane for various types of electrochemical processes: (a) a regular reaction with a reaction resistance *R* at an electrode with double-layer capacitance $C_{d.l}$ [see Ref. (78)]; (b) a two-stage reaction involving, *e.g.*, discharge and another surface reaction [*cf.* Ref. (57, 79); (c) a process involving a reaction resistance *R* with diffusion coupling involving a Warburg impedance with both *C* and *R* components dependent on $\omega^{1/2}$; (d) a process coupled with surface reactions giving instability corresponding to a pseudoinductance [Ref. (79)].

in 1839 of a photoeffect on the potential of an electrode in solution, much work [*e.g.*, see (81-87)] of a new, interesting, and quantitative kind has been done in the 25 year period under review. It has involved: (*i*) the discovery and rationalization of the "5/2" current law for electrochemical photoelectron emission; (*ii*) identification of the role of formation of solvated and "dry" electrons; (*iii*) evaluation of the potential-dependent "red limit" which arises in photoelectron emission at electrodes; (*iv*) evaluation of kinetics of reactions of photoelectrochemically generated solvated electrons with scavenger molecules such as N_2O, H_3O^+, O_2, NO_3^-; and (*v*) development of treatments of photoelectron emission effects in terms of double-layer structure, especially in relation to the ψ_1 potential of the diffuse double layer and the potential of zero charge. Electrochemical reductions have also been carried out with cathodically generated solvated electrons in suitable media, *e.g.*, HMPA and alcoholic solutions (88). The reactions are similar to those that can be effected with the Birch reagent.

Hillson and Rideal (89) made some of the first direct measurements of photoeffects on the kinetics of a cathodic reaction, H_2 evolution at Hg, and found an acceleration of the process under the influence of photons in the wavelength range 200-400 nm.

Using polarographic techniques, Berg (81, 82) investigated the effect of illumination at a dropping Hg electrode, and attributed the observed photocurrents to the supposed increased energy of electrons in Hg which then behaved, he considered, as a "hot electrode."

Heyrovsky (83-85) regarded the photoeffect at electrodes as originating from the photodecomposition of a surface charge-transfer complex formed from the solvent and the electrode interface. This is correct for anodic photocurrents, but not for cathodic ones. He found that the low energy wavelength limit for the photoeffect depended on electrode potential. This is because the normal photoelectric threshold, $h\nu = \Phi$, is modified to $h\nu = \Phi \pm eV$ where V is the applied potential which changes the Fermi level.

Barker (86) gave the first, essentially correct explanation of most photoeffects at metal electrodes, *viz.*, that they originate from photoemission of electrons into the electrolyte where they become solvated and have a short lifetime. While such ideas are to be found in some of Berg's papers, it was Barker who successfully demonstrated photoelectron emission into solutions at electrodes. This work gave impetus to much of the work that followed especially that of the Russian workers, Brodsky and Pleskov (87), Gurevich and Rotenberg, with others.

Photoelectrode kinetics is now a major field in electrode kinetics, and is particularly interesting with regard to development of direct photoelectrical energy conversion systems. However, the more promising of these utilize photoeffects in semiconductors with a

suitable bandgap, so that the effects are quite different from those we are describing here which involve photoelectron emission into an electrolyte solution. The semiconductor photoeffects involve separation of electrons and holes, and light thus facilitates reactions with p- or n-dependent rates, *i.e.*, anodic or cathodic processes, respectively.

For photoelectron emission into a dielectric, the current I is proportional to $(n\nu - \nu_0)^2$ for n-photon photoemission where ν is the frequency and ν_0 the threshold frequency ($h\nu_0 = \Phi$). This is Fowler's parabolic law. For photoemission into dielectrics with large ϵ, or more particularly into strong solutions of electrolytes where screening effects are appreciable, image charge interactions can be neglected. Then I takes the form

$$I \propto (n\nu - \nu_0)^{5/2}$$

which is the "5/2 law" for electrochemical photoelectron emission.

Normally, the current i which is measured in a photoemission experiment is not identical with the ν-dependent I referred to above because of secondary processes which the emitted photoelectrons undergo in the bulk of the solution. These involve, *e.g.*, solvation and reaction with any electron scavengers A (see Fig. 6).

The presence of acceptors is very important in observations of a stationary photocurrent, since in the absence of A, emitted electrons are rapidly returned to the electrode and the resulting photocurrent is then very small. Solvated electron reactions such as $e_{aq}^- + H_2O \rightarrow H + OH^-$ are relatively improbable compared with back diffusion of e_{aq}^- to the electrode.

In dilute electrolyte solutions, the critical region near an electrode into which electrons are photoemitted, a "stretched interfacial barrier" arises, the properties of which depend on the diffuse part of the double layer and hence on the ψ_1 potential. This dependence gives useful information on the double layer, including that at solid metals (87). Then the photoemission current law in $i^{0.4}$ [$i \propto (n\nu - \nu_0)^{5/2}$, hence $i^{2/5} \propto (n\nu - \nu_0)$] gives a linear plot not with electrode potential ϕ but with $\phi - \psi_1$. When diffuse layer effects are significant (dilute electrolytes) the general photocurrent relation is of the form

$$I = K[h\nu - h\nu_0 - e(\phi - \psi_1)]^{5/2}, \quad \psi_1 \leq 0$$

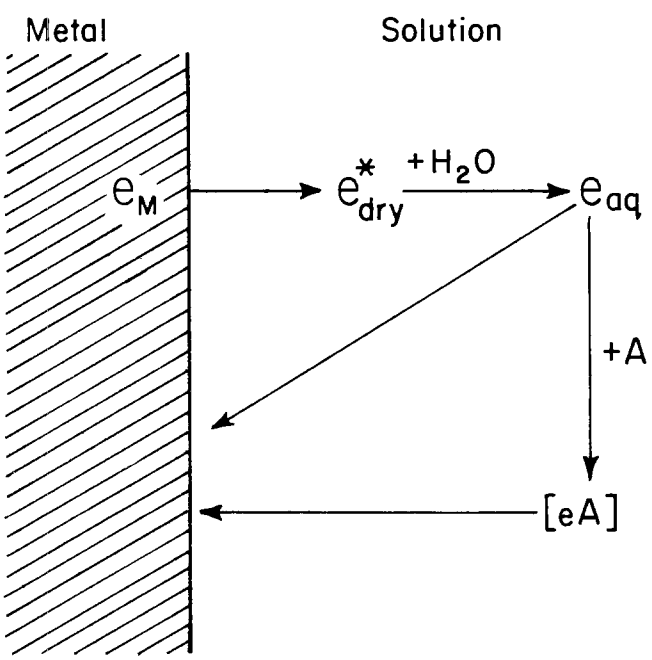

Fig. 6. Schematic representation of photoelectrochemical emission of an electron into solution with anodic return current and scavenger (A) processes [after Ref. (87)].

The dependence of $di^{0.4}/d(-\phi)$ on ϕ gives a minimum at the potential of zero charge where the ψ_1 potential is zero (in the absence of specific adsorption) and $d\psi_1/d\phi$ is a maximum. Potentials of zero charge at solid metals can hence be derived from photocurrent measurements.

Much further work has been done, especially with various acceptor molecules or ions, and with dyes where photoeffects on a substrate in solution as well as the electrode metal arise.

Concluding Summary

It may be useful to give a concluding overview of the contributions of the past 25 years in electrode kinetics. On the theoretical side, electrode kinetics has found its home as a major area in chemical kinetics involving, on the one hand, solution-phase reactants and, on the other, surface-catalyzed processes. The main kinetic phenomenology is rationalized in terms of the framework of absolute rate theory and more recently in terms of quantum-statistical treatments, though these have yet to give meaningful numerical results to compare with experimental data. Future theoretical advances lie in the realm of chemical physics.

Instrumental advances, especially in electronics, have enabled new experimental techniques to be developed for studies on kinetics of electrode processes, programmed in various ways. The facile modulation of kinetics of electrode processes, afforded by the potential variable, makes electrode processes ideal for on-line computer-controlled experimentation. Digital computer simulation of kinetic schemes for diffusion and activation-controlled processes enable quite complex models and mechanisms to be treated with increasing facility in a complementary way.

On the practical side, developments in electrocatalysis and materials science have led to systems of major interest in the fields of energy conversion and electrical energy utilization. Here, kinetic limitations and their attenuation are of major practical interest.

The heterogeneous nature of electrode processes has led to the development of electrochemical techniques for study of surface processes on metals and semiconductors that have high sensitivity and reproducibility, and can give kinetic information on surface reactions unattainable by any other methods. These approaches have generated a new area of "electrochemical surface science" in which kinetic studies play an important role.

Developments in photoelectrochemistry give interesting new information on metal-electron interactions and electron-capture processes in solution near the interface. For the future, this area may have important contributions to make to energy-conversion technology.

The "Structure" of Electrolyte Solutions, 1952-1977

Harold L. Friedman

Department of Chemistry, State University of New York, Stony Brook, New York 11794

"Structural" Concepts

The various phenomena that characterize solutions stem from the forces between molecules rather than from the chemical bonds that hold the molecules themselves together. Of course the chemical bond is the central concept in the part of chemistry that has developed at a spectacular rate; we now are informed in great detail about the geometrical structures and even the electronic structures of many molecules of interest in various fields of chemistry. Moreover, if a structural question about a molecule is posed, our students are well trained to identify the experimental procedure best suited to give the answer. The resulting information is uniquely valuable because a structure is a picture and, as the Chinese tell us, a picture is the best way to convey a lot of information so it can be understood and remembered.

By comparison, our knowledge of intermolecular forces is still in its infancy. The intermolecular interactions, compared to chemical bonds, are less sharply sensitive to distance and orientation, so that the resulting structures are less sharply defined. The bond lengths and angles in a typical molecule are unchanged within a few percent whether the molecule is in the gaseous state, in a liquid, or in a crystal. The contrary is true for the structural parameters determined by the forces between molecules; at least in fluids great variability of intermolecular structures is the rule, and precise statements can only be made for precisely defined averages. This important point may be illustrated by reference to the interesting discussion by Eisenberg and Kauzmann (1) of the structure of liquid water. They define the instantaneous I structure as what one would see in a snapshot taken with a hypothetical camera that could "see" individual atoms if the exposure time were shorter than the period of any of the intermolecular vibrations. If the exposure time is increased to be longer than that of the intermolecular vibrations, but short compared to the time required for a diffusive displacement, then the snapshot would depict the so-called V structure.[1] A still longer increase in exposure times, until they are long compared to the time required for a diffusive

[1] In the V structure snapshot the atomic positions would be blurred because of their vibrational motions, but their positions would be instantaneous relative to the slower movements due to diffusion.

displacement, leads to the D structure. At first one might think that for a fluid the D structure would be a homogenous blur. However, if the hypothetical camera can always be pointed with a particular atom in the center of the field of view, then features such as the Debye-Hückel ionic atmosphere will be visible in the snapshot.

These structural concepts are useful for qualitative discussion. To proceed further we may take advantage of the power of statistical mechanics which enables us to define pictures something like the ones described above but with the added features that the structural functions so defined can be precisely related to the interatomic forces on the one hand and, on the other, to the appropriate experimental data. Various investigations of this kind are reviewed here.

In statistical mechanics the structural information is carried in mathematically defined functions of the locations and velocities of the molecules, and perhaps of the time as well. The most commonly accepted notation is used here, but only the most qualitative definitions of the various functions are given. Precise information is given in the various references.

As an illustration we introduce the pair correlation function (or radial distribution function) (2-4) $g_{ab}(r)$ which is a measure of the probability of finding a particle (atom or molecule) of species a at a distance r from a particle of species b. Thus, if c_a is concentration of species a, the ordinary molarity for example, then $c_a g_{ab}(r)$ is the local concentration of a particles at a distance r from any b particle. One can see that we must have $g_{ab}(r) = 0$ for small r, since each particle occupies some space from which the others are excluded, and one can see that $g_{ab}(r) = 1$ at distances r so large that the force between the particles must be negligible.

According to the theory of Debye and Hückel that leads to the limiting laws we have

$$g_{ab}(r) = 0 \text{ if } r < a$$
$$= \exp\left(-\frac{e_a e_b}{\epsilon r k T} \frac{e^{-\kappa(r-a)}}{1+\kappa a} \right) \text{ if } r > a \quad [1]$$

where e_a and e_b are the ionic charges, ϵ is the solvent's dielectric constant, a is the distance of closest approach of the ions (thought of as charged hard spheres of diameter a) and κ is the famous Debye kappa, proportional to the square root of the ionic strength. In Fig. 1 a graph of Eq. [1] is compared with the correlation function that is calculated for the same charged hard sphere model by methods that are highly accurate in this application. The difference in the graphs shows the refinement of our knowledge of this aspect of the structure of electrolytes since 1923.

The most direct experimental approach to the pair correlation function is through measurement of the scattering of x-rays, electrons, or neutrons by the systems of interest (2-4). Such experiments have led to detailed knowledge of the structure of water, the most important solvent for electrolytes (5, 6), but for electrolytic solutions the corresponding results have not been so definitive until very recently. In Fig. 2 is shown the function

$$G'(r) = 0.277 g_{Ni,O}(r) + 0.637 g_{Ni,D}(r) + 0.080 g_{Ni,Cl}(r) + 0.005 g_{Ni,Ni}(r) \quad [2]$$

as determined by neutron scattering from a 5M solution of $NiCl_2$ in D_2O by Soper, Neilson, Enderby, and Howe (7). The peaks at 2.05 and 2.65A are at expected locations for $g_{Ni,O}$ and $g_{Ni,D}$, respectively, on the basis of the structural data for crystalline $NiSO_4 \cdot 6D_2O$ (8). Their combined area corresponds closely to what may be expected for 6 D_2O molecules, so it may be concluded that $Ni(D_2O_6)^{++}$ is the predominant nickel species in the solution.

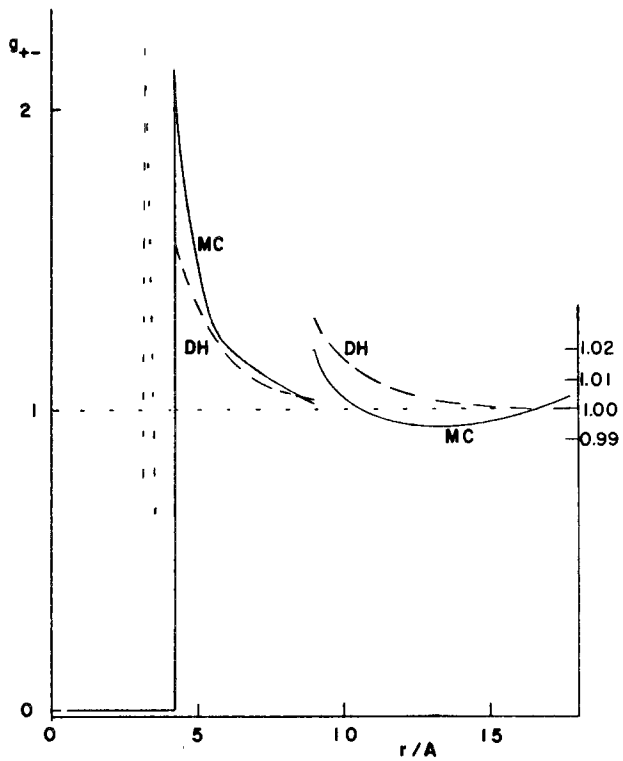

Fig. 1. The pair correlation function $g_{+-}(r)$ at molar ionic strength $I' = 1M$ for charged hard spheres of diam 4.2A. Calculated for a model for 1-1 electrolytes in water. DH: from Eq. [1]. MC: accurate calculation by the Monte Carlo method: [D. N. Card and J. P. Valleau, *J. Chem. Phys.*, **52**, 6232 (1970).] There is a change of scale at 9A to permit the wiggle in the accurate correlation function to be seen. The dashed-line curve showing a sharp peak at 3.25A is the peak in Fig. 2 that is attributed to the pair $Ni(H_2O)_6^{++}$, Cl^-. It is included in this figure to show what part of the ion-ion correlation function may be determined by diffraction from dilute solutions in favorable cases.

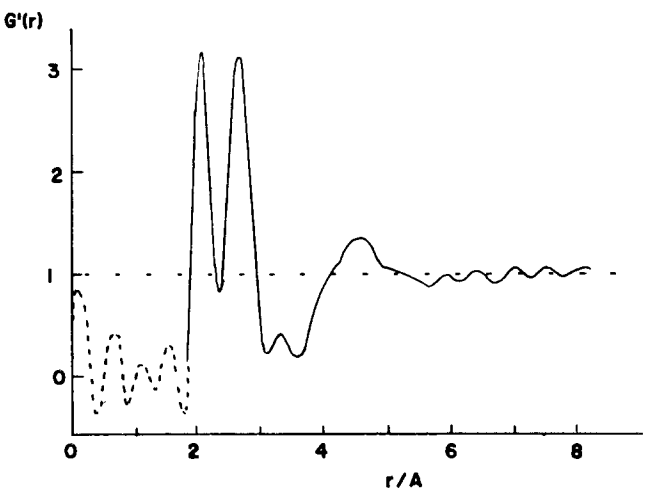

Fig. 2. Graph of Eq. [2] based on data of Soper *et al.*, Ref. (7). The dashed part of the curve is an artifact due to certain experimental limitations.

The authors suggest that the small peak at $r = 3.25$A is due to $g_{Ni,Cl}(r)$. A chloride ion sitting in a triangular face of the $Ni(H_2O)^{++}$ octahedron would give a center-to-center distance for Ni-Cl of 3.90A if the H_2O molecules are represented as spheres of diam 2.76A and Cl^- is represented as a sphere of radius 1.81A, its Pauling ionic radius. The appropriate hydrogen-bonded distances are only slightly smaller (9), so the 3.25A peak, if due to $g_{Ni,Cl}$, shows that the

octahedral $Ni(H_2O)_6^{++}$ is substantially distorted by the Cl^- being in contact with it.

Most of the scattering of radiation by a solution as dilute as 5M is from the solvent. The corresponding terms in Eq. [2], which would be proportional to $g_{O,O}(r)$, $g_{O,D}(r)$, and $g_{D,D}(r)$, were eliminated by the experiments by comparing the scattering from solutions which differ only in isotopic composition (7). The remaining terms may be classified as follows.

The ion-water interactions mainly determine $g_{Ni,O}$ and $g_{Ni,D}$. Conversely, these pair correlation functions bear the primary structural information that is needed for a molecular interpretation of solvation properties, those properties that characterize the interaction of an ion with a solvent. Some examples are given in Table I.

The ion-ion interactions mediated by the solvent determine $g_{Ni,Cl}$ and $g_{Ni,Ni}$. These pair correlation functions, together with $g_{Cl,Cl}$, bear the primary information needed to calculate the excess properties of the solution, those properties that describe how the results of measurements on the solutions vary with solute concentration. Some examples are given in Table II.

Equation [1], and other equations of what is often called the ionic interaction theory, pertain to ion-ion correlation functions, the type related to excess properties. We see from Fig. 2, which represents an unusually successful scattering experiment, that the direct experimental investigation of ion-ion pair correlation functions is, even with the best technology presently available, so difficult that only the strongest features of the ion-ion $g_{ab}(r)$ may be measured accurately. To show this most clearly, the presumed peak for $g_{Ni,Cl}(r)$ has been sketched in to scale in Fig. 1. On the other hand, it is found from model calculations that the thermodynamic excess functions, such as $\ln \gamma_\pm$, are sensitive to changes in the ion-ion $g_{ab}(r)$ at a level far too small to distinguish from the noise in Fig. 2.

Corresponding to the equilibrium pair correlation functions $g_{ab}(r)$, there are other correlation functions, called time-correlation functions (3, 10, 11), that are used to characterize the dynamical aspects of structure and that also are related by equations to the intermolecular forces on the one hand and to the measurable dynamical properties on the other. A simple example is the time-correlation function for the velocity v of a given particle

$$\langle \mathbf{v}(t + t_0) \cdot \mathbf{v}(t_0) \rangle$$

which is the equilibrium average $\langle \ldots \rangle$ of the product of its velocity at a time t_0 times its velocity at time $t + t_0$. It depends upon the fluctuations in a system at equilibrium. A typical simple form for a time correlation function is

$$\langle \mathbf{v}(t + t_0) \cdot \mathbf{v}(t_0) \rangle = \langle \mathbf{v}^2 \rangle e^{-t/t_v} \qquad [3]$$

where t_v is a characteristic time for the particular system. A typical general result is

$$D = \frac{1}{3} \int_0^\infty \langle \mathbf{v}(t + t_0) \cdot \mathbf{v}(t_0) \rangle dt \qquad [4]$$

where D is the diffusion coefficient of the particle whose velocity appears in the time-correlation function.

Intermolecular Forces

The correlation functions that characterize the structures of solutions can be expressed in terms of the solute-solute, solute-solvent, and solvent-solvent intermolecular forces, each the gradient of a potential u_{ab}. If species a and b both are round particles, then u_{ab} depends only upon r, the distance between their centers and we write $u_{ab} = u_{ab}(r)$. In the more general case, it now is customary to write $u_{ab} = u_{ab}(X_a, X_b)$ where X_j is a set of coordinates that specifies the location and orientation of a particle of species j.

The potentials $u_{ab}(X_a, X_b)$ can be calculated by solving Schroedinger's equation for the electrons of a and b moving in the field of the nuclei fixed at positions specified by the coordinates X_a, X_b. This direct theoretical approach is illustrated by the very impressive calculations of Clementi and his co-workers for ions and small sets of water molecules (12).

By studying the collisions of molecules by molecular beam techniques (13) and the thermodynamic and mechanical properties of crystals of known structures (14) one has direct experimental approaches to the relevant potential functions u_{ab}. The experimental approach sometimes is called the inverse process: one assumes functional forms for the needed u_{ab} potentials, thus specifying what may be called a Hamiltonian model. Next, some measurable properties of the model are calculated for comparison with the corresponding actual properties of the system of interest. Then the model potentials $u_{ab}(X_a, X_b)$ are adjusted to improve the agreement of the model properties with those of the real system. The difficult part of this program is the calculation of measurable properties of the model; it cannot be done exactly, but only by using some approximation method which must be evaluated for accuracy in this application.

The direct theoretical and direct experimental approaches to u_{ab} may be expected to be complementary, so it is advantageous to use them together. This procedure is nicely illustrated in the development of the Ben Naim-Stillinger (BNS) potential for the interaction of two water molecules (15). As an important example of the inverse process we cite the work of Rahman and Stillinger on models for water using the molecular dynamics approximation method (16). By applying the inverse process they progressed from the BNS model to the ST2 model for the water-water interaction.

Ionic Solvation

By ionic solvation we mean the interaction of an ion with a macroscopic body of solvent. This is the classical definition, but quite recently the term has been

Table I. Coefficients of solvation (26)

Limiting values of the following coefficients, measured on a solution of solute A in solvent W as the molar ratio $c_A = n_A/n_W$ approaches zero.

Transfer coefficients
ΔG, ΔH, ΔS for the process A(in W) → A(in W') where W' is a reference solvent or the vacuum.

Partial molal coefficients
$\partial/\partial c_A$ of any of the following solution properties: volume, heat capacity, coefficient of thermal expansion, compressibility, ϵ = dielectric constant, η = viscosity, sound velocity, NMR chemical shift of a solvent nucleus, shift of a solvent intramolecular vibration frequency.

Intrinsic solute coefficients
D_A, diffusion coefficient of A
ζ_A, friction coefficient of A (proportionality constant between the average velocity produced by a steady force upon A and the force
$(\tau\theta)_A$, rotational orientation time of A
$(\tau J)_A$, angular velocity correlation time of A
$CTTS_A$, charge-transfer-to-solvent spectrum of A

Table II. Coefficients of excess properties

Thermodynamic functions (HO[a] notation in quotation marks)
G^{ex}, the excess Gibbs free energy and its partial molal components 1 − "ϕ" and ln "$\gamma_\pm$"

H^{ex}, the excess enthalpy, and its partial molal components "L_1" and "L_2"

C_p^{ex}, the excess heat capacity, and its partial molal components "J_1" and "J_2"

V^{ex}, the excess volume, and its partial molal components "$\bar{V}_1 - \bar{V}_1^0$" and "$\bar{V}_2 - \bar{V}_2^0$"

Transport coefficients
"$\Lambda - \Lambda_0$", the excess equivalent conductance
"$D_a - D_a^0$", the excess coefficient of diffusion of component a

[a] HO refers to H. S. Harned and B. B. Owen, "The Physical Chemistry of Electrolyte Solutions," Reinhold Publishing Corp., New York (1943).

stretched to apply to the interaction of an ion with a small number of solvent molecules in the gas phase to form an ion-molecule cluster (17). The formation of small clusters may be regarded as a step in the process of solvation. Moreover, the data for small clusters (17) are exceedingly valuable for testing calculations of the ion solvent potential function $u_{ab}(X_a, X_b)$, as illustrated in several recent studies (12, 18, 19).

The structural aspects of ionic solvation have been greatly elucidated by magnetic resonance studies (20). When the solvent molecules next to an ion in solution comprise a "solvation complex" that exchanges solvent molecules with the bulk sufficiently slowly, then magnetic resonance techniques can be applied to characterize the complex as to stoichiometry, rate of rotation of the complex, and rate of exchange of the solvent molecules between the solvent and the bulk. This approach is specially powerful for studying the solvation of paramagnetic ions, in which case the experiments lead to the determination of certain spin parameters that carry information about the complex's electronic structure. The extensive contribution of work of this kind to our knowledge of solvation complexes in water has been reviewed by Taube (21) and by Hertz and Zeidler (22). The methods may be even more powerful when applied to nonaqueous solvents (23) or their mixtures with water (24) because of the lower exchange rates and the greater temperature range that is accessible. While progress in elucidation of structure in this area has been great, it must be noticed that these advances relate only to ion-solvent complexes with well-defined geometry and relatively long life. A typical example is $Mn(H_2O)_6^{++}$ in water. The lifetime of a water molecule in the complex before it exchanges with the bulk is about 10^{-8} sec, which is rather long compared to the lifetime of 10^{-11} sec expected if the exchange is a simple diffusion process, in which case we would have $t_{\text{lifetime}} = \langle r^2 \rangle / 6D$ with $\langle r^2 \rangle^{1/2} = 3\text{A}$ and $D = 1 \times 10^{-5}$ cm^2/sec.

Another example is $Ni(H_2O)_6^{++}$, for which the exchange lifetime is about 3×10^{-5} sec; it is interesting to note that the stoichiometry of the complex, as established by magnetic resonance methods which only are applicable to relatively long-lived complexes, is confirmed by the data in Fig. 2 which are obtained by a technique that does not have this limitation.[2]

When a complex is long lived and has well-defined geometry, then the concepts and techniques used traditionally in the study of chemical bonds are applicable. Moreover, in such cases the structures actually found in solution are closely similar to those found for the same ions in their crystalline salt hydrates. As mentioned in the opening paragraphs of this paper, the situation is quite different in the study of the "structures" more typically due to intermolecular forces, to which we now return.

A traditional approach to the structural aspects of solvation is through the comparison of solvation data with the predictions of BBB models (26) (brass balls in a bathtub models, a term due to Professor H. S. Frank). In a BBB model the ion is treated as a macroscopic body, and the solvent as a medium characterized by macroscopic properties such as viscosity, dielectric constant, etc. These coefficients, like those of the real solvents, may depend upon field strength, frequency, and other relevant variables as well as temperature and pressure. The BBB model theories for many of the coefficients in Table I are well known (26), for example, Born's equation for the ionic solvation free energy

$$\Delta G_a = (1 - 1/\epsilon)\, e_a^2/2r_a \qquad [5]$$

and Stokes' law for the friction coefficient

$$\zeta_a = 6\pi\eta r_a \qquad [6]$$

In these equations, e_a is the charge and r_a the radius of an ion of species a.

The traditional approach is to attribute deviations of solvation coefficients from the simple BBB model predictions to the formation of solvation complexes. In the case of the equations chosen for examples, the effect of forming the solvation complex would be to increase r_a to a value greater than the ion's Pauling crystal radius. For example, the friction coefficients (inverse ionic mobilities) of the alkali metal ions decrease in the series from Li^+ to Cs^+, in contrast to the prediction of Eq. [6] if ionic radii are used. This suggests that the small ions form rigid solvation complexes so their "hydrodynamic radii" become larger than their crystal radii. However, it has been proposed by several authors, most recently Zwanzig (27), that one should use a more elaborate BBB theory to allow for the "dielectric drag" acting on a charged object when it is pulled through a medium with a frequency-dependent dielectric constant. The resulting theory leads to a graph of ζ_a as a function of r_a that has a minimum (26, 28). The trend in the friction coefficients of the alkali ions in water is accounted for by observing that these ions lie to the left of the minimum, in a region where the effect of the dielectric drag is greater than the hydrodynamic drag accounted for by Eq. [6]. With more extensive data even the minimum can be located (28). One is left with no basis for interpreting these data in terms of structural effects, at least involving rigid hydration.

A similar critique can be made of the extensive work aimed at extracting structural information by comparing Eq. [5] with experiment (29). An interesting approach is to introduce the concept of a nonlocal dielectric constant: In a nonuniform field the polarization per unit volume in a given small region in the medium depends on the electric field everywhere in the medium, not just in the given small region. It has been shown that introduction of a nonlocal dielectric constant modifies the BBB model for the solvation free energy so that it is in reasonable agreement with the data for hydration of alkali and halide ions (30). The resulting picture of ionic hydration is rather close to that provided by the theory of Voet (31), which is better known in its elaboration by Latimer, Pitzer, and Slansky (31), but the implications for the structure of the solvation complex are now greatly weakened.

Another example, pointed out by Onsager and Hubbard (32) concerns the coefficient ϵ_1 in the equation

$$\epsilon = \epsilon_0 + c\epsilon_1 + \ldots \qquad [7]$$

for the dependence of the dielectric constant ϵ of aqueous solutions upon the electrolyte concentration c. While ϵ_1 has been interpreted (33, 34) in terms of the structures of particular solvation complexes, Hubbard *et al.* (32) point out that the dominant contribution from ϵ_1, as it was calculated from the high frequency measurements, comes from the effect that is inverse to dielectric drag according to their BBB model calculations.

It should be pointed out before leaving this subject that BBB model calculations are often amazingly accurate when applied to small solute molecules; the most recent evidence is in the comparison of new theoretical (35) and experimental results (36) for the rotational correlation time (t_θ in Table I) for solute molecules in nonhydrogen bonding situations. These results add to the growing body of evidence that for realistic hydrodynamics in BBB model calculations in systems without hydrogen bonds, the boundary conditions at the surface of a particle should be "slip" rather than "stick." For example in Eq. [6] the coefficient 6 should be changed to 4.

Solutes in water often are classified as structure making or structure breaking, following Frank and Evans (37) who used the behavior of the solute partial molal entropy as a criterion. The distinction shows

[2] Similarly, Bol has shown by a specialized x-ray diffraction method that the coordination of a number of other M^{++} ions is nearly the same in solution as in salt hydrates (25).

up in many other properties as well (29). Alone among the many classifications, that of Stillinger and Ben-Naim (38) is based on the behavior of the equilibrium pair correlation functions. They deal with the correlation between an O atom in a water molecule and the H atoms in all of the other water molecules in the solution. They show how the quantity

$$\int_0^\infty [g_{OH}(r) - 1]4\pi r^2 dr$$

can be calculated from compressibility data and how it changes according to whether a structure maker or structure breaker is added to water.

Information about solvation structural effects sometimes has been deduced from data for the dependence of the diffusion coefficient D_a of a solute particle upon its mass m_a. Mills and Dunlop have reviewed the data for this effect as well as the relevant theories (39). The effect seems in fact to be small to the vanishing point, and there is no evidence, either experimental or theoretical, for having D_a proportional to $1/\sqrt{m_a}$ (39).

The Hall effect for ionic solutions is a very small effect that is easily obscured by other electromagnetic effects associated with convective rather than diffusive motion. It can be used as a probe for the very short time behavior of the time correlation function for the ionic velocities (40). Very recently new measurements for the Hall effect have been reported which seem quite reliable. They indicate that for some ions in water (Li^+, H^+, OH^-, F^-, . . .) the deviations from Eq. [3] are easily detectable by the Hall effect measurements (41). The implications of this finding in more picturesque structural terms are not yet clear.

Excess Properties

Long-range behavior of ion-ion $g_{ab}(r)$.—Progress in the study of the structural aspects of the excess properties has been historically coupled closely to the so-called interionic attraction theory; essentially the Debye-Hückel theory and its close descendants. More recently vast improvements in the theoretical treatment of excess equilibrium properties have derived from developments in statistical mechanics in areas connected remotely, if at all, with the Debye-Hückel theory. Reference may be made to reviews by Friedman (42), Rasaiah (43), Andersen (44), and Outhwaite (45) for accounts of this work; Outhwaite alone has also described the newer developments that are derived from the Debye-Hückel approach. Also, an article by Friedman and Dale (2) is designed to provide the background in statistical mechanics that is necessary to follow and employ many of the new advances in techniques for calculating solute-solute correlation functions $g_{ab}(r)$ and the resulting thermodynamic excess functions of model systems. (For further discussion of the models see the next section.)

In the cluster expansion technique the correlation function of interest is represented by an infinite series whose terms may be written as graphs, each graph being a number of vertices (particles) connected by bonds (interactions.) The first terms in the cluster expansions give the limiting laws. The hypernetted chain (HNC) approximation was first obtained as a partial sum of this series; an infinite number of the graphs including what may be expected to be the most important ones for calculating properties up to moderate concentrations. The mean spherical approximation (MSA) has some of the strong features of the HNC, but for sufficiently simple models the MSA can be solved exactly to give algebraic expressions for the excess thermodynamic properties. In the Monte Carlo approximation method one simulates, by direct computation, the behavior of a system like the one of interest except that the Monte Carlo system is a crystal whose cubic unit cell contains perhaps 200 particles. The distribution of particles within a cell is random like that in the fluid being simulated, but every cell in the infinite crystal has the same distribution, leading to what are called periodic boundary conditions for the cell being simulated. For details of these and other new and promising approximation methods Ref. (2, 42-45) may be consulted.

Here and in the following section, an effort is made to concentrate on the "structural" aspects of these developments. The usual form of the Debye-Hückel limiting law is

$$\ln \gamma_\pm = -|e_+ e_-|\kappa/2\epsilon kT \quad \text{as} \quad \kappa \to 0 \qquad [8]$$

where

$$\kappa^2 = (4\pi/\epsilon kT) \Sigma\, c_s e_s^2 \qquad [9]$$

defines the Debye kappa in terms of the concentrations c_s and charges e_s of ions of species s, and in terms of the temperature T and the solvent dielectric constant ϵ. To pass on to the other limiting laws it is more convenient to begin with the Debye-Hückel limiting law for the excess free energy per unit volume, which we denote as $a^{ex}kT$.

$$a^{ex} = -\kappa^3/12\pi \quad \text{as} \quad \kappa \to 0 \qquad [10]$$

A more complete theory gives a "higher-order limiting law" as well

$$a^{ex} + \kappa^3/12\pi = \kappa^4 \ln(\kappa L) \Sigma\, c_s e_s^3 \quad \text{as} \quad \kappa \to 0 \qquad [11]$$

where L is any length, although some particular choice such as the Bjerrum length $L_B = e_{el}^2/\epsilon kT$ may be especially convenient. The quantity on the left of Eq. [11] is experimentally determinable, and the quantity on the right does not depend on ion sizes and other specific characteristics, so Eq. [11] is indeed a limiting law in the same sense as Eq. [8] or [10]. It was first noticed by Gronwall and co-workers (42) but also has been derived in another way (47). The right side of Eq. [11] vanishes for symmetrical electrolytes and is apparently never larger than both $\kappa^3/12\pi$ and the remaining contributions to a^{ex}, which do depend upon the ion sizes and other specific characteristics, so it is not surprising that it was first measured by precision experiments only recently (48). Gibbard's results (48) are in satisfactory agreement with the theory.

The limiting-law behavior in Eq. [11] is also characteristic of other thermodynamic coefficients such as the excess energy, for which the corresponding equation can be derived by thermodynamic operations on Eq. [11]. Moreover, a similar expression also characterizes nonthermodynamic excess coefficients such as the excess equivalent conductivity Λ-Λ_0, as one can see from the well-known theory (49). (Here we subtract Λ_0 because it is the part of Λ that is a solvation coefficient; the difference is an excess function.)

Other limiting laws have been established for mixtures of two ionic solutions having one ionic species common to the two components. Thus, we consider the experiment in which solutions of pure AX_n and BX_n, both at the same ionic strength, are mixed in various proportions (*cf.* Fig. 3). The deviation of a^{ex} from the linear interpolation at $y = \frac{1}{2}$ (see Fig. 3) is a measurable excess function which we may call

$$\tfrac{1}{4} I'^2 g_0'$$

where the primes specify molar (rather than molal) concentration scales (47, 50). The coefficient g_0' is the simplest excess function that is characteristic of electrolyte mixtures. It plays the same role as the sum of Harned coefficients. It obeys the limiting law

$$(1/g_0')(dg_0'/d\kappa) = e_A^2/\epsilon kT \quad \text{as} \quad \kappa \to 0 \qquad [12]$$

While this example is for a given class of charge types for simplicity, the general form for mixing A_mX_n with B_mX_n or A_mY_n also is known (47). However, in a mixture of two electrolytes of different charge types, in particular with different values of $c_+e_+^3 + c_-e_-^3$, the limiting law in Eq. [12] is unob-

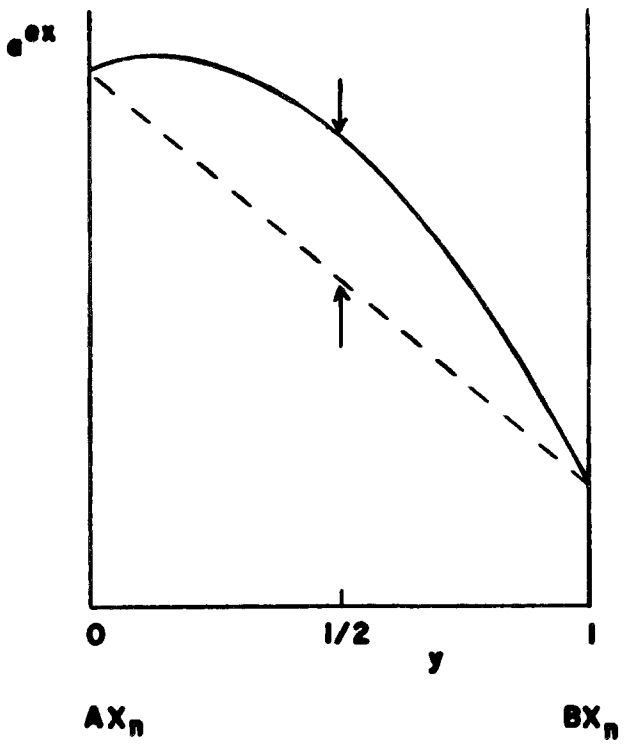

Fig. 3. The excess free energy function of a mixture of electrolyte solutions as a function of the mixing ratio. The initial solutions AX_n and BX_n are taken to have the same molar ionic strength I'.

servable because another limiting law with stronger dependence upon κ (or I') takes over. For a mixture of electrolyte of NaCl type with one of $CaCl_2$, the limiting law is (51)

$$g_0' = 1.205 \times 10^{-4}\left(\frac{4\pi}{3} L_B^3\right) \ln \kappa L \text{ as } \kappa \to 0 \quad [13]$$

These mixture limiting laws reflect failure of the ionic strength principle, according to which ionic activity coefficients only depend upon the ionic strength. Moreover, the coefficient g_0' in Eq. [12] is due to differences in the specific interaction in the pairs AA, AB, and BB, so this limiting law is an exact result that would be disallowed by Bronsted's principle of specific ion interaction, which only allows specific interaction of pairs of ions of opposite sign of charge. Thus, neither the ionic strength principle nor the Bronsted principle is consistent with the nonzero values of g_0' and other mixing coefficients (47, 51) actually found by experiment (50).

The structural consequences of these limiting laws may be found in the behavior of the ion-ion pair correlation functions $g_{ab}(r)$ at large r and small κ. For example, as found by Debye and Hückel, the behavior

$$\ln g_{ab}(r) \to -e_a e_b e^{-\kappa r}/\epsilon kTr \text{ as } r \to \infty \text{ and } \kappa \to 0 \quad [15]$$

is equivalent to Eq. [8] or [10].

Other conditions on the ion-ion correlation functions are the zeroth moment condition (formerly called the local electroneutrality condition)

$$\Sigma_b c_b e_b \int_0^\infty (g_{ab}(r) - 1) 4\pi r^2 dr = -e_a \quad [16]$$

and the second moment condition of Stillinger and Lovett (52)

$$\Sigma_a \Sigma_b c_a c_b e_a e_b \int_0^\infty (g_{ab}(r) - 1) r^2 4\pi r^2 dr = -3\epsilon kT/2\pi \quad [17]$$

where, in both equations, the sums are over ionic species. These exact conditions have structural consequences. It is well known that Eq. [8] implies that each ion of charge e_a is surrounded by an "atmosphere" whose net charge is $-e_a$. That statement is merely a reading of Eq. [16]. The corresponding pictorial interpretation of Eq. [17] has the consequence that in any solution whose κ exceeds a certain value κ^*, the correlation functions $g_{ab}(r)$ must have "wiggles" or oscillations (52). For electrolytes in water at 25° one has $\kappa = \kappa^*$ at an ionic strength near 6M, depending on ion sizes. However, the critical ionic strength for the onset of wiggles is shown to be as low as 2M by various model calculations (45). These wiggles are not predicted by Eq. [1] or any of the other familiar modifications of the Debye-Hückel theory. However, they are given by many more powerful approximation methods which may be used to calculate the $g_{ab}(r)$ from the Hamiltonian models, among them the HNC equation and a method of Outhwaite's that is a generalization of the method of Debye and Hückel (45). Qualitatively similar wiggles also appear in the correlation functions of nonionic fluids at sufficiently high densities.

Any excess property W of a solution can be expressed in the form

$$W = \Sigma_a \Sigma_b c_a c_b \int_0^\infty W_{ab}(r) g_{ab}(r) 4\pi r^2 dr \quad [18]$$

where $W_{ab}(r)$ is a weight function that is different for each property. This equation has a simple meaning: each pair ab at a specified separation r makes a contribution $W_{ab}(r)$ to the excess property W. We can expect that $W_{ab}(r)$ goes to zero as r goes to infinity because the influence of a on b must vanish in that limit. For excess thermodynamic properties, as well as some others, the longest range part of W_{ab} is of the form

$$f_W e_a e_b / r \quad [19]$$

which comes from the coulomb term $e_a e_b/\epsilon r$ in the potential of the force between two ions. For example, to calculate the osmotic coefficient we have $f_W = 1/6\epsilon$, to calculate the excess energy we have $f_W = (\partial/\partial T^{-1})(1/6\epsilon T)$, etc. (47). Because $\Sigma_a \Sigma_b c_a c_b e_a e_b = 0$ we can replace g_{ab} in Eq. [18] by g_{ab}^{-1} as far as the term in Eq. [19] is concerned. Now we must look closely at the expression

$$f_W e_a e_b \int_0^\infty (1/r)(g_{ab}(r) - 1) 4\pi r^2 dr \quad [20]$$

The integral diverges unless g_{ab}^{-1} goes to zero fast enough at large r. Consequently, the exact way in which g_{ab}^{-1} goes to zero as $r \to \infty$, one says the "asymptotic form of g_{ab} at large r," may be decisive in determining the value of the integral in Eq. [18]. So it is interesting to ask what is known about the asymptotic form of g_{ab} at large r.

Most often it has been assumed that Eq. [15] is valid even when κ is nonzero; then we would have

$$g_{ab}(r) - 1 = -e_a e_b e^{-\kappa r}/\epsilon kTr \text{ as } r \to \infty, \quad \kappa \geqq 0 \quad [21]$$

but there is no theoretical basis for this assumption. In fact, the structural question as to the asymptotic form of g_{ab}^{-1} at large r has not been answered in a satisfactory way, although there are two proposals that merit serious consideration. Thus, Stell and Lebowitz (53) find a form just like Eq. [21] but with κ replaced by a new coefficient κ_{ab} that depends upon the short-range interaction of the ions but becomes identical to the Debye-Hückel κ in the limit of zero concentrations of the ions. On the other hand, Stillinger and White, using a very different method, find (54)

$$g_{ab}(r) - 1 = A_{ab}/r^8 \text{ as } r \to \infty \quad [22]$$

at finite ion concentrations, although A_{ab} is proportional to the square of the total ion concentration so that at zero concentration Eq. [21] still governs.

So at the present time the asymptotic form of $g_{ab}(r)$ at large r and at nonzero concentration is not known, important though it may be.

Short range behavior of the ion-ion $g_{ab}(r)$.—As soon as we look beyond the limiting laws to see what structural information is in the remaining contributions to the excess properties, we encounter the short-range behavior of $g_{ab}(r)$. To discuss the advances in this area, it is convenient to supplement the discussion of the potentials $u_{ab}(r)$ and $u_{ab}(X_a, X_b)$. Those potentials now will be termed BO potentials (Born-Oppenheimer potentials) to distinguish them from the MM potentials (McMillan-Mayer potentials) that we need to introduce now (2, 42, 44, 47). The BO potentials are the potentials of the forces among the particles at fixed locations of the nuclei but with the appropriate quantum-mechanical average over the coordinates of the electrons in the system. The MM potentials $\bar{u}_{ab}(r)$ are the potentials of the forces among the ions if we make the appropriate average over the coordinates of the solvent molecules. (The electronic averages are implicitly included in the MM potentials. Also, it should be pointed out that the pair potentials u_{ab} or $\bar{u}_{ab}$ are in general not sufficient to describe a real system exactly; in addition to these 2 point potentials one needs also 3 point potentials, 4 point potentials, etc.) (2).

The theory of McMillan and Mayer (2, 42, 44, 47) shows that all of the equilibrium properties of a solution, as well as the ion-ion correlation functions $g_{ab}(r)$, can be expressed in terms of the MM potentials $\bar{u}_{ab}$ together with the higher n point potentials that will be neglected here. In the limit of small ion concentration we have

$$g_{ab}(r) = \exp(-\bar{u}_{ab}(r)/kT) \qquad [23]$$

For moderate concentrations, say molar ionic strength I' up to about 3M, the typical concentration dependence of $g_{ab}(r)$ is indicated schematically for several cases in Fig. 4. To summarize in words:

1. The behavior at large r, where $g_{ab}(r)$ is near unity, changes drastically as I' increases. This aspect results from the features discussed previously.

2. The small r behavior is weakly dependent upon I'. The changes are qualitatively just those expected on the basis of the Debye-Hückel ion atmosphere effects (55, 56). Thus for a $+-$ pair the first peak in g_{ab} is flattened by Debye-shielding while for a $++$ or a $--$ pair the population of close pairs is increased by the Debye shielding.

While the ionic strength dependence of the close-in part of the ion-ion pair correlation functions is not very strong, small changes in the correlation functions make rather marked changes in the thermodynamic excess functions. Thus, it can be understood that the mean spherical approximation (2, 43, 45) and many of its descendants, although they are consistent with the zeroth moment condition and the second moment condition [so they must give a reasonably accurate account of the I' dependence of the large r part of $g_{ab}(r)$], and which also give qualitatively the correct I' dependence of the small r part of $g_{ab}(r)$, still are not very satisfactory for calculating the measurable properties of model systems just because they are not accurate enough in the small r range. Fortunately, the HNC and Monte Carlo approximation methods do seem accurate enough for most purposes and give consistent results (45). Moreover, for a given model the qualitative features of $g_{ab}(r)$ at small r will be satisfactorily given by the MSA (43, 45) because, as noted above, the I' dependence is not strong in this region.

One can learn about the relatively short-range part of $g_{ab}(r)$ in the following way: (*i*) Construct Hamiltonian models for the solutions of interest by choosing MM potentials $\bar{u}_{ab}(r)$ for each ionic species pair. As far as possible, the model should be consistent with what is known about the ions and the solvent. (*ii*) Calculate the model's ion-ion correlation functions $g_{ab}(r)$ over a range of ionic strength. (*iii*) Use the appropriate version of Eq. [18] to calculate measurable properties from the $g_{ab}(r)$ at each I'. (*iv*) Compare the results with experimental data for the system of interest, correct the model potentials to improve the agreement, and then repeat steps (*ii*), (*iii*), and (*iv*) until agreement is satisfactory.

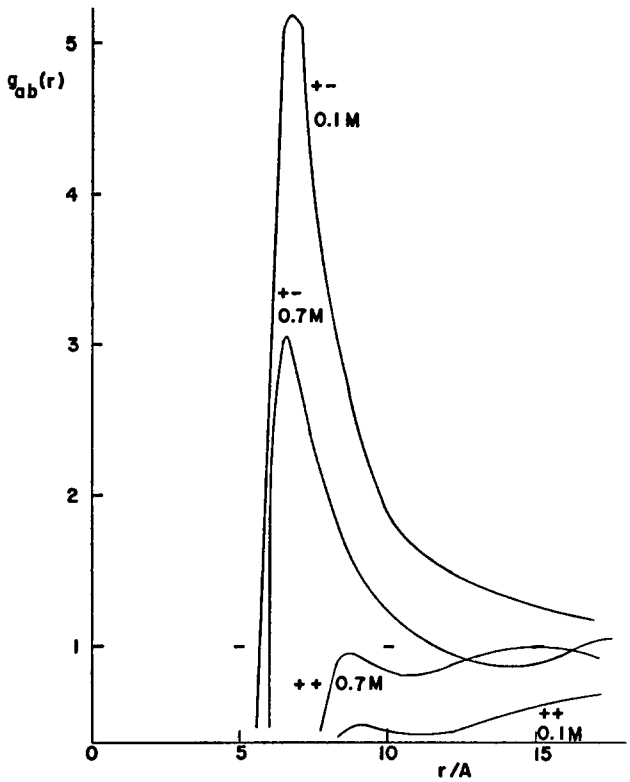

Fig. 4. Correlation functions at 0.1 and 0.7M to show the typical effect of increasing concentration. The curves below 7A are accurately calculated for a model for $NiCl_2$ that fits the osmotic coefficient data fairly well, while above 7A the curves are merely schematic. They show in exaggerated form the oscillations in $g_{ab}(r)$ at large r that appear at high concentrations.

This program has actually been carried out for the excess free energies of aqueous solutions of alkali halides (58), alkaline earth halides (55), tetraalkyl ammonium halides, common-ion mixtures of 1,1 electrolytes with those of charge type 1,1 (58) or 2,1 (51, 55), and with nonelectrolytes (58). In a few cases, calculations also were made for excess enthalpies and excess volumes.

An overview of all of these results (58) shows that in general it is quite easy to fit models to the thermodynamic excess function data, at least when the adjustable part of $\bar{u}_{ab}(r)$ is a sort of adjustable well or mound to represent the effect of overlap of the solvation layers or cospheres on ions a and b when the ions are close together, *i.e.*, close enough so no more than 2 or 3 water molecules will fit on the line of centers (55, 57, 58). It is found that such a term, suggested some time ago by Frank (37) and by Gurney need not be large compared to kT to enable one to fit the model to the data (58). Moreover, the way the Gurney overlap term depends on the species pair ab is reasonably consistent with the results of other investigations of ion interactions in solution (58).

However, there are great problems in trying to find out what model potentials $\bar{u}_{ab}$ uniquely fit the data best, as may be expected from the form of Eq. [18] (58). This situation has led to current efforts to calculate nonthermodynamic excess properties of the same model systems.

Extensive work in this area has already been carried out by Ebeling *et al.* (59, 60). They fit model potentials simultaneously to excess free energy data and to conductivity data for alkali halides and tetraalkyl ammonium halides in a vast least squares loop using approximation methods that they have devised for the purpose. This approach is still in development but the results announced so far are mostly consistent with those reported by Friedman *et al.* (58) and, for R_4NX salts, by Wen and Streng (61).

A strong feature of the program of Ebeling *et al.* (60) is that the electrical conductivity can be measured accurately for every solution for which the thermodynamic excess functions can be determined. On the other hand a qualitative examination of the equations shows that the weight function W_{ab} in Eq. [18] for calculating excess conductivity is not so different from that for the excess free energy. This situation tends to reduce the chance that a model that can be fit well to the thermodynamic data will fail to fit the conductivity data. Of course it is through only failures of this kind that we can, by elimination, identify uniquely satisfactory models!

In some cases, one has weight functions which vanish except for a single species pair, *i.e.*

$$W_{ab}(r) = \delta_{aa'}\delta_{bb'}W_{a'b'}(r) \qquad [24]$$

where $\delta_{ij} = 0$ unless $i = j$, and $\delta_{ii} = 1$. One example is the weight function for the calculation of the results of neutron diffraction experiments with a suitable number of isotopic substitutions (2, 7). A closely related example is one in which there is a range of scattering angles in a diffraction experiment in which only one species pair contributes significantly to the scattering, as for solutions of Ph_4AsCl in water. In this case only the $++$ pair contributes to the scattering in the small angle range, *i.e.*, to $I(s)$ in the range $0 \leq s \leq 0.3/A$ (56).

Finally another suggestion for realizing Eq. [24] is the study of the relaxation rate of a nucleus in one ion (a′) due to dipolar interaction with another ion (b′) (58). In this case the property W calculated in Eq. [18] is just the rate constant of the relaxation reaction, for example

$$^7Li^+(m) + Ni^{++} \rightarrow {}^7Li^+(m') + Ni^{++} \qquad [25]$$

where m is the index of the nuclear spin state of the lithium ion; $-3/2$, $-1/2$, $1/2$, or $3/2$.

These efforts at characterizing $\bar{u}_{ab}(r)$ more completely on the basis of the experimental evidence are no doubt rather limited because Eq. [24] can be realized in actual experiments for only relatively few pairs of ions. However, it is reasonable to expect that in time these new developments will be followed by others; very little work has been done in this area compared to those reviewed before.

A complementary line of investigation is the use of Monte Carlo and molecular dynamics approximation techniques to calculate the McMillan-Mayer potentials $\bar{u}_{ab}(r)$ from the relevant BO potentials, the latter being calculated from the Schroedinger-level Hamiltonian, which is of course well known. The initial reports of work in this area by Heinzinger and Vogel (62), Clementi and co-workers (63), and Beveridge and Schnuelle (64) demonstrate that this approach is feasible. One can expect that it will be complementary to the "inverse method" of determining the MM potentials.

There is reason to hope that in the next 25 years the combination of the two approaches will lead to as detailed information about the potentials $\bar{u}_{ab}$ for ions in solution as we have at present about the potential $u_{Ar,Ar}$ for the interaction of two argon atoms in the gas phase. Then we will know to what extent ions in solution penetrate each other's cospheres when they collide, we will understand how the MM potentials and the excess properties are related to the structure-making and structure-breaking properties, and we will know the structure of a hydrophobic bond as it is reflected in the potentials $\bar{u}_{ab}$ of the force between two hydrophobic species. These are the questions that may be answered by the delicate interaction of theory and experiment along the lines that have developed in the period under review.

DISCUSSION SECTION

This Discussion Section includes discussion of a paper appearing in the *Journal of The Electrochemical Society*, Vol. 124, No. 1; January 1977.

Electronegativity, Ionicity, and Effective Atomic Charges

J. P. Suchet (pp. 30C-35C, Vol. 124, No. 1)

B. Chatterjee:[1] The following comments may be useful to those interested in the nature of chemical bonding in general. The concept of electronegativity is primarily limited by the fact that the effective electronegativity of a free atom is different from that of an atom in a molecule due to a hybridization state and/or a net charge of the atom.[2-5] From the bonding energy data of diatomic molecules, Pauling[6] identified the "excess resonance energy" between the bonded atoms as being equal to the square of the difference of electronegativities of the atoms

$$D_{AB} = \tfrac{1}{2}\,(D_{AA} + D_{BB}) + 23.06\,(X_A - X_B)^2 \quad [1]$$

where D_{AB} is the bond energy between A and B atoms in AB; D_{AA} and D_{BB} are the bond energies of A and B, respectively, in their free states, and X_A and X_B are the corresponding electronegativities. Equation [1] is criticized[7] in not being able to provide a correct bond energy value when more than one bond is involved. For solids containing either divalent or multivalent atoms, Eq. [1] is believed to give an estimate of the energy of the last bond in the molecule after all other bonds have been removed. Following the work of Sanderson, Vijh[7] thus used an equation involving thermochemical parameters to estimate the bond energy of multibonded compounds

$$D_{AB} = [(\Delta H_s)_A + (\Delta H_s)_B + (\Delta H_f^\circ)_{AB}]/n \quad [2]$$

where ΔH_s denotes heat of sublimation of the bonded atoms in free states, $(\Delta H_f^\circ)_{AB}$ is the standard heat of formation of AB, and n is the participating valency. Equation [2] does not require any data on electronegativity. The validity of either of the above equations is next assessed in terms of a fundamental thermal property, namely Debye temperature θ_D. From various theoretical treatments of Lindemann's equation relating θ_D of a metal to its melting point,[8,9] it is feasible to correlate θ_D with D_{AB} as

$$\theta_D = C(D_{AB}/m\,a^2)^{1/2} \quad [3]$$

where C is a proportionality constant, while m and "a" are the molecular weight and lattice parameter, respectively, of AB. In view of the importance of semiconducting compounds as well as Dr. Suchet's reference to such compounds in the paper under discus-

Table I

Semiconductor	Type, $A^X B^Y$ X − Y	Bond energy, D_{AB}: $D_{AB(1)}$ from Eq. [1] (kJ mole^{-1})	Bond energy, D_{AB}: $D_{AB(2)}$ from Eq. [2] (kJ equivalent^{-1})	$\theta_D/(D_{AB}/m\,a^2)^{1/2}$: Using $D_{AB(1)}$	$\theta_D/(D_{AB}/m\,a^2)^{1/2}$: Using $D_{AB(2)}$
AlSb	III-V	413.6	230.1	34.3	45.9
GaAs	III-V	410.2	193.4	35.4	51.6
InAs	III-V		202.5		46.2
InSb	III-V	290.4	178.8	38.1	48.5
β-ZnS	II-VI		230.6		38.1
ZnSe	II-VI		250.3		37.4
ZnTe	II-VI		224.1		39.9
β-CdTe	II-VI		205.6		35.7
HgTe	II-VI		135.4		44.4
HgSe	II-VI		155.1		38.9
PbS	IV-VI		208.9		45.9
PbTe	IV-VI		230.7		43.4

sion, appropriate data for Eq. [3] have been compiled for these compounds with zinc blende cubic structures. The D_{AB} values (Table I) have been estimated from both Eq. [1] and [2] using the necessary data.[10,11] Electronegativities of metals are obtained from those revised by Sanderson.[12] The molecular weights and lattice parameters are obtained from those compiled by Greenwood[13] and Smithells,[14] respectively. From a critical analysis of θ_D values of various semiconductors[15] the best reported data have been used in the present text. A linear relation between θ_D and $(D_{AB}/m\,a^2)^{1/2}$ is obtained in accordance with Eq. [3] with the proportionality constant being estimated to be 36 ± 2 and 43 ± 8 for D_{AB} values obtained from Eq. [1] and [2], respectively (Table I). A similar linear relation is also obtained for metals with face-centered cubic structures where the constant is evaluated as 43 ± 6. It thus appears that the concept of electronegativity affecting the bond energy of intermetallic compounds is not of primary importance in case of solids involving divalent or multivalent atoms. It is to be pointed out that due to the lack of reliable data on bond energies of metals required for Eq. [1] the corresponding values for proportionality constant are shown to be limited (Table I).

In the paper under discussion the ionicity values (Λ) of semiconducting compounds with zinc blende structures are shown to be varying from negative to positive values. According to Dr. Suchet, a negative value implies the compound to be more covalent than the homopolar state selected as a reference. It appears that the Hall mobility, *i.e.*, carrier mobility does not follow the nature of bonding given in the paper under discussion. For example, although Λ values vary from −0.17 for GaSb to +0.16 for GaAs, implying a more covalent bonding and, hence, lower Hall mobility in GaSb, the electron mobilities in these compounds are similar (4000 cm^2/V-sec).[16] A plausible explanation of this apparent discrepancy can be put forward in terms of Goodman's theory[17] according to which the Hall mobility is primarily associated with the interaction of the carriers with the lattice vibrations. The mobility of the carriers with an ionic contribution can be correlated to the energy gap which is taken as a measure of the ionic contribution to the bond. From a plot of the experimental mobilities of various compounds against the bond dipoles it can be suggested that the addition of an ionic component of bonding will strengthen the bond, hence reducing the amplitude of lattice vibrations and the amount of lattice scattering by phonons, and increasing the Hall mobility. However, when the bond becomes more and more ionic in character, optical modes of oscillation become important and the mobility is reduced. The present explanation for similar Hall mobility in compounds with different bond ionicities can be best verified if such mobilities are known in compounds of extreme ionicities, namely the mobilities in ZnS and AlSb whose Λ values are given as +0.54 and −0.33, respectively, in the paper under discussion. A similar Hall mobility is expected in these two compounds.

J. P. Suchet:[18] Dr. Chatterjee really wanted to publish a few remarks himself on the concepts of electronegativity and bond energy, which is what he covered in the first two thirds of his text. I do not object to the publication of these remarks, but I do not see their link with my paper.

In the last paragraph of his text, Dr. Chatterjee refers to my paper, but shows that he entirely misunderstood it. He says that the Hall mobility does not follow the value of the ionicity. Why would it follow this value? I had said that "if no other factor limits the value of the mobility of the majority carriers in a crystal, this mobility must rise with decreasing elementary dipole (and charge q)." There is nothing original in this. Everybody knows it. By "dipole", I mean, of course, q times interatomic distance. In GaSb (−0.17 +0.17) and GaAs (+0.16 −0.16), the dipole has about the same absolute value and there it is not surprising to find about the same mobility (4000 cm^2/Vsec). Where is the discrepancy? Dr. Chatterjee has probably confused the ionicity Λ and the effective static charge q. Moreover, he also mentions the occurrence of lattice vibrations, which would lead to the appearance of a dynamic charge e and modify the situation considered, so that no simple conclusion could be drawn any longer.
