The first stages of the potentiostatic formation of lead dioxide on lead in aqueous sulfuric acid proceeds in a similar manner at 25°C as at lower temperatures (to ≤ −50°C) with one important difference. At 25°C, before application of the charging potential, the electrolyte deep within the pores is relatively dilute and slightly alkaline due to the impermeability of a thick lead sulfate film to certain ions responsible for the creation and maintenance of an alkaline electrode interior. At temperatures much below 0°C, the electrolyte in the pores probably freezes except for a very thin film (a few molecular diameters) of adsorbed water between the pore walls and the frozen electrolyte. At low temperatures, therefore, the diffusion processes must take place through this adsorbed water phase or through a barrier caused by some other mechanism of pore blockage. Furthermore, the chemical reactions, which supply reactants for the electrochemical steps or remove products, must also occur in this interfacial phase, probably with altered equilibrium constants or under conditions further removed from equilibrium.

Rate-limiting diffusion of ions, such as $PbOH^+$ or Pb^{++}, is controlled by an activation process involving partial dehydration of the diffusing ion and/or desorption of interfacial water. Prior to the two-dimensional nucleation and growth interval (when basic sulfates are oxidized in a thin layer beneath the lead sulfate), the current appears to be controlled almost entirely by the diffusion of $PbOH^+$ ions at low temperatures. The interval of control by Pb^{++} ions which appeared at room temperature is almost completely absent at low temperatures due to the relative decrease of $[Pb^{++}]$ with respect to $[PbOH^+]$ as temperature decreases. Following growth of the α-PbO_2 layer separating PbO from $PbSO_4$, further diffusion control occurs. At first, oxidation of PbO beneath the α-PbO_2 layer is apparently limited by $PbOH^+$ diffusion.

The PbO continues to be oxidized at 25°C until consumed, at which time the internal pH decreases to a value less than that of bulk electrolyte and β-PbO_2 production is initiated. At low temperatures, depletion of reactant $PbOH^+$ within the pores results from pore blockage, probably due to ice formation, and to the slowness of reestablishment of the equilibrium controlling its concentration.

The last of the diffusion-controlled processes investigated appeared to involve the diffusion of tetravalent lead at 25°C to product β-PbO_2 nuclei and initiate three-dimensional growth of β-PbO_2 on $PbSO_4$ in contact with bulk electrolyte. At low temperatures, this stage does not appear to be attained and the oscillations of faradaic current and capacitance related to its occurrence (2) are completely absent below −30°C. The current, instead of increasing once more as occurs at higher temperatures, decreases monotonically toward zero. This would be expected if the internal acidity of the electrode remained well below that of the bulk electrolyte and unoxidized PbO remained beneath the $PbSO_4$ and α-PbO_2, near the end of charge acceptance. A steady-state concentration of $PbOH^+$ much lower than its solubility might be attained, limited by the rate of its production within the confinement of the adsorbed water layer or blocked pore spaces, whereas at high temperatures production and diffusion of reactant ions would be much quicker. It is also possible that pores eventually become almost completely closed at low temperatures due to the presence of ice and the positive volume of oxidation of PbO to PbO_2 or due to persulfate production (22) and adsorption.

Still other reasons might be suggested, but first it would be of interest to obtain chemical or physical information to test the model postulated to fit the electrochemical data. Work along these lines has been commissioned and is currently in progress.

Moving Resistive Wire Electrodes

Richard Alkire* and Richard Varjian*,[1]

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

The current and potential distributions have been calculated along the surface of a resistive wire moving with steady speed along the axis of a cylindrical electrolysis cell. The wire movement creates a laminar boundary layer of nonuniform thickness in an otherwise stagnant electrolyte. The mathematical analysis includes consideration of ohmic wire resistance, convective mass transport, ohmic electrolyte resistance, charge-transfer polarization, and cell geometry. Transport equations describing cell operation at all fractions of the limiting current were solved by the method of orthogonal collocation. A comparison between calculations which use a local mass transfer coefficient to describe the mass transfer process, and those which use a complete solution of the convective diffusion equation, gave agreement to within 15% over a wide range of parameter space which includes most practical applications of moving resistive wire electrodes.

The behavior of an electrolysis cell can often depend on factors such as cell geometry electrolyte resistance, electrode polarization, and mass transport. The relative importance of these several factors depends on the level of current passing through the cell. Because the current distribution within a cell is usually not uniform, the relative importance of these factors can vary with position within the cell. Therefore it is helpful to know the current distribution in order to understand which factors control cell behavior.

The present investigation is concerned with a cell having an electrode of significant ohmic resistance. The resistive loss in the metal phase leads thereby to a nonuniform potential distribution in the metal which may adversely affect the current distribution along the surface. For many systems electrodeposits of high quality are obtained only over a narrow range of current density. Therefore a highly nonuniform current distribution can be detrimental to product quality owing to variations in plating thickness, adherence, mechanical properties, composition, and appearance. In light of these practical considerations, the present study has been undertaken to elucidate the behavior of moving resistive electrodes. A mathematical model has been developed (1) which takes simultaneous account of the concentration field and the potential fields in both the electrode and electrolyte phases. The study expands on an earlier analysis of resistive wire electrodes in the absence of concentration overpotential (2).

The development of theoretical models of resistive electrodes was reviewed previously (2) and it was noted that the role of mass transfer was incorporated in only two treatments: with uniform stirring (3) and with unsteady-state diffusion (4). Experimental studies on wire electrodes were also reviewed previously (2); since then, measurements have been reported on the current distribution along resistive wires (5) and the mass transfer rates for various flow configurations (6).

The movement of a continuous wire or sheet through a liquid leads to the formation of a hydrodynamic boundary layer along its surface. The literature on industrial wireplating indicates that for typical wire velocities and tank dimensions, the Reynolds number is 10^7 for tin plating (0.25 m/sec, 4m bath length) and 8×10^4 for alloy plating (0.02 m/sec, 4m bath length). Since the laminar boundary layer is stable up to Reynolds numbers between 1 to 5×10^6 (7, 8), the laminar convective diffusion equation seems to be a reasonable basis for predicting mass transport of reactants to the wire surface in practical cell configurations.

Fundamental studies on laminar heat, mass, and momentum transfer at moving filaments and sheets have been carried out in relation to fiber and sheet processing in the plastic, paper, and film industries. The pioneering hydrodynamic work of Sakiadis (9) employed the von Karman-Pohlhausen integral approximation to integrate the laminar boundary layer equations. The same integral method was used to integrate the heat transfer equation (10) and comparison with experimental data (11) indicated that natural convection effects were important (12). The von Karman-Pohlhausen technique was also used to determine the mass transfer coefficient on a moving cylinder (13), and to evaluate the heat transfer between a cylindrical laminar liquid jet and the surrounding gas phase (14). Sakiadis' tabulated data for the stream function were fit to a power series and substituted into the convective diffusion equation to generate a mass transfer correlation (15). Other integral approximations were also used for the hydrodynamic equations which gave good agreement with drag measurements (16). Numerical methods of integration have also been used for the hydrodynamic boundary layer equations (17-19) and compared with approximate methods (20); non-Newtonian fluids have also received treatment by numerical integration of the hydrodynamic equations (21, 22). An exhaustive theoretical treatment of laminar transport at moving continuous surfaces was provided by Crane (23). The stability of the laminar boundary layer was estimated for wires (7) and sheets (8) to be in the vicinity of Reynolds numbers (based on wire length) of $1\text{-}5 \times 10^6$. Heat transfer to moving surfaces has also been carried out under conditions of turbulent transport (24) and radiative transport (25). Problems involving coupled convection in adjacent liquid phases, as encountered in fiber-spinning operations, have been treated by several methods including similarity transformations (26, 27), numerical methods (28), perturbation methods (29), the method of matched asymptotic expansions (30), and conjugate methods (38).

Comparison of transport rates at moving and stationary surfaces (31) has indicated that the transport coefficients at moving surfaces are higher than at stationary surfaces provided that the Schmidt or Prandtl numbers exceed unity, an observation also noted by Chin (15). Electrochemical limiting current experiments with moving wires in an otherwise stationary electrolyte (7) have confirmed that the limiting current varies with $Sc^{1/2}$ instead of $Sc^{1/3}$ as found at stationary planar solid surfaces. The implications of this observation will be developed more fully in the development of Eq. [4] below.

It is abundantly clear that a great deal of existing fundamental work on laminar and turbulent boundary

layer phenomena can be used to describe mass transfer aspects of moving wire electrochemical systems. The flow configuration of industrial electrolysis cells may, however, be more complex than could be accounted for by simple boundary layer models. Wire vibrations (32) or the existence of more complex flow fields outside the boundary layer (6) require that the mass transfer coefficient be determined experimentally under limiting current conditions. However, mass transfer correlations determined at the limiting current are not strictly valid for predicting mass transport behavior below the limiting current. Naturally the question arises as to what errors would be encountered when an empirical limiting current correlation is used to account for mass transport during electrodeposition below the limiting current.

In the study reported below, a model is developed for a resistive wire electrode moving with steady speed through an electrolysis cell. Mass transfer through the laminar boundary layer on the wire surface is accounted for by a rigorous method and by an approximate method, and the two methods are compared. The rigorous method consists of solving the convective diffusion equation along with the potential field equations in both electrolyte and electrode phases; this approach is valid at all fractions of the limiting current density. The approximate method consists of using a local mass transfer coefficient as measured, for example, by the limiting current distribution, to account for mass transfer processes below the limiting current.

Mathematical Development

Figure 1 illustrates essential features of the electrolysis cell to be studied. A wire electrode moves along the axis of the cell with velocity V_s, and electrolysis proceeds on the wire surface under steady conditions. A cylindrical counterelectrode extends the length of the cell. Owing to the motion of the wire through the cell a steady fluid motion is established within the cell, one characteristic feature being the presence of a hydrodynamic boundary layer adjacent to the moving wire. The thickness of the hydrodynamic boundary, which varies with position along the wire, is depicted in greatly exaggerated fashion by the dashed line in Fig. 1. Although hydrodynamic end effects, at $z = 0$ and $z = L$, are expected to be complex, the region of complexity is small with respect to the wire length and are disregarded in the following treatment. Owing to the nonuniform boundary layer, the limiting current density varies with position along the wire. Electrical contact to the wire may be made on either or both sides of the cell.

The following analysis of a moving resistive wire electrode incorporates the effects of ohmic resistance of the wire electrode, activation overpotential of the electrochemical reaction, ohmic resistance of the electrolyte, concentration overpotential associated with the mass transfer boundary layer, geometry of the electrolysis cell, and mode of electrical contact. Several characteristics of the electrochemical system have been assumed to exist: (*i*) Electrolysis occurs under steady conditions, and the system is isothermal; (*ii*) the wire electrode is long and thin so that the potential distribution within it is one-dimensional; (*iii*) a single electrochemical reaction occurs with reversible Butler-Volmer kinetics; (*iv*) the wire electrode moves with steady velocity and without vibration and the boundary layer along its surface is laminar; (*v*) supporting electrolyte suppresses migration of reactants, and the Schmidt number is large; and (*vi*) the counterelectrode surface area is sufficiently large that it is unpolarized.

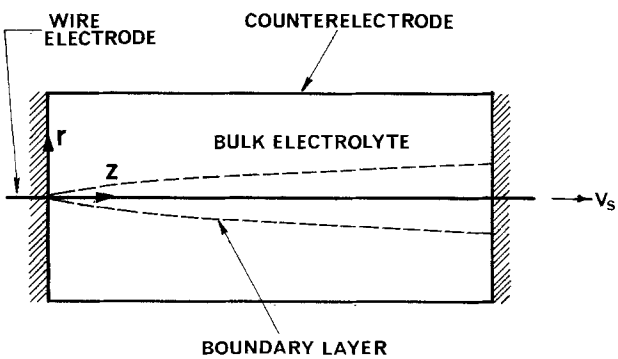

Fig. 1. Cell geometry for moving wire model

Two methods were used for incorporating mass transport effects into the model. The more rigorous method involved integrating the equation of convective diffusion. The second method used an algebraic expression for local variation of the mass transfer coefficient.

As indicated in Fig. 1, the coordinate system is fixed at the left end of the cell, where the wire enters. The z-coordinate is along the wire length, while the r-coordinate extends from the wire surface, r_1, to the tubular counterelectrode surface at r_2.

The electrochemical reaction at the metal surface is

$$s_1 M_1^{z_1} = s_2 M_2^{z_2} + ne^-$$

The local reaction rate depends on the local potential difference between metal and solution phases, and upon the local concentration of reactant at the electrode surface

$$j(z) = i_o \left\{ \left(\frac{c_{s,1}(z)}{c_{b,1}} \right)^{(\gamma+\alpha)} e^{\frac{\alpha nF}{RT}[\phi_m(z) - \phi_s(z)]} - \left(\frac{c_{s,2}(z)}{c_{b,2}} \right)^{(\gamma-\alpha+1)} e^{\frac{(\alpha-1)nF}{RT}[\phi_m(z) - \phi_s(z)]} \right\} \quad [1]$$

The variation of potential in the wire phase is related to the reaction rate distribution along its surface by

$$j(z) = \frac{r_1 \sigma}{2} \frac{d^2\phi_m(z)}{dz^2} \quad [2]$$

The boundary conditions on Eq. [2] depend on the mode of electrical contact. For contact at the left side only

$$\phi_m(0) = \phi_A, \quad \frac{d\phi_m(L)}{dz} = 0$$

for the right side only

$$\frac{d\phi_m(0)}{dz} = 0, \quad \phi_m(L) = \phi_A$$

and for both sides

$$\phi_m(0) = \phi_A, \quad \phi_m(L) = \phi_A$$

Although the variation of potential in the solution phase is generally two-dimensional for the cell configuration under study, our earlier work in the absence of mass transfer effects (2) indicated that a one-dimensional approximation is valid for all cell geometries associated with practical applications. At significant fractions of the limiting current density, the approximation is expected to continue to hold since the ohmic resistance of the electrolyte phase would exert an even smaller influence on the over-all system behavior. The potential in the solution phase at the outer edge of the mass transfer boundary layer is therefore related to the reaction rate distribution by

$$j(z) = \frac{\kappa}{r_1 \ln\left(\frac{r_2}{r_1}\right)} \phi_s(z) \quad [3]$$

In order to obtain a relationship between the reac-

tion rate distribution and the concentration distribution of reactant at the electrode surface, two methods were investigated.

Convective diffusion equation.—When, following our introductory remarks, the Schmidt number is large in a moving wire system, then experiments have shown that the average limiting current varies with the square root of the wire speed. This observation is consistent with the interpretation that the velocity within the mass transfer boundary layer is essentially constant and is equal to the speed of the wire: that is, mass transfer analysis follows the penetration theory formulation (39). The convective diffusion equation is therefore

$$v_s \frac{\partial c_i}{\partial z} = D_i \frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\partial c_i}{\partial r} \right) \qquad [4]$$

In order to use Eq. [4] to relate the surface concentration to the surface flux, it is necessary first to calculate the limiting current density for which the boundary conditions on Eq. [4] would be

$$c_i = 0 \quad \text{at} \quad r = r_1, \quad z > 0$$
$$c_i = c_{b,i} \quad \text{at} \quad r = \infty, \quad z > 0$$
$$c_i = c_{b,i} \quad \text{at} \quad z = 0$$

The solution of Eq. [4] yields (33) the limiting current distribution

$$\underset{\text{lim}}{j(z)} = \frac{n\mathbf{F}D_i}{s_i} \frac{\partial c_i}{\partial r}\bigg|_{r=r_1} = \frac{4n\mathbf{F}c_{b}D_i}{s_i \pi^2} \int_0^\infty e^{\frac{-D_i u^2 z}{v_s}} \frac{du}{u[J_0^2(ur_1) + Y_0^2(ur_1)]} \qquad [5]$$

For electrolysis cells of typical industrial size, the quantity $D_i z/v_s r_1^2$ is less than unity so that Eq. [5] may be expressed as

$$\underset{\text{lim}}{j(z)} \simeq \frac{n\mathbf{F}c_{b}D_i}{s_i r_1} \left\{ \left(\frac{\pi D_i z}{v_s r_1^2} \right)^{-1/2} + \frac{1}{2} - \frac{1}{4\pi} \left(\frac{\pi D_i z}{v_s r_1^2} \right)^{1/2} + \frac{1}{8\pi} \left(\frac{\pi D_i z}{v_s r_1^2} \right) + \cdots \right\} \qquad [6]$$

By applying Duhamel's theorem to Eq. [6], a relationship is obtained between the surface concentration and the surface flux (reaction rate) which is valid at all fractions of the limiting current density for both reactant and product species

$$j_i(z) = \frac{n\mathbf{F}D_i}{s_i r_1} \int_0^z \frac{dc_i}{dz_0}\bigg|_{r=r_1} \left\{ \left[\frac{\pi D_i (z - z_0)}{v_s r_1^2} \right]^{-1/2} + \tfrac{1}{2} - \tfrac{1}{4}\pi \left[\frac{\pi D_i (z - z_0)}{v_s r_1^2} \right]^{1/2} + \tfrac{1}{8}\pi \left[\frac{\pi D_i (z - z_0)}{v_s r_1^2} \right] + \cdots \right\} dz_0 \qquad [7]$$

Equations [2], [3], and [7] describe the transport of chemicals and energy to the reactive surface where electrolysis occurs by Eq. [1] These four equations may be made dimensionless by defining

$$\zeta = \frac{z}{L} \qquad \rho = \frac{r}{r_1}$$
$$C_{s,i} = \frac{c_{s,i}}{c_{b,i}} \qquad \Phi = \frac{n\mathbf{F}}{RT}\phi$$
$$J = \frac{2Lj}{r_1 i^*} \qquad \beta = \frac{n\mathbf{F}Li^*}{\sigma RT}$$

so that the dimensionless model equations are

$$J(\zeta) = \frac{\xi}{\beta} \left\{ C_{s,1}(\zeta)^{(\gamma+\alpha)} \exp\left[\alpha(\Phi_m(\zeta) - \Phi_s(\zeta)\right] - C_{s,2}(\zeta)^{(\gamma-\alpha+1)} \exp\left[(\alpha - 1)(\Phi_m(\zeta) - \Phi_s(\zeta))\right] \right\} \qquad [8]$$

$$J(\zeta) = \frac{1}{\beta} \frac{d^2\Phi_m(\zeta)}{d\zeta^2} \qquad [9]$$

$$J(\zeta) = \frac{2}{\psi\beta \ln \rho_0} \Phi_s(\zeta) \qquad [10]$$

$$J(\zeta) = \frac{\xi}{s_i \chi_i a \beta} \left\{ \int_0^\zeta \frac{\partial C_{s,i}}{\partial \zeta_0}\bigg|_{\zeta=1} \left[\left(\frac{\pi(\zeta - \zeta_0)}{\mathrm{Re_L Sc_i} a^2} \right)^{-1/2} + \tfrac{1}{2} - \tfrac{1}{4}\pi \left(\frac{\pi(\zeta - \zeta_0)}{\mathrm{Re_L Sc_i} a^2} \right)^{-1/2} + \tfrac{1}{8}\pi \left(\frac{\pi(\zeta - \zeta_0)}{\mathrm{Re_L Sc_i} a^2} \right) + \cdots \right] \right\} d\zeta_0 \qquad [11]$$

The method of electrical contact is used to define the boundary conditions for Eq. [9]. Referring to Fig. 1, the conditions

$$\Phi(0) = \Phi_A, \qquad \Phi'(1) = 0$$

correspond to making electrical contact on the left side (where the wire enters) and not on the right side. The conditions

$$\Phi'(0) = 0, \qquad \Phi(1) = \Phi_A$$

correspond to making electrical contact on the right side only (where the wire leaves the cell). Making electrical contact on both sides of the cell corresponds to the conditions

$$\Phi(0) = \Phi_A, \qquad \Phi(1) = \Phi_A$$

Results will be presented for all three possible contact configurations.

In the model, the potential Φ_A is the independent variable. The current β is computed after the potential distribution is known. Notice that β appears in the model only as the product βJ; the current and the current distributions are therefore evaluated after having the potential distribution in hand by requiring that $\int_0^1 J dZ = 1$.

The parameters which appear in the model equations are

$$\xi = \frac{2n\mathbf{F}L^2 i_0}{\sigma r_1 RT}, \qquad \chi_1 = \frac{i_0 L}{n\mathbf{F}c_{b,i}D_i}$$
$$\psi = \frac{r_1^2 \sigma}{L^2 \kappa}, \qquad \mathrm{Re_L} = \frac{v_s L}{\nu}, \qquad \mathrm{Sc_i} = \frac{\nu}{D_i}$$
$$a = \frac{r_1}{L}, \qquad \rho_0 = \frac{r_2}{r_1} \qquad [12]$$

Equations [8], [9], [10], and [11] were solved by the method of orthogonal collocation (34, 35). The basis of the method lies in proposing a trial solution to the problem in the form of a finite series of orthogonal polynomials. The N coefficients of the finite series are then suitably chosen to force the trial solution to satisfy the actual system equations at N distinct points, where N is a small number. The number of collocation points, N, is carefully chosen to obtain the best estimate of the total current passing through the cell. The collocation points are picked as the zeroes of the Legendre polynomials of degree N shifted to be orthogonal in the closed interval [0, 1]. Integral quantities (for example, the total current) are then evaluated with use of Gauss-Legendre quadrature. Details concerning the present problem, including computer program listings, are available (1).

Mass transfer coefficient equation.—The second method used to account for concentration variations is

to use the local mass transfer coefficient, as defined under limiting current conditions, to describe mass transfer processes at currents beneath the limiting current. In order to be comparbale with the preceding rigorous model, the local mass transfer coefficient used here will be chosen so as to give the same limiting current density as Eq. [4]; for simplicity, however, radial curvature terms have been deleted. By this method, the relation between reaction rate and surface concentration is

$$j(z) = \frac{nF}{s_i}\left(\frac{D_i v_s}{\pi z}\right)^{1/2} [c_{b,i} - c_{s,i}(z)] \qquad [13]$$

or, in dimensionless notation

$$J(\zeta) = \frac{\xi}{s_i \chi_i \beta^-}\left(\frac{\mathrm{Re_L Sc_i}}{\pi\zeta}\right)^{1/2} [1 - C_{s,i}(\zeta)] \qquad [14]$$

By this method, the model consists of Eq. [8], [9], [10], and [14]. For this approximation, in which curvature effects have been neglected, the mass transfer coefficient is assumed to vary with position as though the surface concentration were constant, an assumption which would not conform to actual conditions below the limiting current. However, it is of interest to examine such an approximation since, as mentioned earlier, mass transfer behavior in complex flow fields may only be available in the form of limiting current correlations.

The equations were linearized about trial solutions, placed in finite difference form and solved by matrix inversion (36) with successive correction toward convergence.

Results and Discussion

The dimensionless parameters listed in Eq. [12] can be used to estimate the relative importance of wire resistance, electrode polarization, electrolyte resistance, mass transport, and cell geometry. The parameters ξ, ψ, ρ_0, and a appeared in our earlier treatment (2) and received attention as to their qualitative influence on system behavior in the absence of mass transport effects. The parameter ξ has a large value when a very rapid reaction occurs on an electrode of low conductivity; provided that operation is below the limiting current, the applied potential would be consumed more by the electrode resistance overpotential than by charge-transfer overpotential. Therefore the electrochemical reaction would tend to occur primarily near the electrical contact end of the wire and the current distribution along the wire would be nonuniform. The parameter ψ has a large value when the applied potential is consumed more by ohmic losses in the electrolyte than by ohmic losses in the electrode phase. The geometric parameters ρ_0 and a describe the cell configuration and influence the potential distribution in the electrolyte phase.

The influence of mass transport limitations depends on how close the current is to the limiting current. The average limiting current density for moving wires is determined by integrating Eq. [5] over the length of the wire electrode. Numerical results (37) are given in dimensionless form by the solid line in Fig. 2. The dotted line in Fig. 2 corresponds to the limiting current obtained from the approximation of Eq. [6]; it is this approximate form which appears in Eq. [11] of the model. It may be seen from Fig. 2 that the approximation is accurate to within 4.8% when $1/\mathrm{Re_L Sc_i} a^2 = 1$. For typical industrial cells, the value of $1/\mathrm{Re_L Sc_i} a^2$ rarely exceeds unity so that the approximation of Eq. [6] is adequate. The approximation is used because it is more conveniently manipulated than Eq. [5]. Finally, the dashed line in Fig. 2 corresponds to the neglect of all curvature terms in which case the limiting current is

$$\beta_{\mathrm{lim}} = \frac{2\xi}{s_i \chi_i}\left(\frac{\mathrm{Re_L Sc_i}}{\pi}\right)^{1/2} \qquad [15]$$

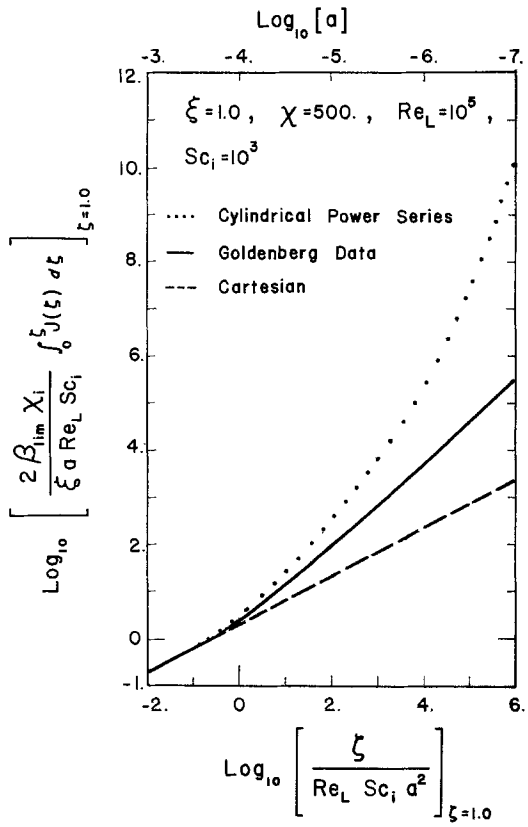

Fig. 2. Average limiting current density for moving wires and sheets

and the limiting current distribution is $J_{\mathrm{lim}} = \frac{1}{2}\sqrt{\zeta}$. As seen from Fig. 2, the neglect of radial curvature terms is appropriate under the condition that $\zeta/\mathrm{Re_L Ss_i} a^2 < 0.1$. In summary, Fig. 2 provides the limiting current density for moving wire electrodes. If the current density flowing in the cell is at an appreciable fraction of the limiting current density then mass transfer processes will influence behavior.

In the following paragraphs the role of mass transfer processes near the limiting current are discussed. Results are given both for the convective diffusion model and for the simpler mass transfer coefficient model. In all cases reported, the potential distribution in the electrolyte phase falls within the region where the one-dimensional approximation of Eq. [3] is accurate as has been described previously (2). The system parameters which were held constant in this study are given in Table I.

Convective diffusion equation model.—Equations [8] through [11] define the convective diffusion equation model. Calculated polarization curves are given in Fig. 3 for three different flow rates and three different electrical contact configurations. At high polarizations, the limiting current plateau is independent of contact configuration since mass tranfer alone controls the system. At currents below the limiting current, the dual contact mode offers the highest current for a given applied potential since the dual contacts offset somewhat the effects of electrode resistance. Above about 25% of limiting current, the left-hand contact provides a higher current than the right-hand mode owing to the variation of mass transfer rates along the wire. When the electrical contact is on the right, much of the applied potential is consumed by IR-drop along the

Table I. Values of system parameters held constant in this study

$\mathrm{Sc_1} = \mathrm{Sc_2} = 10^3$

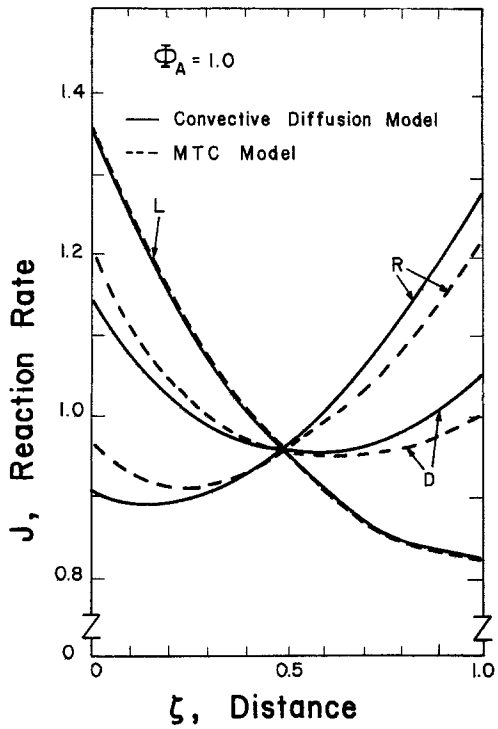

Fig. 4. Current distribution along wire electrode at low applied potential. (———: convective diffusion model; - - - -: MTC model).

wire and by concentration polarization along the downstream regions; when electrical contact is on the left, much more of the applied potential is consumed by charge transfer since the boundary layer thickness is much thinner along the upstream surface. The difference in total current between the dual and single contact modes becomes more significant as the wire speed increases because the ohmic loss along the wire increases as the current increases. The dual contact configuration minimizes ohmic (IR) losses in the wire electrode.

Figure 4 gives current distribution curves for three different contact modes. For Fig. 4, the applied potential is low and the total current is about 3.5% of the limiting current. The solid lines in Fig. 4 correspond to the convective diffusion equation model; the dashed lines will be discussed later. Owing to the electrode resistance, the current distribution is nonuniform and therefore depends on the mode of electrical contact. It is also seen that the dual contact mode is not symmetric, and that the right-hand contact gives a more uniform distribution than the left-hand mode. That is, even at this small fraction of limiting current (3.5%), the mass transport effect on the current distribution is clearly evident.

The solid lines in Fig. 5 give current distribution curves for three different contact modes at a medium polarization. The total current is 56, 51 and 77% of the limiting current for the left- right-, and dual-contact modes. The distributions are similar in shape to those in Fig. 4, but are more nonuniform owing to the higher current which exacerbates the effect of the electrode resistance on the current distributions. It is seen in Fig. 5 that the most uniform current distribution is encountered when electrical contact is made on the right-hand side of the cell.

At an applied potential of 16.0 units, not shown, the current distributions for the left- and dual-contact modes are highly nonuniform and are very close to the limiting current distribution. Under the same conditions, the current distribution for the right-hand contact is extremely uniform, even though at nearly 80% of the limiting current density.

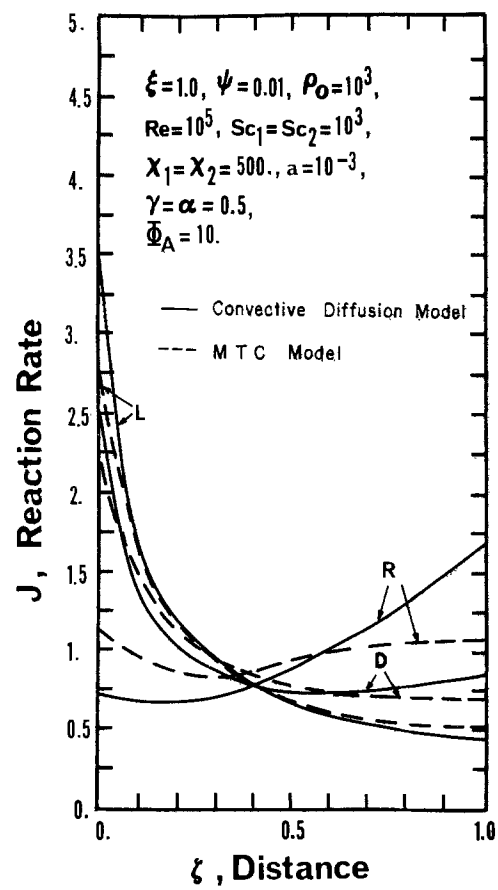

Fig. 5. Current distribution along wire electrode at medium applied potential. (———: convective diffusion model; - - - -: MTC model).

Because the reaction rate distribution is made dimensionless such that $\int_0^1 J d\zeta = 1$, a measure of uniformity of the rate distribution is

$$U = \int_0^1 (|J - 1|) d\zeta$$

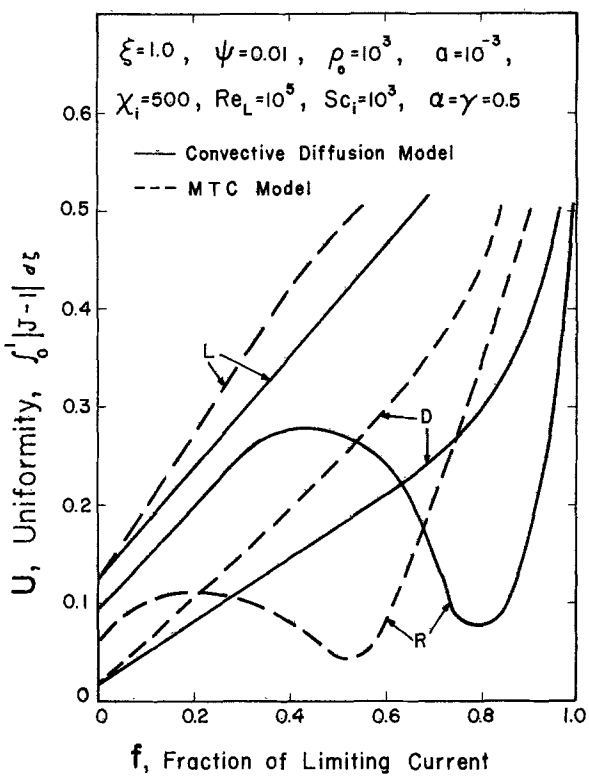

Fig. 6. Uniformity of the current distribution at various fractions of limiting current. (———: convective diffusion model; - - - -: MTC model).

By this definition, U has the value of zero if the current distribution is uniform; the larger the value of U, the more nonuniform the current distribution. Figure 6 illustrates how the reaction uniformity, U, depends on electrical contact mode at various fractions of the limiting current density. The parameter values used in Fig. 6 were chosen so that the electrode resistance would have the greatest effect on system behavior. The solid lines are results calculated with the rigorous convective diffusion equation model. Figure 6 shows the mode of electrical contact which provides the most uniform current distribution depends on the fraction of limiting current at which deposition is carried out. It is seen that above 60% of the limiting current the right-hand contact provides the most uniform current distribution. At low fractions of the limiting curent, near $f = 0$, the uniformity depends upon parameters ξ, ψ, ρ_0, and a, as discussed previously (2). Although the right-hand contact may provide a more uniform current distribution in many cases, the dual contact always consumes the least power since it minimizes the IR-losses associated with electrode resistance.

Calculations have also been made with neglect of curvature terms in the convective diffusion equation. That is, only the first term in the expansion on the right side of Eq. [11] was used. The limiting current for this case is given by Eq. [15] and is shown by the dashed line in Fig. 2. Although the limiting current was affected by neglecting radial terms, it was found that the current distributions were not. That is, the current distributions given by the solid lines in Fig. 4 and 5 (curvature terms included) agree everywhere within 5% of the current calculations obtained upon neglect of curvature terms. Therefore the results presented in Fig. 6 may also be used in the analysis of moving sheets and strips.

Mass transfer coefficient model.—Equations [8], [9], [10], and [14] define the mass transfer coefficient (MTC) model. Results have been calculated for the same system parameters as used for the convective diffusion model in order to ascertain whether the simpler model provides an adequate representation of the system.

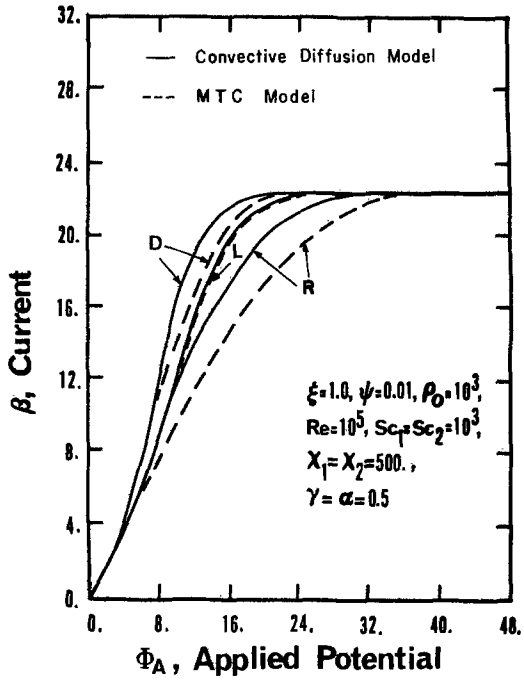

Fig. 7. Comparison of polarization curves predicted by convective diffusion model and MTC model.

Figure 7 gives calculated polarization curves. The dashed lines correspond to the MTC model. Because the simpler model does not include radial curvature terms, it seemed reasonable to make the comparison with the convective diffusion equation model under conditions where curvature terms were not included. Therefore the solid lines in Fig. 7 do not include curvature effects which influence the limiting current plateau. Comparison between the more rigorous model (solid lines) and highly approximate MTC model (dashed lines) shows, for left-hand contact, an excellent agreement over the entire range of potential. For right-hand contact, the approximate MTC model predicts currents which are up to 15% lower than the more rigorous model. The discrepancy is less for dual contact. It is seen that although the simple approximation predicts a greater concentration polarization than may actually occur, the error is relatively small even under the worst of circumstances. That is, for at least some applications, the approximate mass transfer coefficient model can provide results which are within reasonable engineering tolerances.

The dashed lines in Fig. 4 through 6 give results calculated with the mass transfer coefficient model. At low polarizations, Fig. 4 shows that the MTC model shifts the current distribution to the left since it overestimates the concentration polarization along the downstream wire surface. The current distributions agree everywhere within 5%. At medium polarization, Fig. 5 illustrates that the MTC model gives excellent agreement for left- and dual-contact configurations, but that errors up to 60% are encountered for the right-hand case. Depending on the purpose for which current distributions calculations are needed, the simple MTC model may not be suitable for the worst possible case considered here. The reaction uniformity predicted by the MTC model is shown by the dashed lines in Fig. 6. Once again it is seen that the simple MTC model gives an adequate representation of behavior in all but a limited range of operating conditions.

These results illustrate that highly rigorous models are often not necessary for guiding the work-up of engineering applications. For resistive electrodes, it has been shown that appreciable errors with the MTC model are encountered only when the current contact is at the downstream side of the electrode and when operation is between about 30 and 90% of the limiting current density.

Conclusions

A rigorous model has been developed for calculating the current distribution along a moving resistive wire electrode at all fractions of the limiting current. The model includes simultaneous consideration of the potential field in both electrode and electrolyte phases, and the concentration field in the mass transfer boundary layer at the wire surface. The orthogonal collocation method of calculation was found to be highly efficient. The model has illustrated conditions under which advantage of the electrode resistance may be taken to obtain uniform current distributions. The rigorous model does not take into account natural convection effects.

Various approximations to the rigorous model have been investigated. Curvature of the mass transfer boundary layer has been found to influence the limiting current density but not the current density distributions. Therefore the results reported here can be applied to moving sheets or strips as well as to moving wire applications.

A very simple model has been investigated which uses the mass transfer coefficient determined at limiting current conditions in order to calculate the concentration overpotential. The simple model agrees very well with more rigorous calculations except when electrical contact to the resistive electrode is made far from the upstream region where the mass transfer boundary layer is thin. These results indicate that information gained from limiting current measurements can, in most cases, be incorporated in a model to predict behavior below the limiting current.

The models investigated in this study are quite flexible and could be modified to suit special circumstances. For example, other reaction rate expressions could be used instead of the simple reversible case used here. The existence of multiple electrode reactions could be incorporated, as encountered during alloy deposition, gassing, or other situations. Consideration of the counterelectrode could also be incorporated, including charge-transfer, mass transport, and counterelectrode resistance effects. In summary, the modeling procedure reported here provides a rational basis for the study of a wide variety of electrochemical engineering systems.

The Identification of the Mobile Ion during the Anodic Oxidation of Silicon

W. D. Mackintosh and H. H. Plattner

Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada

ABSTRACT

The mobile species during anodic oxidation of Si is shown to be largely, if not entirely, the anion. This was accomplished by introducing noble gases as markers into the surface layer of specimens by ion implantation. The positions of the markers before and after oxidation in a variety of electrolytes were determined by Rutherford backscattering analysis.

During anodic oxidation either the cation or the anion or both must migrate across the thickening oxide film. The mobile ion can be identified, or, if both move, the relative mobilities can be deduced by tagging a thin surface layer with a completely immobile marker atom and determining its position after anodizing the specimen. If the marker is found at the surface then oxidation has taken place by inward migration of the anion to form the film beneath the marked layer. If the marker is found at the substrate/oxide interface the opposite process has occurred. An intermediate position indicates both cation and anion have moved and the relative mobilities are proportional to the relative thicknesses of the oxide on either side of the marker atoms. Such experiments have been carried out for Al (1, 2), Hf (1), Nb (1), Ta (1, 3), U (4), W (1), and Zr (1, 5) using markers of inert gas atoms introduced in the surface layers by ion implantation with low energy accelerators.

The inert gas atoms were chosen as markers on the grounds that they are the most likely to remain uncharged within the oxide lattice and hence are not influenced by the application of the electrical field. In addition their large size suggests that they should not diffuse through the lattice at room temperature. Pringle (3), in particular, discusses the question of the immobility of Ar, Kr, and Xe in the anodic oxidation of Ta.

On the other hand, Brown and Mackintosh (2), Whitton (5), and Mackintosh, Brown, and Plattner (6) have shown that a great many other species introduced into the surface layers of Al or Zr move during anodization. The direction of motion appears to depend on the charge of the species and on the original position of the implanted atoms in the surface layers. Many cases were found in which a species behaves differently when introduced into a preformed oxide layer which was subsequently thickened, than it did when introduced into the metal substrate beneath the air-formed oxide. Such species are obviously unsuitable as markers.

Up to this time the identification of the charge carrier in the anodic oxidation of Si has been based on evidence obtained by introducing P and B into oxide layers by anodizing in electrolytes containing phosphate and borate anions (7, 8). In Ref. (7) ^{32}P was incorporated into an oxide film by anodizing in tetrahydrofurfuryl alcohol containing ^{32}P as the phosphate. When this film was subsequently thickened in either a solution of N-dimethylpropionamide or in tetrahydrofurfuryl alcohol containing nonradioactive phosphate, the active ^{32}P was found in the inner layers. It was concluded that the oxide film had thickened by outward movement of the Si. However, from the same observation an equally valid conclusion could have been reached; that during anodization the phosphate moves inward.

In Ref. (8) the B was found at the outer surface leading to the conclusion that the anion was largely the species that migrated. The apparent difference in behavior was attributed to the presence of the borate in the electrolyte rather than the alternative explanation that either P or B, or both, moved during anodization in the way that many species have been shown to move in Al.

Additionally, it has been shown by Pringle (9) that both P atoms introduced by ion implantation and PO_3^{---} ions introduced via the electrolyte are mobile during the oxidation of Ta. Since experience with other systems indicates that the inert gas atoms were good, if not quite perfect, immobile markers while other species were more likely to be mobile, we have investigated the anodic oxidation of silicon using Kr and Xe as markers. We have also investigated the behavior of P when introduced into oxide films by having phosphate ions present in the electrolyte.

In the literature cited above various methods were used to locate the initial and final positions of the marker. In the present work marker locations were determined by Rutherford backscattering analysis. The principles of this technique for measurements of film thickness and the depth of foreign atoms have been described extensively (10-12) and references therein. The essence of the method is that if a He ion of known energy (in this case 2 MeV) is scattered from a surface atom, the resultant energy loss can be calculated from the kinematics of the system. Any additional energy loss observed is due to the fact that the struck atom is not on the surface and therefore the He ion suffers energy loss in both its ingoing and outgoing trajectories. This loss can be interpreted to give the depth of the atom. Similarly, the difference in energy between He ions scattered from the Si atoms of the outer sur-

Key words: anodic oxidation, ion implantation, noble gas markers, Rutherford backscattering, silicon.

face layer of the oxide and the Si atoms of the outer layer of the substrate (substrate/oxide interface) can be interpreted to give the thickness of the oxide.

Detector resolution and to a lesser extent drifts in accelerator energy and amplifier gain set a limit to the precision with which depths and oxide thickness may be measured. The precision obtainable is ~ 2 $\mu g/cm^2$ and is essentially constant over the range of depths involved in this work.

The number of detected He ions backscattered from the implanted ions is dependent on the number of implanted atoms present. It is possible to obtain the absolute amount of implanted atoms (10-12) but for these experiments it was sufficient to compare the total count after normalization to the same integrated beam current (*i.e.*, same number of incident particles) to observe any changes in the amount of implant occurring during anodization.

Experimental

Anodization.—A variety of specimens was used in this work. Some were thin wafers cut very closely parallel to the (111) plane while others were tablets ⅜ in. thick cut some 10° off the (111) plane. Most were p-type boron-doped although one n-type phosphorus-doped specimen was also used. The surfaces of all specimens were prepared by vibratory polishing with 0.3 μm alumina, followed by ultrasonic cleaning to remove the abrasive. They were then degreased in trichlorethylene, etched for 5 min in 0.5M HF and washed thoroughly. Oxidations were carried out in a Teflon cell constructed for this purpose in such a way that only 0.7 cm^2 of the polished surface was exposed to the electrolyte. The electrical connection was made by diffusing gold into a small area on the back of the specimen and firmly contacting this area to a copper plate contained in the body of the cell. All specimens were anodized, then stripped of oxide in 0.5M HF before proceeding further with the experiments.

Experiments were carried out with the following electrolytes: (*a*) 0.1M aqueous solution of H_3BO_3 and $Na_2B_4O_7 \cdot 10H_2O$ (13), (*b*) 0.4M solution of KNO_3 in N-methylacetamide (14), and (c) 0.3M solution of KNO_2 in tetrahydrofurfuryl alcohol (15). For experiments involving the behavior of P, we used an electrolyte of tetrahydrofurfuryl alcohol containing 15 volume percent (v/o) pyrophosphoric acid (prepared by dissolving P_2O_5 in the minimum amount of water possible) (7). All anodizations were carried out at constant current at densities of 15 mA/cm^2 for electrolyte (*a*) and 6 mA/cm^2 for the remainder. The process was terminated at a voltage commensurate with the thickness desired, the necessary thickness *vs.* voltage data being obtained from the literature cited. Although in most cases, oxides exhibiting even coloration across the whole area were obtained, any chance specimens not evenly colored were discarded.

Marker location analysis.—The experimental arrangements for obtaining the Rutherford backscattering spectra of the He ions were identical with that described in Ref. (2). Briefly, they consist of a Van de Graaff accelerator delivering a beam of 2 MeV He ions, a target chamber, and a surface barrier detector (resolution 17 keV FWHM) placed to observe ions scattered through 150°, together with the electronics and pulse height analyzer. A time of irradiation was chosen that resulted in the accumulation of $\sim$ 500 counts in the peak derived from the marker atoms using a beam current of 15 nA. The beam current was integrated during the irradiation so that the counts derived from the implanted atoms from one run could be normalized to that of another.

Ion implantation.—The inert gas atoms Kr or Xe were introduced into the Si surface layers with a low energy mass separator. The amounts implanted were 5×10^{14} atoms/cm^2 for Xe and 1×10^{15} for Kr. These are the minimum amounts conveniently detected by Rutherford backscattering analysis. The energies employed were in the range 25-110 keV.

Procedure.—Specimens with prepared surfaces were anodized to give a film thickness of ~ 16 $\mu g/cm^2$. They were then implanted with the chosen marker at an energy that would insure that the greater part of the implanted material was located within the oxide film. Rutherford backscattering spectra were obtained. The specimens were then further anodized to a chosen voltage and analyzed again. Computer analysis of the data was then carried out to obtain the position of the markers, the thicknesses of the oxide films, and the count of He ions backscattered from the implanted atoms.

Results and Discussion

Figure 1 shows the spectra obtained from a specimen in which Kr was implanted at 45 keV into a preformed oxide layer. The solid line is the spectrum before the oxide was thickened further, the dotted line that obtained afterward.

The continuum to the left is derived from the substrate. It contains a marked step as the density of the Si atoms in the oxide is considerably less than that in the underlying substrate. The dashed vertical line D marks the energy of the He ions backscattered from the outer surface of the preformed oxide while E and F mark the energies at the surface of the substrate, before and after thickening, respectively. These were obtained by computer smoothing of the data and taking the position to be the point at half-height of the step. The difference in energy between these points can be converted to oxide thickness. The energy interval between the vertical lines D and E corresponds to an oxide thickness of 20 $\mu g/cm^2$, while that between D and F corresponds to an oxide thickness of 35.5 $\mu g/cm^2$. In this example, the specimen was anodized in methylacetamide.

The peaks to the right are derived from scattering from the Kr. The vertical dashed line labeled A represents the calculated energy of He ions scattered from Kr atoms hypothetically located exactly at the surface. That labeled B represents the center of the peak before thickening shown by the solid line. This position was obtained by fitting the data to a Gaussian and determining the center point of the full width, half-maximum height. The peak position B is displaced to a position 15 keV lower in energy than the "surface" position A. This difference corresponds to a depth of 8 $\mu g/cm^2$ for He ions backscattered from Kr in SiO_2. This position is the median range of Kr atoms implanted at 40 keV with the low energy mass separator.

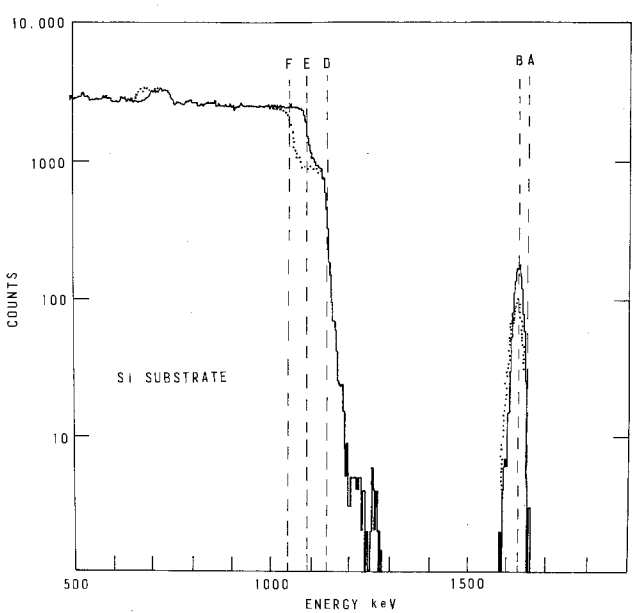

Fig. 1. The solid line shows the spectrum obtained from a specimen in which Kr was implanted at 45 keV into a preformed oxide layer 20 $\mu g/cm^2$ thick. The dotted line is the spectrum after the oxide was thickened to 35.5 $\mu g/cm^2$.

Table I. Marker position for implants in preformed oxides

Sample number	Implant species	Implant energy	Preformed oxide thick., $\mu g/cm^2$	Electrolyte	Additional oxide grown, $\mu g/cm^2$	Position shift, $\mu g/cm^2$	Corrected position, $\mu g/cm^2$
1	Kr	45	8.5	THF	25.5	+2	+4
2	Xe	50	15	THF	19	−3	−2
3	Xe	110	15.5	Acetamide	13	−3	−2
4	Xe	110	13	Acetamide	19	−4	−3
5	Kr	55	15	Acetamide	16	+2	+3
6	Kr	55	15	Acetamide	14.5	+2	+3
7	Kr	45	20	Acetamide	15.5	+2	+3
8	Xe	20	9.5	Borate	41	0	0
9	Xe	30	11	Borate	66	0	0
10	Xe	30	11	Borate	19	0	0
11	Kr	45	8.5	Glycol	19.5	0	+1
12	Kr	45	8.5	Glycol	19.5	+2	+3
13	Kr	50	15	Phosphate in THF	10	+2	+3
14	Kr	50	19	1st phosphate in THF 2nd THF	15	+4	+5
				Average	24		+0.8 ± 0.5

The position of the peak after thickening, shown by the dotted line, is almost coincident with its position before thickening.

All specimens, embracing the use of all electrolytes listed earlier, and the use of Xe as well as Kr, gave much the same result. In Table I we list the details of each and in column 7 give the difference between the original implant position and the position after oxidation. Positive numbers indicate positions deeper in the specimen, negative numbers positions nearer the surface. Those deeper below the surface are within the limits of precision of the analytical method (± 2 $\mu g/cm^2$). However some shifts to positions of higher energy are outside the limits. We attribute this to the known fact that some Si dissolves in the electrolyte during anodization (16). We did not investigate this phenomenon in detail but in Ref. (16) the loss of Si was found to be equivalent to 2 $\mu g/cm^2$ of SiO_2 when anodizing in acetamide for sufficient time to form 30 $\mu g/cm^2$ of oxide. We found evidence that there was a similar loss with other organic electrolytes. Due to the fact that the original implant distribution extends to the surface, loss of Si to the electrolyte results in the loss of some of the implanted atoms. We observed such losses reflected as a diminished peak area in the backscattered spectra. The loss in Fig. 1 is, for example, 25%. Unfortunately the loss of implanted material cannot be directly related to the amounts of Si dissolving in the electrolytes as we have no precise information on the shape of the implant distribution. We can only assume that, because the implant losses were similar from one organic electrolyte to the other, the loss of Si to the electrolyte is much the same as that reported in Ref. (15). We have consequently corrected the values for the implant shift to allow for this loss and list these in the last column. They have been rounded off to the nearest microgram per square centimeter. On the other hand, aqueous borate electrolytes evidently do not dissolve any Si as there was no loss of noble gas. No corrections were made.

In general then, the marked preformed oxide layer was found to be located at, or close to the outer surface after thickening. From this fact and taking into account the precision of the analytical method and the uncertainty in the amount of Si dissolving, we deduced that at least 80% of the new oxide growth had taken place by inward migration of the anion in five (No. 5, 6, 7, 13, 14) of the samples, 85% in two (No. 1 and 12), and 95% in one (No. 11). The remaining six clearly exhibit exclusive migration of the anion. It is also apparent that these results do not show a tendency for any one of the electrolytes used to behave differently from the others in respect to mobile ion migration. Thus, they can reasonably be considered as a group. The average thickness is 24 $\mu g/cm^2$ and the average corrected position is +0.8. The deviation is 0.5. From this it can be said that 95± 5% of the oxide growth was due to inward migration of the oxidizing species.

A similar number of silicon specimens, covered only by the natural air-formed oxide, were implanted with either Kr or Xe. In these the greater fraction of the implanted atoms was located in the substrate beneath the thin surface oxide. On analysis after anodization the implant distribution was found to be broadened and the center displaced to a position of lower energy. Both broadening and displacement were due to the change in mass, density, and stopping power which occur when Si is converted to SiO_2. When suitable corrections were made for these effects, we obtained results that were entirely consistent with those obtained for implants into preformed oxide films. These are shown in Table II.

As these results are in contradiction to those of Ref. (7), clearly, either P or the noble gases are not suitable markers. We therefore carried out a series of experiments to investigate the behavior of P when introduced into oxides by using an electrolyte containing phosphate ions.

In these experiments we formed a film on specimens by anodizing to 150V in an organic electrolyte containing no phosphate. We then anodized a further 20V in the electrolyte containing phosphate. This is illustrated in Fig. 2A. This was again anodized in the first electrolyte for another ~ 80V.

Irrespective of how the film grows the distance from the substrate/oxide interface cannot decrease if the phosphate is immobile (Fig. 2B, C, and D). However, if mobile, we would expect this distance to decrease by the inward movement of the negative ions as did negative ions in aluminum (2). Consequently, the essential test for movement is the distance from the interface to the phosphate-containing layer before and after formation of the third layer.

Measurements of this distance by Rutherford backscattering techniques is not a straightforward matter because the masses of Si and P are so near each other. The peak derived from P on the surface of SiO_2 can be resolved from the Si edge if a beam energy of 2.4 MeV is used, but it cannot be resolved if the P is buried in the oxide. We therefore had to resort to etching techniques so that analysis was always carried out on specimens with the P at or near the surface. The resolution attainable under these circumstances is illustrated in Fig. 3A. The lower data points joined

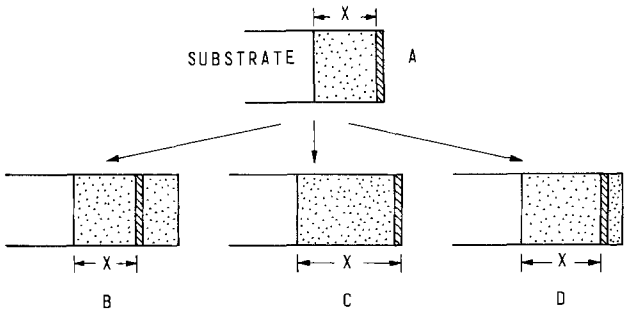

Fig. 2. The positions of a layer of oxide containing P if the phosphate ions are immobile. A, the dotted area represents the oxide which was formed in an electrolyte containing no phosphate and the cross-hatched area that formed with phosphate in the electrolyte. B, illustrates its position if A is further oxidized in phosphate-free electrolyte and if growth takes place solely by outward migration of Si; C, if growth takes place solely by inward migration of the anion, and D, if growth takes place by both outward migration of Si and inward migration of oxidant. In B the distance, x, between the interface and the P layer remains the same as that in A; in C, x increases by the thickness of oxide grown in the final oxidation; in D, x increases by a fraction of the thickness of the oxide grown. In no case should the final value of x be less than its initial value in A.

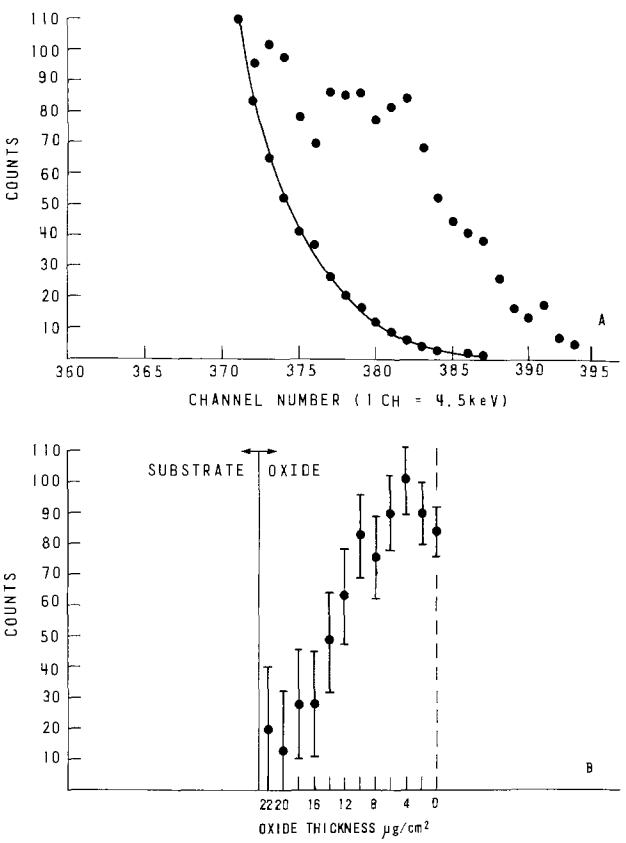

Fig. 3. A. Part of a Rutherford backscattering spectrum derived from Si and P. The lower data points joined by a solid line are derived from Si in a specimen oxidized to 150V in phosphate-free electrolyte. The upper data points are derived from P in the specimen after having been further anodized for 20V in an electrolyte containing phosphate. B. The distribution of P in the oxide deduced from the spectrum. The position of the interface represented by the solid vertical line was obtained from the full spectrum.

by a smoother curve is a part of the spectrum from a specimen anodized in normal electrolyte to 150V. These counts are derived from the Si edge. Superimposed on this are the data points obtained from the specimen after it had been further anodized (20V) in the electrolyte containing phosphate. The counts obtained from the Si have to be subtracted from these data points to give the counts derived from the P itself.

In Fig. 3B this subtraction has been made, the resulting precision indicated by error bars, the channel number (*i.e.*, energy scale) converted to depth scale and the data points folded about the half-height channel which marks the surface position. The line indicating the interface of substrate and oxide was obtained from the oxide step in the full spectrum in the same manner as in the noble gas experiments. Its precision is indicated by the error bar at the top of the line.

Now, it can be clearly seen in Fig. 3B, despite the error introduced by the lack of clean resolution of the P peak from the Si edge, that the distribution of the P is very wide. In the course of this work we had occasion to examine six other similarly prepared specimens. The width of the distribution measured at half-maximum height averaged 10 $\mu g/cm^2$ after correcting for the detector resolution.

If the P were immobile and thus contained entirely within the layer added by anodizing in the phosphate-containing electrolyte, the P distribution should be very close to 2.2 $\mu g/cm^2$ thick (Fig. 2A). This value was obtained in separate experiments. Since oxide thicknesses cannot be determined closer than $\pm$ 2 $\mu g/cm^2$ we could not obtain the thickness of the added layer from the difference in thickness measurements made before and after the layer was formed. Instead we anodized two specimens in normal electrolyte to 150V and two in the phosphate electrolyte to the same voltage, measured the oxide thickness then reanodized to 300V in both cases and again measured. We obtained the same rate of oxide formation for both electrolytes, viz, 0.11 $\mu g/cm^2/V$.

Thus the fact that the P distribution is 10 $\mu g/cm^2$ thick when it should only be 2.2 $\mu g/cm^2$ already provides evidence that the P is penetrating into the original oxide layer, *i.e.*, moving inward.

In the next part of the experiment we prepared a specimen as before (150V no phosphate, 20V phosphate) then anodized in the normal electrolyte for a further 75V. The P peak could not be discerned in its spectrum. This observation confirms that made in Ref. (6), viz., the oxide layer grown in a normal electrolyte on a specimen previously oxidized in an electrolyte containing phosphate, contains no P. In order to locate the P with respect to the interface we had to remove this last formed layer. We therefore determined the etch rate of the normal oxide in 0.2M HF in separate experiments. We used this established rate while removing the third layer to ensure that the correct amount was dissolved. Thus the specimen was again in a state in which the P could be resolved from the Si by our method of analysis.

In Fig. 4A we show the distribution obtained. It is wider and, more importantly, the point of maximum concentration has moved closer to the substrate oxide interface. We were able to reproduce this result in three other specimens within the precision expected of the measurement techniques. All specimens, when etched to thickness less than that of the original normally formed layer, contained amounts of phosphate consistent with the distribution determined by backscattering analysis. One, for example, etched to a thickness of 6 $\mu g/cm$ contained $\sim$ 20% of the original amount of P.

The specimen of Fig. 4A was anodized again in phosphate-free electrolyte and again etched. The result is shown in Fig. 4B. Clearly the point of maximum P distribution is now nearer to the substrate/oxide interface.

All these experiments yield results that indicate inward movement of P during anodic oxidation. It is therefore not a valid marker for the investigation of silicon and oxygen migration.

Conclusions

In our experiments, two different noble gases, Kr and Xe, were introduced into the surface layers of

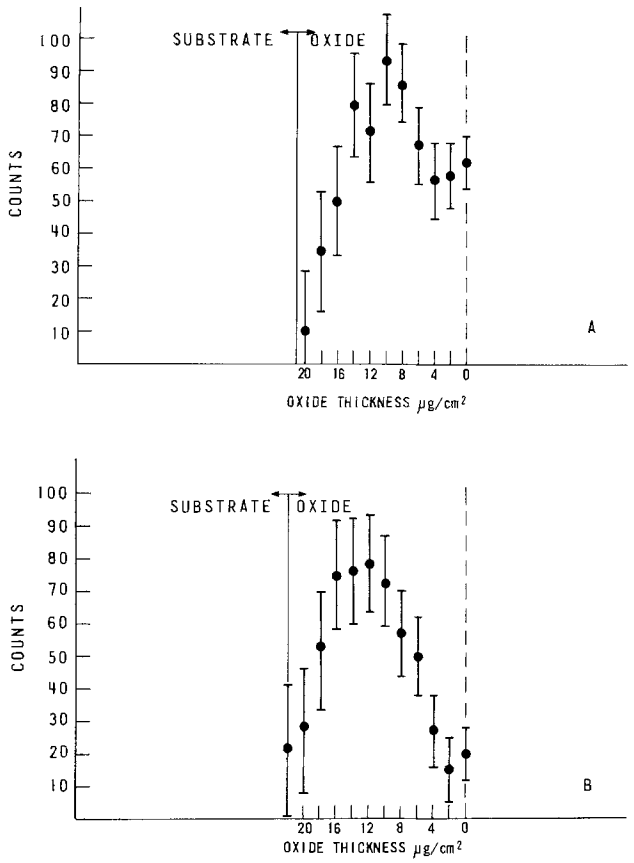

Fig. 4. A. The distribution of P in a specimen anodized to 150V in phosphate-free electrolyte, a further 20V in an electrolyte containing phosphate, and again in the first electrolyte for 75V followed by HF etching to remove the last-formed layer. The data points were derived from the P peak in the spectrum, the interface position from the oxide step in the spectrum, as in Fig. 3. B. The distribution of P in the same specimen as A after reanodizing a further 80V and removing the additional layer formed.

specimens as markers. Some of those specimens were covered only with the natural air-formed oxide, some with a preformed oxide film. Four different electrolytes were used for anodizing. In every case the markers were found to be very close to the outer oxide surface. In view of this consistency of the results we conclude that within the experimental error, the data indicate that inward movement of the anion is responsible for oxide growth when the listed electrolytes and current densities are used. In this respect anodic oxidation resembles thermal oxidation (17). We have also shown that P moves inward somewhat faster than the advancing oxide front, hence accounting for the observation of Ref. (7) that a phosphorus-free layer can be formed over one containing phosphorus even though the oxide grows by anion movement.

The Defect Structure of Phosphorus-Doped CdTe

F. A. Selim*,[1] and F. A. Kröger*

Department of Materials Science, University of Southern California, Los Angeles, California 90007

ABSTRACT

Room temperature Hall effect measurements on P-doped CdTe crystals cooled from equilibrium with atmospheres of well-defined Cd and Te_2 pressures at high temperature have made it possible to arrive at a defect model for P-doped CdTe. Temperature dependence of the Hall effect from 77° to 335°K showed P to give rise to shallow acceptor levels at $E_v + 0.035$ eV. The acceptors are probably P_{Te} and P_i. The number of holes per P atom is close to one at low P contents after annealing at medium Cd pressures. The ratio decreases with increasing P concentration and by annealing at low or high cadmium pressure, indicating self-compensation. At high p_{Cd} the self-compensation involves native defects ($Cd_i^{\cdot\cdot}$). At low p_{Cd} it involved $P_{Cd}^{\cdot\cdot\cdot}$. At high P concentrations neutral associates $(P_{Cd}P_i)^\times$ and $(P_{Cd}2P_i)^\times$ are formed. The same model, with one additional constant, accounts for the solubility of phosphorus in CdTe.

P as a dopant is known to give p-type conductivity in CdTe. While originally acceptor centers formed were thought to give a level at $E_v + 0.38$ eV (1), later investigations showed acceptor levels at $E_v + 0.05$ eV (2-4). Generally, P concentrations $\geqq 10^{18}$ cm^{-3} were used, and the hole concentration was found to be considerably less than that of P, indicating a large degree of self-compensation (3-5). A higher degree of electrical compensation was observed after annealing at low cadmium pressure than at high cadmium pressure (5). An increase in the hole concentration was observed in samples implanted with P if Cd was implanted at the same time (6). Diffusion studies by Hall and Woodbury (5) show a double penetration profile, a fast one and a slow one. The fast diffusion at 900° and 950°C shows a decrease of diffusion rate with increasing p_{Cd} at $p_{Cd} < 0.3$ atm, independence of p_{Cd} occurring for $p_{Cd} > 0.3$ atm; the behavior at low p_{Cd} is uncertain. The same study (5) shows the solubility of P in CdTe at 900° and 950°C in equilibrium with a vapor of variable cadmium pressure but with constant Cd:P weight ratio of 100:1 to be proportional to p_{Cd} at $p_{Cd} > 10^{-1}$ atm, but to be independent of p_{Cd} at $p_{Cd} < 10^{-1}$ atm.

A reference to the defect structure of P-doped CdTe is found in the paper by Arkadeva *et al.* (6) where an increase of the hole concentration in P-doped CdTe after addition of Cd is attributed to an increase of P_{Te}, an acceptor at the cost of P_{Cd}, a donor. In the present paper, new results of Hall effect measurements on P-doped crystals are presented, and a defect model for P-doped CdTe is developed explaining both the new results and Hall and Woodbury's solubility data. Temperature dependence of the Hall effect in quenched crystals at low temperatures is used to determine the position of the acceptor level and the degree of self-compensation.

Experimental

Sample preparation.—Crystal boules of CdTe, doped respectively with 6×10^{16}, 2×10^{17}, 2×10^{18}, and 5×10^{19} P cm^{-3} were grown by unidirectional solidification of the melt by B. V. Dutt and E. Miller of our laboratory. The distribution coefficient $k \approx 0.1$. The P content was determined by spectrographic analysis and by mass spectrographic analysis.[2] The crystals were cut into plates of $10 \times 10 \times 2$ mm, lapped with 3200 mesh abrasive, washed in trichloroethylene, then rinsed in deionized water and etched with a solution of 10 weight percent (w/o) bromine in methanol.

Annealing of samples.—For annealing, crystal samples together with some Cd or Te were enclosed in an evacuated quartz glass tube. The tubes were placed in a two-temperature furnace and then annealed for 2 hr, a time shown to be sufficient to reach equilibrium. Prior to evacuation, the wall of the tube at the end where the crystal is located was thinned down by pulling the quartz when it softened. This procedure, recommended by de Nobel (7), was followed to increase the rate of cooling during quenching after the high temperature anneal. The crystals were annealed under cadmium pressures between the maximum pressure determined by the phase diagram and the minimum pressure region where sublimation occurs. Pressures close to the minimum pressure point where $p_{Cd} \approx 2p_{Te_2}$ were not used to avoid sublimation of the crystal. For pressures between the sublimation region and the tellurium side of the phase diagram, the crystals were annealed under Te_2 pressure. After the anneal, the crystals were quickly cooled to room temperature by shifting the quartz tube out of the furnace followed by quenching with ethylene glycol.

Hall effect and resistivity measurements.—The van der Pauw (8) method was used to measure the Hall effect and resistivity. A cloverleaf-shaped sample made by notching the four sides was used initially, but the notching was abandoned when we learned both from our own experiments and from those by Chwang *et al.* (9) that these notches, which increased the chances of breaking the crystals, do not appreciably increase the accuracy of the measurement. The apparatus used for the measurement of the Hall effect as a function of temperature in the range 77°-335°K was described by Beguwala (10). Carrier concentrations were calculated from the Hall constant R_H by the relation $c_h = 3\pi/8\ 1/R_H q$, where q is the electronic charge. Mobilities (μ_h) were calculated from the conductivity $\sigma_h = c_h q \mu_h$.

Electrical contacts.—Ohmic contacts to the samples, which were almost all p-type were made by electroless gold plating from a $HAuCl_4$ solution on a surface polished chemically with "Mirrolite," a polishing agent (marketed by Materials Development Company, Los Angeles, California). Ag epoxy was alloyed on top of the gold to attach the lead wires. All contacts were tested by a curve tracer to check their ohmicity before the electrical measurements were made.

Results and Discussion

Hole concentrations measured at room temperature on samples of various P concentration annealed at

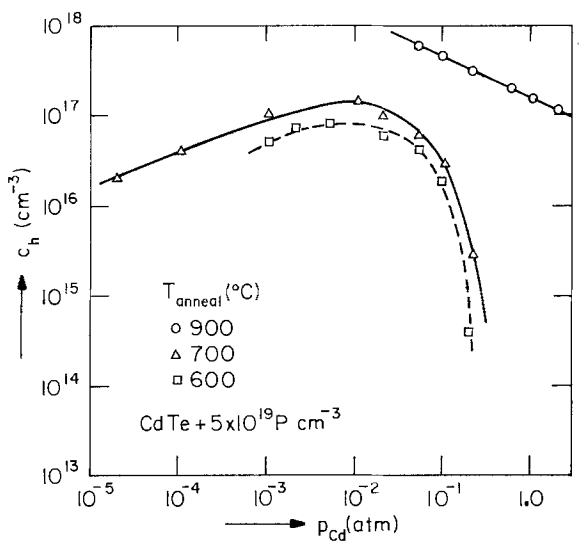

Fig. 2. Hole concentrations in CdTe + 5 × 10^{19} P cm^{-3} quenched after an anneal at high temperature where the crystal is in equilibrium with an atmosphere of different cadmium pressures.

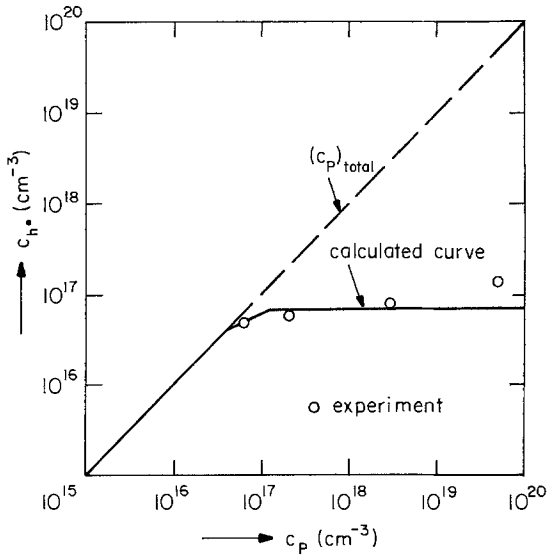

Fig. 3. Hole concentrations for CdTe with various P concentrations cooled after annealing at 700°C at $p_{Cd} = 10^{-2}$ atm.

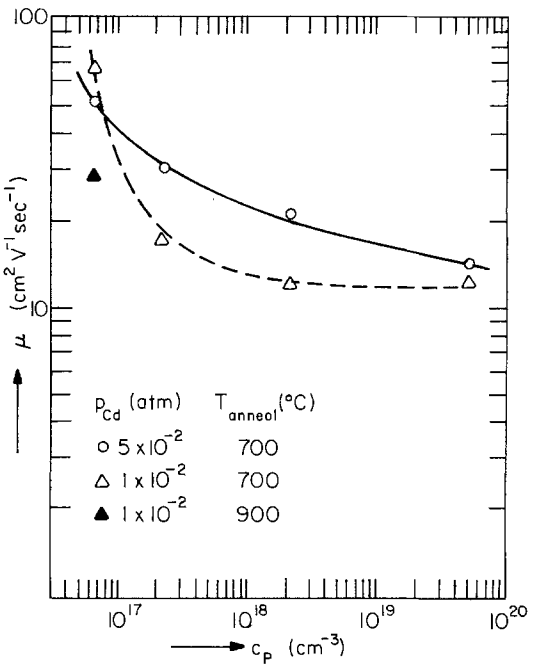

Fig. 4. Hole mobility at 25°C as a function of phosphorus concentration in crystals cooled after annealing under various conditions.

700°C under various cadmium pressures are shown in Fig. 1. Figure 2 shows similar data for CdTe + 5 × 10^{19} P cm^{-3} annealed at 600°, 700°, and 900°C. Samples with 6 × 10^{16} P cm^{-3} cooled after annealing at 900°C at high p_{Cd} have a high resistance. Figure 3 shows the dependence of the hole concentration on P content for samples cooled after annealing at 700°C under $p_{Cd} = 10^{-2}$ atm. Hole mobilities at room temperature in samples of various P content, annealed at 700°C under medium p_{Cd} are shown in Fig. 4. Characteristic features of Fig. 1-4 are:

1. The sharp reduction in c_h at the highest p_{Cd} in all samples annealed at 700°C.

2. Equality of the concentrations of holes and P in the sample with 6 × 10^{16} P cm^{-3} after annealing at $p_{Cd} = 10^{-2}$ atm and the gradual decrease in the ratio c_h/c_P with increasing c_P.

3. Increase of the annealing temperature increases the ratio c_h/c_P.

4. Samples annealed at medium to high p_{Cd} show hole concentration decreasing with increasing p_{Cd}; $c_h \propto p_{Cd}^m c_P^n$, with $m = -1/2$ to $-1/4$ and $n = 1/8$ to $1/2$.

5. Samples annealed at medium to low p_{Cd} show hole concentrations decreasing with decreasing p_{Cd}; $c_h \propto p_{Cd}^m c_P^n$, with $m \approx 1/4$ to $1/3$ and $n \leq 1/6$. This indicates P donor action.

6. At the lowest p_{Cd}, c_h increases with decreasing p_{Cd}, approaching the concentrations expected in undoped CdTe; here native acceptors come to the fore.

7. The hole mobility is largest for the low concentration sample in which $c_h \approx c_P$, it drops at higher c_P where $c_h << c_P$.

Acceptor levels.—In order to obtain information about the ionization energy of the acceptors responsible for the holes observed in the various samples, the Hall effect of a number of samples was measured as a function of temperature between room temperature and 77°K. Results for samples in which P dominates the results are shown in Fig. 5. Two activation

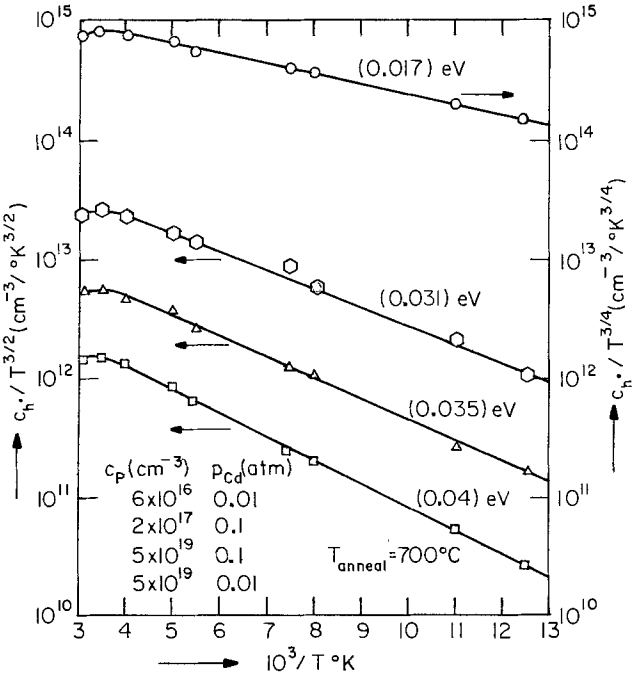

Fig. 5. Plots of $c_h/T^{3/2}$ and $c_h/T^{3/4}$ vs. $10^3/T$ used for determining the acceptor ionization energies in P-doped CdTe.

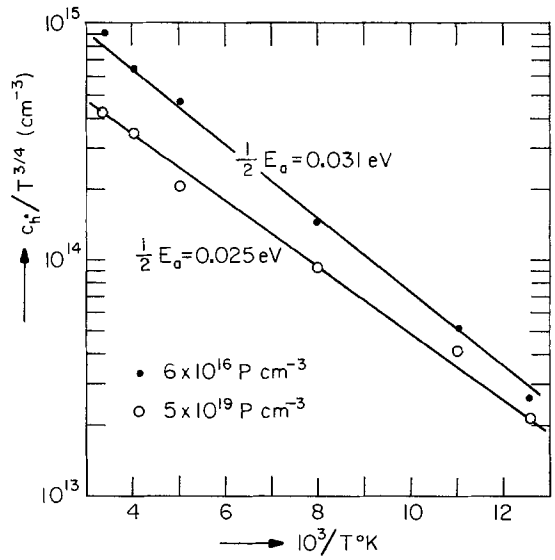

Fig. 6. Plots of $c_h/T^{3/4}$ vs. $10^3/T$ for samples annealed at 700°C and $p_{Cd} = 2 \times 10^{-5}$ atm having V_{Cd}' as the dominant ionized acceptor.

energies, differing by a factor two, are observed. The smaller value, ≈0.017 eV, is found for samples in which $c_h \approx c_P$. All other samples show the larger value. The latter represent the full ionization energy E_{aP} of the P acceptor, either P_i' or P_{Te}'; the small value represents 1/2 E_{aP} to be expected in uncompensated samples. Table I shows our values for E_{aP} together with values reported in the literature. The table also shows mobility values. The highest mobility [neglecting a doubtful value calculated from Ref. (3)] is found in the low concentration sample with $c_h \approx c_P$. The observed value, $\mu_h = 68$ cm^3 V^{-1} sec^{-1}, is almost identical to the value 70 cm^2 V^{-1} sec^{-1} reported for undoped CdTe. Lower values found at higher c_P (see Fig. 4) are the result of increased scattering at impurities expected in the presence of larger concentrations of charged and neutral species. Figure 6 shows the temperature dependence of the hole concentration for samples annealed in a manner to make native acceptors, probably V_{Cd}, dominant. The fact that the acceptors dominant in these samples, which were annealed at low p_{Cd}, are different from those present at a higher p_{Cd} is indicated by the shape of the isotherms of Fig. 1, which show an increase in the hole concentration with decreasing p_{Cd} at low p_{Cd} following a decrease at medium p_{Cd}. These samples show activation energies of 0.025-0.031 eV which, identified with half the ionization energy as expected for $c_h \approx c_{V_{Cd}'}$, gives $E_{V_{Cd}'} - E_V = 0.05 - 0.062$ eV, close to the values reported in the literature (13). For interpretation of the preexponential factors see below.

Defect species expected in CdTe-P.—In principle, P can form three basic defects: P_{Te}, a single acceptor, P_i, a single or multiple acceptor, and P_{Cd}, a triple donor. In addition, complexes of these species, either with ionized native defects or with other P species may occur. In particular, the multiply ionized donor, $P_{Cd}^{\cdots}$ should be expected to associate with negatively charged native defects or with P_i' or P_{Te}', forming species such as $(P_{Cd}V_{Cd})$; $(P_{Cd}P_i)$; $(P_{Cd}P_i)^{\times}$.

The single species will be dominant at low c_P, neutral or charged associates becoming dominant at large c_P. It is this dominance that must be held responsible for the large degree of self-compensation observed at larger c_P.

Local mode studies (14) indicate the presence of two species. One of these is either P_{Te} or P_i. Studies on alloys (Cd,Mg)Te:P and (Cd,Zn)Te:P (15) show that the other is an associate with properties fitting the species $(P_{Cd}P_i)^{\times}$ proposed below to explain the solubility data by Hall and Woodbury (5).

Defect equilibria in the system CdTe-P.—The equilibrium between a binary compound MX such as CdTe and the vapor of one of its constituents can be formulated with the aid of quasichemical defect equations and the corresponding mass action relations (16). Combining mass action relations for various incorporation reactions with the electroneutrality condition and the P balance, one can find expressions for the concentrations of various defects as $f(p_{Cd}, p_{P_2})$ or as

7.	$1/2\,P_2(g) + Cd(g) \rightarrow P_{Te}^{\times} + Cd_{Cd}^{\times}$	$H_{P_{Te}}$	$K_{P_{Te}} = [P_{Te}^{\times}]/(p_{Cd}p_{P_2}{}^{1/2})$
8.	$P_{Te}^{\times} \rightarrow P_{Te}' + h^{\cdot}$	$E_{aP_{Te}}$	$K_{aP_{Te}} = [P_{Te}'][h^{\cdot}]/[P_{Te}^{\times}]$
9.	$2P_i^{\times} + V_{Cd}^{\times} \rightarrow (P_{Cd}P_i)^{\times} + V_i^{\times}$	$H_{(P_{Cd}P_i)}{}^{\times}$	$K_{(P_{Cd}P_i)}{}^{\times} = [(P_{Cd}P_i)^{\times}]/[P_i^{\times}]^2\,[V_{Cd}^{\times}]$
10.	$3P_i^{\times} + V_{Cd}^{\times} \rightarrow (P_{Cd}2P_i)^{\times} + V_i^{\times}$	$H_{(P_{Cd}2P_i)}{}^{\times}$	$K_{(P_{Cd}2P_i)}{}^{\times} = [(P_{Cd}2P_i)^{\times}]/[P_i^{\times}]^3\,[V_{Cd}^{\times}]$

Neutrality condition: $[h^{\cdot}] + 2[Cd_i^{\cdot\cdot}] = [e'] + [V_{Cd}'] + [P_i'] + [P_{Te}']$

Phosphorus balance: $[P_{Cd}^{t\cdot}] + [P_{Te}'] + [P_i'] + 2[(P_{Cd}P_i)^{\times}] + 3[(P_{Cd}2P_i)^{\times}] = [P_{total}]$

$f(p_{Cd}, [P]_{total})$. Although exact solutions can be obtained, insight into complex changes taking place upon variation of p_{Cd} or [P] is more easily obtained by deriving approximate solutions by a procedure in which the neutrality condition and the P balance are approximated by their dominant terms (17).

When this is done, the concentrations of all defects are obtained as expressions of the form [defect] $\propto p_{Cd}{}^m[P]_{total}{}^n$ or [defect] $\propto p_{Cd}{}^r p_{P_2}{}^s$ with m, n, r, and s real integers or simple fractions. Table II lists defect formation reactions and the corresponding mass action relations for the defect species that were found to be important as a result of this work. Symbols used are those proposed by Kröger and Vink (16).

Table III lists values of the exponents m, n, r, and s in the expressions for the concentrations of holes, P species, and native defects that are valid for various approximations to the neutrality condition and the P balance expression. Comparison of the pressure dependence of carriers with those expected for the various models makes it possible to decide which model fits the data.

Expressions for boundaries between ranges characterized by different approximations to the P balance and the neutrality condition are obtained by equating expressions for the concentration of any one of the species in two adjacent ranges. Expressions for range boundaries obtained in this way for the [P] *vs.* p_{Cd} fields and the p_{P_2} *vs.* p_{Cd} fields are given in Table IV.

Establishment of a defect model.—In establishing the defect structure of P-doped CdTe we have to take into account the results of Hall effect measurements by us and others, local mode studies (14, 15), and Hall and Woodbury's diffusion and solubility measurements (5). Also, the model should be consistent with the defect structure and the corresponding thermodynamic parameters for undoped CdTe (13) in such a way that one of the two species dominating the neutrality condition in undoped CdTe also dominates the neutrality condition in the adjoining range in doped CdTe. Further requirements are that P is present as an acceptor species at high p_{Cd}, but as a donor at low p_{Cd}. Consideration of the transformation reactions

$$P_{Cd}^{\times} + Cd(g) \rightleftarrows Cd_{Cd}^{\times} + P_i^{\times};$$

$$\text{and } P_i^{\times} + Cd(g) \rightleftarrows Cd_{Cd}^{\times} + P_{Te}^{\times}$$

shows that we may expect $P_{Te}^{\times}$ to be most important at high p_{Cd}, $P_{Cd}^{\times}$ at low p_{Cd}, and $P_i^{\times}$ in between. Whereas the choice of $P_{Cd}^{\times}$ as the donor species is clear, there are no compelling reasons for favoring either $P_i^{\times}$ or $P_{Te}^{\times}$ as the acceptor species. Yet, as we shall see, a good description of the solubility data requires the presence of both P_{Te} and P_i. Therefore, we introduce both species.

Figure 7 shows a set of isotherms accounting for the observed hole concentrations in CdTe-6 $\times$ 10^{16} P cm^{-3} after annealing at 700°C. The sharp cutoff of the hole concentration observed at high p_{Cd} (see Fig. 1) occurs at the point where at high temperature $c_e = c_h = K_i{}^{1/2}$. At p_{Cd} below the cutoff, $c_h \propto p_{Cd}{}^{-1/2}$ as required for a defect structure dominated by [P'] $\approx 2[Cd_i^{\cdot\cdot}]$, P' being either P_i' or P_{Te}'. The concentration of holes becomes equal to that of P at medium p_{Cd}. In this range $[P_{Cd}^{t\cdot}]$ rapidly increases with decreasing p_{Cd}, leading to a new range (XIV) governed by $[P_i'] \approx t[P_{Cd}^{t\cdot}]$ with $t = 2$ or 3. In this range $c_h \propto p_{Cd}{}^{1/(t+1)}$. The available information is not sufficient to decide between the two values of t, but $t = 3$ is most likely. While c_h decreases with decreasing p_{Cd}, the concentration of native acceptors A_n' increases, leading to a new range (XVI) governed by $[A_n'] = t[P_{Cd}^{t\cdot}]$. Now $c_h \propto p_{Cd}{}^{-1}$, and rapidly range I is reached where $[A_n'] \approx [h^{\cdot}]$. The phase boundary coincides approximately with the boundary between ranges I and XVI. The theoretical isotherms are valid for 700°C. However, most of the concentrations remain unchanged after cooling so that we can compare the room temperature values of c_h with the calculated isotherms. There is only one complication. According to Ref. (13), at 700°C A_n' consists for 42% of V_{Cd}' and for 58% of Te_i' with only the former having a level close enough to the valence band to leave its holes free upon cooling. As a result, one would expect a sharp drop in c_h in the range where $[Te_i'] > [h^{\cdot}]$. This is not observed. Possible explanations are:

1. Te_i' has an acceptor level in a position similar to that of V_{Cd}'.

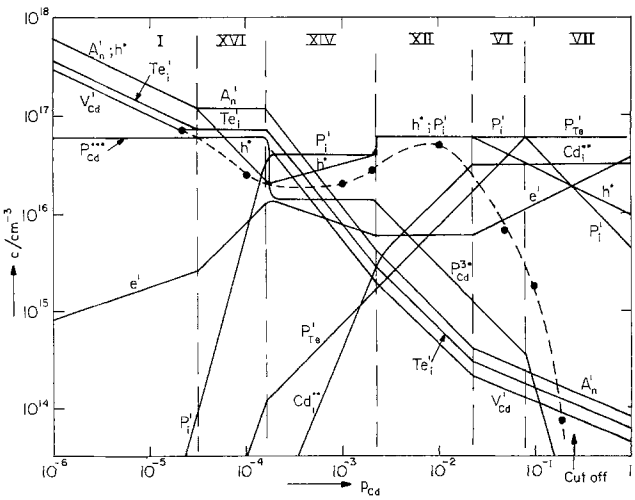

Fig. 7. Defect isotherms in Brouwer approximation for CdTe + 6 $\times$ 10^{16} P cm^{-3} at 700°C.

* t = degree of ionization of $P_{Cd}{}^{t\cdot}$.

2. Te_i precipitates during cooling.

3. The ratio between the concentrations of the two species is different from that reported in Ref. (13). It is not possible to decide this question at this point.

If we accept the ranges governing the sample with a low P concentration as given in Fig. 7, we can predict the manner in which the range boundaries vary with the P concentration by using the information of Table IV. New ranges may occur if new species become dominant. A set of regions accounting for almost all the experimental data is shown in Fig. 8. For the characterization of the various regions, see Table II. The figure is constructed in such a way that transitions between regions occur if one of the species dominating the neutrality condition or the P balance in a region is changed. The defect structure of undoped CdTe as proposed in Ref. (13) is represented by regions I-V. It contains an intrinsic region (III) at medium p_{Cd}, regions IV and V dominated by e' and $Cd_i{}^{\cdot\cdot}$ at high p_{Cd} and regions I and II dominated by $h^{\cdot}$ and $V_{Cd}{}'$. The difference between I and II and between IV and V is due to a difference in the major P species present as a minority species. Regions at high P concentration have neutral associates $(P_{Cd}P_i)^{\times}$ and $(P_{Cd}2P_i)^{\times}$ as the dominant phosphorus species. According to the model as presented, in ranges XIV, XI, and X, $c_h \propto p_{Cd}{}^{1/(t+1)}$ but independent of P concentration and thus does not account for a small increase in c_h observed at the highest P concentration (see Fig. 1 and 3). This discrepancy is removed by replacing range XIV by a range governed by $[h^{\cdot}] = [P_i']$, with $[P]_{total} = 2[(P_{Cd}P_i)^{\times}]$, giving $c_h \propto p_{Cd}{}^{1/4}c_P{}^{1/4}$. However, this model requires that measurement of $c_h(T)$ gives $\frac{1}{2}\,E_{aP}$ as the activation energy of carrier liberation, whereas the full value E_{aP} is $\approx$ 0.038 eV is observed (data not shown in Fig. 5). Also, this model does not give the steep rise in c_h with decreasing p_{Cd} observed at the lowest p_{Cd}. Therefore, this change is not justified. Figure 9 shows a region-plot in terms of p_{Cd} and p_{P2}. Figure 10 shows defect concentrations as a function of $(c_P)_{total}$ for samples annealed at 700°C under $p_{Cd} = 10^{-2}$ atm. Values of constant $K_{(PCdPi)}$ of Table II, reaction 9, has been chosen to fit the results shown in Fig. 3. A similar adaptation to results of Fig. 2 lead to values of this constant at 900°C and thus to the constant as $f(T)$

$$K_{(PCdPi)} = 500 \exp + (1.73\ \text{eV}/kT)\ \text{site}\ fr^{-1}$$

The model as presented finds support in the results of a microstructure investigation by Rustomji and Narayanan (18).

Interpretation of solubility data.—According to Hall and Woodbury (5) the solubility of P in crystals equilibrated at 900°C with a vapor of Cd and P_2 with a constant weight ratio of Cd to P of 100:1 corresponding to a partial pressure ratio $p_{P_2}:p_{Cd} = 1.82 \times 10^{-2}$ varies with $p_{Cd}{}^{m}p_{P_2}{}^{n} = 1.82 \times 10^{-2}\,p_{Cd}{}^{m+n}$ with $m + n$

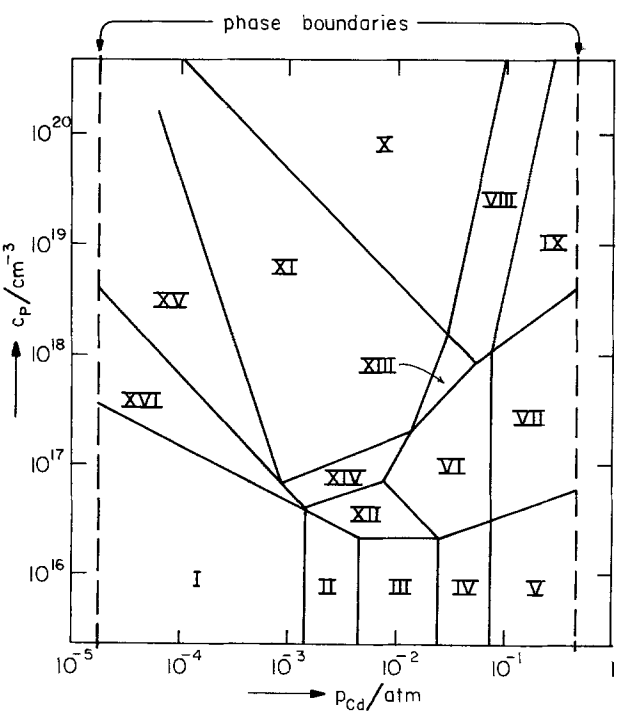

Fig. 8. Range boundary diagram for P-doped CdTe at 700°C in a plot of c_P vs. p_{Cd}.

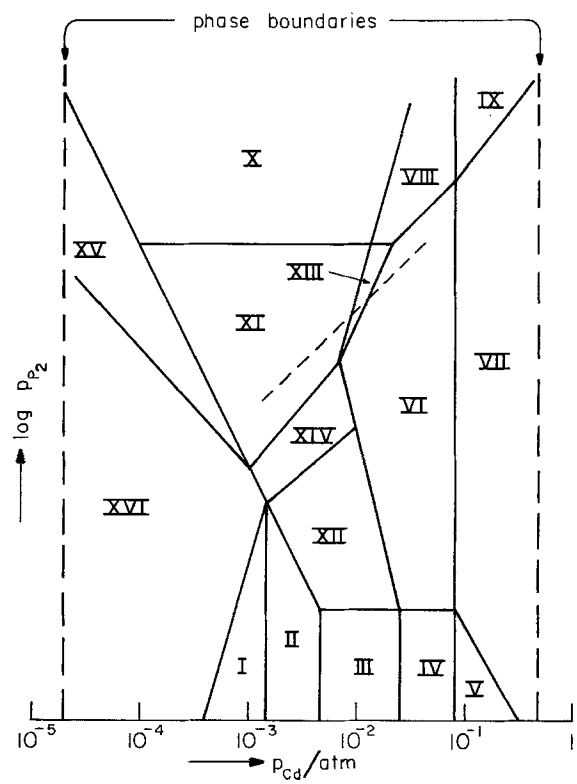

Fig. 9. Range boundary diagram for P-doped CdTe at 700°C in a plot of p_{P_2} vs. p_{Cd}. The dashed line under 45° corresponds to a path with $p_{P_2} \propto p_{Cd}$ as in Hall and Woodbury's solubility experiments.

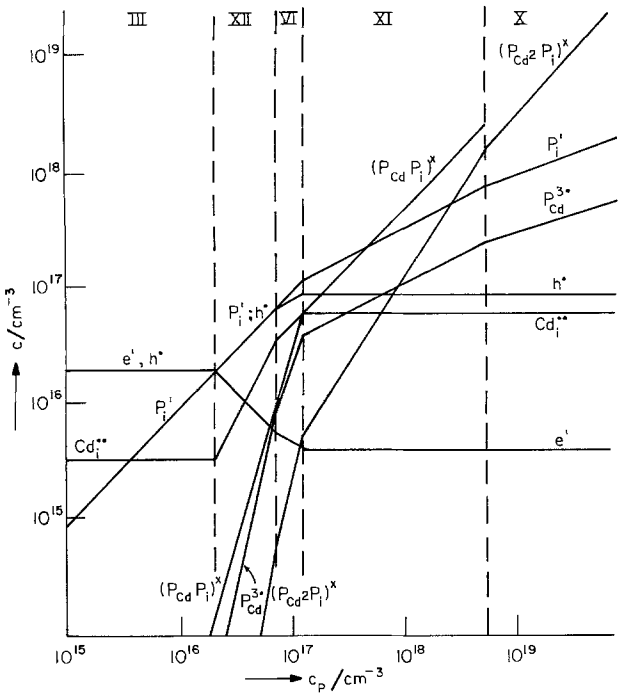

Fig. 10. Defect isotherms as $f(c_P)$ for $p_{Cd} = 10^{-2}$ atm, T = 700°C.

≈ 0 at $p_{Cd} \leq 0.1$ atm and $m + n \approx 0.7$ at $p_{Cd} \geq 0.1$ atm. According to our model, $m + n = 0$ in regions XI and XIII due to the predominance of the species $(P_{Cd}P_i)^\times$. On the other hand, $m + n = 0.67$ in the adjacent region VI, while $m + n = 1.33$ in region VII. Hall and Woodbury's experiments correspond to a line under 45° through a figure such as Fig. 9 (but drawn for 900° rather than 700°C). The experimental results, both as to the absolute value of the concentrations of phosphorus and the variation with p_{Cd} are accounted for by our model if we use for the constants regulating the formation of native defects the parameters given in Ref. (13), and $[(P_{Cd}P_i)^\times] = 3.7 \times 10^{18}$ cm^{-3}, $(K_{P_i\times})_{900°C} = 5 \times 10^{18}$ cm^{-3}, and $(K_{P_{Te}\times})_{900°C} = 10^{19}$ cm^{-3}.

Figure 11 shows the individual contributions to c_P by the various defects

$$[P] = [P_i'] + [P_{Te}'] + [P_{Cd}^{3\cdot}] + 2[(P_{Cd}P_i)^\times] \quad [1]$$

The concentrations of the various charged species are

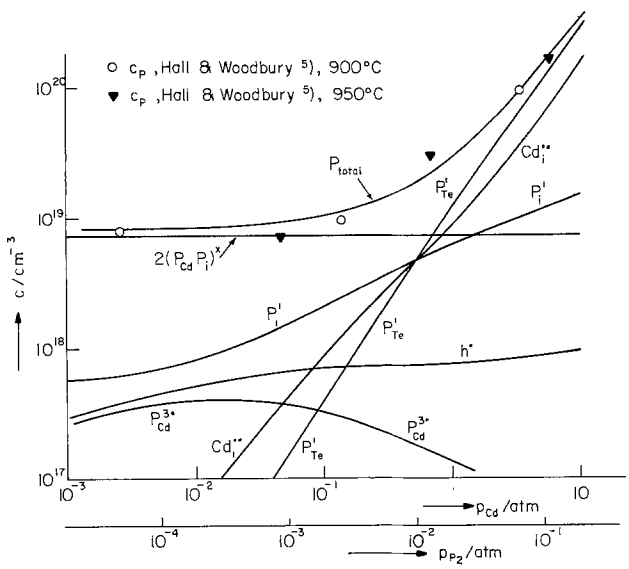

Fig. 11. Contributions to c_P at 900° and 950°C in CdTe equilibrated with a vapor of Cd + P_2 according to Hall and Woodbury (5).

found by expressing in the neutrality condition

$$[e'] + [P_i'] + [P_{Te}'] = 2[Cd_i^{\cdot\cdot}] + [P_{Cd}^{3\cdot}] + [h\cdot] \quad [2]$$

the concentrations of all species in terms of that of $h\cdot$

$$\frac{K_I}{c_h} + \frac{K_{aP_i}K_{P_i}{}^\times f p_{Cd}{}^{1/2}}{c_h} + \frac{K_{aP_{Te}}K_{P_{Te}}{}^\times f p_{Cd}{}^{3/2}}{c_h} = \frac{2K_{CdI}}{K_I{}^2} p_{Cd} c_h{}^2 + f\pi K p_{Cd}{}^{-1/2} c_h{}^3 + c_h \quad [3]$$

with $\pi K = K_{dP_{Cd}} \times K_{P_{Cd}} \times K_i{}^{-3} K_{CdV}{}^{\times -1} = 2.4 \times 10^{-36}$ cm^6, $f = (1.82 \times 10^{-2})^{1/2} = 0.135$, $(K_{AP_i}) \approx (K_{aP_{Te}})_{900°C} = 6.83 \times 10^{18}$ cm^{-3} (see next section). Solving this equation gives $c_h(p_{Cd})$, and the value of each term in the above equation is equal to the concentration of the corresponding defect in the neutrality condition. πK has been chosen to make $P_{Cd}{}^{3\cdot}$ dominant in the neutrality condition as required for range XI; a smaller πK, making holes the dominant positive species, would give an equally good representation of the solubility. On the other hand, dropping of either P_i' or P_{Te}' (with adjustment of the formation constant of the remaining species) leads to loss of accuracy of the representation of the solubility.

Interpretation of the low temperature Hall effect data on the basis of the defect model.—The number of charge carriers as a function of temperature gives information about the degree of compensation of the acceptors and their ionization energy. In the following, the hole concentration as $f(T)$ in p-type samples annealed under conditions corresponding to various regions of the range boundary diagram is discussed on the basis of the defect model.

The concentration of holes is related to the concentrations of neutral and ionized acceptors. For P_i as the major acceptor

$$\frac{[P_i'][h\cdot]}{[P_i{}^\times]} = K_{aP} = \frac{N_v}{gN} \exp(-E_{aP}/kT) \quad [4]$$

where E_{aP} is the acceptor depth measured from the valence band edge, N_v is the density of states in the valence band, equal to $2(2\pi m_h{}^* kT/h^2)^{3/2}$, N is the number of molecules CdTe per cm^3, g is a degeneracy factor equal to g_v (number of valence band maxima) times $g_{P_i\times}/g_{P_i'}$. Square brackets indicate concentrations in site fractions. The general neutrality condition is [2] and the phosphorus balance is [1]. At low P concentrations, medium p_{Cd} of anneal, and $T \geq$ 250°K, $[P]_{total} \approx [P_i'] \approx [h\cdot]$, independent of temperature. At lower temperature, $[P]_{total} \approx [P_i{}^\times]$ but $[P_i'] \approx [h\cdot]$ and

$$\frac{c_h}{T^{3/4}} = \left(\frac{c_{P,total}}{g}\right)^{1/2} \left(\frac{2\pi mk}{h^2}\right)^{3/4} \left(\frac{m_h{}^*}{m}\right)^{3/4} \exp(-E_{aP}/2kT) \quad [5]$$

A plot of log $c_h/T^{3/4}$ *vs.* T^{-1} gives a slope equal to $\frac{1}{2}E_{aP}$. This applies to the sample with 6×10^{16} P cm^{-3} annealed at 700°C at $p_{Cd} = 10^{-2}$ atm (Fig. 5) which yields $E_{aP} = 0.034$ eV. The intercept with the axis at $T^{-1} = 0$ has the value 1.7×10^{15} cm^{-3}/degree$^{3/2}$. Equating this with the preexponential factor of [5] with $m_h{}^* = 0.35$m (19) leads to $c_{P,total}/g = 2.9 \times 10^{15}$ cm^{-3} and thus $g \approx 20$. With $g_v = 4$ this indicates $g_{P_i\times}/g_{P_i'} = 5$.

At larger p_{Cd}, but the P concentration still low

$$[P_i'] \approx 2[Cd_i^{\cdot\cdot}] + [h\cdot] \approx [P]_{total} - [P_i{}^\times] >> [h\cdot]$$

we get

$$\frac{[h\cdot]\{2[Cd_i^{\cdot\cdot}] + [h\cdot]\}}{\{[P]_{total} - 2[Cd_i^{\cdot\cdot}] - [h\cdot]\}} = \frac{N_v}{gN}\exp(-E_{aP}/kT) \quad [6]$$

an expression that is equivalent to the well-known formula for p-type semiconductors in which the acceptors are partially compensated by donors (20). A plot of $[h\cdot]/T^{3/2}$ *vs.* $1/T$ now has the slope E_{aP}. For a sample with 2×10^{17} P cm^{-3} annealed at 700°C with $p_{Cd} = 0.1$ atm (the lower curve of Fig. 5), we find $E_{aP} = 0.04$ eV. The value of the intercept interpreted with $m_h^* = 0.35$m (19), $g \approx g_v = 4$ gives $c_{Cd_i^{\cdot\cdot}} = 1.8 \times 10^{16}$ cm^{-3}, close to the value 2.4×10^{16} cm^{-3} expected from the defect isotherms for this sample under the condition as given. Use of $g = 20$ as indicated by the sample with $[h\cdot] \approx [P_i']$ leads to $c_{Cd_i^{\cdot\cdot}} \approx 9.5 \times 10^{17}$ cm^{-3}, much larger than the expected value.

At higher P concentrations the P balance changes to

$$[P]_{total} = [P_{Te}^{\times}] + [P_{Te}'] + 3[(P_{Cd}2P_i)^{\times}]$$

giving

$$\frac{[h\cdot]\{2[Cd_i^{\cdot\cdot}] + [h\cdot]\}}{\{[P]_{total} - 3[(P_{Cd}2P_i)^{\times}] - 2[Cd_i^{\cdot\cdot}] - [h\cdot]\}} = \frac{N_v}{gN}\exp(-E_{aP}/kT) \quad [7]$$

A plot of $[h\cdot]T^{-3/2}$ *vs.* $1/T$ again has the slope E_{aP}. Samples 3 and 4 of Fig. 5 give $E_{aP} = 0.035$ and 0.031 eV. From the intercepts of the two middle curves of Fig. 6 for $c_{P,total} = 5 \times 10^{19}$ cm^{-3} with $m_h^* = 0.35$m, $g \approx g_v = 4$, and $[Cd_i^{\cdot\cdot}]$ as calculated from the model we compute for the concentration of $(P_{Cd}2P_i)^{\times}$ the values 4.3×10^{18} and 3.3×10^{18} cm^{-3}, close to the value 1.67×10^{19} cm^{-3} calculated from the defect model. Again $g = 20$ gives a worse fit.

We also applied the method of least squares to Eq. [4], [6], and [7], using a programmable calculator HP-65, for the experimental data of $c_h\cdot$ *vs.* $10^3/T$ of Fig. 5 and 6 in order to obtain the values of the unknown parameters of the equations. The results obtained were the same.

Summary

Single crystals of CdTe doped with various amounts of phosphorus were grown from the melt. Samples were annealed at different cadmium pressures at 700°, 800°, and 900°C, and Hall effect measurements were carried out on samples cooled to room temperature after the anneal. Defect isotherms are accounted for on the basis of a model in which phosphorus acts as an acceptor (P_{Te} and/or P_i) at high p_{Cd} and as a donor P_{Cd}, forming ($P_{Cd}P_i$), at low p_{Cd} as well as at high phosphorus concentrations. This model also accounts for the solubility or phosphorus in CdTe under various conditions. The phosphorus acceptor level (of P_{Te}' and/or P_i') is found to be at E_v + 0.035 eV.

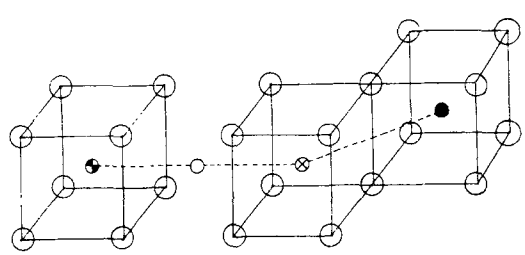
ABSTRACT

Single crystals of CdF_2 doubly doped with YbF_3 and ErF_3 efficiently convert infrared radiation (~0.93 μm) from a Si:GaAs diode to red and green light. By varying the Yb concentration, phosphors have been made which produce a red or green visual response. For the series of crystal samples of CdF_2:1% ErF_3:1-10% YbF_3 studied: at YbF_3 concentrations below 3%, only red Er^{3+} emission peaks were observed (6450-6800Å); at 3% YbF_3, red and green spectra (5300-5700Å) were observed, the green bands being much less intense; the most intense phosphor contained 10 mole percent (m/o) Yb^{3+}, and the green intensity was an order of magnitude higher than the red. Charge compensation by NaF of the rare earth ions in CdF_2:1% ErF_3:10% YbF_3 greatly reduces the intensity of emission bands, as well as the intensity of the absorption band at 976 nm, in agreement with previous studies of the absorption spectra properties of the YbF_3:CdF_2 system (1). Recent results of ^{19}F NMR of single crystals of CdF_2 containing high concentrations of YbF_3 and ErF_3, respectively, indicate that most of the rare earth ions and their associated interstitial fluorides are found in $(M^{3+}\text{-}F^-)_2$ dimers in the crystal (2). The intense absorption band observed at 976 nm in Yb^{3+}-doped CdF_2 can be assigned to this dimer, which is destroyed by the use of Na^+ as a charge compensator in place of interstitial fluoride, the native charge compensating defect. Similarly, as the accepted mechanism of the infrared-to-visible conversion in the Yb^{3+} sensitized Er^{3+} activated systems involves the transfer of two infrared photons from Yb^{3+} to Er^{3+}, phosphor emission by diode excitation will decrease when the $(M^{3+}\text{-}F^-)_2$ complex is destroyed by NaF substitution. The 976 nm strong absorption band was also observed in samples (10% Yb, 1% Er) prepared with 1-50 m/o of CaF_2 substituted for CdF_2 without appreciable decrease in the intensity; however the emission intensities of both green and red bands were significantly enhanced for all of the samples codoped with CaF_2. There appears to be a plateau for the compositions 1.5-3% CaF_2 and a decrease in the 4.5 and 10% CaF_2 samples. Of all the materials investigated to date, YF_3 and $BaYF_5$ codoped with Yb^{3+} and Er^{3+} are reported to be the most efficient upconverting systems with a quantum efficiency between 10^{-4} and 10^{-3} ($\lambda = 0.97$ μm). The quantum efficiency of CdF_2:10% YbF_3:1% ErF_3 is found to be 0.23% and that of CdF_2:10% YbF_3:1% ErF_3:2.5% CaF_2, 0.70%. These values were obtained under intense excitation with a GaAs diode. Lower values might be found at lower excitation densities.

Infrared excited visible fluorescence has attracted considerable attention in recent years (1-5). In combination with GaAs:Si diodes emitting in the near infrared (0.91-1 μm), phosphor materials capable of converting infrared to visible light are potential display or infrared detecting devices.

All the known phosphors of this class use trivalent rare earth ions. The systems which produce the brightest visible light use Yb^{3+} as the sensitizer with Er^{3+}, Ho^{3+}, or Tm^{3+} as the activator. The host crystals in which the most efficient upconversion has been obtained are YF_3, $BaYF_5$, LaF_3, and α-$NaYF_4$, doped with Yb^{3+} and Er^{3+}. The Yb^{3+} ions can absorb the GaAs infrared emission and are able to transfer most of the energy to Er^{3+} ions, both in their ground state and excited state, which then emit the green or red depending on concentration and the host crystal. Similarly, Yb^{3+} in combination with Ho^{3+} upconverts in the green or red and Yb^{3+} with Tm^{3+} in the appropriate host crystals upconverts in the blue.



In the first part of this paper a brief review of the spectroscopic properties of CdF_2 doped with small concentrations of YbF_3 is presented. The infrared visible upconverting properties of CdF_2:Yb:Er system are then discussed in detail.

Fig. 1. The symmetry of sites in the CdF_2 (RE) system

ions can enter the lattice substitutionally at the Cd^{2+} sites. Compensation for the excess charge of the tripositive rare earth ions in CdF_2 has been shown to occur by the incorporation of fluoride ions into the interstitial sites (6). The interstitial fluoride ion is either a nearest neighbor of RE^{3+}, an electrostatically favorable arrangement, in which case the symmetry around the rare earth is reduced to tetragonal, or the interstitial fluorides may be at a distance from the rare earth ion, thus preserving the cubic symmetry of the RE site. Charge compensation can also be attained by the introduction of univalent ions, such as Na^+, for each trivalent ion. The nearest neighbor Cd^{2+} sites are in [110] directions, and if the compensating Na^+ goes into one of these positions the symmetry around the RE is reduced to orthorhombic.

The absorption spectrum of CdF_2:0.1 Yb^{3+} single crystals was found to be unusual (7); the spectrum consists of an intense band at 976 nm and a less intense broad band absorption extending to about 900 nm. As NaF was added to the $CdF_2:Yb^{3+}$ system the intensity of the 976 nm band decreased. A sample containing sufficient sodium for complete charge compensation showed a spectrum which resembled that of Yb^{3+} in other solids, *e.g.*, yttrium gallium garnet, $YbCl_3 \cdot 6H_2O$, or CaF_2. This spectrum consists mainly of a sharp line at 962 nm and a broader absorption at 920 nm (8). In Fig. 2, the energy level diagram of Yb^{3+} in CdF_2 and CaF_2 is shown (9). On the basis of the oscillator strength of the absorption bands as well as the expected crystal field splitting of states in a cubic environment, Abbruscato *et al.* assigned the 962 nm band to the $\Gamma_7 \rightarrow \Gamma_7'$ and the 920 band as due to $\Gamma_7 \rightarrow \Gamma_8'$ transitions. They showed that the 976 nm band cannot be part of a cubic or noncubic spectrum of isolated Yb^{3+} ions in CdF_2. In addition, ESR measurements of $CdF_2:Yb^{3+}$ showed only sites of cubic symmetry, while the ESR of $CdF_2:Yb^{3+}:Na^+$ indicated Yb^{3+} in both cubic and orthorhombic sites. The ESR of $CaF_2:Yb^{3+}$ showed Yb^{3+} in cubic and tetragonal environments in the crystal (9).

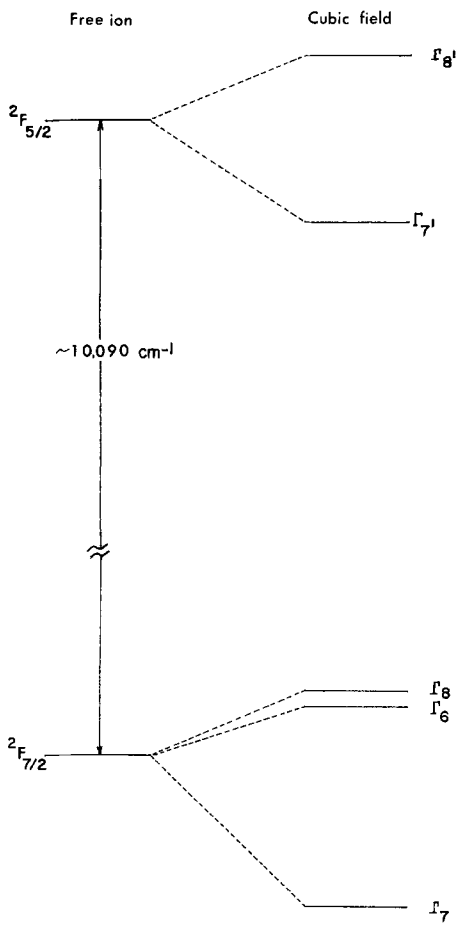

Fig. 2. Energy levels of the Yb^{3+} ion, free and in a cubic crystal field.

The main difference between the optical absorption of Yb^{3+} in CdF_2 and in CaF_2 has been the absence of the intense 976 nm absorption in CaF_2. Weller has shown that as little as 0.1% CaF_2 in the CdF_2:0.1 YbF_3 system decreased the intensity of the 976 nm band drastically and at about 7% CaF_2 content, the 976 nm band disappeared completely (10). Prener and Kingsley have shown that when CdF_2 crystal doped with Yb^{3+} or other RE ion is heated in Cd vapor to 500°C, the insulating transparent crystal becomes semiconducting and colored. Apparently the interstitial fluorides migrate to the surface and oxidize Cd. The liberated electrons do not reduce the rare earth (except Eu) but remain in a diffuse state over the 12 nearest neighbor Cd^{2+} ions. If Ca^{2+} is added the semiconducting property decreases until at 8% CaF_2, it disappears completely (11). On the basis of the above evidence Abbruscato *et al.* postulated that the 976 nm band in $CdF_2:Yb^{3+}$ is not an f-f transition but might be due to some center involving Yb^{3+} and interstitial F^-, Yb^{3+}-Yb^{3+} interactions via interstitial F^- or some similar defect.

^{19}F NMR in $CdF_2:Yb^{3+}$

The ^{19}F NMR measurement of CdF_2 doped with Er^{3+} and Yb^{3+} was undertaken in the hope of finding further evidence for the mechanism responsible for the unusual properties of CdF_2 doped with rare earth ions. In addition to the main resonance from the bulk of the lattice fluorides, weaker anisotropic resonances for two types of fluoride ions were detected (12, 13); one having axial symmetry about the [111] axes and the other one with its symmetry axis along the [100] axis. The [111] resonances were identified as the lattice fluorides adjacent to one rare earth ion. The [100] resonance can only arise from the interstitial fluorides (see Fig. 1) and their intensity indicates that this resonance accounts for nearly all the interstitial fluorides in the crystal. It has been shown that the anisotropy of the [100] ^{19}F resonance can only be explained by assuming each interstitial fluoride must have two rare earth ions at adjacent Cd^{2+} sites in which the RE^{3+}-F^--RE^{3+} angle is 90°. This is most readily explained by assuming that most of the rare earth ions and their associated interstitial fluorides are found in $(Re^{3+}\text{-}F^-)_2$ dimers as shown in Fig. 3. The [100] NMR spectrum could also be explained by zigzag chains of rare earth-interstitial fluoride along the (110) direction.

The ^{19}F NMR results appear to offer an explanation of the above-described ESR and optical spectra of Yb^{3+}-doped CdF_2 which showed only cubic ESR and additional bands not attributable to cubic sites. The additional bands can be assigned to this dimer; the lack of any ESR signal from these dimers can probably be attributed to spin exchange interactions between the two metal ions in the dimer. This would be equally true for the chain model.

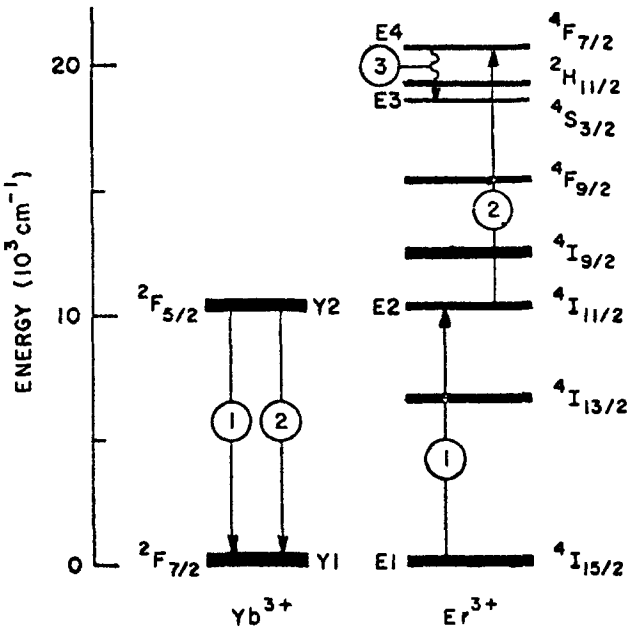

Fig. 4. Energy level diagram for Yb^{3+} and Er^{3+} showing the upconversion process.

CdF_2:Yb^{3+}:Er^{3+}—Infrared Visible Phosphor

The intense absorption band observed in CdF_2:Yb^{3+} at 976 nm suggested that efficient infrared-visible upconversion might be enhanced in CdF_2 crystals doped with Yb^{3+} and Er^{3+} if the primary absorption process is more efficient compared with other systems.

Figure 4 is an energy level diagram of Yb^{3+} and Er^{3+} showing the upconversion process in the green (14). Ytterbium ions absorb infrared radiation in the 0.91-1 μm range; an excited ytterbium ion transfers its energy to an erbium ion which is excited to the $^4I_{11/2}$ manifold; a second transfer of infrared quantum excites the $^4I_{11/2}$ to the $^4F_{7/2}$ level. The erbium then decays nonradiatively to the $^4S_{3/2}$ level, followed by visible fluorescence from $^4S_{3/2}$ in the region of 540 nm. In this process, two quanta of infrared are absorbed for every quantum of visible light emitted, and the intensity of green emission is found to increase as the square of the infrared exciting power (15). The conversion of infrared into red can take place by various routes, by the absorption of two or three quanta. In fluoride hosts, excitation spectra in the 350-500 nm range show that the most important path for red emission in Yb^{3+}-Er^{3+} samples is excitation of Er^{3+} to the $^4I_{11/2}$ level (by the transfer of energy from infrared-excited Yb^{3+}) followed by rapid nonradiative decay to the $^4I_{13/2}$ manifold; a second quantum of energy excites the electron from $^4I_{13/2}$ to $^4F_{9/2}$ from which red fluorescence is observed (16). The three quantum process for red emission has also been observed at high rare earth ion concentrations, with excitation of Er^{3+} by two quanta to ($^4I_{15/2} \rightarrow {}^4I_{11/2} \rightarrow {}^4F_{7/2}$), followed by nonradiative transition to $^4S_{3/2}$; from $^4S_{3/2}$ transition to $^4I_{13/2}$ accompanied by the back transfer of an infrared quantum to Yb^{3+}; a third quantum excites the Er^{3+} from $^4I_{13/2}$ to $^4F_{9/2}$ followed by transition to the ground state and red emission.

The complexity of the mechanism for upconversion implies that many factors affect the efficiency of the process. The purity of the samples is extremely important (17).

Experimental

CdF_2 was prepared from 99.999% pure cadmium metal (American Smelting and Refining Company) by precipitation with hydrofluoric acid. ErF_3, YbF_3, of purity > 99.9% (Lindsay Division of the American Potash and Chemical Corporation), NaF and CaF_2 of 99.99% purity were used. The CdF_2 single crystals doped and codoped with various concentrations of YbF_3, ErF_3, NaF, and CaF_2 were grown by the Bridgman technique; a graphite crucible was slowly lowered through a temperature gradient in the work coil of an rf generator, the crucible being maintained in an argon atmosphere. The weights were measured accurately before and after crystal growth; weight loss was attributed to CdF_2, hence the concentration of dopants reported is the minimum concentration possible. The crystals were cut to a uniform thickness of 1.7 mm and polished. Absorption spectra of samples were recorded on a Cary Model 14 spectrophotometer at room temperature. For the emission measurements, a thin disk (1.7 mm) of a polished single crystal was placed near the dome of a GaAs:Si diode (Texas Instruments Model TIXL 16) operated at 2A. The infrared radiation ($\sim$ 0.93 μm) emitted by the diode is absorbed by the phosphor which then emits visible light. The fluorescent output of the crystal was analyzed with the monochromator of a Spex spectrometer and detected with an (ITT-F-W-130-Products for Research) photomultiplier S20.

Results and Discussion

Figure 5 shows the emission spectrum of CdF_2:10% YbF_3:1% ErF_3 [all percent concentrations represent mole percent (m/o)] the most efficient phosphor in the series CdF_2:1-10% YbF_3:1% ErF_3 studied. A complex spectrum of three stronger bands at 538.3, 543.6, and 552.5 nm and two weaker broad bands at $\sim$ 522 and 530 nm are observed in the green region, and several peaks at 623.3, 652.0, 656.5, and 666.5 nm in the red. The intensity of emission bands in the 550 nm region is an order of magnitude greater than the intensity of the red bands and the crystal displays a bright green visible fluorescence. Samples of CdF_2:1-2% YbF_3:1% ErF_3 showed fluorescence bands only in the red; CdF_2:3% YbF_3:1% ErF_2 emitted in the green and the red, but bands in the green were much weaker than bands in the red. The effect of increasing the concentration of Yb^{3+} on the intensity of several of the emission bands is shown in Fig. 6. The intensity of both green and red emission increases with increasing concentration of Yb^{3+}; apparently the optimum concentration of Yb^{3+} is $\sim$ 20% in the CdF_2:Yb:Er system for green emission.

One of the objects of studying the infrared-to-visible upconverting properties of CdF_2:YbF_3:ErF_3 system was to shed further light on the origin of the 976 nm absorption band. The intensity of the emission bands is greatly reduced when NaF is introduced to replace interstitial F^- charge compensation by substitutional Na^+ which in effect destroys the $(M^{3+}\text{-}F_{int.}^-)_2$ clusters, and reduces the intensity of the 976 nm band. The emission spectrum of CdF_2:3.5% NaF:10% Yb:1% ErF_3 is shown in Fig. 7. The increased structure in

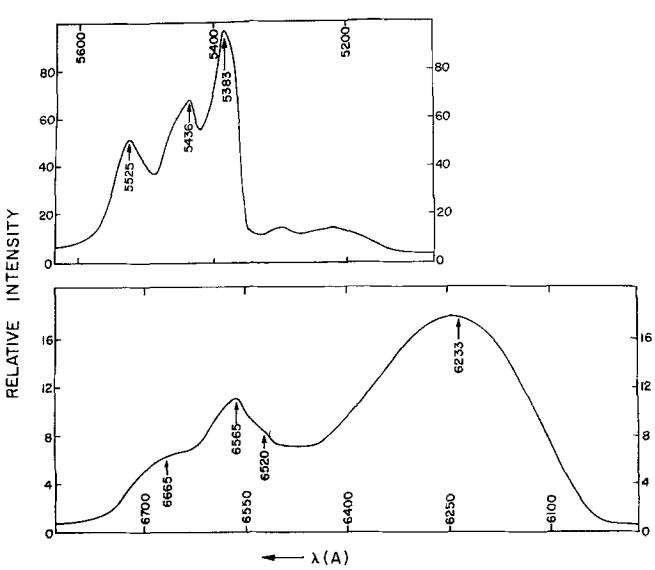

Fig. 5. Emission spectrum of CdF_2:10% YbF_3:1% ErF_3 (room temperature). Excitation by Si:GaAs diode ($\lambda \approx$ 0.93 μm).

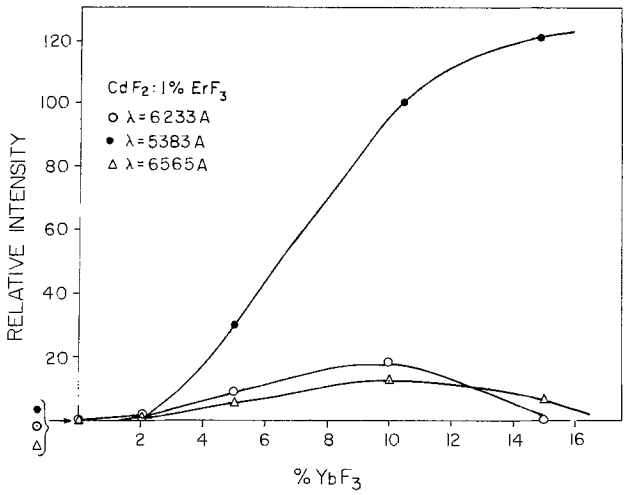

Fig. 6. Variation of relative intensity of various bands *vs.* Yb^{3+} concentration (Er^{3+} constant at 1 m/o).

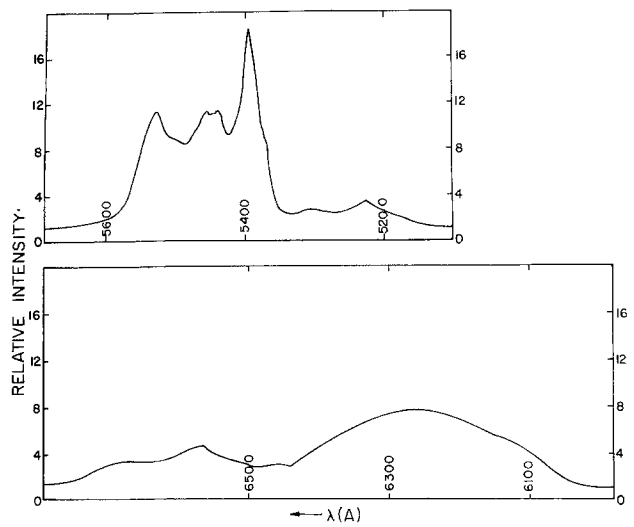

Fig. 7. Emission spectrum of CdF_2:10% YbF_3:1% ErF_3:3.3% NaF (diode excitation).

the emission bands observed is in agreement with the decreased site symmetry of the rare earth ion when Na^+ enters the lattice substitutionally, lifting the degeneracy of the excited states of the rare earth ion giving rise to the emission. The absorption spectra of Yb^{3+}-doped samples charge compensated with NaF show similar decreases in the intensity of the 976 nm band with increasing NaF concentration (7).

The results of CaF_2 substitution into the CdF_2: Yb: Er phosphor were unexpected. In Fig. 8 the variation with

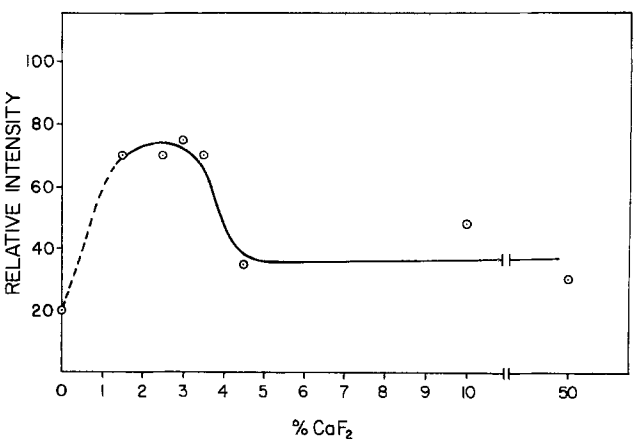

Fig. 8. Variation of relative intensity of 5383Å peak with CaF_2 concentration in $(CdF_2)_{1-x}(CaF_2)_x$:10% YbF_3:1% ErF_3.

CaF_2 concentration of intensity of the strongest green emission band (538.3 nm) is shown. For all the compositions CdF_2: 10% YbF_3: 1% ErF_3: 1.5-10% CaF_2 studied, the intensity of the emission bands is significantly enhanced both in the green and red regions of the spectra; however the increase in intensity is not very sensitive to the CaF_2 concentration. There appears to be a plateau for the composition range 1.5-3.5% CaF_2 and a decrease in intensity of the emission bands for the 4.5 and 10% CaF_2-doped samples. The absorption spectra of CdF_2: 10% YbF_3: 1% ErF_3 doped with 1-10% CaF_2, respectively, show no appreciable diminution in the 976 band intensity, with increasing concentration of CaF_2 at these high Yb^{3+} concentrations. In the light of the results on ^{19}F NMR with the proposed $(M^{3+}\text{-}F^-)_2$ dimers, it is tempting to propose that the effect of CaF_2 may be enhancement of the formation of mixed pair complexes (Er^{3+}-$F_{int.}^-$-Yb^{3+}) over pure complexes (Er^{3+}-$F_{int.}^-$-Er^{3+}) or (Yb^{3+}-$F_{int.}^-$-Yb^{3+}). Such centers would provide the most efficient energy transfer path for upconversion. Previous work has shown that the 976 nm band does not decrease appreciably in intensity when a second rare earth ion is present (8).

Efficiency.—The quantum efficiency of CdF_2: 10% YbF_3: 1% ErF_3 and CdF_2: 10% YbF_3: 1% ErF_3: 2.5% CaF_2 crystals, respectively, was measured as follows: the crystal was placed near the dome of the GaAs: Si diode and the fluorescent output was measured by a Clairex-CL-603 cadmium selenide photocell in conjunction with a Keithley 149 micromillivoltmeter. The voltage reading of the meter with diode alone ($= A =$ total infrared emission), the diode plus phosphor ($= B$ = total infrared transmitted and visible emitted), and the diode + phosphor + filter ($= C =$ visible emitted and transmitted by the filter) was measured, and the quantum efficiency calculated from the formula

$$\eta = \frac{C \times f}{A - B}$$

where f = attenuation factor of the filter (Corning No. 1-57). The formula, although approximate, is valid when $Cf << (A - B)$, which is true in this case. Determined in this way, the quantum efficiency of CdF_2: 10% YbF_3: 1% ErF_3 is 0.23% and that of CdF_2: 10% YbF_3: 1% ErF_2: 2.5% is 0.70%. The efficiency of green emitting GaP diode is about 0.1% (18). The quantum efficiency of the most efficient upconverting systems is between 10^{-2} and 10^{-1}% ($\lambda_{ex} = 0.97$ μm) (19). These values are difficult to compare due to differences in the condition of measurement. Our measurements were on single crystals, and well-known upconverting phosphors are available as powders. Grinding our samples would expose them to the well-known degradation of luminescence efficiency by crystal damage. Since our measurements were made at high excitation densities, the reported high efficiency compared to other materials may be attributable to this, at least in part. On the other hand, preliminary excitation studies on this phosphor system indicate that the quantum efficiency would most likely be improved with 976 nm excitation. These studies show a major excitation peak near 976 nm, corresponding to the "dimer" absorption band. A complete study of the excitation spectra is now in progress.

Conclusion

A new efficient infrared to visible upconverting system CdF_2: YbF_3: ErF_3: CaF_2 in single crystal form has been prepared. At the optimum concentrations of the rare earth ions (10 Yb: 1 Er) and codoped with ~ 3.5% CaF_2, in combination with a GaAs: Si diode emitting at ~ 0.93 μm the phosphor fluoresces a bright green. Quantum efficiency measurements indicate this system to be a highly efficient upconverting phosphor.

The upconverting properties of the system codoped with NaF are in agreement with previously measured spectroscopic properties of the CdF_2: Yb system and

support the existence of $(M^{3+}\text{-}F_{int.}^{-})_2$ dimers, or similar complex centers.

The enhancement of the upconversion upon introducing CaF_2 into the system is contrary to predictions based on previously reported spectral data in the CdF_2:CaF_2:Yb system, which showed quenching of the intense 976 nm absorption band. The quantum efficiency of the most efficient phosphor system CaF_2: 10% YbF_3:1% ErF_3:2.5% CaF_2 studied is 0.70%.

Preparation of Y_2O_2S:Eu Phosphor Particles of Different Sizes by a Flux Method

Luuji Ozawa*

Zenith Radio Corporation, Chicago, Illinois 60639

ABSTRACT

The preparation of Y_2O_2S:Eu phosphor in sodium-sulfide flux was studied as a means of obtaining different particle sizes (3-50 μm). Atmospheric control is absolutely necessary above 1050°C to prevent oxidation of both Y_2O_2S and the flux. It is found that the particle size distribution of the raw material (Y_2O_3) is reproduced in the starting particle of growth Y_2O_2S. The growth rate of small and nonaggregated single crystals of Y_2O_2S:Eu can be expressed by the equation, $d\phi/dt = A \exp(-\Delta E/kT)$.

Y_2O_2S:Eu phosphor is used as the red primary in color TV picture tube screens because of its high brightness (1) and factory reclaimability (2). There are many ways to prepare the powdered Y_2O_2S:Eu (3). Ormand and Banks (4) have reported recently a reproducible procedure of Y_2O_2S preparation by means of firing Y_2O_3 in a controlled gas mixture of N_2, H_2O, and H_2S. They obtain the Y_2O_2S powder of average particle size of 5-20 μm, depending on the firing temperature. The preparation procedure used widely in the phosphor production, however, is the flux method (5): It consists of firing a mixture of Y_2O_3, sodium carbonate, and sulfur. The particle size of Y_2O_2S obtained with this flux method at 1000°C is not a strong function of time and temperature and median particle size is about 4 μm by the sedimentation weight method. Firing above 1050°C in air results in an increase in the amount of Y_2O_3 in the final products.

In this report, we have studied the growth of microcrystals of Y_2O_2S:Eu with sodium sulfide flux under a controlled atmosphere. The growth of the crystals is a strong function of time and temperature. It is suggested that the particles grow from the saturated solution of sodium sulfide by means of a thermal fluctuation caused by dissolution and deposition of Y_2O_2S:Eu.

Experimental Procedure

Y_2O_3 (5-9's) and Eu_2O_3 (3-9's) were used to prepare the Y_2O_2S:Eu. The rare earth oxides were dissolved in hot nitric acid and precipitated with hot oxalic acid. The precipitate was dried and then heated in air at 1000°C for 2 hr to convert it to Y_2O_3:Eu. This oxide plus sulfur and sodium carbonate were mixed in a ball mill. Then the mixture was fired at various temperatures and times, using alumina crucibles mounted in a quartz tube. After firing, the samples were washed with hot deionized water several times to remove the residual sulfur and sodium compounds. The products obtained were analyzed by x-ray diffraction (XRD). The presence of Y_2O_3:Eu in Y_2O_2S:Eu at a concentration less than 5 mole percent (m/o), which is the limit for detection by XRD, can be determined by its luminescence under 254 nm excitation; Y_2O_3:Eu has an isolated luminescence line at 611 nm. The particle size distribution of the

phosphor was determined by the sedimentation weight method using 3g samples. The median particle size was determined graphically from these sedimentation data on log-normal probability graph paper (6).

Results and Discussion

Y_2O_2S:Eu phosphors were prepared by the flux method by heating a mixture of Y_2O_3:Eu, sodium carbonate and sulfur to various temperatures ranging 1000°-1300°C. The technique of heating oxides with a large amount of sodium carbonate and sulfur is well known as the sulfide fusion method used in analytical chemistry to convert oxides to soluble sulfides. The reaction between sodium carbonate and excess sulfur at high temperature produces Na_2S_x (x = 1-5; mp varies from 200° to 950°C, depending on x). Hence Na_2S_x will be referred to as the flux. The products of sulfide fusion are usually sulfides. In our case, however, XRD analysis showed that the final products prepared under well-controlled conditions were always oxysulfides (Y_2O_2S rather than Y_2S_x or $NaYS_2$); about 0.01 weight percent (w/o) sodium in the Y_2O_2S was detected by flame analysis. With an uncontrolled firing atmosphere of air the products usually contained Y_2O_3 and, sometimes, $Y_2O_2SO_4$.

By firing at 1000°C in air, the temperature (T) and time (t) are not critical to the final results; we usually obtained 90-95% oxysulfide, although the final products sometimes had a light brown body color. The body color of the samples before washing was yellow brown. By firing above 1100°C in air, the yield of oxysulfide was markedly decreased with increasing T and t. The surface layer of the samples fired above 1100°C before washing was increasingly white with increasing T and t. The samples fired at 1250°C for more than 5 hr in air had a completely white color which was confirmed by XRD to be Y_2O_3, $Y_2O_2SO_4$, and Na_2SO_4.

Oxidation of products.—A mixture of sodium carbonate and excess sulfur was heated. The mixture was melted above 500°C. After the solution cooled to room temperature, the products heated below 1000°C were brownish yellow, presumably a mixture of Na_2S_x. The colors of Na_2S_x are light pink (x = 1), light yellow (x = 2), and red (x = 5). Above 1100°C, a colorless Na_2SO_4 as a consequence of oxidation of Na_2S_x was obtained.

In order to understand the stability of Y_2O_2S at high temperature in air, the oxidation of Y_2O_2S between 300° and 1300°C has been studied by differential thermal analysis (DTA) and XRD. Figure 1 shows the DTA curve of Y_2O_2S obtained with the temperature rising at a rate 15°C/min. Table I shows the analytical results by DTA and XRD. The results indicate the stepwise oxidation of Y_2O_2S to Y_2O_3 via $Y_2O_2SO_4$ as an intermediate. Y_2O_2S is stable below 700°C. As the temperature is increased to 750°C, the oxidation of Y_2O_2S to $Y_2O_2SO_4$ begins, and in the region 750°-900°C both Y_2O_2S and $Y_2O_2SO_4$ coexist (the first broad exothermic band in Fig. 1). Above 950°C, the DTA curve shows a slight dip followed by another broad exothermic band, and the third phase, Y_2O_3, appears. This three-phase region extends from 950° to 1050°C. In this temperature region, the amount of Y_2O_2S decreases rather sharply while the Y_2O_3 phase increases. However, $Y_2O_2SO_4$ is the major constituent. At 1075°C the decomposition of Y_2O_2S is complete and a two-phase region ($Y_2O_2SO_4$ and Y_2O_3) is maintained for a narrow temperature range; about 12°C wide. Continued heating beyond 1075°C produces a strong endothermic reaction representing complete decomposition of $Y_2O_2SO_4$. Beyond 1100°C, XRD data indicate a one-component phase, Y_2O_3, is present.

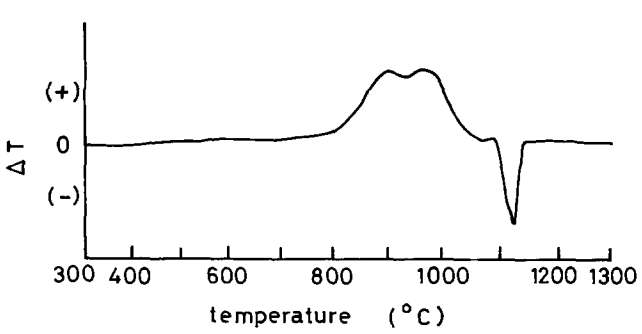

Fig. 1. Differential thermal analysis of Y_2O_2S:Eu in air

Table I. Oxidation of Y_2O_2S between 300° and 1300°C in air

Temperature (°C)	Number of phases	Compounds*
Below 700	1	$\underline{Y_2O_2S}$
750	2	$\underline{Y_2O_2S}$ + $Y_2O_2SO_4$(t)
800-900	2	$\underline{Y_2O_2S}$ + $Y_2O_2SO_4$(s)
950-975	3	$\underline{Y_2O_2S}$(s) + $Y_2O_2SO_4$ + Y_2O_3(s)
1075	2	$Y_2O_2SO_4$(s) + $\underline{Y_2O_3}$
Above 1125	1	$\underline{Y_2O_3}$

* (t) trace, (s) small amount, and underline is major compound.

Thus both Y_2O_2S and Na_2S_x are completely oxidized by heating beyond 1100°C in air.

Control of firing atmosphere.—The above results indicate that atmospheric control is absolutely necessary for the preparation of Y_2O_2S at $T > 1100$°C. Firing in a flow of inert gas such as N_2 resulted in final products containing varying amount of Y_2O_3. The flowing gas probably carried the sulfur out from the crucible. Satisfactory results, even at 1300°C, were obtained with the following procedures: The air in the quartz tube, in which the alumina crucibles were mounted, was first flushed out with wet nitrogen and the tube then put in the furnace. The tube was sealed after the samples reached the given temperature (about 30 min). The pressure in the sealed tube was slightly positive with respect to atmosphere. The amount of sodium carbonate and sulfur was not critical to the particle size and brightness of the final products; however, the best results were obtained with a mixing ratio of Y_2O_3, sodium carbonate, and sulfur of 1:1.5:4 (in mole fraction). Excess sulfur was always required for good reproducible results. With this procedure we obtained Y_2O_2S:Eu phosphors of median particle sizes of 3-50 μm.

The presence of europium in concentration of 10 m/o or less does not affect the crystal growth. When the mixture, fired at temperature above 1050°C more than 2 hr, is properly blended, equal quality phosphor is obtained whether Eu_2O_3 is present initially in solid solution, $(Y_{1-x}Eu_x)_2O_3$, or as a separate phase, Y_2O_3 + Eu_2O_3.

Note that cathodoluminescence intensities of the powder phosphors studied were independent of the particle sizes within the experimental error of ±5%.

Particle size distribution of Y_2O_2S:Eu.—Figure 2 shows a photograph at 260× magnification of particles of Y_2O_2S:Eu prepared at 1300°C for 5 hr. It can be seen that the particles have excellent crystal perfection with uniform faces. Particles of this quality are obtained by firing above 1050°C. If the temperature is below 1000°C, or the firing time less than 2 hr, aggregate particles of low crystal perfection are obtained.

Figure 3 shows the particle size distribution (PSD) of samples prepared at 1250°C for different t (2, 3, 5, and 8 hr) on log-normal probability graph paper. The PSD is determined with 3g samples containing 10^7 particles, so the data in Fig. 3 are statistically

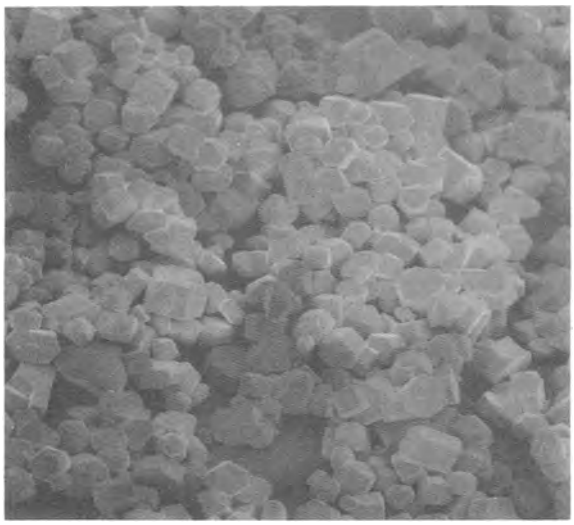

Fig. 2. Scanning electron micrograph of particles of Y_2O_2S:Eu fired at 1300°C for 5 hr under 260× magnification.

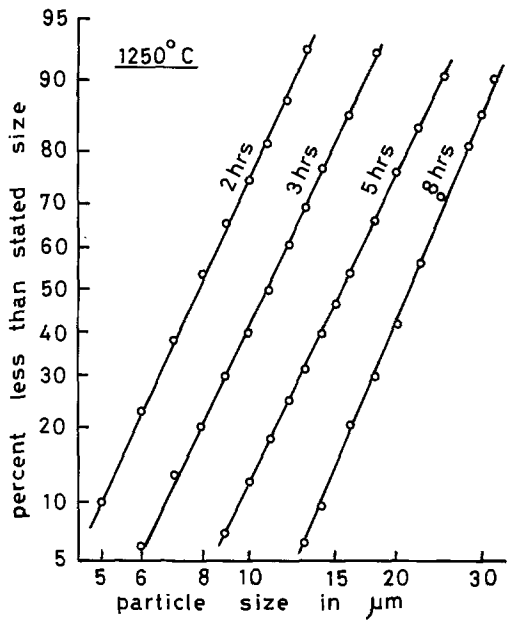

Fig. 3. Particle size distributions of Y_2O_2S:Eu fired at 1250°C for 2, 3, 5, and 8 hr on log-normal probability paper. Particle size was determined by calculation from weight sedimentation method.

representative of the mother PSD of the mother samples. The PSD of all the samples followed a log-normal distribution in which the distribution shifts with t; the standard deviation is $\sigma = 0.44$. Similar results were also obtained for T between 1100° and 1300°C. When the PSD belongs to the same distribution pattern with the same σ, we can use the median particle size ϕ_M in discussion instead of all the parameters of the PSD.

Crystal nucleation and growth.—The growth of Y_2O_2S particles of different sizes is discussed in terms of the formation of crystal nuclei and their growth in the flux. To our knowledge, there is no report regarding this subject, notwithstanding the importance of the preparation of Y_2O_2S:Eu phosphor.

The particles in Fig. 2 appear as smooth, well-formed and nonaggregated single crystals, indicating that they grow from individual seed crystals rather than from aggregates of crystallization nuclei. The result is also indicative that each crystal has its own domain in the flux and the crystals grow from a saturated solution of the domain under a slow cooling rate; however, samples cooled slowly from 1300°C (at 2°C/min) and those cooled quickly (removal of crucible from furnace directly to room temperatures) have the same PSD. Thus the Y_2O_2S particles (crystals) are grown in the furnace at constant temperature. A suggestive observation is the appearance of the fired mixture, which is in the form of a rod standing in the crucible: After 16 hr at 1300°C, the flux solution still remains in the whole of the rod instead of flowing to the crucible bottom, even though the pure flux is liquid at 500°C. This may be explained as follows: Assuming that the solubility and mobility of Y_2O_2S in the flux solution are very small, the dissolution of a particle of Y_2O_3, subsequent crystal nucleation and growth of a Y_2O_2S seed crystal may be restricted to a small volume (domain) of the flux solution just covering one particle. As the temperature increases, all of one Y_2O_3 particle is dissolved suddenly in a small volume V_1 of the flux solution, decreasing the solution temperature locally. The dissolved Y_2O_3 is immediately converted to Y_2O_2S as a result of chemical reaction with the sulfur in the flux. If the solubility of Y_2O_2S in the flux solution is very small (this is proven by the high yield, 95-98%, of Y_2O_2S), the flux solution in V_1 is saturated instantly with Y_2O_2S. A first nucleation of Y_2O_2S then occurs in this saturated solution. The Y_2O_2S dissolved in V_1 deposits on the first crystallization nucleus before several nuclei. If this is true, the size and distribution of the Y_2O_2S seed crystals produced at 1000°C (as described later in this section) should be similar to those of the Y_2O_3 raw material. Figure 4 shows the PSD's of the Y_2O_3 raw material (curve A), the Y_2O_2S prepared at 1000°C for 2 hr firing (curve B), Y_2O_2S prepared at 1100°C for 2 hr firing (curve C), and the primary particles of Y_2O_2S prepared at 1000°C for 2 hr firing (curve D). It can be seen in Fig. 4 curves A and B that the PSD of Y_2O_2S fired at 1000°C ($\phi_M = 3.5$ μm, $\sigma = 0.57$) is in good agreement with the PSD of the Y_2O_3 raw material ($\phi_M = 3.2$ μm, $\sigma = 0.57$). The standard deviations ($\sigma = 0.57$) of both PSD's, however, are larger than that of Y_2O_2S fired above 1100°C for $t > 2$ hr ($\sigma = 0.44$, curve C and Fig. 3). This is because of aggregation of particles of both Y_2O_3 raw material and Y_2O_2S fired at 1000°C. When the Y_2O_2S was prepared from a well ballmilled mixture of the primary (nonaggregated) particles of Y_2O_3 and the fine powder of sodium carbonate and sulfur passed through 200 mesh sieve, the PSD of the resulting Y_2O_2S prepared at 1000°C

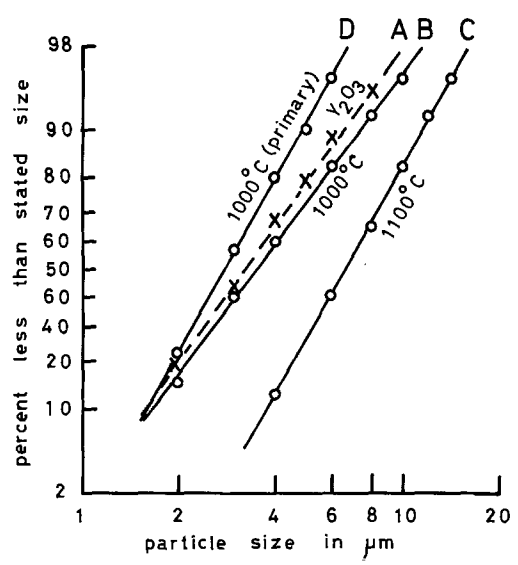

Fig. 4. Particle size distributions of Y_2O_2 raw material (curve A), Y_2O_2S:Eu prepared at 1000°C for 2 hr firing (curve B), Y_2O_2S:Eu prepared at 1100°C for 2 hr firing (curve C), and primary particles of Y_2O_2S:Eu prepared at 1000°C for 2 hr firing (curve D).

was improved: $\phi_M = 2.8$ μm, $\sigma = 0.44$ (curve D). The PSD of Y_2O_2S fired at 1000°C thus corresponds to the PSD of the Y_2O_3 raw material, suggesting that the flux solution surrounds each Y_2O_3 particle, including the aggregated particles, and forms Y_2O_2S particles, thereby reproducing the PSD of the Y_2O_3.

The flux temperature then increases. A few Y_2O_2S particles are dissolved suddenly in the heated flux solution of the volume $V_2 > V_1$, absorbing thermal energy locally. A saturated solution of Y_2O_2S exists in V_2 and Y_2O_2S deposits on the surfaces of one available Y_2O_2S crystal remaining in equilibrium with the solution in V_2. Y_2O_2S particles thus grow by the repetition of the above process (Fig. 5). For such a process of growth, aided by the above-described thermal fluctuation cycle, the rate of the particle growth $d\phi/dt$, as a first approximation, will be given by

$$\frac{d\phi}{dt} = A \exp\left(\frac{-\Delta E}{kT}\right) \quad [1]$$

where A is a constant for a given flux and crystal, k the Boltzmann constant, T the temperature in °K, and ΔE the activation energy which is given by a combination of Gibbs' free energy on the crystal surface and an activation energy of diffusion of Y_2O_2S in the flux. Then we have

$$\phi = At \exp\left(-\frac{\Delta E}{kT}\right) \quad [2]$$

The particle size is thus a function of both firing temperature and time.

Figure 6 shows the curves of particle size as a function of the firing time (hr) plotted on a log-log basis. The parameter is the firing temperature T (°C). All of the data obtained with firing time longer than 2 hr fit the straight lines which converge at 0.5 hr. The particle size at 0.5 hr (the effective seed crystal size) is estimated to be about 3 μm.

Figure 7 shows the curves of the same data used in Fig. 6; here the logarithm of the particle size is plotted against the reciprocal of the temperature (log/°K). The data again fit straight lines in which the slopes depend on the firing times; perhaps the effective diffusion of Y_2O_2S in the flux is increased with the firing times. The lines converge at 1000°C, at which the particle growth is effectively started. The estimated initial seed crystal size at 1000°C is about 3 μm.

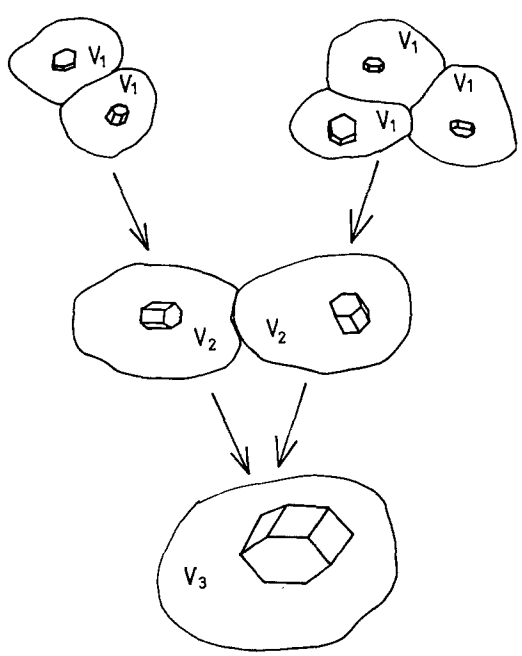

Fig. 5. Particle growth model of Y_2O_2S:Eu with sodium sulfide flux.

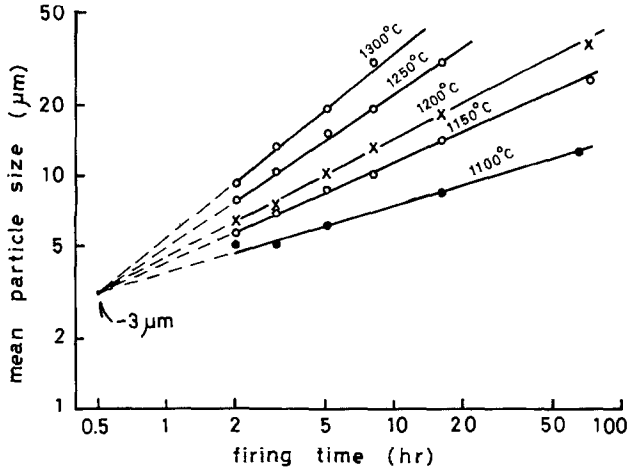

Fig. 6. Relationship between median particle sizes and firing times at various temperatures.

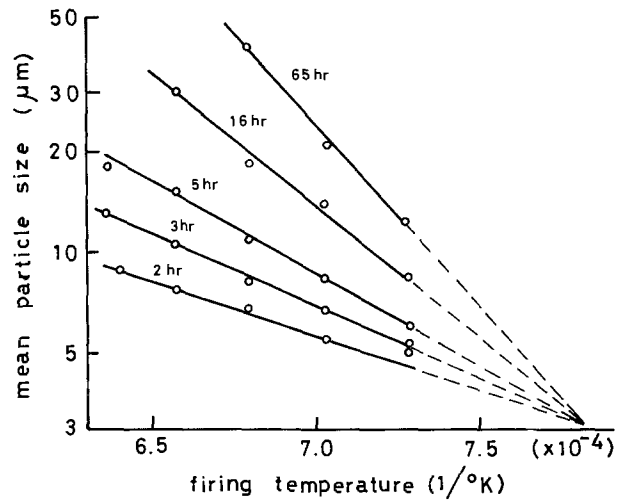

Fig. 7. Median particle sizes as a function of the reciprocal of the firing temperature (°K). Parameter is firing times.

In these experiments we used aggregated particles of Y_2O_3; the PSD of the primary particles was $\phi_M = 2.8$ and $\sigma = 0.44$. Thus the initial (seed) particle size estimated from Fig. 6 and 7 is in good agreement with the primary particle size of the Y_2O_2S fired at 1000°C.

Thus all the experimental data on the growth of Y_2O_2S:Eu crystals (particles) are consistent with Eq. [2].

Summary

We have shown that by using a controlled atmosphere good microcrystalline Y_2O_2S:Eu particles of a wide range of sizes can be grown from a sodium sulfide flux. The particle size distribution (PSD) of Y_2O_3 solid reagent is reproduced in the PSD of the product, Y_2O_2S:Eu. Any aggregated Y_2O_2S particles that are produced from aggregated Y_2O_3 are separated by the flux into primary particles which then grow by deposition on the smooth surfaces of the crystal from the saturated solution in accordance with Eq. [2]. The growth is believed to occur by means of a thermal fluctuation cycle of dissolution and deposition of Y_2O_2S:Eu.

Surface Charge Decay Characteristics of Photoconducting Binder Layers

P. K. C. Pillai, S. K. Aggarwal, and K. K. Roy

Department of Physics, Indian Institute of Technology, Delhi, New Delhi 110029, India

ABSTRACT

Various surface charge characteristics of HgI_2:CdS binder layers in polystyrene are discussed with special reference to their application in electrophotography. The binder layers are made with different compositions of HgI_2 and CdS. From the measurements of such parameters as the charge acceptance, contrast potential, and the spectral sensitivity, it is concluded that the layer containing HgI_2 and CdS in the ratio 60:40 by weight gives the most convincing results for its utilization in charge transfer electrophotography.

The electrophotographic technique consists of (*i*) the charging of a thin layer of photoconducting insulator, (*ii*) discharging the charged surface by a light pattern, and (*iii*) finally, the development with a suitable toner.

The electrophotographic plates consist mostly of an amorphous selenium layer on a metallic substrate or paper coated with zinc oxide in binder (1, 2). A binder-type plate can have significant advantages over Se-coated plates or ZnO-coated paper. It eliminates the costly process of vacuum evaporation of Se on aluminum substrates.

The binder-type plate consists of a mixture of photoconducting powder dispersed uniformly in an insulating resin binder. The resin or binder holds the photoconducting powder together. The binder also plays vital role in the charging and the discharging characteristics (3-6) of the layer. It also protects the layer from the moisture.

A variety of photoconducting material, *e.g.*, ZnO (1), CdS (4), ZnCdS (7-8), etc. have so far been used in binder-type electrophotography. Recently, the authors have developed a photoconductor system with a high value of I_{photo}/I_{dark} (5×10^3) and dark resistivity (10^{13} Ω-cm). The system consists of a uniform mixture of HgI_2 and CdS, in appropriate ratio, dispersed in polystyrene which acts as the binder. The substrate used here is NESA-coated glass plate because HgI_2 reacts chemically with metallic substrates.

The present paper deals with the determination of important electrophotographic characteristics such as contrast potential and spectral sensitivity of the HgI_2:CdS mixed system. The results illustrate that the system containing HgI_2 and CdS in the ratio 60 and 40 by weight has the most optimum characteristics to find its place in transfer electrophotography.

Experimental

Preparation of layers.—Fine powders of HgI_2 (BDH India Limited) and CdS (REACHIM, USSR) were used in the preparation of the layers. The proportion of HgI_2 in the system was varied from 0 to 100%. The powders, taken in appropriate ratio, were mixed and properly ground to get a homogeneous mixture. This mixture was added to polystyrene (60% by weight of the system) dissolved in benzene and the whole was milled to achieve a uniform dispersion of the photoconductor particles in the binder. The mixture was then poured over a conducting glass substrate and was allowed to undergo slow evaporation in benzene atmosphere. By varying the benzene content in the solution, the viscosity and hence the thickness of the layer can be controlled. Residual benzene in the layer was removed by keeping the plate in an air oven at 50°C for 4 hr.

Measurement techniques.—The HgI_2:CdS binder layers backed by the NESA-coated glass was mounted on a platform which could be slided under the corona unit during the charging mode or to the vibrating condenser probe assembly for charge measurements (Fig. 1). The photodischarge of the layers could be achieved by illuminating the layers through the probe by a 100W tungsten lamp. Following studies were made on the layers: (*i*) Surface potential as a function of grid voltage, corona voltage, and the time of charging. (*ii*) Decay of surface potential in dark as well as under different intensities of white light illumination to calculate the maximum contrast potential and optimum exposure to achieve it. The light of different intensities was obtained with the help of Kodak neutral density filters. (*iii*) Photodischarge of the layers at different wavelengths to calculate the spectral sensitivity.

For the determination of the spectral sensitivity, the photodischarge of the layer was noted when irradiated with light of different wavelengths but the same intensity. This was achieved by introducing Kodak narrow bandpass filters against the 100W tungsten lamp whose distance from the photoconductor surface was so adjusted that the radiations of different wavelengths incident on the photoconductor surface have the same intensity. Light intensity mea-

surements at the photoconductor surface was made by a standard 686 Mullard photoelectric bulb.

Results and Discussion

Charge acceptance.—One of the important factors in electrophotographic process is the amount of charge that can be applied to and retained on the surface of the photoconducting insulating layer. The surface charges, besides depending on the nature of the photoconductor, also depend on other ambient conditions, viz., corona voltage, grid voltage, and charging time (Fig. 2-4).

Decay characteristics of the surface potential.—The most important use of the apparatus, described in the measurement technique, is in the study of the decay characteristics of the charged layer. The surface potential depends on the electronic properties of the photoconductor, *e.g.*, carrier generation efficiency and mobility. It also depends on the mode of exposure. The surface potential also varies with temperature and relative humidity which were almost constant, of values 30°C and 40%, respectively, during the course of the investigation.

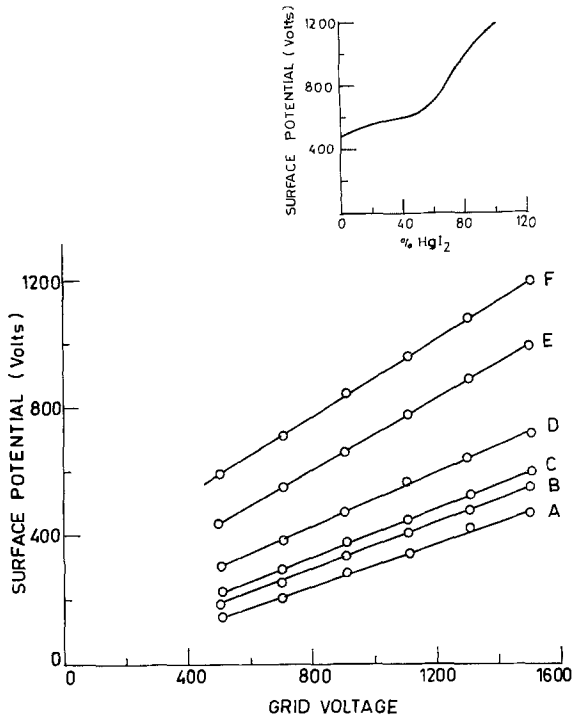

Fig. 3. Surface potential vs. grid voltage for the layer of different HgI_2:CdS compositions. A = 0:100, B = 20:80, C = 40:60, D = 60:40, E = 80:20, F = 100:0. Inset: Surface potential (at 1500 grid voltage) vs. % HgI_2.

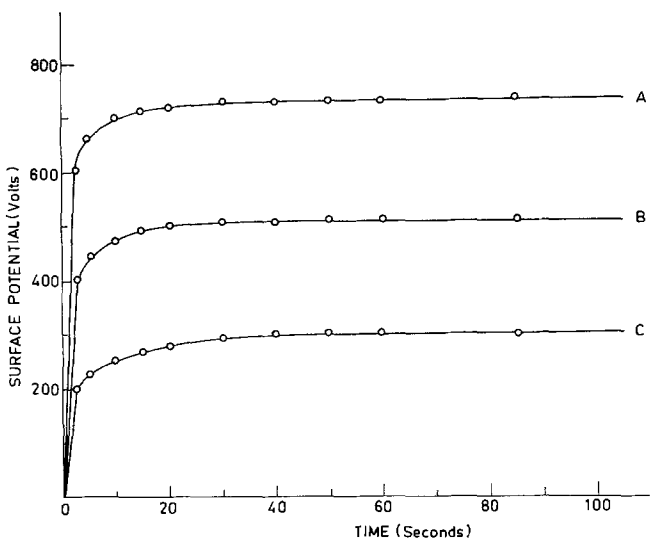

Fig. 4. Surface potential vs. charging time for the (60:40) layer for different grid voltages: A = 1500V, B = 1000V, C = 500V.

Contrast potential.—Contrast potential is one of the most important parameters which determines the applicability of a photoconductor system in electrophotography, since it is this factor which determines the successful toning of the electrostatic image. It is defined as the difference in the surface potential of areas illuminated by different intensities of light for the same duration. In the copying of a black and white document, the light intensities usually differ by an order of magnitude.

Considering two areas of the photoreceptor illuminated with light intensities I and dI, where d is related to the optical density D of the dark subject by $d = 10^{-D}$, the contrast potential V_c could be expressed as

$$V_c(X) = V(dX) - V(X)$$

where X is the exposure ($X = I \cdot t$).

Figure 5 depicts the contrast potential *vs.* exposure curves for layers containing different proportions of HgI_2 and CdS. V_0 indicates the initial potential in the different layers. Maximum contrast potential is found in the layer containing HgI_2 and CdS in the ratio of 60 to 40 by weight. With an initial potential (V_0) of 710V, the maximum contrast potential is almost 430V, *i.e.*, $0.6V_0$ which seems quite satisfactory for electrophotographic purposes.

Spectral sensitivity.—The effective photosensitivity of a particular photoconductive insulating layer is related to the rate of decay of the surface charge when light of a given intensity and wavelength band impinges upon the surface. This rate of decay depends primarily on the quantum efficiency for exciting charge carriers to a state of conduction and the effective mobility of these carriers in moving through the layer. The number of carriers released will depend on the amount (determined by the intensity) and energy (determined by the wavelength) of the incident light.

The photosensitivity of the electrophotographic layer can be expressed in terms of the rate of change of surface charge with exposure

$$S_\lambda = \frac{C\Delta V}{I \cdot t_h}$$

where C = capacitance per unit area, I = light intensity, t_h = half-decay time, and ΔV = reduction in the surface potential to one-half of its initial value.

The above formula is valid only for those systems where dark decay of the surface potential is negligibly small. Since dark decay in HgI_2:CdS binder layers is quite appreciable, the above formula can be modified as

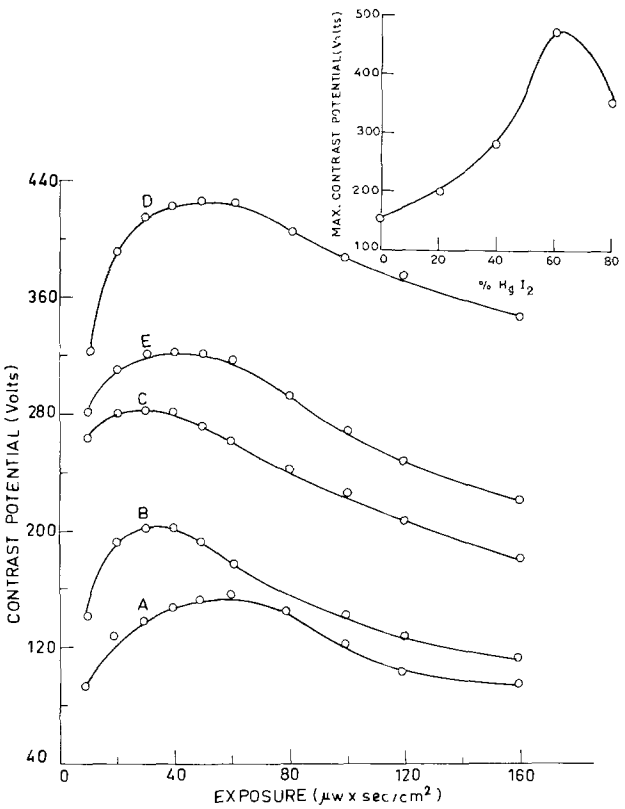

Fig. 5. Contrast potential *vs.* exposure for different HgI_2:CdS compositions at the dark charge level V_0. A = 0:100::HgI_2:CdS, V_0 = 384V; B = 20:80, V_0 = 425V; C = 40:60, V_0 = 446V; D = 60:40, V_0 = 710V; E = 80:20, V_0 = 1097V. Inset: Maximum contrast potential *vs.* % HgI_2.

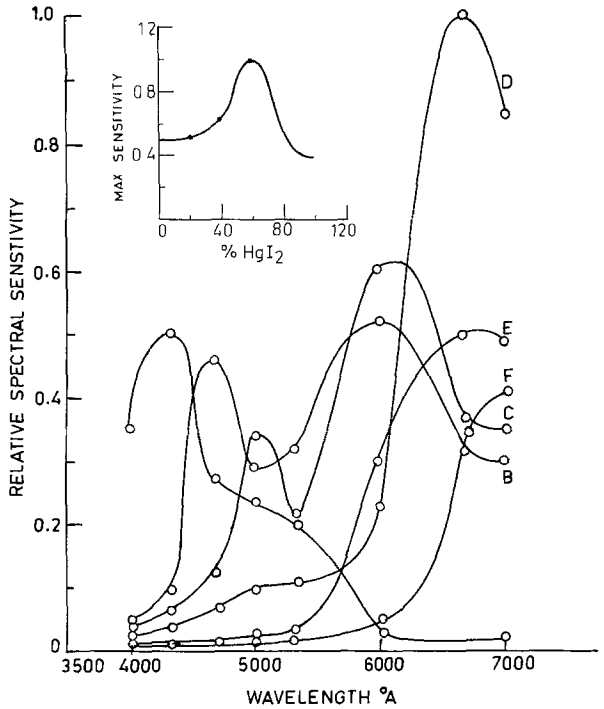

Fig. 6. Relative sensitivity *vs.* wavelengths for different HgI_2: CdS compositions. A = 0:100, B = 20:80, C = 40:60, D = 60:40, E = 80:20, F = 100:0. Inset: Maximum sensitivity *vs.* % HgI_2.

$$S_\lambda = \frac{C\Delta V_f}{I \cdot t_h}$$

where V_f represents the dark potential at the half-decay time and $\Delta V_f = V_f - V/2$.

For the calculation of the photosensitivity, the layers were charged to a fixed initial potential and then their decay was observed under monochromatic radiations of the same intensity.

The plots of spectral sensitivity *vs.* wavelength and maximum sensitivity *vs.* percentage of HgI_2 are given in Fig. 6. From the plot, we get the information that the position of the spectral sensitivity peak gradually shifts toward the long wavelength region as the percentage of HgI_2 is increased. For pure HgI_2 and pure CdS layers, the peak position is at 7000 and 4330Å, respectively. The peaks corresponding to the mixed layer lie between these two values. This implies that the mixing of HgI_2 and CdS has a definite effect on the spectral sensitivity and, together with the shift, the relative magnitude of the sensitivity is also affected as is evident from the inset. It is found that the layer containing 60:40 by weight of HgI_2 and CdS has the maximum sensitivity.

Summary and Conclusion

From the above studies, it is clear that pure HgI_2 and pure CdS layers do not have the desirable electrophotographic characteristics. But the electrophotographic characteristics are considerably improved by mixing the two in the ratio 60:40 by weight. Though the exact phenomenon responsible for this observation is not fully understood, it can be concluded at least that a gradual change in such properties, as the contrast potential and spectral sensitivity, takes place as the percentage of HgI_2 is increased and it is maximum for the 60:40 binder layer. However, the system is not as sensitive as the commercially exploited "Se" and "ZnO," but enough scope exists for further improvement in its characteristics.

The Use of an Internal Reference in Cathodoluminescence

Lyuji Ozawa* and H. N. Hersh*

Zenith Radio Corporation, Chicago, Illinois 60639

ABSTRACT

A new method to determine the slopes of the concentration-dependence curves of cathodoluminescence in the concentration region below 10^{-4} mole fraction is described. The method involves the measurement of the relative cathodoluminescence intenstiy of activator with respect to a deliberately added rare earth used as an internal reference, and gives results of significantly greater accuracy and precision which are independent of the sample preparation and measurement geometry. In Y_2O_3, under electron excitation, Sm^{3+}, Eu^{3+}, and Dy^{3+} are excited predominantly via the host, and Pr^{3+}, Tb^{3+}, Ho^{3+}, Er^{3+}, and Tm^{3+} are excited only directly.

It has recently been suggested (1) that the probability, S, of energy transfer from an excited host to an activator can be determined from the slope of the concentration-dependence curve below 10^{-3} mole fraction measured under conditions of continuous excitation. Since S is a fundamental parameter of cathodoluminescence (CL) efficiency (2-6) it is important to have accurate ways of determining it. Although S can in principle be determined using bandgap irradiation of the host crystal the method is not usually accurate and is not generally applicable because of the existence of interfering bands (*e.g.*, charge transfer) in the bandgap region, as indicated in Fig. 1. In general the concentration-dependence (CD) method can yield more accurate values of S since the slope can be measured accurately.

In this report, we describe a method of determining the luminescence intensity of rare earth activators in phosphors as a function of concentration with greater accuracy and precision than heretofore by measuring the ratio of the cathodoluminescence intensity (RCI) of the activator to that of deliberately added rare earth internal reference. In this method, effects due to variation in synthesis procedure, level of contamination, and measurement geometry can be removed from the final results. Consequently the slope of the CD curves of rare earth activated phosphors can be determined with less than 3% error.

Experimental

The phosphors studied were rare earth activated yttrium oxides where the activators were trivalent Pr, Sm, Eu, Tb, Dy, Ho, Er, and Tm. The yttrium oxide and rare earth components were 6*N* and 4*N* pure, respectively. The phosphor preparation method and the procedure for measuring CL intensities under continuous excitation have been described in previous publications (7, 8). The median particle size of Y_2O_3 was about 3 μm and independent of the firing temperature (800°-1400°C) of the rare earth oxalates (if new crucibles were used). A reproducible procedure for obtaining larger particles is to fire in borax flux (1 weight percent) or to fire large particles of Y_2O_2S in air above 1200°C to convert to Y_2O_3; large particles of Y_2O_2S yield large particles of Y_2O_3 up to 20 μm in size. The median particle size of the phosphor powders was determined by a sedimentation weight method using potassium silicate as the dispersant. Excitation spectra were obtained with a Perkin Elmer fluorescence spectrometer MPF-4.

Results and Discussion

Internal reference.—The rare earth internal reference must not interfere with the rare earth activator by either quenching or enhancing its luminescence. Figure 2 shows examples of such interferences as the concentration of each possible reference rare earth is increased. It can be seen that Ce and Pr are the strongest interferants except in Tb and Ho phosphors. Inter-

ferences in the concentration region below 10^{-2} mole fraction are presumably due to the electrostatic multipolar interactions (9). From the point of view of least interference and highest luminescence intensity, terbium (and dysprosium if Ce and Pr are present to less than 1 ppm) is the best internal reference for Y_2O_3 phosphors.

Accuracy and precision.—Figure 3 shows the RCI of Dy at 572 nm *vs.* Tb (10 ppm). It may be seen that the measured absolute intensities of Tb (10 ppm) and Dy show much scatter from sample to sample, but the RCI's of Dy fall smoothly on a straight line of slope 0.80, indicating the high precision of this method. The 0.80 slope of the RCI (Dy/Tb) curve is independent of the Tb reference concentration below 100 ppm even though the values of the RCI (Dy/Tb) are inversely proportional to the reference concentration. Similar results have also been obtained for the combination Eu and Dy; in this case the Eu/Dy RCI's fall on a straight line of slope 1.0.

Figure 4 shows the results for a triply activated Y_2O_3 containing equivalent amounts of Eu, Dy, and Pr as a function of concentration, using Tb (5 ppm) as the internal reference. (The CL of Pr was not determined because of its relatively weak intensity.) The RCI curves extrapolate smoothly to zero on a linear plot, indicating the high accuracy of this method. Pr interferes with Eu above 3 pm, and with Dy above 5 ppm, but Tb causes no interference with Pr below 10 ppm. At 10 ppm Pr, the Eu and Dy CL intensities are quenched 40 and 20%, respectively. These results are in accord with Fig. 2.

In order to demonstrate the superior precision of the RCI method, the CL data of Fig. 3 were taken by deliberately varying the physical arrangement of the samples and detector in the demountable cathode-

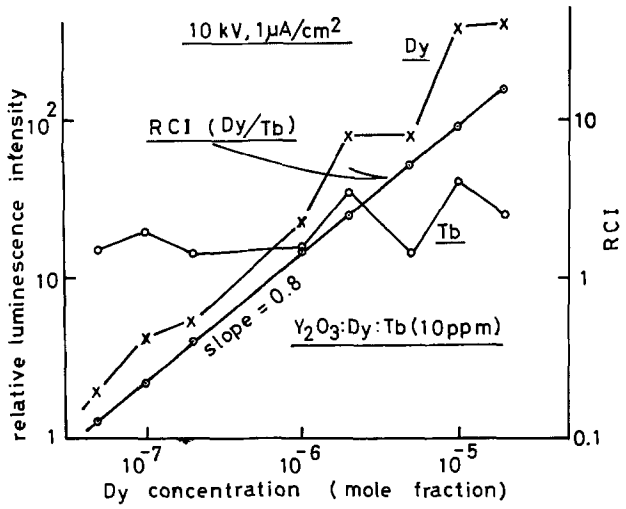

Fig. 3. Cathodoluminescence intensities of Dy^{+3} (572 nm) and Tb^{+3} (543 nm) and RCI (Dy/Tb) of Y_2O_3:Dy:Tb (10 ppm) as a function of dysprosium concentration.

ray instrument which is very geometry sensitive as can be seen from the scatter in the data for Dy and Tb (broken-line curves). The smooth RCI curve of Fig. 3 shows the RCI method removes all the geometry sensitivity from the final results.

The RCI for Y_2O_3 phosphor is furthermore invariant to the synthesis procedure, the degree of crystallization, the firing temperature, and the level of the contamination by common metals. Figure 5 shows the CL intensity and RCI (Dy/Tb) of Y_2O_3:Dy(20 ppm):Tb(30 ppm) prepared at different temperatures (800°-1400°C) and 3 hr firing time. Although the CL intensities of the activator and reference both increase with firing temperature (Fig. 5A), the RCI is independent of the firing temperature (Fig. 5B). The accuracy and precision of the RCI method is still maintained in the presence of 10 ppm Fe, Ni, Mn, or Pb, even though the CL intensities of Dy and Tb are decreased by about 20% (see Table I). Thus the RCI method is a significantly more reliable way of determining the concentration dependence of luminescence of rare earths in Y_2O_3.

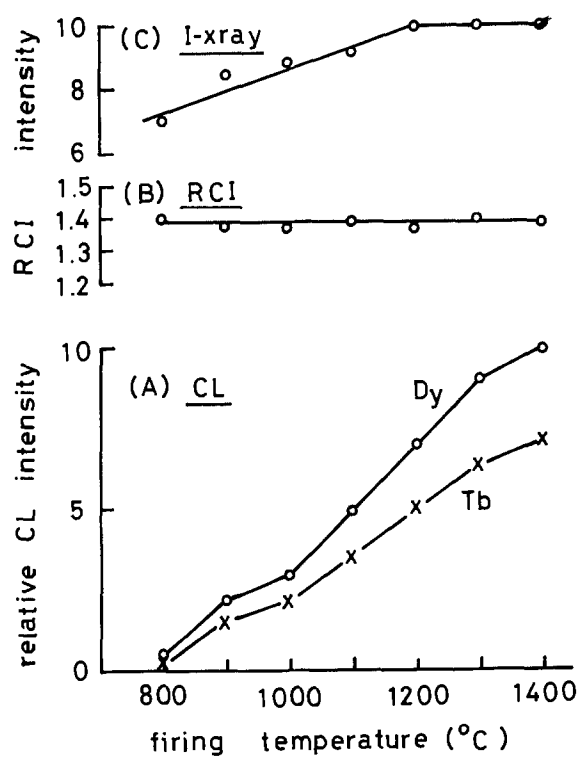

Fig. 5. (A) Cathodoluminescence intensity of Dy and Tb; (B) RCI (Dy/Tb); (C) x-ray reflection intensity from (400) plane. All data for Y_2O_3:Dy (120 ppm):Tb (30 ppm) fired at various temperatures.

Slopes of RCI curves.—There are three types of concentration dependences exhibited when log RCI is plotted *vs.* log activator concentration: the experimental slopes are either numerically equal to unity, or are somewhat greater or less than unity (Fig. 6), depending on the combination of activator and reference. (The slopes are independent of the concentration of the reference although the RCI values are inversely proportional to the reference concentration.) This is related to the fact that some rare earths are excited through the host and others are excited only directly. It has been previously shown for Y_2O_2S (1, 10) that the luminescence intensity of directly excited activators (*e.g.*, Ho) at very low concentrations increases linearly with activator concentration (*i.e.*, $L = kC$) and exhibits no particle size effect whereas the luminescence of host-excited activators (*e.g.*, Eu) increases sublinearly with activator concentration ($L = KCS$, where $0 < S \leq 1$) and exhibits a particle size effect. Table II lists for Y_2O_3 the activators which, under electron excitation, are excited predominantly via the host and those which are excited only directly, as based upon their concentration-dependence curves. If rare earths are classified according to whether they are directly or host excited, there are four possible combinations of

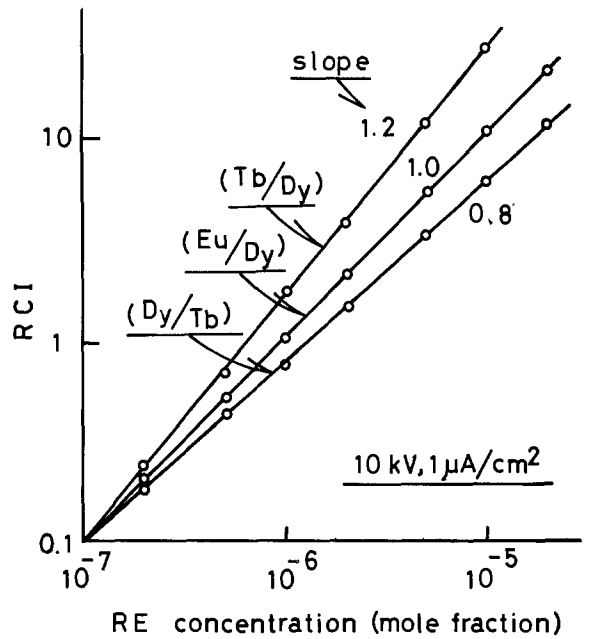

Fig. 6. Normalized RCI curves of the various combinations of excitations of activators by cathode-rays, showing slopes characteristic of the activator/reference combination. The reference concentrations are: 2 ppm (Tb/Dy), 1 ppm (Eu/Dy), and 30 ppm (Dy/Tb).

activator and reference which yield different slopes for the RCI CD curves. The slopes may be calculated from the ratio $L_{activator}/L_{reference}$, as a function of activator concentration, where $L_{reference}$ is a constant at a fixed concentration, *e.g.*, for the host/direct case, the concentration dependence of the RCI is $k'CS$. Thus if we pair a host-excited activator ($S = 0.8$) with a directly excited reference of fixed concentration, the expected RCI slope should be 0.8 (see Table III). Similarly if we pair directly excited activator and a directly excited reference, the RCI slope should be 1.0. This is true for some phosphors but only where the reference is directly excited (Table III). However where the reference is host excited the experimental slope is quantitatively greater than expected and the explanation for this is not clear.

Crystal perfection.—In all the work described above, the median particle size was 3 ± 0.5 μm. In order to determine the role of crystal perfection on the RCI, two types of experiments were performed: in the first, the particle size was maintained constant at 3 μm but the crystal was progressively more thoroughly annealed; in the second, the particle size was increased and the RCI was determined for the two activator concentrations.

Figure 5A shows the increased efficiency of 3 μm particles with increasing firing temperature. The improvement in crystal perfection with increased firing temperature is seen in Fig. 5C by the increased x-ray line intensities (plus decrease in half-widths, not shown). Nonetheless, so long as the particle size remains unchanged, the RCI for the host/direct case (Fig. 5B) does not change with annealing temperature. This is a decided advantage in trace analytical work; in addition this result may be used (see below) to speculate on the role of crystal perfection in luminescence.

Since the x-ray diffraction half-widths decrease with heat-treatment it is clear that the crystal may contain fewer defects and/or the activator may experience a more precisely defined local environment. (Changes in the positions of the ions surrounding an activator result in different crystal field symmetries and electrical field strengths which are known to affect optical transition probabilities.) For the case of a host-excited activator and a directly excited reference, if the increased crystal perfection is due to fewer defects this will result in enhanced energy transfer between the host and activator and the RCI will increase; however, if higher temperatures change the crystal field strength this may equally affect the optical transitions of both the activator and reference, the transitions of interest of both the activators. The reference and the RCI will be relatively invariant to improvement in crystal quality. Since the RCI remains constant (Fig. 5B) it is believed that increased crystal perfection, as developed by a higher annealing temperature, increases the transition probabilities of the emitting ions.

Particle-size effect.—It has been previously shown for cathodoluminescent phosphors that there is a particle size effect superposed on the concentration dependence (1,10), viz., when log CL intensity is plotted *vs.* log concentration, the slope has a break in it at a characteristic concentration (C_D^*) for each particle size. (An explanation for this has been previously given (1, 10).) Thus it is of interest to consider the behavior of the RCI as a function of particle size for the host/direct case (where there is a particle size effect in the phosphor).

The particle size was varied from 3 to 10 μm by growing the Y_2O_3 with two activator concentrations in a borax flux at temperatures between 800° and 1400°C; the median particle sizes for each temperature were: 3 μm, 800°C; 5 μm, 1000°C; 7 μm, 1200°C; and 10 μm, 1400°C. Figure 7 shows the normalized CD curves of Y_2O_3:Dy (3 and 10 μm particle size) under electron and photoexcitation and the corresponding values of C_D^*. It should be noted that the experimental C_D^* value is only approximate because C_D^* depends on the particle size; in the present case there is a log-normal distribution of particle sizes; *i.e.*, the particles are not all of the same size. As expected a particle size effect is present for the two chosen concentrations (Fig. 7). Furthermore, in accordance with theoretical expectation (1, 10) the RCI has two opposite trends, for one concentration, increasing with firing temperature (particle size), and decreasing for the other concentration. The reason for these opposite trends is related to those concentrations, and can be explained qualita-

Table III. RCI concentration dependence for possible combinations of type of excitation and observed slopes of RCI curves

Combinations	Expected slope	Experimental slope
Host/direct	0.8	0.8 ± 0.02*
Direct/direct	1.0	1.00 ± 0.02**
Host/host	0.80	1.00 ± 0.02†

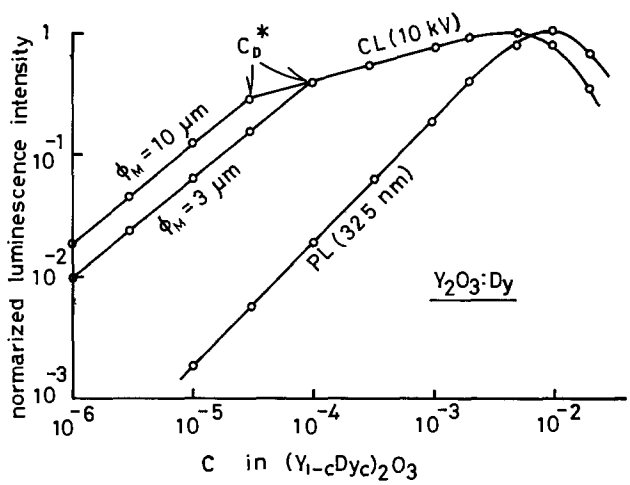

Fig. 7. Concentration-dependence curves of luminescence intensity of Y_2O_3:Dy for two particle sizes, 3 and 10 μm, under electron and direct photoexcitation.

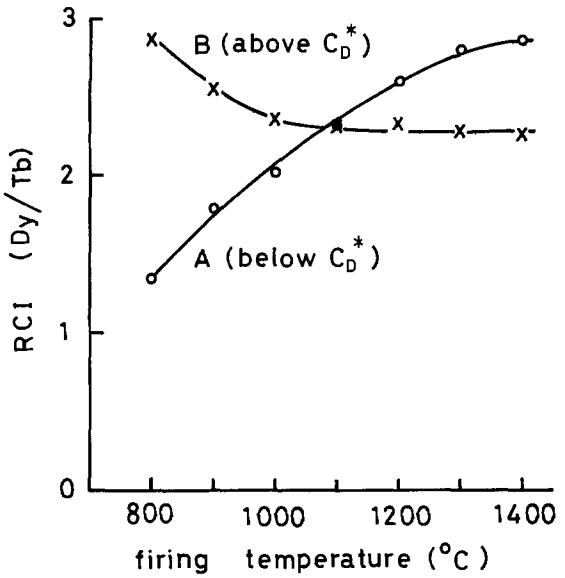

Fig. 8. RCI (Dy/Tb) of Y_2O_3:Dy (20 ppm):Tb (30 ppm), curve A (below C_D^*), and of Y_2O_3:Dy (100 ppm):Tb (50 ppm), curve B (slightly above C_D^*), fired at various temperatures using borax flux.

tively in terms of the active volume V_a involved in the luminescence (1, 10) which is controlled by the concentration in particle volume V_ϕ. The explanation is as follows. In curve A of Fig. 8 the Dy concentration (20 ppm) is somewhat lower than C_D^* for the largest particle size in the series ($C_D^* \sim$ 30 ppm for 10 μm), and the number of Dy activators involved in the excitation is increased as the particle volume V_ϕ gets larger even though the electron penetration depth is constant; consequently the RCI increases as the particle size increases. When $V_a < V_\phi$ (which occurs when the Dy concentration is higher than C_D^* for smallest particle size), V_a is limited by the activator concentration and is constant for a given activator concentration; hence the RCI will not show a particle size effect. Curve B in Fig. 8 shows the RCI of the Y_2O_3:Dy(100 ppm):Tb (50 ppm) prepared at different growth temperatures ($C_D^* \sim$ 100 ppm for 3 μm particle size). The RCI decreases as the particle size increases between 800° and 1000°C, and above 1000°C remains constant. The decrease in RCI between 800° and 1000°C is believed to be caused by the approach of the particle size-limited volume V_ϕ to the concentration-limited volume V_a, *i.e.* the Dy concentration (100 ppm) is effectively slightly higher than the nominal C_D^* value. [Note that without the flux, the particle size was independent of the firing temperature, and the RCI data (using 20 ppm Dy) did not show a particle size effect (Fig. 5B).]

Conclusion

It has been demonstrated that the measurement of the relative cathodoluminescence intensity of activator with respect to a deliberately added rare earth internal reference has certain advantages: (*i*) It yields a more accurate and precise determination of the slopes of concentration-dependence curves for cathodoluminescence (less than 3% error), (*ii*) it can be used to reveal the role of the crystal lattice perfection in cathodoluminescence, (*iii*) it reveals the type of excitation mechanism of the particular activator, and (*iv*) it can be used for quantitative determinations of trace amounts of rare earth impurities.

Electrical Activity of Epitaxial Stacking Faults

ABSTRACT

The scanning electron microscope has been used in the electron beam induced current (EBIC) mode to measure the electrical activity of stacking fault polyhedra formed during the epitaxial growth of (111) and (100) silicon from $SiCl_4$. Epitaxial films were grown in three different epi reactor facilities on wafers processed in two different facilities. Schottky barriers were used to collect the electron beam induced current. Defining electrical activity as carrier recombination seen at zero or low reverse bias (well below avalanche), two main observations are made: *i*) The occurrence of electrical activity is related to the facility in which buried layer processing and wafer cleaning were done prior to epi deposition, and is not due to the epi reactor. One facility in which buried layer processing was carried out was found to be contaminated with heavy metal impurities; all epi faults on wafers processed in this facility were found to be active primarily at the corners of the fault polyhedra; faults on samples which received buried layer processing in another facility were found to be electrically inactive. (*ii*) Transmission electron microscope studies of the identical faults examined in EBIC show that the degree of electrical activity is correlated with the mass of precipitate present at the corner of a fault polyhedron, and both vary from corner to corner within the polyhedron.

One class of Si epitaxial stacking faults nucleates at the epi-substrate interface and grows in size as the film thickness increases (1). The surface density of these faults varies from effectively zero to well over $10^3/cm^2$ depending in part on substrate surface treatment. Stacking faults may limit device performance if they are electrically active and if the surface density of the faults is high compared with the active device area. The electrical activity of individual stacking faults can be probed with the scanning electron microscope in the electron beam induced current (EBIC) mode. This mode of examination has been used to image defects in silicon using pn junctions (2-4) or Schottky barriers (5, 6) to collect the EBIC current. It is expected that a defect that appears as a recombination center in EBIC analysis will act as a current generation center when in the space charge region and thus will contribute to leakage in reverse biased pn and Schottky barrier junctions and in storage time devices; alternatively, the same defect will act as a recombination center when outside the space charge region and contribute to leakage in forward-biased junctions.

In this study the electrical activity of epitaxial stacking faults was determined in material grown from $SiCl_4$ in three deposition reactors, on silicon substrates prepared in two separate processing facilities. It is important to note that the EBIC data were collected under conditions of very low or no applied reverse bias, well below avalanche, and "electrical activity" refers to the ability of a site to act as a recombination center to reduce the local current collected by the junction at that site; Ravi *et al.* (4) defined an "electrically active" fault as one which generated EBIC current in excess of current generated in a defect-free region. In addition to data on the nature of electrical activity at epi stacking faults, certain electrically active stacking faults were examined by transmission electron microscopy for more detailed analysis and these results are reported.

Experimental

Samples.—The substrates used in this investigation were (111) and (100) 2 and 3 in. diameter 5-20 Ω-cm p-type 0.015-0.020 in. thick dislocation-free silicon wafers. Most of these wafers went through standard buried layer processing before being inserted in the epi reactor: high temperature steam oxidation, buried layer photolithography, buried layer Sb diffusion or As implant, 1200° or 1250°C drive-in, oxide strip, HCl vapor etch, and epitaxial deposition. Epitaxial silicon was deposited in a horizontal-type reactor from $SiCl_4$, AsH_3, and H_2 at 1120°-1150°C (optical) immediately after an HCl vapor etch at 1150°-1200°C (optical) which removed 0.3-0.5 μm substrate material. The epi films were 0.2 or 3 Ω-cm n-type and were grown over a thickness range 10-15 μm.

Two different facilities were used for buried layer processing; they are called facility A and facility B in this paper. Two different epi reactors were used in facility A and one epi reactor was used in facility B; these are called reactors A-1 and A-2, and reactor B, respectively.

Samples were prepared for transmission electron microscopy by (*i*) lapping the sample to a thickness of ~0.005 in., (*ii*) ultrasonically punching out a 3.0 mm diameter disk, (*iii*) chemically thinning in HF:HOAC:HNO_3 (3:3:5), and (*iv*) ion milling to a final thickness of ~1 μm. The samples were examined in a 200 keV JEOL microscope equipped with a Kevex x-ray microanalyzer.

EBIC analysis.—EBIC analysis was performed in a Cambridge S-4 instrument, which was equipped with an energy dispersive x-ray analysis system. Samples were prepared for EBIC studies by treating with buffered HF for 10 sec to remove residual surface oxide followed by deionized water rinse and spin dry. 60-800Å gold was deposited by W filament evaporation at ~10^{-5} Torr through a 0.005 in. thick Mo shadow mask consisting of holes 1/16 and 1/8 in. diameter. Most studies were performed on the smaller Schottky barriers. An external, continuously variable battery supply provided reverse bias to the Schottky diode circuit.

Table I. Standard EBIC conditions

		Typical value	Typical range
Beam energy		19 keV	Fixed
Beam current at substrate	Faraday cage	7.0×10^{-10}A	Fixed
	Silicon	5.2×10^{-10}A	Independent of Si thickness (0.015-0.020 in.), orientation ((111), (100))
	Au dot	4.3×10^{-10}A	Varies slightly with Au thickness
EBIC current	Silicon	3.30×10^{-6}A*	$2\text{-}4 \times 10^{-6}$A*
	At strong recombination center	2.95×10^{-6}A*	Within ~10% of background EBIC current

* Over buried layer region. EBIC current is lower over nonburied layer regions.

The signal was fed into a Cambridge Instruments specimen current amplifier. Most of the data were obtained over the range 10^{-6}-10^{-8}A. A gold plated 0.002 in. tungsten probe in the specimen chamber could be externally moved over three coordinates with a precision of ~600 μm per control rotation, and was used to contact the Au dots. Most images were recorded at a frame time of 40 sec and a line scan time of 0.040 sec over a magnification range of 20-1000×.

A standard set of conditions was chosen for a number of the EBIC studies in order to be able to describe semiquantitatively the strength of EBIC signals and relate these data to microstructural details of stacking faults. These conditions are given in Table I. Also shown in Table I are typical variations in values of parameters for a fixed beam energy and current. Most of the studies were performed at 19 keV and at zero or very low (<1V) applied reverse bias. We observed no effect of bias on the EBIC signal. Some studies were made at 10-11 keV in order to improve the spatial resolution of defects near the sample surface.

The EBIC images in this report are direct records; white contrast corresponds to larger current.

Optical microscopy.—Low magnification (<200×) interference contrast optical micrographs were taken on samples with and without gold dots. The stacking faults could be clearly seen due to the slight change in elevation of the Si surface across the fault boundary.

X-ray topography.—X-ray transmission topographs were taken at 45 keV and 25 mA beam current using a Rigaku-Denku x-ray source with a rotating anode. Diffraction occurred off one set of {220} planes normal to the (111) surface. The x-ray topograph in Fig. 1 is a print of the original. Black contrast corresponds to enhanced x-ray signal.

Sampling technique.—Immediately prior to insertion in the scanning electron microscope, each wafer was cleaved into a piece ~ 1 × ½ in. which included an edge of the original wafer. The reverse *I-V* characteristics of 3-5 small (1/16 in. diameter) Schottky barriers were measured, and two of the dots nearest the edge of the wafer and with good reverse characteristics were examined by EBIC.

A total of 26 samples were examined using EBIC. In two cases (samples 6 and 11) Schottky barriers far apart on the original 2 in. wafers were measured with identical results. This gives no assurance, of course, that there were no variations in stacking fault properties across a wafer in each of the 24 remaining cases, but such a variation is considered unlikely.

Results

All samples used in this study contained epitaxial stacking faults. In a number of wafers the faults were observed only over the nonburied layer regions. The faults were easily identified by optical microscopy as complete triangles or squares (depending on substrate orientation) or as the corresponding incomplete figure.

Our ability to identify all epitaxial stacking faults by optical microscopy was established by comparing optical micrographs and x-ray topographs of the same area. In addition to being certain that all faults could be detected optically, we needed to be sure that all faultlike features seen optically were indeed faults and not simply regions where faults had been present and subsequently annihilated. An interference contrast micrograph of sample 1 is shown in Fig. 1a, and Fig. 1b

and 1c show a transmission x-ray topograph and an EBIC image, respectively, of the same area.

Recombination sites appear in the EBIC image as black spots (Fig. 1c) and are correlated with dislocations seen in the x-ray topograph (Fig. 1b). The black-white contrast pairs in Fig. 1b are due to stacking fault strain fields and are correlated with the stacking fault features shown in Fig. 1a. Thus, there is a one-to-one correlation of stacking fault features which appear in the optical micrograph and sites of existing stacking faults, but no recombination is observed at these sites in this particular sample.

Table III. EBIC measurements at stacking fault recombination center, sample 16 (Fig. 2)

E	3.20
F	3.00
G	2.95
H	3.05
I	3.05
Away from center	3.30

Results of EBIC analysis of epi films grown in various reactors are summarized in Table II. Recombination, when it occurred, was generally found only at the dislocations at the corners of the stacking fault polyhedra, or at dislocations bounding single planar faults. Figure 2 shows optical and EBIC photographs of epi faults in 13 μm thick 3 Ω-cm (111) and (100) epi. Note that strong recombination occurs at the corners of the stacking fault polyhedra, and that the magnitude of the recombination varies at different sites. A quantitative measure of EBIC current at the corners of stacking fault polyhedra indicates the recombination strength at these corners. Such data are given in Table III for the faults shown in Fig. 2b. Conditions used for these measurements have been given in Table I. A moderate variation in strength of the nine recombination centers is noted with values ranging from 3 to 10% less than the background EBIC current (3.30×10^{-6}A). These are typical observations.

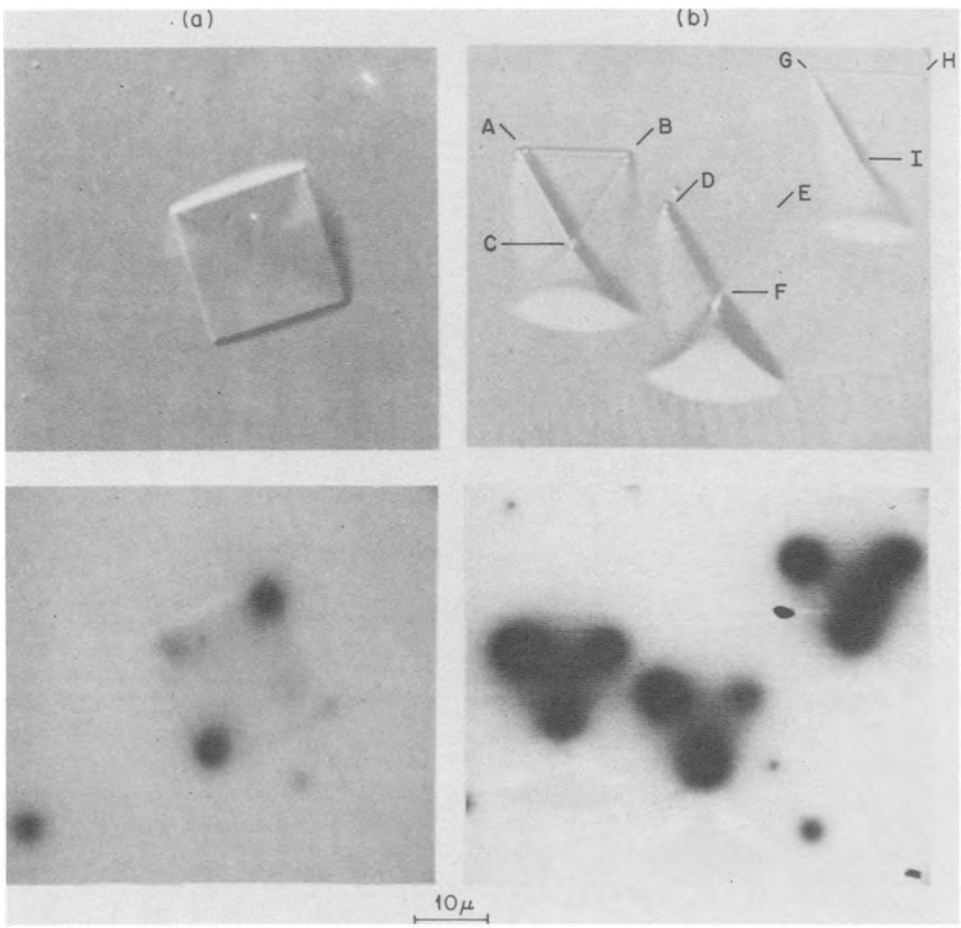

Fig. 2. Interference contrast (upper) and EBIC (lower) photographs of (100) sample 18 (a) and (111) sample 16 (b). Both EBIC conditions were zero volts applied bias; beam energy 15 keV (a) and 19 keV (b).

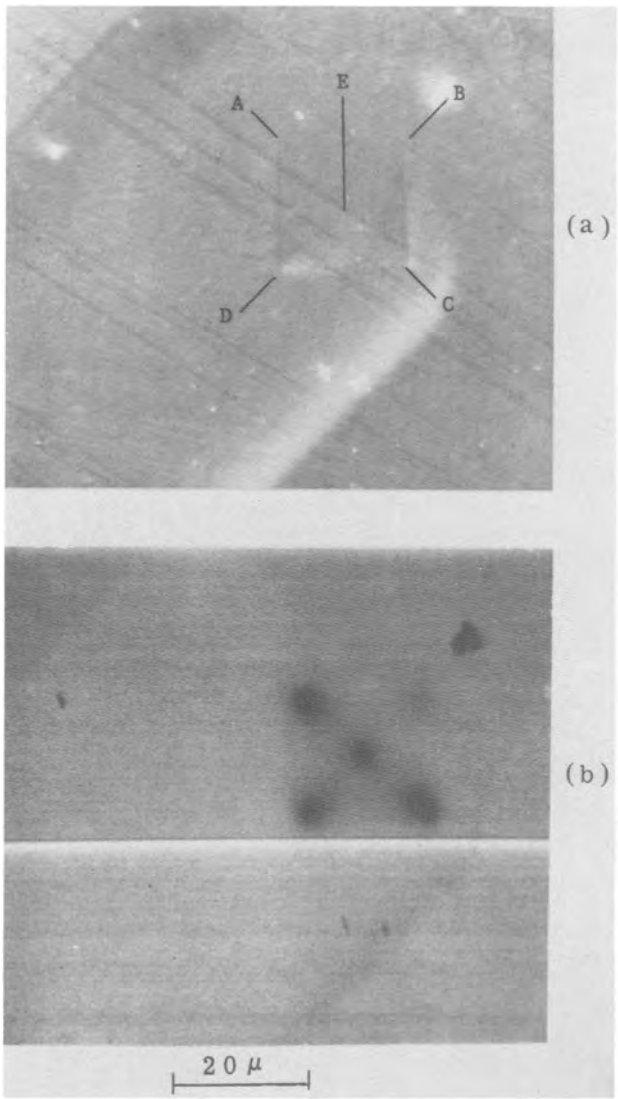

Fig. 3. Interference contrast (a) and EBIC (b) photographs of (100) sample 19. EBIC conditions were zero bias, 13 keV.

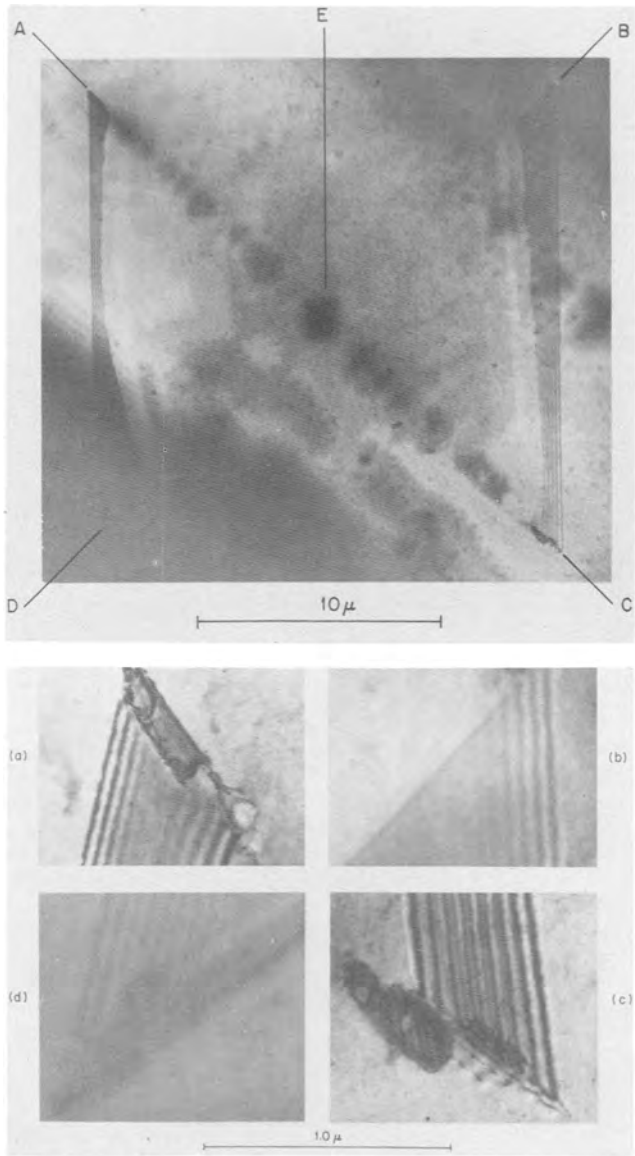

Fig. 4. (a) Transmission electron micrograph of fault defect shown in Fig. 2 and (b) enlargements of micrographs of the ends of the faults. Micrographs are bright field, taken under two-beam conditions.

Figure 3 shows a similar set of photographs of a stacking fault defect in (100) sample 19 with 13 μm thick 3 Ω-cm epi. The large rectangular feature is a buried layer region; corners A, D, C are situated over the buried layer region, while corner B is not. This region was thinned and examined in the transmission electron microscope. A TEM photograph of this fault defect is shown in Fig. 4a and micrographs of the four corners (A, B, C, and D) are shown in Fig. 4b. Dark field examination of corners A, B, and C shows that precipitates are present; large precipitates are present at corners A and C, while a smaller precipitate is present at corner B. This distribution of precipitate correlates with the variations observed in recombination strength. Although corner D could not be examined thoroughly because the sample was quite thick in that region, the bright field photograph of corner D in Fig. 4b indicates that a large precipitate is probably present at this corner too. X-ray analysis of the precipitate at corner A shows the presence of Ni. No diffraction pattern could be obtained from the precipitate and its structure has not been identified.

The dark rectangular feature at the center at E (Fig. 4a) and the chain of dark regions extending from corner A to corner C were examined under various diffraction conditions in the TEM. The conclusion is that these are not precipitates but are rather thick regions of Si, which probably resulted from precipitate shadowing during ion milling. The precipitates have been milled away. The reason for the existence of strong recombination at E is not clear. This point is ~13 μm below the surface as determined from the geometry of the fault. The EBIC images at dislocations which bound faults show that the maximum depth supplying EBIC information is ~5 μm at 20 keV (see Fig. 2 and 3). Therefore it seems unlikely that the point of origin of the two faults is the source of the EBIC recombination signal at E.

Results on samples 1-22 suggest that the electrical activity of faults may be related to the reactor used to grow the epi. Additional experiments (samples 23-26) disproved this idea. Samples 23 and 24 both were cleaned and simultaneously received epi in reactor B; sample 23 received all buried layer processing in facility A while sample 24 had Sb (buried layer) diffusion performed in facility A with the drive-in and all subsequent processing being done in facility B. Epi stacking faults appeared on sample 23, virtually identical in appearance to those shown in Fig. 1. On sample 24 two classes of epi faults appeared, distinguished by their optical appearance as well as by their electrical activity (see Fig. 5). One type appears as a simple polyhedron, typical of epi faults generally found on material grown in facility A and reactors A-1 and A-2 (samples 1-15, Fig. 1). These were electrically inactive. This is the only instance where inactive faults

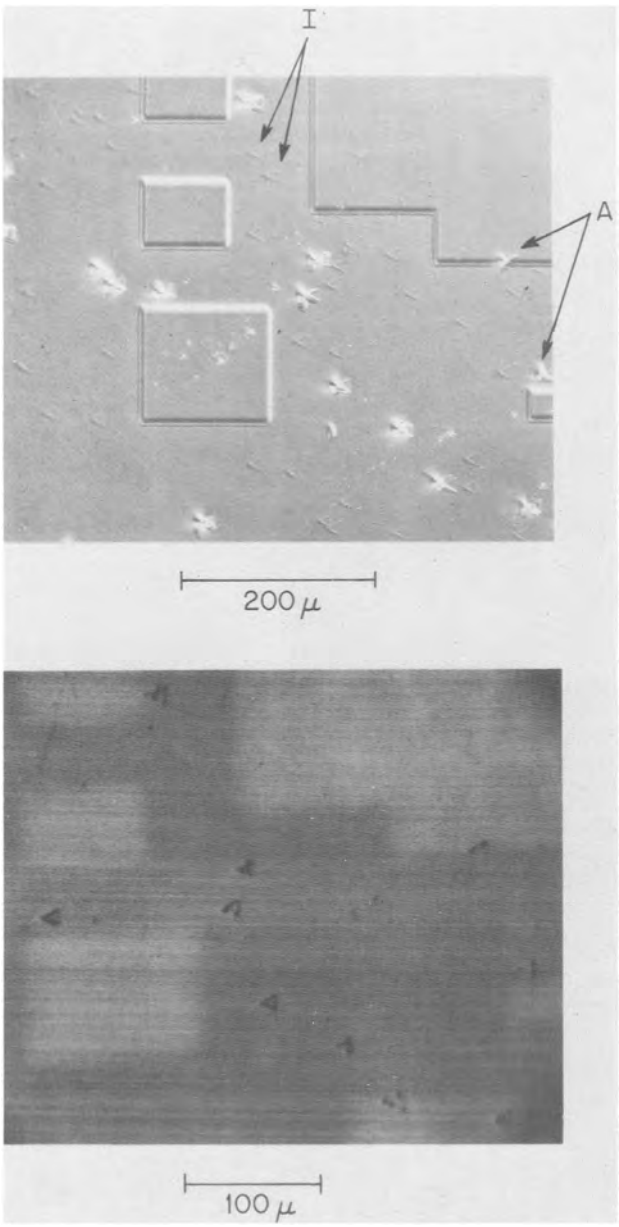

Fig. 5. Interference contrast (a) and EBIC photographs (b) of sample 24. Both inactive (I) and electrically active (A) faults can be seen. EBIC conditions were zero bias, 19 keV.

have been produced in reactor B. A second type appears complex and shows electrical activity at the corners of the polyhedra, typical of epi faults generally found on material grown in facility B (samples 16-22, Fig. 2 and 3). TEM studies of these faults are underway.

Samples 25 and 26 had buried layers processed in facilities A and B, respectively. Epi was deposited simultaneously in reactor A-1. Sample 25 had simple inactive fault polyhedra typical of samples 1-15 and 23 and sample 26 had more complex, electrically active faults typical of samples 16-22. This is the only instance where active faults have been produced in one of the A reactors.

Discussion

The data show that the electrical activity of stacking faults is related to the facility in which buried layer processing was carried out; facility A produces material with inactive faults and facility B produces material with active faults. One exception is sample 18 which received no buried layer processing, yet which had active faults. Active faults are produced in both (111) and (100) material. Neutron activation analysis of the reactor B epi films shows negligible heavy metal contamination, while analysis of wafers receiving standard facility B cleans at the time of these experiments has occasionally shown Au, Br, Cr, Cu, Ni, and Na present on the wafers. The electrical activity of faults in samples that have received all (samples 16-17; 19-22) or part (sample 23) of buried layer processing in facility B, and the activity of faults in sample 18 which received only a clean prior to epi growth in reactor B, is thus attributed to the presence of a contaminant which enters the substrate during buried layer processing or appears on the substrate surface following clean from a contaminant in one of the cleaning solutions. It is noted that in one case (sample 23) a facility B clean did not produce active faults.

The films deposited on facility B substrates contained epi faults which were active only at the partial dislocations which bound a fault.[1] Some similar observations are made by Ravi *et al.* (4), on oxidation-induced stacking faults in silicon. They probed these stacking faults with *I-V* measurements and EBIC analysis using 4 μm deep p^+n junctions formed by B diffusion. Their analysis showed a relationship between stacking fault length and "electrical activity," the latter being defined as the onset of current multiplication (as seen in EBIC) with increasing reverse bias. Their main interpretation of this relationship (one of two they present) is that a stacking fault interferes with the B diffusion process to form precipitates which thereby influence junction properties locally about the defect. The main differences between the experiment of Ravi *et al.* and the one reported here are (*i*) no pn junction was used in these experiments, (*ii*) attention in this work is focused on the magnitude of recombination occurring at very low reverse bias, well below avalanche, and (*iii*) the mechanism of fault formation and the resulting fault properties are quite different. In spite of these essential differences it is quite clear that both studies show that decorated defects (faults and partial dislocations in Ravi's case, dislocations only in our case) have a significant effect on electrical activity compared with undecorated defects.

Kato *et al.* (2) studied epi faults in (111) Si using EBIC on n^+p junctions, and their published micrograph [Fig. 2a, Ref. (2)] shows recombination over the area bounded by the intersection of an epi fault tetrahedron with the surface. Since we have obtained a similar EBIC result [recombination over the entire faulted surfaces of stacking faults forming a tetrahedron in (111) epi Si], only when epi deposition was followed by an oxidation, it is considered likely that Kato's observations are due to the interaction of thermal treatments (P diffusion in Kato's case) with the epi faults.

The only published information to date on EBIC studies of stacking faults using a Schottky barrier instead of a pn junction is an article by Kawado *et al.* (6). They examined oxidation-induced stacking faults in (001) Si and microprecipitates in (111) Si. Their EBIC photograph of oxidation-induced faults is similar to ours in that recombination is visible only at the partial dislocation sites. No analysis had been made of these faults to determine if precipitates were present.

In our case a qualitative correlation has been made between the apparent mass of precipitate and the strength of that site as a recombination center. Quantitative EBIC measurements on other fault polyhedra show a typical attenuation of 3-6 $\times$ 10^{-7}A (3-10%) at a recombination site; presumably this variation is also correlated with precipitate mass.

Conclusion

EBIC analysis has been made of the electrical activity of stacking fault polyhedra formed during epi

[1] An exception is some of the active fault polyhedra in sample 24 where recombination was also found at the intersection of faults with the surface (see Fig. 5b).

growth of Si from $SiCl_4$. Carrier recombination has been observed at the corners of fault polyhedra and at dislocations bounding single planar faults in some samples; no recombination at faults has been found in other samples. The occurrence of electrical activity is related to the facility in which buried layer processing and wafer cleaning was done prior to epi deposition, and is not due to the epi reactor. Au, Br, Cr, Cu, Ni, and other impurities occasionally have been found on wafers cleaned in the facility which produced electrically active faults. TEM analysis of the corners of electrically active polyhedral faults showed precipitates present; with Ni detected in one precipitate. In one polyhedral fault structure the mass of precipitate correlated with the strength of electrical activity as measured by the attenuation of the magnitude of the EBIC signal.

Gallium Arsenide Phosphide Schottky Barrier Field Effect Transistor

R. K. Pancholy[1] and W. W. Grannemann

The University of New Mexico, Albuquerque, New Mexico 87131

ABSTRACT

Fabrication processes have been developed for gallium arsenide phosphide Schottky-barrier field effect transistor (SBFET) on an insulating gallium arsenide substrate. Process techniques as well as results of electrical characterization of the device structure including the GaAsP-GaAs interface are described. Formation of a conductive layer near the GaAsP-GaAs interface is postulated, and an anlaysis of its effects on transistor characteristics is presented.

Interest in gallium arsenide phosphide has been increasing in the past few years due to its potential advantages such as high electron mobility and variable energy bandgap resulting in high frequency, high temperature, and electroluminescence applications including light emitting diodes, lasers, microwave field effect transistors, and infrared detectors. By changing the phosphorus mole fraction x in $GaAs_{1-x}P_x$, the energy bandgap may be changed from 1.43 eV for $x = 0$ (*i.e.*, GaAs, direct bandgap) to 2.25 eV for $x = 1$ (*i.e.*, GaP, indirect bandgap) at room temperature (23°C). Gallium arsenide phosphide on semi-insulating gallium arsenide provides an ideal material for device applications, as device isolation required for circuit applications can be easily achieved by the formation of active GaAsP island regions. For majority carrier devices such as field effect transistors, the conductivity can be modulated by either a metal insulator semiconductor structure, a reverse bias p-n junction, or a Schottky barrier metal-semiconductor junction.

The major difficulty in the development of GaAsP technology has been the dissociation of the semiconductor at high temperature during diffusion and oxidation. This paper reports development of a low temperature (<550°C) process for the fabrication of GaAsP Schottky barrier field effect transistors (SBFET's).

Fabrication

The SBFET's were fabricated on a tellurium-doped n-type $GaAs_{1-x}P_x$ epitaxial layer with a phosphorus mole fraction, $x = 0.34$. The epitaxial layer with impurity carrier concentration of 2.2×10^{16} atoms/cm^3 and electron mobility of 1160 cm^2/Vsec, was grown on a semi-insulating GaAs substrate of 10^8 Ω-cm resistivity (1). The initial epitaxial layer thickness was reduced to approximately 1μ by chemical etching in order to permit complete channel pinch-off against the semi-insulating substrate.

The fabrication process is shown in Fig. 1, where after initial cleaning the active regions of the transistors are defined by selective removal of the epitaxial film (2) as shown in Fig. 1(b). Selective etching of the GaAsP film was performed using a 5:1:1 acid etch (5 parts H_2SO_4:1 part 30% H_2O_2:1 part DI water) in conjunction with positive photoresist (AZ-1350). Negative photoresists were experimentally determined to be less suitable, as the photoresist remover (microstrip) reacts with the GaAsP surface.

The etch rate of GaAsP with 5:1:1 etch was defined for a number of samples with varying phosphorus mole fractions x at room temperature. Figure 2 summarizes these experimental results, which indicate that the etch rate for $GaAs_{1-x}P_x$, with $x = 0.5$ is considerably slower than the reported 2μ per min etch rate for GaAs (3). With $x = 1.0$, *i.e.*, GaP, no sig-

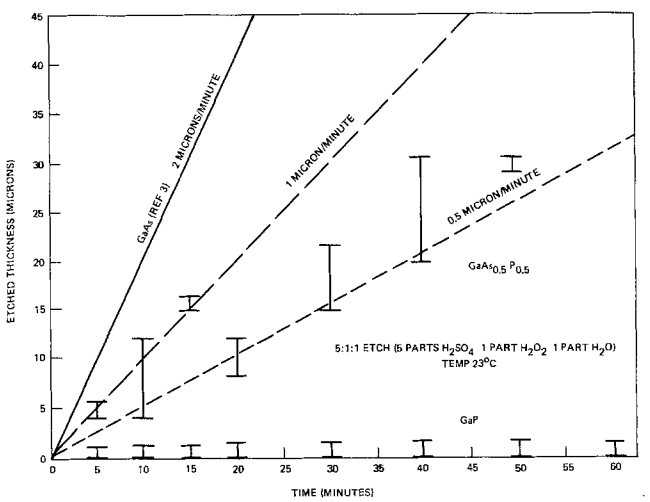

Fig. 2. Thickness of the epitaxial $GaAs_{1-x}P_x$, $x = (0.5, 1.0)$, etched with 5:1:1 etch at room temperature vs. time. The error bars represent data scatter observed in different samples.

nificant reduction in the thickness of the sample could be detected after 1 hr of etching at room temperature. These results indicate that phosphorus content in the epitaxial layer significantly affects the etch rate of these films.

Other acid etchants such as HF, buffered HF, HNO_3, and HCl produced anisotropic etching of $GaAs_{0.5}P_{0.5}$. Under a magnification of 50-100×, a nonuniform grainy surface was observed after the acids reacted with GaAsP for less than 1 min at room temperature.

Both negative photoresist and HCl based acids play important roles in silicon technology. Because of the adverse reaction of reagents with GaAsP, it is apparent that new methods must be developed.

Several metals and metal combinations including Au, Ag, Al, Ge, In, Ni, Cr, and double metallization layers of Au-Ge, Ag-Ge, and In-Ni were evaluated to form ohmic contacts to n-$GaAs_{0.5}P_{0.5}$ (for the source and the drain regions of the SBFET). The contacts were evaluated using a test pattern consisting of 10 mil diam metal dots spaced 25 mils apart on the surface of the $GaAs_{0.5}P_{0.5}$ epitaxial layer. All metal depositions were performed by resistive-heated evaporation at a pressure of less than 1×10^{-6} Torr. The sintering time and temperature were optimized in each case to ensure ohmic contacts. The results of these experiments are summarized in Fig. 3 where contact characteristics of various metal combinations, as functions of sintering time, are shown. Each contact variation was sintered for 15 min in nonoxidizing ambient in temperature increments of 50°C, starting

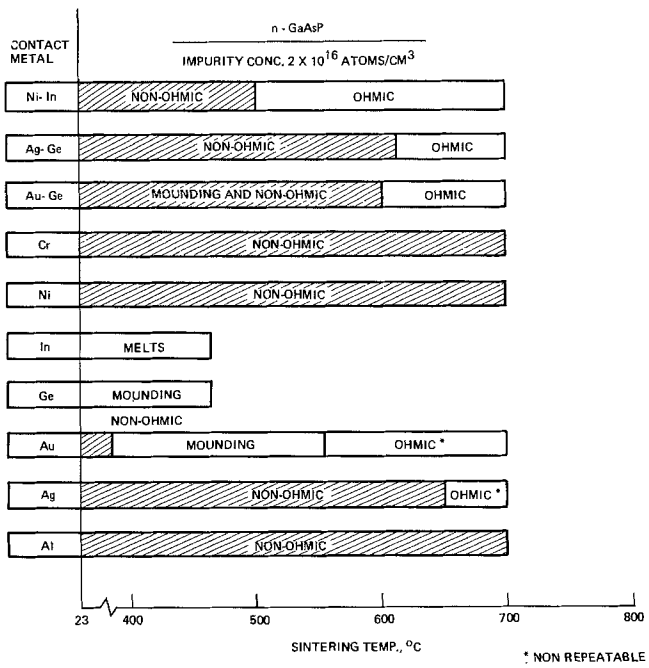

Fig. 3. Contact characteristics vs. sintering temperature

at a temperature of 400°C. The contact characteristics were evaluated at room temperature (23°C) before sintering and after the sample returned to room temperature at the end of each successive sintering cycle. The criterion used to define ohmic quality in Fig. 3 was the appearance of a linear *I-V* characteristic through 0V. The contact sintering cycles were continued until either ohmic characteristics resulted or a temperature limit of 700°C was reached. The upper limit on temperature was established because of possible GaAsP surface damage at temperatures higher than 710°C (4).

The most repeatable low resistance ohmic contacts, at low sintering temperatures, were achieved with a double metallization layer of indium and nickel. Other metal combinations exhibited nonohmic characteristics even after sintering at 600°C. Several metals, *e.g.*, Ge, Au, and Au-Ge double layer, exhibited a "mounding" characteristic due to high surface tension. Gold and silver metal combinations successfully used for ohmic contacts to GaAs (5, 6) produced highly resistive nonrepeatable contacts to n-type $GaAs_{0.5}P_{0.5}$. The presence of phosphorus and a low concentration of Te ($2.2 \times 10^{16}/cm^3$) in the epitaxial layer and a higher percentage of Ge in the Au-Ge double layer are the major experimental differences between the results reported here and those in Ref. (5) and (6). The observed ohmic characteristics of the indium-nickel double layer are probably due to the diffusion of indium into GaAsP during the sintering process, thus providing the higher donor impurity concentration in the epitaxial film under the nickel layer.

The source and the drain regions of the transistor were defined using the double layer of indium-nickel with positive photoresist lifting techniques. The device structure, after source and drain definition, is shown in Fig. 1(c).

The Schottky-barrier gate of the field effect transistor was formed by resistive evaporation of aluminum at a pressure of less than 1×10^{-6} Torr, on a clean GaAsP surface. Before evaporation, the epitaxial GaAsP layer was chemically etched down to approximately 1.0μ thickness in order to pinch off the channel with the gate depletion region. The Schottky-barrier gate was defined by photoresist lifting techniques. The completed device structure is shown in Fig. 1(d), and the device dimensions are shown in Fig. 4.

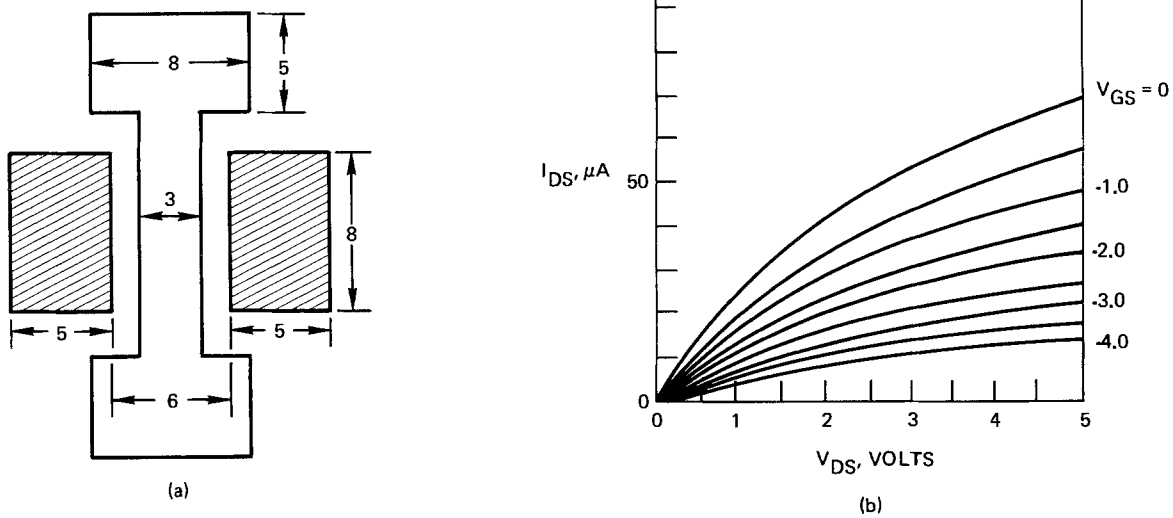

Fig. 4. SBFET structure and characteristics. (a) SBFET structure with dimensions in mils; (b) three-terminal characteristics of SBFET No. 61-3.

Electrical Characteristics of the SBFET

The three-terminal drain characteristics of a typical SBFET fabricated in the manner described above are shown in Fig. 4. The incomplete pinch-off characteristic exhibited by these devices indicates the presence of a current conduction mechanism which is not under the control of the gate. For the SBFET, the pinch-off voltage, V_{PO}, defined as the gate-source voltage required to reduce the channel current to zero, is given by

$$V_{PO} = \frac{qN_D a^2}{2\epsilon_S} \qquad [1]$$

where a, N_D, and ϵ_S are the thickness, impurity concentration, and the dielectric constant of the epitaxial layer, respectively, and q is the electronic charge. The reverse bias depletion region width of the Schottky gate extends from the metal-semiconductor interface to the GaAsP-GaAs interface at this voltage, thus pinching off the channel.

For a GaAsP layer doped to 2.2×10^{16} atoms/cm^3 with a dielectric constant of 11.0, the theoretically calculated pinch-off voltage for 1 μm epitaxial layer thickness is 18V, whereas for a 0.75 μm epitaxial layer it is 10.1V. The pinch-off voltage is experimentally determined by a graphical technique based on the square law transfer characteristics of the SBFET (8-11), where the drain current, I_D, is given by

$$I_D = I_O\left(1 - \frac{V_{GS}}{V_{PO}}\right)^n \qquad [2]$$

where $n \approx 2.0$, V_{GS} is the gate-source voltage, and I_O is the value of I_D at $V_{GS} = 0$, in the saturation region. Therefore, a plot of $\sqrt{I_D}$ *vs.* V_{GS} yields a zero current intercept equal to the pinch-off voltage V_{PO} as shown in Fig. 5.

Assuming a uniform carrier concentration, the observed pinch-off voltage corresponds to an epitaxial layer thickness of 0.82 μm, which is well within the range of thickness established for the epitaxial layer by etching experiments. The maximum transconductance observed for these devices was 1600 μmhos.

The Schottky barrier gate capacitance-voltage characteristics, measured at 1 MHz, are shown in Fig. 6. Two significant effects can be observed in Fig. 6; the decrease in the capacitance at large negative voltage and the hysteresis effect at low negative voltage. The sudden drop in the capacitance at approximately −8V indicates the absence of any charge exchange mechanisms near the edge of the depletion region. This situation can occur when the reverse bias Schottky barrier gate depletion region extends up to the

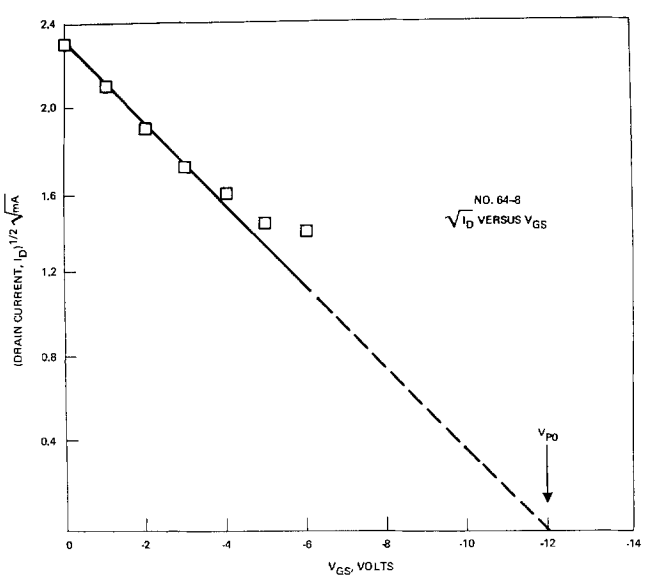

Fig. 5. $\sqrt{I_D}$ *vs.* gate voltage for n-GaAsP SBFET

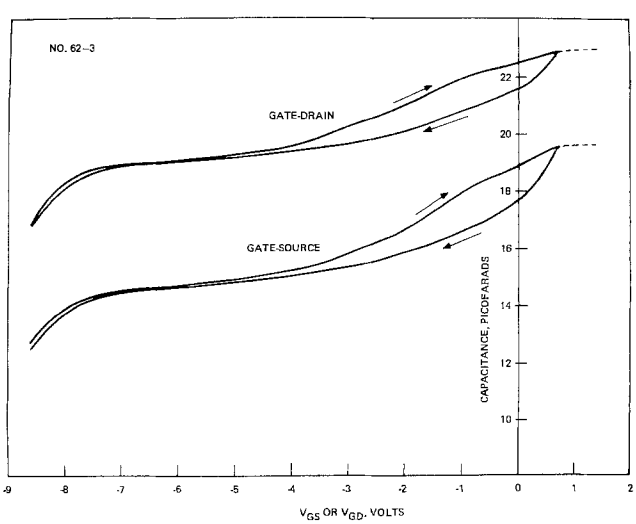

Fig. 6. Schottky gate capacitance-voltage characteristics

GaAsP-GaAs interface and there is a sudden change in the n-type impurity carrier concentration. The observation of a hysteresis effect at low reverse voltages indicates presence of charge trapping and/or ion migration mechanism at the surface of the device. At low gate voltages, the depletion width of the reverse biased Schottky barrier gate does not extend deep into the GaAsP (for the given impurity concentration), thus the hysteresis effect observed here is not related to charge trapping or ion migration at the GaAsP-GaAs interface. Since no surface passivation techniques were used for protection of the device surface, the observed effect could be related to exposure of the device to moisture. A thin layer of oxide (gallium oxide, Ga_2O_3, and gallium phosphate, $GaPO_4$) may form over the exposed surface between the gate and the drain/source region during the fabrication process (4). Hysteresis effects in thermally grown GaAsP oxides have been observed, and similar effects may be responsible for the observed effects here.

Discussion

The *I-V* characteristics of the SBFET's indicate the existence of a current conduction path between the drain and the source which is not modulated by the gate voltage. This current could occur, for example, if the depletion region of the Schottky gate does not extend all the way to the GaAsP-GaAs interface before exceeding the reverse bias breakdown voltage of the Schottky-barrier junction. As the reverse breakdown voltage of the Schottky gate was experimentally determined to be greater than −10V, this possibility can be ruled out. The other mechanisms for current conduction between the drain and source are the formation of a current conduction path near the GaAsP-GaAs interface and possibly edge effects. Edge effects should be partially under the control of the gate voltage. As no control over the drain current is observed beyond low gate voltage, this effect also seems to play an insignificant role.

The observed drain current could be further reduced by application of a reverse bias on the GaAs substrate, indicating that the current flows close to the GaAsP-GaAs interface. For example, at $V_{GS} = 0$, $V_{DS} = 5$V and no substrate bias, the drain current was 1.6 mA for device 63-15. This current was reduced to 0.95 mA at −45V substrate bias. Other device parameters such as channel conductance and transconductance exhibited similar substrate bias modulation characteristics. The *C-V* measurement indicates that the impurity concentration near the interface is very small.

To explain the observed characteristics, formation of a highly disordered conductive layer near the GaAsP-GaAs due to a sudden change in the phosphorus mole fraction is postulated. The inclusion of phosphorus in lattice sites during the growth of $GaAs_{0.5}P_{0.5}$ on a GaAs substrate may result in additional stresses to be present at the interface. The lattice mismatch results in formation of a disordered region near the interface. Similar effects in epitaxial GaAs on a semi-insulating GaAs substrate have been observed (7). These observations suggest formation of a disordered, high resistivity layer near the GaAsP-GaAs interface as shown in Fig. 7. The current conduction through the layer, using this model, is a function of applied drain voltage, but the conduction is independent of gate voltage. The nonsaturation characteristics of the SBFET observed in Fig. 4 can be seen, in part, as a result of the increased conduction through this layer.

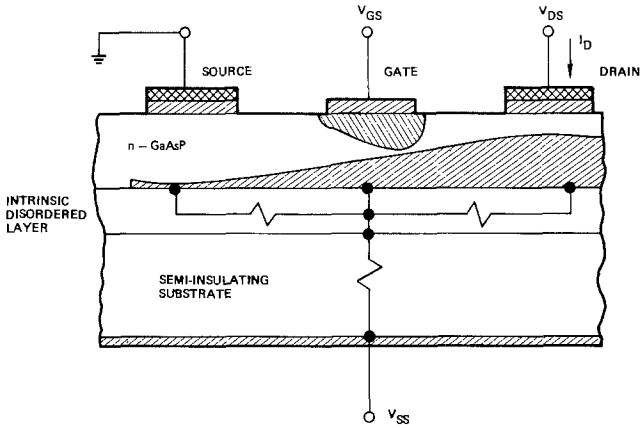

Fig. 7. SBFET with intrinsic layer near the GaAsP-GaAs interface

The GaAsP-GaAs interface thus seems to play an important role in determining the characteristics of the devices. A possible approach to improve the device quality is to grow GaAsP on semi-insulating GaAsP with the same phosphorus mole fraction or to use other techniques such as ion implantation to control the impurity concentration as well as the phosphorus mole fraction x in $GaAs_{1-x}P_x$.

Growth of Monocrystals of the Gallium Analog of β''-Al_2O_3 by Na_2O Evaporation

L. M. Foster* and J. E. Scardefield

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

A crystal growth practice was developed for producing monocrystals of the gallium analog of β''-Al_2O_3. The method involves evaporation of Na_2O from a molten Na_2O-Ga_2O_3 charge held in a boat that is located in a furnace with a steep temperature gradient so that the product grows from one end. Monocrystals up to about 1 cm in size have been grown. Their composition is $Na_2O \cdot 5.7Ga_2O_3$, which corresponds to 96.5% occupancy of the available Na sites. The space group is $R\bar{3}m$ and the lattice parameters are a = 5.84Å and c = 34.53Å.

There are many parallels in the chemistry of gallium and aluminum. In 1951 Foster and Stumpf (1) showed the isomorphism between the oxides of the two systems and, in particular, prepared the alkali gallates analogous to sodium and potassium β-Al_2O_3. In 1974, Foster and Scardefield (2) prepared monocrystals of the β-form of Na-gallate by flux growth from NaF-Ga_2O_3 solutions.

Boilot *et al.* (3) showed that the rhombohedral variant, β''-Na-gallate, also existed, and proposed a tentative phase diagram locating the β- and β''-phase fields in the Na_2O-Ga_2O_3 system. Chicotka (4) reported ionic conductivity measurements on sintered ceramic Na-gallate samples that were principally the β''-form.

In addition to offering the possibility of new solid electrolytes with potential practical applications, the gallium analogs provide an additional medium in which to study the process of fast ion conduction. In particular, since the binary oxide systems where one component is Ga_2O_3 are lower melting than the corresponding systems with Al_2O_3, the synthesis and growth of research crystals is facilitated The present study concerns the preparation of monocrystals of the rhombohedral β''-Na-gallate.

Experimental

The Na_2O-Ga_2O_3 phase diagram proposed by Boilot *et al.* (3) is shown in Fig. 1. We take exception to certain features of that diagram. Namely, we have established the existence of the compound $Na_2O \cdot 3Ga_2O_3$, which does not appear in Fig. 1; we have not been able to demonstrate congruent melting of the β-form at about 85.8 mole percent (m/o) Ga_2O_3, as indicated; and we find a different composition for the Na_2O-rich boundary of the β''-phase field. We have not investigated other aspects of the system to determine if there are other areas of disagreement. Our own investigation of the Na_2O-Ga_2O_3 diagram was interrupted by the finding that the method that both we and Boilot *et al.* employed to locate the various phase fields, namely, x-ray identification of the phases present in small quenched samples, was not yielding reliable results because of composition changes that occurred on heating. For example, three samples of approximately 0.25g each of a well-mixed, prereacted charge of composition $Na_2O \cdot 6Ga_2O_3$ (prepared by reacting Na_2CO_3-Ga_2O_3 mixtures overnight at 1100°C) were encapsulated in autogenously welded platinum tubes, held at 1375°, 1425°, and 1450°C, respectively, for 5 hr to equilibrate, then water quenched. The entire contents of each capsule was then analyzed for sodium with the following results: 1375°, $Na_2O \cdot 5.95Ga_2O_3$; 1425°, $Na_2O \cdot 8.70Ga_2O_3$; 1450°, $Na_2 \cdot 9.15Ga_2O_3$. Clearly, the Na_2O vapor that should be in equilibrium with the samples at each temperature was being lost by reaction with the platinum so that there could be no assurance that the phases present in a quenched sample truly represented equilibrium phases at the high temperature.

However, several features of the diagram of Fig. 1 appear to be qualitatively correct, and the diagram was a useful guide in setting up preliminary crystal growth experiments. It was confirmed in the present study that growth from soda-rich melts yielded only the hexagonal β-phase if the precipitation temperature exceeded $\simeq$1420°C, and only the β''-phase when the temperature was below $\simeq$1400°C, more or less in agreement with the peritectic transition shown at 1410°C in Fig. 1.

It is clear from Fig. 1 that if the composition of a melt were continuously changed by adding Ga_2O_3 or removing Na_2O so as to move toward the liquid + β'' two-phase field from the left, a crystal of β'' would just begin to precipitate when the liquidus was reached. If the Ga_2O_3/Na_2O ratio were further increased, the crystal would grow while the liquid remained at the liquidus composition. A growth procedure was devised wherein such a composition change was effected by Na_2O evaporation. Boilot *et al.* (3) has previously shown that the β''-gallate phase appears in such a process, but had obtained only small platelets.

Whereas an isothermal experiment would be desirable to ensure that the precipitating solid had a fixed composition, it would lead to nucleation and growth throughout the charge and make recovery of the product difficult. The final procedure, therefore, incorporated a steep temperature gradient to ensure that the product nucleated and grew entirely in one end of the container from which it could be easily recovered.

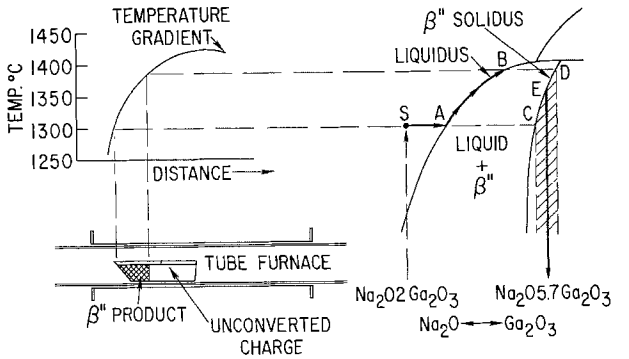

Fig. 2. Procedure for growth of β"-Na-gallate by Na_2O evaporation.

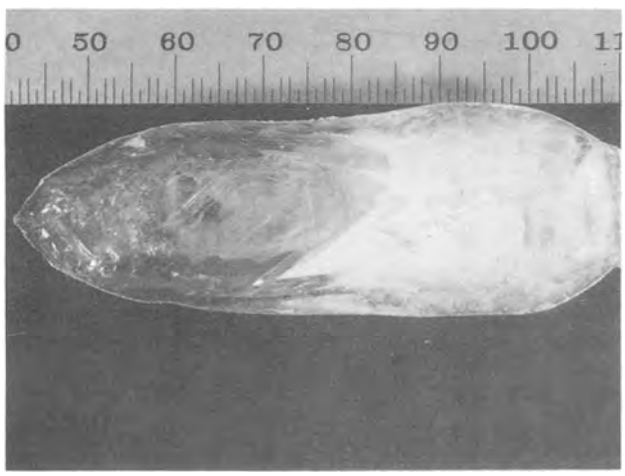

Fig. 3. Na_2O-Ga_2O_3 charge partially converted to β"-Na-gallate (clear crystal in left-hand end).

The growth procedure is described by Fig. 2. A platinum boat with one end drawn out to a point was filled with a charge of composition $Na_2O \cdot 2Ga_2O_3$. This composition was found to be completely liquid at 1300°C. The practice that was generally followed was to melt down a powdered charge, allow this to freeze, add more charge, etc., until the boat was quite full. The boat was placed in the temperature gradient shown, with the cold end at about 1310°C. It was desirable to have the temperature fall off rapidly away from the hot end of the boat as well so that Na_2O vapor would condense there rather than back into the charge in the cold end of the boat. The temperature was very carefully controlled without cycling with a Eurotherm[1] controller.

Referring to Fig. 2, at the start of an experiment the melt in the cold end of the boat is at position S on the right-hand figure, with the composition $Na_2O \cdot 2Ga_2O_3$. As Na_2O evaporates from the boat the composition moves to the right until the liquidus is reached at A. Further Na_2O loss results in precipitation of β"-solid of composition C. As the end of the boat becomes filled with the growing solid, the advancing solid-liquid interface moves up the temperature gradient, the liquidus moves along the heavy curve from A toward B, and the composition of the solid moves from C toward D. The experiment must be stopped at approximately the point shown to avoid converting part of the charge to the β-phase.

In a representative experiment, with a starting charge of 30g in a boat of dimensions ½ × ½ × 2½ in., the condition shown in Fig. 2, with about 30% of the charge converted to β"-solid, was achieved in 2 weeks' time. This resulted from a 6.1% weight loss due to Na_2O evaporation from a charge whose initial composition was $Na_2O \cdot 2Ga_2O_3$. Figure 3 is a photograph showing a top view of the platinum boat with its contents

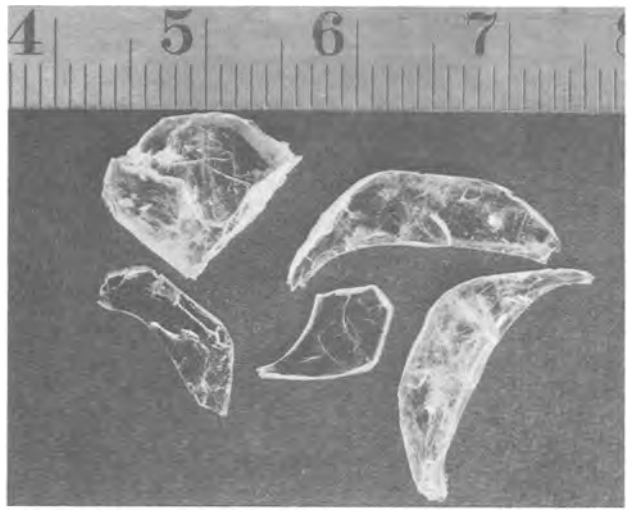

Fig. 4. β"-Na-gallate monocrystals

after a typical run. The entire mass of β"-solid was seldom one crystal, but monocrystals such as shown in Fig. 4 could be easily obtained by cleaving along obvious c planes.

The compositions of the liquidus at 1310°C (point A) was determined as $Na_2O \cdot 2.15Ga_2O_3$ in the following manner. A run was terminated just after β"-solid had begun to form in the cold end of the boat. The entire contents of the boat, excluding the small amount of β"-crystal, was then analyzed to obtain the average composition of the liquid that had been in equilibrium with the solid at the growth temperature.

A melt of $aN_2O \cdot 2.15Ga_2O_3$ composition freezes in the $3Na_2O \cdot 5Ga_2O_3$-$Na_2O \cdot 3Ga_2O_3$ two-phase field. A material balance calculation based on the original charge weight and composition and the Na_2O loss showed the frozen liquid to consist of 49% of $3Na_2O \cdot 5Ga_2O_3$ and 51% of $Na_2O \cdot 3Ga_2O_3$ by weight, in excellent agreement with an x-ray powder diffraction analysis of the ground and mixed residue which showed the two phases present in approximately equal proportions.

In principle, it should also be possible to determine the actual position of the solidus boundary, shown schematically running from C to D in Fig. 2, by analyzing the β"-solid that precipitated at positions in the boat corresponding to known temperatures. This was attempted in one case where the entire β"-solid was one crystal, fortuitously oriented with the c axis normal to the length of the boat so that a flat, clean surface running the entire length of the crystal (≃16 mm) could be exposed by cleaving. The sodium content was determined by electron microprobe analysis, sampling stepwise along the entire length of the crystal. The composition was $Na_2O \cdot 5.76Ga_2O_3$, at all positions with Na determined to ± 5%.

This finding can have two possible interpretations; either the solidus boundary is vertical from C to D, or the solid equilibrated after growth to some average composition indicated by the point E in Fig. 2. It is not possible to choose between these two interpretations. The fact that Na^+ is extremely mobile in an electric field or when it is being exchanged with other ions does not necessarily mean that composition equilibration would also be rapid, since this would be determined by the rate of the slower charge compensation process and not by the rapid Na^+ migration.

The lattice parameters of the β"-crystal are a = 5.84Å and c = 34.53Å. The space group is $R\bar{3}m$.

Discussion

This investigation has yielded large monocrystals of the rhombohedral β"-form of an alkali oxide-sesquioxide fast ion conductor for the first time in pure (*i.e.*, unstabilized) form. Roth *et al.* have presented argu-

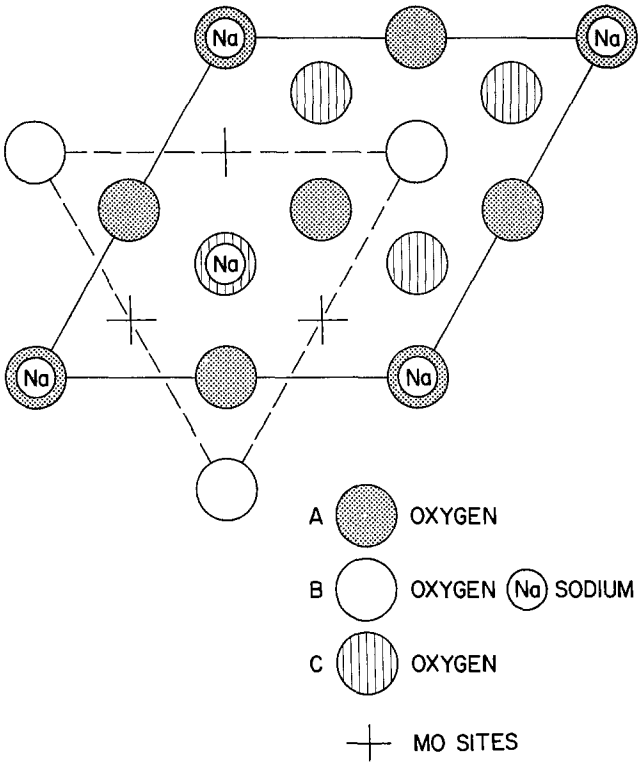

Fig. 5. Three oxygen layers of the β″-structure, including conduction plane. Na sites are shown full, but extra bridging oxygens in + sites required for compensation are not shown.

ments that Mg stabilization is necessary to produce the β″-phase in the aluminum system (5). They suggested that the action of the large Mg^{++} ion is to provide necessary strain relief when substituted for Al^{+++} at a tetrahedral site within the spinel block. In addition, the magnesium increases the concentration of Na^+ available for conduction, since each Mg^{++} that replaces an Al^{+++} is presumably accompanied by a Na^+ for charge compensation. Though Mg stabilization might be required in β″-Al_2O_3, it obviously is not required for the gallium analog. This is additional justification for working in the gallium system, since the basic processes of ionic mobility and conduction can be studied without complications due to the presence of a foreign ion whose role is not completely understood.

Since the β″-gallate that is grown by the present method precipitates at the β″ solidus boundary, its composition is that of the most soda-rich edge of its solid solution phase field. (The composition range of the solid solution has not yet been established and might actually be very narrow.) This material thus has the highest equilibrium Na content possible in the β″-gallate structure. The composition of the product from the illustrative experiment that was described earlier was $Na_2O \cdot 5.76Ga_2O_3$, determined by electron microprobe analysis. In other experiments, the Ga_2O_3/Na_2O ratio ranged from a high of 5.75 to a low of 5.65 to 1, as determined by a more accurate spectrophotometric method. These differ by only about ± 1% in actual Na content, which is well within the precision of the method. A composition of $Na_2O \cdot 5.7Ga_2O_3$ is taken as an average of a considerable number of determinations.

The Na sites that were the Beevers-Ross (BR) and anti-Beevers-Ross (ABR) sites in the hexagonal β-structure (6) are equivalent sites in the rhombohedral β″-structure. They are shown filled in Fig. 5. There are two sites per conduction plane in the unit cell. With the composition $Na_2O \cdot 5.7Ga_2O_3$, there are on the average 1.93 Na atoms per plane; *i.e.*, the sites are 96.5% full. β″-Na-gallate is an excellent Na ion conductor (7), which is perhaps surprising in view of the low density of cation vacancies available, and it suggests that Na^+ migration is principally via the mid-oxygen (MO) spaces shown as + in Fig. 5.

If charge compensation for the additional sodium in the β″-phase over that in the ideal β-composition of $Na_2O \cdot 11Ga_2O_3$ is accomplished by additional bridging oxygens in the (MO) sites, as had been suggested by preliminary results of Kahn *et al.* (8), $0.93 \div 2 = 0.465$ additional sites would thus be occupied, leaving $3 - 0.465$ (MO) sites available to assist in conduction of the sodium.

The Effects of Geometry on Diffusion-Controlled Chemical Reaction Rates in a Plasma

James F. Battey

International Plasma Corporation, Hayward, California 94544

ABSTRACT

The photoresist strip rate at the edge and center of an array of silicon wafers is calculated for an oxygen plasma. The etch rate at the edge is essentially independent of wafer diameter and spacing, whereas the etch rate at the center increases linearly with increasing wafer spacing and is inversely proportional to the square of wafer diameter. Thus, a plasma stripping or etching system has a processing rate which can be specified in silicon area per unit time. The degree of inhomogeneity between edge and center also depends on the probability of reaction when a reactive specie hits the photoresist. Experimental measurements confirm the predicted functional dependence, except with an oxygen plasma the strip rate at the center of the wafer varies inversely as the cube of the wafer diameter rather than as the square. The implication is that two atomic oxygen atoms react simultaneously with the photoresist, perhaps as $CH_2 + 2\,O \rightarrow CO + H_2O$, or more probably as $O + O + \text{wall} \rightarrow O_2 + \text{wall}$.

In most low pressure plasmas created by capacitively coupling rf energy into a cylindrical cross-section reactor, the glow discharge is confined to a region near the walls of the reactor. The effect is analogous to the electrical skin effect in a metal conductor. The electrical current is carried in this region and the active species are created in this region. In an oxygen plasma the active specie is atomic oxygen which has a sufficiently long life to diffuse through the interior of the reactor. If the flow rates are small, the concentration of atomic oxygen is substantially constant, apart from the region immediately adjacent to the walls.

If a boatload of silicon wafers is introduced in an oxygen plasma, the atomic oxygen must diffuse between the wafers in order to strip the photoresist. The strip rate is calculated for the edge of the wafer and the center of the wafer as a function of wafer spacing and diameter, background oxygen concentration, and probability that an oxygen atom reacts when it hits the photoresist. Experimental measurements are made to examine the predicted functional dependence.

The mathematical model is also applicable to calculating the degree of inhomogeneity across the face of a wafer in an etching plasma or in a diffusion operation.

Experimental Arrangement

The experimental work was done in an 8 in. diameter cylindrical quartz reactor 13 in. in length. A schematic of the apparatus is shown in Fig. 1. The back of the reactor is a spherical sectioned quartz dome, and the front is a flat quartz door. The gas is introduced into the reactor through a quartz manifold on the bottom of the reactor and parallel to its axis. The gas is exhausted by a forepump from the reactor through a quartz manifold on the top of the reactor and parallel to the reactor axis. The plasma is excited by a radio frequency generator operating at 13.56 MHz and coupled into the plasma through a 50Ω cable, a pi impedance matching network, and two half-cylinder metal electrodes placed around the outside walls of the cylindrical reactor. The top electrode is at electrical ground, and the bottom electrode oscillates between positive and negative voltage with the generator.

Key words: semiconductors, photoresist stripping, plasma etching.

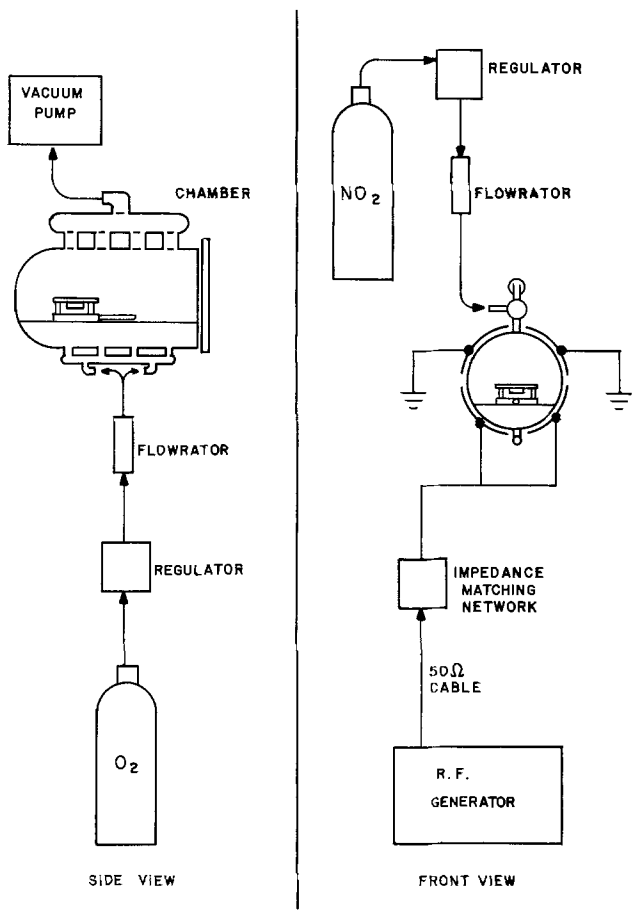

Fig. 1. Diagram of the experimental apparatus

The exhaust manifold is sufficiently large that the pressure drops in it are negligible, and the pressure in the reactor is measured with a Hastings VT4 vacuum gauge in a quartz tube leading out of the exhaust manifold. A metered flow of molecular oxygen is fed into the reactor from a cylinder of 99.6% minimum purity oxygen at high pressure through a regulator which reduces the pressure to approximately 1 atm,

and a flowmeter, which is connected to the inlet manifold. The rf power in the reactor converts some of the molecular oxygen to atomic oxygen, and the flow of atomic oxygen in the exhaust can be measured by titrating it (2) with a flow of NO_2 which is introduced into the quartz tube which extends out of the exhaust manifold.

In order to obtain reproducible stripping times, it was found necessary to put the single wafer on a large aluminum block which had a thermometer inserted in a hole in the block, and to place the block in the same position in the reactor. It was also found necessary to place two thermometers on the external walls of the reactor and require all three thermometers to assume the same temperatures as in a prior experiment.

An additional requirement for reproducibility of strip times is that the internal walls of the quartz reactor, the door, the inlet and exhaust manifolds, the aluminum block and its quartz support structure be cleaned using firepolishing with a glassblower's torch and acid etching. Quartz and aluminum oxide presumably have a lower surface recombination rate for atomic oxygen when they are "clean."

The presence of a second silicon wafer coaxial, parallel, and at a stipulated distance from the first wafer is simulated by a circular glass slide clamped to a heat sink which is thermally coupled to the heat sink on which the silicon wafer rests. The glass slide can be moved with respect to the silicon wafer by means of calibrated set screws.

The experimental procedure was to scrape the photoresist off a small area at the center and the edge of the wafer, measure the photoresist thickness with a Sloan Dektak surface profile measuring system, strip the wafer for a length of time sufficient to remove a significant amount, but not all, of the photoresist from the center and edge of the wafer, and measure the thickness of the residual photoresist.

Analysis

The difference in strip rate between the edge and center of a wafer in a linear array can be calculated, if an assumption is made about the probability that an oxygen atom will chemically react with the photoresist when it hits it.

Assume two 2 in. wafers parallel to one another spaced 3/16 of an inch apart with their surfaces parallel to an axis through their centers, with photoresist covering the facing surfaces. The problem is to calculate the concentration of atomic oxygen as a function of position between the wafers. If it is assumed that the primary method of atomic oxygen removal is by chemical reaction with the photoresist and volume recombination mechanisms can be ignored, and if it is further assumed that the by-products of the reaction are present in concentrations that have a negligible effect on the reaction rate, then the problem becomes mathematically the same as the conduction of heat in a solid cylinder with a radiation boundary condition at the photoresist-covered wafer surfaces and a constant oxygen concentration or temperature at the side of the cylinder formed by drawing lines between the edges of the wafers.

Let ν represent the atomic oxygen concentration, z represent the distance along the axis between the wafers, one of which is at $z = 0$ and the other at $z = \ell$, and r represent the radial distance from the center of the wafers to the edges which are at $r = a$. The radiation boundary condition equates the diffusion current into the wafers, $D \left.\frac{d\nu}{dz}\right|_{z=0}$, where D is the diffusion coefficient of atomic oxygen in molecular oxygen, to the reaction rate at the surface which is assumed (and we have shown experimentally) to be linear in ν. From kinetic theory the number of oxygen atoms striking the wafer surface per unit area and time is $\frac{1}{4}\bar{\nu}\nu$, where $\bar{\nu}$ is the average velocity. If p is the probability of reacting per strike, then the boundary condition can be written

$$D \left.\frac{d\nu}{dz}\right|_{z=0} = \frac{1}{4}\bar{\nu}p\nu(z=0)$$

or

$$\left.\frac{d\nu}{dz}\right|_{z=0} = h\nu(z=0)$$

where $h = \bar{\nu}p/4D$. Kinetic theory also says that $D \approx 1/3\,\bar{\nu}\lambda$ where λ is the mean free path so $h \approx 3p/4\lambda$. At 1 Torr $\lambda \approx 0.01$ cm so $h \approx 130$, and an experimental determination of h will give an approximate value of p.

The boundary condition that $\nu = \nu_0$ at $r = a$ assumes that the photoresist stripping process causes a negligible change in the atomic oxygen concentration outside the region between the wafers.

Since atomic oxygen generation or recombination between the wafers is assumed not to happen, conservation of atomic oxygen requires that ν be a solution to $\nabla^2\nu = 0$. The solution to the equation which conforms to the boundary conditions is (3)

$$\nu = 2\nu_0 \sum_{n=1}^{\infty} \frac{I_0(\alpha_n r)\{\alpha_n \cos \alpha_n z + h \sin \alpha_n z\}}{I_0(\alpha_n a)\{(\alpha_n^2 + h^2)\,\ell + 2h\}} \left\{ \sin \alpha_n \ell + \frac{h}{\alpha_n}(1 - \cos \alpha_n \ell) \right\}$$

where the α_n are the positive roots of

$$\tan \alpha \ell = \frac{2\alpha h}{\alpha^2 - h^2}$$

and

$$I_0(\alpha_n r) = \sum_{m=0}^{\infty} \frac{(\frac{1}{2}\alpha_n r)^2}{(m!)^2}$$

is the zero order solution to the modified Bessel equation. By the ratio test the series is absolutely convergent. Since the convergence is independent of z and r, it is uniformly convergent in any bound region. Thus ν and its derivatives are continuous functions of z and r, and term by term differentiation of its series representation is permissible. The chemical reaction rate at any point on the wafer is equal to the diffusion current at that point into the wafer, or

$$D \left.\frac{d\nu}{dz}\right|_{\substack{z=0 \\ r=a}} = 2D\nu_0 \sum_{n=1}^{\infty} \frac{\alpha_n h \left\{ \sin \alpha_n \ell + \frac{h}{\alpha_n}(1 - \cos \alpha_n \ell) \right\}}{(\alpha^2{}_n + h^2)\,\ell + 2h}$$

and

$$D \left.\frac{d\nu}{dz}\right|_{\substack{z=0 \\ r=0}} = 2D\nu_0 \sum_{n=1}^{\infty} \frac{\alpha_n h \left\{ \sin \alpha_n \ell + \frac{h}{\alpha_n}(1 - \cos \alpha_n \ell) \right\}}{\{(\alpha^2{}_n + h^2)\,\ell + 2h\} I_0(\alpha_n a)}$$

In numerically evaluating I_0 in the interval $r = 0$ to $r = a$, it should be noted that it is a power series, and the remainder value of the terms not calculated is equal to or less than the first term not calculated, evaluated at a.

As $\alpha_n \ell$ gets large

$$\tan \alpha_n \int = \frac{2\alpha_n \int h \int}{(\alpha_n \int)^2 - (h \int)^2}$$

$$\rightarrow (\alpha_n \int)^2 - (n-m)\pi\alpha_n \int - 2h \int \cong 0$$

if $\alpha_n >> h$, and m is the number of the first root to fall in the first quadrant, and

$$\alpha_n \int = \frac{1}{2}(n-m)\pi + \frac{1}{2}[(n-m)^2\pi^2 + 8h \int]^{1/2}$$

$$\cong (n-m)\pi + \frac{2h \int}{(n-m)}\pi$$

if $(n-m)\pi >> 8h \int$. Also

$$\sum_{n-m=r}^{\infty} \frac{\alpha_n h \left\{ \sin \alpha_n \int + \frac{h}{\alpha_n}(1 - \cos \alpha_n \int) \right\}}{(\alpha_n^2 + h^2) \int + 2h}$$

becomes

$$\sum_{n-m=r}^{\infty} \frac{2h^2 \int}{(n-m)^2\pi^2}$$

for even $n-m$, and goes to zero for odd $n-m$. Now

$$\sum_{n-m=2}^{\infty} \frac{1}{(n-m)^2_{\text{even}}} = \frac{\pi^2}{24}$$

so the remainder, Re, for even $n-m$ is

$$\text{Re} \equiv \sum_{n-m=r}^{\infty} \frac{\alpha_n h \left\{ \sin \alpha_n \int + \frac{h}{\alpha_n}(1 - \cos \alpha_n \int) \right\}}{(\alpha_n^2 + h^2) \int + 2h}$$

$$\cong \frac{2h^2 \int}{\pi^2} \left\{ \frac{\pi^2}{24} - \sum_{n-m=2}^{n-m=r-1} \frac{1}{(n-m)^2} \right\}$$

The reaction rates at the edge of the wafer and at the center were calculated for values of h of 25, 2.5, 0.25, 0.025, and 0.0025. The results are shown in Table I. For the reaction rate at the edge of the wafer, 32 terms are calculated for $h = 25$, 5 for $h = 2.5$ and 0.25, 3 for $h = 0.025$, and 2 for $h = 0.0025$ before calculating Re. A single term is adequate for the reaction rate at the center in all instances. The terms corresponding to values of $\alpha_n \int$ lying close to odd $n\pi$'s are quite uncertain since $\sin \alpha_n \int + \frac{h}{\alpha_n}(1 - \cos \alpha_n \int)$ is the difference between two approximately equal numbers. However, since these terms are small, it does not make much difference.

The root equation can be written so that it is a function of $h \int$ and $\alpha \int$. Thus the roots listed here can be used for a different $\int$ spacing by making an appropriate adjustment of the h values. Thus, the $\alpha_n \int$'s calculated here for 3/16 in. spacing can be used for 3/8 in. spacing by associating them with h values smaller by a factor of two than those listed here. Also, by symmetry, the case of one of the facing wafer surfaces coated and a 3/16 in. spacing corresponds to both faces coated at a 3/8 in. spacing.

Similarly

$$\left. \frac{1}{D\nu_0} D \frac{d\nu}{dz} \right|_{\substack{z=0 \\ r=a}}$$

can be written so that it is equal to the product of h and a function that depends only on $h \int$ and $\alpha \int$, *i.e.*

$$h \sum_{n=1}^{\infty} \frac{2\alpha_n \int \left\{ \sin \alpha_n \int + \frac{h \int}{\alpha_n \int}(1 - \cos \alpha_n \int) \right\}}{(\alpha_n \int + h \int)^2}$$

Thus, the value of the function for a different $\int$ can be found by taking the value calculated here for 3/16 in. spacing but at an h value appropriate for the $h \int$ product physically desired. Thus, the functions calculated here for 3/16 in. spacing can be used for 3/8 in. spacing by taking its value for an h that is twice the value physically desired.

In Table I it can be observed that the calculated values of

$$\left. \frac{1}{D\nu_0} D \frac{d\nu}{dz} \right|_{\substack{z=0 \\ r=a}}$$

are equal to h within a few percent for h of 25 or 2.5, and more closely than that for smaller values of h. The implication of this is that the value of the function is substantially equal to one for any physically realizable values of h and values of $\int$ small enough for the assumed boundary conditions to be applicable. $1/D\nu_0 \, d\nu/dz = h$ is the condition for a single plane surface. Thus, the strip rate at the edge of a wafer array is substantially the same as for a single wafer.

If it is assumed that n CH_2 groups are removed for every oxygen atom consumed, the chemical reaction rate for a single wafer is $nhD\nu_0$. It is known that $h \approx 0.158$ cm^{-1} at 160°C from the difference in etch rates at the edge and center in these experiments. ν_0 has been measured by titrating the flow of atomic oxygen with NO_2 and is about 7.4×10^{14} at./cm³. It is not clear what value of D should be used due primarily to the uncertainty in the gas temperature. However, a value of 700 cm/sec² does not seem unreasonable. For the power and pressure associated with ν_0, the strip time is about 94 sec. There are about 4.25×10^{21} CH_2 groups per square centimeter, which leads to a value of n of about 550. Thus, although it has been shown that carbon monoxide and water vapor can inhibit the reaction and thus are probably by-products of the reaction, it seems clear that most of the photoresist must come off in larger atomic groups.

The roots and $D\, d\nu/dz \Big|_{\substack{z=0 \\ r=a}}$ do not depend on a, so the values of these quantities calculated here can be used for different diameter wafers. $D\, d\nu/dz \Big|_{\substack{z=0 \\ r=0}}$ is inversely proportional to $I_0(\alpha_n a)$. However, $I_0(\alpha_n a)$ is proportional to a^2, and the calculated values of $D\, d\nu/dz \Big|_{\substack{z=0 \\ r=0}}$ can be converted to a different diameter wafer by multiplying by the square of the ratio of the old diameter divided by the new diameter. For 4 in. wafers, the calculated values of $D\, d\nu/dz \Big|_{\substack{z=0 \\ r=0}}$ for 2 in. wafers should be divided by four.

If the values of h are small, $2\alpha h/\alpha^2 - h^2 \approx 2h/\alpha$, $\tan \alpha \int \approx \alpha \int \approx 2h/\alpha$, and $\alpha \approx (2h/\int)^{1/2}$. All the terms in the series summation for I_0 contain an α_n^2 and consequently are inversely proportional to $\int$. Thus, the strip rate at the center is proportional to $\int$.

Thus, increasing wafer diameter by a factor, f, leads to greater edge-to-center inhomogeneity in strip rates, which can be corrected by increasing wafer spacing by a factor f^2. Thus, a particular plasma stripping system has a capacity which can be specified in silicon area, independent of wafer diameter.

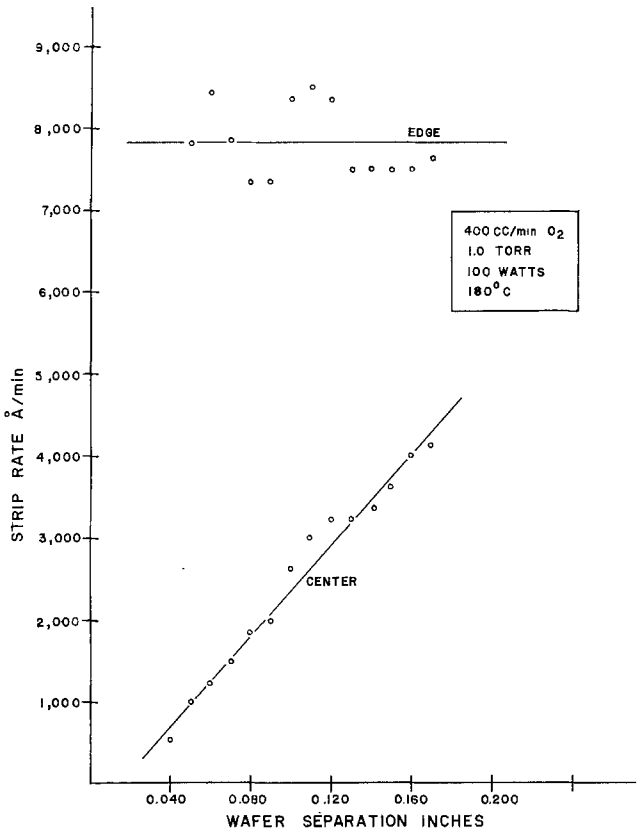

Fig. 2. Strip rate at the wafer edge and center as a function of wafer separation under conditions of constant molecular oxygen flow rate, pressure, and power. The edge strip rate is independent of separation, whereas the center strip rate is linear in separation.

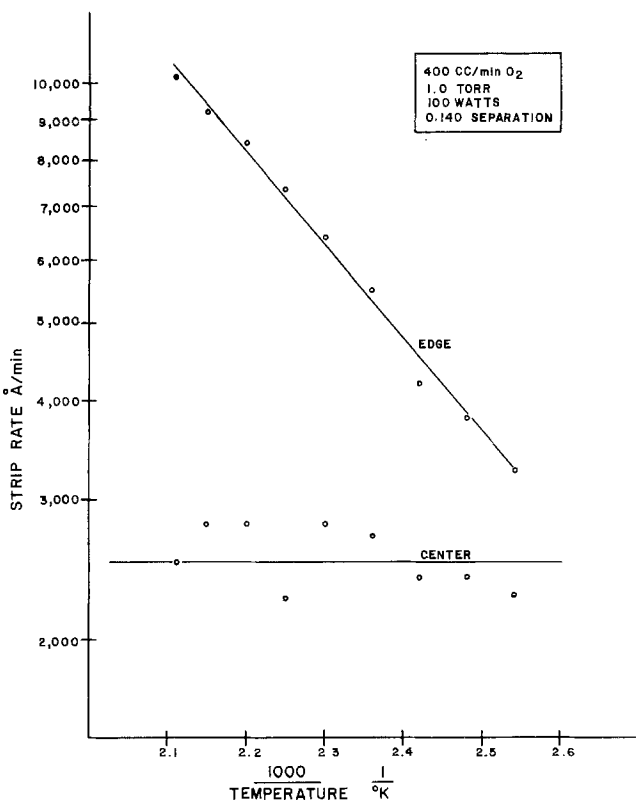

Fig. 3. Strip rate at the wafer edge and center as a function of temperature under conditions of constant molecular oxygen flow rate, pressure, and power. The edge strip rate varies exponentially as $-E/RT$, where E is approximately 6.5 kcal/mole. The center strip rate is approximately independent of temperature.

Experimental Results

The fact that $D\, dv/dz \Big|_{\substack{z=0 \\ r=0}}$ is proportional to $\int$ means that for small wafer spacing the center strip rate should be linear in $\int$ with a slope of 1 and, ignoring thermal effects and loading time, the wafer per hour capacity is independent of $\int$. It is seen in Fig. 2 that the strip rate is linear in $\int$. The reason for this is that larger wafer spacing allows more atomic oxygen between the wafers. If the wafer spacing becomes too large, the boundary condition that $v = v_0$ at $r = a$ becomes a poor approximation, and the analysis fails. Operation in the nonlinear region reduces the capacity of the equipment. The center strip rate experimentally approaches zero more rapidly at small $\int$ because $\int$ is approaching the mean free path which introduces an effect similar to a reduction in the diffusion coefficient.

In Fig. 3 the strip rate at the edge and the strip rate at the center are shown as a function of temperature. The strip rate at the edge varies exponentially as $-E/RT$ where E is about 6.25 kcal/mole. To a first approximation the strip rate at the center is independent of temperature in the range of 120°-200°C. It should be emphasized that this is not true at lower temperatures where the center strip rates are much longer. Also, it will no longer be true once a ring around the edge of the wafer has cleared. Thus, an additional specification on a plasma stripping system is the time to heat a load of wafers from room temperature to 120°C. The approximate temperature in-

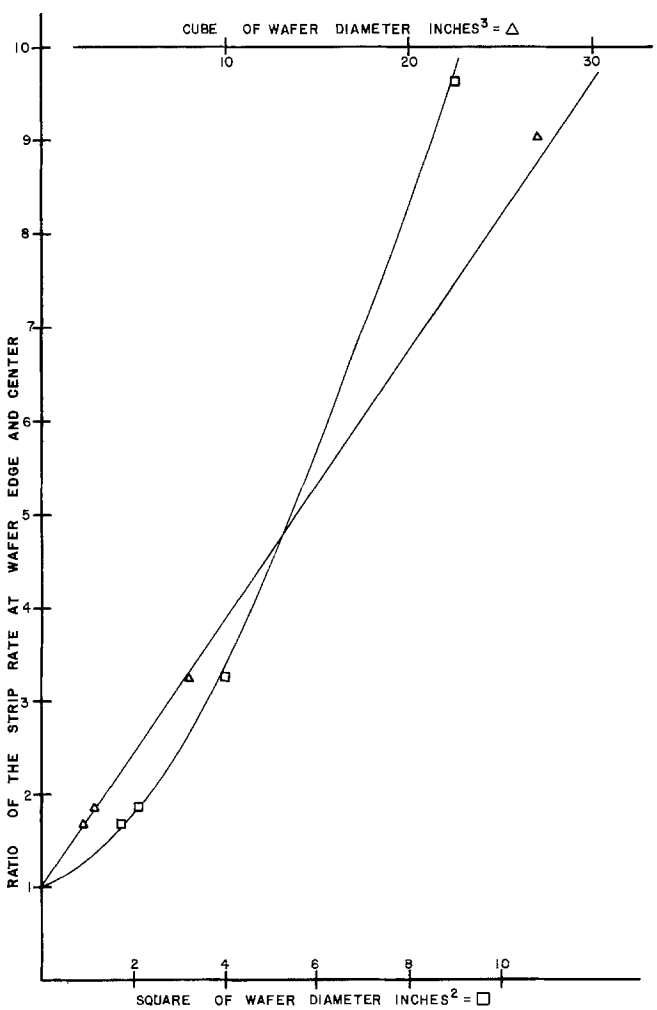

Fig. 4. The ratio of the strip rate at the wafer edge and center as a function of wafer diameter under conditions of constant molecular oxygen flow rate, pressure, and power. The edge strip rate is independent of wafer diameter. The center strip rate is inversely proportional to the cube of the diameter.

dependence of the center strip rate is explained by the fact that the product of the probability of the atomic oxygen atom reacting and the number that reach the center are approximately constant.

In Fig. 4 the ratio of the strip rate at the center of the wafer to the strip rate at the edge is plotted as a function of the square and cube of the diameter of the wafer. The absolute strip rates were not very reproducible, presumably due to varying surface recombination rates at the jigging which held the wafer and the slide. However, the ratios were within a standard deviation of about 10%. Contrary to the predictions of the analysis, it appears that the ratio varies more nearly as the cube of the diameter.

This can be qualitatively understood if it is assumed that two atomic oxygen atoms simultaneously react with a CH_2 group to form CO and H_2O, or an appreciable amount of the atomic oxygen recombines in a three-body reaction involving two oxygen atoms and the wafer. The latter explanation seems more probable since other experiments have shown the strip rate to be linear in oxygen concentration. Three bodies are needed to simultaneously conserve energy and momentum. The correct boundary condition to $\nabla^2 \nu = 0$ would then involve equating the diffusion current of oxygen atoms into the wafer surface to a term proportional to the square of the oxygen atom concentration at the surface.

Wafers of a given diameter have a certain ratio of oxygen concentration and strip rate at the edge and center. A larger wafer may be thought of as a wafer of the smaller diameter surrounded by an additional ring. The ratio of oxygen concentration and strip rate at the smaller diameter and center should be the same for the larger wafers as for the smaller wafers. However, the ratio at the larger diameter to the smaller diameter would be lower for the square law than the linear boundary condition for the larger wafers because the region is one of higher atomic oxygen concentration than the region inside the smaller diameter. If the atomic oxygen concentration and strip rate are presumed to be a fixed quantity at the edge of the wafers, these quantities will be lower at the smaller diameter and center of the larger wafers than the linear boundary condition predicts. Thus, the square law boundary condition has the effect of making the ratio of the strip rate at the center to the edge have a larger than square law dependence on the diameter of the wafers.

Liquid Phase Epitaxial Growth of Semi-insulating GaAs Crystals

Mutsuyuki Otsubo and Hidejiro Miki

Mitsubishi Electric Corporation, Central Research Laboratories, Itami, Hyogo 664 Japan

ABSTRACT

Semi-insulating GaAs crystals were grown by liquid phase epitaxy from a Ga solution doped with Cr metal. The room temperature resistivity of the layers was $10^{-2} \sim 10^{7}$ Ω · cm, depending on the doping concentration of Cr, the background donor concenetration, arsenic vapor pressure, and the cooling rate. It was found that the grown layers became semi-insulating only when the background donor concentration of the undoped layer is lower than 1.0×10^{15} cm^{-3}. Higher arsenic vapor pressure and the higher cooling rate give layers with higher resistivity. The threshold voltage, at which the *I-V* curve changes from linear to $V^{3\sim4}$ dependence, varies with the square of the thickness with electron injecting contacts. The activation energy obtained from the temperature dependence of resistivity increases as the room temperature resistivity increases. The highest obtained was 0.71 eV.

Semi-insulating GaAs crystals have been widely used as the substrates for microwave devices such as planar-type Gunn diodes, Schottky barrier gate field effect transistors (MESFET's), and integrated circuits.

Semi-insulating GaAs bulk crystals can be grown from melt by O_2 doping (1-3) and Cr doping (4). In O_2-doped semi-insulating GaAs crystals, however, it is difficult to produce a homogeneous crystal over an ingot (3, 5-6) and the resistivity in the crystal is readily changed by heat-treatment (5, 7). From these points of view, bulk semi-insulating crystals are currently produced from melt by Cr doping. Cronin and Haisty (4) showed that the solubility of Cr in GaAs is on the order of 10^{17} cm^{-3} and an effective segregation coefficient is 6.4×10^{-4}. So, more than $10^{19} \sim 10^{20}$ cm^{-3} of Cr should be added to the melt in order to compensate the background donor concentration of $10^{16} \sim 10^{17}$ cm^{-3}. Such a high Cr concentration in the melt suggests the presence of a second phase.

In applications for microwave devices such as planar-type Gunn diodes and MESFET's, the device performances at higher frequency are affected by the semi-insulating substrate properties (8-9). The most successful technique is use of an epitaxial buffer layer between a semi-insulating substrate and an epitaxial layer (10-11). The buffer layer must be high quality with very low net doping and, it is hoped, with lower total impurity content than the substrate materials. So epitaxial growth technology is required for the preparation of semi-insulating GaAs films with higher quality.

The semi-insulating GaAs crystals with room temperature resistivities greater than 10^{8} Ω · cm can be grown from vapor phase by using chromyl chloride

Key words: high resistivity materials, III-V compounds, field effect transistors, chromium metals, planar devices.

(CrO_2Cl_2) as a doping agent (12). On the other hand, semi-insulating GaAs crystals have not yet been obtained from liquid phase by Cr doping because it had been considered that Cr acted as a shallow donor (13). However, we have obtained semi-insulating crystals from liquid phase by Cr doping (14).

This paper describes the preparation and properties of the Cr-doped epitaxial semi-insulating GaAs crystals grown by liquid phase epitaxy.

Experimental

Apparatus.—Liquid phase epitaxial growth was performed by a conventional tipping technique (15) and a sliding technique (16). A glassy carbon boat and a graphite boat, which were baked at 900°C for several hours under a Pd-diffused H_2 gas flow, were used for the tipping and sliding techniques, respectively.

Growth solution.—A Ga solution (99.99999%) is saturated at the tip temperature with the undoped boat-grown GaAs polycrystal and then heated at 900°C for 10 hr under an H_2 gas flow prior to the doping experiment of Cr. A massive Cr metal (99.999%) was added into the Ga solution without any cleaning. The Ga solution was heated at 900°C for 3 hr under an H_2 gas flow for every growth.

Substrate.—Growth was carried out mainly on the semi-insulating, Cr-doped, <100> oriented GaAs substrate. Si-doped n^+-crystal was sometimes used for investigating the current-voltage (I-V) curve of the epitaxial semi-insulating layer. These wafers were sliced within 1° from the (100) plane and then lapped with 4000 mesh Al_2O_3 abrasive. After being degreased and rinsed, they were chemically etched with $3H_2SO_4$-$1H_2O_2$-$1H_2O$ prior to the epitaxial growth.

Liquid phase epitaxial growth.—Epitaxial growth was performed at the tip temperatures ranging from 700° to 850°C with cooling rates of 0.1 ~ 7.0°C/min. The details of the growth procedure were reported previously (17). The background donor concentration, C_B, which is defined by the carrier concentration of the layer grown without any Cr doping, was varied by adding a known amount of Sn into the solution.

Resistivity measurement.—The resistivity of the epitaxial layer was obtained by measuring the resistance of the rectangular shaped samples which were cut down from the epitaxial wafers scraped off the substrate. Ohmic contacts to the end of the sample were made by soldering In dots at 450°C for 90 sec under an H_2 gas flow. In order to determine whether the In contacts were ohmic or not, the resistance of the rectangular shaped semi-insulating bulk crystal was measured by the four-probe method with different intervals. Resistivities of these samples were 4.0 ~ 6.4 × 10^7 Ω · cm. Thus, it seems that In contacts may be used for resistivity measurement. The resistance of the sample was measured in the dark using an electrometer (TR-8651).

Evaluation of the epitaxial layers.—Etch pits on a (100) surface were revealed by etching the epitaxial wafer in molten KOH (18) for 5 min and were then observed by an optical microscope. Inclusions were detected by x-ray microanalysis.

Results and Discussion

Preparation of Epitaxial Semi-insulating GaAs Crystals

Effect of background donor concentration on the resistivity of the epitaxial layers.—Figure 1 shows the relation between the resistivity of the epitaxial layer and the content of Cr added into a Ga solution for various C_B. The epitaxial layers were grown at a tip temperature of 800°C with a cooling rate of 2.5°C/min. Flow rate of an H_2 gas was 0.8 liter/min. The resistivity of the layer was increased by increasing

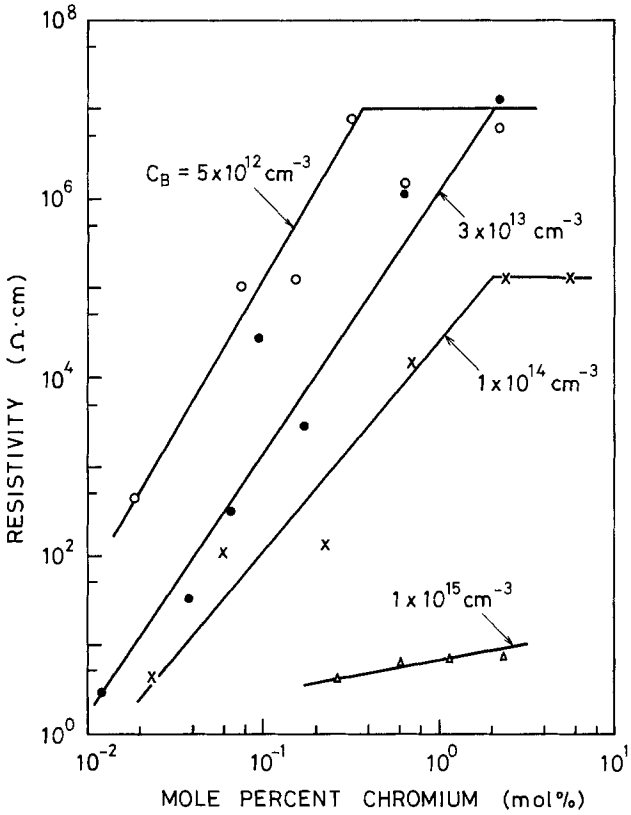

Fig. 1. Relation between the resistivity in the epitaxial layers and the content of Cr to be added to a Ga solution for various background donor concentrations. The epitaxial growth was performed at a tip temperature of 800°C with a cooling rate of 2.5°C/min.

the content of Cr in the solution. The epitaxial semi-insulating layers with room temperature resistivity greater than 10^7 Ω · cm were obtained when C_B was less than 3.0 × 10^{13} cm^{-3}. It was found that the layer becomes semi-insulating only when C_B is lower than 1.0 × 10^{15} cm^{-3} under these growth conditions. It is important to reduce C_B in producing higher quality semi-insulating GaAs layers.

Figure 2 shows the relation between the content of Cr in a solution and the resistivity of the layer grown at a tip temperature of 850°C with a cooling rate of 2.5°C/min. Under these growth conditions, the undoped layers were p-type with the free hole concentrations on the order of 1.0 × 10^{13} cm^{-3}. The resistivity of the layers was almost the same as that of undoped layers even though 3.4 mole percent (m/o) Cr was added to the solution and thus the semi-insulating layers had not been obtained. When 0.02 m/o Sn was added to the solution in addition to the 3.4 m/o Cr, however, semi-insulating layers with room temperature resistivity greater than 10^5 Ω · cm were obtained. This is thought to result from the fact that Cr in GaAs appears to act as an electron trap, reducing the donor concentration. Accordingly, if the grown layer is expected to turn out p-type, then donor impurities should be added to a level in excess of the expected acceptor concentration. The same situation has been observed in producing bulk semi-insulating GaAs crystals from melt by Cr doping.

Effect of cooling rate on the resistivity of the epitaxial layers.—Figure 3 shows the effect of cooling rate on the resistivity of the epitaxial layers. In this experiment, the epitaxial growth was performed under the conditions of a tip temperature of 800°C, Cr content in the solution of 0.8 m/o, and C_B of 1.0 × 10^{13} cm^{-3}. The numbers in Fig. 3 indicate the growth sequence. The resistivity of the epitaxial layers increases exponentially with the cooling rate up to

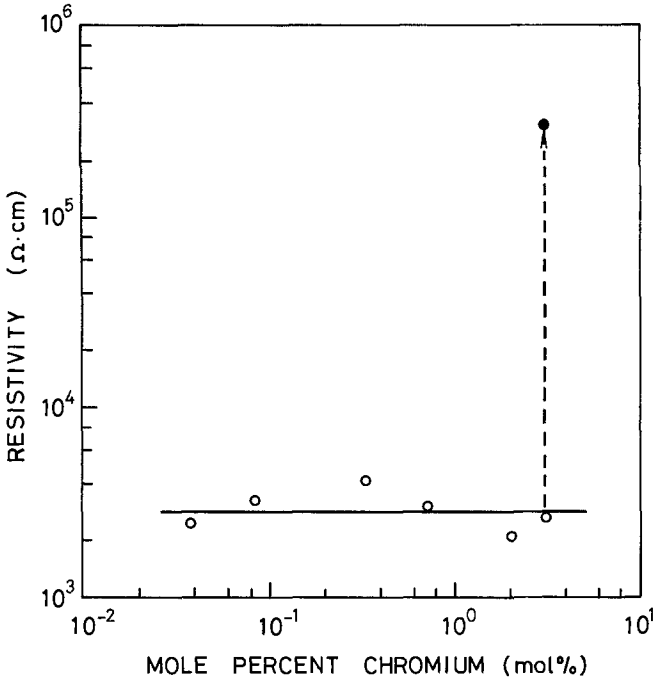

Fig. 2. Relation between the resistivity in the epitaxial layers grown at a tip temperature of 850°C with a cooling rate of 2.5°C/min and the content of Cr for the background hole concentration of 1.0 × 10^{13} cm^{-3}. A closed circle is the resistivity of the layer grown by using a Ga solution containing 0.02 m/o Sn in addition to 3.4 m/o Cr.

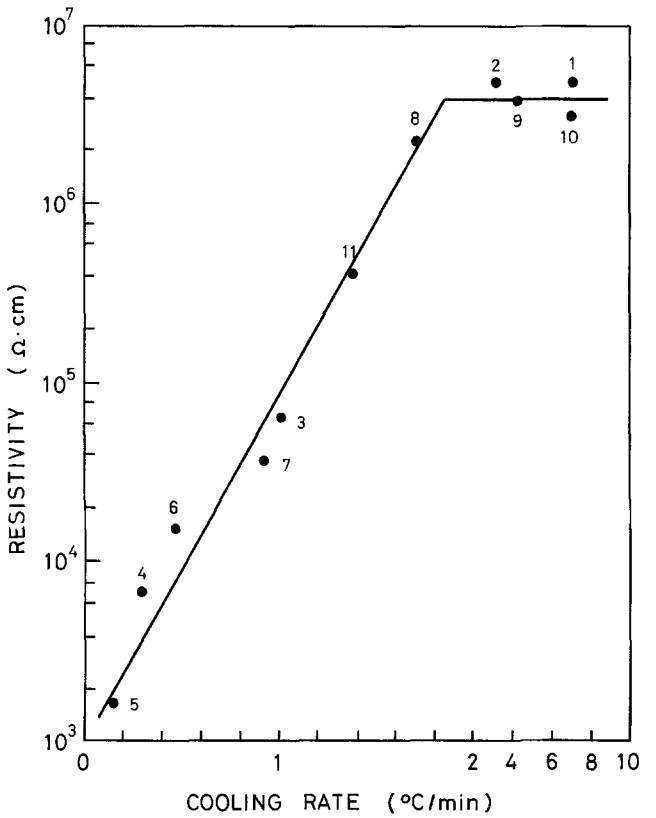

Fig. 3. The effect of cooling rate on the resistivity of the epitaxial layers grown at a tip temperature of 800°C with the doping concentration of Cr of 0.8 m/o and the background donor concentration of 1.0 × 10^{13} cm^{-3}.

1.8°C/min and is then constant, independent of the cooling rate greater than 1.8°C/min. This is supposed to be due to the fact that the rapid cooling rate results in local As supersaturation at the solid-liquid interface and a reduction in As vacancy concentration (19). Also, a change in impurity incorporation associated with cooling rate is expected. This may result in an increase in the effective segregation coefficient of Cr. It is presumed from this experiment that Cr atoms occupy Ga sites and/or complexes associated with Ga vacancies and introduce an electron trap. Fistul *et al.* (20) showed in their investigation of the electron paramagnetic and spin resonance that Fe atoms occupied Ga sites in the Fe-doped semi-insulating GaAs grown from melt. The same situation was observed in the Cr-doped semi-insulating GaP. It is known that Cr atoms replace the Ga atoms in the lattice of GaP (21).

Effect of arsenic vapor pressure on the resistivity of the epitaxial layers.—In order to confirm this hypothesis, the epitaxial growth was performed under a mixed gas atmosphere, a Pd-diffused H_2 gas, and an arsenic vapor. The apparatus used in this experiment is schematically shown in Fig. 4. This is similar to that used by Nelson (15) except that another Ga-GaAs solution (second solution), which supplies an arsenic vapor downstream, is added in addition to a growth Ga-GaAs solution (first solution). An arsenic vapor evaporated from the second solution, which is transported to the region of the first solution, suppresses the evaporation of arsenic from the first solution. It is supposed that this gives higher arsenic concentration at the solid-liquid interface. The details of the growth procedures have been reported previously (22). The epitaxial growth was carried out under the following conditions; a tip temperature of 800°C, a cooling rate of 0.9°C/min, Cr content in the first solution of 0.8 m/o, and GaAs content in the second solution of 2.4 m/o. Results are shown in Fig. 5, in which group a and group b

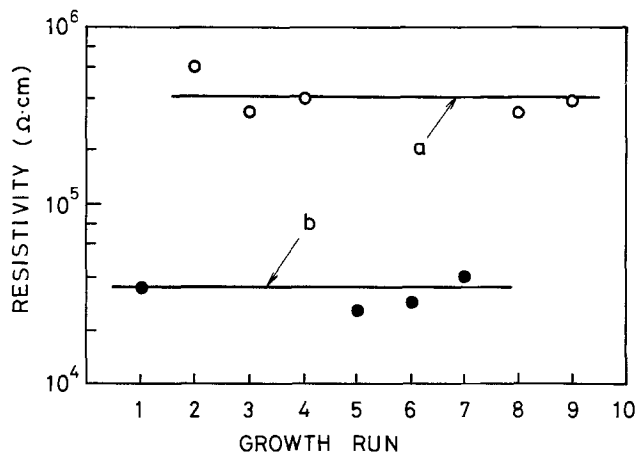

Fig. 5. The effect of the ambient gas on the resistivity of the epitaxial layers. Group a and b were grown under a mixed and an H_2 gas atmosphere, respectively. The layers were grown at a tip temperature of 800°C with a cooling rate of 0.9°C/min with a content of 0.8 m/o Cr.

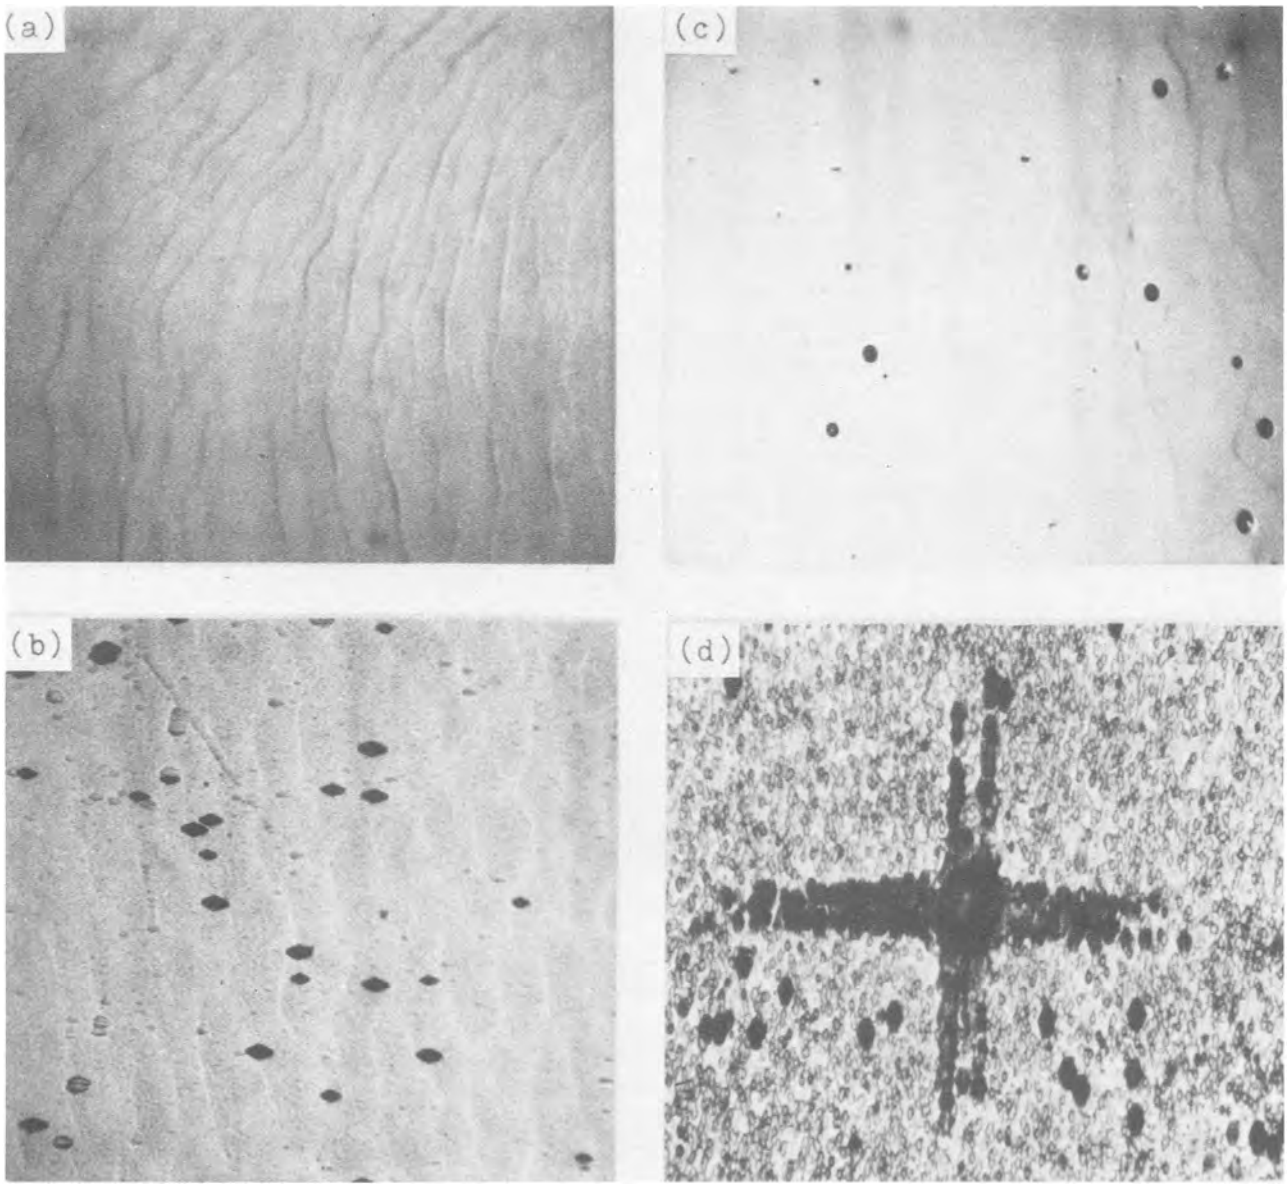

Fig. 6. Microphotographs of as-grown (a, c) and etched (b, d) surfaces in the crystals grown from a Ga solution containing 1.2 m/o Cr (a, b) and 2.2 m/o Cr (c, d). The epitaxial layer surfaces were etched with molten KOH.

show the resistivities in the epitaxial layers grown under a mixed gas and an H_2 gas atmosphere, respectively. The numbers in Fig. 5 stand for growth sequence. The resistivity of the layer grown under a mixed gas atmosphere (a) was one decade higher than that of the layer grown under an H_2 gas atmosphere (b). Growth rate was increased in group a by an amount of 5 $\sim$ 10%. Figure 5 also seems to suggest that Cr atoms occupy Ga sites and/or form complexes associated with Ga vacancies.

Surface morphology of the grown layers.—Figure 6 shows the surface morphology in the epitaxial semi-insulating layers. These layers were grown by a sliding technique at a growth temperature of 800°C. The surface morphology in the layer grown from the solution which contained less than 1.2 m/o Cr was little different from that in the layer without any Cr doping (a, b). However, when more than 2.2 m/o Cr was added in a solution, the grown layer contained inclusions as shown in Fig. 6c and dislocations along with <110> direction originated at inclusions were observed in Fig. 6d. These dislocations are thought to be generated by the difference in the thermal expansion coefficient between GaAs crystal and inclusions.

X-ray microanalysis.—These inclusions were examined by x-ray microanalysis. The Ga and Cr were detected but As was not. Although the composition of these inclusions has not yet been identified, we believe that these are Cr compounds associated with Ga. Gimelfarb *et al.* (23) showed that the inclusion in a Cr-doped bulk semi-insulating GaAs was composed of Cr compound associated with As. It is probable that such a difference is due to the difference in the growth method. From this experiment, Cr content in a solution should be less than 1.0 m/o at 800°C for producing homogeneous semi-insulating layers.

Preparation of n-Type Layers by Cr Doping

As mentioned above, it is thought that Cr atoms act as a shallow donor in the liquid phase epitaxially grown GaAs and that it is not possible to obtain semi-insulating layers from liquid phase by Cr doping (13). This is inconsistent with our experimental findings of the semi-insulating layer from liquid phase by Cr doping (14). So the epitaxial growth conditions for growing n-type layers by Cr doping were investigated.

Epitaxial growth of n-type GaAs layers by Cr doping.—Figure 7 shows the relation between the carrier

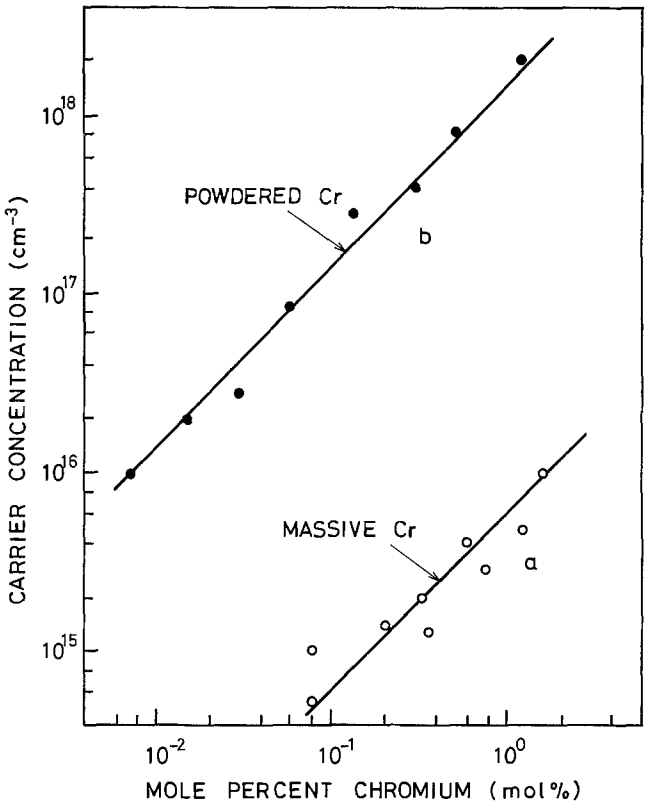

Fig. 7. Relation between carrier concentrations in the layers grown at a tip temperature of 700°C with a cooling rate of 2.5°C/min and the content of Cr in the solution. Groups a and b were grown by using Ga solutions doped with a massive Cr and a 100 mesh powdered Cr, respectively.

concentration of the grown layer and the content of Cr in a Ga solution. In the experiment, growth was performed at a tip temperature of 700°C with a cooling rate of 2.5°C/min. A massive Cr metal (99.999%) and a 100 mesh powdered Cr (99.9% up) were used as the dopants. In both cases, the donor concentration of the grown layer increases with increasing the content of the Cr added to the solution. These results might be taken to show that Cr atoms act as a shallow donor as first indicated by Andre *et al.* (13). However, as the Ga solution containing 1.0 m/o powdered Cr, resulting in the n-type layers with donor concentration of 10^{18} cm^{-3}, was heated at 900°C under a Pd-diffused H_2 gas flow, the resistivity of the grown layer increased with heating times. This is shown in Fig. 8. Figure 8 seems to indicate that the layer with the higher donor concentration is caused by contamination of oxygen in the dopant. It is well known that oxygen acts as a shallow donor in a liquid phase epitaxially grown GaAs (24). It is possible that the epitaxial layer with the higher resistivity was caused by evaporation of oxides due to heating the solution. The difference in the donor concentration in the two layers, one doped with a massive Cr metal and the other doped with a 100 mesh powdered Cr, is supposed to be due to the difference in the content of oxygen in the two dopants.

When the epitaxial growth was performed at a tip temperature of 800°C, the grown layer was still semi-insulating even if a solution doped with a massive Cr metal was used with no heating before epitaxial growth. This is due to the difference in the distribution coefficients of oxygen at 800° and 700°C. The distribution coefficient of oxygen is higher in the lower temperatures (17).

After all, it is possible that the origin of producing n-type layers with higher donor concentration by Cr doping is due to oxidation of Cr. These results indicate that it is necessary to heat the solution containing Cr under a purified H_2 gas flow at the higher temperature for producing the semi-insulating layers.

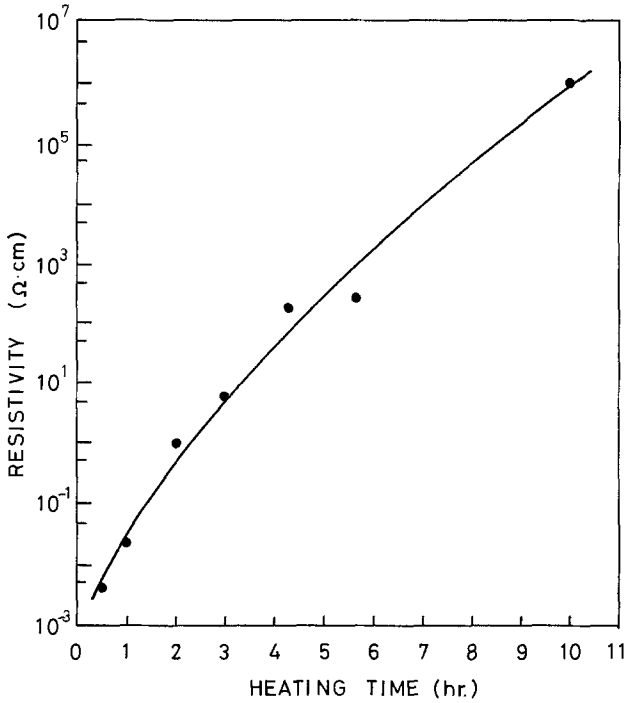

Fig. 8. Heating effect of a Ga solution containing 1.0 m/o powdered Cr. The solution was heated at 900°C under a Pd-diffused H_2 gas flow.

Electrical Properties of Semi-insulating GaAs Crystals

I-V curves.—Figure 9 shows *I-V* curves at room temperature for the epitaxial semi-insulating GaAs with various thicknesses (a-c) and for a bulk semi-insulating GaAs (d). The samples were n^+-i-n^+ shaped in structure. The epitaxial semi-insulating layer (10-40 μm thick) and the n^+ layers (Te doped,

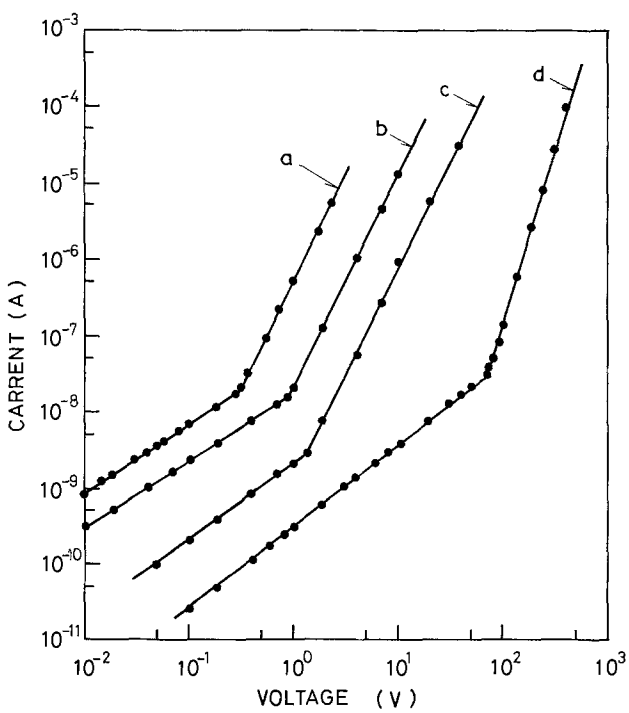

Fig. 9. Current-voltage curves for the epitaxial semi-insulating GaAs crystals with various thicknesses. The samples were n^+-i-n^+ shaped structures. (a-c) and (d) are for the epitaxial and a bulk crystals, respectively. The thicknesses of the samples are 13 μm for (a), 28 μm for (b), 40 μm for (c), and 240 μm for (d).

1-2 μm thick) with donor concentration of 7.0×10^{17} cm^{-3} were successively grown on the Si-doped n^+-substrate ($n \simeq 1.0 \times 10^{18}$ cm^{-3}) by a sliding technique. For a bulk semi-insulating GaAs, the n^+-layers were grown on both faces. Ohmic contacts to the n^+-layers were formed by alloying the evaporated Au-12 weight percent (w/o) Ge eutectic alloy at 450°C for 1 min under a flowing H_2 gas. The mesa-shaped structure was formed by etching with $3H_2SO_4$-$1H_2O_2$-$1H_2O$ through the Au-12 w/o Ge metal.

I-V curves obey Ohm's law at low voltages in all samples. Above a threshold voltage, *I* increases with $V^{3\sim4}$ for the epitaxial semi-insulating layers and with $V^{4\sim5}$ for a bulk semi-insulating GaAs, similar to what has been observed in a Cr-doped semi-insulating GaAs with electron injecting contacts (25). The resistivities of the samples calculated in the ohmic region were $1.0 \sim 9.0 \times 10^8$ $\Omega \cdot$ cm for the epitaxial semi-insulating layers and 1.1×10^9 $\Omega \cdot$ cm for a bulk crystal. The resistivities obtained from *I-V* curves are 1 ~ 2 orders higher than those obtained from the measurement of resistances in rectangular shaped samples. The origin of the difference in resistivity is unclear.

The threshold voltage, at which the *I-V* curve does change from linear dependence to $V^{3\sim4}$ dependence, varies with the square of the sample thickness. This is shown in Fig. 10. This behavior was similar to that observed in the undoped and the oxygen-doped bulk semi-insulating GaAs with electron injecting contacts (25-26) and was identical to the theory predicted by Lampert *et al.* (27, 28).

Heat-treatment.—Figure 11 shows the effect of heat-treatment on the epitaxial semi-insulating GaAs (a, b) grown under the different background donor concentrations, in which it is compared to that on a bulk semi-insulating GaAs (c). Heat-treatment was performed at the desired temperatures for 30 min under a purified H_2 gas flow. Samples a and b were grown under the background donor concentrations of 1.0×10^{13} cm^{-3} and 5.0×10^{14} cm^{-3}, respectively.

Figure 11 indicates that the change in the resistivity in the layer grown under the lower C_B has occurred at a temperature lower than that in the layer grown under the higher C_B. For sample a which was grown under the higher C_B, the resistivity began to decrease at 500°C and finally reduced to the value of the undoped layer followed by a gradual increase above 600°C.

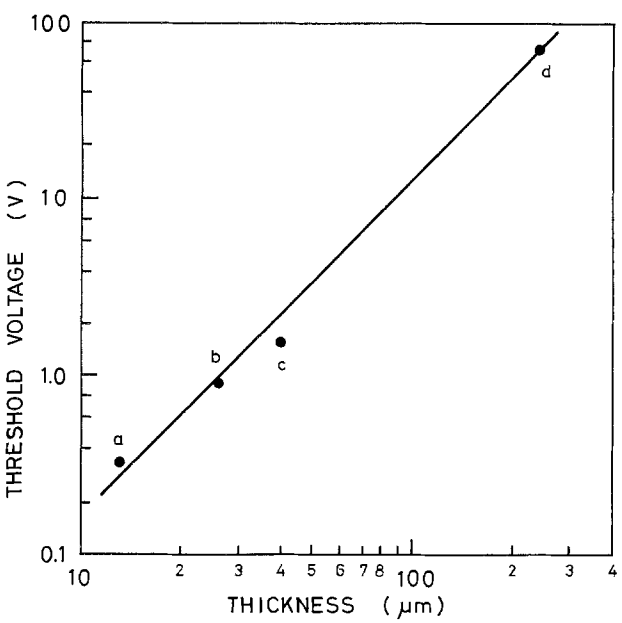

Fig. 10. Threshold voltages *vs.* thickness of the semi-insulating GaAs crystal with electron injecting contacts.

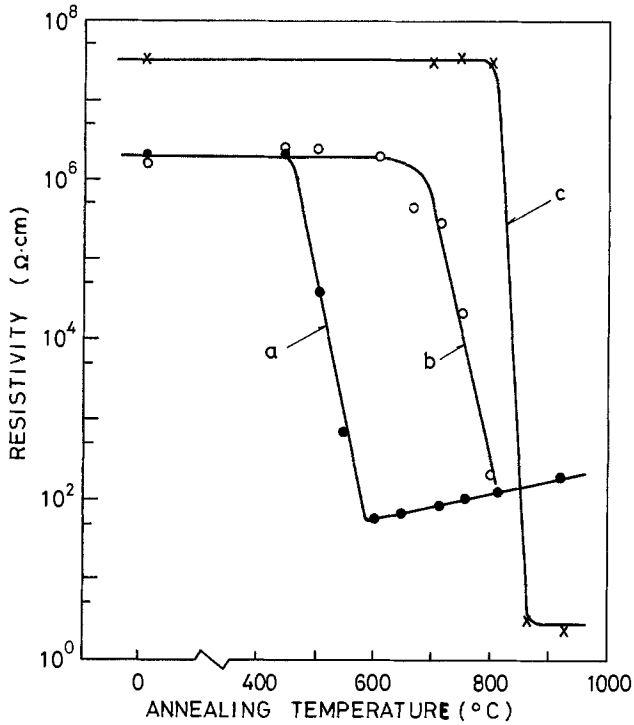

Fig. 11. The effect of heat-treatment on the epitaxial semi-insulating GaAs crystals grown under different background donor concentrations Samples a and b were grown under the background donor concentrations of 1.0×10^{13} cm^{-3} and 5.0×10^{14} cm^{-3}, respectively. Sample c is a bulk semi-insulating crystal. Heat-treatment was performed for 30 min under an H_2 gas flow.

While for sample b the resistivity began to decrease at 650°-700°C, which was higher than that in sample a. On the other hand, in a Cr-doped bulk semi-insulating GaAs (c), no change in the resistivity was observed at less than the heating temperature of 800°C, which was higher than that in the epitaxial semi-insulating samples.

Temperature dependence of the resistivity.—The resistivity in the rectangular shaped epitaxial semi-insulating GaAs was measured at various temperatures and the result is shown in Fig. 12. The resistivity increased exponentially with the reciprocal temperature in all samples with higher room temperature resistivities. The dependence of the activation energy on the room temperature resistivity has already been observed in GaAs (30) and GaP (31) and is well known as Meyer's rule. Although Meyer's rule has not been satisfactorily explained so far, the most likely explanation is thought to be a series of deep levels produced by several impurities (31). The highest activation energy obtained from Fig. 12 is 0.71 eV, which is nearly equal to the activation energy of Cr level of 0.74 eV (32).

Summary and Conclusions

Semi-insulating GaAs layers with room temperature resistivity in the order of 10^7 $\Omega \cdot$ cm have been obtained by liquid phase epitaxy by Cr doping. Preparation and properties of the epitaxial semi-insulating GaAs have been described.

The resistivity of the epitaxial layer increases with increasing the content of Cr added to a solution. Inclusions were present in the layers grown from the solution containing more than 2.0 m/o Cr. The epitaxial semi-insulating layers with higher quality were obtained by reducing the background donor concentration.

Higher cooling rates give layers with higher resistivities, and epitaxial growth under controlled arsenic pressure also gives an epitaxial layer with

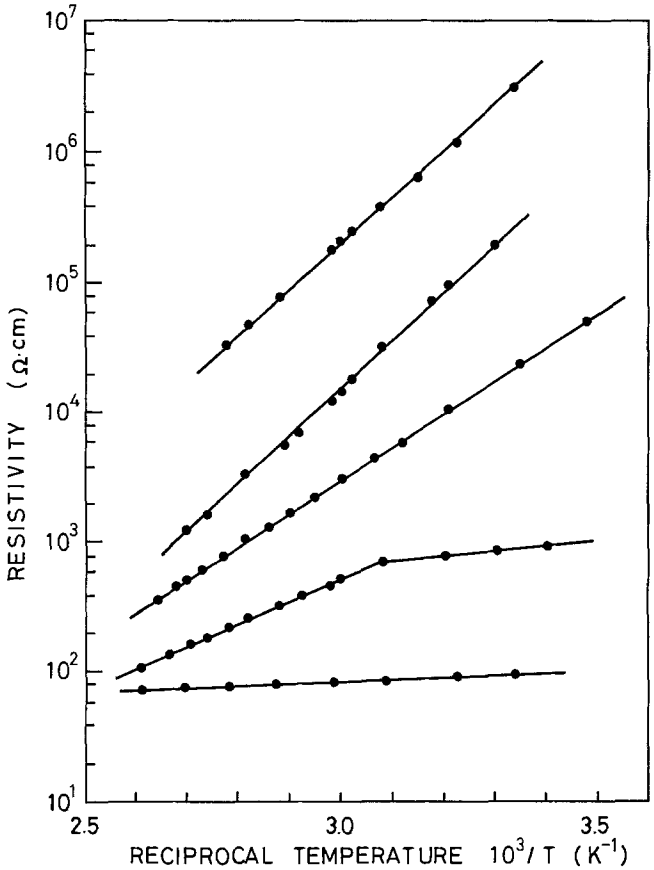

Fig. 12. Temperature dependence of resistivity in the epitaxial semi-insulating GaAs with different room temperature resistivity.

higher resistivity. It is possible that Cr atoms occupy Ga sites and/or form complexes with Ga vacancies.

It is possible that the origin of producing n-type layers with higher donor concentration by Cr doping is due to oxidation of Cr as a dopant.

Current-voltage curves obey Ohm's law at low voltages and above a threshold voltage, current increases in proportion to $V^{3\sim4}$. The threshold voltage varies with the square root of the thickness of the semi-insulating layer.

A decrease in resistivity of the sample due to heat-treatment was observed at lower temperature in the samples grown under lower background donor concentration.

The activation energy obtained from the temperature dependence of the resistivity is higher in the samples with higher room temperature resistivity. The highest one is 0.71 eV.

Oxygen Ions in Individual Nitrate Melts

K. E. Johnson* and P. S. Zacharias

Department of Chemistry, University of Regina, Regina, Saskatchewan, Canada S4S 0A2

ABSTRACT

Sodium nitrate and potassium nitrate melts were electrolytically reduced using a Ag^+/Ag reference electrode and a platinum working electrode in platinum cells. Cyclic voltammograms recorded for the nitrate melts are presented and discussed. Electrolysis was carried out for the individual melts and the products identified chemically. The experimental data indicate the preferential formation of peroxide in $NaNO_3$ and superoxide in KNO_3 besides the primary reduction product, nitrite. Preliminary results on the colored platinum complex formed in the nitrate melts during electrolysis are also presented.

The electroreduction of nitrate ions in fused alkali nitrates has been the subject of numerous investigations by different workers during the past several years. The primary products of the electroreduction of the nitrate have been correctly identified (1, 2) as nitrite and oxide according to reaction [1] though other processes involving the production of nitrogen

$$NO_3^- + 2e^- \rightarrow NO_2^- + O^{2-} \qquad [1]$$

and different oxides of nitrogen were also thought to be occurring concomitantly (2, 3). The oxide species produced in the nitrate melt was regarded to be nonreactive under the experimental conditions on the basis of a simple Lux-Flood formalism. In contrast to this assumption, recent studies on oxide chemistry in molten $NaNO_3$-KNO_3 eutectic by Zambonin and Jordan (4) indicated that the oxide species is unstable in the melt conditions and is converted into peroxide and superoxide ions. These investigations were carried out using a rotating platinum electrode in platinum cells to avoid any side reactions involving silica and the moisture level was kept below 10^{-6}M. Further studies in pure $NaNO_3$-KNO_3 eutectic using voltammetric techniques (5) showed the following processes to be prevalent in the electrochemical reduction of nitrate at a platinum electrode

$$NO_3^- + 2e^- \rightleftharpoons NO_2^- + O^{2-}$$

followed by

$$O^{2-} + NO_3^- \rightleftharpoons NO_2^- + O_2^{2-} \text{ (fast)} \qquad [2]$$

$$O_2^{2-} + 2NO_3^- \rightleftharpoons 2NO_2^- + 2O_2^- \text{ (slow)} \qquad [3]$$

The presence of superoxide in $NaNO_3$-KNO_3 eutectic has been detected by EPR signals also (6).

The oxygen electrode in molten $NaNO_3$-KNO_3 eutectic at platinum or gold surfaces has been described as a superoxide electrode as in [4]

$$O_2 + e^- \rightleftharpoons O_2^- \qquad [4]$$

assuming greater stability for the superoxide (7). However, Fredericks and co-workers (8) state that the potentiometric results obtained at platinized electrodes are in agreement with reaction [5]

$$\tfrac{1}{2}\, O_2 + 2e^- \rightleftharpoons O^{2-} \qquad [5]$$

This implies a greater stability for the oxide ion in molten nitrates.

Bartlett and Johnson studied the reduction of $NaNO_3$ and KNO_3 individually and reported the formation of differently colored catholytes during electrolysis depending on the cathodes used (3). With a platinum cathode at controlled potential they observed the formation of green catholytes which were thought to be due to a platinum nitrosyl complex. If peroxide and/or superoxide are produced in the electroreduction of the nitrates as observed recently, they may greatly influence the composition of the platinum complex produced.

The $NaNO_3$-KNO_3 mixture, which was the solvent for most of the experiments performed, is a suitable melt for the peroxide and superoxide species produced in the reduction of the nitrate. This is because the sodium will favor the presence of peroxide while potassium favors the superoxide species (9). We have carried out experiments separately in $NaNO_3$ and KNO_3 to find out the major reduction species in these systems. In $NaNO_3$, peroxide should be the major species along with nitrite while in KNO_3 the superoxide should be the predominant species apart from the nitrite if the reactions [1], [2], and [3] are the major reduction processes involved.

In the investigations of Zambonin (4-7), except for the instrumental identification of the reduction products, no chemical analysis on the different species is reported. In the subsequent sections of this paper we discuss the results obtained from cyclic voltammetry, electrolysis, and the chemical analysis of the reduction products of $NaNO_3$ and KNO_3. Results from the preliminary investigations of the colored platinum complexes produced during the massive electrolysis of the nitrate melts are also included.

Experimental

AR grade $NaNO_3$ and KNO_3 were dried initially at 120°C for 24 hr in a vacuum oven and by bubbling pure dry nitrogen through the melts. The removal of moisture was monitored by the characteristic cathodic water wave by cyclic voltammetry (10). Experiments were performed at 335°C for $NaNO_3$ and at 345°C for KNO_3.

A platinum crucible was the container for the nitrate melts. Two Pyrex tubes (fritted disk, fine grade) lined with gold foil were dipped into the molten salt and the melt was allowed to diffuse through the frits. The reference electrode (0.06M Ag^+/Ag) was coulometrically generated in one of the frits from pure silver wire using a Sargent coulometer Model IV. The working electrode for the cyclic voltammetry was a platinum microelectrode of area 2×10^{-3} cm^2 obtained by fusing platinum wire (thickness 0.5 mm) into a Pyrex glass tube. For the electrolysis, the working electrode was a platinum macroelectrode obtained by welding a piece of platinum sheet (thickness 0.1 mm) to platinum wire. This was placed in the second fritted disk. All the voltammetric and electrolysis experiments were done with a Princeton Applied Research electrochemistry system Model 170. A nitrogen atmosphere was maintained throughout the experiments.

The chemical analyses for nitrite, peroxide, and superoxide were done by the following procedure (11). Nitrite was estimated spectrophotometrically: The

sample was treated with EDTA, sulfanilic acid, naphthylamine hydrochloride, and sodium acetate buffer to give a reddish purple color in the pH range 2-2.5. By measuring the absorbance of this solution at 520 nm, the amount of nitrite was obtained using a standard curve procedure. The amount of superoxide was determined by measuring the amount of oxygen liberated using a Warburg apparatus (12): a known quantity of the electrolysis product was treated with required quantities of glacial acetic acid and diethyl phthalate solution to convert the superoxide to O_2 and H_2O_2 and from the volume of oxygen measured, the amount of superoxide in the mixture was found. The total amount of peroxide and superoxide was determined by mixing a known amount of the sample with required amounts of concentrated hydrochloric acid, boric acid, and urea at ~ 4°C and titrating with standard $KMnO_4$ solution (13). The oxide content in the melt was determined by dissolving the melt in a known volume of distilled water and titrating with dilute HNO_3 making due allowance for oxide derived from O_2^{2-} and O_2^-.

Results

A cyclic voltammogram of $NaNO_3$ recorded using a platinum microelectrode and Ag^+/Ag reference electrode is presented in Fig. 1. Electrolysis was done in a separate compartment within the melt using platinum foil cathodes. The massive electrolysis produced a dark blue compound. Analytical results of the products are given in Tables I and II.

Figure 2 represents the typical cyclic voltammogram for KNO_3. Massive electrolysis using a platinum foil cathode produced a dark blue product. Analytical results for the electrolysis products are included in Tables I and II.

Discussion

Figure 1 represents the cyclic voltammogram of $NaNO_3$. It consists of a cathodic peak at −1.6V and an anodic peak at −1.26V. The cathodic peak is due to the reduction of the nitrate to nitrite and oxide and the anodic peak to the oxidation of the insoluble oxide formed at the platinum electrode

to superoxide (3, 5). In $NaNO_3$-KNO_3 melt the oxide formed is further converted to peroxide and superoxide. Superoxide gives rise to three additional peaks (*vide infra*) in the cyclic voltammogram (5). The absence of any other peak, other than the two peaks already mentioned for $NaNO_3$, excludes the possibility of any immediate superoxide formation in this melt. The formation of peroxide cannot be monitored by the voltammogram since there is no characteristic peak associated with it. Chemical analysis of the electrolysis products (Tables I and II) shows the presence of peroxide while superoxide is practically absent. It is known that of the two species, sodium easily forms the peroxide while superoxide is formed only under more drastic conditions. Hence it is reasonable to assume that in pure $NaNO_3$ melt, under the present experimental conditions, the oxide is converted to peroxide with greater ease and superoxide is not produced in any detectable quantity.

In another set of experiments, known amounts of Na_2O_2 were added to $NaNO_3$ melt while recording the cyclic voltammogram. This added peroxide did not alter the profile of the current-voltage curve.

The cyclic voltammogram of KNO_3 is presented in Fig. 2: The waves are not well defined. It is characterized by anodic peaks at −0.66, −0.95, and −1.55V and cathodic peaks at −0.8 and −1.3V. The cathodic peak at −1.6V and the anodic peak at −1.26V, observed for $NaNO_3$, are absent in this case. It is well established that the reduction of nitrate results in the formation of a cathodic peak only if sodium (or lithium) ions are present; if potassium is the solvent cation the current rises without the formation of a peak (2, 3). This has been explained by postulating a very large difference in solubility (3) between K_2O and Na_2O (or Li_2O) and, more recently, to the fast production of superoxide which is a much more soluble species than oxide

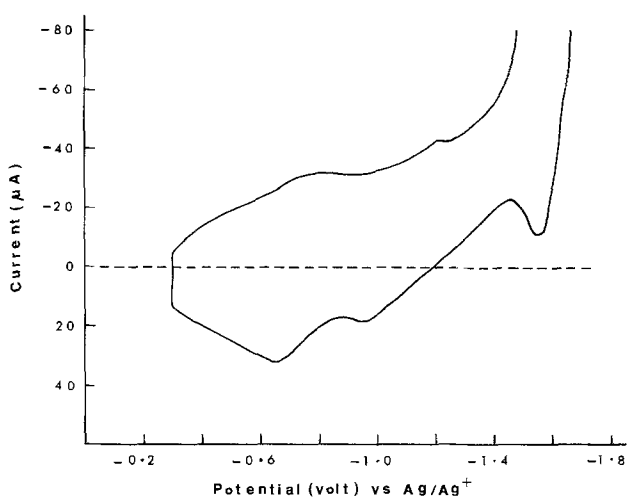

Fig. 2. Cyclic voltammogram of molten KNO_3 at 345°C. Sweep rate 50 mV sec^{-1}.

in nitrate melt (14). The presence of superoxide in $NaNO_3$-KNO_3 mixture is characterized (5) by an anodic peak at −0.69V (oxidation of superoxide to molecular oxygen) and a cathodic peak at −0.8V (regeneration of superoxide). These processes can be represented as in Eq. [6]

$$O_2^- \rightleftharpoons O_2 + e^- \quad [6]$$

Another cathodic peak appears at −1.38V corresponding to the reduction of superoxide to peroxide. By comparing the KNO_3 peaks with those of $NaNO_3$-KNO_3 mixture, it can be said that the anodic peak at −0.66V represents the oxidation of superoxide to oxygen and the subsequent regeneration of superoxide from oxygen is shown by the cathodic peak at −0.8V. The cathodic peak at −1.3V corresponds to the reduction of superoxide to peroxide. Therefore from the current-voltage curve one can infer that superoxide is formed in KNO_3 melt. Massive electrolysis performed in the melt produced a very small quantity of peroxide in addition to superoxide (Tables I and II). Since potassium has a greater tendency to form the superoxide, it is reasonable to assume that in KNO_3 melt, superoxide is the favored species. Addition of known amounts of KO_2 to KNO_3 melt, while recording the cyclic voltammogram, gave a well-defined and stronger cathodic peak at −1.3V as expected. The small peak at −0.95V may arise from the oxidation of soluble K_2O.

The results of the chemical analysis of the products of short term ($\leq$ 1 hr) electrolysis are given in Table I. The major reduction product is nitrite in both $NaNO_3$ and KNO_3. Of the other possible species peroxide forms the major product in $NaNO_3$ while superoxide is the main species in KNO_3. Possible reaction paths for the reduction of $NaNO_3$ and KNO_3 melts are expressed by reactions [1] to [3]. Reaction [1] produces equal amounts of nitrite and oxide, reaction [2] results in equal amounts of nitrite and peroxide, while reaction [3] ends with equal amounts of nitrite and superoxide. However, in the over-all reduction process, oxide is partially consumed in reaction [2] for the production of peroxide which in turn is partially converted to superoxide in reaction [3]. The total sum of the species, oxide, peroxide, and superoxide remaining at the end of the process should equal the amount of nitrite present in the nitrate melts. The experimental results closely follow this pattern. In $NaNO_3$ melt only a small portion of the peroxide is converted to superoxide while in KNO_3 most of the peroxide is converted to superoxide leaving only a small amount of peroxide in this melt. This conversion is controlled by the stability of these species in the two nitrate melts. This observation is in agreement with the results obtained from the cyclic voltammograms (*vide supra*).

Denoting the equilibrium constants of reactions [2] and [3] by K_2 and K_3, thus

$$K_2 = \frac{[O_2^{2-}]\,[NO_2^-]}{[O^{2-}]\,[NO_3^-]}, \quad K_3 = \frac{[O_2^-]^2\,[NO_2^-]^2}{[O_2^{2-}]\,[NO_3^-]^2}$$

we calculate approximate values for the two systems as in Table III. K_3 in the individual melts is much larger than in the $NaNO_3$-KNO_3 eutectic (4) ($\sim 10^{-11}$) as expected.

The results of the chemical analysis of the products of massive electrolysis are given in Table II. In $NaNO_3$ $\sim$ 2% peroxide is formed with no detectable amount of superoxide while in KNO_3 $\sim$ 2% of superoxide is present with very little peroxide. In both these nitrate melts a blue-colored platinum complex is formed during electrolysis. It is reported that both peroxide and superoxide oxidize platinum metal to the +4 oxidation state (15) while they get reduced to oxide. Since in the electrolysis peroxide and superoxide are produced in $NaNO_3$ and KNO_3, respectively, with platinum as the cathode, a substantial amount of these generated species will be lost in the process of oxidizing the platinum electrode, which may very well account for the observed low concentration of these species. The analytical results clearly indicate that in $NaNO_3$ there is a preferential formation of peroxide while in KNO_3 the superoxide predominates. Since both $NaNO_3$ and KNO_3 produced a blue-colored platinum complex, we have carried out some preliminary investigations to identify them. These compounds are unstable and become colorless in air. We could also generate the same colored species by heating a mixture of nitrite, peroxide, or superoxide and platinum metal or a platinum salt. Since peroxide or superoxide is essential for the formation of this species, platinum presumably is oxidized to the +4 oxidation state (*vide supra*). Also the peroxo species are structurally involved in the formation of this blue complex since heating K_2PtCl_6 and nitrite alone could not produce it. Electrolysis of $NaNO_3$ or KNO_3 produces nitrite, peroxide, or superoxide and these products with the platinum electrode produce the blue-colored platinum complex. Based on the preliminary data available we tentatively assign a dimeric structure to the complex with a peroxide or superoxide bridging unit similar to the structure of decammine-μ-peroxo dicobalt cation (16), with platinum in the +4 oxidation state and nitrite groups occupying the coordination sites around platinum. Further work on this is in progress.

β Fe_2O_3: Preparation of Thin Films by Chemical Vapor Deposition from Organometallic Chelates and Their Characterization

Lina Ben-Dor and Eli Fischbein

Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

and Israel Felner and Zvi Kalman

Racah Institute of Physics, The Hebrew University of Jerusalem, Jerusalem, Israel

ABSTRACT

Thin films of a new iron oxide phase, β-Fe_2O_3, were prepared by chemical vapor deposition (CVD) from tris(trifluoroacetylacetonato) iron (III) at 300°C in the presence of oxygen onto a variety of substrates. The films were characterized by x-ray diffraction analysis, scanning electron microscopy, and Mössbauer spectroscopy. For the latter measurements the films were prepared from enriched $^{57}Fe_2O_3$. The ultraviolet, visible, and infrared spectra of the films were also recorded. The iron (III) oxide phase prepared was bcc having the bixbyite structure, Ia3 space group and the lattice constant a_o = 9.393Å. There are 16 formula molecules to the unit cell and the two iron atoms occupy two nonequivalent distorted octahedral lattice sites: $\bar{3}$(8b); 2(24d).

During the last ten years great emphasis has been attached to the preparation of electronic and magnetic materials such as III-V and II-VI semiconductors and oxides by chemical vapor deposition (CVD) using organometallic compounds and chelates, such as trimethyl and triethyl metal compounds (1-7), alkoxides (8-12), metal carbonyls (13-14), and β-diketonates. Among the β-diketonates, the most frequently used are acetylacetonates (15-16), trifluoroacetylacetonates (17), and dipivaloylmethane (18).

These compounds are being used owing to the following advantages: relative high vapor pressure, stability in a definite temperature range, resistance to hydrolysis, and availability and/or ease of preparation and handling. Since these compounds decompose in the appropriate atmospheres at relatively low temperatures, the products obtained contain less defects and stresses and afford the possibility of using temperature sensitive substrates, and high density of coverage is obtained.

The study of Fe_2O_3 by CVD undertaken here was the first step (16) in a project concerned with the study of binary and ternary magnetic oxide films. A large amount of interest is centered around high temperature CVD iron oxide films as magnetic material (19, 20) from starting material of iron chlorides. Deposition of iron oxide films from iron pentacarbonyl was carried out by both MacChesney *et al.* (13) and Gallagher *et al.* (14). Their aim was the study of the films for semitransparent masking. The as-grown films were usually amorphous and after annealing the α-Fe_2O_3 phase was obtained. The films also contained some Fe^{2+} (based on Mössbauer data) and CO and CO_2 as impurity (infrared spectrum). Other films prepared by the sputtering technique were studied for photomask applications by a group in Bell Laboratories (21, 22) and a detailed review of the properties of such iron oxide films was presented (23). Low temperature CVD iron oxide has been obtained also by exposing a substrate to an aerosol of the chelate in an organic solvent (24). There is no mention of the phase obtained and the authors encounter difficulties in the adhesion of the film to the substrate, the control of the size of the aerosol droplets, and the thickness of the films. A report of Fe_2O_3 prepared by CVD from the acetylacetonate discusses the optical qualities of the oxide layers without mentioning experimental or structural details (25).

Recently, ferrocene in an oxidizing atmosphere was used by both Gibart *et al.* (26) and by us as a starting material. Thompson (27) used poly(vinylferrocene) both at 200W, 4 MHz of oxygen plasma, or thermally at 380°C to obtain Fe_2O_3 films. The author points out the advantages and disadvantages of the procedure. In the present work films of a new phase of iron (III) oxide were prepared by low temperature CVD using the trifluoroacetylacetonate. The films were characterized by a wide variety of physical methods.

Key words: chemical vapor deposition, β-Fe_2O_3 (β-iron oxide), bixbyite structure, organometallic compounds, thin films.

Experimental

Preparation.—Thin films of iron (III) oxide were prepared from tris(trifluoroacetylacetonato) iron (III)-$Fe(F_3CCOCHCOCH_3)_3$ (Pierce Chemicals) by chemical vapor deposition in presence of both dry and wet oxygen gas. The system (Fig. 1) used is a conventional one composed of the evaporator kept at 180°C and the reactor kept at 300°C. The evaporator is U-shaped and the reactor is an inverted bell jar on a rotating hot plate. This plate was mounted on a laboratory jack for easy loading and unloading of the substrates. The system is made of Pyrex glass, and Tygon tubing is used for connections. Argon gas is used as the carrier gas and both its flow and that of oxygen is monitored by rotameters. In all cases the flow of the oxygen was ten times that of the carrier gas. The interval between the source and the bell jar was heated to 220°C by means of a heating tape. The temperature at various points was monitored via thermocouples by appropriate controllers and a special heavy-duty thermocouple was used on the rotating hot plate. The substrates were arranged concentrically on the hot plate. The following materials were used as substrates: microscope-cover soda glass, fused silica, potassium bromide and calcium fluoride single crystal slices, and polycrystalline and single crystal alumina. The adhesion of film to all the substrates was very good as was proved by the "Scotch-tape

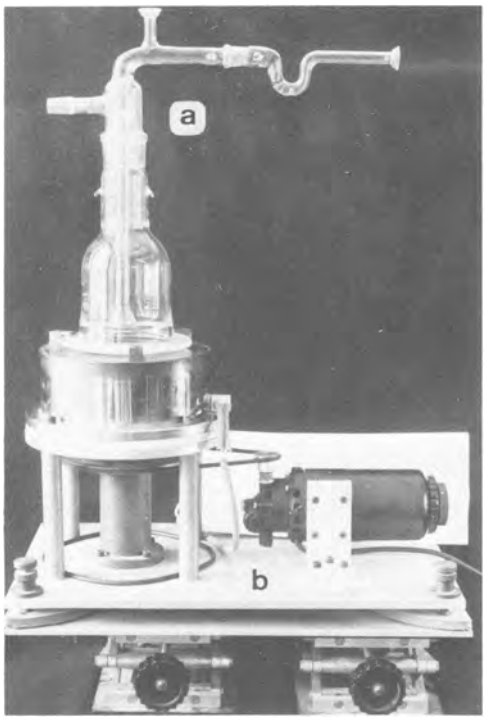

Fig. 1. The CVD system (a) glass bell jar assembly, (b) rotating heating plate on platform with motor.

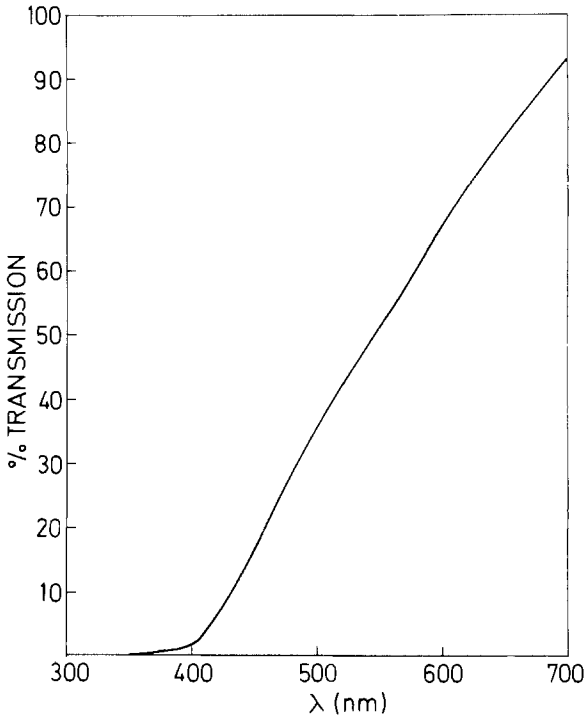

Fig. 2. Transmission of β-Fe_2O_3

test." The thickness of the films was in the range of 0.1 to a few microns. When the deposition rate is comparatively low (low flow of carrier gas) one can see the series of color interference patterns of the film. The color of the thicker films ranges from yellow to brownish red depending on thickness.

The isotopically enriched chelate for Mössbauer measurements is not available commercially and the following procedure was used for preparation, based on Fay and Piper (28):

From A.E.R.E., England, an amount of $^{57}Fe_2O_3$ was purchased, 25 mg of which were dissolved by heating in 30 ml of 6*N* HCl. Solid sodium acetate was added until the *p*H reached 1; then borax was added until *p*H = 3. This mixture of buffers was used in order to prevent formation of the very stable iron acetate; this change thus slightly optimizes the original procedure (28). Dropwise and with stirring an alcoholic 20% solution of the ligand (bidistilled) was introduced into the above buffered iron (III) aqueous solution and the chelate allowed to precipitate overnight. The red precipitate was proven by microanalysis to be tris(trifluoroacetylacetonato) iron (III) and the yield obtained was 85%.

Electronic and vibrational spectra.—The absorption spectra of the films deposited on sapphire or fused silica in the range 700-200 nm show no peaks; however, depending on thickness a broad absorption beginning at ~650 nm and rising steeply into the ultraviolet is observed. This behavior complies with the requirements of "see through" masks (21, 22) which are used in integrated circuit technology, viz.: (*i*) sufficient light absorption below 400 nm, *ca.* 1% transmission; (*ii*) sufficient transmission at the sodium D line (~600 nm) for viewing purposes, a representative film ~2000Å thick has *ca.* 60% transmission; (*iii*) easy and fast etching in 6M HCl due to the actual low temperature existing on the insulating substrate during the growth of the films (cf. Fig. 2 showing percentage transmission of a film).

On annealing the films in air to 500°C the β-phase slowly transforms to the α-phase until complete transformation is achieved, as seen from the distinct and characteristic u.v. and visible spectra and x-ray diffraction. The u.v. spectrum (Fig. 3) shows three charge-transfer bands (L → M) at 320, 260, and 205 nm; the visible spectrum showing d-d transitions, has already been published (16).

The infrared range is clean, showing 90-100% transmission in the range 20,000-400 cm^{-1}. Thus, the films, deposited in this case on KBr or CaF_2 slices, contain neither adsorbed water nor functional "OH" groups and no carbonyl, carbonate, nor residual organic materials.

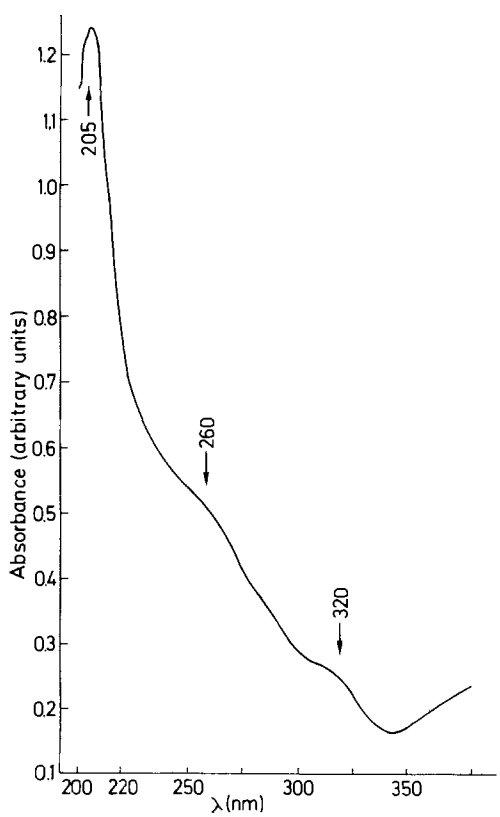

Fig. 3. Spectrum of α-Fe_2O_3 obtained from annealing the β-phase

X-ray diffraction data.—All of the films obtained were well crystallized even though low deposition temperature often gives amorphous films without discernible (x-ray) peaks (14). The line patterns of this iron oxide phase could not be found in the Powder Diffraction File (1975) but reference to an identical cubic phase appeared in Wyckoff's Crystal Structure (29a) and in Structure Reports (29b), Pearson's Handbook of Lattice Spacings (30), and finally in Landolt-Bornstein's Tables (31). This new phase was discovered by Bonnevie-Svendsen (22) who in 1956 had prepared it from the hydrolysis of $FeCl_3 \cdot 6H_2O$, naming it β-Fe_2O_3. This body-centered cubic oxide stemming from CaF_2 structure (Fig. 4) by taking the origin half-way up the edge of the unit cell, belongs to the Ia3 space group ($D5_3$). It is isostructural with α-Mn_2O_3 or bixbyite structure (also referred to as β-Mn_2O_3) and is identical to the C structure of the rare earth oxides (especially the heavier ones).

X-ray powder diffraction diagrams were carried out in three different modes.

Mode I.—Thin films adhering strongly to the substrate were photographed on an oscillation camera (30 mm radius, oscillation range 5°) with Co or Cr radiation, at glancing angles of ~5° to 10°, in order to increase the beam path length of the sample. Photographs so obtained are not sufficient for determination of precise cell dimensions (center of sample inaccurately defined) but can be used for identification of the phases in the sample.

Mode II.—In one case the film could be detached from the substrate by means of adhesive tape. The tape with the adhering film was photographed on a Guinier-De Wolff camera, using Co radiation. The photograph was of sufficiently good quality to give accurate cell dimensions. The sample contained also about 30% α-Fe_2O_3, whose lines were used as internal standard.

Mode III.—One sample (on a polycrystalline alumina substrate) was sufficiently thick to permit the determination of a number of reflected intensities by means of a diffractometer, employing Cr radiation. The patterns obtained showed lines of both the substrate and the film sample. Rather broad slits (1°) were employed as the sample lines were in any case broadened due to small particle size.

Patterns of all samples contained lines (sometimes in addition to those of α-Fe_2O_3) of the cubic body-centered material (32, 33) distinctly different from α-Fe_2O_3.

* Overlap with α-Fe_2O_3 line.
** Overlap with alumina line.

From the Guinier-De Wolff photographs (mode II) the cell edge was determined to be $a_0 = 9.393 \pm 0.03$, Table I, column 2. Visual inspection of intensities showed a close similarity to the pattern published for bixbyite (JCPDS cards 8-10) space group Ia3.

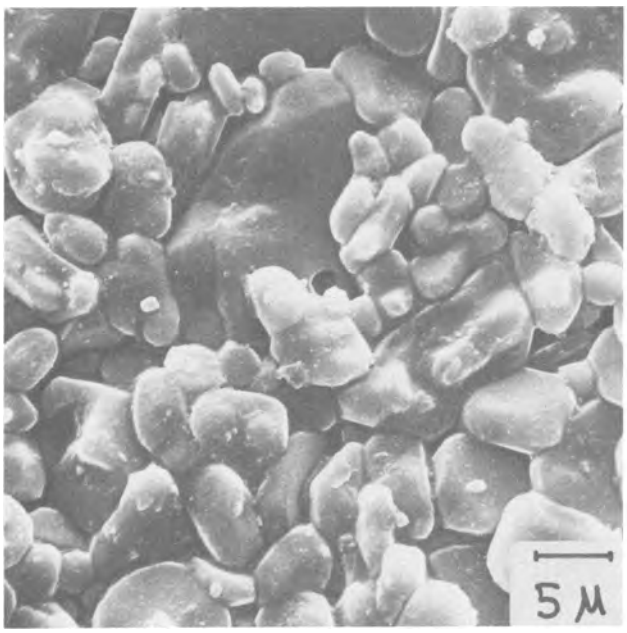
Intensities were obtained from a diffractometer trace (mode III), using CrKα radiation. Measured relative intensities relate to the F values by means of

$$I_{HKL} = K \frac{1 + \cos^2 2\theta}{\sin^2\theta \cos\theta} \cdot \frac{1 - \exp(-2\mu D/\sin\theta)}{2\mu} [F_{HKL}]^2 M_{HKL}$$

where K is a constant for all reflections, D is the sample thickness, μ linear absorption coefficient, and M_{HKL} multiplicity of the plane HKL. The value μD was determined by comparing the intensities of the lines of the substrate (polycrystalline alumina) appearing in the sample pattern, with those of the substrate alone. The value for μD so obtained was 0.08 indicating the sample thickness of ~2 μm. It is to be noted that the β-Fe_2O_3 lines were considerably broader than the alumina lines indicating a mean crystalline particle size of 500Å.

As the material is isostructural with bixbyite the atoms were assumed to be in analogous positions. Structure factors were calculated by the standard equation (neglecting temperature corrections) and best fit with measured intensities was obtained for the following parameter of the space group Ia3

Fe_I in (8b)	¼	¼	¼	
Fe_{II} in (24d)	u	0	¼	$u = -0.026$
O in (48e)	$x = 0.38$	$y = 0.16$	$z = 0.40$	



The estimated error for these parameters is 0.02 (for u it is 0.003).

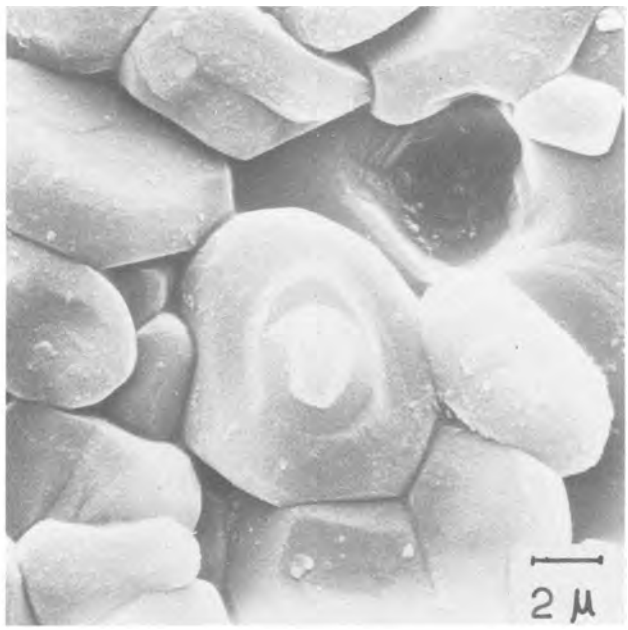


Table I shows the crystallographic data for β-Fe_2O_3. The density calculated from the x-ray data is 5.14 g cm^{-3}. After annealing the films in air to ~500°C, α-Fe_2O_3 is obtained as was proved by x-ray and electron diffraction (26) and absorption spectra.

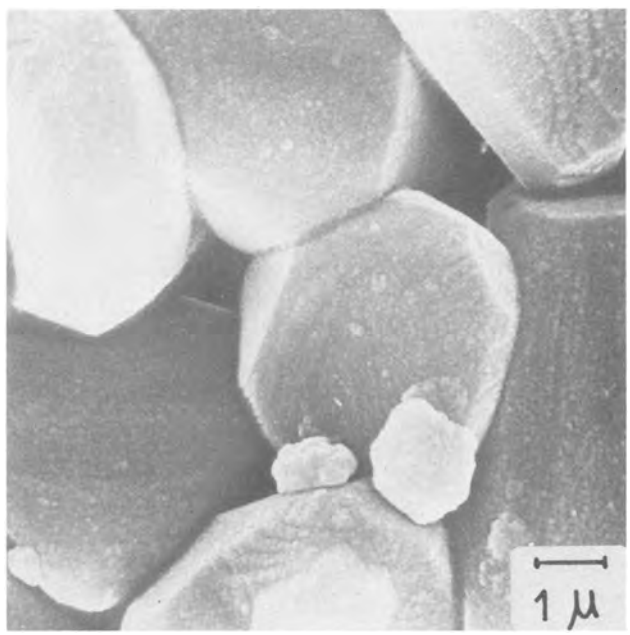
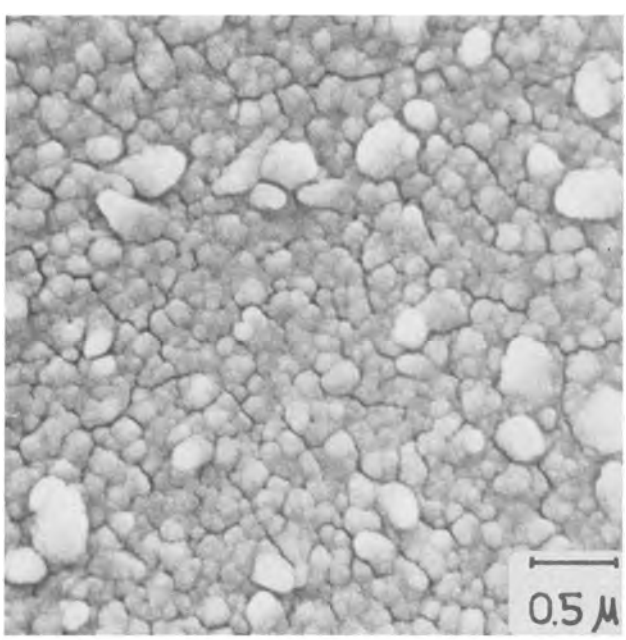
It should be noted that the films deposited under dry conditions were identical with those deposited in the presence of oxygen saturated with water at 20°C. Water does not change the morphology or structure of the films, although it does accelerate the rate of deposition.

Mössbauer data.—Mössbauer spectra[1] of the films prepared from enriched ^{57}Fe were measured in the tem-

[1] A detailed Mössbauer study will be published elsewhere.





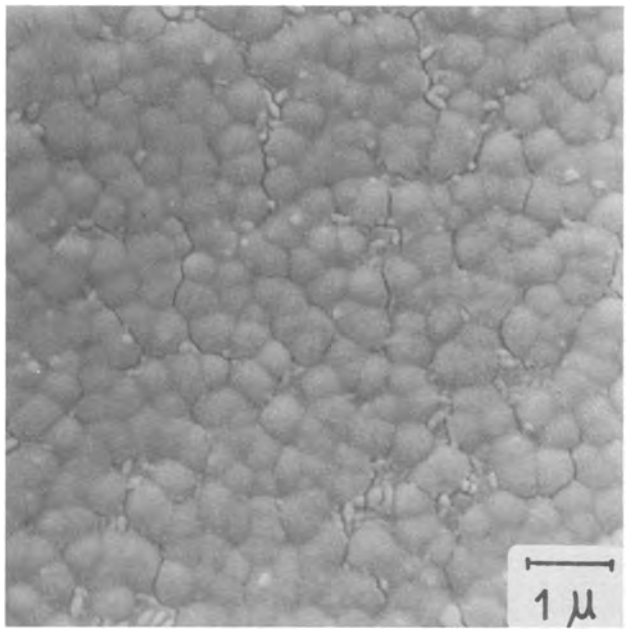


Fig. 5. Surface appearance of iron oxide film (a) as deposited at 300°C; (b) after 500° anneal showing faces of α-Fe_2O_3; (c) after 800° anneal showing well-developed grains.

perature range 4°-500°K, using a ^{57}Co in Cu source. There is no signal belonging to Fe^{2+}, as has been observed by Gallagher *et al.* (14), the isomer shift being typical of trivalent iron. The spectra at temperatures above 106°K are composed of two electric quadrupole hyperfine spectra with relative intensities of 3:1. Below 106°K magnetic hyperfine splittings are observed, which are composed of two subspectra with relative intensities of 3:1. The intense subspectrum corresponds to Fe^{3+} ions in the d sites and the weak subspectrum corresponds to Fe^{3+} in the b sites. This is the only oxide of iron which is not ordered magnetically at room temperature.

Scanning electron microscopy (SEM).—Micrographs were taken on the Stereoscan S4 of Cambridge Instruments, and simultaneously x-ray elemental analysis using an energy dispersive system was used to analyze the films. The only element found within the limits of sensitivity of the instrument was iron (Fe). The films were coated with gold or conducting carbon before introducing the samples into the microscope. Figure 5a shows the film deposited on polycrystalline alumina at 300°C. The size of the average grain is ~5 μm. The hole in the central plate was probably formed by sintering intergrowth with adjacent crystallites. It is to be noted that the grains are irregular in shape, possibly grown from coalescence of several small crystallites. The phase obtained is β-Fe_2O_3. Figure 5b shows the same film after annealing at 500°C in air. The phase shown is mostly α-Fe_2O_3 as seen also from the geometrical crystal faces. Surface diffusion is the predominant transport mechanism for growth as can be seen from the growth of Frank terraces and spirals on top of the crystallites. The size of the cavity is ~3 μm and that of the largest grain is ~8 μm. The same phase further annealed is shown in Fig. 5c, at 800°C. Well-shaped hexagonal grains are seen and terraces on some of their faces, as well.

The β-phase deposited on amorphous fused silica or on single crystal alumina is greatly modified compared to the above-mentioned morphology (Fig. 6a, b). The grains are much smaller (0.4-0.25 μm), very irregular in shape, and densely arranged. We could not explain this difference except perhaps that the

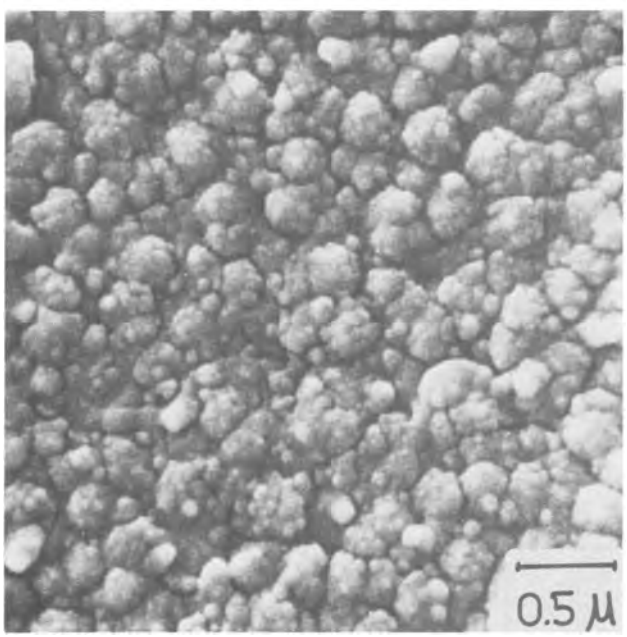

Fig. 6. Surface appearance of iron oxide film as deposited at 300°C: (a) on amorphous silica; (b) on single crystal alumina; (c) on KBr single crystal.

polycrystalline material affords better and more nucleation sites. Other oxide deposits on microscope-cover soda glass, show the same features as those described above. In contrast, sputtered films (22) and those prepared by CVD starting from iron pentacarbonyl (14, 22) have smaller grain size (~500Å). The larger grain size shown in the micrographs here, is probably due to the difference in experimental condition such as starting material and growth temperature, to which the deposits are so sensitive. Figure 6c shows the deposit on KBr; the grains are still small but twice as large as those in Fig. 6a, b. This difference might be due to the rather unsmooth surface of the slice which had not been polished mechanically or chemically before the deposit, contrary to the case in Fig. 6a, b. Figures 7a, b show the effect of 1 mW, red laser irradiation during growth on the morphology of the deposit upon fused silica. Even in the largest magnification obtained no distinct grains could be observed and it is suggested that an epitaxial growth or extremely small grains with preferred orientation were obtained, but further work must be carried out before final decision can be made.

Discussion

The existence of a new cubic stable phase of iron (III) oxide is in fact known since 1958 from Bonnevie-Svendsen's brief study whereby the material was identified as β-Fe_2O_3. For the last 15 years a group headed by Geller of Bell Laboratories has been studying (34-36) various aspects of binary and ternary oxides of the bixbyite structure, those being various systems of sesquioxides with Fe_2O_3. In a study of the solid solution Sc_2O_3-Fe_2O_3 (34) Vegard's law was shown up to the ratio of 1:1 and extrapolated to pure Fe_2O_3. The extrapolated lattice constant obtained was 9.401Å, and the authors declare that if such a material could have existed it would have the bixbyite structure. In a later study (35), solid solutions with Mn_2O_3 were studied (up to 1:1 ratio) and again the possible existence of "β-Fe_2O_3" was predicted despite the former 1958 communication concerning this new phase.

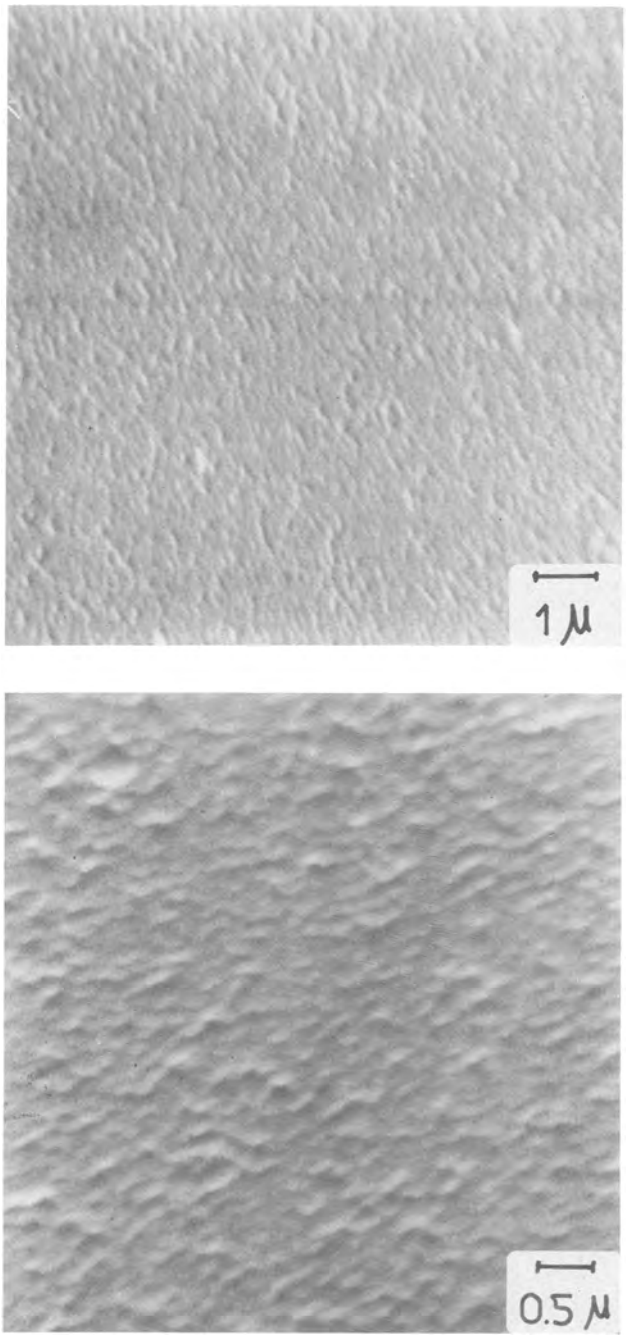

Fig. 7. Micrograph view of iron oxide film laser irradiated during growth: (a) magnification 8000×; (b) magnification 16,000×.

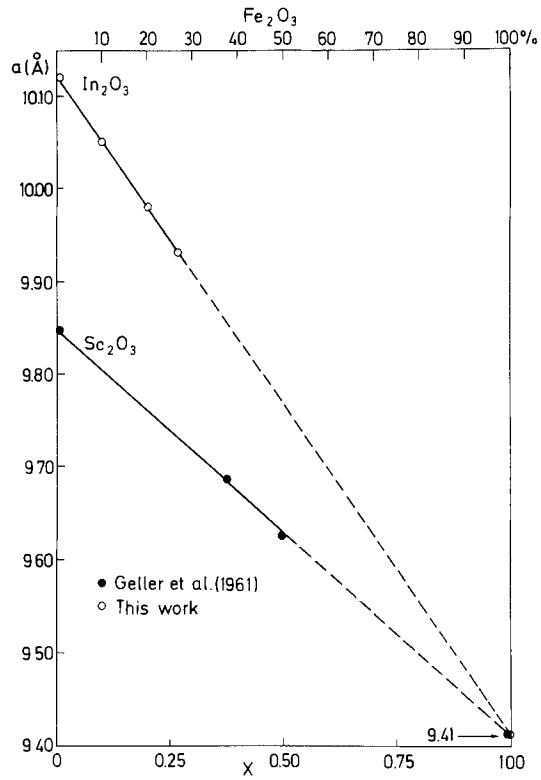

Fig. 8. Vegard's law extrapolation for solid solutions of In_2O_3 and Sc_2O_3 with Fe_2O_3.

Following the above reports, we prepared solid solutions of In_2O_3-Fe_2O_3 (Fig. 8). It can be seen that up to 27% Fe_2O_3 in In_2O_3 one obtains a pure C-structure; above that concentration the pure structure starts to be contaminated with the corundum phase of Fe_2O_3. The linear Vegard's law for both Sc_2O_3 and In_2O_3 with Fe_2O_3 on extrapolation cut at the same lattice constant for 100% Fe_2O_3 thus proving that if this iron phase "could be prepared" it would have a lattice constant identical or very similar to the experimental value 9.41Å. The only mention in the current literature of β-Fe_2O_3 is found in Okamoto's study on β-FeOOH (37) and that only *en passant*. Recently, two reports appeared concerning the preparation of β-FeOOH and "β"-Fe_2O_3 (38, 39). The latter compound was prepared from dehydration of the former, both having a tetragonal structure. The authors claim the use of the letter "β" to their new iron (III) oxide phase having also overlooked the original work of Bonnevie-Svendsen. Clearly, a new letter should be assigned to this tetragonal oxide.

As a result of the fact that the discovery of β-Fe_2O_3 had been overlooked by the scientific community several experimental results in various studies could not be properly understood. Thus, Gallagher *et al.* (14) discussing the preparation of iron oxide films from $Fe(CO)_5$ encounter some strange Mössbauer behavior. We believe that his results could be explained on the basis of formation of β-Fe_2O_3 (probably not well crystallized). Similarly, some other Mössbauer data published by a Russian team (40) could be perhaps due to the formation of β-Fe_2O_3.

The main challenge now is to prepare some bulk material of pure β-Fe_2O_3 in order to study the complete magnetic behavior. Further work is being carried out on various other oxides which are known to have or are predicted to have the bixbyite structure such as Ga_2O_3, Rh_2O_3, etc. and also on ternary systems such as ferrites and garnets.

Conclusions

In this study β-Fe_2O_3 films were deposited and characterized. It is the only known stable oxide of iron (III) which is paramagnetic at room temperature, the ordering temperature being below 106°K. Using the chelate with trifluoroacetylacetone, CVD proved to be a satisfactory and easy method of obtaining films of reproducible qualities. Owing to their structure and magnetic properties, these films might be useful for catalysis in organic synthesis (similarly to Er_2O_3), and based on their absorption qualities they might be useful as photomasks and optical filters.

Acknowledgments

The authors are deeply indebted to Professor B. T. Matthias from San Diego, California, and Professor I. Sunagawa, Sendai, Japan, for fruitful discussions and helpful suggestions. Thanks are due to the immense help invested by Professor S. Ofer and others of the group of Nuclear Physics: to I. Rubinstein for helping with film deposition and, lastly, to the SEM group, all of them, of The Hebrew University.

An Expression for Sheet Resistivity Using Boron Nitride Source

M. Crooke

and A. G. K. Lutsch

Rand Afrikaans University, Johannesburg 2000, Republic of South Africa

ABSTRACT

From experimental data on the use of oxidized boron nitride as a source of boron, computer-derived expressions are obtained which interrelate the deposition sheet resistivity ρ_S, deposition time t, and temperature T according to functions of the form $\rho_S = f(t, T)$; $t = f(\rho_S, T)$; and $T = f(\rho_S, t)$. The resulting expressions fit the experimental data to within the accepted reproducibility limits of the four-point probe and thus provide a useful method of estimating the values of these variables for purposes of processing or design.

Solid oxidized boron nitride, one of the newer sources of semiconductor dopant, has certain advantages over the older liquid and gaseous sources. These advantages include improved stability and reproducibility, which are such that it is possible to attempt to describe source behavior in mathematical terms. The purpose of this paper is to derive equations describing the interrelationships between the sheet resistivity ρ_S ($\Omega/\square$), time t (min), and temperature T (°C), which can be used for estimating the third variable when the other two are known.

* Key words: boron nitride, boron deposition, sheet resistivity.

Experimental

Grade M26 boron nitride disks (The Carborundum Company, Niagara Falls, New York) recommended (1)

for use in the temperature range 975°-1100°C, were precleaned, oxidized, and stabilized in accordance with the suggested procedure (1). The disks were stored in the mouth of the furnace tube when not in use (2).

The product material used throughout the exercise to evaluate ρ_s was precleaned, 30-33 mm diameter n^+ (antimony) substrates containing a n(phosphorus) epitaxial layer of thickness 18-28 μm and resistivity 4-6 Ω cm.

The sheet resistivity of deglazed samples was measured using an A. & M. Fell linear four-point probe with a probe spacing of 1.67 mm; a current source accurate to ±0.1% of the setting in the range of interest, containing a current-reversal facility to monitor contact resistance; and a high impedance digital voltmeter capable of resolving 0.01 mV.

Furnace temperatures were maintained flat to within ±0.5°C over a minimum length of 250 mm. The furnace ambient employed was 99.995% plus purity argon at a flow rate of 500 cm^3/min, in a 60 mm internal diameter quartz tube, as previous experimental work (2) had proved results to be more consistent when argon was used instead of nitrogen of the equivalent purity.

The experimental results given in Fig. 1 show the logarithm of the sheet resistivity plotted *vs.* deposition times varying between 10 and 60 min, in the 900°-1100°C temperature range, the curves being separated by temperature steps of 50°C.

In view of the close approximation to linearity exhibited in the curves of log ρ_s plotted (3) *vs.* $1/T$ or T (Fig. 2), and the plot of log ρ_s against $1/t$ (Fig. 3), obtained from data extracted from Fig. 1, it is possible to derive an expression relating ρ_s to t and T. The first plot provides $\ln \rho_s = A(T) + C$ for constant t, say $\ln \rho_s = A(T) + f_1(t) + c_1$; and the second $\ln \rho_s = B(1/t) + D$ for constant T, say $\ln \rho_s = B(1/t) + f_2(T) + c_2$. Combining both equations we get $\ln \rho_s = A(T) + B(1/t) + c = f(t, T)$. By manipulation, similar functions can be derived for t and T: $t = f(\rho_s, T)$ and $T = f(\rho_s, t)$.

When the coefficients are calculated manually, without rounding off, these expressions become: $\rho_s = \exp [10.84t^{-1} - (1.43 \times 10^{-2}T) + 17.178]$, $t = [10.84 (\ln \rho_s + 1.43 \times 10^{-2}T - 17.178)^{-1}]$, and $T = [(-69.93 \ln \rho_s) + (7.58 \times 10^2 t^{-1}) + 12.013 \times 10^2]$ (with ρ_s in $\Omega/\square$, t in min, and T in °C).

These results agree fairly well with those of Fig. 1 and confirmed the validity of a general expression of the form

$$\rho_s = \exp (Pt^{-1} + QT + R) \qquad [1]$$

Computer-derived equations were then sought for the information contained in Fig. 1 and several runs

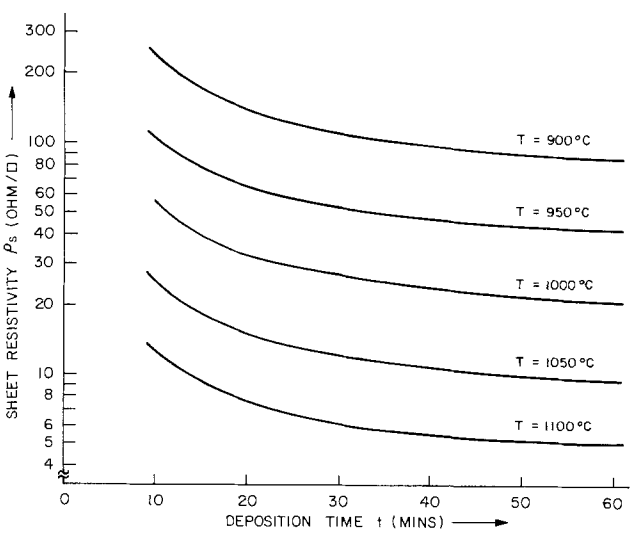

Fig. 1. Log sheet resistivity-deposition time plot using oxidized boron nitride disks as a source of boron.

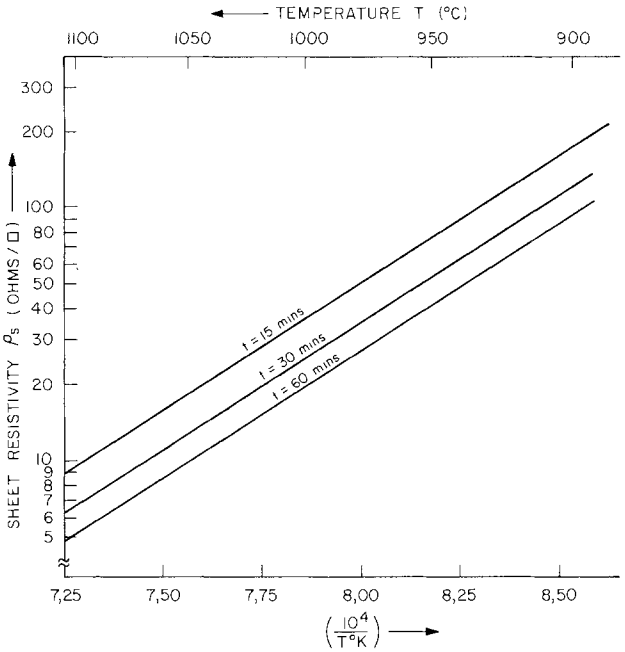

Fig. 2. Log sheet resistivity-temperature/reciprocal absolute temperature plot.

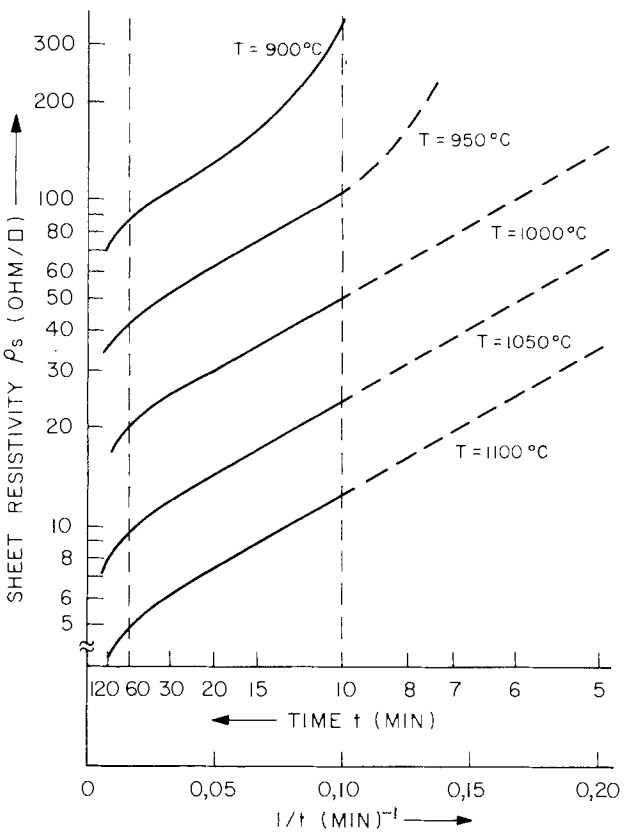

Fig. 3. Log sheet resistivity-reciprocal time plot

were made with slight computer program variations in order to determine the best fit to the experimental data. The final computer-derived equations considered acceptable were those in which the experimental ρ_s data were initially subjected to a smoothing technique and in which it was assumed that t could be better described by the addition of a constant to the experimental t value. These procedures are briefly described below.

Smoothing of the experimental data in Fig. 1 was based on Eq. [1] where, for a given value of t, say t_1, the corresponding values of T are T_1 and T_2, and ρ_{s1} and ρ_{s2} are the values of ρ_s corresponding to T_1 and t_1;

and T_2 and t_1, respectively, so that $\ln \rho_{s1} = (P/t_1) + QT_1 + R$ and $\ln \rho_{s2} = (P/t_1) + QT_2 + R$ and therefore $\ln \rho_{s1} - \ln \rho_{s2} = Q(T_1 - T_2)$. An estimate of the value of Q was made using the experimental data available. Before further calculations were attempted all the experimental values of ρ_s were adjusted to satisfy this formula, and in such a way that for each value of t the rms of the adjustments was a minimum.

The assumption regarding t is based on the consideration that the value of t used in Eq. [1] is in error and a system-dependent characteristic value (Z) must be added according to a formulation of the type $t^* = t + Z$. The value of Z is peculiar to a given experimental system and is dependent on the conditions applicable to that deposition system and may include factors such as the source-silicon spacing, thermal mass of the source holder, etc. Equation [1] can be rewritten as

$$\rho_s = \exp(Pt^{*-1} + QT + R)$$
$$= \exp[P(t + Z)^{-1} + QT + R] \quad [2]$$

An estimate of Z for any boron nitride deposition system is obtained by expanding $P(t + Z)^{-1}$ in a series of ascending powers of t which will provide an approximation to any required degree of accuracy. Thus

$$P/t^* = P/(t + Z) = P/t\left(1 + \frac{Z}{t}\right)$$
$$= (P/t)\left(1 + \frac{Z}{t}\right)^{-1}$$
$$= (P_1/t) - (P_2/t^2) + (P_3/t^3) + \ldots$$
$$(\text{where } P_2 = P_1Z, P_3 = P_1Z^2, \ldots)$$

so that the general expression of Eq. [2], using only the first two terms of this series expansion, is modified to

$$\rho_s = \exp(P_1t^{-1} - P_2t^{-2} + QT + R) \quad [3]$$

Using the smoothed (adjusted) ρ_s data, the method of least squares is used to compute the coefficients P_1, P_2, Q, and R. From the computed values of P_1 and P_2 the required estimate of Z is obtained for Eq. [2], *viz.*, $Z = (P_2/P_1)$. Using this value of Z in the new general expression

$$\rho_s = \exp(P't^{*-1} + Q'T + R') \quad [4]$$

where $t^* = (t + Z)$, and applying the method of least squares to determine the value of the coefficients P', Q', and R', the full expressions relating ρ_s, t^*, and T to each other for any system can be computed.

Under the conditions applicable to our deposition system, solution of Eq. [3] with smoothed (adjusted) ρ_s data (seven points per curve) yielded $P_1 = 16.278$ and $P_2 = 44.215$ and, therefore, $Z = P_2/P_1 = 2.72$. [Since the experimental t (Fig. 1) varies from 10 to 60 min, Z/t, ranging from 0.27 (*i.e.*, 2.72/10) to 0.045 (*i.e.*, 2.72/60) with these data, is not very small, and therefore this value of Z can only be an approximation.] The full expressions, with coefficients not rounded off, interrelating ρ_s, t^*, and T for our system are given by

$$\rho_s = \exp(15.363\, t^{*-1} - 1.44 \times 10^{-2} T + 17.219) \quad [5]$$

$$t^* = (9.4 \times 10^{-4} T + 6.509 \times 10^{-2} \ln \rho_s - 1.121)^{-1} \quad [6]$$

$$T = -69.24 \ln \rho_s + 1063.75\, t^{*-1} + 1192.29 \quad [7]$$

(with ρ_s in $\Omega/\square$, t in min, and T in °C).

Using the smoothed ρ_s values at the given experimental values of t and T of Fig. 1, the percentage error between the calculated t using Eq. [6] and the experimental t, varied between −3.17 and +3.24%, with +3.24% representing a maximum absolute error of 1.9 min in 60 min; while the percentage error between the calculated T using Eq. [7] and the experimental T, varied between −0.085 and +0.161%, with +0.161% representing a maximum absolute error of +1.5°C.

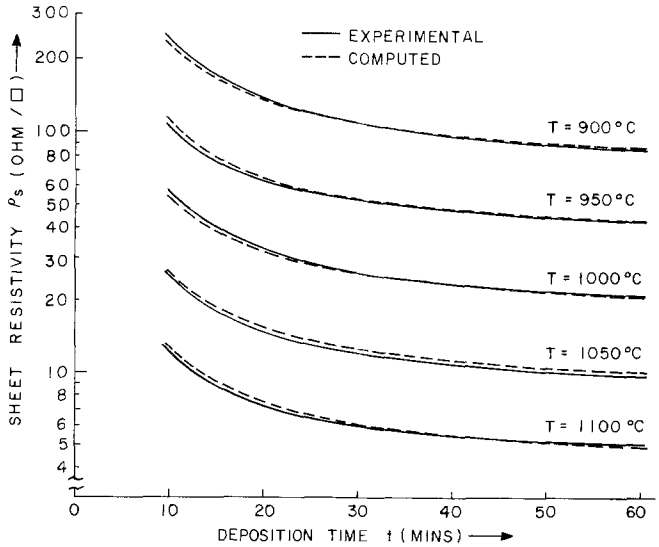

Fig. 4. Log sheet resistivity-deposition time plot. Comparison of experimental and computed data.

The percentage error between the smoothed ρ_s data and that calculated from Eq. [5] varied between −1.09 and +2.23%; while the percentage error in ρ_s between the experimentally determined ρ_s and that calculated from Eq. [5], which is of more practical interest, varied between −8.21 and +5.48%. This latter percentage error is within the accepted reproducibility limits (4-6) of ±10% for routine in-line linear four-point probe measurements. The experimental and computed data for our system are compared in Fig. 4, which shows that there is good agreement.

The indication from computer runs embodying the assumption of an error in experimental t which can be manipulated into an expression for t in ascending powers of t, is that even better fits to the experimental data, especially in t and T, would be obtained if higher powers of t were employed, but considering the reproducibility limits of the four-point probe, such accuracy was not considered warranted.

Conclusion

From experimental data obtained from any given boron nitride deposition system, equations can be computed which relate ρ_s, t, and T and form a basis for the prediction of the third variable when the remaining two are known. In view of the errors inherent in the system of four-point probe resistivity measurement, these predicted values more closely approach best estimates, and, as such, the computed equations form a satisfactory basis for the formulation of a process or design guide for the estimation of ρ_s, t, or T.

Acknowledgments

The authors would like to thank Mr. H. van Eeden for help with the experimental work, Mr. J. D. Stulting for his general assistance, and Miss J. Hewitt of NRIMS for drawing up the computer program and suggesting improvements. The authors acknowledge the support of the C.S.I. R.

Manuscript submitted Aug. 19, 1976, revised manuscript received Nov. 3, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by the National Electrical Engineering Research Institute.

The High Temperature Oxidation of Plutonium-3.3 a/o Gallium

J. L. Stakebake

Rockwell International, Atomics International Division, Rocky Flats Plant, Golden, Colorado 80401

ABSTRACT

Oxidation of plutonium-3.3 atomic percent (a/o) gallium in air was studied over the temperature range 250°-400°C. A paralinear oxidation process was observed at all temperatures although not clearly defined at 400°C. The temperature dependence of the oxidation rates indicated a change in the oxidation mechanism between 350° and 400°C. This was attributed to the selective formation of PuO or Pu_2O_3 at the metal interface in this temperature range during the parabolic stage and film cracking or nonisothermal oxidation in the linear region. Increasing the water concentration from 7 to 160 ppm resulted in increased oxidation at 350° and 400°C but had no detectable effect at 250° and 300°C.

Plutonium metal is extremely susceptible to oxidation, making it difficult to store and nearly impossible to obtain a clean metal surface. The rate of oxidation depends strongly on three parameters: moisture, metal purity, and temperature. During the last 30 years the effects of these parameters on the oxidation of pure plutonium have been studied by a number of workers (1-10). These studies showed that small changes in low level moisture concentrations have very significant effects on the low temperature oxidation rate. For example, Schnizlein and Fischer (4) found that at 190°C an increase in the moisture content of oxygen from 21 to 180 ppm resulted in a rate increase of from 1.2 to 1.5 $\mu g/cm^2 \cdot min$. By further increasing the moisture content to 510 ppm, they found the oxidation rate increased to 3.4 $\mu g/cm^2 \cdot min$. Thompson (5) found that at 85°C an increase in the moisture content of an oxygen atmosphere from 1.5 to 35 ppm resulted in an oxidation rate increase from 19.1 to 38.6 $\mu g/cm^2 \cdot hr$.

Based on this earlier work, the accelerating effect moisture has on plutonium oxidation appeared limited to temperatures below about 200°C. The only published work which has evaluated the effect of moisture at elevated temperatures was that by Schnizlein and Fischer (4) using unalloyed plutonium. Their experiments, performed with less than 5 ppm moisture in oxygen at 300° and 400°C, produced essentially the same rates as those performed with a few hundred parts per million. Two experiments were also carried out with 20,000 ppm moisture in air at 430°C with no evident effect on the oxidation rate. They concluded that the presence of moisture had no effect on the oxidation rate above 215°C.

When considering plutonium oxidation it has generally been found that impurities, particularly if they are metallic, reduce the rate of oxidation. It follows then that plutonium alloys should oxidize slower than the pure metal. Those metals which reduce oxidation when alloyed with plutonium include cerium, hafnium, zinc (2), aluminum (2-3), and gallium (6). The addition of gallium to plutonium has been used primarily to extend the stability of the metal in the delta phase. The fact that it also confers a degree of protection against oxidation is an added bonus. Only a few studies have been made at temperatures below 100°C to evaluate the decreased oxidation resulting from the presence of gallium. Waber (7) investigated the effect of various concentrations of gallium on the rate of oxidation of plutonium at 75°C in both dry air and air containing 50% relative humidity. Figures 1 and 2 show the results for alloys containing 0.7, 2.1, and 3.4 a/o gallium. The addition of gallium had only a minimal effect on the oxidation in dry air but it became significant in the presence of moisture.

At low temperatures water vapor is the major contributor to high oxidation rates. However, with current technology plutonium would rarely be exposed to a high humidity environment. On the other hand, plutonium and plutonium alloys are repeatedly exposed to high temperatures during annealing and homogeniza-

tion. The only work concerned with the high temperature oxidation of a plutonium-gallium alloy was performed by Wright and Waber (6). Their data showed that the addition of 3.5 a/o gallium did confer protection against oxidation in the temperature range 276°-400°C. In all of the runs made by these workers, the oxidation reaction underwent an arrest, the duration of which was temperature dependent. Following the arrest an accelerating rate was observed.

The present investigation was carried out to provide additional information on the high temperature oxidation of plutonium alloys. For this study a plutonium-3.3 a/o gallium alloy was examined. Oxidation kinetics were determined in air from 250° to 400°C. The effect of low moisture concentrations on the high temperature oxidation of this plutonium alloy was also evaluated.

Experimental

Apparatus.—The experimental system used in this investigation is shown in Fig. 3. A Cahn Model RG recording microbalance was used to continuously monitor the reactions. The balance was contained in a glass chamber which was attached to a metal vacuum system. Since plutonium is radioactive, additional precautions were required to prevent the release of any radioactive contamination. These included mounting the entire experimental system in a hood with a high velocity air flow and special sample handling procedures. The working pressure within the system could be varied from 10^{-4} Pa (10^{-6} Torr) to 6.7×10^4 Pa (500 Torr) and was measured with either an ionization gauge or a capacitance manometer. The sample was heated with a resistance heater controlled with a power proportioning programmer. Actual sample temperatures were continuously recorded using a thermocouple located adjacent to the sample inside the hangdown tube. Moisture was monitored with a Panametrics hygrometer with the probe located within the system.

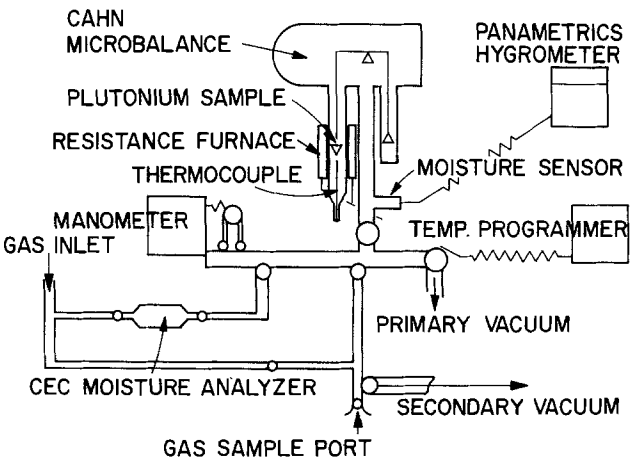

Fig. 3. Experimental system for the study of metal oxidation

Samples.—A plutonium-3.3 a/o gallium alloy was used for these oxidation studies. The presence of gallium stabilized the plutonium in the delta phase and enhanced its desirable metallurgical properties. The concentration of impurities in the alloy totaled 674 ppm_w. Results from a spark source mass spectrometer analysis of the sample are tabulated in Table I. Specimens averaging 1 cm^2 in total surface area were cut from a sheet 0.8 mm thick. This sheet was prepared by cold-rolling a sheet about 3 mm thick. Coupons were individually prepared for oxidation by mechanically abrading with 600 grit SiC paper.

Procedure.—Immediately after abrading, the samples were loaded on the balance and the system was evacuated. The samples were maintained under a dynamic vacuum of 4×10^{-4} Pa for about 20 hr. Following evacuation the sample was heated to the desired temperature and the system was backfilled to 4×10^4 Pa (300 Torr) with air.

Oxidation runs were made at 250°, 300°, 350°, and 400°C. One of the problems encountered in using the microbalance at high temperatures is thermal instability. For the temperatures used in this study, 4×10^4 Pa was the maximum pressure which could be used without creating intolerable thermal effects.

Oxidation was carried out in dry air obtained commercially. The significant difference between the two cylinders of air used for this study was the moisture content. Moisture analyses were made under flowing conditions using both the Panameterics hygrometer and a CEC moisture analyzer. 2 hr were allowed under the flowing conditions for the sensors to reach equilibrium. From these measurements the moisture levels in the air cylinders were determined to be 7 ppm for cylinder D and 160 ppm for cylinder W.

Data from the oxidation runs were processed using a digital computer curve fitting program (11) to determine the best equation for the data. In many cases, it was difficult to fit the data to any one simple rate equation because changes during the oxidation runs were frequent. For this study the first 100-200 min of the oxidation were fit to the parabolic rate equation while the last 200-400 min of the reaction were fit to a linear equation.

Results and Discussion

Oxidation kinetics.—Initially, two different sets of apparatus were used to make triplicate runs at each temperature. However, results from one system could not be reproduced on the other balance even though the results for each system were reproducible. These variations were attributed to two possible causes: temperature variations between the two systems and different moisture concentrations in the two cylinders of air being used. In order to attain reproducibility and also evaluate the effect of low moisture concentrations, all runs reported here were made using the same experimental system.

Oxidation curves for runs made in air between 250° and 400°C are shown in Fig. 4-6. Each curve represents the fit obtained from two or more experimental runs. In Fig. 4 oxidation data from the runs in air containing 7 or 160 ppm water vapor were combined in a single curve. Examination of these curves indicated that the reaction kinetics might best be described by using a combination of parabolic and linear rate equations. Runs at 250°, 300°, and 350°C all showed an initial parabolic behavior which transformed into a linear rate as the run progressed (Fig. 4, 5). At 400°C several different factors appeared to be involved. Initially, the accelerating rate suggested that nucleation was the controlling factor during the first 5-6 min. This was not surprising considering the fast reaction rate and the lack of a perfectly clean surface prior to starting the run. The type of nucleation involved is uncertain. It could involve the growth of new oxide crystals on an oxide base film or merely the cracking of the initial oxide film present on the sample. After the first 6 min it was difficult to tell from the kinetic data alone whether the rate was parabolic as it appeared. The rate process could be linear with the decreasing rate caused by a decreasing sample size. The final sample size was calculated from the total amount of oxide formed. The reduced size did contribute to the decrease in rate but was not significant enough to cause the observed effect.

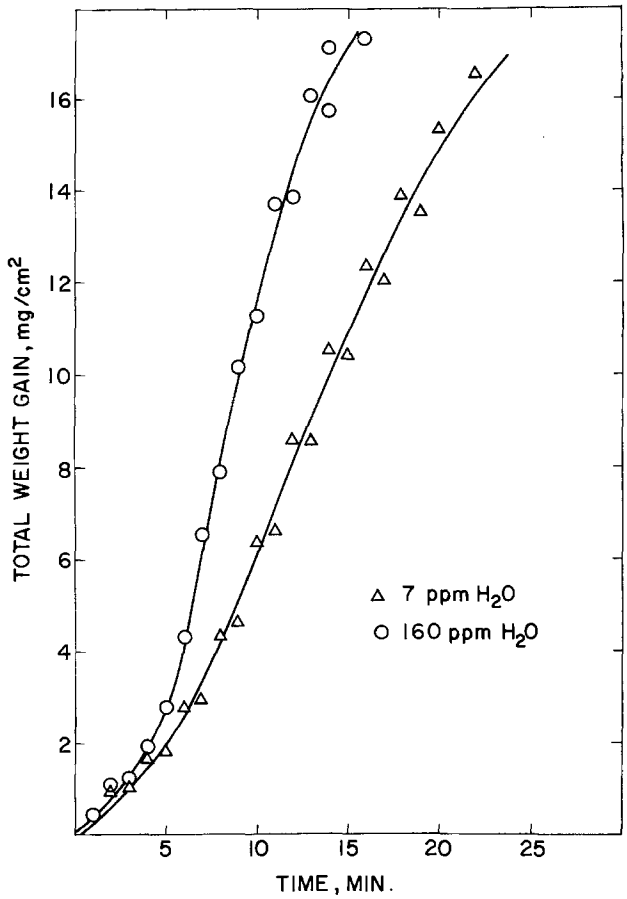

Fig. 6. The effect of low level moisture concentrations on the oxidation of plutonium-3.3 a/o gallium in air at 400°C.

Parabolic kinetics.—Oxidation data for all of the runs were evaluated using the equation $x = kt^{1/2} + c$. A plot of the data obtained in air with 7 ppm water using this equation is shown in Fig. 7. These data are for time intervals up to 400 min. Beyond about 200 min, however, the rate law begins to change from parabolic to linear. The initial portion of these runs deviated from the parabolic rate. This is most likely the result of interface-controlled reactions occurring before the diffusion controlling film forms. A similar set of curves can be obtained for the runs in air with 160 ppm of water. Rate constants for the parabolic portion of all experimental runs were obtained from a computer fit of the data to the above equation and are tabulated in Table II.

The activation energy for the parabolic rate process can be calculated using the Arrhenius equation

$$k = Ae^{-\Delta H/RT}$$

Since the parabolic equation used for this study was in the form $x = kt^{1/2} + c$, a plot of 2 ln k *vs.* $1/T$ is required to satisfy the Arrhenius equation (13). Such a plot is shown in Fig. 8 for the runs in air with both 7 and 160 ppm water vapor. A single curve could not be satisfactorily fit through all the data, thus resulting in two activation energies for the parabolic process. Between 250° and 350°C the activation energy was calculated to be 33 kcal/mole. This value can be compared with the value of 29.2 kcal/mole observed for unalloyed plutonium over the same temperature range (4).

Between 350° and 400°C there was a break in the Arrhenius plot indicating a possible change in the reaction mechanism. The parabolic activation energy was

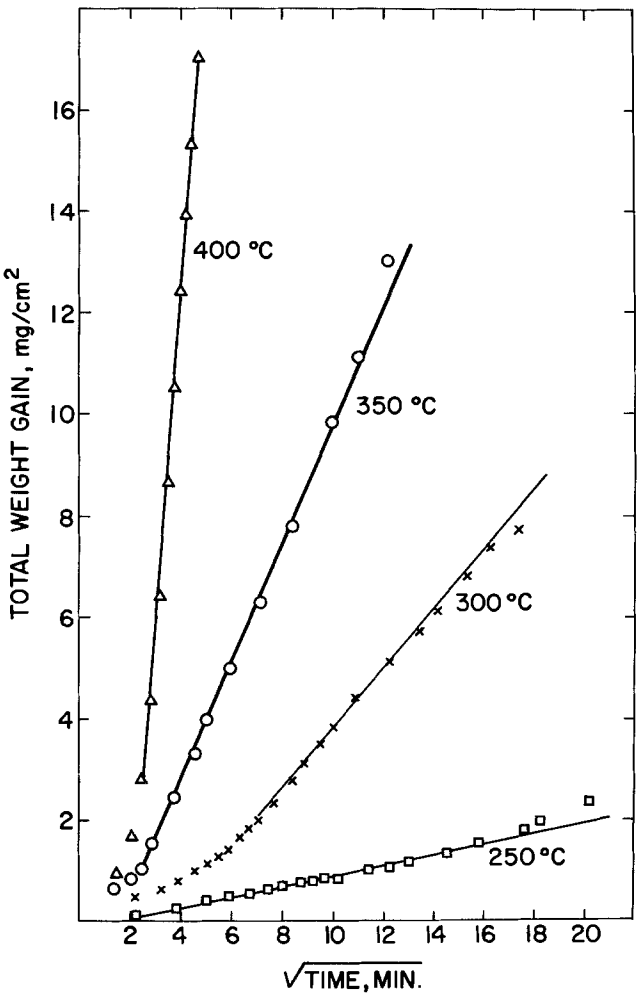

Fig. 7. Parabolic plots of the oxidation data obtained in air with 7 ppm water.

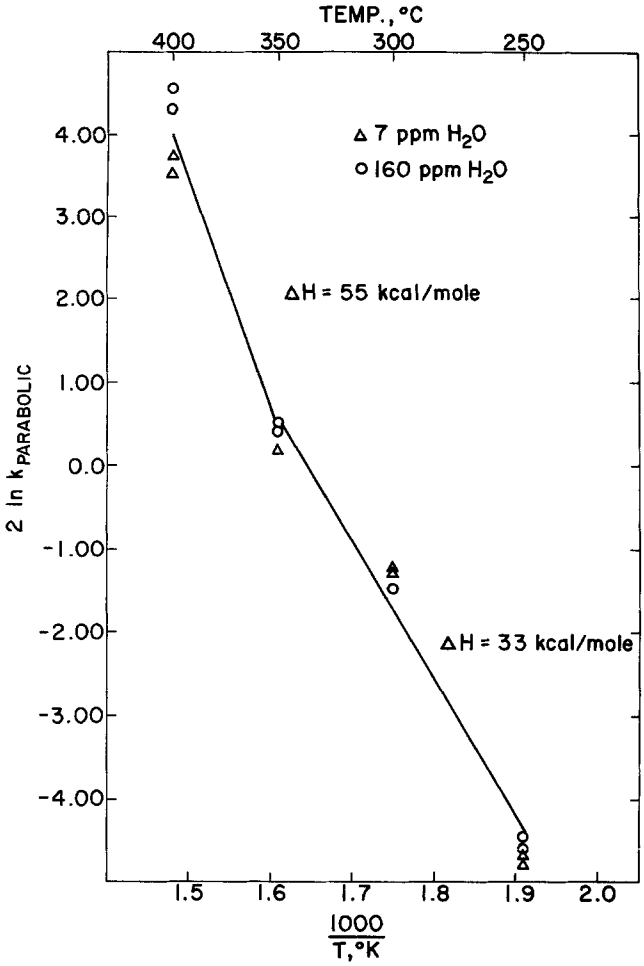

Fig. 8. Arrhenius plot of the parabolic rate constants obtained for runs in air with 7 or 160 ppm water.

calculated to be 55 kcal/mole. This value was significantly higher than the previously reported value of 38 kcal/mole for unalloyed or alloyed plutonium (4).

Linear kinetics.—Following the initial film formation resulting in parabolic kinetics, the oxidation process became linear. Linear rate constants were calculated for each run beginning after about 200 min had elapsed. In the case of the runs at 400°C, data from the last half of the runs were used. Table II tabulates the rates obtained from a least squares fit of the data to the linear equation.

The activation energy for the linear oxidation was obtained from the Arrhenius plot shown in Fig. 9. As in

Table II. Oxidation rates for the oxidation of Pu-3.3 a/o Ga in air

Run	Temperature, °C	Moisture, ppm	Rate constants: Parabolic, mg/cm²min^1/2	Rate constants: Linear, mg/cm²min
250-1D	250	7	0.089	0.0032

the case of the parabolic oxidation, there was a break in the curve indicating a change in mechanism. Between 250° and 350°C, the activation energy was 16

kcal/mole. This is the same value as reported for unalloyed plutonium for the same temperature range. Above 350°C, the activation energy increased to 45 kcal/mole. Again, this activation energy was significantly higher than that previously reported for a linear process.

Oxidation Mechanism

Paralinear kinetics have been observed for the oxidation of a number of metals (12) as well as plutonium (4). The mechanism which explains this behavior suggests an initial growth of a compact adherent oxide film of a limited thickness. This growth process, which is diffusion controlled, results in a parabolic rate law. Following the initial parabolic rate process, the reaction rate becomes linear. The change from a parabolic to a linear rate law can result from several processes. These include: phase boundary processes involving metal/oxide or oxide/oxide interfaces or diffusion through an oxide film of constant thickness. Fracture of the oxide film is still another cause for the change from parabolic to linear rates. Formation of a porous oxide, resulting in a reaction at the adherent oxide/porous oxide interface is probably the most common explanation. This porous oxide can be formed by further oxidation or recrystallization of the adherent oxide film.

Loriers (13) has attributed the paralinear oxidation of cerium to the growth of a porous CeO_2 on a compact layer of Ce_2O_3. Plutonium also forms multiple oxides including PuO, Pu_2O_3, and PuO_2. Terada *et al.* (15) have shown that under vacuum, above 200°C, the PuO_2 film is very rapidly reduced by the metal to α-Pu_2O_3. Furthermore, above 350°C one might expect almost equal amounts of PuO and α-Pu_2O_3 to be present in the oxide film. The proposed reaction sequence is

$$Pu + 3PuO_2 \rightarrow 2\alpha\text{-}Pu_2O_3 \quad [1]$$

$$\alpha\text{-}Pu_2O_3 + Pu \rightarrow 3PuO \quad [2]$$

These oxides have been found to be protective toward further oxidation (16, 17). In the present investigation the samples were heated in vacuum for periods of 10-15 min prior to the start of the run. This would be sufficient time to assure the presence of a layer of PuO or α-Pu_2O_3 on the surface. A compact layer of these oxides would result in a diffusion-controlled parabolic oxidation rate. Further oxidation of PuO or Pu_2O_3 produces PuO_2 which is porous and less coherent. The linear oxidation rate then results from the oxidation of the lower plutonium oxides.

Lindsay *et al.* (17) found that at 175°C the protective film of α-Pu_2O_3 initially increased and then decreased producing an accelerated rate as it was oxidized to PuO_2. Under these conditions it was reported that the α-Pu_2O_3 was completely depleted by oxidation and did not reform. The temperature at which the present runs were made was in the range 250°-400°C where both PuO and α-Pu_2O_3 form more rapidly. During the course of the runs there was no accelerating rate, except at 400°C, which would be expected if the surface film were being depleted. The linear reaction, therefore, is assumed to result from and be controlled by oxidation at the oxide/oxide interface. Additional work is required to identify the oxide film present at the metal/oxide interface.

Calculations of activation energies are frequently useful for evaluating the mechanism of oxidation. During parabolic oxidation the reaction is controlled by the inward diffusion of oxygen ions. The activation energies calculated for parabolic oxidation changed from 33 kcal/mole to 55 kcal/mole at about 350°C. The magnitude of these values is on the order of that expected for diffusion process. The break in the Arrhenius curves which results in the activation energy increasing to 55 kcal/mole is indicative of a mechanism change. This observation is not unusual. It could be caused by two different protective oxides, such as in the case of copper (18). For plutonium, the monoxide, PuO, may be significantly involved at these higher temperatures. However, PuO has not been prepared in bulk and little is known about its behavior. Furthermore, a complete explanation of the role of diffusion requires a knowledge of the defect structure of the protective plutonium oxides. Here again, little information is available on this subject and what work that has been done has been in the single phase region of PuO_2 (3).

During linear oxidation the formation of the nonuniform layer of PuO_2 predominates. The volume ratio of this oxide indicates that it is the least protective of all the plutonium oxides. Since this oxide is porous and allows free access of oxygen to the protective oxide layer, the linear process is controlled by the oxide (PuO + Pu_2O_3)/oxygen interface reaction.

The Arrhenius plot of the linear rate constants gave two straight lines with activation energies of 16 and 45 kcal/mole. At temperatures up to 350°C it is proposed that the activation energy of 16 kcal/mole is associated with the oxidation of the suboxides. There are two possible causes for the observed change in the temperature dependence of the oxidation rate. First is the breakdown of the protective oxide layer and the continuous exposure of fresh metal. The second possible cause is the amount of heat produced by oxidation. When a metal oxidizes linearly, large quantities of heat are produced per unit time. Above a certain temperature the amount of heat produced will exceed the amount conducted away to the surroundings. Therefore, the temperature rises progressively and the oxidation reaction becomes self-accelerating. This type of behavior has been observed for cerium (19) (above 290°C) and thorium (20) (above 500°C). Very likely both of these causes are involved in the oxidation of plutonium above 350°C.

Effect of moisture.—The role of water in the low temperature oxidation of plutonium has frequently been reported (9, 10). At temperatures greater than 100°C, however, the information is very limited. It is generally agreed that moisture will increase the oxidation rate, at least up to 200°C (4). Above 215°C, however, moisture was reported to have no effect on the oxidation of unalloyed plutonium (4). From the present work, runs at 250° and 300°C (Fig. 4) were unaffected by moisture variations of 7-160 ppm. At 350°C (Fig. 5) the difference between oxidation in air with 7 and 160 ppm water appeared to become significant. The error bars for these two curves are smaller than the data points shown on the figure. The parabolic oxidation rate increased from 1.12 to 1.27 mg/cm^{2}min$^{1/2}$ with the moisture increase of from 7 to 160 ppm. At 400°C (Fig. 6) the effect was even more pronounced. The parabolic oxidation rate increased from 6.1 to 9.2 mg/cm^{2}min$^{1/2}$ with the increase of 153 ppm of water.

Water vapor did not appear to significantly affect the linear oxidation process until the temperature was above 350°C. At 250°C there was a slight rate increase, however at 300°C there was no rate change, and at 350°C the oxidation rate actually decreased with the addition of moisture. The linear rate at 400°C began to increase significantly when the moisture level went from 7 to 160 ppm. Under these conditions the rate increased from 0.86 mg/cm^2 to 1.34 mg/cm^2.

Results from this study cannot be considered all inclusive with respect to the effects of water vapor, but they do indicate that water vapor does influence the high temperature oxidation of plutonium. Furthermore, the accelerating effects of very low moisture concentrations increased with temperature beginning at about 350°C.

Conclusion

The oxidation of a plutonium-3.3 a/o gallium alloy was investigated in air between 250° and 400°C. Oxidation kinetics were paralinear with a mechanism change occurring at 350°C. This change was attributed to the formation of plutonium suboxides, probably

PuO, during parabolic oxidation and either nonisothermal oxidation or film cracking in the linear oxidation stage. The temperature dependence of the oxidation rate as derived from the Arrhenius equation resulted in four expressions. Below 350°C the parabolic rate constant is defined as

$$k_{\text{parabolic}} = 8.5 \times 10^{11} [\exp(-33{,}100/RT)] \text{mg/cm}^2\text{min}^{1/2}$$

The linear rate constant between 250° and 350°C was

$$k_{\text{linear}} = 2.9 \times 10^{4} [\exp(-16{,}400/RT)] \text{mg/cm}^2\text{min}$$

Above 350°C the parabolic rate constant could be expressed as

$$k_{\text{parabolic}} = 4.7 \times 10^{19} [\exp(-55{,}400/RT)] \text{mg/cm}^2\text{min}^{1/2}$$

while the linear rate became

$$k_{\text{linear}} = 4.0 \times 10^{14} [\exp(-45{,}000/RT)] \text{mg/cm}^2\text{min}$$

These rate expressions represent average values and no attempt was made to distinguish between the 7 or 160 ppm moisture levels. Above 350°C some accelerating effects on the oxidation rate due to the increased moisture were noted. At 400°C this slight increase in moisture was sufficient to increase the oxidation rate from 6.1 to 9.2 mg/cm^{2}min$^{1/2}$. The greatest deviation from the generalized rate equations was observed at 400°C where the moisture effect was most prominent. All of the reactions were smooth and continuous with no evidence of a reaction arrest.

The efficiency of anodic oxide formation, ϵ_{ox}, on n-GaAs in an electrolyte formulated by Hasegawa and Hartnagel (1) depends on the applied current density (2). In contrast, there is no evidence of parasitic reactions associated with the semiconductor-oxide interfacial charge transfer (2, 3), hence the faradaic efficiency, $\epsilon_F = 1$. The less than 100% efficiency of the growth process may be attributed to: (*i*) transport of reaction product(s) to bulk electrolyte prior to completion of surface coverage (1, 2), (*ii*) dissolution of oxide layer on contact with an electrolyte (1, 2) and (*iii*) transport of nonparticipating species across the growing oxide layer into the bulk electrolyte (2).

This preliminary note is concerned with the effect of growth rate on the accumulation of diffusing substances in the oxide layer and on the oxide structure.

Experimental

Anodic oxides were grown galvanostatically, employing standard procedures and apparatus. Potential decays on open circuit, following current interruption, were displayed on a Hewlett-Packard, Model 7001 AM X-Y recorder. Oxide layers were examined with a Hitachi HU-125 electron microscope operated at 125 kV. Specimens for the microscopic examination were prepared by ion milling from the GaAs substrate side until a small hole was observed. Areas around the hole were sufficiently thin to yield good images.

Results and Discussion

Electrode behavior on approach to V_{rest}.—An approach to the electrode rest potential upon the termination of oxide layer growth to a predetermined thickness, as a function of growth rate, is illustrated in Fig. 1. Qualitatively, the difference in the electrode transient behavior between the fast (solid lines) and the slow (dashed lines) growth rates increases with an increase in the oxide layer thickness. The slow approach to V_{rest} and its dependence on the oxide layer thickness rules out the participation of potential affecting processes within both the electric double layer and the depletion and/or space charge layer. Consequently, the processes responsible for the observed behavior ought to be confined to the oxide layer.

It was shown (2) that anodic oxidation of n-GaAs obeys a relationship

$$j = A \exp(\beta E/RT) \qquad [1]$$

The empirical constant A is related to molecular diffusion, *i.e.*, to a random walk in the absence of field, so that the total current, j, in Eq. [1] is due to a random walk perturbed by an applied electric field, E (β in Eq. [1] contains the jump distance). Thus, upon removal of the applied field, processes operative within the oxide layer are expected to be governed by diffusion. How the driving force, *e.g.*, the concentration or the electrochemical potential gradients needed for the diffusional transport is generated, has not yet been established. It may arise if: (*i*) the electric field is not uniform—presumably not a very likely situation, since the galvanostatic oxide formation is a constant field process, if Eq. [1] is obeyed; (*ii*) there is coupling between the various transports; (*iii*) a reaction of the type: $OH^- + L = O^{-2}L + H^+$ is operative (4); or (*iv*) the dielectric constant of the oxide layer depends on composition which, in turn, may lead to case (*i*).

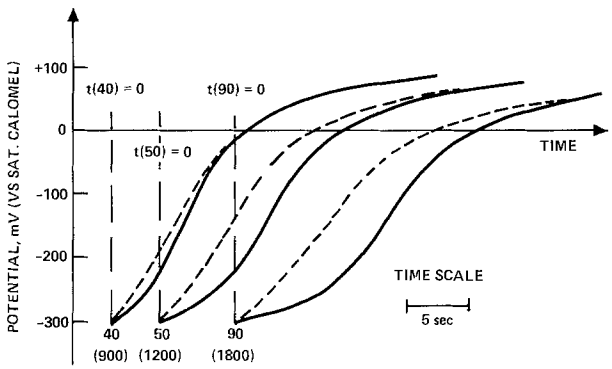

Fig. 1. Approach to electrode rest potential upon interruption of anodic current. Solid lines: $j = 2.25$ mA cm^{-2}; dashed lines: $j = 0.9$ mA cm^{-2} (numbers alongside curves denote cell terminal voltage: 40, 50, 90V or oxide layer thickness 900, 1200, and 1800 in amperes).

The observed potential difference between the initial value of -300 mV and the final value of about $+130 \pm 10$ mV, attained after approximately 30 min, is not unusually large. The approach to the rest potential may be viewed in terms of potential components within the semiconductor-oxide-electrolyte interphase, shown in Fig. 2. During the growth of the oxide layer practically all the potential drop occurs in the oxide with insignificant potential drops in the depletion and/or inversion regions, as well as in the electric double layer. On the open circuit, however, the measured potential is a sum of potentials in the space charge region, V_{sc}, and in the electric double layer, V_{el}, may be affected

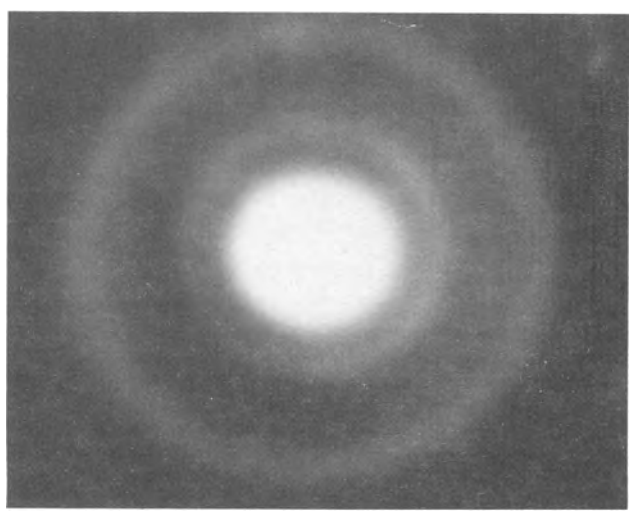
by diffusion of charged species to and from respective interfaces.



Evidently the electrode potential is not affected by the growth rate immediately after current interruption or after attainment of a stationary state. The latter situation is expected, since it may be viewed as mixed potential due to oxide dissolution on contact with an electrolyte. The former also indicates some kind of a stationary state. The approach to the rest potential if, in fact, diffusion controlled, implies a flat concentration profile of diffusing species, except close to the interface. At high rates a flat profile farther removed from the interface may be postulated as if the oxide growth has overtaken the outward migration of the potential determining species generated at the advancing oxide-semiconductor interface.

Growth rate and oxide structure.—Although no exact relation has been established between growth rate and oxide morphology even for the much studied anodic oxides on Al, nevertheless, it appears that the more severe the anodizing conditions, the more open the oxide structure (5). This observation can be extended to the far less investigated structures of anodic oxides on Si (6).

The structural and chemical properties of anodic oxides formed by the so-called AGW-process (1), were recently discussed by Weiss (7). He reported that bulk oxides were amorphous with crystalline β-Ga_2O_3 on the GaAs surface. Although not specifically stated, it is presumed that the anodizing current density did not exceed 1 mA cm^{-2}.

In an effort to shed additional light on the electrode open-circuit behavior as a function of growth rate, the

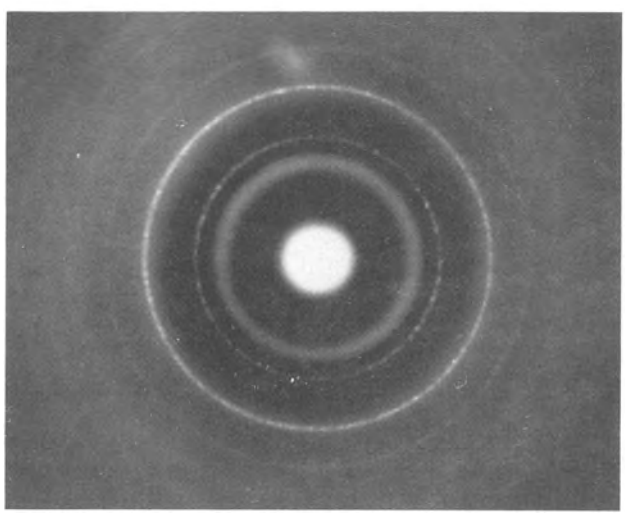


Fig. 3. Diffraction pattern of anodic oxides. (a, above left) Oxide grown at $j = 12$ mA cm^{-2}; (b, above right) oxide grown at $j = 0.25$ mA cm^{-2}; (c, left) effect of heat-treatment on oxide grown at $j = 0.25$ mA cm^{-2}.

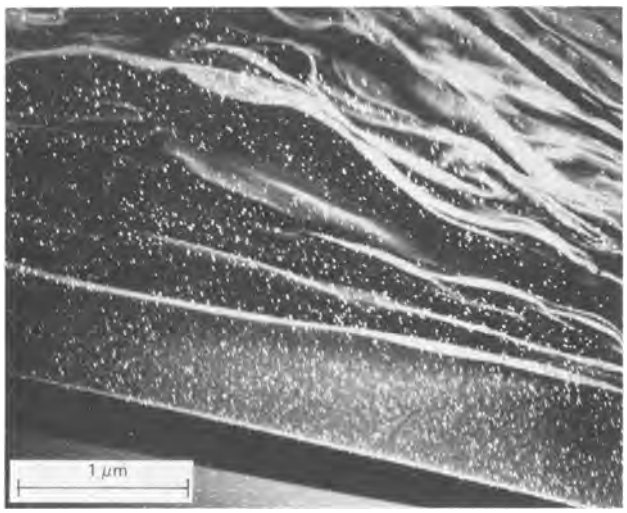

Fig. 4. Electron photomicrograph showing individual crystallites in heat-treated oxide layer imaged by darkfield technique.

bulk oxide grown at high rates ($j = 12$ mA cm^{-2}) and at low rates ($j = 0.25$ mA cm^{-2}) were compared by electron diffraction. As seen in Fig. 3a, oxide grown at high current density (C.D.) differs structurally from that grown at low C.D., Fig. 3b. In the first case, the diffraction pattern consisted of a number of rather sharp rings, while in the second case only few diffuse rings were observed. Thus, oxide grown at low C.D. is less orderly in atomic arrangement than when grown rapidly where well-defined diffraction rings with the absence of spots indicate structurally ordered regions or grains less than approximately 10 nm in size. To distinguish between these structures, we refer to them as amorphous and polycrystalline.

An initially amorphous sample heated in an argon atmosphere showed the diffraction pattern consisting of at least six well-defined rings. As seen in Fig. 3c, these rings are quite spotty, indicating a structure which is even more orderly than either one described previously. This structure is definitely polycrystalline. A dark field transmission electron micrograph, imaged from one of the diffraction spots, is shown in Fig. 4. An abundance of a particular crystallographic orientation of crystallites is evident. The folds or wrinkles in the oxide film are due to distortion induced by heating by the electron beam. Evidently, the initially amorphous oxide layer became, on heating, polycrystalline with randomly oriented grains. However, an attempt to identify the nature of oxides failed. A comparison with ASTM powder diffraction data was not consistent with lattice spacing for either α-, β-, ϵ-Ga_2O_3, or As_2O_3. The diffraction pattern d-spacings and those of respective oxides are shown in Table I. It is possible that, on heating, suboxides or mixed oxides of Ga and As were formed.

Conclusion

The growth rate of anodic oxides on GaAs in a mixed electrolyte consisting of an aqueous solution of tartaric acid and propylene glycol, affects the growth mechanism. This conclusion is reached by observing the electrode approach to its rest potential and by examining the oxide structure. It is, therefore, suggested that the dependence of the process efficiency on the growth rate is related to, and probably governed by, transport phenomena within the growing layer modified by the oxide structure.

Accurate Determination of Shallow Zn-Diffusion Profiles in GaP and $GaAs_{0.1}P_{0.9}$ Using Anodic Oxidation and a Double Radioactive Tracer Technique

J. C. Verplanke

Philips Research Laboratories, Eindhoven, The Netherlands

The diffusion of Zn in the system GaP-GaAs is of considerable technological importance for devices.

In light emitting diodes (LED's), the Zn diffusion normally has a depth up to about 10 μm. Not much is known about the actual shape of the Zn profiles in LED's, however, although such knowledge is required in a detailed analysis of their properties. Moreover, a better understanding of the Zn diffusion mechanism might be obtained from accurate data on shallow profiles.

Essentially all the published studies concerning the diffusion of Zn in GaP, GaAs, etc. relate to deep (50-500 μm) profiles (1-9). Mostly parallel sections were removed using lapping techniques or chemical etching. With such methods it is difficult to remove accurately thin ($\sim$0.1 μm) parallel sections, this being a prerequisite for measuring shallow and steep profiles. Thus for the study of such profiles other techniques have to be found. Logan *et al.* (10) mentioned anodic oxidation as a possible method for diffusion studies.

By using anodic oxidation in combination with a double radioactive tracer technique, we were able to remove and analyze thin parallel sections of about 0.1 μm. Diffusions were performed with radioactive ^{65}Zn. Prior to the anodic oxidation, the diffused slice was irradiated with thermal neutrons in order to activate P to radioactive ^{32}P which activity was used for the determination of the removed layer thickness.

Experimental Method

Zn diffusion was carried out into layers of GaP and $GaAs_{0.1}P_{0.9}$, grown by means of vapor phase epitaxy on GaP substrates. No further surface preparation was applied.

The diffusions were performed at 675°C for periods of between 2.5 and 16 hr in 10 cm^3 silica capsules, evacuated to 10^{-5}-10^{-6} Torr, using an alloy source composed of 70% by weight radioactive Zn and 30% Ga. The radioactive isotope was ^{65}Zn (half-life 244 days; gamma energy 1115 keV) and the specific activity was about 100 mCi g^{-1}. Direct contact between diffusion source and sample material was avoided by interposing a perforated piece of silica between them.

After the diffusion the sample was etched in 2*N* HCl for some minutes. Afterward the edges and the back were removed and the sample together with two non-diffused pieces of GaP as standards were irradiated in a thermal neutron flux of about 5×10^{13} n cm^{-2} sec^{-1} for 5 min. During this irradiation the major components of the sample were activated, *e.g.*, Ga to radioactive ^{72}Ga (half-life 14.1 hr) and P to radioactive ^{32}P (half-life 14.3 days). The thickness of the removed layers was calculated from the ^{32}P activity in those layers, the ^{32}P activity in the standards (GaP), and the weight of the standards. In this way very thin layers, *i.e.*, about 0.1 μm, can be measured accurately in the region where direct thickness measurement and weighing are less accurate or unpractical and time consuming. Another advantage is the possibility of continuing the removal of the layers without interruption for measurements of the thickness or weight loss of the sample. The specific activity of Zn increased by less than 0.1% during the irradiation so no correction had to be applied.

Key words: anodic oxidation, Zn diffusion, GaP, $GaAs_{0.1}P_{0.9}$, III-V compounds, radioactive tracer.

After the ^{72}Ga had decayed, parallel layers were removed by means of an anodic oxidation technique. For this purpose the sample was attached to a glass strip. An electric contact was made on the back of the sample to enable a voltage to be applied to it. The part of the contact situated below the liquid level during the anodization was covered with lute. Small parallel layers were now removed as follows:

1. An isolating oxide layer was grown on the surface by means of anodic oxidation in the following bath (11): one volume part of a 3% citric acid solution whose *p*H was adjusted to 6.0 using ammonia and two volume parts of ethylene glycol. The anodic oxidation was carried out by slowly increasing the applied voltage, taking care meanwhile that the current did not surpass a few mA cm^{-2}. As soon as the desired voltage (150V) was reached, it was maintained at this value for 3 min, while the current dropped quickly.
2. The anodization was then stopped and the formed oxide layer was dissolved in warm 10% phosphoric acid.

Using this anodization procedure at an applied voltage of 150V, layers of about 0.10, 0.14, and 0.23 μm were removed for GaP, $GaAs_{0.1}P_{0.9}$, and GaAs, respectively. The removed layer thickness is proportional to the applied voltage. It is recommended, however, not to surpass 150V because above this voltage the surface condition may deteriorate. Sometimes the anodization stopped suddenly, in which case the process was continued by illuminating the sample homogeneously.

After the anodization and dissolution of the oxide layer, two sample fractions have to be measured, *viz.*, the anodization bath and the dissolution bath.

The removed layer thickness was determined by measuring in both fractions the ^{32}P activity in the case of GaP and $GaAs_{0.1}P_{0.9}$. The ^{32}P activity was measured by means of its Čerenkov radiation in an aqueous solution using a liquid scintillation analyzer. The ^{32}P activities of the simultaneously irradiated standards were also measured. In this way very thin removed layers (*e.g.*, 0.1 μm or less) can be measured fairly accurately, *i.e.*, with a precision, expressed as two times the standard deviation, of 3% or better. The systematic error was estimated not to exceed 3%.

The Zn contents of the removed layers were determined by measuring the ^{65}Zn activities in the sample fractions. For this purpose we used high resolution gamma spectrometry with a Ge(Li) detector coupled to a 2048-channels analyzer as well as measurement of the ^{65}Zn spectrum from 1000 to 1250 keV with a NaI(Tl) scintillation detector. The accuracy of the latter method is better on account of better counting statistics due to its higher efficiency for absorbing the 1115 keV gamma rays of ^{65}Zn. At low Zn content, however, fluctuations in the background activity are very critical, so in those cases only results of mea-

surements with the Ge(Li) detector were available. The contribution of the ^{32}P activity to the Zn measurements proved to be negligible.

The precision of the Zn contents, *i.e.*, the possible error due to random variations, expressed as two times the standard deviation, was about 5%. For low Zn concentrations, however, this value could rise to 30%. The systematic error was estimated not to exceed 3%.

From the measurements we found that about 5% of the total removed ^{32}P activity was present in the anodization bath and about 70% of the removed ^{65}Zn activity.

Results

Figures 1 and 2 show examples of diffusion profiles of Zn in GaP and $GaAs_{0.1}P_{0.9}$, respectively, determined in the above-described way.

The first 500Å show a peak in the Zn concentration. This phenomenon might be ascribed to a transition state between the vapor phase with a relatively high Zn activity and the solid phase with a low Zn activity. Except for this peak the profiles can be described rather well by a diffusion coefficient proportional to the square of the Zn concentration. The solid curves show such theoretical profiles.

Thus the interstitial-substitutional diffusion mechanism, which can explain deeper diffusion profiles in GaAs (6) and GaP (4), applies equally well to shallow diffusions in GaP and $GaAs_{0.1}P_{0.9}$.

From the two theoretical profiles, the values of D_o, *i.e.*, the diffusion coefficient at the theoretical surface concentration, were calculated. For GaP we found $D_o = 4.3 \times 10^{-12}$ cm^2 sec^{-1} ([Zn] = 2×10^{18} at · cm^{-3}) and for $GaAs_{0.1}P_{0.9}$ $D_o = 6.5 \times 10^{-12}$ cm^2 sec^{-1} ([Zn] = 2.7×10^{18} at · cm^{-3}). Normalizing D_o to [Zn] = 10^{18} at · cm^{-3}, adopting the proportionality of D_o with [Zn]^2, gave $D_o = 1.1 \times 10^{-12}$ cm^2 sec^{-1} and $D_o = 8.9 \times 10^{-13}$ cm^2 sec^{-1} for GaP and $GaAs_{0.1}P_{0.9}$, respectively.

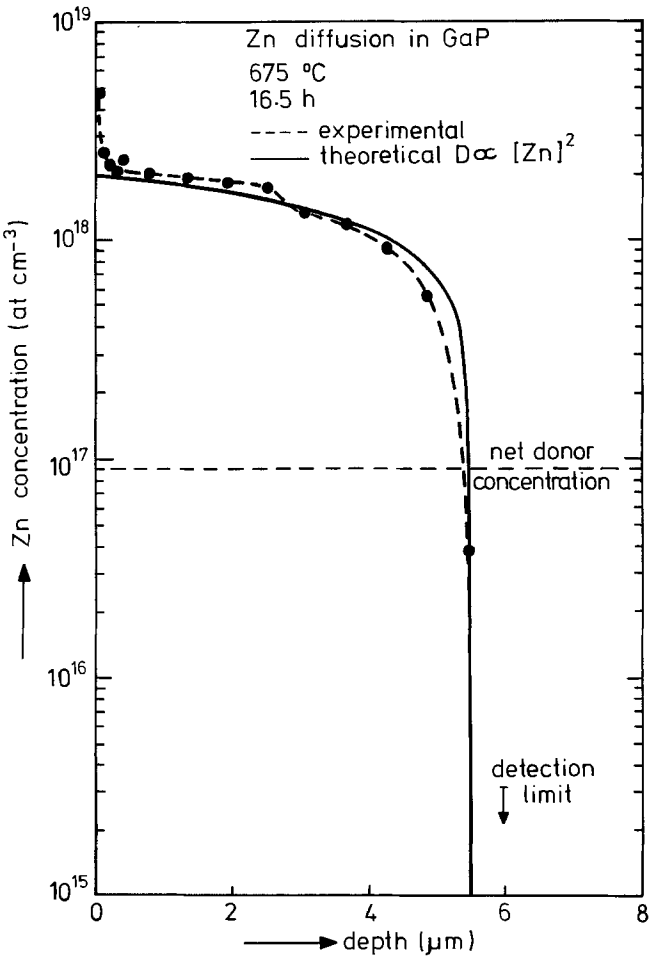

Fig. 1. Zn diffusion profile in GaP. The sample area was 0.57 cm^2. The precision of the lowest Zn concentration is about 20%, that of the other concentrations is about 5%. The indicated detection limit resulted from a 65 hr measurement with a Ge(Li) detector.

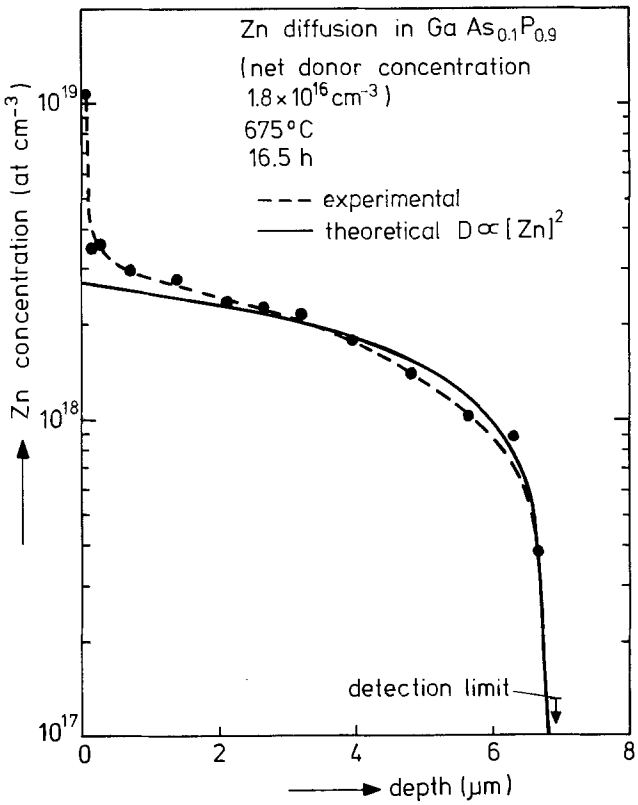

Fig. 2. Zn diffusion profile in $GaAs_{0.1}P_{0.9}$. The sample area was 0.175 cm^2. The precision of the lowest Zn concentration is about 30%, that of the other concentrations is about 10%. The indicated detection limit resulted from a 65 hr measurement with a Ge(Li) detector.

The very good resolution of the present method was confirmed as follows. From the measured profile in GaP, we calculated a gradient of the Zn concentration at the p-n junction of 1.1×10^{22} at · cm^{-4}. This is in good agreement with that obtained from capacitance-voltage measurements, *viz.*, $(1.3 \pm 0.3) \times 10^{22}$ at · cm^{-4} (12). The latter measurements were interpreted by assuming a "mixed graded-abrupt profile" (13), which is indeed the kind of near-junction profile to be expected (14).

The resulting profiles show that the described analyzing method for such shallow Zn diffusion profiles is a very useful technique. Further results will be presented in a later paper.

Low Temperature Diffusion of Boron from Diborane Using Carbon Dioxide as Oxidant

Krishna C. Saraswat* and James D. Meindl*

Department of Electrical Engineering, Stanford University, Stanford, California 94305

Boron is widely used to dope p-type silicon. Diborane (B_2H_6) is one of the most widely used sources for thermal diffusion of boron in silicon. The usual technique for open-tube boron diffusion is to pass a mixture of B_2H_6 and O_2; N_2 being the carrier gas (1, 2). The resultant chemical reaction is

$$B_2H_6 + 3\,O_2 \rightarrow B_2O_3 + 3H_2O \qquad [1]$$

Boron trioxide is then deposited on the surface of silicon and acts as a further source of diffusion. B_2O_3 has the following reaction with Si at the B_2O_3-Si interface

$$2B_2O_3 + 3Si \leftrightarrows 4B + 3SiO_2 \qquad [2]$$

The H_2O generated by reaction [1] also reacts with B_2O_3 to form HBO_2 which subsequently reacts with Si to form elemental boron and SiO_2 (1)

$$B_2O_3 + H_2O \rightarrow 2HBO_2 \qquad [3a]$$

$$2HBO_2 + 2Si \rightarrow 2SiO_2 + 2B + H_2 \qquad [3b]$$

The elemental boron produced by reactions [2] and [3] then reacts with silicon to form a Si-B compound known as boron skin (3)

$$Si + nB \leftrightarrows SiB_n \qquad [4]$$

n usually ranges from 4 to 6.

Apart from this, the silicon is directly oxidized by the oxygen

$$Si + O_2 \rightarrow SiO_2 \qquad [5]$$

From Eq. [2], [3a], and [5], it is clear that a layer of SiO_2 is formed. Because of the presence of this layer, further diffusion of boron is impeded. At high temperatures this is not a problem because B_2O_3 penetrates through this layer of SiO_2 very quickly and thus reactions [2] and [4] keep taking place. However, at lower temperatures the situation changes. B_2O_3 cannot readily penetrate through the oxide layer and thus the boron skin (SiB_n) is not formed. Presence of boron skin is essential to get solid solubility. Therefore, at lower temperatures the diffusion becomes nonuniform and irreproducible. Slight changes in oxygen concentration cause large changes in diffusion profile (3).

An alternative system has been suggested by Nakamura (4) in which CO_2 rather than O_2 is used as the oxidant. The intent here is to study this system in more detail. In this diffusion system, CO_2 oxidizes B_2H_6 to produce B_2O_3 analogous to reaction [1]

$$B_2H_6 + 6CO_2 \rightarrow B_2O_3 + 6CO + 3H_2O \qquad [6]$$

The diffusion of boron then proceeds according to reactions [2], [3], and [4].

Experimental Results

In the experiments performed, the material used was 1-2 Ω-cm, phosphorus-doped, <100> oriented silicon. The diffusion system consisted of a 6 cm diam, 1m long quartz tube, and 15 cm long × 5 cm wide quartz boat. In a series of experiments 30 min predepositions were done. The oxidant (CO_2 or O_2) and B_2H_6 were switched on at least 30 min before the predeposition to ensure the stability of the gas flow. After the predeposition the wafers were etched in dilute HF and sheet resistance was then measured with a four-point probe. Since the junctions involved were very shallow, osmium tip probes with a low force of 45g were used. In all of the experiments the total flow of gases was kept at 2.5 liter/min.

In the first experiment at a temperature of 850°C, keeping diborane at 130 ppm, carbon dioxide was varied from 0.2 to 1.2%. The results of 30 min predepositions are shown in Fig. 1. It seems that around 0.4-0.8% CO_2 gives the lowest sheet resistance.

In the second experiment at the same temperature of 850°C, carbon dioxide was kept at 0.6% and diborane was varied from 25 to 200 ppm. The results of 30 min predepositions are shown in Fig. 2. It seems that 80-160 ppm B_2H_6 gives the best results. In both of these experiments it was found that for correct amounts of CO_2 and B_2H_6 the thickness of boron glass was so small

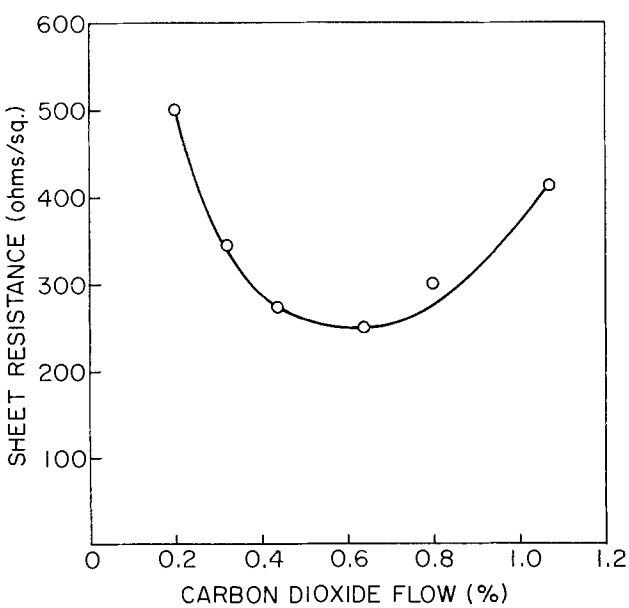

Fig. 1. Effect of CO_2 variation on sheet resistance of 30 min predeposition: T = 850°C, B_2H_6 = 130 ppm.

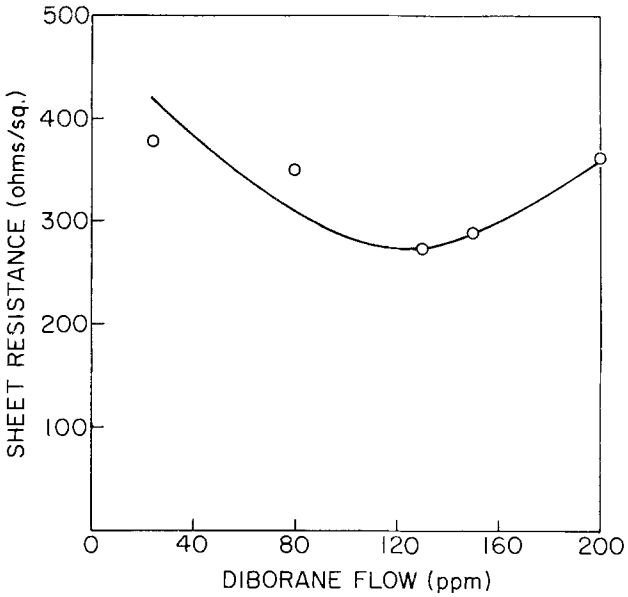

Fig. 2. Effect of B_2H_6 variation on sheet resistance of 30 min predeposition: $T = 850°C$, $CO_2 = 0.6\%$.

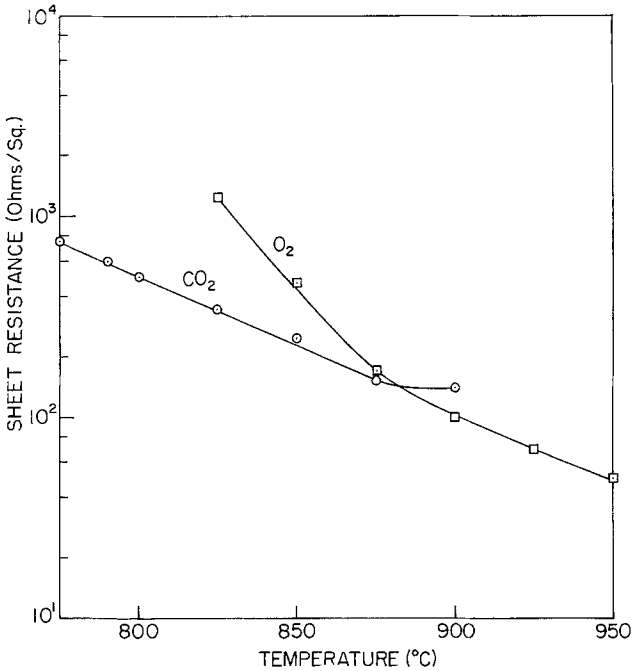

Fig. 3. Effect of temperature variation on sheet resistance of 30 min predepositions: $B_2H_6 = 130$ ppm, $CO_2 = 0.6\%$, $O_2 = 0.2\%$.

that it took only 5-10 sec to etch it using 2% HF in water. However, if too high or too low CO_2 flow or too high B_2H_6 flow was used, deposits of milky color were found on the Si surface. For low and medium flow of B_2H_6 no milky deposits were found. The milky deposits were always associated with higher sheet resistance.

In the third experiment 0.6% carbon dioxide, 130 ppm diborane, and the rest nitrogen were used and 30 min predepositions were done in a temperature range of 775°-900°C. The same experiment was repeated, replacing carbon dioxide with 0.2% oxygen, in the temperature range of 825°-950°C. The results of these experiments are shown in Fig. 3. The flow rates for the B_2H_6-O_2 experiment were optimized to get the lowest sheet resistance (5). Again, it was observed that for the B_2H_6-CO_2 system at temperatures higher than 900°C, milky deposits were found on the surface for all combinations of gas flow and the sheet resistance was very high and uncontrollable.

Discussion

Looking at Fig. 3 it is evident that at temperatures lower than 875°C the B_2H_6-CO_2 system gives much better results than the B_2H_6-O_2 system. However, at higher temperatures the B_2H_6-O_2 system gives better results. As we discussed above, the formation of a SiO_2 barrier between B_2O_3 and SiB_n takes place. Evidently, at temperatures higher than 875°C, in the B_2H_6-O_2 system the B_2O_3 penetrates through this barrier and formation of SiB_n is continuous. However, below 875°C the rate of formation of SiO_2 is faster than the rate of B_2O_3 penetration through it, leading eventually to the disappearance of SiB_n. This results in the reduction of surface concentration of boron (3). This is reflected by a sharp increase in sheet resistance as seen in Fig. 3.

In the B_2H_6-CO_2 system the only oxygen present is because of reduction of CO_2 to CO and O_2

$$2CO_2 \leftrightarrows 2CO + O_2 \qquad [7]$$

However, only 10^{-5} to 10^{-3} of CO_2 decomposes by the above reaction in the temperature range of 800°-1000°C (4). Therefore, the oxidation of SiB_n is negligible. This allows the silicon surface to be saturated with boron. This is reflected in the temperature range of 775°-875°C shown in Fig. 3. At higher temperatures CO decomposes to elemental carbon and oxygen, and carbon deposition on the silicon surface probably changes the diffusion properties of boron

$$2CO \rightarrow C + O_2 \qquad [8]$$

Conclusion

The B_2H_6-O_2 diffusion system for boron diffusion is limited to temperatures higher than 875°C because of a strong oxidizing ambient created by O_2. By replacing O_2 with CO_2, the range of diffusion in the above experiments has been lowered to 775°C. The use of the B_2H_6-CO system allows work at solid solubility. Therefore, the reproducibility of the process is better.

Characterization of Microplasma Sites in Silicon n^+-p Junctions

C. Donolato, P. G. Merli, and I. Vecchi

C.N.R.-LAMEL, 40126 Bologna, Italy

A major requirement for the production of avalanche photodiodes with large active area and high gain is the elimination of microplasmas, *i.e.*, small defective areas with lower breakdown voltages than that of the junction as a whole (1).

Many properties of microplasmas in p-n junctions have been investigated [for a review see (2)], but only in a few cases has the detailed structure of the defect causing premature breakdown been stated. Recently, defects causing excess reverse leakage currents in boron-diffused silicon p-n diodes have been characterized in detail (3, 4).

This note reports the identification and crystallographic characterization of defects associated with microplasma sites in phosphorus-diffused silicon avalanche photodiodes, employing scanning and transmission electron microscopy. The defects are shown to consist in SiP precipitates surrounded by a dislocation network.

Experimental

Polished <111> low dislocation p-type Si wafers with 0.5 Ω-cm resistivity (nominal) were used for diode fabrication. The diode structure was of the type described by Goetzberger *et al.* (5); the active area was a circle 60 μm diameter, surrounded by a diffused guard ring 8 μm deep; the junction was formed by a shallow phosphorus diffusion about 0.3 μm deep with an integrated P concentration $Q = 5.7 \times 10^{15}$ cm^{-2}. The sequence of the main processing steps is listed in Table I.

The diodes were observed first by an optical microscope under reverse bias at high currents (up to 5 mA) to detect the localized light emission typical of microplasmas; subsequently the *I-V* characteristics were examined on a Tektronix Type 576 curve tracer to check the electrical influence of the defects. Some of the diodes were also analyzed by a scanning electron microscope (SEM) in the electron beam induced current mode (EBIC) (3, 6), at beam energies between 2.5 and 20 keV, to obtain a map of the electrical activity of single defects at high magnification. Finally a structural analysis at high resolution was carried out on some representative diodes with the transmission electron microscope (TEM) at 200 keV after jet chemical thinning of the active area of the diode.

Results and Discussion

Figure 1 is an optical micrograph of the active area of a typical defective diode under reverse bias, showing two bright spots in the diffused recombination radiation of the junction. The *I-V* characteristic of this diode up to 1.5V before bulk breakdown ($V_B \approx 30$V) is like that of a defect-free diode, with a reverse current lower than 20 nA. The microplasmas exhibit their influence only in the breakdown region with the presence of of two kinks in the characteristic (Fig. 2).

The same diode was also examined by SEM in the EBIC mode at bias voltages near V_B (at low bias no contrast was observable) using different beam energies. The resulting images always showed two current enhancement spots at positions where microplasmas emission did, indicating that the sites of high radiative recombination are also sites of localized current multiplication (2, 7).

Figure 3 reports the EBIC image at high magnification of a single microplasma site at a reverse bias just below the turn-on voltage and indicates that the current enhancement is not uniform across the defect showing some points of lower current multiplication. A beam energy of 2.5 keV was selected as it allowed

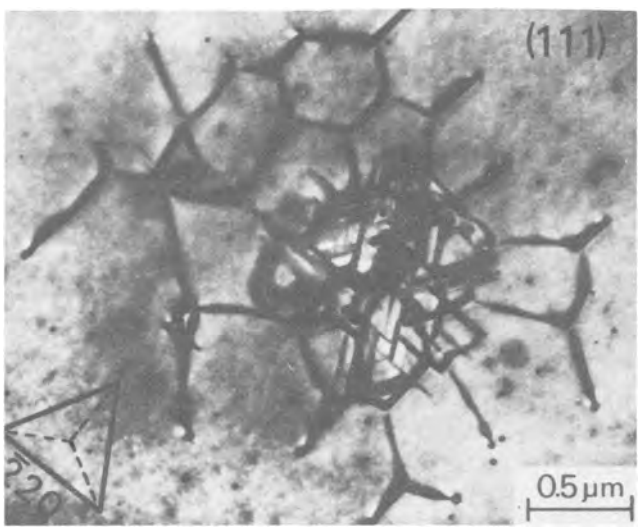

Fig. 4. TEM micrograph of a typical defect corresponding to a microplasma site, showing an aggregate of precipitates surrounded by dislocations.

sufficient carrier injection and the the best spatial resolution; in fact, increasing beam energy reduced the detail of the features of Fig. 3.

To identify the structure of the defects associated with microplasmas, some diodes were also analyzed by TEM. These observations indicated that the defects corresponding to microplasma sites had essentially the same crystallographic structure. The transmission electron micrograph of a typical defect is reported in Fig. 4. The micrograph shows that the defect consists of an aggregate of rodlike precipitates surrounded by a dislocation network. These precipitates, recently studied in detail (8), were found to be SiP orthorhombic crystals aligned with the <110> direction of silicon parallel to the sample surface and lying on the inclined {111} planes. The dislocations of Fig. 4 are of three different kinds, each being in one of the three <211> directions in the (111) plane of the sample; these dislocations are edge-type with Burgers vectors lying in the <110> directions of the sample plane.

It would be interesting to correlate the electrical activity of microplasmas with their crystallographic structure; no simple correspondence, however, appears from Fig. 3 and 4, although the features displayed are typical of all defects. Recent observations (9) showing the vanishing of EBIC dislocation contrast at high reverse bias suggest that the image contrast of Fig. 3 is essentially due to precipitates. Their presence in the space charge region produces a local enhancement of the electric field responsible for the high multiplication effects observed.

For a better understanding of the relationship between electrical activity and structure of a particular defect, images of the same defect by SEM and TEM would be required. Besides the practical difficulties in achieving these results, the much lower resolution of the SEM in the EBIC mode in comparison with the TEM sets definite limits to the detail of the correspondence. This limitation evidences the interest of other techniques which may provide a direct observation of the interaction between a particular defect and the depletion field of the p-n junction (10).

The present observations, however, have established the microstructure of defects causing microplasmas in shallow-diffused n^+-p junctions; their nature indicates that they are related to phosphorus precipitation. Further investigations on the processing step responsible for their nucleation are in progress.

Kinetics and Mechanism of Oxygen Film Electroformation up to a Monolayer Thickness at the Pt/$KHSO_4$ (Melt) Interface and Its Relation with the Electroreduction Process

J. O. Zerbino, N. R. de Tacconi, A. J. Calandra, and A. J. Arvia*

Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas, Sucursal 4, Casilla de Correo 16, 1900 La Plata, Argentina

ABSTRACT

The potentiodynamic E/I response of the Pt/$KHSO_4$(melt) interface in the potential range of the oxygen monolayer electroformation and electrodissolution under different perturbation conditions is investigated. Both the anodic and cathodic experimental results are satisfactorily explained by a reaction model involving different surface species which are formed either in successive electron transfer steps or by simple chemical processes, including the aging of the oxygen-containing species formed as reaction intermediates.

Oxide monolayers, either adsorbed or chemisorbed, can be electroformed under different potential conditions on various noble metal electrodes immersed in both aqueous acid and molten electrolytes (1-10). These monolayers, which involve different oxygen-containing species, can be also quantitatively electroreduced under properly chosen experimental conditions. The electrode processes, either anodic or cathodic, are far more complex than previously thought (7), since the different reacting species and intermediates undergo surface-state transformations and, occasionally, dissolution processes which were overlooked for a relatively long time. The existence of intermediate species was evidenced by means of the modulated voltammetry technique (10).

Nevertheless, under certain circumstances it is possible to keep the chemical transformations (aging) under control and to obtain then reproducible and coherent kinetic data related to a particular process, which can be interpreted in mechanistic terms. In this way the electroreduction of a surface oxygen atom monolayer at the Pt/bisulfate (4, 5, 10) and Au/$HClO_4$ and Au/H_2SO_4 interfaces (11, 12) were better understood, once both the aging and the chemical dissolution were kept under a certain control (4, 5). The situation, however, turned more difficult for the monolayer electroformation since in this case, although the chemical dissolution can be disregarded, the aging occurs simultaneously with the proper electrochemical reaction and it becomes practically impossible to separate the individual contributions into the over-all anodic reaction.

The present report attempts precisely to gain further knowledge about the possible mechanism of the electrochemical reactions occurring at the Pt/$KHSO_4$(melt) interface particularly for the anodic process, taking into account the conclusions derived from the theoretical reaction mechanisms previously discussed (13). The postulated complex reaction pathway explains the various E/I profiles, either anodic or cathodic, resulting under different potential perturbation conditions. Moreover, the electroreduction of the aged surface oxygen-containing species, which has been more extensively studied, can also be interpreted through the same reaction pathway.

Experimental

The experimental setup and the working conditions for the Pt/$KHSO_4$(melt) and Pt/$NaHSO_4$ + $KHSO_4$ (1:1) (melt) interfaces were the same as described previously (4, 5). Experiments were made at temperatures between 223° and 257°C. The potentials are referred to the Pt/H_2(1 atm)/$KHSO_4$(melt) electrode. Two basic experimental techniques are used, namely, either the linear potential sweep (LPS) or the triangular potential sweep (TPS) techniques employing different potential/time perturbation functions, as described elsewhere (12), and the triangular modulated linear potential sweep technique (TMLPS) (14).

The corresponding circuitry is essentially that already referred to in previous publications (11, 12) including a fast risetime potentiostat (Tacussel Type PIT 20-2X, risetime = 0.2 μsec) and an ohmic drop compensator (Tacussel Type CDCO).

Results and Interpretation

When the Pt/$KHSO_4$(melt) interface is perturbed with a symmetric TPS from E_i = 0.2 to 0.6V at potential sweep rates, v, between 10 and 150 mV/sec, the E/I displays, apart from the double layer charging and discharging (Fig. 1), show, as already known, an anodic current region involving the formation of an oxygen monolayer on the metal and a cathodic current region corresponding to its electroreduction. The E/I profiles show a broad anodic current peak and a cathodic current peak, the latter being narrower and more symmetric in shape than the former. The potential of the anodic current peak becomes more positive when

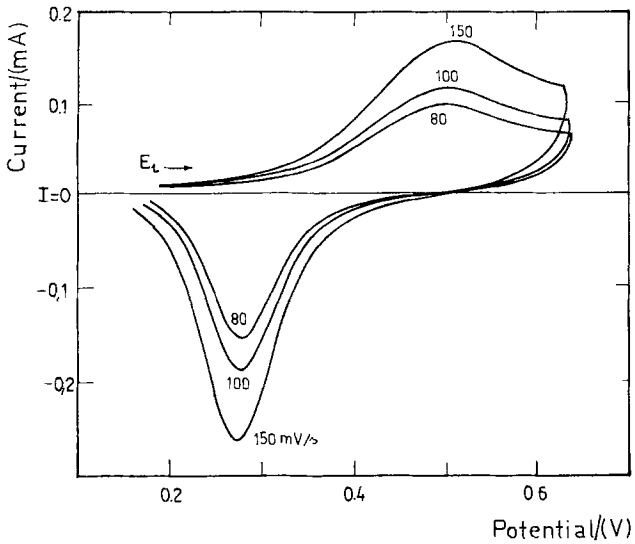

Fig. 1. Single triangular potential sweep voltammograms run at different potential sweep rates ($v_a = v_c$), starting from E_i toward anodic potentials. $KHSO_4$ at 229°C.

v increases. Its rate of shift is, however, small $(d(E_a)_p/d \ln v) = 3$ mV at 257°C. The anodic charge decreases when v increases. The potential of the cathodic current peak depends simultaneously on the various parameters as already discussed (4).

Voltammograms run with a TPS from E_i up to various anodic potential limits at two different v (Fig. 2) show that at a constant potential the initial portion of the cathodic E/I profile exhibits a cathodic current which increases as v increases. This reveals that the characteristics of the reacting species involved in the electroreduction depend on the time spent for its anodic formation.

The E/I display obtained between $E_i = 0.2$ and 0.7V with a TMLPS employing a guide ramp at $v_g = 1.5$ V/sec and a superimposed triangular modulating signal at $v_s = 20$ V/sec, and a potential amplitude $A_s = 60$ mV (Fig. 3) presents well-defined anodic and cathodic contours and an intermediate gap related to double layer charging and discharging due to the modulating signal. The lines corresponding to each modulating half-cycle all along the upper anodic contour are practically straight lines while those corresponding to the lower cathodic contour exhibit at the end a clear curvature. This effect is more remarkable at lower potentials and suggests that the reaction initially exhibits a rather reversible behavior.

When a triangular modulated triangular potential sweep (TMTPS) is used ($v_g = 1$ V/sec, $v_s = 10$ V/sec, $A_s = 40$ mV), the E/I displays corresponding to the anodic and the cathodic scans are completely different (Fig. 4). Thus, while the modulated anodic scan exhibits together with the anodic current a net cathodic contribution, the modulated cathodic scan presents along the whole potential range only a cathodic current.

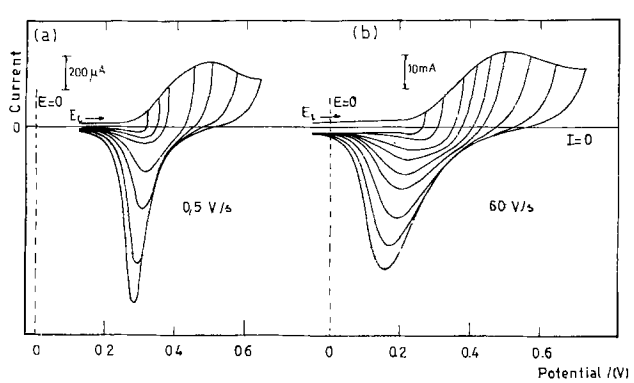

Fig. 2. Single triangular potential sweep voltammograms started at E_i and covering different potential amplitudes. $KHSO_4$ at 256°C. (a) $v_a = v_c = 0.5$ V/sec. (b) $v_a = v_c = 60$ V/sec.

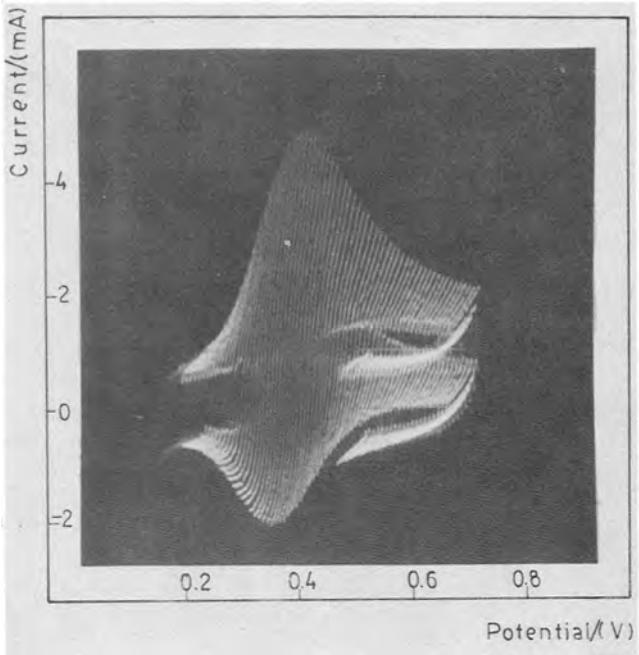

Fig. 3. E/I profile obtained with a triangular modulated linear potential sweep, $v_g = 1.5$ V/sec. $v_s = 20$ V/sec, $A_s = 0.06$V, electrode area 0.5 cm². $KHSO_4$ at 257°C.

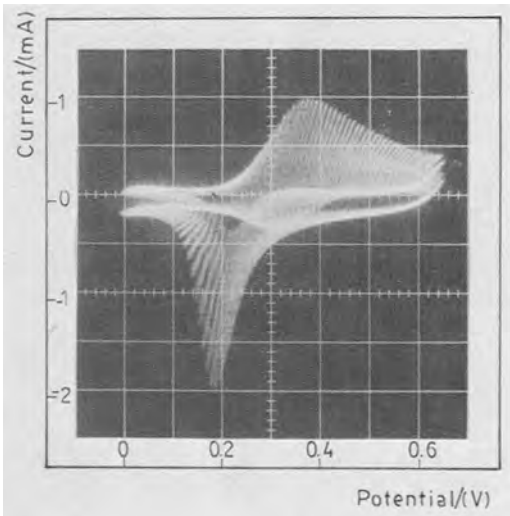

Fig. 4. E/I profile obtained with a triongular modulated triangular potential sweep, $v_g = 1$ V/sec, $v_s = 10$ V/sec, $A_s = 0.04$V, electrode area 0.5 cm². $KHSO_4$ at 223°C.

The experiments run with TMLPS covering increasing amplitudes and keeping both v_g and v_s constant show (Fig. 5) the increase of Q, the total charge, as well as Q_a, the anodic charge, and Q_c, the cathodic charge, although the Q_a/Q_c ratio increases. These results imply a certain degree of irreversibility of the over-all process (13). On the other hand, the cathodic scan exhibits a larger anodic current contribution when the amplitude of the modulating signal increases. In the anodic potential sweep at low anodic potentials, that is, on the very initial portions of the E/I envelope, any change of the amplitude of the modulating signal has no appreciable effect, as should occur for a reversible electrochemical system. But the situation is different at higher anodic potentials, as the difference between the anodic and the cathodic current peak potentials increases with the amplitude of the modulating

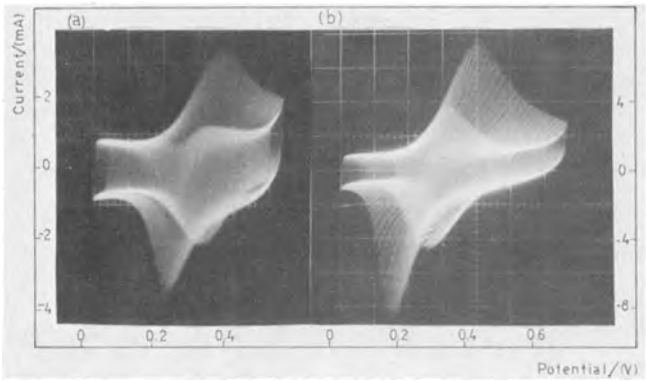

Fig. 5. *E/I* profiles run with a triangular modulated triangular potential sweep. $KHSO_4$ at 250°C. (a) $v_g = 1.5$ V/sec, $v_s = 50$ V/sec, $A_s = 0.045$V. (b) $v_g = 1.5$ V/sec, $v_s = 50$ V/sec. $A_s = 0.180$V.

signal. This indicates the contribution of an irreversible electrochemical process at higher anodic potentials.

Figure 6 shows *E/I* profiles obtained with different potential/time programs as indicated for each run. Thus, the display shown in Fig. 6a, which exhibits only a single electroreduction current peak, entails an initial linear anodic potential scan covering a relatively small amplitude, so that only a fraction of the monolayer is formed, then the system is potentiostated for 5 sec at E_f, and finally the cathodic potential scan is run. The *E/I* record depicted in Fig. 6b comprises a 5 sec aging time at E_f as before, but immediately after, the anodic scan is continued a few millivolts beyond E_f, followed by the reverse cathodic scan. The *E/I* display now exhibits two cathodic current peaks, one at lower potentials which coincides with that already described in Fig. 6a, and another one at higher potentials, corresponding to the electroreduction of the most reactive product of the anodic reaction.

An increase of the interruption time during the anodic potential sweep implies the formation of a relatively larger amount of the more stable species (Fig. 7a), as seen through the charge increase of the cathodic current peak located at more negative potentials. Under a STPS the same effect is noticed when the anodic limit of the potential excursion increases (Fig. 7b). The potential associated with the more cathodic current peak becomes more negative as the anodic charge increases and simultaneously the cathodic contour becomes wider since it includes at least the electroreduction of different species anodically formed. For a constant charge, the larger the time the system is

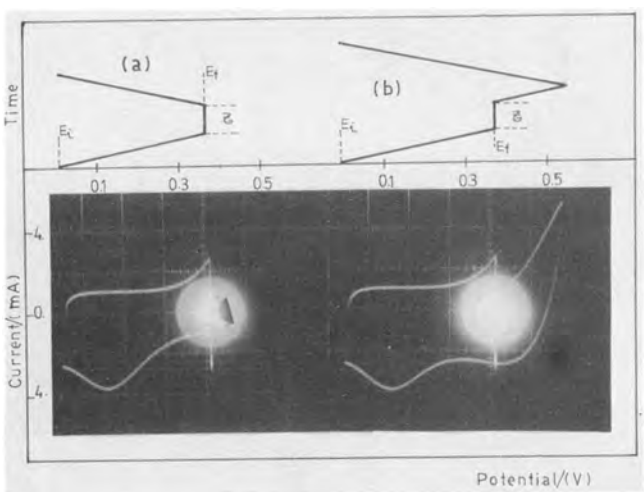

Fig. 6. *E/I* profiles obtained with potential/time programs involving potentiostating at E_f, as indicated in the figure. $v_a = v_c = 80$ V/sec, $\tau = 5$ sec. $KHSO_4$ at 225°C.

Fig. 7. (a) $v_a = v_c = 80$ V/sec, $\tau = 5$, 5×10^{-1}, and 5×10^{-3} sec. (b) $v_a = v_c = 80$ V/sec.

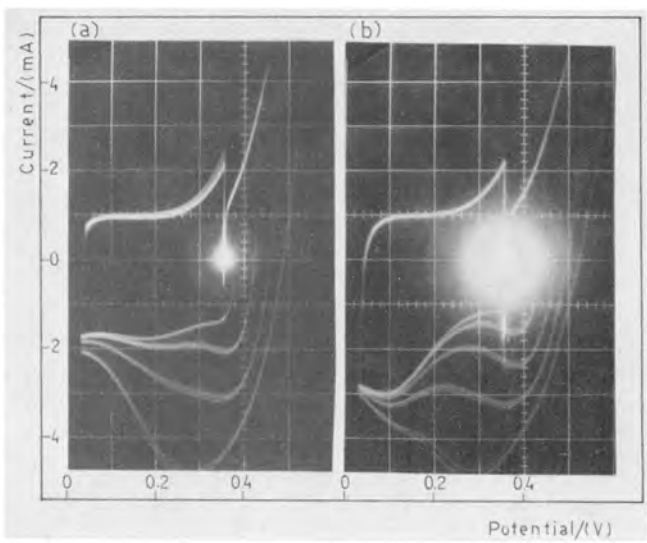

Fig. 8. *E/I* profiles obtained with the potential/time program indicated in Fig. 6b, covering different potential amplitudes. $KHSO_4$ at 225°C. (a) $v_a = v_c = 80$ V/sec $= 5 \times 10^{-2}$ sec. (b) $v_a = v_c = 80$ V/sec, $\tau = 5$ sec.

maintained at E_f, the better the definition of the single cathodic current peak situated at lower potentials.

The *E/I* profiles resulting when the anodic potential scan continues to larger anodic potentials after potentiostating the system (Fig. 8), imply that, during the cathodic scan, an increasing contribution of the electroreduction process is associated with the more reactive species produced during the electro-oxidation. Therefore, the initial species accumulated during the electrooxidation can be reversibly electroreduced before it undergoes a transformation into a more stable state. Hence, if the electroreduction of the anodic species occurs very rapidly, the cathodic *E/I* profile approaches a reversible response. This behavior, in principle, is independent of the surface coverage degree and of the aging time of the anodic product initially formed.

Discussion

The results obtained with the different potentiodynamic techniques reveal that at least two species participate in the over-all electrode process. The different voltammograms can be satisfactorily compared with those derived from a reaction model involving, for the anodic process, two consecutive electron transfer steps, each one involving the formation of surface covering species, coupled to a parallel chemical transformation

of the surface species formed during the first step into the surface species formed during the second step. In terms of the simplest chemical equations the reaction scheme postulated for the anodic reaction is

$$\mathrm{Pt} + \mathrm{H_2O} \xrightarrow{k_1} \mathrm{Pt(OH)} + \mathrm{H^+} + e^- \qquad [1a]$$

$$\mathrm{Pt(OH)} \xrightarrow{k_2} \mathrm{Pt(O)} + \mathrm{H^+} + e^- \qquad [2a]$$

$$\mathrm{Pt(OH)} + \mathrm{Pt(OH)} \xrightarrow{C_3} \mathrm{Pt(O)} + \mathrm{H_2O} + \mathrm{Pt} \qquad [3]$$

where the rate of step [1a] is larger than the rate of step [2a].

The same reaction model applies to the electroreduction of either the monolayer or a fraction of it (13). So the cathodic process corresponds to a first electron transfer involving the electroreduction of the more stable surface species into the more reactive one followed by a second electron transfer step where the latter is further electroreduced to leave finally a clean metal surface. Thus, the simplest cathodic reaction scheme is

$$\mathrm{Pt(O)} + \mathrm{H^+} + e^- \xrightarrow{k_{-2}} \mathrm{Pt(OH)} \qquad [2c]$$

$$\mathrm{Pt(OH)} + \mathrm{H^+} + e^- \xrightarrow{k_{-1}} \mathrm{Pt} + \mathrm{H_2O} \qquad [1c]$$

where step [2c] is now slower than step [1c].

In the following θ_1 and θ_2 refer to the degree of surface coverage by Pt(OH) (species 1) and Pt(O) (species 2), respectively. In principle, the energetic configuration of these species might depend both on the total surface coverage degree and on the rate of the potential perturbation applied to the metal/electrolyte interface.

The reaction pathway involving steps [1] and [2], the former being slower than the latter ($k_{-2} > k_{-1}$), was already postulated as an attempt to explain the cathodic potentiodynamic E/I profile obtained with the Pt/H_2SO_4(aq) interface at room temperature (16). However, when this reaction model is tried with the present results it fails to give a satisfactory explanation of the over-all E/I characteristics. The anodic reaction scheme implies a decrease of the total anodic charge on increasing v at a constant potential amplitude. The slow rate of the second step causes the amount of electro-oxidation product to decrease as the rate of the potential perturbation increases, because the rate of the reaction which produces it is unable to keep along with the rate of the potential perturbation. This effect, however, does not necessarily imply a shift of the anodic current peak potential toward more anodic potentials as one would expect for a simple irreversible process (15).

The existence of a second electrochemical step, which is more irreversible than the first one, requires that the anodic side of the TMLPS voltammogram involving the first reversible couple, at v_g and v_s, be matched to the anodic over-all TPS E/I profile at $v = v_g + v_s$ (13) (Fig. 9). The extent of the contribution of the first reversible process depends, however, on the anodic potential limit. As the latter becomes more anodic the amount of the second species, which is bound to the slower electrochemical reaction, also increases.

A further comparison between the experimental results and the response of the different reaction models to potential perturbations (13) shows that the existence of cathodic current maxima at the end of each triangular modulating cycle in the TMLPS confirms the reversible characteristics of step [1]. Moreover, the occurrence of step [2] at a rate slower than that of step [1] promotes an increase of the Q_a/Q_c ratios above unity and a separation of the corresponding anodic and cathodic current peak potentials. A comparison of the cathodic current maxima of the initial portions of the

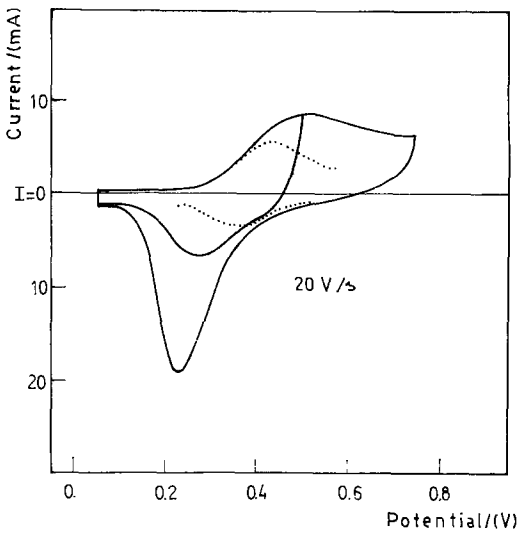

Fig. 9. Comparison between a STPS voltammogram run at 20 V/sec and a TMLPS E/I display run at $v_g = 1.5$ V/sec, $v_s = 20$ V/sec, $A_s = 0.06$V. $KHSO_4$ at 257°C. Full lines correspond to the TPS and dotted lines correspond to the envelopes of the TMLPS.

experimental E/I display with the theoretical one recorded under the same perturbation conditions and involving just only one surface coverage species, permits the estimation of the lower limiting value of the rate constant at equilibrium of step [1]: $k_1 = 2 \times 10^2$ mA/cm^2. Nevertheless, the slope of the E/I line at the inversion of the modulating signal in the potential region of the current peak yields $k_1 = 10^2$ mA/cm^2. The lower value is obviously influenced by the occurrence of step [2]. The slope of the E/I lines decreases due to the change of coverage from θ_1 to θ_2.

The appearance of a single anodic and a single cathodic current peak during the triangular potential excursion suggests that E_D, the potential difference between the equilibrium potentials of step [1] and step [2], is either zero or negative. Complementary kinetic information can be gained through the influence of the amplitude of the modulating signal in the TMLPS experiments as it can be seen in Fig. 5. Thus, during the initial portion of the cathodic E/I profile the anodic contribution increases with the amplitude of the modulating signal since the partial modulating potential excursion goes through a potential region sufficiently cathodic allowing, thus, the electrochemical conversion from a surface covered by species 2 into a surface covered by species 1. This process is assisted both by the fast first electron transfer step and by the potential which is cathodic with respect to the equilibrium potential of step [1]. Consequently, the reaction yields a relatively large extent of bare metal surface, which in the subsequent partial anodic half-cycle is covered through step [1]. Under these conditions the modulating potential scan covers the equilibrium potential of step [1], and species 1 which behaves as a reversible intermediate is, therefore, electrochemically caught up.

The cathodic E/I profile observed for the largest amplitude of the modulating signal (Fig. 5b) shows a double E/I profile, in good correspondence with the maxima of the envelope of the modulated anodic potential scan. This double E/I profile necessarily implies for the cathodic process a slow first reaction step [2c] followed by the more reversible step [1c] whose equilibrium potential either coincides with the equilibrium potential of step [2], or is more anodic than that of the latter (13). The anodic E/I envelope, recorded during the cathodic excursion with a TMTPS, is smaller than the envelope recorded during the anodic excursion, because the surface during the former potential excursion is mainly covered by species 2. The latter hinders the θ_1 to θ_2 transformation and, consequently,

species 1 accumulates on the rest of the metal surface during the cathodic potential excursion.

The mechanism involving three reaction steps explains now why the anodic *E/I* profile under a STPS becomes practically independent of v, namely, the anodic process apparently behaves as a quasi-equilibrium process, while the cathodic scan results are much more irreversible (13). During the anodic reaction steps [1a] and [3] are much faster than step [2a] while the cathodic process is mainly controlled by step [2c]. Nevertheless, the reaction mechanism should be still completed to include the aging of the surface species.

The aging effect must be related to a physicochemical change of species 2, attaining a more stable configuration at the electrode surface. The over-all aging can be formally written as follows

$$\mathrm{Pt(O)} \rightarrow [\mathrm{Pt(O)}]^* \qquad [4]$$

where the asterisk refers to the aged component.

As far as the anodic process is concerned the aging process as well as step [3] occur simultaneously along with the electroformation of the monolayer. The aging has no appreciable influence on the Q_a/Q_c ratio, obtained from the single TPS records. This ratio is always practically one if any chemical dissolution of the oxide film is restrained. The occurrence of step [4] means that the electroreduction may start either from Pt(O) or from [Pt(O)]* and during the potentiodynamic transient, the rate of the over-all process should depend on the relative ratio of those species.

In the quantitative evaluation of the experimental *E/I* profiles the aging effect can be formally taken into account through a time-dependent k_{-2} rate constant, which diminishes as the time elapsed between the anodic and the cathodic processes increases, since any aging of species 2 implies a decrease of the surface activity of the latter. Hence, the rate constant becomes a complex function of θ_1, θ_2, and E.

The former assumption is equivalent to a shift of $(E_{eq})_2$ toward more negative potentials as the electrochemical reaction proceeds, since the rate constant of step [3] should be, in principle, regarded as time independent. Either the k_{-2} time dependence or the shift of $(E_{eq})_2$ when the reaction proceeds, explains the small potential shift of the cathodic current peak when the aging process is uncontrolled. These assumptions, however, are still insufficient to explain why the anodic current peak becomes practically independent of v. To reproduce the whole voltammograms within the range of experimental errors under any perturbation conditions, the reaction model must include the assumption that the rate of any reaction yielding species 2 slows down when the contribution of the aging process increases. Whatever the case the net effect of aging corresponds to a decrease of the rate of the over-all anodic process.

The voltammograms calculated for the reaction pathway just discussed are depicted in Fig. 10. For the sake of simplicity, the rate constant of step [2c] is regarded as independent of θ and E, but it depends on t following an exponential law. The rate of step [2c] is numerically calculated as the sum of the partial rates, $v_{-2} = k_{-2}(t)\Delta\theta_2 \exp[f(E,\theta)]$, the time t is taken from the instant when $\Delta\theta_2$ becomes positive, while the rate constant of step [3] decreases with time analogously as k_{-2}.

Under the experimental conditions of Fig. 10a, the largest θ_1 value ($\sim$0.1), during the anodic scan is observed at 0.006V. This coverage by species 1 is evidenced during the partial cathodic scans of lower potential amplitude giving a rather reversible initial *E/I* response. The electroreduction of freshly formed species 2 which remains unaged, also contributes, although to a lesser extent, to the reversible initial *E/I* profile just described. The *E/I* profiles thus calculated are satisfactorily coincident with the experimental ones, taking into account the small potential shift

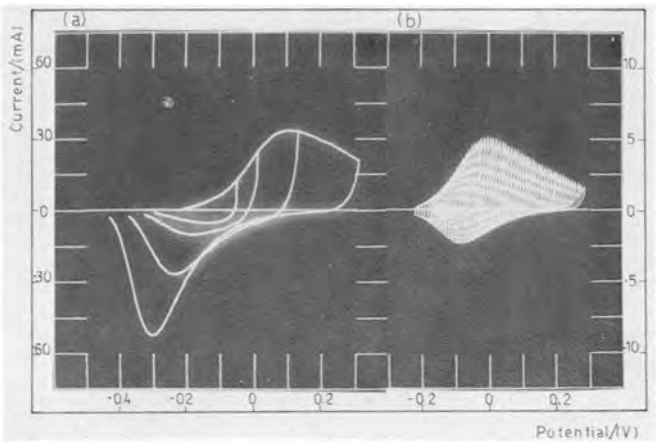

Fig. 10. Theoretical *E/I* displays calculated with the following parameters. $k_1 = k_{-1} = 10^3$ mA/cm^2; $k_2 = 0$; $k_{-2} = a[1 + b\exp(-ct)]$, where $a = 3$ mA/cm^2, $b = 7.5$, and $c = 120$ sec^{-1}; $C_3 = 3 \times 10^3$ sec^{-1}; k (one electron per particle) $= 0.21$ mC/cm^2; $\alpha_1 = \alpha_2 = \beta_1 = \beta_2 = 0.5$; Temkin factors: $g_1 = 10$, $g_2 - g_1 = -2$. T = 240°C. (a) STPS at $v = 60$ V/sec. (b) TMLPS at $v_g = 1.5$ V/sec, $v_s = 20$ V/sec, $A_s = 0.06$V.

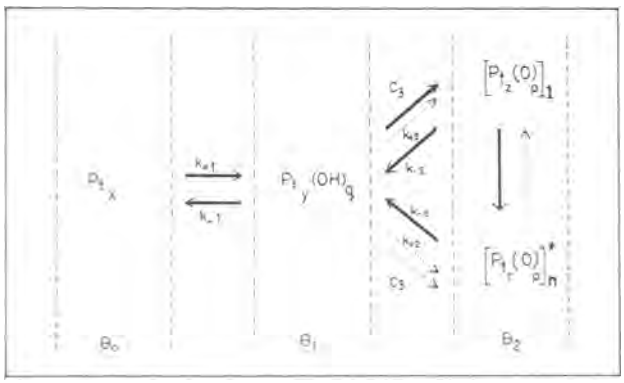

Fig. 11. Scheme of the reaction pathway and definition of the kinetic parameters. $(x + y + z)\theta = 1$; lim $\Sigma(p + q) \rightarrow 1$; $0 < (p/z) \leq 1$; $0 < (q/y) < 1$.

either of the anodic and cathodic current peaks with the potential sweep rate, depending on the perturbation conditions. The simplified diagram of Fig. 11 illustrates the possible reaction pathway involved in both the anodic and cathodic processes.

Although the coincidence between the reaction model and the experimental results is reasonably good, the oversimplification of any reaction model based upon a reduced number of possible reacting intermediates should be emphasized. On dealing with these processes in mechanistic terms one refers to reaction sequences with simple particles which remain unaltered during the course of the reaction. Undoubtedly the interpretation of these processes would be more realistic if it were based upon a continuity of states related to the species existing on the surface either for the anodic or the cathodic reactions. When a monolayer film is either formed or destroyed there is a continuous change of the surface composition between $\theta = 0$ and $\theta = 1$ or vice versa, respectively. This means that the surface energy distribution and the interaction terms, as well as the number of available sites on the surface, should change during the course of the reaction. Therefore, no simple stoichiometries are really representing the actual atom to atom ratio, but a continuous series ranging, for the anodic process, from a O/Pt ratio equal to zero up to a O/Pt ratio equal to 1, and vice versa for the cathodic process. Certainly, some of them may approach relative stable configurations which can be roughly compared to simple chemical stoichiometries of single molecules, as it has been

discussed for the case of gold oxide monolayers formed at the $Au/H_2SO_4(aq)$ and $Au/HClO_4(aq)$ interfaces (11, 12).

ABSTRACT

The electrochemistry of oxide ions was studied in molten $LiF-BeF_2-ZrF_4$ [65.6-29.4-5.0 mole percent (m/o)] and $LiF-BeF_2-ThF_4$ (72-16-12 m/o) at gold, iridium, and glassy carbon electrodes in the temperature interval 500°-710°C. Well-defined and reproducible voltammograms could be obtained only at gold electrodes. Cyclic voltammetric and chronopotentiometric results indicate the following electrochemical reaction pathway

$$O^{2-} = O + 2e$$

$$O + O = O_2$$

$$O + O^{2-} = O_2^{2-}$$

Some evidence for adsorption of O_2 was obtained. O_2^{2-} ions are oxidized further producing a voltammetric postwave which increases with Na_2O_2 additions. O_2^{2-} ions gradually decompose in these media; this decomposition is more rapid in Zr(IV)-containing melts as compared to the Th(IV)-containing melts. NaO_2 additions result in the same voltammetric results as obtained upon the addition of Na_2O_2, indicating that O_2^- ions are more unstable in these melts than in the previously studied LiF-NaF-KF eutectic. The results obtained provide the basis for an *in situ* electrochemical determination of small amounts of dissolved oxide.

The electrochemical behavior of oxide ions and related species in molten chlorides has been studied previously by several workers (1-8). However, only a limited amount of work on the electrochemistry of oxygen-containing species has been performed in molten fluorides other than cryolite (9) [for a brief summary see (10)]. Mathews and Baes (11) have studied the equilibria $H_2O + F^- = OH^- + HF$ and $H_2O + 2F^- = O^{2-} + 2HF$ in molten $LiF-BeF_2$ [66-34 mole percent (m/o)]. Whiting *et al.* (12, 13) have obtained Raman and u.v. spectra of the unstable superoxide (O_2^-) ion in molten LiF-NaF-KF (46.5-11.5-42.0 m/o).

* Electrochemical Society Active Member.

In this work we report studies on the electro-oxidation of oxide ions in molten LiF-BeF_2-ZrF_4 (65.6-29.4-5.0 m/o) and LiF-BeF_2-ThF_4 (72-16-12 m/o), melts in which insoluble oxides, such as ZrO_2, ThO_2, and BeO, are known to form (14). The main purpose of this research was to develop the basis for an *in situ* electroanalytical method for determining low levels of soluble oxide in molten salt streams of interest to the Molten Salt Reactor Program (15). We were also interested in establishing the electro-oxidation pathway for oxide ions in fluoride melts. In this connection we also looked at the electrochemical behavior of peroxide and superoxide ions in these melts. It is worth stressing that a controversy exists regarding the electrochemistry of the "oxygen electrode" in the most commonly studied melt, the LiCl-KCl eutectic. Inman and Weaver (7) state that a clear choice cannot be made from anodic chronopotentiometry between reversible reactions: (*a*) $O^{2-} + MO \overset{-2e}{\rightleftarrows} MO\text{—}O$ $2\,O \rightleftarrows O_2$ (O_2 electroinactive) where MO is the metal surface (platinum or gold) partly covered with oxygen atoms, or (*b*) $O_2^{2-} \overset{-2e}{\rightleftarrows} O_2$ (assumed to occur on a surface covered with oxygen atoms).

Good evidence for the formation of anodic films on both noble metals was provided (7). More recently, Kanzaki and Takahashi (8) from cyclic voltammetry concluded that at platinum, rhodium, and palladium electrodes, oxide is oxidized in one step according to $O^{2-} \rightarrow O + 2e$, $O + O \rightarrow O_2$. They observed a two-step process at gold and favor the following mechanism: $O^{2-} \rightarrow O^- + e$ (first wave), $O^- \rightarrow O + e$, $O + O \rightarrow O_2$. Formation of anodic films on platinum was later considered by Takahashi *et al.* (16).

Our results in fluoride melts containing either Zr(IV) or Th(IV) differ from those in molten LiCl-KCl as is shown below.

Experimental

The experimental setup and procedures have been described previously (10, 17). The melts were prepared and purified by the Salt Production Group, MSR Program, Oak Ridge National Laboratory. These melts were contained in glassy carbon crucibles (obtained from Beckwith Carbon Corporation, Van Nuys, California). Gold, iridium, and glassy carbon unsheathed working electrodes were used. Only at gold electrodes reproducible voltammograms were obtained for the oxidation processes involving oxide and related species. Therefore, the results reported below were obtained at gold wire electrodes (diameter 0.1 cm, typical area 0.25 cm^2). Iridium quasi-reference (10) electrode was employed; the glassy carbon crucible was used as the counterelectrode. Oxide was added as either sublimed Al_2O_3 (18) or "low-temperature fired" BeO (19). The peroxide and superoxide were added as high purity Na_2O_2 and NaO_2, respectively.

Results and Discussion

Typical voltammograms of the prominent anodic wave ($E_p \sim$ 1.1-1.4V, not corrected for iR drop) observed at gold electrodes in molten LiF-BeF_2-ZrF_4 are shown in Fig. 1 and 2; similar results were obtained in LiF-BeF_2-ThF_4. Residual oxide values obtained by chemical analysis were approximately 240 ppm (3.4×10^{-2}M) for LiF-BeF_2-ZrF_4 and 110 ppm (2.3×10^{-2}M) for LiF-BeF_2-ThF_4. Additions of oxide as either Al_2O_3 or BeO produced increases in the peak current of the anodic wave at 650°C, a temperature at which we were not limited by the solubility of BeO and/or ZrO_2 or ThO_2 (20). We, therefore, attribute this wave to the oxidation of oxide ions (free or complexed) in these melts. It is of interest that the oxidation potential of O^{2-} ions is approximately 1.2V positive with respect to the reduction of Ni^{2+} in the same melts.

Scan rate studies are shown in Fig. 2. The postwave following the major anodic peak was generally more prominent at relatively fast (≥1 V/sec) scan rates; it tended to merge with the main wave at 650°C. The prepeak observed at ~+0.6V at fast scan rates (Fig. 2) was not identified. The characteristics of the prepeak varied from one gold electrode to another; its peak current generally increased with scan rate. The prepeak could be minimized by prior cycling of the electrode. The sharp increase in anodic current at ~1.8V represents the anodic limit of the melt (probably the oxidation of the gold electrode). On reverse scans, essentially no cathodic current was seen at slow scan

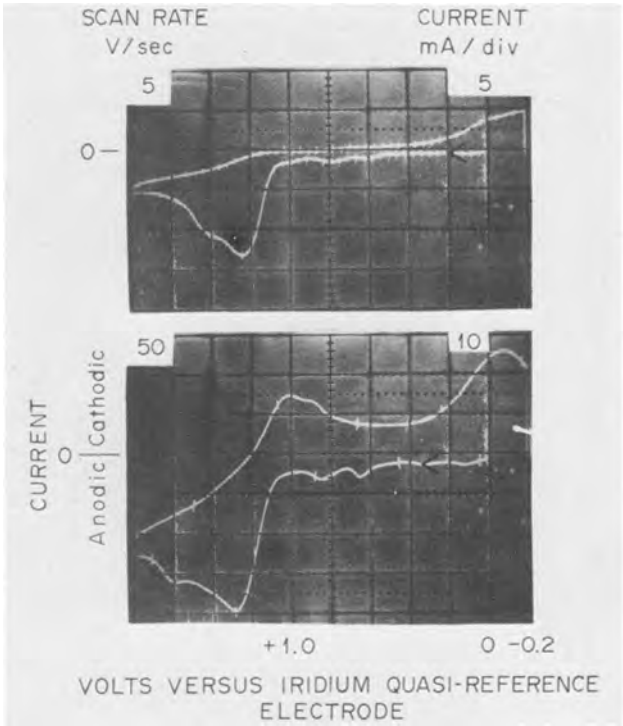

Fig. 1. Single scan cyclic voltammograms for the oxidation of O^{2-} ions in molten LiF-BeF_2-ZrF_4 (65.6-29.4-5.0 m/o). Au working electrode ($A \approx$ 0.25 cm^2), t = 500°C; melt saturated with O^{2-} ions.

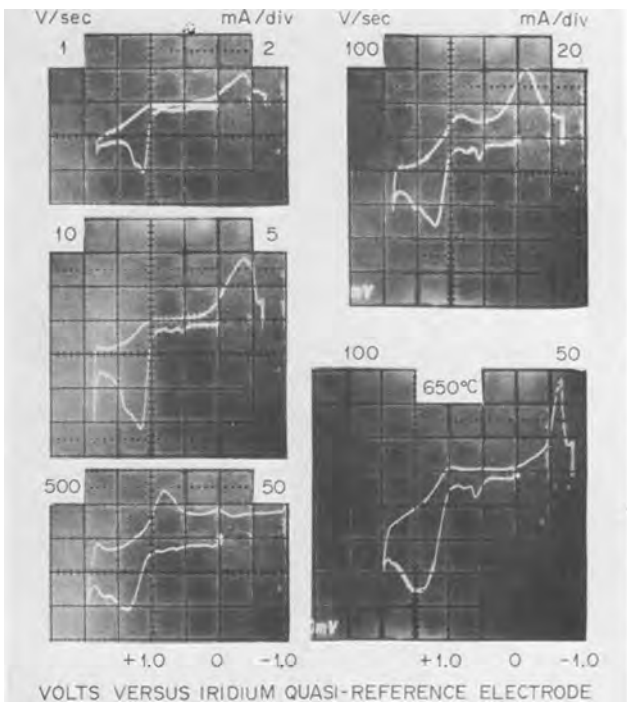

Fig. 2. Effect of scan rate and temperature on cyclic voltammograms for the oxidation of O^{2-} ions in molten LiF-BeF_2-ZrF_4. t = 500°C except where noted. Other parameters same as for Fig. 1.

rates (<0.1 V/sec); at intermediate scans (0.1-10 V/sec), a cathodic peak was observed between 0 and —0.5V. It was also observed that at fast scan rates, if the scan was reversed just after the major anodic peak but before the postwave, the cathodic peak at ~+1.0V became more pronounced while the cathodic peak at ~—0.2V became smaller. For the main anodic wave, current reversal chronopotentiograms showed that $\tau_f/\tau_r >> 3$ (21). These results suggest that we are observing an electrode reaction in which an unstable intermediate is generated which reacts to produce a more stable product.

It was attempted to compare the shape of experimental anodic voltammograms with that of the theoretical ones corresponding to case VI of Nicholson and Shain (22) (a charge transfer followed by an irreversible chemical reaction). Comparisons were made for anodic waves recorded at 0.5 V/sec to minimize iR drop after adjusting the potential-related scale to 650°C and appropriate n value and then normalizing the current function maximum to the peak current on the voltammogram. The best fit was realized at a $k_f/a \sim 4$ (22) and $n = 2$, although the shape of the theoretical waves was rather insensitive to changes in k_f/a. A more sensitive parameter is the peak potential which shifted anodically with increasing scan rate (smaller k_f/a values), although the shift was larger than the theoretical ~78/n mV/decade at 500°C (22). This discrepancy was probably caused, in part, by the large iR drop at fast scan rates.

The separation of the peak and half-peak potentials for the anodic wave, for $n = 2$, case VI of Nicholson and Shain (22), is calculated to be ~70 mV at 500°-550°C. Experimental values in both melts were in the range of 50-70 mV. The agreement is believed to be reasonable in view of the more complicated behavior of the products of the electrode reaction in the melts compared to the theoretical treatment. An $n = \sim 2$ value was also obtained from the ratio of the voltammetric $i_p/v^{1/2}$ and the chronopotentiometric $i\tau^{1/2}$ as defined by the Randles-Sevcik and Sand equations, respectively (21).

Based on these results. we postulate the following reaction pathway

$$O^{2-} \rightarrow O + 2e \quad [1]$$

$$O + O \rightarrow O_2 \quad [2]$$

$$O + O^{2-} \rightarrow O_2^{2-} \quad [3]$$

Thus, the prominent anodic wave represents the oxidation of oxide ions to atomic oxygen. The postwave, seen only at relatively fast scan rates, most likely results from the oxidation of the unstable (at least at the electrode surface) peroxy intermediate. The cathodic peak at ~+1V seen only at fast scan rates is believed to be caused by the reduction of atomic oxygen while the peak at ~—0.2V represents the reduction of molecular oxygen. Both forms of oxygen probably exist as chemisorbed species at the surface of the electrode.

The reactions

$$2\,O^{2-} \rightarrow O_2^{2-} + 2e \quad [4]$$

$$O_2^{2-} \rightarrow \tfrac{1}{2}\,O_2 + O^{2-} \quad [5]$$

appear to be ruled out by the approximate constancy of the parameter $i_p/v^{1/2}$ over a wide range of scan rates [for example, for a typical run at 650°C $i_p/v^{1/2} = 21.9 \pm 3.1$ mA sec$^{1/2}$/V$^{1/2}$ over the range of scan rates 0.1-100 V/sec; for a catalytic case, involving regeneration of reactant, a large increase in $i_p/v^{1/2}$ with decreasing v is expected (22)] and by the separation of $E_{p/2}$ and E_p (23). Although an approximately 10% decrease in the parameter $i_p/v^{1/2}$ is expected over the complete range of scan rates for case VI of Nicholson and Shain (22), the precision of our measurements (see above) is insufficient to utilize this criterion effectively. Thus, the experimental results agree best with the electrode reaction which proceeds first order in oxide with $n = 2$.

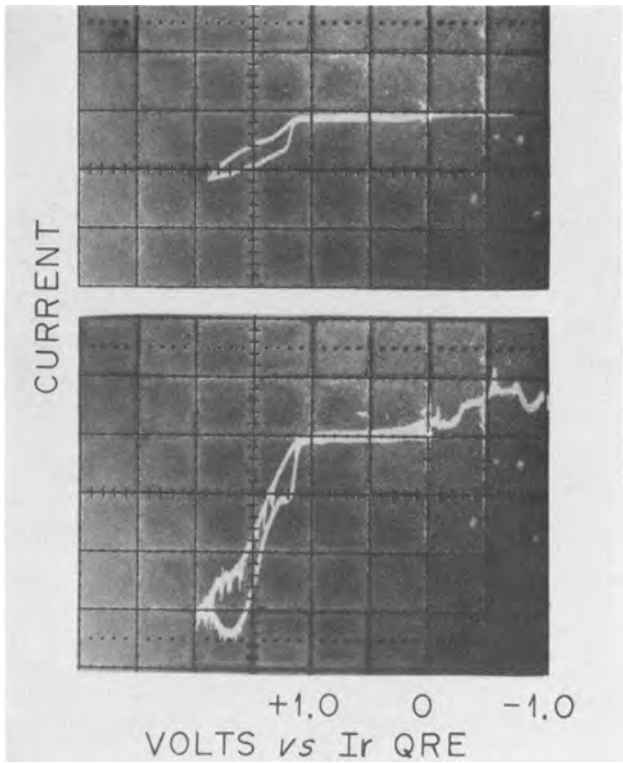

Fig. 3. Effect of Na_2O_2 additions on the height of the postwave in molten LiF-BeF_2-ThF_4 (72-16-12 m/o). Scan rate 0.1 V/sec. Upper curve, before addition; lower curve, after addition of ~3g of Na_2O_2 to ~850g of melt. t = 550°C. Au electrode ($A \approx 0.25$ cm^2). Current: 5 mA/div.

Peroxide additions resulted in a pronounced increase in the height of the postwave for both melts. The increase observed for molten LiF-BeF_2-ThF_4 is shown in Fig. 3. Similar results were obtained for molten LiF-BeF_2-ZrF_4. The equilibrium potential shifted anodically (melt became more oxidizing) and gradually approached the original value as the peroxide decomposed. Within a few hours, the peroxide decomposed from the molten LiF-BeF_2-ZrF_4 as evidenced by the cathodic shift in the equilibrium potential and decrease in wave height of the postwave. The peroxy species appeared much more stable, however, in the thorium-containing melts, taking several days to reestablish background conditions. At this time both melts were saturated in oxide; therefore, no significant changes in the main anodic wave were detected following peroxide additions. No additional reduction wave following Na_2O_2 additions was observed. Superoxide (NaO_2) exhibited the same behavior as peroxide. Apparently the NaO_2 decomposed to peroxide ($2NaO_2 \rightarrow Na_2O_2 + O_2$) and other products immediately after contacting the melts. One may speculate that the greater stability of O_2^- ions in the LiF-NaF-KF eutectic (12, 13) as compared to the melts employed in this study is due to the presence of large alkali counterions, such as K^+ ions in the alkali fluoride eutectic. It is well known (24) that the superoxides of the larger alkali ions are more stable.

The peak height of the reduction wave at ~—0.2V did not change significantly with increasing potentiostatic formation time at ~1.7V. This suggests that a chemisorbed film is formed on the electrode, after which the excess O_2 escapes from the melt. A film "aging" effect (7), however, was observed. Galvanostatic stripping curves following short formation times (5-20 sec) exhibited increasingly cathodic reduction potentials. An approximately constant $i\tau$ product was obtained which also indicates reduction of a surface film rather than a diffusing species.

In conclusion, we have shown that the electro-oxidation of soluble oxide species at gold electrodes in fluoride melts, such as LiF-BeF_2-ZrF_4 and LiF-BeF_2-ThF_4, provides the basis for an *in situ* determination of small amounts of dissolved oxide. The electro-oxidation results in atomic oxygen which rapidly recombines to form chemisorbed O_2 or reacts with the reactant O^{2-} forming O_2^{2-} which is oxidized further.

Film Breakdown on Nickel under Transpassive Dissolution Conditions in Sodium Nitrate Solutions

Madhav Datta and Dieter Landolt*

Materials Department, Swiss Federal Institute of Technology, Lausanne, Switzerland

ABSTRACT

Film breakdown phenomena leading to transpassive high rate dissolution of nickel in nitrate electrolytes were investigated under controlled flow conditions. Current efficiencies for metal dissolution were determined as a function of current density at different pH, temperature, and nitrate ion concentration. Initiation of film breakdown was investigated by performing experiments at very small dissolution times using polycrystalline and single crystal anodes and observing the resulting surface textures by means of optical and scanning electron microscopes. Results indicate that during high rate nickel dissolution, current efficiency is mostly governed by anode potential and nitrate ion concentration while bulk electrolyte pH and temperature have relatively little effect. Transpassive dissolution is initiated by local breakdown of the passive film. Dissolution takes place at the activated sites from a few well-defined crystal planes. With increasing time, these sites grow until they merge together resulting in an etched surface microtexture. Similarities between observed film breakdown phenomena leading to high rate dissolution at potentials above those for oxygen evolution and the pitting behavior of passive metals under corrosion conditions are discussed.

The importance of passivation phenomena in affecting electrochemical machining (ECM) operations has been demonstrated in many publications (1-16). In so-called passivating electrolytes, ECM takes place in the transpassive potential region where the protective property of passive films formed at the anode at low potentials is destroyed. Anodic reactions occurring in the transpassive potential region during high rate dissolution of steel and nickel have been studied by several authors (6-16). In all these studies, oxygen evolution was found to be the predominant anodic reaction at relatively low current densities in the transpassive potential region. At higher current densities, however, the relative amount of metal dissolution increased with increasing current density. Mao (6) investigated high rate dissolution of steel in sodium chlorate and sodium nitrate solutions under ECM conditions. The current

* Electrochemical Society Active Member.
Key words: film breakdown, transpassive dissolution, pitting, nickel, electrochemical machining.

efficiency for metal dissolution was measured while simultaneously the anodically evolved gas was collected and analyzed. The total current efficiency for divalent iron formation and anodic oxygen evolution added up to 100%. Similar results have been reported by Datta and Landolt (8) and LaBoda *et al.* (14) for high rate nickel dissolution in chlorate electrolytes where divalent nickel formation and oxygen evolution were found to account for all charge passed. Recently high rate transpassive dissolution of nickel in concentrated nitrate electrolytes has been studied by the present authors under controlled flow conditions (10). Current efficiency for nickel dissolution was found to increase with increasing current density until a maximum value close to 100% was reached. At current densities below the maximum an etched surface texture resulted from dissolution. Metal dissolution efficiency at low current densities was influenced relatively little by flow conditions, but the current density corresponding to maximum efficiency was higher the higher the flow rate. Anodic brightening occurred at current densities above the maximum. The phenomena of anodic brightening and the factors governing the transition from etching to brightening have been discussed in detail (10, 11). In the present study, attention is focused on the phenomena leading to film breakdown and anodic dissolution in the etching region.

Relatively little is known about the phenomena of film breakdown leading to high rate dissolution under ECM conditions, although different theories have been proposed in the literature. According to Mao (6), the oxide film formed on steel in chlorate solution dissolves under conditions of low *p*H at the electrode resulting from oxygen evolution. However, in a later work Mao, LaBoda, and Hoare (9) explained the dissolution mechanism of steel in different passivating electrolytes in terms of an ion exchange model already mentioned by Hoar (17). According to the model, anions adsorbed on the film are exchanged with the oxygen ions of the oxide matrix which eventually breaks down and dissolves resulting in film thinning leading to high rate dissolution. Recently, Chin and Mao (12) reported that oxide film on steel is ruptured by intergranular attack and high rate dissolution takes place from the underlying bare metal surface.

In order to better define the phenomena of breakdown in the transpassive potential region, high rate dissolution of nickel in nitrate electrolytes has been investigated in the present study under controlled flow conditions. One part of the experimental program consisted of determining the experimental variables which govern nickel dissolution efficiency. For that purpose, metal dissolution efficiencies were determined as a function of current density at different *p*H, temperature, and nitrate ion concentration. In the second part a microscopic study of surfaces of polycrystalline and single crystal anodes having been subjected to short anodic pulses was carried out to further investigate the breakdown mechanism.

Experimental

The experimental apparatus has been described elsewhere in detail (18). It consisted of a rectangular flow channel 3.2 mm wide and 0.5 mm high through which the electrolyte was pumped at a constant linear velocity of 1000 cm/sec corresponding to turbulent flow conditions. In a first series of experiments aimed at the study of current efficiency for metal dissolution, rectangular electrodes epoxy cast into a cylindrical PVC holder were used. Anodes and cathodes were 3.2 mm wide and 10 mm long. They were made of nickel 200 and positioned flush with the channel wall. Before each experiment, the anode was mechanically polished on 600 carborundum paper, degreased with benzene, and cleaned with soap solution and distilled water. It was then subjected to cathodic pretreatment in 1M NaOH solution at 20 mA/cm^2 for 30 sec followed by rinsing with distilled water. In order to maintain the cell geometry, only small amounts of metal were dissolved. All experiments were performed galvanostatically by passing a constant charge of 60 C/cm^2 corresponding to a maximum dissolution depth of 20 μm. During the experiments, current and time were monitored on a digital oscilloscope (Nicolet Type 109). Current densities applied ranged up to 30 A/cm^2. The anode was carefully weighed before and after each experiment using an analytical balance having a precision of 0.01 mg (Sartorius Model 2474.). Before weighing, the samples were cleaned with acetone and dried with air.

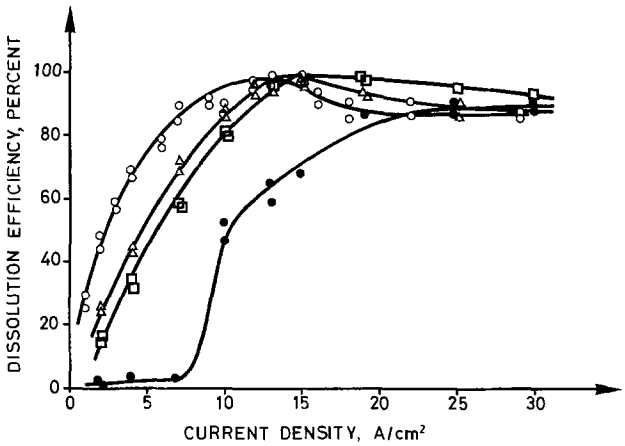

Fig. 1. Influence of electrolyte *p*H on current efficiency for nickel dissolution in 6M nitrate solution. 5M $NaNO_3$ + 1M HNO_3 (○), 5.9M $NaNO_3$ + 0.1M HNO_3 (△), 6M $NaNO_3$ + 0.1M NaOH (□), 6M $NaNO_3$ + 1M NaOH (●).

A second series of experiments was aimed at investigating the initiation of film breakdown leading to high rate dissolution. For that purpose, experiments were carried out at very small dissolution times using 10 mm diameter cylindrical electrodes which could be easily removed from the electrode holder for scanning electron microscope studies. Only a part of the anode corresponding to the width of the channel (3.2 mm) was exposed to the electrolyte while the remaining part was insulated by the Teflon spacer constituting the flow channel. Polycrystalline nickel anodes were machined from a bar of high purity nickel[1] (99.95%). Some experiments were carried out with [111] oriented single crystal[1] (99.95%) anodes. The different electrode assemblies have been described elsewhere in detail (16). Before each experiment nickel anodes were fixed in a plastic mold and the flat part was mechanically polished to 0.25 μm finish using diamond paste. Polished anodes were taken out of the plastic mold, cleaned, and pretreated as before. A test experiment was carried out with an electropolished single crystal anode to assure that the mechanical polishing procedure did not affect obtained results (16).

Electrolyte solutions were prepared from analytical grade chemicals and distilled water. Temperature of the electrolyte was maintained by means of thermostat. Unless otherwise indicated, experiments were performed at 25°C.

Results and Discussion

Current efficiency.—The influence of electrolyte *p*H on current efficiency for nickel dissolution in 6M nitrate solution is shown in Fig. 1 giving data obtained in 5M $NaNO_3$ + 1M HNO_3, 5.9M $NaNO_3$ + 0.1M HNO_3 (*p*H = 0.5), 6M $NaNO_3$ + 0.1M NaOH (*p*H = 12.2), and 6M $NaNO_3$ + 1M NaOH. From anodic weight loss measurements an apparent current efficiency for anodic dissolution was computed on the basis of Ni^{2+} formation (10). The data indicate that in the *p*H range 0.5-12, metal dissolution efficiency is relatively little influenced by *p*H of the electrolyte. In strongly alkaline

[1] Supplier: Cristal Tec, Grenoble Cedex, France.

solutions, on the other hand, transpassive nickel dissolution sets in at much higher current densities only. The observed behavior can be explained by considering the local pH change at the anode due to oxygen evolution. An estimation of H^+ ion buildup at the anode indicates that the local pH can indeed be neutral or acidic even in a slightly alkaline bulk solution (6M $NaNO_3$ + 0.1M NaOH). In a strongly alkaline solution, however, the local pH at the anode remains alkaline and metal dissolution is, therefore, inhibited, *i.e.*, oxygen evolution takes place over a wide range of current density. The results lead to the conclusion that in ECM practice, where neutral electrolytes are commonly used, small changes in electrolyte pH should not affect machining performance.

Figure 2 shows the influence of electrolyte temperature on the metal dissolution efficiency. These data were obtained at 5°, 25°, and 40°C in 5M $NaNO_3$ + 1M HNO_3. Results indicate that at low current densities where metal dissolution efficiency is an increasing function of current density, the electrolyte temperature has little influence on metal dissolution efficiency. This is in contrast with the previously observed dependency of surface brightening on temperature (11).

The influence of bulk nitrate ion concentration on metal dissolution efficiency is shown in Fig. 3 which gives data obtained in 5M $NaNO_3$ + 1M HNO_3, 3M $NaNO_3$ + 1M HNO_3, and 1M $NaNO_3$ + 1M HNO_3. Due to migration, the nitrate ion concentration at the anode surface at a given current density is different from that in the bulk. For a given flow condition, the nitrate ion concentration at the anode increases with increasing current density and it is higher the higher the bulk nitrate concentration. A quantitative estimation of the degree of local nitrate ion buildup is difficult because of gas evolution and because of the use of concentrated multicomponent electrolytes. However, qualitatively, the data of Fig. 3 show that a clear relationship exists between local anion concentration, anode potential (current density), and metal dissolution efficiency. Passive film breakdown is, therefore, favored by high nitrate ion concentration and high anode potential.

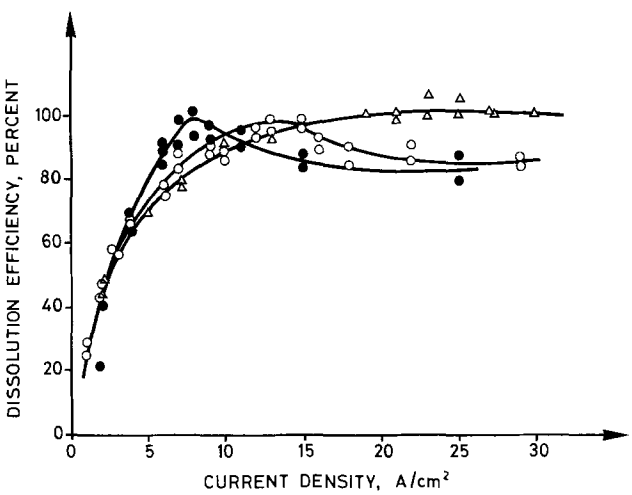

Fig. 2. Influence of electrolyte temperature on nickel dissolution efficiency in 5M $NaNO_3$ + 1M HNO_3. 5°C (●), 25°C (○), 40°C (△).

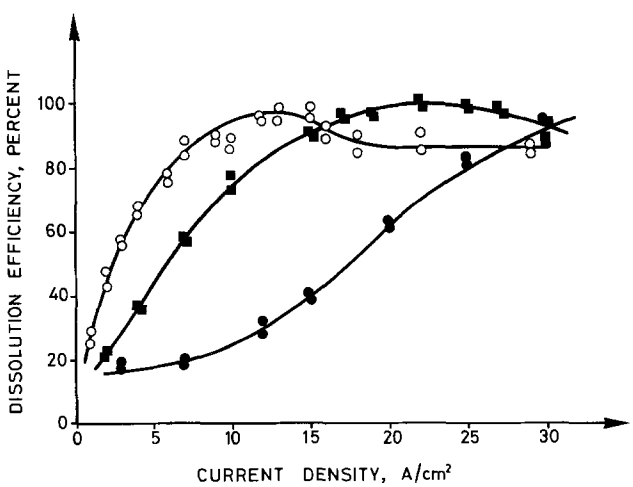

Fig. 3. Effect of bulk nitrate ion concentration on nickel dissolution efficiency. 5M $NaNO_3$ + 1M HNO_3 (○), 3M $NaNO_3$ + 1M HNO_3 (△), 1M $NaNO_3$ + 1M HNO_3 (●).

The behavior presents some analogy to well-known film breakdown phenomena in chloride solutions leading to pitting. For example, the critical pitting potential of stainless steel was found to be strongly dependent on chloride ion concentration by Leckie and Uhlig (19) and more recently by Broli *et al.* (20). The pitting potential was also reported to be independent of pH in the range 1-7 but for pH values higher than 7, the OH^- ions acted as pit inhibitor (19). Similar results were obtained by Venu *et al.* (21) and Rajagopalan *et al.* (22) who reported that the presence of NaOH inhibited passivity breakdown on steel in NaCl solution. Except at very low temperatures, the critical pitting potential was reported to be little influenced by increasing temperature (19).

Because of large ohmic drops associated with high current densities, it was not possible to determine the actual anode potentials in the present study. However, dissolution efficiency in these experiments can be taken as a measure of the stability of the film, *i.e.*, oxygen evolution takes place on stable films whereas increasing metal dissolution efficiency indicates film breakdown. The obtained results for metal dissolution efficiency as a function of pH, temperature, and nitrate ion concentration, therefore, suggest that a pitting-type mechanism leads to high rate dissolution in passivating ECM electrolytes.

Microscopic studies.—To investigate further the above hypothesis, surfaces resulting from dissolution were studied microscopically. The experiments described in the previous section involved passage of 60 C/cm^2 and anodes after dissolution in the ascending part of the current efficiency *vs.* current density curve exhibited an etched surface texture similar to that described in Ref. (10). To study the development of surface roughness experiments at smaller dissolution times were performed in 5M $NaNO_3$ + 1M HNO_3 solution.

On application of a very short current pulse, the anode surface looked unaltered to the naked eye even at a high current density. Under an optical microscope, however, localized breakdown sites resembling etch pits could be seen. Initiation and growth of these dissolution sites were studied as a function of dissolution time and current density.

Figure 4 shows the effect of dissolution time on surface attack at a current density of 3 A/cm^2. Figure 4(a) corresponds to a charge of 1 C/cm^2. It shows that initiation of dissolution occurs at discrete sites which are randomly distributed. With increasing dissolution time, grain boundaries become severely attacked and the dissolution sites grow giving rise to characteristic dissolution patterns which are oriented in definite directions. Figure 4(c), for example, shows three grains and their boundaries. The dissolution lines are pointed toward a particular direction which is different in different grains. The directional growth of the dissolution sites must, therefore, be related to grain orientation.

The surface attack at 5 A/cm^2 corresponding to a higher dissolution efficiency is shown in Fig. 5. For the same charge, the number of dissolution sites here is much higher than at 3 A/cm^2. As before, the breakdown sites grow bigger with time and the whole surface becomes densely covered with small etch pits. The

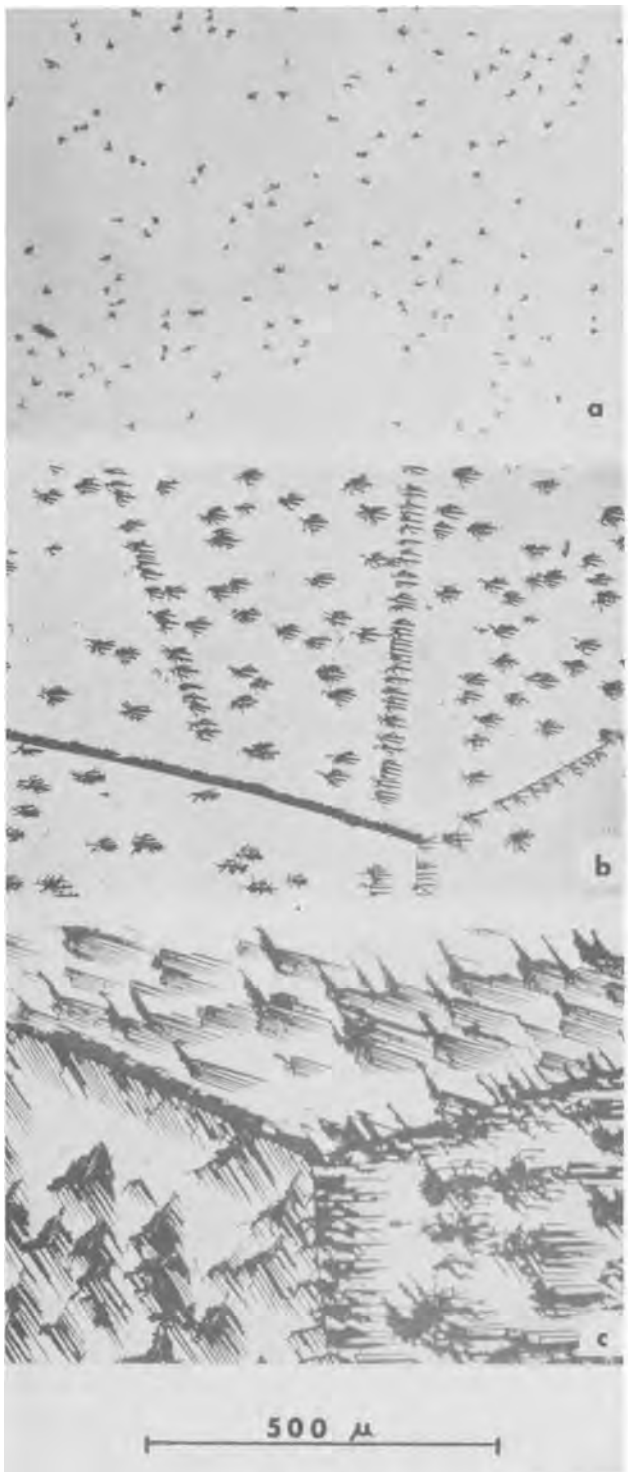

Fig. 4. Effect of dissolution time on surface attack: (a) 0.32 sec, (b) 0.85 sec, (c) 2.97 sec; current density, 3 A/cm^2.

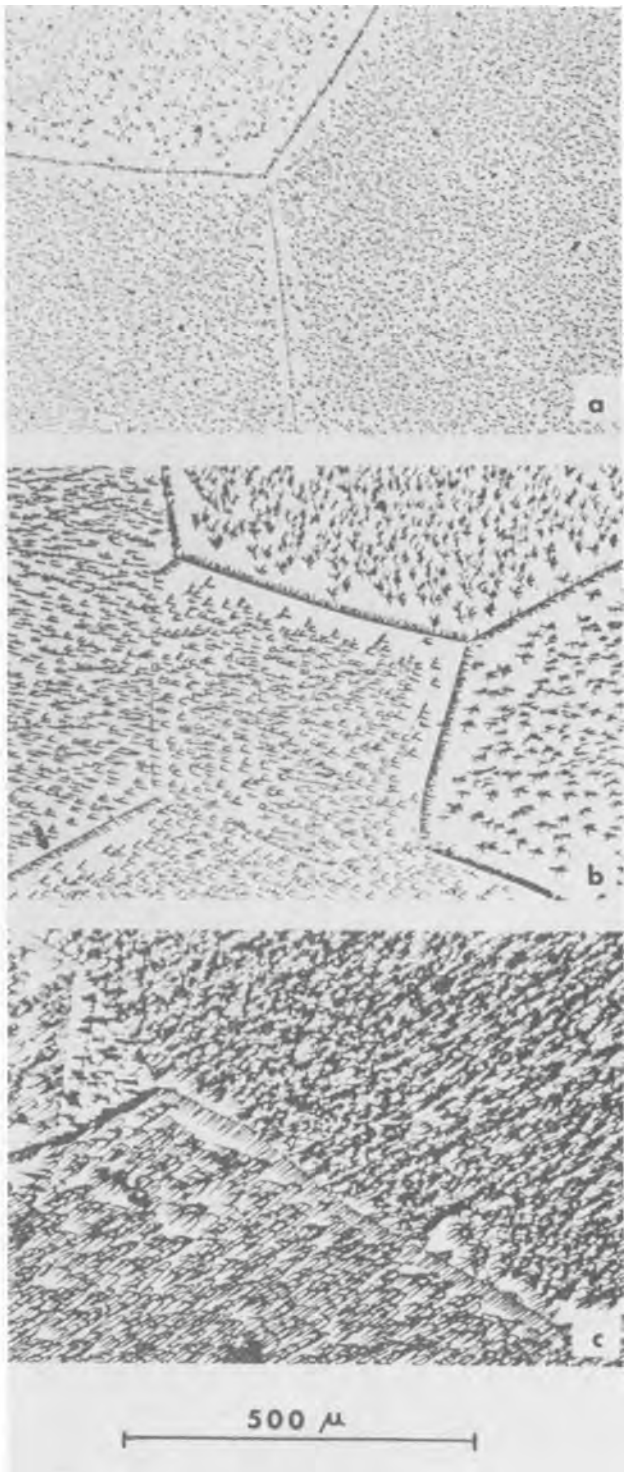

Fig. 5. Effect of dissolution time on surface attack: (a) 0.22 sec, (b) 0.49 sec, (c) 1.01 sec; current density, 5 A/cm^2.

same behavior is also seen in Fig. 6 which represents dissolution experiments performed at a constant current density of 7 A/cm^2. At this current density, even at the smallest dissolution time employed, the surface is fully covered with etch pits. With increasing time of dissolution, they grow in size and finally merge together giving rise to an etched surface appearing black to the naked eye. It is interesting to note that under a given dissolution condition, the number of dissolution sites and their size are different in different grains (cf. Fig. 5 and 6b, 6c) indicating that different crystals in a polycrystalline nickel anode dissolve at different rates. Dissolution efficiency should, therefore, be related to the crystal orientation.

To further illustrate initiation and growth of dissolution sites, surface textures resulting from dissolution were examined under a scanning electron microscope (SEM). SEM pictures of samples obtained from experiments performed at 3 A/cm^2 and different dissolution times are shown in Fig. 7-9. The SEM micrographs presented in Fig. 7 demonstrate that initiation of dissolution is highly localized, *i.e.*, dissolution pits with sharp boundaries are apparent in an otherwise intact passive film on which probably oxygen is evolved. The pits are randomly distributed and their shape is also random. At very high magnification (Fig. 7b) submicroscopic steps are visible within the pit indicating that dissolution proceeds from preferred crystallographic planes similar to active dissolution.

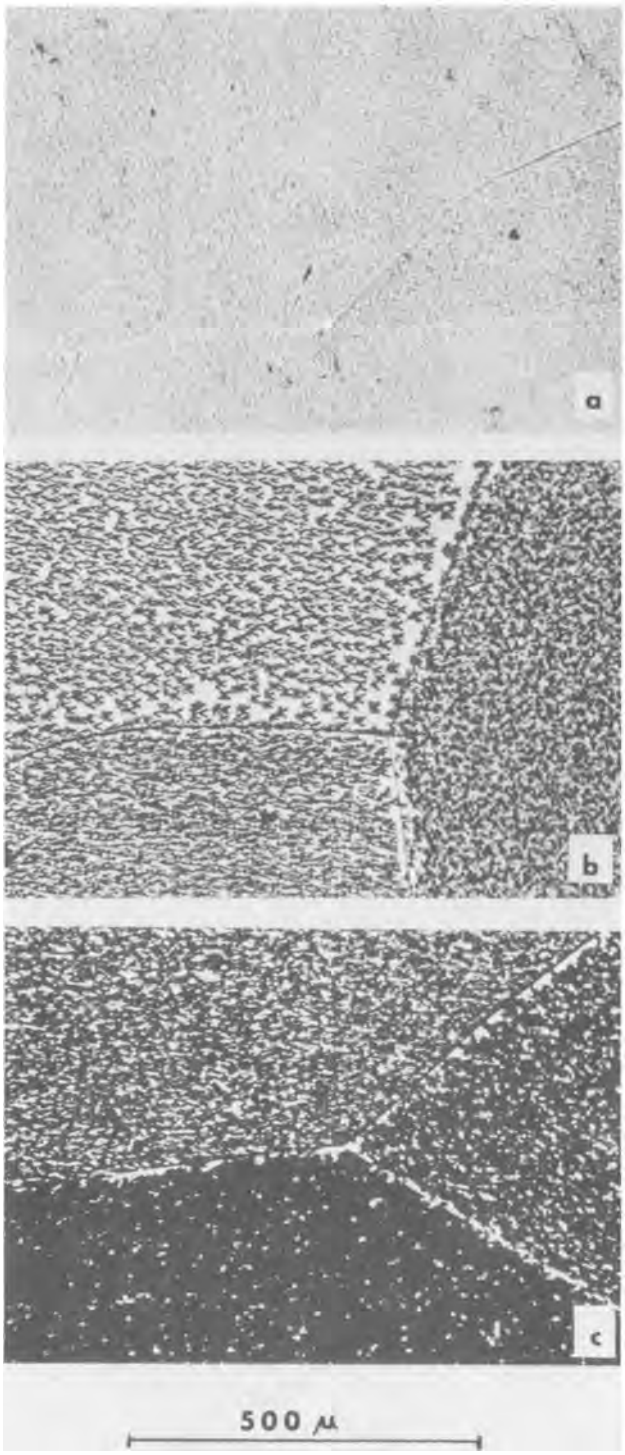

Fig. 6. Effect of dissolution time on surface attack: (a) 0.12 sec, (b) 0.49 sec, (c) 0.74 sec; current density, 7 A/cm^2.

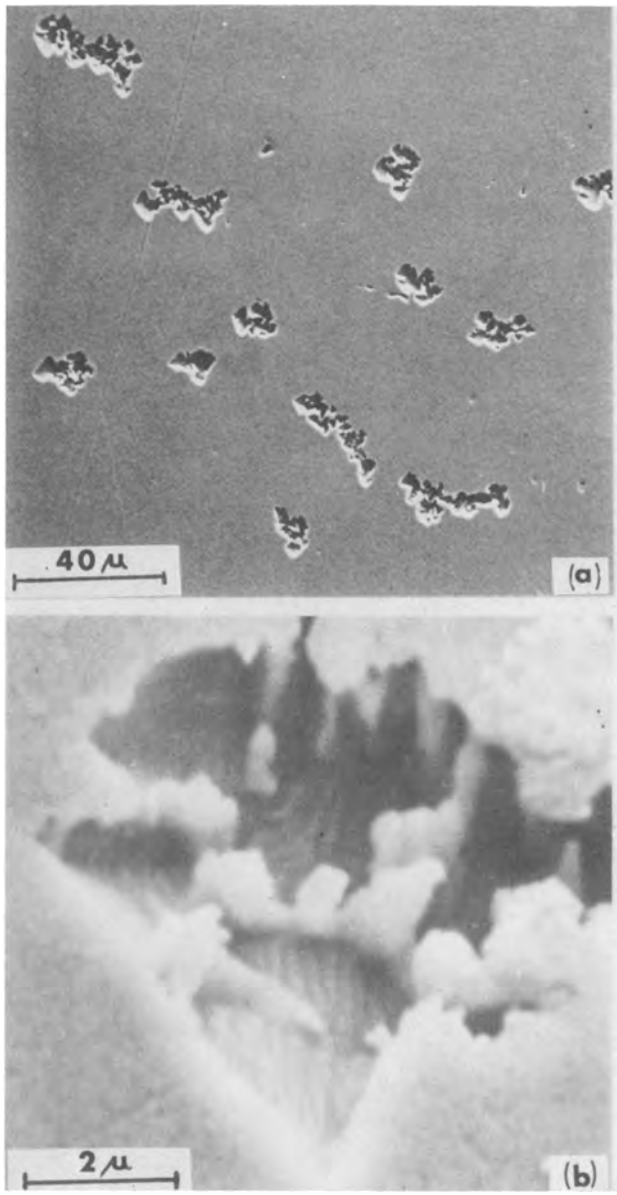

Fig. 7. SEM photographs showing dissolution pits on a polycrystalline nickel anode after a dissolution time of 0.32 sec; current density, 3 A/cm^2.

Figure 8 shows that with increasing dissolution time, the randomly shaped pits grow in certain specific directions giving rise to parallel ditches. Submicroscopic steps are again visible on the side walls. Figure 9 shows that with increasing dissolution time the ditches may grow to considerable length without getting broader. Growth direction is different for different grains but within a single grain growth is usually in the same direction. This confirms that dissolution occurs from a few particular crystal planes.

To further investigate the influence of crystallographic orientation on the dissolution process, experiments were performed using a single crystal with [111] orientation. Figure 10 shows SEM photographs of a surface resulting from dissolution at 3 A/cm^2. Dissolution proceeds in three directions oriented approximately 120° to each other corresponding to the [111] projections. This gives rise to Y-shaped dissolution sites, all oriented in parallel. The behavior further confirms that the process of dissolution is related to grain orientation and probably proceeds from close-packed planes. Some undercutting of the film is observed. This is particularly evident in Fig. 10 (b) which indicates that mechanical removal of the film may be possible under certain conditions. Since oxide film on nickel is in general very thin, such a mechanism should not affect the dissolution efficiency significantly, however.

The different microphotographs clearly demonstrate that transpassive dissolution of nickel in nitrate solution is initiated by local breakdown of the passive film and, therefore, presents some analogies to the pitting behavior of passive metals in aggressive media under corrosion conditions. The process of nucleation and growth of corrosion pits and the electrochemical conditions within pits have been widely studied (17, 23-30) but the mechanism of nucleation is not yet understood. Hoar *et al.* (24) proposed that preferential nucleation occurs on those parts of the film overlying grain boundaries and dislocations and suggested a mechanical

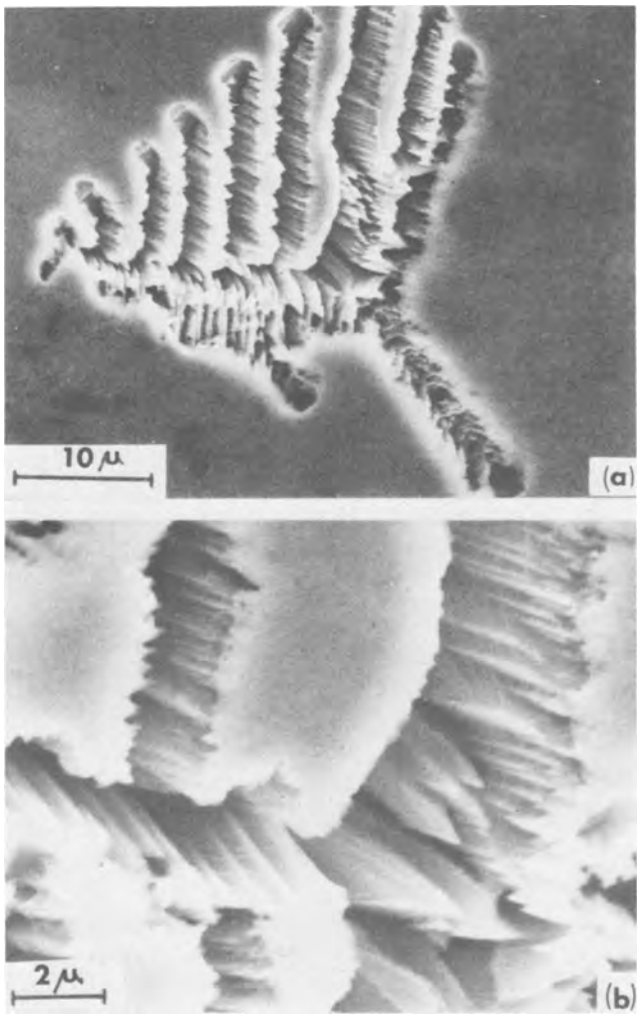

Fig. 8. SEM photographs showing dissolution pits on a polycrystalline nickel anode after a dissolution time of 0.85 sec; current density, 3 A/cm^2.

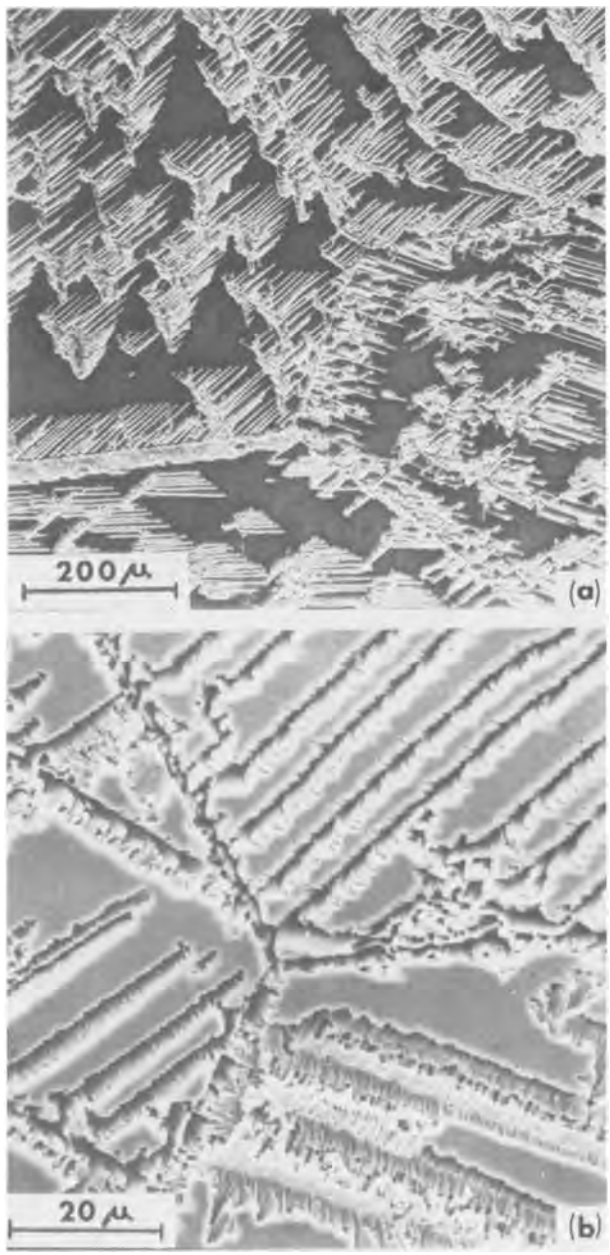

Fig. 9. SEM photographs showing dissolution pits on a polycrystalline nickel anode after a dissolution time of 2.97 sec; current density, 3 A/cm^2.

mechanism for anion penetration into the passive film (17). Smialowska and co-workers (25, 26) studying the pit morphology on stainless steel showed that pits may also nucleate at inclusions in the metal. According to Vetter and Strehblow (27, 28), Sato (29), and Galvele (30), the breakdown of the anodic oxide film is controlled not only by the electrochemical reactivity of the aggressive ions but also by mechanical and dielectric properties of the film itself. Similar factors may play a role in breakdown processes leading to local breakdown and high rate dissolution under ECM conditions but a detailed mechanistic description cannot be given at present.

Conclusions

The results of the present study show that high rate transpassive dissolution of nickel in sodium nitrate is initiated by local breakdown of the passive film and, therefore, presents many similarities with conventional pitting phenomena well known, *e.g.*, in chloride media. For nickel in sodium nitrate film breakdown causes a change from anodic oxygen evolution to high rate metal dissolution. Breakdown is favored by high current density and high anode potential and by high nitrate ion concentration. On the other hand, it depends relatively little on electrolyte temperature and on bulk electrolyte *p*H as long as the latter does not become strongly alkaline. Photomicrographs show that film breakdown is initiated at randomly distributed discrete sites the number of which increases with increasing current density. The nucleation sites grow in distinct directions by anodic dissolution from a few well-defined crystal planes. Eventually they merge together yielding a rough and etched microtexture. It appears that high rate transpassive dissolution at steady state involves a delicate balance between depassivation and repassivation phenomena which govern the extent of the anode surface covered by the passive film and thus determine current efficiency.

The Composition of Passive Films on Ferritic Stainless Steels

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

Auger electron spectroscopy has been used to investigate the influences of pH, Cl^- addition, and potential on the composition of passive films on Fe-Cr-Mo ferritic stainless steels. It was found that the improved corrosion resistance properties obtained by the addition of molybdenum cannot be explained by its enrichment of the protective film. Molybdenum was not found in the film even at those potential and pH values at which its oxide is the stable species. However, the relative iron and chromium content in the film followed predictions based on their solubilities in aqueous solutions. These results also indicate changes in bonding in the film as a function of distance from the substrate.

The development of high purity Fe-Cr-Mo ferritic stainless steels of low interstitial content stimulated the commercial use of ferritics after the results of several studies demonstrated the excellent corrosion resistance of this class of alloys. The improved corrosion resistance is derived mainly from the addition of molybdenum.

The beneficial effect of molybdenum on austenitic stainless steels in increasing its resistance to attack by chloride and acid solutions has been known for many years. Molybdenum- and silicon-containing austenitic stainless steels were investigated by Streicher (1) and by Rhodin *et al.* (2, 3). Bond and Lizlovs (3-7) have extensively studied the corrosion properties of molybdenum-containing ferritic stainless steels exposed to chloride solutions. Besides a substantial increase in pitting potential, the addition of 5% Mo to 13, 18, and 25% Cr alloys produces over an order of magnitude decrease in the critical current density. Further, the effect of molybdenum depends upon the chromium level: the higher the chromium content the greater the effect. Thus, molybdenum interacts synergistically with chromium. The function of Mo, or for that matter Cr, in improving resistance to halide solutions is not understood.

Ambrose and Kruger (8) have presented evidence that Mo increases the passivation rate; they suggest that in the presence of chloride ions the film is constantly breaking down and being repaired. Whether or not pitting occurs depends upon the rate at which the film repairs itself. Uhlig explains the beneficial effects of Mo and Cr using a competitive adsorption model (9). He rationalizes the effects of Cr by its greater affinity for oxygen than Fe and that of Mo by its lower affinity for chloride than Cr.

Rhodin (2,3) found that the improved corrosion behavior of the austenitic stainless steels correlated with the enrichment of silicon and molybdenum and the depletion of iron in the surface films. He used a film-stripping procedure in which an aggressive reagent (an anhydrous methanol bromide solution) was employed to attack the metal and float the film away. The isolated film was then chemically analyzed. However, Lumsden and Staehle (10, 11), using Auger electron spectroscopy (AES), found no enrichment of molybdenum or silicon in the films on these alloys. To the contrary, a depletion was observed.

* Electrochemical Society Active Member.

Key words: passivity, corrosion, molybdenum, Auger electron spectroscopy.

The work reported herein was undertaken to determine correlations between film composition and its protective quality. Auger electron spectroscopy was used to determine film compositions on Fe-Cr-Mo ferritic stainless steels as a function of pH and chloride content.

Experimental

The alloys used were high purity ferritic stainless steels provided by Climax Molybdenum Company with chromium contents of 13, 17, and 25% and with varying additions of molybdenum. They were prepared by induction melting and vacuum casting. The chemical compositions are given in Table I. The surfaces studied were mechanically polished by standard metallographic techniques (12) to ¼ μm diamond paste. Prior to polarization, the specimens were washed in a mild detergent, rinsed in double distilled water, and finally cleaned ultrasonically in methanol.

Polarization was carried out in a glass cell of standard design (13), which was open to the air. Initially, polarization curves were determined potentiodynamically at a scan rate of 0.55 mV/sec to establish the active, passive, and transpassive regions.

Films were formed potentiostatically in 1*N* H_2SO_4, 1*N* Na_2SO_4 + H_2SO_4 (pH 3), 1*N* NaCl + H_2SO_4 (pH 3.45), and pH 14 NaOH at 60, −150, −150, and −700 mV (NHE), respectively. Prior to anodic polarization the specimens were cathodically polarized at −750 mV (NHE) for 1 hr. The alloys were passivated for 1 hr.

After removal from the electrolyte, the specimens were washed in double distilled water and placed immediately in the vacuum system.

Polarization in a NaOH *p*H 14 solution was carried out in an open-to-the-air polypropylene beaker using a Hg/HgO/NaOH reference electrode and a zirconia bridge. The reference electrode was constructed of a platinum wire embedded in a shrinkable Teflon tube which was mounted in the end of a zirconia tube. The zirconia tube contained mercury and HgO on the bottom covered with a mixture of ZrO_2 particles and NaOH. A bridge was made of a ¼ in. Teflon tube filled with the same mixture as the reference electrode and closed on both ends with a porous ZrO_2 plug.

Selected specimens were also passivated in a HNO_3 solution using the same procedure as that employed by Nielsen and Rhodin (2, 3). The surface preparation consisted of first mechanically polishing as above followed by pickling in a 10% HCl solution at 80°C for 1 min. Then the surfaces were passivated by immersion in a 5% HNO_3 solution at 60°C for 30 min. The alloys were subsequently rinsed in demineralized, double distilled water.

Auger analysis was performed using a Varian cylindrical mirror analyzer (14) with a coaxial electron gun. Before analysis the system was pumped to 8×10^{-10} Torr or less using nonmechanical pumping. No bakeout was used in order to avoid changing the composition of the films.

The composition of the passive films was determined using the profiling technique (15, 16). This consists of simultaneous etching by argon ion bombardment and AES analysis. A 600 eV ion beam was used having an ion current density of approximately 1 $\mu A/cm^2$. The Auger spectra were taken using a 2 kV, 50 μA electron beam (static) having a diameter of approximately 50 μm. A 17 kHz modulation frequency was used with a modulation amplitude of 2V (p-p).

Results

The composition profiles are given as plots of normalized peak heights *vs.* sputtering time. The Auger peak heights have been normalized to the sum of those for iron and chromium in order to compensate for any change in surface and experimental conditions which affect the Auger signal. Due to the uncertainty in the sputtering rate, the sputtering time is given rather than the thickness of the film removed; however, the rate of film removal has been estimated to be approximately 3 Å/min before submonolayer coverage is reached. This was determined by sputtering and Auger analyzing oxide films which were formed by exposing iron to chromate solutions. The thickness was determined using an ellipsometer. After coverages of less than a monolayer are attained, the sputtering rate decreases exponentially since the rate at which an element is sputtered is proportional to its surface concentration.

Preliminary experiments were carried out to find the effect of the mechanical surface preparation on the film composition. A chromium deficiency was found in the film.

Figure 1 gives the composition of the passive film formed on the Fe-25.25Cr-5.24Mo alloy which had been exposed to the *p*H 3 sulfuric acid solution and polarized to a potential of −150 mV (NHE) for 1 hr. The Auger peaks used for all profiles were the O 510 eV, Fe 703 eV, Cr 529 eV, Mo 221 eV, S 152 eV, C 272 eV, and Cl 181 eV lines.

The results given in Fig. 1 are typical of those obtained for all the alloys exposed to the *p*H 3 solution. In addition to oxygen and the alloying elements, sulfur was present in appreciable amounts but was localized in the outermost layers and was easily sputtered off. Carbon, which was present in large quantities on the surface, was rapidly removed and reached a level slightly above its content in the steels after 5-10 min of sputtering. Its presence on the surface was probably due to atmospheric contamination. The relative amount

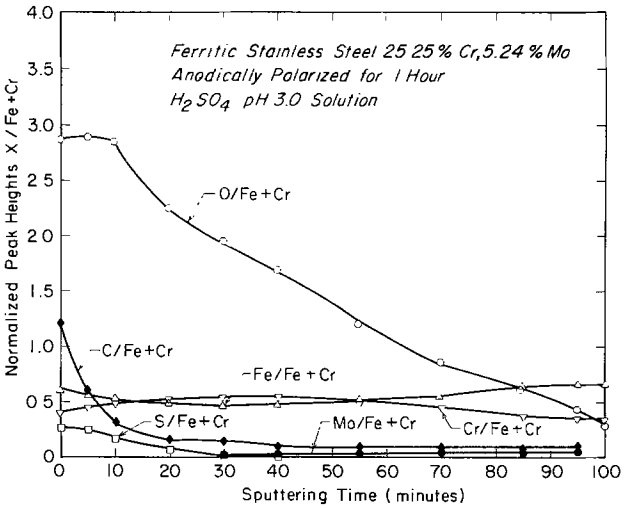

Fig. 1. Normalized Auger peak heights *vs.* sputtering time for the passive film on Fe-25Cr-5Mo ferritic stainless steel.

of molybdenum in the film was the same as that described in previous publications (10, 11), *i.e.*, no molybdenum in the outermost layers of the films and no enrichment in the films. Finally, chromium enriches the film with a corresponding depletion of iron.

The effects of heat-treatment on the anodic film composition were evaluated using alloys 11, 12, 14, and 16 in Table I. No effect was observed, but it should be emphasized that only 25% Cr steels heat-treated at 815° and 980°C were available.

The surfaces of the alloys which were polarized in the *p*H 3.45 chloride solution were examined optically and no attack was observed. The lowest pitting potential, 295 mV (NHE), was obtained for the Fe-13Cr alloy. The potential applied to the alloys exposed to the chloride solution was −150 mV (NHE). This potential is well below the pitting potential of all of the alloys used in this investigation.

The analysis of the film formed on the Fe-25.25Cr-5.24Mo alloy at −150 mV (NHE) exposed for 1 hr to a H_2SO_4-1.0*N* NaCl solution is shown in Fig. 2. The compositions were similar to those obtained for films formed in the *p*H 3 solution without chloride. In all cases the enrichment of chromium in the passive film was observed reaching the highest value for the 25% Cr steels and proportionally lower for the 17 and 13% Cr steels (Fig. 3). Molybdenum was not detected in the surface and near-surface layers nor did it enrich. Chlorine was detected in the surface and near-surface

layers only. Also, there was no significant difference in the thickness of the passive film on the alloys as deduced from the sputtering time necessary to reach the substrate.

Typical results for alloys exposed to 1*N* H_2SO_4 are given in Fig. 4. This is the composition profile of the film on Fe-25.25Cr-5.24Mo which had been polarized at 60 mV (NHE) for 1 hr. Chromium enrichment was found to coincide with a decrease in the iron content in the film. The molybdenum content was the same as that observed previously.

For comparison. an AES analysis was performed on surfaces which had been passivated by immersion in nitric acid. The film compositions resulting from passivation in nitric acid (Fig. 5) differed from those formed anodically only in the chromium content. Whereas anodic polarization resulted in films with varying amounts of chromium enrichment depending upon the chromium content of the alloy, the amount of chromium enrichment which resulted from passivation in nitric acid did not change in either the 17% or the 25% Cr steels with or without molybdenum; the 13% Cr steels were attacked by the 10% nitric acid solution.

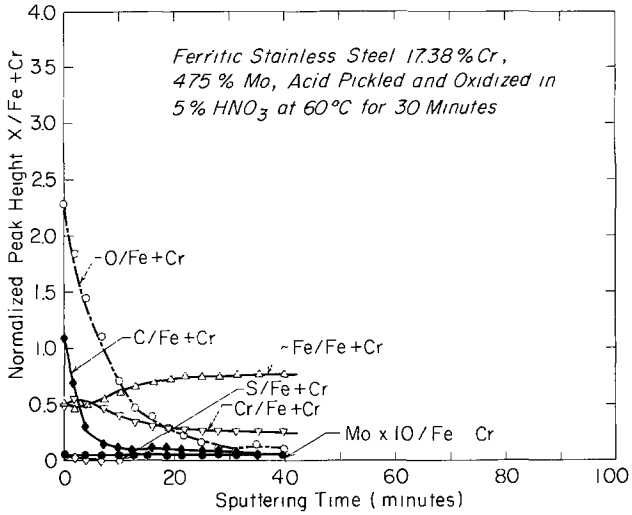

Fig. 5. Passive film composition on 17Cr-5Mo ferritic stainless steel after passivation in 5% HNO_3 at 60°C for 30 min.

The films formed on 13, 17, and 25% Cr alloys (with 0 and 5% Mo) exposed to the *p*H 14 NaOH solution were analyzed. In every case a depletion of Cr and an absence of Mo was observed in the films. An enrichment in iron was found corresponding to the chromium depletion. As the film was sputter etched, the iron and chromium contents uniformly approached the alloy levels. This is shown in Fig. 6.

The effects of potential were determined for alloys exposed to the H_2SO_4-NaCl solution. Figure 7 shows the film composition of the 18% Cr 5% Mo alloy obtained by polarization in the transpassive region at 1250 mV (NHE). For all of the alloys investigated there was a depletion of chromium in the film and an enrichment of iron relative to the bulk composition. Molybdenum was detectable in the surface layers of the film on those alloys in which it was present; however, the depletion-enrichment type of behavior of chromium and iron was independent of its existence in the alloy. Figure 8 shows the Auger results for the 25% Cr 5% Mo stainless steel which had been polarized cathodically at −1150 mV NHE. The film compositions on the ferritic stainless steels which had been polarized cathodically were identical to those resulting from polarization in the transpassive region.

Thus, these results suggest that cathodic polarization changes the surface composition of the alloy. It is not conclusive, however, that the observed film is that

which exists on the alloy in solution. If the air-formed film is removed by cathodic reduction, then oxidation would occur when the alloy is taken out of solution and exposed to the air. However, the air-formed film on the alloys used in this investigation is always enriched in chromium; therefore, air oxidation of an unaltered surface would not produce a film depleted of chromium.

Figures 9-13 show the Auger spectra at various depths in the passive film on the Fe-25.25Cr-5.25Mo alloy which had been passivated in the HNO_3 solution. Each figure has two spectra. One is the complete spectrum showing all of the Auger lines from the constituents of the film; the other is the low energy or valence band spectrum from iron. For the latter, two of the electrons involved in the Auger transition are in the valence band. Thus, these Auger electrons are very sensitive to changes in bonding. Figure 9 shows the spectra which result after 5 min of sputtering. The film for the most part is an iron oxide with only a small amount of Cr. The valence band spectrum shown is that of iron; this is the type of spectrum which results when iron is in the ferric state as reported previously (17). The spectra in Fig. 10 were taken after 10 min of sputtering. Here, a substantial amount of Cr appears in the film; whereas the oxygen and iron content remains approximately the same as that in the previous spectrum. Molybdenum also begins to become detectable. The lower energy peak in the valence band spectrum has shifted in energy; this is the same type of valence band

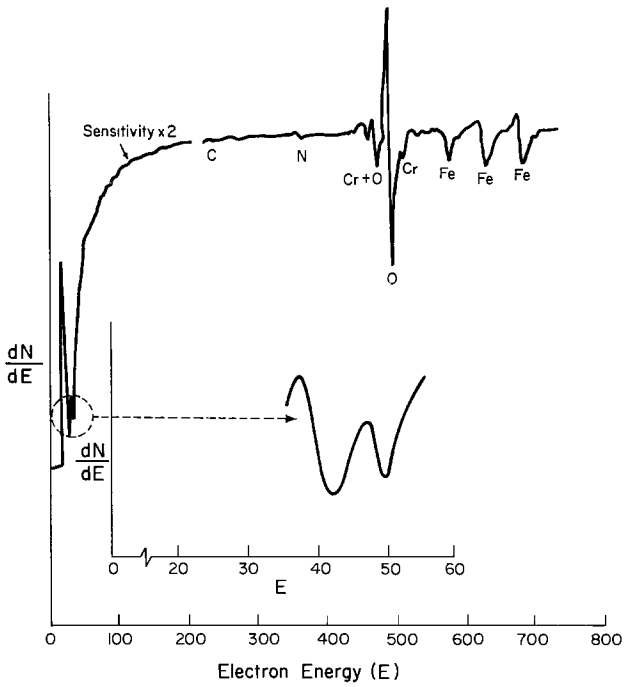

Fig. 9. Auger spectra of the passive film on Fe-25Cr-5Mo after 5 min of sputtering.

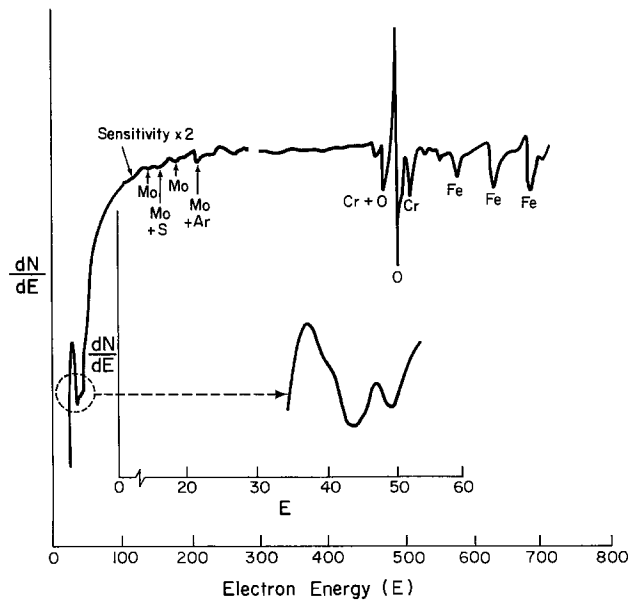

Fig. 10. Auger spectra of the passive film on Fe-25Cr-5Mo after 10 min of sputtering.

spectrum which was observed from Fe in the ferrous state. Figure 11 shows the spectra which resulted after 15 min of sputtering. The valence band spectrum for Fe at this depth is the same as that obtained for a Fe free surface although a substantial amount of oxygen remains here after the film has been sputtered for 15 min. The implication of the latter result is that oxygen is bonded to the Cr with iron being in the metallic state. The spectra obtained after 20 min of sputtering are given in Fig. 12. These spectra are essentially the same as those in Fig. 11 except that the oxygen level has substantially decreased and the Fe lines have increased in amplitude. Figure 13 summarizes the above results. This pattern was also observed for films formed by anodic polarization.

Discussion

The role of alloying elements in improving corrosion resistance properties is frequently interpreted in terms of the relative range of the thermodynamic stability,

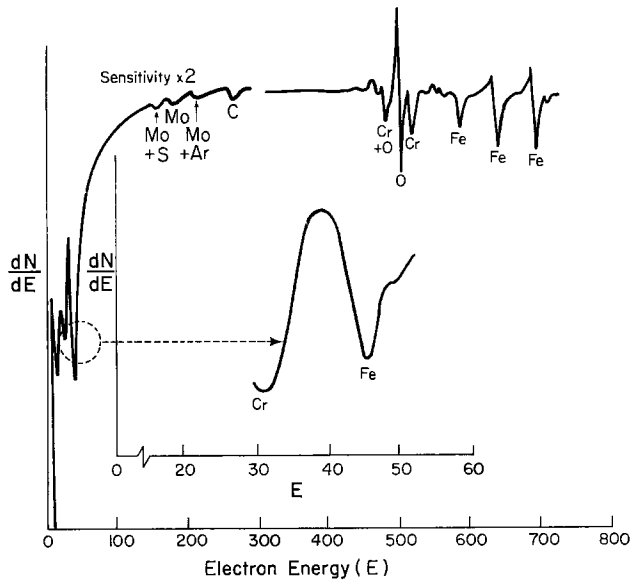

Fig. 11. Auger spectra of the passive film on Fe-25Cr-5Mo after 15 min of sputtering.

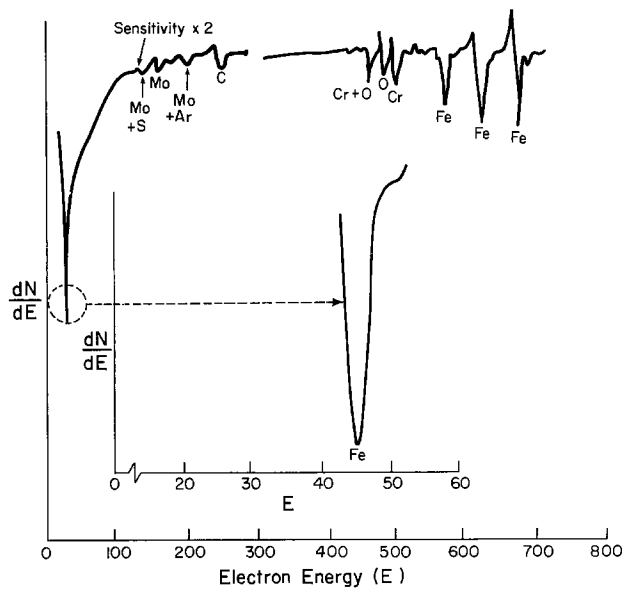

Fig. 12. Auger spectra of the passive film on Fe-25Cr-5Mo after 20 min of sputtering.

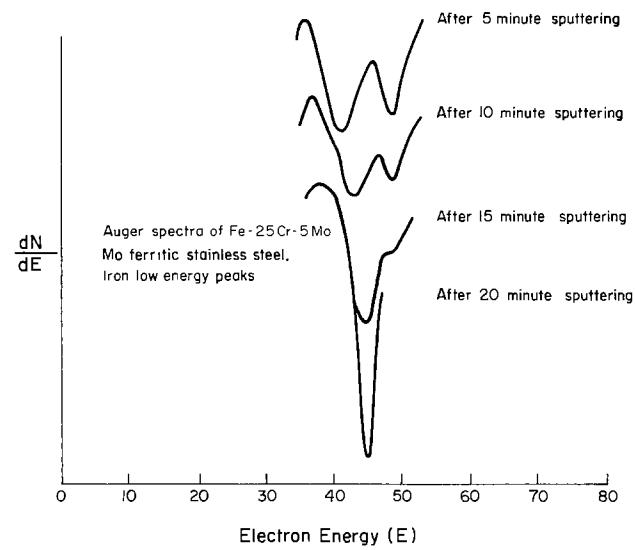

Fig. 13. Valence band spectra of Fe in the passive film on Fe-25Cr-5Mo after various sputtering times.

with respect to pH and potential, of their insoluble species. Thus, the effectiveness of chromium and molybdenum as alloying elements in iron is interpretable in terms of the broader range of acid stability of Cr_2O_3 and MoO_2. This argument can also be extended to rationalize the increased effectiveness of alloys containing chromium and molybdenum in resisting attack in chloride solutions if pitting is assumed to be a result of localized acidification (18).

Using solubility arguments for the effects of alloying on corrosion properties, one can obtain an "enrichment model." According to this concept, in the passive region the oxide or hydroxide of highest solubility selectively dissolves at the film-solution interface. The film then becomes enriched in the more stable species and this oxide or hydroxide governs the rate of dissolution. Thus, the improved corrosion properties in acid and chloride environments obtained by alloying stainless steels with molybdenum could be explained by an enrichment of molybdenum oxide in the passive film. However, no evidence for this was found using AES; on the contrary, a depletion of molybdenum was found in the surface and near-surface layers of the passive film (see Fig. 4). This was the case even for the pH 3 and 3.45 solutions in which the films were formed under conditions at which MoO_2 is thermodynamically stable [see the Pourbaix diagram (19) in Fig. 14]. The same general trends were found for passive films formed in the pH 3.5 sulfate solution with and without chloride ions (Fig. 1 and 2). Thus, the presence of chloride ions in solution had no effect on film composition in the passive region.

Although thermodynamics could not be used successfully to predict the relative amount of molybdenum in the protective film, the general trend of the chromium content followed thermodynamic predictions. Chromium was found to enrich in the passive film under those conditions where Cr_2O_3 was stable (Fig. 14). However, the Pourbaix diagrams are overly pessimistic in the acid region since a passive range was obtained in 1*N* H_2SO_4 although the hydroxides and oxides of iron, chromium, and molybdenum are not the stable phases in this region. This also applies to unalloyed iron and chromium because both have a passive range in H_2SO_4. Since these diagrams were calculated from known thermodynamic data for bulk compounds, either these thin oxide films are a different

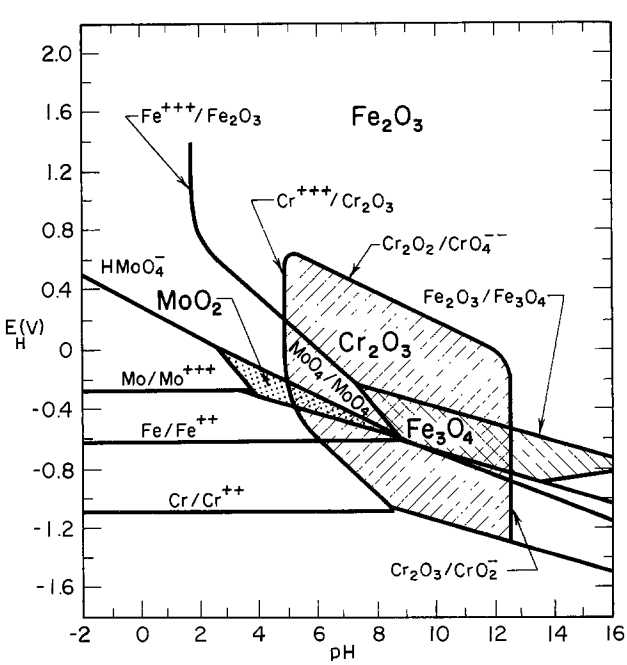

Fig. 14. Superposition of Pourbaix diagrams for chromium, molybdenum, and iron showing the insoluble products and some of the equilibria defining the phase boundaries.

phase or compound whose bulk properties are not known or one must consider the kinetics. The films formed at pH 14 were found to be depleted of chromium; this is consistent with the potential-pH diagram if the insoluble product is considered to be Cr_2O_3. The vertical line representing the boundary between passivity and corrosion, *i.e.*, $[CrO_3^{---}] = 10^{-6}$, is located at approximately pH 12.5 for Cr_2O_3.

The influence of potential on the chromium and iron content of the film is also predictable from thermodynamics. At 1250 mV (NHE) soluble chromate ions and insoluble Fe_2O_3 are the stable species (Fig. 7). The results obtained after cathodic polarization should be compared with those obtained in caustic solutions since the evolution of hydrogen at the electrode is accompanied by the generation of hydroxide ions. This raises the pH at the electrode surface. Both cathodic polarization in the pH 3.5 solution and anodic polarization in pH 14 solution (compare Fig. 6 and 8) resulted in a chromium depleted-iron enriched film.

Legitimate questions can be raised about the effectiveness of the Auger technique in detecting molybdenum since it seems inconceivable that an alloying addition which can increase the pitting potential over 500 mV would not be a major constituent of the film. Yet the Auger results for the relative amounts of chromium and iron in the passive films were consistent with solubility arguments. Thus, one would suspect that if the technique were altering the composition of metal ions in the film, it would be manifested in the behavior of these constituents as well as molybdenum.

A further question is whether or not the electron and ion beams are volatilizing the molybdenum oxide. Figure 15 shows the Auger spectra of a cathodically deposited molybdenum oxide film (from a molybdate solution). This film has a substantial amount of molybdenum and a small amount of iron, thus duplicating a passive film on an iron base alloy enriched in molybdenum. The spectrum remained unchanged after 5 and 15 min bombardments by the electron gun. Figure 16 shows spectra taken before and after 40 min of sputtering. Again, there were no anomalies. Although the carbon and nitrogen levels decrease substantially after 40 min of sputtering, there were only slight changes

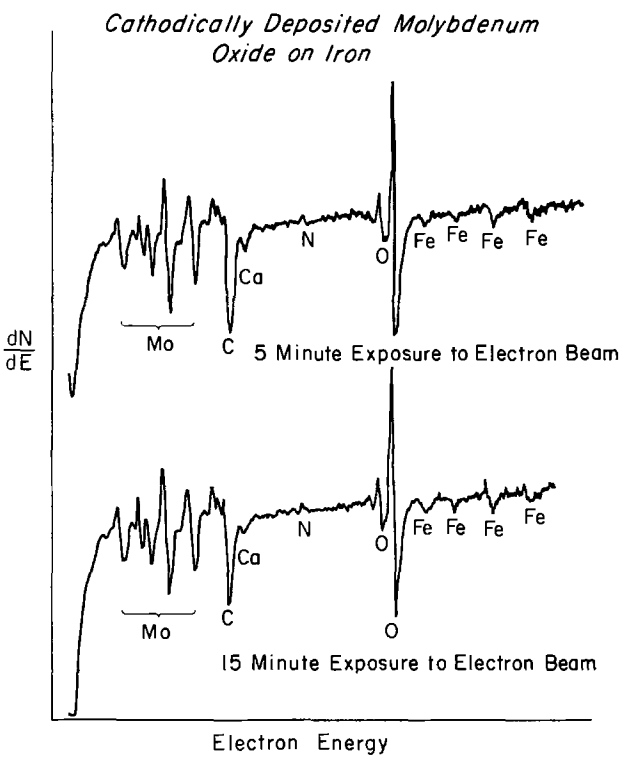

Fig. 15. Effect of electron beam on cathodically deposited molybdenum oxide film.

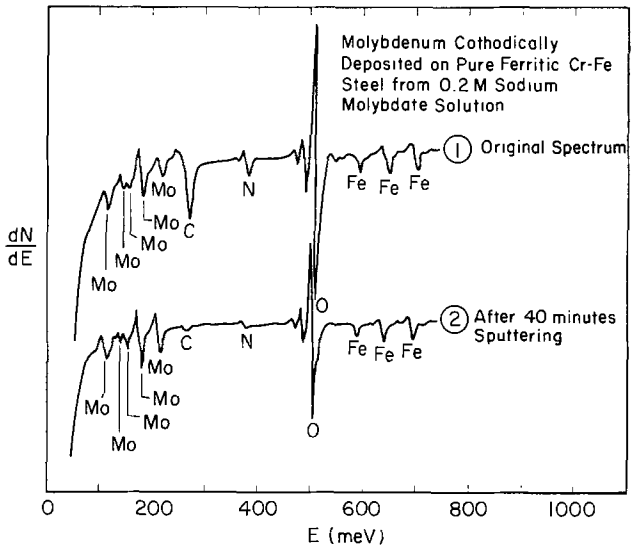

Fig. 16. Effect of sputtering on cathodically deposited molybdenum oxide film.

in the peak height ratios of the other elements. These changes could be due to the removal of adsorbed molybdate ions and water from the surface or due to an inhomogeneous film. However, the important point is that molybdenum is not preferentially removed by sputtering. Thus, these results suggest that if molybdenum is, in fact, enriched in the film, the Auger technique would detect it.

One of the inherent uncertainties in the profiling technique is the possible occurrence of differential sputtering. This arises because elemental sputtering yields are different, which results in an altered surface layer enriched in the element with the lower sputtering yield. Frankenthal and Malm (20) have concluded that films formed on iron-chromium alloys during mechanical polishing are not differentially sputtered. It is uncertain whether these results can be applied to this investigation since a different ion beam energy was used; however, when a 600 eV ion beam is used to sputter a mechanically polished surface, the Auger results are similar to the results of Frankenthal and Malm. Also, there is no evidence that large differences in the elemental sputtering rates exist. For example, if this phenomenon were causing an apparent enrichment of chromium in the films, then one would expect to observe an enrichment in those films in which chromium was depleted from the surface layers.

Carbon contamination was found on all surfaces. This was probably from hydrocarbon or carbon dioxide which was adsorbed when the specimens were transferred from the cell to the vacuum system. The varying concentrations of these overlayers cause the difference in behavior of the oxygen peak decline in Fig. 1, 2, and 7.

When the oxygen level is large relative to that of chromium, the oxygen line (510 eV) causes some distortion in the chromium line (529 eV). Coad and Cunningham (21) have analyzed iron and chromium mixed oxides using both XPS, in which there is no interference between lines, and AES. These results indicate that the errors caused by the distortion are not significant.

The Auger results for the composition of passive films differ substantially from those obtained by chemical analysis. Perhaps the high silicon and molybdenum content found by Rhodin and Nielsen (2, 3) occurs because the film-stripping procedure created an altered layer. It is conceivable that such a layer would contain undissolved silicon and molybdenum from the alloy.

The Auger results eliminate from consideration the enrichment idea for explaining the improved quality

of the protective film derived from the presence of molybdenum in the alloy. Other possibilities for rationalizing the effects of molybdenum include an increased repassivation rate (8) or the prevention of localized acidification (19) by altering the corrosion potential or anodic dissolution kinetics. Electrochemical results indicate that indeed, both the corrosion potential and the potential necessary to maintain the high current density required to sustain pit growth increased with increased molydenum content in the ferritic stainless steels (22).

Perhaps molybdenum exerts its beneficial effects by improving the quality of the bonding at the metal-oxide interface creating a barrier layer. There are two possible interpretations of the results shown in Fig. 9-13. One is metallic iron which is present in a chromium oxide matrix (possibly two-dimensional). The other is that there is a chromium oxide layer adjacent to the substrate. The presence of molybdenum in the layer could have a substantial influence on the quality of the bond.

Oxidation of Copper-Containing Films at Room Temperature

Charles B. Greenberg

PPG Industries, Incorporated, Glass Research Center, Pittsburgh, Pennsylvania 15238

ABSTRACT

In a previous publication, formation of a novel, copper-containing, electroless-replacement film was described. Partial replacement of electroless copper was from an aqueous Ag^{+}-$S_2O_8^{-2}$ solution. The emphasis was on an accompanying, accelerated oxidation reaction in the air, which was also shown to occur after electroless copper was exposed to a solution containing only sodium thiosulfate. Additional data are herein described to elaborate the synergistic dependence of the oxidation of Cu in these films on two impurities, one probably a sulfide, and the other H_2O from the air. These new data show that oxidation in air can be very much inhibited by prior exposure to extra dry O_2 despite the otherwise very strong propensity for oxidation. This suggests some probable mechanisms relative to cationic diffusion and the Cabrera-Mott model for oxide growth.

The oxidation in air and O_2 of metals, including copper, at various temperatures has been seriously discussed since at least the 1940's. Attempts have been made to fit oxidation, for example, to the kinetics of electron tunneling and ionic diffusion through the growing oxide. The complexity of this problem is suggested by the numerous rate equations in the literature, including inverse logarithmic, direct logarithmic, linear, parabolic, and cubic. Apparently, the fit for a particular rate equation varies at least with the temperature and the thickness of the particular metallic oxide. The history and status of this important area of activity have been reviewed by Rönnquist and Fischmeister (1), Fehlner and Mott (2), and Lawless (3).

The focal point for much of recent thinking is an early paper by Cabrera and Mott (4). It forms the basis for the concept of oxide growth at room temperature by ionic diffusion in the growing oxide film. In the case of copper, growth is by cationic diffusion in Cu_2O. Lawless (3, 5) especially, but also Fehlner and Mott, emphasized that the ease of oxidation is very much dependent on impurities, defect structure, and grain boundaries. An impurity may enhance ionic diffusion by promoting a defect structure; it may promote crystallization or recrystallization which hinders or favors grain boundary diffusion. It is, however, usually difficult to identify an impurity or assign a clear role to it. In an earlier publication by this author (6),

impure electroless copper films and copper contained in films made by successive electroless copper deposition and partial silver replacement were shown to oxidize at an unusually rapid rate in air at 24°C. Water vapor was necessary with O_2 in the surrounding gas phase, and a poorly crystallized, sulfur-containing component, probably Cu_2S, was necessary in the films. In each case, copper sulfide had formed by reaction with $S_2O_3^{-2}$. Electroless copper films were treated with aqueous $S_2O_3^{-2}$ solution; $S_2O_3^{-2}$ was contained in the replacement solution. The phenomenon proved to be interesting and of practical value for architectural films; it was explained by invoking the Cabrera-Mott model and assuming favorable defects or grain boundaries.

In the present publication the intent is to elaborate this unusually rapid oxidation of Cu, easily observed by monitoring decreasing specular reflectance. The accompanying increase of luminous transmittance for electroless copper supports the assumption of oxidation; there is no indication of any light scattering. Further observations which have been made with similarly treated electroless copper and electroless-replacement films conform to the hypothesis of ionic diffusion. They illustrate the formation, under adverse conditions, of a thin passivating layer, apparently Cu_2O with a very low defect density, when such fresh films are permitted to first "see" dry O_2 before the ambient air. The conditions are adverse in the sense that all films are prepared from aqueous solutions and therefore hardly free of H_2O at first. They also contain the sulfide impurity.

Experimental Procedures

Sample preparations.—Thin films were deposited on one surface of commercially available soda-lime-silica float glass, 0.6 cm thick, by either electroless deposition or a sequence of electroless and replacement deposition. All sample preparations were carried out at room temperature with demineralized water by puddling each solution on the horizontally positioned substrate (6). Electroless copper films were deposited, after conventional palladium activation, using the solutions and reagent grade chemicals shown in Table I. Film deposition was terminated at a luminous transmittance (T) of 0.23; response was CIE standard C. Spot to spot variations in reflectance within the sample were within ± 0.005 of the center; this is a relatively small variation. Sample area was about 25-50 cm^2. To introduce the sulfide impurity and promote subsequent oxidation, electroless copper was treated at room temperature for 50 sec with an aqueous solution containing 3.0 g/liter $Na_2S_2O_3 \cdot 5H_2O$. This was done after rinsing away the residual coppering solution with water and was done prior to a final rinse, followed by drying with compressed air.

The electroless-replacement films, partial copper replacement by silver, were deposited in the way previously described for the replacement solution shown in Table I. The coppering solution was compositionally different than that used for the above electroless copper but kinetically similar. Final rinsing was with either water or methanol. The latter had been used at times with the intent to inhibit oxidation during rinsing (7); it proved to have no obvious influence at all on oxidation. The $S_2O_3^{-2}$ in the replacement solution, as previously, was the source of sulfide in these films.

Monitoring film oxidation.—The method for monitoring relative reflectance in various environments was also used previously. For purposes of clarity a schematic illustration is shown in Fig. 1. The coating-up sample was placed in a stationary position inside the glass enclosure within about 15 sec of drying. The glass enclosure was over the open port of the head of a gain-modified Gardner precision glossmeter Model GG-9100, precision about ± 0.002. The optics of this system were altered by the necessary reduction of gain and the glass

plate supporting the sample. The reflectance, although therefore not a CIE response, is in the visible portion of the spectrum. Prior to positioning the sample, the bottled O_2 or N_2 gas lines had been purged for at least 10 min through valve no. 1. Thereafter this valve was closed while maintaining a slightly positive pressure preceding it. When the sample was placed over the light source and the glass lid placed over the glass plate, valve no. 2 was opened. Valve no. 3 being closed, a negative pressure was attained so as to bring oxidation of the film to a virtual halt within 30 min. Silicone grease between the lid and plate was used to minimize ingress of air. Thereafter the roughing pump was isolated at the source, valve no. 1 was opened, and

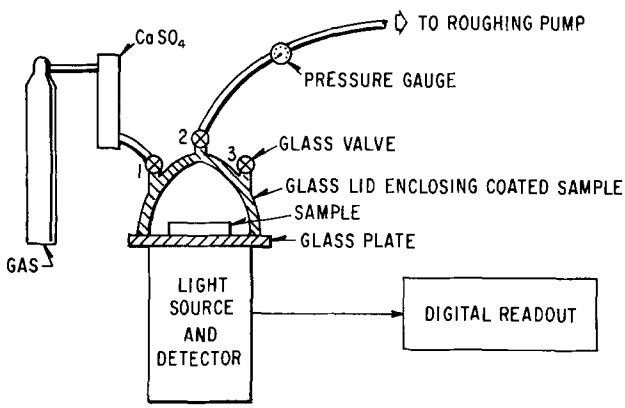

Fig. 1. Schematic diagram of system for monitoring reflectance changing as a function of time. The tungsten light source and selenium detector define an angle of incidence of 20°. The resultant spectral response of the optical head, with internal filtering, but excepting the external glass plate, is a very close approximation to the CIE Standard Co.

the flow of gas was increased until atmospheric pressure was reached. As the pressure became slightly positive, valve no. 3 was opened as an exhaust. The flow of bottled gas was maintained for 30 min, after which time valve no. 1 was closed, and ambient air was drawn through the chamber with the roughing pump.

The bottled gas was extra dry O_2 from Matheson Gas Products, or, in one reference experiment, N_2 from Linde Air Products. In two instances an analysis was supplied for O_2 intentionally doped with CO_2, in one case with 1 ppm by volume and in the other 284 ppm. This was done to determine the importance of CO_2 in the oxidation reaction. In one instance O_2 was passed over water contained at room temperature in an Erlenmeyer flask which took the place of the dryer. This was done to confirm the role of H_2O. One other variation is the position of the pressure gauge. It was either as shown or in the gas line for the same purpose. Purging with dry O_2 may have been more complete having it as shown in Fig. 1.

The ambient conditions were not significantly variable from time to time. The temperature was 22°-26°C, and the relative humidity was approximately 45-65%.

At the end of an experimental run the instrument was checked to be sure that no significant drift had occurred. Only in one instance was the drift observable; this was a shift in the relative reflectance of −0.01. This occurred when monitoring electroless copper. It is a relatively small error in any event but even less significant, as it turned out, in view of the result obtained for that experiment.

Results and Discussion

Inhibition of copper oxidation in extra dry O_2.—The two curves shown in Fig. 2 illustrate film passivation. In contrast to what happens in the ambient after being in N_2, the copper-containing replacement film is passivated by prior exposure to extra dry O_2. This means that a "first-formed" oxide can be protective for the copper component of this film at room temperature, as aluminum oxide is, for example, for aluminum. This oxide must be assumed to be cuprous oxide, in the absence of identification during prior work of other compounds by electron diffraction. When the film has first been exposed to N_2, this oxide growth is inhibited. Thereafter, when growing in the ambient, the oxide which forms is apparently a better medium for cationic diffusion. There is an apparent sensitivity to the water vapor in air, and perhaps CO_2.

The same conclusion follows from inspection of Fig. 3. In this case an electroless copper film, free of silver, is shown to be passivated by exposure to dry O_2. The

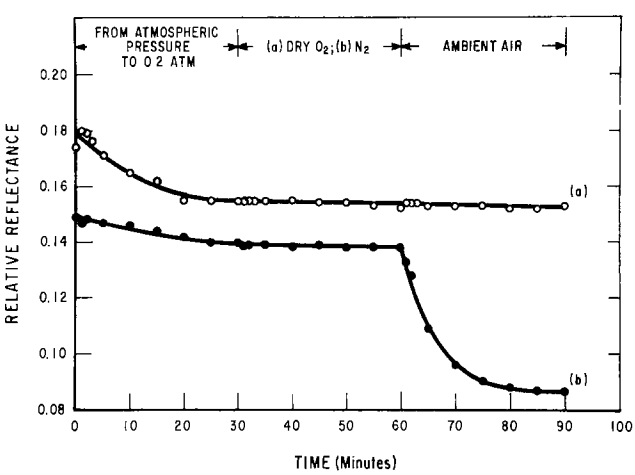

Fig. 2. Relative reflectance from the glass-film interface for two similar copper- and sulfur-containing, electroless-replacement films undergoing successive exposures to indicated environments. The dry O_2 contained 1 ppm in volume percent of CO_2.

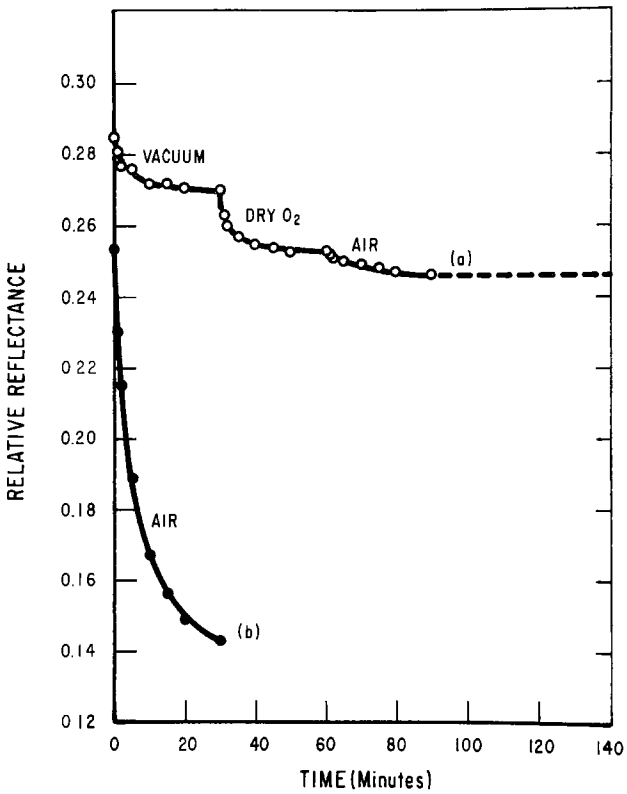

Fig. 3. Relative reflectance from the glass-film interface for two similar electroless copper films immediately after treatment for 50 sec in an aqueous solution of 3.0 g/liter $Na_2S_2O_3 \cdot 5H_2O$. No analysis for CO_2 in O_2.

small decrease in reflectance within the first minutes of exposure to dry O_2 may be a result of an inadequate purge or a momentary leak to the ambient. Nevertheless, there is passivation. The extrapolation of the uppermost curve (a), as indicated by the dashed line, is based on measurements after the conclusion of the 90 min experiment. Approximately 1 hr after the run, the reflectance was unchanged. On the following day there was a decrease of only −0.006. The sample monitored in the air without prior exposure to dry O_2, curve (b), was considerably oxidized after only 30 min. This sample was monitored while it was on the glass plate shown in Fig. 1, so as to preserve the comparison.

It should be pointed out that at the point of switching from one environment to another, a few seconds were consumed in operating valves. This time was not counted so there is some small, but insignificant, error in time in experiments such as those in Fig. 2 and 3. Within each figure the differences in reflectance between curves (a) and (b) at 0 min resulted from uncontrollable variations in sample preparation, exacerbated by the ongoing oxidation during film processing. It is only by chance that (b) in each case has a slightly lower reflectance at the beginning of the experiment.

Role of H_2O and CO_2.—In Fig. 4 there are two curves shown which point directly to water vapor as a necessary impurity. In dry O_2 doped with CO_2 to an extent close to that for dry ambient air (8) it is still evident that the passivating film forms. On the other hand, by passing otherwise dry O_2 over water, the formation of this passivating film is prevented. It cannot be excluded that CO_2 dissolved in the water is synergistic with H_2O, but it is at least clear that H_2O is necessary.

Qualitative mechanism and implications.—When exposed to air without prior exposure to $S_2O_3^{-2}$ or dry O_2, copper, perceived as a film or a component in a film, simply has a thin cuprous oxide growth on it. It is easiest to refer to the case of the electroless, silver-free film to visualize what happens in both types of films cited in this work. The prior treatment in $S_2O_3^{-2}$ re-

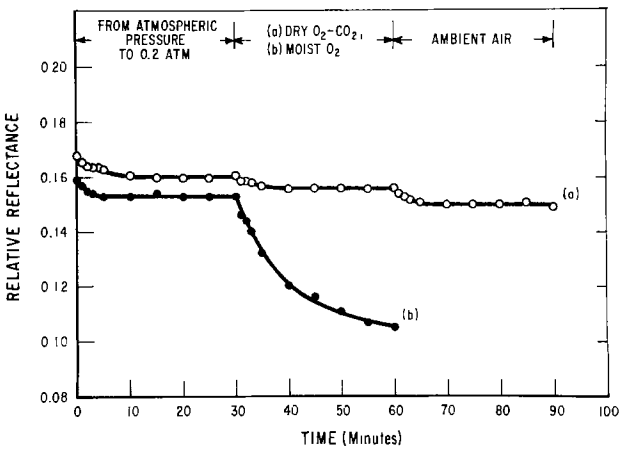

Fig. 4. Relative reflectance from the glass-film interface for two similar copper- and sulfur-containing, electroless-replacement films undergoing sucessive exposures to indicated environments. For sample (a), 284 ppm in volume percent of CO_2 in dry O_2.

sults in the formation of an apparently poorly crystallized sulfide by reaction with Cu^+ at the film surface. Subsequent rapid oxidation in air must proceed by cationic diffusion through the sulfide film, which is probably easy. More than that, however, it must be especially easy in the growing oxide. This would be so if the sulfide film favorably influenced the defect structure and/or morphology of the oxide. This seems very likely because the oxide is growing on a surface other than crystalline copper. Bunn (9) has suggested that impurities may be the cause for inconsistencies between the shape of cuprite crystals and cuprite's atomic structure from x-ray analysis. A further requirement, however, for rapid growth, is that the oxide be "immediately" contaminated by H_2O. Whether H_2O produces favorable defect sites in bulk or in dislocations and/or influences crystallinity or morphology is a speculative matter. The anhydrous oxide being so markedly resistant to further growth confirms, according to the following line of reasoning, that it is at least structurally freer of bond-disruptive hydroxide. By the Cabrera-Mott model, assuming a continuous Cu_2S layer

$$\frac{1}{2}O_2 \xrightarrow{Cu_2S} O^{-2} + 2\,Cu_{\square} + 2e_{\square} \qquad [1]$$

The cationic vacancies, $Cu_{\square}$, and electron holes, $e_{\square}$ are generated after adsorption of O_2. At the Cu_2S-Cu interface there occurs

$$Cu + Cu_{\square} + e_{\square} \rightarrow Cu^+ \qquad [2]$$

This is possible because Cu_2S is a p-type semiconductor and deficient in Cu^+. The cation diffuses to the Cu_2S-O^{-2} interface where the oxide forms. It is driven by the field existing across the Cu_2S film. The over-all reaction is

$$\frac{1}{2}O_2 + 2Cu \rightarrow Cu_2O \qquad [3]$$

Growth of Cu_2O, also a p-type semiconductor, requires continued adsorption of O_2 on the growing oxide and migration of cations. With adsorbed H_2O also present, it is possible that, concomitantly

$$Cu_2O + H_2O \rightarrow 2CuOH \quad (\text{or } Cu_2O \cdot nH_2O) \qquad [4]$$

Two forms of cuprous oxide are recognized, based on colors ranging from red to yellow (10). It is suspected that the yellow is probably of smaller particle size, but it may also exhibit a different growth habit. It has also been mentioned as a hydrated version of the red. These have not been distinguished by x-ray diffraction; therefore, the yellow form might have a different habit but could only contain amorphous hydroxide or a content outside the limits of detection. By flame emission spectroscopy, CuOH has been identified, but this from atomized salt solutions (11). There is, therefore, no real evidence for the existence of CuOH in the solid state; nevertheless, it does not preclude existence in the thin film. Oxide structure and morphology are already established in a favorable way for oxidation in air because of the underlying Cu_2S and its following oxygenated, aqueous rinse. Dehydration of adsorbed water from one crystal face or another in dry O_2 could not affect subsequent growth in air unless the anhydrous oxide which forms is structurally different and passivating; otherwise, rapid oxidation would always occur in air. This is not simple adsorption of H_2O with an electrochemical reaction. By implication, it seems probable that H_2O becomes part of and disrupts the growing oxide lattice. Migration of Cu^+ is thereby promoted, accounting for results herein. To conclude more than this, however, would require knowledge about how traces of hydroxide fit in Cu_2O structurally. However this may be, the significant acceleration of copper oxidation in air after $S_2O_3^{-2}$ treatment, coupled with the need for water vapor, is testimony to the important influence which these impurities have.

Summary

Using electroless copper films and electroless-replacement films containing copper, the rate of oxidation at room temperature has been discussed in terms of a probable sulfide impurity in the films and water vapor in the air. Together, these accelerate oxidation considerably. However, when a fresh film of either type is exposed to dry O_2, prior to the ambient, it is passivated for oxidation in air. Implicit in these data, first of all, is the conclusion that the over-all kinetics of oxidation of copper can be governed by the presence, or temporary denial, of an impurity, in a very significant way. Also, in light of exposure to the growth-promoting $S_2O_3^{-2}$ solution, preceding exposure to dry O_2, it is further concluded that the anhydrous oxide is remarkably resistant to further growth. Finally, while it is certainly not a new idea that impurities influence the kinetics of oxidation, these data provide evidence for behavior that suggests an interesting synergism. The sulfide impurity probably promotes a favorable structure and/or morphology for growth by oxidation; adsorbed H_2O apparently promotes cationic migration by entrainment and hydration in the oxide lattice.

Studies on the Oxide-Coated Metal Anodes for Chlor-Alkali Cells

F. Hine,* M. Yasuda, and T. Yoshida*

Nagoya Institute of Technology, Nagoya 466, Japan

ABSTRACT

Formation of the mixed oxide consisting of RuO_2 and TiO_2 was studied by the DTA/TGA technique and x-ray diffraction. The coating agent containing $RuCl_3$ and tetra-n-butyl titanate converted into the mixed oxide of RuO_2 and TiO_2 at about 400°C on the Ti substrate, and the reaction was exothermic. The electric resistance through the oxide film depends much on the fire temperature, and an optimum condition arises between 450° and 500°C. The solution composition and the time of preparation are also important factors. The anodic polarization behavior in the NaCl solution was also affected by the material or the condition of preparation of the oxide-coated Ti electrode.

Since the dimensionally stable anode (DSA®) has been developed by de Nora, many chlorine engineers have been interested in the metal anodes (1, 2). About 30% of the total chlorine in Japan is being produced by modern amalgam cell plants with DSA and replacement of graphite anodes is continuing.

Some papers on this material have been published, but details are still unclear (3-9). According to Beer's patent (10), the titanium substrate is painted with the coating agent containing $RuCl_3$ and tetra-butyl titanate, $Ti(OBu)_4$, and is fired at 400°-600°C in air for a few minutes.

The properties of the mixed oxide of RuO_2 and TiO_2 is important, also the interface between the Ti substrate and the oxide layer should be clarified in detail. Therefore, the coating agent was dried, fired, then powdered to yield samples for various examinations: the differential thermal analysis (DTA), the thermogravimetric analysis (TGA), and x-ray diffraction.

The polarization measurements of the oxide-coated titanium electrode (OCTE) in chloride solution were carried out by the current interruption technique.

The electric resistance through the interface between Ti and the oxide layer was determined.

Experimental Procedure

The composition of the coating agents examined are listed in Table I. Of these, type 10 was used only several times as reference because of weak adhesion with Ti substrate. The number of the type in this table corresponds to the mole ratio of Ru to Ti in the solution, *e.g.*, Ru/Ti = ½ for type 12, and the same code number is used as the type of OCTE when it is painted on the Ti substrate.

The coating agent was dried to solid at 100°C for about 24 hr and was powdered with an agate mortar. $Ti(OBu)_4$ was also powdered as reference, but $RuCl_3$ was avoided because of its hygroscopic behavior.

A Ti plate 20 mm wide, 22 mm long, and 0.5 mm thick was cleaned with 10% oxalic acid at 80°C for about 3 hr. The chemical composition of the Ti substrate is as follows: 0.071% Fe, 0.0055% N, 0.091% O, 0.0014% H, and 99.86% Ti. Coating was repeated until the oxide layer deposited enough for examination, from 4 to 80 coats. The average increments of weight and thickness per coating are shown in the last column of Table I. It was evaluated from the data of a thick oxide layer (80 coats), while the thickness depends on the viscosity of the coating agent.

The samples, both powdered and OCTE, were baked in an electric furnace under given conditions of the oxygen partial pressure (mostly in air) in the temperature range of 300°-700°C. Most samples were prepared at 300°, 450°, and 600°C.

The sample 20 mm wide and 22 mm long for the conductivity measurements of the interface was prepared in the same manner, while Pt plate was also employed as substrate.

Silver was vapor-plated on the oxide coat of 0.5 cm^2 area under 5-8 $\times$ 10^{-5} mm Hg vacuum, then Ag electroplating was carried out on it in a usual cyanide bath

(36 g/liter AgCN, 60 g/liter KCN, and 45 g/liter K_2CO_3 at room temperature) at 10 mA/cm² for 1 hr, so as to prepare the terminal for the resistance measurements. Unplated surface was insulated with PVC. Copper lead wires were soldered as shown in Fig. 1. We had trouble with mode B, which was one-side coated, because Ti was oxidized during firing at high temperature, and the resistance of the oxidized Ti substrate increased considerably. Therefore, mode A was normally used. It was confirmed that there was no rectification at the interface consisting of metal and oxide. The resistivity measurements were carried out by means of the four-probe method as shown in Fig. 1. The data obtained with specimens of 0.5 cm² were listed and plotted directly instead of the usual presentation in ohms per unit area.

Results

DTA and TGA.—Figures 2-4 are the data of DTA and TGA obtained in air atmosphere. The upper curve is the DTA and the lower the TGA. All samples showed the exothermic change with weight loss. The chemical formula indicated in the figure, such as RuO_2, was identified by x-ray diffraction. TiO_2(A) and TiO_2(R) indicate the anatase- and rutile-type titanium dioxide, respectively. The x-ray chart for the sample prepared at 300°C showed amorphous structure because the temperature was too low. The percent at the right-hand side in the chart shows the weight loss due to firing at 700°C.

Figure 2 shows the data of $RuCl_3$. Some changes at about 100°C would be due to vaporization of water from the sample. While $RuCl_3$ is hygroscopic material, it changes to fine powder by heating and loses its wettability. The data with acidified samples showed small effect of addition of HCl.

A large exothermic change was observed at about 420°C when butanol was added (curve A-2).

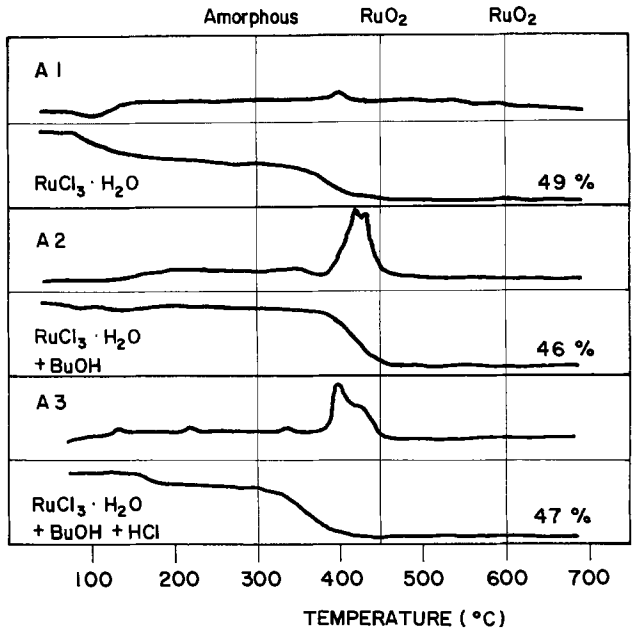

Fig. 2. DTA and TGA curves

The specimen for curve A-3 consists of $RuCl_3 \cdot H_2O$, HCl, and butanol (type 10). Small changes at 140°, 220°, 340°C were observed and a large peak on the DTA curve appeared at about 420°C.

The data of $Ti(OBu)_4$ are shown in Fig. 3. It is evident that the reaction is affected very much by addition of HCl and butanol. A large peak on the DTA curve at about 520°C diminished when HCl was added.

Figure 4 shows the data of the mixture of $RuCl_3$ and $Ti(OBu)_4$. These data showed a large change at relatively low temperatures. The mole ratio of Ru to Ti was widely varied, while only three samples are shown here. The highest peak on the DTA chart moved with the mole ratio in the temperature range between 300° and 400°C (Fig. 5).

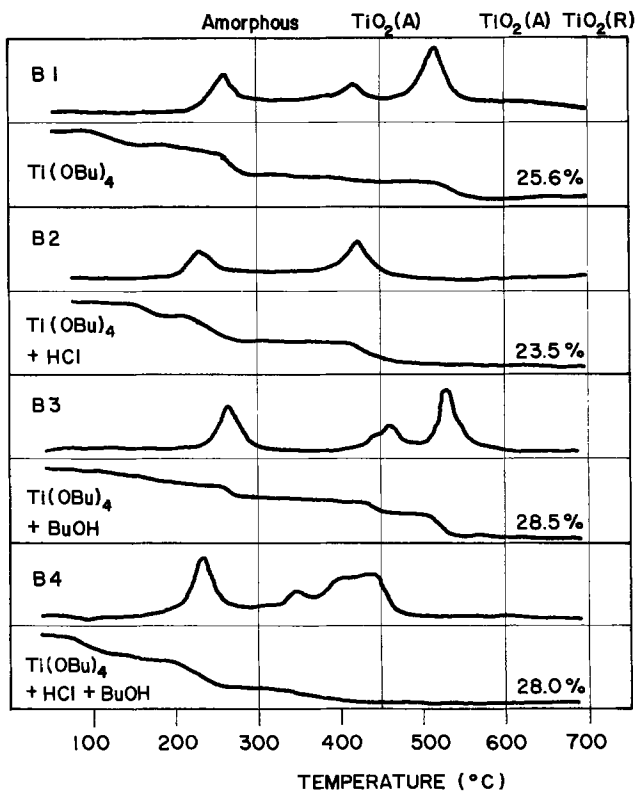

Fig. 3. DTA and TGA curves

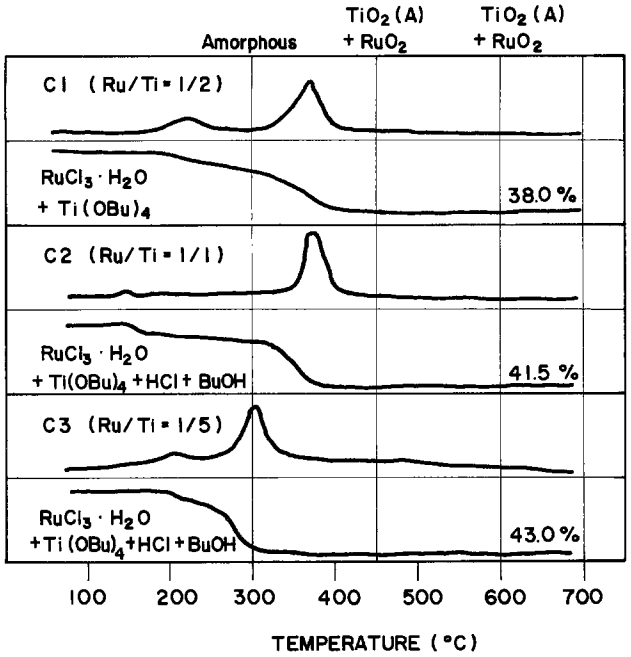

Fig. 4. DTA and TGA curves

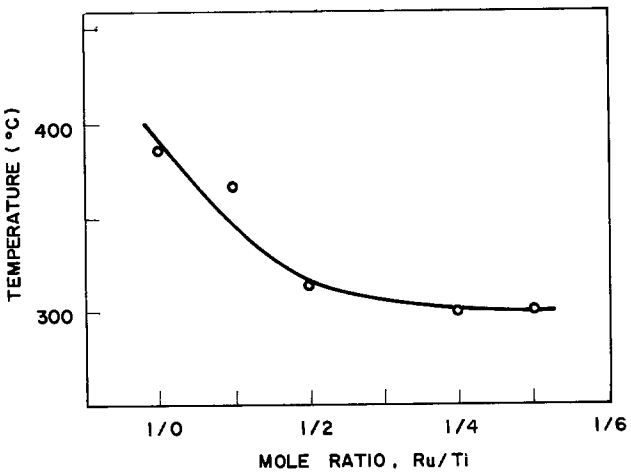

Fig. 5. Peak temperature of the DTA chart as a function of the mole ratio of Ru to Ti.

The experiment with the sample containing Ti powder (100 mesh) was carried out, and no significant effect was found. The chemical composition of Ti powder made by Osaka Titanium Manufacturing Company was as follows: 0.024% Fe, 0.010% Si, 0.030% Cl, 0.002% Mn, 0.009% Mg, 0.015% N. 0.008% C, 0.0078% H, 0.30% O, and more than 99.2% Ti.

X-ray diffraction.—The data for Ru powder fired at 700°C for about 60 min showed some oxidation of RuO_2. It changed completely at 1200°C. Dried then powdered $RuCl_3$ also changed to RuO_2 in the range 450°-600°C, and was not affected by either HCl or butanol.

$Ti(OBu)_4$ converted to TiO_2(A) when it was heated at 450°-600°C for only a few minutes in air. TiO_2(A) became TiO_2(R) at 700°C.

It is interesting to know the behaviors of the specimen painted on Ti substrate. Acidified $Ti(OBu)_4$ on Ti plate changed to TiO_2(A) at 600°C, then to TiO_2(R) at 700°C.

Other samples were prepared with the solutions of types 12 and 15 with Ti substrate at 450°C for 10 min. The x-ray data showed the oxide mixture consisted of RuO_2 and TiO_2(R) instead of anatase (Fig. 6). Its mixed oxide would be a solid solution having the rutile configuration.

It was confirmed that the oxide deposited on a glass plate consisted of RuO_2 and TiO_2(A). Therefore, the

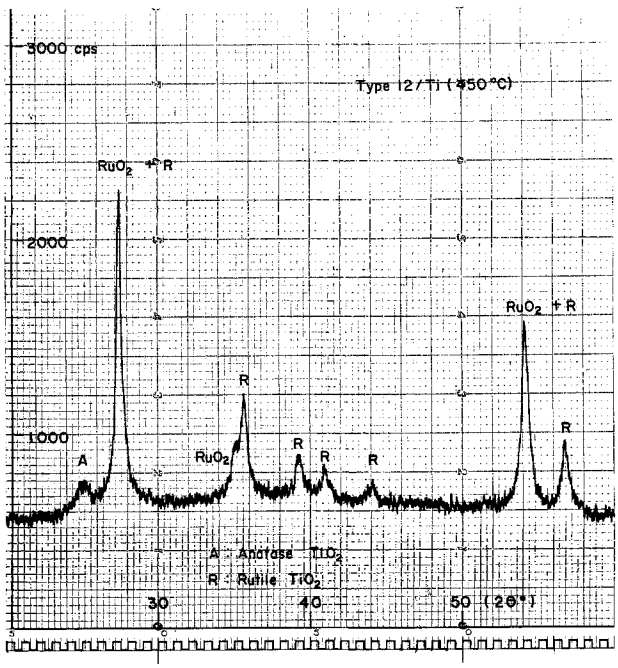

Fig. 6. Type 12 on Ti substrate fired at 450°C for 10 min in air atmosphere.

effect of Ti metal on the formation reaction of oxide is appreciable.

The sample prepared with powdered $Ti(OBu)_4$ and Ti powder consisted of TiO_2(A). On the other hand, the mixture of the powder of type 12 with a small amount of Ti powder converted to the rutile-type oxide mixture with some TiO_2(A) by heating at 450°C (Fig. 7). When the sample was heated at high temperature such as 700°C ,the peak for TiO_2(A) on the x-ray chart lowered gradually, and the peak split: $2\theta = 27°$-$28°$ and 35°-36°, as shown in Fig. 8.

Resistivity measurements.—The resistivity through the oxide layer measured at room temperature is a function of the conditions of preparation such as the mole ratio of Ru to Ti, the number of coating or the thickness of the oxide layer, the fire temperature, the time of firing, and the oxygen partial pressure. It is impor-

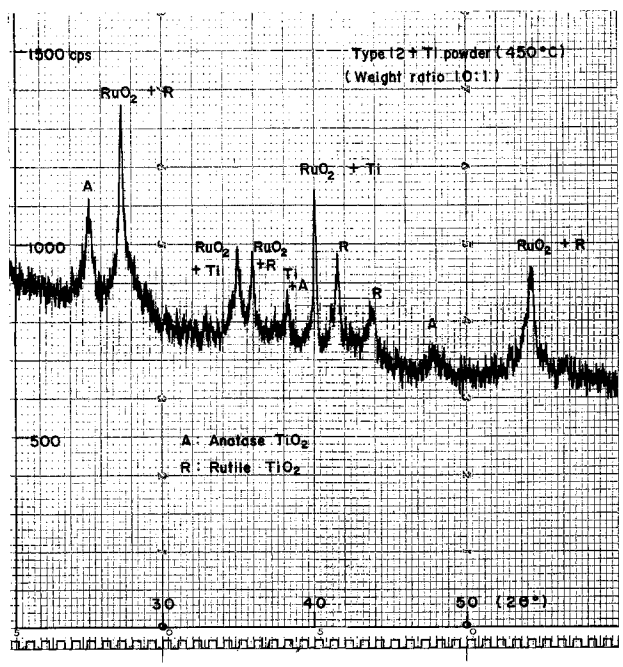

Fig. 7. Type 12 with Ti powder fired at 450°C for 10 min in air atmosphere.

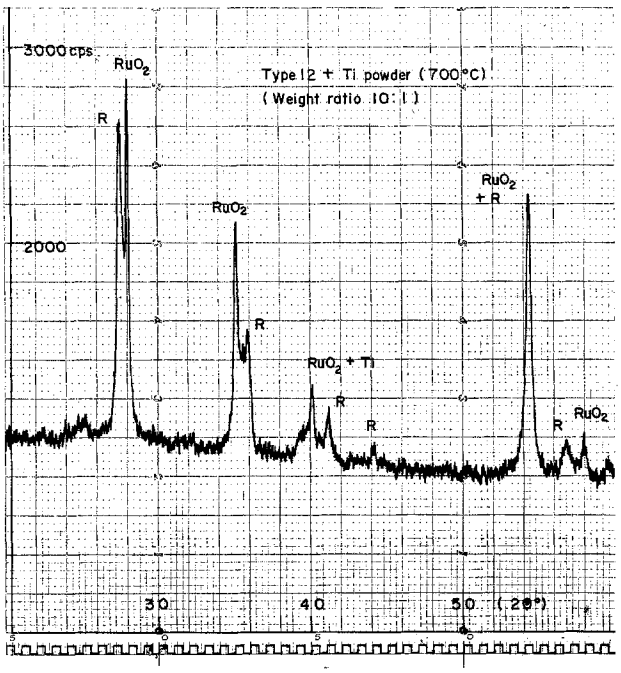

Fig. 8. Type 12 with Ti powder fired at 700°C for 10 min in air atmosphere.

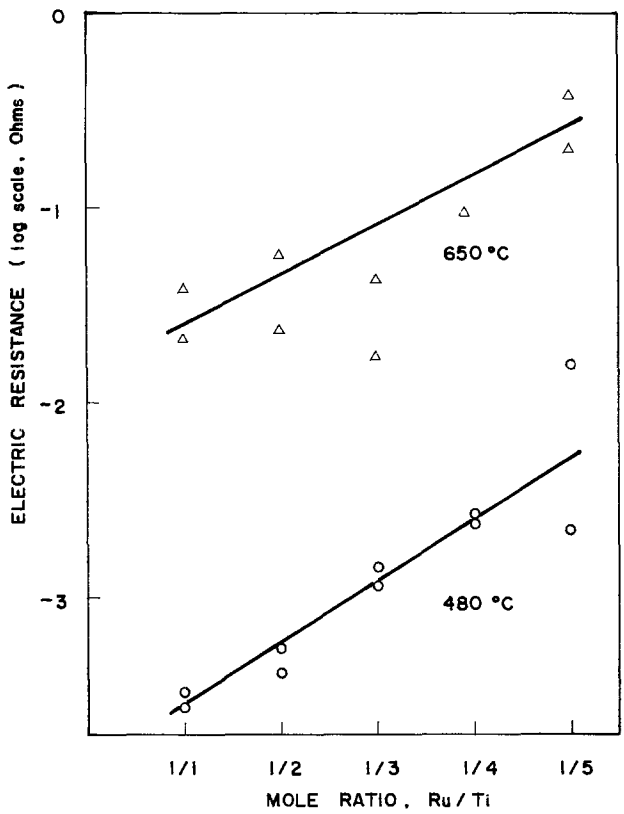

Fig. 9. The electric resistance at room temperature as a function of the mole ratio of Ru to Ti. The fire temperature is shown in the figure. The OCTE, 4 coats, was fired for 5 min.

tant to note that the larger the Ti content the larger is the resistivity (Fig. 9). As shown in Fig. 10, there is an optimum temperature of firing between 350° and 450°C.

When the specimen is fired at low temperatures, say 400°C, for relatively long time such as 30 min, the Ti substrate is oxidized gradually by oxygen passing through the oxide layer and the resistivity increases. Therefore, the heat-treatment should be carried out within a few minutes.

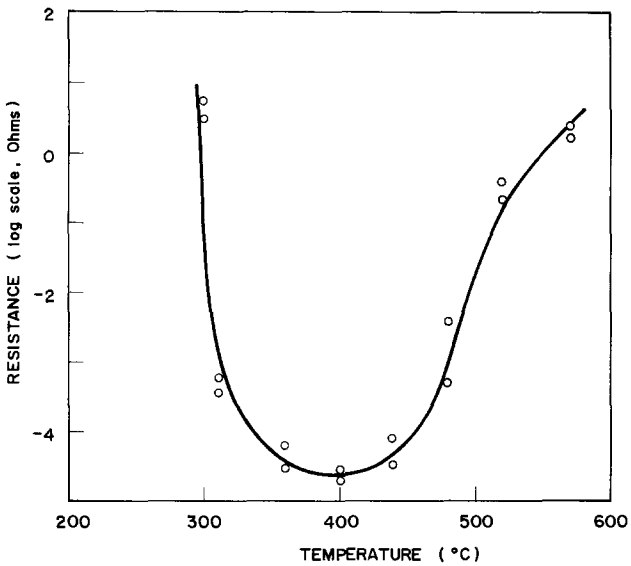

Fig. 10. The electric resistance at room temperature as a function of the fire temperature (type 15). The OCTE, 4 coats, was fired for 5 min.

The specimen prepared under oxygen showed almost the same properties as the specimen fired in air.

Figure 11 shows the electric resistance as a function of the temperature of measurement in a range −50° to 150°C. The temperature coefficient of the resistivity is observed to be negative, which is discussed later. But it is important that it is a typical property of semiconducting materials.

Polarization measurements.—The polarization curves of the specimens of different composition (fired at 450°C for 10 min) in saturated NaCl ($pH = 0.9$) with dissolved chlorine at 40°C are shown in Fig. 12. The specimen, type 10, was avoided because of its weak strength as anode. It is obvious that the curve is almost independent of the oxide composition within the range of our experiment.

It is interesting that the polarization depends so much on the fire temperature as shown in Fig. 13, where the solid line and the dashed line show the data with type 12 on Ti and Pt as substrates, respectively.

The OCTE, type 12, prepared at 400° and 500°C shows relatively low chlorine overvoltage.

The overvoltage of the specimen prepared at 300°C is high, probably due to insufficient thermal decomposition of $RuCl_3$ to oxide.

The Ti substrate is oxidized at temperatures higher than 600°C, and hence, the overvoltage becomes high. At temperatures higher than 700°C, the DTA and the x-ray data show significant crystallization of the oxide.

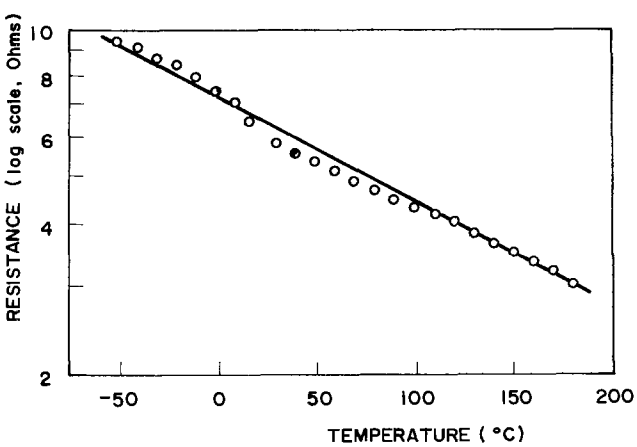

Fig. 11. The electric resistance vs. temperature curve (type 12). The OCTE, 5 coats, was fired at 550°C for 20 min.

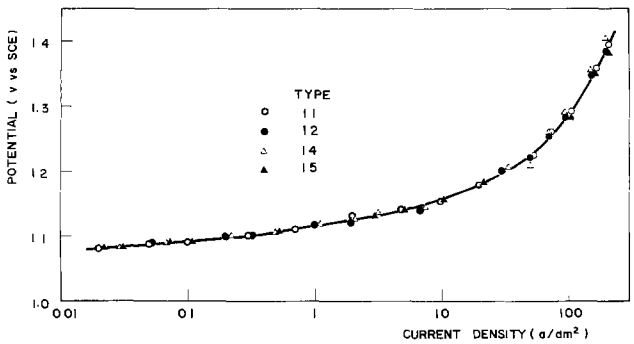

Fig. 12. The anodic polarization curves in saturated NaCl (pH 0.9) at 40°C. The OCTE, 4 coats, was fired at 450°C for 10 min.

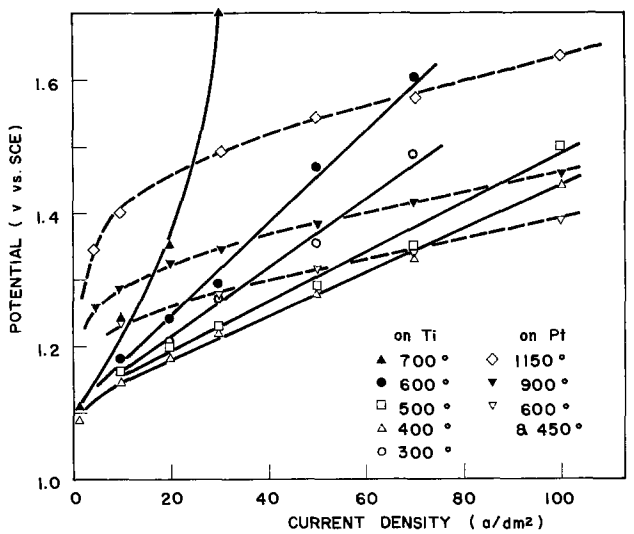

Fig. 13. The anodic polarization curves of type 12 painted on Ti and Pt substrates in saturated NaCl (pH 0.9) at 40°C as functions of the fire temperature. The specimens with Ti and Pt substrates were painted 4 and 8 times, respectively, and were fired for 10 min.

The polarization data of those specimens show poor activity as the chlorine electrode, even when Pt is employed as substrate instead of Ti.

Figure 14 is the summary of the polarization of the specimens prepared at various temperatures. The ordinate is the slope of the polarization curve shown in Fig. 13. The curve shows a minimum resistivity in the temperature range between 400° and 500°C.

Discussion

The active material on the OCTE invented by Beer consists of the mixture of RuO_2 and TiO_2, and is strong under severe conditions of service as chlorine electrode (10). We made a RuO_2 deposited on Ti, and polarized it in a saturated NaCl solution (pH = 2-3) at about 90°C under 100-150 A/dm² for few days. A single oxide (RuO_2) peeled off considerably and failed during electrolysis, whereas a mixture of RuO_2 and TiO_2 was no problem.

The DTA/TGA data of the coating agent without Ti powder show that a large exothermic change in a range 300°-400°C, depending on the composition of the coating agent, appears (Fig. 2-4). At high temperatures (450°-600°C), the peaks for RuO_2 and TiO_2(A) on the x-ray chart are clearly separated from each other.

The DTA/TGA data are not affected by the presence of Ti, either plate or powder. On the other hand, the x-ray data of the sample consisting of the mixed oxide with Ti prepared at 450°-600°C show the peaks of RuO_2 and TiO_2(R).

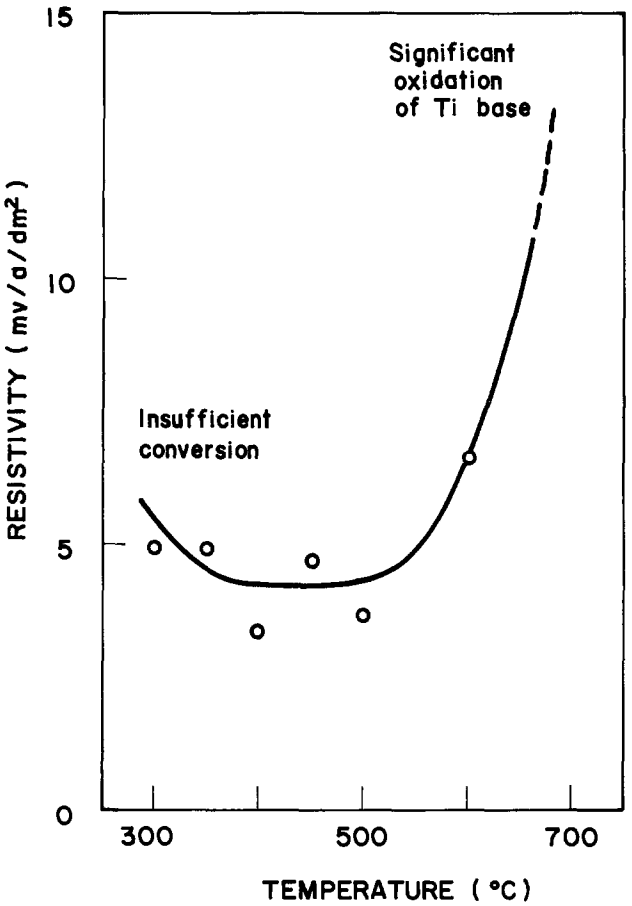

Fig. 14. The polarization resistance as a function of the fire temperature.

Adhesiveness between the oxide mixture and Ti substrate becomes excellent.

The coating agents shown in Table I were dried at 100°C and powdered, with Ti in some cases. The samples were heated at 450°-600°C. The x-ray data describe that three components, *i.e.*, $RuCl_3$, $Ti(OBu)_4$, and metallic Ti, are necessary to form rutile oxide. The TiO_2(A) will form by heating if one of those components is eliminated. In other words, we could obtain a suitable material as anode when we paint Ti substrate with the mixed solution of $RuCl_3$ and $Ti(OBu)_4$.

We require the anode material to have low resistivity, good electrochemical activity, corrosion resistance, and geometrical stability under service conditions.

The experimental data show that the larger the Ru/Ti ratio the lower is the electric resistance. The temperature of firing is also a factor of the resistivity. A preferable material can be obtained at the temperature just beyond the peak of the DTA/TGA chart at about 400°C.

It is assured that the TiO_2 layer on the substrate sustains a major part of the electric resistance through the metal-to-oxide. It is well known that Ti is covered with an oxide layer, and thermal oxidation to TiO_2(R) proceeds at relatively low temperatures such as 400°C (11-14). We experienced difficulty with making measurements of electric resistance with the specimen mode B in Fig. 1, due to significant oxidation of the bare surface of Ti. Even with mode A, the resistivity increased considerably when the specimen was heated at 400°C for 30 min or more.

The x-ray data of the specimen, which was prepared with the coating agent, type 12, on Pt sheet instead of Ti under various temperatures (450°, 620°, 900°, and 1150°C) for 10 min, showed RuO_2 + TiO_2(R). The resistivity of those specimens was one to two orders lower than that of the minimum of OCTE shown in Fig. 10. Those results suggest that increase in the re-

sistivity of the material with Ti substrate is caused by oxidation or diffusion of oxygen through the oxide coat during heat-treatment (15, 16), but the resistivity is a small function of the degree of crystallization.

The temperature coefficient of the resistivity of OCTE is negative as shown in Fig. 11, and agrees with reference data (9). It is said that the single crystal of RuO_2 has the characteristics of metal-like conductivity (17-19), and TiO_2(R), which is also single crystal, behaves like an oxygen-defective n-type semiconductor (20). The behavior of OCTE as a semiconductor has been reported by several authors (7, 21), but only with the experimental data of the resistivity measurements.

The anodic polarization curves of the OCTE prepared at 450°C for 10 min are also independent of the Ru/Ti ratio in the range 1/1-1/5. The polarization behavior of the OCTE has been reported (5, 7). Generally, the electrochemical activity is said to decrease with increase in the Ti content in the active materials. Of course, the polarization behavior is a factor in practice, but the Ru/Ti ratio of 1/2 seems to be optimum from the viewpoint of economical consideration (10).

The scanning electron microscopic observation shows the rough surface of the OCTE and the roughness factor is 80-200 (7, 9, 22). Therefore, it would also be a large factor of low chlorine overvoltage in concentrated NaCl solution, while the relationship between the chlorine overvoltage and the surface roughness has not been clarified yet in detail.

The Tafel slope of the anodic polarization curve shown in Fig. 12 at relatively low current densities is about 40 mV/decade, but the overvoltage increases quickly at high current density ranges. Those phenomena have been described by Kuhn *et al.* (7), who have tried to apply the theory of semiconductors (23). As shown in Fig. 13 and 14, the chlorine overvoltage of the specimen prepared at temperatures higher than 500°C is high, probably due to failure in activity and oxidation of substrate.

The specimen with Pt substrate has the polarization behavior shown by the dotted line in Fig. 13. As described above, the substrate does not oxidize by heating in this case. Therefore, increase in the overvoltage by firing at high temperatures would be due to failure in the electrochemical activity or crystallization of the oxide layer.

According to the x-ray diffraction, the active material prepared with $RuCl_3$ and $Ti(OBu)_4$ consists of the solid solution of the rutile-type mixed oxide of Ru and Ti, while RuO_2 prepared from $RuCl_3$ by firing is a nonstoichiometric compound containing Ru(III) (8).

The crystal size depends on the preparation temperature, *e.g.*, 115 and 201Å at 400° and 500°C, respectively (9). From those reference data and our experiments, the active material deposited on Ti substrate would be a solid solution of the rutile-type oxide of Ru and Ti, which has an oxygen-defective and mosaic structure.

Crystallization proceeds firing at temperatures higher than 700°C, and the peaks of TiO_2(R) and RuO_2 on the x-ray chart split off. The electrochemical activity of such a material is poor.

The Anodic Formation of Cu_2O in Alkaline Solutions

V. Ashworth and D. Fairhurst[1]

Corrosion and Protection Centre, University of Manchester Institute of Science and Technology, Manchester, England

ABSTRACT

Chronopotentiometry has been used in conjunction with electron microscopy to investigate the anodic formation of Cu_2O on copper electrodes immersed in aqueous sodium hydroxide solutions (0.01-1M). The anodic transition time τ for Cu_2O formation is related to the applied current density, i_1, by the relationship

$$i_1\tau^{1/2} = \text{a constant}$$

A nucleation and growth model of film formation is proposed which is in good agreement with the experimental results. The rate-determining step is the formation of a soluble copper(I) species, film growth taking place by precipitation from solution.

It is generally considered that cuprous oxide, Cu_2O, is the first product of the anodic oxidation of copper in alkaline solutions (1-14). In the case of electrochemical reaction in aqueous sodium hydroxide this has been confirmed by electron diffraction (5). Until recently, however (11), very little attention has been focused upon the mechanism by which the reaction proceeds. More importance has been attached to the formation of copper(II) species during subsequent electrochemical oxidation reactions. According to the various sources, cupric oxide, CuO (2, 5, 6, 8, 9), cupric hydroxide, $Cu(OH)_2$ (3-8), and a soluble species thought to be the bicuprite anion, $HCuO_2^-$ (7, 10), may be formed. Nevertheless, there appear to be several conflicting opinions in the literature as to whether these divalent species form in consecutive or concurrent electrode reactions. Further, the knowledge that the treatment of alkaline solutions containing cupric ions with strong oxidizing agents can yield salts of copper(III) (15) has been linked with the possible formation of Cu_2O_3 at potentials somewhat lower than those at which oyxgen evolution occurs at a copper anode (7, 10).

Chronopotentiometry has proven to be the important technique used to investigate the reactions taking place at a copper electrode. In both anodic and cathodic polarization stages the presence of a potential arrest in the potential-time (E-t) behavior of the copper electrode has been linked to the formation, or reduction, of one of the species identified above.

Until very recently it had been considered that Cu_2O forms without appreciable formation of a soluble copper(I) species in accordance with the known instability of the copper(I) aquo ion (16) and the insolubility of Cu_2O (17). Dignam and Gibbs (11) have confirmed this view in experiments in borate solutions (pH 9.19) where the cathodic reduction of an anodically formed Cu_2O film proceeds with a current efficiency[2] of 100%, *i.e.*, there is no charge inbalance brought about by the diffusion of a soluble species away from the electrode surface. Similar conclusions have been drawn from comparable results obtained in 0.1M sodium hydroxide (7) although the electrode potential arrests associated with the electrochemical reduction of Cu_2O to the metal are not so well defined as in borate solutions and the calculations are therefore less precise. Unfortunately the majority of workers who have used chronopotentiometry to investigate the reactions taking place on copper have always reversed the direction of the applied current after the onset of oxygen evolution. The cathodic reduction of higher valent copper species formed anodically up to the oxygen evolution potential renders it impossible to determine the current efficiency for Cu_2O formation and reduction under these circumstances.

Recent work, however, indicates that in concentrated alkali a soluble copper(I) species has a more important role to play in Cu_2O formation than was previously considered (10, 14). Using a rotating split ring-disk electrode, Miller (10) showed that during the chronopotentiometric formation of a Cu_2O film at the copper disk in 1M sodium hydroxide a soluble copper(I) species could be detected by its simultaneous one electron potentiostatic oxidation [to copper(II)] and reduction [to copper(0)] at the gold half-rings. Furthermore, during controlled positive-going potentiodynamic sweeps on the copper disk Miller observed a ring current maximum corresponding to the oxidation of soluble copper(I) species to copper(II) at disk potentials negative to the Cu-Cu_2O active-passive transition. Ambrose *et al.* (14) also recorded that during high rate potentiodynamic sweeps upon a stationary copper electrode in 1M potassium hydroxide a small but definite current peak can be observed at potentials more negative than that attributable to Cu_2O formation and concluded that a soluble copper(I) species is generated prior to the appearance of any Cu_2O. Finally a recent Japanese publication (18) reports that the results of ellipsometric and chronopotentiometric studies, carried out *in situ*, are consistent with the anodic formation of Cu_2O in alkaline solutions by a dissolution-precipitation mechanism.

In the past, chronopotentiometric studies of the anodic reactions taking place at a copper electrode have been carried out at relatively high current densities (>0.5 mA/cm^2). Under these conditions only small quantities of Cu_2O are formed prior to the appearance of copper(II) species, and investigations of the initial oxidation stage are therefore difficult. This paper describes an investigation based upon low current density chronopotentiometry and electron microscopy into the anodic formation of Cu_2O in alkaline solutions. A nucleation and growth model of Cu_2O film formation is proposed which is in good agreement with the experimental results obtained.

Experimental

Chronopotentiometry.—Copper specimens were cut from 0.94 mm thick deoxidized high conductivity copper sheet (Henry Righton and Company, Limited). After annealing at 750°C *in vacuo* the specimens were used to fabricate spade electrodes having an exposed

[1] Present address: The International Paint Company, Felling, Gateshead, England.

[2] Current efficiency = $\frac{\text{charge passed along the cathodic potential arrest}}{\text{charge passed along the anodic potential arrest}} \times 100\%$.

Key words: chronopotentiometry, dissolution-precipitation, nucleation, film growth.

surface area of approximately 430 mm^2. The electrodes were electropolished using Powers' method (19) and, immediately prior to use, were etched in alcoholic ferric chloride (20). It was found that the reproducibility of the results was significantly enhanced by using electropolished and etched, rather than abraded or electropolished, surfaces (21).

The electrochemical cell used for the polarization studies consisted of a 1000 cm^3 reaction vessel with a tightly fitting lid. The working electrode was located centrally within the cell and was surrounded by a cylindrical platinum sheet counterelectrode (110 mm circumference, 35 mm high). A Luggin capillary probe provided electrolyte contact between the working and reference electrodes. All electrode potentials were measured with respect to a saturated calomel electrode (+244 mV *vs.* SHE), but are reported in this paper on the standard hydrogen scale. The electrochemical cell was completed by gas inlet and outlet tubes and an inlet for the introduction of the electrolyte solution. The cell was mounted in a thermostatically controlled water bath maintained at 30° (±0.1°C).

Sodium hydroxide solutions were used as the test environment. Approximately 750 cm^3 of test solution were deaerated by an evacuation and sparging procedure as follows. The solution was placed in a 1000 cm^3 conical flask which was evacuated until there was no further visible evidence of gas disengagement from the solution. Atmospheric pressure was then restored within the flask by allowing hydrogen gas to enter. The solution was sparged subsequently with hydrogen for 30 min before being pumped into the electrochemical cell under hydrogen pressure and without air exposure. (The electrochemical cell had been flushed previously with hydrogen.) For the duration of each experiment hydrogen gas was passed over the surface of the test solution to prevent the ingress of atmospheric oxygen.

The constant current was supplied from a stabilized power supply (Type C346, Wareham Measuring Systems Limited) and measured using a Universal avometer (±2% f.s.d.). The electrical circuit incorporated a reversing switch that enabled polarity reversals to be made in the reaction vessel without altering the direction of the current through the avometer. The electrode potential of the working electrode was measured using a *p*H meter (Model 290, Pye Electronics Limited) and its variation with time monitored on a potentiometric recorder (Speedomax XL681, Leeds and Northrup Limited).

Following the complete assembly of the cell, the working electrode was cleaned cathodically at a current density of 10 $\mu A/cm^2$. Once a sharp fall in potential had indicated the onset of hydrogen evolution on the surface of the working electrode, the current was adjusted to the level required for a particular experiment and reversed, *i.e.*, the specimen was anodically polarized. Similarly as soon as the start of a rapid rise in electrode potential became evident beyond the first anodic potential arrest, the polarity of the cell electrodes was reversed once more causing the anodically formed Cu_2O layer to be reduced.

Electron microscopy.—To examine the morphology of the Cu_2O films, experiments were interrupted at the positive limit of the anodic potential arrest, *i.e.*, the cell current was switched off, the specimen removed from the cell, and, after rinsing and drying, examined electron-optically. Both scanning and transmission electron microscopy were used for this purpose. To employ the former technique, it was necessary to coat the specimens with gold to prevent charging of their surfaces during direct examination. The use of conventional transmission electron microscopy was made possible by preparing positive replicas of the specimen surfaces using the two-stage method (22). This involved preparing an initial negative replica in plastic (M280-D blue replicating material, P.E. Electron Microscope Accessories Limited) onto which was evaporated a thin layer of carbon. The replica was then shadowed with a gold palladium alloy to improve contrast. After dissolving the plastic in acetone, the shadowed positive carbon replica was mounted on a copper grid for examination in the transmission electron microscope.

Results

The *E-t* curves recorded during cathodic cleaning of the copper specimens at a constant current density of 10 $\mu A/cm^2$ indicated that the freshly prepared specimens carried a Cu_2O film between 70 and 300Å thick. Since a 20-40Å thick film is reported to form rapidly upon a clean copper surface when the metal is exposed to air or oxygen at room temperature (23, 24), the thicker films reported here reflect a reasonably high surface roughness introduced by the electrode pretreatment.

A distinctive feature of the *E-t* variation during the anodic formation of Cu_2O was the appearance of a "potential overshoot" which immediately preceded the establishment of the anodic arrest, *i.e.*, the region of constant potential was approached from a more noble potential. As Fig. 1-3 show, the "overshoot" became more pronounced with increasing sodium hydroxide concentration and less pronounced with increasing current density. Furthermore, it was found that the anodic transition time diminished progressively with increasing current density in the same solution although at comparable current densities it increased with an increase in the concentration of sodium hydroxide (Table I).

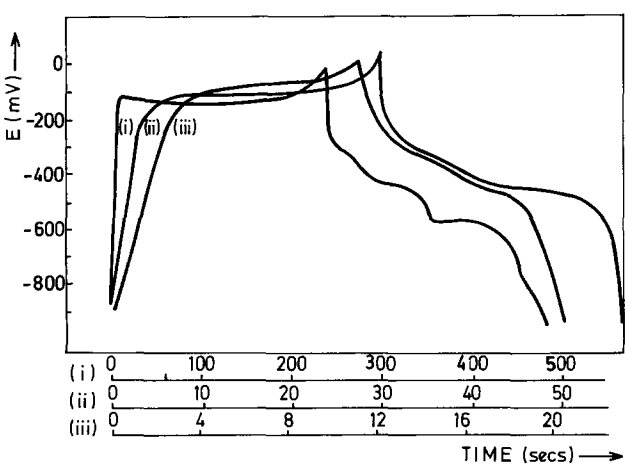

Fig. 1. Chronopotentiometric polarization curves for a copper electrode in 0.01M NaOH (i) 29.8 $\mu A/cm^2$, (ii) 101 $\mu A/cm^2$, (iii) 227 $\mu A/cm^2$.

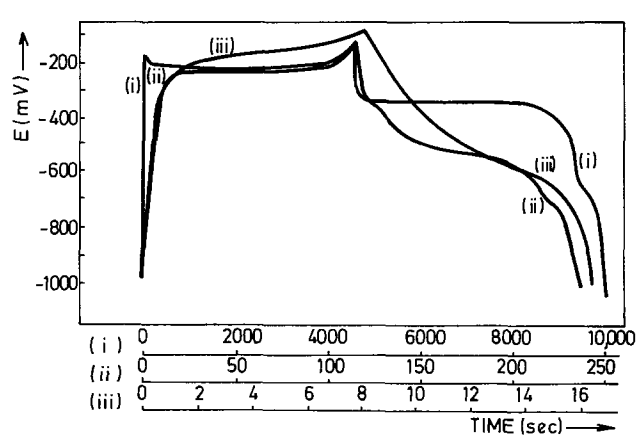

Fig. 2. Chronopotentiometric polarization curves for a copper electrode in 0.1M NaOH: (i) 25 $\mu A/cm^2$, (ii) 120 $\mu A/cm^2$, (iii) 399 $\mu A/cm^2$.

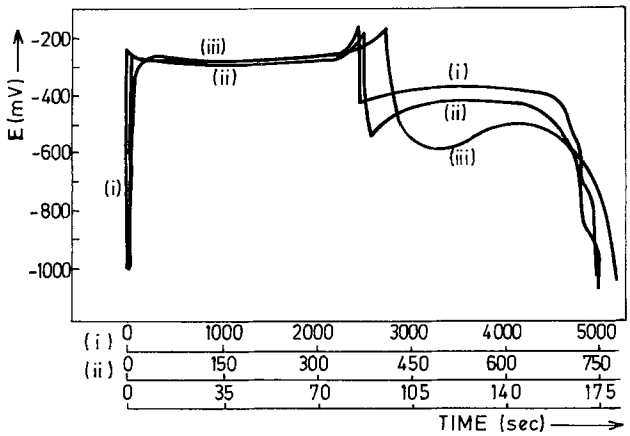

Fig. 3. Chronopotentiometric polarization curves for a copper electrode in 1M NaOH: (i) 91.1 μA/cm^2, (ii) 305 μA/cm^2, (iii) 513 μA/cm^2.

The term "transition time" is most commonly used to describe the duration of an arrest appearing in the chronopotentiogram. Since double layer charging makes a contribution to the apparent transition time in a chronopotentiogram, several methods of determining the real transition time relating to a specific electrochemical reaction have appeared in the literature. However, according to Bos and van Dalen (25), it makes little difference which method is used when carrying out experiments in solutions containing greater than 10^{-3}M of the reactant since above this concentration the charging affects are vanishingly small. In the experiments described here, it was confirmed that the actual method of transition time determination had little bearing upon the over-all results. Thus the τ values in Table I were determined using a simple graphical method similar to that described by Russell and Petersen (26) and attributed to Kuwana.

As can be seen from Fig. 1-3, the cathodic E-t curves were generally more complicated than their anodic counterparts particularly at low current densities. In 0.1 and 1.0M sodium hydroxide solutions, cathodic potential overshoots were sometimes discernible.

Table I. The effect of sodium hydroxide concentration and anodic current density on transition time (τ), film thicknesses, and the current efficiency of the formation and reduction of Cu_2O

The current efficiencies determined by comparing the charge passed in the cathodic E-t curve with that passed in the corresponding anodic curve are compiled in Table I. Measurements of the current efficiency were based on the anodic charge passed up to polarity reversal and the cathodic charge passed subsequently in attaining -956, -1056, and -1106 mV in 0.01, 0.1, and 1.0M sodium hydroxide solutions, respectively. As shown in Table I, these efficiencies varied considerably between 90 and 120% depending on both the electrolyte concentration and the applied current density.

Discussion

The anodic potential overshoot.—None of the existing literature concerning the anodic behavior of copper in alkaline solutions shows any evidence of anodic potential overshoots in the chronopotentiograms. This is not surprising since in the majority of cases experiments were carried out at higher current densities than those employed here. The experimental results showed clearly a progressive diminution in the magnitude of the overshoot with increasing current density. Comparable anodic potential overshoots have been observed during anodic film formation upon a number of metals exposed to a variety of different environments; these results have been summarized by Vermilyea (27). The same author suggests that the phenomenon arises from the additional overpotential required to produce nuclei of the anodic product on the metal surface. Once nucleation has occurred, it is envisaged that the overpotential falls due to the growth of the nuclei being a comparatively facile process.

According to Ambrose *et al.* (14) the growth of a Cu_2O film in 1M potassium hydroxide solution is preceded by the formation of a soluble copper(I) species for which the formula $Cu(OH)_2^-$ has been suggested. By analogy with the explanation put forward by Vermilyea (27), it might be argued that the anodic potential overshoot reported here is due to the kinetically easier formation of the $Cu(OH)_2^-$ ion during the early stages of anodic polarization. The overshoot is thus an indication of the need to supersaturate the solution prior to the initiation of Cu_2O formation. It is conceivable that for an electrochemical dissolution-chemical precipitation mechanism of film growth, continued growth of the Cu_2O nuclei requires saturation and not supersaturation of the electrolyte. Consequently the electrode potential falls as a steady-state situation becomes established.

The solubility of Cu_2O in water has been determined as 6.99×10^{-7} g-moles/liter (17) and one must assume a similarly low value for this compound in alkaline solutions as no data are readily available in the literature. In view of the suggested formula (14) for the copper(I) solution species, the solubility of Cu_2O in alkaline solutions can be expressed as

$$Cu_2O + 3H_2O \rightarrow 2Cu(OH)_2^- + 2H^+ \qquad [1]$$

Thus, assuming, as Eq. [1] implies, that the solubility of Cu_2O in alkaline solutions follows the same trend as CuO and $Cu(OH)_2$ (17), *i.e.*, it increases with increasing *p*H, the more pronounced anodic potential overshoot at higher hydroxyl ion concentrations can be explained.

The possibility that the solution could contain more copper(I) species in solution with increasing alkalinity is supported by the current efficiencies in Table I. The current efficiencies for the anodic formation cathodic reduction of Cu_2O at low current densities in 0.01 and 0.1M sodium hydroxide solutions were found to exceed 100% to a substantial extent, an observation that can be attributed to the simultaneous reduction of dissolved oxygen at the copper electrode. With the counterelectrode surrounding the working electrode, it is to be anticipated that some oxygen generated during the anodic polarization of the counterelectrode should diffuse to the working electrode and be reduced elec-

trochemically. The decrease in oxygen solubility with increase in sodium hydroxide concentration (28) ensures that less cathodic charge is consumed in the reduction of oxygen. Therefore it might be expected that lower current efficiencies, but never less than 100%, would be observed from this source in concentrated solutions. Thus a current efficiency of 91% recorded at 558 $\mu A/cm^2$ in 1M sodium hydroxide clearly shows the involvement of a copper(I) solution species. This particular experiment was repeated a number of times on separate specimens, but with the current being reversed at different points along the anodic Cu_2O potential arrest. The current efficiencies for the different time intervals of anodic polarization prior to current reversal are shown in Table II. The results indicate that the proportion of escaping soluble copper(I) generated remained effectively constant throughout the Cu_2O formation step. This is in agreement with the results of Miller's (10) split ring-disk experiments where, although a maximum in the concentration of soluble copper(I) at very short times (<2 sec) was observed, at longer times the concentration of this species became relatively constant.

Thus the appearance of anodic potential overshoots, becoming more predominant with increasing sodium hydroxide concentration, and the current efficiencies of substantially less than 100% are both consistent with the formation of a soluble Cu(I) species and suggest that the anodic formation of Cu_2O in alkaline solutions may take place by a mechanism of electrochemical dissolution followed by chemical precipitation.

The anodic transition time and its dependence on current density.—The diffusion model.—The empirical relationships between the experimentally determined anodic transition time τ and the applied current density i_l were found to obey the general formula

$$i_l\tau^{1/m} = K \qquad [2]$$

$$\text{units} - (\mu A/cm^2)\ (\text{sec})^{1/m}$$

The values of K and m for the experimental results are compiled in Table III. It can be seen that in all three solutions the value of the index m was close to 2. For this value, Eq. [2] coincides with the fundamental equation of chronopotentiometric analysis for an electrochemical reaction where the over-all rate is determined by the slow diffusion of a solution species (29), *viz.*

$$i_l\tau^{1/2} = \tfrac{1}{2}n\pi^{1/2}\mathbf{F}D_o^{1/2}C_o^b \qquad [3]$$

(n is the number of electrons involved in the electrochemical reaction, $\mathbf{F}$ the Faraday constant, and D_o and C_o^b the diffusion coefficient and bulk concentration, respectively, of the diffusing species). A comparison of experimental results with Eq. [3] has been used by previous workers to argue the role of diffusion in determining the rate of anodic film formation (30). However, the implications behind a compliance of the experimental results with Eq. [3] in a film-forming situation require further consideration.

The electrochemical reduction of a species Ox to a second species Red can be represented as

$$\text{Ox} + ne \rightarrow \text{Red} \qquad [4]$$

Now assuming both Ox and Red are soluble and can undergo unhindered diffusion to or from reaction sites situated upon a plane metal electrode, and that the driving force for diffusion in both cases is the existence of concentration gradients, Fick's laws of diffusion can be used to derive expressions for the time dependence of the interfacial concentrations, C_o^i and C_R^i of the oxidized and reduced species, *i.e.*

$$C_o^i = C_o^b - \frac{2i_l t^{1/2}}{\pi^{1/2}n\mathbf{F}D_o^{1/2}} \qquad [5]$$

and

$$C_R^i = \frac{2i_l t^{1/2}}{\pi^{1/2}n\mathbf{F}D_R^{1/2}} \qquad [6]$$

It is clear that Eq [3] follows directly from Eq. [5] by assuming that at time $t = \tau$ the interfacial concentration of Ox, C_o^i, is zero. Clearly, for an anodic reaction involving soluble reactants and products, an identical treatment to that given above will apply; the time dependence of the interfacial concentration of the reactant being given by Eq. [5] and that of the product by Eq. [6].

However, it may be anticipated that the above expressions may not hold for an anodic reaction producing an insoluble species. Nevertheless, in a number of instances the observation of a direct proportionality between i_l and $\tau^{-1/2}$ for the anodic passivation of metals in sodium hydroxide solutions has been explained as arising from the slow diffusion of hydroxyl ions to the metal surfaces (30). In Fig. 4 i_l has been plotted against $\tau^{-1/2}$ for the results given in Table I. Figure 4 shows that in each solution in which experiments were carried out an i_l *vs.* $\tau^{-1/2}$ relationship can be claimed. Furthermore, the results confirm to some extent those obtained by El Din and El Wahab (7) who passivated copper electrodes under similar experimental conditions. These authors claim that in their experiments the product $i_l\tau^{1/2}$ was approximately proportional to the concentration of the hydroxyl ions in solution. By comparison with Eq. [3], the immediate conclusion from their results is that the diffusion of hydroxyl ions to the metal surface is the slow step in the over-all electrode reaction. However, the best fit slopes of the plots in Fig. 4 are given in Table IV. Although the data indicate a correspondence between the product $i_l\tau^{1/2}$ and the sodium hydroxide concentration, the function does not change by orders of magnitude as Eq. [3] would suggest. Thus rate control by the slow diffusion of hydroxyl ions does not explain the linear i_l *vs.* $\tau^{-1/2}$ relationship recorded here.

There are, of course, good reasons why an i_l *vs.* $\tau^{-1/2}$ relationship arising from diffusion limitations to reaction rate should not be observed at all. Equations [3], [5], and [6] were derived by assuming that the contribution to the mass transport of the reacting species by migration under the influence of the electric field which exists between the counter and working electrodes is negligible (29). This assumption is only valid if the reacting species is accompanied by an excess of a supporting electrolyte such that the transport number of the former is vanishingly small. The as-

Table II. Chronopotentiometric current efficiency following current reversal after different intervals along Cu_2O arrest

Current density ($\mu A/cm^2$)	Time to current reversal (sec)	Current efficiency (%)

554	51	92
563	76	94
558	108 (completion)	91

Table III. Values of the constants m and K in Eq. [2]

NaOH concentration (M)	m	K
0.01	1.70	624
0.1	2.26	1100
1.0	1.86	2416

Table IV. Slope of i_l vs. $\tau^{-1/2}$ plots shown in Fig. 4

NaOH concentration (M)	Slope ($\mu A\ cm^{-2}\ sec^{-1/2}$)
0.01	620
0.1	1142
1.0	5357

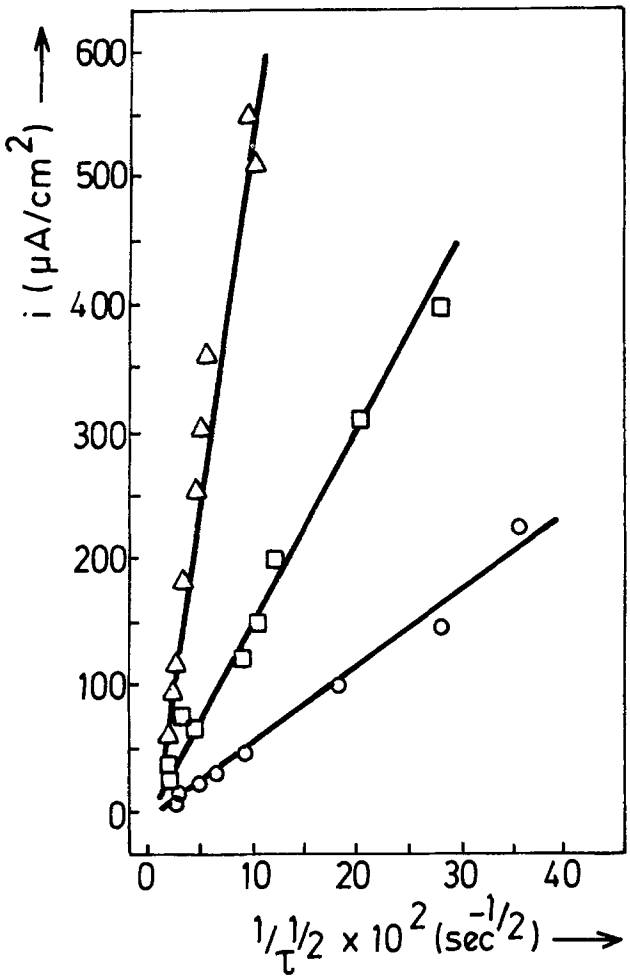

Fig. 4. Plots of i_l vs. $1/t^{1/2}$ for the anodic formation of Cu_2O in sodium hydroxide solutions: ○ 0.01M NaOH, □ 0.1M NaOH, △ 1.0M NaOH.

sumption is acceptable here, although in the general case of experiments made in dilute electrolyte solutions and at high current density it is inappropriate. It is further assumed in the derivation of Eq. [3], [5], and [6] that during the course of the reaction there is no progressive barrier introduced at the metal surface by the reaction products. For the formation of a sparingly soluble compound which accumulates at the metal-solution interface, there must necessarily be some hindrance to the movement of solution species between the bulk of the electrolyte and the metal surface except perhaps where the films formed are very thin (31, 32).

In view of the first objection and the observed $i_l\tau^{1/2}$ relationship, it might be argued that if the Cu_2O film forms by anodic dissolution followed by chemical precipitation it is the slow movement of the soluble copper (I) species between the dissolution sites and the growing Cu_2O nuclei which is rate determining. Under these circumstances the large excess of sodium hydroxide would act as the supporting electrolyte and the soluble copper(I) species might be expected to diffuse solely under the influence of the concentration gradient. By analogy with Eq. [6], Eq. [3] would then become

$$i_l\tau^{1/2} = \tfrac{1}{2}\pi^{1/2}n\mathbf{F}D^{1/2}_{Cu(I)}C^*_{Cu(I)} \qquad [7]$$

where C^* is the maximum concentration of soluble copper(I) attainable at the metal-solution interface. Assuming a diffusion coefficient $D_{Cu(I)}$ of 10^{-5} cm²/sec comparable to that of the Cu^{2+} ion, it is possible to estimate values for $C^*_{Cu(I)}$ from the data of Table II; these values are compiled in Table V. The increase in $C^*_{Cu(I)}$ with increasing alkalinity is in agreement with the trend in the solubility of Cu_2O suggested earlier.

Table V. Estimated solubility of Cu(I) species based on Eq. [7]

NaOH concentration (M)	$C^*_{Cu(I)}$ (g ions/liter)
0.01	3.24×10^{-5}
0.1	5.96×10^{-5}
1.0	28.00×10^{-5}

Furthermore the value for $C^*_{Cu(I)}$ in 1M sodium hydroxide solution is comparable to that estimated by Miller (10) using a rotating split ring-disk electrode system in the same solution (1×10^{-4} g-ions/liter). Nevertheless, from the basic assumptions of the diffusion model it should be added that the Cu_2O film would need to maintain a substantial degree of porosity during its growth. Since the quantity of charge and hence the Cu_2O film thickness was found to vary considerably and in a particular solution was dependent upon the applied current density (see Table I), it is to be anticipated that the mass transport of solution species to and from the metal-solution interface is hindered to an extent which will in turn depend upon the applied current density. It can also be added that with the growth of the Cu_2O film progressively diminishing the metal solution interfacial area, the actual current density at the metal surface must increase correspondingly. It is difficult, therefore, to envisage how this alternative model based upon the rate-limiting diffusion of a soluble copper(I) species would give rise to the observed linearity between i_l and $\tau^{-1/2}$.

The nucleation and growth model.—Apart from the classical interpretation of the $i/\tau^{1/2}$ relationship observed in chronopotentiometry, it is also possible to derive, theoretically, an identical relationship for anodic film formation if there exists a simple dependence upon current density of the number of nuclei formed initially. This alternative model makes two assumptions. First, that τ coincides with the complete coverage of the metal surface by the oxide film. Second, that essentially all of the nuclei that grow are formed instantaneously. In the latter assumption the model follows that put forward by Dignam and Gibbs (11) to explain the formation of Cu_2O in sodium tetraborate solutions (pH 9.2). Nevertheless, it does require some justification.

The initial stage in the growth of the anodic film is the formation of discrete growth centers or nuclei. The total number of nuclei N contributing to the growth of the film is given by the time dependence of the nucleation process. This is normally expressed (27) as

$$N = N_0(1 - \exp(-AT)) \qquad [8]$$

where N_0 is the total number of nucleation sites available and A the nucleation rate constant. If A is large, all the sites are converted to nuclei and we can write $N = N_0$.

According to Fleischmann and Thirsk (33) the nucleation rate constant A is a function of the overpotential η as follows

$$A = Ki_0 \exp\frac{(-k_2\sigma^3)}{\eta^2} \qquad [9]$$

where K is a frequency factor, i_0 the exchange current density, σ the surface free energy of the nucleus, and k_2 is a constant. The relationship between A and η as given by Eq. [9] has been verified for the growth of MnO_2 crystallites upon a platinum substrate (34). Thus it may be assumed that in the present work the formation of nuclei of Cu_2O occurred essentially within the duration of the anodic potential overshoot; the number of nuclei formed at longer times being small by comparison due to the lower overpotential and the substantial decrease in the number of nucleation sites available.

Thus, assuming the near-instantaneous nucleation of N hemispherical nuclei which grow at equal rates in

three dimensions, the volume of oxide V at time t is given by

$$V = \frac{2}{3} N\pi r^3 \qquad [10]$$

where r is the radius of the nuclei.

Now assuming negligible loss of charge due to solubilization, V will be proportional to the total charge passed and we can write

$$\frac{2}{3} N\pi r^3 = k_1 i_1 t \qquad [11]$$

where k_1 is a constant and i_1 the applied current density. On rearranging, Eq. [11] becomes

$$r = \left(\frac{3k_1 i_1 t}{2N\pi} \right)^{1/3} \qquad [12]$$

Since the nuclei are hemispherical, the area of the electrode surface covered is $N\pi r^2$, or from Eq. [12]

$$\text{surface area covered at time } t = N\pi \left(\frac{3k_1 i_1 t}{2N\pi} \right)^{2/3} \qquad [13]$$

If the total surface area of the electrode is S_o square centimeters, then it follows that at time $t = \tau$

$$S_o = N\pi \left(\frac{3k_1 i_1 \tau}{2N\pi} \right)^{2/3} \qquad [14]$$

and rearranging

$$N^{1/2} i_1 \tau = \frac{2S_o^{3/2}}{3\pi^{1/2} k_1} \qquad [15]$$

or

$$N^{1/2} i_1 \tau = \text{constant} \qquad [16]$$

Experimentally $i_1 \tau^{1/2}$ was found to be a constant. Thus

$$\underline{i_1 \propto N^{1/2}} \qquad [17]$$

That is, a plot of i_1 *vs.* $\tau^{-1/2}$ will be linear if the number of instantaneously formed nuclei is directly proportional to the square of the current density.

Figures 5 to 9 show both scanning and transmission electron micrographs of anodically oxidized metal surfaces. As can be seen from Fig. 6 and 7, the Cu_2O films formed in 0.1M sodium hydroxide were comprised of a great many cubic crystallites which entirely cover the surface of the metal. It can be said also that in 0.01M sodium hydroxide the Cu_2O films had a similar morphology (Fig. 5), but due to the small quantities of Cu_2O formed in the most dilute solution it was difficult to obtain highly resolved and informative micrographs from these specimens.

For the purpose of examining the extent to which Eq. [17] is applicable to the results obtained in 0.1M sodium hydroxide it should be noted that an identical result to Eq. [17] is obtained if a cubic rather than hemispherical growth form is assumed. From Fig. 6 it can be estimated that the majority of the cubes formed at 25 μA/cm^2 in 0.1M sodium hydroxide have sides approximately 2500Å in length. Similarly, from Fig. 7(a) the corresponding cubes have sides of approximately 600Å. From the initial assumption that at time $t = \tau$ the metal surface is completely covered by cubes of Cu_2O, the number of nuclei N formed upon 1 cm^2 of surface is given by

$$N = \frac{10^{16}}{a^2} \qquad [18]$$

where a^2 is the area of metal surface (square angstroms) occupied by a single cube. Thus

$$\frac{N_{25}}{N_{67.1}} = \frac{(600)^2}{(2500)^2} = 0.0576 \qquad [19]$$

and from Eq. [17] we also have

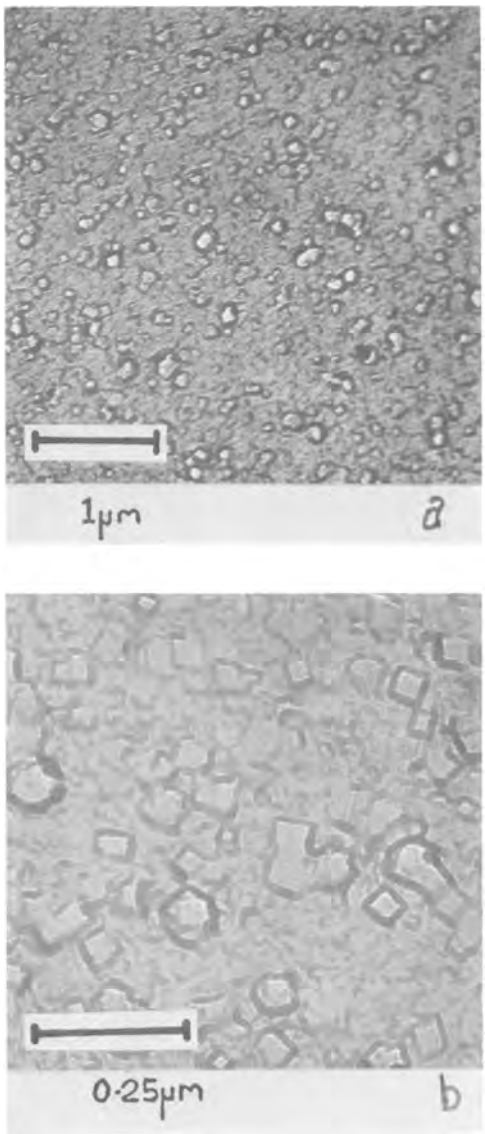

Fig. 5. Transmission electron micrographs of the Cu_2O film formed in 0.01M NaOH at 10 μA/cm^2.

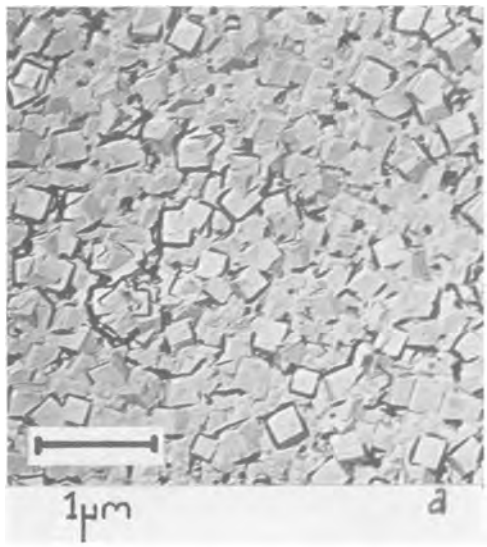
$$\frac{N_{25}}{N_{67.1}} = \left(\frac{25}{67.1} \right)^2 = 0.139 \qquad [20]$$

The agreement here is not particularly good although the values obtained in Eq. [19] and [20] are of a comparable magnitude.



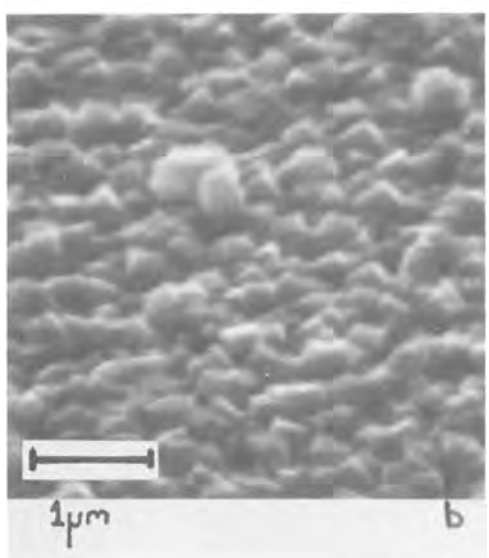
Figures 8 and 9 show that in contrast to the Cu_2O films formed in 0.01 and 0.1M sodium hydroxide the individual crystallites formed in 1M solutions were polyhedral. Similar polyhedral growth of Cu_2O upon copper single crystals exposed to solutions containing cupric ions has been the subject of a series of reports appearing in the literature (35). However, the electron micrographs (Fig. 8 and 9) show that it is permissible to repeat the above calculations, in this case treating the polyhedra as hemispherical crystallites. From the micrographs

$$\frac{N_{90}}{N_{350}} = \left(\frac{800}{3750} \right)^2 = 0.046 \qquad [21]$$

and from Eq. [17]

$$\frac{N_{90}}{N_{350}} = \left(\frac{90}{350} \right)^2 = 0.066 \qquad [22]$$

The agreement here is closer than that obtained from the micrographs of the Cu_2O films formed in 0.1M sodium hydroxide. It can therefore be said that the



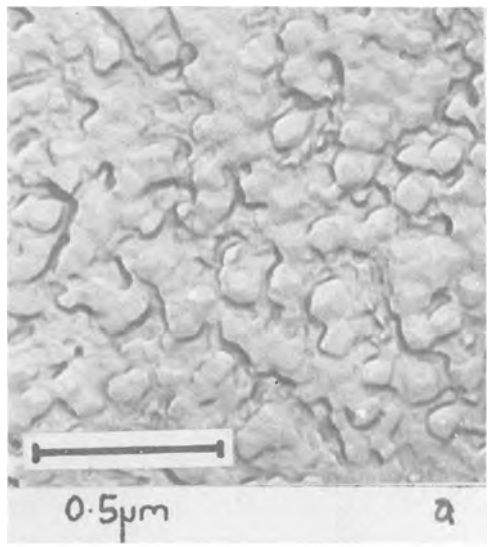


Fig. 6. (a) Transmission electron micrographs of the Cu_2O film formed in 0.1M NaOH at 25 $\mu A/cm^2$. (b) Scanning electron micrograph of the Cu_2O film formed in 0.1M NaOH at 25 $\mu A/cm^2$.

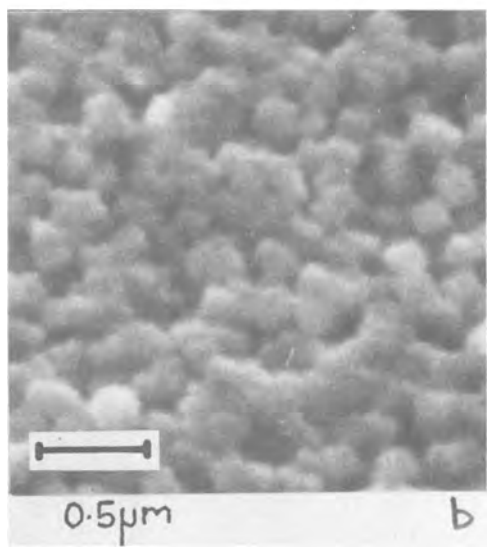
micrographs of Fig. 6-9 do show some evidence that a dependence of N upon i_l^2 does exist during anodic Cu_2O film formation.



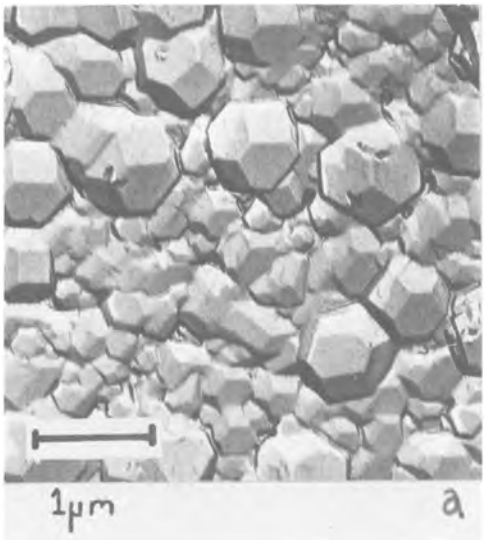


Fig. 7. (a) Transmission electron micrograph of the Cu_2O film formed in 0.1M NaOH at 67.1 $\mu A/cm^2$. (b) Scanning electron micrograph of the Cu_2O film formed in 0.1M NaOH at 60 $\mu A/cm^2$.

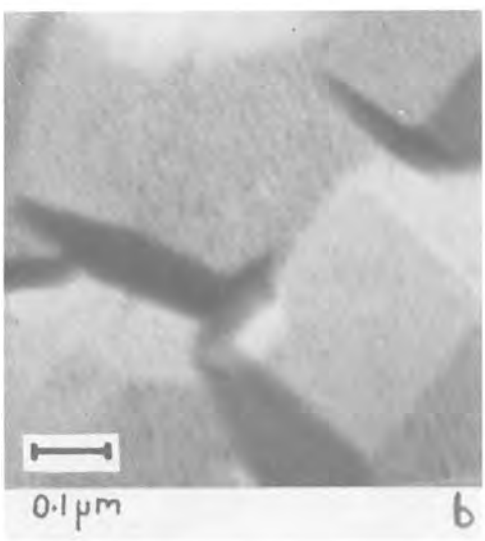
In summary, the results suggest that the dependence of the transition time upon the square of the current density, observed during the chronopotentiometric formation of Cu_2O in sodium hydroxide solutions, arises from the influence of the magnitude of the applied current density upon the number of Cu_2O nuclei formed initially. They further suggest that the i *vs.* $\tau^{-1/2}$ relationship is not due to rate limitations imposed by the slow diffusion of a solution species as put forward by earlier workers to explain similar results obtained during anodic film formation under comparable conditions.

The anodic arrest potential and its dependence on current density.—In Fig. 10 the anodic arrest potential E is shown as a function of the applied current density at each of the three sodium hydroxide concentrations in which experiments were carried out. Despite some scatter of the experimental points in the 0.01 and 0.1M solutions, there appears to be a linear relationship between E and i_l at low values of i_l. With the exception of the results obtained at the two lowest current densities in 1M sodium hydroxide, the linearity between E and i_l was found to extend over the entire range of current densities examined. The scales of overpotential given on the right-hand side of Fig. 10 were derived by obtaining a least squares fit of the linear data extrapolating to zero and using the intercept value of E as the "equilibrium" value for the reaction taking



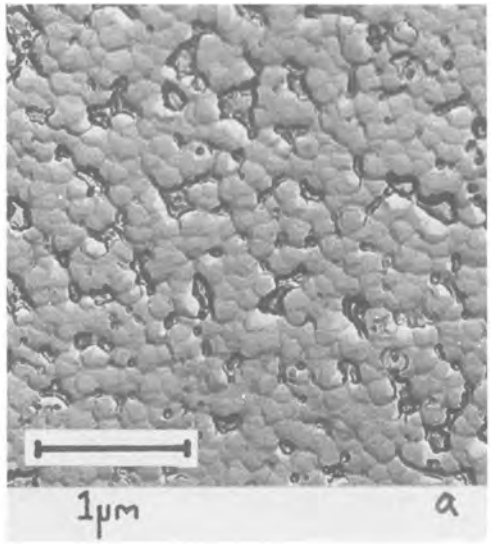


Fig. 8. Transmission electron micrographs of the Cu_2O film formed in 1M NaOH at 90 $\mu A/cm^2$.

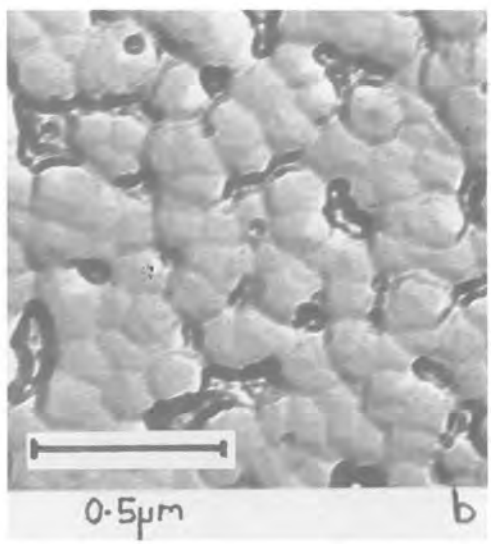

Fig. 9. Transmission electron micrographs of the Cu_2O film formed in 1M NaOH at 350 $\mu A/cm^2$.

place. With the linear plots confined to low overpotentials (< 30 mV), the dependence of E on i_l resembles that predicted by a limiting case of the Butler-Volmer equation (36).

For an electrochemical reaction in which electron transfer is slow due to the transfer taking place via the formation of a high energy intermediate, theory (36) predicts that where a single electron is involved in this, the rate determining step, the current is given by

$$i_l = i_o \left\{ \exp\left[\frac{(1-\beta)\mathbf{F}\eta}{RT}\right] - \exp\left[-\frac{\beta\mathbf{F}\eta}{RT}\right] \right\} \quad [23]$$

where β is the symmetry factor and describes the profile of the energy barrier that must be surmounted for the reaction to proceed, and i_o is the exchange current density. Expanding Eq. [23] and restricting its application to low overpotentials (20-30 mV) gives

$$i_l = \frac{i_o \mathbf{F}\eta}{RT} \quad [24]$$

and substituting for $\mathbf{F}$, R, and T (303°K) yields

$$i_o = \frac{0.026\, i_l}{\eta} \quad [25]$$

Values of i_o calculated by applying Eq. [25] to the linear portions of the curves shown in Fig. 10 are shown in Table VI. According to Ambrose (14), the dissolution of copper(I) in alkaline solutions proceeds by the electrochemical reaction

$$Cu + 2\,OH^- \rightarrow Cu(OH)_2^- + e \quad [26]$$

At low overpotentials metal dissolution is commonly activation controlled, the magnitudes of i_o and β being characteristic of a particular metal-electrolyte system (37). By applying simple kinetic considerations to Eq. (26), it can be shown that the exchange current density i_o for the reaction is given by (21)

$$i_o = K_a [Cu(OH)_2^-][OH^-]^{2\beta} \quad [27]$$

where K_a is a constant. If it can be assumed that the change in $Cu(OH)_2^-$ ion concentration is small compared to the tenfold variations in OH^- ion concentration, then a plot of $\log_{10} i_o$ *vs.* $\log_{10} [OH^-]$ should be linear. This is confirmed for the experimental results by Fig. 11 in which the slope of the curve gives $\beta =$

Table VI. Values of exchange current density (i_o) obtained from Eq. [25]

NaOH concentration (M)	i_o (A/cm²)
0.01	2.90×10^{-5}
0.1	1.53×10^{-4}
1.0	4.33×10^{-4}

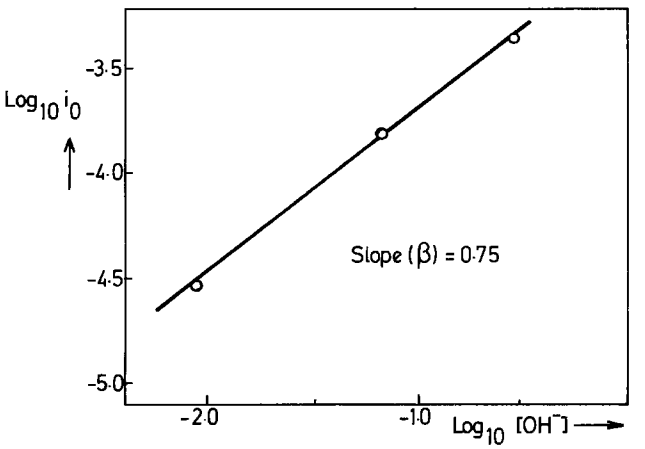

Fig. 11. Exchange current density as a function of hydroxyl ion concentration.

0.375. It should be noted that for this value of β, Eq. [25] is only valid when η is less than 20 mV.

During steady-state galvanostatic polarizations of copper electrodes in sodium hydroxide solutions (pH 12.05-13.06), Kim and Nobe (38) recorded two separate regions of potential in which the overpotential was directly proportional to the logarithm of the applied current density. Applying the Butler-Volmer equation, Eq. [23], to the lower region, attributable to the copper-copper(I) reaction, a somewhat lower value of 0.152 for β is obtained. By way of further comparison, tables of kinetic data show values lying between 0.26 and 0.65 for metal dissolution in aqueous solutions (37). The value of β determined in the present experiments clearly lies well within this range.

From the foregoing mathematical treatment of the experimentally recorded variation in the anodic arrest potential with the applied current density, it can be said that the results are consistent with a model in which the rate-determining step is charge transfer. This suggests that for an electrochemical dissolution-chemical precipitation mechanism of Cu_2O formation in alkaline solutions, which has been previously put forward in the literature (18), it is the former step which is slow and determines the over-all reaction rate. Clearly this would not be consistent with an interpretation of the $i\tau^{1/2}$ relationship based on a model invoking diffusion control.

The anodic potential-time curve profiles.—Low current densities.—From Eq. [14] the area of the electrode surface covered by the anodic film at time t (S_f) after commencement of nucleation is given by

$$S_f = (3/2\, N^{1/2}\pi^{1/2}k_1 i_1 t)^{2/3}$$

Therefore S_t, the area of metal surface remaining uncovered at time t is given by

$$S_t = S_o - (3/2\, N^{1/2}\pi^{1/2}k_1 i_1 t)^{2/3} \qquad [28]$$

S_o being the original surface area of the film-free metal. If the applied current I is concentrated at the exposed areas of the metal surface where metal dissolution is taking place, the actual current density, i_t will be given by

$$i_t = \frac{I}{S_t} \qquad [29]$$

Now I is equal to $i_1 \times S_o$, *i.e.*, the product of the applied current density (relative to a film-free surface) and the original surface area of the film-free metal. Since S_t is given by Eq. [28], we can write for i_t

$$i_t = \frac{i_1 S_o}{S_o - (3/2N^{1/2}\pi^{1/2}k_1 i_1 t)^{2/3}} \qquad [30]$$

or, substituting for S_o from Eq. [14]

$$i_t = \frac{i_1}{1 - (t/\tau)^{2/3}} \qquad [31]$$

with $\tau \propto 1/i_1^2$ we also have

$$i_t = \frac{i_1}{1 - (Ki_1^2 t)^{2/3}} \qquad [32]$$

Equation [32] shows that as a consequence of progressive Cu_2O film formation the actual current density is dependent on both the magnitude of the applied current density and the time from the commencement of Cu_2O nucleation.

Using Eq. [24] and [31], it is now possible to derive a theoretical relationship between the overpotential η and the time t. From Eq. [24] we have at low overpotentials (<20 mV)

$$\eta = \frac{RT}{F}\frac{i_1}{i_o} \qquad [33]$$

Consequently, the change in the overpotential with time follows the same profile as the current density, which is given by Eq. [31]. Thus, letting $i = i_t$ in Eq. [31] we obtain

$$\eta = \frac{RT}{F}\frac{i}{i_o}\left(\frac{1}{1 - (t/\tau)^{2/3}}\right) \qquad [34]$$

Using a simple curve-fitting procedure (21), the curve predicted by Eq. [34] was compared with the experimentally recorded E-t curves. It was found that Eq. [34] gave an exceptionally good description of the rise in electrode potential with time recorded in 0.1M sodium hydroxide at 120 μA/cm² (τ = 111 sec) [see Fig. 12(b)]. At lower current densities in the same solution, the agreement was not quite as good mainly due to the influence of nucleation and the accompanying anodic potential overshoot [see Fig. 12(a)]. As shown in Fig. 13 and 14, an equally satisfactory correspondence with Eq. [34] was also observed in 0.01M sodium hydroxide and in the higher current density experiments in 1M solutions. A significant divergence of the experimental curves from the theoretical E-t profiles as t approached τ that was occasion-

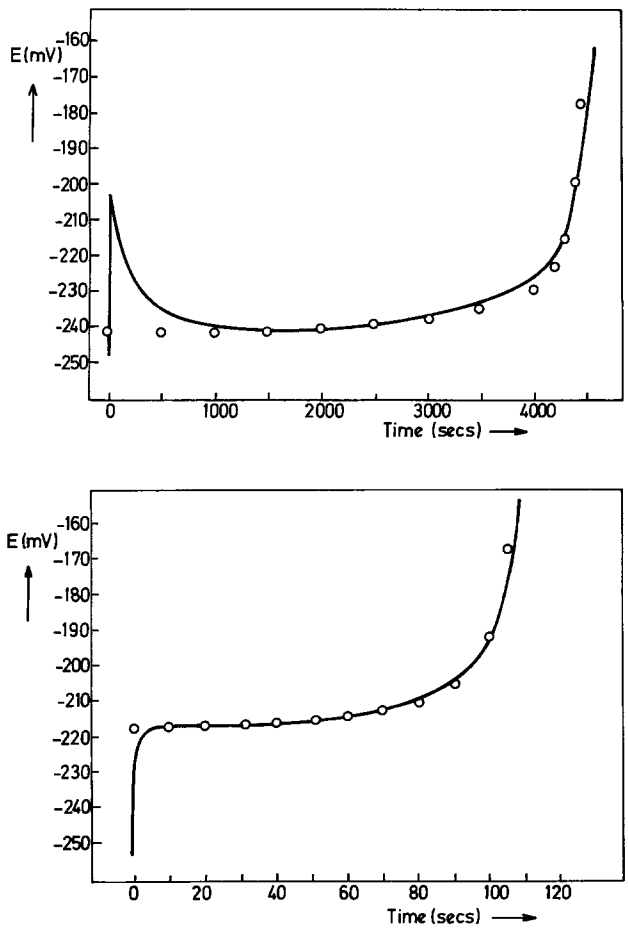

Fig. 12. A comparison of experimental and theoretical *E-t* curves in 0.1M NaOH: ○ theoretical points, — experimental curve; (a) 25 $\mu A/cm^2$, $\tau = 4560$ sec; (b) 120 $\mu A/cm^2$, $\tau = 111$ sec.

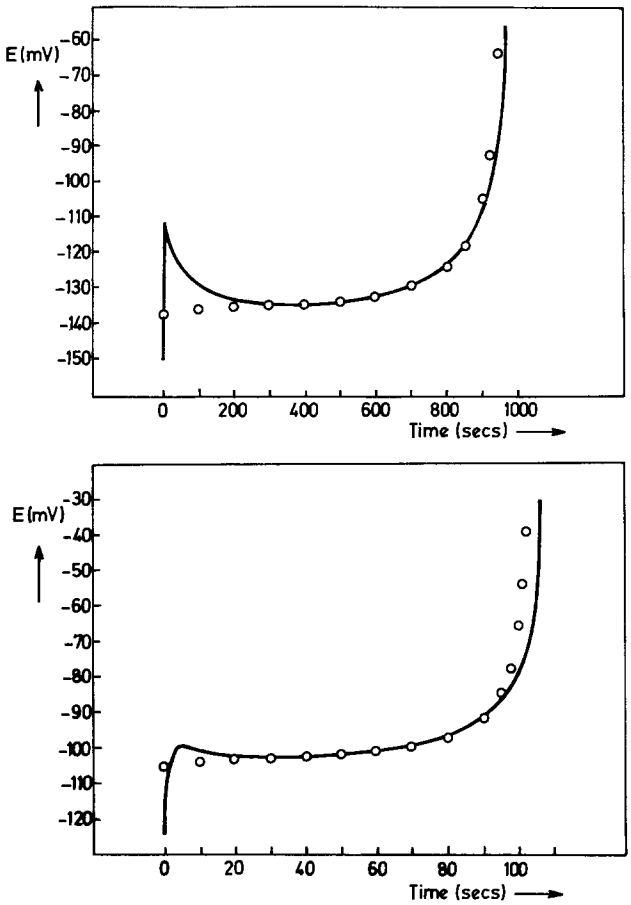

Fig. 13. A comparison of experimental and theoretical *E-t* curves in 0.01M NaOH: ○ theoretical points, — experimental curve; (a) 12.9 $\mu A/cm^2$, $\tau = 972$ sec; (b) 45.5 $\mu A/cm^2$, $\tau = 105$ sec.

ally observed is attributed to two main factors. First, Eq. [34] was derived for overpotentials of below 20 mV. From the experimental results η must necessarily have exceeded this limit as t approached τ. Second, with the very thick films formed at low current densities in 0.1 and 1M solutions, some contribution to the reaction rate from the slow diffusion of the solution species is anticipated at $t \rightarrow \tau$. Nevertheless the excellent agreement between the predicted and the determined curves provides further evidence for the role of charge transfer as the rate-determining step in the reaction which leads to film formation.

High current densities.—As shown in Fig. 10, the linear relationship between the arrest potential and the applied current density broke down in 0.01 and 0.1M sodium hydroxide solutions at current densities greater than 45.5 and 201 $\mu A/cm^2$, respectively. Correspondingly, it was found that above these limits the observed rapid rise in electrode potential with time during Cu_2O formation could not be represented by Eq. [34]. Here the experimental curves were very similar to those derived theoretically by Meyer and his collaborators (31) (Fig. 15) for the anodic formation of a thin film under conditions of rate control by the slow mass transport of a single reacting species. For comparison, the anodic *E-t* curves recorded in this work at 227 $\mu A/cm^2$ in 0.01M and 399 $\mu A/cm^2$ in 0.1M sodium hydroxide have been reproduced in Fig. 16. Both these experimental curves have τ values of 7.9 sec and it is evident from Fig. 16 that they have almost identical profiles. Implicit in Meyer's derivations was the assumption that the growing anodic film in no way affects the rate of electrochemical reaction at the metal-solution interface. In view of the relatively large quantities of Cu_2O formed here and the morphological characteristics of the films (see the electron micrographs of Fig. 5-9), this assumption cannot be applied with any degree of satisfaction here.

At large overpotentials (>60 mV), the second term in the Butler-Volmer equation (Eq. [23]) is negligible compared to the first. Thus, considering only the first term of Eq. [23] and rearranging we obtain

$$\eta = \frac{2.3RT}{(1-\beta)\mathbf{F}} \log_{10} \frac{i}{i_o} \qquad [35]$$

Allowing $i = i_t$ and substituting for i_t from Eq. [31], Eq. [35] becomes

$$\eta = \frac{2.3RT}{(1-\beta)\mathbf{F}} \left\{ \log_{10} \frac{1}{1-(t/\tau)^{2/3}} + \log_{10} \frac{i_l}{i_o} \right\} \qquad [36]$$

i.e.

$$\eta = 0.096 \left\{ \log_{10} \frac{1}{1-(t/\tau)^{2/3}} + \log_{10} \frac{i_l}{i_o} \right\} \qquad [37]$$

The theoretical curves corresponding to i_l/i_o ratios of 1, 5, and 10 and described by Eq. [37] are shown in Fig. 17. It is clear that these curves predicted by Eq. [37] differ very little from those derived theoretically by Meyer (31). Consequently, it is no simple task to decide which of two possible mechanisms of rate control is operating by a direct comparison of the profiles of the experimental curves with those predicted by the theory appropriate to either mechanism. However, it has been shown previously that a nucleation and growth mechanism of film formation in which the number of instantaneously formed nuclei is directly proportional to the square of the applied current density can give rise to the observed i_l *vs.* $\tau^{-1/2}$ relationship. Further, at low current densities the dependence of the arrest potential upon the applied current density is consistent with a model involving a charge transfer rate-determining step. Finally, and most important, in direct contrast with the mathematical treatment of dif-

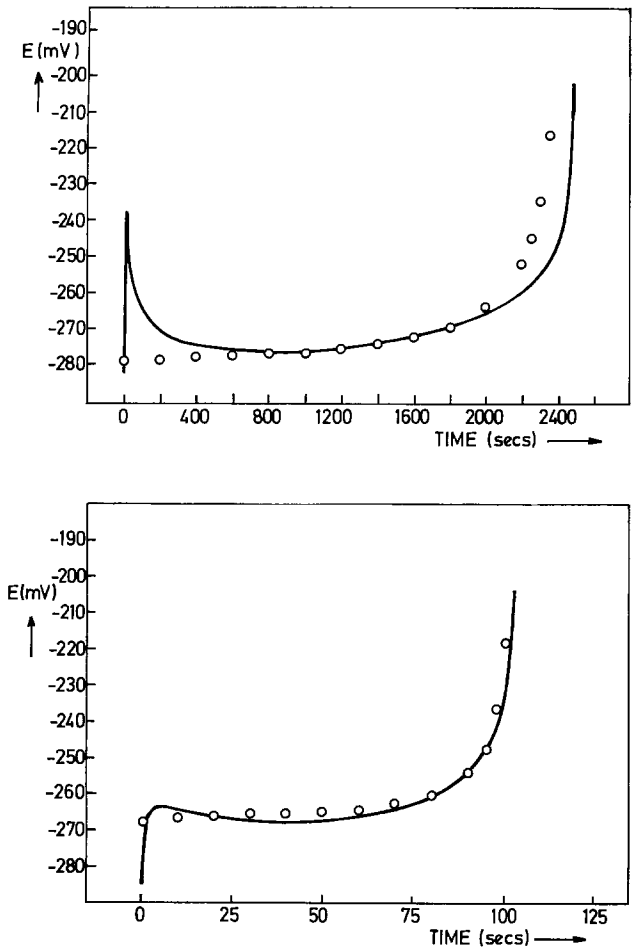

Fig. 14. A comparison of experimental and theoretical *E-t* curves in 1M NaOH: ○ theoretical points, — experimental curve; (a) 91.1 μA/cm^2, τ = 2478 sec; (b) 305 μA/cm^2, τ = 103.5 sec.

fusion control, the model proposed here does not disregard the effect of the progressive buildup of reaction product on the rate of electrochemical reaction at the metal-solution interface. Indeed, it is this which indirectly determines the *E-t* curve profiles. It is therefore considered that the *E-t* curve profiles recorded at high current densities in 0.01 and 0.1M sodium hydroxide solutions are more likely to arise from a slow charge transfer step in the over-all electrochemical dissolution-chemical precipitation mechanism of anodic Cu_2O film formation.

Conclusions

It has been found that the results obtained during the chronopotentiometric formation of Cu_2O upon a copper electrode in sodium hydroxide solutions are in good agreement with an electrochemical dissolution-chemical precipitation mechanism of film growth as follows

electrochemical dissolution

$$Cu + 2\,OH^- \rightarrow Cu(OH)_2^- + e$$

chemical precipitation

$$2Cu(OH)_2^- + 2H^+ \rightarrow Cu_2O + 3H_2O$$

The results suggest that it is the slow transfer of charge during the initial dissolution stage which governs the over-all reaction rate. Nuclei of Cu_2O form instantaneously and grow until the metal surface is entirely covered by the Cu_2O film; the transition time, τ then coincides with complete coverage of the metal surface. The observation of a direct i *vs.* $\tau^{-1/2}$ relationship during anodic film formation has on several previous occasions been taken as an indication of rate control by the slow mass transport of a solution species involved in the over-all electrode reaction. For a number of reasons which have been stated, this interpretation is inadequate. It has been shown that an i *vs.* $\tau^{-1/2}$ relationship will be observed if the number of instantaneously formed oxide nuclei is directly proportional to

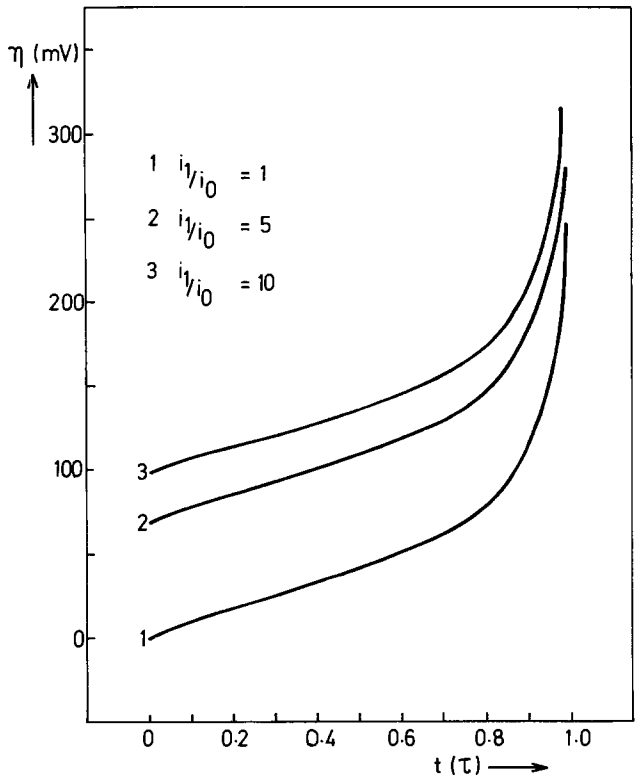

Fig. 17. Theoretical chronopotentiometric waves for a charge transfer controlled reaction at large overpotentials.

the square of the applied current density. Electron micrographs of chronopotentiometrically formed Cu_2O films lend support to this, a more plausible interpretation of the experimental results.

LIST OF SYMBOLS

A	nucleation rate constant
C_x^i	interfacial concentration of species x
C_x^b	bulk concentration of species x
D_x	diffusion coefficient of species x
E	electrode potential
$\mathbf{F}$	Faraday's constant
I	applied current
i	current density
i_l	applied current density
i_o	exchange current density
i_t	current density at exposed metal surface
K, k, k_1, k_2, k_a	various constants
N	number of instantaneously formed nuclei
N_o	number of nucleation sites
n	number of electrons involved in electrochemical reaction
R	gas constant
r	radius of the nuclei
S_o	total surface area of film-free metal
S_f	area of surface covered by film after time t
S_t	area of surface free of film after time t
T	temperature
t	time
V	total volume of oxide at time t
β	symmetry factor
η	overpotential
σ	surface free energy of nucleus
τ	transition time

Variational Approximations to Current Distribution Problems

The Rotating Disk Electrode

S. H. Glarum

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A variational function for electrolytic cells of arbitrary geometries and overpotential functions is presented, and low order approximations for the rotating disk electrode (RDE) are examined. A simple analytical solution for the total RDE current exists when the overpotential function is linear, and is used in the analysis of time-dependent boundary condition problems. Nonlinear overpotential functions may often be effectively linearized, leading again to analytical solutions. The influence of periodic reverse plating on the mean current distribution is analyzed in this approximation.

The determination of current distributions in electrolytic cells remains one of the pivotal problems of electrochemical technology. It demands the solution of Laplace's equation within arbitrary volumes with arbitrary, and generally nonlinear, boundary conditions. Analytical solutions of primary current distributions (fixed boundary conditions) are possible for those geometries amenable to conformal or imaging transformations to simpler configurations (1-3). Analytic techniques have been suggested for situations in which boundary conditions are linear, but few solutions are available (2, 4). The development of numerical computational techniques utilizing high speed computers currently makes possible the solution of specific problems but, because of the large number of parameters entering into such calculations, specific solutions are necessarily limited in their application (5). The developing interest in problems with time-dependent boundary conditions further complicates numerical procedures.

In other areas of science and engineering, variational analysis has provided a powerful tool for seeking approximate solutions to complex problems. Although the applicability of variational analysis to current distribution problems is recognized, it is doubtful that the power of this technique has been adequately exploited (6). Certainly a major virtue of the variational approach is its ability to yield a first-order solution with a modicum of effort, and to improve systematically this approximate solution by passing to more involved calculations.

The rotating disk electrode (RDE) is presently one of the more useful tools for the study in the laboratory of metal deposition phenomena. Its properties reflect not only the microscopic aspects of this process, but also the macroscopic effects of nonuniform current distributions and hydrodynamic flow. Although the latter effects are sometimes considered a hindrance, limiting the usefulness of the RDE, they should be realistically viewed as an advantage, making possible controlled studies of the combined effects of microscopic and macroscopic processes, provided one can easily determine their interaction and unravel their influence upon experiments.

It is the intent of this paper to demonstrate the use of variational analysis for the study of current distributions in electrolytic cells by considering its specific application to the RDE. Although the geometry of this system is trivial in the sense that the mathematics reduce to a one-dimensional problem, we believe the analytic simplicity of the results derived is of value to users of the RDE, and the approach is strongly suggestive of procedures by which more difficult problems may be attacked. Numerical solutions to a variety of RDE problems have been presented by Newman and colleagues and afford a basis for judging the accuracy of variational approximations (7-11). It should be clear that our purpose is not to find approximate answers to problems already adequately solved, but to explore the usefulness of approximate solutions in analyzing current distribution problems.

Key words: variational analysis, current distributions, rotating disk electrodes.

A Variational Function

Let us examine the function

$$W(\phi) = \kappa \int_\tau d\tau\, \underline{\nabla}\phi \cdot \underline{\nabla}\phi + 2\int_s ds\, f(s) \int_0^{\phi_0(s)-\phi} d\theta\, F(\theta) \qquad [1]$$

where the first integral extends over a volume τ enclosed by the surface s. The functions $\phi_0(s)$, $f(s)$, and $F(\theta)$ are assumed given, κ is a constant, and ϕ is an arbitrary function of τ. Taking the first variation with respect to ϕ yields

$$\delta W = -2\kappa \int d\tau\, \delta\phi \nabla^2\phi + 2\int ds \left[\kappa \frac{\partial \phi}{\partial n} - f(s)\, F(\phi_0 - \phi) \right] \delta\phi \qquad [2]$$

where $\partial/\partial n$ denotes a derivative with respect to the outward normal at the surface. The condition that W be stationary for arbitrary variations in ϕ thus requires

$$\nabla^2\phi = 0 \qquad \text{in } \tau$$

$$\mathcal{I}(s) \equiv \kappa \frac{\partial \phi}{\partial n} = f(s)\, F(\phi_0 - \phi) \qquad \text{on } s \qquad [3]$$

Taking ϕ to be the potential and κ the bulk conductivity the latter expression then defines the current density, $\mathcal{I}(s)$, on the surface. When applied to the electrolytic cell, it is evident that $f(s)$ vanishes on insulating portions of the bounding surface, that it reflects the concentrations of electroactive species on the electrode surfaces, and that $F(\theta)$ is an overpotential function. In a complete solution $f(s)$ is dependent upon the particulars of mass transport and the current distribution, and a general procedure requires iterative calculations, first assuming an approximate $f(s)$, determining ϕ variationally, recalculating $f(s)$, etc.

For linear boundary conditions, $F(\theta) \propto \theta$, the stationary value of W becomes

$$W_s = \kappa \int ds\, \phi_0(s) \frac{\partial \phi_s}{\partial n} \qquad [4]$$

and the total energy dissipation in the combined sur-

face-volume system is stationary (actually a minimum) for the specified $f(s)$. In particular, for a two-electrode system the total electrode current is a minimum. In problems where linear boundary conditions exist, variational calculations should be especially helpful in determining this most often measured experimental parameter. The accuracy in determining the total current at a given level of approximation will significantly exceed that of the current distribution itself.

When boundary conditions are nonlinear and mass transport effects are important, the total current is no longer a minimum. One may often, nevertheless, linearize these effects in an initial approximation and obtain useful results. Variational analysis remains applicable under all circumstances, but the procedure is certainly more demanding when linearization is inadequate.

The RDE Variational Function

Levich and Newman have derived basis functions appropriate for the RDE (6, 7). For purposes of completeness and definition, we shall here summarize their derivations and introduce this functional set into the variational equation. The RDE consists of a circular electrode, radius r_o, flushly imbedded in an infinite insulating mantle. The exposed half-space is filled with electrolyte, and the potential in this space vanishes as r and z (cylindrical coordinates) become infinite. With the transformation to coordinates ξ and η defined by

$$z = r_o\xi\eta$$
$$r^2 = r_o^2(1 + \xi^2)(1 - \eta^2) \quad [5]$$

the Laplacian is separable, yielding

$$\frac{\partial}{\partial\eta}(1-\eta^2)\frac{\partial F_l(\eta)}{\partial\eta} = -l(l+1) = -\frac{\partial}{\partial\xi}(1+\xi^2)\frac{\partial G_l(\xi)}{\partial\xi} \quad [6]$$

where

$$\phi_l = F_l(\eta)G_l(\xi) \quad [7]$$

These differential equations are recognized as those of Legendre, and a particular solution for ϕ is of the form

$$\phi = [AP_l(\eta) + BQ_l(\eta)][CP_l(-i\xi) + DQ_l(-i\xi)] \quad [8]$$

where P_l and Q_l are Legendre functions of the first and second kinds. For ϕ to be well behaved as $\eta \to 1$ and vanish as $\xi \to \infty$ requires $B = C = 0$, while the boundary condition upon the insulating mantle is fully satisfied if l is restricted to positive even integers or zero. A general solution to the potential distribution for the RDE is therefore

$$\phi = \sum_l{}' a_l P_l(\eta) Q_l(-i\xi) \quad [9]$$

where the summation prime indicates that l is restricted to the values 0, 2, 4. 6, ... This function satisfies the conditions that $\nabla^2\phi = 0$ in τ and $\partial\phi/\partial n = 0$ on the mantle. The coefficients a_l can only be found when the remaining boundary conditions on the electrode are known.

At the electrode surface ($\xi = 0$)

$$\phi = \sum_l{}' c_l P_l(\eta)$$
$$\frac{\partial\phi}{\partial n} = -(r_o\eta)^{-1}\left(\frac{\partial\phi}{\partial\xi}\right)_{\xi=0} = (2/\pi r_o\eta)\sum_l{}' c_l[P_l(0)]^{-2}P_l(\eta) \quad [10]$$

where

$$c_l = (i\pi/2)P_l(0)a_l = (2l+1)\int_0^1 d\eta\,\phi(\eta)P_l(\eta) \quad [11]$$

and the value for $Q_l(-0i)$ has been introduced.

Substitution into the variational function finally yields

$$W = 4\kappa r_o\sum_l{}'(2l+1)\left\{\int_0^1 d\eta[P_l(\eta)/P_l(0)]\phi(\eta)\right\}^2 + 4\pi r_o^2\int_0^1\eta d\eta\, f(\eta)\int_0^{\phi_o-\phi(\eta)} d\theta\, F(\theta) \quad [12]$$

In this expression ϕ is an arbitrary function, and solution of the RDE problem reduces to finding that ϕ which minimizes W, given $f(\eta)$, $F(\theta)$, and ϕ_o. The total electrode current

$$I = 2\pi\kappa r_o^2\int_0^1\eta d\eta\frac{\partial\phi}{\partial n} \quad [13]$$

is more conveniently given by

$$I = 4\kappa r_o\int_0^1 d\eta\,\phi(\eta) \quad [14]$$

Linear Solutions

RDE solutions to problems with linear boundary conditions, *i.e.*

$$f(\eta)F(\theta) = \theta/z \quad [15]$$

z being the normalized surface impedance, are readily handled variationally, and are of especial importance in that convenient analytical expressions can be derived to achieve any reasonable degree of accuracy. A natural choice for ϕ is

$$\phi(\eta) = \sum_l{}' c_l P_l(\eta) \quad [16]$$

in which case

$$I = 4\kappa r_o c_0 \quad [17]$$

Substitution of this expansion, together with the linear boundary value condition, into Eq. [12], followed by setting $\partial W/\partial c_l = 0$, gives the set of linear equations

$$g_l\Gamma c_l + \sum_{l'}{}' K_{ll'}c_{l'} = K_{0l}\phi_o \quad [18]$$

where

$$g_l = [2(2l+1)P_l(0)^2]^{-1} \quad [19]$$
$$K_{ll'} = \int_0^1\eta d\eta\, P_l(\eta)P_{l'}(\eta)$$

and

$$\Gamma = 4\kappa z/\pi r_o = (z/\pi r_o^2)/(4\kappa r_o)^{-1} = Z/R_\infty \quad [20]$$

Z is the total impedance associated with the electrode surface and R_∞ is the high frequency or primary resistance of the cell. The parameter Γ is thus the reciprocal of ρ as defined by Albery and Hitchman, or equal to $(4/\pi J)$ in Newman's notation (7, 12). The convention adopted here simplifies the form of following expressions.

Clearly the ratio I/ϕ_o is constant for this problem and we may define a total cell impedance

$$\begin{aligned} Z_{tot} \equiv \phi_o/I &= R_\infty|g_l\Gamma\delta_{ll'} + K_{ll'}|/|g_l\Gamma\delta_{ll'}(1-\delta_{l,0}) + K_{ll'}| \\ &= R_\infty + Z\,g_0|g_l\Gamma\delta_{ll'} + K_{ll'}|'/|g_l\Gamma\delta_{ll'}(1-\delta_{l,0}) + K_{ll'}| \\ &= R_\infty + Z_{eff} \end{aligned} \quad [21]$$

where the prime on the determinant indicates that l and l' are restricted to values 2, 4, 6, ... Both determinants yield polynomials of the same degree in Γ, and in the limit $\Gamma \to \infty$, $Z_{eff} \to Z$. The ratio for Z_{eff} may be rewritten as

$$Z_{eff} = Z\left[1 + \sum_i\frac{\alpha_i}{1+\Gamma\beta_i}\right] \quad [22]$$

Solutions for α and β may be found from the roots, Γ_i, of the determinantal equation

$$|g_l\Gamma\delta_{ll'} + K_{ll'} - 2K_{ol}K_{ol'}|' = 0 \quad [23]$$

Thus

$$\beta_i = 1/\Gamma_i$$
$$\alpha_i = \frac{-|g_l\Gamma_i\delta_{ll'} + K_{ll'}|'}{\Gamma_i(\prod_{l\neq 0} g_l)\prod_{j\neq i}(\Gamma_i - \Gamma_j)} \quad [24]$$

The order of solution is equivalent to the number of roots found. In a trivial first approximation $(\alpha, \beta) = (1/3, 64/15)$. For second and third approximations $(\alpha, \beta) = (0.1250, 3.251)$, $(0.4083, 9.752)$ and $(0.1197, 3.238)$, $(0.1053, 5.978)$, $(0.4511, 17.330)$, respectively.

In a finite approximation, truncation of this series gives a constant limiting value as $\Gamma \to 0$. In fact, the sum diverges logarithmically. A practical lower limit to the useful range of Γ for a particular order of approximation is set by its smallest root. For the first three orders of approximation this is equivalent to the condition that no more than 77, 90, or 94% of the monitored potential drop occurs within the electrolyte.

The difficulties encountered as $\Gamma \to 0$ occur because the current distribution approaches the primary distribution, with a singularity at the electrode's edge, and its representation by a low order polynomial is inadequate. Newman has discussed this difficulty when the surface impedance is capacitive (8). We can estimate the asymptotic behavior of Z_{eff}/Z as $\Gamma \to 0$ by supposing

$$1 + \sum_i \frac{\alpha_i}{1 + \Gamma\beta_i} = -\frac{1}{4}\ln\Gamma + A + B(\Gamma)^{1/2} + C\Gamma + D(\Gamma)^{3/2} + \ldots \quad [25]$$

The left-hand expression is valid when Γ is large, while the right-hand side is correct for small Γ. The logarithmic term and the expansion in $\sqrt{\Gamma}$ are suggested by Newman's analysis. We assume that both series converge in the vicinity of some intermediate value. From a comparison of derivatives in this region one can then deduce $A, B, C, \ldots$. As the accuracy of the left-hand side improves, the range of Γ broadens, and $A, B, C, \ldots$ become insensitive to the choice of Γ. When the third-order expansion is employed, the coefficients are stationary for $\Gamma \simeq 0.6$, giving

$$-\frac{1}{4}\ln\Gamma + 0.562 + 0.637\,\Gamma^{1/2} - 0.138\,\Gamma + 0.008\,\Gamma^{3/2} \quad [26]$$

Newman's numerical calculation for the constant yields 0.623, when the factor of $4/\pi$ relating Γ to his variable is taken into account (8). A higher order solution is presumably required to achieve a more accurate set of coefficients. In the real world, when Γ is very small, the properties of electrolytic cells are sensitive to deviations from the assumed geometry, and precise expressions are more of theoretical than practical interest.

It should be duly noted that the system of linear equations here solved is equivalent to that used by Newman and later by Nisancioglu and Newman in studying frequency dispersion at the RDE (8, 9). Thus the coefficients β_i approach the eigenvalues $\pi\Lambda_i/4$ in the latter work as the order of approximation increases. We would emphasize, however, that Eq. [22] constitutes a general solution to all linear RDE problems. If Γ is frequency dependent, one can easily use this equation to find the behavior of the RDE, and the electrode's response in the time domain is given by a straightforward Fourier transform. It is apparent from the variational origin of our analysis that an approximate or truncated solution for Z_{eff} will always be less than its correct value when Γ is real.

Newman has solved these equations to high order for the case $\Gamma = i\omega CR_e\pi r_o^2$, where C is the double layer capacitance per unit area (8). Results are expressed in terms of an effective series resistance and capacitance, *i.e.*

$$Z_{tot} = R_{eff} + (i\omega\pi r_o^2 C_{eff})^{-1} \quad [27]$$

Our interest here is in examining the usefulness of low order approximations. Results are plotted in Fig. 1 and 2 for the first three orders of approximation and compared with Newman's calculations. Low order approximations appear sufficient for the interpretation of all but the most precise data. With a second-order approximation, the error in the effective capacitance is less than 4% in a region where the capacitive current itself is but 10% of the total current.

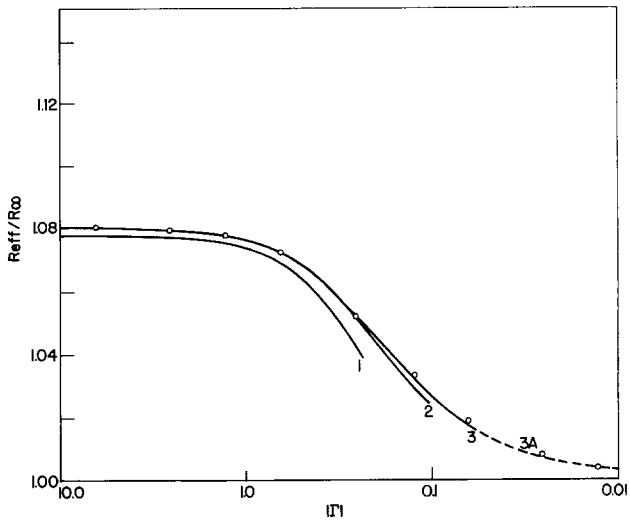

Fig. 1. Dispersion of effective series resistance for RDE calculated to first, second, and third order. Curve 3A is obtained from the low Γ asymptotic expansion. Exact values are indicated by circles.

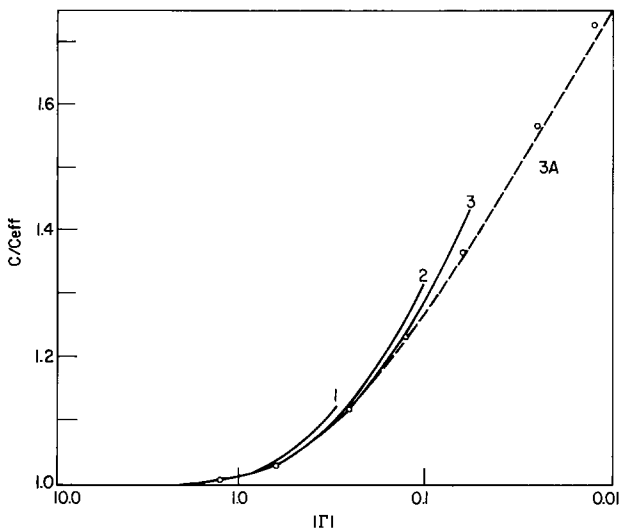

Fig. 2. Dispersion of effective series capacitance for RDE calculated to first, second, and third order. Curve 3A is obtained from the low Γ asymptotic expansion. Exact values are indicated by circles.

Complex plane plots are becoming a useful means for studying electrode reactions. The effects of nonuniform current distributions at the RDE on such measurements are readily gauged by letting

$$\Gamma = \Gamma_o/(1 + i\omega\tau) \quad [28]$$

Then, for a normalized dispersion

$$Z_{eff}/Z_o = (1 + i\omega\tau)^{-1} + \sum [\alpha_i/(1 + \Gamma_o\beta_i)][1 + i\omega\tau/(1 + \Gamma_o\beta_i)]^{-1} \quad [29]$$

In addition to the leading term for a uniform current distribution, a series of additional relaxation times appears. Actual plots are shown in Fig. 3. The major distortion introduced by these relaxations is an enlargement of the over-all dispersion, and a slight flattening of the plot when $\omega\tau > 1$. The maximum remains close to $\omega\tau = 1$. These observations apply even when

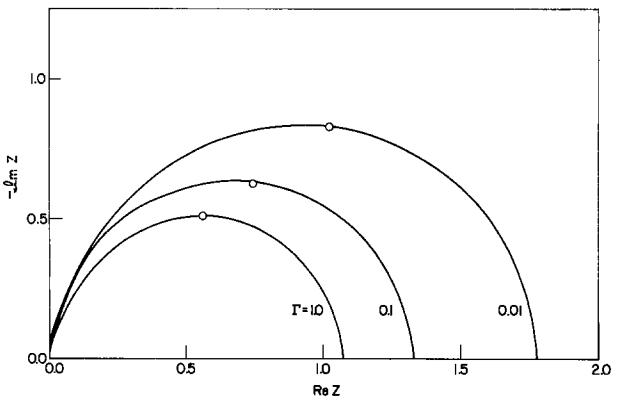

Fig. 3. Complex impedance plots for a simple double layer dispersion. Circles show points for $\omega\tau = 1$.

the asymptotic expansion ($\ln + A$) is used, as shown by the plot for $\Gamma = 0.01$. We may conclude that, at least for linear systems, qualitative interpretations of complex impedance plots obtained with the RDE are not seriously complicated by nonuniform current distributions. For the quantitative analysis of high frequency data, however, the use of Eq. [22] can prevent erroneous interpretations of high frequency dispersions.

Returning to Eq. [18], this set of equations may also be solved for c_l, and the current density distribution is then given by

$$\mathcal{I}(\eta) = (1/z)\left[\phi_0 - \sum\nolimits' c_l P_l(\eta)\right] \qquad [30]$$

Second-order approximations for current distributions are shown in Fig. 4. The agreement with exact results is adequate for $\Gamma > 0.5$ (7). Because of the variational basis for our analysis, it is to be expected that the current distribution will be given less accurately than the total current, and that the calculation weights most heavily those regions of the electrode where the current density is greatest. As $\Gamma \to 0$ the current density at the electrode's boundary becomes infinite, and its central area is of lesser importance. The apparent minimum seen when Γ is small is an artifact of trying to approximate a steeply rising function by a fourth-order polynomial.

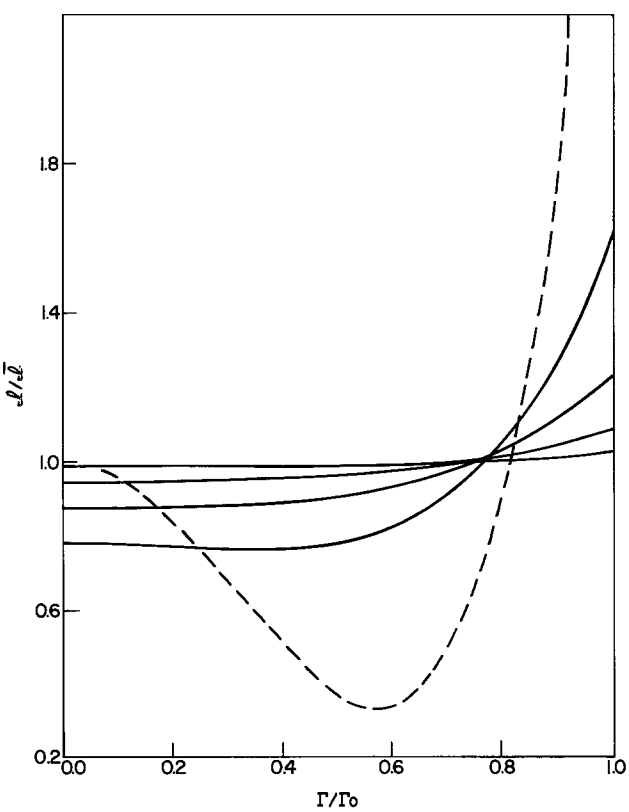

Fig. 4. RDE current distributions calculated to second order (quartic approximation) for linear polarization. Values for Γ are 10, 3, 1, 0.3, and 0.0, with uniformity increasing with Γ.

Alternating current distributions are of growing interest in electrodeposition studies. Qualitatively, one anticipates that at high frequencies the current distribution should become less uniform, approaching the primary distribution. If we let

$$1/z = (1/r) + i\omega C = (1/r)(1 + i\omega\tau)$$

$$\Gamma = \Gamma_0/(1 + i\omega\tau) \qquad [31]$$

assume faradaic current flows only through r, and use a first-order solution

$$\mathcal{I}_F = (1/r)\phi_0 e^{i\omega t}\Gamma \frac{64\Gamma + 30(1 - \eta^2)}{64\Gamma^2 + 84\Gamma + 15} \qquad [32]$$

For a linear system the time average $\mathcal{I}_F$ vanishes, and no influence upon the macroscopic aspects of electrodeposition would be expected. An a-c current may nevertheless have an influence, of currently unknown origin, upon the microscopic properties of an electrodeposit, and this calculation provides an estimate of the spatial uniformity of this influence. The modulus of $\mathcal{I}_F$ is readily found, and in Fig. 5 the ratio $\mathcal{I}_F(\eta = 1)/\mathcal{I}_F(\eta = 1/\sqrt{2})$ is plotted as a function of frequency. This ratio may be viewed as a measure of the uniformity of the a-c current distribution. As expected, this ratio increases with frequency, and the worse the initial distribution, the more rapidly nonuniformity rises.

Nonlinear Solutions

Let us choose as an expression for the potential

$$\phi = \sum\nolimits' c_l P_l(\eta) \qquad [33]$$

The condition that the variational function (Eq. [12]) be stationary with respect to variations in c_l is

$$\frac{4\kappa}{\pi r_0} g_l c_l - \int_0^1 \eta d\eta\, f(\eta)\, P_l(\eta)\, F(\phi_0 - \phi) = 0 \qquad [34]$$

When $F(\theta)$ is a general function, exact solutions can only be found by numerical integration. One can, however, linearize these expressions within a limited domain. Let us suppose that $\phi(\eta)$ is a slowly varying function over the electrode surface so that we may expand $F(\phi_0 - \phi)$ about a mean function $\bar{\phi}(\eta)$

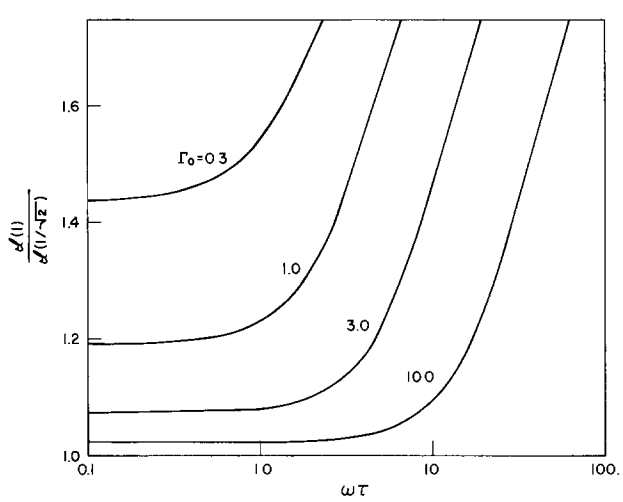

Fig. 5. Variation with frequency of the ratio of the current density at $r/r_0 = 1$ to that at $r/r_0 = 1/\sqrt{2}$ for linear a-c polarization.

$$F[\phi_o - \phi(\eta)] = F[\phi_o - \bar{\phi}(\eta)] - F'[\phi_o - \bar{\phi}(\eta)]\,\Delta\phi(\eta) \quad [35]$$

and let

$$\bar{\phi} = \sum_l{}' \bar{c}_l P_l(\eta)$$

$$\Delta\phi = \sum_l{}' \Delta c_l P_l(\eta) \quad [36]$$

For a first-order linearization

$$c_0 = \bar{c}_0 + \Delta c_0$$
$$c_l = \Delta c_l \qquad l \neq 0 \quad [37]$$

These substitutions then give ($f(\eta) = 1$)

$$\frac{4\kappa}{\pi r_o}\bar{c}_0 = F(\phi_o - \bar{c}_0)$$

$$\Gamma g_l c_l + \sum_{l'} c_{l'} K_{ll'} = K_{0l}(1 + \Gamma)\bar{c}_0 \quad [38]$$

where

$$\Gamma = 4\kappa/[\pi r_o F'(\phi_o - \bar{c}_0)] \quad [39]$$

The equations to be solved involve one nonlinear expression for $\bar{c}_0$, and a set of linear expressions equivalent to those encountered in our discussion of the linear boundary value problem. The differences are only that Γ is now a function of $\bar{c}_0$, and ϕ_o has been replaced by $(1 + \Gamma)\bar{c}_0$. As Eq. [17] for the total current still applies, using our previous solution to the linear problem we obtain

$$I_{TOT} = \pi r_o^2 F(\phi_o - \bar{c}_0)(1 + \Gamma)/\left[1 + \Gamma\left(1 + \sum \frac{\alpha_i}{1 + \Gamma\beta_i}\right)\right] \quad [40]$$

Formally, linearization may be carried to second order by solving parametric expressions for $\bar{c}_0$ and $\bar{c}_2$. The remaining linear equations are no longer those previously encountered, and, when first-order linearization is inadequate numerical procedures appear more appropriate.

A conventional nonlinear overpotential function is the exponential one

$$F(\theta) = i_o[\exp(\theta/\lambda) - \exp(-\theta/\lambda)] \quad [41]$$

where $\lambda \sim kT/e$. Calculated current-voltage curves are plotted logarithmically in Fig. 6 for various values of γ, where γ is given by

$$\Gamma = 2\gamma \exp[(\phi_o - \bar{c}_0)/\lambda] + \exp[-(\phi_o - c_0)/\lambda] \quad [42]$$

Thus γ is the value of Γ in the linear regime about $\phi_o = 0$. These plots are of little value in estimating Tafel parameters when $\gamma < 100$. From our discussion of linear solutions, however, it should be apparent that the major correction involves linear IR_∞ compensation. Applying such a correction shows that useful information can be extracted even when $\gamma = 1$ (Fig. 7).

Current distributions are found when the equations are solved for the coefficients c_l. It is easily shown that when the expanded overpotential function is employed

$$\mathcal{I}(\eta) = F(\phi_o - \bar{c}_0) - F'(\phi_o - \bar{c}_0)\sum_l \Delta c_l P_l(\eta) \quad [43]$$

one obtains a spatial distribution identical to that for the linear problem with the same Γ value. When this approximation suffices, Newman's numerical calculations for linear and Tafel polarization should coincide for equal values of his indexing parameter (7, 12). The similarity is striking.

As a better estimate we might instead evaluate

$$\mathcal{I}(\eta) = F\left[\phi_o - \sum_l c_l P_l(\eta)\right] \quad [44]$$

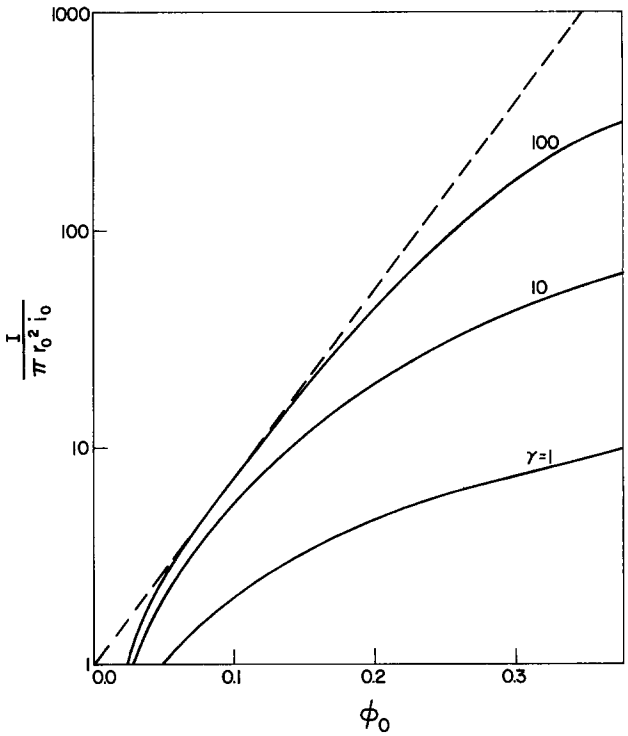

Fig. 6. Tafel plots for an exponential overpotential function with finite electrolyte conductivity. ($\lambda = 0.05$).

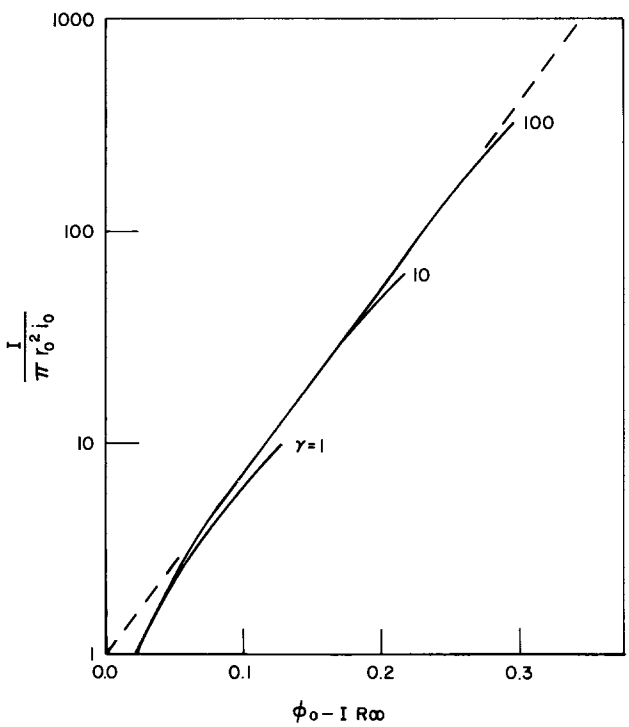

Fig. 7. The data of Fig. 6 replotted with an IR_∞ correction.

When a specific example is considered, say the point for $\phi_o = 0.2$V on the $\gamma = 1$ curve in Fig. 6 ($\Gamma = 0.386$), both functions give similar results differing by typically 3% for a second-order solution.

This analysis has useful implications for periodic reverse plating (13). In this process one plates out metal under conditions giving a nonuniform distribution. The current is then reversed, and a portion of the plated metal is removed. If the current distribution on the anodic portion of the cycle is less uniform than on the cathodic portion, macroleveling can be achieved. We have found that the distribution is determined by a parameter Γ which may be evaluated for each point

on a current-voltage curve. Therefore, if the value of Γ at the cathodic operating point is greater than its value at the anodic operating point, leveling occurs. If it is less, the resulting distribution will be less uniform than if no reversal had been employed. In the special case of a symmetric current-voltage curve for which Γ continually decreases as $|\phi|$ increases (Eq. [41]), the magnitude of the anodic potential must always exceed that of the cathodic potential to obtain a more uniform distribution of metal.

By way of illustration we shall take as a specific example cathodic deposition at a potential of -0.2V for $\gamma = 10$ with $F(\theta)$ given by Eq. [41]. The cathodic operating point may be found in Fig. 6. The anodic and cathodic periods are assumed to be sufficiently long that transient processes may be safely ignored. The anodic duty cycle is adjusted to give a constant mean current which is taken as 50% of the cathodic current. Current distributions are plotted in Fig. 8 for different anodic potentials, ϕ_a. When $0 < \phi_a < |\phi_c|$ periodic reversal leads to a less uniform deposit. For $\phi_a = 0.38$V one finds a uniform distribution, and for more anodic potentials the distribution is reversed.

In this example the current distribution is sufficiently uniform that a first-order approximation suffices. In more general instances multilevel anodic waveforms can be envisioned to suppress higher order terms. Chemistry sets a practical limit to periodic reversal. Its successful application requires rather large anodic potentials, and the chemistry which actually occurs in this region may be considerably different from that in the cathodic region. Only when one can anodically etch away deposited metal with no complications from metal oxide film formation does periodic reversal appear to be a viable technique for producing more uniform electrodeposits.

Discussion

The ease with which we have found solutions for the problems considered in the preceding sections testifies to the usefulness of variational analysis for the study of current distributions in electrolytic cells. The examples given required handling of only 2×2 or 3×3 determinants, and can be (and were) solved with a pocket calculator. A minor amount of computer time would obviously yield more exact answers.

The RDE is a particularly useful tool, both theoretically and experimentally, for the study of electrode processes and current distributions. Mathematically, it has a hydrogenic simplicity, while manifesting all the complications of "real" cells. When total electrode currents are measured, the stricture that meaningful results can be had when $\Gamma > 10$ is unduly severe (12). This limit can easily be extended by two orders of magnitude with minor corrections, because the total current in linear systems is a stationary quantity, and insensitive to first-order variations in the current distribution. For nonlinear systems this is not precisely true, but, barring pathological examples, the total current is still less sensitive to the current distribution than is the distribution itself. For linear problems an arbitrarily precise solution exists for the total current. This solution can be especially useful in analyzing time-dependent phenomena.

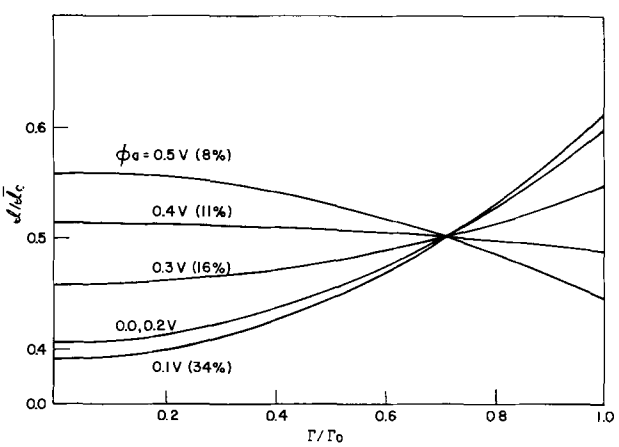

Fig. 8. Current density distributions calculated to first order for period reverse plating on a RDE. Anodic potentials and duty cycles are indicated on each curve. A symmetric exponential overpotential function is assumed, with cathodic deposition occurring at -0.2V.

Several RDE problems remain to be scrutinized in greater detail. We have not considered the influence of mass transport on current distributions, other than to indicate how it can be formally introduced into these problems. As an approximation one might neglect concentration correlations across the electrode, in which case a spatially independent $F(\theta)$ can be defined as a function of bulk concentration and hydrodynamic layer thickness. At no point could the current density exceed a defined limit, and a uniform distribution would imply a uniform potential outside the double layer. Neither consequence holds for an exact solution (7). Proper consideration of mass transport in RDE problems necessitates replacing the matrix elements K_{ll}, by

$$\sum_{l''} b_{l''} \int \eta d\eta \, P_l(\eta) \, P_{l'}(\eta) \, P_{l''}(\eta) \qquad [45]$$

where the coefficients $b_{l''}$ need be found by iterative procedures.

A second problem for analysis is the interaction of a-c and d-c current distributions in nonlinear systems. For quasi-static conditions our treatment of periodic reverse plating illustrates a limiting behavior. Frequency-dependent effects are more complex. A portion of the a-c current will be rectified, contributing to the d-c current. Both the a-c current distribution and its rectification efficiency will be spatially and frequency dependent. Proper solution requires expansion of $\Gamma(t)$, $\bar{c}_0(t)$, and $c_l(t)$ to second order when the a-c modulation is small and is beyond the scope of this presentation.

The determination of current distributions in real plating bath geometries can present greater difficulties. The art of variational analysis is in finding a tractable set of basis functions which closely approximate the real solution. It is obviously desirable, and not difficult, to find sets satisfying Laplace's equation. The variational equations then reduce to surface integrals.

A distinction is often drawn in the literature between primary and secondary current distributions. This nomenclature is perhaps unfortunate, for it bears the implication that the primary distribution must first be found before the real or secondary distribution can be deduced. The primary distribution possesses nontrivial singularities at edges and corners. Unless these singularities are carefully incorporated into variational functions, very high order approximations are necessary. This is evident from our discussion of linear solutions to the RDE as $\Gamma \to 0$. By contrast, in respectable plating baths these singularities are erased by electrode polarization, and the current distribution at edges and corners can be effectively described by variational functions which are not exact in these regions. The determination of secondary current distributions is thus a simpler problem than finding primary distributions (4).

There is no obvious reason to suppose that our conclusions regarding time-dependent effects on current distributions at the RDE are not also relevant to more general geometries. Thus, periodic reverse plating should only lead to more uniform macrodeposits when rather stringent requirements are met. The conditions under which time-dependent currents produce salubrious results on the microscale remain to be examined. These may not depend explicitly upon nonlinear proc-

esses, and a linear approximation can then be used to deduce the spatial distribution of microscopic changes.

Technical Notes

Observation of a Substructural Network in the Positive Plates of Lead-Acid Storage Batteries

J. Perkins and M. T. Coyle

Materials Science Group, Naval Postgraduate School, Monterey, California 93940

In terms of realizing capacity, most contemporary lead-acid batteries are positive limited, *i.e.*, reach a fully discharged state in a given cycle when the capacity of the positive plate is exhausted, while the negative plate at that point is not fully discharged. Furthermore, the positive plates typically realize only about 50% of their theoretical capacity, and are prone to a variety of deterioration modes during cyclic service. These facts are well known, and there has been considerable effort to improve the lead-acid system by means of analyses of the performance of the positive plate. Among these studies have been a number of investigations that have emphasized the importance of the microstructural features of the active material. The morphological state of the positive plate is of great importance, particularly with respect to mechanical stability of the active material mass and realization of capacity. The microstructure of lead-acid positive plates has been widely studied in the past utilizing cross-sectional optical microscopy (1, 2) and replica transmission electron microscopy (3-7). These studies have been reviewed by Burbank *et al.* (8) and Perkins (9). The present paper reports on the results of a detailed scanning electron microscopy investigation into the substructural evolution of positive plate microstructures. The results of the present investigation correlate with previous results by other microscopic methods, and add to the understanding of these microstructures and their significance.

Experimental

The observations reported here are based on cycling of laboratory lead-acid cells in a trickle-discharge routine. The cells were constructed from 12 cm square sections of standard full-size lead-calcium-grid submarine (TLX-39B) battery plates, received from Gould, Incorporated in the formed and dried condition. The cells were loaded for positive plate limitation, with two negative and one positive plate per cell, and a large electrolyte reservoir. Microporous rubber separators and fiberglass retainer mats were used. The cells were prepared and cycled in accordance with rather standard procedures for this type of lead-acid cell (10, 11). The cells were first filled with 1.255 specific gravity electrolyte, and prior to initial charge were allowed to stand for 15 hr in order to cool. An initial constant current (500 mA) charge was carried out for at least 65 hr and continued until cell voltage and specific gravity stabilized at 2.32-2.36 and 1.295-1.275, respectively. The trickle-discharge routine consisted of a full charge, trickle discharge at a rate of 50 mA for 96 hr, recharge

to full cell voltage, and a capacity test discharge at a nominal 3 hr rate of 4500 mA, terminated when cell voltage reached 1.6V. A constant potential charging method was utilized, according to standard procedures (11), with a 800 mA constant current finishing rate for these cells; limited overcharge was allowed.

At selected intervals, cells were removed from the cycling. The positive plates were carefully removed and washed, first by immersion for 5 min in cold tap water, then by rinsing with a gentle stream of water over each face. No mechanical cleaning or blotting was used. After washing, the plates were allowed to dry for 24 hr in an oven at 70°C. The plates were sectioned with a jeweler's saw and active material was selectively broken away from grid bars, or fractured through, or razor-cut wedge sections were removed. The samples were observed in a Cambridge S4-10 scanning electron microscope operated at 20 kV. No conductive coating was necessary for observation, and good resolution was obtained at magnifications up to 20,000×.

It should be noted that in related work, float and deep discharge routines were also imposed on cells, and lead-antimony-grid batteries were also evaluated. This comprehensive work will be reported in a future paper. The present paper reports only on observations on the structure of trickle-discharged Pb-Ca positive plates.

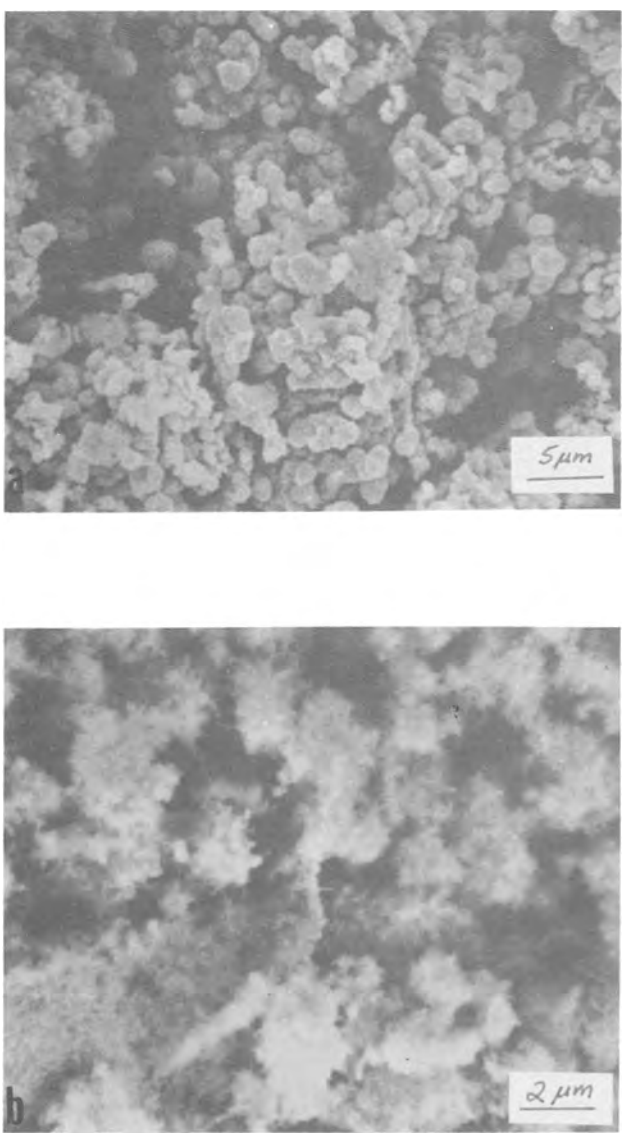

Fig. 1. Initial microstructure of positive plate in formed condition: (a) regular arrangement of nodular masses averaging about 2 μm in diameter, (b) fine structure on the surface of the nodules, consisting of a field of short whisker crystals averaging less than 0.5 μm in length.

Results and Discussion

The initial, as-formed microstructure of the positive plate active material is shown in Fig. 1, and can be described as an aggregate of small (2 μm) nodular masses in a regular arrangement, with limited structural contiguity. The surface of the individual nodules, when observed at higher magnification, shows a fine whiskerlike substructure (Fig. 1b); the majority of these whiskerlike microcrystals are a few tenths of a

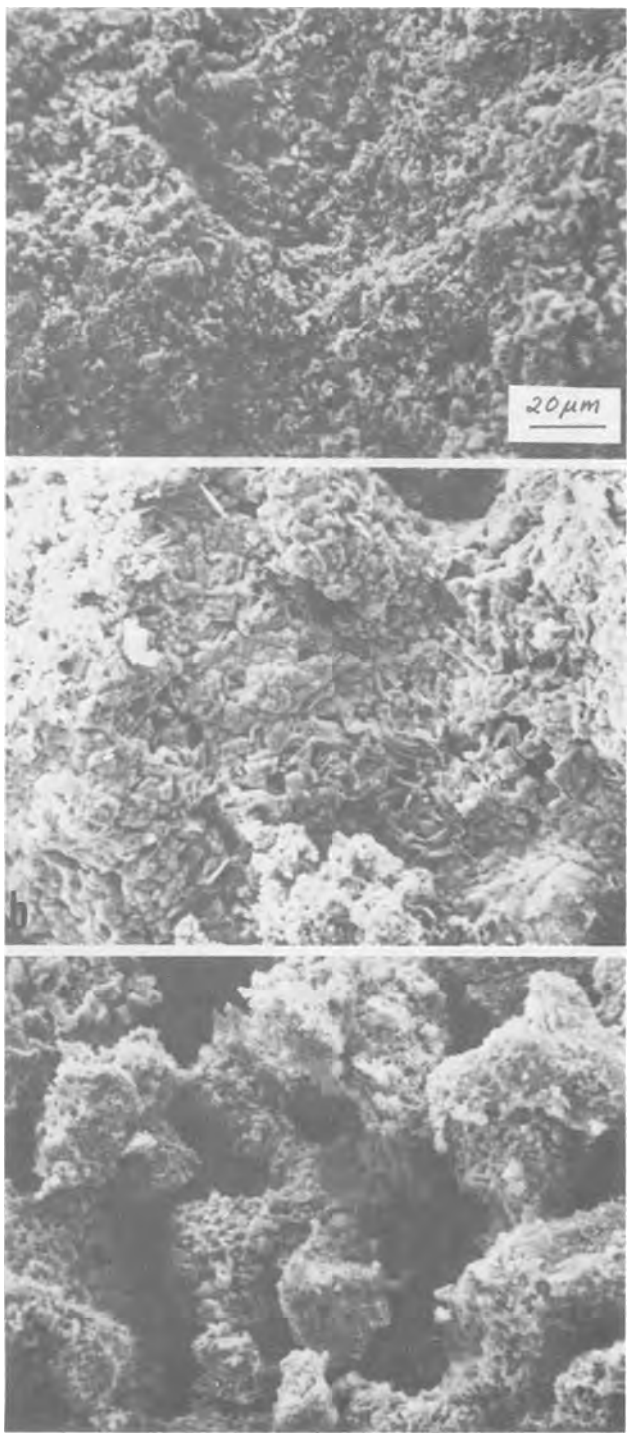

Fig. 2. Active material microstructural changes with cycling. (a) 5 cycles: regular and uniform distribution much like initial microstructure, (b) 13 cycles: agglomeration into more consolidated masses with less uniform distribution, (c) 60 cycles: fully developed "coralloid" labyrinth structure with large open spaces. All plates observed in the charged condition. All photos same magnification.

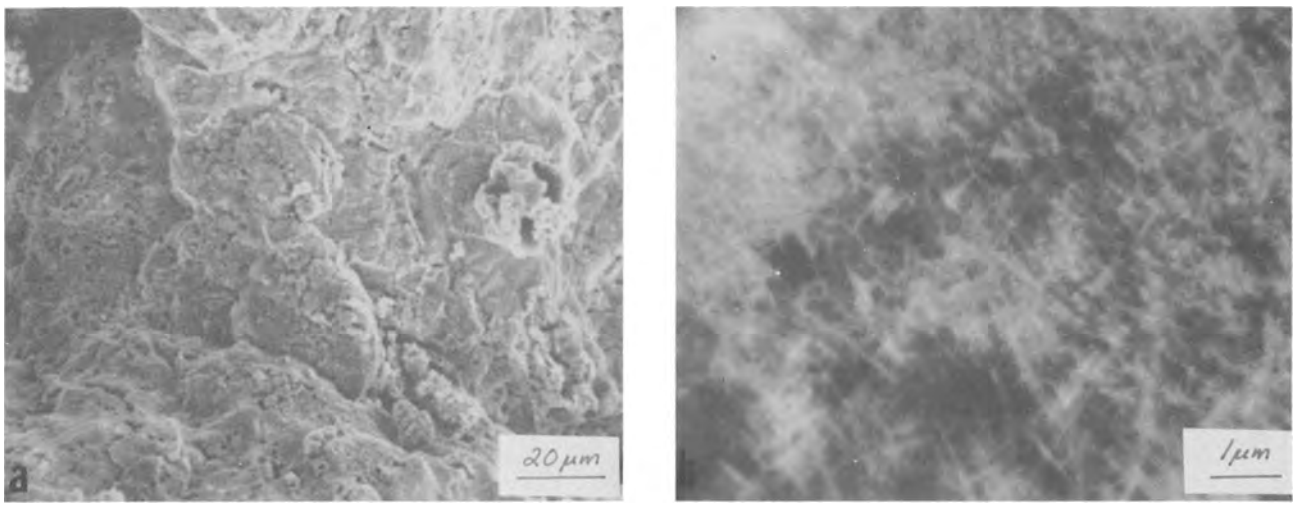

Fig. 3. Submicrostructure observed in active material after about 10 cycles: (a) structure observed developing near middle thickness layer of active material pellets which appears, at low magnification, as a coating over the active material particles, (b) at high magnification is seen to consist of a very fine whisker like network.

micron in length. In addition, there are some more distinct "spiny" crystal arrays, which average about 1.5 μm in length. This substructure resembles certain PbO_2 morphologies reported by other workers, based on observations by less distinct microscopic techniques. Burbank and Ritchie (3) described branched prismatic crystals of PbO_2 which existed individually and clustered together in "Christmas tree" dendrites, together with more complex aggregates composed of compound spikes of dendritic growth, covered with so-called sessile (static, unchanging) crystallites of varying sizes. It is believed that these are the same sort of structures as seen in Fig. 1.

Microstructural changes in the active material with cycling, for plates subjected to the trickle-discharge routine, are shown in Fig. 2. The originally regular nodular array gradually evolves into a more consolidated labyrinth structure containing large open spaces. Simon and co-workers observed similar microstructural developments during continuous charge/discharge cycling, and termed the three-dimensional structure a "coralloid" structure (12).

A more subtle development noticed with cycling is illustrated by Fig. 3. At relatively low magnification, this appears as an apparently dense layer that coats the surface of the PbO_2 crystals in the recharged positive plate. At this point in the cyclic history (13 cycles), this structure was found only near the middle thickness plane of the active material pellets in the grid. At higher magnification, the substructure of this layer is revealed, and is seen to be made up of the same sort of fine whiskerlike crystalline forms previously described.

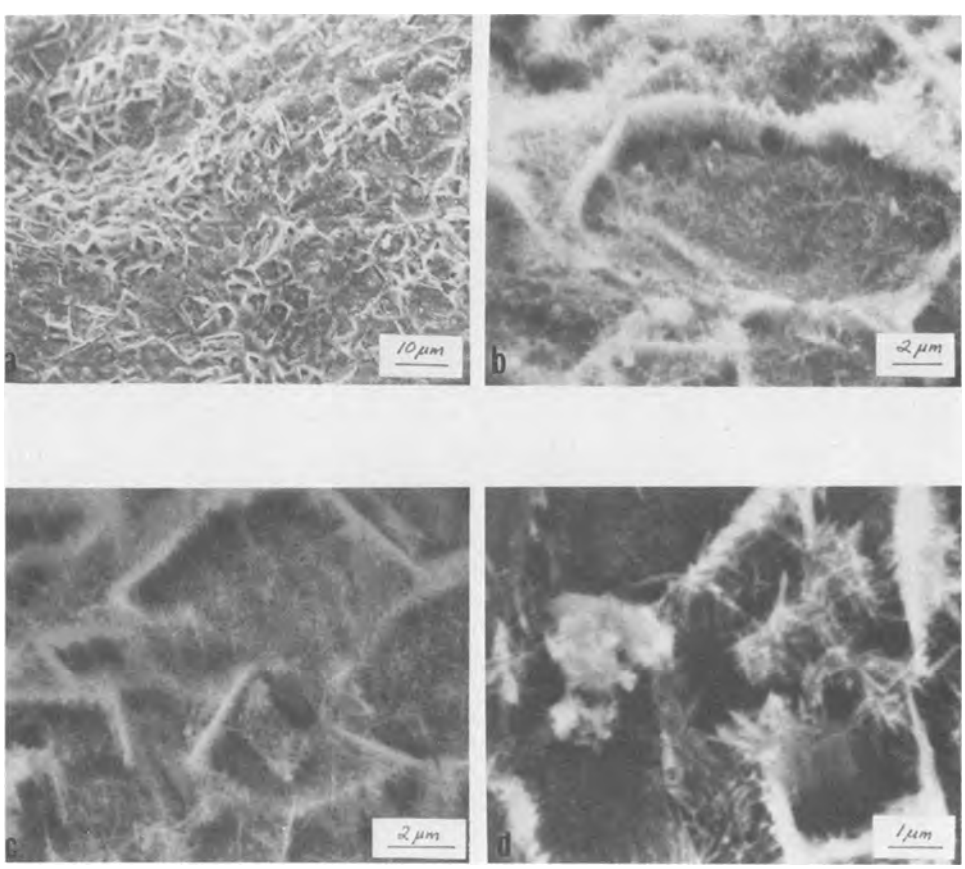

Fig. 4. (a) Patterned imprint of cell-like substructural network observed on grid surface when active material broken away. (b) ond (c) Higher magnification views showing rectilinear outlines consisting of denser whisker network. (d) Very high magnification view, showing dendritic crystals.

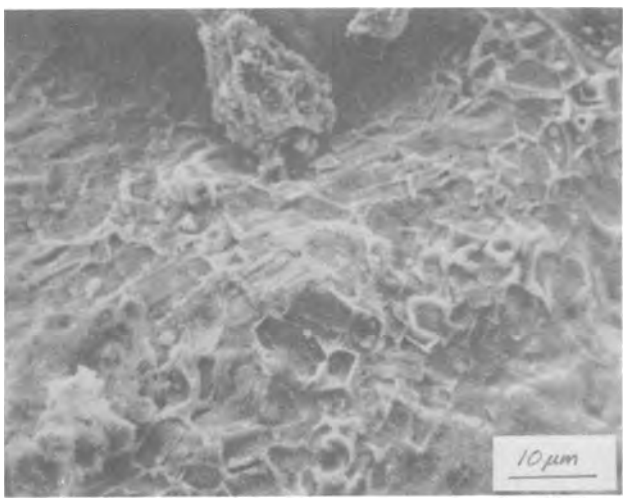
More of the larger, linear spiny crystals are evident, now developed into a branching network extensive enough to completely blanket the underlying nodular aggregate.

Further indication of the evolution of an extensive substructural network during trickle-discharge routine is seen on the surface of the grid as a patterned structure when the active material is broken away (Fig. 4). What appears at lower magnification as a white pattern against the grid surface is made up, on the fine scale, of a whisker network similar to those already described. The pattern of "walls" typical of this structure can also sometimes be revealed within the active material mass, as seen in Fig. 5, when the active material pellets are fractured through. It is obvious that the patterns observed on various two-dimensional surfaces represent a structure that is part of a cell-like three-dimensional distribution throughout the active material mass. Furthermore, when the two-dimensional patterns are studied, it is obvious that the shapes of the spaces mapped out represent the outlines of polyhedral lead sulfate crystals which have since transformed to PbO_2 during recharging (oxidation). The cell-like three-dimensional network structure, composed of a dense weave of whiskerlike crystals, extends throughout the charged positive plate, with the regions of greatest density determined by the prior location of the edges of the polyhedral lead sulfate crystals in the discharged plate.

This hypothesis is confirmed by Fig. 6, which shows an area on the grid surface, at a point of incomplete recharge, where some $PbSO_4$ crystals exist in a state of partial transformation. The correspondence between the slow dissolving edges of these crystals and the patterned outline observed for the fully charged condition is quite vivid.

Therefore, the mechanism of formation of the substructural network is based on the transformation of fairly large $PbSO_4$ crystals formed during the trickle-discharge routine. These are transformed in a typical preferred crystallographic sequence, with the edges of the polyhedra transformed more slowly than the planar faces, so that the crystal faces and interior are consumed first, leaving behind a "framework" structure of the edges. This final framework eventually converts to PbO_2, but forms a denser array of whiskers arranged in cell walls that correspond to the prior $PbSO_4$ crystal edges. At the grid surface and other surfaces within the active material mass, this structure can be seen as a sort of imprinted pattern. The exact genesis of the fine whiskerlike form which makes up the substructural network is not known, but obviously is a preferred morphological form of PbO_2 associated with $PbSO_4$ transformation under particular electrochemical conditions. It seems that the size and spacing of these whiskers decreases as the rate of oxidation decreases, *i.e.*, such as at the end of a recharging procedure on the positive plate. X-ray diffraction indicates the presence of only β-PbO_2 in these networks.



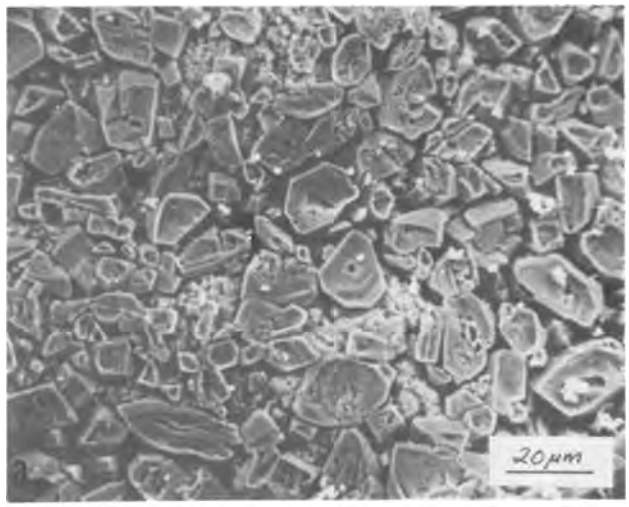


Fig. 5. Cell-like pattern of the substructural network observed within the active material mass when a pellet is cracked open.

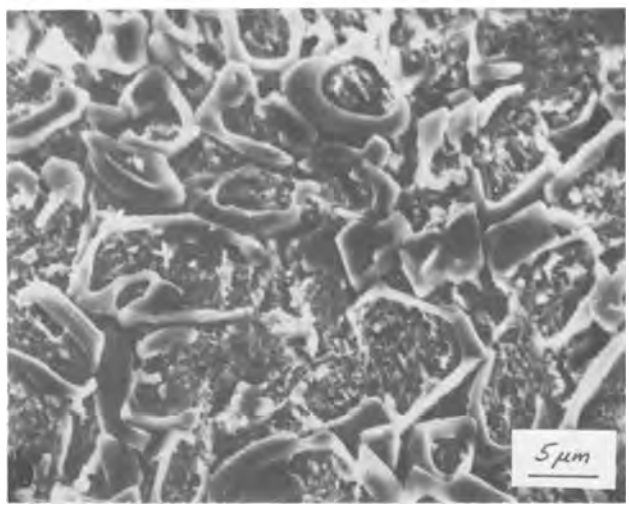

Fig. 6. (a) Array of lead sulfate crystals beginning to transform during charging. Compare the shapes of these polyhedra with the patterns seen in Fig. 4a and 5. (b) Array of almost fully transformed lead sulfate crystals, indicating the correspondence between the slow transforming edges of the polyhedra and the denser rectilinear regions of the whiskerlike substructural network.

Conclusions

The extensive fine scale whiskerlike network of PbO_2 observed in these trickle-discharged plates is considered to impart both favorable electrochemical characteristics and structural integrity to the active material mass of the positive plate. This structure is apparently the same structure observed by Simon (13) using light microscopy, and referred to as a "reticulate" structure. This structure was observed by cross-sectional optical microscopy to be arranged in a cell-like network with generally rectilinear sides (13). The present observations also correlate with the replica electron microscope work of Burbank (7), which revealed branched prismatic crystals in satisfactorily floated positive plates, whereas the crystal morphology in unsatisfactory plates was nondescript. Simon was also able to notice fine prismatic crystals in association with the reticulate structure (13). It was suggested that the reticulate structure serves as a sort of "microgrid," from both an electrical and mechanical standpoint. This proposal is supported in this study by observation of

the three-dimensional form of the structure. In a later paper, which will compare the structure of trickle-discharged and floated plates, it will be shown that these structures are indeed correlated with more satisfactory performance, particularly in association with capacity retention in repeatedly cycled plates.

Anodization Constants for Tantalum

L. Young*

Department of Electrical Engineering, The University of British Columbia, Vancouver, British Columbia, Canada V6T 1W5

In device applications of anodic oxide films, it is common practice to use so-called "anodization constants" (in units of angstroms per volt) to predict the thickness of oxide which will be produced by anodizing at constant current until a chosen voltage, V, is reached and then holding at this constant voltage for a fixed time ("soaking"). In experimental determinations of anodization constants, plots of film thickness D *vs.* V are prepared, a straight line is drawn, and the slope dD/dV is taken as the anodization constant.

It is interesting to relate anodization constants to the published kinetic data for steady-state anodization at constant current density. These data give the ionic current density J as a function of the field in the oxide ($E = V/D$) and the temperature. [Here, V is strictly the overpotential for oxide production less a correction for interfacial overpotential which turns out (1, 2) to be negligible.] The expression $J = J_0 \exp(-W/kT) \exp BE$ was used in earlier work but it was found that B was not inversely proportional to temperature if taken as independent of E. It was later proposed (1) that data for constant current anodization of tantalum in dilute sulfuric acid could be fitted by

$$J = J_0 \exp(-W/kT) \exp(q(\alpha E - \beta E^2)/kT) \quad [1]$$

where $J_0 = 10^{8.24}$ A cm^{-2}, $W = 2.185$ eV, $\alpha = 6.995$Å, $\beta = 3.35$ Å/(10^7 V cm^{-1}), $q = 5e$, and k = Boltzmann's constant. The thicknesses of oxide were determined optically and were based on a value of refractive index which later work has confirmed to within about 1%. Dreiner and Tripp (3) in a detailed study over an extended temperature range have confirmed the need for either an expression of the form of Eq. [1] or a Schottky expression as used by Young and Zobel (4). Their data seem also to be in excellent numerical agreement. This paper may be consulted for references to further work not quoted here, including Dignam's work on aluminum. We are not concerned here with the theoretical basis of Eq. [1]. This is discussed, for example, by Dell'Oca *et al.* (5). Siejka Nadai, and Amsel (2), using nuclear microanalysis of oxygen, determined fields for current densities of 10 and 1 mA cm^{-2} which agreed within 1%, provided the density was as assumed below. The earlier data of Vermilyea (6) were based on an assumed density of 8.74 g cm^{-3} and agree within a few percent after correction to $p \simeq 8$ g cm^{-3}, although fitted to a different form of expression.

The ionic current density which is produced by a given field depends, in general, on the history of previous currents of fields which have been applied. However, Young and Zobel (4) found that their experimental data on J as a function of E obtained during constant voltage anodization agreed within experimental error with the data (Eq. [1]) obtained at constant current. We can, therefore, use this expression for the constant voltage part of the anodization as well as for the constant current part. We assume that the current efficiency is 100% during the constant current anodization. As far as is known, the current efficiency during the constant voltage part does not affect the result.

With the expression of Eq. [1], numerical methods become necessary and the University of British Columbia Computing Centre's Runge-Kutta routine (7) with error correction was used to calculate D after a fixed time at constant voltage with initial conditions $D = D_0 = V/E_0$, where E_0, is the constant field during the initial constant current phase, and with $dD/dt = \chi J$, where $\chi = M/\rho 10\mathbf{F}$, J being given by Eq. [1] with $E = V/D$, M = molecular weight of Ta_2O_5, ρ = density of oxide, and $\mathbf{F}$ = Faraday's constant. The density was taken as 7.93 g cm^{-3}. This value (8) was given as ±3% but agrees within 1% with the more accurate value of 8.03 ± 0.04 g cm^{-3} (for formation in 0.1% H_3PO_4) given by Schrijner and Middelhoek (9). Even

Table I. Computed thicknesses at listed voltages. Formation is at constant current density J_1 giving field E_0 until the voltage V is reached and then at constant voltage V

	Thickness (Å)			
Voltage	J_1 = 1.55 mA cm^{-2} $1/E_0$ = 16 Å/V 238°K 20 min soak	J_1 = 13.5 mA cm^{-2} $1/E_0$ = 15 Å/V 298°K 20 min soak	J_1 = 13.5 mA cm^{-2} $1/E_0$ = 15 Å/V 298°K 60 min soak	J_1 = 11.5 mA cm^{-2} $1/E_0$ = 15 Å/V 296°K 60 min soak
10	198.5	198.5	204.6	203.3
50	949.9	949.8	978.8	973.1
100	1864.0	1863.8	1920.8	1909.9
150	2765.2	2764.8	2849.4	2833.4
200	3658.1	3657.3	3769.4	3748.1

with an error of ±3%, since the constant voltage phase accounts for only 15-20% of the final thickness, the extra error would be ±0.6%.

Some typical calculated thicknesses are given in Table I, both for a 20 min soak as used by Schwartz *et al.* (10, 11) and for a 1 hr soak which is believed to be typical of some device applications. Data are given for different initial current densities and one column is for 296°K rather than 298°K. More figures are given than are absolutely significant in order that relative trends may be seen.

We note first that D is not linear in V. This fact turns out to cause surprise, even disbelief, and to require discussion. It may be explained as follows. A given ionic current density gives a fixed dD/dt independent of D but $dE/dt = -(V/D^2)dD/dt$ at constant voltage. At the start of the soak, the current density is independent of thickness. Therefore, the field starts to fall at a rate which is initially inversely proportional to thickness. The ionic current density decreases less rapidly the thicker the film but this only partially compensates, so that the final field, which might be regarded as a reciprocal of the anodization constant, will still be bigger the smaller the voltage.

The nonlinearity might escape notice in a plot of D *vs.* V but is apparent in a plot of D/V *vs.* V. (Fig. 1). The anodization constant which would be found from a plot of D *vs.* V would, of course, tend to be determined by the larger values of D. The dependence on the value of the initial current is slight (up to 0.1% for the example chosen), the temperature dependence would be quite appreciable for some applications (*e.g.*, up to 0.6% for a 2°C change in the examples chosen).

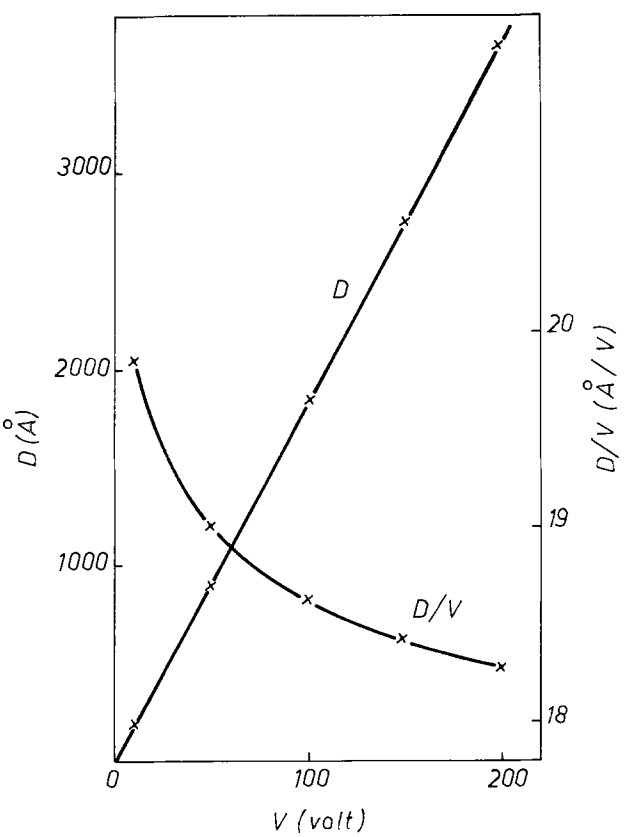

Fig. 1. Plot of D and D/V vs. V from data in first column of Table I.

Experimentally determined anodization constants have been compared with reciprocal fields for constant current formation, even for current densities as high as 10 mA cm^{-2}. To confuse the two concepts is greatly to underestimate the accuracy with which film thickness should be predictable. This should be of the order ±1% with a reproducibility much better than this if the second electrode has a defined potential. Muth's angstroms per volt values (12), which receive some use as anodization constants, are for constant current formation in dilute citric acid (17-15.6 Å/V for 0.1-1 mA cm^{-2}). The angstroms per volt value found by Klerer (13) (16 Å/V ± 3.2%) and his widely quoted dielectric constant (21.2 ± 3.3%) seem low. He used sputtered tantalum films (14) but this may or may not account for the difference. Mills, Young, and Zobel (15) found that the permittivity of the oxide formed on sputtered tantalum was close to that of films formed on bulk tantalum. It should be added that the electrolyte can have a strong effect on anodization constants, even in dilute solutions. Take-up of electrolyte tends to reduce thickness and permittivity together, so that the capacitances of films formed to a given potential in different solutions tend to be less different than the thicknesses. In some practical applications, the capacitance rather than the thickness is to be controlled.

Potassium Ion-Selective Electrode

Potassium Zinc Ferrocyanide in a Silicone Rubber Matrix

Peter A. Rock,* Terry L. Eyrich,[1] and Steven Styer[2]

Department of Chemistry, University of California, Davis, California 95616

We report here a new Pungor-type, potassium ion, heterogeneous membrane electrode in which the active material is potassium zinc ferrocyanide imbedded in a silicone rubber matrix. The electrode responds to potassium ion in a Nernstian manner over the concentration range 1 to 10^{-3}M; the electrode is operational down to 10^{-4}M. The K^+/Na^+ ion selectivity of the electrode is comparable to commercially available cationic glass electrodes. The electrode is simple and inexpensive to fabricate from readily available materials. A simple and effective procedure for the preparation of leak-free, reproducible, heterogeneous rubber matrix membranes is also described.

Experimental

The procedure used to prepare the heterogeneous salt-plus-silicone rubber membrane disks is as follows. The dried salt is thoroughly mixed with silicone rubber. The salt-plus-rubber mixture is then cured in the barrel of a disposable plastic syringe from which the tip end has been cut off with a razor blade. Fresh membrane disks of the desired thickness are cut with a razor blade from the end of the cured cylinder after extrusion with the syringe plunger. This simple procedure greatly facilitates the preparation of leak-free and reproducible membrane disks. The membrane disk is glued with rubber cement to the end of a glass tube. Several centimeters of 0.1M KCl is placed in the tube and a silver-silver chloride (thermal-electrolytic type) electrode (1) is inserted into the KCl solution. The electrode lead wire is then glued in place with a plug of silicone rubber at the upper end of the tube; the resulting electrode is rugged and insensitive to moderate shock. The electrode is represented diagrammatically as

$$\mathrm{Ag(s)\,|AgCl(s)\,|KCl(aq)\,|KX(memb)} \qquad [1]$$

where KX is a water-insoluble potassium salt. Several potassium salts were investigated including $KB(C_6H_5)_4$, KUO_2AsO_4, and potassium metal ferrocyanides (iron, manganese, cobalt, copper, and zinc). The best electrode performance was obtained with the salt $K_2Zn_3[Fe(CN)_6]_2 \cdot 8H_2O$ which was prepared as described in the literature (2). Electrical measurements were made using a Keithley 602 electrometer as a unity gain amplifier in conjunction with a Leeds and Northrup K-3 potentiometer. The reported voltages are the average of five readings taken at 2 min intervals during a period after the cell voltage stabilized (usually 3 to 5 min). The weight percentage of salt in the mixture was varied over the range 40-80%; the best results were obtained with *ca.* 55 weight percent (w/o) of $K_2Zn_3[Fe(CN)_6]_3 \cdot 8H_2O$.

Results

The cells used to study the potassium electrodes were of the type

$$\mathrm{Ag(s)\,|AgCl(s)\,|KCl(aq, M)\,|KX(memb)\,|KCl(aq,\ M_1),NaF(aq, M_2)\,|Hg_2Cl_2(s)\,|Hg(l)} \qquad [2]$$

for which, with M held constant

$$\mathcal{E} = \mathcal{E}^\circ - \frac{RT}{\mathbf{F}} \ln [a_{K^+}\, a_{Cl^-} + k_{K^+,Na^+}\, a_{Na^+}\, a_{F^-}] \qquad [3]$$

with $M_2 = 0$, we have

$$\mathcal{E} = \mathcal{E}^\circ - \frac{2RT}{\mathbf{F}} \ln M_1 \gamma_\pm \qquad [4]$$

and therefore the theoretical Nernst slope is 118 mV/decade at 25°C.

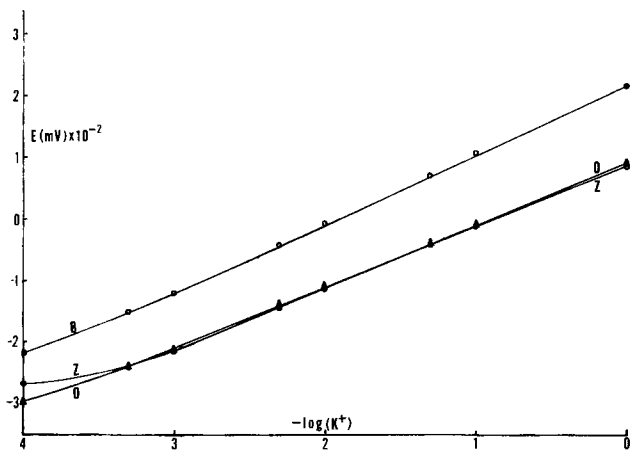

Fig. 1. Plot of voltage *vs.* $-\log (K^+)$ for a potassium zinc ferrocyanide/silicone rubber membrane electrode (Z), an Orion potassium ion electrode (O), and a Beckman cationic glass electrode (B). The cell solutions are KCl(aq) of the indicated concentration in contact with a calomel electrode (25°C).

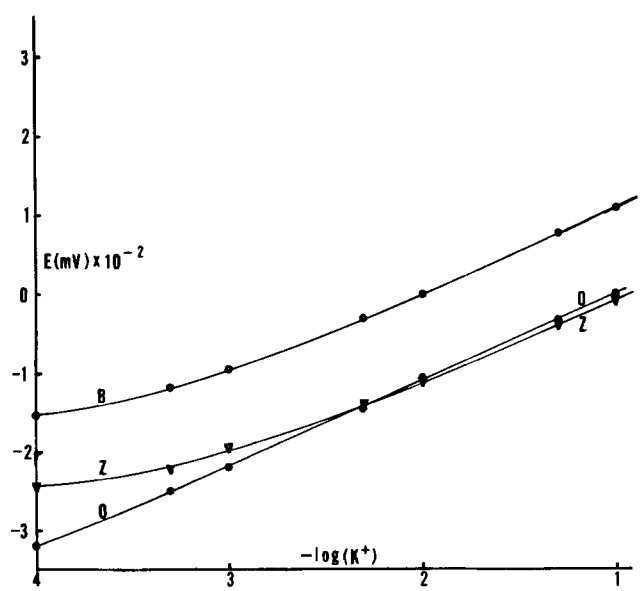

Fig. 2. Plot of voltage *vs.* $-\log (K^+)$ for a potassium zinc ferrocyanide/silicone rubber membrane electrode (Z), an Orion potassium ion electrode (O), and a Beckman cationic glass electrode (B). Key words: potassium, ion-selective, electrode, membrane.

Figures 1 and 2 show the results of a comparison between $K_2Zn_3[Fe(CN)_6]_2 \cdot 8H_2O$/silicone rubber heterogeneous membrane electrode (Z), an Orion liquid ion-exchanger potassium selective electrode (O), and a Beckman (39137) cationic glass electrode (B). The comparison is made for both KCl(aq) and KCl(aq) in the presence of 0.010M NaF(aq). The test solutions were in contact with a Hills and Ives type calomel electrode (3). For the KCl(aq) solutions the slopes (millivolt/decade) (uncorrected for activity coefficients) over the range 1 to 10^{-3}M for three electrodes are: 101 mV (Z), 102 mV (O), and 112 mV (B). Correction for activity coefficients gives an observed slope of 116 mV for the potassium zinc ferrocyanide electrode. The selectivity coefficient for the $K_2Zn_3[Fe(CN)_6]_2$ electrode can be estimated by the extrapolation-intersection method (4) from the data in Fig. 1 as $k_{K^+,Na^+} \approx 0.10$, which is about the same as that for the cationic glass electrode. In contrast to the above results we found that although several other insoluble potassium salts in silicone rubber responded satisfactorily to the activity of potassium ion in aqueous solution, their selectivity characteristics were not as good as the potassium zinc ferrocyanide membrane. For example, $k_{K^+,Na^+} = 0.5$ for $KB(C_6H_5)_4$ (50 w/o) in silicone rubber.

Brief Communication

Catalysis of Oxygen Cathodic Reduction in Cobalt Ammoniacal Solutions

A. Bettelheim and J. Manassen[1]

Atomic Energy Commission, Nuclear Research Centre-Negev, Beer-Sheva, Israel

Oxygen electrodes, which can reach nearly reversible behavior, are important for fuel cell research. Usually these electrodes are coated with catalytic layers (1-3) or are immersed in catalytic suspensions (4, 5) to overcome their great deviation from thermodynamic reversibility. The homogeneous catalysis of the oxygen electrode is treated in previous studies (6, 7).

The electrocatalytic influence of iron-phthalocyanine (Fe-PhC) on oxygen cathodic reduction in KOH and H_2SO_4 aqueous solutions is known (1-3). Manassen (1) found that the electrocatalytic effect of Fe(II)-phthalocyanine (Fe(II)-PhC) equals that of Fe(III)-phthalocyanine (Fe(III)-PhC).

In a previous work (8), we have shown that use of the peroxo complex $[(NH_3)_5Co\text{-}O_2\text{-}Co(NH_3)_5]^{+4}$ increases the limiting current of oxygen reduction on a platinum electrode without decreasing the overpotential. This homogeneous effect was explained as an increase of dissolving oxygen capacity of the cobalt-ammoniacal solution. In the present work, reduction of oxygen on Fe-PhC electrodes was studied in cobalt-ammoniacal solutions.

Two types of electrodes (1.0 × 2.8 cm each) were prepared (1): the noncatalytic electrode (type A) was a Ni gauze on which carbon was deposited, and the catalytic one (type B) was a similar electrode but impregnated with Fe(III)-PhC. The instrumentation is described elsewhere (6, 8).

The Fe(III)-PhC electrode catalyzes oxygen reduction in ammoniacal solutions by reducing the overvoltage by about 350 mV. This heterogeneous effect

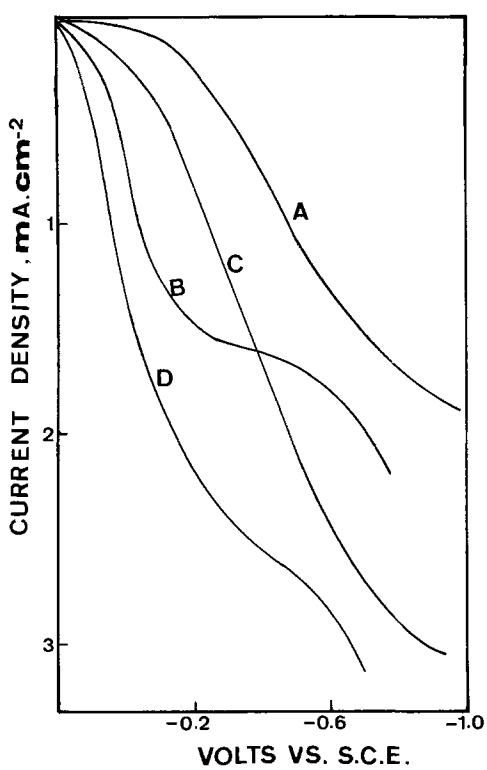

Fig. 1. Potentiostatic voltammograms (voltage sweep rate: 200 mV · min^{-1}) of oxygen reduction in oxygen-saturated solutions containing NH_3 (6.3M) and NH_4Cl (1M) (pH: 10.3). A, Type A electrode; B, type B electrode; C, type A electrode with $CoCl_2$ (10^{-2}M); D, type B electrode with $CoCl_2$ (10^{-2}M).

[1] Present address: The Weizmann Institute of Science, Rehovot, Israel.

Key words: catalysis, oxygen, cobalt-ammonia.

is demonstrated by comparing curves A and B in Fig. 1: For a type B electrode, a current density of 1 mA · cm^{-2} is obtained at −0.15V, whereas the same current density is reached at −0.50V for a type A electrode. Addition of Co(II) ions to the ammoniacal solution causes an increase of current, on type A as well as on type B electrodes (Fig. 1, curves C and D). A Fe-PhC cathode in a cobalt-ammoniacal solution will improve the performance of the oxygen electrode by reducing its overvoltage and increasing the cathodic current. A combination of homogeneous and heterogeneous effects, as shown here, may be useful in fuel cell research.

Photoelectrochemical Energy Conversion and Storage

The Polycrystalline CdSe Cell with Different Storage Modes

Joost Manassen and Gary Hodes

Department of Plastics Research, The Weizmann Institute of Science, Rehovot, Israel

and David Cahen

Department of Structural Chemistry, The Weizmann Institute of Science, Rehovot, Israel

The photoelectrochemical cell (PEC) furnishes an alternative to the commercially available photovoltaic cells for the direct conversion of sunlight into electrical energy (1, 2). As we have indicated previously (3), it has the distinct advantage over a photovoltaic cell in that storage of the converted energy is possible *in situ*.

We want to discuss here some general principles connected with storage in a PEC and to give experimental evidence that, after due development, this mode may be able to compete with the combination photovoltaic cell/storage battery.

In Fig. 1(a) the PEC is schematically indicated. P is the photoelectrode, in our experiments a polycrystalline layer of CdSe on titanium metal, which is obtained by electrolytic codeposition of Cd and Se, which combine *in situ* to give CdSe. Subsequent heating in an inert atmosphere improves the performance of the electrode considerably. C is the counterelectrode which is prepared by applying an aqueous paint of high surface area carbon, cobalt(II) acetate and Teflon suspension onto a stainless steel gauze and subsequent sintering in an inert atmosphere at ~300°C. The electrocatalytically active species is presumably the cobalt sulfide which is formed when this electrode is immersed in the electrolyte. This electrode is only slightly polarized with the currents to be expected in a solar cell exposed to nonconcentrated sunlight (4). The cell is filled with an aqueous solution, which is typically 1M in OH^-, S^{--}, and sulfur. On illumination with light, sulfide is oxidized to sulfur at P and electrons flow over the load L to C, where sulfur is again reduced to sulfide. Typical open-circuit voltages are greater than 0.5V and typical short-circuit currents more than 10 mA/cm^2 (AM1 sunlight).[1]

Key words: photoelectrochemistry, energy conversion, energy storage.

[1] In more recent experiments stable cells have shown open-circuit voltages up to 0.67V, short-circuit currents up to 12 mA/cm^2, and fill factors up to 40%, in laboratory tests.

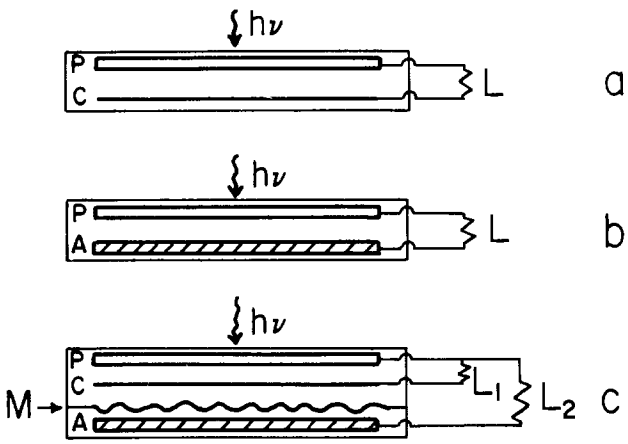

Fig. 1. (a) A photoelectrochemical cell without the possibility of *in situ* storage. (b) A photoelectrochemical storage cell with two electrodes. (c) A photoelectrochemical storage cell with three electrodes.

In order to convert such a PEC into a storage cell, C is replaced by a storage electrode A as pictured in Fig. 1b. A must be capable of undergoing a reversible chemical change, which schematically can be indicated as

$$AX + ne^- \rightleftharpoons A + X^{n-} \qquad [1]$$

where X is a solute present in the electrolyte. If the redox potential of reaction [1] is intermediate between the potential of P during illumination and that of the redox potential of the S/S^{--} couple, equilibrium [1] moves to the right under illumination, consuming electrons. In the dark it produces electrons by reaction in the opposite direction. A typical example is Ag_2S, which reacts according to

$$Ag_2S + 2e^- \rightleftharpoons 2Ag + S^{--} \qquad [2]$$

A cell using the arrangement of Fig. 1b has some serious disadvantages, however, which make it unsuitable for practical use. On current inversion, which occurs in the dark, P now serves as the counterelectrode, and sulfur is reduced to sulfide at its surface. As we have pointed out before (5), this reaction should be minimized at P in order to obtain maximum efficiency during illumination. Therefore an efficiently working photoelectrode makes a poor counterelectrode and in the arrangement of Fig. 1b it will severely limit the back current in the dark. The second disadvantage is that since A should have a reasonably high surface area if it is to be used efficiently, then it will also act as a good counterelectrode. Thus it will not only give reaction [2] under illumination, but will also reduce sulfur from the solution to sulfide resulting in a loss of storage capacity. These disadvantages can be overcome by using the arrangement pictured in Fig. 1c.

A cation-specific membrane M separates the compartment containing A from that containing P and C. In the present case cation-exchange membranes containing sulfonic acid groups bound to various polyaromatic matrixes were used.[2] The membrane was held in place between the two cell compartments by two rings of Parafilm on either side, which were pressed into an annular groove in one compartment of the glass vessel by a Viton O-ring from the other side. Sulfide as well as sulfur may be absent from the storage compartment and other redox couples which do not pass the membrane may be added. According to our experience neither sulfur nor sulfide passes through the membrane. The loads L_1 and L_2 can be chosen in such a way that during illumination part of the current produced flows over L_1 to C and can be used, while part flows over L_2 to A where it is stored. In the dark, current flows over L_2 and L_1 from A to C and the direction of the current over L_1 does not change. The fact that P is a bad counterelectrode is now turned to advantage and, according to our experience, less than 10% of the dark current flows to P if C is properly constructed. By the use of a relay or photosensitive switch, the arrangement of Fig. 1c can be refined even further.

In Fig. 2 the current-voltage characteristics are given of a CdSe cell used by us, and on the vertical axis the potentials of some redox couples are indicated, taken from Ref. (6). When no current is drawn under illumination (open circuit) the potential of P is about −1.0V *vs.* NHE, while the potential of C is that of the S/S^{--} couple (−0.48V *vs.* NHE). When current is drawn from the system the potential of P moves gradually towards that of C, an undesirable feature of the PEC which will have to be improved. Also indicated is the voltage-current behavior of a typical solid-state cell, which it is hoped will be obtained for a PEC in the future.

If a silver/silver-sulfide electrode is added to a cell of the type of Fig. 1c and when no sulfur is present in the storage compartment, almost theoretical storage efficiencies can be obtained, but the open-circuit potential of the storage cell is only −0.69 + 0.48 = −0.21V, which is rather low. Such a low voltage not only decreases the conversion efficiency of the cell, but also excessive quantities of the expensive silver are needed to store a reasonable amount of electrical energy. Mercury suffers from the same disadvantage, but can be useful for the amalgamation of other electrodes. Iron sulfide is cheap and can be used, but it gives unwanted side reactions. When sulfur as well as sulfide is omitted from the storage compartment, redox couples other than those containing sulfide can be used, but here other complications occur. When, for instance,

[2] These membranes are under investigation at this Institute and their long-term performance and comparison to the behavior of other commercial membranes in this system will be the subject of a later report. We thank Dr. Gerald Tanny for supplying the membranes and advice in their use.

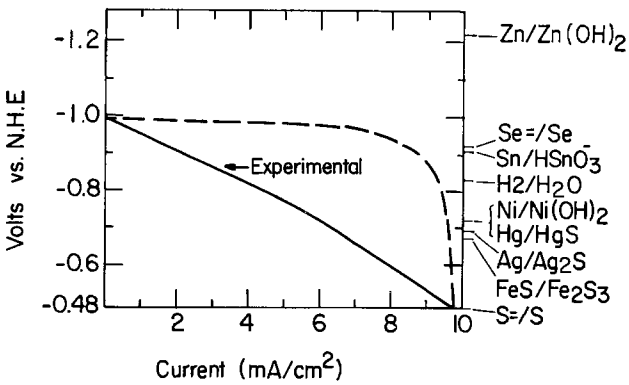

Fig. 2. The current/voltage characteristics of a working CdSe cell. On the vertical axis the redox potentials (pH 14) of some possible storage systems are indicated. The dotted line shows the I-V characteristic of a good solid-state cell.

a porous nickel electrode is used in a storage compartment, free from sulfur as well as sulfide, hydrogen evolution can be observed at its surface, when the cell is illuminated, in spite of the fact that the potential of the $Ni/Ni(OH)_2$ couple is more positive than that of hydrogen formation (at *p*H 14). This imposes another restriction, *viz.*, the material of which the storage electrode is made should have a high overpotential for hydrogen evolution.

If the current-voltage characteristics of the PEC were better, *i.e.*, less voltage drop under load, tin could be used. With the PEC in its present state, the charging current with a tin storage electrode is too low (see Fig. 2) and an arrangement with two PEC's in series is necessary. The experimental arrangement is pictured in Fig. 3. A is a strip of tin foil immersed in an alkaline solution. R is a recorder, L a variable load. K_1 and K_2 are on/off switches. The other symbols have their usual meaning. The light intensity of the lamps illuminating P_1 and P_2 was regulated such that with K_1 closed and K_2 open a current of 2 mA flowed by way of R to A. When the lamps were switched off, K_1 opened and K_2 closed automatically and L was chosen such that a current of also 2 mA flowed from A over R to C_2. 12 hr cycles of illumination and dark

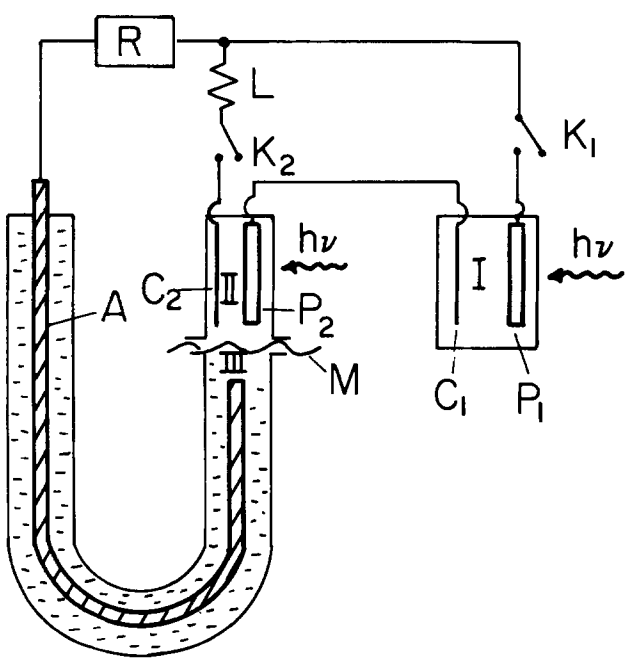

Fig. 3. The experimental setup for testing storage electrode materials as a function of time. I and II contain $S^=$, sulfur as well as alkali; III only alkali.

periods were used and the arrangement worked uninterrupted for three weeks. The quantity of tin taken was 0.4g and fifteen 12 hr periods at a current of 2 mA would have sufficed to consume the tin entirely, were no recharge to have taken place.[3] During the illumination period the tin crystallized at the side nearest to the membrane, where it assumed a porous structure. Open-circuit voltages in the dark were near to theoretical and no hydrogen evolution was observed. The same experiment was repeated with zinc instead of tin. A piece of foil weighing 0.2g was taken and this cell also worked uninterrupted for three weeks. The crystal growth was much more dendritic than in the case of tin and traces of hydrogen evolution could be observed.

Tin seems to be the suitable material for the idealized cell (indicated in Fig. 2), which also under load keeps its voltage of 0.5V. The dark voltage of $-0.91 + 0.48 = 0.43$V is only 14% lower than the voltage under illumination, which is a realistic loss for a storage operation. Zinc is attractive because of its low price, low molecular weight, and high dark voltage of $-1.24 + 0.48 = -0.76$V.

To supply an average power of 1 mW during 30 hr, a theoretical quantity of ~80 mg of tin[3] would be needed and only 50 mg of zinc. Both quantities fall well within economical and constructional possibilities. An alternative possibility which was only superficially checked is to add a redox couple to the storage compartment using an inert electrode. The Se/Se^{--} couple has the right redox potential for such a system. It appeared, however, that the dissolved selenium underwent too many side reactions. It is clear that there is scope here for the use of good water soluble coordination complexes, which have to be charged in order to ensure impermeability through an ion-selective membrane and which have a suitable redox potential.

A practical system for the conversion of solar energy to electrical energy should also include storage capacity. Therefore the economic feasibility of using photovoltaic cells must be considered together with that of using storage batteries. In a PEC the addition of one electrode and a membrane may be compared with that of a complete storage battery to a solid-state cell. From the preliminary results presented here, it is clear that the future prospects for a practical PEC are enhanced considerably by its capability of storing the converted energy without the need for a separate external storage device.

[3] Here, a four-electron change is assumed for tin, corresponding to the $Sn/HSnO_3^-$ couple.

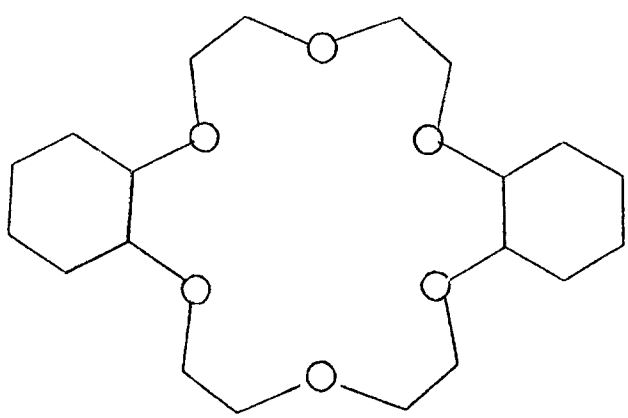
Determination of Ion Complexation Constants in Electrochemical Double Cells Without Liquid Junction

Arnold Z. Gordon*,[1] and Peter A. Rock**



Department of Chemistry, University of California, Davis, California 95616

We have developed a novel electrochemical method for the study of ion complexation reactions. The method employs electrochemical double cells without liquid junction for which the ion complexation reaction of interest is the net cell reaction. The method involves setting up two electrochemical cells in series opposition that are the same except that one cell contains the complexing agent in the cell electrolyte.

This communication outlines the general method and reports the use of the electrochemical double cell

$$Pb(Hg,2\text{-phase})\,|PbCO_3(s);\ BaCO_3(s)\,|BaXCl_2(aq,m),X(satd)\,|Hg_2Cl_2(s)\text{-}Hg(l)\,|Hg_2Cl_2(s)\,|BaCl_2(aq,m)\,|BaCO_3(s);\ PbCO_3(s)\,|Pb(Hg,2\text{-phase}) \quad [1]$$

where X is the crown ether dicyclohexyl-18-crown-6 (1)

to determine the equilibrium constant for the complexation of $Ba^{2+}(aq)$ by dicyclohexyl-18-crown-6.

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.
[1] Present address: Department of Chemistry, University of California, Santa Cruz, California 95060.

Key words: cell, complexation, crown, barium, electrode.

Experimental

Because of the sensitivity of the two-phase lead amalgam [~5 weight percent (w/o) Pb] to oxygen, the entire cell was set up on a high vacuum line; all cell components were introduced to the cell under oxygen-free conditions (2). The $Pb(Hg)\,|PbCO_3(s);$

$BaCO_3(s)|Ba^{2+}(aq)$ and $Hg(l)|Hg_2Cl_2(s)|Cl^-(aq)$ electrodes were prepared as recommended in the literature (3, 4). The $PbCO_3$ was freshly precipitated from dilute aqueous solution and authenticated by x-ray powder pattern and electron microprobe analysis. The reagent grade $BaCO_3(s)$ was covered with distilled water and held at *ca.* 80°C for about a week. The dicyclohexyl-18-crown-16 (technical grade) was obtained from the Aldrich Chemical Company. All other chemicals used were reagent grade. The cell electrolytes were deoxygenated with argon prior to introduction to the cells. Emf measurements were made with a Keithley 630 potentiometric electrometer which was calibrated against a certified Leeds and Northrup K-3 potentiometer. The cells attained a stable voltage (± 0.5 mV) within a few hours and maintained a stable voltage for over 48 hr. Voltage vs. current reversibility checks showed no evidence of a hysteresis loop.

Results

The electrode reactions for cell [1] are

$$Pb(Hg) + BaCO_3(s) + X(s) = PbCO_3(s) + BaX^{2+}(aq) + 2e^-$$

$$Hg_2Cl_2(s) + 2e^- = 2Hg(l) + 2Cl^-(aq)$$

$$2Hg(l) + 2Cl^-(aq) = Hg_2Cl_2(s) + 2e^-$$

$$PbCO_3(s) + Ba^{2+}(aq) + 2e^- = BaCO_3(s) + Pb(Hg)$$

and the net cell reaction is

$$BaCl_2(aq) + X(s) = BaXCl_2(aq) \qquad [2]$$

Application of the Nernst equation to reaction [2] yields

$$\mathcal{E} = \mathcal{E}^\circ - \frac{RT}{2\mathbf{F}} \ln \left\{ \frac{a_{BaX^{2+}} a^2_{Cl^-}}{a_{Ba^{2+}} a^2_{Cl^-}} \right\} \qquad [3]$$

$$\mathcal{E} = \mathcal{E}^\circ - \frac{RT}{2\mathbf{F}} \ln \left\{ \frac{[BaX^{2+}][Cl^-]^2}{[Ba^{2+}][Cl^-]^2} \cdot \left(\frac{\gamma_{BaX^{2+}} \gamma_{Cl^-}{}^2}{\gamma_{Ba^{2+}} \gamma_{Cl^-}{}^2} \right) \right\} \qquad [4]$$

The cells are set up with $[BaCl_2]_{total} = [BaXCl_2]_{total}$ and, thus, if the complexation equilibrium is such that in the presence of excess X, $[BaX^{2+}] >> [Ba^{2+}]$ (strong complexation), then Eq. [4] reduces to $\mathcal{E} \simeq \mathcal{E}^\circ$ (assuming that the activity coefficients are the same for dilute solutions of $BaCl_2(aq)$ and $BaXCl_2(aq)$ of equal concentrations), and $K_{comp} \simeq \exp(2\mathbf{F}\mathcal{E}^\circ/RT)$. If the above assumptions are valid, then the observed voltage of cell [1] should be independent of the concentration of $BaCl_2$. For cell solutions with barium chloride concentrations (the two cell electrolytes are taken from the same stock solution, and one is then saturated with the crown ether) of 0.476, 3.00, and 4.69 mM, the observed cell voltages (22° ± 1°C) were 62.0 ± 0.6, 58.2 ± 1.0, and 61.2 ± 0.5 mV, respectively. The average of these $\mathcal{E}^\circ$ values (60.5 ± 1.3 mV) yields a value of $K = (1.16 \pm 0.18) \times 10^2$ (22°C) for the reaction

$$Ba^{2+}{}_{(aq)} + X(s) \rightleftharpoons BaX^{2+}(aq) \qquad [5]$$

where X is dicyclohexyl-18-crown-6. The value of K for reaction [5] can be combined with the solubility of the crown ether in water of about 0.038M (22°C) (1) to yield a value of $K = 3.1 \pm 0.5 \times 10^3$ for the reaction

$$Ba^{2+}(aq) + X(aq) = BaX^{2+}(aq) \qquad [6]$$

Izatt *et al.* (5) report values of K for reaction [6] of 2.0×10^3 and 4.0×10^3 for the two conformational isomers of dicyclohexyl-18-crown-6. Since our sample of the crown ether is a mixture of the two isomers, the agreement between our calculated value of K for reaction [6] and the measured values of Izatt *et al.* is within the experimental uncertainty.

The method outlined above for the determination of complexation constants has definite advantages over conventional techniques. The double cell method gives $\mathcal{E}^\circ$ directly from a single measurement, rather than as a small difference between two large numbers, and the minimization of activity coefficient effects is accomplished automatically by the manner in which the cell solutions are prepared.

Ionic Conduction in Ternary Chalcogenides

B. Tell and Sigurd Wagner

Bell Laboratories, Holmdel, New Jersey 07733

and H. M. Kasper*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Ionic conduction has been discovered in the chalcopyrite-type semiconductors $CuGaS_2$, $AgGaS_2$, and $AgGaSe_2$, in $LiInS_2$, and in the cation-deficient chalcogenides $CuGa_5S_8$, $CuGa_5Se_8$, and $AgGa_5S_8$.

In a recent study (1) the n into p interdiffusion coefficient in the chalcopyrite-type semiconductor $CuInSe_2$ was determined as $D(cm^2\ sec^{-1}) = 164 \exp [-1.19\ (eV)/kT]$. The magnitude of the preexponential term was taken as an indication for concentrations or mobilities of point defects substantially above those of the related II-VI compounds. If these point defects carry electrical charge, their migration will lead to ionic conduction. It is therefore tempting to investigate the ionic conductivity of I-III-VI_2 compounds especially since ZnS and CdS under certain conditions have been found to be ionic conductors (2).

In electronically highly conducting chalcopyrites such as $CuInSe_2$, ionic conduction will make an insignificant contribution to the total conductivity, *i.e.*, the ionic transference number $t_i = \sigma_i/(\sigma_e + \sigma_i)$ will be small (σ_i and σ_e denote the ionic and the electronic conductivity, respectively). However, it is known that several I-III-VI_2 chalcopyrites can only be prepared with high electronic resistance, and that others can be made electronically resistive by appropriate anneals (3). These compounds may, like $CuInSe_2$, contain point defects in large concentration or with high mobility, and may therefore be predominantly ionic conductors. With experiments described below we have, in fact, detected ionic conduction in single crystals of $CuGaS_2$, $AgGaS_2$, and $AgGaSe_2$.

Because of the current interest in electrolytes containing IA metals for high emf, we have also investigated cells with a $LiInS_2$ electrolyte. This compound is a ternary tetrahedrally coordinated chalcogenide with the rhombohedral $BeSiN_2$ structure, a superstructure of wurtzite.

Taking our considerations a step further, we have sought, and found, evidence for ionic conduction in single crystals of several ternary chalcogenides of the composition I-III_5-VI_8, *i.e.*, in $CuGa_5S_8$, $CuGa_5Se_8$, and $AgGa_5S_8$. In the notation of Parthé (4) these compounds are written as $1_3{}_5 0_2 6_8$. Each formula unit includes two metal vacancies, 0. In general, the metal atoms seem to be randomly distributed leading to a zinc blende type structure. With a quarter of the metal sites vacant, a high mobility can be expected for defects. This class of ternary chalcogenides is closely related to the well-known ionic conductors α-Cu_2HgI_4 and α-Ag_2HgI_4 (5), $1_2 2 0 7_4$-compounds in the Parthé notation. These iodides also contain a quarter of vacant metal sites; the metals are also randomly distributed over the metal sublattice leading to a zinc blende structure; $1_3{}_5 0_2 6_8$ and $1_2 2 0 7_4$ compounds equally have a valence electron concentration of 4.57.

We have measured the open-circuit emf and the two-point a-c resistance of galvanic cells incorporating the ternary compounds as electrolytes, the corresponding Group I metal as one electrode, and a mixture of the appropriate Group VI element with carbon powder as the other electrode. These cells may be represented as (−Pt) I|I-III_a-VI_b|VI,C (Pt+) with Pt lead wires on both sides. The polarities shown are those developed during discharge of the cell. The observed open-circuit emf, E, is related to the thermodynamic value E_o for the formation of the appropriate I_2-VI compound, *viz.*, Cu_2S (6), Cu_2Se (7), Ag_2S (6), Ag_2Se (6), and Li_2S (8) by the relationship $E = E_o t_i$ where t_i is the ionic transference number as previously defined (9).

Not-intentionally-oriented platelets were cut 0.5-1.0 mm thick from melt-grown crystals, polished, and cleaned with organic solvents in an ultrasonic bath. On one face (5-10 mm^2) metal electrodes were applied by evaporation followed by electroplating. After cementing the other face onto the flat-ground ends of high melting glass tubes (3 mm^2 open area), the latter were filled with the chalcogen-carbon mixture. With Pt wires connected to both electrodes, these were sealed for protection from the atmosphere. A schematic cross section of a cell is shown in Fig. 1. The cells, provided with iron-constantan thermocouples, were kept in a resistance-heated oven for experiments between room temperature and ~250°C.

The Li/$Li_{1.1}InS_2$/S,C cells were prepared by cementing glass tubes to both faces of $LiInS_2$ platelets, filling one with Li metal and the other with the sulfur-carbon mixture. Both tubes were closed with carbon piston contacts and then sealed.

Table I shows the principal experimental results. EMF's were measured with a Keithley Model 610B electrometer, and the 1 kHz a-c resistances R with a General Radio Model 1650A impedance bridge. We have listed the highest measured emf, E, of the one to three cells prepared with each electrolyte, in the range

* Electrochemical Society Life Member.

Key words: ionic conductor, ternary chalcogenide, battery.

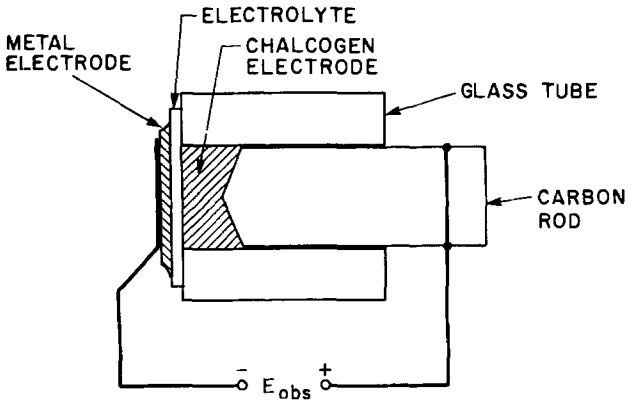

Fig. 1. Schematic cross section of a cell with a copper or silver electrode. Not shown is the sealant which covers the electrode, the electrolyte, and part of the carbon rod at the end of the glass tube.

of temperature investigated. E is compared to the thermodynamic value, E_o, that corresponds to the formation of I_2-VI compounds. The ionic transference number t_i is also tabulated.

The highest emf's of cells incorporating $AgGaS_2$ or $AgGa_5S_8$ lay above E_o. It is difficult to locate the source of this excess emf, E-E_o. $E_o(Ag_2S)$ used in Table I is the maximum value, *i.e.*, that for Ag_2S in equilibrium with saturated sulfur vapor (9). Any other composition of Ag_2S would lead to an even lower value for $E_o(Ag_2S)$ and thus would raise E-E_o. A shunt path within the cell would reduce E below the open-circuit value. The temperature along the cell being uniform within 2°C, thermal gradients cannot significantly contribute to E. It is possible that the excess emf results from the dissolution of silver and sulfur in the ternary electrolytes.

The 1 kHz cell resistances, R, reflect the combined ionic and electronic resistances of the ternary electrolytes. Because of the two-point measurement technique, R also contains contact and electrode resistances.

In several compounds the ionic and electronic conductivities are of comparable magnitude which reduces t_i to values below unity. Evidence presented in Fig. 2 suggests that σ_i/σ_e can be raised to achieve $t_i = 1$. Figure 2 displays the emf as a function of reciprocal temperature for three lithium-doped $AgGaS_2$ samples, one cut from boule No. 606, and two from boule No. 782. In sample No. 606 σ_i is evidently much greater than σ_e at all temperatures. In samples No. 782A and B $\sigma_e < \sigma_i$ near room temperature but $\sigma_e > \sigma_i$ at 250°C. The solid line for samples 782A and B is a least squares fit to the experimental data of the form $E = E_o[1 + (\sigma_e^o/\sigma_i^o) \exp(-\Delta\epsilon_A/kT)]^{-1}$, with $\sigma_e^o/\sigma_i^o = 2.8 \times 10^3$ and $\Delta\epsilon_A = 0.29$ eV.

By adding iodine to the anode compartment of the $AgGaS_2$ and $AgGaSe_2$ cells we have reached emf's of 0.5-0.6V at temperatures above 100°C compared to 0.7V, the theoretical voltage for the formation of AgI. We

believe that a leaky AgI layer, which passes mainly Ag^+ ions, forms on the $AgGaS_2$ or $AgGaSe_2$ and that the result of this experiment demonstrates that Ag^+ is the principal mobile ion in $AgGaS_2$ and $AgGaSe_2$.

Acknowledgments

We would like to thank Dr. K. D. Becker, Ruhr University, Bochum, for helpful discussions, and D. H. Olson and L. M. Schiavone for the application of metal electrodes.

Manuscript submitted Sept. 23, 1976; revised manuscript received Dec. 3, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by Bell Laboratories.

Single Carrier Steady-State Theory for Formation of Anodic Films Under Conditions of High Space Charge in Very Large Electric Fields

A. T. Fromhold, Jr.*

Department of Physics, Auburn University, Auburn, Alabama 36830

ABSTRACT

The kinetics of growth of anodic films are modeled in the high space charge limit; the predictions of the model are examined analytically and numerically. The results illustrate that space charge due to the mobile ionic species can lead to a marked retardation of the rate of growth as measured under constant voltage conditions. Time increases by factors as large as 3000 are found to be required for growth to a given thickness. For a given film thickness the time factors are somewhat greater at larger voltages; at a given voltage the time factors increase nearly linearly with increasing thickness. These observations lead to the following major conclusion: Space charge effects do not disappear and do not saturate with increasing electric field value; on the contrary, the space charge retardation is even more pronounced in the realm of very high electric fields, large applied voltages, and very thick anodic films. For the case of growth under constant current conditions in the presence of space charge, a given growth rate was found to require a significantly larger voltage than would be predicted in the usually considered homogeneous field limit; however, the increase in voltage is relatively less in the higher voltage regime (*e.g.*, a factor of 2) than it is for growth at very low voltages (where factors as large as 10 to 100 are not uncommon). The voltage at constant current was found to increase quasi-linearly with thickness in the thick film high voltage realm, whereas at low voltages the space charge produced marked curvature in the voltage-thickness plots. The quasi-linear variation of voltage with thickness found for the thick film high voltage realm constitutes proof *sine qua non* that present experimental data in the literature indicating experimental constancy of the field at constant current cannot be employed to disqualify anodic film growth models having uncompensated space charge.

The experimental situation.—There have been a number of experimental studies carried out which have a direct bearing upon various aspects of transport during growth (1) of anodic films. Pringle (2, 3) has done a series of beautiful inert marker experiments in order to deduce the transport numbers of the mobile metal species and the mobile oxygen species during the anodic oxidation of tantalum. In one series of experiments (2), for example, radioactive noble gases were implanted by means of a mass separator into thin films of anodic tantalum oxide. The transport numbers for the tantalum and the oxygen were found to be 0.243 and 0.757, respectively, thus leading to the conclusion that it is the oxygen species which is the more mobile under the conditions for that experiment. The noble gas concentration profiles were found to broaden on further anodization, and this was interpreted as being due to the simultaneous movement of tantalum and oxygen atoms during the charge transfer event. In a later series of experiments (3), Pringle measured ^{18}O concentration profiles in thin anodic tantalum oxide films by combining a sectioning technique for locating the isotope with a nuclear technique based on proton bombardment of the ^{18}O and counting of the emitted neutrons in the $^{18}O(p,n)^{18}F$ reaction in order to detect the ^{18}O. The results could be interpreted very well ". . . in terms of a forced diffusion (under the influence of the electric field during anodization) from a constant source (the electrolyte) into a semi-infinite medium (the oxide) . . . ."

Agius and Siejka (4) investigated the passivity of iron by nuclear microanalysis using the $^{16}O(d,p)^{17}O$ reaction, and found that the relationship between the number of oxygen atoms and the potential is approximately linear in the passive region. The results agreed satisfactorily with corresponding data taken by Foley, Kruger, and Bechtoldt (5) by ellipsometry and the data of Frankenthal (6) based on coulometric measurements. It is definitely not clear whether or not sufficient data have been taken over an extended thickness range (several decades) for any given anodic system to be able to say with any degree of certainty whether or not a small curvature (as predicted by the present analysis) exists or not. It is hoped such studies will be undertaken by competent experimentalists in the not-too-distant future.

Rigo and Siejka (7) have carried out interesting Rutherford backscattering studies using 1.8 MeV He ions in order to characterize the long range migration of niobium during the anodic oxidation of tantalum and aluminum on niobium, and Cherki and Siejka (8) have utilized the method of nuclear microanalysis of stable oxygen isotopes by the reactions $^{16}O(d,p)^{17*}O$ and $^{18}O(p,\alpha)^{15}N$ to investigate the mechanisms of growth, dissolution, and transport associated with oxygen during the formation of porous anodic layers $\lesssim$ 7000Å in thickness on aluminum. It was concluded by means of ^{18}O tracer techniques that the growing oxide layer is formed at the metal-oxide interface by oxygen transport through the base layer. The isotope analysis of oxygen at various depths in anodic layers was developed by Amsel and Samuel (9) to investigate migration mechanisms of ionic charge carriers during the growth of compact anodic aluminum oxide films. The method consists of an analysis of the excitation curve as a function of bombarding energy in the vicinity of a narrow resonance of the $^{18}O(p,\alpha)^{15}N$ reaction measured for the sample under investigation.

Earlier studies on anodic films have been summarized in the review by Vermilyea (10) and in Young's classic book (11). A thoughtful review of many of the major

* Electrochemical Society Active Member.

theoretical ideas which developed over the years, together with some extension into the realm of two-carrier transport, has been given by Young (12).

Present work.—Without a doubt, the simultaneous migration of two charged ionic species as observed by Pringle is a much more complex situation than the simple case of one charged ionic species. The *raison d'être* of the present approach, based as it is on the theoretical and numerical analysis of a single uncompensated ionic charge carrier, is to carry out, first, the simplest calculation in order to develop some intuitive understanding of space charge effects, and at some later time to try to do the more complex numerical problem involving two species. Moreover, there may well exist experimental systems where a single mobile ionic species predominates, and in such cases the present analysis will be immediately applicable. This is an exciting area of present-day research, with many types of experiment being developed all the time for deducing new information on the microscopic processes operative during anodic growth. It is anticipated that new theoretical approaches will need to be developed as our understanding of the experimental situation continues to broaden.

The effects of single carrier space charge and defect concentration gradients on anodic film formation have already been examined in an earlier study (1) for the limit of thin anodic films and low voltages. Discrete hopping equations were utilized to take into account the atomic nature of the diffusion medium and to include high field current nonlinearities. One of the most important conclusions of the earlier work (1) is that, for a fixed voltage, the uncompensated space charge of the mobile ionic species can be a critical factor in retarding the growth rate of the anodic film. The question of whether or not this effect persists in the higher electric field, higher space charge, and thicker film domains is an interesting and a critical one, and it is to answer this question that the presently reported work was undertaken.

First of all, new calculations utilizing the earlier numerical approach are illustrated briefly in the present paper. This serves to review the major effects predicted at lower voltages and thinner anodic films, and extends the results to situations involving higher valence and larger space charge. Next, the analytical development constituting the major thrust of the present paper is presented. This development is appropriate for very high electric fields and very thick anodic films. This development is followed by specific numerical evaluations of the analytically derived equations. These include the single carrier diffusing defect and electric field profiles, the kinetics for constant voltage growth, and the thickness dependence of the voltage for constant current growth. Conclusions are then summarized.

Numerical Evaluation of Space Charge Effects at Low Voltages in the Thin Film Limit

Previous work.—The published computations of Fromhold and Kruger (1) for thin anodic film growth utilized an iterative scheme developed for the domain of electric field strength for which the electric-field-produced current contributions were generally of the same order as the concentration-gradient-produced current contributions. The relevant microscopic equations for this space charge gradient model (1) include the potential well to potential well hopping current and Poisson's equation in discrete form, and the computations were carried out in the steady-state limit. To supplement these published calculations, to test their generality, and to explore the effects of increasing the charged defect concentration by an order of magnitude and the valence by a factor of 2, a set of calculations has been carried out utilizing the new parameter values as listed in Table I.

Table I. Values utilized for parameters in numerical computations for transport through a passive* anodic oxide film layer. (These values are appropriate for Fig. 1 through 12.)

Symbol	Terminology	Value	Units
n_0	Areal defect density of mobile species at position $x = 0$	10^{12}	no./cm^2
n_N	Areal defect density of mobile species at position $x = L$	10^{10}	no./cm^2
W	Activation energy for diffusion of mobile ionic defect species	0.5	eV
T	Temperature	300	°K
ν	Attempt frequency of mobile ionic defect species	10^{13}	sec^{-1}
$2a$	Lattice parameter of anodic oxide	3.2	Å
Z	Valence of diffusing species determining its charge	−2	—
ϵ	Relative dielectric constant of anodic oxide (in units of ϵ_0, the permittivity of free space)	6	—
R	Volume of oxide per ionic defect transported through the anodic film	25	Å^3

* The author is indebted to Dr. J. Kruger of the National Bureau of Standards for his aid in choosing a set of parameters which should be fairly typical for the anodization of iron.

Particle currents.—Although the complete results are presented elsewhere (13), the essential retarding effects of the space charge on the ionic current can be noted directly from Fig. 1. The solid curves constitute logarithmic plots of current *vs.* thickness for several voltages with space charge effects included. The dashed curves show the corresponding results when space charge is neglected. It can be seen that at a given thickness, such as 100 monolayers, the current at a given voltage is decreased by orders of magnitude by the space charge.

The curvature in the very thin film region exhibited by both the solid and dashed curves is a manifestation of the nonlinear diffusion effects (14) attributable to very large electric field values. The breakaway between the pairs of solid and dashed curves at a given voltage occurs because of the space charge, and it can

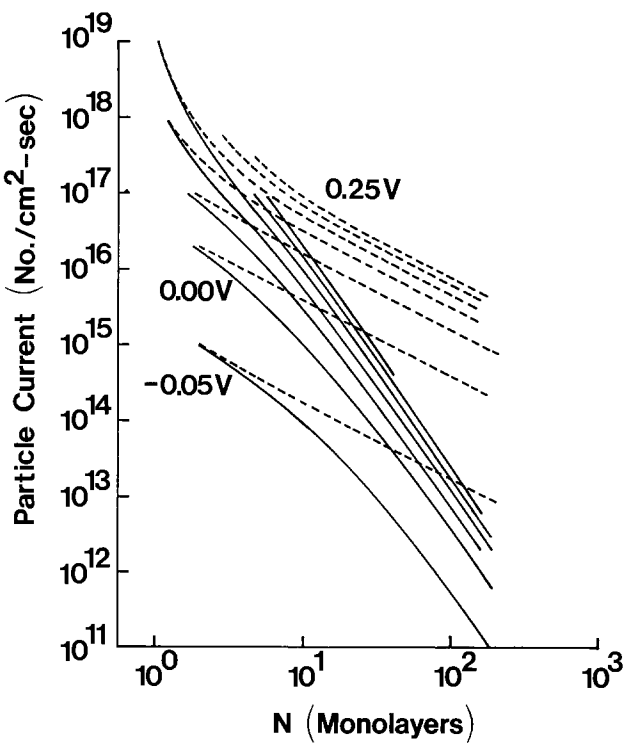

Fig. 1. Logarithm of the defect particle current *vs.* logarithm of the anodic oxide thickness for growth with space charge (solid curves) under constant electrostatic potentials ranging from −0.05 to 0.25V in increments of 0.05V. (Microscopic parameter values are listed in Table I.) Dashed curves illustrate the corresponding homogeneous field calculations.

Table II. Particle current densities J_0 associated with a given curve number in Fig. 2, 3, and 4 for the low voltage anodization regime

Curve No.	Particle current density J (No./cm²-sec)
1	1×10^{11}
2	5×10^{11}
3	1×10^{12}
4	5×10^{12}
5	1×10^{13}
6	5×10^{13}
7	1×10^{14}
8	5×10^{14}
9	1×10^{15}
10	5×10^{15}
11	1×10^{16}
12	5×10^{16}
13	1×10^{17}
14	5×10^{17}
15	1×10^{18}

be noted that the separation between the two curves in each pair increases markedly with increasing thickness. The greater slopes of the solid curves relative to the dashed curves reflect the greater limiting-thickness behavior of growth kinetics for the space-charge-modified situation relative to the homogeneous-field case. The slopes of the thicker film portions of the dashed curves in Fig. 1 are approximately 1, whereas the slopes of the solid curves in this figure range as high as 2.8. Such slopes lead to semiempirical growth laws $L(t) \propto t^{1/n}$, with $n \simeq 4$ for the later stages of space-charge-modified growth. It is interesting to compare these slopes with those in the very thin film growth stages where nonlinear electric field effects are very pronounced and the resulting growth kinetics are sharply rate limiting, as follows from considerations quite analogous to those of Cabrera and Mott (15) for thermal oxidation. In this thickness region the slope in Fig. 1 has values as large as 5, corresponding to $n \simeq 6$ in the corresponding semiempirical growth law $L(t) \propto t^{1/n}$. As a final word on the kinetics in this low voltage regime, it should be pointed out that the -0.05V curve in Fig. 1 represents anodization produced by the ionic concentration gradient under reverse bias conditions for the voltage.

Defect profiles.—A series of constant current anodization curves was computed for the new set of microscopic parameter values listed in Table I, with the several currents utilized listed in Table II. The computed diffusing areal defect density profiles for this set of computations including space charge effects are illustrated in Fig. 2; the corresponding defect profiles as computed in the homogeneous-field limit are illustrated in Fig. 3. The key relating curve number to current density is given in Table II. A comparison of Fig. 2 and 3 shows that the qualitative and quantitative differences between the space-charge-modified profiles and the homogeneous field profiles are quite pronounced

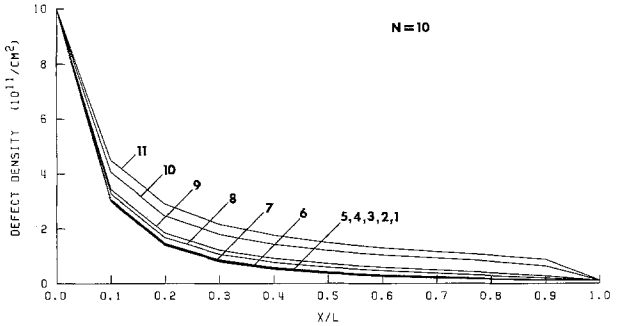

Fig. 2. Defect density for a 10-monolayer anodic oxide film computed with space charge effects *vs.* normalized position x/L for several values of the current. (Microscopic parameter values are listed in Table I and particle current densities for the several curves are listed in Table II.)

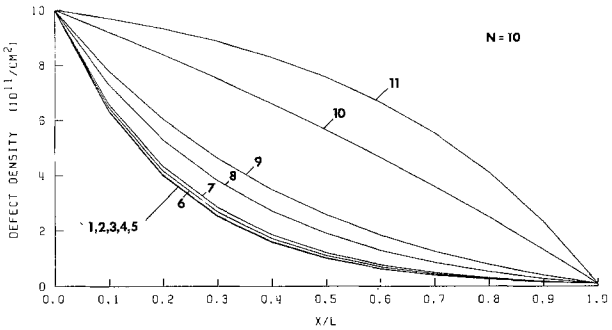

Fig. 3. Defect density for a 10-monolayer anodic oxide film computed in the homogeneous field limit *vs.* normalized position x/L for several values of the current. (Microscopic parameter values are listed in Table I and particle current densities for the several curves are listed in Table II.)

even for thicknesses as small as 10 monolayers. This reflects the very large space charge values chosen for the present set of computations. [An areal density $n_0 = 10^{12}/\text{cm}^2$ with $2a = 3.2$Å as listed in Table I corresponds to the value $C(0) = 3.125 \times 10^{19}$ cm^{-3} for the bulk density of charged defects near the interface.] Note that the ionic defect densities are significantly less for the case of space charge (Fig. 2) than in the corresponding homogeneous-field limit (Fig. 3). One can argue qualitatively that the reason the defect density is relatively lower for the ionic space-charge-modified profile (as compared to the homogeneous field profile) is the following: The space charge of the single diffusing species gives rise to large forward values for the electric field, so the defect density must drop accordingly to maintain the fixed value chosen for the presently considered forward hopping current. This reasoning neglects several factors, including concentration gradient effects and the reverse hopping current. The qualitative argument is actually independent of the particular transport equation employed for the field-modified diffusion, just as long as the transport current increases locally with an increase in the local value of the diffusing defect density and with an increase in the local value of the electric field.

Voltage under constant current growth.—The voltage *vs.* thickness curves computed for the series of currents listed in Table II are shown in Fig. 4. The upper set constitutes the space-charge-modified sequence, whereas the lower set is the homogeneous field sequence computed for comparison purposes. The concave curvature so evident in the upper sequence in the thicker film growth region is quite characteristic of the presence of space charge; on the other hand, the homogeneous field curves in the lower sequence are very closely linear for thicknesses beyond those where the concentration gradient gives rise to some initial convex curvature. It can also be noted from Fig. 4 that a given current at a given thickness requires a much larger voltage with space charge than is the case in the absence of space charge.

The consideration of space charge effects for the opposite extreme limiting case of high voltage anodization in the thick film region is now examined. The approach utilized is basically analytical, but with numerical evaluations of the resulting equations carried out to obtain qualitative insight into the predictions of the model.

Analytical Formulation for Evaluation of Space Charge Effects at High Voltages in the Thick Film Limit

Particle current.—As a starting point, it is convenient to utilize a very high field equation closely analogous to the one employed by Dewald (16)

$$J_0 = (D/2a)C(x) \exp [ZeE(x)a/kT] \qquad [1]$$

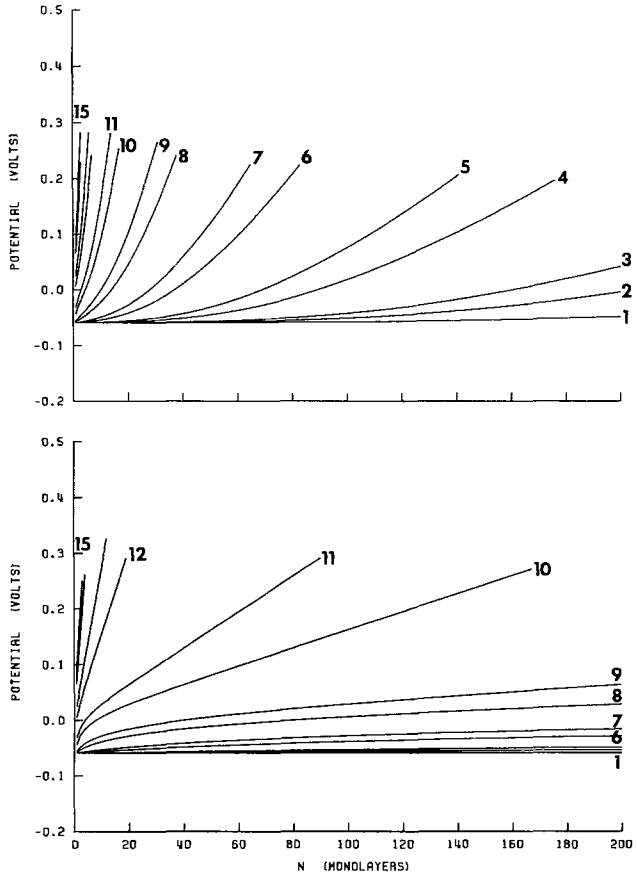

Fig. 4. Comparison of homogeneous field results (lower portion) with computations including space charge (upper portion) for electrostatic potential vs. thickness in monolayers for a growing anodic film. (Microscopic parameter values are listed in Table I and particle current densities for the several curves are listed in Table II.)

where J_0 is the steady-state particle current through the existing anodic oxide film, $C(x)$ is the bulk defect concentration of the uncompensated charged diffusing ionic species at position x in the oxide, $E(x)$ is the macroscopic electric field at position x, D is the diffusion coefficient, $2a$ is the hopping distance between potential minima within the oxide for the diffusing species, Ze is the charge per particle of the diffusing ionic species, and kT is the thermal energy at temperature T involving the Boltzmann constant k. The origin of Eq. [1] can be easily traced to the microscopic hopping model (13-17) and the assumption that the electric field is so large that the forward hopping current so greatly exceeds the reverse hopping current that the latter can be entirely neglected (13). The essential point involves the ratio of the electrostatic energy difference $ZeE(x)a$ between a potential energy minimum and the adjacent potential energy barrier maximum to the thermal energy kT. A sufficient condition for the validity of Eq. [1] is that $|ZeE(x)a/kT| >> 1$, but as a practical matter Eq. [1] can generally be utilized whenever the ratio exceeds 2 or 3. The complete development of Eq. [1] from the consideration of the hopping of defects over field-modified potential energy barriers in the anodic oxide, together with the specific conditions of applicability, can be found in a review article (13) on anodic oxidation.

Electric field.—The electric field $E(x)$ must be obtained from Poisson's equation of electrostatics

$$E(x) = E_0 + (4\pi/\epsilon) \int_0^x ZeC(x)dx \qquad [2]$$

where E_0 is the surface charge field at the interface at $x = 0$, and the term involving the integral of the charge density $ZeC(x)$ of the uncompensated mobile ionic defect species in transit represents the total space charge contribution to the electric field. The parameter ϵ is the static dielectric constant of the anodic oxide. Differentiation of Eq. [2] gives

$$\frac{dE(x)}{dx} = \frac{4\pi Ze}{\epsilon} C(x) \qquad [3]$$

Solving for $C(x)$ from this equation and substituting into Eq. [1] gives

$$J_0 = (D/2a)(\epsilon/4\pi Ze) \exp[ZeE(x)a/kT] \frac{dE(x)}{dx} \qquad [4]$$

This constitutes a differential equation for the electric field, with all of the remaining quantities being position-independent parameters and physical constants. To solve Eq. [4], it is convenient to change variables by defining

$$\beta(x) \equiv \exp[ZeE(x)a/kT] \qquad [5]$$

It follows directly that

$$\frac{d\beta(x)}{dx} = \frac{Zea\beta(x)}{kT} \frac{dE(x)}{dx} \qquad [6]$$

Equations [5] and [6] are sufficient to convert Eq. [4] to the form

$$J_0 = (D/2a)(\epsilon/4\pi Ze)(kT/Zea) \frac{d\beta(x)}{dx} \qquad [7]$$

Equation [7] can be integrated immediately to give

$$J_0 x = (D/2a)(\epsilon/4\pi Ze)(kT/Zea)[\beta(x) - \beta_0] \qquad [8]$$

where

$$\beta_0 = \exp[ZeE_0 a/kT] \qquad [9]$$

It is convenient to introduce a parameter λ

$$\lambda \equiv 4\pi(Ze)^2 a/\epsilon kT \qquad [10]$$

which has the dimensions of an area. Equation [8] then can be written simply as $J_0 x = (D/2a\lambda)[\beta(x) - \beta_0]$, from which we obtain

$$\beta(x) = \beta_0 + (2a\lambda J_0/D)x \qquad [11]$$

The definition for $\beta(x)$ (Eq. [5]) then leads to the electric field

$$E(x) = (kT/Zea)\ln[\beta_0 + (2a\lambda J_0/D)x] \qquad [12]$$

Defect profile.—The defect profile obtained from Eq. [3] and [12] is

$$C(x) = (\epsilon/4\pi Ze)(kT/Zea)\left(\frac{(2a\lambda J_0/D)}{\beta_0 + (2a\lambda J_0/D)x}\right) = \frac{2aJ_0/D}{\beta_0 + (2a\lambda J_0/D)x} \qquad [13]$$

where Eq. [10] has been employed.

By utilizing Eq. [1] as evaluated at $x = 0$

$$J_0 = (D/2a)C(0)\exp(ZeE_0 a/kT) = (D/2a)C(0)\beta_0 \qquad [14]$$

Eq. [13] can be written as

$$C(x) = \frac{C(0)\beta_0}{\beta_0 + \lambda C(0)\beta_0 x} = \frac{C(0)}{1 + \lambda C(0)x} = \frac{C(0)}{1 + (x/x^*)} \qquad [15]$$

where

$$x^* \equiv [\lambda C(0)]^{-1} \qquad [16]$$

The parameter x^* will be referred to as the "space charge screening parameter" because it is the distance in which the concentration $C(x)$ in Eq. [15] falls to one-half of its largest value $C(0)$. It should be strongly emphasized, however, that the space charge is not actually "screening" the surface charge field E_0 in the

usual physical sense of the word[1] because the charge density $ZeC(x)$ is of the same sign as the surface charge density which is the source of the surface charge field E_o.

Alternate electric field expressions.—Equations [14] and [16] allow us also to simplify Eq. [12] to the form

$$\begin{aligned} E(x) &= (kT/Zea)\ln[\beta_o + \beta_o\lambda C(0)x] \\ &= (kT/Zea)\ln\beta_o + (kT/Zea)\ln[1 + (x/x^*)] \\ &= E_o + E^*\ln[1 + (x/x^*)] \end{aligned} \quad [17]$$

where Eq. [9] and [16] have been used for β_o and x^*, and the parameter E^* (which can be called the thermal fluctuation field) is defined by

$$E^* \equiv kT/Zea \quad [18]$$

Electrostatic potential and voltage.—The electrostatic potential follows from the electric field expression

$$V(x) \equiv -\int_0^x E(x)dx \quad [19]$$

Substituting Eq. [17] into Eq. [19] gives

$$\begin{aligned} V(x) = &- E_o x + E^* x \\ &- E^* x^*[1 + (x/x^*)]\ln[1 + (x/x^*)] \end{aligned} \quad [20]$$

One of the most useful quantities is the total voltage $V(L)$ across the anodic film. This follows directly by evaluating Eq. [20] at $x = L$

$$V(L) = -E_o L + E^* L \ln \mathcal{Q} \quad [21]$$

where

$$\ln \mathcal{Q} \equiv 1 - (x^*/L)[1 + (L/x^*)]\ln[1 + (L/x^*)] \quad [22]$$

The parameter $\mathcal{Q}$ contains the essential space charge modification of the voltage. In the absence of space charge effects, $x^* \to \infty$, $\ln \mathcal{Q} \to 0$, and $\mathcal{Q} \to 1$, as shown in Appendix A. Since $\mathcal{Q}$ is film thickness dependent, the voltage under constant current conditions has a complex dependence on thickness which is examined numerically in the next section. To obtain the voltage $V(L)$ *vs.* thickness L under constant current conditions, the following procedure is employed. For the current J_o in question, the surface charge field is first obtained from Eq. [14]

$$E_o = E^* \ln[2aJ_o/DC(0)] \quad [23]$$

where E^* is determined from Eq. [18]. This expression for E_o is substituted into Eq. [21] to give the voltage

$$V(L) = -E^* L \ln[2aJ_o/\mathcal{Q}DC(0)] \quad [24]$$

Then $V(L)$ can be evaluated numerically for a series of film thicknesses, utilizing Eq. [22] to determine $\mathcal{Q}$ for each thickness.

Particle current under constant voltage conditions.—To obtain the current J_o *vs.* thickness L under constant voltage conditions, the following procedure is employed. For the fixed voltage $V(L)$ in question, the surface charge field is determined by Eq. [21] for any film thickness L

$$E_o = E^* \ln \mathcal{Q} - [V(L)/L] \quad [25]$$

with $\ln \mathcal{Q}$ given by Eq. [22]. The required parameters x^* and E^* are given by Eq. [16] and [18], respectively. This value of E_o is substituted into Eq. [14] to give the current

$$\begin{aligned} J_o &= (D/2a)C(0)\exp(E_o/E^*) \\ &= [\mathcal{Q}DC(0)/2a]\exp[-V(L)/(E^*L)] \end{aligned} \quad [26]$$

and J_o can then be evaluated for a series of film thicknesses. Alternatively, this expression for the current can be substituted directly into the growth rate expression

$$\frac{dL(t)}{dt} = RJ_o \quad [27]$$

to give

$$\begin{aligned} \frac{dL(t)}{dt} &= [\mathcal{Q}RDC(0)/2a]\exp[-V(L)/(E^*L)] \\ &= (\mathcal{Q}RDC(0)/2a)\exp[L^*/L] \end{aligned} \quad [28]$$

where L^* is the positive quantity

$$L^* \equiv -V(L)/E^* = -ZeaV(L)/kT \quad [29]$$

and R is the volume of new oxide formed per ion which is transported through the anodic film.

Approximate forms for the growth rate expression.—Although $\mathcal{Q}$ is a sufficiently complicated function of L so that an exact integration of the above growth rate expression will generally require numerical techniques, there are two important limiting cases which can be solved analytically. These limiting cases are the zero space charge (homogeneous field) limit and the opposite extreme of the very large space charge limit. For the homogeneous field limit, $x^* \to \infty$ and $\mathcal{Q} \to 1$, as shown in Appendix A, so that the above growth rate expression [28] reduces in this limit to

$$\frac{dL(t)}{dt} = \Theta\exp(L^*/L) \quad \text{(zero space charge)} \quad [30]$$

where

$$\Theta \equiv RDC(0)/2a = R[4a^2\nu\exp(-W/kT)]n_o/4a^2 \quad [31]$$

On the other hand, for the very large space charge limit, $x^* \to 0$ and $\mathcal{Q} \to \infty$ asymptotically as $(2.718x^*/L)$, as shown in Appendix B, so that the growth rate expression [28] reduces in this limit to

$$\frac{dL(t)}{dt} = (\gamma^*/L)\exp(L^*/L) \quad \text{(large space charge)} \quad [32]$$

where

$$\gamma^* = 2.718x^*\Theta = 2.718RDC(0)x^*/2a \quad [33]$$

Rate laws.—The limiting case growth rate expressions [30] and [32] can be integrated to obtain growth laws. The integral forms are, respectively

$$\Theta t = \int_0^L \exp(-L^*/L')dL' \quad [34]$$

and

$$\gamma^* t = \int_0^L L'\exp(-L^*/L')dL' \quad [35]$$

Changing dummy variables from L' to η according to the definition

$$\eta \equiv L/L' \quad [36]$$

$$\begin{aligned} d\eta &= -[L/(L')^2]dL' \\ &= -(1/L)\eta^2 dL' \end{aligned} \quad [37]$$

lead to the expressions

$$\begin{aligned} \Theta t &= \int_\infty^1 \exp(-\eta L^*/L)[-(L/\eta^2)]d\eta \\ &= L\int_1^\infty \eta^{-2}\exp(-\eta L^*/L)d\eta \\ &= L\mathcal{E}_2(L^*/L) \quad \text{(zero space charge)} \end{aligned} \quad [38]$$

and

$$\begin{aligned} \gamma^* t &= \int_\infty^1 (L/\eta)\exp(-\eta L^*/L)[-L/\eta^2]d\eta \\ &= L^2\int_1^\infty \eta^{-3}\exp(-\eta L^*/L)d\eta \\ &= L^2\mathcal{E}_3(L^*/L) \quad \text{(with space charge)} \end{aligned} \quad [39]$$

[1] Usually the word "screening" denotes an assembly of mobile charge in the neighborhood of some fixed source charge of opposite sign, in which case the "screening charge" reduces the electric field in the surrounding region over the value it would have in the absence of screening.

Table III. Values of space charge parameters and ionic diffusion coefficient computed from the microscopic physical parameter values listed in Table I

Symbol	Definition	Terminology	Value	Units
$C(0)$	$n_0/2a$	Bulk defect density at $x = 0$	3.125×10^{19}	no./cm^3
λ	$4\pi(Ze)^2a/\epsilon kT$	Parameter	7.47×10^{-15}	cm^2
x^*	$[C(0)\lambda]^{-1}$	Space charge screening parameter	4.28	Å
E^*	kT/Zea	Thermal fluctuation field	-8.08×10^5	V/cm
D	$4a^2\nu\exp(-W/kT)$	Ionic diffusion coefficient	4.08×10^{-11}	cm^2/sec
θ	$RDn_0/4a^2$	Homogeneous field preexponential growth factor	99.46	Å/sec
γ^*	$2.718\ x^*\theta$	Space-charge-modified preexponential growth factor	1159	Å^2/sec

The quantities $\mathcal{E}_2(L^*/L)$ and $\mathcal{E}_3(L^*/L)$ are the second and third order exponential integrals (18). Recurrence relations and polynomial approximations are readily available (18) so that numerical evaluations of these limiting high field growth expressions can be carried out. The domain of validity of the growth expressions is specified in Appendixes A and B, respectively. The results of such numerical evaluations are presented in the following section.

Numerical Evaluation of Analytical Expressions for High Voltages and Thick Films

Parameter values.—To gain the desired insight into the predictions of the equations derived in the last section for the high voltage thick film limit, a numerical evaluation has been carried out with an HP-65 programmable electronic calculator. The values chosen for the primary microscopic physical parameters are those listed in Table I which were utilized for the low voltage computations illustrated above. This, of course, facilitates a comparison of our results for the low voltage and the high voltage limits. The values of the secondary space charge parameters depending only on the microscopic parameter values listed in Table I are given in Table III.

Let us consider a 1000Å anodic oxide film having the microscopic parameters listed in Table I. With an applied voltage of 100V, the average field[2] $\langle E\rangle = -V(L)/L$ has the enormous value of -10^7 V/cm, so that the condition [B-9] given in Appendix B for the very high field limit might be expected to be well met, since $Ze\langle E\rangle a/kT \simeq 12.4$. The self-consistency of this assumption for all values of the field throughout the film will be tested shortly. The value $n_0 = 10^{12}$/cm^2 leads to a defect concentration $C(0) = n_0/2a = 3.125 \times 10^{19}$/cm^3. The value of the parameter λ defined by Eq. [10] is 74.71×10^{-14} cm^2, and the value of the space charge screening parameter x^* defined by Eq. [16] is 4.2832Å. The thermal fluctuation field defined by Eq. [18] is $E^* = -8.0785 \times 10^5$ V/cm. The value of $\ln \mathcal{Q}$ defined by Eq. [22] is -4.4807 which gives $\mathcal{Q} \simeq 1.1326 \times 10^{-2}$. Substituting these values into Eq. [21] gives the surface charge field $E_0 = -6.3803 \times 10^6$ V/cm. These values, which of course are specific to the film thickness and voltage under consideration, are listed for reference purposes in Table IV. Since $ZeE_0a/kT \simeq 7.90$, the very high field condition [A-11] given in Appendix A is definitely met in the region $x \simeq 0$. The space charge is negative since $Z < 0$, so that the field can only increase in magnitude from $x = 0$ to $x = L$. Therefore the very high field condition is met throughout the anodic oxide film, and the equations developed are thus applicable to the presently considered situation.

[2] Since $V(x) \equiv -\int_0^x E(x)dx$, the average field $\langle E\rangle$ in the oxide, defined as $\int_0^L E(x)dx/\int_0^L dx$, is simply equal to $-V(L)/L$.

Table IV. Values of space charge parameters computed from microscopic physical parameter values listed in Table I and the computed parameters listed in Table III when a voltage $V(L) = 100$V is impressed across an anodic film of thickness $L = 1000$Å. (These values are appropriate for Fig. 5-7.)

Symbol	Definition	Terminology	Value	Units
$\ln \mathcal{Q}$	Eq. [22]	Parameter defined by $1 - (x^*/L)[1 + (L/x^*)] \ln [1 + (L/x^*)]$	-4.48	—
$\mathcal{Q}$	$\exp\{\ln \mathcal{Q}\}$	Space charge growth retardation parameter	1.13×10^{-2}	—
E_0	—	Surface charge electric field as obtained from Eq. [21]	-6.38×10^6	V/cm
ZeE_0a/kT	—	Ratio of electrical energy between barrier minimum and barrier maximum to thermal energy	7.90	—
L^*	$-ZeaV(L)/kT$	Critical thickness parameter	12,380	Å

Profiles.—The concentration profile (solid curve) for these parameters as given by Eq. [15] including space charge effects is illustrated in Fig. 5. The corresponding homogeneous field concentration profile (again not explicitly including any imposed concentration gradient) is illustrated by the dashed curve in this figure. The marked difference between the two is especially noteworthy, since it highlights the very important point that the space charge will greatly modify the defect distribution in a growing anodic film. Were the concentration gradient to be included in the computations, the fixed lower defect density at the outer interface would cause a rapid drop-off of the dashed curve near that interface, so in one sense the constant value dashed curve illustrated in Fig. 5 is not actually physically meaningful. The distinction between the solid and dashed curves is, however, very illuminating, since it delineates specifically the effect of the space charge. The rapid falloff of the solid curve near the high defect density interface is required if the current is to remain position independent (*i.e.*, independent of x) in the film, since the increasingly larger values of electric field (see Fig. 6) at larger x values represent larger and larger values of the driving force per particle, which requires in turn smaller and smaller numbers of mobile particles at larger x values to maintain a fixed value for the current.

The integral of the defect distribution of Fig. 5 gives the total defect density as a function of position within the anodic film, which in turn determines the spatial variation of the electric field, as illustrated in Fig. 6.

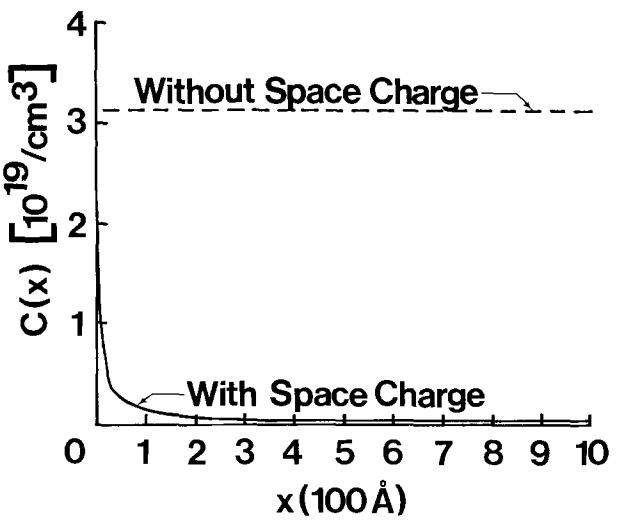

Fig. 5. Defect concentration profile in the large space charge very high field limit for a 1000Å anodic film with an impressed potential of 100V. (Microscopic parameter values are listed in Tables I, III, and IV.)

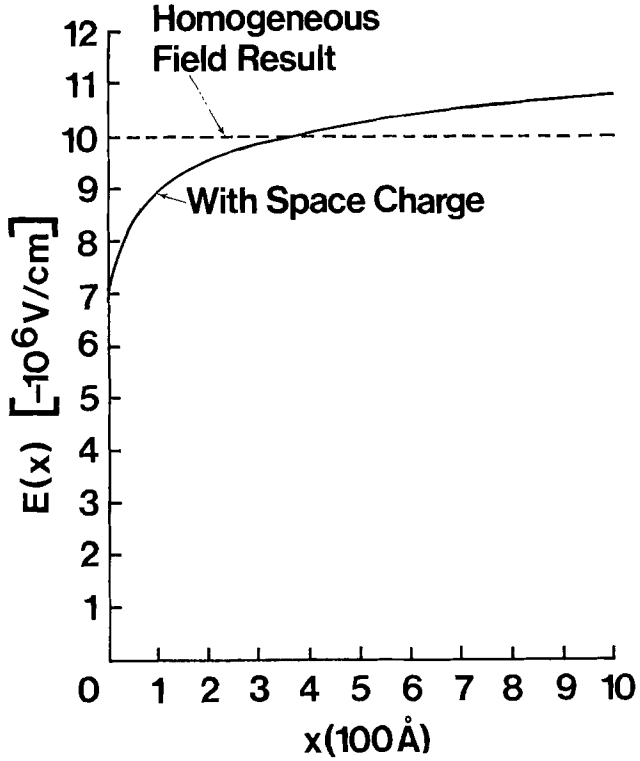

Fig. 6. Electric field profile in the large space charge very high field limit for a 1000Å anodic film with an impressed potential of 100V. (Microscopic parameter values are listed in Tables I, III, and IV.)

This quantity is obtained from Eq. [12]. The departures from the corresponding homogeneous field, as also illustrated in this figure, are noteworthy. Two points should be noted, namely, that the uniform (homogeneous) field approximation would be quite poor, and the high field limit is a poorer approximation with space charge because near $x = 0$ the field is significantly less than it would be in the homogeneous field limit.

The electrostatic potential (Eq. [20]) for the present situation is illustrated in Fig. 7. It is interesting that the electrostatic potential variation within the film in the presently considered very high field situation does not depart greatly from a linear variation appropriate

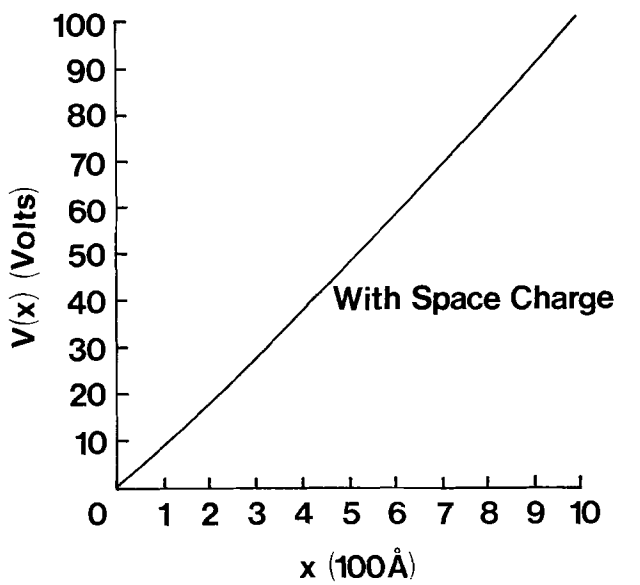

Fig. 7. Electrostatic potential profile in the large space charge very high field limit for a 1000Å anodic film with an impressed potential of 100V. (Microscopic parameter values are listed in Tables I, III, and IV.)

for a homogeneous field. The reason is that the space charge is so large that the space charge screening parameter $x^* \simeq 4.3$Å is only a tiny fraction of the film thickness $L = 1000$Å; thus the defect density drops to very low values throughout most of the anodic film (*cf.* Fig. 5), with the consequence that the electric field over the major portion of the anodic film is indeed approximately homogeneous. For example, the defect density in the center of the film given by the computations leading to Fig. 5 is 2.65×10^{17} cm^{-3}, which is a factor of 0.848×10^{-2} below the fixed value at the interface chosen for the calculations. This drop in space charge density to a value below 1% of the interfacial value means that the defect density is lower deep within the anodic film because of space charge effects, and the electric field varies much more slowly deep within the anodic film than it does near the fixed defect density interface. Figure 6 shows that the variation of the electric field is less than 10% over the latter 70% or so of the film. It is interesting to compare the potential distribution illustrated in Fig. 7 with that of Fig. 12 in Ref. (1). The greater curvature manifested in the 160 monolayer film in Fig. 12 of Ref. (1) is due primarily to the lower defect density with the accompanying larger value for the space charge screening parameter. [Figure 12 of Ref. (1) is based on the microscopic parameter values listed in Table I of Ref. (1), which lead to the value $x^* = 286$Å, whereas the curves illustrated in that figure are for thicknesses of 80 and 640Å.] In this way we see a resolution of a seemingly paradoxical situation in which moderate space charge densities introduce large changes in the potential distribution within the film whereas large space charge densities lead to a potential variation which is not too different from that expected in the homogeneous field limit. That the situations of zero space charge and large space charge are nevertheless quite different can be inferred from a comparison between the defect profiles shown in Fig. 5. The kinetics of anodic film growth are also quite different in the two situations, as has already been verified by computations for the current (*cf.* solid and dashed curves in Fig. 1). [The computations illustrated in Fig. 1 are comparable to those shown in Fig. 16 and 17 of Ref. (1) for a lower space charge density. The high voltage thick film limit space charge computations have also been carried out for the parameter values utilized in Ref. (1), but the results will not be presented since they are qualitatively the same (though not quite so pronounced) as the space-charge-modified results presented herein.]

Anodic film growth under constant current conditions.—For constant current growth, the surface charge field E_0 for the presently considered situation is independent of thickness, according to Eq. [14]. Equations [15], [12], and [20] then show, respectively, that at a given position x within the anodic film the defect concentration, the electric field, and the electrostatic potential will be essentially independent of anodic film thickness in the very high field limit. (The total electrostatic potential difference across the oxide film, *i.e.*, the voltage, does of course depend upon the thickness.) The further limit of considering a homogeneous field ($\epsilon \to \infty$, $\lambda \to 0$, $x^* \to \infty$) for these profile equations yields $C(x) \to C(0)$, $E(x) \to E_0$, and $V(x) \to -E_0 x$, as shown in Appendix B.

The most important result for growth under constant current conditions is the relation for the total electrostatic potential, *i.e.*, the voltage, developed across the anodic film *vs.* the thickness given by Eq. [21]. This is the very high field analog of the numerically computed curves illustrated in Fig. 4. Whereas the homogeneous field voltage $V(L) = -E_0 L$ increases linearly with thickness, Eq. [21] predicts a logarithmic modification which is introduced by the space charge. This logarithmic factor might be expected to give rise to a noticeable curvature in the voltage *vs.* film thickness plot at constant current. Numerical computations to

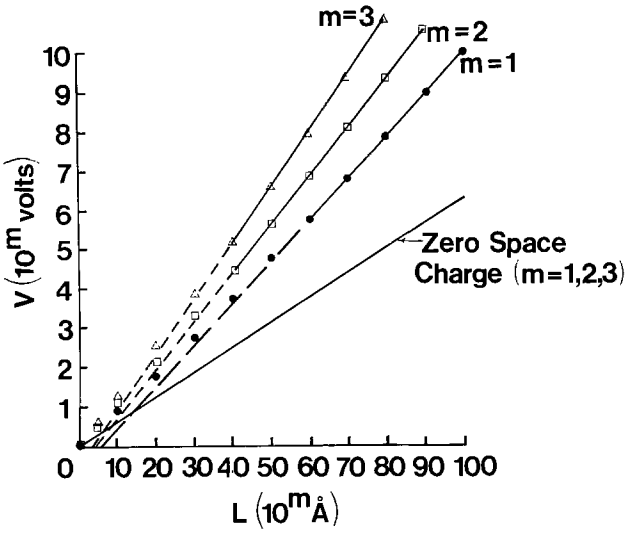

Fig. 8. Voltage vs. thickness over three decades for anodic film growth with space charge for a constant current ($J = 1.071 \times 10^{20}$ cm^{-2}-sec^{-1} for the value of the diffusion coefficient listed in Table III) and comparison with zero space charge results. (Microscopic parameter values are listed in Tables I and III.)

delineate this effect are illustrated in Fig. 8. It is very interesting that the curvature present in the computed voltage *vs.* thickness curves is not pronounced enough to be noticeable over a limited range of film thicknesses, although it is evident from the lack of superposition of the curves $m = 1$, 2, and 3 for the three successive decades shown in Fig. 8 that indeed there is a nonlinearity in the voltage-thickness relationship. This nonlinearity, however, is not nearly as pronounced for the presently considered high voltage limit as it is for the corresponding low voltage limit illustrated in Fig. 4. Therefore a great deal of care is needed in taking experimental data in order to avoid missing the curvature. Otherwise, one could very easily conclude (erroneously) on the basis of sparse data points taken over a limited thickness range that current is simply a linear function of voltage. This in turn might lead one to interpret experimental results (again erroneously) as indicating a strictly homogeneous field, and on this basis deduce entirely wrong values for the microscopic physical parameters for transport through the anodic film.

The voltage has been examined above at some length for the presently considered situation of growth under constant current conditions because it contains the experimentally measurable effects of space charge on the kinetics. The anodic film thickness itself simply increases linearly with time for this case.

The growth kinetics under constant voltage conditions.—Even though anodic film growth is often carried out under constant current conditions, at other times anodization is carried out with a fixed voltage drop across the film. For a given voltage $V(L)$, the values of the time t corresponding to a given value of thickness L can be obtained from Eq. [38] and [39], and then kinetics curves $L(t)$ *vs.* t at constant voltage $V(L)$ can be plotted for the cases of zero and nonzero space charge, respectively. The process can be repeated successively for different voltages $V(L)$ to give a family of growth curves. Such curves should be terminated with (or before) $L = L^*$, as indicated in Appendixes A and B. The value of L^* increases linearly with applied potential, according to Eq. [29]. It is also important to verify that E_0 does not drop below the magnitude required for validity of the very high field approximation. A typical family of curves computed for the homogeneous field case is shown in Fig. 9. The corresponding growth curves computed with space charge effects are shown in Fig. 10.

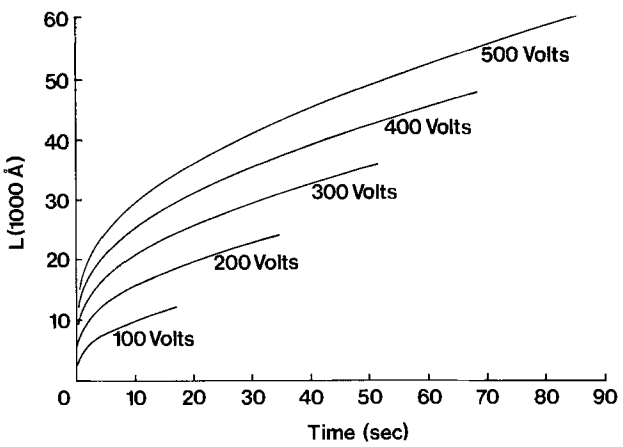

Fig. 9. Constant voltage growth kinetics in the homogeneous field limit for very high electric fields. Microscopic parameter values are listed in Tables I and III.

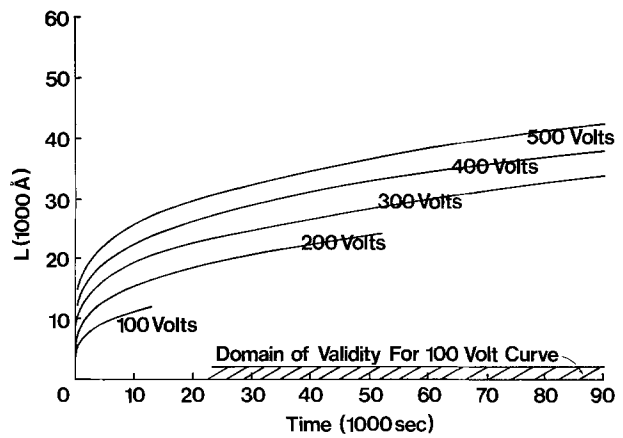

Fig. 10. Constant voltage growth kinetics in the large space charge very high field limit. Microscopic parameter values are listed in Tables I and III.

The curves in these two figures represent the growth of an anodic oxide film having the microscopic parameter values listed in Table I under several different applied voltages, namely 100, 200, 300, 400, and 500V. The quantities which are determined by the microscopic physical parameters of Table I are listed in Table III. The defect profile, the electric field profile, and the electrostatic potential profile have already been illustrated for a 1000Å film at 100V for the set of parameters listed in Table I (*cf.* Fig. 5-7). The diffusion coefficient defined (19) by $D = 4a^2\nu \exp(-W/kT)$ has, for the microscopic parameter values listed in Table I, the value 4.0778×10^{-11} cm^2/sec. Utilizing the value $R = 25$Å^3, as would be appropriate for either Fe_2O_3 or Fe_3O_4 to an accuracy of 1% or so, the value of γ^* defined by Eq. [33] is 1.159×10^{-13} cm^2/sec, and the value of Θ defined by Eq. [31] is 99.56×10^{-8} cm/sec. The parameter L^* defined by Eq. [29] for this case varies linearly with the voltage; it has the value 12,380Å for $V(L) = 100$V. Several interesting features emerge from a comparison of Fig. 9 and 10. Qualitatively the homogeneous field kinetics curves (Fig. 9) do not bend over quite so sharply as the kinetics curves including space charge (Fig. 10), thus illustrating the tendency of space charge to increase the limiting-thickness character of the growth kinetics. The splitting between the several curves for different voltages is greater in the homogeneous field limit than in the more exact nonhomogeneous field situation. Both of these effects are quite analogous to the results noted above for the exact numerical computations for lower voltages and thinner films. Thus the marked effects of space charge on the kinetics persist throughout the entire domain of film thickness. The retardation effect of

Table V. Values of the t_{sc}/t_{nsc} ratio evaluated from the computations illustrated in Fig. 9 and 12 which indicate the increase in time required to grow anodic films of various thickness when space charge effects are important

Voltage (V)	Thickness 10,000Å	20,000Å	30,000Å	40,000Å	50,000Å
100	651				
200	706	1300			
300	736	1370	1950		
400	754	1410	2020	2600	
500	768	1450	2080	2680	3250

space charge on the growth rate is especially evident when the time scales of Fig. 9 and 10 are compared, since it can be noted that there is a difference of a factor of 1000. For example, a 40,000Å film for the microscopic parameter values in question requires in excess of 70,000 sec for growth at 500V, whereas in the homogeneous field limit the growth time would be of the order of or less than 30 sec. It is perhaps unnecessary to emphasize that this is an enormous effect.

It is of some interest to understand the decrease in current at a given voltage and thickness when space charge is present. Equation [1], evaluated at $x = 0$, indicates that the current depends exponentially on the surface charge field E_o. Since $|E_o| < |\langle E \rangle|$ to the extent that space charge is present, the current will drop accordingly.[3]

[3] The reason the surface charge field at fixed voltage drops in the presence of space charge is due to the following fact: The space charge itself produces a contribution to the voltage, and this contribution is of the same sign as the surface charge field contribution; therefore the surface charge field must be lower in magnitude to maintain the fixed voltage. One can easily develop a qualitative understanding of these effects by carrying through a very simple analysis based on the oversimplified model of a uniform space charge C_o, in which case the surface charge field E_o takes the form $\langle E \rangle - (2\pi Ze C_o/\epsilon)L$.

The ratio t_{sc}/t_{nsc} of the time required for the anodic film to achieve a given thickness when space charge is present to the corresponding time computed in the homogeneous field limit indeed provides a good measure of the retarding effects of space charge. Table V lists this ratio deduced in the computations leading to Fig. 9 and 10. The ratio is plotted as a function of voltage for several thicknesses in Fig. 11, and it is plotted as a function of thickness for different voltages in Fig. 12. It can be noted (Table V) that the time factors range from 600 to 3000 for films 10,000-50,000Å in thickness under applied voltages of 100-500V. For a given film thickness, the time factors are somewhat greater at larger voltages (Fig. 11). At a given voltage, the time factors increase nearly linearly with increasing thickness (Fig. 12).

Although Fig. 9 and 10 serve the purpose of illustrating the predictions of the kinetics equations [38] and [39] for growth in the homogeneous field and large space charge limits, respectively, it should be pointed out that Fig. 10 does not provide a good representation of the kinetics over the entire film thickness domains illustrated for the several voltages. The reason for this is peculiar to space charge, in that the electric field in some regions of the film can differ markedly from the average electric field obtained from taking the ratio of voltage to film thickness. If the electric field in any portion of the anodic film drops below the magnitude required for validity of the very high field limit, then the equations for this limit become inapplicable to the situation at hand. Since the electric field for single species anodic film growth generally has its lowest magnitude at $x = 0$, namely $|\langle E \rangle| > |E_o|$, it is necessary to test to see whether E_o as obtained from Eq. [21] for a given voltage and film thickness remains sufficiently large to satisfy the very high field criterion

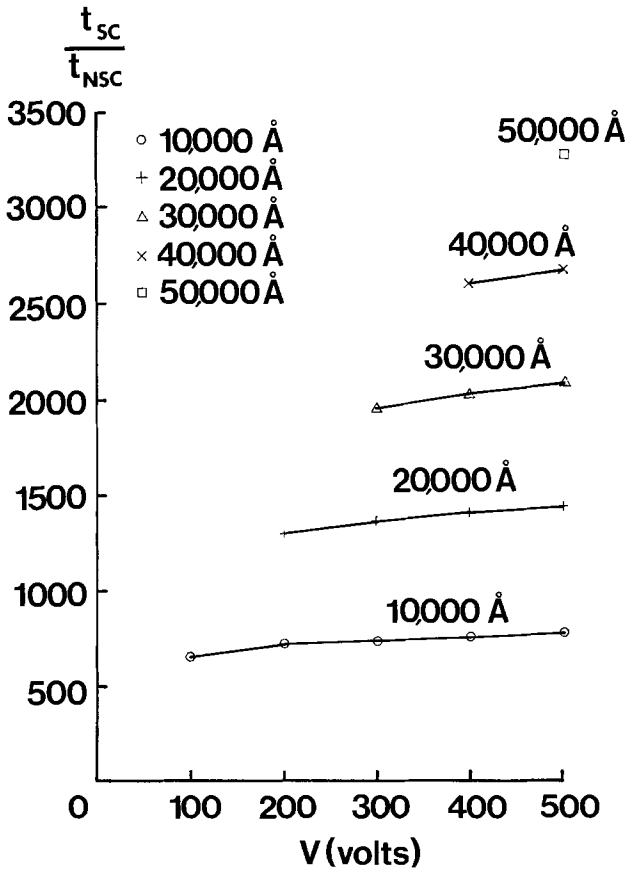

Fig. 11. Ratio of time t_{sc} required to grow an anodic film of several specified thicknesses with space charge to corresponding time t_{nsc} without space charge vs. anodizing voltage. Microscopic parameters are listed in Tables I and III.

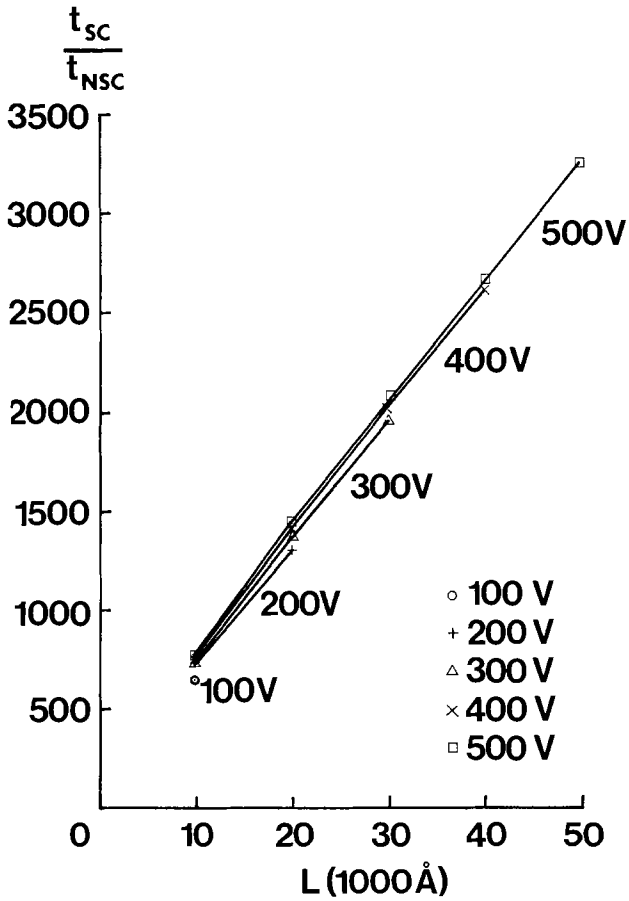

Fig. 12. Ratio of time t_{sc} required to grow an anodic film with space charge at several specified voltages to corresponding time t_{nsc} without space charge vs. anodic film thickness. Microscopic parameters are listed in Tables I and III.

(listed in Appendix B) with increasing values of the film thickness. It is indeed found that $|E_0/E^*|$ drops below unity for the presently considered parameter values whenever the film thickness exceeds 2000Å or so with an applied voltage of 100V. (This contrasts with the homogeneous field case illustrated in Fig. 9 for which $|E_0/E^*|$ exceeds unity over the entire range of the illustrated growth curve.) The major portion of the growth curve illustrated in Fig. 10 therefore represents only an upper limit to the actual thickness, since the consideration of some reverse hopping (13-17) against the applied field in the thicker film lower field domain means that the actual growth rate will be even slower than illustrated in Fig. 10. This additional space charge effect is also in the retarding direction, thus yielding an even greater tendency towards limiting-thickness-type growth. This means that the time factors listed in Table V and illustrated in Fig. 11 and 12 are overly conservative, since the other space charge retarding effects mentioned above will yield longer times for growth under space charge conditions, thus leading to somewhat larger values for the concomitant time factors. Although Fig. 10 could have been restricted to contain only the lower thickness portions of the kinetics curves for which the high field condition $|E(x)/E^*| \gtrsim 1$ is well met throughout the anodic film, the curves are illustrated in their entirety to emphasize the fact that much greater caution is required in utilizing equations for the very high field limit when space charge is present than is required in the homogeneous field limit, due to the fact that the large field limit is violated earlier when space charge is present.

Summary and Conclusions

An analytical development for single carrier steady-state ionic transport and anodic film growth valid in the "very high field" limit with space charge of the mobile ionic species included has been carried out to complement published (1) "intermediate field" numerical computations which utilized a space charge gradient model. The published intermediate field computations illustrated that the growth rate is significantly retarded by space charge of the diffusing ionic species producing film growth. The purpose of the presently reported work was to examine whether or not this pronounced space charge retardation of the growth rate would persist at higher electric fields, and if so, whether it would constitute a larger or a smaller effect relative to the situation at intermediate field strengths. The results of the present analytical development lead to the following major conclusion: Space charge effects do not disappear and do not saturate with increasing electric field value; on the contrary, the space charge retardation is even more pronounced in the realm of very high electric fields, large applied voltages, and very thick anodic films. It is convenient to consider the results in terms of time factors, where a given time factor is defined as the ratio of the time required for the anodic film to grow to a given thickness under a given applied voltage when space charge effects are included to the corresponding time which would be required in the absence of space charge retardation effects. A specific evaluation of the derived analytical expressions for anodic film growth times with and without space charge effects yields time factors ranging from 600 to 3000 for films 10,000-50,000Å in thickness under applied voltages of 100-500V. For a given film thickness the time factors are somewhat greater at larger voltages; at a given voltage the time factors increase nearly linearly with increasing thickness.

Acknowledgments

The author wishes to thank Dr. Charles H. Holmes for his long-term interest in this research on space charge effects, for his frequently enlightening technical discussions on scientific topics and areas of broader mutual interest, and for providing the programmable HP 65 electronic calculator utilized in carrying out the numerical work presented herein for the high voltage thick film limit. The author also acknowledges the support of the Auburn University Computer Center in carrying out the low voltage thin film computations, and wishes to thank the personnel for their cooperation.

APPENDIX A

Limiting Case of a Homogeneous Field

The homogeneous field approximation consists of neglecting the space charge contribution to the electric field. From Eq. [2] it can be noted that this is easily simulated from a mathematical standpoint by taking the limit

$$\epsilon \to \infty \qquad [A\text{-}1]$$

since then $E(x) \to E_0$. This leads to the corresponding limiting values

$$\lambda \to 0 \qquad [A\text{-}2]$$

$$x^* \to \infty \qquad [A\text{-}3]$$

as obtained from Eq. [10] and [16]. The limiting value of the space charge parameter $\mathcal{Q}$ follows from Eq. [22] by employing l'Hospital's rule for evaluating indeterminant forms. The algebraic details are worthwhile from the standpoint of those who may be unfamiliar with the various rules and procedures for the evaluation of indeterminant forms

$$\ln \mathcal{Q} = \lim_{x^* \to \infty} \{1 - (x^*/L)[1 + (L/x^*)]\ln[1 + (L/x^*)]\}$$

$$= 1 - \lim_{x^* \to \infty} \ln[1 + (L/x^*)] - \lim_{x^* \to \infty} \left(\frac{\ln[1 + (L/x^*)]}{L/x^*} \right)$$

$$= 1 - 0 - \lim_{x^* \to \infty} \frac{\frac{d}{dx^*}\ln[1 + (L/x^*)]}{\frac{d}{dx^*}\left(\frac{L}{x^*}\right)}$$

$$= 1 - \lim_{x^* \to \infty} \left[\frac{-L/(x^*)^2}{\frac{1 + (L/x^*)}{-L/(x^*)^2}} \right]$$

$$= 1 - \lim_{x^* \to \infty} \left[\frac{1}{1 + (L/x^*)} \right] = 1 - 1 = 0 \qquad [A\text{-}4]$$

Therefore

$$\mathcal{Q} = e^{\ln \mathcal{Q}} \to e^0 = 1 \qquad [A\text{-}5]$$

(zero space charge limit)

This leads to a very interesting result, namely that the ratio of the growth rate (Eq. [28]) with space charge to that computed without space charge at a given thickness and voltage is simply

$$\frac{(dL/dt)|_{\text{with space charge}}}{(dL/dt)|_{\text{zero space charge}}} = \frac{(QRDC(0)/2a)\exp(L^*/L)}{(1RDC(0)/2a)\exp(L^*/L)} = \mathcal{Q} \qquad [A\text{-}6]$$

(constant or fixed voltage)

where $\mathcal{Q}$ must be computed from Eq. [22] for the value of x^* given by Eq. [16] (together with Eq. [10]) and the thickness in question. Table III, for example, gives the value $\mathcal{Q} \simeq 0.0113$ for a typical set of parameter values, whereas the value of $\mathcal{Q}$ for another typical set of parameter values, *viz.*, those used in Ref. (1), is approximately 0.393.

Utilizing the above value $x^* = \infty$ appropriate for the homogeneous field limit in Eq. [15], [17], and [20] then yields for the concentration, electric field, and electrostatic potential profiles the following limiting values

$$C(x) \to C(0) \qquad [A\text{-}7]$$

$$E(x) \to E_o \qquad [A\text{-}8]$$

and

$$V(x) \to -E_o x \qquad [A\text{-}9]$$

The first two relations follow directly, but to obtain the last relation it is necessary to evaluate an indeterminant form in Eq. [20]

$$\begin{aligned} V(x) &\to \lim_{x^* \to \infty} \{-E_o x + E^* x \\ &\quad - E^* x^* [1 + (x/x^*)] \ln [1 + (x/x^*)]\} \to -E_o x \\ &\quad + E^* x - E^* x \lim_{x^* \to \infty} \{\ln [1 + (x/x^*)]\} \\ &\quad - E^* \lim_{x^* \to \infty} \left[\frac{\ln [1 + (x/x^*)]}{(1/x^*)} \right] \to -E_o x \\ &\quad + E^* x - 0 - E^* x = -E_o x \end{aligned} \qquad [A\text{-}10]$$

where the evaluation proceeds along the same lines as Eq. [A-4].

The validity of Eq. [1] utilized in the present analytical development of high voltage thick film expressions hinges on the assumption of very large forward fields, as discussed in the text following Eq. [1]. In the presently considered homogeneous field limit this requires

$$|ZeE_o a/kT| \gtrsim 1 \qquad [A\text{-}11]$$

which, with the aid of Eq. [29] and the homogeneous field voltage expression $V(L) = -E_o L$, can be written in the form

$$|L^*/L| \gtrsim 1 \qquad [A\text{-}12]$$

Hence the domain of the high field growth expressions in the absence of space charge is

$$L \lesssim L^* \qquad [A\text{-}13]$$

APPENDIX B

Limiting Case of Very Large Space Charge

The effect of space charge on the electric field can be noted from Eq. [2] to be enhanced for lower values of the dielectric constant ϵ. Therefore the large space charge limit can be simulated mathematically by taking the limit

$$\epsilon \to 0 \qquad [B\text{-}1]$$

This leads to the corresponding limiting values

$$\lambda \to \infty \qquad [B\text{-}2]$$

$$x^* \to 0 \qquad [B\text{-}3]$$

as obtained from Eq. [10] and [16]. The limiting value of the space charge parameter $\mathcal{Q}$ follows from Eq. [22] by employing l'Hospital's rule for evaluating indeterminant forms. The evaluation proceeds as follows

$$\begin{aligned} \ln \mathcal{Q} &= \lim_{x^* \to 0} \{1 - (x^*/L)[1 + (L/x^*)] \ln [1 + (L/x^*)]\} \\ &= 1 - \lim_{x^* \to 0} \left[\frac{\ln [1 + (L/x^*)]}{(L/x^*)} \right] \\ &\quad - \lim_{x^* \to 0} \{\ln [1 + (L/x^*)]\} \\ &= 1 - \lim_{x^* \to 0} \left[\frac{-L/(x^*)^2}{\dfrac{1 + (L/x^*)}{-L/(x^*)^2}} \right] \\ &\quad - \lim_{x^* \to 0} \{\ln [1 + (L/x^*)]\} \\ &= 1 - 0 - \infty = -\infty \end{aligned} \qquad [B\text{-}4]$$

Therefore

$$\mathcal{Q} = e^{\ln \mathcal{Q}} \to e^{-\infty} = 0 \qquad [B\text{-}5]$$

and the current and growth rate given by Eq. [26] and [28] approach zero in this limit. Prior to reaching this extreme, however, a good asymptotic expression for $\ln \mathcal{Q}$ follows from Eq. [22] by neglecting 1 relative to L/x^*, in which case

$$\ln \mathcal{Q} \simeq 1 - (x^*/L)(L/x^*) \ln (L/x^*) \simeq 1 - \ln (L/x^*) \qquad [B\text{-}6]$$

and

$$\mathcal{Q} = e^{\ln \mathcal{Q}} \simeq e^{1 - \ln (L/x^*)} \simeq 2.718\,(x^*/L) \qquad [B\text{-}7]$$

This provides the approximation needed to deduce an analytical expression for the growth law from Eq. [28].

It should be noted that the limiting expression for $\mathcal{Q}$ deduced above involves the approximation

$$L/x^* >> 1 \qquad [B\text{-}8]$$

which in some sense requires a large thickness L. On the other hand, the validity of Eq. [1] hinges on the requirement of very large forward field, which requires

$$|ZeE(x)a/kT| \gtrsim 1 \qquad [B\text{-}9]$$

as discussed in the text following Eq. [1]. In addition, as already shown in a footnote in the text, $\langle E(x) \rangle = -V(L)/L$, so the inequality [B-9] certainly requires

$$|-ZeV(L)a/kTL| \gtrsim 1 \qquad [B\text{-}10]$$

which, with the aid of Eq. [29], can be written in the form

$$|L^*/L| \gtrsim 1 \qquad [B\text{-}11]$$

Hence the domain of applicability of the high space charge growth equations deduced herein is fixed by

$$x^* << L \lesssim L^* \qquad [B\text{-}12]$$

LIST OF SYMBOLS

Lower case English characters

a	half of the hopping distance for defects in anodic film ($2a$ is the lattice parameter or the nearest neighbor distance)
e	electronic charge magnitude
k	Boltzmann's constant
m	power exponential ($m = 1, 2, 3$) in 10^m
n	power in n^{th} root growth law ($L(t) \propto t^{1/n}$)
n_N	areal defect density at anodic oxide interface located at $x = L$
n_o	areal defect density at anodic oxide interface located at $x = 0$
t	time
t_{sc}	time to grow anodic film under a given set of conditions with space charge effects included
t_{nsc}	time to grow anodic film under a given set of conditions in the homogeneous field limit
x	position in anodic film
x^*	space charge screening parameter defined by $[\lambda C(0)]^{-1}$

Upper case English characters

C_o	hypothetical uniform charged defect density
$C(0)$	bulk defect density of the mobile ionic species at $x = 0$
$C(x)$	bulk defect density of the mobile ionic species at position x
D	ionic diffusion coefficient
$E(x)$	electric field at position x in anodic film
$\langle E \rangle$	average electric field in the anodic oxide defined as

$$\int_0^L E(x)\,dx \Big/ \int_0^L dx = -V(L)/L$$

E^* thermal fluctuation field defined by kT/Zea
E_0 surface charge electric field (*i.e.*, the electric field at position $x = 0$ in the anodic film)
J_0 particle current of the mobile ionic defect species in the anodic film
L^* critical thickness parameter defined as $-ZeaV(L)/kT$
L' dummy variable of integration
$L(t)$ anodic film thickness in units of distance
N thickness of anodic film in monolayers (and total number of barriers across the film)
R volume of oxide per ionic defect transported through the anodic film
T temperature
$V(L)$ total electrostatic potential across the anodic film (equal in magnitude to the voltage across the anodic film)
$V(x)$ electrostatic potential at position x in anodic film defined by $V(x) = -\int_0^x E(x)\,dx$
W zero field activation energy for motion of mobile ionic defect species
Z charge per particle of mobile ionic defect species (in units of e)

Upper case English script characters

$\mathcal{E}_n$ nth order exponential integral ($n = 1, 2, 3$)
$\mathcal{Q}$ space charge growth retardation parameter given by $e^{\ln \mathcal{Q}}$
$\ln \mathcal{Q}$ parameter defined by $\{1 - (x^*/L)[1 + (L/x^*)] \ln[1 + (L/x^*)]\}$

Lower case Greek characters

β_0 parameter defined by $\exp(ZeE_0a/kT)$
$\beta(x)$ variable defined by $\exp(ZeE(x)a/kT)$
ϵ static dielectric constant of anodic film (in units of ϵ_0, the permittivity of free space)
η dummy variable of integration
γ^* growth rate preexponential parameter (for growth with space charge) defined as $[2.718\,RDC(0)x^*/2a]$
λ parameter defined by $4\pi(Ze)^2a/\epsilon kT$
ν attempt frequency of mobile ionic defect species
π 3.14159...

Upper case Greek character

Θ growth rate preexponential parameter (for homogeneous field limit) defined as $[RDC(0)/2a]$

The Phase Transformation during Crystallization of ZnS

M. Sakaguchi, M. Ohta, M. Satoh, and T. Hirabayashi

Department of Applied Chemistry, Faculty of Engineering, Niigata University, Nagaoka, Niigata, Japan

ABSTRACT

In order to investigate the cubic → hexagonal transformation during crystallization of ZnS, microcrystalline ZnS and microcrystalline ZnS containing CdS or Cu_2S with various ratios were thermally treated at 850° or 1150°C in atmospheres of He, HCl, H_2S, or their mixtures, and the cubic content in the crystals obtained was estimated by the x-ray powder diffraction method. The cubic →hexagonal transformation in ZnS crystal containing CdS was promoted with a certain amount of blended CdS at 850°C in all atmospheres. In HCl, the percent cubic in unblended ZnS decreased rapidly in the initial stage, then increased over 0.5 hr ("retransformation"). The percent cubic in blended samples also decreased temporarily but the degrees of retransformation decreased with increasing CdS content. In H_2S, unblended ZnS remained cubic, while it transformed to hexagonal due to blending with CdS. The transformation reaction in the (0.95)ZnS-(0.05)CdS sample was followed by using a high temperature x-ray diffractometer. The result showed that the cubic peak intensity for CdS decreased with temperature and disappeared near 550°C, while the hexagonal peak intensity for the solid solution emerged near 650°C. The cubic → hexagonal transformation in microcrystalline ZnS containing Cu_2S was inhibited with the amount of blended Cu_2S at 1150°C in all atmospheres.

In the phase transformation reaction of ZnS crystals, an important role is played by a trace of foreign ions (1-8). McKeag *et al.* (1), Aven *et al.* (2), Nickerson *et al.* (3), and Gashurov *et al.* (4) have found that the hexagonal → cubic transformation in ZnS crystals was promoted by a trace of copper, and recently Kozielski (5) has reported that the "hexagonality" of (Zn, Cd)S solid solution increased with Cd concentration.

It has also been found that the transformation reaction was affected by the presence of a foreign anion. That is, Skinner *et al.* (6) have noted that the cubic → hexagonal transformation occurred readily below its normal temperature when O_2 was occluded in the crystals, and Bansagi *et al.* (7) and Sakaguchi *et al.* (8) have found that the transformation rate is affected by the adsorption of anion on the crystal surface during the transformation reaction. Although several studies have been done on the effect of individual foreign ions on the transformation reaction in ZnS, no work has been reported on the combined effect of promotive and inhibitive ions on this reaction.

In this paper, the ZnS crystal containing CdS (hexagonal at low temperature) or Cu_2S (cubic at high temperature) is thermally treated in atmospheres of He, HCl, H_2S, or their mixtures, and then the combined effect of promotive and inhibitive factors on the transformation phenomena of ZnS crystals is discussed.

Experimental

The starting materials used in this study were unblended ZnS powder and blended samples as follows, *viz.* $(1-x)$ZnS-(x)CdS samples and $(1-y)$ZnS-$(y)Cu_2S$ samples. Samples of $(1-x)$ZnS-(x)CdS and $(1-y)$ZnS-$(y)Cu_2S$ compositions were prepared by carefully blending the microcrystalline ZnS powder with ratios of $0 \leq x \leq 0.5$ microcrystalline CdS powder and $0 \leq y \leq 0.01$ microcrystalline Cu_2S powder, respectively.

He was of high purity purified by passage through a glass tube containing the molecular sieve 5A at −196°C. HCl and H_2S were pure materials for the preparation of semiconductors, further purified by vacuum distillation using both dry ice alcohol and liquid O_2 baths.

The apparatus for heating by a static method was constructed of borosilicate glass, except for the reaction tube which was made of quartz. Dead space of the reaction system was about 100 ml. The heating temperature was detected by a Pt-Pt 13% Rh thermocouple and maintained constant to ±1°C by an automatic controller, and the thermocouple was checked at the melting points of Sn (231.9°C), Zn (419.5°C), and Cu (1083°C) before and after the experiments.

The starting material (2.0g) was initially evacuated in high vacuum for 30 min at 25°C, then heated for 0-3 hr at 850° or 1150°C in each ambient gas (1 atm). The time interval required to reach the heating temperature was adjusted to be 30 min in all cases, and the heating time denoted as zero, meaning that the heating was stopped instantly at the given temperature. After heating the sample was rapidly cooled at the rate of ~200°C/min.

The crystal structure of the heated samples was examined by x-ray powder diffraction using Cu(Ni)K_α radiation, and the cubic content (percent cubic) was determined by the method reported by Bansagi *et al.* (7). High temperature x-ray measurements were done in a special high temperature diffractometer attachment equipped with a wide-angle goniometer (Rigaku Denki Company, Limited Type SG-7).

Results

The effect of ambient gases on the sintering reaction during crystal growth of microcrystalline ZnS is shown in Fig. 1. The BET surface area of the ZnS heated at 850°C showed a remarkable drop during the initial stage of heating, especially in H_2S atmosphere, indicating that considerable sintering occurred.

To observe the effects of both the ambient gas and the presence of CdS on the transformation reaction, $(1-x)$ZnS-(x)CdS samples were heated for 1 hr at 850°C in He, H_2S, or HCl. The results are shown in Fig. 2. The percent cubic in unblended ZnS decreased in the order of H_2S, He, and HCl, although at lower than the normal transition point. These results suggest that the cubic → hexagonal transformation was promoted by HCl and inhibited by H_2S relative to He. On the other hand, the percent cubic in the blended samples decreased considerably with the amount of CdS, and no cubic structure was detectable in HCl above 10 mole percent (m/o) CdS, while the cubic form still remained in H_2S and He above 50 m/o CdS.

Figure 3 shows the dependence of cubic structure on heating time when the sample is heated in the promo-

Key words: phase transformation, zinc sulfide, copper(I) sulfide, solid solution.

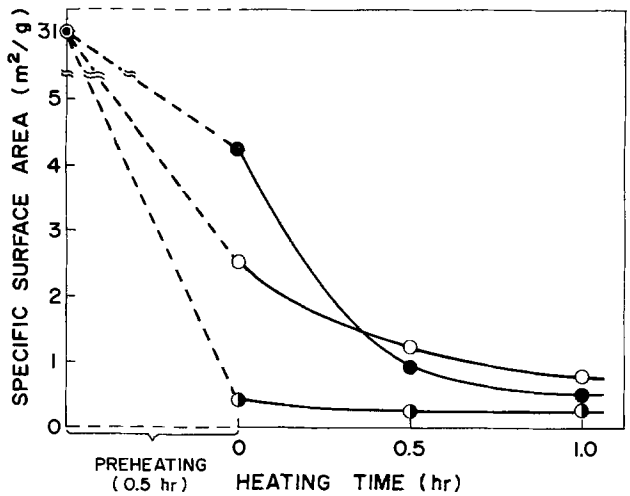

Fig. 1. Dependence of heating time or specific surface area of ZnS crystal heated at 850°C: ○, in He; ◑, in H_2S; ●, in HCl; ◉, starting material.

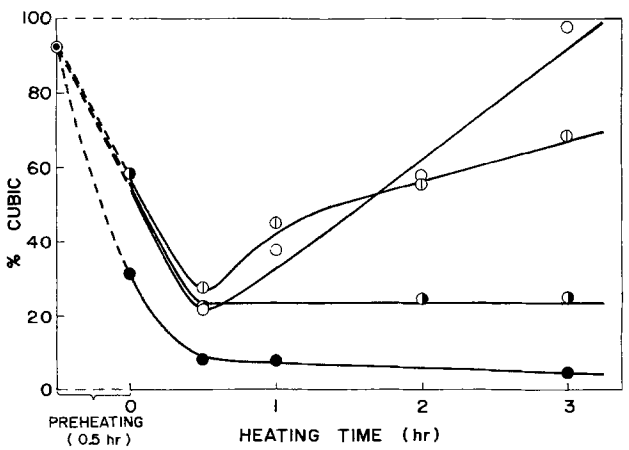

Fig. 3. Relation between heating time and percent cubic of (1 — x)ZnS-(x)CdS samples heated at 850°C in HCl: ○, x = 0; ◑, x = 0.01; ◑, 0.03; ●, x = 0.05; ◉, starting materials.

tive atmosphere of HCl. The percent cubic in unblended ZnS decreased rapidly in the initial stage, then increased after 0.5 hr. This reversal in behavior indicates that the crystal structure reverted to cubic ("retransformation"), which is the stable form at this temperature. Similarly, the percent cubic in blended samples also decreased temporarily, but the degree of retransformation decreased with increasing CdS content.

Figure 4 shows a similar plot for the sample heated in the inhibitive atmosphere of H_2S. The inhibitive effect of H_2S decreased with the amount of CdS.

The transformation reaction in the (0.95)ZnS-(0.05)CdS sample as a function of temperature was followed by using a high temperature x-ray diffractometer. Figure 5 shows that the cubic peak intensity for CdS decreased with temperature and disappeared near 550°C, while the hexagonal peak intensity for the solid solution emerged near 650°C. The latter peak intensity was constant above 800°C. It is interpreted, therefore, that CdS dissolved readily in ZnS.

Similar experiments were done on (1 — y)ZnS-(y)Cu_2S samples; the cubic structure of Cu_2S is stable at high temperature in contrast to CdS. Figure 6 shows percent cubic *vs.* Cu_2S content for such samples heated in H_2S or HCl for 1 hr at 1150°C. Under these conditions the unblended ZnS transformed completely to hexagonal. On the other hand, ZnS blended with Cu_2S was more effectively returned to cubic by H_2S than by HCl, depending on the amount of Cu_2S present. The cubic → hexagonal transformation was inhibited more effectively by a smaller amount of Cu_2S than the amount of CdS required to promote the reaction at 850°C.

Table I shows the effect of ambient gas on the structural transition of (0.999)ZnS-(0.001)Cu_2S at 1150°C. The inhibitive effect due to Cu_2S was greatly enhanced by heating in H_2S; no effect was observed after heating for 1 hr in HCl, but the inhibitive effect emerged after 3 hr heating. These results suggest that the transforma-

tion reaction during the crystallization of the microcrystalline ZnS powder was noticeably affected not only by the presence of a second component (CdS or Cu_2S) in the solid phase but also by the ambient gases (HCl, He, or H_2S).

Experiments were also carried out to observe the influence of mixed gases, that is, H_2S mixed in various ratios with HCl. These results of mixed gases on unblended ZnS and (0.95)ZnS-(0.05)CdS sample are shown in Fig. 7. In Fig. 7 a sharp increase in cubic content occurred in the unblended ZnS by mixing HCl with a small amount of H_2S, while the cubic content increased gradually in the blended sample.

Similar examination of the unblended ZnS and (0.999)ZnS-(0.001)Cu_2S sample was carried out in H_2S-HCl mixtures at 1150°C. The results in Fig. 8 are in distinct contrast to the $(1-x)$ZnS-(x)CdS samples at 850°C. That is, the effect on the unblended ZnS was slight with the variation of gas composition, while the effect on the blended sample showed a strong dependence on the partial pressure of H_2S.

Discussion

The phase transformation phenomena observed during crystallization of the microcrystalline ZnS blended CdS reported herein showed a similar tendency to earlier reports (5, 10).

The promotive effect of CdS on the cubic →hexagonal transformation in ZnS crystals as shown in Fig. 2 and 5 results from the formation of a solid solution of CdS in ZnS prior to the transformation step, *i.e.*, each individual ZnS-CdS solid solution had an inherent transition point. Furthermore, the effectiveness of the CdS presence was enhanced in HCl, and was rather depressed in H_2S compared with He.

The combined effect resulting from the presence of promotive and inhibitive factors can be explained as follows. The original microcrystalline ZnS precipitated

Table I. Percent cubic of (1 — y)ZnS-(y)Cu_2S samples heated at 1150°C in various ambient gases

Sample	Heating conditions: Ambient gas (1 atm)	Time (hr)	Percent cubic
ZnS	H_2S	1	12.3
(0.999)ZnS-(0.001)Cu_2S	H_2S	1	87.5
(0.999)ZnS-(0.001)Cu_2S	HCl	1	0
(0.999)ZnS-(0.001)Cu_2S	HCl	3	52.3
(0.999)ZnS-(0.001)Cu_2S	He	3	70.0

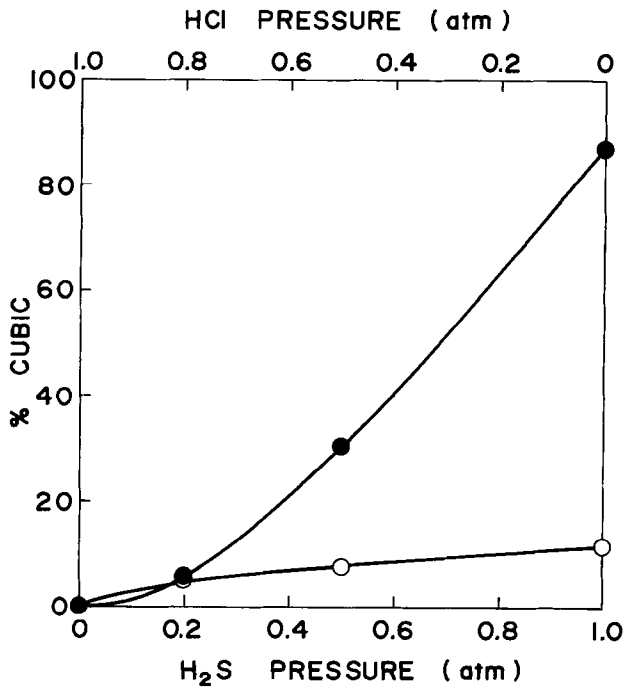

Fig. 8. Relation between composition of ambient gases and percent cubic of (1 — y)ZnS-(y)Cu_2S samples heated for 1 hr at 1150°C: ○, $y = 0$; ●, $y = 0.001$.

from aqueous $ZnSO_4$ with H_2S can hardly avoid the inclusion of SO_4^{2-} (as $ZnSO_4$) even after most careful washing. Therefore, on heating at 850°C the contamination of the sintered ZnS with oxygen is expected even in He, where the incorporated $ZnSO_4$ would decompose to ZnO.

An earlier study (6) has reported that the hexagonal structure of ZnS crystals was stabilized by the included oxygen below the normal transition point. Accordingly, although ZnS was unblended the crystal obtained by heating in He will be transformed to about 30 m/o hexagonal (Fig. 2).

The deoxidization occurred as soon as ZnS was heated in H_2S where H_2S is expected to react rapidly

with $ZnSO_4$ prior to sintering, therefore, a higher cubic content resulted. In HCl atmosphere, however, $ZnSO_4$ should remain in the sintered samples as would be expected in the case of He; HCl cannot react directly with $ZnSO_4$, but $ZnCl_2$ produced by the reaction between HCl and ZnO formed by thermal decomposition would sublime. Accordingly the "retransformation" or reversion to the stable cubic form may occur progressively with heating time.

In Fig. 7, the increase in cubic content of the unblended ZnS is due to the presence of H_2S, which is expected to deoxidize the included $ZnSO_4$. On the other hand, the cubic content of the blended sample decreased in the gas mixtures more than was estimated from Fig. 2. From these results it can be assumed that the solubility of oxygen in the ZnS crystals increased in ZnS-CdS solid solution, but a more detailed discussion must await further work.

The unblended cubic ZnS transformed completely to hexagonal on heating in H_2S or HCl at 1150°C. On the other hand, blending ZnS with a trace amount of Cu_2S, the cubic content was remarkably increased by heating in H_2S (*i.e.*, copper sulfide-induced transformation), but no detectable change was observed in HCl (Fig. 6, Table I). This behavior can be explained by postulating that the effective force for a copper sulfide-induced transformation was damaged by the presence of SO_4^{2-}, which was initially present in the sintered samples heated in HCl. The increase in cubic structure content with heating time in HCl gas was coincident with oxygen removal as ZnO, resulting from the thermal decomposition of the $ZnSO_4$ and the reaction with HCl. Furthermore, this discussion of Table I is supported by the data in Fig. 8 where the percent cubic of the Cu_2S blended sample increased in a linear relation with the partial pressure of H_2S, a deoxidizing agent for $ZnSO_4$.

Preparation and Fluorescent Properties of Lithium Rare Earth Phosphate Phosphors

Y. Tsujimoto, Y. Fukuda, and M. Fukai

Matsushita Electric Industrial Company, Limited, Central Research Laboratories, Moriguchi, Osaka 570, Japan

ABSTRACT

Efficient emission has been found in the phosphate phosphors, $LiY_{1-x}Tb_xP_4O_{12}$ and $LiY_{1-y}Eu_yP_4O_{12}$ under u.v. excitation. For the preparation of these phosphors, an appropriate firing temperature must be selected in regard to the ionic radius of rare earth ions. The luminescence intensity changes little over the wide range of activator concentration, The rare earth metaphosphate phosphors such as $Y_{1-x}Tb_xP_3O_9$ and $Y_{1-y}Eu_yP_3O_9$ were found to show similar properties. Under vacuum u.v. excitation by Xe lamp, the brightness of $LiY_{0.1}Tb_{0.9}P_4O_{12}$ exceeds that of Zn_2SiO_4:Mn. The enhancement of Tb^{3+} emission by Ce^{3+} ions was found in both $LiTb_{1-x}Ce_xP_4O_{12}$ and $Tb_{1-y}Ce_yP_3O_9$.

In usual phosphate phosphors, the increase of an activator concentration over several percent results in a quenching of fluorescence. In recent years, however, phosphate compounds which contain Nd^{3+} as a cation have attracted special interest as low threshold laser materials. First, Danielmeyer and Weber proposed NdP_5O_{14} (1) in 1972 and then Yamada *et al.* found $LiNdP_4O_{12}$ (2) in 1974. Hong analyzed the crystal structures of a series of phosphates (3-6) including neodymium metaphosphate and made clear that those low threshold laser materials had a crystal structure favorable for suppressing the interactions between Nd^{3+} ions and thus concentration quenching was reduced. One of the merits of the above-mentioned materials is that they have a very high concentration of luminescent centers. This fact suggests to us the application of these phosphates to a visible light emitting phosphor activated with rare earth ions.

Key words: rare earth luminescence, photoexcitation, high activator concentration, sensitization.

The present work is an extended application of $LiLnP_4O_{12}$ and LnP_3O_9 (Ln = rare earth ions) phosphors in which the preparation method, fluorescent properties of Tb^{3+} and Eu^{3+} centers, and sensitization of Tb^{3+} emission by Ce^{3+} ion are related.

Experimental

Preparation of phosphors.—Phosphors were prepared from intimate mixtures of high purity raw materials by conventional solid-state reactions in air. Starting materials were ≧ 99.99% rare earth oxides and reagent grade Li_2CO_3 and $NH_4H_2PO_4$. For the preparation of $LiLnP_4O_{12}$ (Ln = rare earth elements) 150% Li_2CO_3 and 110% $NH_4H_2PO_4$ were weighed, compared with the stoichiometric ratio. In firing the LnP_3O_9, 110% $NH_4H_2PO_4$ was used and 0.2 mole fraction of LiF was added as a flux. Fired samples were washed in hot water to remove unreacted lithium and phosphorous compounds.

Measurements.—Emission and excitation spectra were obtained with the aid of a grating monochrometer whose blaze wavelengths were 500 and 300 nm, respectively. A hydrogen discharge lamp was used as a u.v. excitation source. A photomultiplier with S-4 sensitivity was applied as the detector. Calibration of the spectral response of the apparatus used was not made. Vacuum ultraviolet (v.u.v.) excitation spectra were measured by the double beam method with a Hinteregger type hydrogen lamp and concave grating monochrometer.

Two kinds of relative brightness are obtained with the photomultiplier of S-4 response coupled with a Wratten 106 filter. One is by excitation with 254 nm of a mercury discharge lamp and the other is with a xenon lamp which has emission in the v.u.v. region from 150 to 200 nm.

Fluorescence decay times were measured by exciting the samples with a short time pulse (~4 nsec) from a deuterium flash lamp and observing the luminescence decay on an oscilloscope.

All measurements were carried out at room temperature.

Results and Discussions

Sample preparation conditions.—For the preparation of $LiLnP_4O_{12}$, the firing temperature must be below a critical value which related to the Ln^{3+} ionic radius. Above this critical temperature, resulting material was found to become Li-free rare earth metaphosphate. Figure 1 shows the relation between the ionic radius of Ln^{3+} ion and the temperature at which this transformation occurs. When the ionic radius of Ln^{3+} ion was larger than that of Tb^{3+} (1.09Å), rare earth metaphosphate did not appear within the temperature studied. At the critical firing temperature, which is shown by triangles, two compounds, $LiLnP_4O_{12}$ and LnP_3O_9, exist.

This critical temperature might change with the mole ratio of starting materials. Detailed experiments, however, have not been carried out. Sample firings were made at temperatures ranging from 750° to 850°C in regard to the average ionic radius of Ln^{3+} ion. Firing periods were 3-17 hr.

Obtained powder samples showed the same x-ray diffraction pattern as monoclinic $LiNdP_4O_{12}$. Under the firing conditions of 850°C and 3 hr, rare earth metaphosphate has an orthorhombic or monoclinic structure depending on whether the Ln^{3+} ion is larger than Eu^{3+} (1.13Å) or smaller than Gd^{3+} (1.11Å) (6).

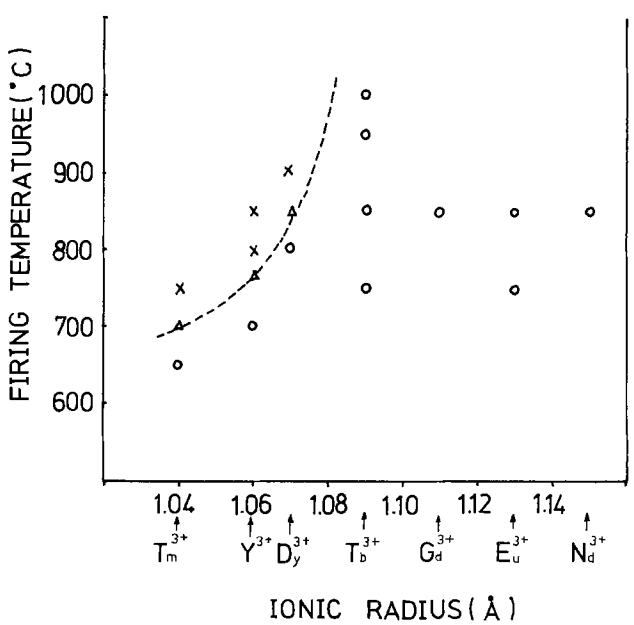

Fig. 1. Relation between the ionic radius of Ln^{3+} ion and the compounds obtained in regard to the firing temperature. Mole fractions of the starting materials of Li_2CO_3, Ln_2O_3, and $NH_4H_2PO_4$ are 1.5, 1.0, and 8.8, respectively: x rare earth metaphosphate, ○ lithium rare earth metaphosphate, △ mixture of the two phosphates.

Emission and excitation spectra.—All the phosphors investigated show emission lines characteristic of Eu^{3+} and Tb^{3+}. The emission spectra of $LiEuP_4O_{12}$ and $LiTbP_4O_{12}$ under 254 nm excitation are given in Fig. 2. In the rare earth metaphosphate. emission spectra of Eu^{3+} and Tb^{3+} are essentially similar to those of Fig. 2, except that the emission line corresponding to the $^5D_0$-$^7F_2$ transition of Eu^{3+} is stronger than that in $LiEuP_4O_{12}$.

Excitation spectra of Tb^{3+} fluorescence in $LiGd_{1-x}Tb_xP_4O_{12}$ when x is varied, are given in Fig. 3. Judging from the variation of excitation intensity *vs.* Tb^{3+} concentration, the excitation band at about 225 nm can be attributed to host excitation and those in longer wavelength rather than that of the f-f and the f-d excitation bands. In this longer wavelength region, bands at 240 ~ 270 nm are estimated to belong to the 4f-5d transition, since the ratio of magnitude variation of 4f-5d bands with Tb^{3+} concentration is smaller than that of 4f-4f bands (7).

The excitations at wavelengths of 273 and 312 nm seem to originate from a Gd^{3+} center whose energy is transferred to the Tb^{3+} center, since these excitations are not observed in $LiY_{1-x}Tb_xP_4O_{12}$ and the peak intensities increase with increased Gd^{3+} concentration. The similar behavior of these two peaks is observed in $Gd_{1-x}Eu_xP_3O_9$ as well. This suggests that energy transfer from Gd^{3+} to Eu^{3+} is also operative.

The excitation spectra of $LiY_{1-x}Tb_xP_4O_{12}$ and $LiGd_{1-x}Tb_xP_4O_{12}$ in the v.u.v. region are given in Fig. 4 together with that of Zn_2SiO_4:Mn for comparison. Zn_2SiO_4:Mn is known as a good phosphor for v.u.v. excitation (8, 9). From Fig. 4, however, $LiY_{0.1}Tb_{0.9}P_4O_{12}$ is found to have higher emission intensity than Zn_2SiO_4:Mn in the wavelength region longer than 160 nm. When it was excited by a Xe lamp the brightness was 115% of that of Zn_2SiO_4:Mn (Fig. 7).

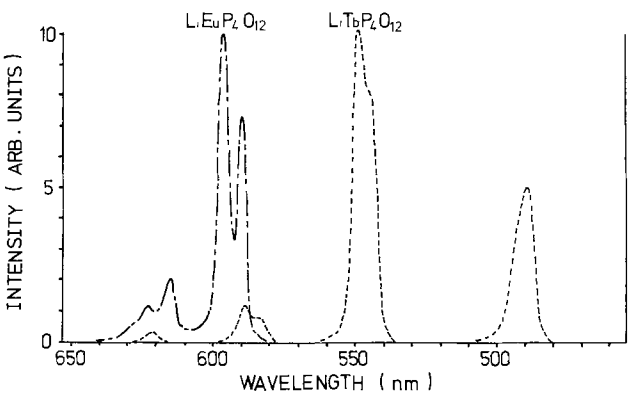

Fig. 2. Emission spectra of $LiTbP_4O_{12}$ and $LiEuP_4O_{12}$ under 254 nm excitation.

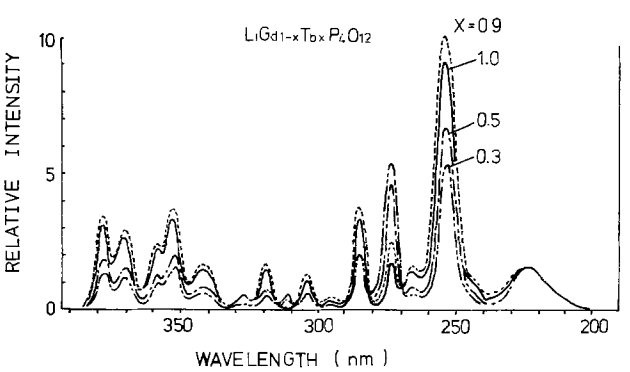

Fig. 3. Excitation spectra of $LiGd_{1-x}Tb_xP_4O_{12}$

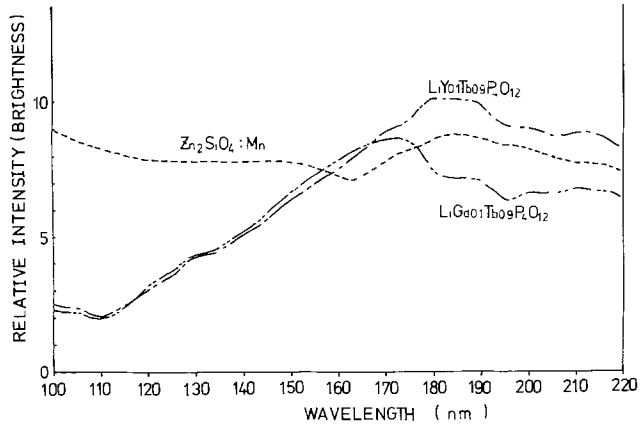

Fig. 4. Vacuum ultraviolet excitation spectra of $LiY_{0.1}Tb_{0.9}P_4O_{12}$ and $LiGd_{0.1}Tb_{0.9}P_4O_{12}$ compared with that of Zn_2SiO_4:Mn.

Emission intensity.—The dependences of relative brightness of each phosphor on activator concentration are given in Fig. 5-7. The curves in Fig. 7 are the results obtained under v.u.v. excitation and the rest are those obtained under 254 nm excitation. What is common to all the curves in Fig. 5-7 is that there is little concentration quenching of emission even at the highest activator concentration.

In the case of $LiLnP_4O_{12}$, this is due to the crystal structure in which the Ln^{3+} ion shares no O^{2-} atom and interactions between the Ln^{3+} ions are considered to be weak (3, 4). As mentioned previously, rare earth metaphosphate shows two kinds of crystal structure, *i.e.*, orthorhombic and monoclinic. In the former structure each Ln^{3+} atom shares two O^{2-} atoms with one of the neighboring Ln^{3+} atoms and two other O^{2-} atoms with another Ln^{3+} atom, which seems to enhance Ln^{3+}-Ln^{3+} pair interaction (5). The latter structure, however, has LnO_6^{9-} octahedra which are isolated from each other with no atom common to any two Ln^{3+} atoms (6) and less interaction between Ln^{3+} ions is expected.

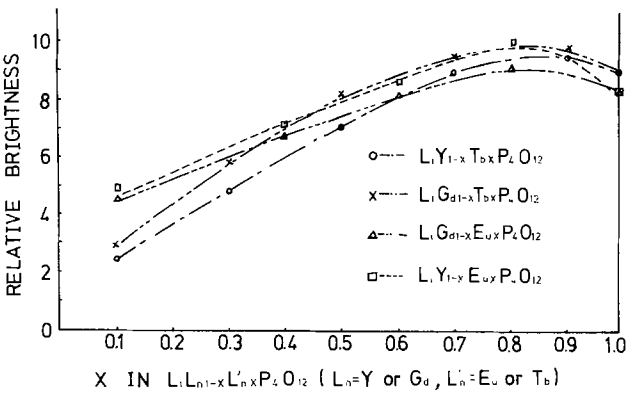

Fig. 5. Relative brightness of lithium rare earth metaphosphate activated with Tb^{3+} or Eu^{3+} vs. activator concentration (254 nm excitation).

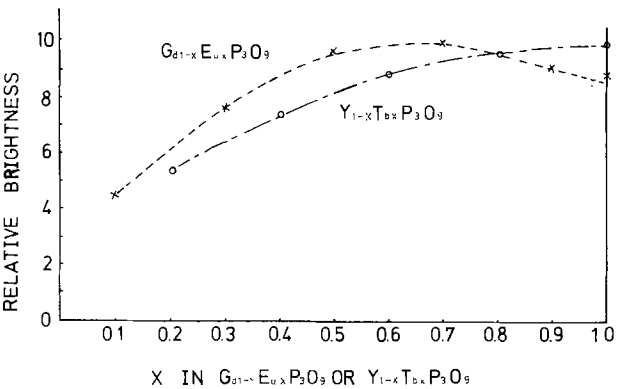

Fig. 6. Relative brightness of rare earth metaphosphate activated with Tb^{3+} or Eu^{3+} vs. activator concentration (254 nm excitation).

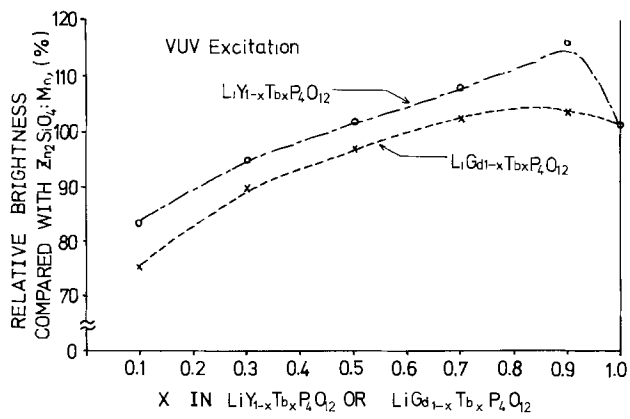

Fig. 7. Relative brightness of Tb^{3+} activated lithium rare earth metaphosphate compared with that of Zn_2SiO_4:Mn under v.u.v. excitation.

From the results in Fig. 5 one could expect the gradual variation of emission decay time. In Fig. 8 decay rates of $LiY_{1-x}Tb_xP_4O_{12}$ are given and a weak dependence on Tb^{3+} concentration is observed. These decay rates are affected by the sample preparation conditions rather than Tb^{3+} concentration. A low firing temperature for short period, *e.g.*, 750°C, 3 hr, results in a light brown coloration of samples and a decrease in decay time. The light brown body color suggests the existence of Tb^{4+} and this acts as an energy acceptor (12). The decay rates of colored $LiTbP_4O_{12}$ samples are shown in Fig. 8 by the vertical bar. Under the firing conditions of 750°C and 18 hr, $LiTbP_4O_{12}$ has a slight body color and shows the decay rate corresponding to the top of the bar in Fig. 8. Samples fired at higher temperature show longer decay times. These values of the samples fired at 850°C are given by the dashed curve in Fig. 8. At this temperature, however, samples tend to change to rare earth metaphosphates

Though not so obvious, $Gd_{1-x}Eu_xP_3O_9$ with orthorhombic structure shows a little concentration quenching, while $Y_{1-x}Tb_xP_3O_9$ with monoclinic structure indicates no quenching even at 100% Tb^{3+} replacement. This difference can be partially explained by the above-mentioned fact. The degree of quenching of Eu^{3+} emission is small compared with, for example, $La_{1-x}Nd_xP_3O_9$ (10) which is isomorphous with $Gd_{1-x}Eu_xP_3O_9$. This indicates that exchange coupling between Eu^{3+} ions is weak (11).

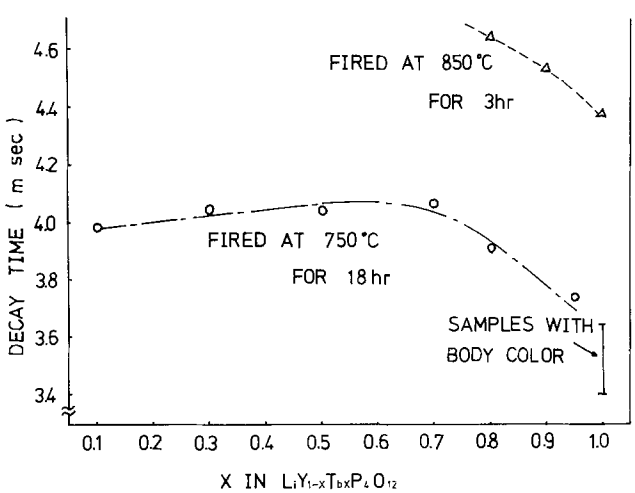

Fig. 8. Luminescence decay times of $LiY_{1-x}Tb_xP_4O_{12}$ when x is varied.

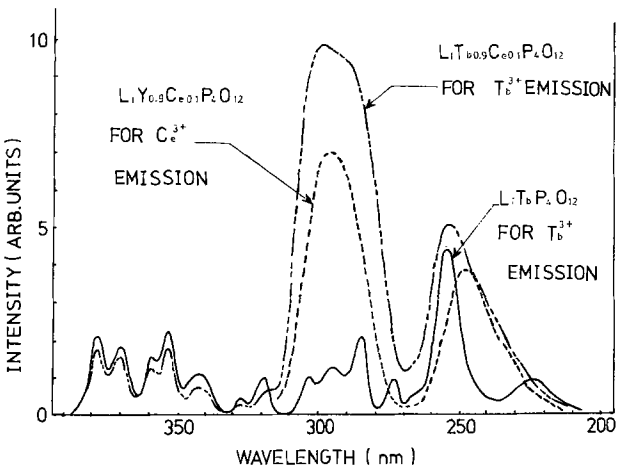

Fig. 9. Excitation spectra of Ce^{3+} emission in $LiY_{0.9}Ce_{0.1}P_4O_{12}$ and of Tb^{3+} emission in $LiTb_{0.9}Ce_{0.1}P_4O_{12}$ and $LiTbP_4O_{12}$.

with increasing Y^{3+} concentration, so data are taken only to the concentration of 20% Y^{3+}. The increase of decay rate is probably due to the decrease of some defects which acts as energy acceptor.

Sensitization.—It is well known that Tb^{3+} emission is enhanced by Ce^{3+} ion (13, 14). Even in $LiLnP_4O_{12}$ and LnP_3O_9, strong interaction between the d state of Ce^{3+} ion and the f state of Tb^{3+} ion compared with the interaction between f-f states of Tb^{3+} ions can be expected. In $LiTb_{1-x}Ce_xP_4O_{12}$ and $Tb_{1-x}Ce_xP_3O_9$, this sensitization was observed. In Fig. 9 three kinds of excitation spectra are shown for comparison. The solid curve is the already stated excitation spectrum of $LiTbP_4O_{12}$. When a portion of Tb^{3+} is replaced by Ce^{3+}, excitation intensity at about 300 nm increases greatly. This is given by the dot-dashed curve. Maximum enhancement is obtained at 5% Ce^{3+} replacement. The dashed curve is the excitation spectrum of $LiY_{0.9}Ce_{0.1}P_4O_{12}$ when a longer wavelength side of Ce^{3+} emission is monitored. As can be seen from these spectra, the excitation curve overlaps with that of Tb^{3+} emissions. This indicates efficient energy transfer from Ce^{3+} to Tb^{3+}. The same kind of excitation spectra were observed in $Tb_{1-x}Ce_xP_3O_9$.

Two broad excitation bands at 300 and 250 nm of Ce^{3+} emission in Fig. 9 can be attributed to the 4f-5d transitions of Ce^{3+} ions. These bands are assigned as the excitation from ground $^7F_{5/2}$ state to the $^5D_{5/2}$ and $^5D_{3/2}$ manifold.

To see how the energy transfer from Ce^{3+} to Tb^{3+} occurred, the relative intensity of Ce^{3+} emission under 254 nm excitation was compared when the Ce^{3+} concentration was fixed at 10% and the Tb^{3+} concentration was varied. The results are shown in Fig. 10 together with the excitation spectrum of Tb^{3+} emission of $LiTbP_4O_{12}$. The emission intensity of Ce^{3+} is, of course, decreased with increasing Tb^{3+} concentration, but its shape is not affected by the Tb^{3+} excitation spectrum, that is, by the absorption of Tb^{3+} ions. If there is radiation transfer, one would expect that in the emission spectrum of Ce^{3+} some dips at the location of Tb^{3+} absorption lines would appear together with the decrease of emission intensity. The results of Fig. 10 mean that the mechanism of energy transfer from Ce^{3+} to Tb^{3+} is of the nonradiative type (13).

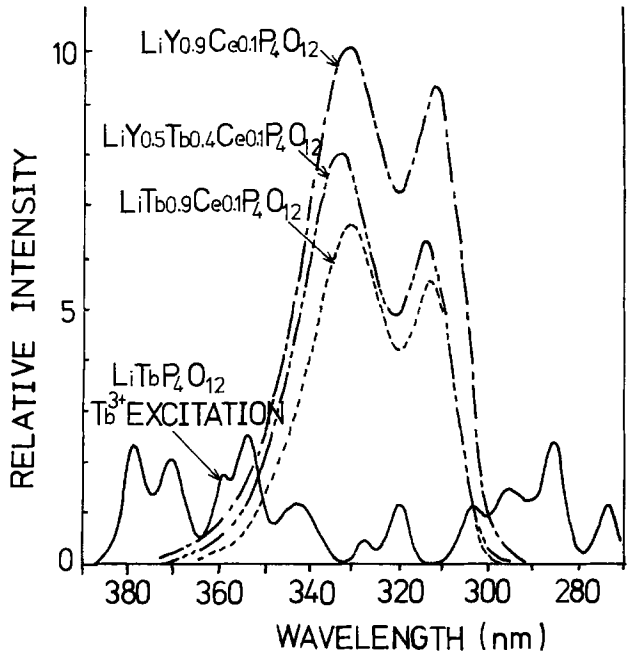

Fig. 10. Variation of intensity of Ce^{3+} emission in $LiY_{0.9-x}Tb_xCe_{0.1}P_4O_{12}$ when x is varied (254 nm excitation).

When Tb^{3+} was replaced by Eu^{3+} ion, the sensitization of Eu^{3+} emission by Ce^{3+} ion was not observed.

Liquid Crystal Alignment Produced by RF Plasma Deposited Films

G. J. Sprokel* and R. M. Gibson

IBM Research Division, San Jose, California 95193

ABSTRACT

Exposure of surfaces to the reaction products of an rf plasma induces specific aligning properties for smectic and nematic liquid crystals. Oxygen etched indium-tin oxide (ITO) films and surfaces on which SiO_2 or SnO_2 is deposited show strong parallel alignment. ITO surfaces exposed to a CF_4 plasma or surfaces on which a polyfluorocarbon film is deposited by a C_2F_4 plasma show strong perpendicular alignment.

Plasmachemistry has found application in many fields and a monograph on the subject is now available (1). In the semiconductor industry one application, photoresist "ashing," is now quite common (2). In principle the organic layer is oxidized in an O_2 rf plasma leaving a clean surface provided the resist is metal free (3). The method can be applied to transparent conducting films of indium-tin oxide (ITO) deposited on glass. It was found that such "oxidized" surfaces cause parallel alignment for cyanobiphenyls in particular if the sample is placed outside the plasma region avoiding surface damage by electron or ion bombardment. However, there is an undesirable side effect: The resistivity of the ITO film increased by one or two orders of magnitude. It was found that this can largely be overcome by exposure to a hydrogen plasma after the O_2 etching. Nevertheless the method is only applicable to ITO and glass surfaces. A method was developed to deposit SiO_2 or SnO_2 on almost any surface and it was found that such layers, although extremely thin, cause the same parallel orientation found for glass or ITO surfaces. In principle the deposition consists of establishing an O_2 plasma and introducing a sufficiently volatile organo-silicon or organo-tin compound in the plasma. Complete oxidation to SiO_2, that is, SnO_2, must be obtained and the oxides are carried by the gas stream onto the substrate. Again, the substrate is placed well outside the plasma region.

An rf plasma system operated in this way can also produce films which cause perpendicular alignment. Exposing glass or ITO surfaces to the fragments produced in a CF_4 plasma, mainly $F\cdot$ and $CF_3\cdot$, causes removal of Si and the resulting F-rich surface induces perpendicular alignment. Again the resistivity of ITO layers was found to increase but, as in the case of O_2 etching, the resistance can be reduced again by exposure to a H_2 plasma. For surfaces other than glass, a CF_4 plasma has little effect. However, if the CF_4 gas is replaced by C_2F_4 one can deposit a polyfluorocarbon film (4) which again causes perpendicular alignment for smectic or nematic alkylcyanobiphenyls. The oxide layers as well as the polymer layers conform to surface topology. They stick well and are stable in time. No long term change has been noticed in cells stored at 100°C.

Little prior literature exists on alignment by rf plasma polymerized films. Dubois *et al.* (5) found perpendicular alignment for films produced by glow discharge polymerization of hexamethyldisiloxane. The organo-silicon polymer is produced in the discharge region which usually leads to polymers which cannot be identified. The oxide films produced in the present work are essentially free of C-H bonds.

The subject of this paper is the production and characterization of oxide and polymer films which have strong aligning properties. The properties of the aligned liquid crystals have been discussed elsewhere (6). This separation is made possible by the nature of continuum theory which is essentially thermodynamic. The observed alignment is introduced as an energy term and does not require specification of the surface forces. Reference (6) can be summarized as follows: Data on the alignment are obtained by measuring the permittivity of the liquid crystal layer as a function of temperature while the sample is subjected to a strong magnetic field. One single compound, n-octylcyanobiphenyl, was used to compare the surface aligning effects. This compound is convenient because it is smectic A at room temperature and has a nematic phase between 32° and 40°C. In the smectic phase, the surface forces determine the alignment regardless of the previous history of the sample. In the nematic phase, if the magnetic field direction is parallel with the direction of the surface forces no additional alignment is observed. If the magnetic field is orthogonal to the direction of the surface forces, only incomplete alignment is obtained in the H direction. For parallel as well as for perpendicularly aligned cells the threshold is increased and the slope of the $\epsilon(H)$ curve near threshold is steeper. The energy stored in the liquid crystal layer in producing the alignment is of the same order of magnitude as the differential surface tension for cells up to 10 μm thick.

Plasma Deposited Layers

Table I summarizes the plasmas which have been used and the type of alignment caused by the deposited film. The plasma equipment is a modified Tegal (7) plasma-etcher. The pumping system was changed to avoid pump oil contamination and a manifold was made to mix gases outside of the system. Metalorganics are contained in vials which can be heated to obtain the desired vapor pressure. For SiO_2 deposition a number of silanes or siloxanes are suitable. Bis (dimethylamino) dimethylsilane (Silar No. 1420) has about the desired vapor pressure at room temperature. There are, however, many others which can be used. For SnO_2 deposition tetrabutyl tin was used as it affords better control than $Sn(CH_3)_4$. Gas pressures are in the 0.1-0.5 Torr range. Exposure time is ¼-½ hr; deposition rate 2-5 Å/min, film thickness 100Å.

Deposited films are analyzed by infrared and x-ray fluorescence (ESCA). All ESCA data were obtained by

Table I. Plasma conditions and liquid crystal alignment

Plasma		Substrate	Alignment
O_2	Etch	Glass, ITO	Parallel
O_2 + silane	Deposit	Glass, ITO, Cr/Au, Al	Parallel
O_2 + Sn (bu)$_4$	Deposit	Glass, ITO, Cr/Au, Al	Parallel
CF_4	Etch	Glass, ITO	Perpendicular
C_2F_4	Deposit	Glass, ITO, Cr/Au, Al	Perpendicular

* Electrochemical Society Active Member.

D. W. Rice of this laboratory. Infrared did not show hydrocarbons in oxide films supporting the contention that the oxide film is indeed SiO_2, that is, SnO_2, rather than a polymer. ITO films exposed to an O_2 plasma followed by CF_4 have approximately the composition $In_{0.22}Sn_{0.01}F_{0.24}O_{0.54}$ as calculated from ESCA data. Comparing this to the original stoichiometry, $In_{0.36}Sn_{0.03}O_{0.60}$ it is seen that the ratio O/In has increased from 1.67 to 2.45. The F/O ratio is 0.44, thus O is incorporated by the O_2 plasma and some of it is replaced by F during the CF_4 plasma. If ITO samples are exposed to a C_2F_4 plasma after a brief O_2 plasma etch, the ESCA spectra indicate a fluorocarbon surface with $^{-}CF_2$ and $^{-}CF_3$ peaks. Only traces of In^{III} are left even if the film is only approximately 50Å thick. CF_4 etched glass or ITO shows fluorine as F^{-}; the polyfluorocarbon film has covalent F exclusively. Since both surfaces cause the same type of alignment ionic interaction must be excluded Figure 1 shows the F^{-} peaks for CF_4 etched glass or ITO and the covalent F found in a film deposited by a C_2F_4 plasma Figure 2 shows the hydrocarbon on a ITO surface prepared by rf sputtering after a few weeks storage in a container but exposed to laboratory air. These CH_2 peaks disappear after O_2 etching. The top part of the figure shows the relative intensities of CF_2 and CF_3 peaks in a polyfluorocarbon film. Thus, in summary, it is seen that parallel aligning layers are oxides such as SiO_2, SnO_2, or In_2O_3. Perpendicular alignment is obtained by using polyfluorocarbon films or F-rich ITO or glass. Other oxides have not been investigated. Cells are usually completed and filled shortly after the aligning layers have been deposited, however, storing the substrates at this state has not shown adverse effects. Completed cells have been aged at 80°C for several months without change in alignment.

Permittivity Measurements

Permittivity is the ratio of the capacitance of the filled cell to that of the empty cell, both corrected for stray capacitance. The capacitance is measured by a gain-phase technique rather than a standard R-C bridge. The stray capacitance can be kept to a minimum and data can be obtained over an extended range of frequencies. It has been shown (8) that a liquid crystal cell can be represented by a parallel R-C circuit only in the middle of the audio range. At very low frequencies the electrode space charge causes the cell to resemble a series circuit C_s-R, where C_s is much larger than the capacitance of the liquid crystal layer. In addition, aligning layers are blocking layers and cause phase shift. Such cells are best represented by two R-C circuits in series. The time constants are quite different and one can separate the effects by taking data over a wide frequency range. Cells prepared by oxygenation or fluoridation of ITO behave as series R-C circuits where R represents the resistance of the layer rather than the cell. Again one can separate the contributions from gain-phase data taken over a wide frequency range.

Figure 3 shows the measuring circuit and an exploded view of the cell. The cell, represented by R_1C_1 is placed in a double-walled thermostat. A strip heater between the walls and an external control circuit regulates the cell temperature to about 0.05°C between 25° and 150°C. One side of the cell is connected to a low impedance audio oscillator, the other to a fast operational amplifier connected as source follower. R_2 is a standard resistor in the range of 10 kΩ to 1 MΩ. C_2 represents the stray capacitance, a small standard capacitor is sometimes added. The circuitry is packaged in a rectangular aluminum box which fits between the

poles of a 12 in. Varian magnet. The operational amplifier compartment can be cooled with dry nitrogen.

The phase shift in the operational amplifier can be neglected for frequencies up to 500 kHz. The gain and phase for the series circuit R_1C_1-R_2C_2 is determined by

$$\frac{V_o}{V_i} = \left| \frac{Z_2}{Z_1 + Z_2} \right| \exp j(\omega t + \phi) \qquad [1]$$

The experiment yields data for the phase angle ϕ and the gain q at the measuring frequency

$$q = \left| \frac{V_o}{V_i} \right| = \left| \frac{Z_2}{Z_1 + Z_2} \right| \qquad [2]$$

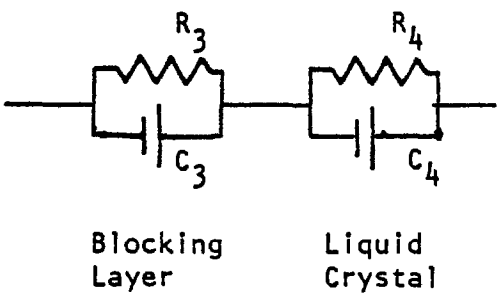
From Eq. [1] and [2] an explicit form for the cell parameters is obtained

$$X_1 = \omega R_1 C_1 = \frac{1}{q_o} \cdot \frac{q}{\sin\phi} - \frac{1}{tg\phi} \qquad [3]$$

where

$$q_o = \frac{R_2}{R_1 + R_2} \qquad [4]$$

As stated above, in general q_o cannot be obtained from d-c measurements. In a frequency range where R_1 and C_1 are independent of frequency, q_o is calculated from



$$\frac{1}{q_o} = \frac{\frac{1}{\nu_1} \cdot \frac{1}{tg\phi_1} - \frac{1}{\nu_2} \cdot \frac{1}{tg\phi_2}}{\frac{q_1}{\nu_1 \sin\phi_1} - \frac{q_2}{\nu_2 \sin\phi_2}} \qquad [5]$$

where the indexes refer to the two frequencies. For hand calculation it is advantageous to choose the frequency ratio large, say $\nu_2/\nu_1 > 50$. Then the low frequency data dominate and Eq. [5] simplifies to

$$\frac{1}{q_o} \approx \frac{\cos\phi_1}{q_1} \qquad [6]$$

For computer calculations the simplification is immaterial.

For high resistivity liquid crystal material ($\rho \approx 10^{11}$ Ω-cm) and cells with metal electrodes q_o is constant down to a few hertz. For cells with blocking layers q_o decreases with frequency below about 200 Hz depending on the thickness of the blocking layer and the permittivity of the liquid crystal material. Cells with blocking layers must be represented by two R-C circuits:

This readily converts to a single parallel R-C circuit but the resulting parameters R and C are now frequency dependent. If the index 3 represents the blocking layer and 4 the liquid crystal, R_1 in Fig. 3 is now determined by

$$R_1 = R_4 \cdot \frac{\left(\frac{R_3 + R_4}{R_4}\right)^2 + X_4^2 \left(\frac{R_3}{R_4} + \frac{X_3}{X_4}\right)^2}{\frac{R_3 + R_4}{R_4} + X_4^2 \left(\frac{R_3}{R_4} + \left(\frac{X_3}{X_4}\right)^2\right)} \qquad [7]$$

For $\omega \to 0$, $R_1 \approx R_3 + R_4$. For $X_3 >> \frac{R_3 + R_4}{R_4}$, $R_1 \approx R_4$ since $C_3/C_4 >> 1$.

Experimentally R_3 and R_4 are of the same order of magnitude although the blocking layer is much less than 1% of the cell thickness. Thus R_1 in Eq. [4] starts to increase at the frequency where X_3 is of the order of unity. Permittivity data for cells with blocking layers are obtained in a frequency range such that the calculated R and C change by less than 1% over the range. Then the low frequency data are used to calculate the resistance of the blocking layers. An abnormally low value usually indicates pinholes. The resistivity of oxide blocking layers is at least 10^{12} Ω-cm; fluorocarbon films usually have higher resistivities.

Finally, for completeness, Eq. [8] and [9] list the empty cell capacitance and the stray capacitance

$$\omega R_2 C_0 = \frac{q}{\sin\phi} \qquad [8]$$

$$\omega R_2 C_s = \frac{1}{tg\phi} - \frac{q}{\sin\phi} \qquad [9]$$

R_2 is the standard resistor, C_0 the capacitance of the empty cell, C_s the total stray capacitance at the junction. C_0 is about 50 pF for 10 μm cells. C_s is about 10 pF including the input capacitance of the operational amplifier.

Electrical Effects of Plasma Etching of ITO

As was shown above, exposure of ITO to the products of an oxygen or CF_4 plasma leads to incorporation of O and F in the ITO layer. This has a profound effect on the resistivity of the film. Figure 4 shows the increase in resistivity of a number of test samples after exposure to a pure O_2 plasma. As before the sample is downstream from the plasma and not subjected to ion bombardment. Test samples are prepared by photolithography from rf sputtered ITO coatings 700-1000Å thick. The test pattern is a stripe, 1 × 0.050 in., with the usual four contacts. The sheet resistance of the coating is 0.5-1.5 kΩ/sq. Each data point in Fig. 4 represents one test sample. The ratio of the sheet resistance after exposure and the original resistance is plotted *vs.* the exposure time. Notice that for short exposure times, say up to 30 min, the data agree reasonably well but for longer exposure time there is considerable deviation. This is probably caused by

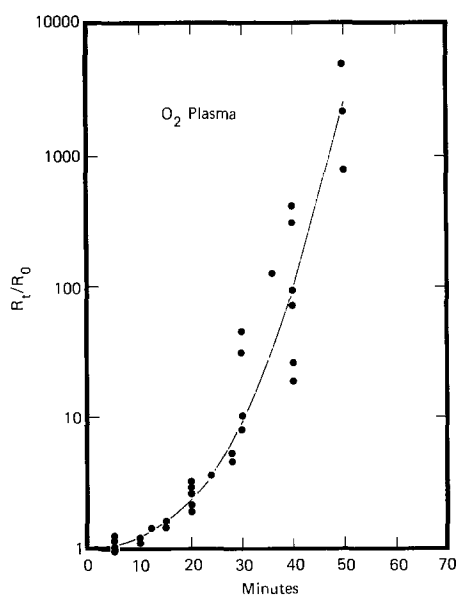


Fig. 4. Increase in sheet resistance vs. exposure time to an O_2 plasma. Each data point represents one sample.

thickness variations along the stripe. (30 min is enough to obtain alignment.)

It is generally assumed that Sn^{IV} acts as a donor center in the oxide semiconductor In_2O_3 (9). Thus, oxygen incorporated in the film removes donor centers or acts as a trap. Assuming that the decrease in carrier concentration is proportional to the increase in oxygen one can regard the process as oxygen diffusion and calculate the diffusion coefficient of O into the ITO film. Numerical values for D calculated from data in Fig. 4 are $D = 3\text{-}8 \times 10^{-15}$ cm^2 sec^{-1}. The process is likely to be more complicated than simple diffusion but the accuracy of the data does not permit evaluation of a two-parameter model. The numerical value for D is about the same as that for P diffusion in silicon at 1000°C. The inverse process is exemplified in Fig. 5. Exposure to forming gas plasma (95% N_2, 5% H_2) removes bound oxygen and creates new carriers. Thus the sheet resistance can be reduced to approximately the starting value and this will not affect the aligning properties of the surface.

Alignment by ITO Films

The alignment produced by oxide or polyfluorocarbon films has been discussed elsewhere (6). In this section we compare the alignment produced by O_2 etched ITO films and that obtained if the O_2 exposure is followed by reduction in a H_2 plasma. Figures 6 and 7 list the observed permittivity of n-octylcyanobiphenyl as a function of temperature while the sample is held in a magnetic field aligned parallel with the surface-induced orientation or orthogonal to it. Figure 6 refers to a cell after exposure to an O_2 plasma. Figure 7 shows data for a cell exposed to a H_2 plasma after the O_2 treatment. In the smectic phase both samples are aligned parallel to the electrode surface, $\epsilon_1 \approx 5.1$. If the sample is heated without a magnetic field or with a 14 kG field directed parallel to the surface, ϵ changes slowly and continuously with temperature until the transition to isotropic is reached. In particular there is no discontinuity at 32°C, the SmA → N transition temperature. Thus the alignment remains controlled by the surface throughout the nematic phase and a magnetic field does not cause additional alignment. If the sample is heated in a magnetic field orthogonal to the surface-induced alignment, a sharp increase in ϵ occurs at 32°C and ϵ is about 10 throughout the nematic region. In the isotropic phase ϵ decreases to the same value as before. Figures 6 and 7 are almost identical and it is concluded that exposure to H_2 plasma does not change the surface alignment. At this stage of knowledge these results cannot be taken for granted, *e.g.*, exposure to CF_4 would have produced a perpendicularly aligned cell.

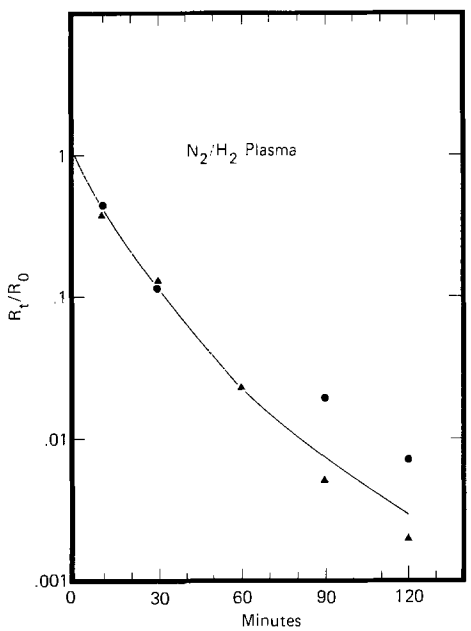

Fig. 5. Decrease in sheet resistance vs. exposure time to an N_2/H_2 plasma. Data points represent two samples previously exposed to an O_2 plasma.

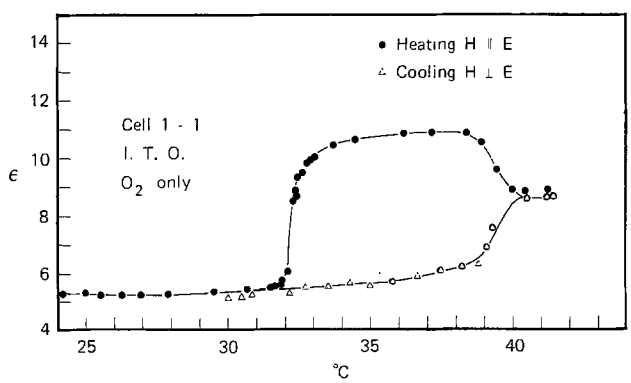

Fig. 6. Permittivity vs. temperature for OCBP in a cell having ITO electrodes exposed to an O_2 plasma for 20 min.

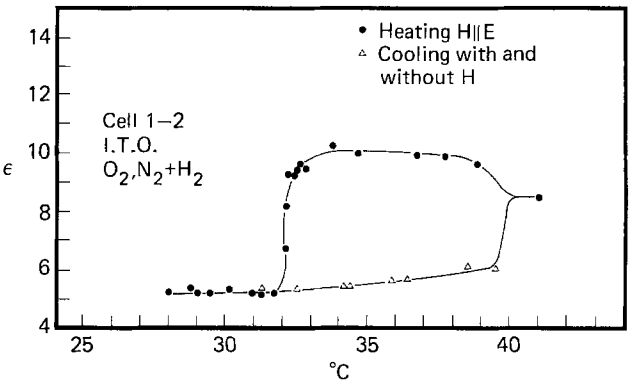

Fig. 7. Permittivity vs. temperature for OCBP in a cell having ITO electrodes exposed to O_2 plasma followed by exposure to N_2/H_2 plasma for 30 min.

Summary

Plasma etching and deposition techniques can be used to obtain aligned liquid crystal cells. Oxygen etched glass or ITO surfaces, and surfaces on which SiO_2 or SnO_2 is deposited show strong parallel alignment. Glass or ITO surfaces exposed to CF_4 plasma or surfaces on which a polyfluorocarbon film is deposited by a C_2F_4 plasma show strong perpendicular alignment. The alignment is permanent and the cells can be temperature cycled at will without changing the original alignment. The composition of the surface layer was studied using electron spectroscopy (XPS). The electrical characteristics of the deposited films were obtained by R-C measurement.

Acknowledgment

We thank D. W. Rice of this laboratory for the surface analysis by ESCA and Vance Hoffman of Varian for preparing the ITO films.

Analysis of Transport Processes in Vertical Cylinder Epitaxy Reactors

C. W. Manke* and L. F. Donaghey**

Materials and Molecular Research Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Momentum, heat and mass transfer processes were studied in a vertical cylinder reactor for the epitaxial growth of Si from $SiCl_4$ in H_2 by chemical vapor deposition. An analytical solution to the problems of heat and mass transfer in a tapered annulus is presented based on constant transport properties and fully developed laminar flow. The mean gas-phase temperature and deposition rate distribution of silicon are calculated within the reactor using a developing temperature model. Results of experimental studies of silicon deposition from $SiCl_4$ in H_2 at 1200°C in a vertical cylinder reactor are compared with the analytical results and with other models of diffusion-controlled chemical vapor deposition. This study provides an analytical method for calculating epitaxial deposition rate distributions in vertical cylinder reactors, and for designing reactors to improve the yield and uniformity of epitaxial growth.

Vertical cylinder (barrel) reactors have been developed recently for the epitaxial growth of semiconductor layers by chemical vapor deposition (CVD). This type of reactor has already demonstrated the potential for scale-up of the epitaxial growth process. The increased throughput of the vertical cylinder reactor as compared to the horizontal reactor is particularly important in the semiconductor industry where high volumes of silicon bipolar devices are involved.

Growth rate uniformity of epitaxial silicon by CVD is of great importance for semiconductor applications. The yield of finished devices is sharply diminished by nonuniformity of the thickness of the epitaxial silicon layer either on the individual wafers or from wafer to wafer within the processing batch. Growth rate uniformity, of course, must be accomplished using an economical quantity of reactant gas. Successful processing, therefore, requires the development of reactor design principles for achieving optimum growth rate uniformity at reasonable reactant flow rates. The development of mathematical models for the description of transport processes and the deposition rate distribution of silicon in the vertical cylinder reactor is examined in this paper.

Models for the CVD rate of silicon have been studied by a number of investigators. Eversteyn and coworkers (1, 2) and Rundle (3, 4) have developed models for the growth rate of silicon in horizontal reactors based on diffusion through a laminar sublayer adjacent to the susceptor, and on diffusion in a fully developed laminar flow, respectively. Fujii *et al.* (5) developed a quantitative model of silicon deposition rates in vertical cylinder reactors, and quantitative studies were reported by Dittman (6).

In the above works, the gas temperature profile was considered to be constant over the entire length of the reactor. In a real reactor, however, the temperature, velocity, and concentration profiles can be expected to change rapidly in the entrance region near the leading edge of the constant-temperature susceptor before achieving the constant, or fully developed distributions assumed by the above models.

Several of the above models recognize the need for incorporating boundary layer theory into a growth rate model. For example, Eversteyn assumes a boundary layer thickness equal to a fraction of the channel width. Dittman used a modified form of the Chilton-Colburn analogy to obtain properties of boundary layer flow over a flat plate. Unfortunately, the geometry and transport phenomena of the vertical cylinder reactor are not well described by either of these models. It is shown in this paper that mass transfer analogies based on turbulent flow over a flat plate do not give a satisfactory prediction of the silicon growth rate in the vertical cylinder reactor, and that what is needed is a method for predicting the growth rate based on the theory of developing heat and mass transport in the laminar flow regime, the Graetz problem in an annular passage.

Important theoretical methods for assessing transport in a fluid in fully developed laminar flow can be found in the fluid mechanics literature. Graetz (7) solved the problem of developing heat transfer in tubes by means of an eigenfunction expansion. Nusselt (8) improved the accuracy of Graetz's calculation of the first three eigenvalues. Brown (9) solved the Graetz problem in a flat duct, and the extension to a right circular annulus has been studied by Hatton and Quarmby (10), and by Reynolds and co-workers (11, 12).

In this paper, a solution to the Graetz problem of heat transfer in an annular passage is used to demonstrate that the mean gas temperature in the vertical cylinder reactor increases with distance over a significant portion of the axial susceptor length, and that a fully developed temperature profile is not attained under typical operating conditions for silicon deposition. Mass transfer is shown to have a positive temperature dependence resulting in enhancement of the growth rate as temperature increases. A method for calculating the growth rate is presented which takes into account the effects of the developing heat and mass transfer

profiles in the annular passage. The method is used to study the effects of gas flow rate and susceptor tilt angle on growth rate uniformity and reactant yield. Finally, growth rate calculations are compared to those predicted by other published models and to experimental results obtained in a commercial vertical cylinder reactor.

Theory

The vertical cylinder reactor.—For silicon epitaxial growth from $SiCl_4$, a dilute mixture of $SiCl_4$ in hydrogen is passed through an annular passage between a cylindrical outer quartz wall of the reactor and an octagonal silicon carbide-coated, graphite susceptor, idealized here as the frustrum of a cone or, in the limit of a constant inner radius, a right-circular cylinder. The vertical cylinder reactor is shown schematically in Fig. 1.

In the vertical cylinder reactor studied here, silicon substrate wafers are placed on the faces of a graphite susceptor which is radiantly heated by quartz lamps placed outside a forced air-cooled quartz cylinder which is the outer wall of the reactor. Typical operating conditions for silicon epitaxial growth from $SiCl_4$ are a susceptor temperature near 1200°C, a reactant gas mixture containing about 1% $SiCl_4$ in hydrogen, and a flow rate yielding Reynolds numbers of order 10^2. Under those conditions the fluid is in laminar flow. Shaw (13) reports that the temperature at which mass transfer control of the growth rate predominates over kinetic control is not precisely known; however, several experimental studies indicate that deposition of epitaxial silicon from a dilute $SiCl_4$ reactant is entirely diffusion controlled at 1200°C. The silicon deposition reaction is surface-catalyzed and therefore occurs only at the surface of the heated susceptor. Silicon deposition occurs on all parts of the susceptor surface. Calculation of the growth rate, then, is a matter of determining the rate of mass transfer of the reactant from the gas stream to the susceptor surface. Since the mass transfer rate is dependent on the velocity and temperature distributions in the gas phase, equations governing all three transport phenomena must be considered.

Transport equations.—The steady-state equations governing transport are the following.[1]

1. The momentum equation in the axial direction

$$\rho V_r \frac{\partial V_z}{\partial r} + \rho V_z \frac{\partial V_z}{\partial z} = -\frac{\partial p}{\partial z} + \rho g_z + \mu \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial V_z}{\partial r}\right) \quad [1]$$

2. The energy equation in the axial direction

$$V_r \frac{\partial T}{\partial r} + V_z \frac{\partial T}{\partial z} = \alpha \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T}{\partial r}\right) \quad [2]$$

3. The equation for continuity of the diffusing species, in the axial direction

$$V_r \frac{\partial X}{\partial r} + V_z \frac{\partial X}{\partial z} = \mathcal{D} \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial X}{\partial r}\right)$$

4. The equation of continuity

$$\frac{1}{r}\frac{\partial}{\partial r}(\rho r V_r) + \frac{\partial}{\partial z}(\rho V_z) = 0 \quad [3]$$

The fluid physical properties in the above equations, μ, ρ, α, and $\mathcal{D}$, are assumed to be constant, a necessary condition for a simplified analytical treatment.

The radial velocity distribution for fully developed laminar flow is the solution to Eq. [1]. In a cylindrical annulus the solution has the form

[1] Variables are defined in the list of symbols at the end of the paper.

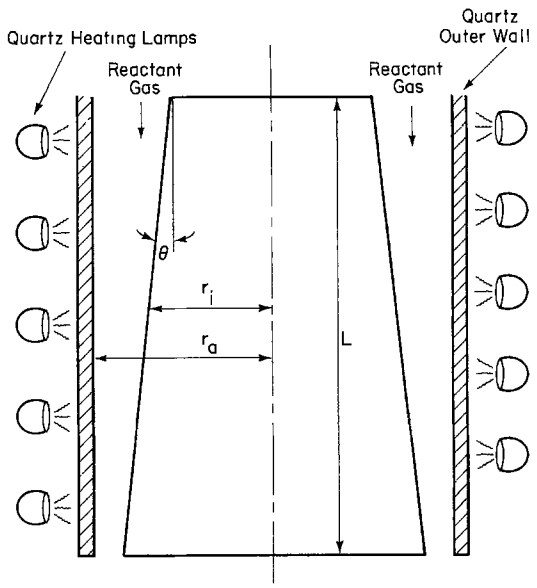

Fig. 1. The vertical cylinder reactor

$$U(\bar{r}) = \frac{2U_m}{A}(1 - \bar{r}^2 + B\ln\bar{r}) \quad [5]$$

where A and B are constants. The buoyancy term, g_z, of Eq. [1] is neglected in deriving Eq. [5]; this assumption leads to a small error at the susceptor leading edge where a large thermal gradient is present, but the omission of the buoyancy term is a simplification necessary for analytical treatment. The condition of stable, fully developed laminar flow in the reactor is the basis for the following mathematical description of transport processes.

The following dimensionless parameters are useful in reducing the transport equations to simple forms

$$\bar{r} = r/r_o$$

$$\theta(\bar{x}) = \frac{T - T_i}{T_e - T_i}, \quad \bar{x} = \frac{z}{\mathrm{Re\,Pr}\,d_h} \quad [6]$$

$$\chi(\bar{z}) = \frac{X - X_i}{X_e - X_i}, \quad \bar{z} = \frac{z}{\mathrm{Re\,Sc}\,d_h}$$

In addition, it is useful to define the bulk-mean reduced temperature and reactant mole fraction as follows

$$\theta_m = (AU_m)^{-1}\int_A U\theta\,dA$$

$$\chi_m = (AU_m)^{-1}\int_A U\chi\,dA \quad [7]$$

where the integral is over the cross-sectional area of the annulus at a given axial position.

For fully developed velocity, the energy equation, Eq. [2], can be reduced to the following dimensionless temperature equation

$$\frac{\partial^2\theta}{\partial\bar{r}^2} + \frac{1}{\bar{r}}\frac{\partial\theta}{\partial\bar{r}} = \frac{U(\bar{r})}{\alpha}\frac{\partial\theta}{\partial\bar{x}} \quad [8]$$

Using the dimensionless mole fraction defined above, the reactant mass continuity equation can be reduced to a similar form

$$\frac{\partial^2\chi}{\partial\bar{r}^2} + \frac{1}{\bar{r}}\frac{\partial\chi}{\partial\bar{r}} = \frac{U(\bar{r})}{\mathcal{D}}\frac{\partial\chi}{\partial\bar{z}} \quad [9]$$

The boundary value problems for solving Eq. [8] and [9] can be made homogeneous by subtracting the fully developed solutions which are valid as $\bar{x}$ and $\bar{z}$

tend to infinity. The complete solutions to Eq. [8] and [9] can then be solved by separation of variables in the form

$$\theta = \theta_{fd} + \sum_{n=0}^{\infty} C_n F_n \exp(-\lambda_n \bar{x}) \quad [10]$$

where the functions F_n satisfy a differential equation of the Sturm-Liouville type.

Solution of the transport equations for developing flow is a difficult problem. Reynolds, McCuen, and Lundberg (11, 12) have obtained solutions for the coefficients C_n by numerical integration using an iterative method developed by Berry and de Prima (14). As a result of their work, θ_m and the Nusselt number, Nu, (and by analogy χ_m and Sh for mass transfer) can be obtained for several types of boundary conditions in an annular passage. These functions will be used in a differential expression for material balance to calculate the growth rate of silicon in the vertical cylinder reactor, taking into account the effects of developing heat and mass transfer in a fully developed velocity distribution.

Boundary conditions and initial values.—Heat transfer.—Heating of the susceptor in the vertical cylinder reactor is typically achieved with rf or quartz-iodide lamp heating, which hold the entire susceptor at a constant temperature. The outer quartz wall is air-cooled but subject to radiant heating from the hot susceptor (and from the quartz lamps) as well as to convective heating both inside and outside the reactor. As a result the boundary condition at this wall is quite difficult to determine. Experimental measurements of the outer wall temperature indicate that the quartz wall reaches a temperature near 500°C over the major portion of the wall (15). Therefore the temperature boundary condition can be approximated by assuming the entire outer wall to be at a constant temperature of 773°K. Thus

$$T = \begin{cases} 1473°K, \ r = r_i, \ 0 < z & [11] \\ 773°K, \ r = r_o, \ 0 < z & [12] \end{cases}$$

Since the gas enters the reactor at room temperature, the initial value is taken as 298°K.

For the boundary conditions of specified temperatures at both walls of the annulus, the mean temperature of the gas at a downstream location is determined from dimensionless temperature functions according to the following equation

$$T_m(\bar{x}) = T_e + \theta_{mi}(\bar{x}) \cdot (T_i - T_e) + \theta_{mo}(\bar{x}) \cdot (T_o - T_e) \quad [13]$$

Mass transfer.—The boundary condition for mass transfer at the susceptor surface is specified by chemical reaction equilibria at the temperature of the susceptor, since for susceptor temperatures near 1473°K the growth rate is limited by diffusion rather than by the kinetics of the surface reactions. The deposition reaction is

$$SiCl_4 + 2H_2 = Si_{(c)} + 4HCl \quad [14]$$

In addition, other gas phase species are formed by reactions such as

$$SiCl_4 + H_2 = SiCl_3H + HCl \quad [15]$$

$$SiCl_4 + H_2 = SiCl_2 + 2HCl \quad [16]$$

Sirtl, Hunt, and Sawyer (16) indicate that other species are negligible. A very low partial pressure of $SiCl_4$ (10^{-5}) exists in the equilibrium composition at 1473°K for the Si-H-Cl system at low values of the Cl/H ratio (0.02327 for 1.15% $SiCl_4$ in H_2). Since the driving force for diffusion of the reactant to the susceptor surface is the difference between the partial pressure in the bulk gas stream (10^{-2}) and the partial pressure at the susceptor surface (10^{-5}), the boundary condition for mass transfer at the inner surface can be approximated very well by taking the reactant concentration to be zero. Since deposition does not occur at the outer wall, a flux equal to zero is specified. The boundary conditions for mass transfer are then

$$X = 0, \ r = r_i, \ z > 0 \quad [17]$$

$$\frac{dX}{dr} = 0, \ r = r_o, \ z > 0 \quad [18]$$

For an inlet gas containing 1.15% (volume) $SiCl_4$, the initial condition is

$$X = 0.0115 \text{ at } z = 0 \text{ and } r_i \leq r \leq r_o \quad [19]$$

Thermodynamic yield from reactant gas.—While Eq. [14] is the principal reaction for silicon deposition, the gas species $SiCl_3H$ and $SiCl_2$ will also be formed in an equilibrium mixture by the competing side reactions given in Eq. [15] and [16]. The yield of epitaxial silicon produced from the reactant diffusing to the susceptor will be reduced if these as well as other species are formed in significant quantities. Sirtl *et al.* report the equilibrium yield of solid silicon from $SiCl_4$ as a function of the $SiCl_4$ mole fraction. For a $SiCl_4$ mole fraction of 0.0115 and a temperature of 1473°K, the yield of silicon is approximately 70% (16). To account for the reduction in deposition efficiency caused by the side reactions forming vapor species other than $SiCl_4$, HCl, or H_2, the fluxes of $SiCl_4$ to the susceptor surface must be multiplied by the deposition efficiency, η, to obtain the yield of deposited silicon from the reactant gas. Since reaction kinetics are assumed to be very fast at the temperature of the susceptor, 1473°K, the deposition efficiency used in this study is the equilibrium yield for a $SiCl_4$ mole fraction of 0.0115, which is 0.70.

Growth rate equation.—The dependence of the growth rate on axial distance can be easily developed by taking a material balance on a differential ring element of the reactor annulus. The molar flow rates of reactant entering and leaving the element are $\dot{M}\bar{X}|_z$ and $\dot{M}\bar{X}|_{z+\Delta z}$, respectively. The molar flux to the susceptor surface of a differential element $2\pi r_i \Delta z$ is

$$2\pi r_i \Delta z \, Sh \frac{\mathcal{D}}{d_h} (\bar{X} - X_i) p/(RT_m) \quad [20]$$

where $X_i = 0$. By balancing the above rates one obtains the differential equation for the reactant concentration

$$-\dot{M} \frac{d\bar{X}}{dz} = \frac{p 2\pi r_i \, Sh \, \mathcal{D}}{d_h RT_m} \bar{X} \quad [21]$$

After integration this equation becomes

$$\bar{X} = X_o \exp\left\{ -\frac{2\pi p}{\dot{M}R} \int_0^z \frac{r_i \, Sh \, \mathcal{D}}{d_h T_m} dz \right\} \quad [22]$$

The flux to the surface is then given by

$$\frac{p}{RT_m} \mathcal{D} \frac{d\bar{X}}{dr}\bigg|_{r=r_i} = \frac{p}{RT_m} Sh \frac{\mathcal{D}}{d_h} (\bar{X} - X_i) \quad [23]$$

From Eq. [22] and [23] and the deposition efficiency, η, the linear growth rate expression in μm/min becomes

$$G = 6 \times 10^5 \frac{M_{Si}}{\rho_{Si}} \frac{p \, Sh \, \mathcal{D} \eta}{RT_m d_h} X_o \exp\left\{ -\frac{2\pi p}{\dot{M}R} \int_0^z \frac{r_i \, Sh \, \mathcal{D}}{d_h T_m} dz \right\} \quad [24]$$

Equation [24] can be used together with values of Sh and T_m resulting from the solution of the transport equations to predict the variation of growth rate with axial position in the reactor.

Transport properties.—Transport properties are functions of both temperature and composition. Since these properties are taken to be constants in the transport equations, however, they must be evaluated at a composition and temperature representative of average conditions in the reactor. Since the reactant mixture is dilute, the choice of the inlet composition for evaluation of properties should not lead to significant errors. A simple choice of a representative temperature is the mean cross-sectional temperature, T_m, from Eq. [13], with reduced distance, $\overline{X}$ evaluated using transport properties at the inlet temperature. The length-averaged value of T_m can then be calculated and used as the representative temperature for evaluation of mean transport properties.

Transport properties evaluated for the composition of the inlet gas containing 1.15% $SiCl_4$ and 98.85% H_2 on a molar basis are summarized in Table I. For heat transfer, the viscosity, density, thermal conductivity, and heat capacity of the above mixture are evaluated at 298°K. An important result of the evaluation of properties for heat transfer is that the Prandtl number for the mixture is 0.44 at 298°K, much lower than the value of 0.7 usually found for pure gases. For the growth rate equation, properties are evaluated at average temperatures which were determined from the results of the heat transfer calculation. Viscosity, density, and the diffusion coefficient are given at different temperatures in Table I.

Equations used to determine the values of transport properties were obtained from experimental data and from Reid and Sherwood (17). A complete description of the evaluation methods for transport properties is given in the Appendix.

Temperature dependence of the growth rate.—The temperature dependence of the transport coefficients can be utilized to estimate the dependence of the growth rate on temperature. As explained in the Appendix, the diffusion coefficient for $SiCl_4$ in H_2 is calculated by the equation

$$\mathcal{D} = 7.0861 \times 10^{-9} T^{3/2} \Omega_o^{-1} p^{-1} \qquad [25]$$

The approximate temperature dependence of the diffusion coefficient in the temperature range of interest is $T^{1.674}$. If the effect of the exponential term in Eq. [22], the reactant depletion term, is neglected, the temperature dependence of the growth rate equation, Eq. [24], is $T^{0.674}$. The growth rate will therefore be enhanced as the temperature increases. A limit to this increase is established by thermodynamic conditions, however, since the amount of $SiCl_3H$, $SiCl_2$, and other species in the vapor phase increase with temperature, causing the thermodynamic yield to reach a maximum at about 1430°K.

Results and Discussion

Flow regime.—The range of Reynolds numbers for the operating conditions considered in this study is from 50 to 500. Bird *et al.* (18) indicate that laminar flow will prevail in annular passages for Reynolds numbers less than 2000. Flow instability in the presence of a large thermal gradient can occur even in laminar flow, however. Curtis and Dismukes (19) and Fujii *et al.* (5) discuss this possibility and conclude that flow instabilities do not occur for hydrogen-rich systems under the conditions for epitaxial silicon deposition.

Temperature variation along the susceptor.—The variation of the mean temperature of the gas as a function of the axial position along the susceptor is shown in Fig. 2, for a pressure of 1 atm (101.325 kPa) and Reynolds numbers of 50, 100, 250, and 500 at 1 atm, and for an initial gas temperature of 298°K. All of the curves in Fig. 2 show the characteristics of developing heat transfer. In a region near the leading edge of the susceptor, the temperature of the gas increases very rapidly with distance. The rate of increase of temperature with distance becomes more gradual at increasing distances from the leading edge. As shown in Fig. 2, the axial mean temperature gradient becomes small, corresponding to the approach of the fully developed temperature distribution, only for low Re numbers and large axial distances. For the barrel reactor in the present study, the fully developed value of the mean temperature is 1088°K. The calculated mean temperature of the gas is less than 90% of the fully developed value on the first 10 cm of the susceptor at Re = 50, and on the first 20 cm of the susceptor at Re = 100. For Reynolds numbers of 250 and 500, the mean temperature is well below the fully developed value on the entire 40 cm length of the susceptor. As these results indicate, entry region temperature development occurs over a significant portion of the susceptor at Reynolds numbers greater than 50. Since the growth rate is roughly proportional to $T^{0.674}$, the effects of axial temperature variation on growth rate are expected to be large.

Qualitative effects of entry region temperature development on growth rate.—Because of the positive temperature dependence of the growth rate, entry region temperature development can be expected to affect the growth rate in three important ways:

1. Over-all growth rates will be lower than those predicted by theories which consider temperature to be at the maximum, fully developed value.
2. Lower than average temperatures at upstream positions and higher than average temperatures at downstream locations will enhance deposition on the downstream portion of the susceptor, partially compensating for the negative effect of reactant depletion on growth rate. Deposition will therefore be more uniform than predicted by growth rate models which evaluate gas temperature at the fully developed value or a constant length averaged value.

Table I. Transport coefficients for a reactant mixture of 1.15% $SiCl_4$-98.85% H_2

T (°K)	μ_{mix} (μ-poise)	ρ (g/m^3)	$\mathcal{D}$ (m^2/sec) × 10^4	Sc
298	97.9	1.511		
592	161.1	0.7606	1.162	1.823
726	187.0	0.6202	1.648	1.830
912	219.5	0.4937	2.426	1.833
997	2337.0	0.4516	2.818	1.836

Molecular weight of mixture: 3.695.
Thermal conductivity of mixture at 298°K = 0.38 J/(m-sec °K).
Heat capacity of mixture at 298°K = 29.45 J/(g-mol °K).
Pr at 298°K = 0.44.

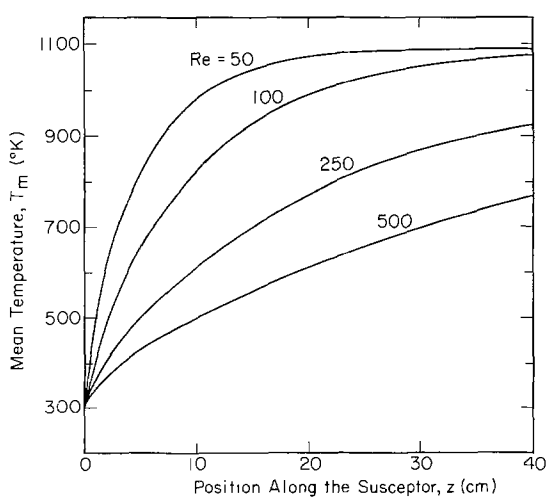

Fig. 2. Variation of the mean temperature of the gas with position along the susceptor.

3. In spite of the decrease in reactant depletion with increased velocity, the over-all growth rate should reach a maximum value as velocity is increased and then decrease with further increases in velocity due to the decrease in average gas temperature. These three effects are discussed further as quantitative growth rate expressions and experimental results are presented.

A constant temperature method for growth rate calculation.—Because of the similarity between the heat and mass transfer equations discussed in the theory section, the dimensionless heat transfer solutions of Reynolds *et al.* (11, 12) can be applied directly in the calculation of the growth rate using Eq. [24]. With this analogy, developing mass transfer rates in the annular passage are determined subject to the conditions of laminar flow, constant fluid and transport properties, and a fully developed velocity field. Results are shown in Fig. 3 for Reynolds numbers 50, 100, 250, and 500. High deposition at upstream susceptor positions and low deposition at downstream positions are characteristic of all of the predicted curves. At the lower Reynolds numbers of 50 and 100, the decrease in growth rate with distance is largely a result of reactant depletion. For the higher Reynolds numbers, however, reactant depletion is a less important factor. Lower resistance to radial diffusion is reflected in high values of the Sherwood number in the leading edge region and is expected to produce higher growth rates on the front portion of the susceptor, especially at high flow velocities. A major limitation of the above method of calculating mass transfer rates is that it does not include the effect of the simultaneously developing temperature profile in the reactor.

The developing temperature model for growth rate calculation.—The heat transfer solutions of Reynolds *et al.* (11, 12) are valid only for constant property flow. Strict application of these solutions to Eq. [24] requires that all parameters be evaluated at a constant temperature as described above. The heat transfer calculation, however, indicates that the temperature will increase with downstream position. An approximate calculation of the growth rate with variable temperature can be made by using Eq. [24] with $\mathcal{D}$ and T_m evaluated at the local value of T_m in the gas. The basis for this approximation is the assumption that the Sherwood number at a downsteram location for flow with changing properties will be nearly equal to the value evaluated at the length averaged mean temperature defined by

$$T_{mL} = L^{-1} \int_0^L T_m dz \qquad [26]$$

The assumption should be fairly good if the temperature variation in the region of interest along the susceptor is small, but less accurate as temperature variation from the length average value increases. For this reason, the developing temperature model is expected to work best for low gas velocities, but the model cannot be expected to give accurate results in the leading edge region of the susceptor where the rate of temperature change with axial position is extreme. Since the leading edge region is extended as the Reynolds number is increased, the developing temperature model becomes less accurate in the leading-edge region as the Reynolds number increases. Nevertheless, over the susceptor region of commercial interest, the model is expected to give reasonable accuracy.

The accuracy of this method is supported by experimental studies in the barrel reactor carried out at a Reynolds number of 92.6, as is shown below.

The results of growth rate calculations using the developing temperature model are shown in Fig. 4. Lower temperatures in the upstream region of the reactor result in calculated growth rates which are lower than those predicted by the constant property method. Deposition in the downstream region is higher because the temperature is greater than the length averaged value and because the lower predicted values in the upstream portion result in a smaller depletion of the reactant in that region of the reactor.

A comparison of the developing temperature model to the constant temperature method is shown in Fig. 5 for high and low flow rates. The difference between the two methods is more pronounced at the higher flow rate since the variation of the local temperature from the length average value is greater. For Re = 50, flow is close to being fully developed and the growth rates predicted by the two methods are similar. As expected the variable temperature method predicts a more uni-

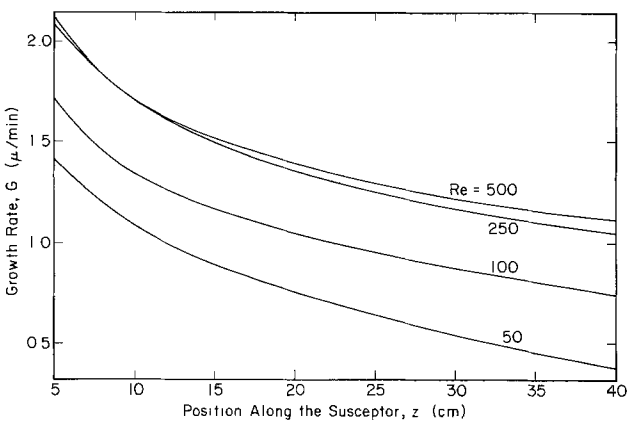

Fig. 3. Variation of growth rate with position along a constant diameter susceptor according to the constant temperature model. Transport properties are evaluated at the average mean temperature of the gas.

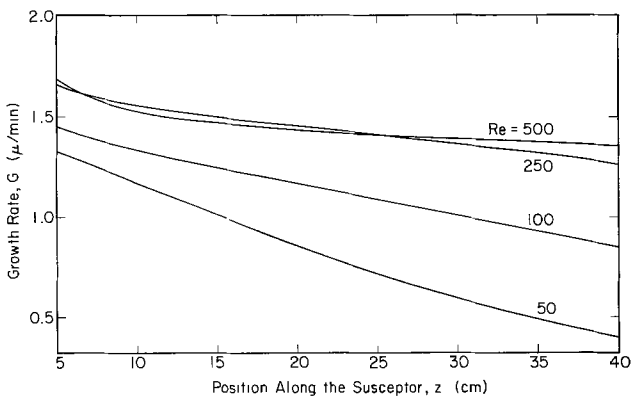

Fig. 4. Variation of growth rate with position along a constant diameter susceptor according to the developing temperature model.

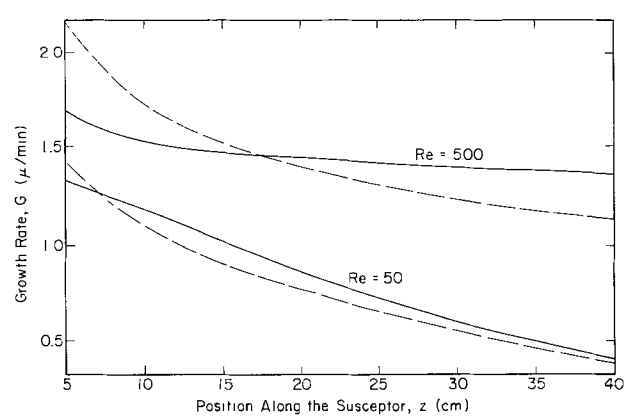

Fig. 5. Comparison of the growth rate variation predicted by the constant temperature modes (– – –) and the developing temperature modes (———).

form growth rate distribution than the constant temperature method.

An assumption of the present study is that there is no preheating of the gas entering the vertical cylinder reactor. Depending on the reactor design, some preheating could occur by radiative heat transfer or by convection via recirculation currents. The effect of reactant gas preheating would be to raise the mean temperature and decrease the temperature gradients in the region near the leading edge of the susceptor, from those shown in Fig. 2. Reactant gas preheating therefore increases the deposition rates near the leading edge of the susceptor. Thus, the growth rates predicted by the developing temperature model, shown in Fig. 5, would then be brought closer to the growth rates predicted by the constant temperature model.

Near the leading edge of the susceptor, the developing temperature model predicts deposition rates which are lower than the experimental values, because the gas phase region adjacent to the susceptor has the greatest influence on thermally activated CVD reactions. This error in the method becomes the error introduced by using a cross-stream average temperature in mass transfer calculations diminishes with increasing distance from the susceptor leading edge. A correction of the model in the region near the susceptor leading edge is not needed if substrate wafers are excluded from this part of the reactor.

Growth rates for a reactor with a tapered susceptor.—The Sherwood number varies slowly with the parameter, r_i/r_0. If the taper angle is small, the approximate growth rate for a tapered susceptor reactor can be calculated by Eq. [24] using the Sherwood number distribution for the average value of r_i/r_0. Growth rates for a reactor with an average inner diameter of 8.25 cm and a taper angle of 3.58° are presented in Fig. 6. Growth rates were calculated by the variable temperature method. Mass transfer to the susceptor is enhanced by the increasing inner radius. For Re of 250 and 500, the predicted deposition rate is higher at downstream positions. For Re of 100, enhancement of the growth rate due to the increasing inner radius offsets the effect of reactant depletion and a nearly uniform growth rate distribution is predicted. The constant diameter growth rate is shown for comparison. The Re value of 100 is very close to the design flow for the reactor for which Re is 92.6. At Re = 50 the enhancement due to taper angle is insufficient to compensate reactant depletion and the growth rate declines with distance.

Yield, over-all growth rate, and growth rate nonuniformity.—Table II summarizes yield, over-all growth rate, and growth rate nonuniformity predicted by the developing temperature method. Values are calculated

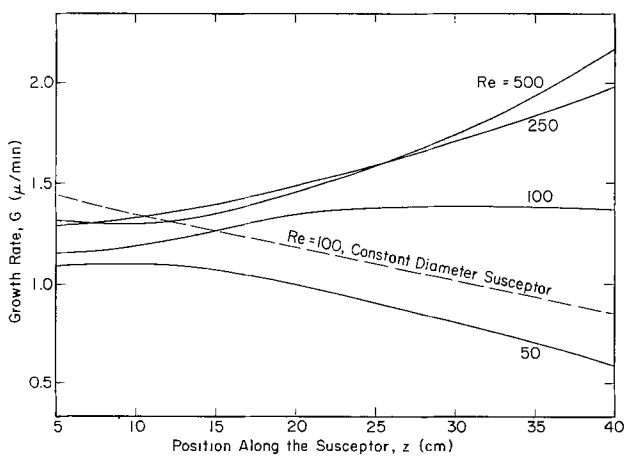

Fig. 6. Variation of growth rate with position along a tapered susceptor (taper angle = 3.58°) according to the developing temperature model.

Table II. Yield, over-all growth rate, and growth rate nonuniformity

Susceptor diameter	Re_{298}	Yield (%)	$\bar{G}$ (μmin^{-1})	$\Delta G/\bar{G}$ (%)
		Constant diameter susceptor		
Constant	500	7.42	1.43	10.8
Constant	250	14.5	1.42	13.2
Constant	100	29.8	1.13	25.9
Constant	50	42.7	0.81	53.0
		Tapered susceptor		
Tapered 3.58°	100	33.7	1.25	5.9
Tapered 3.58°	92.6	35.5	1.21	4.7

for ($5 \leq z \leq 40$), the approximate useful area of the susceptor. Growth rate nonuniformity is evaluated by Eversteyn's method (1)

$$\Delta G = \frac{G_{max} - G_{min}}{G_{max} + G_{min}} \times 100\% \qquad [27]$$

For a constant diameter susceptor, deposition uniformity is achieved by increasing the flow rate at the expense of reactant yield. Predicted results indicate low growth rate nonuniformities at Re = 250 and 500, but very poor reactant yields. The choice of flow rate for a constant diameter reactor would involve a compromise between the cost of higher reactant throughput at low reactant yield and the added cost of reduced yield of finished devices due to nonuniform epitaxial layer deposition. The tapered susceptor reactor offers an attractive alternative to this compromise. Using this innovation, the taper angle can be set to minimize growth rate nonuniformity at a specified velocity. The predicted growth rate nonuniformity for the tapered susceptor reactor at Re = 100 is much smaller than that for the constant diameter reactor at Re = 500. At the design value, Re = 92.6, growth rate nonuniformity is further reduced. With the tapered susceptor, predictions indicate that a small growth rate nonuniformity (4.73%) can be attained at an acceptable reactant yield (35.5%).

Comparison to experimental results and other growth rate models.—The growth rate predicted by the developing temperature method for a tapered susceptor reactor is compared to the calculations of other models and to experimental values in Fig. 7.

Experimental data were taken for a commercial barrel reactor, the AMT 740, of the dimensions shown in Fig. 1, with a susceptor taper angle of 3.58°. A flow of

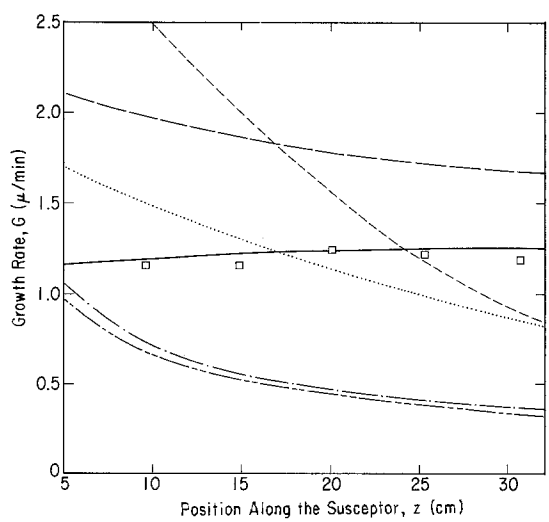

Fig. 7. A comparison of growth rate models and experimental data. (——) Developing temperature model, this work; (— — —) Eversteijn and Peek; (— —) Fujii et al.; (· · · ·) Rundle; (—·—) Dittman; (——— — ———) Chilton-Colburn analogy. Squares are experimental data.

112 liters/min (1867 cm^3/sec) of reactant gas containing 1.15% $SiCl_4$ in H_2 was introduced at the top of the reactor by entrance tubes which were adjusted to the optimum orientation. The deposition rates of epitaxial silicon were measured at multiple points on each wafer. Values were then azimuthally averaged for each axial position. The values shown in Fig. 7 are the average values at the substrate wafer centers. The theoretical predictions are based on a reactor of the same dimensions as the experimental reactor with the same initial $SiCl_4$ mole fraction, with Re = 92.6, corresponding to a flow rate of 112 liters/min in the experimental reactor. The growth rate is predicted by the developing temperature method for a tapered annulus. Agreement between the theoretical prediction and the experimental data is excellent, as shown in Fig. 7.

Fujii's model for the growth rate in a barrel reactor with a tapered susceptor predicts values which are higher than the observed values, especially for the first 20 cm of the susceptor. This result is expected, as mentioned earlier, because Fujii's growth rate equation is for the fully developed temperature. The fact that Fujii's growth rate equation contains adjustable parameters which were optimized for a barrel reactor of different dimensions could also be partly responsible for the high growth rates obtained using his method. A comparison of Fujii's model to the results of this work shows that the developing temperature method of this work is more accurate in both predicting values for the growth rate and in representing the variation of growth rate with susceptor position.

Dittman's correlation and the Chilton-Colburn analogy to flow over a flat plate both fail to represent the data quantitatively or qualitatively. Dittman's correlation is based on experimental data taken on a reactor with a very short susceptor and a large separation between the susceptor and reactor wall. Apparently, neither Dittman's correlation nor the Chilton-Colburn analogy to flow over a flat plate provided a realistic description of the growth rate distribution in a reactor of industrial dimensions.

Of the horizontal reactor models. Rundle's method gives growth rates which compare closest with the experimental data. Eversteyn's stagnant layer model predicts growth rates which are much higher than the experimentally observed values for the barrel reactor. Rundle's model, based on a laminar, parabolic velocity distribution is apparently much more representative of flow in the vertical cylinder reactor than is the turbulent-flow stagnant-sublayer model. This again confirms the need for applying laminar flow transport theory to the vertical cylinder reactor.

Of the models examined, the developing temperature method proposed in this work gives the best agreement with the experimental data. It is the only model which predicts the observed lower growth rate values at upstream positions on the susceptor. The developing temperature method incorporates two features not found in the other models studied: It accounts for the effect of increasing temperature on growth rate distribution and it accounts for the reduction in deposition efficiency due to side reactions. The excellent agreement between the developing temperature method and the experimental growth rates demonstrates the importance of considering these effects in developing an accurate method for growth rate prediction.

After comparing the results of several models to experimental data, the three predicted effects of developing heat transfer can be further examined. Experimental growth rates and growth rates predicted by the developing temperature method are both lower than those for Fujii's barrel reactor model in which temperature is considered to be fully developed. This comparison confirms the first prediction, that the over-all growth rates are lower than those predicted for constant, fully developed temperature. Since Fujii's model predicts less uniform growth than either values predicted by the developing temperature method or those observed experimentally, the second expected effect is confirmed. The third expected effect is that the over-all growth rate should reach a maximum value and then decrease as the flow rate is increased. The decline in growth rate does not occur in the range of Reynolds numbers 50-500, studied in this paper. Fujii *et al.* (5) have reported experimental results which show that the over-all growth rate does decrease at high flow rates.

Conclusion

Calculation of heat transfer using the solution by Reynolds *et al.* (11, 12) for developing heat transfer in an annular passage indicates that entry region temperature development will occur over a significant portion of the susceptor in a barrel reactor at Reynolds numbers greater than 50. Since barrel reactors typically operate at Reynolds numbers of order 10^2, the assumption of a constant temperature or constant temperature profile throughout the reactor is clearly unsatisfactory.

Due to the positive dependence of the silicon growth rate on mean gas temperature, over-all growth rates are expected to be lower than those predicted by models which incorrectly assume the temperature of the gas to be fully developed throughout the reactor. Furthermore, growth rates are expected to be more uniform than predicted by fully developed temperature models. The enhancement of mass transfer rates which accompanies the increase in temperature with downstream position helps to offset the decrease in growth rate caused by reactant depletion. The decline in over-all growth rate at very high reactant flow rates observed experimentally by Fujii *et al.* (5) is also a consequence of developing heat transfer and the positive temperature dependence of growth rate. As the reactant flow rate is increased beyond flow rates for which reactant depletion is significant, the mean temperature of the gas becomes the primary factor influencing growth rate. Further increase in the flow rate results in extension of the entry length for heat transfer and a lower length average mean gas temperature for the reactor, hence a lower over-all growth rate.

The developing temperature model for growth rate calculation proposed in this work gives a growth rate temperature dependence of $T^{0.674}$. The developing temperature method predicts growth rates which are in excellent agreement with experimental data obtained for a commercial barrel reactor. The model gives a more satisfactory description of the growth rate in a barrel reactor than any of the previously published models studied. Among the previously published models, Rundle's model for a horizontal reactor seems to give the best comparison to experimental growth rate values. The model based on the Chilton-Colburn analogy to boundary layer flow over a flat plate gave a particularly poor comparison to the experimental growth rates. This comparison confirms that the analogy to flow over a flat plate is an unsatisfactory representation of the geometry and boundary conditions for mass transfer in a barrel reactor of commercial dimensions.

The developing temperature model was used to study the effects of reactant flow rate and susceptor tilt angle on growth rate uniformity and reactant yield. For reactors with nontapered susceptors it was found that high reactant flow rates would be required to obtain growth rate nonuniformity of 10% or less. With the susceptor tilted slightly to an angle of 3.58°, however, an optimum growth rate nonuniformity of about 5% could be achieved at a much lower reactant flow rate. Reactant yield was found to drop off sharply with increased flow rate; therefore the over-all performance of the tapered susceptor reactor is expected to be far superior to that of the nontapered reactor. This exercise demonstrates the usefulness of the developing temperature model in evaluating process design alternatives in addition to giving the specific result described

above. It is hoped that this work will be useful as a process design tool as well as a contribution to the understanding of transport processes in the vertical cylinder reactor.

Transport Properties

Viscosity.—H_2.—The viscosity of pure H_2 was calculated by the equation of Maitland and Smith (20)

$$\ln(\mu/S) = A\ln(T) + B/T + C/T^2 + D \quad [A\text{-}1]$$

where $A = 0.68720$, $B = -0.61732$, $C = -111.49$, $D = -3.9001$, and $S = 88.0$, and where μ is given in μ-poise.

$SiCl_4$.—Viscosity of pure $SiCl_4$ was obtained from the corresponding state method of Stiel and Thodos (21-23)

$$\mu = \begin{cases} (34.0)(10^{-1})\,T_r^{0.94}, & T_r \leq 1.5 \\ (17.78)(10^{-1})(4.58\,T_r - 1.67)^{5/8}, & T_r > 1.5 \end{cases} \quad [A\text{-}2]$$

where $\xi = T_c^{1/6}/M^{1/2}p_c^{2/3}$, $T_r = T/T_c$, T_c = critical temperature = 506°K, p_c = critical pressure = 37.1 atm (3.76 MPa), and M = molecular weight of $SiCl_4$ = 169.9.

$SiCl_4$-H_2 mixture.—The viscosity of the gas mixture is calculated by Wilke's method (24)

$$\mu_{mix} = \sum_{i=1}^{n} \mu_i \Big/ \left[1 + \sum_{\substack{j=1 \\ j=i}}^{n} \phi_{ij}(y_j/y_i)\right] \quad [A\text{-}3]$$

where $\phi_{ij} = [1 + (\mu_i/\mu_j)^{1/2}(M_j/M_i)^{1/4}]^2/(8 + 8M_i/M_j)^{1/2}$, y_i = mole fraction of i, and M_i = molecular weight of i.

Mixture density.—The density of the mixture is calculated according to the ideal gas law

$$\rho_{mix} = \frac{p}{RT}\sum_{i=1}^{n} y_i M_i \quad [A\text{-}4]$$

Heat capacity.—Heat capacity data for each of the components is given in Ref. (25). These data were fit to a quadratic form

$$C_p = A + BT + CT^2 \quad [A\text{-}5]$$

Constants for Eq. [A-5] are as follows: for H_2; $A = 14{,}534$, $B = -0.4023$, and $C = 9.816\ (10^{-4})$, and for $SiCl_4$; $A = 561.4$, $B = 6.417\ (10^{-2})$, and $C = -8.640\ (10^{-6})$. Heat capacity is given in units of J/(kg°K).

The heat capacity of the mixture is determined by adding the component heat capacities weighted according to mole fractions

$$C_{pmix} = \sum_{i=1}^{n} y_i C_{pi} \quad [A\text{-}6]$$

Thermal conductivity.—H_2.—Experimental data from the literature has been fit to the following second order polynomial

$$k = 0.080796 + 3.7312(10^{-4})T - 7.4683(10^{-9})T^2 \quad [A\text{-}7]$$

where k is given in J/(m-sec °K).

$SiCl_4$.—Euken's method (17) is used to relate thermal conductivity to viscosity

$$k = (C_{pSiCl_4} + 61.18)\,\mu_{SiCl_4} \quad [A\text{-}8]$$

$SiCl_4$-H_2 mixture.—The mixture thermal conductivity is calculated by the Mason and Saxena (26) formulation of the Wassiljewa equation

$$k_{mix} = \sum_{i=1}^{n} k_i \left[1 + \sum_{j=1}^{n} A_{ij}(y_j/y_i)\right]^{-1} \quad [A\text{-}9]$$

The parameter A_{ij} can be taken as equal to the parameter ϕ_{ij} used in Wilke's equation (6) for the mixture viscosity.

Binary diffusion coefficients.—Binary diffusion coefficients are estimated using the equation deduced from kinetic theory (17).

$SiCl_2$-H_4.—Using the combined potential parameters

$$\sigma_{12} = 4.31\text{Å}$$

$$\frac{\epsilon_{12}}{k} = 144\text{°K}$$

the theoretical equation gives

$$\mathcal{D}_{SiCl_4\text{-}H_2} = 7.0861\ (10^{-9})\,T^{3/2}/\Omega_{\mathcal{D}} \quad [A\text{-}10]$$

in units of $m^2\ sec^{-1}$.

The collision integral $\Omega_{\mathcal{D}}$ can be evaluated from tabulated values or from Ref. (27)

$$\Omega_{\mathcal{D}} = \frac{A}{BT^*} + \frac{C}{\exp(DT^*)} + \frac{E}{\exp(FT^*)} + \frac{G}{\exp(HT^*)} \quad [A\text{-}11]$$

where $T^* = kT/\epsilon_{12}$, $A = 1.06036$, $B = 0.15610$, $C = 0.1930$, $D = 0.47635$, $E = 1.03587$, $F = 1.52996$, $G = 1.76474$, and $H = 3.89411$.

Reduced transport parameters.—Reynolds number

$$Re_{mix} = \frac{\rho_{mix} d_h v}{\mu_{mix}} \quad [A\text{-}12]$$

Prandtl number

$$Pr_{mix} = \frac{\dfrac{C_{pmix}}{(M_{mix})}\mu_{mix}}{k_{mix}} \quad [A\text{-}13]$$

Schmidt number for $SiCl_4$-H_2

$$Sc_{SiCl_4\text{-}H_2} = \frac{\mu_{mix}}{\rho_{mix}\mathcal{D}_{SiCl_4-H_2}} \quad [A\text{-}14]$$

An Examination of the Product Catalyzed Reaction of Trimethylgallium with Phosphine and the Mechanism of the Chemical Vapor Deposition of Gallium Phosphide and Gallium Arsenide

D. J. Schlyer and M. A. Ring

Department of Chemistry, San Diego State University, San Diego, California 92182

ABSTRACT

The formation of GaP via reaction of Me_3Ga with PH_3 was examined. The reaction follows a Langmuir-Hinshelwood mechanism (adsorption of both reagents prior to reaction). The GaP surface was also found to catalyze the unimolecular decomposition of PH_3 and Me_3Ga. These results and similar ones for the reaction of Me_3Ga with AsH_3 are discussed.

The chemical vapor deposition (CVD) of single crystal layers of III-V semiconductor compounds, such as GaAs, from the reaction between Group III organometallics and Group V hydrides has now been well established (1-9). The mechanism involved in these potentially very important processes or in similar processes [i.e., formation of II-VI semiconductor compounds (10)] is not understood and has only been briefly discussed (1, 5, 11).

Key words: CVD, GaAs, GaP.

We have recently reported (12) our results on the reaction of $(CH_3)_3Ga$ [trimethylgallium (TMG)] with AsH_3 over the product surfaces $[(CH_3)_{3-x}GaAsH_{3-x}$, $x = 1.1$ to 2.2]. In this paper we report results for reaction of TMG with PH_3 over our GaP surfaces $[(CH_3)_{3-x}GaPH_{3-x}$, where x averaged 2.8] as well as for some experiments for the TMG-AsH_3 system. In the discussion section we incorporate these results with those reported by other groups. While the surfaces present in our investigations were not identical to those

present in the chemical vapor deposition (CVD) processes, the fact that the apparent activation energy for our reactions and those for the CVD GaAs process were identical suggests that the mechanism may be similar.

We have examined these reactions at lower temperatures than those used in the CVD processes. This was necessary to allow for reactant adsorption on the surfaces to effect the kinetics so that these adsorptions could be detected in an effort to understand the mechanisms.

Experimental

Pyrolysis apparatus.—The experiments listed in Tables I and II were carried out in an 80 cm^3 Pyrex reaction vessel wrapped with a heating tape and heavily insulated to stabilize temperature. The temperature of the vessel was monitored by a Chromel-Alumel thermocouple inserted into a well which extended to the center of the vessel. A U trap with an attached 200 cm^3 expansion bulb was connected to this vessel. This assembly was incorporated into the standard high vacuum system. Pressures were measured with a mercury manometer read through a traveling telescope which gave an accuracy of 13 Pa (0.1 mm Hg). The interior of the vessel was coated with the solid product from previous experiments at 240° or 270°C which, as is explained later, can be described as $(CH_3)_{3-x}GaPH_{3-x}$, where x averaged about 2.9 at 270°C and about 2.7 at 240°C.

Kinetic runs.—In a typical experiment, TMG (1.0 mmole) was expanded into the 200 cm^3 expansion bulb. The pressure was noted, the Teflon valve to the bulb was closed, and the TMG removed from the rest of the system. Phosphine (2.5 mmoles) was expanded into the trap which gave a higher pressure of PH_3 in the trap than of TMG in the bulb. The Teflon valve connecting the trap to the bulb was then opened for 5 sec, and the hydride was allowed to flow into the bulb. During this interval, the pressure in the two parts came to equilibrium, and the pressure was read to obtain the ratio of the two reactants. It was assumed that no TMG was lost from the bulb by diffusion. Control experiments were carried out to show that this was the case. The PH_3 left in the trap was removed and the two reactants allowed to stand for about 1 min to ensure that complete mixing had taken place. This mixture was then expanded into the reaction vessel and the temperature and pressure were noted. From these data, it was possible to calculate the number of millimoles of each reactant in the vessel.

After the reaction was completed, the products were toepler pumped into a known volume and a pressure reading taken. The products were then recirculated through a −78°C trap and again toepler pumped into the known volume. The pressure was read and the amount of TMG removed determined by difference. It was determined by infrared spectral analysis that a −78°C trap would quantitatively separate TMG from PH_3 in this system. The remaining products were recirculated through a −196°C trap to remove the PH_3 for quantitative determination. The noncondensable products were then toepler pumped into the same vol-

ume and measured. A sample of the noncondensable gases was taken, and a mass spectrum obtained. This spectrum was compared with that of a known standard to determine the relative quantities of H_2 and CH_4.

Results

The results reported for the reaction of PH_3 with TMG were carried out over the product surfaces. The bulk product had the formula $(CH_3)_{3-x}GaPH_{3-x}$, where x averaged 2.9 at 270°C and 2.7 at 240°C. The data for these analyses are presented later.

Control reactions and heterogeneous nature.—The only volatile products from the TMG-PH_3 [and TMG-AsH_3 (12)] reaction were CH_4 and H_2. In control experiments we observed that our product surfaces $[(CH_3)_{3-x}GaPH_{3-x}]$ prepared at 270°C catalytically decomposed both TMG and PH_3 to form CH_4 and H_2, respectively. These decompositions occurred at 240°C and pressures similar to those in Tables I and II. These decompositions were not observed over a silicon surface (for PH_3) or an arsenic surface (for TMG) at higher pressures and temperatures up to 340°C. Similar catalytic results were observed for AsH_3 and TMG over their product surfaces $(CH_3)_{3-x}GaAsH_{3-x}$, where x averaged 1.1 at 203°C and 2.2 at 259°C (12).

The results of the reactions of TMG with PH_3 over the product surfaces are listed in Tables I and II. The minimum set of equations required to explain our data are as follows

$$PH_3 \rightarrow 1/4\,P_4 + 3/2\,H_2 \qquad [1]$$

$$2(CH_3)_3Ga \rightarrow \text{product} + CH_4 \qquad [2]$$

$$(CH_3)_3Ga + PH_3 \rightarrow (CH_3)_2GaPH_2 + CH_4 \qquad [3]$$

$$(CH_3)_2GaPH_2 \rightarrow (CH_3)GaPH + CH_4 \qquad [4]$$

$$(CH_3)GaPH \rightarrow GaP + CH_4 \qquad [5]$$

The product in reaction [2] was not identified. It could be $(CH_3)_2GaCH_2Ga(CH_3)_2$.

The initial results indicate a need to follow reaction [3] by some variable other than the consumption of TMG or PH_3 or the production of CH_4 or H_2. We have found the most reliable value to be the PH_3 consumed corrected for the PH_3 decomposed via reaction [1]. We have defined a term D, where

$$D = (PH_3 \text{ consumed} - 2/3\,H_2 \text{ produced}) \qquad [6]$$

It is possible that some hydrogen-containing polymer may remain after the reaction. However the correction ($-2/3$ H_2 produced) was small, so that a small error in the correction would only result in a very small error in D.

The rate of the reaction between TMG and PH_3, determined by D, was obtained at 190°C over surface areas of 130 and 305 cm^2. The relative rate of reaction increased by 2.1 ± 0.2 as the surface area increased by 2.3. Thus this reaction was essentially heterogeneous under these conditions. Similar results were found for the TMG-AsH_3 reaction at 260°C (12).

Solid product.—In principle, the average value of x in the solid product, $(CH_3)_{3-x}GaPH_{3-x}$, can be determined from the value of D and the CH_4 produced only from reactions [3]-[5]. We have defined a term M, which is the CH_4 produced from reactions [3]-[5]. The term M has been set equal to the total CH_4 production $-$ $[(CH_3)_3Ga$ consumed $- D/2]$. The CH_4 correction attempted to account for the CH_4 formed by reaction [2]. The ratio of CH_4 formed to TMG consumed in the TMG heat decompositions averaged close to 0.5.

The value of x in the solid product $(CH_3)_{3-x}GaPH_{3-x}$ would be equal to M/D. Thus the results in Tables I and II indicate that x averaged 2.9 at 270°C and 2.7 at 240°C. The solid products were obtained as very thin films and were not examined. It is unlikely that our product films were of uniform composition.

Reaction order and mechanism.—The results listed in Tables I and II can be used in an effort to elucidate aspects of reaction [3] [*i.e.*, formation of $(CH_3)_2GaPH_2$]. The rate of reaction [3] was followed by the quantity D.

Rate control for heterogeneous reactions can be due to five factors: (*a*) diffusion of reactants to the surface, (*b*) adsorption of the reactants (this is an activation energy of adsorption and not the heat of adsorption which is usually not rate controlling), (c) reaction on the surface, (*d*) desorption of the products (heat of adsorption equal to heat of desorption, and (*e*) diffusion of products from the surface. In our unpacked reaction vessel, gaseous diffusion to and from the surface would be fast and not rate controlling. The adsorption process is usually fast compared to the surface reaction. Thus, rate control will only depend on the surface activation energy and the heats of adsorption of the reactants and products.

Bimolecular heterogeneous reactions can occur by the adsorption of both reagents on the surface followed by the surface reaction (Langmuir-Hinshelwood mechanism) or by the adsorption of one reagent and reaction with the other in the gas phase (Rideal-Eley mechanism). These two mechanisms can be distinguished by the kinetic reaction orders.

The general form for the rate of a heterogeneous reaction (Langmuir-Hinshelwood mechanism) for a two-site model will take the form of Eq. [7] (13)

$$\text{rate} = \frac{k b_a b_b p_a p_b}{(1 + b_a p_a)(1 + b_a p_a)} \qquad [7]$$

where p_a is the pressure of species a and b_a is the equilibrium adsorption constant for species a. This equation is based on Langmuir adsorption isotherms which assume all similar catalytic sites are equivalent. This form appears generally valid even though Langmuir isotherms are not generally obeyed. Equation [7] assumes that product desorption does not effect the rate. This was the case for our system where the rate did not change when excess CH_4 was added initially to the reaction system. The Langmuir-Hinshelwood mechanism is operative when the reaction orders of both reagents are less than one. This lower reaction order can be due to reactant poisoning (when $bp > 0.05$) or to lower values of the adsorption equilibrium constants. b, at higher pressures.

The reaction orders with respect to PH_3 and TMG for reaction [3] were determined by the change in ln D with respect to ln p of PH_3 or TMG while the pressure of the other reagent was held constant. The reaction orders for PH_3 were 0.6 ± 0.2 and 0.8 ± 0.2 at 270° and 240°C, respectively, while those for TMG were 0.5 ± 0.2 and 0.6 ± 0.2 at 270° and 240°C, respectively. Since these reaction orders are clearly less than one, the reaction occurs via the Langmuir-Hinshelwood mechanism (*i.e.*, adsorption prior to reaction).

The reaction orders obtained for the TMG-AsH_3 reaction were clearly less than one for TMG but only slightly less than one for AsH_3 (12). This result again demonstrated that TMG was adsorbed prior to reaction; however, the AsH_3 could have reacted in the gas phase with adsorbed TMG. We did demonstrate the AsH_3 adsorbed on our surfaces and was catalytically decomposed by these surfaces at 172°C (12). These results suggested that AsH_3 adsorbed prior to reaction with TMG. It would appear that both reactions (TMG with AsH_3 or PH_3) occur by similar mechanisms since they have very similar activation energies. Thus we suggest that the TMG-AsH_3 reaction also occurs via a Langmuir-Hinshelwood mechanism.

Activation energy.—The apparent activation energy for the TMG-PH_3 reaction obtained from the data in Tables I and II was about 54 kJ/mole. The rate was followed by the term D. The apparent activation energy, E_a, is related to the activation energy of the surface reaction, E_s, by Eq. [8] (13)

$$E_a = E_s + Q_{TMG} + Q_{PH_3} \quad [8]$$

where Q_i is the heat of adsorption of the species i at the same surface coverage present during the kinetic runs.

The apparent activation energy for the TMG-AsH_3 reaction was also about 54 kJ/mole (12).

Reaction of PH_3 and AsH_3 with the solid products.— The solid products from our TMG-AsH_3 reactions were $(CH_3)_{3-x}GaAsH_{3-x}$, where x averaged 1.1 at 203°C and 2.2 at 259°C (12). When these solid products were heated to 420°C for 18 hr, CH_4 and H_2 were produced. However the values of x for the new solid products were only about 1.3 and 2.6 (12). We have now examined the reaction of AsH_3 with the initial product surface. In a typical experiment, TMG (0.0820 mmole) and AsH_3 (0.0783 mmole) were expanded into a vessel at a temperature of 364°C. This gave a pressure in the vessel of 9917 Pa (74.4 mm Hg). The reaction was allowed to proceed for 10 min at which time the products were removed and analyzed. The quantity of TMG consumed was 0.0553 mmole and the quantity of AsH_3 consumed was 0.0734 mmole. After correction for H_2 produced, this gave a value of 0.0434 mmole for D. The corrected quantity of CH_4 produced was 0.1106 mmole giving x a value of 2.5. When the product surface was then exposed to 0.218 mmole of AsH_3 at a pressure of 13,500 Pa (101.3 mm Hg) for the same time and at the same temperature as the initial run, 0.0209 mmole of CH_4 was produced, while 0.0635 mmole of AsH_3 was consumed. Therefore, the total CH_4 produced from both the initial reaction and exposure to AsH_3 was 0.1316 mmole. The value of x now becomes 0.1316/0.0434 = 3.0. This titration of the surface shows that there were methyl groups remaining on the surface after the initial reaction was complete. It also demonstrates that AsH_3 reacts with $(CH_3)_{3-x}GaAsH_{3-x}$ to form GaAs. It should be noted that the solid products represented as $(CH_3)_{3-x}GaEH_{3-x}$ (E = P or As) could in reality be $(CH_3)_{3-x}GaEH_{3-y}$, where $y > x$.

In one experiment, where AsH_3 and TMG (0.027 mmole each) were allowed to react at 365°C at a total pressure of 3332 Pa (25.0 mm Hg) for 15 min over "GaAs"; the ratio, M/D was 2.94. When this solid was treated with AsH_3 at 365° only a trace of CH_4 was produced.

A similar experiment was carried out for $(CH_3)_{3-x}GaPH_{3-x}$ prepared at 270°C on a silica gel (30/60 mesh) supported surface with a $(CH_3)_{3-x}GaPH_{3-x}$ surface area of 320 m^2 as determined by the BET method (14). When the product surface was exposed to PH_3 at 270°C, the quantity of CH_4 produced was sufficient to account for a 3% coverage of the Ga sites by methyl groups. Thus, the surface contained a small number of methyl groups as suggested by the M/D ratios in Table I.

Discussion

The CVD formation of GaAs and GaP via reaction of TMG with AsH_3 or PH_3 can now be examined. Manasevit and Simpson (1) prepared high quality single crystal thin films of GaAs and GaP from reaction of TMG with AsH_3 or PH_3 in H_2 flow. The hydride to TMG partial pressures used were about 10/1. It was suggested that AsH_3 and TMG react in the gas phase and that reaction with TMG prevents its thermal decomposition.

Ito, Shinohara, and Seki (5) found a transition from p-type product GaAs to n-type GaAs when the AsH_3/TMG ratio reached about 10/1. They proposed a mechanism involving the gas phase reaction of TGM with H_2 to yield CH_4 and Ga which was adsorbed on the surface. This Ga then reacted with surface bound As from the gas phase decomposition of AsH_3.

Petzke, Gottschalch, and Butler (11) have drawn several conclusions regarding the kinetics of the reactions in the $(CH_3)_3Ga$-AsH_3-H_2 system from an analysis of data reported by Manasevit and Simpson (1) and that of Inoue and Asahi (15). Petzke *et al.* found that (*i*) the reaction was first order in TMG and (*ii*) the apparent activation energy was 54 kJ/mole. From these observations, they concluded that the reaction must be heterogeneous, since the third Ga-CH_3 bond dissociation energy is $\approx$ 322 kJ/mole.

From our data, we have calculated an apparent activation energy of 54 kJ/mole for the reaction of TMG with both AsH_3 and PH_3. This suggests that the process occurring in our low temperature reaction may be similar to the process occurring during the deposition as carried out by Manasevit and Simpson (1).

From the surface to volume studies, we can eliminate any mechanism which involves reaction completely in the gas phase. This view is also supported by Petzke *et al.* (11) who also found the reaction to be heterogeneous. On the basis of the heterogeneous character of the reaction, we cannot exclude the possibility of the formation of a gas phase complex which then diffuses to the surface and reacts. However, we were unable to detect any gas phase complex formation even at room temperature where complex formation would be greatest.

We, therefore, propose a mechanism we feel is consistent with all the data for both systems

$$(CH_3)_3Ga_{(g)} + S1 \rightleftharpoons \underset{I}{(CH_3)_3Ga \cdot S1} \quad [9]$$

$$AsH_{3(g)} + S2 \rightleftharpoons \underset{II}{AsH_3 \cdot S2} \quad [10]$$

$$I \rightarrow \frac{1}{2} CH_{4(g)} + \text{products} \quad [11]$$

$$II \rightarrow \frac{3}{2} H_{2(g)} + As_4 \quad [12]$$

$$I + II \rightarrow (CH_3)_2GaAsH_2 + CH_{4(g)} \quad [13]$$

$$(CH_3)_2GaAsH_2 \rightarrow (CH_3)GaAsH + CH_{4(g)} \quad [14]$$

$$(CH_3)GaAsH \rightarrow GaAs + CH_{4(g)} \quad [15]$$

Those species not subscripted are solid phase, I and II are surface complexes of $(CH_3)_3Ga$ and AsH_3, respectively, and S1 and S2 are two different types of sites.

The mechanism above is written with two types of sites. The same conclusions would be made for a one-site mechanism. We have proposed a two-site mechanism since AsH_3 (and PH_3) are good Lewis bases and TMG is a good Lewis acid. The As (or P) site would be a good Lewis base site (to complex TMG) and the Ga Lewis acid site should complex AsH_3 or PH_3 very well.

The consequences of the above mechanism have significance to the process of chemical vapor deposition. The most important point to be made is that care must be taken to remove all CH_3 groups from the surface before they are buried by further deposition. Buried CH_3 groups could then thermally decompose via reaction [16]. When this occurs

$$H_3CGaAs \rightarrow CGaAs + 3/2\, H_2 \quad [16]$$

an arsenic atom would be replaced by a carbon atom with one less electron in the outer shell which would result in a p-type site. The H_3CGaAs group could be formed via reaction [17]

$$H_3CGaAsH \rightarrow H_3CGaAs + 1/2\, H_2 \quad [17]$$

since the As-H bonds are relatively weak. In fact, it is not unlikely that the solid products described as $(CH_3)_{3-x}GaEH_{3-x}$ (where E is P or As) should be described as $(CH_3)_{3-x}GaEH_{3-y}$, where $y > x$. We have demonstrated that AsH_3 and PH_3 can remove CH_3 groups bound to gallium. This result coupled with the reactions represented by Eq. [16] and [17] can explain the results of Seki and co-workers (5) who found a

transition from p-type to n-type GaAs at a mole ratio of AsH_3 to $(CH_3)_3Ga$ of 10/1.

AL/Si and Al/Poly-Si Contact Resistance in Integrated Circuits

H. M. Naguib* and L. H. Hobbs

Bell-Northern Research, Ottawa, Ontario, Canada K1Y 4H7

ABSTRACT

This paper presents results on the effects of sintering temperature, sintering time, and contact geometry on Al/Si and Al/poly-Si contact resistance. At sintering temperatures >450°C the resistance of p-type contacts is virtually constant and independent of time. The resistance of n-type contacts, particularly to poly-Si, increases with increasing sintering temperature for $T > 450$°C. This is attributed to the precipitation of a p-type (Al-doped) layer on n-contacts during sintering. The interface resistance of both Al/Si and Al/poly-Si contacts is independent of the length of the contact and inversely proportional to the width of the contact.

It is widely recognized that Al is the most suitable contact material for conventional integrated circuits with junction depths of ~1.5 μm (1). Typically Al films for this purpose are deposited onto the Si wafers by electron beam evaporation to a thickness of the order of 1 μm. To form a low resistance ohmic contact, it is standard practice to follow the deposition of the Al layer by a heat-treatment cycle at temperatures below the Al-Si eutectic point (*i.e.*, <577°C). This is usually referred to as "sintering." However, at temperatures well below the eutectic, excessive dissolution of Si into Al films at the contact windows can be observed (2-4) which can lead to a vertical or lateral shorting of a junction. It has also been reported (5) that Al films in contact with polycrystalline silicon (poly-Si) layers, as in Si-gate MOS devices (6) or poly-Si resistors (7), could induce dissolution and recrystallization of the Si at temperatures as low as 400°C. Accordingly, it appeared desirable to carry out the sintering cycle at temperatures as low as possible, consistent with achieving ohmic contacts to both single crystal Si substrates and poly-Si layers.

In this work we have measured the contact resistance at Al/Si and Al/poly-Si interfaces after various sintering cycles in order to establish the optimum cycle for producing reliable, low resistance contacts in integrated circuits. We have also investigated the effect of contact geometry on the contact resistance so as to achieve optimum design for integrated circuit resistors.

Experimental Determination of Contact Resistance

The main problem in the experimental determination of contact resistance is the separation of the metal-semiconductor interface resistance, R_c, from the semiconductor bulk resistance, R_s. Recently, various methods of measuring contact resistance have been analyzed (8). The method developed by Berger (9, 10) and Murrman and Widman (11, 12), provides a high degree of measurement accuracy using the resistor structure shown in Fig. 1. Three contacts are made to a rectangular diffused region, where the width of the contact (ω) is, as nearly as possible, equal to the full width of the diffused region (W). Two of the contacts are spaced closely together at a distance l_1, while the third contact is located at a much greater distance l_2

Key words: aluminum metallization, contact characterization, ohmic contacts, silicon technology.

from the central contact ($l_2/l_1 \geq 10$). To exclude any contact resistance introduced by the probes, the current probes are separated from the voltage probes as shown in Fig. 1. The total resistance, R_{total}, between any two contacts can be expressed as

$$R_{total} = R_s \cdot \frac{l}{W} + 2R_c \quad [1]$$

Applying Eq. [1] to the separately measured resistance values R_1 and R_2 leads to

$$R_c = \frac{R_1 l_2 - R_2 l_1}{2(l_2 - l_1)} \quad [2]$$

and

$$R_s = \frac{(R_2 - R_1)W}{l_2 - l_1} \quad [3]$$

Using the resistor structure shown in Fig. 1, Si and poly-Si resistors with various contact configurations were fabricated on Si wafers which were subjected to the diffusion, oxidation, and passivation processes used in conventional MOS Si-gate technology. The preparation of the contacts involves: opening windows in the pyroglass passivation layer overlying the wafer, electron beam evaporation of a pure Al film onto the wafer, photoengraving and etching of aluminum interconnect patterns, and a subsequent sintering cycle. A typical process sequence is shown in Table I.

After sintering, the dimensions l_1, l_2, ω, W, and d were measured at several locations on each wafer using a Leitz digital microscope. It was found that the average error in these measurements was <1 μm. The electrical measurements were carried out on a large number of chips using an Electroglas Model 103 automatic wafer prober. One probe was placed on each of the six bonding pads associated with each resistor (cf. Fig. 1). The prober was connected to a Hewlett Packard 3050A automatic data acquisition system including a Model 9830A programmable calculator to control a Model 3490A digital multimeter, Model 9866A printer, and a Leeds and Northrup 2740 scanner. The computer controlled automatic tester measured R_1 and R_2, calculated R_c and R_s (Eq. [2] and [3]) for all resistors on each wafer, and printed out statistical information of the results. Following each sintering the resistivity data were collected using 2-3 wafers prepared at different runs.

Results and Discussion

The effect of sintering on Al/Si contact resistance.— Si-diffused resistors prepared as described in Table I were sintered for various periods of time (5-60 min) at temperatures varying between 300° and 560°C. The average sheet resistance of the Si substrates in these experiments was 9 Ω/sq for phosphorus-doped resistors and 40 Ω/sq for boron-doped resistors. After sintering,

the contact resistance of resistors having contact windows of 12 × 10 μm were measured.

Using a 5 min sintering, a major drop in R_c values was observed at 350°C as shown in Fig. 2. This drop in R_c represents the first stage of the contact formation as the Al penetrates through the barrier layer at the Al/Si interface. Until recently, it was usually assumed that this barrier was a thin SiO_2 film formed on the Si surface over the contact base prior to evaporation. However, the penetration rate of Al into SiO_2 at 350°C is $\simeq 6 \cdot 10^{-4}$ Å/min (1). Therefore, a film of SiO_2 approximately 15Å thick, which is normally formed on Si at room temperature, would be penetrated in $\simeq$17 days during a 350°C sintering cycle. However, recent work indicated (13) that the film present on a freshly etched Si surface is primarily an oxidized impurity film rather than a pure SiO_2 film. Since, as yet, no attempt has been made to measure the penetration rate of Al through such impurity films, the initial stage of Al/Si contact formation remains poorly understood.

R_c values continue to decrease slowly between 350° and 450°C. At temperatures $\geq$450°C, R_c values for boron-doped (p-type) resistors are virtually constant and also found independent of sintering time between 5 and 60 min. Si in solid solution with Al has relatively little effect on the electrical conductivity of the resultant alloy (14). Therefore, once Al penetrates through the barrier layer in the contact area to form an ohmic contact with the Si, further interaction of Al and Si has a minor effect on the Al/Si contact resistance. For phosphorus-doped (n-type) resistors a gradual increase in R_c at temperatures >450°C is observed. This may be the result of an interaction between the aluminum, which is a p-type dopant, and the n^+-doped layer at the contact. Such an interaction is discussed in more detail in connection with phosphorus-doped poly-Si resistors.

Some data on the effect of various sintering conditions on Al/Si contact resistance have been previously reported (15-17). However, a direct comparison of the present results with the previously reported ones is not possible. Measurements reported by Hopper *et al.* (15, 16) were obtained on contact areas ~10^4 times larger than those used in our diffused resistor structures and, therefore, the dependence of R_c on process

differences and on Si surface doping is probably significantly different. In the work of McNeil (17) the measuring technique did not separate R_c from R_s and consequently the measured resistivities were much higher (10-100 times) than those reported here. However, in agreement with the present results, McNeil did report an increase in contact resistance for n-type Si resistors at sintering temperatures >500°C.

Berger (8) showed that the Al/Si contact resistance decreased with increasing substrate doping level. The surface dopant concentration for our Si-diffused resistors was ~6.5 × 10^{20} atoms/cm³ for n-type resistors and ~8 × 10^{19} atoms/cm³ for p-type. The contact resistivities (ρ_c) for these resistors following a 400°C/30 min sintering cycle was 1.3 × 10^{-6} and ~4 × 10^{-6} Ω · cm², respectively. These values are in good agreement with Berger's results obtained in sintering cycle of 400°C/20 min.

The effect of sintering on Al/poly-Si contact resistance.—In this series of experiments the contact resistance of poly-Si resistors, with a contact window size of 12 × 10 μm was measured before and after 5 min sintering at temperatures varying between 300° and 560°C. The average sheet resistance of the poly-Si used in these experiments was 26 Ω/sq for phosphorus-doped resistors and 56 Ω/sq for boron-doped resistors.

As shown in Fig. 3 the effect of sintering on Al/poly-Si contact resistance is strongly dependent on whether the dopant is n- or p-type. A 5 min sintering of boron-doped resistors at temperatures between 300° and 560°C always results in a reduction in the contact resistance: the percentage reduction varies between 55% at 300°C to 69% at 560°C. Values of R_c of the p-type resistors decline slowly between 300° and 450°C and then become constant at temperatures >450°C. After sintering current-voltage measurements at 1 mA have shown that the contacts are ohmic.

Using a sintering time of 5 min a reduction of ~31% in the contact resistance of phosphorus-doped resistors is observed between 300° and 350°C. The reduction decreases at higher sintering temperatures and changes to an increase in R_c at temperatures >450°C. Resistors sintered at 560°C for 5 min showed an increase of ~900% in Al/poly-Si contact resistance. Values of R_c increase slowly between 300° and 450°C for these n-type resistors followed by a sharp increase in R_c at sintering temperatures >450°C. Current-voltage measurements have shown that the contacts are ohmic except at 560°C sintering where the measurements became irreproducible, particularly at currents higher than 0.2 mA.

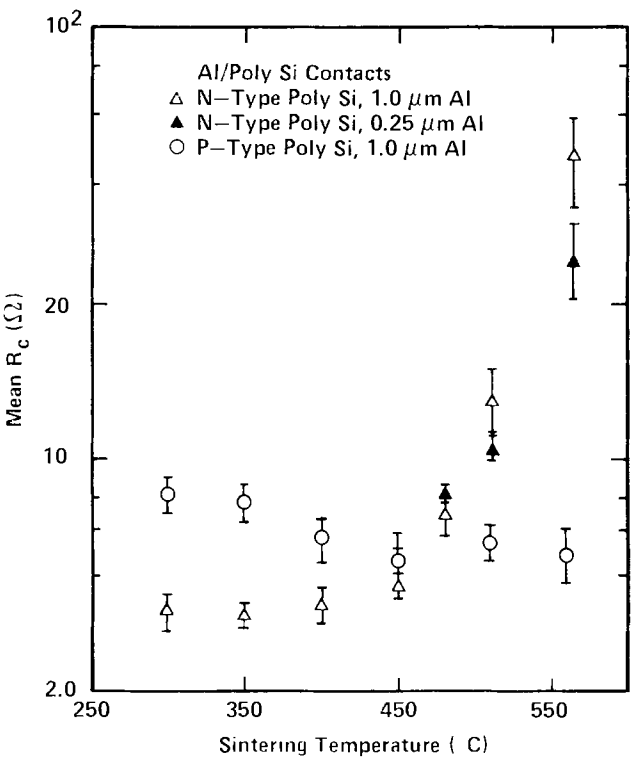

Fig. 3. Al/poly-Si contact resistance, R_c, as a function of sintering temperature. The sintering was carried out for 5 min in N_2.

The substantial increase in contact resistance of phosphorus-doped poly-Si resistors, particularly at temperatures >450°C, can be attributed to the formation of what might be termed a "quasi-Schottky diode." During sintering, Si dissolves into the aluminum to the solubility limit at that sintering temperature. On cooling the dissolved Si precipitates onto the n-Si substrate as a thin, electrically active, p-type (Al-doped) layer. The formation of such a layer on n-contacts has been confirmed recently using scanning electron microscopy (18, 19) and in-depth Auger analysis (20). Also, it has been shown (21) that the formation of a p-layer on n-type Si is responsible for the increase in Schottky barrier heights, ϕ_B, of Al/Si junctions during low temperature heat-treatments (<600°C). It is interesting to note that the increase in ϕ_B (22) occurs at 450°C, the same temperature at which the increase in contact resistance of n-type contacts was observed in our work. In addition, the magnitude of ϕ_B is known to be dependent on the amount of Al available for reaction, as determined by the thickness of the Al metallization (20). We have also found that Al/n-poly-Si contact resistance increases with increasing thickness of the Al metallization, particularly at temperatures >500°C, as shown in Fig. 3.

In another series of experiments Al/poly-Si contact resistance was investigated as a function of poly-Si doping level, as measured by dopant deposition time. The results are summarized in Table II. In general, the contact resistance decreased with increasing doping level. However, it appears that the sintering temperature is the dominant effect in determining R_c values rather than the effects of the dopant concentration.

The effect of contact geometry.—We have also examined the effect of contact geometry on the contact resistance of both Si and poly-Si resistors following a sintering cycle of 450°C/5 min. The contact window dimensions of these resistors are shown in Fig. 4. The aluminum was evaporated on unheated wafers to a thickness of 1 μm. The results are summarized in Tables III and IV. These results are compared with Berger's (9,10) and Murrman and Widman's (11, 12) theoretical analysis.

These authors have shown that a contact to a planar device can be described in terms of a "transmission line

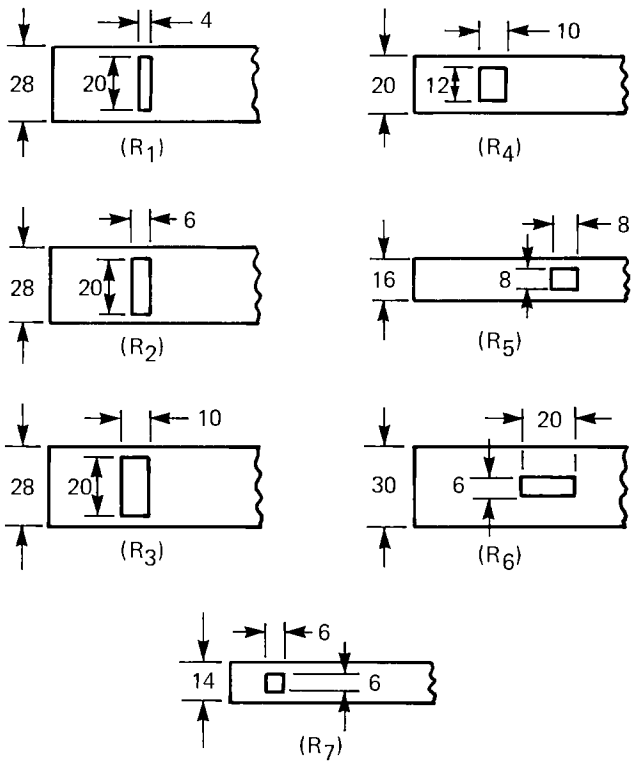

Fig. 4. The end structures of resistors used to determine the effect of contact geometry.

model" (TLM) and may be characterized by; the geometry, the semiconductor sheet resistance R_s beneath the contact, and the contact resistivity, ρ_c. According to the TLM model, R_c is given by the following expression

$$R_c = Z \coth \alpha d \quad [4]$$

where

$$Z = \frac{\sqrt{R_s \cdot \rho_c}}{\omega} \quad [5]$$

and

$$\alpha = \sqrt{R_s/\rho_c} \quad [6]$$

The parameter α can be determined from the equation

$$\frac{R_s \cdot d}{R_c \cdot \omega} = \alpha d \tanh d \quad [7]$$

where R_c, R_s, d, and ω are known. Values of the contact parameter αd calculated for various resistors used in the present investigation are given in Table III and IV.

The TLM model assumes that the contact extends over the total resistor width, *i.e.*, $\omega = W$ and, therefore, it neglects the effect of the crowding resistance,, R_d, which should be considered when $\omega << W$. Ting and Chen (23) have calculated R_d and their results may be written in the following form

$$\frac{R_d}{Z} = \frac{\omega}{2\pi}\left(\frac{1}{k}\ln\frac{k+1}{k-1} - \ln\frac{k^2}{k^2-1}\right) \quad [8]$$

where

$$k = \frac{\omega + 2\delta}{2\delta}$$

$$\delta = \frac{W - \omega}{2}$$

Here, δ is the distance between the contact edge and the resistor edge and is determined by mask alignment and etching tolerances. Taking $\delta = 12$ μm for resistor R_6 and $\delta = 3.75$ μm for all other resistor structures, R_d was calculated for all the resistors, using Eq. [8]. The results are also shown in Tables III and IV.

Within experimental error, the results shown in Tables III and IV are, at least qualitatively, in good agreement with the TLM model. As predicted in this model, for "electrically long contacts" ($\alpha d \geq 2$) of the same contact width, such as resistors R_1, R_2, and R_3, R_c is independent of the contact length. On the other hand, comparison of R_c values for resistors of the same contact length, such as R_2 and R_7, clearly indicate the dependence of R_c on the width of the contact, again as predicted by the TLM model. The dependence of R_c on ω can also be illustrated by comparing resistors R_4 and R_2 which have the same area (120 μm^2), but different geometries.

Except for resistor R_6, where $W >> \omega$, the estimated values of the crowding resistance, R_d for Si and poly-Si resistors, seems to be too small to have a significant influence on the results.

Conclusions

The main conclusions of the present investigation are the following:

1. Sintering at 450°C gives the lowest Al/Si and Al/poly-Si contact resistance for integrated circuit device applications.
2. At sintering temperatures >450°C, the contact resistance for boron-doped resistors is independent of temperature.
3. Phosphorus-doped resistors, particularly poly-Si ones, show a gradual increase in the contact resistance at temperatures >450°C. This is attributed to the precipitation of a p-type (Al-doped) layer and the formation of Schottky diodes on n-contacts during sintering.

* Average number of measurements ≈190.

4. The use of low sintering temperatures and thin Al metallization minimizes the thickness of the p-type layer precipitated on n-contacts and reduces the contact resistance.

5. For contacts most frequently used in integrated circuit devices, the contact resistance is independent of the length of the contact and approximately inversely proportional to the contact width, in agreement with the theoretical predictions of the transmission line model.

Acknowledgments

We wish to acknowledge R. Poulsen for his contribution in designing the test masks and in setting up the computer program used in this work. We also thank R. J. Kriegler for suggesting this investigation and for a critical review of the manuscript. Useful discussions with A. Aitken, J. White, D Colton, and A Ibrahim at BNR are also sincerely appreciated.

Manuscript submitted July 27, 1976; revised manuscript received Nov. 23, 1976. This was Paper 94 presented at the Washington, D. C., Meeting of the Society, May 2-7, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by Bell-Northern Research.

Cathodic Mapping of Leakage Defects

S. M. Hu

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

A new method for diagnosing integrated circuits by mapping leakage defects has been developed. It is based on the cathodic plating of metallic ions, such as nickel, on leaky devices. The method is simple, reliable, and nondestructive, and makes defects easy to spot. Also, it avoids many of the drawbacks of the anodic method of defect mapping. Correlation with *I-V* characteristics is shown. The method has been applied to the study of transistor pipes and swirl defects in silicon substrates. In particular we have used this method to demonstrate that dislocations in silicon can lead to transistor leakage but not necessarily always through enhanced diffusion. The method is complementary to the anodic mapping method; for many applications, each of the methods has its limitations.

Excessive leakage currents in transistors and diodes constitute an important yield detractor in integrated circuits. They may be caused either by the generation of electron-hole pairs at some metallic precipitates at the reverse-biased p-n junctions, or by pathological conductive paths between the emitters and the collectors of transistors. Leakage diagnosis is often important in the development of new processes for manufacturing integrated circuits. *I-V* characterization by direct probing of devices would serve well but for the small size of modern devices, which makes this method not only excessively laborious, but usually impractical. One practical method of diagnosis resorts to certain test vehicles, such as kerf transistors. However, the probabilities of defects on the large test devices and on the actual devices are often not identical. Therefore, a simple method of mapping leaky transistors is needed. The anodic method, though widely used in one version or another, has its drawbacks, and in certain cases does not work at all. The present paper introduces another method, cathodic mapping, which was developed to avoid such drawbacks and limitations.

Anodic Method

To help the reader choose between the two methods, anodic and cathodic, let us begin with a review of the anodic method. Currently there are three variations. In Plantinga's original method (1), the silicon wafer is made an anode by the application of 4V across the cell, and is placed in an electrolyte, the Sirtl etch. Leaky emitters are etched much faster and hence deeper than the nonleaky transistors. The principle of this method is diagrammed in Fig. 1, in which the two main causes of leakage currents are shown to effect charge transfer in the electrochemical reaction

$$Si \rightleftarrows Si^{4+} + 4e \qquad [1]$$

This method, however, is destructive, and the difference between the etch depths of leaky and nonleaky emitters does not lend itself to easy visual recognition in the rapid scan under the microscope that is necessary in examining a large number of transistors on a wafer.

In a modification of the anodic method, described by Kulkarni *et al.* (2), an electrolyte containing no HF (*e.g.*, a solution of 10% $NaClO^4$) is used, and thus the dissolution of silicon is replaced by the oxidation of silicon

$$Si + 2\,O^{=} \rightleftarrows SiO_2 + 4e \qquad [2]$$

This method, although a small layer of silicon is consumed, is less destructive than Plantinga's anodic etching method. A serious drawback is that the anodically grown SiO_2 film has an insulating property. It quickly takes up the major part of the applied voltage; eventually, at a thickness that depends on that voltage, it stops the current flow and ceases to grow. The leakage criterion is usually defined at certain current levels and at an applied voltage of one to a few volts. In the method of Kulkarni *et al.*, the initial applied voltage is 3V, which allows only 200Å of SiO_2 to be grown anodically; such a film on a silicon substrate is, in effect, invisible. It is then expedient to gradually increase the applied voltage stepwise, say at 3 V/min, to 19V; hold it constant for half an hour; and then increase it again steadily to 30V in order to reach a visible oxide about 500Å thick. In the course of these increases, the normally nonleaky transistors will also start to leak at some points, with the result that the devices become covered by SiO_2 of different thicknesses and colors. Since the mapped devices are not clear-cut black-and-white cases, defect counting is inconvenient and sometimes discretional, making the operator hesitate.

Seto *et al.* (3) describe a third variation of the anodic method. By aluminum evaporation and photolithography, thin aluminum pads are formed on the contact areas (*e.g.*, emitter windows). Then the wafer is placed in an electrolyte, an aqueous solution of 8% sulfuric acid, and acts as an anode with an applied voltage of 2.5-5V. If a device has a leakage current above a cer-

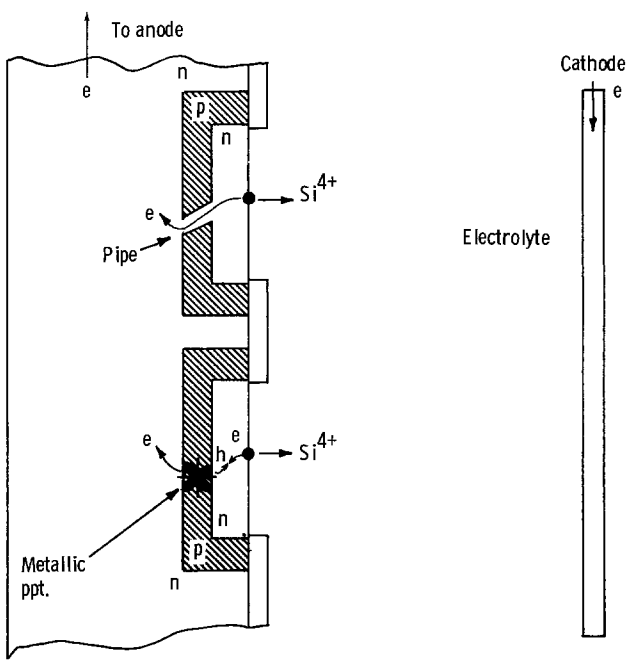

Fig. 1. Anodic etching of leaky transistors. The top transistor is "piped," the bottom one contains a generation-recombination defect.

Key words: electrical leakage, semiconductor devices, defect diagnostics, cathodic plating, pipes, swirl defects.

tain level, the aluminum pads (instead of the silicon) on the device contacts will be oxidized

$$2Al + 3\,O^{=} \rightleftarrows Al_2O_3 + 6e \qquad [3]$$

This version is a vast improvement over the two preceding versions, in two respects. First, the high contrast in reflectivity between the unoxidized and the oxidized aluminum pads makes excellent visibility for rapid scanning of leaky units. Second, the anodic aluminum oxide films, which are electrically fairly leaky by comparison with anodic SiO_2 films, take up very little of the voltage drop across the devices and thus make possible the use of a constant applied voltage. As a result, the oxidized and unoxidized aluminum pads are immediately distinguishable, leaving no need for discretion and hesitation. A drawback of this method is that it requires two extra processing steps, aluminum evaporation and photolithography. Another is that under certain evaporation conditions, the aluminum pads do not anodize at the set voltage. A possible explanation of this peculiarity is that presumably the anodic films formed of aluminum having suitable grain structure are leaky enough to keep the applied voltage almost wholly across the reverse-biased junctions of the devices, whereas the anodic oxide films formed of aluminum having larger grain structure are better insulators and soon become blocking to anodic reactions.

The anodic method, in all three of these versions, has one important limitation: it does not work in certain cases such as n-on-p diodes or multiple emitters with a very large common base. When the substrate is made anodic, the junctions of n-on-p diodes are forward biased, with the result that all the diodes are anodized, whereas we should be interested only in the reverse leakage of the diodes. For multiple-emitter transistors, a very large common base brings a high probability of leakage defects somewhere at the base-collector junction; that is, a very large base-collector junction is most often leaky. This then leads to a case of n-on-p diodes, as illustrated in Fig. 2. In fact, it was the author's experience of such a case that motivated the development of the cathodic leakage-mapping method.

Cathodic Method

In the cathodic leakage-mapping method, the emitter-base junctions are reverse biased, and the leakage

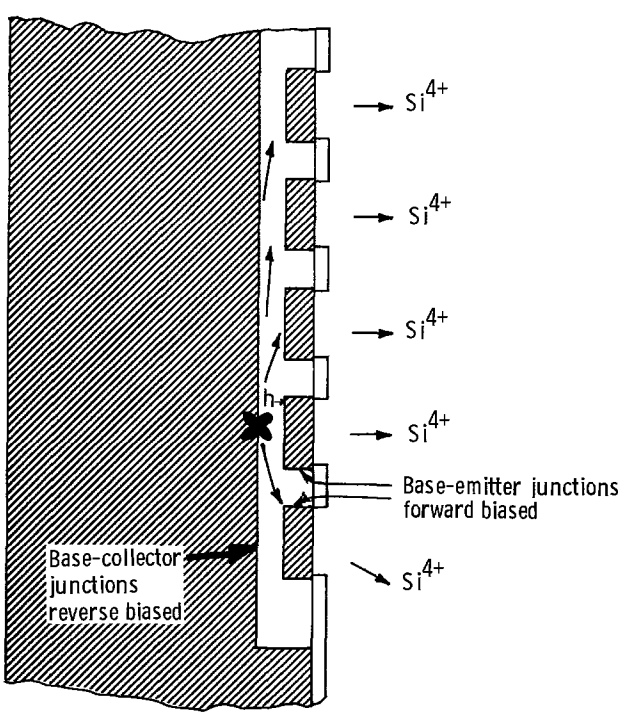

Fig. 2. In the anodic method, a single defect in a large common base-collector function will cause all the emitters in the large common base to be mapped out.

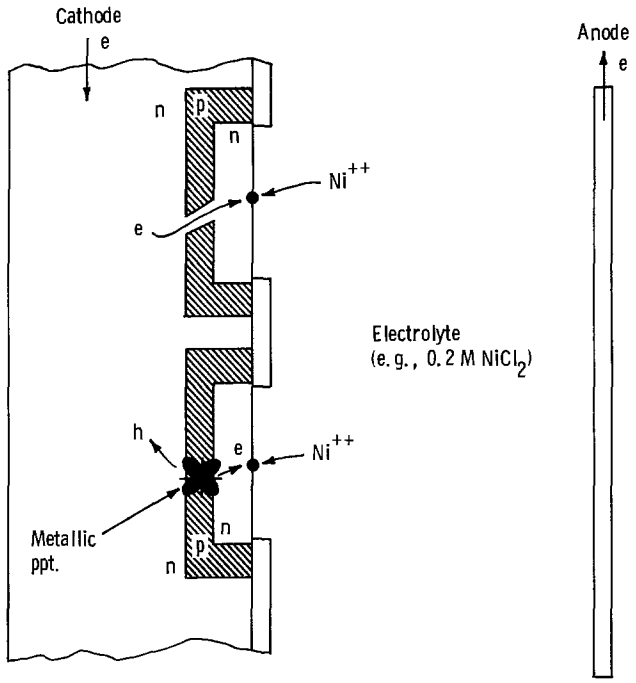

Fig. 3. Cathodic plating of suitable metallic ions, such as nickel, on leaky transistors. The top transistor is "piped," the bottom one contains a generation-recombination defect.

is accompanied by a reverse flow of electrons, which leads to the electrode reaction (Fig. 3). This method is far simpler than the anodic method. The wafer is simply made a cathode with respect to a platinum electrode in a suitable electrolyte containing suitable cations. We found that a 0.2M aqueous solution of nickel chloride with 0.1% of 47% HF gave good results. Other metallic ions having oxidation potentials close to that of nickel can also be used. Ions with low oxidation potentials, such as copper, are not suitable; they tend to plate out automatically even without an externally applied voltage. This tendency, however, can be suppressed by adding a suitable sequestering agent. We have also tried electrophoresis of positively charged colloidal particles, which have the promise of being colored easily; but the results were not quite satisfactory.

Next, a voltage of 2-5V, depending on the particular criterion of leakage current, is applied across the electrodes. Because the nickel films plated on the leaky transistors are highly conductive, the voltage across the device junctions remains essentially constant throughout the mapping operation. This is an important factor in contributing to reliable results by keeping the basis of the leakage criterion constant.

For good visibility, the plated nickel films should be at least 200Å thick. The plating time (in seconds) should then be about $0.03/j$ or longer, where j is the leakage current density (in amperes per square centimeter of emitter area) chosen to distinguish between leaky and nonleaky devices. A longer plating time, for improved visibility, would cause the nominally nonleaky devices to be plated too, with the result that in the neighborhood of the defined leakage criterion, the shade of the mapped emitters might undergo continuous variation. The experimenter would then have to exercise some degree of discretion to count the leaky devices, and the resolution would necessarily be poor. Fortunately, this case has not arisen in the author's experience. There are two possible reasons for this. The first, somewhat speculative, is that this mapping method may have benefited from the overpotential phenomenon (in some ways analogous to the Schottky barrier). Usually, an overpotential develops between an electrode and an electrolyte and is dependent on the electrode material. It appears that the overpotential on a semiconductor silicon surface is high when the sur-

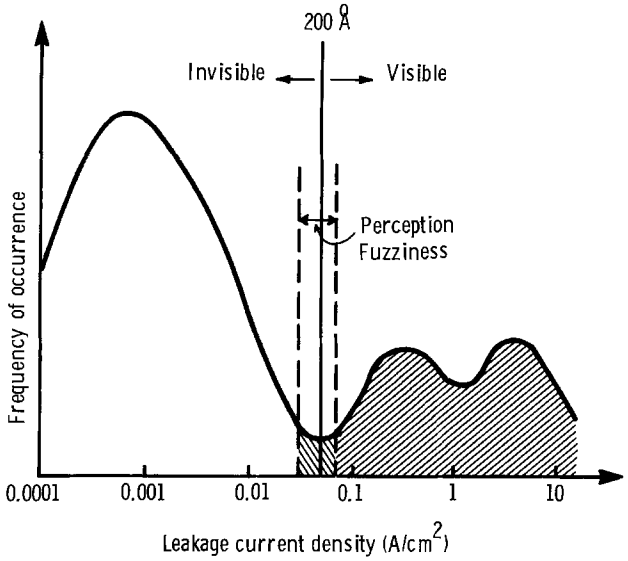

Fig. 4. Schematic illustration of a trimodal leakage current distribution in transistors, fairly representative of actual cases. It is seen that when the cathodic plating voltage and the plating time are so adjusted as to separate the modes, the resulting error due to fuzziness in visual perception will be a very small percentage even without the benefit of the overpotential phenomenon.

face is bare but is suddenly lowered when it is plated with a thin layer of nickel. Once this overpotential is lowered or removed, the plating increases much faster. Thus, for the leaky transistors that have plated past the incubation period, the plated film will be massive and easily distinguishable both from those that are still within the incubation period and from those that will not plate. The second reason, which also helps in reducing the resolution problem, is that in general the leakage current densities of devices carry over many decades in their statistical distributions. Thus, a ±100Å fuzziness in visual perception constitutes a leakage current range that comprises a very small percentage of the devices, particularly if this leakage range is chosen to fall at some node in a multimodal distribution. This is illustrated in Fig. 4.

The cathodic method is nondestructive; the plated nickel films can later be removed, if desired, by placing the wafer in, for example, nitric acid.

Correlation of Cathodic Mapping and *I-V* Characteristics

To demonstrate the correlation between the cathodic mapping and the *I-V* characteristics of devices, and to establish experimental conditions suitable for cathodic mapping, we used a test vehicle consisting of multiple emitters on a common base. The base was formed by blanket diffusion of boron into a n-type, 0.1 Ω-cm substrate. The emitters were formed by diffusion of arsenic through photolithographically defined SiO_2 emitter openings of various sizes. The wafer was placed in a 0.2M $NiCl_2$ solution (with the back side insulated from the solution). Then a voltage of 2.5V was applied between the electrodes, with the silicon wafer as the anode, for 5 min. After being rinsed with deionized water and dried, the wafer was ready for the usual visual counting of leaky devices under a microscope (special chip layouts are usually needed so that the leaky units can be checked conveniently). For correlation, photomicrographs were taken. A plated map is shown in Fig. 5. The appearance of the plated films depends on the additives in the solution and on how the wafer surface has been prepared; they may show up as areas of dark color, as in Fig. 5, or of bright metallic luster. In either case, the contrast with an unplated silicon surface is very strong.

I-V curves were then taken on some of the large devices, both plated and unplated. Only large emitters are accessible to probing. Units 1, 2, 3, and 7 in Fig. 5 measure 125 × 175 μm, and units 5 and 6 measure 75 × 550 μm. Panels of *I-V* curves for units 1-7 are placed alongside the cathodically mapped devices for comparison.

Application of Cathodic Mapping to Defect Study

Study of transistor pipes.—Although the transistor pipe is often discussed, its physical identity and the mechanism of its formation remain unresolved. It is generally thought to be caused by enhanced diffusion of either emitter or subcollector dopant along a segment of dislocation traversing the transistor base. As an example of the application of the cathodic method, we now report an experiment designed to demonstrate that dislocations traversing transistors can cause leakage, but not necessarily only through enhanced diffusion.

We again used a test vehicle with multiple emitters on a large common base. After blanket diffusion of boron into n-type, 0.1 Ω-cm substrate, and photolithographic opening of emitter windows in the SiO_2 film, the sample was given a series of indentations, with a 20g load at 600°C. The apparatus and the procedure of indentation are described elsewhere (4). Two zigzag rows of indentations were made. Each indentation produced an indentation dislocation rosette, whose structure has been described elsewhere (5). Briefly, the rosette consists of four columns of triangular dislocation half-loops, moving parallel to the surface plane of a (001) substrate, as well as four columns of prismatic loops moving down at an angle to the surface. After cleaning, the wafer was given an arsenic emitter diffusion. The cross section of the device is now as shown in Fig. 6, where an inset shows the structure of an indentation dislocation rosette. We may expect that any dislocation segments traversing the transistors will either become pipes by enhanced arsenic diffusion along their length, or accumulate metallic impurities such as copper, nickel, and iron. In either case, the transistors

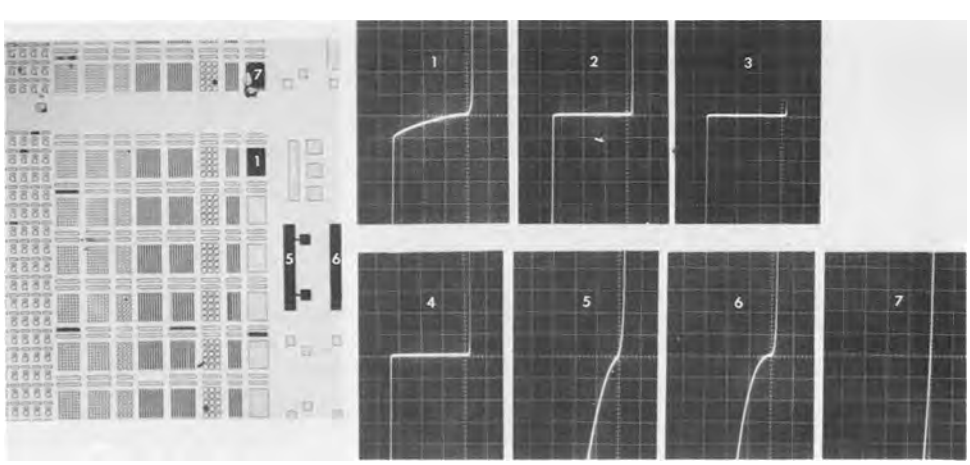

Fig. 5. Correlation between cathodic mapping of leakage defects and *I-V* characteristic. The left-hand side is a photomicrograph of a test chip consisting of multiple emitters of various sizes sitting on a blanket base-collector junction. The darkened units are the leaky units that had been nickel plated. Scales for the *I-V* curves for the corresponding numbered units on the right-hand side are: vertical, 10 μA/div; horizontal, 2V/div.

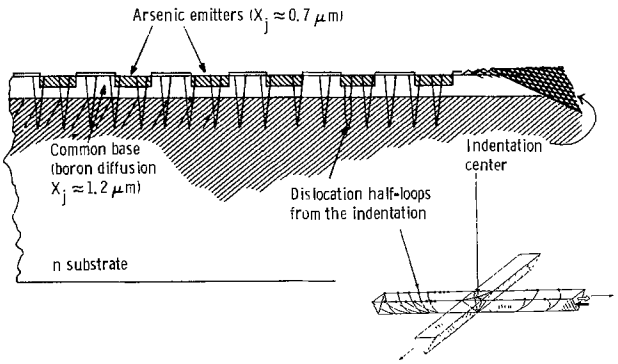

Fig. 6. Schematic illustration showing a number of emitters sitting on a blanket base which have been traversed by a column of dislocation half-loops that had emanated from the indentation center at the right. The emitter diffusion was done after the formation of the indentation dislocation rosette so that there was a chance for enhanced arsenic diffusion along the dislocations. The inset shows a schematic structure of the dislocation rosettes.

traversed by the dislocation half-loops should become leaky. One would then expect the cathodic mapping to reveal these leaky transistors clustered in a pattern of crosses. This was what was observed, as is seen in Fig. 7, showing the results of two separate experiments. The figure serves also to show the possible variation in the texture of plated nickel films.

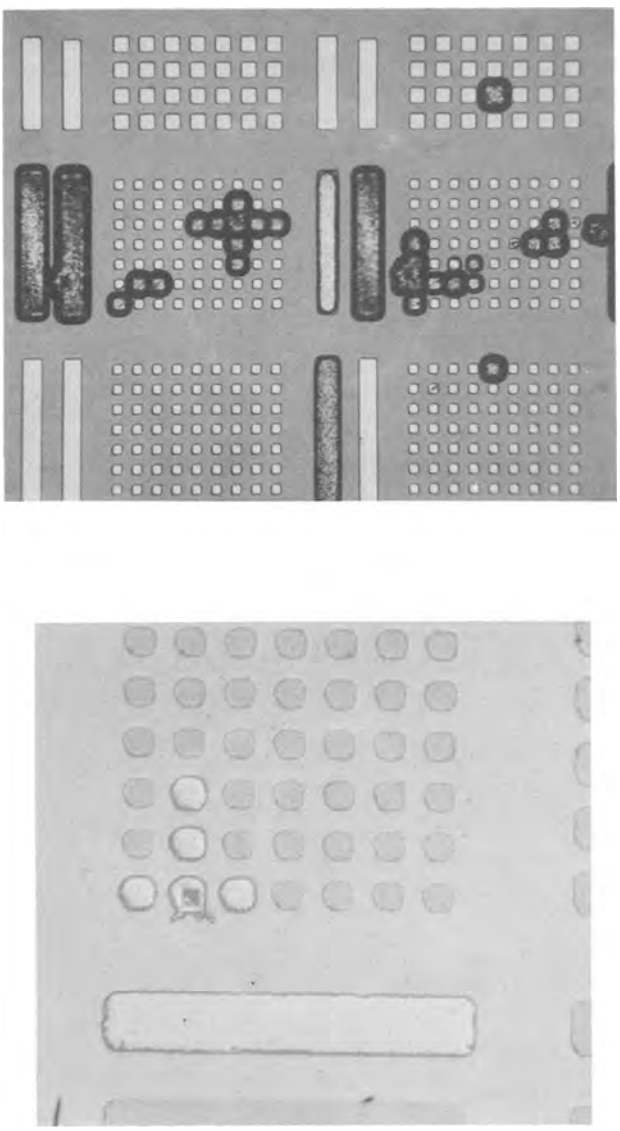

Fig. 7. Photomicrographs showing that the emitters which were traversed by dislocation half-loops in the indentation dislocation rosettes were decorated with high contrast nickel films after cathodic mapping.

To investigate whether the leakage mechanism is enhanced arsenic diffusion (pipe) or an accumulation of metallic precipitates at the dislocations, we applied nitric acid to remove the nickel films plated on the emitters of the leaky transistors. Then a proprietary method of gettering was applied to the back side of the wafer, which, after being annealed in nitrogen at 900°C for 1 hr, was subjected to cathodic mapping for the second time. This time, only the indentations themselves were plated; the emitters in the previously decorated arms of the rosettes were not decorated. This result indicated that the leakage mechanism in the present case is the precipitation of fast diffusing and hence getterable metallic impurity, not the enhanced diffusion of the slow diffusing and hence ungetterable arsenic. It is prudent to add that, though this is true for this particular case of transistor geometrical dimensions and processing parameters, it need not be generally true for other cases. Further study of this subject is being considered.

Leakage from swirl defects.—A second leakage phenomenon is known to be associated with "swirl" defects. In particular, leaks in vidicon diodes reveal themselves as swirls of bright spots (6). Swirl defects are clusters of point defects or microdislocation loops, which are frozen in during the crystal growth but usually are transformed and interact with high temperature processes such as oxidation to produce oxidation stacking faults, etc. The nature of swirl defects is beyond the scope of this paper; here we merely want to demonstrate dramatically, by means of cathodic mapping, that they can lead to junction leakage in devices.

The test vehicle was the same as that described earlier in this paper; here, however, since the occurrence of swirls is very much dependent on the conditions of crystal growth and the particular position in a crystal from which the wafer was cut, the wafer had to be specially chosen. After the device processing and cathodic mapping described earlier, the plated emitters, on n-on-p diodes, were found to cluster in a swirl as shown in Fig. 8. This particular mapping results in highly reflective nickel films on the leaky units, which make the form of the swirl pattern readily visible to the naked eye. Note that in the quarter wafer shown in Fig. 8, a small corner segment of the sample was placed above the electrolyte and hence was not cathodically mapped.

Conclusion

This paper has introduced a new method for diagnosing integrated circuits and their test vehicles by mapping leakage defects. The method is very convenient and simple to use, in contrast with the anodic method.

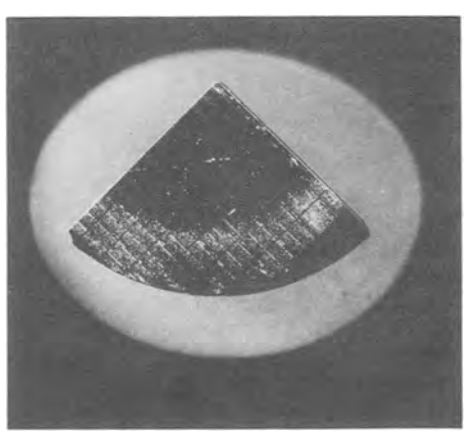

Fig. 8. Cathodic mapping of leakage transistors that images swirl defect distribution (bright band) in a silicon wafer quarter.

It makes the mapped leaky devices highly visible, it is free from the drawbacks associated with the anodic method, it is nondestructive, and it lends itself to repeated use on the same sample. It keeps the voltage drop across the devices constant, thus leading to reliable and interpretable results. It makes for clear distinction between leaky and nonleaky devices, probably because overpotential is reduced once a thin film of nickel has been plated; this effect is in direct contrast with the effect of the insulating anodic oxide film formed in the anodic method.

After mentioning all these virtues of the cathodic method, we must conclude by mentioning its limitation, which is essentially complementary to that of the anodic method. Specifically, it cannot be applied to n-p-n transistors that are completely isolated from the substrate. In modern integrated circuits, many transistors are so isolated. In such cases, the cathodic method would be useful in mapping, for example, leakage in the isolation itself. Another of the numerous possible applications would be the mapping of n-channel FET integrated circuits.

Four-Point Sheet Resistance Measurements of Semiconductor Doping Uniformity

David S. Perloff, Frederick E. Wahl, and James Conragan

Signetics Corporation, Research and Development Laboratory, Sunnyvale, California 94086

ABSTRACT

A system is described for automatically measuring the sheet resistance of doped semiconductor wafers using either a conventional four-point probe or microelectronic van der Pauw resistors. Graphic display formats useful for conveying information about doping uniformity are discussed, and the tendency of random measurement error to degrade equivalue contour maps is illustrated. Excellent agreement is observed for sheet resistance data obtained from van der Pauw resistors which differ in area by more than three orders of magnitude. It is shown experimentally that the four-point probe and van der Pauw resistors may be used interchangeably for doping uniformity measurements.

The spatial uniformity of the processes employed in semiconductor microcircuit fabrication is an important determinant of the matching of components and of the yield of functional circuits. Even a highly controlled doping process such as ion implantation may be subject to intrinsic sources of variability which can adversely affect component matching (1, 2).

Parameters such as sheet resistance and film thickness have been shown to vary systematically over the surface of a processed silicon wafer (3, 4). The equivalue contour maps (topographs), which were used in Ref. (4) for exhibiting spatial variations, summarize a great deal of information in a compact and easily comprehended format. This method of display is, however, extremely sensitive to random measurement error, particularly when such error becomes comparable to the difference in parametric values at adjacent test sites.

In this paper, four-point sheet resistance measurement techniques are described which provide data sufficiently free of random error to justify the use of equivalue contour maps. It will be shown that the four-point probe (FPP) (5, 6) and van der Pauw resistors (7), although sampling areas of the wafer which differ by as much as five orders of magnitude, nevertheless provide comparable information about the spatial distribution of impurities.

Key words: four-point probe, resistor, silicon.

Data Acquisition System

A general-purpose system for the acqusition of four-point sheet resistance data is shown schematically in Fig. 1. This system consists of a standard X-Y probing apparatus, data terminal, recording devices, prober control, and sequencing and interface modules. Two of the four sample probes carry current supplied by a Keithley Model 225 constant (±0.005% stability) current supply; potential differences[1] are measured across the remaining two probes with a resolution of 10 μV by a Nonlinear Systems Corporation Model MX-1 digital voltmeter. The magnitude of the measurement current is adjusted to achieve a potential difference in the range of 30 ± 10 mV for both FPP and van der Pauw resistor measurements.

A rectangular array of up to 99 rows and 99 columns is employed for one-dimensional profiling as well as two-dimensional mapping of wafers. The wafer probe

[1] The polarity of the current supply is reversed and readings of the potential difference averaged to eliminate small offset voltages associated either with thermoelectric effects or instrumentation.

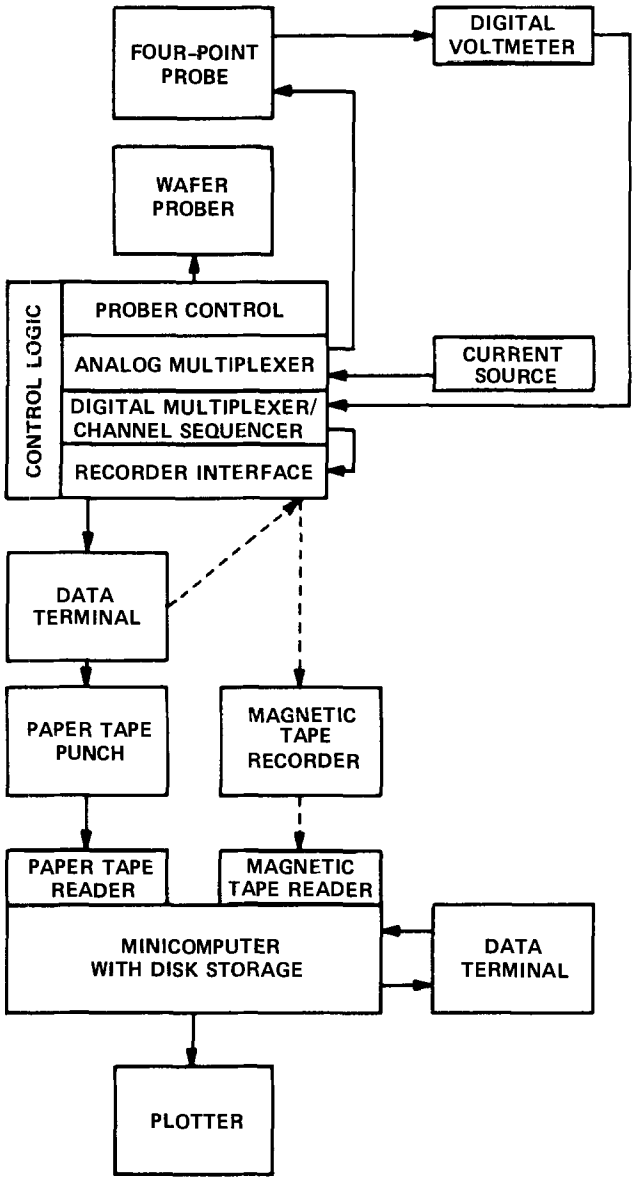

Fig. 1. Data acquisition system

step-and-repeat distances ΔX and ΔY may be varied between 10 and 999 mil in increments of 1 mil along both the X and Y axes of movement. At each test site, an analog multiplexer is used to switch analog signals. For each analog channel, a digital multiplexer and its associated digital channel sequencer select up to nine channels for transfer by the interface system to the recording device (paper tape punch or incremental magnetic tape recorder).

Data are analyzed off-line by a Digital Equipment Corporation Model PDP 11/40 minicomputer with associated system and program disk drives, tape reader, and terminal. Conventional disk management and program overlay techniques make it possible to handle an extensive data base. The hard copy output device (Versatec Incorporated "Matrix") may be operated as a conventional line printer or as a high resolution plotter. In the latter mode, images are built up and stored on disk until the analysis has been completed, then printed continuously.

Presentation of Data

There are a number of alternatives for displaying the spatial variation of sheet resistance data. These include one-dimensional profiles, two-dimensional maps (1, 4, 6, 8-10), and three-dimensional perspective drawings (3, 9, 10). Discussion in this section is restricted to the one- and two-dimensional formats, since these are considered by the authors to be more easily interpreted than perspective drawings, particularly for smoothly varying data.

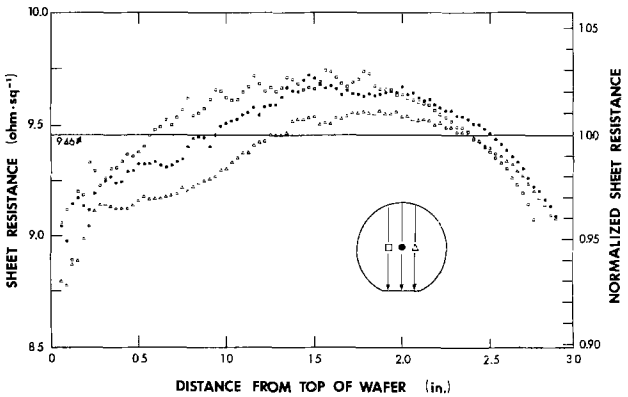

Fig. 2. One-dimensional FPP sheet resistance profiles for a phosphorus-diffused wafer ($\bar{\rho}_s$ = 9.46 Ω/sq and $\sigma^*(\%)$ = 2.47%).

One-dimensional profiles.—Figure 2 illustrates the variation in sheet resistance from top edge to bottom edge of a 3 in. diameter p-type silicon wafer doped with phosphorus from a phosphine diffusion source. Three parallel profiles (ΔX = 444 mil, ΔY = 30 mil) have been obtained using an in-line FPP (11) oriented perpendicular to the direction of travel. The solid line (9.46 Ω/sq) represents the mean sheet resistance as determined by averaging data from 118 sites on the wafer, as described below. The scale on the right side of the figure represents the fractional deviation from the wafer mean and permits comparison with the equivalue contour map discussed below.

One-dimensional profiles provide detailed information concerning the point-to-point variation in doping across the surface of a semiconductor wafer. They are particularly useful for exhibiting rapid local fluctuations such as are known to occur in ion-implanted wafers (1).

Two-dimensional maps.—The method of mapping sheet resistance variations employed by the authors involves measurements at 118 standard test sites located on the square grid shown in Fig. 3a. The distance between grid points is L = 222 mil for a 3 in. diameter wafer. The mean sheet resistance $\bar{\rho}_s$ and standard deviation σ are given by the expressions

$$\bar{\rho}_s = \frac{1}{118} \sum_{i=1}^{118} (\rho_s)_i \qquad [1]$$

and

$$\sigma^2 = \frac{1}{117} \sum_{i=1}^{118} [(\rho_s)_i - \bar{\rho}_s]^2 \qquad [2]$$

For an ideal gaussian distribution, ~95% of the data fall within two standard deviations of the mean. For this reason, the authors employ as a quantitative measure of the doping uniformity $\pm 2\sigma^* \times 100\%$, where the relative standard deviation σ^* is defined by the relation

$$\sigma^* = \frac{\sigma}{\bar{\rho}_s} \qquad [3]$$

After evaluating $\bar{\rho}_s$ and σ, the 118 sheet resistance values are displayed in one of the three formats which will now be described.

Deviation maps.—Figure 3b is an example of a deviation map for the same wafer for which one-dimensional profiles are plotted in Fig. 2. Deviations from $\bar{\rho}_s$ are computed according to the formula

$$\Delta_i(\%) = [(\rho_s)_i/\bar{\rho}_s - 1] \times 100\% \qquad [4]$$

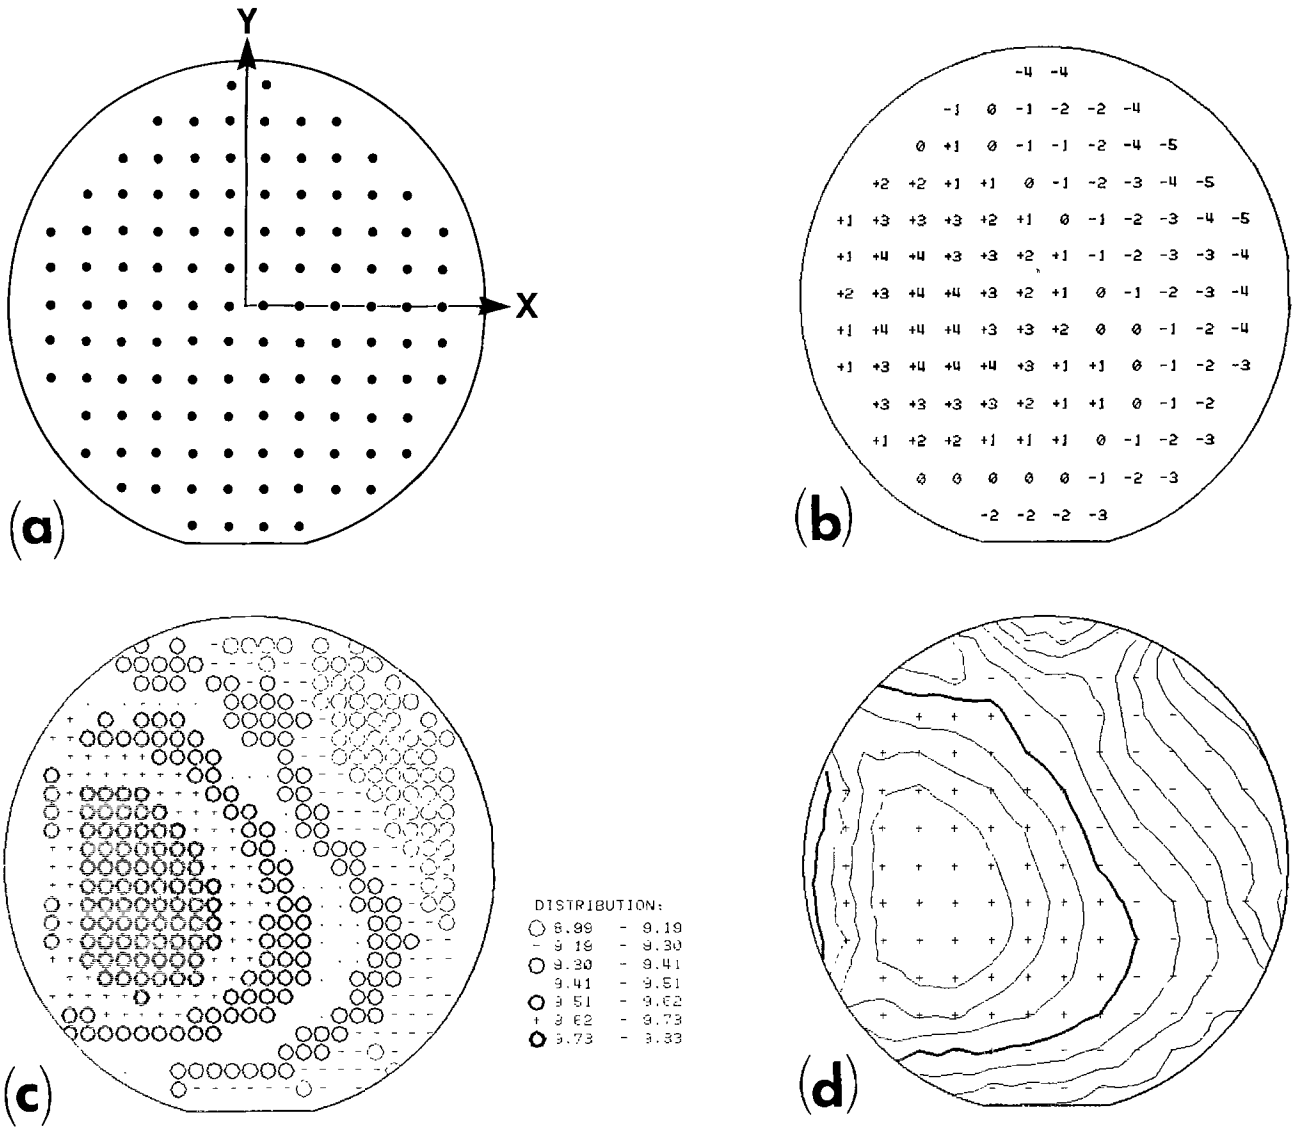

Fig. 3. Methods of displaying spatial sheet resistance variations: (a) standard 118 test site configuration; (b) percent deviation map; (c) histograph; (d) equivalue contour map. The data were obtained from FPP measurements of the wafer of Fig. 2.

rounded to the nearest integer value and plotted at the appropriate test site locations.

This display format requires the least amount of computation and can be implemented with a standard line printer. The underlying pattern of variation (Fig. 3c and 3d) may be observed by drawing smooth contour lines which enclose equal values of $\Delta_i(\%)$. (These contours may be drawn automatically using the graphic display techniques described in this paper.)

Histographs.—It is common practice to employ histograms to summarize the distribution of data over a range of values. Figure 3c is a histograph (two-dimensional histogram) which associates each measured value, and the interpolated values discussed below, with one of seven intervals into which the full range of experimental data has been divided. These intervals, each of which contains an equal number of values, are identified by circles of various line thicknesses and the symbols +, ·, and −. Unlike the deviation map, for which the + (−) sign identifies values which are above (below) the wafer mean, this method of display identifies values which are above (below) the wafer median.

The histograph succeeds in revealing the underlying pattern of variation by separating the data into seven bands of alternating character density.[2] In order to obtain continuous bands, it was necessary to first subdivide the initial network (Fig. 3a) by employing an interpolation scheme (described below) which results in a fourfold increase in the density of grid points. The distance between subgrid points for a 3 in. diameter wafer is 111 mil.

Equivalue contour maps.—Figure 3d shows an equivalue 1%-contour map obtained from the same data used for Fig. 3b and 3c. The heavy contour represents the mean sheet resistance $\bar{\rho}_s$, computed using Eq. [1], while the lighter contours differ from $\bar{\rho}_s$ in increments of $0.01\ \bar{\rho}_s$. The symbols + (−) identify experimental values which are greater (less) than $\bar{\rho}_s$. A curve representing the variation of ρ_s along any particular direction (as in Fig. 2) may be constructed by determining the points of intersection with the equivalue contours.

As in the case of the histographs discussed above, interpolation has been used to increase the density of grid points. This procedure assures that the contours, which are constructed from discrete line segments, will appear smoothly varying to the eye. In addition, a linear extrapolation scheme is utilized which allows contours to extend to the edge of the map.[3] These refinements help, in the opinion of the authors, to make

[2] A similar approach is employed in Ref. (10), in which the magnitude of a parameter is indicated by the darkness of the position characters.

[3] The contours drawn near the edge of the map may not be quantitatively correct since resistance values may change more rapidly near the edge of the wafer than over its interior. The extrapolation procedure is justified, however, as an aid to achieving a qualitative appreciation of the spatial variation of the parameter.

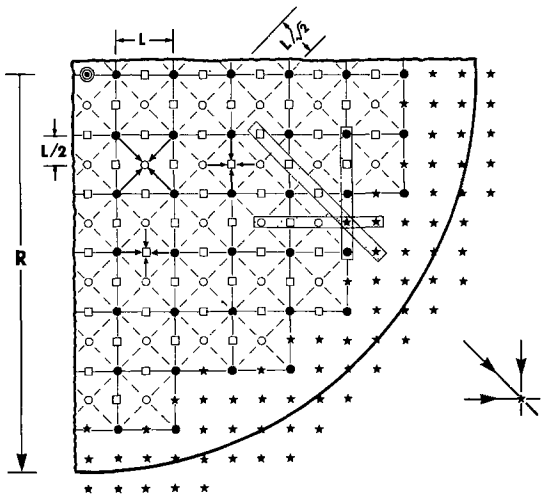

Fig. 4. Interpolation and extrapolation of data in the lower right quadrant of the wafer. The principal directions along which extrapolation is carried out are shown at the lower right.

equivalue contour maps the most effective means of displaying the patterns of spatial variation which are characteristic of semiconductor doping processes.

Interpolation and extrapolation of data.—Figure 4 illustrates the manner in which interpolation is carried out in the lower right quadrant of the wafer. A subgrid with cell parameter $L/2$ is obtained from the initial network of data points (●) in two stages. The first stage involves averaging the four experimental data points at the corners of the original grid cell to obtain the values represented by the symbol ○. This procedure results in a new grid rotated through 45° and having a cell parameter $L/\sqrt{2}$. The second stage involves averaging the four values at the corners of each $L/\sqrt{2}$ grid cell to obtain new values identified by the symbol □.

At the periphery of the expanded data array, extrapolation is used to obtain those subgrid values (★) which cannot be generated by the four-corner averaging technique described above. One estimate at an empty subgrid site is obtained by employing a least squares linear fit to a set of four nearby data points lying along one of the principal directions shown in Fig. 4. Using estimates obtained for the other two principal directions, one computes an average value for the sheet resistance at that point on the wafer. An example of this treatment of the data is shown in Fig. 4 for the case of the empty site nearest the center of the wafer. (In this instance, only three values are used along two of the principal directions, since the fourth value corresponds to an empty site.) This procedure is carried out, one site at a time, always filling the empty site nearest to the center of the wafer. Off-wafer sites are also filled in order to allow equivalue contours to extend to the wafer boundary, thereby significantly improving the comprehensibility of the contour map.

Measurement error.—The influence of random measurement error on the one-dimensional profiles in Fig. 2 is revealed by the scattering of data points. In a two-dimensional equivalue contour map, random error is manifested by irregular, distorted, or—in extreme cases—isolated contours. A technique for experimentally determining random error and the effect of such error on equivalue contour maps will now be discussed.

Experimental assessment.—The most direct way to assess random error is to determine the variation among a series of independent measurements of the sheet resistance. The procedure employed by the authors is illustrated in Table I, which summarizes a series of independent FPP (11) sheet resistance measurements made at nine different locations in a 3 × 3 square array ($\Delta X = \Delta Y = 120$ mil) centered on the phosphorus-diffused wafer for which data are presented in Fig. 2 and 3. After recording the first ($j = 1$) set of nine readings (probes along the X axis), the FPP is returned to its initial position, displaced 2 mils along the X axis, and a second ($j = 2$) set of nine readings recorded. This procedure is repeated until five readings have been obtained at each location. Each set of five readings is in turn used to compute a local standard deviation given by the expression

$$(\sigma_e)_i^2 = \frac{1}{4}\sum_{j=1}^{5}[(\rho_s)_{ij} - (\bar{\rho_s})_i]^2 \qquad [5]$$

where $(\bar{\rho_s})_i$, the local mean sheet resistance, is

$$(\bar{\rho_s})_i = \frac{1}{5}\sum_{j=1}^{5}(\rho_s)_{ij} \qquad [6]$$

These nine standard deviations are then used to compute an average standard deviation of the measurement error according to the formula

$$\sigma_e^2 = \frac{1}{9}\sum_{i=1}^{9}(\sigma_e)_i^2 \qquad [7]$$

When comparing values of σ_e for wafers of different sheet resistance, it is convenient to employ the relative standard deviation of the measurement error

$$\sigma_e^* = \frac{\sigma_e}{(\bar{\rho_s})_e} \qquad [8]$$

where $(\bar{\rho_s})_e$ is the average sheet resistance for the 45 measurements. The value $\sigma_e^*(\%) = 0.136\%$ obtained from Table I is typical of the random measurement error which the authors experience with a 25 mil FPP assembly on layers having sheet resistance ≤ 500 Ω/sq.

Effect on contour maps.—The effect of measurement error on a two-dimensional display format may be simulated by systematically introducing randomness into a set of data, $P(X, Y)$, whose relative standard deviation is $\sigma_P^* = \sigma_P/\bar{P}$. The influence of measurement

Table I. An example of the determination of FPP measurement error for the phosphorus-diffused wafer of Fig. 2 and 3. According to Eq. [7], $\sigma_e^*(\%) = 0.136\%$.

† The location $X = 0$, $Y = 0$ represents the center of the wafer.

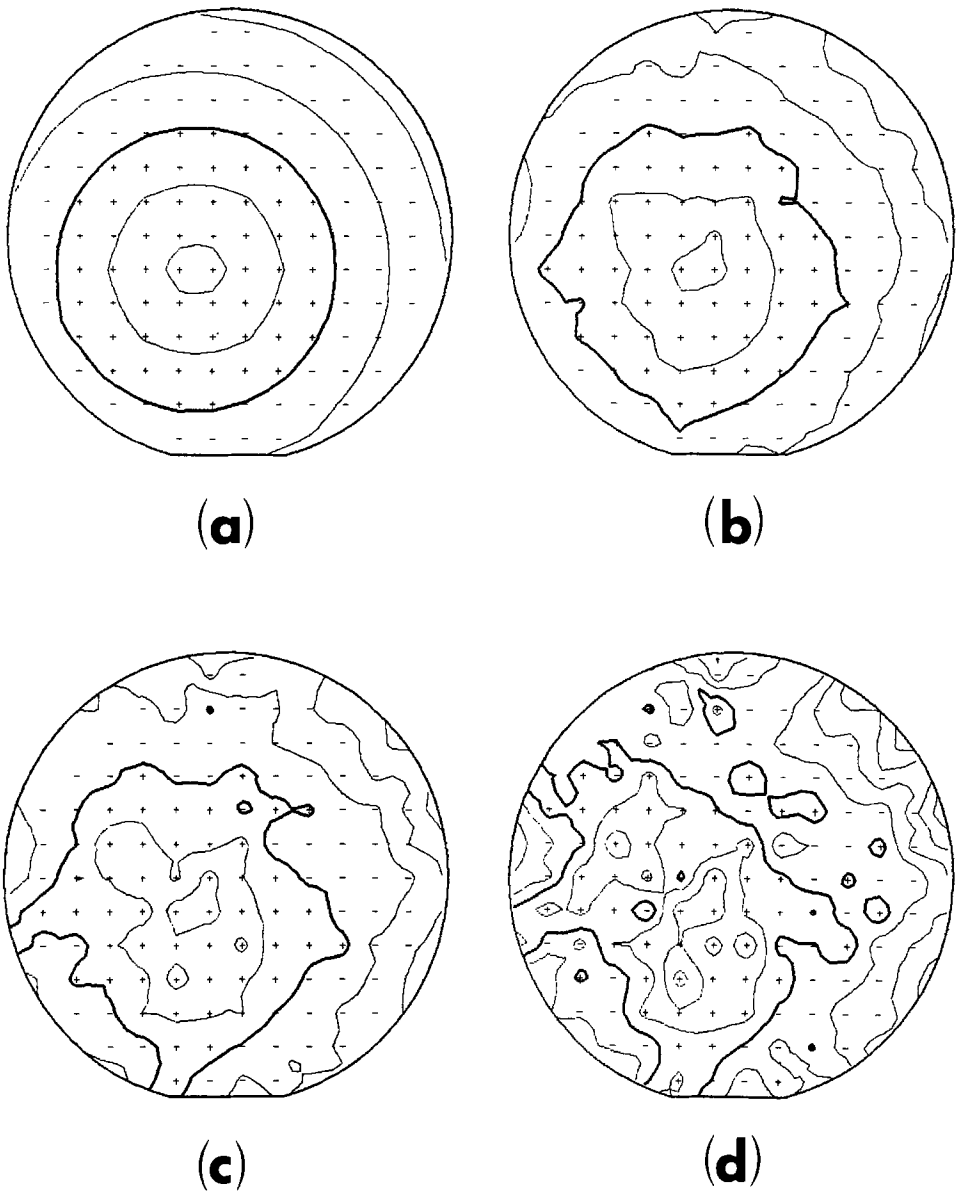

Fig. 5. The effect of random error of magnitude $\sigma_\epsilon^*(\%)$ on a hypothetical distribution for which the over-all uniformity is $\sigma_P^*(\%) = 1.00\%$: (a) $\sigma_\epsilon^*(\%) = 0$; (b) $\sigma_\epsilon^*(\%) = 0.25\%$; (c) $\sigma_\epsilon^*(\%) = 0.50\%$; (d) $\sigma_\epsilon^*(\%) = 1.00\%$.

error is simulated by adding to each of the 118 $P(X, Y)$ values a random number $\epsilon(X, Y)$ selected from a normal distribution with a nominal mean of 0 and a relative standard deviation $\sigma_\epsilon^* = \sigma_\epsilon/\bar{P}$.

Examples of this procedure for various values of σ_ϵ^* are shown in Fig. 5a-5d for the case of a pattern of concentric circles (note similarity to Fig. 3d) for which $\sigma_P^*(\%) = 1.00\%$. As σ_ϵ^* increases in magnitude, the contours become progressively less regular until a point is reached at which it is no longer possible to recognize the underlying pattern of variation shown in Fig. 5a. This point appears to occur when $\sigma_\epsilon^*(\%) \approx 0.50\%$, since the underlying pattern, which can be detected in Fig. 5b despite the irregular contours, can no longer be identified in Fig. 5c. Figure 5d illustrates the consequences of the measurement error becoming comparable to the intrinsic variability of the data. Not only have the circular contours become so distorted that they reach the edge of the wafer map, but many isolated regions have appeared as a result of large excursions from the correct local behavior.

Measurement Techniques

In this section the FPP and van der Pauw resistors are discussed from the perspective of producing data suitable for mapping sheet resistance variations. A special test mask is then described which incorporates both vehicles on the same wafer, making it possible to carry out a direct experimental comparison.

FPP measurements.—It is common practice to employ an in-line FPP, as shown in Fig. 6, for characterizing the sheet resistance of doped semiconductor wafers (5, 6). If the probe separation distance s is at least twice the thickness of the layer being measured, then

$$\rho_s = k\frac{\Delta V}{I} = kR \qquad [9]$$

where k is a geometrical correction factor which depends on the location of the probes and the shape of the sample, I is a current through two of the probes, ΔV is the potential difference measured between the remaining two probes, and the resistance R is defined

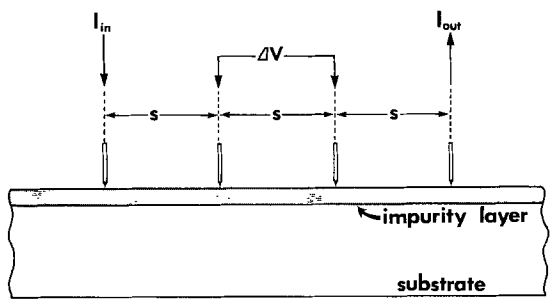

Fig. 6. Conventional current/voltage configuration for an in-line FPP array.

as $\Delta V/I$ (12). Ordinarily, the outer two electrodes of the in-line FPP carry current and the inner two electrodes are used to measure voltage since, for an FPP having equal distances of separation between the probe needles, this assignment results in the largest value of ΔV (13).

Logan (14) has shown that a circular sample doped on both sides (such as the phosphorus-diffused wafer described above) should behave as if its front surface were part of a continuous infinite sheet. Thus the correction factor is a constant value ($k = \pi/\ln 2 = 4.532$), independent of the location of the FPP. In contrast, a thin circular sample doped on one side will require knowledge of the orientation and position of the probe array in order to utilize Eq. [9]. General expressions have been derived for the case of the FPP oriented along the radius (14) and for the FPP oriented perpendicular to the radius (15) of a thin circular sample. Perloff (6) has derived expressions for the FPP oriented at an arbitrary angle with respect to the wafer radius, making it possible to employ automatic wafer probing equipment for evaluating doping uniformity.

An alternative approach to FPP measurements, which is particularly useful for ion-implanted wafers, involves the application of photolithographic techniques to define rectangular regions of sufficient size to accommodate the FPP array, as shown in the cross-sectional view of Fig. 7a. If an automatic wafer probing apparatus is employed to position the FPP so that it occupies the same relative location in each pattern (Fig. 7b), k will assume a constant value over the entire wafer. When the FPP is positioned equidistant from the edges of a rectangular test pattern (RTP), the solution furnished by Smits (12) may be employed to compute the correction factor. Figure 8 is a plot of k *vs.* $b/3s$ for the case of an in-line FPP, probe separation s, situated symmetrically within RTP's of length b and width a. The magnitude of k, for fixed values of the ratio $b/3s$, decreases rapidly as the aspect ratio b/a increases. Experimental points were obtained for

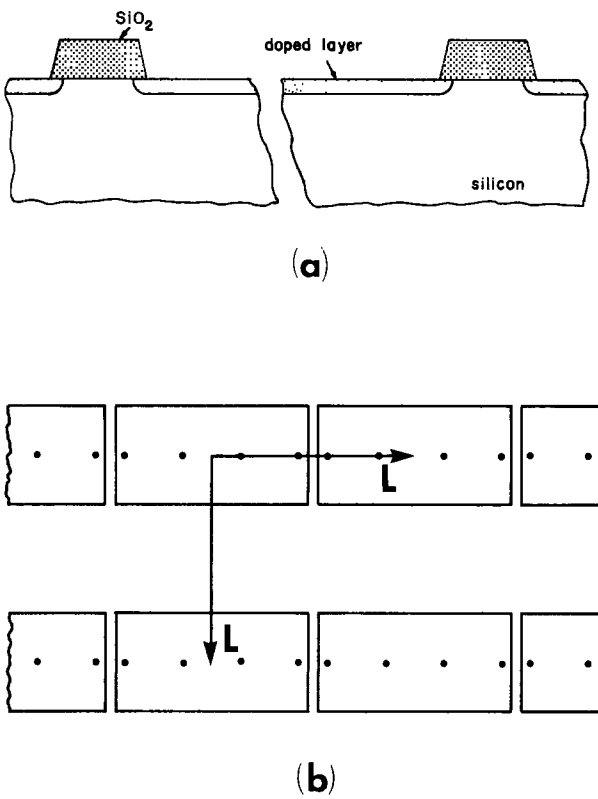

Fig. 7. Rectangular test patterns used in conjunction with an in-line FPP to eliminate variations in correction factor: (a) cross section through test pattern; (b) arrangement of patterns on a square grid (L = 222 mil for a 3 in. diameter wafer).

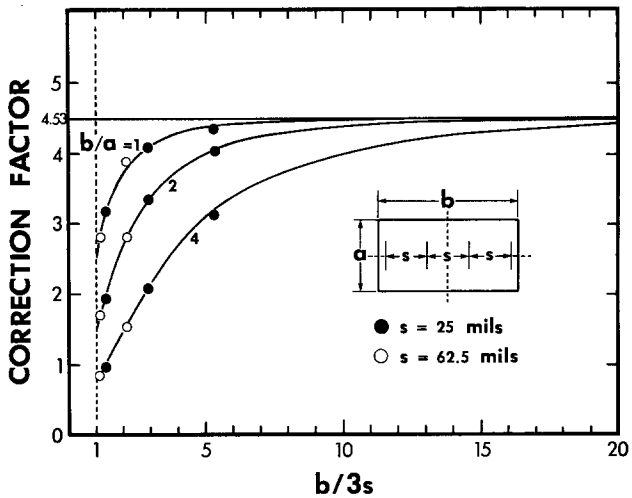

Fig. 8. Correction factor k *vs.* $b/3s$ for a FPP symmetrically positioned within a rectangular test pattern of length b and width a.

various size RTP's using FPP assemblies for which s = 25 and 62.5 mil.

The sensitivity of the FPP to small doping variations is illustrated in Fig. 9a which represents a typical pattern of variability obtained for a 3 in. diameter n-type silicon wafer implanted with boron in a mechanically scanning implantation system (1). (These data were obtained by employing an s = 62.5 mil FPP in conjunction with 220 × 110 mil^2 RTP's.) Figure 9b represents the pattern predicted on the basis of small changes in the linear velocity of the wafer as it traverses a stationary ion beam. This pattern, which is unique to the Ferris wheel mechanism employed for moving the wafers, corresponds extremely well to the experimental results of Fig. 9a. The irregularity in the contours of Fig. 9a is, as discussed above, a consequence of random error in the experimental sheet resistance data. The effect is not, however, significant enough to impair the interpretation of the resulting contour map.

The use of the FPP for evaluating the sheet resistance of junction isolated implanted layers has been discussed by Stephen (16) who identified the following sources of error when making such measurements: surface effects, junction leakage, geometrical factors, magnitude of the measuring current, probe loading, and ambient temperature. In practice, by employing commercially available "precision" probe assemblies and restricting the measurement to layers greater than 2000Å in thickness and less than 500 Ω/sq, one can achieve an absolute accuracy of ±1% and a $\sigma_e^*(\%) \leqq 0.5\%$. The primary source of error, under these circumstances, is associated with variation in the distances between adjacent probe needles due to mechanical tolerances of the probe assembly (17).

Van der Pauw resistor measurements.—The FPP cannot conveniently be used to evaluate a series of doping steps on the same test wafer, as would be desirable when examining the spatial variation of device parameters. Van der Pauw (7) has described a resistor geometry which can be fabricated simultaneously with active devices and should be insensitive to variations in both the photomask and the exposure and etching steps used to delineate the pattern. The sheet resistance of a van der Pauw resistor is determined from the relation

$$\rho_s = \frac{\pi}{\ln 2}\,\frac{R_a + R_c}{2}\,f(R_a/R_c) \qquad [10]$$

where, with reference to Fig. 10, $R_a = \Delta V_{23}/I_{14}$, $R_c = \Delta V_{43}/I_{12}$, and the function $f(R_a/R_c)$ satisfies the transcendental expression

$$\frac{R_a/R_c - 1}{R_a/R_c + 1} = \frac{\cosh^{-1}[(1/2)\exp(\ln 2/f)]}{\ln 2/f} \qquad [11]$$

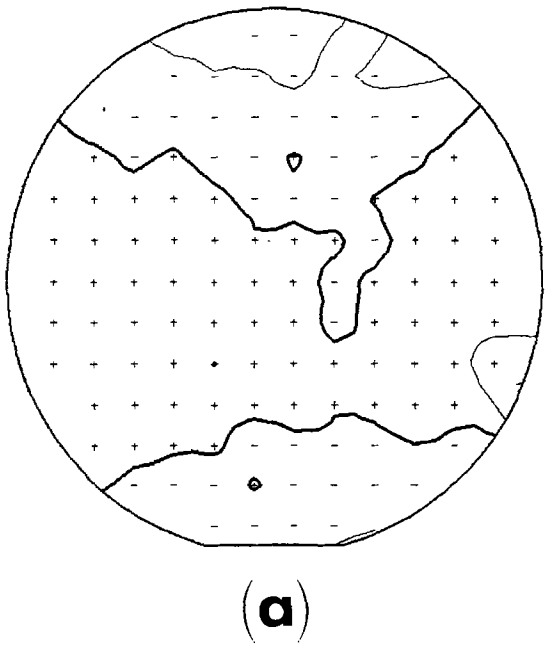

Fig. 9. Pattern of variation for a wafer implanted in a mechanically scanning system: (a) experimental results ($\sigma^*(\%) = 0.50\%$, $\bar{\rho}_S = 34.5$ Ω/sq; (b) predicted behavior ($\sigma^*(\%) = 0.35\%$).

A third current/voltage configuration, $R_b = \Delta V_{24}/I_{13} = R_a - R_c$, is ordinarily used for Hall effect measurements. For a symmetric pattern and symmetrically arranged contacts, one has that $R_a = R_c$ and consequently $f(R_a/R_c) = 1$.

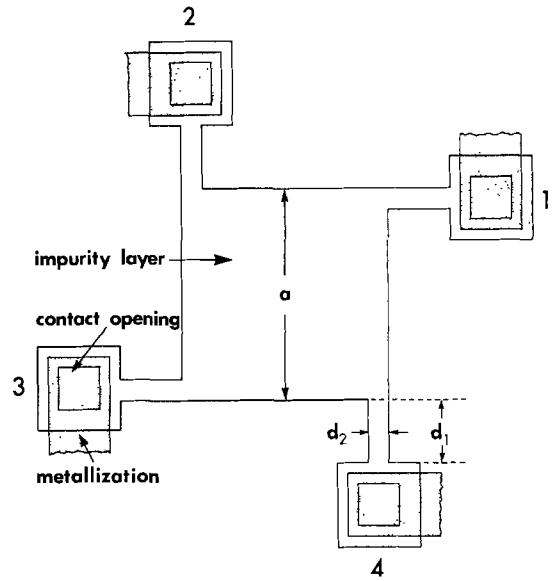

Fig. 10. Van der Pauw four-point resistor structure

Van der Pauw's analysis is based on the assumption of point contacts. In practice, however, one is obliged to make contact to the body of a van der Pauw resistor through arms of finite width. David (18) has determined the error associated with measuring the sheet resistance of a structure with orthogonal boundaries and finite-width contact arms. For the offset quadrate cross shown in Fig. 10, which is the geometry employed in the National Bureau of Standards process evaluation mask set (NBS-3) (19), Eq. [10] is correct to better than 0.1% as long as the requirement $d_1/a \geq d_2/a$ is fulfilled.

Comparison of FPP and van der Pauw measurements. —In order to compare directly FPP and van der Pauw measurements, the authors have employed a specialized test mask which permits both types of measurements to be made at each of the 118 standard test sites shown in Fig. 3a. A 212 × 50 mil² RTP, designed to accommodate a 62.5 mil FPP, and four different size van der Pauw resistors of the design shown in Fig. 10 are employed for this comparison. For each size van der Pauw resistor, three identical structures are clustered as close together as possible to facilitate a determination of random measurement error.

Table II summarizes the results of an evaluation of a 3 in. diameter boron-implanted (150 keV, 5×10^{14} cm^{-2}) n-type silicon wafer. The excellent agreement among values of ρ_S and $\sigma^*(\%)$, for structures varying in area over almost five orders of magnitude, is typical of the comparative behavior observed by the authors at impurity concentrations above ~10^{18} cm^{-3}. Figure 11 compares equivalue contour maps constructed from data for (a) the 10 × 10 μm² van der Pauw resistor, (b) the 100 × 100 μm² van der Pauw resistor, and (c) the 5400 × 1260 μm² = 212 × 50 mil² RTP. These maps, which convey essentially identical information about

the spatial variation of sheet resistance, demonstrate conclusively that the FPP and van der Pauw resistors may be used interchangeably. [Changes in the velocity of the wafer in a mechanically scanning implantation system employing track-mounted wafer carriers are responsible for the distinctive pattern (1).]

As discussed in the preceding section, random error plays an important role in determining the visual quality of equivalue contour maps. Table II provides results for $\sigma_e^*(\%)$ for the five different test structures. The van der Pauw resistor data were obtained by measuring the three "identical" structures for each of the four resistor sizes at nine different wafer locations. The FPP data were obtained by performing five independent measurements on each of nine different RTP's.[4] It is clear that the use of two independent current/voltage configurations leads to a dramatic reduction in $\sigma_e^*(\%)$ for each size van der Pauw resistor but particularly for the 10 × 10 μm^2 resistor, for which the one-configuration value is 0.832% and the two-configuration value is 0.020%. It is noteworthy that even the 500 × 500 μm^2 van der Pauw resistor is influenced by geometric variations to a small extent as evidenced by the one-configuration value of 0.078% *vs.* the two-configuration value of 0.057%. The value of 0.057% for the FPP measurements compares favorably with the two-configuration values for the van der Pauw resistors.

The importance of using two-configuration data for small van der Pauw resistors may be appreciated by comparing the maps of Fig. 12, representing $4.532R_a$ and $4.532R_c$ data for the 10 × 10 μm^2 resistor, with the map of Fig. 11a, which was constructed by combining these data in accordance with Eq. [10]. The contour maps of Fig. 12 exhibit the influence of random error as irregular contours and isolated features, just as occurs in the measurement error simulations of Fig. 5c and 5d.

Table III summarizes the measurement error data used to compute $\sigma_e^*(\%)$ for the 10 × 10 μm^2 van der Pauw resistor. The large variation among the one-configuration values $(\rho_s)_{i1}$, $(\rho_s)_{i2}$, and $(\rho_s)_{i3}$ is attributed to fluctuations in photolithography and etching which cause the dimensions of nominally identical structures to vary randomly. The variability which still remains in the two-configuration data is associated, at least for the 10 × 10 μm^2 resistor, with the finite resolution of the digital voltmeter and stability of the current supply. This conclusion is based on the fact that, irrespective of resistor size, repeated measurements of the same van der Pauw resistor lead to values of $\sigma_e^*(\%)$ in the range 0.015-0.020% for both the one- and two-configuration cases. Additional sources of variability are attributed to local gradients in sheet resistance, junction leakage current, and changes in ambient temperature. Some of these effects may be influencing σ_e^* for the larger van der Pauw resistors, particularly local resistivity gradients, since these would be expected to become more important as the center-to-center spacing between patterns increases.

Conclusion

The results of this investigation demonstrate that both the conventional FPP and van der Pauw resistors of microelectronic dimensions are suitable for use with automated wafer probing equipment for characterizing the doping uniformity of semiconductor wafers. Both vehicles are capable of providing sheet resistance data sufficiently free of random measurement error to

[4] The FPP was displaced in 2 mil increments parallel to the 212 mil side of the RTP, with the third repetition corresponding to the symmetry position. The geometric error inherent in this choice of probe locations is not a significant contribution to the measured value of σ_e^*.

Table III. An example of the determination of measurement error for resistor vdP-1 of Table II. According to Eq. [7], $\sigma_e^*(\%) = 0.832\%$ for the one-configuration case and 0.020% for the two-configuration case.

justify the use of high resolution two-dimensional graphic display techniques.

The procedure employed for assessing the random error associated with four-point resistance measurements may be applied to any device or process parameter for which it is possible to carry out a series of independent measurements at various locations on the semiconductor wafer. By evaluating the relative measurement error in this way, one may predict the extent to which graphic display techniques will be an effective means of exhibiting spatial variations.

Acknowledgments

The authors wish to acnowledge the able assistance of Mr. D. Mar in the areas of mask design and wafer characterization. Technical discussions with Mr. J. D. Reimer, Dr. J. T. Kerr, Dr. J. A. Marley, Dr. S. W. Mylroie, Dr. H. J. Sigg, and Dr. M. G. Buehler (National Bureau of Standards) have been extremely valuable both in carrying out this investigation and preparing the results for presentation.

Boron Autodoping during Silane Epitaxy

Paul H. Langer*

Bell Laboratories, Allentown, Pennsylvania 18103

and Joseph I. Goldstein

Lehigh University, Bethlehem, Pennsylvania 18015

ABSTRACT

In order to calculate the redistribution of boron in silicon by both diffusion and autodoping during epitaxial growth, certain materials parameters must be known as a function of temperature. The parameters are the diffusion coefficient of boron, the evaporation coefficient of boron from silicon, and the silicon evaporation rate in a hydrogen ambient. The value of the diffusion coefficient of boron is already well known while the values for the other two parameters have not been determined over the temperature range usually used for epitaxial growth. The evaporation coefficient of boron in silicon in a hydrogen ambient was experimentally determined to be $h = 1.674 \times 10^7 e^{-2.48/kT}$ where h is in microns per minute, the energy is expressed in electron volts, and temperature is in degrees Kelvin. The evaporation rate of silicon in a hydrogen ambient was measured as 0.013 ± 0.003 microns/min in a hydrogen ambient. These results were obtained in the temperature range from 1190° to 1380°C. These results allowed the accurate prediction of boron back surface "autodoping" effects during epitaxial growth using a numerical solution to Fick's second law. Radial as well as in-depth concentration *vs.* distance plots were experimentally determined illustrating boron autodoping for both lightly and heavily doped substrates. Reduction of boron autodoping was obtained by the addition of HCl to the ambient during epitaxial growth, permitting the growth of lightly doped layers on heavily boron-doped substrates.

In order to calculate the impurity redistribution during epitaxial growth or other high temperature semiconductor device processing steps, accurate values of the diffusion coefficient, segregation coefficient, and evaporation coefficient must be known for each of the dopant elements in silicon. Any time a lightly doped region is exposed to a heavily doped region transport of dopant will occur both through the solid and gaseous phases. The transport of dopant from one wafer to another or from one region on a wafer to another region on the same wafer has been known as "autodoping." The presence of excess dopant via autodoping in regions where it is unwanted leads to the inability to fabricate certain types of transistors and integrated circuit structures. The epitaxial growth process has long been the principal processing step in which autodoping may occur. Especially in the fabrication of integrated circuits, autodoping must be suppressed or at least controlled.

The purpose of this paper is to first obtain the physical constants necessary to characterize boron autodoping. With these constants available, predictions of the boron distribution during epitaxial growth are made. These predictions are then compared with experiments as an over-all test of the mathematical model being employed.

Background: Epitaxial Growth

The existence of dopant in an epitaxial layer over and above that dopant which was transported by solid-state diffusion from the substrate has been a subject of interest from the earliest work on epitaxial deposition. Thomas *et al.* (1) and Grossman (2) explain the existence of this extra dopant by a mechanism which involves transfer of dopant from the front surface of the wafer, mixing of this dopant with the gas phase, and reincorporation of some fraction of the dopant in the gas phase back into the wafer. Thomas worked exclusively with arsenic-doped substrates. Since solid-state diffusion was ignored in this model, application near the substrate-layer interface was difficult. Another approach to the autodoping problem was developed separately by Rice (3) and Grove *et al.* (4). They proposed that solid-state diffusion alone was the only mechanism for dopant transport from the substrate into the layer. They neglected the effects of the ambient gas phase. Abe *et al.* (5), studying arsenic autodoping with the aid of a numerical model, also ignored the ambient gas phase. The third approach to the explanation of the source of the unwanted dopant was put forward by Joyce *et al.* (6), Shepherd (7), and Skelly (8). These authors showed that dopant from the back of the wafer could also be a source of added impurity to the growing layer. Langer and Goldstein (9) developed a mathematical model of the process that essentially combines all three effects. Their model was solved numerically using a program called "CASPER" (9) (computer aided semiconductor processing and epitaxial redistribution). They proposed that while all of the autodoping mechanisms may be operative simultaneously their relative importance varies with the dopant species under consideration.

Using the evaporation coefficient of boron estimated by Grove (4), predictions were made for layer autodoping. It was calculated that, while no measurable effect could be detected in the transition region between the substrate and the epitaxial layer, a very sizable effect on the mean layer doping would occur once this transition region was past. Grove had not observed this predicted effect.

Theory

A model developed by Langer and Goldstein (9) solved Fick's second law using the implicit Crank-Nicolson method (CNM)

$$\frac{\partial C(x,t)}{\partial t} = D \frac{\partial^2 C(x,t)}{\partial x^2} \qquad [1]$$

in one dimension. They assumed that the diffusivity, D, is independent of the concentration $C(x,t)$, where x and t are the spatial and time variables, respectively. The boundary conditions at the front surface of the wafer are as follows

* Electrochemical Society Active Member.

Key words: silicon, semiconductor, deposition, autodoping.

$$D\frac{\partial C(i,t)}{\partial x} = h[C(i,t) - k_e C_m(t)] + v[C(i,t) - k_g C_m(t)] - fh[C(b,t) - k_e C_m(t)] \quad [2]$$

where i is the instantaneous position of the front gas-solid interface, h is the evaporation coefficient, $C_m(t)$ is the mean gas phase concentration, f is the fraction of back or side area acting as an autodoping source, k_e is the effective segregation coefficient between the gas and the solid, k_g is an arbitrary constant that will depend upon the gas velocity distribution in the boundary layer and relates the mean gas phase concentration to the concentration near the interface, v is the velocity of movement of the interface, while $C(b,t)$ represents the concentration at the back or side of the wafer.

At the back surface the boundary condition is

$$D\frac{\partial C(b,t)}{\partial x} = h[C(b,t) - k_e C_m(t)] \quad [3]$$

Figure 1 schematically shows the various sources of dopant in an epitaxial reactor. Autodoping during the growth cycle in an epitaxial reactor occurs principally from three major sources. The sources may vary in their contribution of dopant at any one point in the reactor. The three sources are: (*i*) the edges and back of the wafer, (*ii*) dopant from edges and backs of other wafers either down or upstream from the wafer of interest, and (*iii*) dopant from the susceptor coating.

In order to apply Eq. [1] along with the boundary conditions to an autodoping problem, the evaporation coefficient, h, of boron from silicon must be determined. In order to determine the evaporation coefficient, the evaporation rate of silicon in a hydrogen ambient must first be ascertained.

Experimental

Evaporation experiments.—Evaporation of silicon.— Figure 2 is a schematic of the reactor system that was used to perform the high temperature cycling for the evaporation experiments. This reactor was of circular cross section and was water cooled. The inner tube was 60 mm ID fused quartz. Power was supplied using a 450 kHz radio-frequency generator. The susceptor consisted of a graphite slab 25 cm long by 4.8 cm wide. The slab was made from General Electric pyrolytic infiltrated graphite. The susceptor was used uncoated after a 1 hr bakeout at 1450°C in hydrogen. The susceptor was supported in the reactor on a fused quartz sled. The specimens used were (111) oriented silicon wafers, 1.5 in. in diameter. Two wafers per run were placed in the reactor shown in Fig. 2.

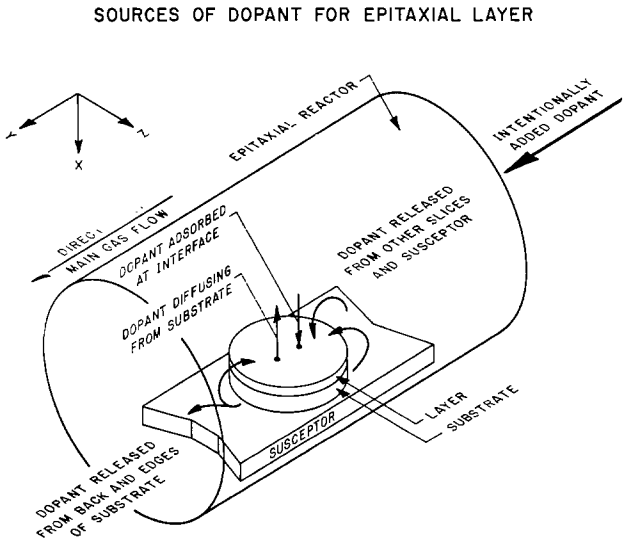

Fig. 1. Schematic representation of an epitaxial reactor showing sources of dopant.

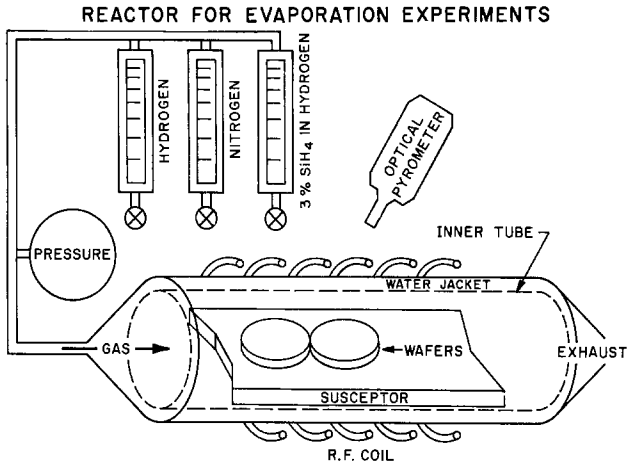

Fig. 2. Schematic of epitaxial reactor system

The standard cycle consisted of the following: 10 min nitrogen, 10 min hydrogen, raise power and stabilize (10 min), 1 hr at temperature in 20 liters/min of hydrogen, lower power, 10 min hydrogen, 20 min in nitrogen. Precautions were taken to prevent moisture from condensing inside the tube when it was opened for loading or unloading of wafers. No cooling water was run through the system when the reactor was open. The flush schedule was arranged so that at least 300 volume changes of dry gas (~1 ppm water) were passed through the reactor before the temperature was raised. Even with these precautions, pitting of the silicon surface was observed when the wafers were heated above 1050°C. Therefore silane was introduced during the initial nitrogen flush cycle to getter any residual water that may have been condensed on the reactor walls or the susceptor. This technique proved completely successful in eliminating the pitting of the silicon surface.

All evaporation samples were held at temperature for 1 hr. The temperature was recorded using a Leeds and Northrup (L&N) automatic optical pyrometer (Model No. 8641) which had been calibrated by L&N at five temperatures against a high precision automatic optical pyrometer traceable to the National Bureau of Standards. The adsorption corrections for the two thicknesses of fused quartz, the cooling water, and the plexiglass safety shield were determined experimentally in the following manner. A graphite block with two holes in it was placed in a resistance-heated diffusion furnace. In one hole a Pt-Pt-10%Rh thermocouple was placed and the pyrometer was sighted on the interior of the second hole. The block was brought to temperature and the fused quartz and plexiglass were placed between the heated block and the pyrometer while the optical temperature was determined. The quartz and plexiglass were withdrawn and the optical temperature was again determined. This procedure was repeated at temperatures from 900° to 1350°C. It was found that a constant adsorption correction of 25°C was sufficient over the experimental range of temperatures used for the evaporation and growth procedures. Emissivity corrections were made using Allen's (10) values for a polished silicon surface in vacuum.

To determine the evaporation rate of silicon in a hydrogen ambient the following procedure was used. A lightly boron-doped wafer [~10 parts per billion atomic (ppba)] with 7000A of thermally grown oxide was etched in a buffered hydrofluoric acid solution to remove the oxide film covering one-half of the front surface. The rest of the oxide was protected by Kodak metal etch resist during the etch. The photoresist was then removed and the wafers were cleaned using a mixture of nitric and sulfuric acids followed by a rinse in deionized water. The wafers were then scrubbed using a mild detergent, and rinsed again and spun dry.

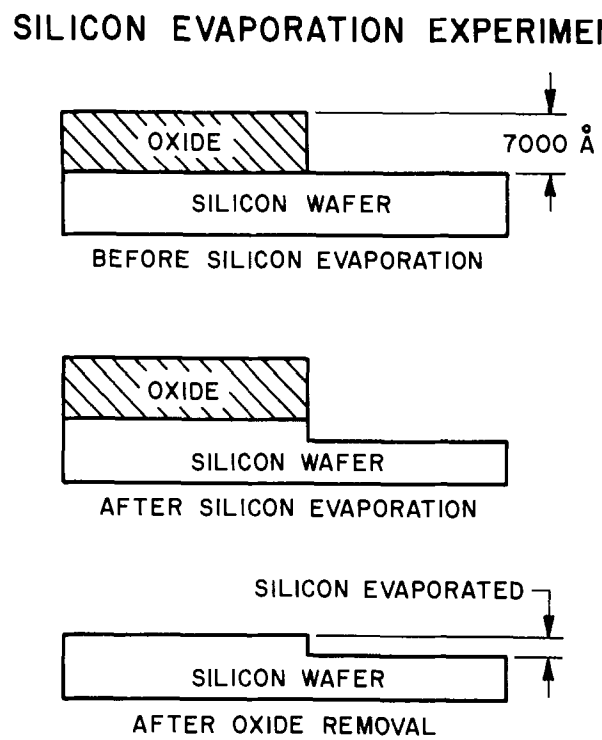

Fig. 3. Silicon evaporation experiment

Following the drying, the wafers were heated in the reactor for a period of 1 hr.

After the high temperature cycle, the remaining oxide was completely removed by a buffered HF etch. The step height was then measured between the area protected by the oxide during the high temperature treatment and the area that had been exposed to the ambient (20 liters/min hydrogen stream). This height measurement was performed using a Talysurf profilometer.[1] Figure 3 schematically shows the evaporated and protected parts of the silicon surface and exactly what quantities were measured in the determination of the evaporation rate. A control was run with no thermal treatment to check for the attack of the buffered hydrofluoric acid solution on the silicon wafer surface. Etching of the silicon by the buffered solution was 0.05 μm or less. Therefore the measured step height was due entirely to the evaporation of silicon. It was assumed that no reaction occurred under the oxide since the thickness of the oxide did not change during the thermal treatment.

Evaporation of boron.—Once the evaporation rate of the silicon had been determined, the next step was the determination of the boron evaporation coefficient. This was acomplished by measuring the concentration distribution of the boron in the silicon wafer after evaporation had been allowed to occur. This boron distribution was then fitted to calculated boron concentration distributions in which the only variable was the evaporation coefficient of the boron. The procedure that was used to determine the actual boron concentration distribution in the wafer is given below.

The wafers used to determine the evaporation coefficient of boron had to be doped enough that the surface concentration after evaporation was still above the background of the reactor. A 10 min deposition run was made at a rate of 0.4 μm/min to determine the reactor background concentration. The resultant resistivity measured by four-point probe on the epitaxial structure showed the system background concentration to be 2 ppba n-type. Therefore, wafers doped to 4 ppma with boron were chosen for the evaporation study. These wafers were grown by the Czochralski method and were oriented in the (111) direction. The wafers

[1] Commercial diffusion height gauge.

RADYNE REACTOR
WAFER POSITION FOR BORON AUTODOPING EXPERIMENTS

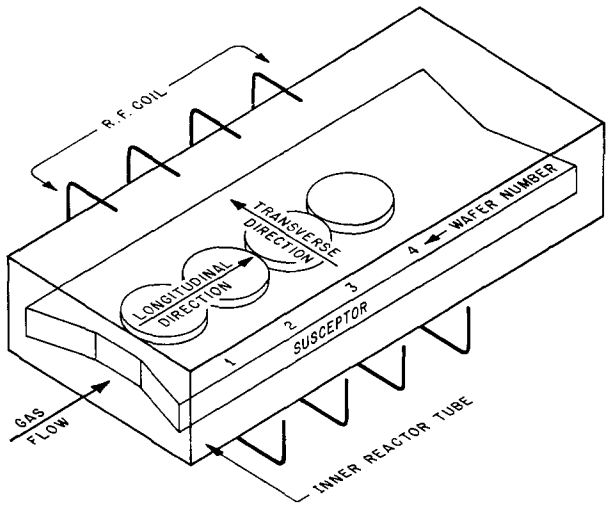

Fig. 4. Radyne reactor

were sawed, chemically etched, and then polished with Syton.[2] The cleaned wafers were subjected to 1 hr at temperature in a 20 liters/min hydrogen ambient. The range of temperature used was 1190°-1380°C. After the evaporation heat-treatment, the resultant wafers were angle lapped at a nominal 0.5° angle using Linde A abrasive on a glass plate, followed by a quick polish with Syton abrasive on a plexiglass plate. The prepared samples were measured on a Solid State Measurements ASR-100 spreading resistance probe test set to obtain plots of spreading resistance *vs.* depth from the wafer top surface. This data was then fed into a computer program containing the empirical calibration data and was converted to uncorrected resistivity. The Schumann (11) multilayer correction modified by Morris (12) was applied to the uncorrected resistivity before conversion to carrier concentration was made. Resistivity values were converted to concentration using Lee's polynomial fit (13).

Boron autodoping experiments.—A second epitaxial reactor was used for the boron "back" surface autodoping studies. It was a commercial Radyne unit shown schematically in Fig. 4. It differed from the first system in two major respects: the cross section was rectangular (38 × 76 mm), and the gas flow used was 108 liters/min (76 cm/sec). The susceptor was 9.5 mm thick and tilted at an angle of 1.5° from the horizontal. These two factors result in greater uniformity of deposition rate in both the longitudinal direction (direction of the gas flow), and in the transverse direction (perpendicular to the gas flow) as shown by Takahashi (14). The susceptor used in this case was silicon-carbide-coated graphite with a layer of undoped silicon covering all surfaces. Two consecutive runs were made of 10 min each. Arsine was introduced during the deposition cycle to achieve a n-type doping level in the growing epitaxial layer of about 10 ppba. Both runs were made with four 32 mm diameter wafers placed near the center of the susceptor as shown schematically in Fig. 5. A deposition rate of 0.92 μm/min was achieved in both runs at a temperature of 1120°C. No preheat, HCl etch, or postepitaxial growth heat cycle was employed. The wafers in the first run were all lightly doped p-type (100 ppba). In the second run the first and third wafers were also lightly doped, while the second and fourth wafers (position relative to gas inlet end) were heavily doped with boron to about 200 ppma. It was these heavily doped wafers that would become the autodoping source. After the layer was

[2] Syton is a commercially available silicon polishing compound manufactured by the Monsanto Chemical Company.

deposited, all wafers were measured at 25 μm intervals across the surface both in the direction of the gas flow and in a direction 90° to the gas flow. All measurements were made using an automatic spreading resistance probe (20) with on-line correction capabilities. Selected wafers were also profiled in depth for concentration.

Results and Discussion

Boron evaporation.—The evaporation coefficient of boron from silicon was determined over the temperature range from 1190° to 1380°C. The measured evaporation coefficient enables one to calculate the movement of boron across gas-solid interfaces so that doping and autodoping during epitaxial growth may be accurately predicted. The folowing equation derived by Grove (4) gives the value of the evaporation coefficient, h, at a boundary ($x = i$), in terms of the concentration at the boundary $C(i,t)$, the flux of dopant, $D\frac{\partial C(i,t)}{\partial x}$, and the boundary velocity, v

$$h = \frac{D}{C(i,t)}\frac{\partial C(i,t)}{\partial x} - v \qquad [4]$$

Equation [4] assumes that the gas phase concentration of boron is negligible compared to the value in the solid, $C(i,t)$. Therefore, the evaporation coefficient can be measured if the velocity of movement of the boundary, v, and the concentration gradient as a function of distance into the solid is determined. During the evaporation experiments, v is simply the evaporation rate of the silicon. If h is large compared to v, v may be neglected. For some elements such as antimony, arsenic, and phosphorus, this is the case. However the evaporation rate of silicon was measured experimentally and found to be significant, in the determination of the boron evaporation coefficient. The evaporation rate of silicon was determined to be 0.013 $\pm$ 0.003 μm/min over the temperature range from 1190° to 1380°C. This measured value is much smaller than the value of 0.023 $\pm$ 0.005 μm/min determined by Tung (15). Tung observed gross nonuniformity of the evaporation effect and his samples may have experienced etching by residual water vapor in the system. This form of attack had been eliminated in this work by the addition of 3% silane to the room temperature nitrogen flush.

The measured boron concentration was normalized to a concentration determined deep into the wafer ($\sim 3\sqrt{Dt}$), where the concentration gradient was almost zero. The depth was normalized ($x/2\sqrt{Dt}$) using the published diffusivity of boron (16). This normalization was performed so that comparison between experimental and calculated results for the concentration *vs.* depth distribution of boron could be easily accomplished in order to graphically determine the boron evaporation coefficient. The rate of silicon evaporation was also normalized using the diffusivity of boron, D_B, in the following manner

$$v_n = \frac{v}{\sqrt{D_B/t}} \qquad [5]$$

Solutions of concentration *vs.* distance were then obtained to Fick's second law for various assumed values of the normalized evaporation coefficient, h_n, where

$$h_n = \frac{h}{\sqrt{d_B/t}} \qquad [6]$$

These normalized solutions were then plotted with respect to the experimental data that had also been normalized. When a graphical fit was obtained between calculated and experimental concentrations, a value of h_n was determined from the closest curves. The calculated and normalized concentration *vs.* depth values for different values of the evaporation coefficient are plotted in Fig. 5 as solid lines at 1263°C (real). The solid circles (Fig. 5) are the experimental data. The experimental data fit the calculated curves quite well. The normalized values of h_n were then converted to evaporation coefficients by mutliplying by $\sqrt{D/t}$, and these results are summarized in Table I, over the temperature range from 1205° to 1382°C.

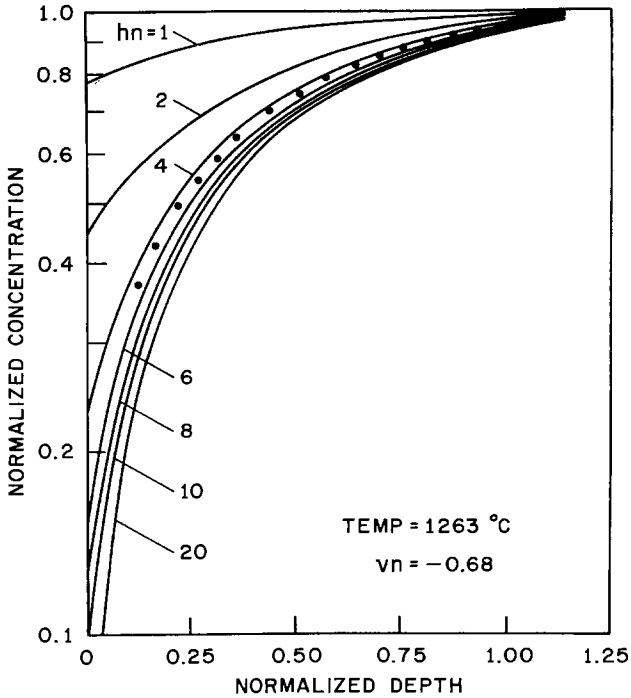

Fig. 5. Experimental values of normalized concentration *vs.* depth plotted along with analytical solution (solid line). Time: 1 hr, temperature: 1263°C, normalized silicon etch rate: —0.7 μm/min, dopant: boron.

The experimentally determined values of h are plotted against the reciprocal of the temperature in Fig. 6. A least square first order polynomial was fit to an Arrhenius type of equation to produce

$$h = 1.674 \times 10^7 e^{-2.48/kT} \qquad [7]$$

where h is given in units of microns per minute, the energy is in electron volts, the temperature in degrees Kelvin, and the value of k used is 8.62×10^{-5} eV/°K.

Values of $h_n > 20$ cannot be determined by the above technique. This is not a serious drawback since $h_n > 20$ is very close to the diffusion-limited case (all dopant reaching the surface by diffusion evaporates). Very little difference can be seen in the calculated concentration distributions for $h_n = 20$ and $h_n = \infty$.

Boron autodoping.—To completely test the numerical model, the contribution to layer doping from dopant escaping from the back and edges of the wafer was calculated and is shown in Fig. 7. The numerical model predicts that when a heavily doped boron substrate (200 ppma) is used, a level of about 120 ppba is predicted for the epitaxial layer. A major difficulty arises when trying to simulate back surface (back and sides) autodoping, *i.e.*, one does not know what fraction of

the back surface (effective area) of the wafer is contributing dopant to the gas stream. This fraction has been estimated by other workers studying arsenic as between 0.9 (8) and 4% (7). The smaller value of effective area (8) represents work done using silane in a single wafer reactor at 1050°C. Since only one wafer was present, it was impossible to assess the results of the evaporated dopant on other wafers in the system. The authors also used a rather small total gas flow, *i.e.*, 2 liters/min. The larger value of effective area (7) represents the results of multiwafer system using silicon tetrachloride at 1200°C. Both heavily and lightly doped substrates were present in the system. According to the method of Shepherd (7), the effective source area for back surface autodoping would increase as the number of wafers in the system increased. All of the Shepherd data were taken at the center of the wafers.

Two factors had been neglected by the previous authors in their treatment of back surface autodoping. The first factor is that dopant released from the sides of the wafer must also be considered as a potential autodoping source, since this side area represents 2-4% of the wafer-to-surface area for normal semiconductor wafers. The second factor is the size of the source of the autodoping species (edges and back of the wafer) relative to the size of the sink for this dopant (front surface of the wafer). This size difference results in a decrease in transferred dopant as one moves further from the source. This decrease in dopant can result in a large radial concentration gradient if the intentional doping level is small. If diffusion was the only transport mechanism in the gas phase adjacent to the wafer, then the radial concentration profile (from the center of a given wafer out in any direction) of transferred dopant would be the same in any direction relative to the gas flow. If other dopant transport mechanisms are present, dopant from upstream wafers would affect the ambient gas phase concentration and appear to give effects similar to intentionally added dopant with the effect increasing in the downstream direction.

To assess the validity of the back autodoping model using the experimentally determined value of the evaporation coefficient of boron, consecutive epitaxial runs were made. The first run (control run) contained only lightly doped wafers (0.1 ppma). The first and third wafers in the second run were also lightly doped while the second and fourth wafers were heavily doped with boron to a level of about 200 ppma. The surface concentration results across all wafers in the direction of the gas flow for the first run (all lightly doped substrates) are plotted in Fig. 8. The results in Fig. 8 were obtained by spreading resistance measurements from the upstream (inlet) edge of wafer No. 1, going in the direction of the gas flow. to the downstream edge of wafer No. 4 (exit end of reactor). Data were taken

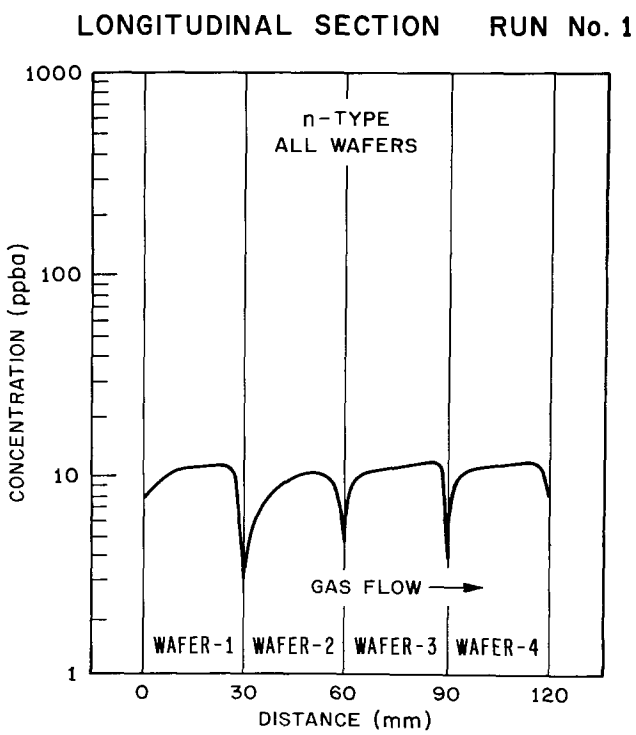

Fig. 8. Composite plot over all four wafers of surface concentration vs. distance of first epitaxial deposition run. All substrates lightly doped. Temperature: 1120°C, time: 10 min, growth rate: 0.92 μm/min, dopant: arsine, silicon source: silane.

every 25 μm at the surface of the 9.2 μm thick epitaxial layer. For this section longitudinal or axial will mean in the direction of the gas flow (inlet to outlet), while transverse will refer to data obtained perpendicular to the gas flow across the center of a given wafer. The concentration results displayed in Fig. 8 for run No. 1 show a level of about 10-12 ppba, n-type, with a small rise in the dopant level from the leading edge of each wafer. This decrease in concentration at the edges of the wafers may be caused by boron autodoping from the lightly doped substrates or contamination from the susceptor. Figure 9 is a transverse surface section taken across the center of the third wafer, and shows about a 20% difference in concentration from the center to the edge of the wafer. These results will be compared to the results of the second run, and the differences in concentration level and type will be used to characterize any autodoping that is present.

The second run (wafers No. 1 and 3 lightly doped, wafers No. 2 and 4 heavily doped) showed some very interesting autodoping effects. The longitudinal concentration profile across all the wafers on the susceptor is shown in Fig. 10. The first wafer is n-type until about 8 mm from its trailing edge (Fig. 10). The concentration level over the first 20 mm (in the direction of the gas flow) shows no signs of autodoping and is characteristic of the results of the first epitaxial run (control run). It establishes that the intentionally added dopant is n-type. Continuing across wafer No 1 in the direction of the gas flow, a p-n junction is encountered. The concentration then rises above 200 ppba, p-type, as one approaches the boundary between the first and the second wafer.

The second wafer (heavily doped) is completely p-type with extremely high values of concentration seen at both the leading and trailing edges. It appears that dopant released at the leading edge of the wafer is swept downstream across the wafer by the ambient gas because the autodoping effect is much more pronounced in the direction of the gas flow. Therefore, diffusion is not the only mechanism for the transport of dopant in the gas phase. Looking at the transverse concentration profile (Fig. 11) across the center of wafer No 2, one again sees an autodoping effect at both edges

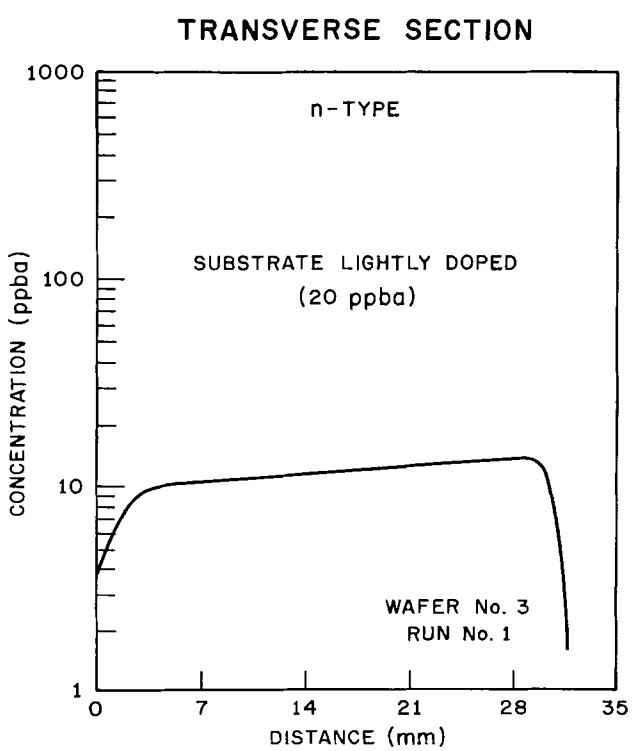

Fig. 9. Transverse plot of surface concentration vs. distance for the third wafer in run No. 1.

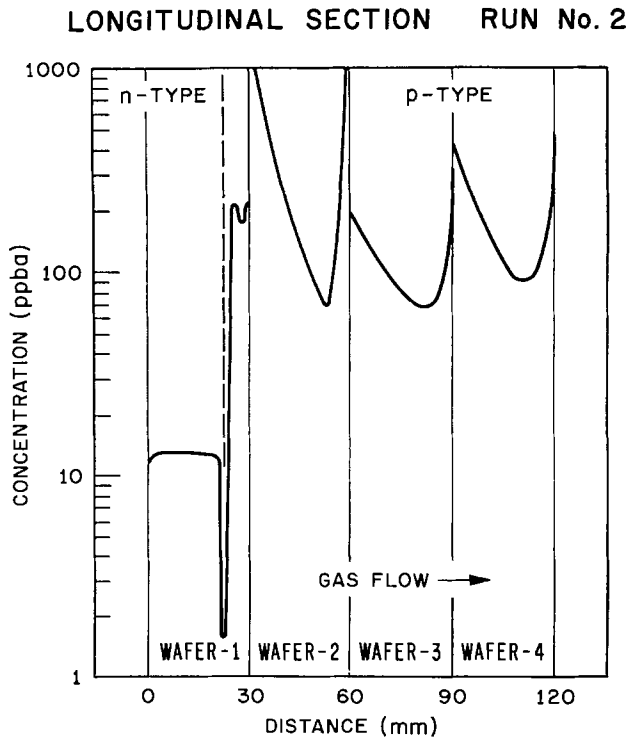

Fig. 10. Composite plot over all four wafers of surface concentration vs. distance in the second epitaxial run. Substrates one and three were lightly doped with boron while two and four were heavily boron doped. Temperature: 1120°C, time: 10 min, growth rate: 0.92 μm/min, gas phase dopant: arsine, silicon source: silane.

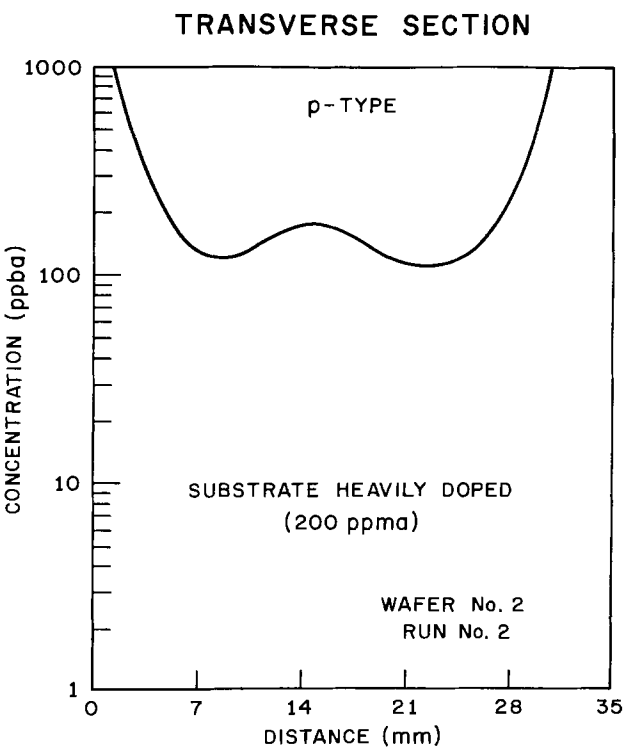

Fig. 11. Transverse plot of surface concentration vs. distance for the third wafer in run No. 2.

of the wafer and a small peak in concentration in the central region. The transverse section does not exhibit the large directional effect seen in the longitudinal profile. Also, the boron concentration at the edges of the transverse section are similar to the size of the autodoped region at the trailing edge. This indicates that the effect of the gas flow on diffusion of released dopant is negligible. The implication of this result is

that dopant released at an edge goes into the mean gas phase well above the surface of the wafer where the temperatures are lower and the gas velocities higher. The shape of the transverse profile (Fig. 11) near the center of the wafer may be due to the transverse variation in gas velocity above the susceptor (18). The increased concentration near the edges (Fig. 11) is due to dopant transported from the back and sides of the wafer and diffusing perpendicular to the gas flow during epitaxial growth of the layer. The concentration above the surface of the third wafer (lightly doped) which does not contribute boron to the reactor ambient is also completely p-type. Again, one sees the smearing of dopant (Fig. 10) from the leading edge toward the downstream end of the wafer. The transverse profile (Fig 12) of this wafer (No. 3) does not show an increased edge concentration. This is expected since this wafer is lightly doped and therefore cannot contribute dopant to the gas stream for reincorporation through the autodoping process. The p-type dopant in this layer comes from wafers No. 2 and No. 4. At the trailing edge of wafer No. 3, dopant released from wafer No. 4 and diffusing upstream against the gas flow is present. The maximum concentration at both the leading and trailing edges of the wafer is less than on either of the heavily doped structures. The fourth wafer (heavily doped) also shows the smearing effect of the autodoped species. Also, the minimum concentration found on the wafer is higher than the minimum concentrations found on any of the previous wafers. This is further evidence that dopant released from the sides and the back of the heavily doped upstream wafer (No. 2) is also affecting the mean gas phase concentration downstream from the source.

The experimental concentration *vs.* depth plot (open circles) taken at a point 15 mm from the leading edge on wafer No. 4 parallel to the gas flow is shown in Fig. 13 along with the results of the numerical simulation using "CASPER" (solid line). The simulation was performed assuming 1% of the back and side area was acting as a source of the autodoping species. Errors in the simulation involve not only the source area but also the effective distribution coefficient between the gas and the solid as well as the value of the evaporation coefficient. Even though agreement between calculations and experimental results (Fig. 13) is excellent, the presence of the large transverse and longitudinal concentration gradients tends to complicate the interpretation. Calculations were also made at 8 and 24 mm (dashed lines, Fig. 13) from leading edge of wafer No. 4 using 4 and 0.8% for the side and back area. The effect of this area factor shows almost a linear relationship to the average layer doping, *i.e.*, the concentration gradient in the layer is the same except that the levels are different. As one can see from Fig. 10 (wafer No. 2), the concentration at the surface varies by a factor of ten from the leading edge of wafer to a point about 20 mm downstream. Therefore, the problem can no longer be described by a one-dimensional model and a more complex interpretation is needed. One could empirically determine f (the fraction of effective area acting as a source) as a function of position in the reactor. This approach could give a reasonable first approximation to the concentration profiles measured. A one-dimensional approach would still be valid in systems (antimony substrates) that do not exhibit large transverse and longitudinal concentration gradients.

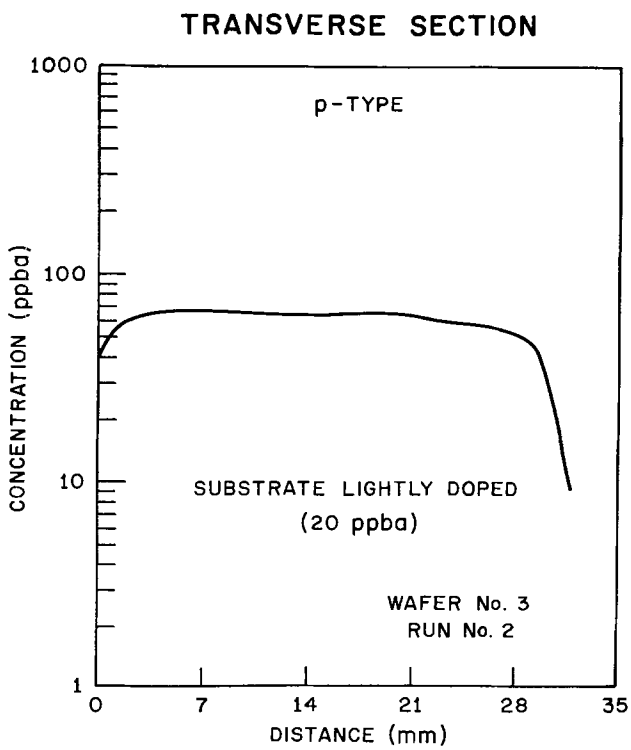

Fig. 12. Transverse plot of surface concentration vs. distance for third wafer in run No. 2.

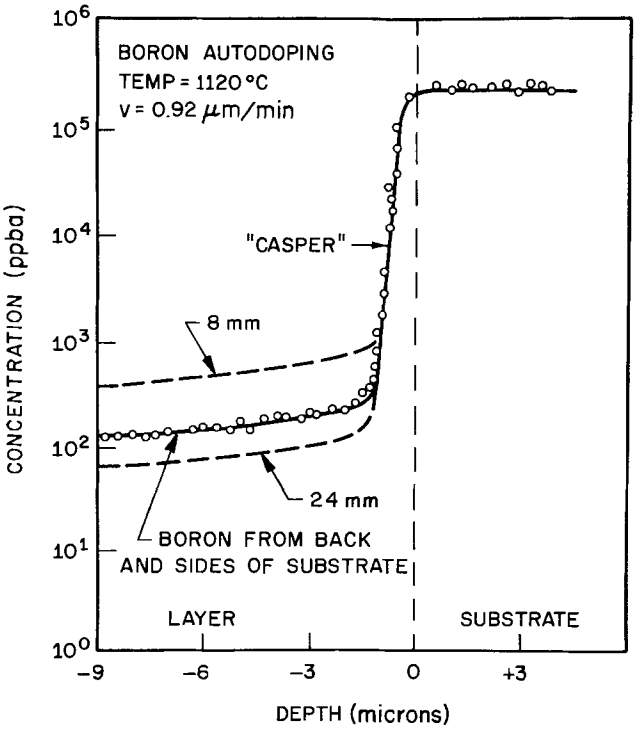

Fig. 13. Plot of concentration vs. depth 15 mm from leading edge of wafer No. 4 in the second run. "CASPER" simulation (solid line) is plotted along with the experimental results (open circles). Other "CASPER" calculations (dashed lines) at 8 and 24 mm.

The concentration gradient over the top few microns of the layer for a multiwafer system may also vary as a function of position from the source of the autodoping species. This is due to the fact that the time rate of change of the mean gas phase autodoping component is different from that dopant that is transferred without going through the mean gas phase. Therefore downstream wafers should show a smaller slope in the gradient near the surface than upstream wafers due to the larger component of the mean gas phase effect with downstream position. This change in slope was experimentally observed even within one wafer.

These results are not valid as a check on the evaporation coefficient determined in the previous series of experiments due to the presence of the large transverse and longitudinal concentration gradients. These autodoping results do indicate that the product, $k_e \cdot f \cdot h$ was chosen correctly as can be seen from the agreement between theory and data in Fig. 13.

Effect of HCl on boron autodoping.—The extension of these results to a system in which chlorine atoms are present during the deposition cycle (*e.g.*, silicon tetrachloride, or dichlorosilane) is not straightforward. Bloem (17) has shown that additions of HCl or water vapor to a reactor ambient will result in decreased doping efficiency of diborane. He postulates the formation of a stable boron chloride compound which ties up some of the available boron that would normally be available for doping or autodoping. This may explain why Grove (4), using silicon tetrachloride as his silicon source, did not report any autodoping when using heavily boron-doped substrates. Oxide masking may not be as effective in preventing autodoping of boron as with n-type elements since the segregation coefficient for boron between the oxide and the silicon is about 4 to 5 (18). Therefore, the concentration of boron in the oxide layer would be larger than in the silicon. Depending on the relative diffusivity of boron in the oxide to the evaporation rate of boron from the oxide, one might even postulate that an oxide layer would act as a larger source of dopant during the initial stages of epitaxial growth than the exposed silicon wafer back and edges. In order to establish whether HCl additions during epitaxial growth would reduce or eliminate boron autodoping, a third run was made. Substrate wafer doping levels were the same as in run No. 2. The HCl to silane ratio was maintained at unity. Figure 14 is an in-depth concentration profile on wafer No. 4 taken at the center. As one can see, the layer is n-type and no autodoping is evident. Traces of autodoping were still found near the edges of the wafers extending in 1-2 mm. Therefore, addition of HCl to the ambient during epitaxial growth over heavily doped boron substrates will significantly reduce the boron autodoping effects and will allow one to grow a lightly doped layer over a heavily doped boron substrate (2000 ppma).

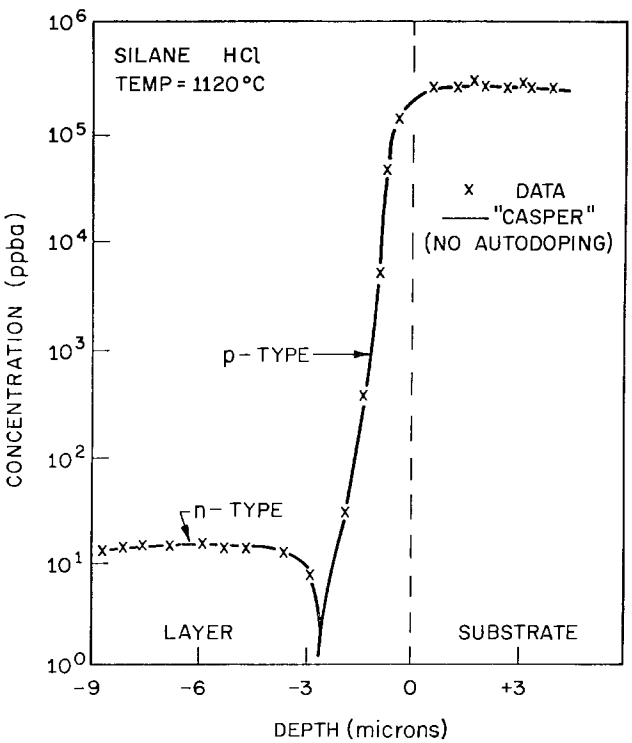

Fig. 14. Plot of concentration *vs.* depth showing reduction of boron autodoping with HCl addition to gas phase.

Summary

In summary, a set of equations [1]-[3] has been used to describe the redistribution of dopant (autodoping) in a silicon wafer during epitaxial growth. The evaporation rate of silicon and the evaporation coefficient of boron were determined as a function of temperature and these experimental results were used to predict the autodoping contribution from heavily doped boron substrates. Though the numerical model was unsuccessful in characterizing the distribution of dopant over the entire wafer diameter due to the large longitudinal and transverse concentration gradients, it was very successful in predicting the in-depth distribution at the center of the wafer where these gradients were negligible. Boron autodoping during silane epitaxy can be suppressed using a low concentration of HCl added to the gas phase during epitaxial growth.

ABSTRACT

Silicon oxynitride films ($Si_lO_mN_p$) have been deposited from SiH_4-CO_2-NH_3-H_2 chemical system in a vertical, cold-wall, multiple wafer, barrel-type reactor. The kinetics of SiH_4-CO_2 and SiH_4-NH_3 reactions, both in H_2, have also been studied in the same reactor. All three reactions are first order with respect to SiH_4 under conditions of "isolation technique." Within the selected experimental range, the SiO_2 deposition rate is independent of CO_2 concentration, the Si_3N_4 deposition rate is independent of NH_3 concentration, and the $Si_lO_mN_p$ deposition rate is nearly independent of both CO_2 and NH_3 concentrations. The deposition rate of SiO_2, Si_3N_4, and $Si_lO_mN_p$ are not dependent on the H_2 flow rate in the experimental range of 60-130 liters/min; thus all three reactions are chemical-surface rate limited within the experimental range. The activation energies are 23.5, 24, and 29 kcal/g-mole for $Si_lO_mN_p$, SiO_2, and Si_3N_4, respectively. An anomalous effect of deposition temperature on silicon oxynitride refractive index (composition) was discovered and has been explained by the use of adsorption theory.

Silicon oxynitride films ($Si_lO_mN_p$) are of interest in large scale integration (LSI) fabrication because they can be employed, for example, as barriers to diffusion and oxidation in the field region of integrated field effect transistor (FET) circuits and in the gate region as part of the metal-oxynitride-oxide-silicon structure. Other attractive properties and uses of $Si_lO_mN_p$ films have been reported (1-5).

Many chemical systems have been used for chemical vapor deposition (CVD) of silicon oxynitride (4, 6-10), of which all are SiH_4 based except for that of Koltsov *et al.* (9) who used $SiCl_4$. We preferred SiH_4 because it eliminates the possibility of NH_4Cl formation and associated difficulties (11). NH_3 is used as the nitriding agent without exception. Various oxidants have been used; *i.e.*, O_2 (7), N_2O (8), and NO (4, 6). Nutall *et al.* (10) used a mixture of O_2 and CO_2 as an oxidant at high temperatures (900°-1100°C), but abandoned the use of CO_2 after they determined there was no advantage in adding CO_2 to O_2. Thus, chemical systems for silicon oxynitride deposition which use SiH_4 as the silicon-bearing compound encounter two common conditions: (*i*) Very high NH_3/oxidant ratios ($\sim$ 50 to $\geq$ 5000) are required during the gas phase to produce films with refractive indexes $\geq$ 1.73; and (*ii*) the oxidation and nitriding reactions, when considered independently of each other, have very different activation energies ($\geq$ 12 kcal/g mole). The oxidation reaction has the lower activation energy, and is faster (6).

The first condition leads to poor process control, especially in forming Si_3N_4-rich $Si_lO_mN_p$ films. To improve the process control, we sought an oxidant such that the rates of oxidation and nitriding reaction (or activation energies) would be nearly equal. Reported activation energies of the SiH_4-CO_2 reaction (12) and the SiH_4-NH_3 reaction (6) are within 2 kcal/g mole of each other. Thus, silicon oxynitride of 1.73 refractive index was deposited with an NH_3/CO_2 ratio of $\sim$ 6 at 900°C, using the SiH_4-CO_2-NH_3-H_2 system.

Despite the fact that the silicon oxynitride deposition was reported in the literature as early as 1968, to the best of our knowledge no successful attempts have been made to extract a rate expression or to obtain an activation energy for silicon oxynitride deposition. Therefore, purposes of our study were to: (*i*) investigate deposition kinetics of silicon oxynitride films and empirically derive a rate expression; and (*ii*) examine the kinetic relationship between SiO_2 and Si_3N_4 rate expressions on the one hand, and the silicon oxynitride rate expression on the other.

Key words: thin films, chemical vapor deposition, deposition kinetics.

The underlying principles described in this paper and used in this study are of fundamental importance. With slight modifications, they could be used to analyze other complex CVD depositions which are limited by surface chemical reaction rates. This is especially true if the objective is to obtain empirical rate expressions, the importance of which, from an engineering point of view, cannot be overemphasized. The isolation of an empirical rate expression, however, does not automatically lead to a reaction mechanism, and we will not attempt to postulate any. However, from data analysis we did discover a mutual chemical interference phenomenon which gives some insight into the reaction mechanism of SiO_2, Si_3N_4, and $Si_lO_mN_p$ formation.

Experimental

Equipment.—The equipment used for this investigation was a vertical, cold-wall, barrel-type, induction-heated, multiple wafer reactor which has been previously described (12, 13). Figure 1 is a schematic cross-sectional view of the reactor.

Temperatures were measured by optical pyrometer;[1] all reported values have been corrected for system transmission losses and emissivity (14). Gases (carrier and reacting) were introduced at the top of the reactor. All gases were metered by calibrated rotameters, except SiH_4 (5% in H_2), which was controlled by a mass-flow controller.

Deposition conditions and measurement techniques.—Three 57 mm diameter Si, 11-25 Ω-cm, p-type <100> wafers were usually processed in each experimental

[1] Temperature along the susceptor length is $\leq \pm 10$°C of any reported value.

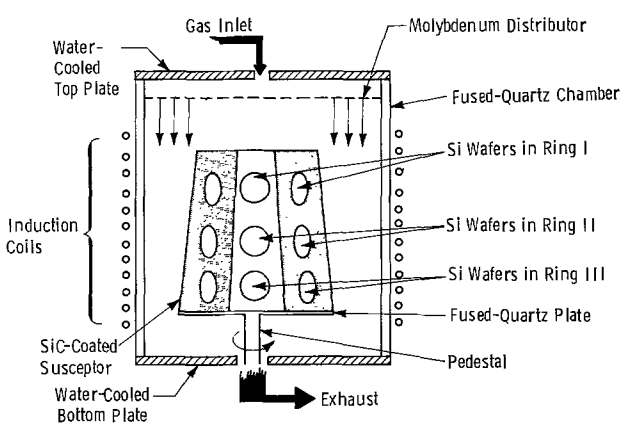

Fig. 1. Cross section of the reactor

run. One wafer each was placed in ring 1, 2, or 3 (Fig. 1) at a predetermined, fixed position. The remaining positions on a susceptor were filled with dummy wafers to protect the susceptor. Before being loaded in the reactor, wafers were cleaned ultrasonically in deionized water for 5 min, followed by a 3:1 H_2SO_4/HNO_3 at 120°C cleaning (10 min). The wafers were then dipped in 10:1 dilute HF and rinsed in running deionized water (5 min) and subsequently spin dried. After this cleaning procedure, the wafer surface is hydrophobic.

During the experimental work, the H_2 flow rate was typically 110 liters/min, SiH_4 (5% in H_2) $\sim$ 200 cm³/min ($\sim$ 10 cm³/min pure SiH_4). The sum of CO_2 and NH_3 flow rates was kept constant at $\sim$ 2.3 liters/min.

The deposited film thicknesses were measured by either constant angle reflection interference spectroscopy (CARIS) (15) or ellipsometry, whereas the refractive index was always measured by ellipsometry.

The typical deposition uniformity within a run (*i.e.*, all three wafers) was $\sim \pm$ 5% at 1000°C. The worst-case uniformity was $\leq \pm$ 15% at any deposition temperature in the 850°-1050°C experimental range. Because of nearly uniform deposition within a run, we used average deposition rates (an average of three rings). Thus, as a first approximation the silane concentration variations along the susceptor length were not taken into account.

Results

The units of deposition rate used throughout this paper are in moles per minute rather than the usual angstroms per minute because material thicknesses of varying density and molecular weight cannot be compared directly. Silicon oxynitride density, molecular weight, and composition were assumed to vary with the refractive indexes. For justification of these assumptions, refer to Appendix A.

Deposition rate vs. effective silane concentration.—Figure 2 is the log-log plot of effective SiH_4 concentration inside the reactor *vs.* deposition rate at 900° and 1000°C. The effective SiH_4 concentration, C_{SiH_4}, is defined as the product of SiH_4 feed concentration, $C^0_{SiH_4}$, and $(1 - Y_{SiH_4})$, where Y_{SiH_4} is the fraction of SiH_4 converted to deposit (see Appendix B for a detailed derivation and explanation of terms).

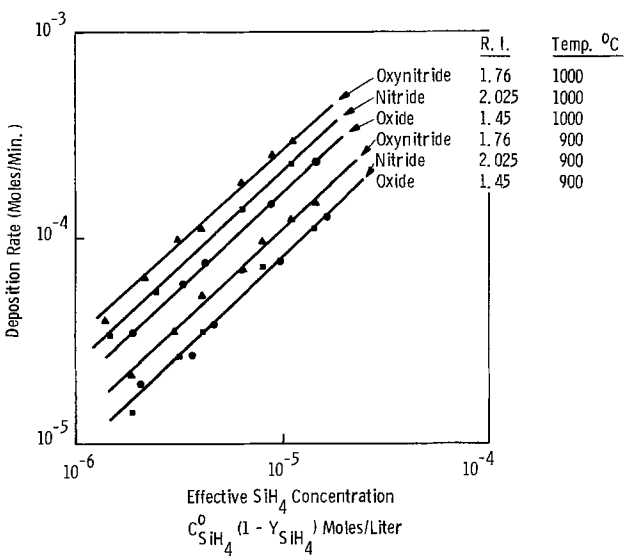

Fig. 2. Deposition rate as a function of effective SiH_4 concentration. The H_2 flow rate constant is $\sim$ 110 liters/min. For oxynitride the NH_3 + CO_2 flow rate constant is 2.3 liters/min. For nitride the NH_3 flow rate constant is 750 cm³/min. For oxide the CO_2 flow rate constant is 750 cm³/min.

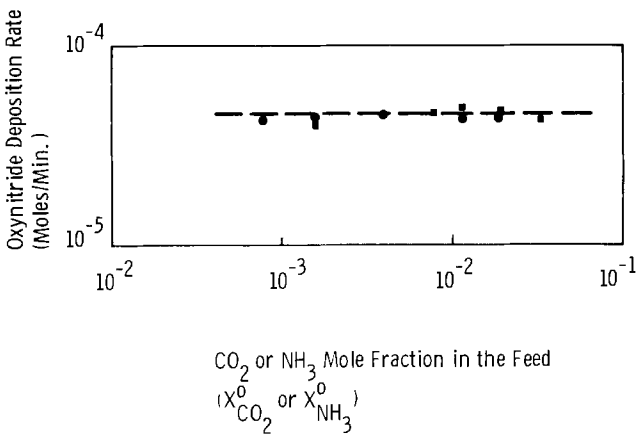

Fig. 3. Oxynitride deposition rate as a function of CO_2 or NH_3 mole fraction. SiH_4 mole fraction in feed ($X^0_{SiH_4}$) = 7.1 × 10⁻⁵. ● = $X^0_{NH_3}$ constant at 5.93 × 10⁻³, $X^0_{CO_2}$ variable. ■ $X^0_{CO_2}$ constant at 5.93 × 10⁻³, $X^0_{NH_3}$ variable. H_2 flow rate 110 liters/min, deposition temperature 1000°C.

In Fig. 2 note: (*i*) The slope of all the curves is nearly unity in all cases; *i.e.*, the order of the reaction is one with respect to SiH_4 for SiO_2, Si_3N_4, and $Si_lO_mN_p$;[2] (*ii*) the deposition rates of oxide and nitride are nearly identical for a fixed effective SiH_4 concentration at 900°C; (*iii*) silicon oxynitride deposition rates are larger than either Si_3N_4 or SiO_2 deposition rates at both temperatures; (*iv*) the silicon oxynitride deposition rate is less than the sum of the deposition rates of SiO_2 and Si_3N_4.

Deposition rate vs. CO_2 or NH_2 mole fraction.—The deposition rate of the silicon oxynitride films as a function of CO_2 mole fraction, with NH_3 mole fraction constant at 5.93 × 10⁻³, is shown in Fig. 3. For this experiment, the deposition temperature was kept constant at 1000°C as was the H_2 flow (110 liters/min) and SiH_4 mole fraction in the feed ($\sim$ 7.1 × 10⁻⁵). The above experiment was then repeated with the exception that the CO_2 mole fraction was kept constant (5.93 × 10⁻³) with NH_3 mole fraction as a variable. The results are also shown in Fig. 3.

The refractive index of silicon oxynitride films deposited during the above experiments changed from 1.5 to 1.82. As can be seen from Fig. 3, the silicon oxynitride deposition rate as a first approximation is independent of NH_3 or CO_2 concentration. These results are consistent with the "isolation technique" (16); *i.e.*, since both CO_2 and NH_3 concentrations used here are considerably larger than SiH_4 concentration, the rate of silicon oxynitride deposition should be independent of NH_3 and CO_2 concentrations.

Similarly the deposition rates of SiO_2 and Si_3N_4 are independent of CO_2 and NH_3 concentrations when the CO_2:SiH_4 and NH_3:SiH_4 ratios are kept larger than 7:1 and 5:1, respectively (12, 17). These results were verified during the course of this investigation.

Deposition rate vs. flow rate.—Deposition rate was nearly a constant ($\sim \pm$ 4%) for SiO_2, Si_3N_4, and $Si_lO_mN_p$ for a fixed SiH_4 feed rate (mole fraction), when the H_2 flow rate was varied from 60 to 130 liters/min. The ratios of SiH_4:CO_2, SiH_4:NH_3, and SiH_4:NH_3:CO_2 were kept constant, respectively, for SiO_2, Si_3N_4, and silicon oxynitride deposition. The experiment clearly showed that the reactions in all three cases are surface-chemical rate limited in the flow range of interest here (see Appendix C for additional justification).

[2] Though only one oxynitride (*i.e.*, n = 1.76) is shown, identical behavior is observed for all oxynitrides in the 1.5-1.9 refractive index range.

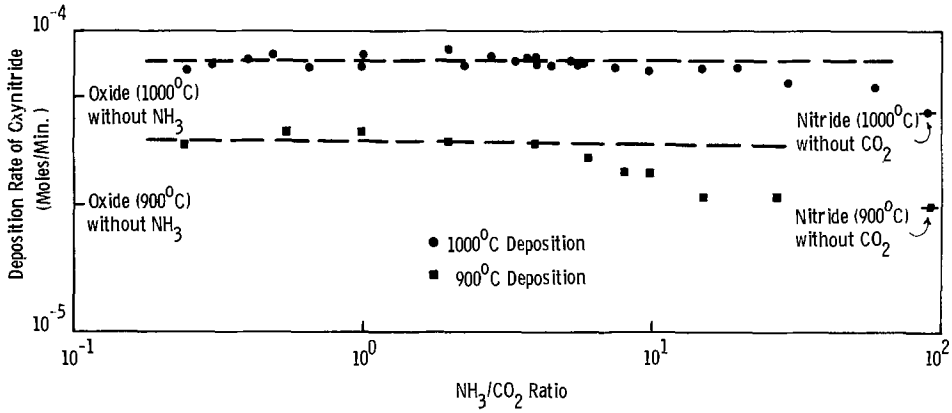

Fig. 4. Oxynitride deposition rate as a function of NH_3:CO_2 ratio. H_2 flow rate constant at ~ 110 liters/min, $NH_3 + CO_2$ flow rate constant at ~ 2.3 liters/min, 1000°C data reproduced at $NH_3 + CO_2$ flow rate of ~ 3.9 liters/min. SiH_4 mole fraction in the feed ($X^o_{SiH_4}$) = 9.3×10^{-5}.

Deposition rate of oxynitride vs. NH_3:CO_2 ratio.— The deposition rate of silicon oxynitride is independent of the NH_3:CO_2 ratio, as a first approximation (Fig. 4). However, at a high NH_3:CO_2 ratio (*i.e.*, > 10) the silicon oxynitride deposition rate appears to approach the deposition rate of Si_3N_4, both at 900° and 1000°C, as can be seen from the data in Fig. 4. The difference between the experiment of Fig. 4 and that of Fig. 3 is that the sum of NH_3 and CO_2 flow rates were kept constant at ~ 2.3 liters/min in the experiment of Fig. 4, whereas that was not the case in the experiment of Fig. 3. The feed mole fraction of SiH_4 is also higher in Fig. 4.

Refractive index vs. NH_3:CO_2 ratio.—The refractive index and, hence, the composition of deposited silicon oxynitride films (see Appendix A) is a function of NH_3:CO_2 ratio as shown in Fig. 5. The change of deposition temperature from 1000° to 900°C produced anomalous and unexpected results. These results, however, have been reproduced several times and, thus, the phenomenon of higher refractive index for oxynitrides deposited at 900°C than those deposited at 1000°C for a fixed NH_3:CO_2 ratio is quite real. However, because of the data presented in Fig. 2, we expected that the silicon oxynitride at 1000°C would have higher refractive index for a fixed NH_3:CO_2 ratio because the deposition rate of the Si_3N_4 is higher than the SiO_2 at 1000°C. Thus, the results of Fig. 5 cannot be explained by separately studying the deposition rates of the Si_3N_4 and the SiO_2.

We attempt to explain this anomalous effect of deposition temperature on silicon oxynitride composition later in this paper.

Theory and Calculations

The reaction for formation of silicon oxynitride can be stoichiometrically expressed as follows

$$1\,SiH_4 + mCO_2 + pNH_3 \xrightarrow{k_{on}} Si_lO_mN_p + mCO + \left(2l + \frac{3}{2}p\right) H_2 \quad [1]$$

Knowing that the above reaction is surface-chemical rate limited, a rate expression is formulated, as shown below, following the general procedure used for heterogeneous reaction (18)

$$r_{oxy} = k_{on}\theta^{n_1}_{SiH_4}\theta^{n_2}_{NH_3}\theta^{n_3}_{CO_2} \quad [2]$$

where r_{oxy} is the rate of deposition of silicon oxynitrides in moles/minute, θ_{SiH_4}, θ_{NH_3}, and θ_{CO_2} are the fractions of the surface (on which reaction is occurring) covered by SiH_4, NH_3, and CO_2, respectively, and k_{on} is the surface-chemical rate constant for the silicon oxynitride formation in moles/minute. The order of reaction with respect to SiH_4, NH_3, and CO_2 is given by n_1, n_2, and n_3, respectively. These orders will vary from 0 to 1 (18). Zero order implies strong adsorption by a given reactant (*i.e.*, $\theta = 1$), a fractional order implies that the reactant dissociates during the reaction (18, 19). If the reaction order is 1 with respect to a given reactant, then that reactant participates in the reaction as a whole; *i.e.*, without dissociation (18).

Since the fractional surface coverage by any chemical species is proportional to its partial pressure which in turn is proportional to the concentration of that species in gas phase inside the reactor, Eq. [2] can be rewritten as

$$r_{oxy} = K'_{on}C^{n_1}_{SiH_4}C^{n_2}_{NH_3}C^{n_3}_{CO_2} \quad [3]$$

where C_{SiH_4}, C_{NH_3}, and C_{CO_2} are, respectively, the concentrations of SiH_4, NH_3, and CO_2 inside the reactor.

We have intentionally used considerably higher concentrations of NH_3 and CO_2 with respect to SiH_4 (*i.e.*, isolation technique). This was done due to four reasons: (*i*) to prevent the formation of silicon-rich films; (*ii*) to make the deposition of silicon oxynitrides dependent on as few variables as possible; (*iii*) to minimize refractive index (composition) variations within a run; and (*iv*) to facilitate data analysis from a kinetic point of view. Thus, under the conditions of isolation technique, C_{NH_3} and C_{CO_2} (also θ_{NH_3} and θ_{CO_2}) are nearly constant, and therefore the deposition rate of silicon oxynitride would be independent of NH_3 and CO_2 concentration. This is indeed the case as shown in Fig. 3 and 4.

Thus, Eq. [3] reduces to

$$r_{oxy} = K''_{on}C^{n_1}_{SiH_4} \quad [4]$$

Following similar reasoning and under the conditions of isolation technique, the rates of Si_3N_4 and SiO_2 can be expressed as follows

$$r_n = K''_nC^{n'_1}_{SiH_4} \quad [5]$$

$$r_{ox} = K''_{ox}C^{n''_1}_{SiH_4} \quad [6]$$

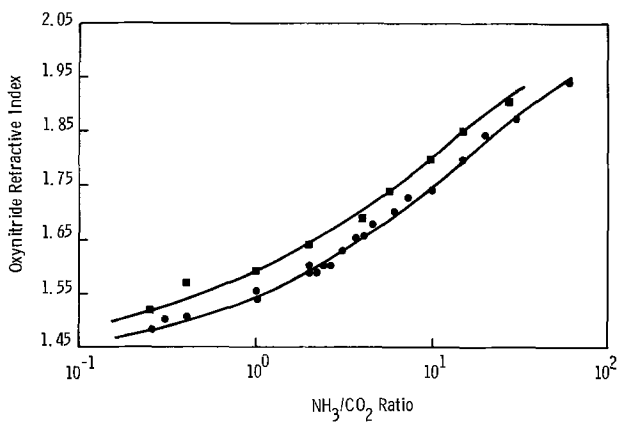

Fig. 5. Oxynitride refractive index as a function of NH_3:CO_2 ratio at two deposition temperatures. ■ = 900°C deposition, ● = 1000°C deposition. Rest of the condition some as Fig. 4.

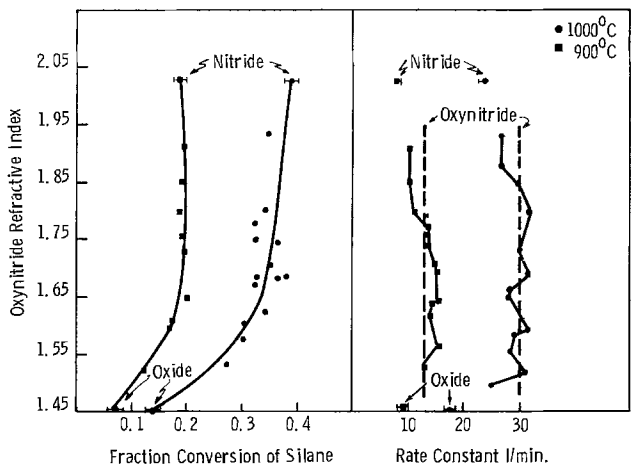

Fig. 6. Fractional conversion of silane and rate constants for oxide, nitride, and oxynitride as a function of refractive index (composition). ■ = 900°C deposition, ● = 1000°C deposition.

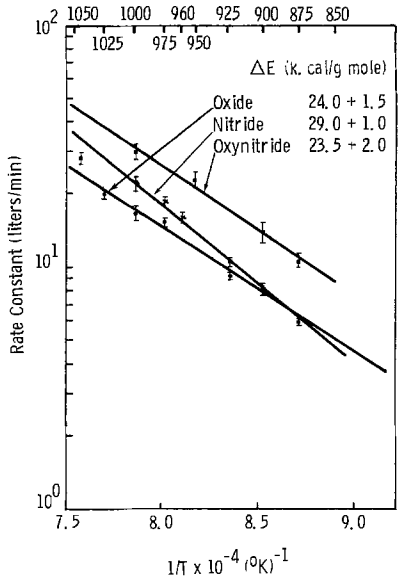

Fig. 7. Rate constant as a function of $1/T$ for SiO_2, Si_3N_4, and $Si_lO_mN_p$.

where r_n and r_{ox} are the rates of Si_3N_4 and SiO_2 deposition, respectively, in moles/minute, K''_n and K''_{ox} are the respective rate constants, and where C_{SiH_4} is the effective SiH_4 concentration in the reactor. From Fig. 2 it is seen that n_1, n'_1, and n''_1 are all equal to 1, thus showing that SiH_4 participates in these three reactions as a whole; *i.e.* without dissociation.

Evaluation of rate constants.—The rate constants of $Si_lO_mN_p$, Si_3N_4, and SiO_2 can be readily calculated from Eq. [4] through [6] provided the SiH_4 concentration inside the reactor is known. Since C_{SiH_4} is equal to $C^0_{SiH_4}(1 - Y_{SiH_4})$ as shown in Appendix B, knowledge of fractional conversion (Y_{SiH_4}) is important. Y_{SiH_4} can be readily obtained by mass balance (cf. Appendix B). In Fig. 6 the rate constants and fractional conversion of SiH_4 are shown as a function of the refractive index at two deposition temperatures of 900° and 1000°C. Note that the silicon oxynitride rate constants are nearly independent of the silicon oxynitride refractive index (1.5-1.93). Similar results are obtained at all temperatures in the experimental range of 850°-1000°C.

Since both NH_3 and CO_2 are present in the reactor during the deposition of silicon oxynitride, one may hypothesize that SiH_4 oxidation and nitriding reactions proceed simultaneously and in parallel without mutual interference. If this were the case, then

$$r_{oxy} = r_{Si_3N_4} + r_{SiO_2} \qquad [7]$$

From Eq. [4], [5], and [6], with n_1, n'_1, and n''_1 equal to 1, we have

$$K''_{on}C_{SiH_4} = (K''_n + K''_{ox})C_{SiH_4} \qquad [8]$$

Thus due to above hypothesis, K''_{on} should be equal to $K''_n + K''_{ox}$. This is not the case as can be seen in Fig. 6. Therefore, one is forced to accept the converse hypothesis; *i.e.*, the simultaneous presence of NH_3 and CO_2 changes either the oxidation rate constant or the nitriding rate constant, or both. These possibilities are investigated further on in this paper.

Rate expression (empirical).—The rate constant for any surface-chemical reaction can be expressed as a product of a frequency factor and an exponential term; *i.e.*, $K = Ae^{-\Delta E/RT}$, where A is the frequency factor, ΔE the activation energy in cal/g mole, R is the gas constant (1.98 cal/g mole °K), and T is the temperature in °K. The activation energies of SiO_2, Si_3N_4, and silicon oxynitride reactions are determined in Fig. 7 by the usual Arrhenius plot of logarithm of rate constant *vs.* inverse absolute temperature. The calculated values of frequency factors are shown in Table I.

Thus, under the conditions of isolation technique, the rate expressions for all three materials (*i.e.*, SiO_2, Si_3N_4, and silicon oxynitride) may be expressed as follows

$$r_{ox} = 2.4 \times 10^5 \exp[-24 \times 10^3/RT]C_{SiH_4} \qquad [8]$$

$$r_n = 22.3 \times 10^5 \exp[-29 \times 10^3/RT]C_{SiH_4} \qquad [9]$$

$$r_{on} = 3.5 \times 10^5 \exp[-23.5 \times 10^3/RT]C_{SiH_4} \qquad [10]$$

Equations [8] through [10] are applicable within the temperature range of 850°-1050°C and in those reactors where the flow of gases is nearly parallel to the wafer surface.

Investigation of anomalous temperature effect on refractive index.—In Fig. 5 we have shown that the refractive index of silicon oxynitride is higher at 900°C than at 1000°C for a fixed NH_3:CO_2 ratio. We pointed out earlier that these results were anomalous and cannot be explained by separately investigating the deposition rates of the Si_3N_4 and SiO_2. We now show that this phenomenon is explainable.

Expressing oxynitride deposition rate as a sum of equivalent Si_3N_4 ($r'_{Si_3N_4}$) and SiO_2 (r'_{SiO_2}) deposition rates (cf. Appendix A)

$$r_{oxy} = r'_{Si_3N_4} + r'_{SiO_2} \qquad [11]$$

where $r'_{Si_3N_4}$ is not equal to $r_{Si_3N_4}$ and r'_{SiO_2} is not equal to r_{SiO_2}. The $r_{Si_3N_4}$ and r_{SiO_2} are defined by Eq. [5] and [6].

Now

$$r'_{Si_3N_4} = K_1\theta_{SiH_4}\theta^{m_1}_{NH_3} \qquad [12]$$

and

$$r'_{SiO_2} = K_2\theta_{SiH_4}\theta^{m_2}_{CO_2} \qquad [13]$$

Considering Eq. [12] only for the present, one can write an expression for θ_{NH_3} in a multicomponent system using Langmuir adsorption theory (19); *i.e.*

$$\theta_{NH_3} = \frac{b_{NH_3}p_{NH_3}}{1 + b_{NH_3}p_{NH_3} + b_{CO_2}p_{CO_2} + b_{H_2}p_{H_2} + b_{SiH_4}p_{SiH_4}} \qquad [14]$$

Table I. Frequency factors for SiO_2, Si_3N_4, and silicon oxynitride. Applicable temperature range 850°-1050°C

Material	A (liters/min)* ($\times 10^5$)
SiO_2	2.4 (±0.3)
Si_3N_4	22.3 (±2.5)
$Si_lO_mN_p$	3.5 (±0.4)

* Values in parenthesis are twice the standard deviation.

where various b's are the ratio of adsorption and desorption rate constants for a given gas and p's are the respective partial pressures.

Assuming that NH_3 and CO_2 adsorb more strongly than the other components, *i.e.*

$$b_{NH_3}p_{NH_3} + b_{CO_2}p_{CO_2} >> 1 + b_{H_2}p_{H_2} + b_{SiH_4}p_{SiH_4} \quad [15]$$

Equation [14] then reduces to

$$\theta_{NH_3} \approx \frac{b_{NH_3}p_{NH_3}}{b_{CO_2}p_{CO_2} + b_{NH_3}p_{NH_3}} = \frac{p_{NH_3}}{K_3 p_{CO_2} + p_{NH_3}} \quad [16]$$

where $K_3 = b_{CO_2}/b_{NH_3}$. Substituting Eq. [16] in Eq. [12] and noting that partial pressures are equal to mole fraction, provided the total pressure is 1 atm, which is the case here, Eq. [12] becomes

$$r'_{Si_3N_4} = K_1\theta_{SiH_4}\left[\frac{X_{NH_3}}{K_3X_{CO_2} + X_{NH_3}}\right]^{m_1} \quad [17]$$

where X_{NH_3}, X_{CO_2} are mole fractions of NH_3 and CO_2, respectively.

Now if an experiment is performed such that the partial pressure of SiH_4 is kept constant and the NH_3:CO_2 ratio varied keeping the $NH_3 + CO_2$ partial pressure constant, the resulting silicon oxynitride deposition rate is first normalized for changes in SiH_4 fractional conversion as the film composition changes (cf. Fig 6 and Appendix B), and then it is separated into equivalent Si_3N_4 and SiO_2 deposition rates (cf. Appendix A). Equation [17] can then be used to predict the variation of equivalent Si_3N_4 deposition rate as a function of NH_3:CO_2 ratio depending on one of the following two limiting conditions

(*i*) If $K_3X_{CO_2} > X_{NH_3}$, then

$$r'_{Si_3N_4} \approx K'_1\left[\frac{X_{NH_3}}{X_{CO_2}}\right]^{m_1} \quad [18]$$

(*ii*) If $X_{NH_3} > K_3X_{CO_2}$, then

$$r'_{Si_3N_4} \approx K''_1 \quad [19]$$

The expected trends from Eq. [18] and [19] show excellent agreement with the experiment as shown in Fig. 8. Note that $r'_{Si_3N_4}$ first increases as a function of NH_3:CO_2 ratio and then saturates to a constant value according to Eq. [19]. The value of m_1 obtained from this experiment is 0.6.

Following similar development as with Eq. [12], Eq. [13] modifies to

$$r'_{SiO_2} = K_2\theta_{SiH_4}\left[\frac{X_{CO_2}}{K_4X_{NH_3} + X_{CO_2}}\right]^{m_2} \quad [20]$$

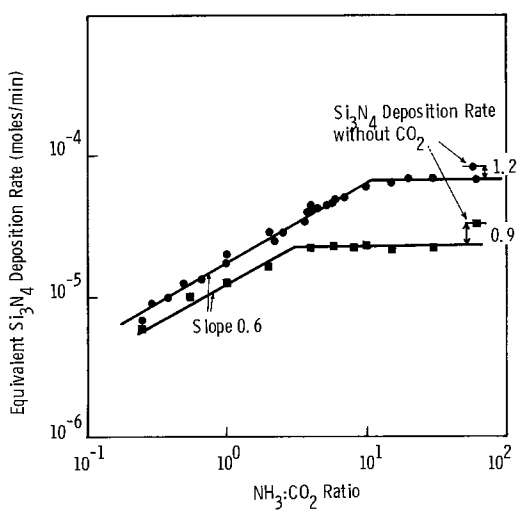

Fig. 8. Deposition of "equivalent" Si_3N_4 in the oxynitride films *vs.* NH_3:CO_2 ratio. ● = 1000°C deposition, ■ = 900°C deposition. H_2 flow rate ~ 110 liters/min, $NH_3 + CO_2$ flow rate constant at 2.3 liters/min. Effective SiH_4 concentration in the reactor (C_{SiH_4}) ~ 3.75 × 10^{-6} moles/min.

Equation [20] can then be used to predict the variation in deposition rate of equivalent SiO_2 as a function of CO_2:NH_3 ratio depending on one of the following two limiting conditions

(*i*) If $K_4X_{NH_3} > X_{CO_2}$, then

$$r'_{SiO_2} \approx K'_2\left[\frac{X_{CO_2}}{X_{NH_3}}\right]^{m_2} \quad [21]$$

(*ii*) If $X_{CO_2} > K_4X_{NH_3}$, then

$$r'_{SiO_2} \approx K''_2 \quad [22]$$

Thus, the deposition rate of equivalent SiO_2 would increase first as a function of CO_2:NH_3 ratio (*i.e.*, Eq. [21]) and finally saturating according to Eq. [22]. Figure 9 shows this behavior is in excellent agreement with the theory. The value of m_2 obtained from the above experiment is 0.5.

The purpose of generating the above theoretical analysis and Fig. 8 and 9 is to compare the saturation value of $r'_{Si_3N_4}$ with $r_{Si_3N_4}$ and r'_{SiO_2} with r_{SiO_2}.

The values of $r_{Si_3N_4}$ and r_{SiO_2} are shown for both 900° and 1000°C on Fig. 8 and 9, respectively. Note that the saturation value of $r'_{Si_3N_4} < r_{Si_3N_4}$ and $r'_{SiO_2} > r_{SiO_2}$. The above facts lead us to the conclusion that the simultaneous presence of NH_3 and CO_2 changes both the oxidation and nitriding rate constants. This is consistent with the hypothesis previously accepted that the simultaneous presence of NH_3 and CO_2 changes the rate constants of both nitriding and oxidation reactions.

The above changes in the rate constants of Si_3N_4 and SiO_2 deposition are the root cause of the phenomenon of temperature dependence of refractive index at a fixed NH_3:CO_2 ratio. These changes are the reason why the data of Fig. 2 could not predict the results of Fig. 5. The impact of alteration of the rate constants is best seen if the ratio of equivalent Si_3N_4 to equivalent SiO_2 (from Fig. 8 and 9) is plotted against the NH_3:CO_2 ratio. This is done in Fig. 10. Note $r'_{Si_3N_4}/r'_{SiO_2}$ ratio is higher for 900°C deposited films; *i.e.*, higher relative amount of Si_3N_4 is formed in the films deposited at 900°C than at 1000°C in the presence of CO_2. This is precisely the reason for observing a higher refractive index at 900°C than at 1000°C for a fixed NH_3:CO_2 ratio.

Discussion

We have shown that SiH_4-CO_2-NH_3 reaction, which leads to the deposition of silicon oxynitride films, is first order with respect to SiH_4. This was determined by using the isolation technique (16); *i.e.*, NH_3 and CO_2 concentrations (mole fractions) were considerably larger than SiH_4 in the gas phase.

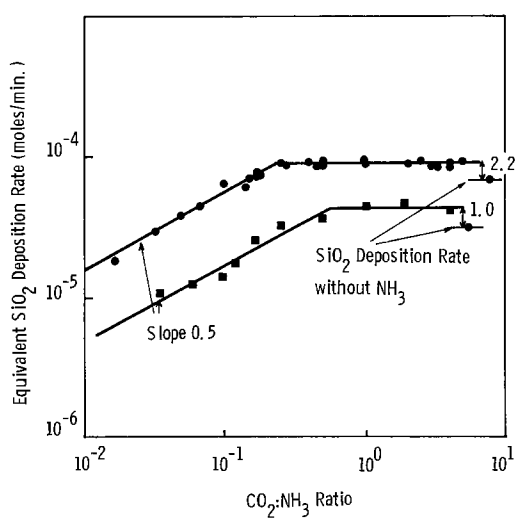

Fig. 9. Deposition rate of "equivalent" SiO_2 in oxynitride films *vs.* CO_2:NH_3 ratio. ● = 1000°C deposition, ■ = 900°C deposition. Rest of the condition the same as Fig. 8.

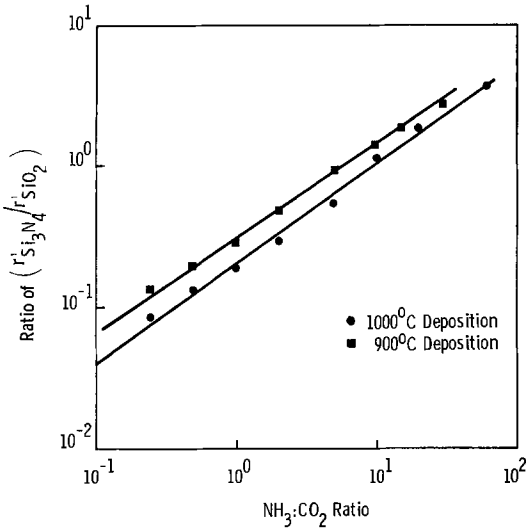

Fig. 10. The ratio of "equivalent" Si_3N_4 to SiO_2 in oxynitride at two deposition temperatures, showing a higher relative amount of nitride incorporation in the oxynitride films at 900°C than at 1000°C for a fixed NH_3:CO_2 ratio.

The same technique (*i.e.*, isolation) cannot be used to isolate the orders of reaction with respect to CO_2 and NH_3 since this would involve using larger concentrations of SiH_4 than CO_2 or NH_3, which in turn leads to the deposition of silicon-rich films. However, in the process of explaining the anomalous deposition temperature effect (Fig. 5) on the silicon oxynitride refractive index, we did indirectly discover the order of reaction with respect to both NH_3 and CO_2 (Fig. 8 and 9). We have shown that the rate of equivalent Si_3N_4 deposition first increases as a function of NH_3:CO_2 ratio with an order of 0.6 (Fig. 8) and then saturates when $X_{NH3} > K_3X_{CO2}$. In the region where the $r'_{Si_3N_4}$ is still increasing as a function of NH_3:CO_2 ratio, the CO_2 mole fraction, X_{CO2}, is larger than the NH_3 mole fraction, X_{NH3}. Thus, as compared to X_{NH3}, the X_{CO2} is approximately a constant; therefore, the order of reaction with respect to NH_3 is 0.6 for the nitrogen incorporation in silicon oxynitride films. Similarly, from Fig. 9 we deduce that the order of reaction with respect to CO_2 for oxygen incorporation, in the silicon oxynitride films, is 0.5. Since fractional orders imply decomposition (18, 19) we conclude that both NH_3 and CO_2 decompose prior to participating in the reaction with SiH_4.

The above analysis and inferences not only provide some insight into SiH_4-NH_3-CO_2 reaction, but also increase our understanding of SiH_4-CO_2 and SiH_4-NH_3 reactions. Take, for example, Si_3N_4 and $Si_lO_mN_p$. Assuming that the nitrogen incorporation follows similar reaction paths in both cases, we can conclude that NH_3 first dissociates into possibly $NH_2\cdot$ and $H\cdot$. Then $NH_2\cdot$ reacts with SiH_4 to form a substitutional compound where all hydrogen atoms are replaced by $NH_2\cdot$. This reaction will probably involve many steps, only one of which will be rate controlling, such that the first-order participation of SiH_4 is satisfied. The substituted silane compound then decomposes to Si_3N_4 (in the absence of CO_2) or forms a silicon, nitrogen, and oxygen "polymer" in the presence of CO_2.

Similarly, if we assume that the oxygen incorporation in $Si_lO_mN_p$ and SiO_2 follow similar paths, then we conclude that CO_2 first dissociates into CO and O. The oxygen reacts with SiH_4 to form SiO_2 in the case of SiH_4-CO_2 reaction, possibly in more than one step, one of which will be rate controlling. In the presence of NH_3 (or $NH_2\cdot$), the atomic oxygen reacts with the substituted SiH_4, leading to silicon, oxygen, and nitrogen polymer. Note that we have not mentioned the role of the so-called "water-gas" reaction for the oxygen incorporation in $Si_lO_mN_p$ films. We have done this because of two reasons: (*i*) the water-gas reaction is very slow and would be rate controlling; and, if that were the case, the order of the reaction with respect to CO_2 should have been 1 (20); (*ii*) much evidence has been generated against water-gas reaction mechanism when we investigated the SiH_4-CO_2-H_2 reaction (12).

In Fig. 2 we show that when investigated independently the SiH_4-CO_2 and SiH_4-NH_3 reactions result in equal deposition rates at 900°C. Why then is a NH_3:CO_2 ratio of $\sim$ 6 required in the gas phase to produce silicon oxynitride composition of Si_2ON_2 at 900°C? The answer lies in Fig. 8 and 9. The presence of CO_2 retards the rate of nitrogen and the presence of NH_3 enhances the rate of oxygen incorporation, respectively, in the silicon oxynitride films. Now the questions become: (*i*) Why should CO_2 retard the nitrogen incorporation rate? (*ii*) Why should NH_3 enhance the oxygen incorporation rate? The answers probably are that the CO_2 adsorbs more strongly than the NH_3 (*i.e.*, $K_3 > 1$, Eq. [17]). Since K_4 (Eq. [20]) is the reciprocal of the K_3, it must be less than 1, and thus the enhancement of oxygen incorporation in the presence of NH_3 (*i.e.*, Eq. [20]). The above analysis, of course, is correct in the region before $r'_{Si_3N_4}$ and r'_{SiO_2} have reached the saturation values. Figures 8 and 9 support the point that $K_3 > 1$ and $K_4 < 1$. The saturation value of $r'_{Si_3N_4}$, being less than $r_{Si_3N_4}$, is consistent with the explanation that the CO_2 adsorbs more strongly than NH_3. However, the role of NH_3 in the enhancement of the saturation value of r'_{SiO_2} is unclear and not understood at present.

Despite the fact that the chemical reactions involved here are very complex, we have nonetheless gained some insight into reaction mechanism of $Si_lO_mN_p$, Si_3N_4, and SiO_2.

Summary and Conclusions

Much is known about silicon oxynitride properties (1-10); however, to the best of our knowledge, nothing exists in the literature regarding the kinetics of oxynitride deposition from any chemical system. We have thus attempted to bridge the knowledge gap between oxynitride properties and kinetics.

During this study we have obtained the empirical rate expressions for SiO_2, Si_3N_4, and $Si_lO_mN_p$. Despite the fact that these rate expressions were obtained under somewhat restricted experimental conditions, they should nonetheless be widely applicable. This especially holds for those multiple wafer reactors where the flow of the gases is nearly parallel to the wafer surface and the objective is to deposit uniform and stoichiometric (nonsilicon rich) films.

Some of the fundamental concepts used in this paper are quite general and important since they increase the understanding of complex chemical reactions. These concepts are: (*i*) The use of moles/minute as unit of deposition rates. This approach permits the comparison of the deposition rates of materials which are changing in composition, density and molecular weight. (*ii*) The simple, yet powerful, concept of fractional conversion and its use in the correction of the SiH_4 concentration. The direct comparison of chemical reactions with differing efficiency (*i.e.*, fractional conversion) was made possible by the correction of SiH_4 concentration. (*iii*) The use of the absorption theory in theoretical descriptions of surface-chemical rate-limited chemical reactions. It is our hope that the use of these concepts will increase the understanding of CVD reactions in general.

The use of CO_2 as an oxidant for the deposition of silicon oxynitride is quite novel and has not been previously reported. In our experience the use of CO_2 leads to significantly better process and film property control than when other oxidants, such as N_2O or O_2, are used. The above is especially true when high deposition temperatures (*i.e.*, $\sim$ 1000°C) are used for $Si_lO_mN_p$ deposition. The key advantage of using the SiH_4-CO_2-NH_3-H_2 system, however, is the ability of this chemical system

to deposit silicon oxynitride films with refractive index larger than 1.73 with relative ease, especially at high deposition temperatures.

We have also analyzed and discussed the anomalous effect of deposition temperature on silicon oxynitride composition. In the process of this analysis we have discovered some fundamental facts regarding the mechanism of SiH_4-CO_2, SiH_4-NH_3, and SiH_4-NH_3-CO_2 reactions, even though it was not our purpose to unravel the mechanism of these reactions.

Finally it is our hope that this paper will help in the transition of chemical vapor deposition from an art into a science.

Acknowledgments

Our thanks are due to Dr. W. A. Pliskin for extensive discussions and assistance during the course of this study. Contributions of V. L. Elliott, in the preparation of samples, are also gratefully acknowledged.

APPENDIX A

Refractive index vs. infrared absorption maxima.—Figure 11 presents the infrared absorption maxima as a function of refractive index. The infrared spectra was taken in transmission; *i.e.*, the silicon wafers with deposited films were broken in half, and one-half was used in sample beam and the other half was stripped of its deposit in HF and used in the reference beam. Similar data is presented for the SiH_4-NO-NH_3-N_2 system (4). Note that the two systems (*i.e.*, CO_2-NH_3 and NO-NH_3) follow the same curve, indicating similarity of the deposited films. We also observed weak absorption bands $\sim$ 3380 cm^{-1} and a very weak and broad absorption at $\sim$ 1200 cm^{-1} (4). The absorption maxima at $\sim$ 3380 and $\sim$ 1200 cm^{-1} were not present when SiO_2 was deposited from SiH_4-CO_2-H_2. The 3380 cm^{-1} band is attributed to N-H stretching.

Note that the absorption maxima are only a function of refractive index and not a function of deposition temperature. Though we only show the data points of two temperatures, the absorption maxima of all silicon oxynitride films deposited at any temperature within the 850°-1000°C experimental range fall on the same general curve as shown in Fig. 11. Thus, we conclude that the composition and structure of oxynitride films are only dependent on refractive index and are independent of deposition temperature and the chemical system used to produce them.

Composition vs. refractive index.—The interdependence of the composition and the refractive index for oxynitride has been established previously (4, 6). For

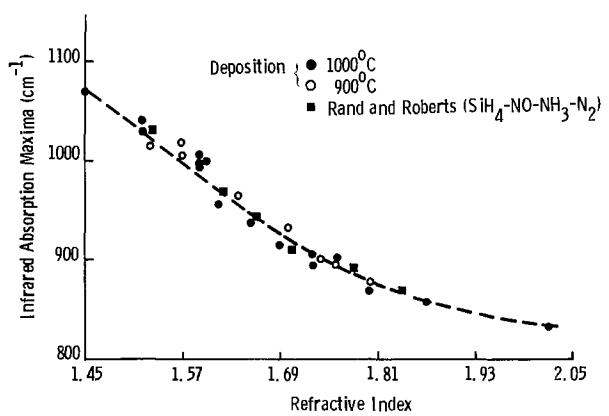

Fig. 11. Infrared absorption maxima as a function of refractive index.

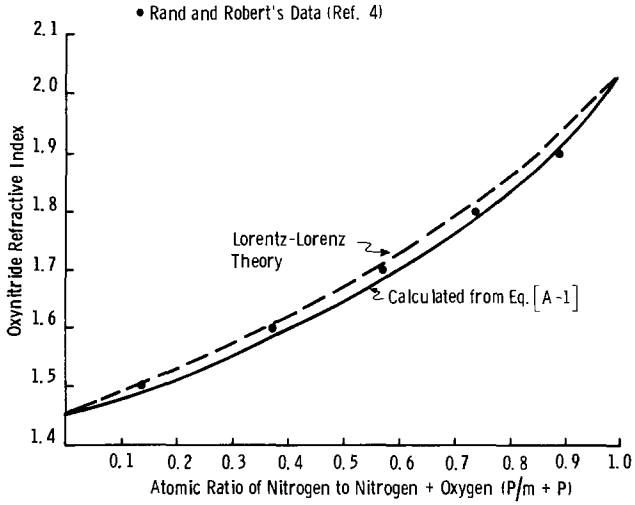

Fig. 12. Plot of refractive index vs. the ratio of atomic nitrogen to the sum of atomic nitrogen and oxygen in silicon oxynitrides.

ease of calculation, we have chosen to represent oxynitride films ($Si_lO_mN_p$) as $xSiO_2 \cdot ySi_3N_4$, where x and y are mole fractions. It should be clearly understood that by representing silicon oxynitride as $xSiO_2 \cdot ySi_3N_4$ we are not implying any structure. It is merely a convenient mathematical representation. The obvious relationships between l, m, p and x and y are $x + 3y = l$, $2x = m$, and $4y = p$, whereas $x + y = 1$.

For the purposes of calculating x and y we have used two methods: (*i*) Lorentz-Lorentz theory (21-24), and (*ii*) the oxynitride refractive index (n_{on}) is assumed to vary linearly with the refractive indexes of SiO_2 ($n_{ox} = 1.45$) and Si_3N_4 ($n_n = 2.025$) as shown in Eq. [A-1] (24)

$$n_{on} = n \cdot n_{on} + y \cdot n_n \qquad [A\text{-}1]$$

Once x and y are known, calculations of l, m, and p are a trivial matter. Figure 12 is a plot of refractive index *vs.* the ratio of atomic nitrogen to the sum of atomic nitrogen and oxygen in silicon-oxynitrides. Data of Rand and Roberts' (4) is provided for comparison. Note the excellent agreement between either method and the experimental data. Throughout this paper we have used the mean value of the composition calculated by the methods described above.

Density and molecular weight vs refractive index.—Once the composition of oxynitride is known as outlined above, the calculation of molecular weight is straightforward. Then, by the use of Lorentz-Lorenz theory (21, 24) the molar refractivity and density can be computed. The results of these computations are shown in Table II.

Conversion of deposition rate units.—By direct thickness measurements, and knowing the deposition time, we obtained the deposition rates in Å min^{-1}. The deposition rates in the units of moles min^{-1} were obtained as shown in Eq. [A-2]

$$r = \frac{\rho \times A_s \times r' \times 10^{-8}}{M} \qquad [A\text{-}2]$$

where r is deposition rate in moles min^{-1}, r' the deposition rate in Å min^{-1}, A_s the susceptor area (1058

Table II. Oxynitride, molecular weight, molar refractivity, and density as a function of refractive index

cm^2), ρ and M the density (g cm^{-3}) and the molecular weight (g $mole^{-1}$) of the deposited film, respectively.

APPENDIX B

Silane concentration along the length of the susceptor is assumed to be constant.

Effective concentration of SiH_4 along the susceptor is defined as

$$C_{SiH_4} = \frac{N}{V} \text{constant} \qquad [B\text{-}1]$$

where N is the number of molecules of SiH_4 and V is the volume of reacting mixture. At feed conditions the concentration of SiH_4 is given by

$$C^o_{SiH_4} = \frac{N^o}{V^o} \qquad [B\text{-}2]$$

where O superscript represents the feed conditions. Due to deposition, the Y_{SiH_4} fraction of SiH_4 is converted to deposit, then

$$N = N^o\,(1 - Y_{SiH_4})$$

and $$V = V^o\,[1 + \phi(Y_{SiH_4})] \qquad [B\text{-}3]$$

But since the reacting mixtures are mostly H_2 in every case, therefore $V^o \sim V$.

Thus

$$C_{SiH_4} = \frac{N^o(1 - Y_{SiH_4})}{V^o} = C^o_{SiH_4}\,(1 - Y_{SiH_4}) \qquad [B\text{-}4]$$

Y_{SiH_4} can be readily calculated by mass-balance, *i.e.*

$$Y_{SiH_4} = \frac{l \times \text{moles of deposit/min}}{\text{moles of silane/min}}$$

The value of l varies between 1 (for SiO_2) and 3 (Si_3N_4), and can be readily calculated by the procedure described in Appendix A knowing the refractive index of a given oxynitride film.

APPENDIX C

For any heterogeneous reaction which is only dependent on the concentration of a single reactant, the rate of reaction may be written as (25)

$$r = \frac{h_G K_s}{h_G + K_s} C_A \qquad [C\text{-}1]$$

where h_G is the mass transfer coefficient, K_s is the surface-chemical reaction rate constant, and C_A is the concentration of the reactant in gas phase. Now, if the reaction rate was mass transfer limited (*i.e.*, $K_s > h_G$), then Eq. [C-1] would reduce to

$$r \approx h_G C_A \qquad [C\text{-}2]$$

For any condition of flow and temperature distribution within a reactor the mass transfer coefficient may be expressed as follows (26)

$$N_{Nu} = a N_{Re}^{n} N_{sc}^{n'} \qquad [C\text{-}3]$$

where N_{Nu} = dimensionless number (Nusselt) = $h_G L/D$, where h_G is mass transfer coefficient, L length of reaction zone, D the diffusivity of the reactant; N_{Re} = dimensionless number (Reynolds) = $\rho VL/\mu$, where ρ is density of the gas, V flow velocity, L the length of reaction zone, μ the viscosity of the gas; N_{sc} = dimensionless number (Schmidt) = $\mu/\rho D_G$, symbols have same meaning as before; n, n', and a are dependent on reactor shape, temperature profile, and flow profile.

From Eq. [C-3] we se that

$$h_G \propto N_{Re} \propto \text{velocity} \propto \text{flow rate}$$

Thus, from Eq. [C-2], if the reaction is mass transfer limited, the reaction rate must increase in proportion to flow rate. We have shown that the reaction rate is independent of flow rate (60-130 liters/min) for Si_3N_4, SiO_2, $Si_lO_mN_p$; therefore, all three reactions are independent of mass transfer coefficient.

The question may arise as to what happens to deposition rate when the flow rate is decreased to a very low value of, say, ~20 liters/min or increased to a very high value of, say, ~200 liters/min. In both cases the average deposition rate over three rings (Fig. 1) is less than the one obtained in the flow range of 60-130 liters/min. This is due to the SiH_4 depletion as indicated by extreme nonuniformity within a run ($> \pm 50\%$).

For multiple wafer reactors, the criterion of mass transfer limited *vs.* surface-chemical reaction rate-limited regions must take into account the deposition uniformity. Since nonuniform depositions are of little practical value, the flow rate range used to check the validity of Eq. [C-2] must be such that the deposition uniformity within a run is at least $\pm 15\%$. This is indeed the case for Si_3N_4, SiO_2, and $Si_lO_mN_p$ depositions in the flow range of 60-130 liters/min at 1000°C. Under identical flow conditions and uniformity constraints the deposition rate of silicon epitaxy, deposited from $SiCl_4$-H_2 reaction, increases as a function of flow rate at 1150°C. Thus, the deposition of silicon epitaxy from $SiCl_4$ and H_2 is a mass transfer limited reaction, whereas the depositions of the Si_3N_4 from SiH_4-NH_3, the SiO_2 from SiH_4-CO_2, and the $Si_lO_mN_p$ from SiH_4-CO_2-NH_3 are surface-chemical reaction rate limited within the appropriate experimental constraints of this study.

Gas Phase Composition Considerations in the Thermal Oxidation of Silicon in Cl-H-O Ambients

R. E. Tressler,* J. Stach,* and D. M. Metz

Departments of Materials Science and Electrical Engineering, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

The improved electrical stability and accelerated growth kinetics of thermal SiO_2 grown in oxygen ambients containing Cl_2 and HCl have been well documented, but the mechanisms of this improvement are still poorly understood. This paper presents calculations of equilibrium partial pressures of the possible gaseous species in the Cl-H-O system under thermal oxidation conditions. These results are correlated with published results on (*i*) oxidation kinetics; (*ii*) detrimental effects of water vapor in the growth ambient; and (*iii*) chlorine content in the as-grown oxide.

It is well known that silicon thermal oxidations performed in HCl- or Cl_2-containing ambients result in an improvement in the control of mobile sodium ions which are major contributions to the instabilities as observed in bias temperature stressed MOS structures (1-3). The oxidation kinetics in these environments are modified (much more rapid than in dry O_2), indicating that the incorporation of a chlorine species modifies the transport rate of oxidant species to the Si-SiO_2 interface, at least in the parabolic growth rate regime (4-7). Clearly, solute chlorine species also interact with the sodium ions to produce the passivation effect.

This analysis was undertaken in an attempt to correlate the observed solute effects on the parabolic oxidation rate with the observed solute effects on the sodium ion passivation process. To fundamentally analyze the physical chemistry of this process, the composition of the gas phase in equilibrium with the growing oxide and the corresponding solubilities of the gaseous species in the oxide must be known. Unfortunately, most of the published studies do not give the partial pressures of the gaseous species or enough data to calculate these equilibrium pressures. The ability to depth profile SiO_2 films for chlorine concentrations is a rather recent and less-than-routine technique using nuclear backscattering spectroscopy (2) or ion machining coupled with Auger spectroscopy (8).

In this paper the results of equilibrium gas phase composition calculations in the Cl-H-O system are presented in conjunction with some correlations that have been made of these compositions with published kinetic results, elemental analyses, and electrical measurements on oxides.

Thermodynamic Calculations

Equilibrium partial pressures of the various gaseous species in the Cl-H-O system were calculated using a modified SOLGAS program (9). The calculations were performed from 700° to 1300°C for given ratios of the input gases holding the total pressure at 1 atm.

In Fig. 1 the equilibrium partial pressures in HCl-O_2 ambients as a function of temperature are presented for two HCl concentrations. For the ratio R = H/O = Cl/O, R = 0.10 corresponds to 20 volume percent (v/o) HCl and R = 0.01 corresponds to 2 v/o of HCl in the input mixture. The predominant species are HCl and O_2 plus Cl_2 and H_2O from the reaction $2HCl + 1/2\ O_2 \rightarrow Cl_2 + H_2O$. It can be seen that for a given R the Cl_2 and H_2O partial pressures (p_{Cl_2}, p_{H_2O}) decrease with increasing temperature although it has been reported that the chlorine concentration in the SiO_2 layers increases with temperature (2). This reported chlorine increase with temperature indicates that the solubility of Cl_2 in SiO_2 increases more rapidly with temperature than its partial pressure decreases with temperature at a given input composition. The partial pressures of HOCl, ClO, and HO are at somewhat lower pressures and increase with temperature at a given input composition.

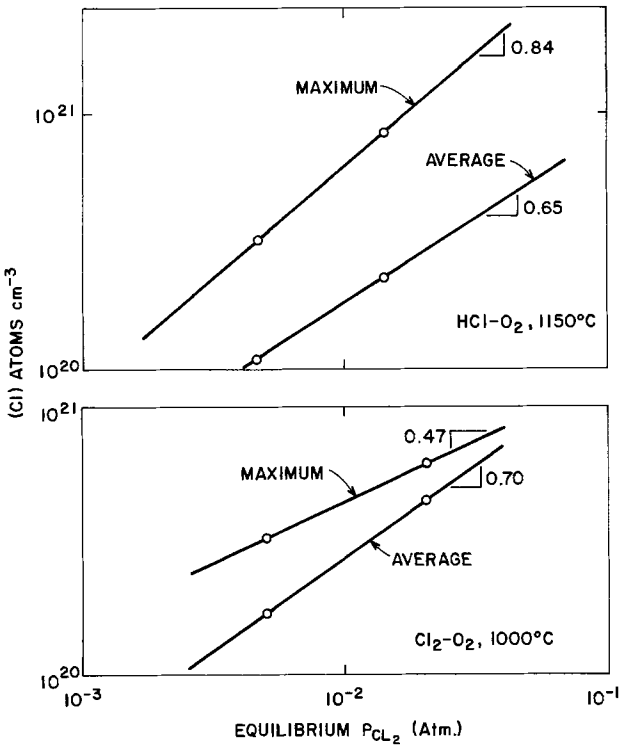

Fig. 2. Chlorine concentration in SiO_2 vs. equilibrium chlorine pressure in HCl-O_2 and Cl-O_2 oxidation ambients [after van der Meulen et al. (2)]. Maximum and average concentrations are shown.

To complete the equilibrium considerations the concentrations of the gaseous species in the growing oxide in equilibrium with the particular gas phase composition are needed. Although published data are scarce, van der Meulen *et al.* (2) have reported the chlorine concentrations in SiO_2 grown in HCl-O_2 and Cl_2-O_2 ambients. Figure 2 shows a plot of chlorine concentration as a function of equilibrium Cl_2 partial pressure calculated from the input gas compositions from the experimental data of van der Meulen *et al.* (2). Very few data points are available and maximum and average Cl concentrations, which reflect a nonuniform distribution in the SiO_2 layer, are plotted. From the equilibrium constant for Cl_2 dissolution in SiO_2 as a monatomic species, the slope of the chlorine concentration *vs.* equilibrium pressure of Cl_2 plot should be 1/2. Note that the tentative straight lines produce slopes that do not all agree with a slope of 1/2. Ideally, one must have similar plots for $(OH)^-$ (or H^+) as a function of H_2O partial pressure, and likewise for the other possible species, including Cl over much larger ranges of T and p_{Cl_2}, to fully characterize the equilibrium situation.

Growth Kinetics

The survey (1-7) of oxidation kinetics in Cl-H-O environments indicates certain trends in rate constants in the parabolic oxidation regime, where diffusion of the oxidant species is generally accepted to be rate limiting. Of particular interest are the p_{Cl_2} effects on the parabolic rate constant B (1-3) for HCl-O_2 and Cl_2-O_2 ambients.

From the data of Kriegler *et al.* (1), it is obvious that the parabolic rate constant is not directly dependent on the total concentration of chlorine in the gaseous ambient since the rate constant for 2.5% Cl_2 is much larger than the rate constant of 5% HCl. This result suggests that B may be directly related to p_{Cl_2} (or p_{ClO} since both quantities show similar trends). In Fig. 3, the parabolic rate constant is plotted as a function of equilibrium p_{Cl_2} at 1100° and 1150°C showing an obvious increasing trend with the chlorine partial pressure rather than the total concentration

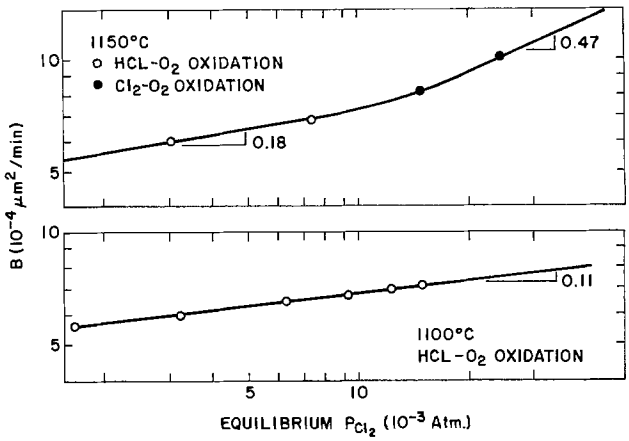

Fig. 3. Log of the parabolic rate constant vs. log of the equilibrium chlorine pressure, at 1150°C [rate constants determined from Kriegler et al. (1)] and 1100°C [rate constants from Hirabayashi and Iwamura (3)].

of chlorine species which suggests that the HCl molecules are not directly involved in the reaction of HCl/O_2 ambients with SiO_2. However, the change in B cannot be simply related to the incorporation of chlorine via the reaction $Cl_2 \rightarrow 2Cl$, assuming that the dissolved Cl controls the oxidation at the Si-SiO_2 interface by some undetermined mechanism, since the slope of the B *vs.* p_{Cl_2} plot is not 1/2 as predicted by the parameters included in B (4). If the partial pressure of H_2O affects the oxidation kinetics, which is well known to be the case for H_2O-O_2 ambients, the magnitude of the effect cannot be assessed at this point; since experimental data are not available for H_2O-O_2 ambients at 1100° and 1150°C in the compositions of interest. Clearly, much additional experimentation is required to elucidate the precise mechanism(s) by which the p_{Cl_2}, p_{H_2O}, or p_{ClO} controls the oxidation of Si in H-Cl-O ambients.

Electrical Properties of Oxides

In order to interpret the electrical characteristics observed by Kriegler (10), his data were replotted as a function of p_{Cl_2}. Figure 4 shows mobile ion density as a function of log p_{Cl_2} as a result of varying the initial HCl/O_2 ratio. It can be seen that above a critical

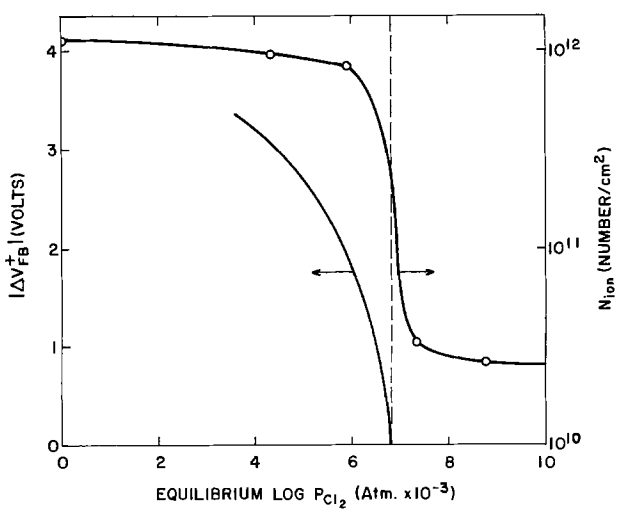

Fig. 4. Number of mobile ions and flatband voltage shift vs. equilibrium chlorine pressure for (100)Si, 1150°C HCl oxidation [after Kriegler (9)]. In the upper curve p_{Cl_2} variations are the result of variations in the initial HCl/O_2 ratio. In the lower curve, p_{Cl_2} variations are due to added H_2O vapor in a 6% HCl/O_2 oxidation ambient. The range of added water vapor to produce the 4-7 $\times$ 10^{-3} range of p_{Cl_2} was 5-25 Torr H_2O.

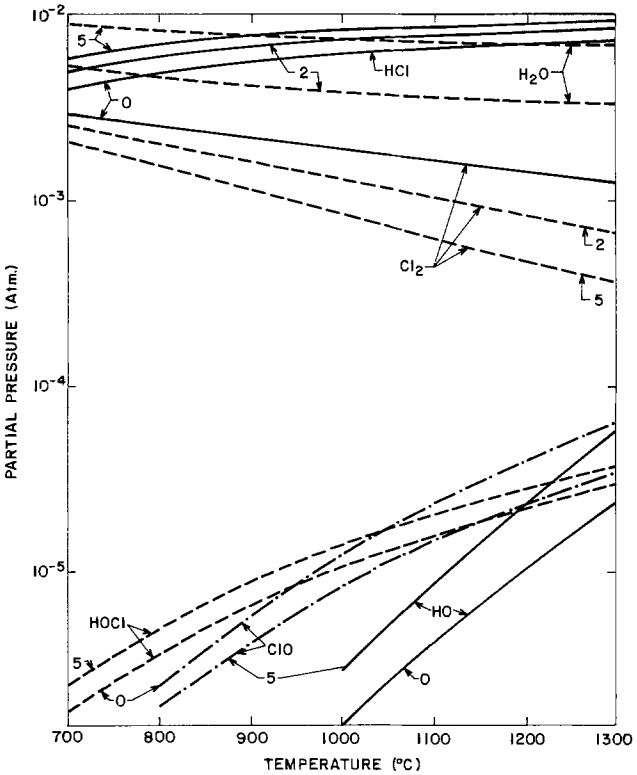

Fig. 5. Simulation of HCl-O ambient with added H_2O vapor. Cl/O atom ratio = 0.005. Total pressure = 1 atm. The numbers indicate the level of added H_2O in Torr.

$p_{Cl_2} \sim 7 \times 10^{-3}$ atm (for this particular total Na concentration), the mobile ion density approaches a lower level of $5 \times 10^{10}/cm^2$. One can also reduce the p_{Cl_2} at a given HCl-O_2 ratio by introducing H_2O. In Fig. 5, the calculated equilibrium partial pressures of gaseous species in HCl-O_2 ambients with added H_2O partial pressures of 2 and 5 Torr are presented. Note that at 1150°C with 5 Torr of added H_2O the p_{Cl_2} drops to ~20% of the corresponding partial pressure in dry O_2. Also, plotted in Fig. 4 is the flatband voltage shift, $|\Delta V^+_{FB}|$, as a function of p_{Cl_2} where p_{Cl_2} was decreased in a 6% HCl-O_2 ambient by adding H_2O to the atmosphere. These data show that $|\Delta V^+_{FB}|$ is also minimized at $p_{Cl_2} \sim 7 \times 10^{-3}$ atm.

From this preliminary analysis, it becomes clear that the partial pressures of the gaseous species in equilibrium with the growing thermal oxide determine the kinetics of growth and also determine the concentration of "passivating" species in the oxide. The suggestion is made that trends in growth constants and electrical characteristics are related to the partial pressure of Cl_2 (or ClO) in the gas phase and not the total chlorine content of the gas phase. Extensive experimentation with oxides grown in systematically varied compositions in the Cl-H-O system over a wide range of temperatures is necessary to unequivocally establish the nature of the gas/solid interaction and the mechanism of passivation.

Ionic Conductivity of Cuprous Chloride Containing Cuprous Sulfide

Tsuneo Matsui[1] and J. Bruce Wagner, Jr.*,[1]

Materials Research Center and Department of Materials Science and Engineering, Northwestern University, Evanston, Illinois 60201

ABSTRACT

The electrical conductivity of undoped cuprous chloride and cuprous chloride containing cuprous sulfide as an impurity in concentrations between 0.20 and 1.0 mole percent (m/o) has been measured as a function of temperature between 60° and 370°C using the a-c method. The results have been analyzed to obtain the values of the energies of formation and migration, mobility of copper interstitial ions, and concentrations of Frenkel defects. The solubility limit of cuprous sulfide in cuprous chloride has also been determined by using electrical conductivity measurements and x-ray diffraction.

Electrical conductivity measurements of cuprous chloride have been measured (1, 2). However, information on the concentration and mobility of ionic defects in cuprous chloride has not yet been reported. The predominant lattice defects in ionic crystals have been conveniently investigated by measuring the ionic conductivity of samples containing known concentrations of aliovalent cations (3-8). However, there is virtually no solid solution between cuprous chloride and divalent metal chlorides [for example $PbCl_2$ (9), $ZnCl_2$ (9), $CaCl_2$ (10), and $MgCl_2$ (10)]. Hsueh and Christy measured the electrical conductivity of CuCl doped with $PbCl_2$, $CaCl_2$, $CdCl_2$, and $ZnCl_2$ but they could not obtain information about the concentration and mobility of lattice defects because of the limited solubility (11).

In this paper the ionic conductivity of pure CuCl and CuCl doped with Cu_2S has been measured. The experimental results are analyzed to obtain the value of the migration energy and mobility of copper interstitial ions, and formation energy and concentrations of Frenkel defects.

Theory

It has been recently found that cuprous chloride is predominantly an ionic conductor above 100°C (2). Several different investigations (1, 11, 12) indicate that the predominant intrinsic defects in copper halides are Frenkel cation pairs (*e.g.*, copper interstitial, $Cu^{\cdot}_i$, and copper vacancy, V'_{Cu}). The ionic conductivity, σ, may be written as

$$\sigma = Nq\,(x_v u_v + x_i u_i) \qquad [1]$$

where N is the number of copper ions per unit volume, u the mobility, q the absolute electronic charge, x the molar fractions of defects, and the subscripts v and i refer to vacancy and interstitial copper ions, respectively. Using the notation of Kröger and Vink (13), the reaction equation and the law of mass action for Frenkel defects may be written as

$$Cu_{Cu} = V'_{Cu} + Cu^{\cdot}_i \qquad [2]$$

and

$$x_v \cdot x_i = K_F \equiv x_0^2 \qquad [3]$$

where x_0 is the molar fraction of the intrinsic defects. By doping Cu_2S in CuCl, copper interstitials are produced as follows

$$Cu_2S = Cu_{Cu} + S'_{Cl} + Cu^{\cdot}_i \qquad [4]$$

The condition of electroneutrality requires that

$$x_i = C + x_v \qquad [5]$$

where C is the molar fraction of cuprous sulfide. Thus Eq. [3] becomes

$$x_i(x_i - C) = x_0^2 \qquad [6]$$

or

$$x_i = \frac{C}{2}\left\{1 + \left(1 + \frac{4x_0^2}{C^2}\right)^{1/2}\right\} \qquad [7]$$

Substituting Eq. [3] and [7] into Eq. [1], we have

$$\sigma = Nq\,x_0\,(u_v + u_i)\left\{\sqrt{\left(\frac{C}{2x_0}\right)^2 + 1} - \left[\frac{C}{2x_0}\cdot\frac{\phi - 1}{\phi + 1}\right]\right\} \qquad [8]$$

where

$$\phi = u_v/u_i \qquad [9]$$

For undoped crystals, the electrical conductivity is written as

$$\sigma_0 \equiv Nq\,x_0\,(u_v + u_i) \qquad [10]$$

Thus, the conductivity isotherm is expressed as

$$\frac{\sigma}{\sigma_0} = \left\{\sqrt{\left(\frac{C}{2x_0}\right)^2 + 1} - \left[\frac{C}{2x_0}\cdot\frac{\phi - 1}{\phi + 1}\right]\right\} \qquad [11]$$

When $C >> x_0$, Eq. [11] may be written as

$$\frac{\sigma}{\sigma_0} = \frac{C}{x_0(1 + \phi)} \qquad [12]$$

For any constant temperature, a plot of σ *vs.* C should be linear for extrinsic conduction. For cuprous halides, $\phi << 1$ (14) and from Eq. [10], the slope can be written as

$$\frac{\sigma_0}{x_0\,(1 + \phi)} \cong \frac{\sigma_0}{x_0} = Nq\,u_i \qquad [13]$$

By using Eq. [13], we can calculate the mobility of copper interstitials and concentrations of intrinsic Frenkel defects for each temperature.

Experimental

Sample preparation.—The samples used in this study were sintered pellets of pure CuCl and CuCl doped with Cu_2S. For pure CuCl, ultrapure anhydrous CuCl powder (99.999% Semi-elements Incorporated) was used without further purification. Doped samples were made by mixing the ultrapure CuCl powder with the appropriate amount of Cu_2S powder (99.0% Alfa Products, Ventron Corporation, with the major impurity being Fe and Ni) from which some of the absorbed water had previously been removed by heating at about 110°C in a Vycor glass tube connected to a vacuum pump.

* Electrochemical Society Active Member.
[1] Present address: Center for Solid State Science, Arizona State University, Tempe, Arizona 85281.
Key words: copper interstitial mobility, Frenkel defects.

The Cu_2S was added in concentrations of 0.20, 0.30, 0.40, 0.70, and 1.0 m/o. These undoped and doped powders were pressed at 75,000 psi in a 0.319 in. diameter steel die. The freshly prepared pellets were sealed in an evacuated Vycor glass and then sintered at 390°C for 72 hr. After the first sintering, the pellets were pulverized, pressed, and again sintered in an evacuated Vycor glass tube at 390°C for 96 hr. The sintering conditions were strictly controlled so as to produce final sintered densities in a narrow range (in this study, 88-89% of the theoretical value of pure CuCl) so that a valid comparison could be made from one pellet to another. After sintering, the size of the pellets was about 8 mm in diameter and about 2 mm long. The pellets were then polished and washed in acetone.

Total conductivity measurements.—To make the conductivity measurements, the sample was sandwiched between reversible copper electrodes which were 99.999% pure copper rod obtained from American Smelting and Refining Company, and electrical contact was ensured by applying a slight pressure by means of springs. The sample was annealed at 370°C for 2 hr prior to measurements to ensure a good interface contact. Copper halides, when equilibrated with copper electrodes, exhibit virtually 100% ionic conduction (1), just as the silver halides equilibrated with silver electrodes (15). The electrical conductivity was mainly measured using a General Radio a-c bridge (1650A) at 1000 Hz. It was also measured in the frequency range 0.80-20 kHz by using audio oscillator Model 202D (Hewlett-Packard Company). For pure CuCl, 0.30, 0.70, and 1.0 m/o samples at 153°, 250°, and 302°C there was no frequency dependence. Conductivity values were calculated from resistance measurements, pellet dimensions, and density. Correction for porosity was made by the following equation (16)

$$\sigma_t = \sigma_m\left(1 + \frac{P}{1 - P^{2/3}}\right) \qquad [14]$$

where σ_t is the conductivity after correction, σ_m the conductivity before correction, and P the porosity.

Electronic conductivity measurements.—Electronic conductivity was measured by using Wagner's polarization cell where a sample was sandwiched between a reversible electrode, copper, and a blocking electrode, graphite (pyrolytic graphite from the Union Carbide Company). Before measurements the polarization cell was annealed at 370°C for 2 hr. Wagner (17) showed that the total electronic current I_T passing through a cell under steady-state conditions is given by

$$I_T = RTA/L\mathbf{F}\{\sigma_{\ominus}^{\circ}[1 - \exp(-EF/RT)] + \sigma_{\oplus}^{\circ}[\exp(+EF/RT) - 1]\} \qquad [15]$$

where A is the cross section area of the interface between graphite and the sample, L the thickness of the samples, $\mathbf{F}$ Faraday's constant, $\sigma_{\ominus}^{\circ}$ electronic conductivity due to excess electrons in the sample coexisting with copper, and $\sigma_{\oplus}^{\circ}$ electronic conductivity due to excess electron holes in the sample coexisting with copper. The other symbols have their usual meanings. If $\sigma_{\oplus}^{\circ} >> \sigma_{\ominus}^{\circ}$, $I_{\oplus}$ becomes

$$I_T \simeq I_{\oplus} = RTA/L\mathbf{F}\{\sigma_{\oplus}^{\circ}[\exp(E\mathbf{F}/RT) - 1]\} \qquad [16]$$

and when $E >> RT/\mathbf{F}$, Eq. [16] can be written as

$$I_{\oplus} = RTA/L\mathbf{F}\{\sigma_{\oplus}^{\circ}\exp(E\mathbf{F}/RT)\} \qquad [17]$$

By using Eq. [17], we can determine the electronic hole conductivity from a plot of the log $I_{\oplus}$ *vs.* E, the applied potential. A Keithley 260 nanovolt source was used to apply various stable d-c potentials, and the current was measured by reading the voltage drop across a series resistor with a Doric Digital microvoltmeter.

Both total electrical conductivity and electronic conductivity measurements were carried out under a slow flow rate of purified argon gas (about 0.2 cm/sec). A Marshall resistance furnace was used in a horizontal position. The temperatures were controlled to ± 1°C by Leeds and Northrup Electromax controller and temperature was measured by Doric Digital voltmeter using Chromel-Alumel thermocouple. The thermocouple was calibrated by using the phase transition temperatures of CuI (14).

X-ray diffraction analysis.—The x-ray diffraction patterns of the pure and doped CuCl were obtained at room temperature by using a Philips diffractometer with CuKα radiation through a Ni filter.

Results

Measurements of the total electrical conductivity of a pure CuCl sample and five doped samples containing different concentrations of Cu_2S have been carried out in the temperature range of 60°-370°C. The results are shown in Fig. 1. The previous data on the total electrical conductivity of polycrystalline (1) and single crystalline (2, 11) CuCl are also shown in Fig. 1. The total electrical conductivity increased with increasing concentration of Cu_2S.

Electronic conductivity measurements were carried out on one sample doped with 0.70 m/o Cu_2S. The results are shown in Fig. 2. The previous data on partial electronic hole conductivity of pure CuCl (single crystal) by Joshi and Wagner (2) are also shown in Fig. 2. Polarization curves are also shown in Fig. 3. Between 0.2 and 0.4V, the theoretical slope based on Wagner's theory (17) fitted the experimental results. But when higher polarization potentials were applied, slopes with less value than the theoretical value were obtained. This anomalous behavior may be attributed

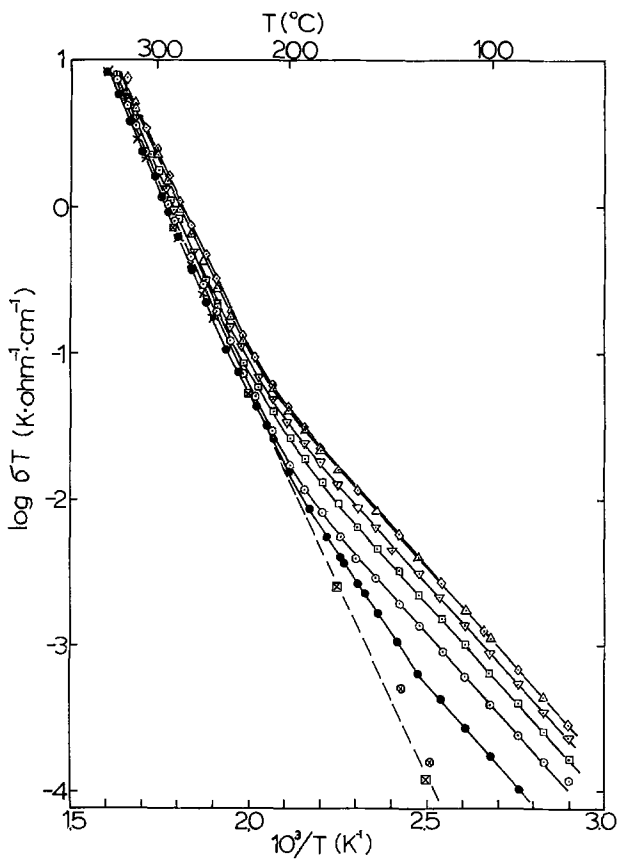

Fig. 1. The temperature dependence of the electrical conductivity of pure CuCl and CuCl-Cu_2S. This study: ●-●-● pure CuCl, ⊙-⊙-⊙ 0.20 m/o Cu_2S, ⊡-⊡-⊡ 0.30 m/o Cu_2S, ▽-▽-▽ 0.40 m/o Cu_2S, △-△-△ 0.70 m/o Cu_2S, ◇-◇-◇ 1.0 m/o Cu_2S. Fig. 4. The electrical conductivity vs. concentration of Cu_2S: - - - - solubility limit (0.53 m/o Cu_2S).

to the high concentration of electron holes at the electrolyte/blocking electrode interface resulting from the high polarization potential. The same phenomena were obtained in the case of PbF_2 by Joshi and Liang (18). From Fig. 1 and 2, it is concluded that the electron hole contribution to the total electronic conductivity can be neglected, *i.e.*, the total conductivity of doped samples is virtually ionic conductivity which is the same as pure CuCl.

In the doping studies, association or precipitation appeared to steepen the slope of log σT *vs.* $1/T$ in the extrinsic region and affect the conductivity values (7, 8). To eliminate this error, the limits of simple extrinsic conduction and solubility limits were determined by applying Eq. [12], which shows that the σ *vs.* concentration isotherm should be linear (Fig. 4). As seen in Fig. 4, the solubility limit of Cu_2S in CuCl was 0.53 ± 0.03 m/o and did not change from 110° to 200°C within experimental error.

We also have checked the solubility limit of Cu_2S in CuCl by means of x-ray diffraction at room temperature. The x-ray diffraction peaks of all doped samples were the same as that of pure CuCl (19), and no other diffraction peaks were observed.

However, the solubility limit could be determined from the concentration dependence of lattice constants based on the electrical conductivity data. The x-ray data are shown in Fig. 5. It can be seen that the solubility limit found by x-ray diffraction at room temperature is consistent with electrical conductivity results. The solubility limit at high temperatures could not be determined since even by quenching from 200°C

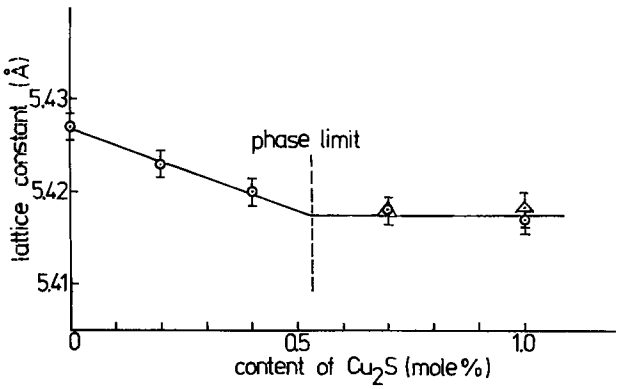

Fig. 5. Lattice constant vs. concentration of Cu_2S at 22°C: ⊙ annealed sample, △ sample quenched from 200°C.

to ice water the lattice constant was almost the same as that at room temperature, which indicated the difficulty of quenching.

Discussion

The increased conductivity observed when CuCl was doped with Cu_2S is due to an increase in ionic conductivity since the electronic hole conductivity is far below (five or six orders lower) the total electrical conductivity, and the ionic conductivity of CuCl increased monotonically with increasing dopant concentration of Cu_2S. These indicate that the predominant defects in the extrinsic region below 230°C are copper ion interstitials according to Eq. [4]. Above 230°C the steeper slope, shown in Fig. 1, represents the change from the extrinsic region to the intrinsic region where the Frenkel defects (copper ion interstitials and copper ion vacancies) are thermally generated in greater concentration than the defects introduced by the Cu_2S ($x_0 >> C$).

At higher temperatures, our results of the electrical conductivity on polycrystalline CuCl are in good agreement with the previous data on polycrystalline (1) and single crystalline (2, 11) CuCl, but in the extrinsic region below 230°C our conductivity values are higher than the single crystal data (2, 11, 20). To check the effect of short-circuit paths such as grain boundaries on the conductivity values, two samples with different densities (82 and 88%) each containing the same dopant concentration (0.30 m/o Cu_2S) were studied. The conductivity values of these two samples and their temperature dependence were in good agreement with one another within experimental error (± 3%) after correcting for porosity using Eq. [14]. Generally, in the pure single crystals of alkali halides and silver halides a knee in the conductivity curve is exhibited at low temperature, below which the conductivity is affected by very small amounts of impurities (extrinsic region) which are accidentally present (6-8, 21-23). The electrical conductivity of pure single crystal CuI which exhibits the same crystal structure as CuCl at low temperature has been also studied by Jow and Wagner (24). According to their data, curvature of an Arrhenius plot of the electrical conductivity of CuI was obtained for all temperatures below 369°C. The difference between the conductivity data for the single and polycrystalline samples may be inferred to be due to the small amount of impurities present in the polycrystalline samples.

As seen in Fig. 1, activation energies of pure CuCl ($90° \leq T \leq 130°C$) and doped samples ($60° \leq T \leq 200°C$) in the extrinsic region did not change (12.5 ± 0.5 kcal/mole) with increasing the dopant concentrations. Thus, the basic assumption which is made in doping studies that the mobility does not change with doping level holds in this case.

By using Fig. 4 the mobility and migration energy of copper interstitial ions, and the concentration and formation energy of Frenkel defects were then calculated.

Table I. Mobility of copper interstitial ions and concentration of Frenkel defects at various temperatures for CuCl

Temperature (°C)	u_i (cm²/Vsec)	x_0 (mole fraction)
110	$(2.34 \pm 0.37) \times 10^{-7}$	$(5.83 \pm 0.93) \times 10^{-5}$
120	$(3.52 \pm 0.67) \times 10^{-7}$	$(8.96 \pm 1.70) \times 10^{-5}$
130	$(4.98 \pm 0.64) \times 10^{-7}$	$(1.34 \pm 0.17) \times 10^{-4}$
150	$(9.73 \pm 1.30) \times 10^{-7}$	$(2.88 \pm 0.38) \times 10^{-4}$
180	$(2.46 \pm 0.18) \times 10^{-6}$	$(7.63 \pm 0.58) \times 10^{-4}$
200	$(3.85 \pm 1.84) \times 10^{-6}$	$(1.45 \pm 0.69) \times 10^{-3}$

The data between 0.20 and 0.40 m/o and between 110° and 200°C which exhibited linear isotherms were used. The calculated data of the mobility of copper interstitial ions and concentrations of Frenkel defects are summarized in Table I and Fig. 6. The migration energy of copper interstitials was 12.1 ± 0.9 kcal/mole, and the formation energy of Frenkel defects was 5.6 ± 0.2 kcal/mole.

Another important feature of the extrinsic isotherms in Fig. 4 was that they were all extrapolated to the same finite concentration of Cu_2S. This is evidence for a common level of impurity binding a fixed amount, 0.01 m/o, of Cu_2S. This may account for the difference between the electrical conductivity of polycrystalline undoped CuCl in this study and the data obtained previously on single crystalline CuCl (2). A similar effect has been also observed for NaCl doped with $MgCl_2$ (7, 25) and NaCl doped with $CdCl_2$ (8, 26).

Summary

Conductivity measurements have been performed on undoped CuCl and CuCl doped with different concentrations of Cu_2S. The mobility and migration energy (E_m) of copper interstitial ions, and concentrations and formation energy (E_f) of Frenkel defects were calculated: $E_m = 12.1 \pm 0.9$ kcal/mole and $E_f = 25.6 \pm 0.2$ kcal/mole.

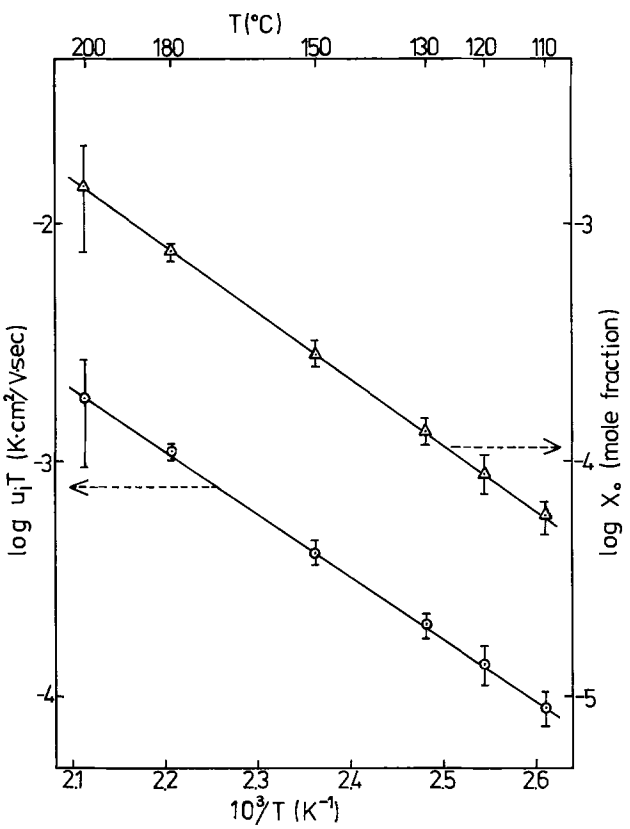

Fig. 6. The temperature dependence of the mobility for copper interstitial ions and of the concentration of Frenkel defects in CuCl: ⊙ mobility (u_i), △ concentration (x_0).

The solubility limit of Cu_2S in CuCl was found to be 0.53 ± 0.03 m/o from room temperature to 200°C by using x-ray and electrical conductivity measurements.

Polycrystalline Aluminum Oxide Anodization on Silicon

Kiyoto Iida

Nippon Electric Company, Limited, I.C. Division, Nakaharaku, Kawasaki, Japan

ABSTRACT

Anodization of aluminum oxide, deposited by $AlCl_3$ hydrolysis on silicon, is investigated in various electrolytes and a new selective etching technique is studied. Polycrystalline aluminum oxide is converted into amorphous film by anodization. The anodized film is soluble in various acidic solutions. At a specific anodizing stage, anodic current shows an abrupt change under a fixed anodic voltage. Characteristics of current density *vs.* anodizing time are successfully explained by the solubility of the anodized aluminum oxide in the electrolyte and by the formation of new anodic SiO_2. Anodization effects on electrical properties of MA(O)S structures with the anodized film are investigated.

Recently, there has been an increasing interest in the use of aluminum oxide as gate-insulator and passivating dielectric for MIS (metal-insulator-silicon) devices. The charge storage phenomenon of this film is especially interesting, regarding its memory application (1, 2). For forming this film, chemical vapor deposition technique is ordinarily used, because a uniform film of excellent quality can be obtained at relatively low temperatures. The electrical properties of MA(O)S (metal-aluminum oxide-(silicon dioxide)-silicon) structures with CVD aluminum oxide are sensitive to the thermal history, ambient gases, and various other processing factors of aluminum oxide formation. Among these factors, oxygen heat-treatment has an especially large influence on $Si\text{-}Al_2O_3$ structure, for it forms a new silicon dioxide underneath the original aluminum oxide (3, 4).

In the anodization of preexisting dielectric film on silicon substrate, an interesting feature is that a change in the chemical composition of the film depends on the mobile species. In the case of amorphous silicon nitride films on a silicon substrate, it has been shown that conversion of the nitride film to anodic SiO_2 occurs by oxygen ions replacing nitrogen. Here, oxygen ion migration through amorphous silicon nitride would change its composition (5). Schmidt and Wonsidler (5) reported that in the anodization of polycrystalline α-alumina films on silicon substrate in aqueous borate solution, growth of new oxide occurred at the oxide-silicon interface, increasing the total film thickness. They reported that, in the preexisting aluminum oxide anodization, silicon ion migration changes the chemical composition of the film, whereas oxygen ion migration does not. Kamoshida and Mayer also studied aluminum oxide film anodization on a silicon substrate and observed the formation of anodic SiO_2 using MeV $^4He^+$ ion backscattering spectra (6).

In the present work, it was found that, in the anodization of preexisting aluminum oxide on a silicon substrate, polycrystalline aluminum oxide is converted into amorphous aluminum oxide and the anodized film becomes soluble in various acidic solutions. Anodization effects on electrical properties of MA(O)S structures with the anodized aluminum oxide film

Key words: anodization, aluminum oxide, physicochemical properties, conversion, selective etching technique.

were studied. Furthermore, the anodization process is applied for opening windows in Si-Al_2O_3-SiO_2 structures.

Experimental

Aluminum oxide films were deposited by the reaction of $AlCl_3$ with CO_2 and H_2 onto 3 ~ 4 Ω-cm, p-type silicon substrates. The temperature of the silicon substrate during deposition was kept at 850°C to give a deposition rate of 100 Å/min. Thickness of the film was extended from 500 to 2500Å, which was measured by ellipsometry. The film has polycrystalline form and was hardly soluble in acidic solutions, except by hot H_3PO_4. Detailed descriptions of film preparation and physicochemical and electrical properties of the film appear in previous papers (3, 4, 7). After deposition of aluminum oxide film onto silicon substrates, the film was covered with chemically vapor deposited silicon dioxide. Windows were then opened in the silicon dioxide to expose a part of the aluminum oxide surface. The back side of the wafer was also covered with silicon dioxide. The layers of silicon dioxide served as an electrically insulating barrier to anodization.

Both ammonium borate dissolved in ethylene glycol and 2 volume percent (v/o) sulfuric acid were used for electrolytes. Anodizations were performed at various anodic voltages in an open vessel at room temperature. Anodic current was measured relative to a platinum cathode.

Thicknesses of converted film and remaining aluminum oxide film after anodization were measured by taking advantage of the great difference in solubility of the film in H_2SO_4. Film thickness was measured by ellipsometer with 5461Å of Hg lamp. Infrared absorption spectrum was recorded on a grating spectrophotometer, and a 100 Ω-cm silicon substrate was used as a spectrum reference. For evaluation of anodization effects on electrical properties of the anodized film, MA(O)S devices were constructed by evaporation of aluminum electrodes onto the film. Capacitance-voltage (*C-V*) measurements were made at 1 MHz at 25°C and automatically plotted on an X-Y recorder.

Results

Typical anodic current *vs.* electric field, which is applied to polycrystalline CVD aluminum oxide film on silicon, is shown in Fig. 1, where ammonium borate in ethylene glycol is used as an electrolyte. Anodic voltage is continuously applied to samples with a constant sweep rate of 3 V/sec. In the anodization of 730Å aluminum oxide, anodic current begins to flow through the film at an electric field of 1.3×10^7 V/cm. In an electric field above 1.7×10^7 V/cm, anodic current increases exponentially with electric field, due to an anodic oxidation of silicon substrate. In the anodization of 1280 and 1850Å aluminum oxides, current density *vs.* electric field continues to show deviation from an exponential curve until higher electric fields are reached.

Figure 2 shows that the electric field (*Ei*), at which anodic current begins to flow through aluminum oxide, depends on aluminum oxide film thickness. These values correspond to dielectric breakdown field strength in the film. When an electric field above *Ei* is applied to a sample, the aluminum oxide surface begins to react with an electrolyte. Interference color of the top surface of the anodized aluminum oxide changes with anodizing time, indicating an increase in total film thickness.

Physicochemical properties of the anodized aluminum oxide are entirely different from those of the original oxide. Figure 3 shows the electron diffraction patterns of the original CVD aluminum oxide (Fig. 3a) and the anodized aluminum oxide in ammonium borate in ethylene glycol (Fig. 3b). In the

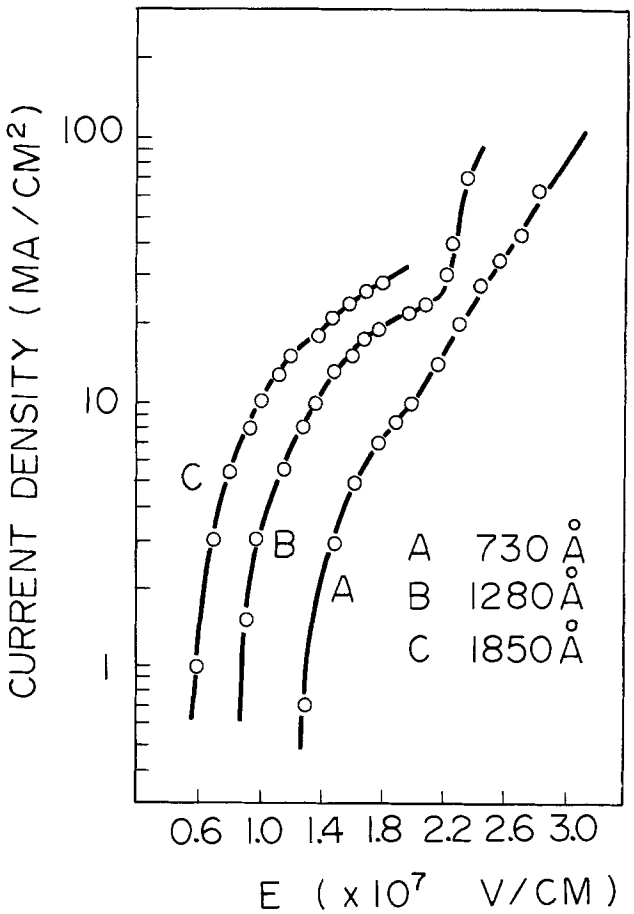

Fig. 1. Current and electric field relation for polycrystalline Al_2O_3 anodization in ammonium borate in ethylene glycol electrolyte.

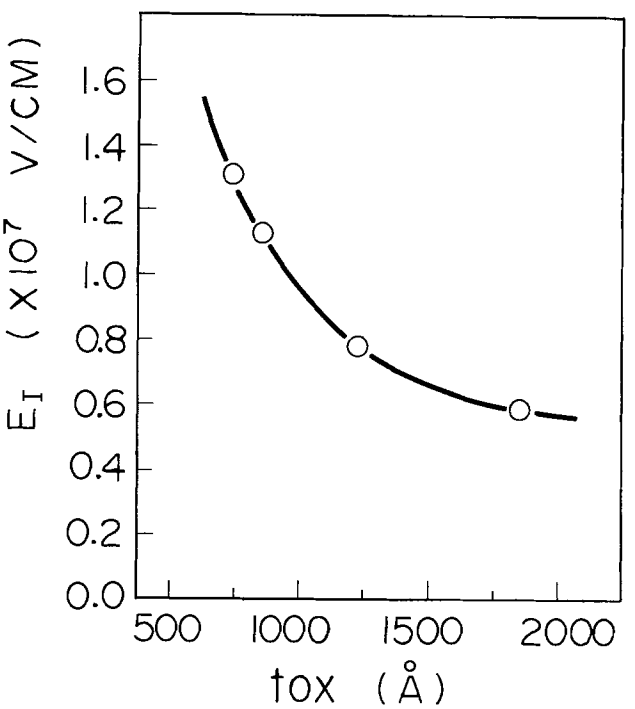

Fig. 2. Relationship between *Ei* and film thickness. *Ei* is the electric field at which anodic current begins to flow through the film.

case of the original aluminum oxide, Debye rings are observed, typical of polycrystalline material, while the anodized film gives amorphous signature.

Table I summarizes physicochemical properties of the anodized aluminum oxide and the original poly-

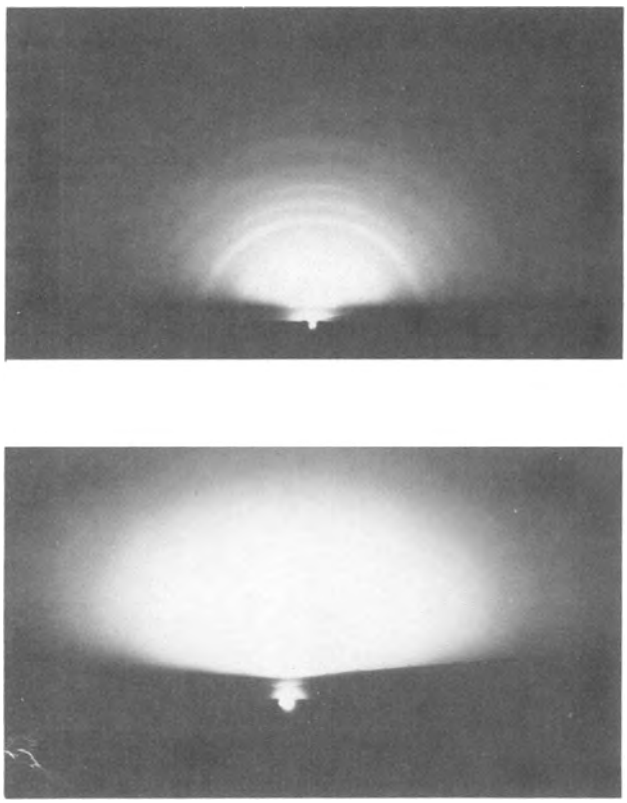

Fig. 3. Al_2O_3 electron diffraction patterns: (a, top) original CVD Al_2O_3, (b, bottom) anodized Al_2O_3 in ammonium borate in ethylene glycol electrolyte.

crystalline CVD aluminum oxide for comparison purposes. The anodized film is easily soluble in various acidic solutions, and is partly soluble even in boiling water. The anodized aluminum oxide, however, is hardly soluble in organic solutions, such as acetone or trichloroethylene or the electrolyte of ammonium borate in ethylene glycol. The anodized aluminum oxide is very susceptible to scratching or to mechanical stresses. Anodized aluminum oxide density and refractive index are 2.1 ± 0.2 and 1.45 ± 0.05, respectively. These values are smaller than those of the original oxide.

Figure 4 shows changes in aluminum oxide film thickness with anodizing time, where a sample with 1100Å thick CVD aluminum oxide is anodized at a fixed voltage of 180V ($E = 1.65 \times 10^7$ V/cm) in ammonium borate in ethylene glycol electrolyte. t_{ANOD} indicates the total film thickness after anodization. t_{ANOD} increases with increasing anodizing time. For investigating the amorphous film thickness (t_{AMOR}) converted by anodization, the anodized aluminum oxide was dipped into boiling H_2SO_4 solution at 100°C. Then, the remaining aluminum oxide thickness (t_{REM}) was measured. t_{AMOR} indicates the film thickness which is etched out by boiling H_2SO_4 solution

Table I

	Anodized Al_2O_3	C.V.D Al_2O_3
Etchant Applicability		
Buffered HF	Yes	No
H_3PO_4	Yes	50-70Å/MIN(160°C)
H_2SO_4	Yes	No
HNO_3	Yes	No

Refractive Index	1.45±0.05	1.76±0.02

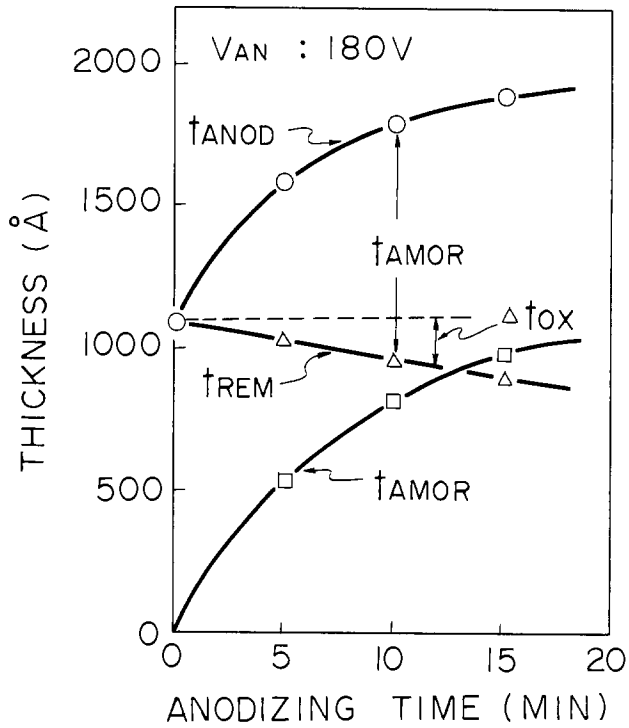

Fig. 4. Total anodized Al_2O_3 thickness (t_{ANOD}) and the amorphous film thickness (t_{AMOR}) as a function of time during Al_2O_3 anodization on Si.

$$t_{AMOR} = t_{ANOD} - t_{REM}$$

t_{AMOR} increases with increasing anodizing time, approximately in proportion to the square root of time. Polycrystalline CVD aluminum oxide is converted into amorphous film from the top surface of the film by anodization.

Figure 5 shows t_{ANOD} and t_{AMOR} *vs.* initial polycrystalline CVD aluminum oxide thickness or *vs.*

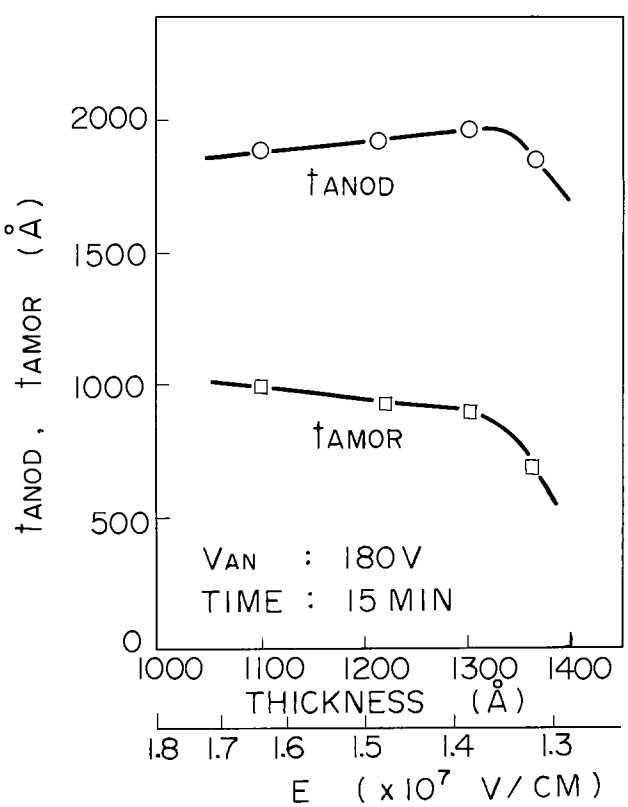

Fig. 5. t_{ANOD} and t_{AMOR} *vs.* initial polycrystalline Al_2O_3 thickness, or *vs.* electric field.

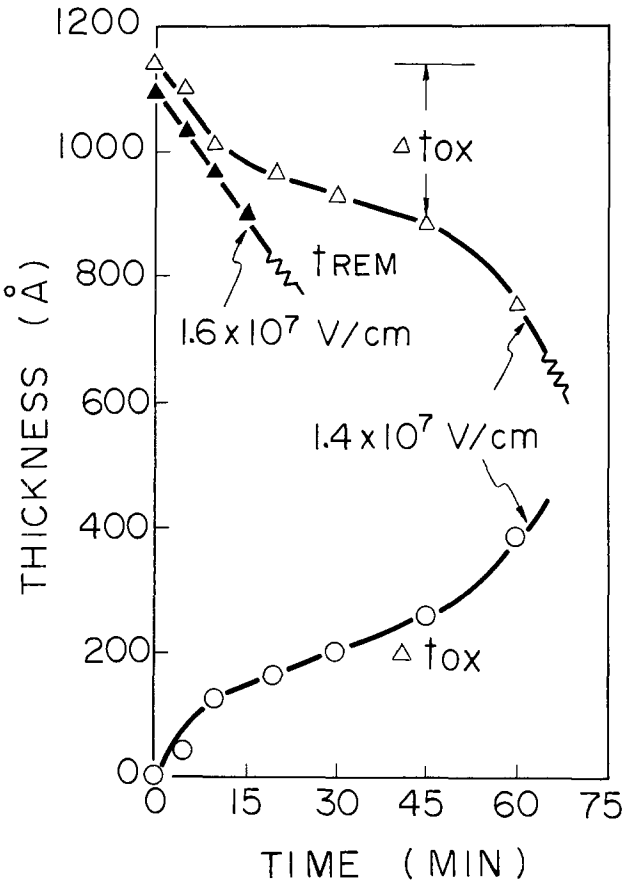

Fig. 6. t_{REM} and Δt_{ox} vs. time

electric field, where anodization is carried out at 180V for 15 min. Converted amorphous film thickness (t_{AMOR}) decreases with decreasing electric field. t_{ANOD}, however, gradually increases with decreasing electric field until lower electric fields are reached. At an electric field lower than 1.3×10^7 V/cm, t_{ANOD} as well as t_{AMOR} abruptly decreases with decreasing electric field.

Figure 6 shows t_{REM} and Δt_{ox} *vs.* anodizing time, where Δt_{ox} indicates that the thickness difference between initial polycrystalline CVD aluminum oxide (t_{ox}) and remaining film dipped into boiling H_2SO_4 solution (t_{REM})

$$\Delta t_{ox} = t_{ox} - t_{REM}$$

Δt_{ox} increases with anodizing time, approximately in proportion to the square root of time for a relatively short duration. However, at a longer anodization Δt_{ox} abruptly increases with anodizing time, and destructive breakdown of dielectric film is observed. The higher the electric field, the earlier the destructive breakdown occurs. In this case, destructive breakdown means lack of surface uniformity of the anodized film.

Figure 7 shows dependence of electric field on Δt_{ox}, where 1220Å thick polycrystalline CVD aluminum oxide is anodized at various voltages for 30 min. At an electric field lower than 1.1×10^7 V/cm, Δt_{ox} is negligibly small. Destructive breakdown of the anodized film occurs at an electric field higher than 1.7×10^7 V/cm.

Typical current density *vs.* anodizing times under various fixed anodic voltages for a 1280Å CVD aluminum oxide film are shown in Fig. 8, where ammonium borate in ethylene glycol is used as an electrolyte. In anodization at 190V ($E = 1.48 \times 10^7$ V/cm), the anodic current gradually decreases with increasing anodizing time. Here, polycrystalline CVD aluminum oxide reaction with the electrolyte gradually proceeds with anodizing time. Microscope examination

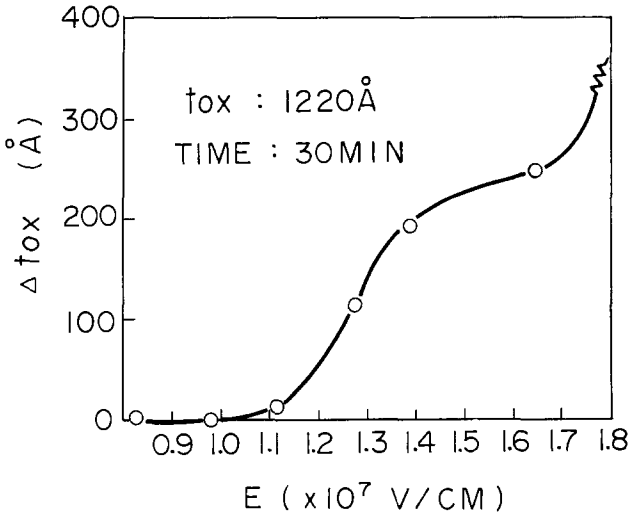

Fig. 7. Electric field dependence on Δt_{ox}

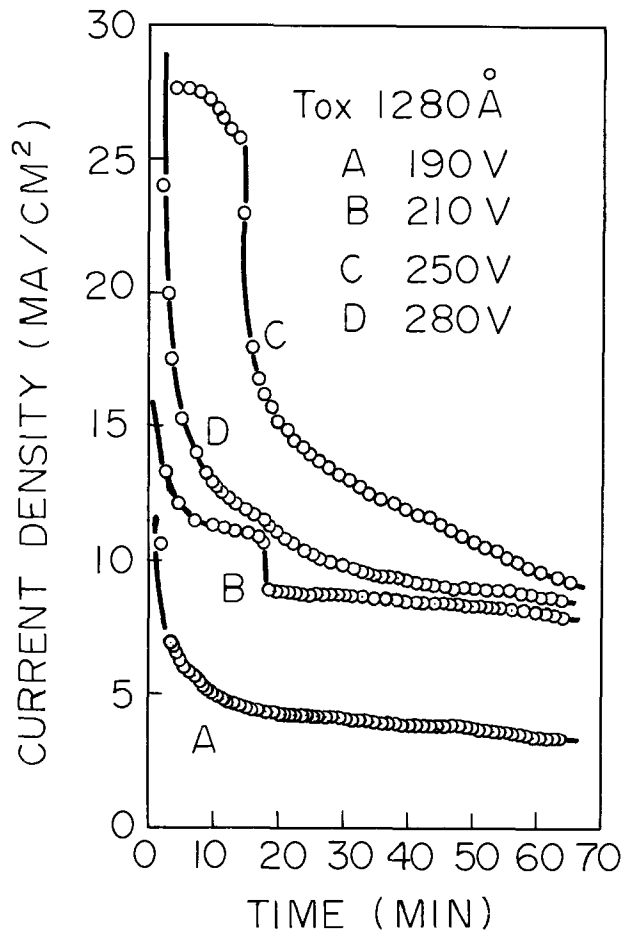

Fig. 8. Current density *vs.* time under various fixed anodic voltages, using ammonium borate in ethylene glycol electrolyte.

showed surface uniformity. In an anodization at 210V ($E = 1.6 \times 10^7$ V/cm), an abrupt anodic current change is observed immediately after 18 min of anodizing time. After the abrupt change of anodic current, it gradually decreases with anodizing time again. The higher the anodic voltage, the earlier the abrupt anodic current change appears. In an anodization at 250V (1.95×10^7 V/cm), it appears in 15 min of anodizing time. After the abrupt change, the surface of the film becomes nonuniform and formation of anodic silicon dioxide is observed. In an anodization at 280V ($E = 2.19 \times 10^7$ V/cm) anodic current decreases abruptly in the beginning stage. No distin-

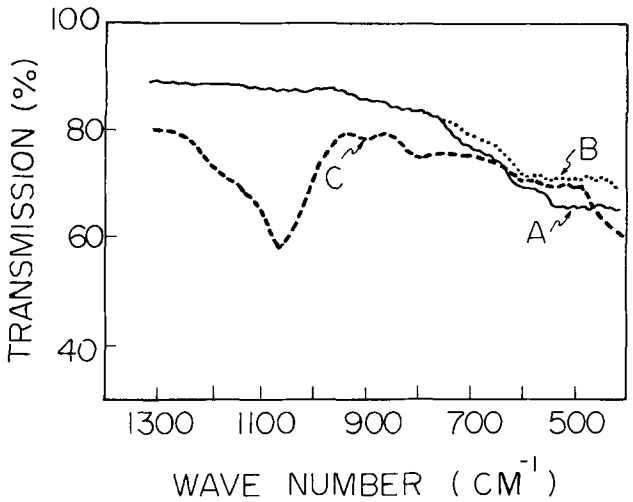

Fig. 9. Infrared absorption spectra of the anodized aluminum oxide: A, as-grown polycrystalline Al_2O_3; B, before current density vs. time transition; C, after current density vs. time transition.

guishable critical abrupt change is observed because the reaction at the surface of the film is violent.

Figure 9 shows the infrared absorption spectra of the anodized samples, compared with an as-grown one, before and after the abrupt change in anodic current. The spectrum of the anodized sample before the abrupt current change (sample B) is similar to that of an as-grown one (sample A), except for smaller absorption below 700 cm^{-1} in wave number. After the abrupt anodic current change, an absorption of 1070 cm^{-1} in wave number is observed (sample C), which is related to Si-O stretching band (8). Formation of anodic silicon dioxide follows the complete conversion of a polycrystalline aluminum oxide to an amorphous aluminum oxide since no Si-O stretching band is present in the spectrum at an incomplete conversion stage (sample B).

When polycrystalline aluminum oxide anodization is carried out at relatively low voltages (*e.g.*, below 2.0×10^7 V/cm in electric field for 1300Å aluminum oxide), the film surface converts to the anodized film uniformly. When anodized at higher anodic voltages and/or longer anodizing time, the aluminum oxide surface becomes nonuniform. Figure 10 shows photographs of an aluminum oxide surface anodized at a high voltage. Small holes are first observed in the film (Fig. 10a). Anodic silicon dioxide is formed at the holes by continued anodic oxidation of the silicon substrate. After longer anodization, the hole size increases and the region covered with anodic silicon dioxide expands to the entire area of the wafer (Fig. 10b).

Figure 11 shows typical current density *vs.* anodizing time under various fixed anodic voltages using 2% sulfuric acid as an electrolyte. Initial aluminum oxide thickness is 1280Å. In contrast with that of ammonium borate in ethylene glycol electrolyte, a current peak is observed at a specific anodizing time. The higher an applied anodic voltage, the earlier a peak appears. In an anodization in 2% sulfuric acid, the anodized aluminum oxide is etched out by the electrolyte during anodization and a decrease in the aluminum oxide thickness is observed. Later, as the silicon substrate is anodically oxidized, the total thickness of the oxide film increases with anodizing time. The polycrystalline aluminum oxide anodizing rate is faster and occurs at lower voltage in 2% sulfuric acid electrolyte than in ammonium borate in ethylene glycol electrolyte.

The anodization process can be used to open windows in polycrystalline aluminum oxide in Si-Al_2O_3-SiO_2 structures. Figure 12 shows sequential steps for opening windows in polycrystalline aluminum oxide.

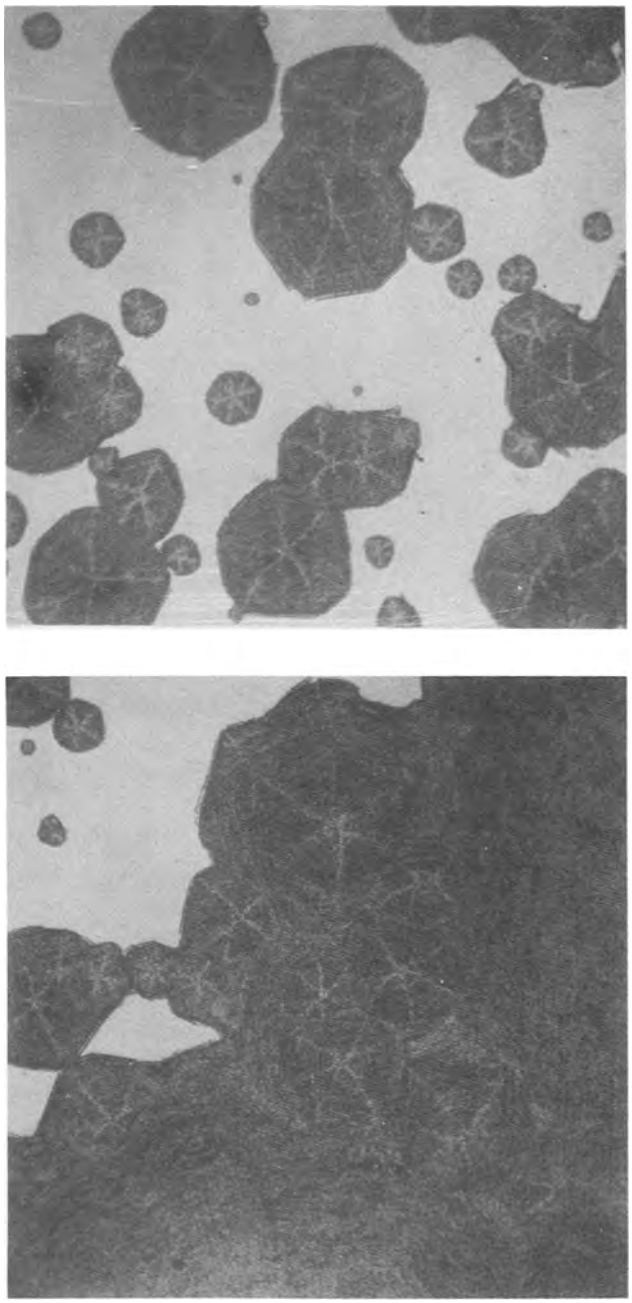

Fig. 10. Photographs of the surface of Al_2O_3 anodized at high voltage.

The technique principle involves anodized aluminum oxide solubility in various acidic solutions, as shown in Table I. During anodization, the silicon dioxide and/or photoresist serves as a mask confining anodization to the open window areas of the silicon dioxide.

Anodization effects on electrical properties of MAS structures were studied using *C-V* characteristics. Figure 13 compares MAS diode *C-V* characteristics with 1100Å thick as-grown aluminum oxide with diodes using oxide films anodized at 50 and 100V in ammonium borate in ethylene glycol electrolyte. Anodization causes electrical instability at the aluminum oxide-silicon interface, and broadening and negative shift of the *C-V* curve are observed. The capacitance decrease in accumulation region for a sample anodized at 100V indicates that the aluminum oxide thickness (t_{ANOD}) increases due to anodization, as shown in Fig. 4.

Figure 14 shows V_{FB} shift of *C-V* curve *vs.* anodic voltage in MAS diodes. Negative V_{FB} shift depends

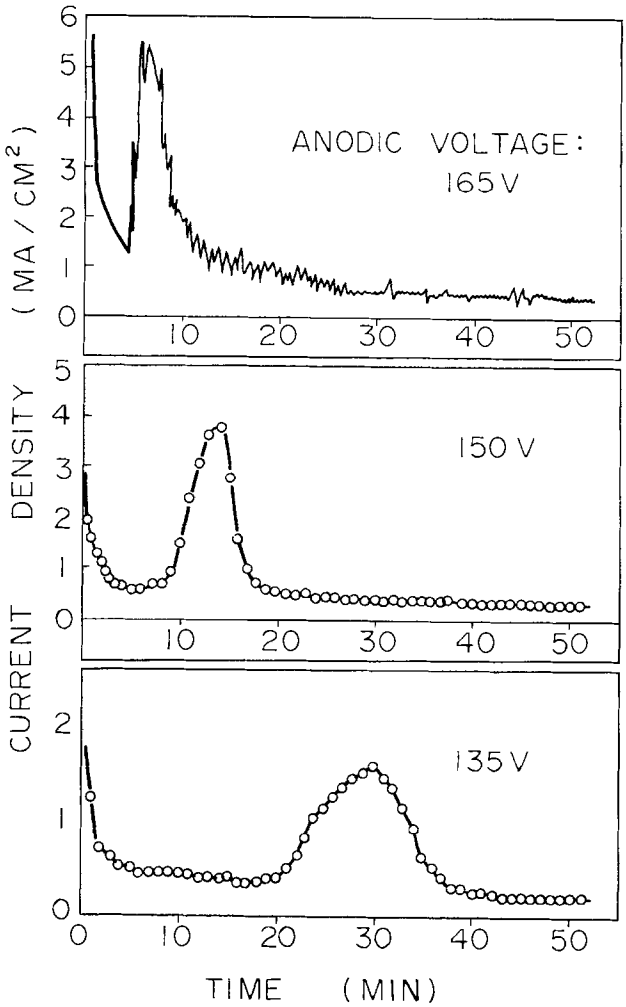

Fig. 11. Current density vs. time under various fixed anodic voltages using 2% sulfuric acid electrolyte.

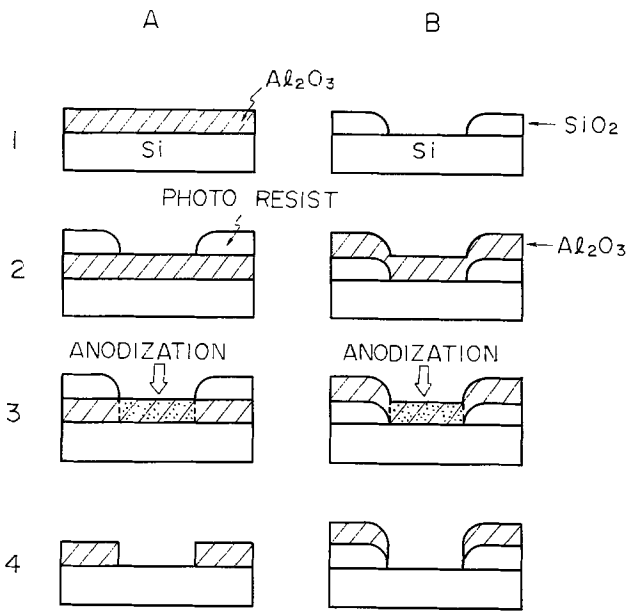

Fig. 12. Sequential steps for opening windows in polycrystalline Al_2O_3 by anodization.

on the anodic voltage magnitude. No V_{FB} shift in positive direction is observed.

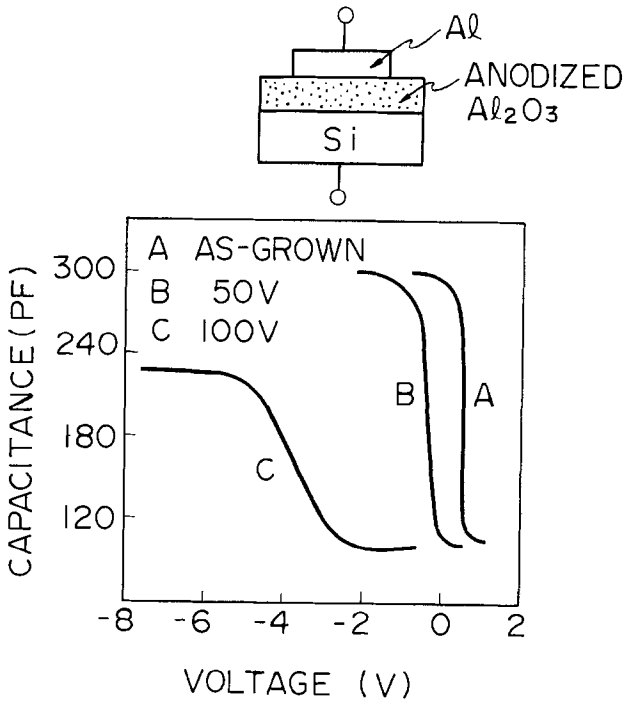

Fig. 13. MAS diodes C-V curves with anodized Al_2O_3

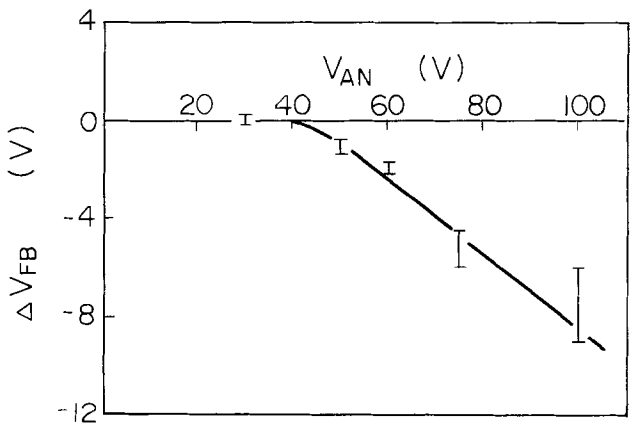

Fig. 14. V_{FB} vs. anodic voltage in MAS diodes with anodized Al_2O_3

Figure 15 shows an anodization etching effect on electrical properties in MAS diodes. The V_{FB} shift characteristics with applied voltage on gate electrode in MAS diodes were similar to those in previous papers (7, 9). The sample etched by anodization process, shown in Fig. 12, initially has a negative V_{FB}, in contrast to that in the sample etched by hot phosphoric acid solution.

Electrical instabilities generated by anodization shown in Fig. 13-15 are completely recovered by additional heat-treatment. Figure 16 shows an effect of heat-treatment on C-V characteristics in a MAS diode etched by anodization process. C-V characteristic in a sample heat-treated at 400°C in nitrogen ambient after anodization is almost the same as that in the sample etched by hot phosphoric acid solution. The V_{FB} shift characteristics in the heat-treated sample were also the same as that in the sample etched.

Discussion

Polycrystalline CVD aluminum oxide physicochemical properties are changed by anodization from the top surface of the film. As shown in Fig. 3b the film anodized gives an amorphous signature. The film is soluble in various acidic solutions, as shown in Table I. Although anodization changed the properties of aluminum oxide, no special infrared absorption band,

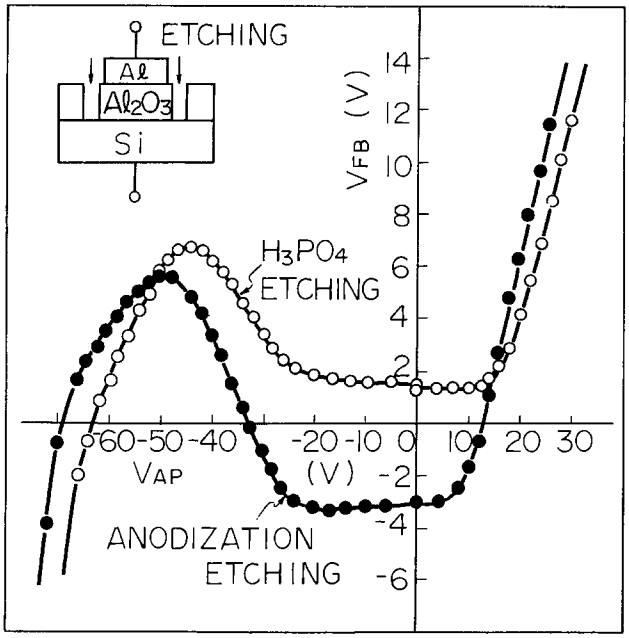

Fig. 15. C-V shift characteristics of MAS diodes etched by hot phosphoric acid and by anodization technique.

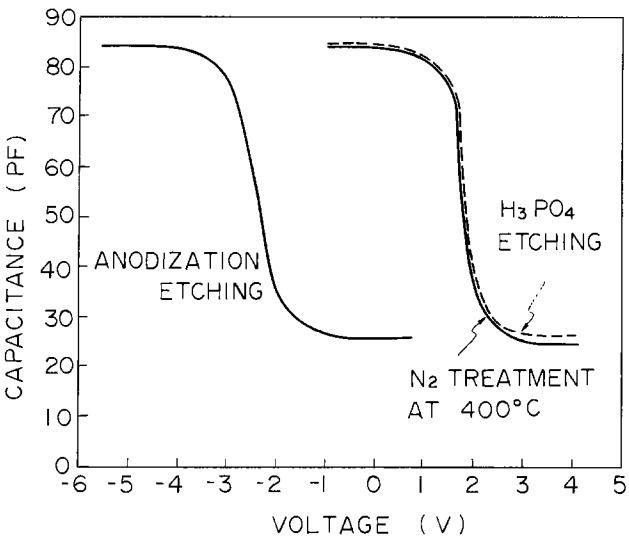

Fig. 16. Heat-treatment effect on C-V curve in a MAS diode etched by anodization technique. Heat-treatment was performed in nitrogen ambient at 400°C for 30 min.

except for aluminum oxide, could be detected, as is shown in spectrum B in Fig. 9. Anodized aluminum oxide physicochemical properties are relatively similar to those of a film deposited at low temperatures (4). Judging from the properties of the anodized film, it is assumed that the bond between Al and O atoms is weaker than that of the original film.

Anodized aluminum oxide thickness (t_{ANOD}) increases with anodizing time, in proportion to square root of time, as shown in Fig. 4. This depends on the structural conversion from the top surface of the anodized film, resulting in t_{AMOR} increase with anodizing time. t_{ANOD} may be determined by the conversion rate (Δt_{AMOR}/time) and the solubility of the anodized film by ammonium borate in ethylene glycol electrolyte during anodization. The anodized aluminum oxide is not soluble in the electrolyte at room temperature. However, it is slightly soluble at high temperature. In the t_{ANOD} dependence on electric field shown in Fig. 5, the higher the electric field, the smaller the observed t_{ANOD}, until lower electric fields are reached. This dependence may be caused by anodized film solubility at high electric field because of the reaction heat.

At later stages of anodization and/or under high voltage application to a sample, aluminum oxide is broken down in dielectric. Silicon substrate is anodized forming anodic silicon dioxide in locations of holes in the aluminum oxide and/or underneath the anodized aluminum oxide. Formation of anodic silicon dioxide is detected by the infrared absorption spectrum shown in Fig. 9 (sample C), and by viewing through an optical microscope shown in Fig. 10.

Characteristics of current density *vs.* electric field (Fig. 1) and of current density *vs.* anodizing time (Fig. 8 and 11) can be successfully explained by the structural conversion of polycrystalline CVD aluminum oxide to amorphous film due to anodization and by the solubility of the anodized film in the electrolyte. In the case of electrolytes, which have no solvent action with the anodized aluminum oxide, such as ammonium borate in ethylene glycol, anodized aluminum oxide thickness increases with increasing anodizing time, as shown in Fig. 4. The rapid anodic silicon dioxide formation at later anodization stages leads to an abrupt decrease in current density, as shown in Fig. 8. Exponential current density increase in the higher electric field region shown in Fig. 1 (sample A) is due to an anodic silicon substrate oxidation. The deviation from an exponential curve shown for 1280 and 1850Å aluminum oxide shown in Fig. 1 results from the fact that the thicker films have not yet broken down to allow silicon dioxide formation. With an anodized aluminum oxide-dissolving electrolyte such as sulfuric acid, a peak of current density is observed as shown in Fig. 11. Decrease in aluminum oxide thickness during anodization leads to an increasing current density. The abrupt current density decrease from the peak indicates the rapid anodic silicon dioxide formation. Schmidt (5) and Kamoshida (6) did not observe the conversion of aluminum oxide to amorphous film in their examinations. This lack may be caused by the use of anodized aluminum oxide-dissolving electrolyte in the anodization.

The electrical instabilities caused by anodization, shown in Fig. 13 and 14, are similar to those of negative bias application to MA(O)S structures. In MA(O)S structures with aluminum electrodes, C-V curve broadening or distortion, as well as positive and following negative V_{FB} shifts, are often observed after negative bias application to the electrode (9, 10). When evaporated Au is used as a MA(O)S structure electrode, electron injection from the electrode and positive V_{FB} shift is rarely observed (11, 12). In anodization of aluminum oxide on silicon, the electrolyte takes the role of an electrode and a positive bias is applied to the substrate. A negative bias, therefore, is applied to the electrode of the electrolyte. Electrical instabilities caused by anodization may be caused by hole injection from the silicon substrate into the film. In anodization of aluminum oxide on silicon, ionic current from the electrolyte to the silicon substrate through the film becomes dominant. Consequently, lack of shift of V_{FB} in the positive direction is a reasonable result, as no electron injection from the electrode to the film occurs during the anodization. These instabilities generated by anodization are completely recovered by additional heat-treatment, as shown in Fig. 16.

Anodization process can be used to open windows in polycrystalline aluminum oxide in Si-Al_2O_3-SiO_2 structures. The technique principle involves anodized aluminum oxide solubility in various acidic solutions, as shown in Table I. During anodization, the silicon dioxide or photoresist serves as a mask, confining anodization to the open window areas of the silicon

dioxide. In selective etching of polycrystalline aluminum oxide less than 500Å thick, conventional photoresist can be used for the dielectric anodization mask.

Conclusions

Anodization of aluminum oxide, deposited by aluminum trichloride hydrolysis on silicon, has been investigated in various electrolytes. As an application of this result, a new polycrystalline aluminum oxide selective etching technique has been studied. A series of experiments on aluminum oxide anodization on silicon has shown that the film changes its physicochemical properties from the top surface of the film, and the anodized film becomes easily soluble in various acidic solutions. Anodized film thickness increases with anodizing time, approximately in proportion to the square root of the time involved. At later anodization stages, the silicon substrate is anodized as well and anodic SiO_2 is formed. Oxidizing species penetrate through the anodized aluminum oxide to form anodic SiO_2 but do not penetrate through the original film, directly. The anodized aluminum oxide has an amorphous structure and is very susceptible to scratches or mechanical stresses, as well as to chemical solvents. In the current density *vs.* anodizing time characteristics in ammonium borate in ethylene glycol electrolyte, an abrupt change in anodic current is observed. This is in contrast with the characteristic in the 2% sulfuric acid electrolyte, where an anodic current peak appears. These current density *vs.* anodizing time characteristics can be successfully explained by the fact that the anodized film is not soluble in the former electrolyte during anodization while it is soluble with the latter case. In the study of MA(O)S structure electrical properties with as-anodized aluminum oxide, broadening and negative C-V curve shifts were observed. These instabilities, however, are completely recovered by additional heat-treatment. Electrical instabilities by anodization may be caused by hole injection from the silicon substrate to the film. The anodization process is applied for opening windows in polycrystalline aluminum oxide in Si/Al_2O_3/SiO_2 device structures. In selective polycrystalline aluminum oxide etching, an etching operation preceded by anodic conversion is more practical and useful than the conventional method using hot H_3PO_4 etchant.

Technical Notes

Oxidation of Ni_3Sn_4, Metastable SnNi, Ni_3Sn_2, and Ni_3Sn

H. G. Tompkins and J. E. Bennett

Bell Laboratories, Columbus, Ohio 43213

The equiatomic metastable tin-nickel alloy is being considered for use as an underplate for connector contacts. This electrodeposited material has been shown to be exceptionally passive in various atmospheres and aqueous solutions (1). A previous paper by the authors (2) considered the nature of its passive film. One of the tentative conclusions of that work was that the passivity may not depend on the metastable nature of the alloy. The purpose of this work was to further investigate that tentative conclusion. It is generally accepted that the passivity of a material in the presence of various atmospheric and aqueous corrodants is somehow related to the oxide film which forms on the surface. Although it is essential, for completeness, to study the effects of the various corrodants on the material, the first efforts, it seems, should be directed toward understanding the nature of the oxide film. Upon heating or aging above certain temperatures, the metastable alloy transforms to a mixture of Ni_3Sn_2 and Ni_3Sn_4 (3). In this work, the low temperature (room temperature and 156°C) oxidation of the separate alloys Ni_3Sn_4, metastable tin-nickel, Ni_3Sn_2, and Ni_3Sn_1

was investigated using Auger electron spectroscopy to determine the effect of a range of compositions on the nature of the oxide film.

Experimental

The metastable equiatomic alloy was prepared by electrodeposition, as described in a previous paper by the authors (3). Verification of the metastable structure was made by x-ray diffraction using both diffractometer and powder techniques as also previously reported (3). The Ni_3Sn_4, Ni_3Sn_2, and Ni_3Sn_1 equilibrium compounds were prepared by induction melting of 99.999% pure nickel rod (Research Organic/Inorganic Chemical Corporation) and 99.999% pure tin sheet (Ventron Corporation) in the proper proportions. The compounds were double melted and solidified under flowing helium. After cooling, the compounds were placed in a resistance tube furnace and given a homogenizing anneal of 5 hr at 500°C in flowing hydrogen. They were withdrawn from the hot zone and allowed to cool in flowing hydrogen. Slices from each ingot were analyzed by x-ray diffraction and found to be essentially the desired compounds.

Flakes from the electrodeposited alloy and slices from the compound ingots were used for the Auger analysis.

The samples were initially sputtered clean to remove all effects of the sample fabrication (diamond saw cutting, lubrication, etc.). In all subsequent experiments, a reproducible surface condition was obtained by sputtering with the same argon ion energies. Although the surface generated was not quite representative of the bulk due to preferential sputtering, it was, in the authors' opinion, the closest representation of the bulk which could be obtained and was quite reproducible. After a half-hour equipment cool-down time at a pressure on the low 10^{-8} Torr range, the system was backfilled to atmospheric pressure with O_2. After 1 hr the O_2 was pumped out and the system pumped to the low 10^{-8} Torr range (pumping time, 3 hr). For the 156°C oxidation the samples were removed from the system and placed in a small oven (Pyrex tube wrapped with heating tape) for the allotted time. The atmosphere in these cases was room air.

The Auger analysis was done with a commercial instrument purchased from Physical Electronics Industries using a 3 kV, 1 μA incident electron beam. The sputtering was done with a 1 kV argon ion beam operated at 4.7 $\mu A/cm^2$. In a separate experiment in the same vacuum system, sputtering yields of 2.93 and 2.3 atoms/ion were measured for Sn and Ni, respectively, by sputtering through a known thickness of material. This gives a sputtering rate between 7.6 and 8.2 Å/min for all of the alloys studied.

Results and Discussion

A typical spectrum is shown in Fig. 1 (in this case, Ni_3Sn_2 after 1 hr of exposure to O_2 at room temperature). Profiles (peak-to-peak height plotted *vs.* sputtering time) were obtained and typical ones are shown in Fig. 2. The relative magnitude of the tin and nickel

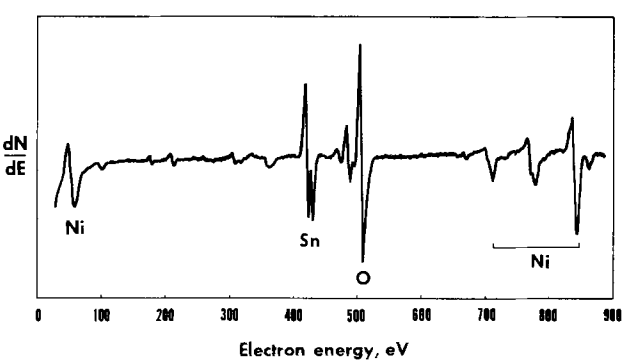

Fig. 1. Typical Auger spectrum (in this case, Ni_3Sn_2 after 1 hr exposure to O_2 at atmosphere pressure at room temperature).

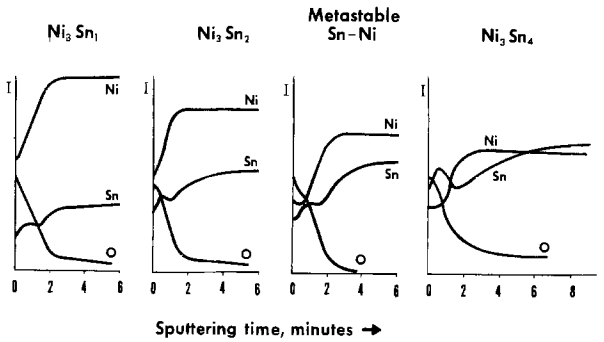

Fig. 2. Profiles of the passive films on Ni_3Sn_4, Sn-Ni, Ni_3Sn_2, and Ni_3Sn_1. Sputtering rate was about 7.9 Å/min.

signals is not normalized, but instrumental magnifications of two for nickel and one for tin were used. This gives a signal ratio which is roughly proportional to the relative concentration of tin and nickel. The profiles were obtained under identical sputtering conditions. Although the peak heights in the bulk (after the profiles leveled off) were different, illustrating the different bulk compositions, the films which formed on these materials showed similar features. These are that the tin profiles showed an initial rise, followed by a decline, followed in turn by an increase to the bulk value. The nickel profile increased to slightly above the final bulk value and then gradually decreased to the bulk value with the increase somewhat lagging the initial tin signal increase. The oxygen profile decreased monotonically. These features occurred in all four materials. Using the sputtering time for the oxygen to decrease to half its original value, and a sputtering rate of 7.9 Å/min, we see that the thickness of the film for all of the material was from 8 to 14Å. The previous work (3) pointed out that a nonzero value for nickel before sputtering does not necessarily imply nickel on the surface, since the escape depth of the high energy nickel peak used here is 11Å. The profiles clearly illustrate the similarity of the oxide films which form on these four materials.

After the room temperature oxidation studies were completed, sputter-cleaned samples were removed from the system and heated at 156°C in air for 1 hr and then analyzed. Following this analysis, samples were removed from the system, heated to 156°C in air for 5 days, and again analyzed. For both of these treatments the profiles obtained were essentially identical with the ones shown in Fig. 2, obtained after 1 hr in oxygen at room temperature. Specifically, no additional film growth was observed. In contrast, the oxide film on a pure tin coupon heated at the same time (1 hr) was about 2.5 times as thick as the film exposed to O_2 for 1 hr at room temperature. The results of Graham and Cohen (4) suggest that the film on pure nickel should be about 1.5 times as thick when heated at 150°C than when exposed at room temperature. The significant observation is that no additional oxidation of the various compounds could be detected beyond the films which form in 1 hr at room temperature, even when samples were heated at 156°C for as long as 5 days.

No specific quantitative measurements were made concerning the identity of the species making up the film. X-ray photoelectron spectroscopy (XPS) measurements have been made on the metastable alloy by Sharma and Thomas (5). Their data indicate that after 10 min at 760 Torr of O_2, the film content is a combination of nickel hydroxide and tin oxide or hydroxide with significantly more tin in the film than nickel.

These measurements, of course, say nothing about the species on the other alloys studied in this work. The similarity in film thickness and profile suggests however, that the films are, at least, not grossly different. The lack of change in the profiles after heating

at 156°C for 5 days indicates a rather strong stability of the films on all four alloys.

Cd(S,Se):Cu-Photoconductive Material for Electrophotography

S. Faria* and V. Chiola*

GTE Sylvania Incorporated, Towanda, Pennsylvania 18848

For almost three decades amorphous selenium and zinc oxide binder layers have dominated the field of electrophotography (1-2). The two best known electrophotographic methods are Xerography and Electrofax, where selenium and zinc oxide in a binder are the insulating photoconductive materials, respectively. A third technology, Canography, is now receiving appreciable attention and application.

In recent years numerous organic and inorganic compounds have been developed and are being field tested as potential electrophotographic materials. Wide attention has been given to polyvinylcarbazole (3), with or without trinitrofluorenone (4), as an efficient organic photoconductive material. The most investigated inorganic materials are the chalcogenides (5) of which cadmium sulfide has received considerable attention.

Claus (2) reported that early work with electrophotographic-grade cadmium sulfide was plagued by poor copy quality due to rough photoreceptor surface, poor resolution, and high background.

The purpose of this paper is to report on the electrophotographic properties of selenium-modified cadmium sulfide. This material has advantages of good resolution, high durability, and good copy quality.

Experimental

Materials preparation.—Solid solutions of cadmium sulfide and cadmium selenide were prepared from luminescent-grade materials and were activated with copper and coactivated with chlorine. Thermal treatments were conducted in inert atmospheres at temperatures between 400° and 600°C to properly diffuse the copper into the matrix and to prevent oxidation of the cadmium sulfide or selenide. Excess copper and copper sulfide are removed by washing with dilute potassium cyanide solution. Subsequent water washings were carried out to insure complete removal of ionic species from the Cd(S,Se):Cu surface.

Photoreceptor screens preparation.—Photoreceptor screens containing the cadmium-sulfoselenide, copper-activated material were prepared for evaluation of electrophotographic properties. These were made by thoroughly mixing and suspending the Cd(S,Se):Cu powder in a lacquer and depositing a 40-50 μm thick layer on a clean aluminum substrate using a conventional blading technique. The lacquer binder suspension consisted of a dibasic acid-modified vinyl chloride-vinyl acetate resin dissolved in methyl-isobutyl ketone. The photosensitive layer was air dried and then thermally bonded by lamination with a layer of transparent adhesive-backed polyester film. Figure 1 depicts the structure of the screen and its various layers.

Experimental Results and Discussion

Electrophotographic evaluation of Cd(S,Se):Cu.—Although there are other ways of evaluating the surface charge, for example, the revolving turntable (6, 7), for this work, we used two Saxon plain paper copying machines (PPC-1) manufactured by Copystatics Manufacturing Corporation, Division of Saxon Industries. Three screens, usually 25 × 10 cm each, were secured to the aluminum drum of the machine and their electrical properties, copying qualities, and maintenance were measured. Lifetime performance was carried to extended periods in excess of 30,000 cycles.

The principle of operation is widely known as Canography (7, 8). In operation the surface of the photoreceptive screen is charged positively in the dark with a d-c corona discharge. Negative charges injected from the aluminum layer into the CdS:Cu or Cd(S,Se):Cu layer are attracted to the interface by the positive charges on the insulating surface. The image from an original copy is then optically projected to the positively charged photoreceptive surface. Dark areas from the original, representing the letters, numbers, etc. do not dissipate the positive charges on the photoreceptor screen, while the light areas, *i.e.*, the background, tends to dispel the positive charges. The invisible electrostatic image thus formed is made visible by means of negative toner particles attracted by the positive charges. A more detailed description of this process is found in Ref. (9-10) and in Ref. (7). An electrostatic voltmeter known as a Microprobe and sold by Monroe Electronics Incorporated is placed near the surface of the drum to measure the electrostatic charge potential from both the dark and light areas. An original white sheet, one-half of which is covered with black paper served as the test pattern for measuring the electrostatic potential

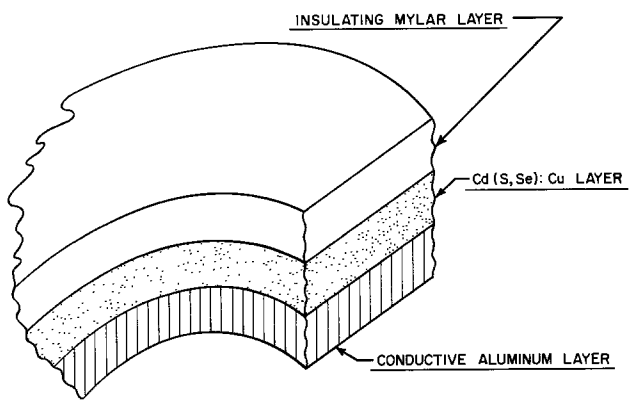

Fig. 1. Composition of photoreceptor showing the Cd(S,Se):Cu material sandwiched between the insulating and conductive layer.

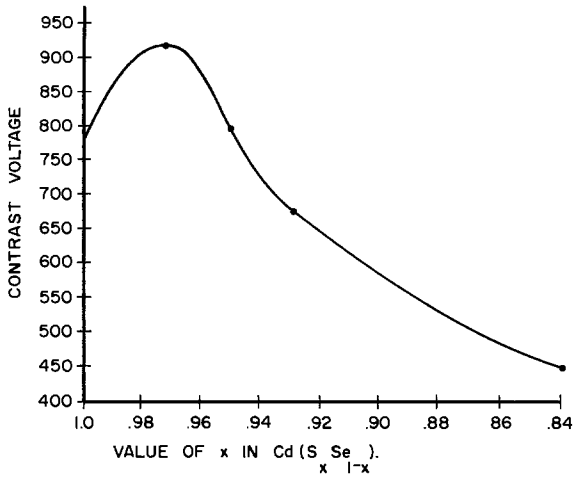

Fig. 2. Relationship of contrast voltage to CdSe addition to CdS

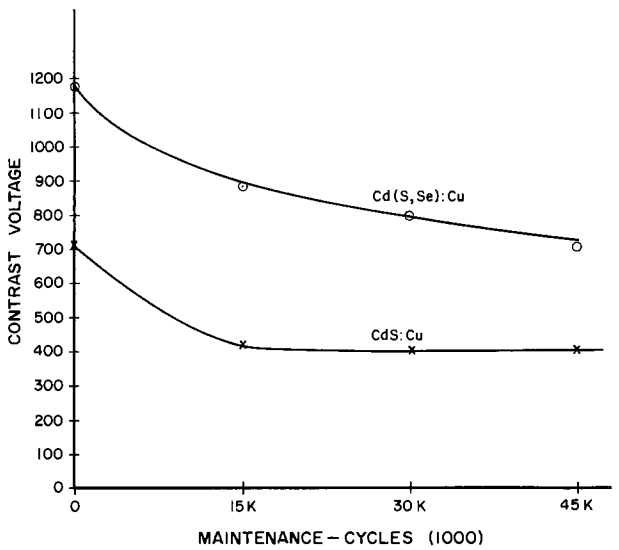

Fig. 3. Comparison of contrast voltage for the systems CdS:Cu and Cd(S,Se):Cu with maintenance.

drop between the light (background) and dark (image) areas.

The difference in electrostatic voltage between dark and light areas is known as the contrast voltage. The relationship of contrast voltage with varying amounts of CdSe addition to CdS are shown in Fig. 2. The best contrast in copy quality was obtained when a range of 0.02-0.05 moles CdSe is incorporated in CdS. Specific data showing the relationship of contrast voltage with cadmium sulfide to cadmium selenide ratio are shown in Table I.

The low negative (background) voltage indicates a strong photosensitive material. Continued light exposure and corona charging and discharging reduces the potential drop from both light and dark areas. This is shown in Fig. 3 and 4. Figure 3 shows a comparison of the electrophotographic system CdS:Cu and the Cd(S,Se):Cu. We find that the small amount of CdSe added to CdS extends the life of the photoreceptor, *i.e.*, the contrast after 30,000 copies is better than unmodified CdS:Cu. Copies of excellent contrast are not unusual after 50,000 cycles with the Cd(S,Se):Cu material.

Table I. Contrast voltage relationships to CdS-CdSe concentration

Moles CdS	Moles CdSe	Dark voltage	Light voltage	Contrast voltage
1.00	0.000	+660	−120	780
0.979	0.0210	+740	−180	920
0.957	0.0430	+700	−100	800
0.936	0.0640	+580	−100	680
0.840	0.1560	+400	−50	450

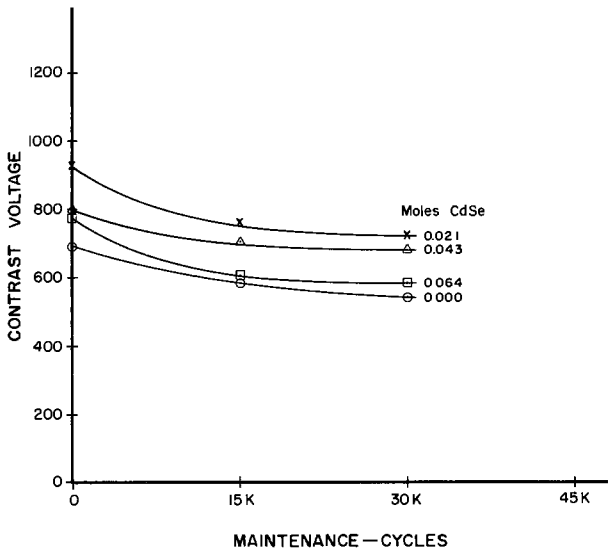

Fig. 4. Contrast voltage relationship maintenance at various CdSe additions.

Particle size.—One important requirement for smooth screen deposition is that the particle size of the Cd(S,Se):Cu be small. Two techniques of controlling particle size have been employed: (*i*) start with very small size CdS, and (*ii*) adjust the firing temperature and flux parameters. Photosensitivity is very much dependent on firing temperature and use of a correct amount of activator. High temperature increases the sensitivity but also promotes particle size growth. By controlling both the size of the starting sulfide and firing temperature, material displaying the particle size distribution shown in Fig. 5 is obtained. Most of the particles are between 2 and 4 μm. This size range material disperses well in the type of binder used for making the screens. Smaller, more uniform size, as for example 0.5 to 1 μm, would be desirable for achieving improved resolution and contrast.

Cd(S,Se):Cu spectro-response.—Figure 6 shows the photoconductivity excitation spectrum for the 46.5 moles S to Se ratio of the Cd(S,Se):Cu material as measured with a microwave photoconductive spectrometer, Model 815R, made by Micro-Now Instrument Company.

The short wavelength peak is the characteristic absorption band of CdS, while the long wavelength peak

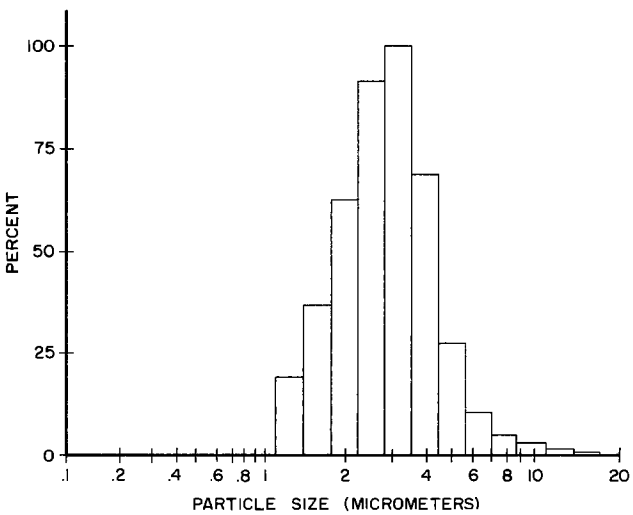

Fig. 5. Particle size distribution of Cd(S,Se):Cu as measured by the Coulter Counter method.

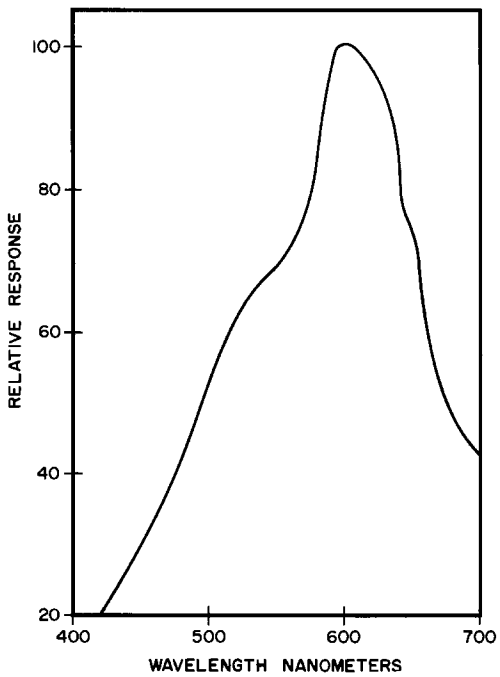

Fig. 6. Photoconductivity excitation spectrum of Cd(S,Se):Cu

is mainly due to CdSe and the effect of Cu on the matrix. Image transfer with a light source matching its emission spectrum to that of the photoconductor response will result in high contrast reproduction.

Figure 7 shows a comparison of copy quality between an image reproduced in a commercial machine and a machine using the Cd(S,Se):Cu electrophotographic material.

Conclusions

We have shown that Cd(S,Se):Cu containing a specific ratio of CdS to CdSe, when processed in a control manner, is an effective electrophotographic material. The combination of high photosensitivity, small particle size, and broad absorption response has yielded material having excellent reprographic characteristics and life or maintenance. Copying machines using Cd(S,Se):Cu and based on the Canographic technology have produced good image quality, high resolution, and exceptional life expectancy and durability.

Acknowledgments

Physical Contact Properties of Beryllium Metallization on Silicon Devices

J. B. Mooney[1] and J. O. McCaldin*

California Institute of Technology, Pasadena, California 91125

With the advent of electron beam lithography and associated high resolution techniques, integrated circuit device dimensions will decrease, and this will obviously increase the problems associated with contact metallization. Aluminum has been widely used in silicon devices, and, since it is a single element metallization, it has best fulfilled the requirements for device metallization

Key words: Be ohmic contacts, metallization, ultramicro-devices.

(1-3). However, the solubility of Si in solid Al at device processing temperatures is significant, and the dissolution and diffusion of Si are very rapid at temperatures well below the eutectic temperature of 577°C (1-5). The results of this attack upon the Si are dissolution pits (3, 6, 7). Several remedies for this problem are in use today, particularly the inclusion of Si in the original Al metallization and the addition of barrier metals at the Al-Si interface (3). These pits are likely to become a more serious problem as device dimensions shrink, however. Most other metallization systems that have been considered are composed of multiple metal layers (8, 9) or systems based on the formation of silicides (10, 11), but the simplicity of a single metal system without compound formation has many advantages.

The elements of the periodic chart have been classified as to their chemical reaction with Si (8, 12). Table I lists those elements which do not form silicides and their melting points, eutectic temperatures, and resistivities. The elements which meet the 4 $\mu\Omega$-cm resistivity criterion of Sello (1) and are solids at reasonable device processing temperatures are Al, Au, Ag, and Be. Of these, Be has only recently been considered as a Si device metallization, possibly because of its well-known toxicity. In semiconductor processing, the existing requirements for cleanliness are such that process modification required to provide toxicity protection would be relatively minor.

As stated above, Be meets the resistivity criterion of Sello (1, 14). Also, beryllium (13) is scratch resistant, will not corrode, can withstand high temperatures, its deposition and patterning are simple processes, it is an acceptor in Si (15), and it affords a low solid solubility for Si (4). In its low solid solubility for Si and its scratch resistance, Be is superior to Al as a potential metallization for ultramicro-devices. Recently Hall, Koblinski, and Cragg (16) have reported on the electrical properties of Be and Be-Al alloys as a contact metallization for Si. It was the purpose of this study to determine the adherence of Be to Si and SiO_2 (3), and the extent of chemical attack which will occur at device processing temperatures.

Experimental

The substrates were [111] oriented Si wafers with a 4000Å thermal oxide layer. Windows of various sizes and geometries were photolithographically opened in the oxide. The wafers were prepared for Be deposition by cleaning in trichlorethylene, acetone, methanol, and deionized water, followed by a 20 sec etch in 10% HF solution and thorough rinsing with deionized water. The wafers were blown dry with a jet of dry nitrogen and immediately introduced into the evaporator which was an ion-pumped system equipped with a liquid nitrogen cryopump, an electron gun, and a quartz crystal deposition rate monitor. Evaporations were made after the Be source had been melted with a shutter shielding the substrate until the background pressure could be maintained at or below 6×10^{-5} Torr during the deposition.

Two sources of Be were used. Beryllium flake 99.99+% purity (Spex Industries, Incorporated) and Be distillate (Nuclear Metals). Although spectrographic analysis indicated that the two sources were of similar purity, processing characteristics demonstrated that the distillate was superior. The Be flake was contaminated with spectrographically undetectable gases, which evolved violently upon melting with the electron beam. Electron microprobe analysis of the Be flake showed a relatively high Cl content. Even after outgassing in the vacuum system prior to evaporation, the evaporated layers were only partially adherent. Where Be did adhere, the strain was such that the oxide was lifted from the Si in some areas. There also appeared to be some attack upon the Si substrate. When the Be flake was thoroughly melted in a W boat in an Ar stream prior to introduction into the vacuum system, the layers were comparable to the high quality layers obtained with the Be distillate. When the Be distillate was used as received, and with thorough melting by the electron beam prior to opening the shutter, good adherent layers were obtained.

The results of various heat-treatments in Ar are summarized in Table II. The lowest temperatures studied produced no detectable substrate/metal reaction, whereas at the highest temperatures gross reaction occurred. Portions of the wafer with the evaporated Be layer were introduced directly into a tube furnace at the indicated temperature. After the indicated time the sample was removed from the furnace and plunged directly into room temperature deionized water. The samples were examined by optical and scanning electron microscopy (SEM). Portions of the sample were examined as treated, after removal of Be by concentrated HCl, and after removal of Be and SiO_2 by HCl and HF. In the cases where there was sufficient reaction of the Be with the SiO_2 to produce an insoluble residue, portions of the remaining deposit were removed mechanically to observe whether the Si had been attacked by the Be. Be layers of 2500 and 5000Å thickness yielded the same results. One sample which was not cleaned prior to Be evaporation showed some lifting and cracking of the Be layer over the SiO_2 free area (scribe lines). In the other experiments with properly cleaned substrates, Be layers were adherent and did not crack. The color of the SiO_2 after removal of the Be with HCl was interpreted as a measure of the amount of SiO_2 reacting with the Be. Consistent with this interpretation is the presence of an insolube residue after higher temperature treatments and the electron microprobe results discussed next.

Table III presents the results of an electron microprobe determination of the Si content of the Be layer at a beam energy of 5 keV for which there is expected to be negligible contribution from the substrate Si. The Si signal detected over oxide-free portions of the substrate (scribe line) is mostly background, and the variation is not considered significant within the expected precision of the analytical method. However, the enhanced signal detected over the SiO_2 covered regions of the substrate (field) reflects the presence of Si in the metallization overlying these regions. These results and the observed acid insoluble residue indicate that a chemical reaction occurs between the SiO_2 and the Be.

Table I. Melting points and resistivity of nonsilicide formers (13,4)

Table II. Summary of heat-treatments of Be-metallized Si wafers

Temperature (°C)	Time (minutes)	Oxide color	Residue after HF treatment
No heat treatment		Pink	None
440	5	Pink	None
475	5	Blue tint	Trace
535	5	Green	Edges
625	5	Gray*	Insoluble
625	20	Gray-green*	Insoluble
765	5	Green*	Insoluble

* Color of insoluble residue on SiO_2 surface.

Table III. Electron microprobe results*

Heat-treatment	Scribe line (Si) counts	Field (SiO_2) counts**
535°-5 min	56.2	141
625°-5 min	70.2	352
625°-20 min	60.7	567
765°-5 min	78.7	1352

* 5 keV beam.
** Ratioed from 36,000 counts on bare Si, 1352 counts represents about 3.7% Si.

The possible reactions are

$$2SiO_2 + 2Be \rightarrow Be_2SiO_4 + Si \quad [1]$$

$$SiO_2 + 2Be \rightarrow 2BeO + Si \quad [2]$$

After HCl and HF treatment the sample which was treated at 535°C for 5 min had the insoluble residue concentrated around what had been the edges of the openings in the original SiO_2 layer. When this residue and the over-all residue remaining on samples which were treated at higher temperatures were removed by mechanical agitation, there was no evidence of attack on the Si substrate as observed with the SEM. Although there was no apparent attack upon the Si, there was a thin residue over the Si in the scribe lines after Be removal by HCl from the 625°C-20 min and 765°C-5 min samples. This residue did not dissolve after 1 hr in concentrated HCl.

Conclusions

The present investigation found that Be metallization of integrated circuits has some substantial advantages over the present widely used Al metallization. Beryllium metallization adheres to both the Si and the oxide of an integrated circuit wafer and does not crack or lift the oxide layer upon being quenched in water from temperatures as high as 765°C. There is no visible attack upon the Si substrate up to 765°C for 5 min. A definite limitation to Be metallization, however, is the reaction between Be and SiO_2 that occurs at temperatures exceeding 440°C, and at least partially converts the SiO_2 to an HF insoluble product at temperatures above 535°C.

Optimization of Alignment Marks and Their Electron Signals in a Semiconductor Process

H. Friedrich, H.-U. Zeitler, and H. Bierhenke

Siemens AG, Research Laboratories, 8 München 80, Germany

Direct pattern generation on the wafer using an electron beam system to realize integrated circuits makes alignment and therefore alignment marks necessary. Figure 1 shows the secondary electron signal of a 1 μm oxide step covered with 0.3 μm resist. The asymmetric secondary electron signal is caused by the asymmetric collection of secondary electrons due to the position of the detector. This signal quality allows good signal detection for wafer positioning. But, when coming to thinner layers, as necessary when using the scaling principle for integrated MOS circuits (1), the signal-to-noise ratio *vs.* scaling factor α becomes worse as shown in Fig. 2. That means smaller steps lead to smaller signals, which cannot be processed in the short time necessary for automatic alignment.

But using an electron beam system means smaller structures and therefore demands a higher absolute positioning accuracy, which is approximately 20% of the smallest structure size, *i.e.*, 0.5-1 μm-structures need a positioning accuracy of about 0.1 μm and a layer thickness of about 0.2 μm. Hence it follows that the main problem to realize small structures is not only their size but also the positioning accuracy required.

These conclusions lead to demands on alignment marks which give good and exact signals for small layers and which are not affected by the manufacturing process (2).

Several suggestions for alignment marks required above have been investigated, *e.g.*, silicon and silicon dioxide steps proposed in Ref. (3). A new method will be offered here. An additional processing step has been used. Etching anisotropically (4) through a field oxide mask into a (100)-silicon substrate leads to V-grooved alignment marks which give good SEM signals. Figure 3 shows a principal cross section of such a structure and the backscattered electron signal expected. An alignment mark like this is a well-defined structure with a constant flank angle of about 55° and without appreciable edge roughness. Therefore one can use narrow grooves, *e.g.*, of a width of only 1 μm for alignment purposes.

The signal measured is a function of the number of backscattered electrons reaching the detector. Therefore the edges result in a maximum and the bottom of

Key words: electron beam writing, automatic alignment, direct pattern generation, electron detectors.

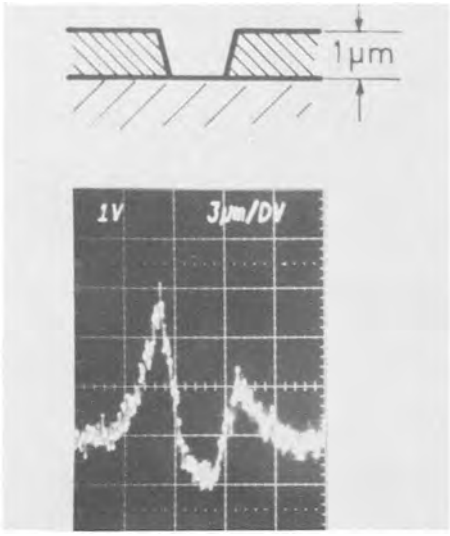

Fig. 1. Secondary electron signal of a 1 μm oxide step

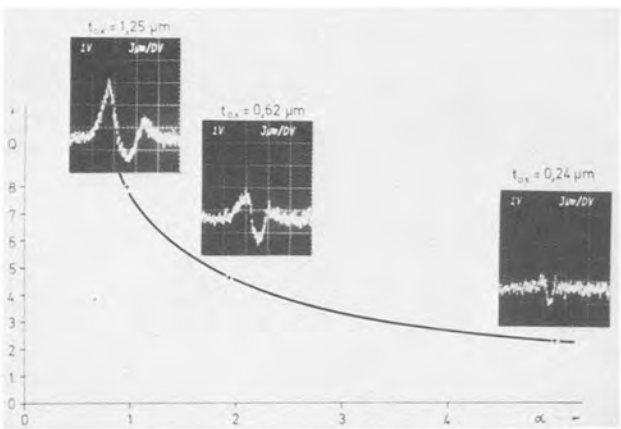

Fig. 2. Signal to noise ratio Q vs. scaling factor α

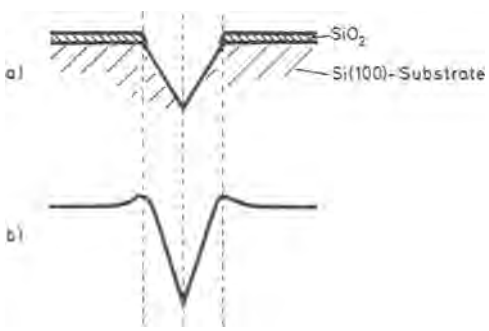

Fig. 3. Principal cross section of V-grooved alignment mark (a) and the belonging backscattered electron signal (b).

the groove gives the minimum. In Fig. 4 one can see a SEM micrograph of such a structure and of the measured backscattered electron signal which has been taken using a primary energy of 20 keV. The correspondence between the expected and the measured signal is quite good.

In the following, the signals measured at this alignment mark are shown for different important steps of an n-silicon gate process. These signals have been observed using two different electron detectors: (*i*) a conventional secondary electron detector especially sensitive for the electrons of low energies, and (*ii*) a silicon diode detector for backscattered electrons with higher energies. In every case the primary energy has been 20 keV, the slice was covered with 0.3 μm PMMA resist and the width of the structures was 1 and 2 μm, respectively.

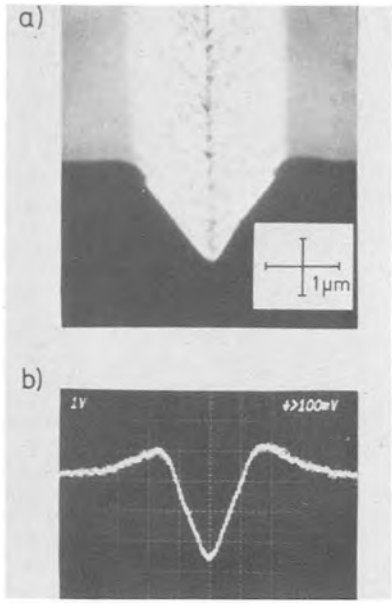

Fig. 4. SEM micrograph of V-grooved alignment mark (a) and the belonging backscattered electron signal (b).

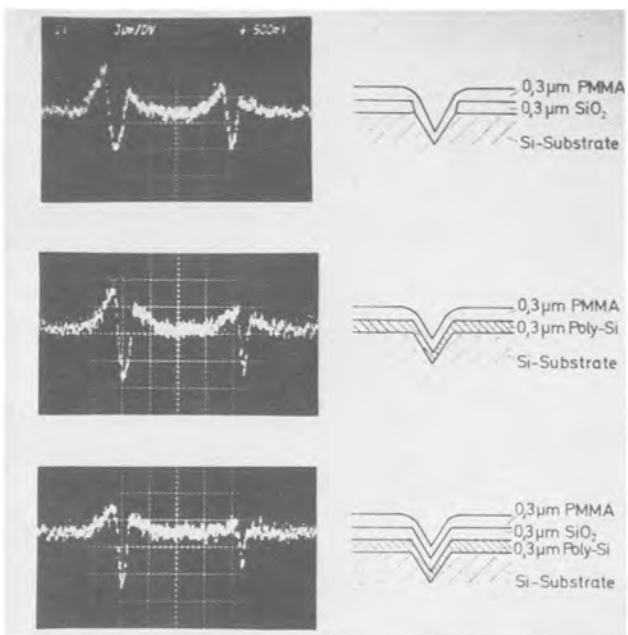

Fig. 5. Secondary electron signals for different steps of a n-silicon gate process.

Figure 5 shows these signals, measured with a secondary electron detector for a substrate covered with 0.3 μm silicon dioxide and resist, for a substrate with 0.3 μm polysilicon and resist and for a substrate with polysilicon, silicon dioxide, and resist. Even the last one gives useful signals for detection and computing.

The symmetrical silicon-diode detector for backscattered electrons consisting of four parts has been used for the signals of the same structure which are shown in Fig. 6. The signal-to-noise ratio of these signals is 18 *vs.* 9 for those shown in Fig. 5. Therefore one should use a backscattered electron detector for alignment mark detection with good signal-to-noise ratio. An additional advantage of this detector is that it is free of any potential that influences the electron beam.

The example of a n-silicon gate process for the use of those grooved alignment marks has shown that narrow structures give very good electron signals, which are insignificantly influenced by the processing steps.

For special purpose it might be necessary to decrease the primary energy. The influence of this on the de-

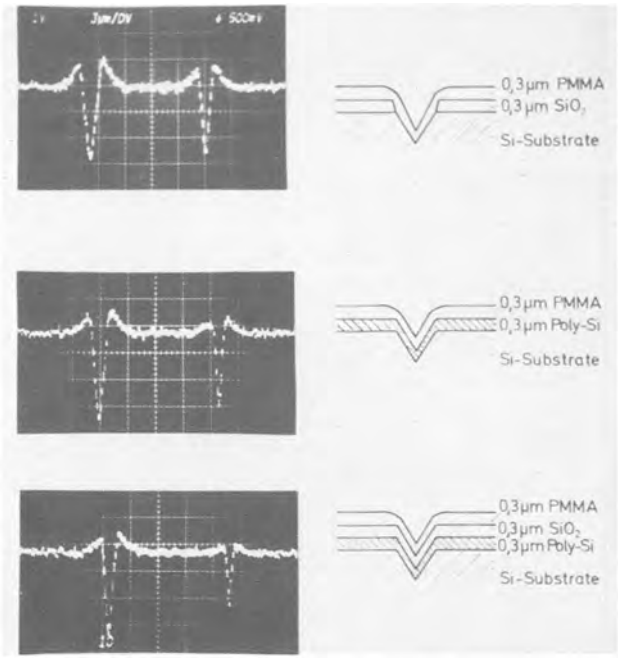

Fig. 6. Backscattered electron signals for different steps of a n-silicon gate process.

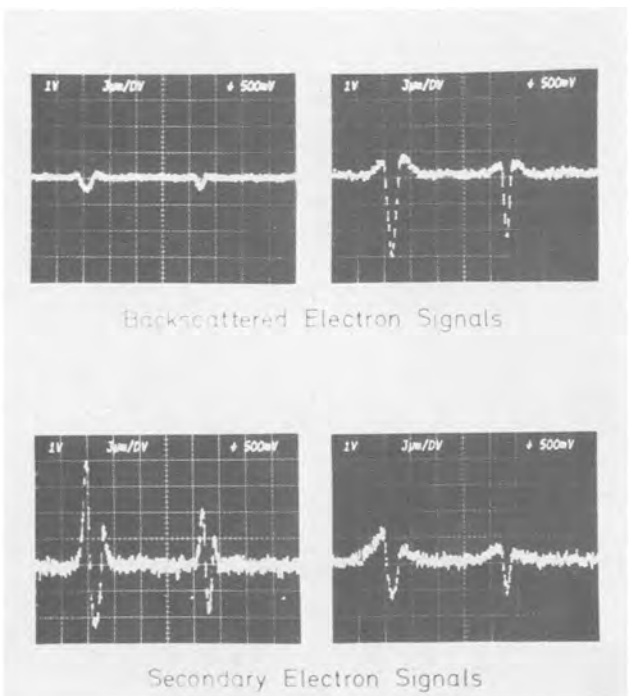

Fig. 7. Electron signals of V-grooved Si substrates with poly-Si layers for various primary energies.

tected signals is shown in Fig. 7, for 10 and 20 keV. The decrease of sensitivity for lower energies of the backscattered electron detector results in decreased backscattered signals while the higher secondary electron efficiency leads to better secondary signals.

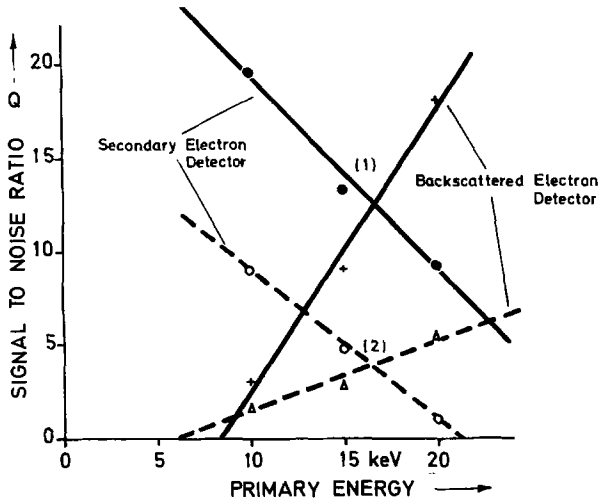

Fig. 8. Signal to noise ratio vs. primary energy with (1) and without (2) substrate etching.

Figure 8 shows a graph of the signal-to-noise ratio *vs.* primary electron energy for alignment marks with and without V-grooved substrate etching. In every case the signal quality of the substrate etched structures is much better and the selection of which detector to use for the best signal depends on the energy needed.

With these marks, described above, a positioning accuracy between two different mask levels, each adjusted to an earlier etched alignment mark level, of $\Delta x = 60 \pm 80$ nm measured with a vernier could be achieved for approximately one hundred alignments.

It has been shown in this paper that V-grooved alignment marks for a semiconductor process using electron beam technology give improved electron signals independent of the type of layer sandwich which are not affected by the process.

Mechanism of Arsenic Diffusion into Silicon from Arsenic-Doped Oxide Source

K. D. Beyer*

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

The diffusion properties of arsenic in Si and SiO_2 for arsenic-doped oxides have been studied previously (1) by varying the arsenic concentration in the arsenic-doped glass. Ghezzo and Brown (1) found that, after the diffusion in argon, the sheet resistance of diffusions from arsenic-doped oxide sources decreased with increasing arsenic concentration in the doped oxide glass, up to a certain concentration. Above this concentration of the arsenic-doped oxide, the sheet resistance increased with increasing arsenic concentration in the doped oxide. However, this deviation from the monotonic dependence of the sheet resistance on the arsenic concentration, after arsenic-doped oxide diffusion in argon, has not been explained.

Sakurai *et al* (2) studied the effects of N_2 and O_2 atmospheres on the arsenic diffusion from arsenic-doped oxide into silicon by the backscattering method and discovered the accumulation of elemental arsenic at the interface of arsenic-doped oxide and silicon. The differences between the O_2 and N_2 diffusions of arsenic-doped oxides were attributed to the property differences of the silicon–arsenic-doped oxide interface in O_2 and N_2.

Baak (3) studied the thermodynamics of arsenic in arsenic-doped oxide and found a higher chemical stability of arsenic-doped oxides in O_2 at high partial pressure than in O_2 at low partial pressure.

To study the relationship between the properties at the arsenic-doped oxide–silicon interface and the arsenic diffusion from the arsenic-doped oxide into silicon, a neutron-activation analysis of the arsenic-doped glass and the silicon was done after diffusion as well as the measurement of sheet resistance and junction depth.

Experimental

Arsenic-doped oxides were deposited by a 30 min O_3 decomposition at 215°C of an arsenic paint-on diffusion source consisting of 1.2g polymethylsiloxane glass resin, 1.2g $As[O\text{-}Si(C_6H_5)_2Si\text{-}O]_3As$, and 10.0g n-butylacetate, and were spun at 3000 rpm for 30 sec on p-type <100> 1-2 Ω-cm silicon wafers (4). After O_3 decomposition of the film at 181°C for 30 min, the wafers were diffused at 1175°C for a total diffusion time of 140 min under the following ambient conditions: 140 min in argon, 15 min in oxygen followed by 125 min in argon, and 140 min in oxygen. After diffusion, the wafers were cut into halves. On one half, sheet resistances and junction depths were measured; on the other half, the arsenic in the doped oxide and in the silicon was profiled by the neutron-activation analysis technique.

Results

Table I shows the sheet resistance and junction depth values and the surface quality at the arsenic-doped oxide–silicon interface, after diffusion, as functions of the diffusion ambient. The quality is described in terms of the presence or absence of a residue layer at the silicon surface after removal of the arsenic-doped oxide in hydrofluoric acid.

Figures 1, 2, and 3 present the arsenic profile, taken by neutron-activation analysis, in the arsenic-doped oxide and in the silicon after diffusions in argon for 140 min, in oxygen for 15 min followed by 125 min in argon, and in oxygen for 140 min, respectively. In these figures, the arsenic concentration, measured in atoms per cubic centimeter, is plotted on a semilogarithmic scale of the ordinate. On the abscissa the thickness of the arsenosilicate glass is measured in angstroms, while the silicon depth is measured in micrometers. In these arsenic profile figures, the zero value of the abscissa is set at the interface of arsenic-doped oxide and silicon.

Table I. Sheet resistance and junction depth values and the silicon surface quality after the arsenic-doped oxide diffusion in various ambients and after doped-oxide removal by HF

Diffusion ambient	Sheet resistance (Ω/□)	Junction depth (μm)	Surface quality
140 min in Ar	44.1	1.9	Residue
15 min in O_2, 125 min in Ar	8.5	2.5	No residue
140 min in O_2	12.5	2.4	No residue

As shown in Table I, a higher sheet resistance is observed for the arsenic-doped oxide diffusion in argon than in O_2; this is in agreement with the results of previous investigations (1). A lower sheet resistance is observed for arsenic-doped oxide diffusions that received a 15 min O_2 heat-treatment, followed by a 125 min diffusion in argon, than for diffusions in O_2 for 140 min. According to Table I, a residue layer is present, after completion of the arsenic-doped oxide diffusion at the arsenic-doped oxide–silicon interface, only

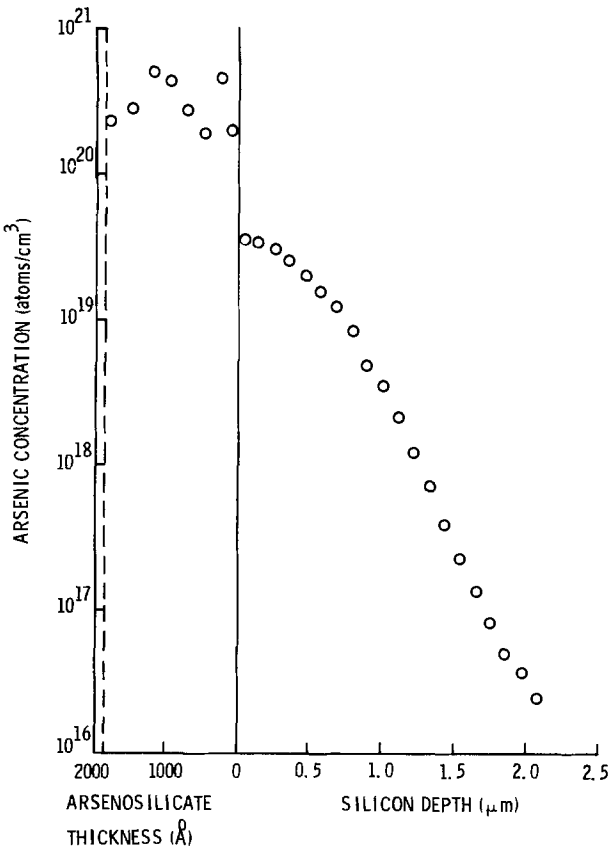

Fig. 1. Profile of arsenic concentration in the arsenic-doped oxide and in the silicon after diffusion in argon for 140 min.

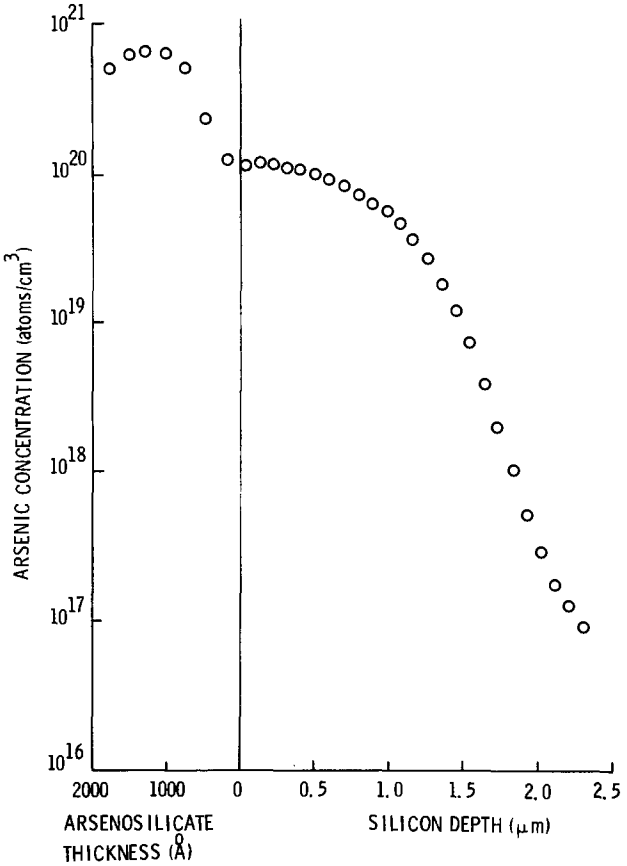

Fig. 2. Profile of arsenic concentration in the arsenic-doped oxide and in the silicon after diffusion in oxygen for 15 min followed by 125 min in argon.

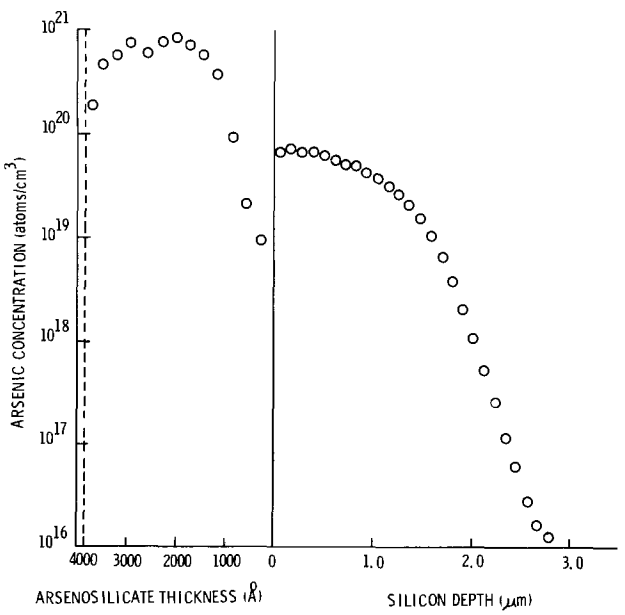

Fig. 3. Profile of arsenic concentration in the arsenic-doped oxide and in the silicon after diffusion in oxygen for 140 min.

if the whole arsenic-doped oxide diffusion is done in argon.

Figure 1 indicates that arsenic-doped oxide diffusions in argon cause an abrupt change of the arsenic concentration at the arsenic-doped oxide–silicon interface, with the arsenic concentration being one order of magnitude higher in the arsenic-doped oxide than in the silicon. For the arsenic-doped oxide diffusion with the 15 min O_2/125 min argon heat-treatment, as shown in Fig. 2, no arsenic concentration change between arsenic-doped oxide and silicon at the interface can be detected. For the arsenic-doped oxide diffusion in O_2, as seen in Fig. 3, the arsenic concentration is an order of magnitude higher in the silicon than in the arsenic-doped oxide at the arsenic-doped oxide–silicon interface.

Discussion

After the arsenic-doped oxide diffusion in argon, the arsenic concentration is an order of magnitude higher in the arsenic-doped oxide than in the silicon at the arsenic-doped oxide–silicon interface (Fig. 1). This arsenic concentration step at the arsenic-doped oxide–silicon interface can be explained by the presence of an arsenic barrier layer at the interface. Physical evidence of a layer formation at the arsenic-doped oxide–silicon interface is the residue layer which is formed after arsenic-doped oxide diffusion in argon, as shown in Table I and reported in previous investigations (1). One can assume that the residue layer is the barrier layer, which is responsible for the arsenic concentration step at the interface after the arsenic-doped oxide diffusion in argon. The higher sheet resistance value after arsenic-doped oxide diffusion in argon in comparison with the arsenic-doped oxide diffusion in O_2, as seen from Table I and as reported by other authors (1), also supports the assumption of the presence of an arsenic barrier layer at the interface after arsenic-doped oxide diffusions in argon. The formation of a residue layer was also reported when argon was replaced by N_2 as a diffusion ambient (2, 5). Sakurai *et al.* (2) pointed out that the differences between O_2 and N_2 diffusions of arsenic-doped oxides can be attributed to property differences of the arsenic-doped oxide–silicon interface. These property differences can be explained by the higher chemical stability of arsenosilicates in O_2 than in N_2 (3, 6).

The arsenic-doped oxide diffusion in O_2 followed by a 125 min heat-treatment in argon produces the same arsenic concentration in the arsenic-doped oxide as in the silicon at the arsenic-doped oxide-silicon interface (Fig. 2). Apparently, no barrier layer is present at the interface after a 15 min O_2/125 min argon heat-treatment of arsenic-doped oxides. This is confirmed by the absence of a residue layer under identical diffusion conditions. The absence of a residue/barrier layer at the interface, after a 15 min O_2/125 min argon arsenic-doped oxide diffusion, is in contrast to the presence of a residue/barrier layer at the interface after a 140 min arsenic-doped oxide diffusion in argon. Consequently, under the conditions of this experiment, such as arsenic concentration in the arsenic-doped oxide, arsenic-doped oxide thickness, and diffusion temperature and time, the choice of the diffusion ambient during the first 15 min of the diffusion heat-treatment determines whether a residue/barrier layer is formed. The diffusion in O_2 prevents the formation of a residue/barrier at the interface, while the diffusion in argon causes the formation of a residue/barrier layer at the interface during the first 15 min of the arsenic-doped oxide diffusion. The prevention of a residue/barrier layer at the arsenic-doped oxide–silicon interface in oxygen ambients can be explained by the chemical stability of arsenosilicate in oxygen during heat-treatments (3, 6). The absence of a residue/barrier layer formation at the arsenic-doped oxide–silicon interface during the 125 min argon heat-treatment, following the initial 15 min heat-treatment in oxygen, can be explained in three ways:

1. The initial O_2 heat-treatment transforms the arsenosilicate glass into the chemically stable As_2O_5-type arsenosilicate (3, 6). Upon further heat-treatment in argon, the arsenosilicate remains in the chemically stable As_2O_5-type arsenosilicate.

2. During the initial 15 min O_2 diffusion of arsenic-doped oxide, the arsenic concentration in the arsenic-doped oxide is depleted because of outdiffusion and arsenic diffusion from the arsenic-doped oxide into silicon. As low concentration arsenic-doped oxides do

not form a residue/barrier layer at the arsenic-doped oxide–silicon interface after an argon diffusion (1), the arsenic depletion of the arsenic-doped oxide during the initial O_2 heat-treatment may be sufficient to form a low arsenic concentration doped oxide that is chemically stable in an argon ambient.

3. A thin SiO_2 layer between arsenic-doped oxide and silicon (1, 7), which can be formed during the initial 15 min heat-treatment in O_2, will prevent the formation of a residue layer at the arsenic-doped oxide–silicon interface during the argon diffusion.

The first explanation, the transformation of arsenosilicate glass into the chemically stable As_2O_3-type arsenosilicate during heat-treatment in oxygen and the stability of As_2O_5-type arsenosilicate in a subsequent heat-treatment, does not account for the sheet resistance minimum of arsenic-doped oxide diffusions for longer heat-treatments in O_2 than for shorter ones (8).

For the second explanation, higher arsenic depletion of arsenic-doped oxides for oxygen than for argon during initial heat-treatments, no evidence can be found, because the arsenic concentration in the arsenic-doped oxide after diffusion is approximately equal for the 140 min argon and 15 min oxygen/125 min argon heat-treatments (Fig. 1 and 2).

The third explanation, the elimination of a residue layer at the arsenic-doped oxide–silicon interface during diffusion in argon by the presence of a thin SiO_2 layer between arsenic-doped oxide and silicon, is supported by previous experiments (1, 8). Higher sheet resistance values are observed for arsenic-doped oxides deposited on thin SiO_2 layers and diffused in argon than for arsenic-doped oxides deposited on silicon and diffused in oxygen (1, 8). This discrepancy can be explained by the lower arsenic diffusivity in undoped SiO_2 layers than in arsenic-doped SiO_2 layers (9). According to previous experiments (10), a sheet resistance minimum for arsenic-doped oxide diffusions into silicon can be obtained, not only by certain oxygen-argon or oxygen-nitrogen ambient cycles (8), but also by a certain constant ambient ratio of oxygen and nitrogen. It can be assumed that, during diffusion, such a constant ambient ratio would produce a SiO_2 layer that is sufficient to prevent a residue/barrier layer formation and that is too thin to inhibit the arsenic diffusion from the arsenic-doped oxide into silicon.

An arsenic concentration step at the arsenic-doped oxide–silicon interface, with a higher arsenic concentration in the silicon than in the arsenic-doped oxide, can be observed after a 140 min oxygen diffusion of arsenic-doped oxides, as seen in Fig. 3. During the 140 min O_2 diffusion, the film thickness of the arsenic-doped oxide increased from 2000 to 3850Å. This increase can be explained by the growth of an oxide layer at the arsenic-doped oxide–silicon interface during the 140 min oxygen heat-treatment at 1175°C.

In order to interpret the higher arsenic concentration in the silicon than in the arsenic-doped oxide after the completion of the arsenic-doped oxide diffusion in oxygen, one can assume that, during the initial oxygen heat-treatment, arsenic diffuses easily from the arsenic-doped oxide through the initially thin SiO_2 layer, formed during the oxygen diffusion at the interface of arsenic-doped oxide and silicon, into the silicon. In the late stages of the arsenic-doped oxide diffusion in oxygen, the arsenic concentration in the doped oxide near the doped oxide-silicon interface depletes and the SiO_2 layer thickness at the doped oxide-silicon interface increases. The arsenic depletion and the SiO_2 layer thickness increase cause the formation of a SiO_2 mask, which prevents further arsenic diffusion from the arsenic-doped oxide into the silicon and from the silicon into the arsenic-doped oxide.

Conclusions

During diffusions from arsenic-doped oxides, in argon, an arsenic diffusion barrier layer is formed at the arsenic-doped oxide–silicon interface. The formation of this layer can be prevented if the arsenic-doped oxide is diffused, first, in oxygen and, then, in argon. Arsenic-doped oxide diffusion entirely in oxygen causes the formation of a SiO_2 layer at the arsenic-doped oxide–silicon interface, thereby slowing the arsenic diffusion from the arsenic-doped oxide into the silicon.

Brief Communication

Current-Induced Solution Growth of Garnet Layers

L. Jastrzebski, H. C. Gatos,* and A. F. Witt*

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Yttrium-iron-gallium garnet layers were grown isothermally on single crystal YIG and GGG substrates from a BaO-BaF_2-B_2O_3 solution by applying an electric current across the seed solution interface. The growth rate and composition were found to depend strongly on the current density. Growth is qualitatively explained on the basis of electromigration of charged species to the crystal-solution interface.

It has been reported (1) that growth of semiconductor compounds from solution can be initiated and sustained by passing electric current across the growth interface while the temperature of the system is maintained constant; growth, originally attributed to Peltier cooling (1), was subsequently shown to be due to electromigration of charged Group III and Group V atoms in the liquid phase (2). InSb (1), GaAs (2, 3), and GaAs (4) layers have been successfully grown by this method. In the present note experimental results are reported on the growth of $Y_3Fe_{5-x}Ga_xO_{12}$ layers.

All experiments were carried out, without substrate rotation, in a standard apparatus for epitaxial growth of garnets from solution (5); electrical contacts (with Pt) were made to the seed and the crucible. A 25 mole percent solution of oxides (37.5% Y_2O_3 + 52.1% Fe_2O_3 + 10.4% Ga_2O_3) in 41% BaO + 18% BaF_2 + 41% B_2O_3 was used; the seeds were single crystals of GGG with (111) orientation and YIG with a high index orientation. Growth was carried out at 1195°C (the equilibrium liquidus temperature 1190°C) employing current densities of 10^{-4} to 2 A/cm^2; the polarity of the seed was positive. With the electrical contacts connected to the power supply, growth was initiated by immersing the seed into the solution and terminated by withdrawing the seed while the system was at the growth temperature of 1195°C. With the above current densities, layers of $Y_3Fe_{5-x}Ga_xO_{12}$ were obtained ranging in thickness from 8 to 800 μm. The flux attached to the grown layer was removed with dilute (50%) HCl and the average thickness of the layer was determined by measuring the weight gain of the seed and optically by employing a cross section of the seed with the epitaxial layer. The grown layers were monocrystalline with inclusions identified as flux (see Fig. 1).

The average growth rate as a function of current density is plotted in Fig. 2. The normalized growth rate (growth velocity/current density) decreases with increasing current density (Fig. 2); *i.e.*, the growth efficiency decreases with increasing current density. Figure 3 shows the composition of the grown layers (determined by an electron microprobe) as a function of current density. It is seen that the Ga concentration increases significantly with increasing current density. The lattice parameter of a layer grown

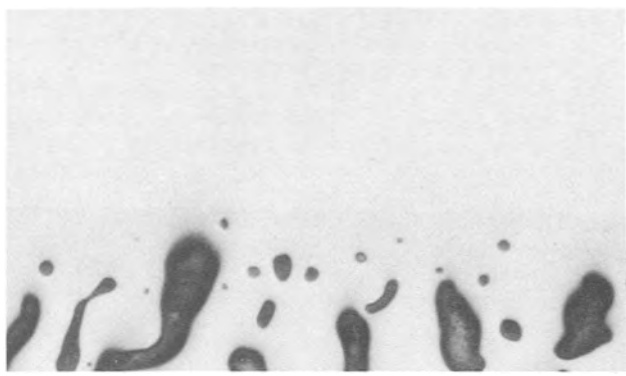

Fig. 1. Photomicrograph of a layer (lower part) grown on a YIG substrate (upper part) at a current density of 0.5 A/cm^2 (880X).

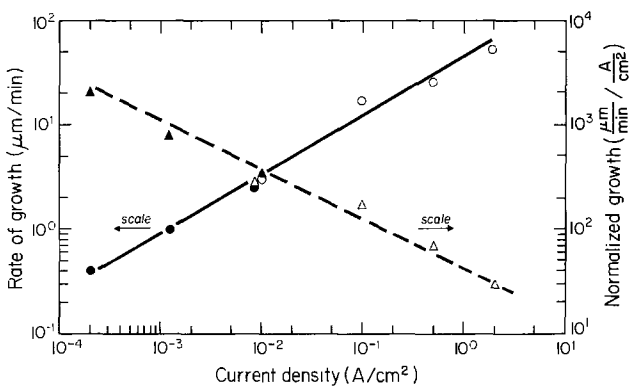

Fig. 2. Average current-induced growth rate and normalized growth rate as a function of current density; ▲, ● = GGG substrate; △, ○ = YIG substrate.

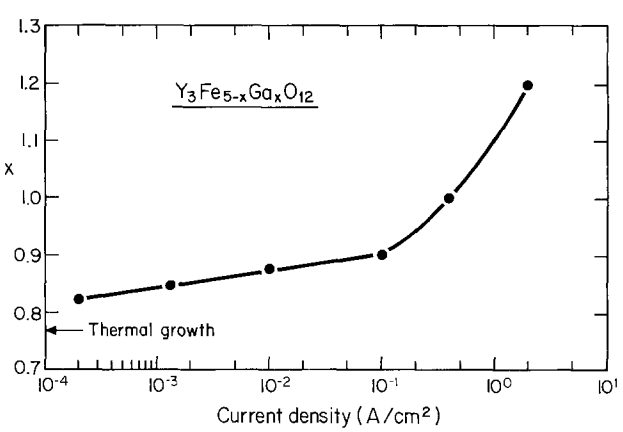

Fig. 3. Composition of the grown garnet layers as a function of current density.

* Electrochemical Society Active Member.
Key words: garnets, solution growth, current-induced growth.

at 0.5 A/cm^2 was found to be 12.360Å, which corresponds to the composition $Y_3Fe_4GaO_{12}$ (6). The composition of a thermally grown layer from the same solution (by decreasing the temperature 8°C below the equilibrium temperature) was found to be $Y_3Fe_{4.3}Ga_{0.7}O_{12}$ and the average growth rate 0.5 μm/min.

A quantitative interpretation of the experimental results is not possible since there is no detailed information available on the type of the species present in the solution, their charge, and their mobility. However, a qualitative explanation will be presented. During current flow negatively charged yttrium, iron, and gallium oxide species migrate toward the seed (positive) and charged boric oxide species migrate away from the seed. Thus, the solution becomes supersaturated at the seed-solution interface and growth takes place. The negative charge of the above three oxide species probably results from association with F^- whereas the positive charge of the boric oxide results from association with Ba^{++}. Apparently, the relatively high charge of these species and the relatively high resistance of the solution (of the order of 1Ω) are responsible for the fact that, for a current density of 1 A/cm^2, the growth rate of garnets is about three orders of magnitude higher than that reported for GaAs (2) where the resistance of the solution is about $10^{-4}\Omega$.

The increase in the gallium concentration with increasing current density (Fig. 3) is attributed to the higher mobility of the charged gallium species as compared to that of the yttrium and iron species. The observed decrease of the normalized growth velocity with increasing current density is believed to be associated with the increase in concentration of BaO and BaF_2 (with increasing current density) at the seed solution interface. Actually, at current densities greater than 10 A/cm^2 seed dissolution took place rather than crystal growth. At this current density a (positive) platinum electrode, used in the place of the seed, was attacked by the solution, apparently because the solution became depleted in boric oxide which migrated to the opposite electrode; this type of platinum attack has been reported for solutions rich in BaO and BaF_2 (7).

In summary, current-induced solution growth of garnet layers was achieved. The growth velocity and composition were found to depend strongly on current density. This dependence is qualitatively consistent with migration of charged species during current flow. The implications of the present finding to the growth and composition of oxide epilayers and crystal growth by top seeding are being pursued.

Direct Observation of the Structure of Thin, Commercially Useful Silicon on Sapphire Films by Cross Section Transmission Electron Microscopy

W. E. Ham,* M. S. Abrahams, C. J. Buiocchi, and J. Blanc

RCA Laboratories, David Sarnoff Research Center, Princeton, New Jersey 08540

Observations of the defect structure in thick (8-10 μm) silicon on sapphire films by transmission electron microscopy (TEM) were recently reported by Abrahams and Buiocchi (1). These films were grown by the pyrolysis of silane on polished single crystal $(1\bar{1}02)$ sapphire substrates. Such thick films are of little practical use and it is conceivable that their defect structure does not represent the structure of the thinner SOS films normally used for device fabrication. It is therefore necessary to examine the actual films of interest in order to be confident of the defect structure existing in practical devices. The observation of thick films allows examination of only the so-called "bottom" interface of the SOS film; the top interface was not observed nor would it be of great technical interest, although the observation of the top interface in device-like composites is of great importance.

* Electrochemical Society Active Member.

Key words: TEM, cross sections, thin films, SOS, electrically active defects.

The limitation to making observations on thick films is due to the ion thinning method used for final thinning of these specimens (2). If the "top" surface is unprotected during thinning, it will be eroded. Two methods have previously been proposed to alleviate this problem: in one, two samples are sandwiched together with an intermediate aluminum layer and bonded by thermal compression (4); in the other, the sample is encapsulated in an appropriate epoxy (5). Although these are moderately successful, the former leads to the possibility of additional defects being introduced during the relatively high temperature, high stress thermal compression, and the latter still seems to have some difficulty retaining the very top surface, presumably because of differential thinning.

We have here sought another method of protection which would further minimize these problems and which also would be compatible with routine operations in the semiconductor industry. Here, we describe the successful use of a protective layer of deposited

Fig. 1. Transmission electron micrograph of thinned sapphire-silicon-deposited oxide. Some silicon has been removed entirely by the ion beam but the protection layer is still intact after approximately 25 μm of ion thinning. (Bright field image).

SiO_2 on SOS. The SiO_2 composite was then thinned in an argon ion beam by our usual techniques for transmission electron microscopy. Details of these methods may be found in Ref. (2) and (3).

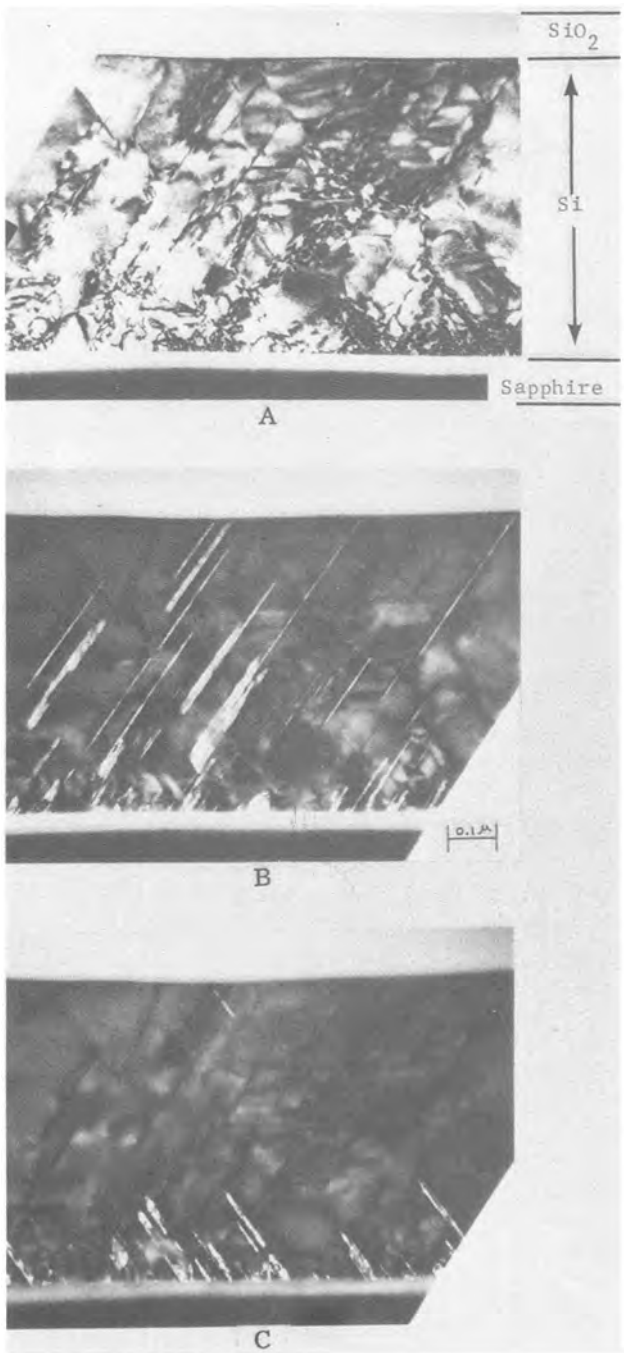

Fig. 2. Transmission electron micrographs of Al_2O_3-Si-SiO_2 composite at higher magnification. [For diffraction pattern and imaging conditions, see Ref. (1)]. (a) Many-beam bright field; (b) and (c) dark field images showing the two different sets of twins. The white band immediately below the silicon is thin sapphire; this region is free of contrast features as the substrate has very few defects.

Figure 1 shows a low magnification TEM (montage) of such a specimen. Much of the silicon above the sapphire has been eroded, but substantially all of the deposited oxide has been retained. (In the normal course of events, we would, of course, have attempted to preserve more of the silicon.) It is thus clear that a protective deposited SiO_2 layer less than 1 μm in thickness could be used.

Figure 2 shows, at higher magnification, the right-hand area of Fig. 1 where the sapphire, silicon, and deposited SiO_2 have all been preserved. Figure 2(a) shows a many-beam bright image, while 2(b) and 2(c) are dark field images showing two different sets of twins, *i.e.*, microtwins and isolated stacking faults. [For diffraction patterns and imaging conditions, see Ref. (1).] Note that in Fig. 2b, one set of twins extends from the bottom silicon-sapphire interface to the silicon-SiO_2 interface, while the second set (Fig. 2c) terminates at 2000Å from the silicon-sapphire interface. The latter may possibly have been annihilated by interaction with the first set. The defects shown in Fig. 2b closely resemble the structure proposed by Ham for electrically active defects in SOS films (6).

The defect structure shown here for a 6000Å SOS film is strikingly similar, qualitatively and quantitatively, to that previously presented (1) for a 10 μm SOS structure. This result suggests that the defects are grown in during the silicon deposition and are not produced by cooling or subsequent processing. It also shows that the twins are not annihilated by the longer times at growth temperatures required by the thick deposit, compared to the standard thickness.

Finally, the region of the film where the MOS conducting channel forms near the top interface is clearly observed to within perhaps 10Å of that interface. A clear, concise, and complete picture of films of actual technological interest has been obtained. A more detailed study of defects in such thin SOS films is in progress. It is clear, in addition, that this protective technique can be applied to other semiconductor interfaces for study by TEM.

Summary

1. It is possible to observe the structure of thin SOS layers by transmission electron microscopy including both interfaces which terminate the silicon layer.
2. The defect structure in the thin film is similar to that of the thicker films.
3. The defect structure is similar to that predicted from electrical data (6).
4. Deposited SiO_2 is a suitable protection layer for ion beam thinning processes.
5. A key step to the successful direct comparison of the structure of SOS films with their electrical properties has been developed.
6. Some effects of the defects on the surface channel conductance of MOS devices would be expected at a film thickness of 6000Å since the defects are clearly present within a few angstroms of the top surface. A sharp reduction in the channel conductance may be expected in the 2000Å thickness range where the second set of twins commences.

Acknowledgments

The authors would like to express their appreciation to A. S. Bucholz who carefully and skillfully prepared the samples for the ion thinning operation and to E. Strouse who expertly processed the SOS wafers.

Dielectric Isolation: Comprehensive, Current and Future

K. E. Bean* and W. R. Runyan*

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

The continually increasing, widespread use of integrated circuits requires improved isolation techniques and characteristics beyond those obtainable with p-n junctions. Junction isolated planar circuits have several limitations that dielectric isolation (DI) can substantially impact. For example, DI allows increased packing density, eliminates unwanted SCR action with the substrate (particularly important in cross points and radiation hardened devices), and provides higher collector-base breakdown voltages. Unfortunately, such structures also have some limitations such as cost and manufacturing process problems. The advantages, problems, and future projections of DI circuit manufacturing are discussed following a review of the semiconductor industry's current DI processing technology.

A comprehensive paper on dielectric isolation seems fitting since 1974 marked the end of the first decade of development and production of dielectrically isolated silicon integrated circuitry. Several authors published the first papers almost simultaneously in 1964 (1-4) and originally suggested it for low capacitance, high speed circuits. It was almost immediately adapted to radiation hardened IC's because it eliminated interaction between components during gamma irradiation, and is still widely used for this purpose. It has subsequently been used for high voltage isolation, reduction of substrate parasitics, and high packing density. Table I summarizes applications that have been reported and indicates the wide potential.

Dielectric isolation (DI) is a method of fabricating integrated circuits in which the circuit components are isolated by other than p-n junctions. Figure 1 is an idealized cross section showing DI and comparing it to p-n junction isolation. Each component in the DI circuit is completely isolated by an SiO_2 film. The oxide replaces the p-n junction and the components are made in mechanically polished melt-grown material instead of in an epitaxial layer. The substrate is polycrystalline silicon rather than p-type single crystal (assuming an npn circuit). Figure 2 is a top view of an actual dielectrically isolated circuit. The SiO_2 isolation is clearly visible as the black outline around each of the components.

* Electrochemical Society Active Member.

Key words: dielectric isolation, radiation-hardened IC's, silicon orientation dependent etching, silicon circuit isolation.

Table I. DI applications

Year	Device	Feature	Ref.
1964	Simple IC	Low capacitance	(1-3)
1965	Complementary IC		(6)
1965	Radiation resistant IC	Isolation during irradiation	(3)
1969	Nixie tube driver	Selective Au doping	(42)
1969	High voltage IC's	High breakdown voltage	(42)
1972	High speed CMOS	Low capacitance	(43)
1973	Power IC	High breakdown voltage	(44)
1973	High performance op amp	Low capacitance complementary structure	(45)
1973	Thermal printer	Process control	(46)
1974	Silicon vidicon	High packing density	(47)
1974	Cross points	Substrate interaction eliminated	(48)

Despite the number of applications proposed, the percentage of integrated circuits built by full DI remains very small and for several years have been primarily for the military market [radiation hardened (5, 6)]. The reasons for the lack of growth are not that the technical advantages have been overstated,

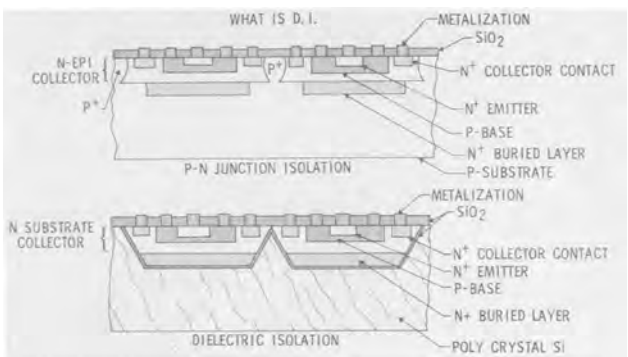

Fig. 1. Graphic comparison of junction and dielectric isolation

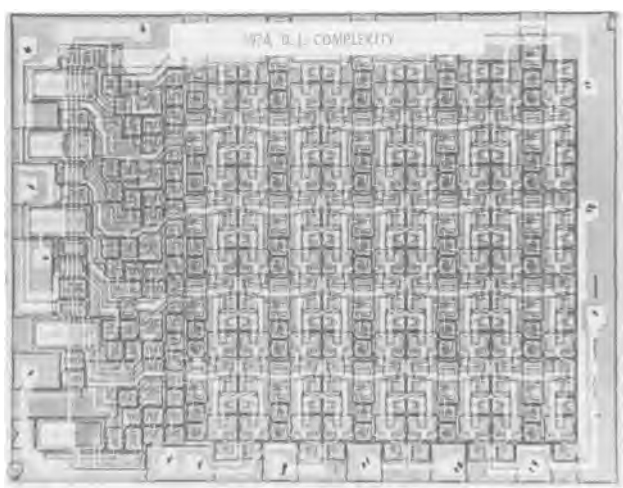

Fig. 2. State-of-the-art DI circuit complexity

but rather that it has proved exceedingly difficult to provide cost competitive products made with DI. It has continued to be used only when the designer can find no other way of achieving the desired performance and when the market is willing to pay a premium. However, it appears that some of the newer refinements described herein may allow it to be more widely used.

DI Processes

Today's DI processes may be divided into three methods: precision grind, lap, and polish (1-3, 7-12); double poly (4); and selective etch and deposition (9, 13). Each method has its own advantages and disadvantages as related to device performance and to problems of substrate fabrication. The materials have been primarily (100) and (111) orientation Si, with the early work using (111) due to its common usage at that time and the later and current work being primarily (100). The preference for (100) is due to a combination of the fourfold symmetry of the (100) system and the fast orientation-dependent (OD) etching in the [100] direction (14-24) which provides built-in process control.

Other processes considered in the past have involved the use of glass or ceramic matrix material (25-29) instead of the polycrystalline Si of Fig. 1. In addition, there are numerous composite structures in which a portion of the isolation is solid dielectric and part is p-n junction (30), or a portion is solid dielectric and a portion air (31). Some of these composites, sketched in Fig. 3, are currently receiving wide attention because of the improved packing density that they afford over junction isolation, but will not be discussed in this paper which will be devoted only to full DI.

The precision grind, lap, and polish process, sometimes referred to as single poly, with an n^+ buried layer to reduce collector saturation resistance is shown in Fig. 4. An oxide is grown on the substrate, whose resistivity is determined by the desired collector resistivity, and windows opened by conventional photolithography processing. These windows allow the isolation moats to be etched, usually with an orientation dependent etch which attacks the silicon in the <100> direction as much as 100 times faster than in the <111> direction (19, 21-23). Thus the cross section of an etched groove will appear triangular as shown in Fig. 4 if the mask is aligned on the slice so that the grooves are parallel with the traces of (111) planes. Thanks to the fourfold symmetry of the {100} system in silicon, adjacent sides of a rectangular mask can both be aligned with the traces of {111} planes on the (100) surface so that square or rectangular arrays of grooves can be etched. Due to the large difference in etch rate in the <100> *vs.* <111> directions, when the etch reaches the (111) plane intersecting the (100) surface at the edge of the mask, the etch rate becomes less than 0.03 μm/min

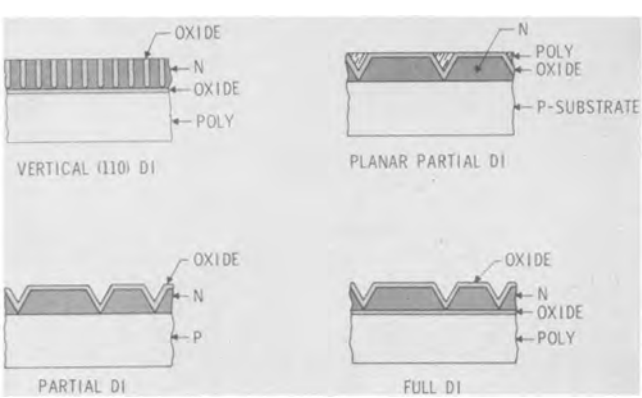

Fig. 3. Combination isolation approaches

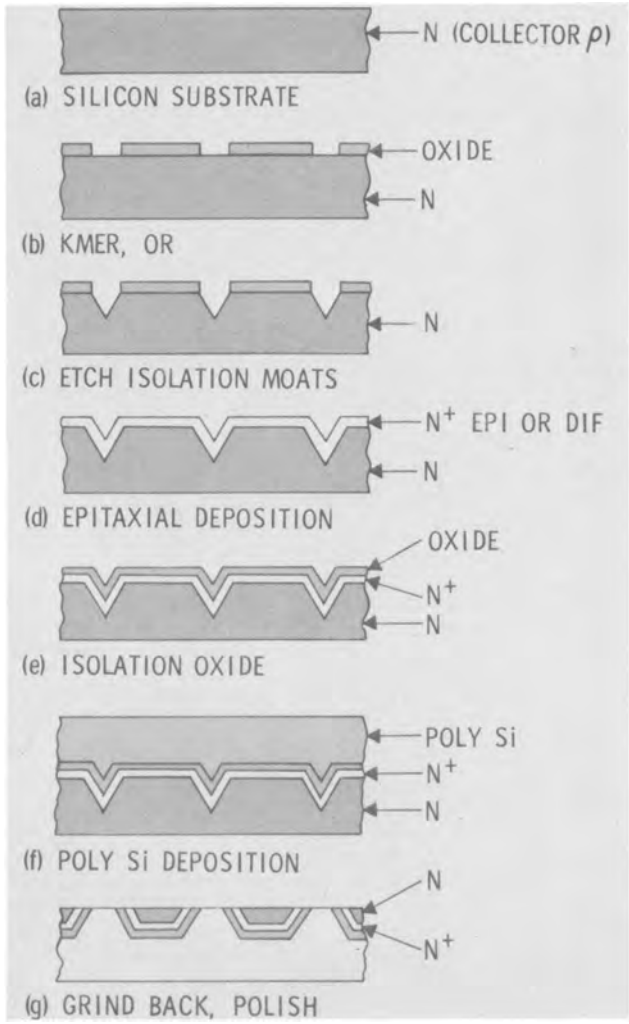

Fig. 4. Standardized DI process. Precision grind, lap, and polish method. Surface N^+ contact.

and for practical purposes, etching stops.[1] Since the {111} planes intersect the (100) surface at a fixed angle (54.74°), the width of the oxide opening determines the depth of the OD (isolation) etch moat. After the isolation moats are etched a n^+ diffusion or a heavily doped epitaxial film may be deposited across the entire surface. A thermal oxide is then grown across the top of the wafer. This oxide becomes the isolation between the single crystal and a polycrystalline silicon layer which is added next. The thickness of this layer is approximately equal to the thickness of the original slice, in general 15-20 mils. The polycrystalline silicon deposition can be made in a conventional epitaxial reactor using a silicon halide-hydrogen reduction process. For example, 10 mole percent (m/o) $SiHCl_3$ in hydrogen at 1150°C gives a deposition rate of about 10 μm of polycrystalline silicon per minute. After the polycrystalline silicon is deposited, the poly surface is ground on a Blanchard or similar type surface grinder to reestablish parallelism between the top of the slice (polycrystalline silicon) and the bottom (original single crystal silicon substrate) of the slice. Should deposition conditions be such that a polycrystalline lip is present on the single crystal side it must first be removed to allow the slice to seat well on the grinder chuck. The slice is then inverted and the original substrate is ground back far enough to reveal the isolation oxide in the deepest thickness indicators

[1] The effective mask undercutting and the measured etch rate at this point are a strong function of how carefully the mask is aligned to (111) traces. [See *e.g.*, Ref. (22)].

(which may be the scribe lines) and the single crystal islands of silicon, and then polished. After polish the slice is ready for conventional device processing except that the isolation diffusion steps are eliminated. In the process described, an n^+ surface collector contact is provided by the epi or diffused n^+ film. If a buried layer of n^+ material is desired which does not contact the top surface, the epi or diffusion may be performed prior to step b in the process. In that case the isolation moats are etched through the buried layer thus leaving it across the bottom of the final isolated tank. The precision grind and polish process is fairly simple compared to other processes but the final surface is mechanical-polished and the uniformity of the n-layer thickness across the slice is determined by how nearly parallel the final surface, after lap and polish, is with the original one.

Figure 5 shows the selective etch and deposition method. This one begins as the grind lap and polish process but has some additional steps. However the original substrate is chosen to be very low resistivity. After grind and polish-back an oxide is grown across the surface. The oxide is opened up in the areas where the individual active components are to be formed. The slice is then placed in an epitaxial reactor and the low resistivity silicon is selectively HCl vapor etched from the oxide-free areas to a depth required for the transistor collector region. An epitaxial film of the desired resistivity for the collector is redeposited *in situ* into this selectively etched region. This process gives rise to a near perfect epitaxial surface in which to build the final device and an n^+ collector contact at the surface completely surrounding the collector to provide minimum R_{CS}. Further, the thickness of the collector region is determined not by the mechanical tolerance of the lapping operation but by the etch and refill control, and is independent of any warping of the slice. The primary problem in using this process is reestablishing surface planarity in the epi refill and preventing either grooves or sharp spikes at the edges of the window. Since it is difficult to prevent the grooves/spikes formation, some process variations provide a deliberate overfill followed by a polish back. This retains some advantages, but the superior surface finish is lost.

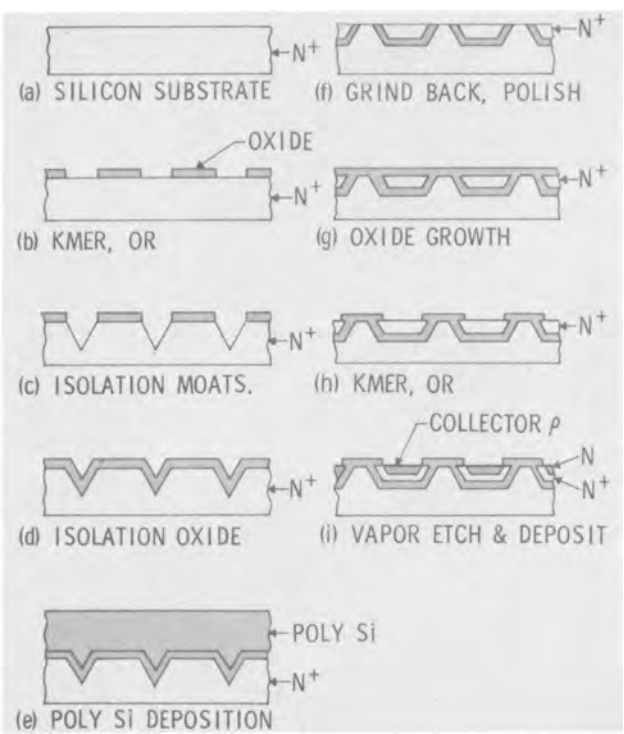

Fig. 5. Selective etch and deposition process for DI

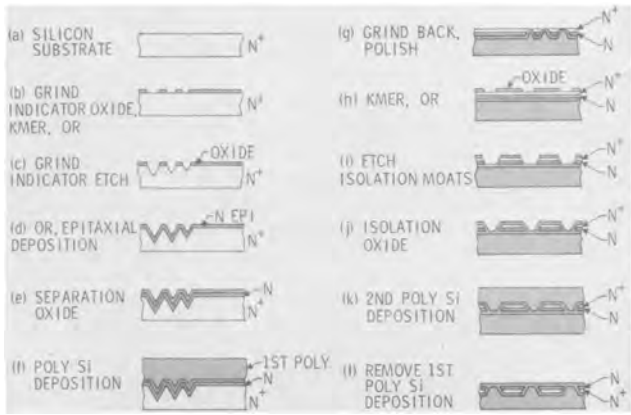

Fig. 6. Double polycrystal silicon DI process

Figure 6 shows the somewhat more complicated double poly process. To understand this process, skip to step d and neglect for the moment the grind indicators mentioned in steps b and c. An n-epi film, the thickness and resistivity determined by the collector parameters of the device or circuit to be fabricated, is deposited over the n^+ substrate. An SiO_2 layer called the separation oxide is grown or reactor deposited across the epi surface. Next a temporary polycrystalline silicon layer is grown over the oxide. The slice is inverted and ground and polished back to a thickness equal to that of the epi layer plus a suitable amount of n^+. At this point a problem arises. Unless great care is taken in keeping track of reference surfaces and the amount of material removed, there is no way of knowing when to stop lapping. To assist in this, the thickness indicator grooves shown in steps b and c of Fig. 6 are used.[2] When the grinder or polisher cuts through to them they become visible and the operator can cease grinding or polishing. There will normally be a series of grooves of increasing depth to assist in more accurate control. Assuming no mask undercutting, the depth d of an indicator groove is given by

$$d = (W/2) \tan \theta$$

where W is the width of the mask opening and θ is the angle the appropriate (111) plane makes with the surface (54.7° for a (100) surface). Typically, 6 to 8 depths will be used in an array, and the array will be placed in 5 positions over the slice for double poly process or in each circuit bar for single poly processing, as shown in Fig. 7.

Oxide is thermally grown or deposited across the surface. The oxide is opened for isolation moats as

[2] The same problem also occurs in single poly and thickness indicators are used.

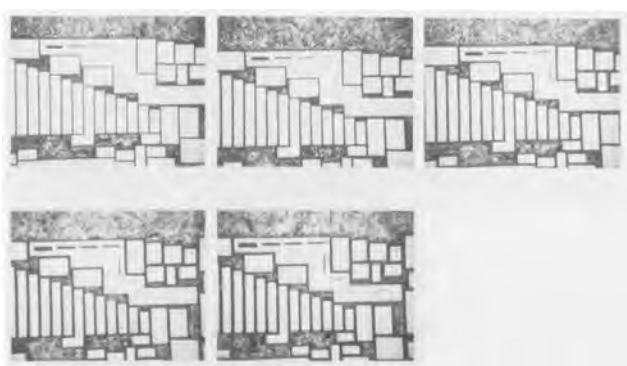

Fig. 7. Designed-in process control and monitoring through the use of OD etching of {100} silicon. Successive thickness indicator array designed into each circuit to show thickness of remaining single crystal silicon at polish back. Upper left four indicators showing. Upper right six indicator showing, etc.

in the single poly process. However, in this case, the moat depth will not be determined by the oxide opening, but by the distance to the separation oxide. An isolation oxide is then thermally grown or vapor deposited. A second poly silicon deposition is made over this isolation oxide. The slice is then inverted and the first poly silicon layer is ground, polished, and/or chemically etched back to the original epi film surface which is protected by the separation oxide. As can be seen in Fig. 6l, the resulting structure is a dielectrically isolated epitaxial film above an n^+ buried layer. This process is used in cases where very exact control of the collector thickness is required. It is quite long and costly but provides a very good surface for the fabrication of shallow devices since they are formed in an epitaxial film which has not been subjected to mechanical or wet chemical processing.

Application of Anisotropic Etching

The fourfold symmetry of {100} oriented silicon is extensively used in OD etching to provide for the very exact control of isolation pattern and thickness indicator etch widths and depths mentioned as well as to allow maximum packing density. (The ratio of active area to isolation poly area is maximized when the isolation oxide surrounding adjacent single crystal regions just touch each other and form an inverted V). Figure 8 is a scanning electron micrograph (SEM) which shows a top view and cross-sectional view of a 50 μm deep isolation moat OD etched in a {100} silicon substrate. It shows very clearly how the OD etch precisely terminates on the {111} plane which intersect the (100) surface at 54.74°.

Figure 9 is a cross-sectional view (step f, Fig. 4) after polysilicon deposition comparing the use of planar etch and a (111) surface with OD etch and a (100) surface. Note in the (111) cross section the rounded bottom shape of the planar-type etching. In this case the undercutting or lateral spreading on each side under the mask is approximately equal to the depth of the etching. However, in the (100) cross section, the undercutting is practically zero if the mask is perfectly aligned (22). Note the process control provided by OD etching of the (100) surface, and the very exact crystallographic {111} intersections which make it possible to use this phenomena for the thickness indicators previously described. Figure 10 is a photomicrograph of a section through the thickness indicators. The isolation oxide and polycrystalline silicon are also evident. The bottom photograph shows the mask used on the (100) surface to produce the thickness indicator etch. Again the depth of the etch moat is directly controlled by the width of the oxide or mask opening. At outside corners only, there is undercutting by the etch because other fast etching planes are exposed. In order to minimize this difficulty, "corner compensation" is used. That is, the masks are deliberately shaped so that after undercut, the corners are relatively sharp. Figure 11 is a top view of a (100) slice which has been etched using an oxide mask with built-in corner compensation. Here the oxide mask projecting out over the corners

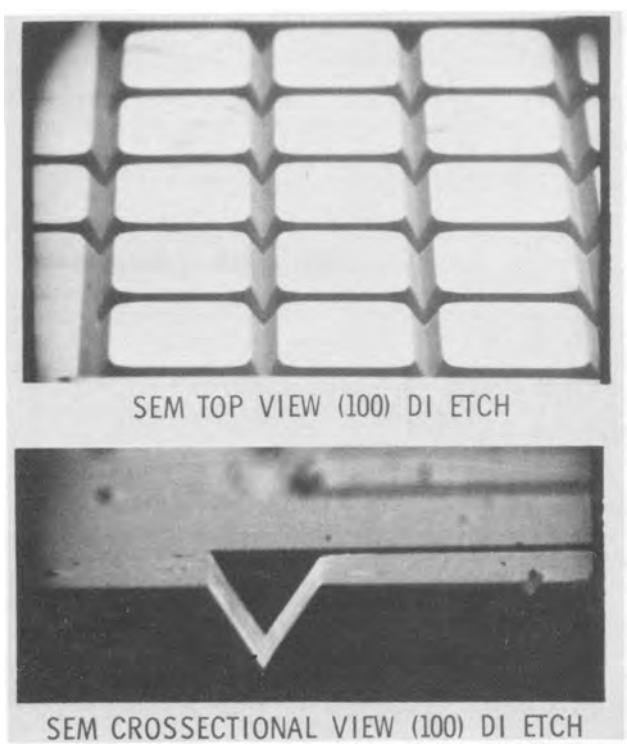

Fig. 8. (100) DI processing. OD etched isolation moat process control.

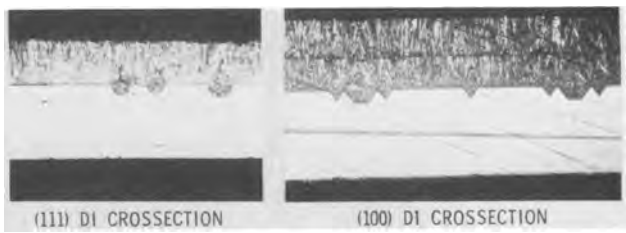

Fig. 9. DI processing (111) vs. (100) silicon

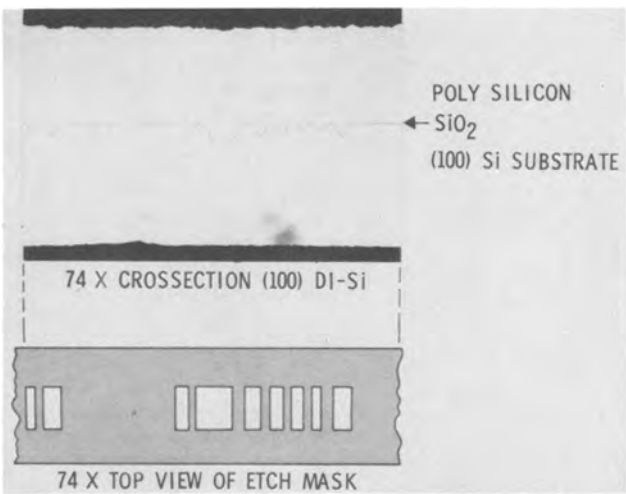

Fig. 10. Thickness indicator mask and cross section through indicator area of DI slice.

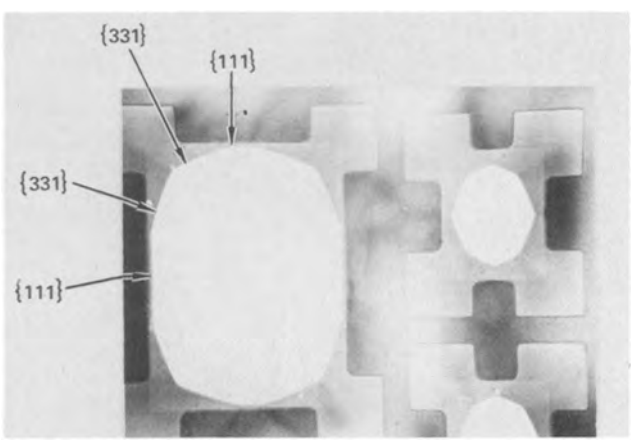

Fig. 11. Undercutting and OD etch termination planes in (100) silicon. {331} planes revealed by overetching of (100) silicon with OD etch.

of the isolation etched silicon islands can be plainly seen. This slice was purposely over etched in order to show very clearly the effect of such over etching. The corner faceting was determined to be {331} planes which etch relatively slowly but still faster than the {111} planes. This etching or undercutting at the corners is a result of the {331} planes being exposed at that point. The faster etching {331} planes also have fourfold symmetry in the {100} system; in fact they have double fourfold symmetry [the set $(\bar{1}33)$, $(\bar{3}13)$, (133), $(3\bar{1}3)$ and the set $(\bar{3}13)$, $(\bar{1}33)$, (313), $(1\bar{3}3)$], each of which intersect the (100) surface at an angle of 46.5°. One may use these shallower angle (46° *vs.* 54°) etch terminations when running metallization (leads) up and down over the sides of the moats, *e.g.*, in air isolation of Fig. 3.

In Fig. 11 the small islands on the right have undercut to the point where there is no {111} termination around the periphery of the silicon island and the entire island is bounded by {331} low angle planes. Figure 12 shows two examples of OD etch using an uncompensated mask. In Fig. 12a the etch depth is 23μm. The corner oxide undercutting can be seen and the {331} planes are well defined. In Fig. 12b the OD etch step is 54 μm and the need for corner compensation is further emphasized. Figure 13 is a top view of a properly corner compensated slice which has also been OD etched to a depth of 54 μm. The oxide compensation can be seen overhanging the four corners and near perfect 90° corners are revealed. If the compensated corner mask is used and under etching occurs, a slight projection of the silicon is left at the top in each corner. Figure 14 is a top view of two OD etched (100) silicon slices using different mask alignment. The same mask pattern was used on both slices and the slices were etched simultaneously in the same etch bath. In Fig. 14a the mask was aligned with the grooves running in a <310> direction so that etch termination occurs on the {331} planes which intersect the (100) surface at angles of 46°. Notice the exact square corners even though no corner compensation was used. In Fig. 14b the mask used was aligned with the <110> direction so that etch

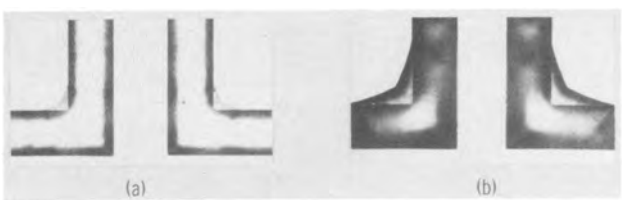

Fig. 12. Mask (outside) corner undercutting in (100) silicon *vs.* OD etch depth. (a) 23 μm etch depth. (b) 54 μm etch depth.

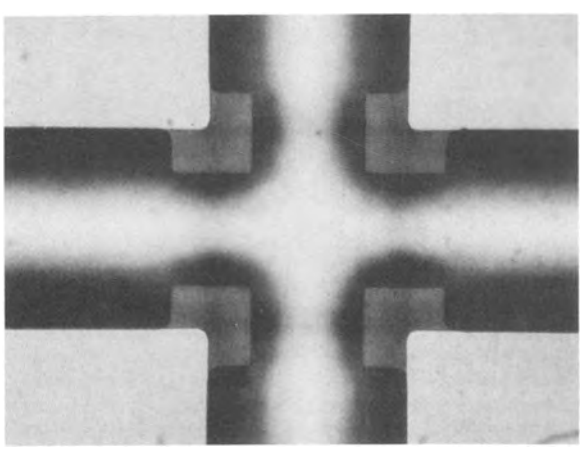

Fig. 13. Mask design compensation for OD etch corner undercutting.

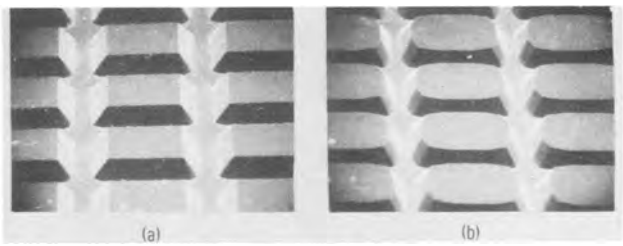

Fig. 14. OD etch pattern alignment effects in (100) silicon. (a) [310] alignment. (b) [110] alignment.

termination is on the steeper {111} planes. In this case corner undercutting occurs and the need for compensation is emphasized. As before, the lower angle <310> alignment may be desirable if one wishes to run metallization or leads up and down over islands and moats (30-31). However, the sidewall undercutting will be greater with the <310> alignment.

The OD etch used in this work was 20% KOH, 64% deionized water, and 16% normal propanol by weight (21). Other etches such as hydrazine-catechol, hydrazine-alcohol, and ethylene diamine are also very orientation dependent (14, 15, 17). The corner undercutting and faceting plane at the corners appears to be different depending on the etch used. For example corner terminations on {221} planes are reported when using hydrazine etches (17, 24).

Defects in DI (32)

Table II is a summation of some of the defects and problems which may arise during DI processing. Figure 15 is a view of two DI slices. The top portion shows a slice which was bowed before lapping so that the center portion of the slice has been polished through to the underlying oxide or polycrystalline silicon. The lower photograph shows a 100% isolated slice, with uniform depth from island to island in the single crystal tanks. Figure 16 shows the effect of nonparallelism of the top and bottom of the slice at grind and polish-back. The top view has uniform

Table II. Summation of defects

DEFECT	PROBABLE CAUSE
NON-ISOLATED REGIONS ON SLICE	SLICE BOWING OR TAPER
GAPS OR HOLES IN ISOLATION OXIDE	SLICES NOT CLEANED PROPERLY PRIOR TO OXIDATION
"COSMETIC" DEFECTS ON FINISHED DEVICES	DAMAGE TO KMER, DAMAGED MASK, POOR KMER TECHNIQUE
SMALL POLY INTRUSIONS IN SINGLE REGION	MASK DEFECT DURING ISOLATION "MOAT" ETCHING
"CROWS FEET" OR SCRATCHES ON SLICE SURFACE	POOR OR INADEQUATE POLISHING
HUMPS WHERE ISOLATION OXIDE INTERSECTS SURFACE (SINGLE POLY)	TOO SOFT AN ABRASIVE AND/OR POLISHING PAD USED DURING POLISHING
GROOVES WHERE ISOLATION OXIDE INTERSECTS SURFACE	OXIDE ETCHING STEPS DURING SUBSEQUENT PROCESSING WHICH DO NOT PROVIDE ISOLATION OXIDE MASKING
SINGLE CRYSTAL ISLANDS CHIPPING OUT	POLY SILICON GROWN IN EXTREME THERMAL GRADIENT, INCORRECT DEPOSITION PARAMETERS DURING POLY SILICON DEPOSITION, INSUFFICIENT CLEANUP PRIOR TO ISOLATION OXIDATION

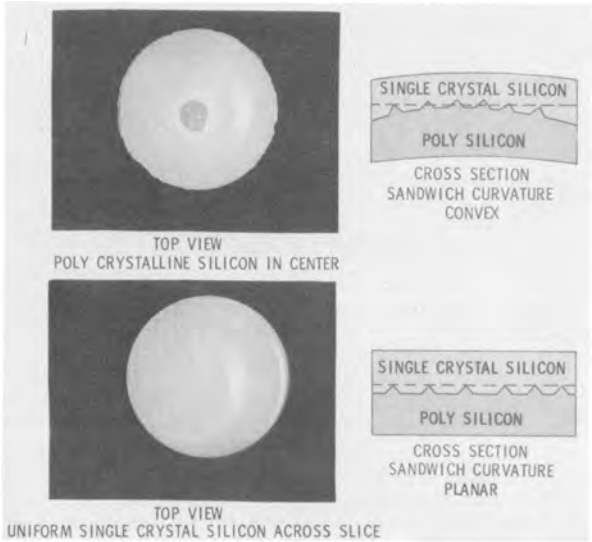

Fig. 15. DI processing problems and effect; effect of sandwich curvature on collector thickness uniformity using the DI process.

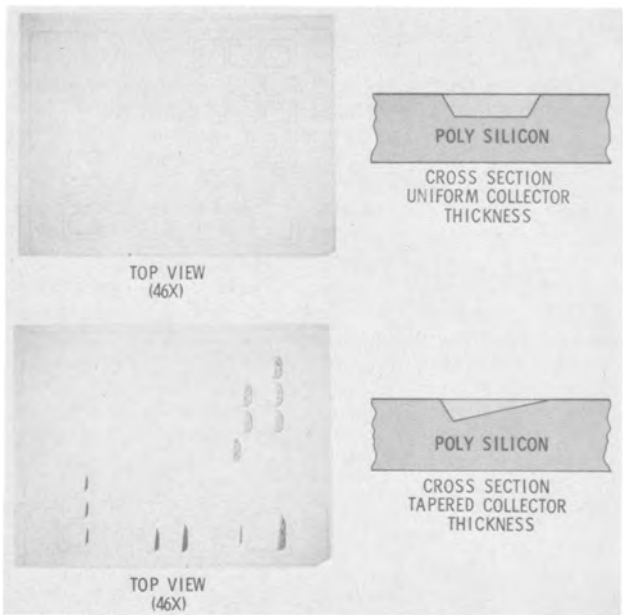

Fig. 16. DI processing problems and effect; effect of parallelism on collector uniformity.

island thickness whereas the bottom view shows a nonuniform island thickness and the effect of grinding and polishing through the single crystal region into the oxide or polycrystalline region below. Figure 17 is the top view of an integrated circuit chip along with enlarged views of two of the adjacent single crystal islands. At the upper left is a small island showing only one defect present in the top surface, whereas the figure on the right is a larger island showing many defects. This area-related defect phenomena has often been observed, it is also noted in the large peripheral area around the integrated circuit. In the bottom view one may see many defects. It is believed that these defects are mobile and move to sinks at the single crystal-oxide interface. It should be noted from the bottom photograph that only one thickness indicator is shown in the lower left portion of the array. This indicates that the slice did not have the proper polishing after grind-back, thus leaving gross damage in the surface. Figure 18 is a top view photograph of a selective etch and refill component in a DI circuit. Note the center section of the single crystal island has been selectively etched

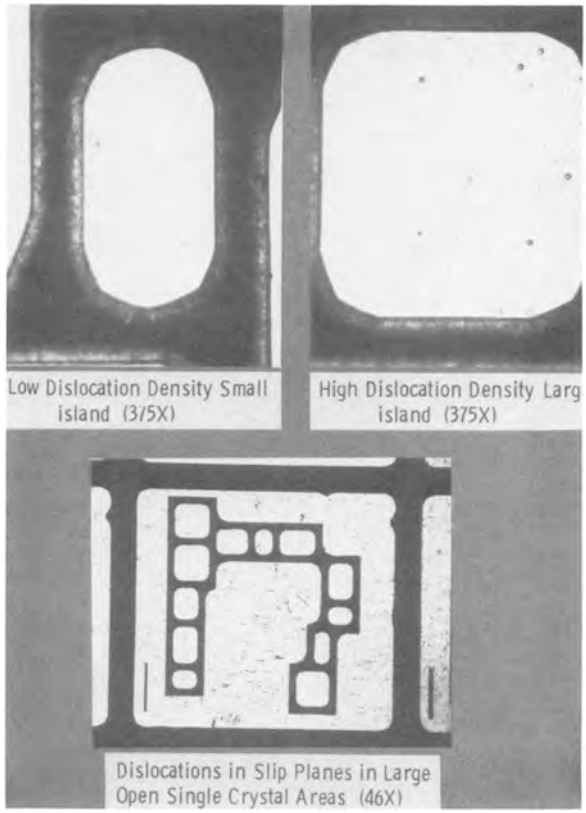

Fig. 17. DI process induced material defects; defect density vs. island size.

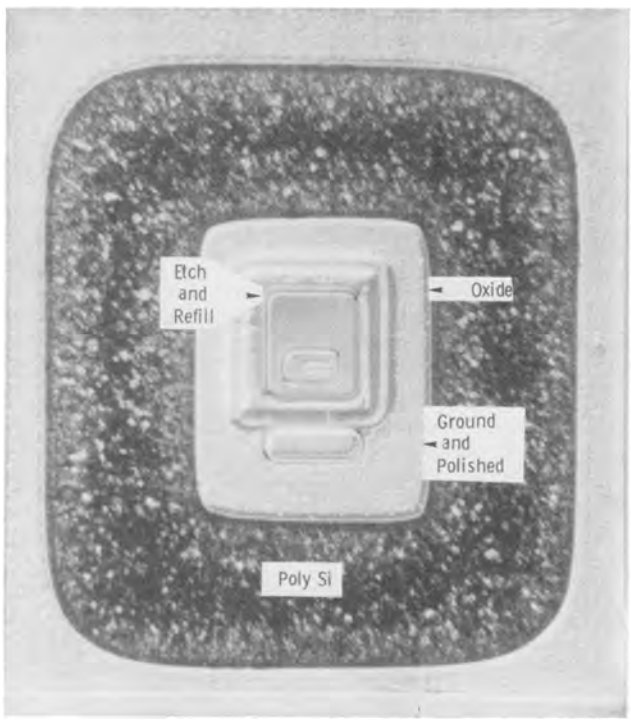

Fig. 18. DI component in integrated circuit selective etch and refill process.

out and then epitaxially regrown. It is evident that the damage in the original silicon crystal of the island after polish is much greater than that of the etch and refilled portion.

New Processes

A new process under development in several laboratories is shown in Fig. 19. One approach makes

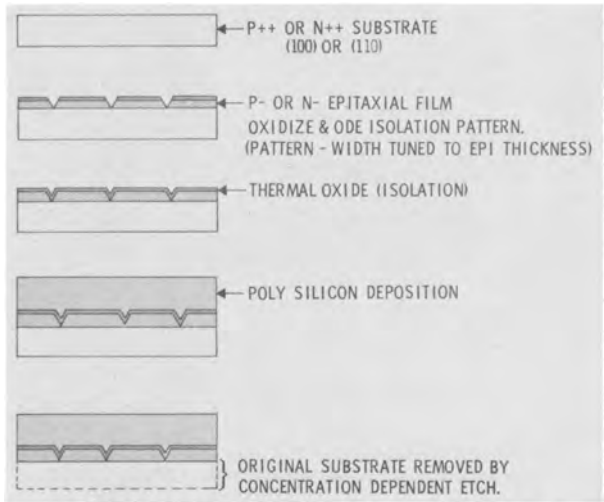

Fig. 19. Current DI development processes

use of a p^{++} or n^{++} substrate of {100} silicon with an epitaxial layer. The layer thickness is adjusted to the width of the isolation pattern mask which will be used for OD etching. That is, it is adjusted so that the OD etch will just penetrate the epitaxial film but not reach into the p^{++} or n^{++} substrate. The slice is then thermally oxidized and polycrystalline silicon deposited. Next, the polycrystalline silicon is protected by an oxide or some other media and the slice etched with a solution which attacks the p^{++} or n^{++} original substrate material but stops at the higher resistivity n or p epitaxial layer. Dash etch (1 HF, 3 HNO_3, 10 acetic) or some variant is suitable for this purpose (33, 34). Another approach makes use of an electrochemical etch which also stops at an n or p layer (35-39). Still a further approach utilizes the concentration-dependent etch of the KOH-normal propanol-water etch which does not etch a p^+ region (21, 40). Ethylene diamine-pyrocatechol-water will also stop at p^+ regions (41) and has been used as an alternate to the other etches.

This kind of process appears to have several theoretical advantages. (*i*) It eliminates mechanical polish damage inherent in present processing and allows fabrication of very shallow devices in a chemically polished surface which should be damage free. (*ii*) It reduces the critical parallelism required in the existing precision grind, lap, and polish processes, and allows a decrease in polycrystalline silicon thickness requirement. (*iii*) It provides the possibility of improved process yield due to the slice breakage which normally occurs at the (mechanical) precision grinding and polishing process. (*iv*) It provides increased packing density capability.

Another new technology which may be utilized for high packing density dielectric isolation is shown in Fig. 20. This is a SEM of a cross section of a {110} silicon slice which has been OD etched. It shows 5 μm moats etched 80 μm deep with 5 μm wide ridges between. Orientation dependent etch rate differences as great as 600:1 ([110] direction to [111] direction) have been observed in the {110} silicon slices (22). The undercutting in the etch used for {110} silicon processing is primarily a function of the mask alignment with the trace of the {111} plane at the (110) surface (22-23). The sidewalls of the moats are {111} planes perpendicular to the surface. It should be mentioned however that the intersection of the traces of the four {111} vertical planes in the (110) crystal forms a rhombus having angles of 109° and 71° rather than a rectangle. Therefore circuit designs would be layed out in rows of rhombi rather than in rectangles or squares. For cases where the moats are very narrow, the isolation oxide will completely fill in the gaps and the poly silicon will be eliminated or go only across the surface.

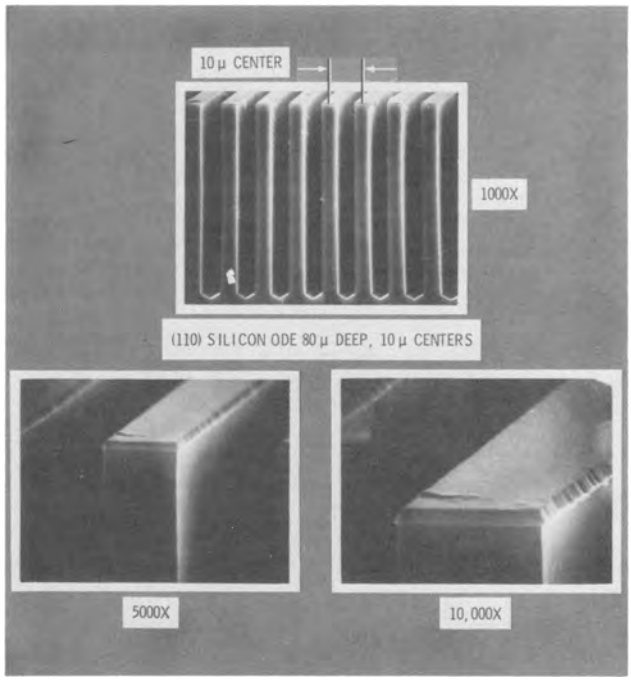

Fig. 20. Current DI development technology

Acknowledgments

The authors wish to thank Mrs. Hettie L. Smith for manuscript typing and proofing and R. L. Yeakley and the reviewers for several helpful comments and references.

Manuscript submitted Dec. 8, 1975; revised manuscript received April 26, 1976. This was Paper 138 presented at the New York Meeting of the Society, Oct. 13-17, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by Texas Instruments Incorporated.

Chlorine—Caustic Soda

I. Production.—Chlorine production in the United States reached a level of 9,228,000 short tons in 1975, which was 14.8% below the record high 1974 output of 10,872,000 tons (1-3). Canadian production of chlorine in 1975 was 860,000 tons, representing a decrease of 19.6% from the 1974 level of 1.07 million tons (1-3). January through July of 1975, the chlorine production rates significantly dropped due to the economic downturn to the levels approaching those of 1968-1969 (1, 2, 4). The recovery from the recession in the last 5 months of the year brought the chlorine production rates back to the 1972 level in the month of December (6).

Despite the lower production rates of 1975, the U.S. chlorine production capacity increased by 7.8% in 1975. The Canadian chlorine capacity rose 13.6%. During the year 1975, a total of eleven locations in the U.S. started up new, expanded or modernized facilities. Some of the plants replaced their older facilities completely. In Canada, a new chlorine plant came on stream and another one was expanded (5) (See Table 1). The Chlorine Institute estimates that the U.S. chlorine capacity will be boosted from the present 34,600 tons per day to about 41,100 tons per day by January 1, 1978, which represents an increase of 18.8% (See Table 2). By 1980 the capacity is estimated to be 42,000 tons per day (6). Several significant expansions have been announced in Mexico, one being scheduled to start up in 1976 (5).

In 1975, 73.4% of the installed U.S. chlorine capacity was in the diaphragm cells, 21.8% in mercury cells, and 4.8% in all other production routes. In Canada, 64.6% chlorine capacity was in the diaphragm cell process and 35.4% in the mercury cell process (5).

Markets for chlorine remained in the traditional areas such as vinyl chloride monomer, other chlorinated organics, inorganic chemicals, water and waste treatment, and the rest going to numerous miscellaneous applications. Demand for chlorine was less than 70% of the capacity from March through July and the situation improved during the rest of the year (6). Chlorine prices remained at $115 per ton level on the Gulf Coast, the price that was posted in the fall of 1974,

[1] This report is sponsored by the Industrial Electrolytic Division of The Electrochemical Society. While it is primarily a summary of production and developments in the chlor-alkali industry, reports of other electrolytic industries are included.
The material presented herein has been gathered from many sources, as noted in the References, and does not necessarily represent the opinions of the authors.

* Electrochemical Society Active Member.

for most of the year as producers cut the chlorine output to match the market (7, 8). The prices for chlorine were raised toward the year end due to higher costs; for example the Gulf Coast prices were raised to $125 per ton. Elsewhere prices for chlorine were as high as $150 per ton (6).

Chlorinated organic products continued to make the news in the health and the environmental arena. Since chlorinated organic products consume a large fraction of the chlorine produced in the U.S., factors that affect these industries are in turn reflected in the chlorine industry. The potential of carcinogenesis by compounds such as vinyl chloride, chloroform, and trichloroethylene, was widely publicized (13-24). OSHA worker exposure standards for vinyl chloride monomer (VCM) became final on April 1, 1975. Since, the Supreme Court refused to review the challenges brought against the OSHA standards by the Society of the Plastics Industry and other vinyl producers (14). The polyvinyl chloride producers were able to meet the OSHA standards for 1975 with no major problems. The industry could meet the stricter 1976 standards with the workers using appropriate protection gear. The VCM producers which use mainly closed systems did not have many problems (13). The vinyl makers were also getting ready to meet the EPA requirements to limit VCM emissions to a concentration level of 10 ppm in all exhaust gases except for emergency relief valve discharges (16). The emissions control is reportedly going to be costly (16).

After some controversy over the use of chloroform in drug products, the FDA was removing chloroform from such use (17-20). The EPA found trace quantities of chloroform and other chlorinated organics in a number of city water supplies (25). Another chlorinated hydrocarbon widely used in the industry, trichloroethylene, was found by the National Cancer Institute (NCI) to cause liver cancer in mice and the NCI issued a "Statement of Concern" (21, 22). Trichloroethylene is widely used in the vapor degreasing of metal parts, and it is a very large volume chlorinated solvent (23).

The controversial issue on fluorochlorocarbons and the stratospheric ozone layer depletion continued to boil (26-32). A federal Task Force on Inadvertent Modification of the Stratosphere (IMOS) recommended that the use of fluorochlorocarbons in aerosols be banned and other uses be restricted (26). If the government were to ban the use of fluorochlorocarbons, the economic dislocations would run into billions of dollars (28). The industry proposed more research on the problem (28). The state of Oregon has already banned the use of fluorochlorocarbons (27), and a number of other states are considering it (30). If the ban on the fluorochlorocarbons were promulgated, which may be more than likely according to a study by A. D. Little, Incorporated (32), it is not known how or to what extent it would affect the chlorine industry.

According to the U.S. Department of Commerce data, the caustic soda production in 1975 reached a level of 9,266,000 short tons as 100% NaOH compared to the 1974 production of 11,189,000 short tons (33). The recent recession knocked down the caustic production significantly, and it represents the largest single drop from one year to the next in more than 25 years (9).

Markets for caustic traditionally are in the area of general chemical manufacture, pulp and paper, alunina, rayon, and cellulosics. The market breakdown is given below (9):

General chemicals	46%
Pulp and paper	16%
Alumina	5%
Rayon and cellulosics	4%
Other industries	12%
Miscellaneous and exports	17%

As in other years the supply of caustic depended on the production of chlorine. As the chlorine output was reduced in early 1975, caustic soda became tight in the market. This situation continued through the summer partly due to inventories of caustic built up at the consumer plants in anticipation of continued strong demand. The chlorinated organics and PVC markets began to recover from the recession in the fall, and as the chlorine output was increased, necessarily the caustic availability improved to the point that the caustic market softened late in the year (9). The caustic market is expected to improve as the pulp and paper and aluminum industries recover from the recession. The prices for caustic remained at the $140-160 per ton range in the first half of 1975 (11). The midyear prices were raised to $150-170 depending on the plant location (11, 12). These prices remained steady at year end, although some downward price pressure was reported as the caustic demand was relatively weaker than the chlorine demand, particularly on the Gulf Coast (9).

II. Developments.—A. Chlorine cells and components.—Conversion of chlorine cell rooms to the coated titanium anodes is continuing (see Table 1) and reportedly half of the chlorine capacity in North America will have switched over to the metal anodes (34). Corning Glass Works and Electronor Corporation, an affiliate of O. DeNora of Italy, have entered into an agreement to jointly develop new types of anodes and cathodes for electrochemical and electrometallurgical processes (35).

Commercial chlorine cells utilizing the cation exchange membranes are coming of age. Hooker Chemical and Plastics Corporation installed membrane cells

Table 1. Changes in the current chlorine operations (5)

Producer and location	Cell type/change	Capacity tons/day	Completion date
1. Canadian Industries Becancour, Que., Canada	Hooker H-2A (diaphragm)	385	October 1975
2. Diamond Shamrock Corp. LaPorte, Texas	Diamond MDC-29 (diaphragm)	1200	January 1975
3. Dow Chemical Co. Freeport, Texas	Dow (diaphragm)	1000	January 1975
4. Georgia Pacific Corp. Plaquemine, La.	Hooker H-4 (diaphragm)	800	January 1975
5. Hooker Chemical and Plastics Corp. Taft, La.	Hooker H-4 (diaphragm)	900	January 1975
6. Pennwalt Corp. Tacoma, Wash.	Glanor® 1144 (diaphragm) Conversion of cell room	200	December 1975
7. Reed Paper Co. Dryden, Ont., Canada	Hooker MX (membrane) Conversion of mercury cell room	45	November 1975
8. Vulcan Materials Co. Wichita, Kans.	Hooker H-4 (diaphragm) 25% expansion	—	December 1975
9. Weyerhaeuser Co. Longview, Wash.	Diamond MDC-29 (diaphragm) Conversion of mercury cell room and expansion	385	May 1975

11. Brunswick Chemical Co. Brunswick, Ga.	Conversion to metal anodes	—	December 1975
12. Georgia Pacific Corp. Bellingham, Wash.	Conversion to metal anodes	—	June 1975
13. PPG Industries New Martinsville, W.Va.	Columbia N-3 and N-6 (diaphragm) Conversion to metal anodes	—	December 1975

with a 45 tons per day chlorine capacity at Reed Paper Company's Dryden, Ontario, plant and the cells have been operating successfully since November 1975 (4, 36). Hooker Chemical and Plastics Corporation has cells using the Nafion® membranes operating at its Tacoma, Washington, facility (36, 37). Diamond Shamrock will start up a line of cells at its Muscle Shoals plant employing its modification of du Pont's Nafion® membrane (37). The Diamond Shamrock membrane cells produce high strength caustic soda with minimal salt concentration directly in the electrolyzer at high current efficiencies (36). The regular Nafion® membranes permit hydroxyl ions to migrate from the cathode compartment into the anode compartment resulting in current efficiency losses. The Hooker MX cell consumes 2800 kW-hr/ton Cl_2 compared to 2500 kW-hr/ton Cl_2 with a typical asbestos diaphragm. Finding methods to cut down this migration is the aim of the development work at du Pont, Diamond Shamrock, Hooker, and several Japanese companies who are hard at work on the membrane improvements (37).

The Japanese producers have been very active in chlorine cell development work using cation exchange membranes (37, 41). Asahi Chemical is operating a membrane cell plant of 44,000 tons per year in caustic capacity using Nafion® membranes. Tokuyama Soda is operating a 2200 tons per month plant at Tokuyama City to compare its own membranes with Nafion®. Toyo Soda hopes to build a 2200 tons per month plant at Sekata City, Honshu, by spring 1977 using Hooker MX cells. It is also testing its own membranes as well as du Pont's in a pilot plant. Asahi Glass test data from a 220 tons NaOH per month pilot plant using its own fluorinated membrane shows a 90-92% current efficiency at a caustic concentration of 40-41% and a cell voltage of less than 4V at an unknown current density (37, 38).

Du Pont is reportedly carrying out engineering design as well as development of construction cost estimates for a plant to produce the Nafion® perfluorosulfonic acid products. If demand warrants, commercial production could begin by 1980 (42, 43).

Oronzio DeNora, Italy, has patented a new electrolytic cell suitable for gas evolving electrodes. By withdrawing the generated gas behind the electrode the cell avoids increase in cell resistance resulting from gas bubbles present in the electrolyte gap between the electrodes (44).

Ionics and du Pont are offering sodium hypochlorite generating systems for destroying cyanide containing wastes in the plating industry. The cells use Nafion® membranes, and du Pont will market the systems (45).

B. Other developments.—Another large chemical company, Mond Division of ICI, Ltd., has opted for the Kel-Chlor® process for a 330 tons per day chlorine plant to recover by-product HCl. The design of this plant will use a lower pressure version (4 atm *vs.* 15 atm) of the du Pont unit that started up in 1974. The ICI plant will use lower temperatures and proprietary brick-lined process vessels rather than the tantalum-lined equipment used earlier (49, 50).

In Japan, where solid salt resources are not available, the Agency of Industrial Science and Technology is studying a process which utilizes concentration of seawater. The brine produced by electrodialysis of seawater would be used in a diaphragm cell chlorine plant (51).

Hydrogen from a chlorine plant would supply part of the hydrogen requirements of an ammonia plant. The hydrogen will be used after purification by scrubbing (52).

A highly accurate chlorine monitor sensitive to 1 ppb chlorine has been developed by the National Bureau of Standards at Gaithersburg, Maryland. The direct readout instrument measures, in addition to chlorine, hypochlorites, and chloroamines in seawater, fresh or waste waters. The instrument is based on iodide oxidation and detection with a coulometric cell (53).

After some controversy the FDA rescinded the permit for the sale of salt from the diaphragm chlor-alkali cell process as table salt. The salt produced in the caustic concentration step was found to contain asbestos fibers and hence was not suitable for food grade use (54).

OSHA is calling for a still tighter ceiling for worker exposure to asbestos, 0.5 fibers/cm^3 time averaged over an 8 hr period. This is significantly lower than 2.0 fibers/cm^3 already on the books for compliance by July 1976, and 5.0 fibers/cm^3 in effect now. The peak exposure would also be halved under the standard (to 5 fibers/cm^3 in a 15 min period). New requirements for monitoring medical surveillance and worker training would also be set. No timetable on this change has been announced (49).

A process for purifying the diaphragm cell caustic has been developed under the sponsorship of Research

Table 2. New or expanded chlorine plants planned or under construction (5, 6)

	Producer and Location	Cell type and capacity	Status	Completion date
1.	E. I. du Pont de Nemours and Co. Corpus Christi, Texas	Diamond MDC-55 (diaphragm) 1000 tons/day	Engineering	1st Quarter 1977
2.	NL Industries, Inc. Magnesium Div. Rowley, Utah	Bayer $MgCl_2$ 80,000 tons/yr	Building	
3.	Olin Corp. McIntosh, Ala.	Hooker (diaphragm) 1000 tons/day	Engineering	1st Quarter 1978
4.	Vulcan Materials Co. Geismar, La.	Diamond MDC-55 (diaphragm) 600 tons/day	Engineering	3rd Quarter 1977
5.	BASF Wyandotte Corp. Geismar, La.	Diamond (diaphragm) modest expansion	Underway	2nd Quarter 1976
6.	BASF Wyandotte Corp. Port Edwards, Wis.	DeNora (mercury) modest expansion	Engineering	1977
7.	Dow Chemical Co. Plaquemine, La.	Dow (diaphragm) expansion 1000 tons/day	Underway	1976
8.	Dow Chemical Co. Freeport, Texas	Dow (diaphragm) expansion 2000 tons/day	Underway	1977-1979
9.	Georgia Pacific Corp. Bellingham, Wash.	DeNora (mercury) 20% expansion 103 tons/day	Underway	2nd Quarter 1976
10.	Hooker Chemical and Plastics Corp. Niagara Falls, N.Y.	Hooker H4 (diaphragm) 450 tons/day expansion	Engineering	2nd Quarter 1977
11.	Hooker Chemical and Plastics Corp. Tacoma, Wash.	Hooker (diaphragm) 400-675 ton/day expansion	Engineering	4th Quarter 1977
12.	Kaiser Aluminum and Chemical Corp. Gramercy, La.	Hooker (diaphragm) 7% expansion 37 tons/day	Underway	2nd Quarter 1976
13.	Mobay Chemical Co. Baytown, Texas	Uhde (HCl) expansion 100 tons/day	Engineering	1st Quarter 1976
14.	Pennwalt Corp. Portland, Ore.	Diamond (diaphragm) expansion 200 tons/day	Building	1st Quarter 1977
15.	PPG Industries, Inc. Lake Charles, La.	Glanor® 1144 Bipolar (diaphragm) 1500 tons/day expansion	Underway	1976
16.	Stauffer Chemical Co. Henderson, Nev.	Diamond MDC-29 (diaphragm) 320 T/D conversion	Engineering	4th Quarter 1976

and Development Corporation of Japan. Mitsui Shipbuilding will construct a 10 tons per day pilot plant. Fifty per cent diaphragm cell caustic is diluted first to 40% NaOH. According to the Secondary Refrigerant Freezing Process (SRFP), 40% NaOH is cooled to precipitate the hydrate $NaOH \cdot 3.5\ H_2O$ by direct injection of a refrigerant. The crystalline caustic soda hydrate is separated in a centrifuge and is washed to give a 39% NaOH product with 0.01% NaCl. The next phase of this work would include using the hydrate system $NaOH \cdot 2H_2O$ and a solid-solid separation system since the salt will coprecipitate with caustic soda (38, 46-48). This caustic purification process could allow production of rayon grade caustic at a price comparable to the caustic from the ion exchange membrane cells (47).

C. Mercury cells.—No new mercury cell plants were built or planned for construction in 1975 in the United States or Canada. There were a few planned expansions as detailed in Table 2. The mercury cell plant at the Reed Paper Mill Company, Dryden, Ontario, was converted over to a Hooker MX membrane cell plant. The Weyerhaeuser Company's mercury cell plant at Longview, Washington, was changed over to diaphragm cells. The recession has affected the Japanese program of conversion of mercury cell plants over to the diaphragm cells. The Japanese Ministry of International Trade and Industry has now given the industry until March 1978, for completion of the conversion program and is suggesting that the industry should convert over to membrane cells rather than diaphragm cells (38). Elsewhere in the world mercury cell plants are still being planned for construction.

New treatment techniques aim to recover heavy metals from waste waters. Du Pont has a system called "Extended Surface Electrolysis." Using flow-through sandwich type porous electrodes the system can cut contamination by as much as 90% and can recover gold, silver, mercury, and lead (55). A number of selective adsorbents have been cited in the literature last year (55). Akzo Zout Chemie is offering a mercury pollution abatement package for chlor-alkali plants (56).

EPA researchers have confirmed that inorganic mercury can be transformed into toxic methyl mercury by common agricultural plants and soils (58). That transformation was once thought to be possible only under anaerobic conditions in mud and sediments of streams and lakes (57, 58). The researchers have recommended no additional major new controls on mercury. Concern is about the increasing amounts of mercury that will be emitted into the air as coal becomes a more favored fuel (58).

Total mercury consumption in the U.S. declined in 1975 by 14% from 59,500 flasks (76 pound) to 51,100 flasks. The domestic U.S. production of primary mercury totaled 6750 flasks according to the U.S. Bureau of Mines. Secondary production increased by 30%. Imports fell 14.6% to 44,500 flasks in 1975 compared to the 1974 level of 52,100 flasks. Imported mercury came mostly from Canada, Algeria, Italy, Yugoslavia, Spain, Mexico, and Peru. The chlor-alkali producers purchased 15,223 flasks of mercury in 1975 compared to 16,813 flasks in 1974 representing a decline of about 10%. Mercury prices continued their decline throughout 1975. As the year began, the New York price ranged from $190-225 per flask and the London price from $165-185 per flask. By year end, the average price had plummeted to about $117 per flask and about $75 per flask in London. Not even the organization of the largest mercury producing nations, officially formed in April 1975, could control the downslide of mercury prices (59, 60).

Other Alkalis and Electrolytic Processes

Caustic potash.—Caustic potash production in 1975 was 196,971 short tons as 88-92% liquid which represents a decrease of 4.5% over the 1975 production total of 206,252 short tons (61). U.S. demand for caustic potash for 1975 was estimated at 185,000 tons (62).

U.S. production of marketable potassium chloride, sulfate, magnesium sulfate, and manure salts was 2.5 million tons of K_2O equivalent. Domestic U.S. production of K_2O equivalents remained the same in quantity as 1974 but increased in value by 43% to about $227 million. About 84% of the production of potassium salts came from New Mexico and the rest from Utah and California (63).

The price of potassium muriate in bulk f.o.b. Carlsbad, New Mexico, and Saskatchewan, Canada, was quoted in early 1975 at 63 to 68 cents per unit of K_2O (20 lb of K_2O); in November 1975, the price was quoted at 65 to 70 cents per unit (63). Caustic potash price in early 1975 was quoted at a U.S. price for tank car quantities of $7.50 per 100 pounds, 45% basis (62).

Mississippi Chemical, a fertilizer cooperative, acquired the Teledyne potash mine in New Mexico and returned it to production after improvements (63). A multimillion dollar expansion of this Carlsbad, New Mexico, mine is planned by Mississippi Chemical with an onstream target of mid-1976 (64).

The dispute between the Canadian potash producers in Saskatchewan and the provincial government has added another twist. A Crown Corporation, the Potash Corporation of Saskatchewan, was formed in early 1975 to act as the vehicle for the province's participation in future expansions and new potash mining ventures (63). Now, the government is trying to buy a 51% holding in the Saskatchewan potash industry. If the producers refuse, a bill introduced in the legislature, would expropriate the assets at fair market value (65, 66). This action was prompted by the failure of producers to expand the output according to the Saskatchewan governor. The potash industry did not see a favorable investment climate since the tax load is 83% on pretax earnings (65-67). Regina Duval Corporation of Canada expected the Potash Corporation of Saskatchewan (the government corporation) to make a bid to acquire its 1.5 million short tons per year mine at Duval. This would be the first offer by the province in a program aimed at acquiring at least half of the potash industry by negotiated purchase or expropriation (68).

Nippon Soda Company Limited established an ion exchange membrane process for caustic potash using du Pont's Nafion® membranes (69).

Soda ash.—Production of natural soda ash increased an estimated 2% in 1975 despite an over-all soda ash production decline of about 10% (70). Natural soda ash (trona) increased from 4.05 to 4.15 million tons while synthetic or Solvay process soda ash decreased from 3.5 to 2.9 million tons (71).

The number of synthetic plants decreased from six to four with a capacity at year end of 2.85 million tons (72). Allied Chemical closed its 800,000 ton per year plant at Baton Rouge, Louisiana, in May (73). Olin Corporation shut down its Lake Charles, Louisiana, plant in September and went out of the soda ash business. This plant had produced as much as 350,000 tons per year, but recently had been operating at 80% of this rate (74). The synthetic plants are all quite old (the most recent having been built in 1935). The reason for most synthetic plant closings is the difficulty of meeting environmental standards (75). It has been predicted that all the synthetic plants would close because of energy and environmental problems, perhaps before 1980. However, the remaining synthetic producers—Allied, BASF Wyandotte, Diamond-Shamrock, and PPG Industries—say they plan to keep operating their synthetic plants for the foreseeable future (76).

All producers of natural soda ash in Wyoming and California were in the process of increasing production. The present capacity for natural soda ash production is 6.4 million tons. By 1977 the capacity of plants for which increases have been announced will be 8.75 million tons per year (72).

The current consumption of soda ash, which closely matches production, is distributed 51% to glass manufacture, 22% to chemicals, and small percentages to pulp and paper, soaps and detergents, water treatment, and other uses (72). Soda ash net exports were up from 6 to 7% (70).

Average prices of soda ash rose 20% in 1975 (70). Transportation costs are the main factor in the pricing differential between the eastern synthetic product and western trona. Producers of trona increased their price from $38 to $42 per ton on January 1, 1975 (75). In December, Allied Chemical raised bulk prices from $40 to $49 per net ton f.o.b. Green River, Wyoming, and from $59 to $71 per net ton f.o.b. Syracuse, New York (78). PPG increased the bulk price from $60 to $67 per ton (79).

In Western Europe, synthetic soda ash staged a mild comeback, taking back some of the market lost to electrolytically produced caustic soda. Local caustic soda manufacturers had reduced production because of weakness in chlorine. There are no known natural deposits of any size on the continent. Belgian Solvay is now considering making as yet unspecified investments in synthetic soda ash capacity (80).

Potential supplies of soda ash as a by-product of oil shale processing could affect the U.S. market once recovery of oil from shale reaches commercial scale (75). Use in stack gas scrubbing for removal of sulfur dioxide has the potential for becoming a major new market for soda ash (76).

Sodium chlorate.—According to the U.S. Department of Commerce data, the sodium chlorate production in the United States in 1975 amounted to 167,700 short tons (81). Estimated U.S. demand for sodium chlorate was 200,000 tons (production plus imports) (82). By 1979 the U.S. sodium chlorate demand is estimated to be 260,000 tons and growth per year for this commodity through 1979 is reported to be 3% per year. Canadian sodium chlorate production and consumption for 1975 was estimated at 140,000-150,000 tons (83).

In early 1975, the bulk price for sodium chlorate was raised to $215 per ton for the dry material (84). In mid-year, sodium chlorate on the same basis was quoted at $220-$225 per ton (82, 85) and toward the end of the year the prices were raised to $250 per ton (86).

Erco Industries, a division of Albright and Wilson Limited, started a 9000 tons per year sodium chlorate expansion at its plant in North Vancouver, Canada (87). At the same location Erco Industries will add another 10,000 tons per year capacity to come on stream in early 1977 (83). This expansion in Western Canada is coupled with a similar move by the company's chlorate plant in Buckingham, Quebec, where an expansion of 12,000 tons per year sodium chlorate is also scheduled for start up in early 1977. At that time the total production in the two plants should reach 110,000-120,000 tons per year (83).

Dow Chemical of Canada Limited is planning to build a sodium chlorate plant with an initial capacity of 30,000 tons per year expandable to 50,000 tons per year at Thunder Bay, Ontario, Canada. Completion is planned for late 1977 at a cost of $13 million (88, 89).

A sodium chlorate cell adaptable to input load variation, higher level of brine impurities, quick start ups and shutdowns is available from Diamond Shamrock Corporation. The compact unit is particularly suited for sodium chlorate needs of a pulp mill (90).

Squamish Chemicals, Limited has sold its sodium chlorate plant at Squamish, British Columbia, Canada, to Hooker Chemicals (Nanaimo) Limited a subsidiary of Canadian Occidental Petroleum, Limited. The plant has a capacity of 10,000 tons per year (91).

Aluminum.—U.S. production of primary aluminum reached 3,879,000 short tons in 1975, representing a substantial drop of 21%, compared to the record 1974 production of 4,903,000 tons. The total U.S. aluminum supply also fell 23% to 5.6 million tons in 1975, almost 1.7 million tons below the record 1974 supply. Withdrawals from the government stockpile were only 2,000 tons in 1975 compared to 500,000 tons of the stockpile material sold in 1974. Secondary aluminum recovery in the U.S. totaled 1,182,000 tons in 1975 down only 6% from 1974, according to the Bureau of Mines estimates (92, 94). The aluminum can recycling program of the aluminum industry has started to pay off. In 1975, 82,500 tons of aluminum were recovered from this source, and it represents a significant increase over that of 51,500 tons in 1974 (92).

In the aluminum industry the brunt of the production cutbacks was borne by the primary aluminum producers in the recession year 1975. The demand for aluminum started easing in late 1974 which resulted in producers cutting back the primary aluminum production rates. In March 1975, the operating rate dropped to 83% and by July to a low of 73%. A small pick-up in November brought the rate to 75% where it remained for the remainder of the year (92, 93).

U.S. primary aluminum imports fell by 75,000 tons in 1975 to 434,000 tons which was the lowest level since the 1970 recession. Due to the decreased world demand, U.S. exports of crude and semicrude primary aluminum decreased by 50% during the year. China purchased almost 90,000 tons of aluminum from U.S. producers helping the U.S. export situation, otherwise the net import balance which was 80,000 tons in 1975 would have been even greater (92).

The shortage of aluminum ended in late 1974 shortly after decontrol of aluminum prices, and aluminum was usually available below the published list prices. Markets for aluminum remain in end use areas of building and construction, containers and packaging, transportation, electrical, consumer durables, machinery and equipment, and exports. For all 1975, shipments totaled 4.95 million tons down 27% from the 1974 total of 6.81 million tons. The largest reductions in the aluminum end use markets compared to 1974 were in electrical uses including conductors, consumer durables and machinery, and equipment. The smallest reduction in shipments was in the containers and packaging area (92). By the 1977 model year the usage of aluminum will jump to 100 pounds per car making the transportation sector a significant market for aluminum, according to the Aluminum Association (95).

The U.S. domestic list price of primary aluminum ingot remained at 39 cents per pound until August when major producers increased the price to 41 cents per pound where it remained for the rest of the year. However, due to the supply-demand of 1975, producers discounted the published price during the last quarter to the 34-36 cents per pound range to encourage demand (92, 93).

Free world primary aluminum production declined 11% in 1975, compared to that of 1974, to a total 10,685,000 tons, U.S. plants accounting for much of this decline (92).

The production of bauxite in the United States declined from 2.18 million tons in 1974 to about 2.01 million tons in 1975. Total imports of dried and calcined bauxite into the United States, reflecting the aluminum production cutbacks, decreased 20% to an estimated 14.2 million tons. Jamaica, Surinam, and Guinea were the principal bauxite suppliers. Alumina imports declined slightly in 1975 to about 3.5 million short tons. Australia supplied 60% of the total alumina imported with Jamaica and Surinam providing most of the remainder. Exports of alumina from the United States increased to over 1 million tons (92, 93).

Free world alumina production fell 10% in 1975 to an estimated 24.3 million tons. The International Bauxite Association (IBA) formed in 1974 has now 11 members: Australia, Dominican Republic, Ghana, Guinea, Guyana, Haiti, Indonesia, Jamaica, Sierra Leone, Surinam, and Yugoslavia. These countries produce over 75% of the world's bauxite. Australia is the largest producer with 25% capacity followed by Jamaica with 19% of production capacity. IBA did not conclude an agreement on a uniform pricing formula for bauxite (92).

Jamaica negotiated the principles of an agreement with Reynolds Metals Company along the lines of the agreement reached with Kaiser Aluminum and Chemicals Company. The companies will sell 51% of their mining operations and land to the Jamaican government (96). Lower taxes will be levied if expansions are financed by the companies. Revere was also near a

similar agreement with the Jamaican government; however, its operations there were shut down in August 1975. Revere's capacity expansions in Jamaica were postponed due to the recession in 1975 (92, 96).

Throughout the world, a number of new and expansion projects for bauxite and alumina have been delayed in 1975. Agreements with local governments were reached by a number of aluminum producers for payment of special levies on ore in terms of a percent of the realized base price for aluminum ingot (92).

The Trombetas project in Brazil is progressing with bauxite production of 3.25 million tons per year (92). After the Brazilian government made some adjustments, the joint Japan-Brazil project is on again. An initial eight month feasibility study is planned for a 352,000 tons per year aluminum smelter in Belem in the state of Para (97). Another aluminum project with hydroelectric power may be in the making on the Brazil-Paraguay border (97, 98).

Australian authorities have given consent to a feasibility study for constructing a large aluminum smelter 600,000 tons per year on the Purari River in Papua, New Guinea. The study sponsored by Papua, New Guinea, Japan, and Australia will include a hydroelectric power plant (99).

Japanese producers signed an agreement with the Indonesian government for the Asahan hydroelectric project and aluminum project. It will consist of a 247,500 tons per year aluminum smelter on the Indonesian island of Sumatra with start up in 1981 (100).

The Bureau of Mines and ten companies are continuing a research project to recover alumina from domestic nonbauxite ores. A nitric acid leach process using kaolinitic clay was tried for one week. Hydrochloric acid leaching of clay was tested in late 1975 and a mini pilot plant is under construction (92, 93).

According to the Bureau of Mines, Colorado oil shale could prove an important source of alumina. Heat energy from the oil shale is adequate for power needs and would also yield large amounts of soda ash (101).

A 24 ton per day pilot plant to make alumina in which Southwire has a 40% interest has started using Russian knowhow after the Golden, Colorado, facility ran into trouble with the U.S. technology. Southwire assumed sole U.S. rights to sell Soviet aluminum, copper, iron, and steel processes (102).

Ash from a coal-fired 2000 MW power station in the Hot Creek area of British Columbia could provide an important source of alumina. Ash output from the power plant is expected to total 3 million tons per year containing 27-33% alumina. On the basis of 28% average alumina content the ash could yield 840,000 tons per year alumina (103).

Aluminum producers are grooming new production methods. Alcoa's new aluminum chloride process that challenges the conventional Hall process will slice electrical energy requirements to 9 MW-hr per ton and over-all lower operating costs. The other feature of the process is that it can tolerate considerable load variations. The production using this process with initial capacity of 30,000 tons per year will start up in early 1976. Alcoa will also produce more than 100,000 tons per year of aluminum chloride at the Palestine, Texas facility (104, 105). Japan Electrochemistry Association also wants to build a 15,000 tons per year pilot plant based on the aluminum chloride process developed by them (106).

Sumitomo Chemical has begun commissioning its newest aluminum plant at Toyo City on Shikoku Island in Japan. Initial capacity would be 100,000 tons per year in this plant which uses 13.5 MW-hr of electrical energy per ton of aluminum representing an energy saving of 1.5 to 2 MW-hr per ton. The process deals with more stable linings around the anodes with more stable electrode surfaces and closer electrode spacing. The cells will have a longer life of 6 years, two times the life for conventional cells. Kaiser also has a similar process (105, 107).

Tel Aviv University's researchers have developed an inexpensive aluminum electroplating method using $AlBr_3$ + KBr in aromatic hydrocarbons. The coatings are claimed to be smooth homogeneous and ductile and cost about the same as zinc electroplating (108).

Beryllium.—Data on production of beryllium metal and products are not published; however, both Kawecki Berylco Industries Incorporated (KBI) and Brush Wellman Incorporated experienced declines in beryllium product sales in 1975 (109). These companies are the only substantial producers of beryllium metal in the free world. Brush extracts beryllium from bertrandite ores [$Be_4Si_2O_7(OH)_2$] mined in Utah. KBI relies mainly on imported beryl ores.

Battelle Columbus Laboratories estimates the average consumption of beryllium in the U.S. during 1973-1975 to have been 260 tons per year (109). Of this 66-75% is used as beryllium-copper alloys, 19-25% as beryllium metal, and 6-8% as beryllium oxide. Use of beryllium was about evenly divided between electronic and electric, aerospace and mechanical, and other applications. Beryllium-copper alloys containing 0.5-2.0% beryllium have high hardness and strength after heat-treating and excellent thermal conductivity. They are used in electrical connectors, springs, bellows, clips, sensing mechanisms for seatbelts, injection molds for plastics, and nonsparking tools.

Beryllium metal is used primarily in the aerospace industry where its low density is important and for nuclear applications. Beryllium oxide is used in electronics because of its unique combination of high thermal conductivity and low electrical conductivity (110). Prices for beryllium metal, quoted as 5 in. rod, rose from $135 to $155 per pound during 1975 (111, 112). The price of imported beryl (10-12% BeO) remained steady at $30 per short ton.

The over-all production and consumption of beryllium ores was significantly lower in 1975 than in 1974 (113). No domestic beryl production was reported. An estimated 1550 tons of beryl was imported during 1975, primarily from Brazil, which accounted for 41% of imports, followed by the Republic of South Africa and Uganda. This continues the decline from the peak importation of 6422 tons in 1969 (110).

Exports of beryllium metal and alloys exceeded $1 million by the end of October, approximately the same as in 1974. The export destinations were the United Kingdom, Canada, Japan, and France (109).

As of November 30, 1975, government stockpile inventories contained 17,986 tons of beryl (11% BeO), 7,397 tons of beryllium-copper master alloy (containing about 4% beryllium) and 229 tons of beryllium metal. The stockpile objectives for both beryl and the master alloy are zero and for beryllium metal 88 tons. Although each commodity exists in surplus, the holdings have not changed in the past two years (113).

In October the U. S. Department of Labor proposed new standards which, if adopted, would reduce worker exposure to beryllium by one-half (113).

Chromium.—In 1975, as in earlier years, the United States continued to rely on imports. The imports were received mostly from South Africa, Japan, Rhodesia, U.S.S.R., the Philippines, and Turkey. Domestic production of chromite was last reported in 1961 (114, 115). Domestic consumption of chromite was 870,000 short tons in 1975, 40% lower than the 1974 level of 1,446,000 short tons, as all the three consuming industries recorded an off year. The consumption in the metallurgical industry was down 41%, in the refractory industry it was off 39%, and in the chemical industry it fell 34%. Production of chromium alloys in 1975 decreased by 42% compared to that in 1974 (114, 115).

Although consumption of chromite decreased because of slackening demand, imports of chromite in 1975 totaled 1.25 million tons, a 13% increase over that of 1974. Owing to the low demand, stocks in the consuming industries increased 74%. Ferrochromium imports in 1975 were the highest in history at 318,823 tons nearly doubling imports of 1974 (114, 115). No material from the government stockpile was available during the year because congressional legislation is

required for further stockpile disposal of chromium material (114).

Demand for chromium alloys fell substantially as stainless steel production in 1975 dropped nearly 50%. Both producer and consumer inventories of chromium alloys swelled during the year due to the large influx of imported ferrochromium and the economic recession (114, 115).

Published chromite prices rose despite the weak chromium demand. With the possibility of a new ban on the U.S. imports of chromite from southern Rhodesia, Russian and Turkish suppliers boosted their prices to almost three times the early 1974 levels. The year end price for Russian chromite (48% Cr_2O_3) was \$136 per ton. The Turkish chromite prices ranged from \$118 to \$127 per ton. The South African Transvaal chromite ranged from \$33 to \$46 per ton. South African and Phillippines suppliers were attempting to boost the prices of new contracts (114, 116).

Due to the increased ore costs despite the lower demand levels ferrochrome producers were forced to raise their prices. Low carbon ferrochrome prices were in the range \$0.92-\$1.20 per lb and the charge chrome (66-70% Cr) quotes ranged from \$0.48 to \$0.57 per pound (116).

Expectations in early 1975 were that the new Congress would repeal the 1971 Byrd amendment to the Military Procurement Authorization Act. Under the Byrd amendment, which states that if the U.S. imports a strategic material from a communist country it may not refuse it from a noncommunist country, the Southern Rhodesian chromite imports were permitted. In September, the repeal of the Byrd Amendment was defeated in the Congress by 209-187 vote (114, 116).

A number of new world chromium supply developments are continuing. African Metals plans start up of two plants producing a total of 220,000 tons per year of chrome-containing pellets in South Africa. Tubatsi Ferrochrome, a joint venture of Union Carbide and South Africa's General Mining, expects the start up of a 132,000 tons per year ferrochrome at Steelport, South Africa, in late 1976. Johannesburg Consolidated Investments is planning a 132,000 tons per year ferrochrome operation to start in late 1977. Turkey's state-owned Etibank will start a 55,000 tons per year ferrochrome plant in 1976 (116).

Millions of pounds of chromium, nickel, and molybdenum that go to waste each year during stainless steel production can be converted into a recyclable alloy by an experimental recovery process that is developed by the U.S. Bureau of Mines (117).

A new commercial chromium plating process based on trivalent chromium has been developed by Albright and Wilson Limited, of England. The system has a number of advantages over the hexavalent chromium baths. It is applicable over a wide range of current densities providing more uniform decorative deposits, at rates of 3-5 microinches/min at 100 ASF. The absence of toxic spray, improved throwing power and coverage, haze-free deposits and generation of microcracks and micropores in the coating without other additives and lower chromium concentrations in the bath are the other claimed benefits (118).

Copper.—The U. S. mine, smelter, and refinery outputs, consumption of copper, and net imports of unmanufactured copper were all substantially lower in 1975 than in 1974 (119). Supply exceeded consumption with a resultant buildup of refined copper stocks and price reduction during the year.

Production from primary materials was estimated at 1.40 million tons at smelters and 1.50 million tons at refineries, reductions of 7 and 9%, respectively, from 1974. Production of refined copper from scrap was approximately 345,000 tons compared to 497,000 tons in 1974.

While there were some production starts, the more general trend was toward trimming production schedules.

Asarco, Incorporated was scheduled to bring on stream in late 1975 or early 1976 an electrolytic refinery near Amarillo, Texas, which is to be one of the world's largest. The plant has a design capacity of 420,000 tons per year of refined copper (120).

The Lakeshore copper mine of Hecla Mining Company is coming into production. The complex is located 30 miles south of Casa Grande, Arizona. Production of sulfide and oxide ores began in September and October; full production is estimated to require an additional 6 months. The complex is designed to produce 9,000 tons per day of sulfide ore and 6,000 tons per day of oxide ore which will be treated to produce 30,000 tons per year of electrowon cathodes from the sulfide ore and 55,000 tons per year of precipitate, containing 65% copper, from the oxide ore. Total project cost, including working capital, was estimated at \$185 million early in 1975. The Lakeshore deposit is reported to contain more than 500 million tons of ores (121, 122).

Production was slated to begin in the final quarter of 1975 at the new solvent extraction electrowinning plant of Anamax Mining Company at Twin Buttes, Arizona, treating low-grade oxide ores. Construction of the \$100 million plant is a joint venture between the Anaconda Company and Amax, Incorporated (123).

Anaconda Company announced the closing of its 77 year old Raritan Copper Works in Perth Amboy, New Jersey. The plant had been Anaconda's main processor of copper from the company's properties in Chile. Copper cathode production at the plant last year totaled 113,000 tons (124). Lack of feed material, high inventories, and low prices forced the shutdown.

Anaconda Company temporarily shut down its Arbiter process plant at Anaconda, Montana, in July citing faltering prices and mechanical difficulties (125). The \$20 million plant, which went on line in September 1974, had a capacity of 36,000 tons per year of copper cathodes. The process employs an ammoniacal leach on sulfide ores and employs new technology aimed at more efficient flexible metal recovery without air pollution (126).

United States and foreign copper producers, both mine operators and smelters, began wholesale production cutbacks in December 1974 (127). These generally ranged from 10 to 20% and persisted throughout 1975 (128).

The decline in demand for copper was a reflection of general economic conditions, particularly in the large copper-consuming areas of automobiles, home construction, and utility construction. (119).

Consumption of refined copper was projected to be only 1.5 million tons, a 32% drop from 1974 and the smallest annual consumption since 1961.

The 68 cents per pound base cathode price posted December 27, 1974, was reduced again to 63 cents per pound on January 23, 1975 by major manufacturers. The U.S. market price was not strengthened by the gap, well over the usual 5 cents per pound which existed between the U.S. producer and London Metal Exchange prices (129).

Two U.S. producers lowered prices by 3 cents per pound in June (131). This was not followed by other producers and for a while there were as many as four different prices for cathode and five different prices for wirebar (132). This price cut was rescinded by the end of July. There was some enthusiasm in the market when the price on the London Metal Exchange surged to over 58 cents per pound (133). The large (world) refined copper stocks, above 1.1 million tons, and the failure of the market demand to pick up left the market in the doldrums. The year closed with the U.S. price at 63 cents per pound and the London Metal Exchange at 53-54 cents per pound. The consensus is that a significant turnaround for copper will not occur until the second quarter of 1976 (134).

Stocks of refined copper at primary producers built up rapidly from 101,000 tons at the start of the year to 225,000 tons by the end of June, then declined to 189,000 tons by the end of October. Stocks of refined copper at brass plants and wire mills were 145,000 tons at the

start of the year, peaked at 163,000 tons in March, and declined to 133,000 tons by the end of September (119). Worldwide stocks of refined copper reached 1.41 million tons which is considered to be twice the desirable level (134).

Net importation of copper is a small component of supply compared to the U.S. production. Importation of unmanufactured copper was estimated at 270,000 tons compared to 609,000 tons in 1974 while exports increased from 198,000 tons to 240,000 tons (119). There was a net exportation of refined copper as imports plunged from 340,000 tons to 85,000 tons while exports increased from 127,000 tons to 170,000 tons. Imports of blister copper dropped from 208,000 tons to 95,000 tons (119).

The attempts of the Council of Copper Exporting Countries (CIPEC) to bolster sagging prices were largely ineffective. The group, whose members, Chile, Peru, Zaire, and Zambia, have been providing approximately 37% of the free world copper mine production, agreed to cut copper exports by 10% in December 1974, and to extend the cutback to 15% in April 1975 (135).

U.S. mine production during 1975 was 1.40 million tons, 11% less than 1974 and the smallest quantity since strike-disrupted 1968. Principal copper producing states were Arizona, with 57% of the total, followed by Utah, New Mexico, Montana, Nevada, and Michigan. The weak demand and increased costs of production led to permanent closure of several underground operations, cutbacks or temporary closures at other operating properties, and a slowdown of several new developments (119).

Duval Corporation announced a substantial production cutback in February and a further cutback in September at the Mineral Park open-pit property near Kingman, Arizona. This property produced 20,000 tons of copper in 1974 (138).

A major closing announced in November to take place over a period of months affected Anaconda Company's Butte, Montana, underground mines. Lack of profitability over several years and the desire to preserve the potential of large low-grade ore zones under Butte Hill for future large-scale underground development were the reasons given for the decision (139).

Phelps Dodge reduced operating schedules at mines in Metcalf, Morenci, and Ajo, Arizona, and Tyrone, New Mexico, from 5½ days to 5 days a week. These facilities account for 97% of the company's mining output (140).

Underground mining at Phelps Dodge Corporation's Copper Queen branch at Brisbee, Arizona, was scheduled to end in June. The mines, operated since 1880, accounted for 15,000 tons of the company's total copper production of over 280,000 tons in 1974 (141).

Phelps Dodge also halted exploration at the historic Shattuck Mine in Brisbee. This decision was due to "a combination of the poor copper market and the need to conserve cash for essential expenditures, such as the Hidalgo Smelter." Company officials indicated that exploration work would be resumed someday (142).

In Canada, copper mine production for 1975 was estimated at 821,000 tons of copper in concentrate compared to 933,000 tons for 1974. Production of blister copper dropped from 602,000 tons of copper to an estimated 567,000 tons. The combination of massive tax increases and depressed metal prices has wiped out most of Canada's major mine development plans. Nearly 300,000 tons per year of new mine capacity in the development stage, all in British Columbia, has been shelved (143).

A production cut from 825,000 to 550,000 tons per year scheduled for early in October was announced for the Cobar Mine by Australia's Broken Hill South. The Port Kembla Smelter of Electrolyte Refining and Smelting Company of Australia, Limited, which treats all of Cobar's concentrates was expected to announce a similar cutback. However, Australia's two largest copper mining companies. Mount Isa Mines and Mount Lyell Mining and Railway both stated that they had no plans to decrease production (144).

Cities Service Company's Pinto Valley deep pit mine west of Miami, Arizona, is estimated to contain some 350 million tons of ore averaging 0.44% sulfide copper. The mine and mill, begun ahead of schedule in June 1974, has a design capacity of 40,000 tons per day and will recover more than 60,000 tons per year of copper. A solvent extraction electrowinning plant is under construction to be completed in mid 1976. (145).

Continental Copper is evaluating plans for a new 2000 tons per day underground mine and mill on Marble Peak near Tucson, Arizona. Continental currently estimates indicated and inferred reserves to be 12 million tons with an average of 2.2% copper. For an initial production rate of 2000 tons per day the capital cost is expected to be appreciably greater than the $8-10 million projected in 1973. Testing indicated that the mill will recover 90% of the metal values in a concentrate of 30% copper with some silver (146).

A $200 million expansion is underway at Cyprus Mines Corporation's Baghdad Mine west of Prescott, Arizona. The present 6000 tons per day concentrator will be replaced by a 40,000 tons per day system. Start up is scheduled for late in 1977 (147).

The Anaconda Company continues with its Carr Fork project in Utah. This project involves a major underground mine and a 10,000 tons per day concentrating complex. Operation of the $135 million complex is scheduled for 1979 (148).

Utah Copper Division of Kennecott Copper Corporation is having difficulties with the Environmental Protection Agency over its Garfield, Utah, smelter (149).

A $152 million complex at Khatri in Rajasthan, India, was formally opened in February. The complex includes an electrolytic refinery with a capacity of 34,000 tons, a smelter, a concentrator, and two mines. Ore reserves are estimated at 52 million tons, containing 0.72% copper at Khatri and 32 million tons of 1.56% copper at Kalihan (150).

A spokesman for Liard Copper Mines announced that drilling results at the Shaft Creek deposit in British Columbia "support a new geological concept which strongly suggests that the presently stated reserve of 300 million tons may eventually be doubled" (151).

A major copper find may be in the making in northwestern Quebec and eastern Ontario. Over 7000 claims have been filed (152).

Texasgulf, Incorporated announced that its new smelter to be built at Timmins, Ontario, will incorporate a continuous smelting process developed by Mitsubishi Metal Corporation and electrolytic refining technology used for several years by the Onahama Smelting and Refining Corporation. The company hopes to have the 130,000 tons per year, $200 million smelter and refinery on stream by 1976 (153, 154).

In a surprise move during February, Secretary of the Interior, Rogers C. B. Morton, proposed issuing permits for manganese nodule mining to U.S. companies if the United Nations fails to agree on a Law of the Sea Treaty by January 31, 1976. This move would particularly displease the developing nations who fear for the loss of any possible participation in this resource and in some cases fear loss of markets for copper, nickel, cobalt, and manganese. An excellent review of the political, economic, and technical situation is contained in Ref. (155).

A variety of advanced technologies are presently employed in working plants, being tested on pilot scale, or are under active research and development.

Solvent ion exchange is used in a small number of operating plants with a total capacity of 175,000 tons per year of cathodes, and is planned or under consideration for others. This process, pioneered at the Ranchers Exploration and Development Plant in Miami, Arizona, is highly versatile for purifying leach liquors and concentrating metal values (156).

An increased usage of titanium starter sheets in copper refineries has occurred (156). Among the advantages cited for titanium are that the oxide film on the titanium acts as an excellent parting agent and that

less distortion is observed during the start of the plating cycle.

Mechanized stripping of starter sheets, using both copper and titanium blanks, has been employed in the Pori Copper Refinery of Finland's Outokumpu Oy since 1974 (122).

At plants near Tucson, Arizona, Duval Corporation and Cyprus Mines Corporation are each testing a ferric chloride leach process. Duval operated a pilot plant for 2 years and is now building a 32,500 tons per year plant. Cyprus Mines Corporation is operating a pilot plant producing 7 tons per day of copper powder (157).

The electric furnace has been gaining a bigger role in the U.S. copper industry for smelting copper concentrates. In 1972, Cities Service installed the first electric smelting furnace in recent years. Inspiration Consolidated Copper has just completed a $54 million smelter, and the Anaconda Company is presently installing an electric furnace in its smelter in Anaconda, Montana (158).

The top blown rotary converter, developed by The International Nickel Company and Dravo Corporation, based on oxygen steel-making technology is now in use for smelting nickel concentrates at Copper Cliff, Ontario, and has been demonstrated in full scale tests on copper concentrates. The converter can produce high SO_2 exhaust gases to facilitate sulfur removal or recovery (158).

A commercial Noranda process continuous smelter came on stream at Noranda, Quebec, in March 1973, at a design capacity of 800 tons per day of copper concentrate. Kennecott Copper Corporation is installing this process at its Garfield, Utah, smelter (158).

Kennecott Copper Corporation has been experimenting with a solution mining process at its copper deposit 9 miles north of Safford, Arizona. The wells at Safford go as deep as 5000 feet and, if successful, the system could recover low grade ores that would not be economically accessible by conventional open pit or underground methods (159). Kennecott has not permanently shelved the possibility of using a nuclear blast to establish an underground leaching cavity.

Chile will test an electrolytic process to recover copper and make phosphoric acid as a by-product. The process apparently involves the reduction of copper sulfate solution with white phosphorus to obtain pure electrolytic copper. Codelco, the state copper corporation, is providing financial backing for a pilot plant (160).

Research by the Bureau of Mines suggests that sulfur in copper sulfide concentrates can be converted to insoluble anhydrite ($CaSO_4$) by roasting with lime. The calcine is then leached with HCl to take metal values into solution. An alternative process uses a ferric chloride leach to precipitate elemental sulfur (161).

Several techniques are under development to raise the current density limits above the 15-20 A/ft^2 typically observed. Successful techniques have included periodic current reversal, rapid flow of electrolyte over electrode surfaces, air agitation, high frequency sound, and use of a rotating-drum cathode (162).

Lithium.—In 1975 lithium chemicals were produced by Foote Mineral Company Lithium Corporation of America, and Kerr-McGee Corporation. At the Kings Mountain, North Carolina, mine Foote Mineral Company extracted spodumene ore to be processed into ceramic or chemical-grade spodumene concentrate. At the Silver Peak, Nevada, location Foote Mineral produced lithium carbonate from the lithium-bearing underground brine deposits. The Foote Mineral plant at Silver Peak, Nevada, is rated at 14 million pounds per year of Li_2CO_3 equivalent. Lithium Corporation of America produces a variety of lithium chemicals at its Bessemer City, North Carolina, plant which is rated at 27 million pounds per year Li_2CO_3 equivalent. At Searles Lake, California, Kerr-McGee Chemical Corporation reportedly has an annual capacity of 1 million pounds of lithium carbonate as a by-product (163, 164). In 1975 the General Services Administration sold 161 tons of lithium hydroxide monohydrate on the open market (163).

Demand for lithium products was strong until April 1975, when inventory accumulation was halted and the demand fell in response to the economic recession during the rest of the year. The largest application for lithium carbonate in the aluminum industry declined significantly since the aluminum production decreased 21% in 1975. The dramatic growth in lithium chemical usage during the 1972-1974 period did not continue through 1975 (164). Other major uses for lithium chemicals were in the manufacture of heavy duty greases, glass, ceramics, brazing fluxes, batteries, and for absorption air conditioning equipment. The ceramic industry is the second largest user of lithium ores and chemicals in applications where low thermal expansion characteristics of lithium-aluminum-silicate are required (163, 164). According to U.S. Geological Survey, conventional uses could consume currently recoverable resources by 2000 leaving nothing for the applications in the area of thermonuclear power unless new deposits are found and developed (165). There is also potential for use of lithium as the heat transfer medium in a fusion reactor (164).

In early 1975, the prices of lithium compounds were quoted at: lithium hydroxide monohydrate at $1.02 per pound, lithium fluoride at $2.22 per pound, lithium chloride at $1.47 per pound, and lithium metal ingots at $10.65 per pound (166). In November 1975, lithium chemical prices were: lithium hydroxide monohydrate $1.10 per pound, lithium carbonate at $0.84 per pound, lithium fluoride at $2.42 per pound, lithium bromide at $1.86 per pound, lithium chloride at $1.26 per pound, and the lithium metal ingots at $11.10 per pound (167).

Estimated U.S. consumption in 1975 fell to 28 million pounds of lithium carbonate equivalent from the 1974 level of 32 million pounds. The world consumption of Li_2CO_3 equivalent in 1975 was estimated at 48 million pounds and decreased from the 1974 level of 53.4 million pounds (164).

The Corporation of Development in Chile and the Foote Mineral Company announced the formation of a company to explore lithium deposits at Salar de Atacama near Antofagasta, Chile. Exploration continued in 1975 at the deposits which are similar to those at Silver Peak, Nevada (164).

The battery development using solid lithium alloy negative electrodes, iron sulfide positive electrodes, and LiCl-KCl molten electrolyte is continuing, particularly for the peak power demand in power plants. Argonne National Laboratories is working on increasing the life of the battery from five months to eight years (165, 168). If these batteries are developed, they are being groomed for the automotive applications also (168).

Magnesium.—Magnesium metal is produced in the United States by Dow Chemical Company, Freeport, Texas; American Magnesium Company, Snyder, Texas; and NL Industries, Inc., Rowley, Utah (169). Domestic production during 1975 was estimated to be 125,000 tons (170).

Both the American Magnesium Company and the NL Industries facilities employ an advanced technique using dehydrated brine for electrolyte feedstock which permits simultaneous manufacture of chlorine as a by-product. Neither plant is in full production (171). The former plant suffers from ecological problems. Although the latter plant was announced to be operating in May at a rate of 13,000 tons per year out of a capacity of 45,000 tons per year (172), the company subsequently announced suspension of production because of technical problems until late in 1976 at the least (170, 173).

The principal use for magnesium, about 45% of consumption, has been in aluminum-based alloys much of which is used for aluminum can tops. About 35% of world consumption is for structural magnesium and 20% is used for chemical, electrochemical, and metallurgical processing (171). The price of magnesium, relative to that of aluminum, is too high to permit much

penetration into the structural market (171). The price is high enough, however, to attract capital into new magnesium production facilities, which is not the case with aluminum. It has been suggested that if the price of aluminum rises sufficiently to provide a reasonable return on investment in new aluminum production facilities, the structural market should develop for magnesium (170).

In contrast to the rising trend of the last three years, magnesium prices remainded steady during 1975 at 82 cents per pound, quoted as primary ingot (174, 175).

During the period January to September, 5,214 tons of magnesium metal were imported, and 20,103 tons were exported (169). The major foreign producer is Norsk Hydro, Heroya, Norway. Together with other western European and Japanese producers, the total foreign production was estimated to be 70,000 tons (171).

Several new plants are under construction or have been announced. Northwest Alloys, Incorporated, a subsidiary of the Aluminum Company of America, is reported to be bringing its 26,000 tons per year plant at Addy, Washington, on stream in 1976. This plant is to use the French Magnetherm® process which is based on thermal reduction of dolomite with ferrosilicon. If the start up is successful, magnesium production in the western hemisphere might reach 155,000 tons per year late in 1976, a figure which includes the 5,500 tons per year capacity of Chromasco, the Canadian producer (170).

Dow Chemical has plans for a 50,000 tons per year plant to go on stream by 1978 or 1979. Abroad, Norsk Hydro has announced plans to erect a 16,500 tons per year plant at Heroya, Norway, to develop a new process before proceeding to a 55,000 tons per year plant in the early 1980's (171). The Scalistiri Group is reported to be planning a 120,000 tons per year plant on the Greek island of Euboea starting in 1978 (176).

Manganese.—According to the U.S. Bureau of Mines there was no 1975 U.S. production of manganese ore, concentrate, or nodules containing 35% or more manganese. The production of ferruginous manganese ore concentrates containing 10-35% Mn was continued in New Mexico and the Cuyuna range in Minnesota, although at a reduced rate. Most of the manganese requirements were met by imports and sales from the government stockpile (177).

U.S. production of ferromanganese (high carbon, medium and low carbon grades) amounted to 607,700 short tons in 1975. The ferromanganese stocks in 1975 reached all-time highs. Silicomanganese production was 222,772 tons and 22,114 tons of manganese metal were produced (178, 179).

The price for U.S. produced standard (minimum 78% Mn content) high carbon ferromanganese held at $393 per ton in early 1975. Imported standard high carbon ferromanganese prices slid steadily from $402-$411 per ton at the start of 1975 to $348-$370 per ton in late 1975. Cutbacks in steel production at home and abroad and consumers drawing on their inventories were factors contributing to lower prices. Imported medium carbon ferromanganese prices dropped by 2-5 cents to $0.43-$0.455 per pound in the first half of 1975 and then dropped further to $0.38-$0.44 per pound in late December 1975. Electrolytic manganese metal held at $0.54 per pound in most of 1975 but drastic production cutbacks were necessary to maintain this price level (177, 179).

Cumulative sales of government stockpile excesses in 1975 by the General Services Administration were: natural battery ore 43,700 short tons; 18,000 short tons of type B chemical ore; and metallurgical ore, 63,826 short tons of stockpile grade and 409,991 short tons of nonstockpile grade (177). In 1975 manganese ore imports returned to traditional levels after domestic producers restarted some blast furnace ferromanganese production. Imports of the manganese ore in 1975 amounted to 1,574,045 short tons compared to the 1974 total of 1,188,145 short tons (178). U.S. imports of ferromanganese in 1975 amounted to 406,922 short tons with 313,936 short tons of Mn content. The manganese ore imports in terms of Mn content were from Brazil, Gabon, South Africa, Australia, Mexico, and Zaire in decreasing order of supply. Major ferromanganese supplying countries were France, South Africa, Japan, and Norway (178).

World 1975 manganese ore production was estimated at about 24,420,000 tons (gross weight) (179). An exploration success was scored at Morro de Sete Lagoas in Uapes district in Brazil near the Venezuelan border with samples running at 47.5% Mn. Deposits of 25-30 million tons of 47-51% Mn are claimed for the find (179).

When the Trans-Gabon Railway will be completed in the 1980's it will be possible to double production of the Comilog mine to 4 million tons per year (177, 179).

The Indian state mining company, Mysore Minerals, expects to develop iron manganese deposits in Karnataka where about 1.1 million short tons of manganese mineralization has been found in association with iron ore (179).

A five nation 14 company consortium plans to develop the Tambao mine in Upper Volta by investing $24 million. Production is slated for 1980 at 625,000 tons per year (177, 179).

Union Carbide is discussing with the U.S.S.R. a possible manganese complex at Nikopol with 1.2 million tons per year ferromanganese plant (179).

Australia's Broken Hill Pty. held discussions on a possible Saudi Arabian ferromanganese plant in cooperation with the Saudi Arabian firm Petromin (179).

France's Pechiney is expanding its Saint-Beron ferromanganese plant by 11,000 tons per year and its subsidiary Eurominas is constructing a 110,000 tons per year ferromanganese plant in Portugal (179).

Satralloy Incorporated switched one of its six ferrochrome furnaces at Steubenville, Ohio, to ferromanganese production in October 1975 (177, 179).

Associated Manganese Mines of South Africa plans new furnaces at its Cato Ridge ferromanganese plant with start up scheduled for 1977.

The proliferation of multinational consortia for mining deep ocean manganese nodules continued in 1975. INCO formed a consortium, Ocean Management Incorporated, with AMR group of West Germany and Deep Ocean Mining Company, a 23 company Japanese group led by Sumitomo. A reported $30 million is budgeted for the four year project. The U.S. Department of the Interior has set up Ocean Mining Administration (OMA) to promote and encourage ocean mineral resource recovery from seabeds beyond the limits of national jurisdiction. Before ocean mining can begin, however, agreement between the developed and the developing countries will have to be reached on how to administer the seabed mining internationally. The ocean floor is considered to be the "common heritage of mankind" (180). The U.S. Government proposed to issue permits to begin ocean mining if the "Law of the Sea Treaty" in the U.N. fails to go through by January 31, 1976 (155). A 600,000 km^2 area in the coastal seabed off Western Australia has mineral nodules containing manganese, copper, nickel, uranium, and gold (182).

Manganese nodules are enlisted in boosting the upgrading of heavy petroleum fractions in work at Mobil R&D Corporation and Hokkaido University. Mobil reported that using the crushed nodules in an experimental fixed bed reactor, removal of trace metals from heavy petroleum fractions was attained with good results. Successful commercial application of the technology could mean an increased supply of low sulfur fuel oils and gasoline (177, 181).

The organometallic compound methyl cyclopentadienyl manganese tricarbonyl (MMT) can be used, according to Ethyl Corporation, to raise the octane rating of unleaded gasoline by two points at 0.125g per gallon level consumption rate. At 1980 gasoline consumption rate this would amount to 17,300 tons per year of manganese (177, 179).

Nickel.—Due to the reduction in production of specialty steels caused by the worldwide economic slump, a substantial oversupply of nickel developed during 1975. These developments of 1975 may have significant influence on the future worldwide supply-demand balance of nickel (183).

The U.S. continued to rely on foreign sources for a major portion of its nickel requirements. Domestic nickel producers increased their activity in 1975 over that in 1974 as a result of Freeport's renovated nickel-copper-cobalt refinery in Louisiana. The only domestic mine operator, Hanna Mining, produced approximately 16,500 tons of nickel from laterite ore, as measured by mine shipments. The associated smelter recovered about 13,000 tons of nickel as ferronickel. By-product plants recovered another 900 tons of nickel in various forms. Copper smelters and refiners and other manufacturing plants, including iron and steel, recovered an estimated 58,000 tons of nickel from scrap (184). Canadian production of nickel through the first 11 months of 1975 totaled 244,964 short tons and was about 7% lower than that in the corresponding period for 1974 (184). Smelter production of nickel in New Caledonia through the first 11 months of 1975 was 4% greater than that reported for the same period in 1974 and totaled 70,585 tons. Of this quantity, 52,417 tons was in ferronickel and 18,168 tons in matte nickel (184).

The nickel oversupply situation resulted from the reduced nickel consumption and the continued high level of imports in anticipation of the possibility of future price increases. The oversupply situation caused the record high levels of consumer stocks of nickel. The pattern of nickel usage was similar to that in earlier years with approximately 42% consumed in steels, 26% in nickel and nickel alloys, and 14% in electroplating. Pure unwrought nickel increased its share of the total U.S. nickel market at the expense of ferronickel and nickel oxide. Primary nickel consumption was estimated to be 144,000 tons in 1975, compared to the 1974 level of 208,107 tons (185, 186).

The price of nickel was stable at $2.01 per pound through nearly August of the year when the price was raised to $2.20 per pound. Reportedly, however, consumers were able to buy considerable quantities of nickel at the old price of $2.01 per pound for the rest of the year. Hanna Mining Company raised the price of the domestically produced ferronickel from $1.97 to $2.16 per pound of Ni content in September. The price of the imported ferronickel in the last four months of the year ranged from $2.15 to $2.19 per pound of nickel content (184).

In 1975, U.S. imports totaled 162,271 short tons of nickel compared with the 1974 imports of 221,399 tons. Canada remained the principal supplier of nickel accounting for 62% of the total. New Caledonia was the second most important supplier of nickel followed by Norway and the Dominican Republic. Imports from U.S.S.R. in 1975 were about one half the 1974 level (184, 185)

Major new nickel capacity projects expected to come on stream failed to reach the objectives. Several projects including Greenvale, Marinduque, and Selebi-Pikwe (Bostswana) experienced cost overruns and delays. A number of other projects were canceled or shelved, major reasons being inflation and adverse government policies. The capital investment for developing new nickel capacity is estimated at $10.00 per lb of annual capacity in terms of 1975 dollars (183).

Long awaited approval, on a much reduced scale however, is now foreseen for the Agnew nickel project in Western Australia in which London's Selection Trust group has a 60% stake with MIM Holdings having the remaining 40%. Plans are now for 10,000 tons per year nickel capacity starting sometime in 1978 (187).

A nickel smelting plant costing about $500 million is being planned by a group of Japanese companies in association with the Indonesian government. Indonesian Nickel Development Company will initially produce 29,200 tons of ferronickel (25% Ni) annually starting in 1980, on the Gebe Island in the Moluccas. The plant is eventually projected to produce 110,000 tons of ferronickel annually (188).

The Rhodesian Nickel Corporation Limited will start ore production early in 1976 at its third nickel mine at Epoch near Filabusi in Matabeleland. Due to inflation, the cost of the development of the mine has increased from $10 million to about $12 million (189).

Johannesburg Consolidated Investment Company Limited has started ore production from the new Shangani mine which is about 60 miles northeast of Bulawayo. Planned throughput of 75,000 tons of ore per month will be achieved in 1976 and by 1977 the annual capacity will be 5500 tons of nickel (183).

The prospects for mining asteroids for iron and nickel is being proposed by Massachusetts Institute of Technology scientists. They envision attaching an impulse generating device to an asteroid of 1 km in diameter and gradually moving it into an orbit closer to the earth. Part of the asteroid would be melted in space to shape it into a space vehicle to lower it to a landing site in the ocean. Some $140 billion worth of metals could be brought to earth annually in this fashion (190).

UOP, Incorporated has developed a nickel extraction process for a wide range of nickel laterite and other nickel-bearing ores. By adding various chemicals during the roasting step the process makes the nickel more extractable. The new hydrometallurgical/additive technique attains 90 + % yields as pyrometallurgical techniques but uses 30-50% less energy. The process is a takeoff from reductive roasting/ammoniacal leaching methods for low grade ores (191).

According to a Bureau of Mines Report of Investigations, nickel and cobalt could be recovered from low grade domestic laterites. The process involves selective reduction of oxides with carbon monoxide at 350°-600°C and extraction by multistage leaching with aqueous ammonium hydroxide and ammonium sulfate in the presence of oxygen followed by solvent extraction. Low energy requirement for the process is claimed (184).

According to a report by the National Research Council, airborne nickel and its compounds may be carcinogenic. Significantly increased incidence of lung and nasal cancers were found in workmen working in nickel smelters and refineries. The report prepared for EPA suggests how nickel should be monitored and the maintenance of comprehensive health records of nickel workers (192).

Sodium.—United States sodium metal production is showing a gradual down trend. The estimated total production for 1975 is 160,000 tons. This compares to 173,212 tons in 1974 and 173,903 tons in 1973 (193).

The total U.S. capacity is 189,000 tons per year which consists of five plants with yearly tonnages as follows: du Pont at Memphis, Tennessee, 35,000, and at Niagara Falls, New York, 42,000; Ethyl Corporation at Baton Rouge, Louisiana, 45,000, and at Houston, Texas, 30,000; and R. M. I. at Ashtabula, Ohio, 37,000 (193).

The dominant use for sodium metal has been for antiknock compounds. The increasing usage of unleaded gasoline, and the general downturn of the economy have accounted for the decreased use of sodium metal. At present 65-70% of the U.S. consumption of sodium is for making antiknock compounds like tetraethyl lead. Other uses include metal refining (particularly titanium metal) and manufacture of pharmaceuticals. A possible large scale usage is in liquid-metal-cooled nuclear reactors, but this use has not yet been realized (194).

The average annual price for sodium has shown a gradual upward trend being 15.9 cents per pound in 1970, 17.4 cents per pound in 1973, 17.9 cents per pound in 1974, and 22 to 22.5 cents per pound in 1975 (194).

The production of tetraethyl lead in 1975 was down an estimated 2% from 1974 (195). Domestic prices dropped following a drop in lead prices. Effective May 15, Ethyl Corporation, followed by du Pont cut its

quotes on antiknock mixes by 0.7 cents per pound to 56.8 cents per pound for standard tetraethyl lead mix (196).

Titanium.—The titanium industry experienced a period of reduced production and demand while the price of domestic titanium sponge rose, and prices of ores and imported sponge moved within narrow limits.

The two U.S. producers of sponge, Titanium Metals Corporation of America and R. M. I. Incorporated, have a total capacity of approximately 18,500 tons per year. Production in 1975 was 4% less than in 1974. Consumption of sponge and scrap was 17,000 tons and 7,700 tons, respectively. Sponge inventory in the hands of producers and consumers reached 6500 tons. Imports of sponge for consumption were 3425 tons at the end of September. Of this quantity, 61% was from Japan, 28% from the U.S.S.R. and 11% from the United Kingdom (197). This proportion of imports was typical of recent years except for 1974 when a disproportionately large quantity was imported from the U.S.S.R. (199).

Production of ingot was about 27,000 tons, down one third from 1974 (197). Titanium ingot melting capacity is being raised 20% in a $2 million expansion by Timet Division of Titanium Metals Corporation of America. Timet is also doubling welded tube facilities in Toronto at a cost of $1 million. R. M. I. Incorporated announced a delay in its previously publicized plan to expand the capacity of its Ashtabula, Ohio, sponge plant. Timet announced the initial operation of a commercial size cell to produce sponge by an electrolytic method (200).

Robert S. Nycum, Timet president, expects the market for titanium mill products to be about 25,000 tons by 1980 and 35,000 tons by 1985 compared to last year's record 17,500 tons. Major growth will be in industrial uses (198).

The principal consumer of titanium metal, the aerospace industry, was affected by reduced commercial aircraft production.

The price of domestic sponge rose from $2.45 per pound in January to $2.70 per pound in December (201, 202). This compares to $1.42 per pound early in 1974 (199). In a contrary action, the price of Japanese sponge decreased slightly from $2.85 to between $2.65 and $2.70 per pound.

The price of rutile (96% TiO_2), which soared from $275 per short ton in 1974, held at $710 per short ton throughout the year. Ilmenite (54% TiO_2) held at $55 per short ton and slag at $60 per short ton throughout the year (201, 202).

U.S. mine production of titanium minerals was about 640,000 tons, a decline of 16% from 1974. Ethyl Corporation completed the feasibility study of Paris Landing, Tennessee, but has postponed further action (197).

Imports of ilmenite increased to 150,000 tons, mostly from Western Australia. Imports of natural rutile were about 165,000 tons, a decrease of 15% from 1974. Imports of synthetic rutile were 50,000 tons. Imports of slag were approximately 300,000 tons, 27% more than in 1974 (197).

Australian production of rutile was estimated at 320,000 tons, continuing the decline from the peak of 405,200 tons in 1970. Australian ilmenite production was just under 900,000 tons, which is about equal to 1974 production (197).

The 1975 report of the Department of the Interior to Congress under the 1970 Mining and Minerals Policy Act voiced concern over the vulnerability of the U.S. resulting from dependence on imports. At present 97% of the U.S. demand of rutile is supplied by imports, principally from Australia and India, and 23% of ilmenite is supplied by imports, primarily from Canada and Australia (203). A report in a similar vein by the U.S. Geological Survey listed titanium as a material for which the U.S. (in 1974) was more than 90% dependent on imports for primary materials (204).

A pending shortage of rutile is one of the major problems facing the titanium industry. Best estimates place world rutile reserves at less than 10 million tons. With annual production of TiO_2 for pigments running close to 2.5 million tons, this is a fairly small supply. Alternative sources of titanium include alluvial deposits and titaniferous magnetites scattered throughout the world, which will provide a source of TiO_2 far into the future. Known reserves of pigment grade ilmenite (more than 45% TiO_2) total about 165 million tons. Lower grade ilmenite resources add about 225 million tons (205).

Demand for titanium dioxide pigment declined 38% between June 1974 and April 1975. By the end of the year, however, recovery seemed to be well established. Production for 1975 was estimated at 720,000 tons, 9% less than in 1974. Du Pont and Kerr-McGee Chemical Company have recessed plans for new construction at DeLisle, Mississippi, and Mobile, Alabama, respectively (197).

Du Pont, SCM-Glidden, and NL Industries all increased the price of titanium dioxide by 3.5 cents per pound in August. This put the new price at 43.5 cents per pound for rutile and 38.5 cents per pound for anatase (206).

Du Pont closed its 70,000 tons per year sulfate process plant at Edgemoore, Delaware, and replaced it with a 80,000 tons per year chloride process plant (207). In April the new plant was briefly closed to investigate the cause of a leak of $TiCl_4$ (208, 209). The new plant creates less than one-third the waste of the sulfate-process plant but even that amount will cause headaches for some time to come.

NL Industries announced the temporary closing of their 128,000 tons per year TiO_2 plant at Sayreville, New Jersey, for installation of pollution control equipment and routine maintenance (210).

New technology is under development for production of metallic titanium as an alternative to the presently used Kroll process (reduction of titanium tetrachloride with magnesium). Howmet Corporation of Whitehall, Michigan, is developing an electrolytic process using a fused salt bath. Timet Division of TMCA has produced 400,000 pounds of titanium electrolytically in a variety of laboratory and semiworks plants. The United Kingdom's Electricity Council Research Center in Capenhurst, Chester, is working on a plasma process employing titanium tetrachloride and sodium. Bethlehem Steel Corporation in Bethlehem, Pennsylvania, is considering a plasma process which is also at the laboratory stage (211).

Zinc.—Smelter production of primary slab zinc was 445,000 tons, down 20% from 1974, continuing the decline of zinc smelter production since 1969 (212). American Smelting and Refining closed its 50,000 ton per year zinc smelter in Amarillo, Texas, during May. The firm announced that the 50 year old smelter could not absorb the cost of being brought into compliance with air pollution standards (213). This reduced U.S. zinc smelting capacity to 680,000 tons per year, which is well below U.S. zinc consumption. Imports for consumption of slab zinc were about 375,000 tons, representing a decrease of 35% from 1974. Canada was the leading source of metal imports, providing 58% of the total, followed by Australia, Peru, Belgium, and Luxembourg.

"Zinc producers bite the bullet" fairly well summarized the market for 1975 (214). In face of a market which remained sluggish for most of the year, metal inventories increased early in the year. By mid-year, U.S. producers were curtailing production (215). Foreign production was even more dramatically reduced (216).

Producer and consumer stocks, at 256,736 tons on January 1, had climbed to 269,455 tons in April, the highest level in recent years. However, as smelter production declined and demand increased later in the year, stocks fell to a more normal level of 145,000 tons by the year end (212).

The General Services Administration delivered 5000 tons of zinc from the government stockpile. The last three quarters of the year were declared closed because of the high producer stock balance. The total amount

of zinc authorized for sale at the year end was 172,000 tons (212).

In August the President signed Public Law 94-89 suspending the duty on zinc ores, concentrates, and zinc-bearing materials until June 30, 1978 (212).

In spite of the falling demand for zinc, the U.S. producer price remained very close to 39 cents per pound for prime western zinc for essentially the whole year. This contrasts to a high of over 90 cents per pound in May 1974. New Jersey Zinc announced in September a price increase of 2 cents per pound effective October 10 but was forced to rescind the increase when other producers failed to follow (212, 217). Prices for zinc on the London Metal Exchange had dropped late in the year because of weakness of the pound sterling and unwillingness of European sellers to appear to be raising prices (217). To get out of this difficulty, most foreign producers were quoting prices in U.S. dollars at the year end (218).

Over the past several years the end use of slab zinc has remained proportionately fairly steady: 40% for die casting, 38% for galvanizing, 13% in brass, 4% as zinc oxide, 3% as rolled zinc, and 2% for other uses. The lowered demand for zinc which appeared during 1974 and continued through 1975 was largely due to weakness in the automotive industry (219). The total consumption of slab zinc in 1975 was 925,293 short tons compared to 1,310,000 short tons in 1974 and 1,504,000 short tons in 1973 (212).

Mine production was approximately 474,000 short tons, down 5% from 1974. Tennessee, Missouri, and New York account for one-half of domestic ore production. New Jersey Zinc began shipping concentrate from its new Elmwood mine in Tennessee in January. American Smelting and Refining shut down the Mascot mill in east Tennessee in October and brought its new Young mill on stream. This mill can process 20% more ore than the Mascot mill it replaced. The Park City mine in Utah began production in May. Callahan Mining Corporation and New Jersey Zinc, through a joint venture, began to develop a zinc-copper deposit in north central Virginia (212).

Imports for consumption of zinc ores and concentrates reached 428,544 short tons in 1975. Canada supplied about two-thirds of the total. Other major suppliers were Mexico, Honduras, and Nicaragua (212).

A new 50,000 tons per year electrolytic zinc refinery is under construction at Bartlesville, Oklahoma, by New Jersey Zinc. This is scheduled to come on stream by May 1976. It will replace the old horizontal retort plant in Bartlesville (212, 219).

A partnership of New Jersey Zinc and Union Miniere SA of Belgium announced plans for a 90,000 tons per year electrolytic refinery at Clarksville, Tennessee. The agreement also covers four zinc mines in mid-Tennessee. The total project will involve $190 million of which $97 million will be allocated to the refinery and $67 million to mine development and ore processing capital requirements. Construction is scheduled to begin in 1976 with completion in 1979. This project replaces the 160,000 tons per year refinery announced last year by New Jersey Zinc (220, 221).

American Smelting and Refining suspended work on its proposed 180,000 tons per year electrolytic zinc plant at Stephensport, Kentucky. The refinery and associated sulfuric acid plant will cost more than $200 million to build. Ralph L. Hennedach, the company president, cited depressed metal markets, increased inventories, steeply rising capital costs, and the difficulty in obtaining capital as reasons for the temporary suspension of the project (222).

A number of projects for development of mines and refineries in Canada and abroad are in various stages of development (223). The unfavorable market has caused postponement of some plans (224).

Texasgulf disclosed significantly higher reserves than previously announced at the Kidd Creek Mine in Timmons, Ontario. These include proven reserves of 86.1 million tons, probable reserves of 51.9 million tons, and inferred reserves of 6.4 million tons. The metal content of proven and probable reserves in 6.11% zinc and small concentrations of copper, silver, and lead (225). A series of lead, zinc, and silver occurrences has been discovered about two miles inside the proposed National Arctic Range in the Brooks Range in Alaska according to the U.S. Bureau of Mines, which calls the deposits "significant" (225).

A 60,000 tons per year refinery is being constructed in Thailand by Thai Zinc. A majority of this company is owned by New Jersey Zinc. The refinery costing $87 million is scheduled for completion in 1977. Of technical interest is the ore which consists of a 2:1 mixture of hemimorphite (zinc silicate) and smithsonite (zinc carbonate). This combination poses unique problems in separating the zinc from the silica without losing too much of the metal. A new process was developed by Electrolytic Zinc of Australia and a 1.1 tons per day pilot plant was operated by New Jersey Zinc at Palmerton, Pennsylvania (226).

The Environmental Protection Agency laid down more stringent regulations for operation of Bunker Hill Company's Kellogg, Idaho, lead-zinc smelter. The new rules require an 82% control on sulfur oxide emissions from the plant. EPA orders superseded less stringent regulations adopted by the state (227).

The Electrical Industry

It is impossible to separate the electrical industry from the over-all energy situation in the United States today. This situation is dominated by the potential shortage of petroleum and natural gas and long-term uncertainties.

The National Research Council's Committee on Mineral Resources and the Environment found it essentially impossible for the United States to achieve independence from external energy sources over the next decade by increasing domestic production of oil and natural gas. Further, if present trends of world consumption continue, the world's resources of these commodities will be substantially consumed in the next 50 years. The committee estimated total U.S. reserves, known plus undiscovered, at 150 billion barrels of oil and 600 trillion cubic feet of natural gas. Current U.S. annual consumption is about 6 billion barrels of oil and 23 trillion cubic feet of natural gas. The difficulty with raising production rapidly is that 70% of the undiscovered reserves lie under the outer continental shelf or in Alaska (228).

A petition to the president signed by 25,000 scientists and engineers claimed that increased use of coal and nuclear energy was the only way to energy independence. Use of these materials presents no problems "incapable of being solved" while alternative energy sources like geothermal, solar, and fusion suffer from geographical and technological limitations (229).

Concern was voiced that neither Congress nor the Administration had shown the required sense of urgency over energy matters. Important problems which require resolution include financing an embryonic coal conversion industry and setting guidelines for a compromise between quick action and environmental acceptability (230).

At a recent Research Directors Conference, reserved optimism was expressed that U.S. technology could overcome the pressing energy problems. Doubts were expressed about the possibility of raising the staggering amounts of capital required for development of domestic resources. Participants in the conference generally agreed that nuclear energy was a major hope for the future, if its development is not derailed by inappropriate environmental concerns, and that geothermal, solar, and other exotic electrical energy alternatives will have little impact on the energy problem for the foreseeable future although these processes may contribute to the energy pool (231).

Energy needs may produce significant shortages of engineering manpower in the near future. The Labor Task Force of Project Independence predicted that the project would create a need for 78,895 engineers, of

various backgrounds, in 1977, and 119,847 by 1990 (232).

An optimistic note is the 8% reduction in energy consumption (in 1974 compared to 1972) achieved by the 26 companies participating in the Manufacturing Chemists Association's plan to report to the Federal Energy Administration. The goal of this program is for the chemical industry to achieve a 15% reduction by 1980 (234).

The Organization for Economic Cooperations and Development has formed the International Energy Agency to deal with difficulties created by tightening fuel supplies. Stated aims include reducing dependence on oil imports and promoting cooperation between oil-producing and oil-consuming countries (235).

US power generation.—Tables 3-7 summarize the production, installed generating capacity, fuel consumption, sales to ultimate consumers, cost, and average usage of electrical energy for the period January to December 1975, except where noted. The figures are preliminary and in some cases partially estimated. For comparison, revised final figures are given for 1974 except for Table 7 where a longer time span is examined.

Table 3. Production of electrical energy* in 1975 (236)
(Billions kW-hr)

Electric utility	1974	1975	% Change
Coal-fired	829.8	844.4	+1.76
Oil-fired	299.3	292.0	−2.43
Gas-fired	319.9	297.1	−7.13
Nuclear	112.7	167.5	+48.62
Other**	2.9	3.4	+17.24
Total generated by consumable fuels	1564.6	1604.4	+2.54
Hydroelectric	260.9	268.2***	+2.80
Total	1825.5	1872.6	+2.58

* Excluding generation of approximately 100 billion kW-hr by private industry.
** Includes production from known geothermal sources, wood, and waste.
*** Estimated.

Table 4. Installed generating capacity by fuel type (236, 237)
(Millions kW)

Fuel type	1974	1975	% Change
Hydro	54.3	55.8	+2.76
Pumped storage	8.8	9.7	+10.23
Fossil fuel	336.9	351.2	+4.24
Nuclear	30.3	38.9	+28.38
Internal combustion	5.0	5.0	0
Combustion turbine	39.3	43.5	+10.69
Total	474.6	504.3	+6.26

Table 5. Fuel consumption by electric utilities (236)

Fuel	1974*	1975*	% Change
Coal, million tons	392.3	402.6	+2.63
Oil, million barrels	536.1	513.4	−4.23
Gas, billion cu ft	3429.2	3123.2	−8.91
Coal equivalent, million tons**	739.7	765.0	+3.42

* For 12 months ending November 1975.
** Includes equivalent for oil, gas, nuclear, geothermal, wood, and waste.

Table 6. Electric utility sales to ultimate consumers in 1975 (236)
(Billions kW-hr)

Consumer	1974	1975	% Change
Residential	555.0	591.1	+6.50
Commercial	392.7	421.1	+7.23
Industrial	689.4	656.4	−4.79
Other	63.7	67.3	+5.65
Total	1700.8	1735.9	+2.06

Table 7. Cost and average usage of electrical power (236)
(Cost ¢/kW-hr)

Consumer	1965	1969	1976
Residential	2.25	2.09	3.25
Commercial	2.13	1.99	3.27
Industrial	0.90	0.91	1.99

(Average use kW-hr/yr)

Consumer	1965	1969	1976
Residential	4,933	6,571	8,246
Commercial	27,399	36,950	49,313
Industrial	1,380,618	1,633,362	1,574,095

The production of electrical energy from all sources in 1975 was up slightly from 1974. This was composed of a decrease in use of gas and oil and an increase in all other sources. A notable increase was in nuclear energy which produced over 10% of the energy generated by consumable fuels.

The distribution of installed capacity shows the increase in nuclear capacity as well as significant increases in combustion turbine capacity and in pumped storage, an increasingly popular method of leveling the highly variable energy demand curve.

The data on fuel consumption, like the energy production data, reflect the decreasing use of gas and oil. They also reflect a slight decrease in the efficiency of fuel utilization. A rather disturbing fact is that during the past decade the coal rate in pounds per kilowatt has steadily increased from 0.858 in 1965 to 0.943 in 1975.

The data on sales to consumers show that residential and commercial consumption increased by about 7% for both categories while industrial consumption decreased by almost 5%.

A partial explanation of this is seen in the cost of electrical energy. The trend of average costs over the past decade is seen in Table 7. The year 1969 was the year of minimum cost when the gradual reduction of costs of electrical energy was replaced by relatively more rapid increase of costs. The policy of offering preferential rates to users of very large quantities is diminishing. In 1965 the cost to the industrial consumer was less than half that of the residential or commercial use; in 1975 it was almost two-thirds. And while everybody's electric bill had gone up, the cost per kilowatt hour to the industrial user in 1975 was more than twice what it had been in 1969 (236).

Energy from fossil fuels.—The President in his State of the Union Message asked for curtailment of the use of imported oil, for a speedy conversion from oil to coal, and for postponement of clean air standards for several years for power plants to help them convert from oil to coal. This fairly well summarized the problems in the area of fossil fuels (238).

The Supreme Court ruled in March that the U.S. Government owns the energy resources of the continental shelf, rejecting the claims of 12 Atlantic coast states (239).

A shale oil project based on Lurgi-Ruhrgas coal gasification technology was announced by American Lurgi Corporation and Dravo Corporation. A 4000 tons per day plant somewhere in the western United States is planned at a cost of $25-$30 million (240).

The Lawrence Livermore Laboratory announced an *in situ* process for removal of oil from deeply buried oil shale with minimum mining and surface disturbances. A cost of $6-$9 per barrel is claimed. The process involves rubblizing the shale in place with explosives followed by underground retorting (241).

The Organization for Economic Cooperation and Development predicted that the industrialized free world would turn more to coal as a source of electric power than to any other energy source over the next

10 years (242). They forecast that coal's share of all electricity generated in the OECD countries would jump to 2836 × 10^9 kW-hr by 1985, a full 22% higher than previous forecasts. By contrast, oil's share will decrease 57%, to 991 × 10^9 kW-hr.

The Energy Supply and Environmental Coordination Act of 1974 gave the Federal Energy Administration broad powers to reduce oil and gas consumption by directing industry to use coal. Potential oil savings, ranging from 0.85 to 1.175 million barrels of oil per day, will be realized by converting utility and industrial power plants to coal, by ensuring that central stations do not convert from coal to oil or gas and by requiring that new central stations have the capability to burn coal (243).

The United States has sufficient coal resources to allow consumption to triple, but a lack of local water resources may prove to be a major difficulty. This problem is expected to become particularly acute in the attempt to develop the largely untapped western coal reserves (245).

The Coalcon coal conversion demonstration plant will be located outside Belleville, Illinois. Coalcon is a joint venture of Union Carbide and Chemical Construction Company. The $237 million plant, financed largely by ERDA, is scheduled to start up in 1990. Some 2600 tons per day of coal will be converted to 4000 barrels of liquid and 22 million standard cubic ft of pipeline-quality gas (246).

Battelle Memorial Laboratories unveiled a new process for removing sulfur from coal. The process involves leaching the coal with sodium hydroxide, which converts both sulfur and part of the ash to soluble forms (247).

According to data released by the EPA at the end of January, electric utilities around the country are operating, building, or planning over 100 systems to control emissions of sulfur oxides from power plant stacks. Of these, the scrubber on Arizona Public Service Company's 115 MW Cholla I Station is the first to meet the National Academy of Engineering's criterion for proven, industrial scale scrubber reliability. The scrubber, developed by Research Cottrell, is a wet limestone/sludge throwaway system. Operational data include over 90% SO_2 removal, 91.5% scrubber availability with 97% boiler availability, and operating cost of 0.6 mills per kW-hr based on 3.78 mill busbar cost. Capital costs are quoted at $50-$60 per kilowatt (248).

Energy from nuclear sources.—Although the operating nuclear capacity was increased in 1975, the overall nuclear picture is mixed. By September of the year seven reactors had been completed during 1975: Calvert Cliffs 1, Annapolis, Maryland (845 MW); Hatch 1, Baxley, Georgia (786 MW); Cook 1, St. Joseph, Michigan (1060 MW); Prairie Island 2, Minneapolis, Minnesota (530 MW), Fitzpatrick, Oswego, New York (821 MW), Fort St. Vrain, Denver, Colorado (330 MW); and Rancho Seco, Sacramento, California (916 MW). Completion was expected during the remainder of 1975 on four more reactors: Brunswick 2, Wilmington, North Carolina (821 MW); St. Lucie 1, Fort Pierce, Florida (810 MW); Millstone 2, New London, Connecticut (828 MW); and Trojan, Portland, Oregon (1130 MW) (250).

The number of nuclear power plants scheduled to go on line between 1976 and 1985 is 128 with a total capacity of 139,000 MW.

During the period September 1974 to September 1975, rising costs forced cancellation or indefinite postponement of seven major plants. One of these plants, consisting of two 1160 MW high temperature gas cooled reactors, was projected to cost over $2.4 billion, or over $1000 per kilowatt. Another was shelved when the cost increase, because of a two year delay in schedule, reached about $800 per kilowatt. Seven plants with a total capacity of 8010 MW were committed during this period. This is the lowest annual figure since the industry really got off the ground (250).

A serious problem which may be hampering growth of fission energy use is the lack of acceptance of nuclear energy by the general public. Although fears of reactor safety have diminished in recent years, public apprehension is now focused on the "back end" of the cycle—the processing of spent fuel to recover plutonium and uranium and the management of radioactive wastes. Further complicating the picture is the corporate reluctance to go nuclear in view of the critical shortage of capital funds, the large investments required for nuclear facilities and the pending shortage of fissionable material, which can be avoided only with substantially increased activity in exploration, mining, and processing (251).

Even more uncertainty surrounds development of the breeder reactor. The Administration's top priority program for development and commercialization of the liquid metal fast breeder reactor is being increasingly attacked by Congress and environmentalists. At the center of the controversy is the proposed Clinch River breeder reactor demonstration plant on which construction is scheduled to start in 1976. Although admitting the value of the reactor in conserving uranium, the environmentalists would like to see the entire program delayed, for as much as 5-10 years, until problems involved in production, transportation, security, and disposal of the large quantities of plutonium involved can be resolved. There is also concern about the safety of the breeder itself (252).

Nuclear commitments outside the United States increased 34% to 294,000 net MW, between the second quarter of 1974 and the first quarter of 1975. Total commitments break down to a 20% increase in operable capacity, a 19% increase in capacity under construction, a 3% decrease in capacity on order, and a 68% increase in capacity in the planning stage (253).

According to Dr. Arnoldo Angelini, President of the National Board of Electric Power in Italy, nuclear plants will generate most of the electrical power in Europe by 1990. Power generated from fossil fuels will decrease from 80% today to less than 30%. In the next 10 years alone $100 billion will be invested in nuclear plants (254).

Other energy sources.—The largest direct hydro unit in the United States, believed to be the largest in the world, was placed in operation. The unit, the 19th generator at the Grand Coulee Dam, is certified at 600 MW but has a rated capacity of 690 MW. Two further units of similar capacity and three 805 MW units will be installed at 6 month intervals (255).

Combustion of industrial wastes and municipal refuse offers the opportunity to conserve fossil fuels and at the same time to eliminate environmental pollution. As experience is accumulated, this practice can be expected to spread. A large facility to generate electricity from municipal waste is to be built in central New Jersey. The plant, based on technology of Von Roll, Limited, of Switzerland, is designed for disposal of 4000 tons of refuse per day with a generating capacity of 110 MW (256). EPA officials have found "significant" levels of bacteria and viruses at Union Electric's prototype refuse powered plant in St. Louis, Missouri. Undaunted, the company plans to start construction on a commercial 8000 tons per day plant to be fed with solid waste (257).

Geothermal energy activities are progressing on a broad front. Activities center around a phenomenon called a geothermal anomaly, a spot in the earth's crust where temperatures are much higher than would normally be expected. Such spots are believed to be related to volcanism caused by crustal plate motion. The geothermal resource may consist of steam, hot water, a mixture of steam and water, or hot rock. Geothermal water is often much more saline than normal ground water (258).

World generating capacity from geothermal sources today is slightly more than 1000 MW. About 500 MW of that comes from one field, the Geysers, in California and most of the remainder from Italy (258).

As the value of steam produced by fossil fuels has increased, geothermal prospecting has been able to at-

tract investment capital. In the most geothermally attractive portion of the United States, the western states, the majority of the land is held by the Government. Federal lands first became available for geothermal exploration in January 1974, when the Geothermal Steam Act of 1970, Public Law 91-581, was implemented. Under this Act, lands are categorized as being either in or out of Known Geothermal Resources Areas (KGRA). Lands within KGRA's are leasable only on competitive bids. In highly prospective areas like the Geysers, industry has shown willingness to enter multimillion dollar bids. Competitive sales have been conducted in California, Utah, Oregon, and Nevada. Other areas may be leased on noncompetitive bids. In January 1974, 2456 applications for noncompetitive geothermal leases were received. While a variety of techniques of geothermal prospecting are in use, wildcat drilling is on the increase. Fuchs and Huttrer have provided a survey of activities and problems in geothermal energy (259).

A major legal difficulty is the continuing question of whether geothermal resources are water or mineral.

According to the U.S. Geological Survey, the nation has geothermal resources capable of producing about 42,000 MW centuries of electricity with recovery costs varying from present levels to more than two times higher (260).

The Electric Power Research Institute has commissioned a $595,000 study to determine whether power conversion techniques in which geothermal hot water is flashed to steam for power use can be cost competitive and still meet environmental constraints. EPRI's program manager for geothermal projects predicts that U.S. use of this resource could triple every 5 years and reach 200,000 MW by the year 2000 (261).

Geothermal energy may not be as clean as once believed. A study of the Wairakei, New Zealand, geothermal steam plant showed that the plant produced nine times the waste heat of a coal- or oil-fired plant and emitted high levels of water vapor, carbon dioxide, sulfur, arsenic, hydrogen sulfide, and mercury compounds (263).

Substantial technological problems face development of geothermal power, and this power source is admittedly not the panacea for the U.S. energy problems, but it can provide a supplemental power resource in the future.

Although radiant energy incident upon the earth from the sun far exceeds the world's present energy needs and although it was the source of much of our present energy reserves, its diffuse nature has thus far made large scale direct conversion of solar energy uneconomical.

A National Solar Energy Program has been organized by ERDA. Under this plan solar would provide 0.8% of the U.S. energy demand by 1985, 7% by 2000, and 25% by 2020. The plan is strongly dependent on progress in research and development and on economic relationships with other energy sources (264).

ERDA is funding the first large scale solar power plant, a 10 MW plant to be located in the southwestern United States within the next 5 years (265).

In a program aimed at developing low cost solar cells, ERDA has selected 16 organizations for contracts. The program is designed to foster industrial capability, by 1985, of producing silicon solar arrays at a market price of $500 per peak kilowatt in place of the $20,000 to $25,000 present day price (266).

Argonne National Laboratory has awarded contracts to seven firms for production of prototype collectors. These will be the first industrial versions of the compound parabolic concentrator being developed by Argonne. The concentrator can be used for generation either of electricity or usable heat (167).

The Solar Energy Research Institute, mandated by Congress in the Solar Energy Research, Development, and Demonstration Act of 1974, is in the process of formation. The new institute was proposed by a National Research Council committee to have a staff of 1400 with an annual budget of $48 million. This is in contrast to the recommendations of the U.S. solar industry, as surveyed by Mitre Corporation, which consists of a staff of 120 and a budget in fiscal 1976 of $6-$10 million. The committee envisions both contributive and supportive roles for SERI (268).

Recent developments in magnetohydrodynamic power indicate that it is still under active investigation in a number of countries. In the Soviet Union, a team of U.S. and Soviet engineers recently completed a continuous test of U.S. built electrodes in a Soviet built 1 MW plant. Cooperation between the United States and the U.S.S.R. began in 1973 and is intended to give U.S. researchers access to facilities not available in the United States (269).

Manuscript received June 23, 1976. This report was presented at the Industrial Electrolytic Division at the Washington, D.C., Meeting of the Society, May 2-7, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Sept. 1, 1976.

Electronegativity, Ionicity, and Effective Atomic Charges

J .P. Suchet

Laboratoire de Chimie Structurale, Université René Descartes, F-75270 Paris Cedex 06, France

ABSTRACT

This paper reviews the concepts of electronegativity and ionicity, together with the concept of effective static atomic charge which is associated with them. It is briefly recalled that the ionicity of a chemical bond has two components: a chemical component linked to the valency of the atoms and to their short distance spatial arrangement, and an electrostatic component linked to their effective charge. In solids, however, the appearance of group vibrations of the atoms also introduces the concept of effective dynamic charge, taking account of dielectric phenomena. Emission, absorption, and diffraction of x-rays are related to these two kinds of effective atomic charges and may be used for evaluating them. The substitution, in the second component of ionicity, of the dynamic charge for the static charge probably defines something different from what is usually called ionicity.

The Concept of Electronegativity

Pauling (1, 2) defined electronegativity χ as the attractive power of an atom for an excess electron with respect to its normal electronic cloud, and calculated it empirically from the bond energies prevailing between the different atoms. Shortly thereafter, Mulliken (3) defined it more rationally as the mean between the ionization potential of the first electron and the electronic affinity of the atom. He then realized that electronegativity depends on the valency and on hybridization, and then inferred that the establishment of a chemical bond between two atoms of different electronegativities gives rise to a transfer of electrons between them, namely the appearance of an effective charge (4).

Sanderson (5-7) continued the work of Mulliken and defined the relative electronegativity χ_r of an atom as the ratio of its compactness C to the compactness C_o of the atom of the isoelectronic rare gas

$$\chi_r = C/C_o = (Z/4.19r^3)/(Z_o/4.19r_o^3) = Zr_o^3/Z_or^3 \quad [1]$$

This concerns a "stability ratio," with low values corresponding to the least electronegative elements (metals), and high values to the most electronegative elements (nonmetals). This ratio naturally depends on the electrical charge supported by the atom. As Mulliken observed, an interatomic bond involves a transfer of electrons to the more electronegative atom. In these conditions, the relative compactness of the two linked atoms are certainly closer than those of the two same atoms when isolated from each other (Fig. 1). Sanderson (6, 7) thus intuitively discovered that the bond between two atoms must correspond exactly to the "equalization of electronegativities" between them. By establishing an arbitrary hypothesis on the electronic transfer occurring in the compound NaF, taken as a reference, he then suggested empirical equations for calculating the initial electronegativities of the atoms.

The importance of the concept of effective atomic charge in defining electronegativity was confirmed and intensified in subsequent investigations. Iczkowski and Margrave (8) defined the latter as the derivative of the energy of the atom with respect to its charge. Hinze and Jaffe (9) calculated the energies of promotion of valency states for a large number of atoms and ions in different states, and combined them with the ionization potentials and the electronic affinities to obtain the "orbital electronegativities" of different σ and π orbitals. Ferreira (10) employed Sanderson's principle of equalization of electronegativities to calculate "effective electronegativities" which took account of hybridization and charge transfer. This matter is dealt with further in this paper.

Key words: electronegativity, ionicity (parameter), charge (electric, effective), bond (chemical).

The Concept of Ionicity

Pauling (11) employed the very old concept of ionicity in his approach to the "valence bond" and suggested evaluating the ionic character of a chemical bond from the difference in electronegativities of the elements involved. He then determined the proportionality constant such that the atomic charges in hydracid molecules were in good agreement with their measured dipolar moment. Syrkin and Dyatkina (12), followed by Coulson (13), subsequently gave a better definition, by incorporating two standardized wave functions corresponding to purely ionic and purely covalent bonds. Hence they wrote the general wave function of a bonding electronic pair as

$$\psi = P_c(M{:}X) + P_i(M^+X^-) = P_c\psi_{cov} + P_i\psi_{ion} \quad [2]$$

where P_c and P_i are probability coefficients and the square of the second can be taken as the ionicity parameter. Equation [2] shows clearly that if one of the electrons of the pair always gravitates in the sphere of influence of the nucleus of the nonmetal X, the position of the other depends on the ionicity parameter and the choice of extreme configurations for

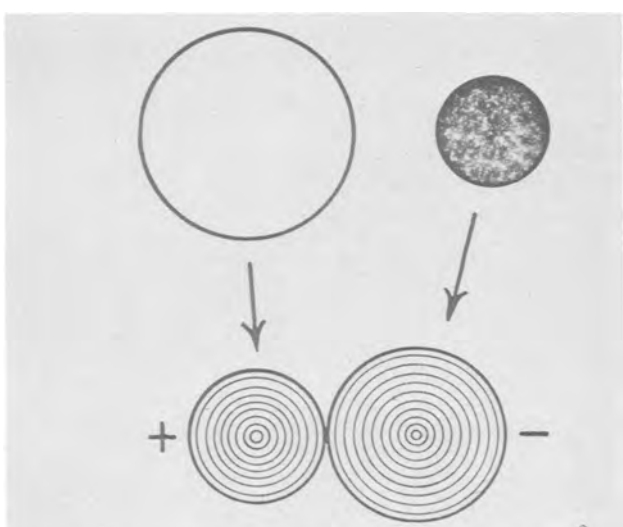

Fig. 1. Schematic representation of the combination of an atom with low electronegativity and an atom with high electronegativity, according to Sanderson (7).

which $P_i = 0$ and $P_i = 1$. The approximation embodied in the concept of effective atomic charge, while requiring the integration of these electrons in the point charges located on the nuclei M and X, establishes a simple link between the charge and the ionicity parameter. For example, in hydracid molecules, the effective charge q_p supported by the hydrogen atom is by definition the hundredth portion of the ionic character percentage mentioned by Pauling.

Nevertheless the definitions of Pauling and Coulson differ widely in the general case. The former takes as the zero ionicity state the homopolar state, in which the atoms present do not support any charge, identical to the covalent state in hydracids. In general, however, the homopolar state already incorporates a certain ionicity. Coulson's definition takes as the zero ionicity state the pure covalent state, in which the electronic distribution is rigorously identical to that of the elements of the same structure. For Pauling, an ionicity equal to zero corresponded to the configuration M^oX^o (neutral atoms) and an ionicity of 100% corresponded to the customary ionic formula $M^{+n}X^{-n}$ (elements M and X of the same valency n) (Fig. 2). During the fifties, however, certain investigations on semiconductor compounds led their authors to conclude that the figures thus determined were too low and failed to permit a satisfactory interpretation of physical properties.

The Nature of Ionicity

Goodman (14) recalled that the neutral formula Zn^oS^o of zinc blende is as divergent from a purely covalent formula $Zn^{-2}S^{+2}$ (in which the distribution of valency electrons on the hybrid orbitals sp^3 is identical to that of diamond) as from the purely ionic formula $Zn^{+2}S^{-2}$. Hence, as he stated, the neutral formula already has an ionic character of 50% as compared with the former, without mentioning the additional ionicity created by the appearance of a positive charge on the zinc atom. This observation perfectly corresponds to the definition embodied in Eq. [2], and Fig. 2 depicts the distinction between the two possible definitions of ionicity.

Suchet (15-20, 22-24) and Suchet and Bailly (21) resumed the definition of Syrkin and Dyatkina, together with that of Coulson, and simplified Eq. [2] by ignoring the permutation of the two electrons in the function ψ_{cov} and by using the monoelectronic orbital ϕ_X as a factor

$$\psi = [(1 - \lambda)^{1/2}\,\phi_M + \lambda^{1/2}\,\phi_X]\,\phi_X \qquad [3]$$

$P_c = (1 - \lambda)^{1/2}$ and $P_i = \lambda^{1/2}$ (Fig. 3). The electrons of the pair thus represented are distributed into $(1 - \lambda)$ electrons on M and $(1 + \lambda)$ electrons on X. If

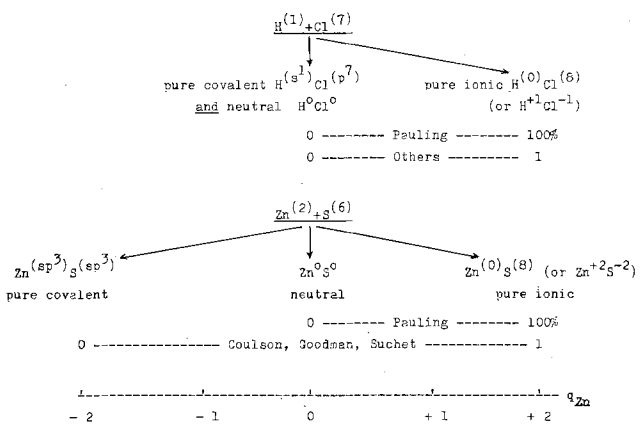

Fig. 2. Comparison of definitions of the ionic character, according to Pauling (11), and of ionicity according to Coulson (13), Goodman (14), and Suchet (15-17). Corresponding values of the charge supported by the zinc atom in the compound ZnS.

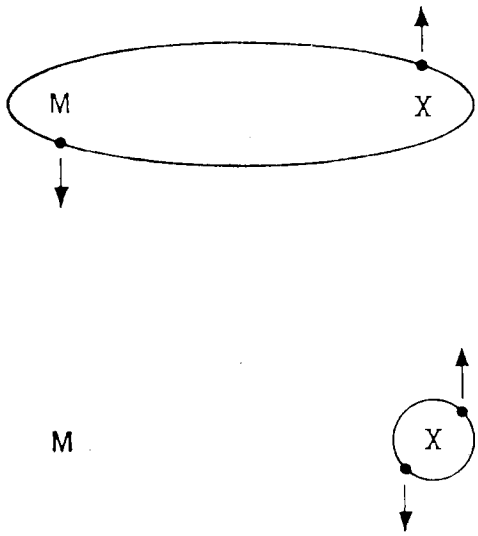

Fig. 3. Diagram showing the purely covalent distribution and purely ionic distribution of electrons in a pair of valency electrons, according to Suchet (15-17).

each atom participates in c bonding pairs, the 2c electrons of an arbitrarily isolated "molecule" MX are distributed into $c(1 - \lambda)$ on M and $c(1 + \lambda)$ on X (general formula). In the neutral or homopolar state, M possesses n electrons (those which it loses in case of ionization) and X thus possesses the remainder, namely $2c\text{-}n$. This distribution can be written as coinciding with the general formula for a special value λ_o, leading to

$$\lambda_o = 1 - n/c \qquad [4]$$

Thus the chemical ionicity of the homopolar state depends only on the positions of the elements M and X in the periodic table of elements and on the type of bond. The heteropolar state is derived from the homopolar state by transferring a certain number q of electrons to an atom X at the expense of the neighboring atoms M. The new distribution is thus $c(1 - \lambda_o) - q$ and $c(1 + \lambda_o) + q$. This can be written as coinciding with the general formula for a value λ, leading to

$$\lambda = \lambda_o + q/c \qquad [5]$$

Hence the ionicity of a bond in a molecule or a crystal is obtained by adding to the chemical ionicity an electrostatic ionicity which is proportional to the effective atomic charge. The latter ionicity corresponds qualitatively to the ionic character of Pauling. For a quantitative representation, it is better to use (25)

$$\Lambda = (\lambda - \lambda_o)/(1 - \lambda_o) \qquad [6]$$

At about the same time, Batsanov (26-27) also arrived at an ionicity composed of two components. The first only depends on the valency of the atom, and on the types and number of the orbitals. The second is linked to the effective charge. For this author, the deformation of the electronic cloud of the anion and its shift toward the cation become increasingly greater with increasing electronegativity χ of the cation and with decreasing ionization potential I of the anion. Hence, in the molecule MX, the valency electrons are thus distributed in the ratio $I/(I + \chi)$ on M and $\chi/(I + \chi)$ on X.

The Concept of Effective Charge

It has just been shown that the concept of effective atomic charge is implicit in the definition of electronegativity as well as in that of ionicity. The question arises as to whether the charge is the same in both cases. *A priori*, one is tempted to reply in the affirmative, since the chemical conception integrating these

two concepts is the same: atoms at rest (hence at low temperature) and absence of external disturbances. Furthermore, the various numerical evaluations, which roughly approach each other, do not contradict an affirmative conclusion.

Returning to the work on electronegativity, it can be seen that if the charge transfers serve to calculate the effective electronegativities of Ferreira (10), the latter can accordingly be used to calculate the effective charges

$$q_F = (\chi_X - \chi_M)/(\Delta\chi_i^+ + \Delta\chi_j^-) \qquad [7]$$

However, the variations $\Delta\chi$ incorporated in this equation can only be obtained from rarely known electronic screen constants. Nevertheless, Tables I and II provide some values of q_F for certain simple compounds. Hinze *et al.* (28) showed that the orbital electronegativity is the derivative of the energy of the atom (in the given valency state) with respect to the electronic occupation of the orbital in question (0, orbital vacant; 1, case discussed by Mulliken; 2, nonbonding pair). This is a parabolic function in which the coefficient k of the quadratic term serves to calculate the effective charge, taking account of Sanderson's principle of equalization of electronegativities

$$q_H = (\chi_X - \chi_M)/2(k_X + k_M) \qquad [8]$$

Yatsimirskii (29) fairly closely follows the reasoning of Hinze *et al.*, but prefers to employ the energy of the orbital instead of that of the atom, thus introducing a correction coefficient α, which is inversely proportional to the interatomic distance M-X

$$q_Y = (\chi_X - \chi_M)/2(k'_X + k'_M + \alpha) \qquad [9]$$

Table I mentions two values of q_Y.

Working in another direction, Suchet (16, 24) and Suchet and Bailly (21) proposed a direct semiempirical calculation of the effective charge from the ionic charge, by considering the progressive deformation of the electronic clouds of the ions M^{+n} and X^{-n} (Z and Z' electrons, ionic radii r and r') when they approach each other (Fig. 4). They inferred the appearance at b of dipoles Δ and Δ', partially neutralized at c with the interpenetration of the two clouds. By dividing the residual charge $\Delta - \Delta'$ equally between the two atoms, the calculation shows that

$$q_S = n - (\Delta + \Delta')/2 \qquad [10]$$

By assuming that the dipolar moments Δx and $\Delta' x'$ are proportional to the products of the mean fields

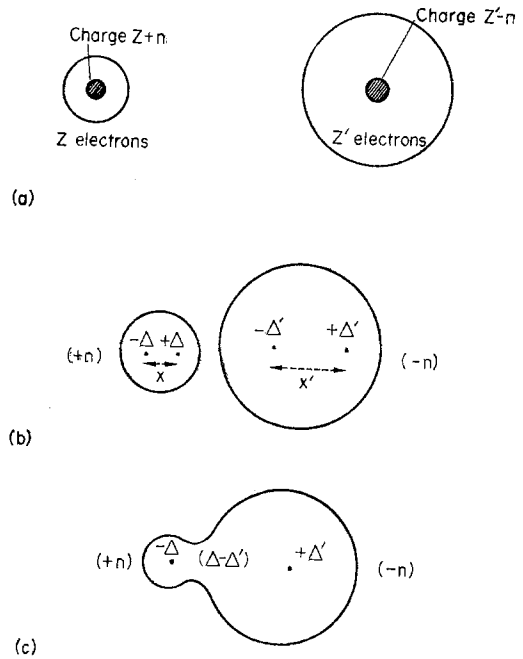

Fig. 4. Diagram showing the mutual polarization of two ions, leading to a partial return to a covalent bond: (a) no interaction, (b) slight interaction, (c) overlap, according to Suchet and Bailly (21) and Suchet (24).

n/r^2 and $-n/r'^2$ by charges Z' and Z, and that the distances x and x' are inversely proportional to r and r', this leads to

$$q_S \sim n[1 - (Z/r' + Z'/r)C^t] \qquad [11]$$

The evaluation of the constant at 0.01185 gives zero charges on the atoms of crystals of the element germanium and on those of the element tin. Suchet and Bailly (21) and Bailly (30) also derived the ionicities λ by direct calculation from the thermochemical data, so that the use of Eq. [5] in the opposite direction leads to

$$q_{SB} = c(\lambda - \lambda_o) \qquad [12]$$

Actually, the values of λ thus obtained are identical to those calculated by Eq. [5] from the charge q_S of Eq. [11], within the range of accuracy of the thermochemical data. Tables I, II, and III provide various values of q_S and q_{SB}. Table I corresponds to hydracid molecules and shows fairly good agreement with the values of q_P derived from the ionic characters of Pauling.

Effective Dynamic Charge

It was observed in the foregoing section that, on the basis of both electronegativity and ionicity, the atomic lattice considered was always at rest. This state of things corresponds to the intuitive conception of chemists, for whom solids are formed by the association of atoms whose electronic clouds undergo a temporary disturbance during the establishment of the bond, following which the nuclei and electrons reach a new equilibrium. We are obliged to say that the exchanges of energy between the solid and the exterior, whether thermal, electromagnetic, or corpuscular energy, can in no conditions be dealt with

Table III.

	q_S	e^*	e_S
InAs	0.68	0.56	0.49

GaSb	−0.50	0.33	0.58
AlSb	−0.98	0.53	0.67

within such a framework. The atoms are subjected to forces which draw them away from their equilibrium positions and, owing to interatomic forces, their movements are coordinated and periodic, giving rise to group vibrations (phonons).

To simplify matters, suppose that a molecule MX is arbitrarily isolated and that the interatomic distance R of the two atoms is increased by a quantity x in the direction M-X. This might lead one to believe (31) that the effective static charge $q(0)$ supported by atom M in the initial situation is replaced, in the new situation, by a charge $q(x)$. One of the simplest relationships imaginable between $q(x)$ and $q(0)$ is

$$q(x) = q(0) + xdq/dx \qquad [13]$$

In this case, the dipolar moment can be written as the sum of the relative shift of two atoms with charges $\pm q(0)$ and the transfer of the charge dq/dx over their mutual distance R

$$P = xq(0) + xRdq/dx \qquad [14]$$

By defining an effective dynamic charge e such that $P = ex$, it can be seen that

$$e = q(0) + Rdq/dx \qquad [15]$$

Thus the new charge is due to the sensitivity of the static charge to small relative shifts of the atoms. It is still clear that more complex movements can occur, simultaneously comprising components which are parallel and perpendicular to the direction M-X, and leading to a charge of a slightly different nature. Moreover, the inertia of the nuclei and the electrons leads to a strong influence of the vibration frequency on the values of these charges. Although a single static charge is inferred by the foregoing, all these reasons indicate a large number of dynamic charges, depending on the structure of the solid, the types of vibration, and their frequency.

Comparison of Charges

The dielectric properties of crystals constitute one of the major phenomena indicating the presence of dipoles in solids. If an attempt is made to connect the dielectric constant ϵ (low frequency), ϵ_∞ (high frequency), and infrared dispersion frequencies with microscopic data, one is led to attribute the existence of dipolar moments to the deformation and movement of atoms, which introduce effective dynamic charges e. At the frequencies of visible light waves, these movements are negligible, but at lower frequencies (infrared), they must be taken into consideration.

The first rigorous analysis was the work of Szigeti (32), who employed a theorem of Lorentz relative to cubic crystalline lattices to simplify the calculation of macroscopic polarization by taking account of close neighbors only. This gave for the charge

$$e^2 = 3.4(\epsilon - \epsilon_\infty)MX/[(\epsilon_\infty + 2)/3]^2\lambda_t^2\rho \qquad [16]$$

where M and X are the atomic weights of the two elements making up the compound, ρ is its density in g/cm^3, and λ_t is the reststrahlen wavelength in μm. Equation [16] can be slightly modified if the longitudinal or transversal vibration modes are the only ones in action. This is notably the case of diffusion by optical modes (longitudinal) (33).

Table II concerning alkaline halogenides compares the numerical values given by Ferreira (10) and Suchet (16, 19, 20) for static charges q, with those given by Szigeti (32) and Hass (34) for special dynamic charges e^* derived from the study of infrared spectra. The former reveal a certain consistency, and there is a deviation between charges q and e^*.

The Role of X-Rays

About 12 years ago, Syrkin (35) remarked the difficulty of arriving at accurate values of effective atomic charges, as all the methods employed to determine them relied in various degrees on uncertain theories or empirical calibrations, and called for more direct experimental methods, such as those employing x-rays.

The first investigations carried out in this direction concerned the successive transitions of the electron expelled from layer K by an energy quantum X. In effect, these transitions occurred in the field of an atom whose initial effective charge, depending on its sign, is increased or diminished by a unit. A fine analysis of the absorption spectrum should thus permit an evaluation of this charge. However, Nefedov (36) soon discovered that the spectral shifts of **x** emission lines are far more sensitive to the value of the effective charge. Leonhardt and Meisel (37) recently indicated that the shifts obtained in the latter method by different quantum mechanics calculations using the free ion model provide consistent values, at least with respect to the satellite lines $K\alpha_1$ and $K\alpha_2$.

Sapre and Mande (38-40) observed that the K absorption discontinuity shifts toward the high energy side in certain compounds and toward the low energy side in some others, depending on whether the absorbing atom supports a positive or a negative effective charge. In a series of experiments on arsenic, selenium, gallium, and germanium compounds, they established that the shift is related to an effective static charge q and found that the charges computed by Suchet (20) give a good representation. On Fig. 5 appear three compounds where arsenic is negatively charged (InAs, GaAs, AlAs) and three where it is positively charged (As_2O_3, As_2S_3, As_2Se_3). The shift increases much faster than the charge, approximately as $aq + bq^3$ (41).

On the other hand, Sirota and Gololobov (42) employed diffraction methods to construct electronic density distribution cards for III-V compounds. A graphic integration then permitted them to plot the limits of the electronic clouds at levels below 0.03 electron/Å^3. Table III compares the numeric values given by Suchet (16, 19, 20) for static charges q, those given by Szigeti (32) for dynamic charges e^*, and those given by Sirota and Gololobov (42). It appears that the latter, while not identical to the values of e^*, are nevertheless dynamic charges, and are hence designated by the symbol e. It has already been shown that all the dynamic charges, especially when deter-

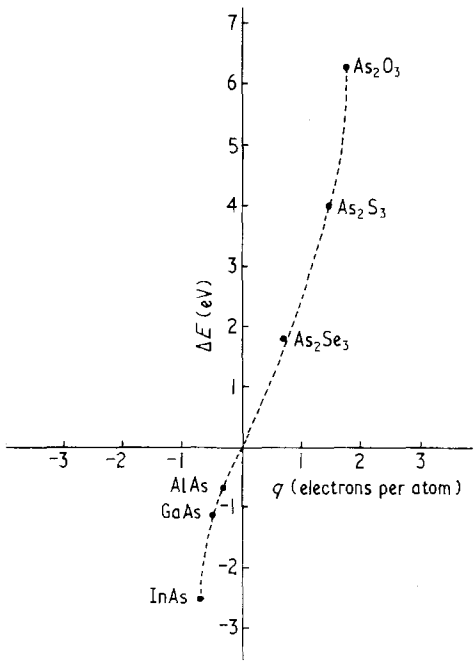

Fig. 5. Plot showing the dependence of the chemical shift ΔE on the effective static charge q_S, according to Sapre and Mande (38).

mined by different methods, are not necessarily equal in value.

Correlations with Properties

Depending on whether the physical phenomena considered leave the atoms in the lattice substantially at rest, or whether they cause them to vibrate, correlations can be found with the static charge q and the associated parameters (such as ionicities λ or Λ), or with dynamic charges such as e^* and the parameters which may be associated with them.

The pairing of ionized interstitial impurities and charged vacancies does not involve any periodic disturbance of the lattice or of the electronic distribution. The diffusion of ions Li^+ in the interstitial sites of III-V compounds reveals a pairing with a negatively charged Sb vacancy for AlSb (43) and GaSb (44), and with a negatively charged Ga vacancy for GaAs (45), indicating that the charges q carried by the metal in these compounds are negative for Al and Ga in the former and positive for Ga in the latter, respectively. Similarly, if no other factor limits the value of the mobility of the majority carriers in a crystal, this mobility must rise with decreasing elementary dipole (and charge q). Hence one can expect to find for InSb, in which the electronic mobility reaches 10^6 cm^2/Vsec, a value of q which is substantially nil, which has been confirmed by ERP (46). This also applies for HgTe. These observations, which besides form the basis of the semiempirical model of Suchet (15, 16), contributed to give the charges q_S a certain credibility from the start. The direct calculation of the ionicities of III-V compounds on the basis of thermochemical data subsequently confirmed their correct order of magnitude (21).

Correlations with static charges also exist for the magnetic interaction energy (20, 23, 47-49), and also, in a less evident manner, for the thermal conductivity of the lattice (20, 50-52) and the semiconduction excitation energy (20, 22, 23, 53).

The dielectric properties, and particularly the measurement of the dielectric constant in alternating current, provide a periodic disturbance of the position of the atoms, which are capable of shifting slightly in the field as far as the infrared frequencies, as well as that of the electronic clouds, which can follow the electrical attractions up to the ultraviolet region. The correlations with the e charges, which appeared very early (32), are in fact at the very source of their definition. This also applies to infrared absorption and emission (32), as well as to infrared reflectivity (34, 54) and piezoelectric properties (55).

The Phillips f_i Parameter

Phillips (56, 57) recently developed a semiempirical model which will not be dealt with in detail here, except to state that it is based on a parameter f_i, which is determined from the dielectric constant at optical frequencies. By his references to the work of Pauling and Mulliken, Phillips clearly showed that he considered this parameter as a classic ionicity corresponding, like the ionic character of Pauling, to the electrostatic component only of Eq. [5]. Hence, in order to compare it with the ionicity defined above, it is necessary to use the form Λ of Eq. [6], which takes, like f_i, the value 0 for the homopolar state and the value 1 for the ionic state. The correlation on which the Phillips' parameter was based, and which was responsible for its initial success, is an exact forecast of the stable region of the structures of blende and wurtzite ($f_i \leq 0.785$) and of rock-salt ($f_i \geq 0.785$) in inorganic compounds.

Table IV provides a comparison of f_i and Λ for compounds in which the nonmetal is relatively light and where the metal has substantially the same dimensions as the nonmetal. The two series of values seem to vary approximately regularly in the same direction.

Table IV.

	Λ	f_i		Λ	f_i
AlAs	0.09	0.274	LiCl	0.63	0.903
GaAs	0.16	0.310	NaCl	0.69	0.935

AlP	0.52	0.307	CaO	0.73	0.913
ZnS	0.54	0.623	MgO	0.73	0.841
CuCl	0.60	0.746	KF	0.75	0.955
			NaF	0.78	0.946
			CaS	0.82	0.902
	Zinc blende			Rock salt	

Table V.

	Λ	f_i		Λ	f_i		Λ	f_i
AlSb	−0.33	0.426	MgTe	−0.04	0.554	LiI	−0.09	0.890
GaSb	−0.17	0.261	ZnTe	−0.02	0.546	NaI	0.27	0.927
InSb	−0.01	0.321	CaTe	0.25	0.394	KI	0.42	0.950
	Zinc blende			Miscellaneous			Rock salt	

Table V, on the other hand, lists compounds in which a small metal atom is associated with a large nonmetal atom, whose electronic cloud is strongly polarizable (antimony, tellurium, iodine). These figures immediately reveal a large, significant divergence, as the periodic, highly rapid disturbances of the large electronic clouds greatly reduce their polarizability. The ionicity $\Lambda = f(q)$ calculated from a static charge reflects strong polarization, causing a return of electrons to the metal atom, this process becoming more intense as the atom is smaller and highly charged. The negative values simply imply that the compound is more covalent than the homopolar state selected as a reference (AlSb has practically four electrons per atom, like diamond). On the contrary, the Phillips parameter reflects practically no polarization. The value of 0.321 for InSb is a medium value and does not stand out in any way from that of the other III-V compounds. In the previous section, it was shown that no static electric dipole could exist in this compound. Hence the matter involves a function $f_i = f(e)$ calculated from a dynamic charge, as the author remarked recently (25). Moreover, Lawaetz (58) had emphasized the close relationship between f_i and e^*.

Conclusion

Although the physical models were greatly improved during the last fifty years, they are still unable to represent the large variety of chemical compounds (59). The concept of effective atomic charge is typically the kind of approximate model which the chemists strongly need and its future is promising because, although the static charge is derived from the old concepts of electronegativity and ionicity, the dynamic charge has several links with the new physical ideas. Equation [15] establishes between the charges q and e a simple relation which schematizes their roles.

From the point of view of effective atomic charge, the controversy prevailing a few years ago between Phillips (60) and Pauling (61) seems meaningless, as the latter used for the ionicity a function $f(q)$, although the former introduced a function $f(e)$ for which the term "dynamic ionicity" would probably be more adequate.

Manuscript received Feb. 3, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

The Electrochemistry of Some n-Heptylviologen Salt Solutions

Raymond J. Jasinski*

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

n-heptylviologen dibromide, and other viologen derivatives, form insoluble, stable, adherent, and colored radical cation salts when reduced cathodically from aqueous solution. As a result, such compounds are under study as the basis for alphanumeric displays. The presence of bromide ion in these solutions results in a number of undesirable side effects which can be minimized, in part, by replacement of bromide with dihydrogenphosphate anions. During these experiments it was found that the anion and viologen concentrations determined the potential at which the n-heptylviologen radical cation was formed and the adherence of the film. The metal substrate influenced the kinetics of side reactions, and the film adherence. The possibility of specific chemical interaction of HPO_4^{-2} with the radical cation is suggested by the data.

The "viologens" (1) are alkyl derivatives of 4,4′ dipyridyl. The dimethyl and diethyl compounds have been used as soluble redox potential indicators in biological systems (2), and as herbicides (3, 4) (the dimethyl compound is discussed in the literature in this context under the name "paraquat"). The electrochemistries of these compounds in aqueous solution are discussed in Ref. (10)-(12), (17), and (18). The general sequence of reaction is reduction of the dication to a stable, soluble, blue radical cation, followed, at more negative potentials, by reduction of the radical cation and/or the dication to the nominally colorless compound. It was recently shown (5, 16) that cathodic reduction of the longer chain alkyl derivatives yields a colored radical cation that is also stable in water and, in particular, is insoluble, adheres to the substrate on which it was formed, and can be anodically oxidized back to the dication. A number of these compounds are now being considered as active ingredients for "electrochromic" alphanumeric displays. Cathodic reduction of N,N′ diheptyl-4,4′ dipyridinium dibromide, potassium bromide solution yields an insoluble red violet film (5, 13, 16); reduction of N,N′ di(p-cyanophenyl)-4,4′ dipyridinium dichloride solution yields an insoluble green film (6).

The present paper discusses some properties of n-heptylviologen redox processes as they are influenced by the electrolyte anion and by the metal substrate at which the charge transfer takes place. This paper does not deal with long term effects, such as aging of films, or with low temperature effects.

Experimental

The term "diradical" will be used to indicate the two-electron reduction product of the viologen dication, as it is present on the electrode surface. Little information is available in the literature on whether or not these two electrons are paired. This question, relative to soluble reduced viologens, is discussed in Ref. (18) and (20); magnetic measurements on soluble dibenzyl-viologen (21) indicated that the two-electron reduction compound was diamagnetic.

The equipment used in these studies included the following: Wenking ST72 potentiostat, Wenking VSG72 scan generator, PAR digital coulometer, Keithley 616 digital electrometer, TI No. 341 recorder, Lab Con Company glove box.

The glass test cell was of the standard three-compartment design; a glass frit separated the counterelectrode compartment from the working electrode; a capillary, within 1 cm of the working electrode, isolated the PermaProbe reference electrode. The test cell and the glove box were deaerated with nitrogen which had been passed over copper at 300°C.

Open-circuit ("equilibrium") potentials were recorded 5-7 min after depositing a nominal 2 mC/cm² of radical cation film at potentials positive to those for diradical formation. No attempt was made to control cell temperature during these studies nor to confirm the day-to-day reproducibility of the PermaProbe reference electrode.

Because of the chemical reaction between the diradical and the dication, it was not possible to obtain open-circuit potentials that were stable and were not mixed potentials. Therefore the diradical formation potential was taken from the constant current charging curves. To minimize the influence of ohmic effects, the value recorded was that potential halfway between the cathodic and anodic potential plateaus. This technique, in spite of its lack of rigor, was also found to be necessary for obtaining potentials of poorly adherent radical cation films.

The n-heptylviologen dibromide was synthesized in-house from dipyridyl and n-heptylbromide (12); NMR indicated no detectable monosubstituted dipyridyl, excess heptylbromide or dipyridyl; the infrared spectra (KBr pellets) for this synthesized viologen were identical to those taken on the small samples of purchased material.

Bromide ion was replaced with the various other anions of interest via passing an aqueous solution of the viologen dibromide down a column of anion exchange resin (Amberlite 1RA-400) in the appropriate form. We were not successful in isolating solid salts other than the bromide. The anions which were found to be compatible with the viologen and its reduction products were Br^-, $H_2PO_4^-$, SO_4^{-2}, F^-, formate, and

* Electrochemical Society Active Member.

Key words: displays, electrochromics, dipyridinium salts, radical cations, colored films.

acetate; Br^-, Cl^-, BF_4^-, and ClO_4^- viologen solutions have been studied by others (7). Bicarbonate, at pH 7.5, slowly hydrolyzed the viologen; BH_4^- and CN^- discolored viologen bromide solutions; PF_6^-, SbF_6^-, AsF_6^-, and SCN^- generated precipitates on addition to n-heptylviologen solutions. Nitrate chemically oxidized the viologen radical cation.

The metal electrodes used were platinum (Corning No. 476060), silver (Corning No. 476065), and gold foil. The gold was cleaned by anodization in KCN solution, the only procedure found effective after the viologen diradical had been deposited on the gold electrode surface in bromide solution.

The negative potential limits, at pH 5.5, were −740 mV for gold, −540 mV for platinum, and −600 mV for silver, as measured by the irreversible generation of cathodic charge. The reaction is, of course, the generation of molecular hydrogen; the H_2/H^+ electrode potential *vs.* the PermaProbe at pH 5.5 was measured (14) as −520 mV. Obviously the potential range available for studying the viologen radical cation films on platinum is limited. Nevertheless (see Table I), there is a sufficiently large potential difference between viologen reduction and hydrogen evolution, that films can be formed, at least in some electrolytes; such deposits have been reported from fluoride, Br^-, Cl^-, BF_4^-, and ClO_4^- solutions (7). It was also found here that short excursions to −1V, in the presence of n-heptylviologen dication, did not yield visible hydrogen gas or a defined plateau on the constant current charging curve. A classical technique for increasing the overvoltage for hydrogen evolution from active metals is amalgamation of the surface with mercury. This was done with platinum by cathodization in mercurous ion solution. The electrode surface so prepared did not generate hydrogen during the 24 hr hold at −600 mV, as had the original platinum electrode; radical cation films were stable on this amalgamated surface when formed within the potential range of −450 to −850 mV.

The anodic limits of these metals were set by the oxidation of the electrode rather than the electrolyte. Silver is the least noble metal studied; reaction took place at +87 mV in 0.3M KBr^-, and at +26 mV in 2M $H_2PO_4^-$. Although the silver/salt reactions were reversible, the metal-to-salt-to-metal cyclic process tarnished the silver surface via the finely divided silver so formed. The initiation of gold oxidation in the bromide and phosphate solutions occurred at nominally the same potential (+700 mV). At higher potentials, in bromide, the electrode discolored and finally bromine evolution was observed; gold did not visibly discolor in phosphate at any potential.

Results and Discussion

Shown in Table I are the reduction potentials for n-heptylviologen dication as a function of anion and metal substrate. The least negative number for each pair of potentials is the steady-state open-circuit potential for the metal coated with a film of radical cation; the more negative potential is that for the radical cation/diradical reaction; for reasons discussed above, only two significant figures are listed for the potential values.

Thus, it is the anion rather than the metal substrate which determines the redox potential; within the accuracy of the data, the potentials of the radical cation formation, for a given anion, were independent of the metal substrate on which the film was formed.

The physical properties of the radical cation film also depended on anion. For example, radical cation films generated on gold and silver from formate solution showed an obvious tendency to "recrystallize" on open circuit. The electrode initially covered uniformly with radical cation salt would, within a short time, become lighter at the edges and darker in the center of the electrode. Addition of formate to phosphate solutions resulted in radical cation formation on both gold and silver electrodes, which also showed this recrystallization effect; the effect was not observed in the original phosphate solution. (Measurements could not be taken on platinum since formate oxides at −470 mV.)

"Well-behaved" radical cation films were generated from viologen bicarbonate solutions; these were adherent, stable, and free of recrystallization effects. However, the minimum pH possible with bicarbonate was 7.5, and slow hydrolysis of the viologen dication became obvious after a few days.

Acetate was investigated briefly. Radical cation films formed from this solution were stable if the salt concentration was at or above 0.5M; films generated from 0.3M acetate slowly lost adherence and drifted off into the solution as a blue haze.

The metal was not entirely without effect however. Of interest are the observations noted in Table I for gold, platinum, and silver electrodes in fluoride and sulfate solutions of the n-heptylviologen dication. As reported by others (7), stable red violet films were obtained by reduction on platinum from fluoride solutions. We have found the same to be true for platinum and silver in sulfate solution. However, color was not found when gold was cathodized in either viologen solution, yet the charging curves showed well-defined plateaus on cathodization and on anodization. The addition of 2*N* KF to a phosphate/formate viologen solution completely suppressed the color normally generated on gold electrodes. The red violet film formed on silver from fluoride was not all that stable, slowly converting over to a blue haze which floated away from the electrode surface. This did not happen with platinum, nor was this blue material formed from a gold electrode. The mechanism involved has not been established.

Stable "well-behaved" radical cation films were obtained with phosphate solutions of the appropriate pH; the remainder of this paper discusses the electrochemistry of the n-heptylviologen/phosphate system, using the behavior of the same viologen in bromide as reference (5, 7).

Unlike the n-heptylviologen bromide electrode, the properties of n-heptylviologen phosphate are pH dependent. The trends observed in formation and equilibrium potentials were in agreement with the solubility product mechanism (7) and the sole involvement of monovalent phosphate in controlling the radical cation concentration. Fitting the measured potentials for ten viologen/dihydrogenphosphate solutions (pH 5-7.5) to the Nernst equation resulted in an E_0 of -357 ± 6 mV (average error) *vs.* PermaProbe (or −147 *vs.* NHE); K_{12} for the dihydrogenphosphate/hydrogenphosphate equilibrium was taken as 6.71 (15). The potential for the second electron reduction, yielding the neutral diradical, was in the range of −750 to −800 mV, and was independent of pH, viologen concentration, and total phosphate concentration.

The dynamics of the viologen phosphate electrode are illustrated by the charging curve shown in Fig. 1, for 0.036M viologen, 2M phosphate, pH 6 on gold at a constant 0.1 mA/cm^2. In most of its features, this curve

* Millimolar viologen.

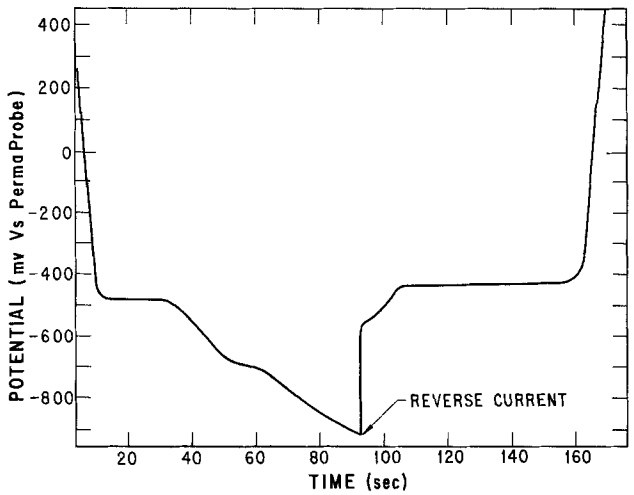

Fig. 1. Shown is a charging curve taken on gold at 0.1 mA/cm² in pH 6 molar phosphate containing 0.036M n-heptylviologen dication. At zero time the current was made cathodic; at nominally 92 sec the current direction was reversed.

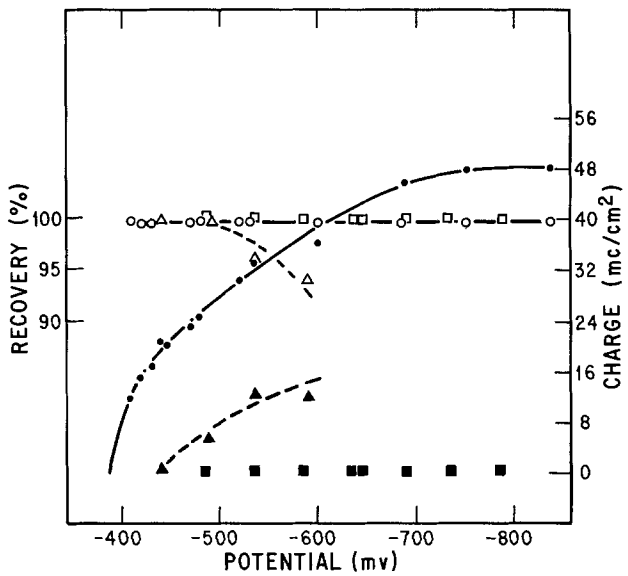

Fig. 2. Plotted vs. potential are the percent cathodic charge recovered anodically (open symbols) and the total cathodic charge passed (closed symbols). The electrode was gold, scanned at 20 mV/sec from +100 mV to the potential listed and back to +100 mV. The solutions were (○) 0.01M n-heptylviologen in 2M phosphate, pH 5.5, (△) 0.02M n-heptylviologen in 0.3M KBr, and (□) 0.2M n-heptylviologen in 0.3M KBr.

resembles closely those obtainable in KBr/viologen solutions. Two well-defined cathodic plateaus were observed, associated with the dication/radical cation and radical cation/diradical reactions. The disparity in lengths of the corresponding anodic and cathodic plateaus is due, presumably, to the intervening chemical reaction of the diradical with the dication (16); some of the remaining diradical is, obviously, oxidizable anodically. As the potential rises, here at 160 sec, the electrode cleared of the last traces of color. It is in this aspect that these phosphate charging curves differ from those taken in KBr. In bromide solution containing essentially the same amount of viologen, color remained visible to at least +300 mV and the ascending branch of the anodic curve was well spread out along the X axis. When the cathodic charging in bromide solution was restricted to the first plateau, complete erasure was obtained before the anodic curve rose to +300 mV. This restriction on potential avoided the diradical process, but also decreased the amount of charge passed into the electrode. The latter was the dominant factor as shown by the following results.

The experiment consisted of a series of cyclic voltammograms from +100 mV to a given potential and back at 20 mV/sec; the potential was then held at +100 mV until the coulometer stopped counting anodic charge for 60 sec. In Fig. 2 are six curves which relate the percent cathodic charge recovered as anodic charge (the open symbols) and the total input cathodic charge (closed symbols) with the negative potential limit of the cyclic scan.

Under these conditions, then, it was possible to anodize totally the high charge capacity radical cation films formed from the phosphate electrolyte. However, total anodization was not achieved for the radical cation films generated from 0.02M viologen/KBr, even though the negative limit of the potential sweep was kept positive of that required for diradical formation. Repeating these experiments but with a lower viologen concentration resulted in less cathodic charge (0.8 mC/cm²) and greater reversibility. Thus, within the accuracy of the coulometer and the background charge correction, the over-all reversibility of the radical cation redox process in 0.02M viologen bromide solution is more sensitive to the quantity of charge passed, *i.e.*, the thickness of the film than to the potential limit of formation.

To further test the effective reversibility of the high charge content deposits formed from phosphate solution, a series of fifteen repetitive cycles was made between +100 mV and −431, −481, and −531 mV each; no hold period was used; the total cathodic charge input per cycle was essentially as shown in the figure. Within the accuracy of the experiment, the cumulative anodic charge was equal to the total input cathodic charge.

Although anodization of the radical cation film formed out of the dilute viologen/KBr solution was essentially complete to the coulometer, and independent of the negative potential limit, a side reaction did become visible at potentials more negative than −732 mV, *i.e.* the accumulation of black spots on the gold surface. This effect is related to the formation of the diradical which occurs in this potential region (Fig. 1).

The electrode material and solution composition also affected the side reaction. This spot generation phenomenon was not observed in phosphate solution on gold over the entire potential range, or on platinum in the same bromide solution over the entire potential range.

(Repetitive scans of the phosphate solution into the diradical region did generate spots eventually. It has not yet been established whether this cosmetic effect is inherent to the gold/viologen system or whether this was due to an impurity generated electrochemically at the counterelectrode. There is some support for the latter, in that phosphate solutions cycled in the test cells described did "age," particularly when the contents of the counter and working electrode compartments were combined. In these solutions freshly cleaned gold and platinum electrodes showed the discolorations while freshly prepared phosphate solutions did not yield discoloration on the same electrodes. In any event, gold cathodized in fresh phosphate viologen solutions is less affected by side reaction discoloration than gold cathodized in fresh viologen bromide solutions.)

Positive potential excursions also had an effect on the cosmetics of the viologen redox processes. It was observed that prior oxidation of the gold electrode in KBr at +450 to +650 mV resulted in the generation of residue and spots on subsequent reduction at the dication/radical cation plateau. These spots were slow to clear on anodization and reappeared on subsequent cathodization. Similar results were observed in phosphate solutions at and above +750 mV. Degradation in

cosmetics was found in phosphate for pure and amalgamated platinum that had been anodized at potentials in excess of +600 mV. Such electrodes, subsequently cathodized, developed blue black spots and a yellow, oil-like film which could not be removed electrochemically, but could be wiped off physically. Pulsed anodization of platinum to +1.2V produced a green yellow material on the surface which was extremely adherent.

Besides potential-dependent side reactions, there are also chemical side reactions. Consider the following. The color, adherence, and general appearance of the viologen radical cation/phosphate films formed at and below pH 5.5 were comparable to those of viologen radical cation in KBr. At higher pH values this was not the case. The color of the radical cation films formed in pH 6 phosphate were lighter than at the lower pH values; no problem was noted with adherence. The electrode behavior in pH 7, molar phosphate was inferior to that at pH 6, in that, on open circuit, a blue haze slowly developed about thick deposits of radical cation film. Although the dihydrogenphosphate at pH 7 is only 34% of the total phosphate (15), the $H_2PO_4^-$ concentration was still 0.34M; at pH 6, 0.1M phosphate was sufficient to form a stable, adherent radical cation film with 0.036M viologen. At pH 7.5 [14% of the anion is the dihydrogenphosphate (15)], constant current reduction yielded a prominent blue haze; it formed more rapidly and eventually erased the red violet radical cation film from the surface of the electrode. The same results were obtained on gold and silver.

The cyclic voltammogram accompanying the effects on gold, at pH 7.5, is shown in Fig. 3 (100 mV/sec).

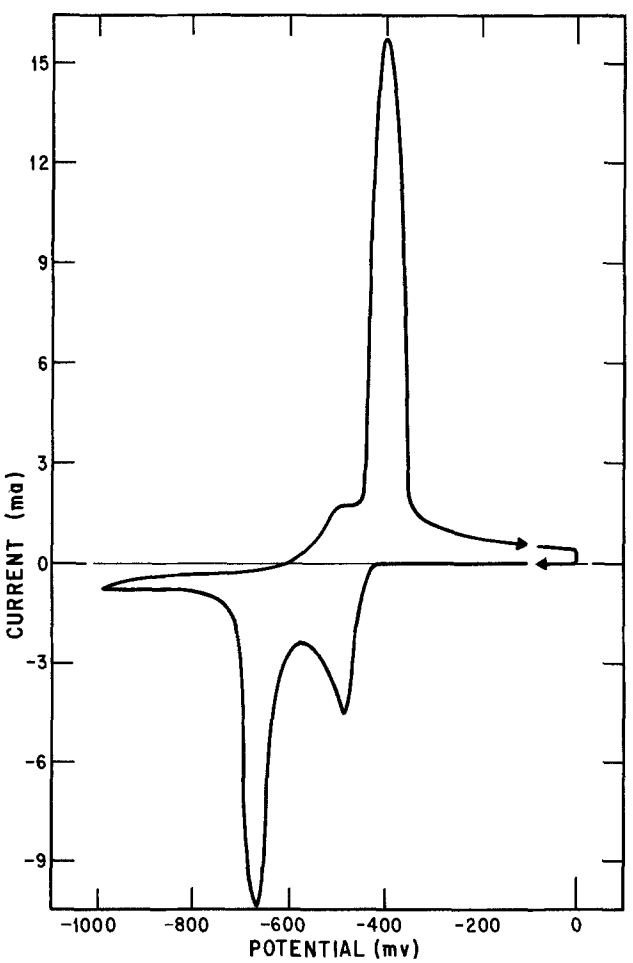

Fig. 3. Shown is a reproduction of a 100 mV/sec cyclic voltammogram, starting at 0 mV *vs.* PermaProbe. The electrode was gold immersed in pH 7.5, molar phosphate containing 0.036M n-heptyl-viologen dication.

There are distinct cathodic peaks at −485 mV and at −640 mV, the latter, associated with diradical formation, being much larger than found at lower pH values. Subsequent anodic oxidation yielded a shoulder at −510 mV, and the sharp peak at −420 mV, characteristic of radical cation oxidation.

The interpretation here is the following. Both the radical cation and the diradical form on cathodic reduction of the solution. The adherence of the radical cation is much less than at lower pH values (a blue haze was observed) so that the electrode surface does not passivate. Thus more diradical can form than at lower pH, and the diradical is held strongly to the surface; the electrode passivates. As the potential goes more positive, the diradical either reacts chemically with the dication and is oxidized via the radical cation, or it is oxidized directly in one step, accounting for the −420 mV peak. The tailing of the anodic portion of the curve could be due to the irreversibility of the diradical oxidation or to the diffusion-controlled oxidation of the "blue haze."

The effect of pH on response time is also consistent with the idea that, in phosphate, higher pH results in a less adherent radical cation film. Plotted in Fig. 4 are the current-time relationships in pH 5 and pH 6 phosphate/viologen solution for gold electrodes first pulsed cathodically (−500 mV) and then pulsed anodically (−250 mV). Obviously, the radical cation film generated out of the pH 6 solution erases (anodizes) faster than that generated out of pH 5 solution. This experiment was repeated with silver electrodes; the anodic portions of the curves were essentially identical to those obtained for gold at pH 5, *i.e.*, pH had little effect on adherence, at least in this low pH range. As mentioned both silver and gold electrodes showed the presence of blue haze at pH 7.5.

These adherence effects cannot be the result of a pH interaction with the viologen dication or radical cation; well-behaved films were generated out of viologen bicarbonate solution, pH 7.5. Nor can these effects be due to the lack of monovalent anion, as shown above. Excess divalent sulfate did not give rise to the phenomenon either with or without phosphate present (pH 6). The cause then must be the chemical properties of the HPO_4^{-2} anion. It is unlikely that this anion would

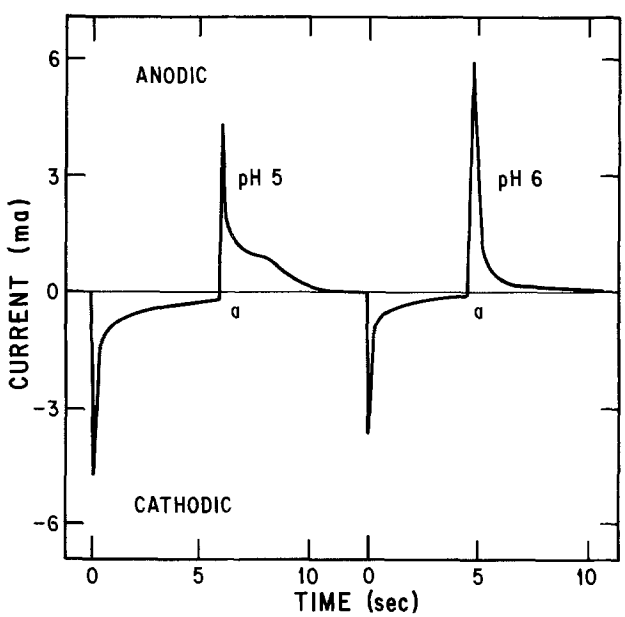

Fig. 4. Shown are the current pulses resulting from the following constant potential sequence: at time zero, −500 mV was applied to generate the cathodic currents; at time (a) the potential was increased to −250 mV to generate the anodic current. The electrode was gold in molar phosphate containing 0.16M n-heptyl-viologen dication. The pH values were 5 and 6.

specifically adsorb on the electrode surface at these negative potentials and displace the viologen radical cation film. More likely (19) is the chemical interaction of HPO_4^{-2} with the radical cation film to yield a reduced but soluble complex ion, colloid, or micelle as the blue haze. Molecular models are consistent with interaction between hydrogenphosphate ions within the radical cation film [assuming the "sandwich" structure proposed in Ref. (7)].

Summary

Thus, regarding the properties of the viologen/phosphate electrode system, (*i*) stable radical cation films can be formed on gold, platinum, and silver from $H_2PO_4^-$ solutions; (*ii*) the effective potential region available for viologen redox reaction study is greater than in bromide electrolytes; (*iii*) formation potential, adherence, erasure times are pH dependent; and (*iv*) side reactions are less significant to electrode cosmetics.

To generalize, (*i*) the equilibrium potential of the n-heptylviologen radical cation films is determined by the viologen concentration and the anion composition of the electrolytes; to this extent the electrode is an inert substrate for charge transfer, (*ii*) the metal substrate exerts an effect with regard to the kinetics of side reactions and film adherence, and (*iii*) chemical reactions can and do occur between the radical cation film and other ions in solution.

ABSTRACT

The behavior of Na_2O-NaCl melts at 830°C has been studied by three techniques: (*i*) potentiometric studies, using oxide ion specific zirconia electrodes in the reversible galvanic cell

$$Ag|AgCl, NaCl|glass|NaCl, Na_2O|ZrO_2|O_2 (Pt)$$

(*ii*) manometric experiments in which the uptake of O_2 by the melts was observed, and (*iii*) chemical analyses in which oxide and peroxide were found in quenched melts. All three kinds of experiments are thus consistent with the partial conversion of oxide to peroxide by the reaction $Na_2O + \frac{1}{2} O_2 = Na_2O_2$, but the calculated equilibrium varies with the technique employed. Both chemical and electrochemical studies indicate that the peroxide/oxide ratio does not change as the oxygen pressure is changed from 0.1 to 10^{-6} atm. Various explanations for this result are examined.

The behavior of dissolved oxides in molten salts has been a subject of continued interest since Lux (1) first studied acid-base behavior in melts during the 1930's. Knowledge of the state of dissolved oxides is required for understanding the behavior of the oxygen electrode, the solubility product of slightly soluble oxides, and the corrosion of metals.

Until Zambonin and Jordan (2) discovered that the oxide ion in molten nitrates largely transformed

* Electrochemical Society Active Member.

Key words: oxide melts, zirconia electrodes, molten NaCl, peroxides.

to peroxide and superoxide ions, the oxide ion was considered to be a stable species in molten salts. Although nitrate melts may be anomalous in this respect because the NO_3^- ion can oxidize the O^{2-} ion to O_2^{2-} and O_2^-, the absence of this phenomenon in other melts, *e.g.*, halides, sulfates, and carbonates, should no longer be taken for granted, particularly since in nitrate melts the oxidation involves molecular oxygen when that substance is present and the reduction of the melt anion by O^{2-} when O_2 is absent (3). Some evidence for the formation of peroxides and superoxides in molten chlorides has already been presented (4), but all the proposed mechanisms require the presence of molecular oxygen. Whether some lower limit for the required oxygen pressure exists has not yet been established. At any rate, on the basis of the evidence presented so far, O^{2-} would be expected to be stable in halide melts when O_2 is absent.

Most earlier studies used the oxygen electrode on platinum as an oxide ion reversible electrode. However, the nonspecificity of the platinum surface for a particular electron exchange reaction means that more than one such reaction may occur on this surface, depending on experimental conditions. For example, both one- and two-electron processes have been observed for the oxygen electrode on platinum (5). Moreover, the use of this electrode necessarily precludes studying oxides in the absence of O_2.

More recently, solid-state electrodes reversible only to oxide ions have been used in melts. These electrodes, which are generally oxide-doped zirconia, have the great advantage of serving as oxide ion specific membrane electrodes, with no electron exchange possible at the phase boundary between the solid oxide electrode and the oxide-containing melt. Such an electrode was used by Combes, Vedel, and Tremillon (6) to carry out potentiometric titrations of Cu^{++} and Ni^{++} by O^{2-} in 1:1 NaCl-KCl. We have recently used these electrodes in nitrate melts (3). However, since several reactions occur after the addition of Na_2O to these melts and their equilibria are established at different rates, it was never possible to associate a particular cell emf with an absolute oxide activity, although the correct Nernst slopes were obtained from changes in the added oxide concentration. This problem is in fact quite general. Assuming that a stable reference electrode is available, then a change in cell emf measures (through the Nernst equation) changes in the O^{2-} activity. However, even if the reference electrode is well defined and reversible so that a reversible cell reaction can be identified with an independently determined E° (a condition not commonly fulfilled), emf measurements of such a cell can only be used to determine oxide ion activities and not the mechanism by which this oxide activity arises—a characteristic of all thermodynamic measurements. A mechanistic interpretation of the potentiometric measurements thus requires extra thermodynamic assumptions and/or measurements. For example, the obtaining of the correct Nernst slope for a postulated electrode reaction is frequently taken as evidence for the correctness of the postulate. but as we have shown (3), more than one reaction may give the correct slope if several mobile equilibria are operating.

A more stringent test of a postulated reaction is obtained if, in addition to the correct slope, the correct E° is also obtained. Such a test requires that all electrode potentials, melt activities, and phase boundary potentials must be known for the cell in question. At the present state of knowledge in molten salts, such an independent calculation of E° is generally out of reach because the data obtained from a galvanic cell are themselves used to obtain E°. A more modest goal is to study a cell in which a well-defined, reversible reaction takes place, and to test the interpretation by some independent method.

In the present work we studied solutions of Na_2O in NaCl electrochemically by using oxide-doped zirconia electrodes, and manometrically in order to observe the uptake of oxygen by these melts. In addition, chemical analyses were carried out on quenched melts.

The cell used can be written formally as

$$\text{Ag}|\text{AgCl, NaCl}|\text{solid Na}^+\text{ conductor}|\text{NaCl},\ \text{Na}_2\text{O}|\text{stab. Zirconia}|\text{O}_2\text{(Pt)} \quad \text{[I]}$$

The cell reaction therefore is

$$2\text{Ag(s)} + 1/2\,\text{O}_2\text{(g)} = (2\text{Ag}^+ + \text{O}^{2-})\text{ in NaCl} \quad \text{[1]}$$

The selectivity of fused silica, a pure cation conductor, for silver ion and oxide ion is so low (7) that there is no significant contribution to the phase boundary potential across the membrane from these two ions, the only contribution to the cell emf arising from the difference in NaCl activity across the membrane. Mullite behaves similarly. The total cell emf therefore is

$$E = E^\circ - RT/2\mathbf{F}\ln[a^2_{\text{AgCl(R)}}\cdot a_{\text{Na}_2\text{O}})/p_{\text{O}_2\text{(R)}}{}^{1/2}] + RT/\mathbf{F}\ln a_{\text{NaCl(Na}_2\text{O)}}/a_{\text{NaCl(R)}} \quad \text{[2]}$$

$a_{\text{AgCl(R)}}$ and $a_{\text{NaCl(R)}}$ are the activities in the reference melt. $a_{\text{NaCl(Na}_2\text{O)}}$ is the activity of NaCl in the melt to which Na_2O is added. For the dilute solutions of Na_2O used in this work, $a_{\text{NaCl(Na}_2\text{O)}} \approx 1$. Separating out the constant terms gives

$$E = [E^\circ - RT/\mathbf{F}\ln(a_{\text{AgCl(R)}}/a_{\text{NaCl(R)}})] - RT/2\mathbf{F}\ln a_{\text{Na}_2\text{O}}p_{\text{O}_2\text{(R)}}{}^{1/2} \quad \text{[3]}$$

Since thermodynamic data for AgCl-NaCl solutions are known (8), $a_{\text{AgCl(R)}}$ and $a_{\text{NaCl(R)}}$ can be determined from the reference melt composition. $p_{\text{O}_2\text{(R)}}$ represents the oxygen pressure inside the zirconia electrode and not the pressure of O_2 above the Na_2O-NaCl melt. Suppose, for example, that in the presence of O_2 the equilibrium

$$\text{Na}_2\text{O} + 1/2\,\text{O}_2 = \text{Na}_2\text{O}_2 \quad \text{[4]}$$

is established in the melt. Then $a_{\text{Na}_2\text{O}}$ is related to the equilibrium constant for reaction [4]

$$a_{\text{Na}_2\text{O}} = a_{\text{Na}_2\text{O}_2}/K_{\text{eq}}p_{\text{O}_2}{}^{1/2} \quad \text{[5]}$$

The purpose of this work is to examine Na_2O-NaCl melts to see if reactions like [4] involving Na_2O_2 or NaO_2 occur to a significant degree and must be taken into account when these melts are used, for example, as solvents for heavy metal oxides, or when they occur in corrosive environments. Electrochemical experiments have been supplemented by manometric and chemical studies to gain information on this system.

Experimental

Experiments were carried out both in a helium-filled dry box (Vacuum/Atmospheres Corporation) with recirculating dry train in which moisture and O_2 were generally kept at the 1 ppm level and in a similar dry box in which an equally dry and CO_2-free helium-oxygen atmosphere could be maintained at approximately 10% O_2. The general methodology follows that of our earlier work (3), both for the electrochemical and manometric experiments, with some changes necessitated by the corrosive nature of Na_2O-NaCl melts. All experiments were carried out at 830° ± 5°C.

Materials.—Salts.—Reagent grade NaCl was vacuum-dried at 500°C before use. Reagent Na_2O (Alfa Inorganics) (94% Na_2O by analysis) containing ~2% Na_2O_2 impurity, and reagent Na_2O_2 were used without pretreatment. All weighing and transfer operations involving these substances were carried out in the dry boxes in which the experiments were done.

Containers.—The following crucible materials were examined as containers: high-purity alumina, magnesia, calcia-stabilized zirconia, zirconium, platinum, and gold. None were completely inert. Results are described in the next section.

Reference electrodes.—Both fused silica and mullite tubes were examined. The reference melt inside these tubes was ~10 mole percent (m/o) AgCl in NaCl, and a silver wire functioned as electrode. The potential-determining processes of the glass electrodes had previously been studied in detail (7). A comparison of fused silica and mullite in NaCl over 1-2 day periods showed the mullite electrodes to have better emf stability. Since both materials are attacked even by dilute Na_2O-NaCl melts, the electrodes were kept in the melt only during the actual measurements and just above the melt the rest of the time.

Oxide-reversible electrodes.—Three types of zirconia electrodes were studied, all made by Zircoa Corporation: CaO-, Y_2O_3-, and MgO-stabilized ZrO_2. All three function as pure oxide ion conductors and would be expected to be reversible only to O^{2-} ions in the melt. The inside of the tubes, fitted with platinum gauze and wire in contact with the ceramic, is reversible to oxygen gas. It was found that CaO-stabilized tubes frequently were so weakened by their exposure to the melt that they cracked unpredictably even when great care was taken to protect them from thermal shock. Consequently only results with MgO- and Y_2O_3-stabilized electrodes are reported. Both kinds were very stable and could be used for many experiments if they were protected from thermal shock. No systematic differences in their electrochemical behavior were found.

General procedure.—Electrochemical studies.—Crucibles to be used as melt containers were filled with NaCl and placed in an alumina crucible fitted with a fired lava stone top having holes to accommodate the salt addition tube, glass reference electrode, zirconia electrode, and Chromel-Alumel thermocouple in an alumina sheath. For experiments in the He-filled box the tops of the zirconia electrodes were fitted with ultraTorr O-ring connectors so that the oxygen gas pressure inside the tube could be adjusted through a copper tube sealed through the dry box wall. For experiments in the O_2-filled box, the electrodes were left open to the box atmosphere. The actual O_2 pressure, generally between 8 and 12%, was measured with a Beckman oxygen analyzer for each experiment. The entire cell assembly was placed in a platinum wire-wound furnace whose temperature was controlled through a thermocouple in the furnace well. The actual melt temperature was measured by a Chromel-Alumel thermocouple in an alumina tube placed directly in the melt. After this melt temperature had been reached, the thermocouple and its alumina sheath were removed from the molten NaCl to minimize contact of alkaline melts with alumina.

In order to be able to prepare very dilute Na_2O-NaCl melts, "stock melts" containing ~1 m/o Na_2O in NaCl were prepared by dissolving reagent Na_2O in NaCl at 830°C in a gold crucible, keeping the melts hot in the helium-filled dry box for several hours, pouring the melts into stainless steel trays for quenching, grinding, and analyzing by titration with standard HCl. Additions of these melts as well as of reagent Na_2O allowed oxide concentrations between $\sim 5 \times 10^{-4}$ to several mole percent to be prepared.

Some electrolysis experiments were carried out using a conventional d-c power supply, ammeter, and electronic coulometer.

Manometric studies.—Gold or platinum crucibles were sealed into a fused silica envelope of 835 ml capacity. This container had one standard taper opening through which the crucible could be filled and one attachment to the ultraTorr fitting through which gas, generally oxygen, could be passed in and out of the envelope. The lower half, containing the crucible, was placed in the furnace, the entire operation being conducted in the helium-filled dry box. The system was calibrated so that the actual number of moles of oxygen taken up or released by the melt could be measured in terms of pressure changes in the system (3).

In order to produce sufficiently large pressure changes in the system, $\sim 5 \times 10^{-2}$ mole Na_2O in ~1 mole NaCl were mixed in the container, sealed into the envelope, and attached to the measuring system and a gas reservoir of known volume from which O_2 could be metered into the cell. The mixture was heated under continuous pumping to decompose any Na_2O_2 impurity. After the final temperature had been reached, pumping was continued until no further pressure increase could be measured over a period of ~10 min. During this time a very small amount of some metal deposited on the inside wall of the cooler parts of the glass vessel. This material turned white as soon as O_2 was admitted. (The attainment of zero pressure implies that under the experimental conditions, the thermal dissociation of Na_2O is negligible compared to that of the higher oxides present as impurities, consistent with the thermodynamic stability of Na_2O.) A known amount of O_2 was then added to the system. After an initial decrease, the pressure became constant in ~30 min. The reverse process could be carried out by then pumping out the reservoir and letting the gas from the envelope expand into the reservoir. Assuming that the uptake and release of O_2 were produced by shifts in the oxide-peroxide equilibrium, the amount of peroxide dissociated could be calculated from the pressure increase. The dissociation appeared to take a little longer than the formation of peroxide, but generally not more than an hour.

Several values of the equilibrium constant could be obtained by such successive operations during one day, the length of the experiment generally being limited by the continuing vaporization of NaCl from the melt, and the corrosion of the crucibles. In fact, most experiments were done in heavy-walled platinum crucibles since a 5 m/o Na_2O-NaCl melt rapidly corrodes through gold.

Chemical studies.—Chemical analyses of melts prepared in various ways were carried out to aid in the interpretation of the electrochemical studies, primarily those done in the He-dry box. These analyses were: (*i*) titrations with standard (0.02*N*) HCl which give the sum of oxide, peroxide, and superoxide, and (*ii*) titrations with $KMnO_4$ (standardized against $Na_2C_2O_4$) in ice water which give the sum of peroxide and superoxide. Since no distinction between peroxide and superoxide is made in this work, results are calculated as peroxide. Analysis of the reagent Na_2O used showed that the actual oxide content was 94% of theoretical and that it contained 2% peroxide. Before the quenched melts were analyzed, the method was checked by analyzing synthetic unmelted NaCl-Na_2O and NaCl-Na_2O_2 mixtures of similar composition. The end point of the synthetic as well as of the melt samples was sharp at ~pH 5, indicating the absence of carbonate.

Results

General observations.—None of the container materials studied were completely inert to even dilute (<1 m/o) Na_2O-NaCl melts. Some of the changes undergone by the containers are obvious from visual examination; others can be detected from the time dependence of the emf of cell [I]. High purity Al_2O_3 dissolves slowly: $NaAlO_2$ was found in the aqueous solution of a quenched melt. MgO appeared to dissolve rapidly so that the O^{2-} concentration in the melt increased continuously. Gold crucibles, which were used in most of the experiments, produced small amounts of colloidal gold in suspension, but stable emf's could be obtained in them if the melts were dilute, and O_2 was absent. If even small amounts of reagent Na_2O were added in an O_2-containing atmosphere, corrosion was greatly accelerated and the melt leaked out through the holes thus produced. Platinum crucibles which were initially shiny bright acquired a very adherent brown-black coating, insoluble in molten NaCl, which seemed to partly protect the crucible from further attack. Results obtained in these crucibles will be described. The behavior of zirconia was more complex. Figure 1 shows the emf-time curve after sufficient reagent Na_2O (21 mg) had been added to NaCl in a CaO-stabilized zirconia crucible to make the resultant melt 3.9×10^{-4} mole fraction in O^{2-}. Over a 20 min period the O^{2-} concentration increased by a factor of 20 after the added Na_2O had already dissolved (the polarity of the ZrO_2 electrode becomes more negative with increasing O^{2-} concentration) and then decreased again over long periods of time. The sequence recurred after each subsequent addition of Na_2O. As is shown later, the decrease of O^{2-} is the phenomenon normally observed in Pt and Au containers where it is attributed to O_2^{2-} formation and vaporization of Na_2O. The increase of O^{2-} was, however, found only in ZrO_2 containers and suggests some solubility of the crucible material itself. This was of concern since zirconia electrodes were used in these experiments. The behavior of these electrodes was therefore carefully studied. The initial emf of cell [I] before the addition of NaCl was usually in the range 250-350 mV. Steady emf's were generally obtained after 1-2 hr. This emf may be associated with the solubility of ZrO_2 and/or its stabilizing agent in the melt (see below). The initial emf of cells employing electrodes used in previous runs tended to drift lower with progressive use, though rarely below 200 mV. These old electrodes were roughened and slightly whitened, indicating some attack by the alkaline melts. For runs in the O_2 atmosphere the electrodes were pulled up just above the melt to avoid contact as much as possible. For runs in the He-filled box this was not possible since the electrodes had to be attached to the O_2-containing manifold. However, stable emf's were measured when the dilute stock melt was added, indicating the stability of the electrodes at least in dilute melts.

Electrochemical studies.—Approximately 40 different runs of cell [I] were made, employing variations of container materials, electrode materials, atmosphere, and operating procedures. In all cases in which the container material was not obviously reactive, results were quite similar. Therefore, only typical results are presented.

According to Eq. [2] and [3] the emf of cell [I] should vary with O_2 pressure according to $RT/4F \ln p_{O_2}$. A test of this relation is shown in Fig. 2. Some hysteresis is noticeable before any Na_2O had been added to the melt, slightly better agreement with theory being obtained when the pressure was decreased from 1 atm.

In order to reach lower concentrations than is possible by adding pure Na_2O to NaCl, a stock melt was prepared as described previously, and analyzed for O^{2-} by titration with 0.02*N* HCl under an inert atmosphere. Under these conditions the analysis yields the sum of oxide and any peroxide and superoxide that may be present. With this stock melt it was possible to reach nominal oxide concentrations lower than 10^{-5} mole fraction. After the addition of each increment a stable emf was obtained in a few minutes both in the He and the O_2 atmospheres. As shown in Fig. 3, the initial dependence of emf on X_{O2-} is very much less than the theoretical $RT/2F$ for $X_{O2-} < 1 \times 10^{-4}$. Above this concentration, the theoretical slope was attained. Possible reasons for the low concentration curvature are discussed later. The reproducibility of the data is described by a value of X_{O2-}

$= (4.6 \pm 2.2) \times 10^{-3}$ when $E = 0$ for seven experiments with different combinations of crucibles and electrodes.

Entirely different results are obtained, both in He and O_2 atmospheres, when reagent Na_2O is added to NaCl. The emf is not constant but becomes increasingly positive for several hours after each addition, indicating that the O^{2-} concentration is decreasing after the rapid initial change associated with solution of Na_2O in the melts. Moreover, the actual emf values are more negative by ~140 mV than would be expected on the basis of the dilute stock-melt additions. The effect is illustrated in Fig. 4 for an experiment in the He box. The filled circles represent the concentrations calculated from the stock melt; the open triangles are for additions of reagent Na_2O made so rapidly that no appreciable decrease of emf occurred. Both sets of data have a slope of $RT/2F$, but are separated by ~140 mV. In the O_2 atmosphere the decrease of emf after addition of Na_2O is so rapid that only a single point for reagent Na_2O after addition of stock melt could be obtained. If it is assumed that the addition of reagent Na_2O initially produces an equivalent O^{2-} concentration in the melt, then it follows that the O^{2-} concentration produced by addition of stock melt is considerably less than expected from the nominal concentration. The ratio between the O^{2-} concentration immediately after the addition of reagent Na_2O and the final value obtained after the emf had become approximately constant is ~7. (The emf never becomes exactly constant because of slow corrosion reactions with the container and the electrodes.) Similar results were obtained

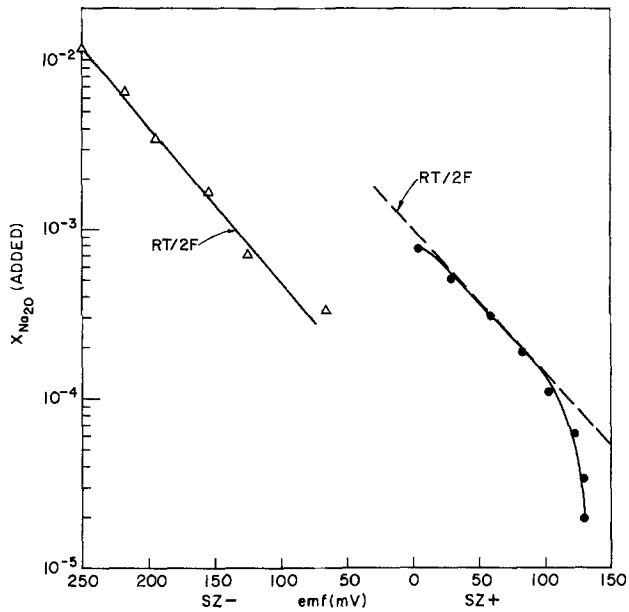

Fig. 4. Emf dependence of cell [I] on melt composition. ●, Nominal $X_{O^{2-}}$ (stock melt); △, reagent Na_2O. For discussion, see text.

in both Au and Pt crucibles. Typical data are shown for Au in Table I.

The value of X_{Na_2O} in Table I is that from the Na_2O calculated to have remained from the previous plus the new addition. It is apparent from the ratio in the next to the last column that a major part of the Na_2O added disappears. The first point is not anomalous but was reproduced in Pt as well. Apparently the first additions of Na_2O are almost entirely used up, after which the ratio becomes approximately constant. The initial portion of the emf-time curve is always linear, and the slope (last column of Table I) is, within a factor of ~3, independent of the initial O^{2-} concentration. Both of these observations are consistent with O^{2-} disappearing by a first-order reaction. The rates observed in the O_2-filled box are higher than in helium, but not by the factor of at least 10^4 by which the oxygen pressures differ. The rates are thus likely to be limited by some process in the melt.

Since corrosion reactions also lead to a decrease in the O^{2-} concentration, reproducible emf-time data are difficult to obtain and electrode kinetic techniques might prove useful. These are beyond the scope of the present paper.

On the assumption that the above results might be accounted for by peroxide formation, an attempt was made to measure emf's after addition of reagent Na_2O_2 to the melt. However, the results were the same as for the addition of pure Na_2O. Most likely solid Na_2O_2 decomposes to Na_2O before it dissolves in NaCl. Similar results were obtained for additions of NaO_2.

Table I. Ratio between $X_{O^{2-}}$ immediately after addition of Na_2O and at equilibrium

X_{Na_2O} (initial)	$E_{initial}$ (V)	E_{final} (V)	$X_{initial}/X_{final}$	dE/dt (mV/min)
5.38×10^{-4}	−0.206	+0.204	5760	2.2
2.55×10^{-3}	−0.527	−0.410	11.85	2.9
1.55	−0.496	−0.298	65.6	0.56
4.23	−0.504	−0.430	9.22	0.94
7.54	−0.486	−0.383	8.82	2.4
1.29×10^{-2}	−0.422	−0.384	3.49	0.98
2.10	−0.769	−0.672	7.76	2.8

If similar experiments are carried out with stock melts which have been heated only briefly instead of several hours, the emf is also time dependent, similar to additions of reagent Na_2O. This shows that the transformation from an unstable emf to a stable one is not a function of concentration or of the melting process, but depends on a reaction occurring in the melt itself, *i.e.*, the reagent Na_2O undergoes reaction after solution in NaCl.

Chemical studies.—Synthetic mixtures of ~1 m/o Na_2O + NaCl and 1 m/o Na_2O_2 + NaCl were melted in Pt crucibles both in the He and O_2 boxes. Samples taken at intervals for analysis by dipping cold ceramic rods into the melt and by dipping into the liquid with a thermally equilibrated Pd bucket gave the same results, showing that no phase separation occurs on quenching. Melts taken from these crucibles shortly after melting and for several hours thereafter were black; samples taken at subsequent intervals were increasingly white. Similar melts prepared in alumina crucibles were white. Spectroscopic analyses of the melts from the Pt crucibles showed ~1% Pt in the black melts and ~0.1% in the white ones. This is consistent with the observations that (*i*) the analytically determined (oxide + peroxide) concentration was always less than expected from the weighed additions, and (*ii*) that a brownish coating was always found in the crucibles at the end of the runs. Evidently the Pt first reacts with the dissolved Na_2O to produce a platinic oxide in solution which slowly precipitates out. The peroxide/oxide ratio becomes constant within ~1 hr, but the absolute values of the concentrations continue to decrease slowly over many hours, indicating slow vaporization and/or thermal decomposition. Typical results for a run in a 15% O_2 atmosphere are shown in Table II. Similar results are obtained when starting with Na_2O_2 except that the initial peroxide/oxide ratio tends to be higher and then decreases.

Since platinum is attacked by even 1 m/o Na_2O solutions, similar experiments were also run in zirconium crucibles which are commonly used for peroxide fusions. In order to duplicate concentrations used in the manometric experiments, the initial concentrations were ~5 m/o Na_2O. Duplicate experiments run in He and in 20% O_2 atmospheres gave rather different results. In He more than half the oxide added initially had disappeared in half an hour, and peroxide was virtually absent. In O_2 much more of the added oxide was retained in the melt and substantial amounts of peroxide were formed. As in the experiments done in platinum, both oxide and peroxide concentrations decreased by a factor of ~2 in 5-6 hr while the peroxide/oxide ratio remained approximately constant at $(7.2 \pm 0.8) \times 10^{-2}$. Both crucibles were covered by an adherent white coating, probably ZrO_2, slightly in the He experiment and extensively in the O_2 atmosphere. Assuming that the peroxide found in solution is formed by the reaction $Na_2O + 1/2\ O_2 = Na_2O_2$, the equilibrium constant for this reaction can be calculated from the chemical analysis. The results are summarized in Table III.

The most striking result is that in Pt the peroxide/oxide ratio is approximately independent of the oxygen pressure rather than exhibiting the expected $p_{O_2}^{1/2}$ dependence, whereas in Zr no peroxide is formed at very low p_{O_2}. In oxygen both kinds of crucibles give similar results. As expected for an equilibrium, the same peroxide/oxide ratio is obtained whether the starting material is Na_2O or Na_2O_2. The comparison of these results with those obtained from the other experiments and their interpretation are taken up in the discussion.

Table II. Analysis of a Na_2O-NaCl melt initially 1.0 m/o Na_2O; 830°C; Pt crucible; 15% O_2 in He atmosphere

Zr	~10^{-6}	5.1×10^{-2} (Na_2O)	8	—	—

All of the HCl titration curves were those characteristic of strong acid-strong base neutralization and exhibited no inflections of the type observed by Shams El Din and Hosary (9) in molten nitrates, and attributed by them to pyronitrate formation. For this reason and because of the high melt temperatures, it seems reasonable to exclude intermediate species, such as oxychlorides, as well as carbonate contamination from consideration.

Manometric studies.—The experimental procedure for determining the amount of O_2 taken up by an NaCl melt containing Na_2O has already been described. Uptake of O_2 was generally complete in 20-30 min, a period somewhat shorter than observed in the electrochemical studies. The experiment was also done by starting with Na_2O_2 which evolved O_2 rapidly, consistent with the electrochemical and chemical observations.

In all cases the amount of O_2 taken up corresponded to partial conversion of O^{2-} to O_2^{2-}. Thus, although the presence of O_2^- cannot be ruled out on the basis of these experiments, its formation is probably negligible. In all further calculations, therefore, it is assumed that the only significant reaction occurring in these melts is $Na_2O + 1/2\ O_2 = Na_2O_2$. Over the range of pressures attainable in our apparatus (0.1-1 atm), the equilibrium constant is independent of pressure. The same value is obtained from both increasing and decreasing pressure experiments, indicating that the equilibrium is mobile. Since the oxide/peroxide ratio necessarily shifts with changes in pressure, the constancy of K_{eq}, expressed in concentration units (mole fraction), indicates that the activity coefficient ratio is independent of concentration for these rather dilute melts. It was noticed that, for a given initial filling of the crucible, the value of K_{eq} obtained from successive absorptions and desorptions of O_2 tended to decrease after the first few reversals. This phenomenon, indicating the loss of O^{2-}, may be associated with the progressive corrosion observed for both crucibles and/or vaporization of Na_2O. Consequently only the first few K_{eq} in each run were used to calculate the average. This interpretation is consistent with the observation that even the initial K_{eq} values in Au are lower than those in Pt by a factor of ~2, and corrosion of Au is more rapid than that of Pt. The average of seven determinations in Pt containers and two in Au is 2.51 ± 0.76 for the equilibrium constant expressed as

$$K_{eq} = \frac{X_{Na_2O_2}}{X_{Na_2O} \cdot p_{O_2}^{1/2}} \qquad [6]$$

with p in atmospheres.

Calculation of the oxide-peroxide equilibrium constant.—On the basis of the chemical, manometric, and

electrochemical results presented in the preceding sections, it seems reasonable to suppose that, at least in the presence of oxygen, oxide ions are partly transformed to peroxide. Methods for calculating the equilibrium constant of reaction [4] from manometric and chemical data are quite straightforward. The method used to calculate the equilibrium constant from the electrochemical results is somewhat more complicated. The procedure has been described elsewhere (10). The result is that at equilibrium in the He-box (Fig. 4)

$$K_{eq}p_{O_2}^{1/2} = X_{Na_2O_2}/X_{Na_2O} = 6.83/0.98 = 6.97 \quad [7]$$

A similar experiment done at an oxygen pressure of 0.123 atm is illustrated in Fig. 3. The open circles represent the nominal oxide concentrations resulting from the addition of stock melt. The open triangle is for the addition of pure Na_2O. Using the same method described previously for the He-box experiments gives $K_{eq}p_{O_2}^{1/2} = 5.92$. This approximate constancy of $K_{eq}p_{O_2}^{1/2}$ is quite similar to that found in the chemical studies. Since the atmospheres in the two dry boxes differ by a factor of at least 10^4, the K_{eq} values differ by a factor of 100; yet for some reason the peroxide/oxide ratio appears to be independent of oxygen pressure. We note first that the equilibrium constant determined electrochemically lies close to the values of $K_{eq}p_{O_2}^{1/2}$ determined manometrically and chemically. For example, when $p_{O_2} = 0.1$ atm, $K_{eq} = 5.92/(0.123)^{1/2} = 22$, which is at least within an order of magnitude of the manometric results. Considering that the electrochemical and manometric experiments are completely independent and make different assumptions, this agreement is reasonably satisfactory. It follows that the electrochemical experiments in the He atmosphere are anomalous since K_{eq} is approximately three orders of magnitude too large. One possible resolution seemed to lie in the distinction between O_2 in the atmosphere above the melt and O_2 dissolved in the melt. As defined by Eq. [6], the standard state for O_2 is the gas at 1 atm, although the reaction can only occur through O_2 dissolved in the melt. For equilibrium conditions this is reasonable since the concentration of dissolved O_2 is proportional to p_{O_2} through Henry's law. However, as recently pointed out by Fouletier, Fabry, and Kleitz (11), oxide-doped zirconia functions as a semipermeable membrane for O_2. Thus in the He box an O_2 pressure gradient of $\sim 10^6$ exists from the inside to the outside of the electrode. If O_2 is then transported across the membrane from inside the electrode into the melt, the O^{2-} in the melt might be converted to O_2^{2-}. Such transport has in fact been measured (13), but on the basis of the activation energy for diffusion, this mode of O_2 transport should be negligible at 830°C. An experimental test carried out in a manner similar to that in Ref. (12) confirmed this conclusion.

A further source of O_2 is the impurity concentration in helium. If the partial pressure of O_2 in He is 10^{-6} atm, a simple calculation based on the kinetic theory of gases shows that 5.8×10^{-3} mole O_2 will collide with the melt surface (~ 12 cm^2) per minute. For a typical oxide content in the melt (8×10^{-3} mole) and rate (1 mV/min = 2%/min), the reaction rate is 1.6×10^{-4} mole/min. Thus, assuming that a substantial fraction of the oxygen impinging on the surface dissolves, the amount of O_2 available from the gas phase is sufficient to account for the observed decrease of the O^{2-} concentration.

To test this hypothesis, a similar experiment was carried out in a closed container of ~ 500 ml capacity. In this case the total O_2 available for reaction comes from the impurity in the helium, $\sim 10^{-8}$ mole. The decrease in the added oxide concentration should therefore be negligible and a stable emf should be observed after the addition of Na_2O. However, the emf actually still changed in the direction associated with decreasing oxide ion concentration, indicating that even in the absence of O_2, O^{2-} is not stable in NaCl, either because it reacts with the container and/or electrodes, or because of reactions in the melt not yet considered. These are discussed in the next section.

A similar experiment was carried out in a graphite crucible which would be expected to enhance the stability of O^{2-} ($C + Na_2O_2 = Na_2O + CO$). Although the concentration of O^{2-} still decreased with time, its rate of disappearance was noticeably slowed.

Finally, we consider possible reasons for the deviation from the Nernst slope observed at low oxide concentrations (cf. Fig. 3). It has been suggested (6) that stabilized zirconia might possess some selectivity for chloride ions at low oxide concentration. Alternatively, the same results might be accounted for by an oxide impurity concentration in the 1-10 ppm range. Thus, if the initial emf is considered to arise from such an impurity and the appropriate concentration is added to the purposely added (solid circles) concentration, the resulting concentrations (open circles) lie on the Nernst slope. To distinguish between these explanations, reagent NaCl was electrolyzed at 2.0V between a platinum and a zirconia electrode so that any oxide ions in the melt would be transported through the zirconia. At intervals the open-circuit voltage between the zirconia and a mullite reference electrode was measured in order to follow the oxide concentration in the melt. When the electrolysis was carried out in a platinum crucible, the initial current decreased by a factor of ten. Concomitantly, the open-circuit voltage changed from about 200 to 500 mV, corresponding to a change in the oxide concentration (open triangles in Fig. 4) from 6×10^{-7} to 1×10^{-9}. After the current flow was interrupted, the emf rose fairly rapidly toward its initial value, suggesting that the initial impurity oxide concentration arises from the solubility of the ceramic electrodes. This seems a reasonable explanation, particularly since in an alumina crucible no emf higher than 350 mV could be obtained, corresponding to an oxide concentration of 2×10^{-8}. In this case the additional oxide ions arise from the solubility of the crucible. Although the selectivity of zirconia for chloride ions cannot be ruled out entirely on the basis of these results, the contribution of Cl^- to the transport of charge through zirconia must be minor, since the current through the ceramic would not otherwise decrease so markedly in the presence of such a great excess of Cl^-.

Discussion

Because of the extremely corrosive nature of even dilute Na_2O-NaCl melts, none of the measurements reported here were entirely free of container effects. Reactions carried out in Al_2O_3, MgO, and ZrO_2 crucibles probably reflect as much the reactions of the melts with the containers as they do the interactions in the NaCl-Na_2O-O_2 system itself. Even reactions carried out in Pt and Au crucibles suffer somewhat from slow dissolutions of the metals. For this reason the precision normally expected from potentiometric measurements is probably not attainable for this system. Moreover, an interpretation of the data requires the isolation of those features which are common to all the experiments and therefore associated with interactions in the melt rather than with the containers.

We first summarize the results obtained in the various experiments.

1. Both in ~ 0.1 atm O_2 and in $\sim 10^{-6}$ atm O_2, the emf-concentration and emf-time dependences of cell

[I] are a function of the manner in which Na_2O is added: (*i*) If the Na_2O is added as an aged, dilute (~m/o Na_2O in NaCl) stock melt, stable emf's are rapidly obtained in both atmospheres after each addition and the concentration dependence is $RT/2F$. (*ii*) If the Na_2O is added as reagent material or as an unaged stock melt, the emf changes with time in a direction indicative of a decrease in O^{2-}. If the reagent Na_2O additions are taken to represent "real oxide," then the stock melt additions contain almost an order of magnitude less oxide than expected from their nominal composition.

2. The manometric experiments show that O_2 is taken up by a Na_2O-NaCl melt and that this O_2 can be removed by pumping. If it is assumed that the reaction responsible for this phenomenon is $Na_2O + 1/2\ O_2 = Na_2O_2$, then the value of K_{eq} for this reaction is 2.51 ± 0.76, independent of p_{O_2} between 0.1 and 1.0 atm.

This result can be compared with calculations based on known thermodynamic data. Using values in the JANAF tables (13), the equilibrium constant for the reaction

$$Na_2O(s) + 1/2\ O_2(g) = Na_2O_2(s) \qquad [8]$$

at 1100°K is 3.14, the value to be expected in any solvent in which Na_2O and Na_2O_2 form ideal solutions, and in excellent agreement with our experiment.

3. The chemical analyses show that both oxide and peroxide are slowly lost from the melt, whereas the oxide/peroxide ratio becomes constant after ~1 hr when starting with either oxide or peroxide.

4. All three kinds of experiments, when done in Pt or Au crucibles, show that peroxide is formed from oxide and that the steady-state peroxide/oxide ratio is independent of oxygen pressure for each kind of experiment; but agreement among the three experiments is not as good: chemical 0.1, manometric 1.1, electrochemical 7.2 (at 20% O_2).

5. Only in the manometric experiments could the pressure be varied systematically from 0.1 to 1 atm. Within this range the melt concentration ratio was consistent with the equilibrium of reaction [4].

6. The equilibrium constants for reaction [4] calculated for the three methods are: chemical 0.3, manometric 2.5, electrochemical 22.

7. At very low oxygen pressures the peroxide/oxide ratios for the chemical and electrochemical experiments are virtually the same as at higher pressures when done in Pt and Au, but no peroxide could be detected in zirconium crucibles.

We consider first possible reasons for the discrepancies between the results obtained by the three methods in oxygen. Since it was shown (by a comparison of dipped and quenched melts) that the chemical analyses represent melt compositions, we assume provisionally that the chemical analyses represent melt composition. The higher values of K_{eq} (higher peroxide concentrations) obtained by manometry and potentiometry then remain to be accounted for. In the former, K_{eq} is calculated from the manometrically observed uptake and release of O_2. Thus, if there were another reaction which also reversibly absorbs O_2, the higher K_{eq} obtained by manometry could be accounted for. The only substances present capable of reacting with O_2 are NaCl and the container material. The reaction

$$2NaCl + \tfrac{1}{2}\ O_2 = Na_2O + Cl_2$$

is slight, $K_{eq} = 4.3 \times 10^{-18}$, and can only be made to occur by bubbling O_2 through the melt (14), a procedure not employed in these experiments. The oxides of both platinum and gold exist but are considered too unstable. Nevertheless, as indicated by the extensive corrosion of the metals and the platinum found in the analyzed melts, some oxygen-containing metal species may exist and account for the higher peroxide/oxide ratio.

The electrochemical experiment is even more indirect. Here peroxide formation is inferred from a comparison of equilibrated stock melts and additions of reagent Na_2O. Thus the calculation requires the correspondences: change of emf ↔ decrease of oxide ↔ increase of peroxide to hold. From what has been observed of the zirconia electrodes, the first of these is probably correct over the period of several hours during which an experiment is carried out. The second can only hold if there exists no other path for the disappearance of oxide. As the chemical experiments have shown, however, oxide does disappear from the melt, most rapidly immediately after addition and more slowly for several hours thereafter, either by vaporization and/or by reaction with the container; yet this decrease rarely exceeds a factor of two, corresponding to a change of $(RT/2F)\ln 2 = 33$ mV, much smaller than is actually observed for the emf time dependence over a period of several hours (*cf.* Table I). Moreover, if the vaporization of Na_2O during the addition is taken into account, the peroxide/oxide ratio would be larger since the line through the triangles in Fig. 4 would shift left.

The potentiometric results show that oxide disappears not only at low (1 ppm) oxygen pressure, but even when the total amount of O_2 has been limited by working in a closed He-filled container. The chemical analyses indicate that in Pt containers peroxide is formed both at 1 ppm and at higher O_2 content, but in zirconium crucibles peroxide forms only at higher O_2 content. We note that ZrO_2 was also observed to form at 1 ppm O_2. Since this oxide is much more stable than PtO_2, it is conceivable that Zr acts as a "getter" for O_2 and keeps it from reacting with the melt, whereas PtO_2 probably can only form as an unstable intermediate in some reaction sequence.

What still requires explanation is how oxide can disappear from the melt (to a much greater extent than can be accounted for by vaporization alone) even when O_2 is absent and why the peroxide/oxide ratio is virtually independent of O_2 pressure. This is in fact the situation obtaining in nitrate melts: In the absence of O_2, NO_3^- is reduced to NO_2^- by O^{2-}. In chloride melts the anion is, however, not reducible; but the oxidation of O^{2-} could proceed if even traces of Cl_2 were present since the equilibrium constant for the reaction

$$2Na_2O(s) + Cl_2(g) = 2NaCl(l) + Na_2O_2(s) \qquad [9]$$

is 2.05×10^{17} at 1100°K (13). The only Cl_2 in the system would arise from the thermal dissociation of NaCl itself

$$NaCl(l) = Na(g) + 1/2\ Cl_2(g) \qquad [10]$$

for which the equilibrium pressure of Cl_2 is 1.8×10^{-10} atm. Assuming ideal solution behavior and substituting this value of p_{Cl_2} into

$$K_{eq} = \frac{X_{Na_2O_2}}{X^2_{Na_2O}} \cdot \frac{X^2_{NaCl}}{p_{Cl_2}} = 2.05 \times 10^{17} \qquad [11]$$

gives, for dilute solutions ($X_{NaCl} \approx 1$), $X_{Na_2O_2}/X^2_{Na_2O} = 3.7 \times 10^7$. Since p_{Cl_2} cannot exceed its equilibrium value, this is the highest possible value of the ratio. Because of the nonlinear form of the equation, the ratio $X_{Na_2O_2}/X_{Na_2O}$ increases with the concentration of added oxide, rising from 3.9 when $X^\circ_{Na_2O} = 10^{-6}$ to 430 when $X^\circ_{Na_2O} = 10^{-2}$. [Under the same conditions the sodium from the dissociation of NaCl is not sufficient to reduce Na_2O_2: for the reaction

$$Na_2O_2 + 2Na = 2Na_2O \qquad [12]$$

K_{eq} (at 1100°K) $= 1.58 \times 10^{12}$ (14). $p_{Na} = 3.6 \times 10^{-10}$

atm from which $X^2_{Na_2O}/X_{Na_2O_2} = 5.7 \times 10^2$. Thus for example, if $X_{Na_2O} = 1 \times 10^{-2}$, then $X_{Na_2O_2} = 1.8 \times 10^{-7}$ which is negligible.]

Thus, if reaction [9] actually occurred, all of the added oxide would be converted to peroxide. This is clearly not the case, probably because the concentration of dissolved Cl_2 is too low for the reaction to occur at measurable speed. At any rate, the functional relation predicted by Eq. [11] does not agree with the electrochemical results shown in Fig. 4. Thus, as can be seen from Eq. [11], the ratio $X_{Na_2O_2}/X_{Na_2O}$, and hence the ratio $X°_{Na_2O}/X_{Na_2O}$, is dependent on $X°_{Na_2O}$. For example, while $X°_{Na_2O}$ rises from 10^{-6} to 10^{-2}, X_{Na_2O} changes from 1.2×10^{-7} to 1.2×10^{-5}. Since the plotted concentrations for the stock melt (solid circles) represent $X°_{Na_2O}$, the slope for this plot should have been twice that for addition of pure Na_2O, rather than the same, regardless of O_2 pressure. This leaves the electrochemical results obtained in the closed container unexplained unless one assumes that the observed decrease of oxide is produced by vaporization and/or decomposition or that traces of O_2 were introduced each time that the container was opened to add fresh Na_2O.

The question which then remains is why the ratio $X_{Na_2O}/X°_{Na_2O}$ appears to be independent of oxygen pressure. If the decrease of O^{2-} with time is to be accounted for by reaction [4], then the ratio should vary with p_{O_2}; if by reaction [9], the ratio should vary with $X°_{Na_2O}$. Neither condition obtains, and the ratio is independent of both p_{O_2} and of $X°_{Na_2O}$. Moreover, the chemical results show that the decrease of oxide inferred from the potentiometric results is equivalent to the formation of peroxide and that the peroxide/oxide ratio is also independent of O_2 pressure, at least in Pt containers. In the presence of sufficient oxygen there is not much doubt that the results are well accounted for by reaction [4]. The anomalous results are those obtained at low oxygen pressure.

The question of superoxide (O_2^-) formation in these melts has not been addressed, not because it may not be significant, but because the present data cannot be interpreted in terms of more than one equilibrium. In fact, for the reaction $Na_2O_2 + O_2 = 2NaO_2$, $K_{eq} = 3.72 \times 10^{-3}$ at 1100°K (13), so that superoxide formation may become appreciable at higher oxygen pressures. Polarographic measurements would be helpful in providing information on this point.

We consider next the calculation of $E°$ for cell [I], *i.e.*, reaction [1].

The data presented in Fig. 3 and 4 permit the calculation of $E°$ from Eq. [3]. The composition of the reference AgCl-NaCl melt was $X_{AgCl} = 0.102$. Activity coefficients at 800° are (8) $\gamma_{AgCl} = 1.37$, $\gamma_{NaCl} = 1.00$, from which $a_{AgCl} = (0.102)(1.37) = 0.140$, $a_{NaCl} = 0.898$. Since the Na_2O concentration was generally below 0.01 mole fraction, the activity of NaCl in that melt was unity. Substituting these values into Eq. [2] gives for the $E°$ values in the 12.3% O_2 box

$$E° = E - 0.141 + 0.109 \log X_{Na_2O}$$

and in the He-filled box (p_{O_2} inside the zirconia tube = 1 atm)

$$E° = E - 0.187 + 0.109 \log X_{Na_2O}$$

assuming that Na_2O-NaCl solutions are ideal ($a_{Na_2O} = X_{Na_2O}$). Using the data shown in Fig. 3 and the procedure previously described for obtaining the real oxide concentration yields $E = -0.010$ when $X_{Na_2O} = 3.89 \times 10^{-4}$ from which $E° = -0.523$. Similarly, in the helium box, $E = 0$ when the nominal $X_{Na_2O} = 4.6 \times 10^{-3}$. From the distance between the curves in Fig. 4 we have $X_{nom.}/X_{real} = 7.81 \times 10^{-4}/0.98 \times 10^{-4} = 7.97$. Hence, $X_{real} = 5.77 \times 10^{-4}$. Therefore $E° = -0.582$V, in fair agreement with the value in the O_2-filled box.

It is interesting to compare these results with those of a previous study (15) in which the equilibrium constant of reaction [1] was determined by analysis of melts prepared by direct mixing of NaCl-AgCl and NaCl-Na_2O melts.

These earlier results resemble the present ones in that nearly the same value of $X^2_{Ag^+} \cdot X_{O^{2-}} = K_{eq} p_{O_2}^{1/2}$ was obtained in air and in a helium-filled dry box, whereas the ion product would be expected to differ by a factor of ~100 in the two atmospheres. In air the value of the ion product was 3.8×10^{-7}. Since the oxide concentration was determined by titration with HCl, it would consist of the sum of O^{2-} and the higher oxides. Applying the results of the present work, the actual oxide concentration would be

$$X_{O^{2-}} = \frac{3.8 \times 10^{-7}}{(0.140)^2(5.9)} = 4.6 \times 10^{-7}$$

from which $K_{eq} = 2.0 \times 10^{-8}$, and $E° = -0.840$V, compared with -0.523V based on the present work alone. Although this difference is too large to provide satisfactory agreement, the two studies exhibit qualitatively similar results: the independence of an oxide concentration from oxygen pressure, when a dependence is expected.

Kinetics of Electrochemical Incorporation of Lithium into Aluminum

Carlos A. Melendres*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

The electrochemical incorporation of lithium into aluminum was investigated by chronocoulometric, galvanostatic, and potentiostatic techniques. Results of the chronocoulometric measurements were interpreted in terms of the theory developed by Astakhov. Incorporation of lithium to form the solid solution α-phase is limited by its rate of diffusion into aluminum, with a measured diffusion coefficient of about 4×10^{-10} cm^2/sec at 450°C. Implantation at potentials where a layer of intermetallic compound forms on the electrode surface was found to be limited initially by the reaction to form the compound LiAl (β-phase) and subsequently by the rate of lithium diffusion into the growing β-phase layer. The results of galvanostatic transient measurements indicate a diffusivity of lithium in β-LiAl of the order of 10^{-8} cm^2/sec and a fast charge transfer step. The initial steps in the formation of the intermetallic compound appear to involve typical electrocrystallization (*i.e.*, nucleation and growth) processes.

Lithium-aluminum alloys appear promising for use as negative electrodes in molten-salt-based secondary batteries which are being developed for off-peak energy storage in utility networks and for electric vehicle propulsion (1, 2). Contributions to the understanding of the electrochemical behavior of these alloy electrodes have come from the emf measurements of Yao *et al.* (3) and Selman (4) in molten LiCl-KCl; the galvanostatic and potentiostatic studies of L'vov and Gnilomedov (5) and L'vov (6); and the polarization measurements of James (7, 8). The charging of the Li-Al electrode involves phenomena collectively termed by Kabanov and his school (9) as "incorporation" or "implantation." The occurrence appears to be widespread when alkali and alkaline earth metals are electrolytically deposited onto a foreign substrate with which they can form an alloy. In an attempt to understand the overpotential behavior of Li-Al electrodes in LiCl-KCl electrolyte, interesting aspects of the kinetics of the incorporation process became evident and are presented here. The conclusions are based on the analysis of galvanostatic transients and chronocoulometric measurements.

Experimental

The electrochemical measurements were carried out in a glove box under high purity helium atmosphere. The apparatus is shown in Fig. 1. The cell consisted of three electrodes: a working electrode of aluminum wire, a counterelectrode of Li-Al alloy, 2.54 cm in diameter × 0.64 cm thick, and a reference electrode also of Li-Al alloy, 1 cm in diameter × 1.5 cm long. The aluminum wires were nominally 0.1588 cm in diameter, and were Marz grade (99.99% Al) material, obtained from Materials Research Corporation, Orangeburg, New York. The Li-Al electrodes were prepared by casting from 40 atomic percent (a/o) Li-Al powder [a composition in the $\alpha + \beta$ region of the phase diagram (10)] at ~800°C in alumina crucibles and attaching tantalum leads while the liquid metal alloy was cooling. Li-Al electrodes in the $\alpha + \beta$ composition range have been shown (3) to give a stable and reproducible emf of about 290 mV anodic of Li/Li$^+$ at 450°C. Electrodes of this type when used here as potential reference will be called the LiAl electrode. A 5.5 cm diameter alumina crucible was used as the electrolyte container. The electrolyte was polarographic grade LiCl-KCl eutectic obtained from Anderson Physics Laboratories, Champaign, Illinois.

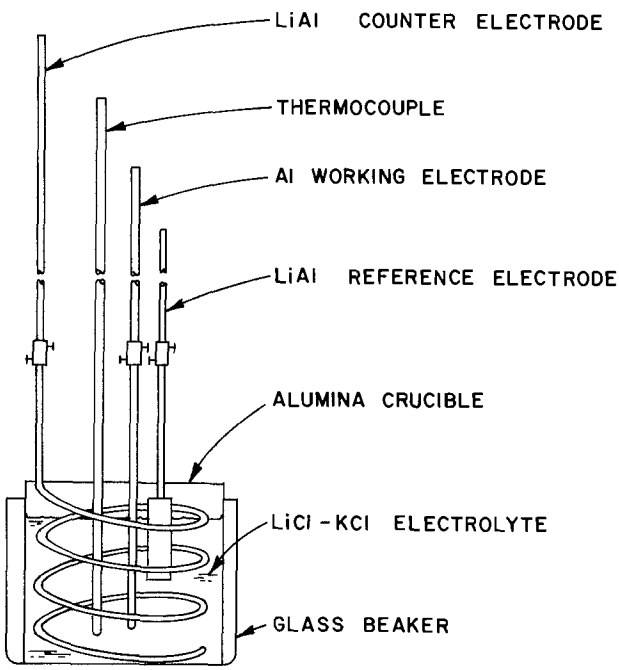

Fig. 1. Experimental apparatus

All measurements were made at a temperature of 450° ± 4°C. A potentiostat/galvanostat (Princeton Applied Research Model 173) with a risetime of about 6 μsec was used in either a constant current or a constant potential mode. Current integration was accomplished by using a digital coulometer (PAR Model 179) which plugs into the potentiostat/galvanostat. Fast transients were displayed by a Hewlett-Packard Oscilloscope, Model R5103N (equipped with a D15 single beam storage unit, 5A22N Differential Amplifier, and a 5B12N Dual Time Base) and photographed with a Polaroid camera attachment. Long-term potential-time or charge-time behavior was displayed on a Hewlett-Packard Model 7040A X-Y recorder.

Results and Discussion

Although the undervoltage deposition of metals on solid substrates with which they can form alloys or intermetallic compounds is fairly well known (11), the over-all processes which eventually lead to the implantation of the discharged atom into the electrode have

* Electrochemical Society Active Member.
Key words: lithium-aluminum electrodes, electrochemical incorporation, kinetics of incorporation.

not been extensively investigated. Kabanov *et al.* (8) first recognized (*i*) the special position that electrochemical incorporation (or perhaps a better term would be intercalation) occupies between the electrocrystallization of metals and the formation of liquid metallic solutions (or amalgams) and (*ii*) the fact that the rate of incorporation depends substantially on the microstructural condition of the electrode. The system Li-Al provides an interesting example for testing theories on incorporation. An understanding of its electrochemical behavior is also important for the further engineering development of electrochemical energy storage devices that make use of Li-Al alloys as negative electrodes (1, 2).

Incorporation at potentials anodic of LiAl.—The time development of the electrode potential that is observed on charging lithium into pure aluminum wires at constant current is illustrated in Fig. 2. As lithium is incorporated into the aluminum at low current densities, *i.e.*, < 5 mA/cm^2 (Fig. 2a), the potential decreases from the aluminum rest potential of about 1.2V *vs.* LiAl (12), and asymptotically approaches that of LiAl ($\sim$290 mV *vs.* Li/Li$^+$). At higher current densities, the cathodic polarization curve appears as in Fig. 2b. Following an initial jump, the overpotential remains roughly constant for some time then gradually increases with time. The behavior in Fig. 2a typifies the incorporation of lithium into aluminum to form the α-phase which is a solid solution of lithium in aluminum (10). During incorporation at high current densities, formation of the β-phase (an intermetallic compound of 45-55 a/o Li in Al) occurs (13). It was of interest to determine the process that limits the rate of incorporation in each case.

The onset of lithium deposition into aluminum occurs well below the reversible potential of the Li/Li$^+$ couple and the potential for the formation of the LiAl compound, as may be deduced from Fig. 2a. The incorporation rate to form the α-phase is evidently low. To investigate the rate-limiting process, potential step experiments with current integration, herein referred to as chronocoulometry [also termed the potential-step-integral method (14)], were undertaken. In this method, the potential is stepped to a desired value and the charge passed during the controlled-potential electrolysis is measured as a function of time by electronic integration of the observed current. According to Astakhov's theory (15), if the incorporation rate is limited by diffusion of lithium into the aluminum, the amount of lithium (in equivalent coulombs, Q) incorporated is proportional to the square root of the time of electrolysis, $t^{1/2}$. When the rate is limited by a reaction to form an intermetallic compound, Q is directly proportional to t, provided that the potential is held constant and no concentration polarization occurs in the solution. Figure 3 shows chronocoulometric curves obtained when the potential is stepped from the open-circuit voltage of about 1.2-0.020V *vs.* a LiAl reference electrode at 450°C. Excellent agreement with a diffusion-controlled rate is observed. From potential *vs.* time plots similar to Fig. 2a, the diffusion coefficient of lithium in aluminum may be obtained approximately (neglecting the effect of cylindrical geometry) using the Sand equation (16)

$$C(t) = C(o) + \frac{2\,i\,t^{1/2}}{F\Pi^{1/2}D^{1/2}} \qquad [1]$$

Taking $C(t)$ to be the saturation concentration of lithium in the α-phase [7.3 a/o at 450°C (10)] at the time t when LiAl potential is reached and $C(o) = 0$, a value of diffusivity, D, equal to $4.0 \pm 1.0 \times 10^{-10}$ cm^2/sec is obtained at 450°C. This is in good agreement with the value of 4.5×10^{-10} cm^2/sec measured by Costas (17) using a different technique.

Incorporation with compound formation.—At current densities where the rate of lithium deposition on the aluminum surface exceeds the diffusion flux into the interior of the electrode, accumulation of lithium in the surface layers results in the formation of the intermetallic compound LiAl. The electrode polarization is shown in Fig. 2b. Electrochemical incorporation under this condition was examined further by chronocoulometry. Potential steps from the open-circuit voltage to more negative potentials *vs.* the LiAl reference were applied to aluminum wires and the resulting current was integrated electronically over time to obtain the charge passed. Typical results are shown in Fig. 4, where it can be seen that a linear relation exists initially between Q and t, but a deviation from linearity occurs at later times. This deviation begins when the lithium charged into the electrode corresponds to about 20-30% of the theoretical capacity calculated on the basis of complete conversion of the whole wire to 45 a/o Li-Al. When the above data are replotted as Q *vs.*

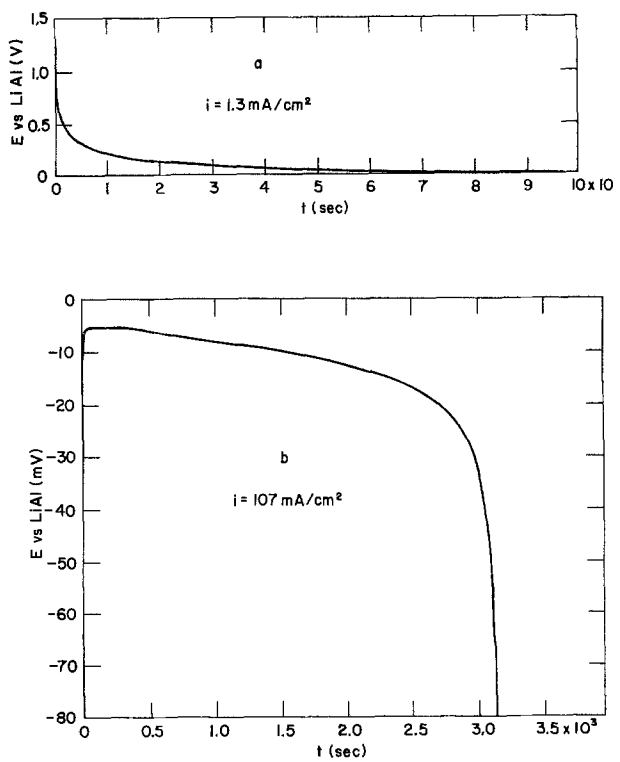

Fig. 2. Charging curves for lithium incorporation into aluminum: (a) at low current densities, (b) polarization at high current densities.

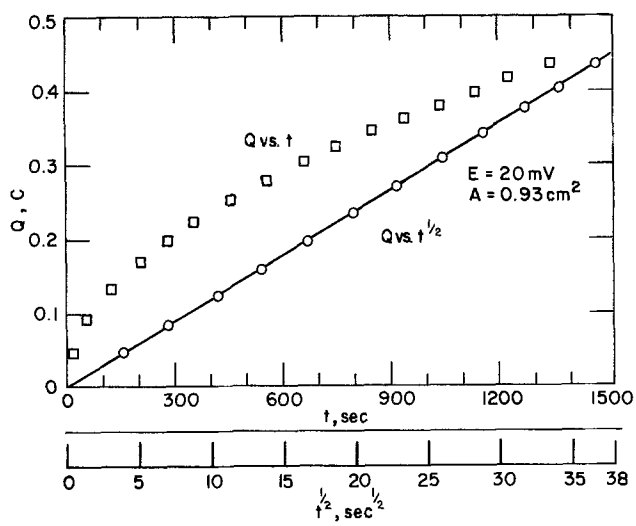

Fig. 3. Chronocoulometric curves for lithium incorporation to form the α-phase Li-Al alloy.

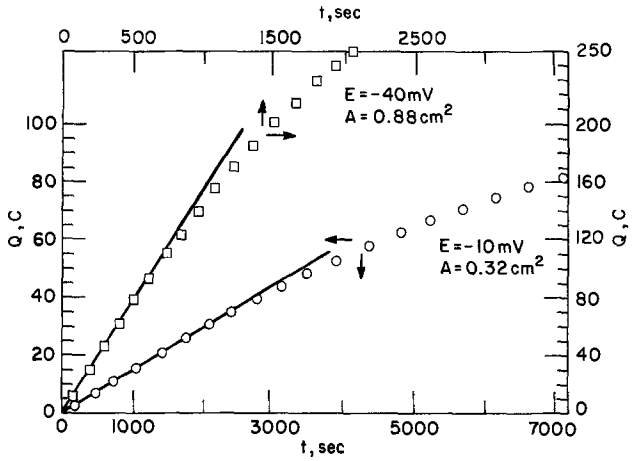

Fig. 4. Chronocoulometric curves for lithium incorporation with formation of the β-phase.

$t^{1/2}$, a linear relation is obtained for $t > 2000$ sec, as shown in Fig. 5. In line with Astakhov's theory, the rate of incorporation appears to be controlled initially by compound formation but, as the β-phase layer thickens, a transition to diffusion control occurs. The reactive propagation of the interphase between the intermetallic compound layer and α-phase depends on the diffusion rate of lithium through the growing compound layer. This diffusion is presumably through a vacancy mechanism. The rate of incorporation as measured by the initial slope of Q/A *vs.* t is found to increase with potential, as shown in Table I. The possibility was also considered that the deviation from linear behavior of the Q *vs.* t plots above roughly 20% loading may result from concentration changes in the solution in the vicinity of the electrode. To examine this, the potentiostatic charging process was interrupted for about 10-15 min, to allow solution equilibrium to be established, and then continued to completion. Again, the linear Q *vs.* $t^{1/2}$ relation was obtained with loadings above 20-30%.

Further evidence for diffusional process.—Additional experiments were conducted to confirm the existence

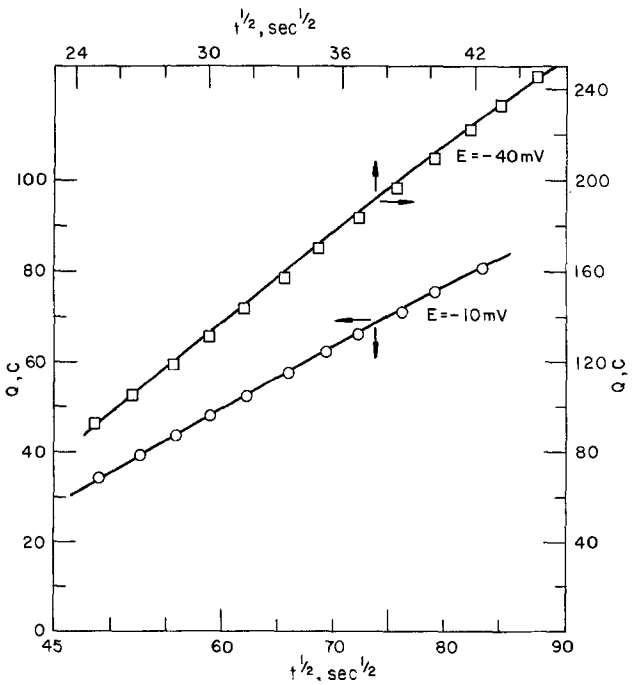

Fig. 5. Replot of later portions of chronocoulometric curves in Fig. 4.

[a] A = Electrode area, cm².

of diffusional overpotential in incorporating lithium into aluminum at high rates.

In one experiment, lithium was charged galvanostatically into a wire, in selected increments, at a current density of 81.4 mA/cm² to desired loadings. Between these chargings, but after a waiting period of 15 min to allow equilibrium conditions to be reestablished, a potential step of −40 mV *vs.* LiAl was applied and the current measured after 50 sec. The results are shown in Table II. It is seen that the current remains constant initially, as is characteristic of kinetic control in a potentiostatic experiment, then decreases slowly as the amount of lithium charged increases. This decrease in current is indicative of the predominant effect of diffusion.

Galvanostatic charging curves similar to Fig. 2b also show an apparent transition time (τ) which decreases as the current density (i) increases. The difficulty in precisely defining the transition time did not, however, permit the constancy of the product $i\,\tau^{1/2}$ to be established. The existence of a transition time is nevertheless generally considered a strong diagnostic test for the existence of diffusional overpotential (18).

Finally, galvanostatic transient measurements which were undertaken to elucidate the initial steps of the incorporation process also showed diffusional behavior when the β-phase layer has thickened considerably (percent loading >20% at the current densities normally used). Typical overpotential *vs.* time curves are shown in Fig. 6. If only charge transfer and diffusional overpotentials are present, the time dependence of overpotential should follow the equation (18)

$$\eta = \frac{RT}{n\mathbf{F}}\,\frac{i}{i_o} + \frac{2}{\sqrt{\pi}}\,\frac{RT}{n^2\mathbf{F}^2}\cdot\frac{i\sqrt{t}}{C_o\sqrt{D}} \qquad [2]$$

at low overpotentials. Figure 7 shows plots of η *vs.* $t^{1/2}$ for the transients shown in Fig. 6. A linear relation is obtained. The lines pass through the origin indicating that the charge transfer component of overpotential (the first term on the right-hand side of Eq. [2]) is negligible, *i.e.*, the exchange current density is high. The overpotential is thus purely diffusional. An approximate value of the diffusion coefficient of lithium in β-LiAl may be calculated from the slope of the η *vs.* $t^{1/2}$ plots. Using C_o equal to 0.045 g-atoms/cm³ for the lithium concentration in the β-phase, and current

densities calculated on the basis of the wetted areas of the original wires, values of diffusivity in the order of 10^{-8} cm²/sec at 450°C are obtained. More precise numbers cannot be obtained without accurate knowledge of the electrode areas of the charged wires; the effect of the cylindrical wire geometry will also have to be considered. Differences in the present values and those given by L'vov (6) and James (7) (2×10^{-6} and 5×10^{-5} cm²/sec, respectively), which were obtained on discharge of LiAl electrodes, may be due to a difference in actual electrode areas. There may also be a real difference between the "in" and "out" diffusivities of Li in LiAl similar to what has been observed in Au-Ag alloys (19). More accurate diffusivity measurements are being attempted using a Li^6 isotope tracer and ion probe microanalysis.

The above experiments confirm the previous conclusion made based on Astakhov's theory. The deviation of the Q *vs.* t plot from linearity during incorporation at negative potentials *vs.* LiAl is due to a change in the rate-limiting mechanism from intermetallic compound formation to lithium diffusion through the thickening β-phase layer. L'vov's previous conclusion (5) that the rate is determined wholely by the first mechanism appears incorrect.

Initial steps in the formation of the intermetallic compound LiAl.—The question may be asked as to whether the mechanistic steps that lead to the building up of the crystal lattice during electrodeposition of metals on the same or a foreign unreactive substrate occur also during deposition onto a surface where alloy formation is favored. This question has not been extensively considered in works that have appeared in the open literature. Vetter (18) has summarized the prevailing ideas on the kinetics of electrocrystallization of metals on the same substrate. The analysis of galvanostatic and potentiostatic transients could lead to some understanding of the steps involved in the early stages of the incorporation process and the formation of the intermetallic compound; therefore, a study of the overpotential *vs.* time behavior was made for electrodes of pure aluminum and aluminum precharged with lithium to desired loadings. Potential-time transients following a current step were recorded over various time scales and at different current densities. Typical results are shown in Fig. 8. On deposition into pure aluminum at high current densities, a marked superpolarization (20) is observed as in Fig. 8a. Immediately after switching off the current step (which is a few hundred milliseconds duration), the electrode potential on open circuit is found to be that of LiAl. Upon standing at open circuit for a few minutes, the potential of the electrode again approaches 1.2V; application of a current step shows again a superpolarization. If, however, the step is applied while the electrode potential is still that of LiAl, the transient appears as in Fig. 8b. No superpolarization is observed but the transient is characterized by a relatively long rise time in the order of 3-60 msec. The appearance of superpolarization has been attributed by Bockris and

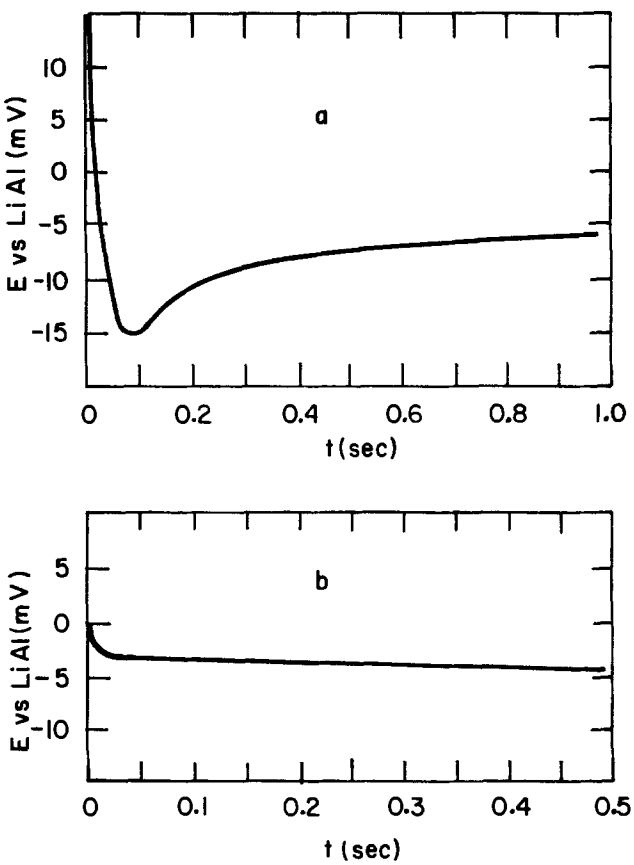

Fig. 8. Galvanostatic transients for initial charging of lithium into aluminum (i = 30 mA/cm²): (a) initial transient, (b) after predeposition of lithium.

co-workers (20) to the presence of impurities. The possibility that the superpolarization is due to an oxide film was considered. Such a film should, however, be reduced following the initial deposition of lithium so that subsequent current pulses should no longer exhibit superpolarization. This is clearly not so. Moreover, in some experiments the aluminum wires were preanodized at ~1.3V to clean up the surface. Superpolarization was also observed reproducibly with such pretreated wires indicating that oxide films are not responsible for the phenomenon. Vermilyea (21), however, has shown that such transient effects may be expected due to changes in surface configuration during electrolytic crystal growth. In the present case, the superpolarization is probably associated with the difficulty of initially forming the surface layers of β-phase LiAl, *i.e.*, it indicates the onset of electrocrystallization of the intermetallic compound and the large overpotential is due to slow nucleation (22). Calculation of the charge passed at the peak of the transient shows that the amount of lithium deposited corresponds to a few atomic layers. The superpolarization increases nearly linearly with current density from 8 mV at 20 mA/cm^2 to 25 mV at about 160 mA/cm^2. This variation indicates a dependence of supersaturation on overpotential. These values, considered as overvoltage for nucleation, are in accord with theoretical predictions (21). Following Kabanov (9), the superpolarization may also be associated with the difficulty of initially incorporating lithium atoms into the aluminum at high rates, owing to the relatively few vacancy sites available on the surface. A return of the superpolarization on standing at open circuit presumably results from diffusion and dissolution of the surface layer lithium into the interior of the electrode or chemical dissolution of lithium in the electrolyte and dissipation of the vacancies into sinks within the electrode. The time needed for the electrode potential to relax from 0 to ~1.2V *vs.* LiAl depends on the amount of charge passed, *i.e.*, the amount of lithium incorporated during the cathodic pulse.

Following the predeposition of lithium equivalent to a few atomic layers on an aluminum wire, the transient exhibits no superpolarization but rather a fairly flat overpotential with a slow risetime in the order of milliseconds (Fig. 8b). It is interesting to examine the process that gives rise to this overpotential. The slow risetime suggests that the rate-controlling step is not the charge transfer process. For the latter, the risetime, t_R is approximately

$$t_R \approx \frac{4RT}{Fi_0} C$$

e.g., t_R would be about 40 μsec for a double layer capacity, of 20 μF/cm^2 and an exchange current density, of 30 mA/cm^2 at 450°C. The large time constant can be associated with a high pseudocapacitance which may be caused by an adsorption layer on the electrode surface (23). Values of the pseudocapacitance calculated from the initial portion of the overpotential-time ($\eta - t$) curves, *i.e.*, $C = i/(d\eta/dt)_{t\to 0}$, are in the order of mF/cm^2 of apparent electrode area. One interpretation is that the discharge of Li^+ under the present condition occurs via the intermediate state of a chemisorbed lithium atom (24). The slow risetime may also be explained in terms of the high solubility of lithium in aluminum and a change of surface coverage upon switching on the current. This type of behavior is analogous to that observed for hydrogen discharge on palladium which has been postulated to occur also via an adsorbed state (18, 25, 26). The possibility of the high pseudocapacitance being due to a large surface area of the electrode cannot be ruled out at the present time. It appears unlikely, however, that the deposition of only a few atomic layers of lithium could cause such a large area change. The interpretation that appears most plausible to us is that of Rangarajan (27) who showed that a slow risetime in overpotential could arise from a slow incorporation of the discharged species at the lattice building sites. This appears more consistent with the current-potential relation (overpotential measured at 250 msec after applying the current step) shown in Fig. 9. The nonlinear behavior clearly rules out charge transfer or diffusion as the cause of the overpotential. The linear i *vs.* η^2 replot is indicative of the "square law" relation that is characteristic of electrocrystallization processes controlled by a slow lattice growth (22). The large change in lattice parameters (4.05Å for the α-phase to 6.4Å for the β) (28) and accompanying volume expansion during crystallization of the β-phase LiAl presumably are also responsible for the slow lattice growth. Further details of the kinetics of nucleation and growth of the β-phase are being investigated.

It appears that an interesting analogy exists between the process of electrochemical incorporation with compound formation to that of the high temperature oxidation of metals (29). In the latter, the chemical reaction leading to the formation of a metal oxide on the surface occurs first. Further growth and thickening of the oxide layer then occurs in many instances by the diffusion of oxygen through the oxide film and reaction at the oxide-metal interface. The parabolic law governing the rate of growth of the oxide layer is analogous to the Q *vs.* $t^{1/2}$ behavior observed in this work on electrochemical incorporation. This is not surprising, since in both cases the rates are limited by the diffusion of the reacting species. Interestingly, electrochemical incorporation appears to differ also from conventional electrodeposition in that while crystal growth occurs progressively on the surface in the latter case, it occurs at the intermetallic compound-metal interface in the former and progressively moves inward toward the center until all the aluminum is converted to the new phase.

Conclusions

From the foregoing results and discussion, the following conclusions can be made:

1. The incorporation of lithium into aluminum to form the α-phase (at potentials anodic of LiAl) is limited by the rate of lithium diffusion into the aluminum. The diffusivity of lithium in aluminum was measured to be 4.0 $\pm$ 1.0 $\times$ 10^{-10} cm^2/sec at 450°C.

2. At potentials that allow the formation of a layer of the intermetallic compound LiAl on the electrode surface, incorporation is limited initially by the reaction to form LiAl and subsequently by the rate of diffusion of lithium into the β-phase as it thickens. The apparent diffusivity of lithium in the β-phase was found to be in the order of 10^{-8} cm^2/sec.

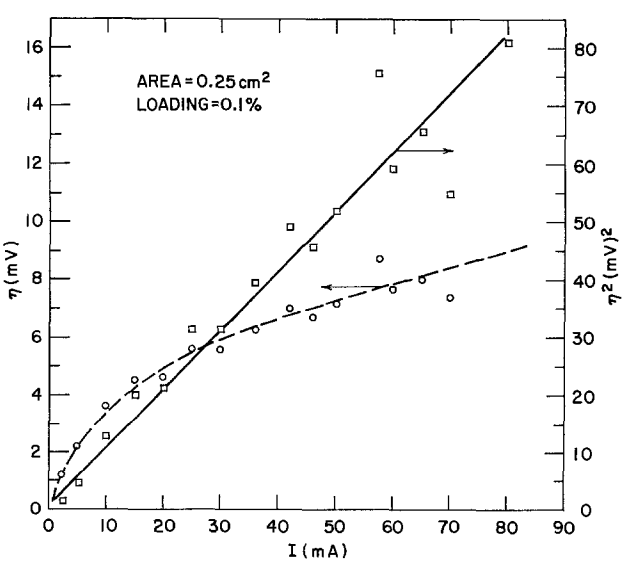

Fig. 9. Current-potential curve at short times

3. The initial steps in the formation of the intermetallic compound LiAl appear to involve typical electrocrystallization processes (nucleation and lattice growth). The process of electrochemical incorporation with compound formation bears a striking similarity to the high temperature oxidation of metals.

The Determination of the Corrosion Rate of Zinc in Solution by the Differential Pulse Method

Kevin G. Boto[1] and Lindsay F. G. Williams

Department of Defence, Materials Research Laboratories, Ascot Vale, 3032 Melbourne, Australia

ABSTRACT

The electrochemical measurement of the corrosion rate of zinc in near-neutral solutions using a differential pulse polarograph has been achieved to a greatly improved accuracy compared with previous work. The perturbation of the corroding system is minimized as the potentiostatic polarizing pulse is applied for only 60 msec. The double layer charging of the electrode is monitored on an oscilloscope and the faradaic current measurements made by the normal Y recorder output of the polarograph. The iR correction facility on the polarograph is used to determine the Tafel parameters and can also be used if resistance overvoltage is a problem during the polarization resistance measurements. Four different solutions are examined where the cathodic processes are either separately or jointly oxygen reduction or hydrogen evolution. Where only one cathodic process occurs, the correlation of the weight loss with the corrosion current calculated by the Stern-Geary method is within 7%. Where two cathodic processes occur, errors of up to 15% are encountered.

Recent studies on the corrosion of zinc in aerated near-neutral aqueous solutions (1-3) highlight two important areas which have been overlooked in past investigations. The first is a comprehensive study of the cathodic reactions which control the rate of corrosion of zinc in these solutions. Despite the common use of zinc as a sacrificial coating, a thorough study of the oxygen reduction reaction on zinc has been reported only recently (1) and it is obvious from this work that a concurrent hydrogen evolution reaction occurs in near-neutral solutions. Therefore, the exact nature of the cathodic reactions on zinc still requires further investigation to determine the extent of the hydrogen evolution in near-neutral solutions.

The second area where further research is required is in the electrochemical methods for determining instantaneous corrosion rates. When studying corrosion reactions and particularly at rotating ring-disk electrodes, it is important to be able to monitor the corrosion rate of the disk because the cathodic reactions are usually surface dependent and, therefore, vary throughout the course of any one experiment. The refinement of simple methods such as linear polarization (4, 5) by Oldham and Mansfeld (6, 7) and the derivation of new methods by Barnartt (8) and others (9-11) have not produced any dramatic improvements in the correlations between electrochemically calculated corrosion currents and the weight loss for zinc freely corroding in aqueous solution. Impedance measurements (12) have been shown to yield reasonably accurate corrosion rates for steel, but they are limited to reactions where the corrosion current does not alter during the course of the experiments. In practice, this does not usually occur, particularly where corrosion products are formed on the surface.

It has been our experience with corrosion rate measurements that the inaccuracies in determining the polarization resistance, $\Delta E/\Delta i$, and Tafel parameters usually result in far greater errors than the use of the simple Stern-Geary equation (4). Standard corrosion rate measurements on zinc in aqueous solution involve a constant current and the measurement of small potential changes (2, 3, 13). The applied constant current results in drifts in the potential of the zinc particularly in the pH range where corrosion products form on the surface. When superpolarization (14, 15) does not occur, the ΔE is usually measured after a few seconds to avoid the slow polarization of the electrode. For example, when zinc is immersed in an aerated, neutral chloride solution, a typical set of ΔE values after 5, 30, 60, and 180 sec at a polarizing current of 0.11 μA/cm^2 was 1.0, 1.5, 1.8, and 2.0 mV (16). When superpolarization occurs, it is normal to allow this to decay before recording the ΔE value (2).

One way of overcoming these problems is by the use of a potentiostatic method where a potential pulse is applied to the corroding specimen for a relatively short period of time. In this way, the perturbation of the system from its corrosion potential is minimized. These measurements can be recorded using a modern polarographic analyzer with a differential pulse mode.

A previous communication (17) described the differential pulse method for corrosion rate determinations, and the present paper shows the application of the method to a number of systems where zinc is freely corroding in near-neutral aqueous solutions with oxygen reduction and hydrogen evolution as cathodic processes.

Experimental

Zinc (99.99%) specimens (approximately 5 cm^2) were machined to a cylindrical shape to fit a standard electrode assembly (18). The zinc electrode assembly, an auxiliary electrode, and a saturated calomel electrode (SCE) with a Luggin capillary were fitted through a 75 mm multisocket, flat flange lid. The lid was placed on a jacketed beaker with a capacity of 600 ml and in all experiments the temperature was maintained at 25.0°C. The lid also contained facilities for bubbling either high purity grade nitrogen or medical grade air through the solution.

The solutions used in experiments were made from either AR- or R-grade chemicals with double distilled water. A 0.1 mole/liter ethylenediaminetetra-acetic acid (EDTA) and 0.1 mole/liter sodium acetate solution was adjusted to a pH of 8.5 by additions of NaOH. Similarly, a 0.2 mole/liter succinic acid solution was adjusted to a pH of 5.6. The other solution used was an unbuffered 0.1 mole/liter NaCl solution with a pH of 6.3. The volume of solution used in each experiment was 500 ml.

The weight loss of zinc during each experiment was determined in one of two ways. Where the weight change was greater than 10 mg, the specimen was weighed before and after the corrosion experiment. In all other experiments, the solution was analyzed for zinc using a Princeton Applied Research (PAR) Model 174 polarographic analyzer in the differential pulse

[1] Present address: Australian Institute of Marine Science, Townsville 4810, Australia.

Key words: corrosion, linear polarization, differential pulse, zinc.

mode with a scan rate of 2 mV/sec, a pulse amplitude of 25 mV, and a drop time of 1 sec.

The differential pulse corrosion rate measurements were made using the PAR 174 polarograph with the following sequence. The corrosion potential (E_{corr}) of the zinc in the solution was measured using a Tacussel S70 millivoltmeter. With the polarograph in the normal mode (*i.e.*, as an ordinary potentiostat), the potential of the zinc was set at the E_{corr} value by adjustment of the initial potential settings, so that if the polarograph were disconnected there would be no change in potential of the zinc. The final adjustment of E_{corr} was achieved by zeroing the current output of the potentiostat. During all these measurements the scanning facility was not used and the operations were all conducted with the polarograph set on initial potential. The polarograph was switched to the differential pulse mode usually with an amplitude of 5 mV and a pulse frequency of 1 sec. This operation superimposed a 5 mV pulse of 60 msec duration on the E_{corr} value every 1 sec. The current response for the zinc electrode was photographed on a Tektronix oscilloscope Type 561A connected to the PAR 174/50 a-c interface unit or measured on a Moseley Model 7030A recorder.

The Tafel slopes for the anodic dissolution of zinc were determined in the N_2 saturated solutions. As there was appreciable curvature of the log *i vs. E* plots at higher current densities, the *iR* compensation facility available on the PAR a-c interface unit was used. The Tafel slope for the hydrogen evolution reaction was determined in a similar manner.

Results

The corrosion rate of zinc in solution has been measured by the differential pulse method for four different situations. They are where; (*i*) oxygen reduction is the major cathodic process; (*ii*) hydrogen evolution is the major cathodic process; (*iii*) both hydrogen evolution and oxygen reduction occur, but at a pH where no corrosion products precipitate on the surface; and (*iv*) both cathodic processes occur as in (*iii*) but corrosion products precipitate on the surface.

(i) Zinc in an aerated EDTA solution (pH = 8.5).— The results for this solution are used to demonstrate the two different methods of recording the current response to the potential pulse. The first method involves the use of an oscilloscope to display the complete current response and the clock monitor on the PAR interface unit enables the oscilloscope to be triggered just prior to the application of each pulse. The current-time profile resulting from the application of a 5 mV potential pulse of about 60 msec duration to the zinc electrode immersed in this solution is shown in Fig. 1 for both anodic and cathodic pulses. The decay in current associated with double layer charging was complete within the first 10 msec, after which a constant faradaic current was observed. At the completion of each pulse, there was a similar but inverted current decay associated with the reversion of the double layer to its previous state at E_{corr}. The frequency of the pulses could be adjusted as discussed above and in these measurements the pulse frequency was 2 sec^{-1}.

The second method of recording the current uses the current sampling system on the PAR polarograph where the current flow is measured just before the application of the pulse and again at the end of the pulse. The readout presented to the recorder is the difference between these two sampled currents. However, there is one further complication because this difference between the two currents is averaged with the previous difference readings in the PAR memory before being displayed on the recorder. Therefore, when the current response to the first pulse is measured it is displayed as an average with zero and is much less than the final reading obtained after numerous pulses. For this reason about twenty pulses are required before the recorder reaches the actual current value as

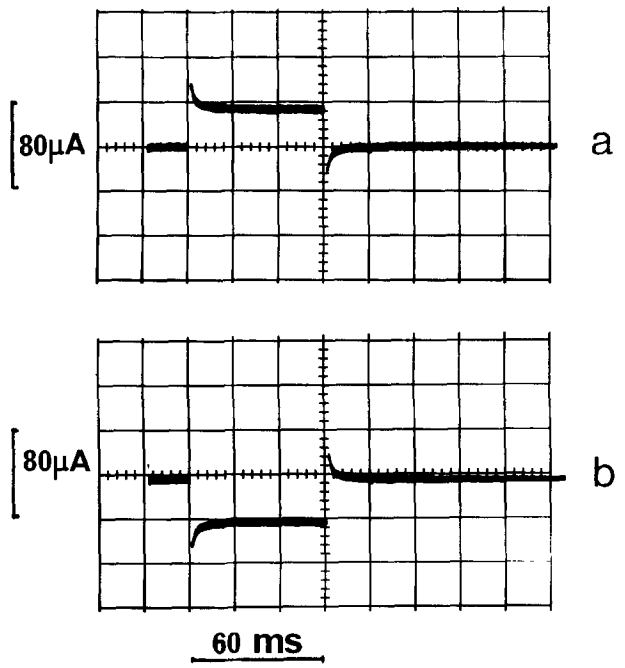

Fig. 1. Oscilloscope traces showing the current-time profiles for 5 mV pulses to a zinc electrode after 3 hr immersion in an air-saturated 0.1 mole/liter EDTA, 0.1 mole/liter sodium acetate solution at pH 8.5: (a) cathadic; (b) anodic pulses.

shown in Fig. 2 where about fifty potential pulses of 5 mV were applied in the anodic direction before inverting the pulse to make it cathodic using the scan direction switch. After another 50 pulses the potential pulse was again reversed and the procedure repeated. With a pulse frequency of 2 sec^{-1}, the total time for the recording in Fig. 2 was 100 sec. The currents re-

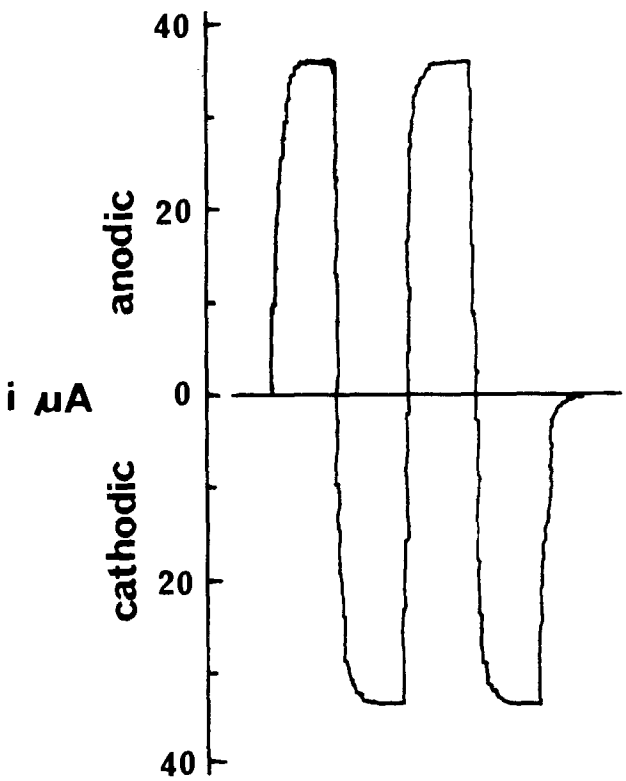

Fig. 2. Recorder trace showing the sampled current when two series (of about 50 pulses each) of anodic and two series of cathodic pulses are applied to a zinc electrode after 29 hr immersion in an air-saturated 0.1 mole/liter EDTA, 0.1 mole/liter sodium acetate solution at pH 8.5.

corded in this way agreed with those measured using the oscilloscope. In general, the oscilloscope was used to monitor the decay curves and the recorder output was used for current measurements.

The cathodic process in this solution is diffusion-controlled oxygen reduction as shown by rotating disk studies (1). Therefore, the corrosion current, i_{corr}, was calculated using the Stern-Geary equation (4)

$$\frac{\Delta E}{\Delta i} = \frac{\beta_a}{2.3\, i_{corr}} \qquad [1]$$

where β_a was the Tafel slope for the anodic dissolution of zinc in this solution. Using the iR correction facility on the PAR interface unit, the value of β_a was found to be 81 ± 2 mV. It is recognized that there is some deviation from linearity of the E *vs.* i plot with the 5 mV pulses as evidenced by the fact that anodic currents were typically 7-12% larger than cathodic currents. However, this relatively small deviation leads only to small errors in the calculated i_{corr} values. In all experiments, the corrosion potential was sufficiently different from the reversible zinc potential to be able to use Eq. [1].

The average i_{corr} value for each experiment was obtained by plotting the individual i_{corr} values against time and measuring the area under the curve. The average i_{corr} values for duplicate experiments where zinc samples were immersed in an aerated EDTA solution at pH 8.5 were 13.2 and 12.9 $\mu A/cm^2$ compared with 13.1 and 13.3 $\mu A/cm^2$ calculated from the weight loss, respectively.

As previously reported (17), the values calculated by the Barnartt method (8) were about 25% higher than those calculated as above. For the Barnartt method pulses of 10 and 25 mV were used and similar results were obtained with both pulse amplitudes.

There was some superpolarization of the zinc, usually occurring after several hours immersion in this solution. The recorder trace in Fig. 3 shows the worst case of superpolarization encountered with potentiostatic pulses of 4 sec duration. However, the differential pulse method which only permits a 60 msec polarization of the zinc does not allow sufficient time for an equilibrium value to be achieved. The presence of superpolarization effects can be identified with even 60 msec pulses by a U-shaped current trace. Superpolarization was not observed in all experiments in this solution despite the fact that there was no insoluble corrosion product.

(ii) Zinc in a deaerated succinate buffer solution (pH = 5.6).—The cathodic process in this solution was hydrogen evolution, which is an activation-controlled process as shown by rotating zinc-disk studies (1, 19).

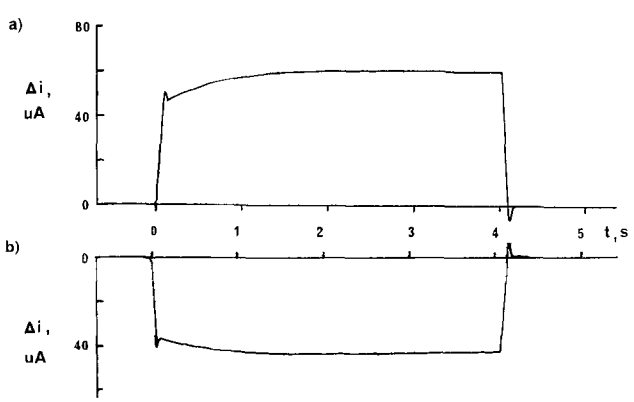

Fig. 3. Recorder traces showing the superpolarization effect in the current-time profiles for 5 mV pulses of 4 sec duration to a zinc electrode after a 4 hr immersion in an air-saturated 0.1 mole/liter EDTA, 0.1 mole/liter sodium acetate solution at pH 8.5; (a) anodic; (b) cathodic pulses.

The oscilloscope traces of current *vs.* time when 5 mV pulses were applied to the corroding zinc specimen are shown in Fig. 4. The capacitive current decay associated with the application of the potential pulse was generally complete by the time the current measurements were made. Where corrections were necessary, the current near the end of the 60 msec pulse was corrected in the following way. From the cathodic current decay after the end of the anodic pulse, the capacitive current was measured after 50 msec and subtracted from the cathodic i value. The decay curves in Fig. 4 are typical of the results for this solution and, therefore, these corrections were very minor.

The currents were generally obtained from the recorder trace and used in the Stern-Geary equation (4)

$$\frac{\Delta E}{\Delta i} = -\frac{\beta_a \beta_c}{2.3\, i_{corr}\,(\beta_a + \beta_c)} \qquad [2]$$

where β_c was the Tafel slope for the hydrogen evolution reaction. Both β_a and β_c were measured using iR correction and were 38 and −111 mV, respectively.

The i_{corr} values depended on the pretreatment of the zinc surface and this led to substantial changes in the corrosion rate during many experiments. An example of this is shown in Fig. 5 where the calculated i_{corr} values increased from 640 to 950 μA during the course of the experiment. This surface dependence of the reaction has been studied in greater detail (19). The average i_{corr} values were from the area under the i_{corr} *vs.* time plots, and two representative corrosion rate experiments resulted in average i_{corr} values of 55.0 and 782 μA compared with the i_{corr} values calculated from analysis of the zinc in the solution of 52.7 and 749 μA, respectively. The lower currents were obtained using

a chemically polished zinc surface, while the higher currents were from the same sample after several days immersion in the deaerated succinate buffer solution.

(iii) Zinc in an aerated succinate buffer solution (pH = 5.6).—In this solution a mixed cathodic process occurs, that is, the diffusion-controlled oxygen reduction reaction and the activation-controlled hydrogen evolution reaction. Therefore, to accurately calculate i_{corr} from the measured polarization resistance values ($\Delta E/\Delta i$), the relative contribution of each process to the over-all cathodic reaction must be known. It is difficult with the present stationary electrode set up to accurately measure the contribution of each process. This is because of irreproducible stirring effects in the cells due to air bubbling which affects the rate of oxygen reduction from one experiment to the next. Also, as discussed above, the hydrogen evolution reaction appears to change drastically during the course of an experiment and thus would require continuous monitoring, *e.g.*, by deaerating the solution and measuring the change in i_{corr} to yield an accurate average value.

Instead, it was assumed that the oxygen reduction reaction was the major cathodic reaction, and hence Eq. [1] with $\beta_a = 38$ mV was used to calculate i_{corr}. As seen below, the worst correlation achieved with the weight loss value was within 7%. Thus it appears that even with this seemingly gross assumption, the method still yields reasonably accurate values of i_{corr}. The good correlation is probably due to the fact that the calculation is relatively insensitive to the contribution of each reaction as can be easily seen by simple calculations using, *e.g.*, both Eq. [1] for a diffusion-controlled reaction and Eq. [2] for an activation-controlled process with $\beta_a = 38$ mV and $\beta_c = -111$ mV and assuming a 50% contribution for each reaction. Also, as the experiments were not unduly long (only a few days), it is likely that the hydrogen evolution reaction was only a minor contribution at first and increased slowly as the experiment proceeded, giving a low average contribution over about two days.

It is recognized that the calculation accuracy is limited by this assumption and the error would probably be greater for long-term experiments. However, the correlation achieved is much better than has been obtained by other workers.

Typical anodic and cathodic current-time traces are shown in Fig. 6. In these experiments the capacitive current decay was complete within the first 15 msec and the recorder trace was used to measure the Δi values. The corrosion rate of the zinc in this solution increased for both specimens during the course of the experiments as shown in Fig. 7, even though the potential remained relatively constant for the latter part of the runs. Integration of the i_{corr} *vs.* time curves yielded average i_{corr} values of 206 and 129 μA/cm^2 for the two specimens shown, compared with the values from the weight loss measurements of 191 and 126 μA/cm^2, respectively.

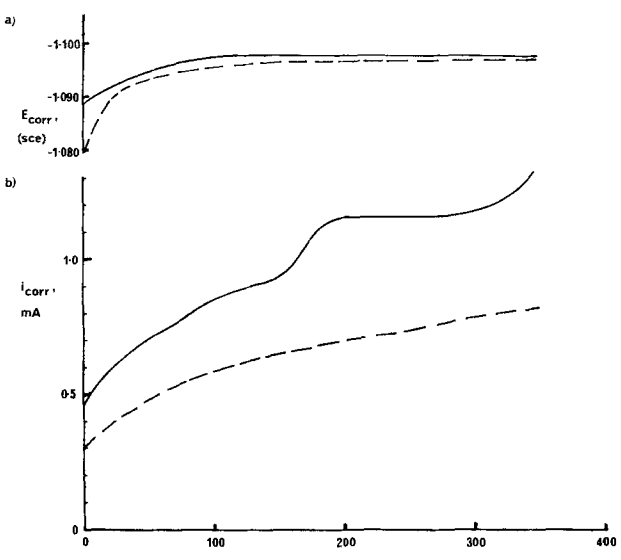

Fig. 7. Plots of (a) corrosion potential, E_{corr}, and (b) calculated corrosion currents, i_{corr}, for two experiments where zinc was immersed in an air-saturated succinate solution at pH 5.6.

(iv) Zinc in an aerated chloride solution (pH = 6.3).—In an aerated 1 mole/liter sodium chloride solution at pH 6.3, corrosion products formed on the zinc surface. Accordingly, this was the most complicated corrosion reaction studied, as there was also a mixed cathodic process. In the first part of the corrosion ex-

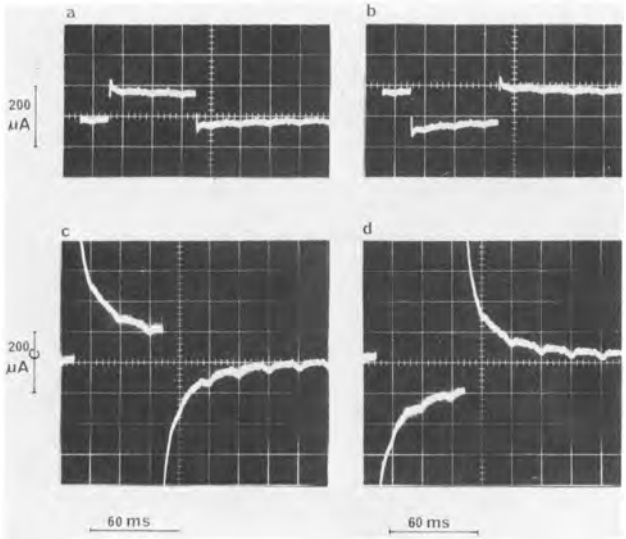

Fig. 8. Oscilloscope traces showing the current-time response to 5 mV pulses applied to a zinc electrode after (a) and (b) 20 min and (c) and (d) 24 hr immersion in an air-saturated 1.0 mole/liter NaCl solution; (a) and (c) cathodic; and (b) and (d) anodic pulses.

periments where the zinc surface remained relatively free from corrosion products, the current-time profiles were similar to those in Fig. 8 a and b for 5 mV pulses. As the experiment proceeded, the current decay associated with the double layer charging increased in magnitude and became more drawn out, as shown in Fig. 8 c and d. In the later part of these experiments, correction for the slow decay of the capacitive current was made by the methods described above.

The cathodic process in these solutions was essentially oxygen reduction and, as discussed above for the aerated pH 5.6 succinate solutions, the extent of hydrogen evolution is not known. It is likely to be less significant here because of the higher pH of the 1 mole/liter NaCl solution which being unbuffered results in an increase in the pH near the electrode surface due to the cathodic processes. Because of the buildup of corrosion product on the zinc, the reaction was not controlled simply by diffusion of oxygen through the solution to the reacting zinc surface, *i.e.*, as normally shown by rotating disk studies (1). The reaction was controlled by the rate of arrival of oxygen at the metal surface and this varied with the rate of nucleation, lateral spreading, and thickening of the films of corrosion product (20). Consequently, Eq. [1] was used to calculate i_{corr} values. The Tafel slope needed for the calculation was found to increase as the corrosion product built up on the surface. In all the Tafel plots the iR correction facility on the PAR polarograph was adjusted immediately before each polarization curve was determined. β_a was 10.7 mV initially and increased over a period of several days to 12.1 mV. The value of 10.7 was used in the calculations because most experiments only lasted one day. This value is lower than β_a values reported in the literature (3, 21) for similar solutions where no iR correction was used.

The average corrosion currents calculated from two experiments were 88 and 101 $\mu A/cm^2$ compared with the values obtained from the weight loss of 84 and 85 $\mu A/cm^2$.

Discussion

Differential pulse measurements.—The inaccuracies in most electrochemically determined corrosion rates originate from the experimental problems of measuring Tafel slopes and the polarization resistance. Without any modifications, commercial polarographs with a differential pulse mode are ideally suited to the differential pulse method of estimating the corrosion rates of metals immersed in aqueous solutions. The method results in the rapid, accurate measurement of the polarization resistance used in the calculation of corrosion rates by the Stern-Geary methods for either diffusion- or activation-controlled cathodic processes. As some polarographs are fitted with an iR correction facility, the Tafel parameters used in the equations can be determined with minimal resistance overvoltage effects. Accurate ΔE values are automatically obtained with pulses as small as 5 mV in amplitude. The errors associated with the nonlinearity of the E *vs.* i plot in the vicinity of E_{corr} is minimized by the use of small potential pulses and i_{corr} values with only small inherent errors are readily obtainable. The current ranges available on the polarographs suit slow corrosion reactions. With relatively fast corrosion reactions such as zinc in acidic solutions, the surface area of the specimen must be relatively small.

For the polarograph used in these experiments the duration of each pulse was about 60 msec and this could not be adjusted. With the corrosion reactions studied, only the neutral chloride solution resulted in decay profiles which were not essentially complete during the 60 msec. Clearly, in circumstances like this it would be advantageous to be able to extend the duration of the pulse. Nevertheless, a correction can be made by subtracting the decay associated with the end of the oppositely polarized pulse. In order to ensure that the recorded output does not suffer from inaccuracies due to slow capacitive decays, the oscilloscope should always be used to monitor the decay profile.

The amplitude of the pulse can be varied in 5 set steps for the PAR polarograph but other models offer continuous adjustment which would be better suited to examining the linearity of the E *vs.* i plot and using more complex equations for the calculation of i_{corr}. The time between pulses can be varied from 0.5 to 5 sec. The iR correction facility can be used for the Δi measurements if it is thought to be necessary (22).

Correlation of i_{corr} with weight loss.—The differential pulse method for zinc in the EDTA solution (pH 8.5) resulted in an i_{corr} value within 4% of that calculated from the weight loss as shown in the table. This was the best correlation achieved probably because the cathodic process was a simple diffusion-controlled oxygen reduction with negligible contribution from the hydrogen evolution reaction. This obviates the need to measure a cathodic Tafel slope. In addition, the electrode remained free from corrosion product and so the capacitive decay was always complete within 20 msec. Barnartt's method (8) for 10 and 25 mV pulses resulted in i_{corr} values about 25% high. However, even these results are much better than those reported by Walter using a galvanostatic technique and a similar calculation method (2) where typically the i_{corr} values were 80% higher than those calculated from chemical analysis of the zinc in solution.

In the deaerated succinate buffer solution (pH = 5.6), the cathodic reaction was hydrogen evolution. The rate of this cathodic process and, therefore, the rate of corrosion of the zinc was dependent on the surface pretreatment, with electropolished surfaces yielding very low i_{corr} values. The hydrogen evolution reaction is currently being studied (19) and is an activation-controlled process as shown by rotating disk studies. The correlation of i_{corr} in these deaerated solutions with weight loss was within 5%.

The correlations between electrochemically determined corrosion currents and the weight losses were excellent when only one cathodic process occurred. However, when oxygen reduction and hydrogen evolution occurred concurrently, the correlations in the worst figures were 7% for the succinate solution (pH = 5.6) where no corrosion products formed on the surface and about 15% in a neutral chloride solution with corrosion products present. It was not feasible in these experiments to estimate the relative contributions of

Table I. Comparison of electrochemically determined corrosion currents with those calculated by either weight loss [(a), (c), and (d)] or chemical analysis (b)

Solution	i_{corr}, μA/cm²		
	Electrochemical	Actual	% error
(a) Aerated EDTA	13.2	13.1	0.8
(pH = 8.5)	12.9	13.3	3
(b) Deaerated succinate	55.0	52.7	4
(pH = 5.6)	782	749	4
(c) Aerated succinate	206	191	7
(pH = 5.6)	129	126	2
(d) Aerated NaCl	88	84	5
(pH = 6.3)	101	85	16

the two cathodic processes but previous experience (1) indicated that hydrogen evolution was a minor contribution. If corrections for the hydrogen evolution were made it would result in lower calculated i_{corr} values. As all the i_{corr} values were too high in the solutions where both cathodic processes were occurring, a correction for the hydrogen evolution reaction would improve the correlation between the i_{corr} and weight loss.

In conclusion, the corrosion rate of zinc immersed in a number of near-neutral solutions can be accurately determined electrochemically by using iR compensation for the Tafel parameters and the differential pulse method as shown in Table I. The correlations with weight loss are an order of magnitude better than those normally experienced for zinc in near-neutral solutions. The method has been applied to rotated zinc-disk electrodes (19) and opens up great possibilities for rotated ring-disk studies on corroding metals. The use of iR correction can overcome the inaccuracies recently reported by Mansfeld (22).

Hardening Effect of Ultrasonic Agitation on Copper Electrodeposits

C. T. Walker[1] and R. Walker

Department of Metallurgy and Materials Technology, University of Surrey, Guildford, Surrey GU2 5XH, England

ABSTRACT

Studies have been made of the properties of copper electrodeposited from ultrasonically agitated, acid sulfate solutions. The intensity of ultrasound was measured with an acoustic calorimeter and the value for cavitation was determined. Transmission electron microscopy was used to examine annealed foil and deposits. Ultrasonic agitation was found to increase the hardness, reduce the porosity, and change the grain size. It also produced a high dislocation density compared with deposits from still or stirred baths. Hardening is considered to be due to a substantial reduction in porosity in deposits produced at low intensity and to work-hardening caused by the collapse of cavities at high intensities.

Ultrasonic agitation of the electrolyte increases the hardness of electrodeposits (1). The reason for this is not understood and the explanations so far advanced seem invalid. Thus, Müller and Kuss (2) propose that hardening is due to dislocation blocking caused by the incorporation of foreign particles in the plate. No experimental evidence supports this view; rather it has been demonstrated that deposits formed in an ultrasonic field contain fewer extraneous particles (3). According to Kochergin and Vyaseleva (3) hardening is caused by a decrease in grain size. Although some experimental results (1) appear to support this, it is more generally accepted that ultrasound in fact increases the grain size of deposits.

This paper provides a new explanation for the hardening effect of ultrasonic agitation: namely, that it is caused by work-hardening and by a decrease in porosity. In connection with the work-hardening we have previously presented experimental evidence (4) that ultrasound hardens both copper deposits plated

[1] Present address: Europäisches Institute für Transurane, Karlsruhe, West Germany.

from a stirred electrolyte and annealed copper sheet. In these cases hardening was associated with indentations in the surface caused by cavitation.

Equipment

Plating tank.—The plating solution was contained in a Perspex tank (15 × 30 × 15 cm) which was seated on the transducer probes (diameter 12.7 cm) of the ultrasonic generator; acoustic contact was made through a water layer (Fig. 1). The tank was modified to reduce the amount of ultrasonic energy lost by reflection at the water-Perspex-electrolyte interfaces formed with the base. This was effected by two acoustic windows in the base of the plating tank that were of a slightly smaller diameter (12.5 cm) so that the tank rested on top of the probes. The windows were formed by stretching a 500 gauge polythene sheet (100 μm thick) over two holes cut in the base of the tank. This material is favorable to sound transmission: its specific acoustic impedance is similar to that of water (their values are 1.85×10^6 and 1.5×10^6 kg^{-2} sec^{-1}) and it is thin compared with the wavelength of the sound used (15 cm in polythene).

Acoustic calorimeter.—The calorimeter is shown in Fig. 2. Ultrasound entered through a polythene acoustic window, J (diameter 4.8 cm), in the base. This was bonded to the body of the calorimeter and was secured by a push-fit Perspex ring, H. The Dewar flask, E (height 14 cm, ID 5 cm), ensured almost total internal reflection of sound and good thermal isolation. Castor oil, F (200 ml), was the sound absorbing fluid because it has a high sound absorption coefficient (1.85×10^{-5} neper cm^{-1}) compared with other fluids and its specific acoustic impedance (1.42×10^6 kg^{-2} sec^{-1}) is about the same as that of water.

Materials and Methods

Intensity measurement.—Calorimetry is the only reliable way of measuring the total acoustic energy dispersed in a cavitating liquid. A substitution system (5) was used in which the calorimeter was first calibrated by simulating the heating effect of ultrasound with a 1.2Ω resistance wire. Electrical power in the range 0.4-5.3W was applied to the heating coil from a d-c power pack for a fixed time of 3 min ± 1 sec. To calibrate the instrument heating curves were constructed for each power input to the coil by noting the temperature rise in the castor oil at 30 sec intervals. A calibration curve which covered the expected range of ultrasonic power in the electrolyte, was obtained from the heating curves by plotting their slopes, $d\theta/dt$, against the electrical power, I^2R, using the equation

$$\frac{d\theta}{dt} = \frac{I^2R - h}{MJS} \qquad [1]$$

where I = power pack current (A), R = heating coil resistance (Ω), M = mass of castor oil (g), S = specific heat of castor oil (cal g^{-1} °C^{-1}), J = mechanical equivalent of heat (Jcal^{-1}), and h = heat losses (W).

It can be seen from Eq. [1] that the calibration curve, $d\theta/dt$ *vs.* I^2R is a straight line with slope $(MJS)^{-1}$ and intercept $-h/MJS$. Heat losses from the calorimeter were small because the value of h, which was assumed to be independent of θ, was only 0.15W.

After calibration, the calorimeter, together with its heating coil, was transferred to the plating bath where the ultrasonic intensity in the electrolyte was measured. The ultrasonic power was estimated from the slope of each heating curve using the calibration curve and the intensity was determined by dividing the power value by the area of the acoustic window.

Although calorimetric methods of intensity measurement are generally agreed to be unreliable at low intensities, the substitutional technique gave good reproducibility on repetition of experiments and intensity values are believed accurate to better than ±10%.

Cavitation threshold intensity.—The cavitation threshold intensity in the electrolyte was determined with a piezoelectric disk connected to an oscilloscope. The disk, a PXE modified lead zirconate titanate ceramic was encapsulated in Araldite and mounted inside a plastic sleeve to avoid wetting and to give it rigid support. Initially at low intensity, the disk produced a sine wave trace on the oscilloscope, but as the intensity was increased the trace became distorted and eventually complete breakdown occurred. The cavitation threshold intensity was that at which distortion of the sine wave was first observed, and was found to be about 20 Wm^{-2}.

General plating techniques.—Ultrasound of frequency 13 kHz was applied to a standard plating technique: namely copper deposition from an acid sulfate electrolyte. Since in ordinary industrial practice the electrolyte is stirred to increase bath efficiency and because ultrasonic agitation is often thought of only as a superior form of mechanical stirring, the properties of deposits from a stirred bath were compared with those of deposits from an ultrasonic bath and deposits from the still bath were used as a control. Electrodeposition was carried out with the three baths connected in series so that fluctuations in plating conditions such as deposition time and current density were the same. Each bath contained 4.1 of electrolyte the composition of which was $CuSO_4 \cdot 5H_2O$ 125 gl^{-1}, H_2SO_4 49 gl^{-1}. General grade chemicals and distilled water were used.

Both electrodes (15 × 5 cm) were made of copper: the anode of Analar grade foil (110 μm) and the cathode of either Analar foil or commercial grade sheet. The electrodes were placed 15 cm apart and in the ultrasonic plating tank they were above the acoustic windows parallel to the direction of sound propagation (Fig. 1). Before use the electrodes were degreased with acetone, etched in 50% HNO_3, and washed in distilled water. The backs of the cathodes were lacquered with "Lacomit" to give an electrode area of 20 cm^2 and a Perspex sheet was bonded to the back of electrodes subjected to ultrasonic intensities greater than 596 Wm^{-2}. This prevented the removal of lacquer during plating.

Deposits were produced at current densities in the range 20-700 Am^{-2}. Their thickness was fixed nominally at 78 μm and plating was performed at ambient temperature, which was 20° ± 2°C. The plate thickness was calculated from Faraday's law assuming a cathode current efficiency of 100%. Since ultrasound causes heating of the electrolyte, the above temperature was maintained in the ultrasonically agitated plating solution by copper cooling coils in the surrounding water bath (Fig. 1).

Hardness.—An Akashi microhardness machine with a diamond indenter and a 50g load was used. Because the surface of the deposits was rough (Fig. 3), before measuring the hardness it was necessary to smooth the

plate with 600 grade emery paper and lightly buff with metal polish.

Measurements were made on the surface of planar samples with the deposits attached to the cathode (copper sheet 720 μm thick). Eight determinations were carried out on each deposit (Fig. 4) and the mean and standard deviation calculated (illustrated in Fig. 5). Consistent hardness values were obtained on repetition of experiments. Thus Fig. 4 exemplifies the results from a number of observations. Since the deposit thickness was considerably more than ten times the maximum indentation depth (6.5 μm for copper of hardness 50 HV) the hardness values are unaffected by the hardness of the substrate cathode. The hardness was also unaffected by the procedure of smoothing and burnishing.

Grain size.—The linear intercept method (6) was used to determine grain size. Measurements were made on the surface of planar samples taken from the deposits used for hardness determination.

Sections of deposit with electrode were taken from the center of the cathode to avoid anomalous structures. They were mounted, ground, and polished parallel to the surface of the plate using standard metallographic techniques and etched in acidic ferric chloride solution to reveal the grains. The mean intercept length was determined from the linear distance containing about 100 grains and was measured using a Bausch and Lomb optical microscope.

In the ASTM standard (6) the correlation factor between the average intercept length and estimated grain size is about 1.12, but several other factors have been used including 1.5 (7) and 1.6 (8). To avoid confusion, therefore, the mean intercept length is reported here.

Porosity.—The porosity of plate was assessed from its density. Deposits were formed on foil cathodes at current densities of 100, 200, 300, and 400 Am^{-2} and density measurements were made with the deposits attached to the cathode. Three deposits were produced

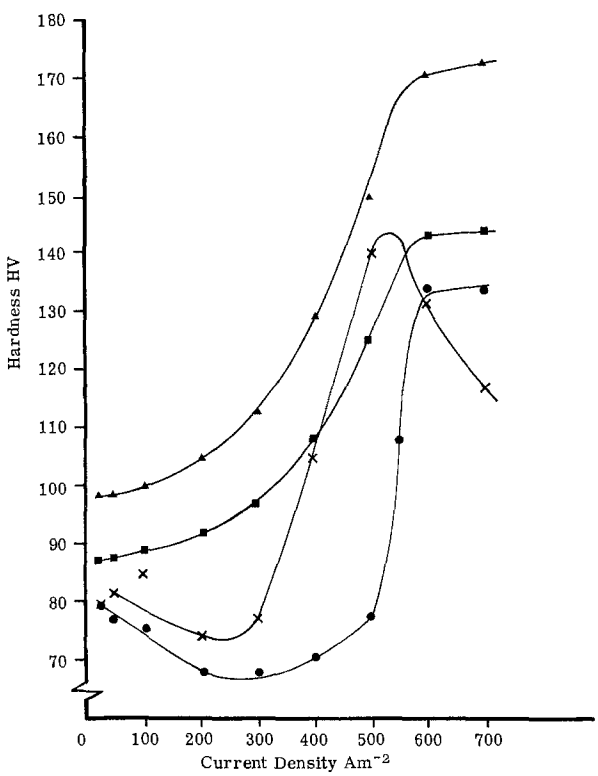

Fig. 4. Deposit hardness related to agitation and current density. ▲, Ultrasonic agitation, I = 928 Wm^{-2}; ■, ultrasonic agitation, I = 596 Wm^{-2}; X, still; ●, stirred. Each point represents the mean of eight separate determinations.

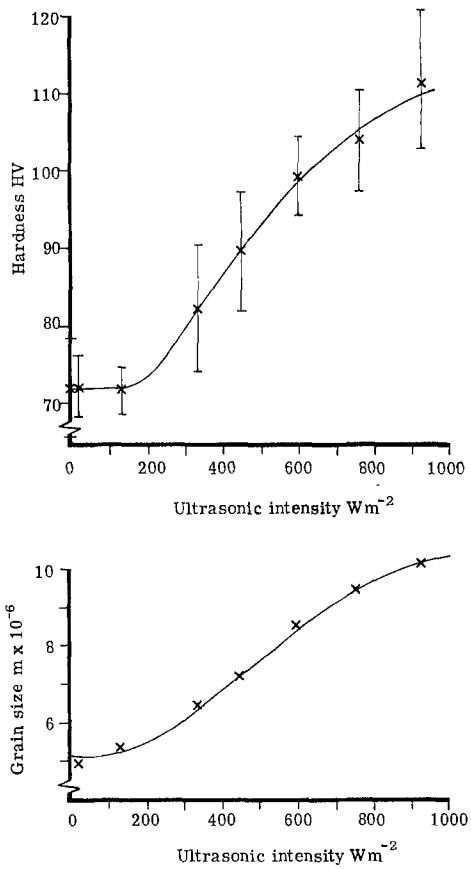

Fig. 5. Effect of ultrasonic intensity on deposit hardness and grain size, current density 300 Am^{-2}.

at each current density. The lacquer was removed from the back of the cathodes with acetone and the edges were trimmed to remove atypical structures.

Four specimens, each about 2 cm square, were cut from each cathode for density determination. The specimens were weighed in air and then in 100 ml of water containing about 0.1 ml of teepol to reduce surface tension. The deposit density, ρd, was calculated from Eq. [2] and the percentage porosity, P, from Eq. [3]

$$\rho d = \frac{T_t \rho m - T_f \rho f}{T_d} \qquad [2]$$

$$P = 100 - \left(\frac{\rho d}{\rho F} \times 100 \right) \qquad [3]$$

where T_t = total thickness of cathode foil and copper deposit, ρm = measured density, T_f = thickness of copper foil, ρf = density of copper foil, T_d = thickness of deposit, and ρF = density of the pore-free deposit.

This method gave a mean density for Analar copper foil of 8.956 gcm^{-3} which is close to the theoretical value of 8.96 gcm^{-3}. It was, therefore, accepted as a reliable method for the determination of deposit density. Deposit thickness was determined from metallographic sections, examples of which are contained in Fig. 3. Thickness values together with determined errors are reported in Table I which also lists deposit density and porosity.

Transmission electron microscopy.—A JEOL 100B electron microscope was used at 100 kV to examine the structure of: (*i*) deposits formed at a current density of 300 Am^{-2} (plating time 2 hr), (*ii*) an annealed copper foil cathode removed from a deposit after being subjected to ultrasound of intensity 596 Wm^{-2} for 2 hr, and (*iii*) an annealed copper cathode after the application of ultrasound (intensity 928 Wm^{-2}) through a continuous growing deposit.

Table I. Porosity of deposits related to agitation and current density

200	62 ± 5	8.95	0.01	8.93 ± 0.03	0.3 ± 0.3
300	56 ± 4	8.95	0.01	8.93 ± 0.03	0.3 ± 0.3
400	58 ± 4	8.95	0.01	8.93 ± 0.03	0.3 ± 0.3

The foil cathodes were annealed at 550°C for 15 min before use. In the experiment in which ultrasound was applied to the cathode through a growing deposit (3), a Perspex sheet was bonded to the back of the cathode to stop cavitation impact from that direction.

Thin foil preparation.—Several specimens about 2 cm square were cut from each plated cathode. Before examination in the microscope they were thinned to about 1000Å to enable transmission of the electron beam. Thus, the specimens were first chemically thinned to a thickness of about 5 μm in a solution of equal parts orthophosphoric acid (sp gr 1.76), nitric acid (sp gr 1.42), and glacial acetic acid at the temperature of mixing, about 50°C. In the case of specimens from the cathodes, before thinning began, unwanted material (deposit or electrode) was removed in a solution of 50% nitric acid. Prior to immersion in the nitric acid the surface of the material required for electron microscopy was lacquered with Lacomit to protect it from chemical attack.

A potentiostatic electropolishing method (9) was used for final thinning. The polishing cell arrangement was similar to that used for conventional electropolishing, but with the addition of a calomel reference electrode between the anode and platinum cathode. The window technique (10) was used to aid perforation, and polishing was carried out at room temperature in an electrolyte consisting of 4 volumes orthophosphoric acid (sp gr 1.76), 3 volumes ethanol, and 3 volumes distilled water. The polishing potential was between 1.3-1.4V (relative to the standard calomel electrode).

Results

Hardness.—Figure 4 shows, that in general, deposit hardness increases with current density although deposits from the still and stirred baths exhibit an initial slight fall in hardness followed by a steep rise. In the still bath this is succeeded by a sharp decrease associated with the production of completely powdery, nonadherent deposits.

Mechanical stirring produces softer deposits whereas ultrasonic agitation considerably increases deposit hardness, especially at the higher intensity (928 Wm^{-2}). At the lower intensity (596 Wm^{-2}), however, there is a slight overlap in hardness with that of deposits from the still bath. The increase in hardness with rising intensity is larger at higher current densities.

The effect of increasing ultrasonic agitation at a specific current density (300 Am^{-2}) is illustrated in Fig. 5 together with the standard deviation of each reading. It is apparent that hardness inreases with a rise in intensity above about 150 Wm^{-2}. Below this value no change occurs.

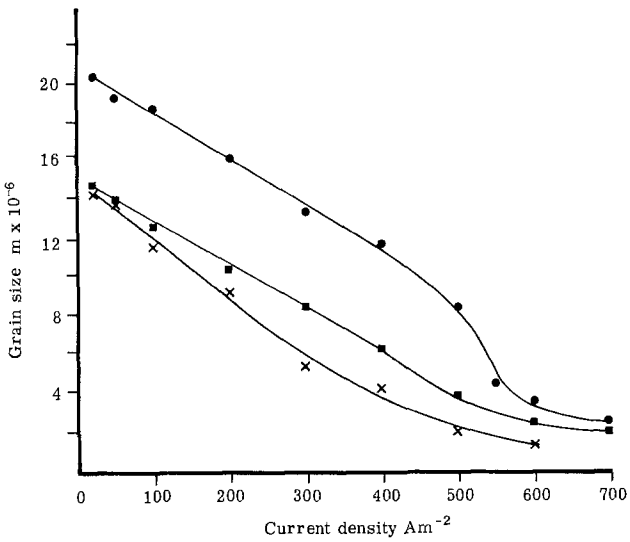

Fig. 6. Deposit grain size related to agitation and current density. ●, Stirred; ■, ultrasonic agitation, I = 596 Wm^{-2}; X, still.

Grain size.—In all three baths deposit grain size decreases with increase in current density (Fig. 6). The grains of deposits from the ultrasonic bath were larger than those of deposits from the still bath. At all but the highest current density, however, they were considerably smaller than the grains of deposits from the stirred bath. Figure 6 illustrates the effect of only one intensity on deposit grain size. The result of increasing ultrasonic intensity at a specific current density (300 Am^{-2}) is presented in Fig. 5. This shows that grain size increases with rise in intensity above 100 Wm^{-2}. Below this value no significant change occurs.

Porosity.—It is evident from Table I that plate from the ultrasonic bath is almost pore free whereas deposits from the still and stirred baths are considerably more porous with the single exception of those from the stirred bath at the lowest current density.

The porosity of still and stirred deposits, which is somewhat higher than that encountered in normal industrial practice, varies with current density and is a maximum at 200 and 300 Am^{-2}, respectively.

Structure and dislocation density.—Transmission electron micrographs (Fig. 7) show that twins are present in plates from all three baths, but they are much more numerous in deposits from the ultrasonic bath, particularly in those formed at the higher ultrasonic intensity (micrograph d). Figure 7 also shows that ultrasound of high intensity (928 Wm^{-2}) causes a significant increase in dislocation density. Further, most of the dislocations appear to be associated with twin boundaries. At the lower intensity (596 Wm^{-2}) a slight increase in dislocation density is apparent.

Effect of ultrasound on the dislocation density of annealed foil cathodes.—Figure 8 shows that ultrasound causes a considerable increase in the dislocation density of annealed copper foil cathodes and the formation of a dislocation cell structure. Moreover, micrograph c shows that an increase in dislocation content even occurs when ultrasound is applied to the cathode through a growing deposit. Dislocation tangles and the beginnings of a cell structure are exhibited. The significance of this slight increase in dislocation density is referred to later.

Discussion

Ultrasonic agitation causes an obvious increase in the hardness of deposits (Fig. 4). Further, grain size

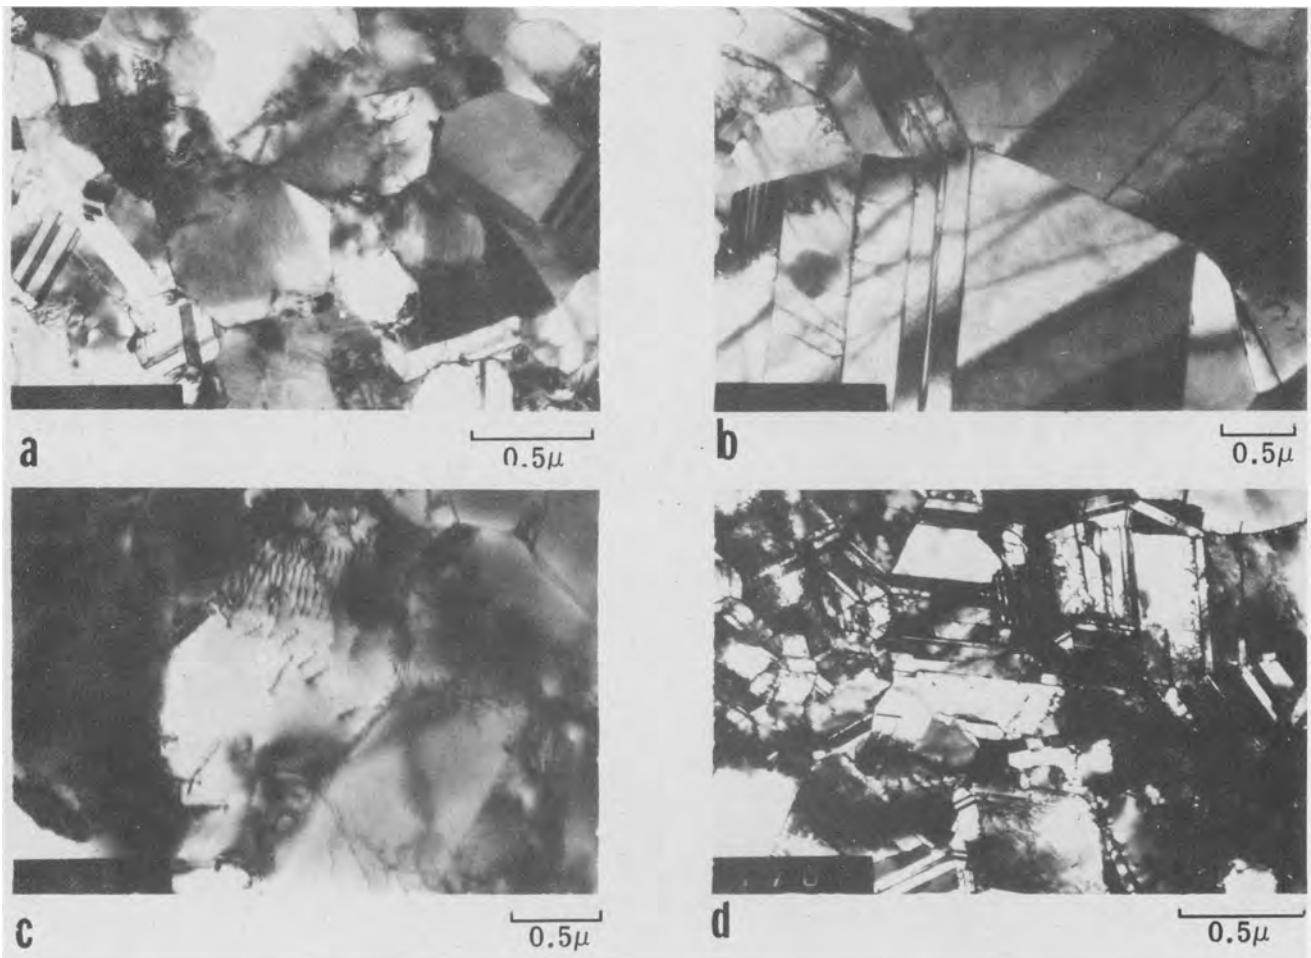

Fig. 7. Electron micrographs of deposits formed under various conditions of bath agitation. (a) Still, (b) stirred, (c) ultrasonic agitation intensity 596 Wm^{-2}, (d) ultrasonic agitation intensity 928 Wm^{-2}.

measurements, porosity determinations, and electron microscopy indicate that more than one factor is responsible.

A plot, Fig. 9, of the variation of deposit hardness with grain size for deposits from the three baths suggests that deposit grain size is the main factor determining hardness. The correlation may be explained by the fact that in small grained deposits there are many grain boundaries to block the slip planes along which deformation occurs (Petch relationship).

Decrease in grain size is largely responsible for the general increase in deposit hardness with rise in current density observed for deposits produced under all agitation conditions (Fig. 4). Thus, the steep hardness rise exhibited by deposits from the still and stirred baths results from the formation of small grains. In the still bath small grains (< 5 μm) are due to deposition under diffusion-controlled conditions. At high current densities (> 500 Am^{-2}) diffusion control (concentration polarization) leads to the formation of almost completely powdery deposits in this bath and hence a sharp fall in hardness (Fig. 4). Before the decrease occurs, however, the hardness of the plate from the still bath exceeds that of deposits formed in the low intensity ultrasonic field (596 Wm^{-2}) over a narrow range of current densities. This is because deposits from the still bath have very small grains (Fig. 5).

It can be seen from Fig. 5 that ultrasonic agitation increases both the grain size and the hardness of deposits. The large grain size results from the decrease in the concentration polarization caused by the stirring associated with the collapse of cavities. Further, the hardness of deposits from the different baths generally decreases with an increase in grain size (Fig. 9), so it is probable that in ultrasonic deposits the larger grain size reduces the hardening effect caused by other factors.

It is apparent from Fig. 9 that the hardness of still and stirred deposits is not determined by grain size alone: above a certain grain size, hardness is seen to increase with grain size. This suggests that another factor, absent in ultrasonic deposits, modifies hardness. The second factor is porosity, and its influence is such that for a specific grain size the less the porosity the higher the hardness. Since deposits from the still and stirred baths are porous (Table I) the average hardness measured is below the value for the pore-free material. Thus, a relation exists between the hardness curves in Fig. 4 and the porosity values in Table I. For instance, the current density at which the softest deposits are obtained from the still and stirred baths corresponds to that at which the most porous deposits are formed. Further, the initial slight fall in hardness with increase in current density observed for deposits from these baths is associated with an increase in porosity. Deposits from the ultrasonic bath at an intensity of 596 Wm^{-2} are almost pore free (Table I); hence, it is likely that hardening caused by low intensity ultrasound results from the decrease in porosity.

The reason for the decrease in porosity caused by ultrasonic agitation is not clear. Metallographic sections (Fig. 3) indicate, however, that porosity in deposits from the still and stirred baths is mainly caused by the failure of adjacent grains to meet during growth. If this is so, then it can be assumed that ultrasound reduces porosity by promoting the coalescence of grains. A SEM study of deposit nucleation and growth lends support to this. Ultrasound was found to

produce lateral growth whereas deposits from the still and stirred baths exhibit mainly three dimensional growth (Fig. 10). It is suggested that ultrasound favors such growth because cavitation removes the crystals and whiskers that grow normal to the surface (11).

The hardness of deposits from the ultrasonic bath continues to rise with increase in intensity above that at which pore-free deposits are formed (Fig. 4). Hence it is clear that a further factor is causing hardening. The hardening caused by high intensity ultrasound (> 596 Wm^{-2}) is considered to be mainly work-hardening and results from the repeated impacts of high pressure impulses caused by the collapse of cavities at the cathode. That cavitation is an important factor controlling deposit hardness is inferred from Fig. 6. The figure shows that hardness is unaffected by ultrasound of intensity below about 150 Wm^{-2}. This is probably because at such low intensities the impact pressures arising from cavitation collapse are too small either to cause work-hardening or to reduce porosity.

Electron microscopy of deposits and annealed copper cathodes confirms a high dislocation density. When an ultrasonic field of high intensity acts upon an annealed copper cathode through the growing deposit, the change in dislocation density and arrangement indicate that it is slightly work-hardened. This experiment was based on the inference that if cavitation work-hardens the cathode through the deposit then the deposit ought also to be work-hardened. The deposit removed from the cathode and other deposits formed under identical conditions contain more dislocations than deposits from the still and stirred baths (Fig. 7), but the increase alone is probably insufficient to account for the hardening observed (15 points) on raising the ultrasonic intensity from 596 to 928 Wm^{-2}. It is likely, however, that the increase in the number of growth twins contributes to the hardening, and that hardening is due to dislocation blocking by boundaries (twin and grain) rather than dislocation interaction.

Thus, the greater hardening at high current densities (28 points at 600 Am^{-2}) caused by raising the ultrasonic intensity from 596 to 928 Wm^{-2} can be explained on the grounds that more boundaries are available to block dislocation movement; although deposit grain size increases with intensity (cf. Fig. 5 and 6) the grains of deposits formed at 928 Wm^{-2} are remarkably small (not more than 4 μm).

Ultrasonic agitation increases the density of growth twins because it promotes faulting in the stacking se-

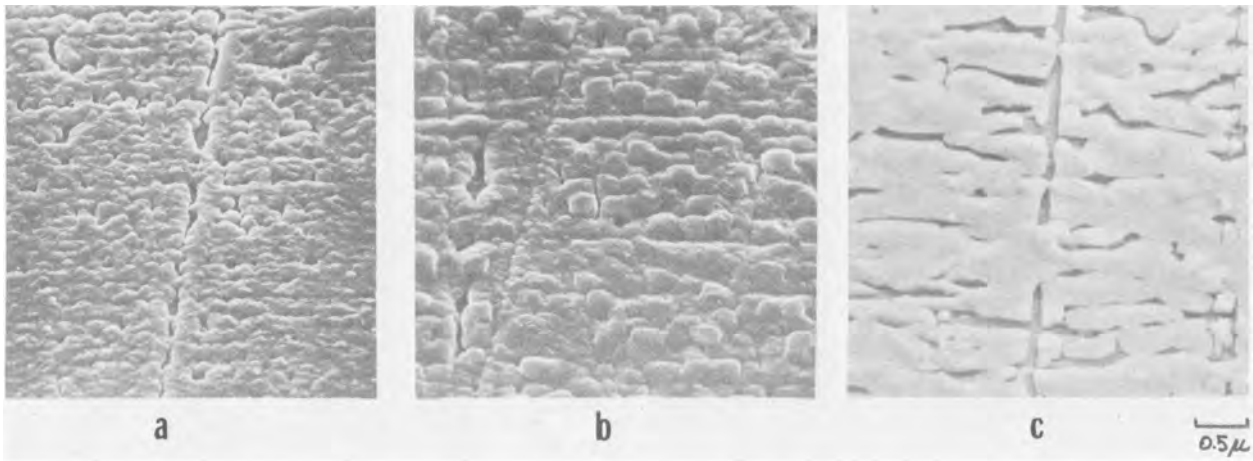

Fig. 10. Growth of deposits after 5 min. Current density 50 Am^{-2}. (a) Still solution, (b) stirred solution, (c) ultrasonically agitated solution, $I = 596$ Wm^{-2}.

quence of atoms on the {111} copper planes. Increased faulting is not surprising since, even at the lower intensity, ultrasonic energy in the electrolyte is equivalent to about 596 Jm^{-2}. If it is assumed that only 1% of this energy is transmitted to the copper deposit, the energy required to produce a coherent twin boundary, 2.0×10^{-2} Jm^{-2} (12), is still greatly exceeded. Further, the energy from cavitation implosions at the cathode will also contribute to the production of growth twins.

It is evident from a comparison of Fig. 7 and 8 that the work-hardening effect of ultrasound is greater on annealed copper cathodes than on copper deposits. For instance, plate formed at the lower intensity (596 Wm^{-2}) exhibits only a small increase in dislocation density, whereas the cathode removed from the deposit has a dislocation cell structure that is equivalent in conventional mechanical working terms to about 5% strain. This is expected because the deposits have a considerably smaller grain size than the annealed copper foil. Deposits are, therefore, intrinsically harder than annealed copper foil and have a greater resistance to cavitation impact.

It is well known that damage is caused when cavitation occurs in a liquid near a metal surface, but disagreement exists as to whether this is due to the impact of shock waves or liquid jets arising from collapse. Rayleigh (13) believes that the impact of shock waves arising from imploding cavities some distance away from the solid boundary causes damage. Parsons and Cook (14), however, suggest that the destructive action of collapsing cavities is caused by the direct impact of the liquid against the surface of the solid. Kornfeld and Suvorov (15) attributes damage to jets of liquid striking the metal surface during the asymmetrical collapse of cavities on or close to the surface. Observations by Ellis and co-workers (16, 17) and Shutler and Mesler (18) give support for the mechanism. They actually saw the formation of such jets in collapsing cavities and also damage on adjacent solid surfaces.

For cavitation to work-harden copper the impact stress at the surface due to cavitation collapse must exceed a value comparable to the hardness, which for annealed copper is about 5×10^8 Nm^{-2}. The intensity of the stress pulse on the surface of a solid exposed to cavitation appears uncertain at present, but may be expected to vary within wide limits depending on bubble size and the details of collapse.

Using the equations of Rayleigh (13) we have calculated the magnitude of the stress pulse arising from the collapse of a spherical cavity at a distance from the cathode to be 2.0×10^8 Nm^{-2}, and that due to the impact of an electrolyte jet to be 1.2×10^9 Nm^{-2}. The calculations were performed for an ultrasonic intensity of 900 Wm^{-2}, and a spherical collapse to 5% of the cavities original diameter was assumed. At an intensity of 928 Wm^{-2}, the actual stress in an acoustic wave is 5.4×10^4 Nm^{-2}, so cavitation is capable of producing a "stress concentration factor" of 4.0×10^3 to 2.0×10^4. It is to be noted that in the case of cavitation collapse at a distance from the cathode, a stress pulse of 2.0×10^8 Nm^{-2} is produced only by a bubble that is in the immediate vicinity of the cathode, and which remains spherical during collapse. In practice most bubbles undergo distortions when they collapse (15). Thus, calculation shows that the stress pulse arising from electrolyte jets is about a factor of 10 higher than that due to the collapse of spherical cavities in the electrolyte and it appears that only the stress pulse resulting from the impact of electrolyte jets is capable of causing plastic deformation of copper deposits and copper cathodes. These findings lead us to conclude that cavitation hardening is due solely to the impact of electrolyte jets arising during the asymmetrical collapse of cavities.

Conclusions

The hardness of deposits produced under all agitation conditions generally increases with rise in current density. This is accompanied by a decrease in grain size. Grain size is largely responsible for the hardness differences between deposits from the still and stirred baths, although variation in porosity with current density is also a contributing factor to the hardness of deposits from these baths.

Ultrasonic agitation increases the hardness of deposits. The change is dependent on the ultrasonic intensity; the higher the field intensity the greater the hardness. The increase in hardness caused by ultrasonic agitation is due to two factors: (*i*) a substantial reduction in deposit porosity, and (*ii*) work-hardening.

The first is the predominant factor at low intensities (below about 600 Wm^{-2}), whereas the second is the controlling factor at high intensities. Work-hardening results from repeated impacts of electrolyte jets on the surface of the deposit during the collapse of cavities. Hardening is due to dislocation blocking by twin and grain boundaries rather than dislocation interaction.

The degree of cavitation occurring in the electrolyte is the principal factor controlling the properties of deposits produced in an ultrasonic field. Cavitation influences deposit properties in two ways. Firstly it has an electrochemical effect. This causes the increase in grain size. It results from a decrease in concentration polarization caused by the stirring resulting from cavitation collapse. Secondly, cavitation has a mechanical effect, which causes the increase in hardness.

ABSTRACT

The hydrometallurgy of copper may involve leaching of the metal from its ore with an aqueous solution containing cupric and ferric chloride. The subsequent deposition of copper from such a process stream is modeled here in an idealized electrochemical cell with a rotating-disk electrode. The potential distribution and concentration profiles within the diffusion layer are predicted for given potential differences between the electrode and the solution. The cuprous ion, which is formed by the reduction of the complexed cupric ion at the electrode, is stabilized in the chloride solution and can react either at the electrode or with ferric species within the diffusion layer. The assumption is that this fast and irreversible homogeneous reaction generates a reaction plane, whose position is shown in the concentration and potential profiles. In addition, the position of the reaction plane is plotted as a function of the potential difference between the electrode and the adjacent solution. Predicted current-potential and current efficiency-potential curves are also reported. Finally, the iron contamination of the deposited copper is estimated to be less than 10^{-5} atom percent for some cases. Also, because some of the partial current densities are below their limiting values, the analysis is strictly valid only at the center of the disk.

Among the numerous hydrometallurgical schemes for extraction and recovery of copper currently under consideration there are several which employ an aqueous chloride solution as a lixiviant (1-11). The tendency of chloride to form metal complexes provides high metal solubilities; and, in conjunction with a suitable oxidizing agent such as chlorine, oxygen, ferric ions, or cupric ions, excess chloride facilitates rapid leaching of not only scrap metal but also sulfide ores such as chalcopyrite, $CuFeS_2$ (12-15).

The possibility of regenerating a leaching agent such as ferric ions at an anode while depositing copper cathodically makes the prospect of direct electrolysis of copper chloride leach liquors attractive. There are, however, two major difficulties with this approach. First, copper deposits from chlorides in a rough, porous, or even powdery form under most operating conditions so that the copper product would probably require remelting (11, 16, 17). The second problem is that the pregnant leach liquors may contain oxidized species that could react in the electrolysis cell and cause low current efficiencies for metal deposition. For example, iron occurring in an ore, or as the leaching agent, may appear in the electrolysis cell as ferric ion

and be reduced to ferrous ion at the cathode. This latter problem can be avoided by assuring reduction of the electrolyte prior to electrolysis, or by precipitating iron, to eliminate ferric ions, while using a diaphragm to prevent transport of ferric ions from the anode to the cathode. Nevertheless, it is interesting to investigate the quantitative effect of ferric ions on the deposition of copper from chloride solutions to determine whether removal of ferric ions prior to electrolysis is necessary. In this paper we compute the cathodic current efficiency for deposition of copper from a copper chloride solution which contains high levels of ferric ions and identify some interesting phenomena that can occur in this situation. The current efficiency for a cupric chloride solution which contains no ferric ions is considered elsewhere (18).

The process stream that results when copper ore containing iron is leached under mildly oxidizing conditions is presumed to contain the following ionic species in water at 25°C: $CuCl^+$, $FeCl^{2+}$, H^+, and Cl^-. Available stability constant data (19, 20) indicate that these are the most stable forms of the possible cupric-chloride and ferric-chloride complex ions in chloride solutions. Subsequently, these complex ions will be referred to as the cupric and ferric species, respectively.

Deposition of copper from the process stream is assumed to involve two steps. The first step is the reduction of the cupric species

$$CuCl^+ + e^- + 2Cl^- \rightarrow CuCl_3^{2-} \quad [1]$$

The second step is the reduction of the resulting cuprous-chloride complex ion (hereafter referred to as the cuprous species) to copper

$$CuCl_3^{2-} + e^- \rightarrow Cu + 3Cl^- \quad [2]$$

Stability constant data (19, 21) also indicate that this cuprous species is the most stable form of those possible in the solution considered here. It should be emphasized that the stability of the cuprous species enables it to exist at a much higher concentration than its counterpart could in other solutions, such as copper sulfate in aqueous sulfuric acid [see Ref. (22), for example].

Two additional electrode reactions are the cathodic deposition of iron

$$FeCl^+ + 2e^- \rightarrow Fe + Cl^- \quad [3]$$

by reduction of a ferrous-chloride complex ion, which is produced within the diffusion layer (see reaction [5]), and the reduction of hydrogen ions to form dissolved hydrogen gas

$$H^+ + e^- \rightarrow \frac{1}{2} H_2 \quad [4]$$

This ferrous species, $FeCl^+$, is also considered to be the most stable form that could exist in this solution (19).

One could also conceive of the direct reduction of ferric to ferrous species on the electrode, and this would occur at quite positive electrode potentials (where copper and iron would, in fact, dissolve). However, the presence of the ferric species is incompatible with the simultaneous presence of the cuprous species, and the ferric species cannot exist in the region near the electrode in the range of potentials where reactions [1] and [2] may occur. Instead, in addition to its participation in reactions [1] and [2] at the rotating-disk electrode, the cuprous species can diffuse away from the electrode and react with the ferric species, which is being transported toward the working electrode from the bulk solution, according to the following oxidation-reduction reaction

$$CuCl_3^{2-} + FeCl^{2+} \rightleftarrows CuCl^+ + FeCl^+ + 2Cl^- \quad [5]$$

This reaction occurs within the diffusion layer adjacent to the rotating-disk electrode. Since such ionic reactions are usually relatively rapid, reaction [5] is essentially equilibrated locally, and the treatment is similar to that for partial dissociation of bisulfate ions within a diffusion layer (23).

The ferrous species produced by reaction [5] diffuses back into the bulk solution and is also transported toward the electrode (where it may react according to reaction [3]).

The equilibrium constant K for reaction [5] can be estimated to be 1.55×10^5 (kg/mole)^2 by using standard electrode potentials as well as the stability constant data referred to above. Because this is a large number, the analysis can be simplified by assuming that K is infinitely large. (Further work on this problem in which K is not set equal to infinity is contemplated.) As a consequence of the assumption that reaction [5] has an infinitely large equilibrium constant, a reaction plane forms within the diffusion layer and thereby separates it into two regions (see Fig. 1). Furthermore, because of this assumption the ferric species is absent in region 1 and the cuprous species is absent in region 2.

The formation of a reaction plane by an instantaneous, irreversible bimolecular reaction was treated first by Hatta (24) within the context of simultaneous gas absorption and chemical reaction. Van Krevelen and Hoftijzer (25), Danckwerts (26), Perry and Pigford (27), Olander (28), and others have applied this concept in similar work. Recent treatment of reaction planes can be found in books by Sherwood and Pigford (29), Astarita (30), Danckwerts (31), Albery and Hitchman (32), Sherwood, Pigford, and Wilke (33), and Carberry (34). Friedlander and Litt (35) and Acrivos (36) used the reaction plane concept in their analyses of laminar boundary layer flows with a homogeneous reaction. Others (37-51) have also studied this subject.

Also of concern with this system is the possibility that the chloride complexing will stabilize the cuprous species to such an extent that iron is deposited in preference to copper. The standard electrode potentials of reactions with the chloride-complexed species were calculated from those of reactions of noncomplexed species and the stability constants from the literature. Table I shows that, at the potentials at which copper will begin to be plated, the ferrous ion is more stable than either the ferric ion or metallic iron, and this is true in both the complexed and noncomplexed systems.

The desired process in the electrochemical cell is the reduction of cupric species to deposited copper, which requires two electrons per copper atom deposited. The current efficiency will therefore be defined as the number of copper atoms deposited for each two electrons passed through the cell. The principal process which tends to reduce the current efficiency is the diffusion

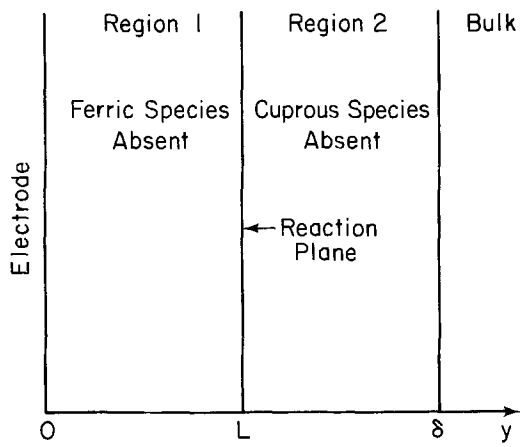

Fig. 1. The separation into regions of a diffusion layer within which a fast oxidation-reduction reaction occurs with an infinitely large equilibrium constant.

Table I. Standard electrode potentials with and without complexing by chloride, at 25°C

Reaction	U^θ, V	
	Noncomplexed	With chloride
Ferrous/ferric	0.771	0.745
Cuprous/copper	0.521	0.233
Cupric/copper	0.337	0.3355
Cuprous/cupric	0.153	0.438
Ferric/iron	−0.036	−0.0523
Ferrous/iron	−0.440	−0.451

of cuprous species back into the solution where it can escape or lead to the indirect reduction of ferric species to ferrous according to reaction [5]. Any reduction of ferrous ions to iron at the electrode will also lower the current efficiency as well as contaminate the deposit. In addition, the current efficiency is lowered by the reduction of hydrogen ions according to reaction [4].

The electrochemical cell used to model the physical phenomena discussed above consists of a rotating-disk electrode (the active portion of which is made either of copper or of an inert material such as platinum), a normal calomel reference electrode (whose standard electrode potential is 0.2676V), a distant counterelectrode, and a bulk solution of the same composition as the process stream. Deposition of copper from this electrochemical cell can be analyzed by applying dilute-electrolytic-solution theory with constant physical properties (22, 52). The results of this analysis include concentration profiles of the ionic species within the diffusion layer on the electrode, current-potential curves, and current efficiencies for this system.

For convenience, the current density distribution was assumed to be uniform on the surface of the electrode. Newman (53) showed how one should calculate the current distribution on a rotating-disk electrode, but consideration of the problem treated here at that level of sophistication is beyond the scope of this work. However, the results to be presented are applicable at the center of the disk.

Newman (54) also showed that for the rotating-disk electrode, on which one electrode reaction occurs at its limiting value, the governing equations for electrolytic mass transfer are the same as those for other flow configurations. Consequently, the assumption that the results reported here are also applicable to other flow configurations (54) should be a reasonable first approximation.

Governing Equations

Material-balance equations for species within the diffusion layer on a rotating-disk electrode are (55)

$$(D_i/D_R)c_i'' + 3\xi^2 c_i' + (z_i u_i F/D_R)(c_i\Phi'' + c_i'\Phi') = 0 \quad [6]$$

where the prime denotes differentiation with respect to the dimensionless distance ξ. For the rotating disk

$$\xi = y/\delta \quad [7]$$

where y is the normal distance from the surface and δ is the thickness of the diffusion layer, expressed as

$$\delta = \left(\frac{3D_R}{a\nu}\right)^{1/3}\left(\frac{\nu}{\Omega}\right)^{1/2} \quad [8]$$

with $a = 0.51023262$ (56). The position of the reaction plane, the ionic species concentration profiles, and the potential distribution can be determined by solution of these equations together with the condition of electroneutrality

$$\sum_i z_i c_i = 0 \quad [9]$$

and the following boundary conditions.

The boundary conditions in the bulk solution are that

$$c_i \to c_{i,\infty} \quad \text{as} \quad \xi \to \infty$$

At an arbitrary position, Φ can be specified, corresponding to the arbitrary zero of potential. At the reaction plane the boundary conditions are:

1. The total flux of each element (Cu, Fe, and Cl) as well as the flux of H^+ and dissolved H_2 is continuous.
2. The concentration of both the cuprous and the ferric species is zero.
3. The fluxes of ferric and cuprous species to the reaction plane are equal.

The boundary conditions at the rotating-disk electrode are that the normal component of the flux of species i evaluated at the electrode surface is equal to the sum of its reaction rates

$$N_i = -z_i u_i F c_i \frac{d\Phi}{dy} - D_i \frac{dc_i}{dy} = -\sum_{j=1}^{m} \frac{s_{ij} i_j}{n_j F} \quad [10]$$

where m is the number of reactions occurring at the electrode and s_{ij} and n_j are the stoichiometric coefficient of species i and the number of electrons transferred in electrode reaction j when written in the abstract form

$$\sum_i s_{ij} M_i^{z_i} \to n_j e^- \quad [11]$$

The current density due to reaction j was approximated by the Butler-Volmer equation

$$i_j = i_{oj}\left[\exp\left(\frac{\alpha_{aj}F}{RT}\eta_{sj}\right) - \exp\left(-\frac{\alpha_{cj}F}{RT}\eta_{sj}\right)\right] \quad [12]$$

where the composition dependence of the exchange current density was assumed to have the form

$$i_{oj} = i_{oj,ref}\prod_i\left(\frac{c_{i,o}}{c_{i,ref}}\right)^{\gamma_{ij}}\prod_k a_k^{\gamma_{kj}} \quad [13]$$

The symbol $i_{oj,ref}$ represents the exchange current density evaluated at the reference concentration of the ionic species, with $c_{i,ref} = 1M$, and at unit relative activity of the metallic species. In Eq. [13], i ranges over the ionic species and k over the metallic species. The relative activity of iron was taken to equal its mole fraction in the deposit, and the relative activity of copper was set equal to unity since little iron was expected to be deposited. Thus, a_{Fe} was set equal to $0.5\, i_3/i_2$, and the activity coefficient was ignored. The activity coefficient of iron should be greater than unity since iron and copper are not completely miscible, and consequently the deposition rate of iron should be even lower than that calculated here.

The transfer coefficients α_{aj} and α_{cj} are taken to sum to n_j. The exponents for both ionic and metallic species were given the values

$$\gamma_{ij} = q_{ij} + \frac{\alpha_{cj}}{n_j} s_{ij} \quad [14]$$

where $q_{ij} = -s_{ij}$ for a cathodic reactant and is zero otherwise.

The surface overpotential for reaction j is

$$\eta_{sj} = V - \Phi_o - U_{j,o} \quad [15]$$

where V is the potential of the rotating disk, Φ_o is the potential of the solution just outside the diffuse part of the double layer as measured by a reference electrode of a given kind, and $U_{j,o}$ is the theoretical open-circuit potential for reaction j at the composition prevailing at the electrode surface—again relative to the reference electrode of a given kind. For a normal calomel reference electrode

$$U_{j,o} = U^\theta_j - U^\theta_{cal} - \frac{RT}{n_j F}\left[\sum_i s_{ij}\ln\left(\frac{c_{i,o}}{\rho_o}\right) + \sum_k s_{kj}\ln a_k\right] + \frac{RT}{F}\ln\left(\frac{c^\lambda_{Cl^-}}{\rho_o}\right) \quad [16]$$

Here, $c^{\lambda}_{Cl^-}$ is the concentration of chloride ion in the reference electrode compartment, and the concentrations must be expressed in moles/liter if the usual tabulations of standard electrode potentials U^{θ}_j are to be used. Note that possible activity-coefficient corrections to the concentrations of the ionic species have been ignored.

Solution Technique

Equations [6] and [9] together with the above boundary conditions constitute a boundary-value problem involving coupled, ordinary, nonlinear, differential equations. The governing equations and boundary conditions were cast in finite-difference form accurate to order h^2, where h is the dimensionless distance between mesh points, and solved by a numerical solution technique developed by Newman (22). An interesting aspect of this problem is the unknown reaction plane position. In conditions 2 and 3 there is one more boundary condition than would be needed for a fixed plane position. Consequently, the plane position L must be treated as an unknown constant. To use the same computer subroutines, the treatment of this unknown constant was similar to that used by Newman (57) for the eigenvalues of the Graetz problem.

Parameter values used to obtain numerical results are presented in Table II. Mobilities were calculated from the tabulated diffusion coefficients by means of the Nernst-Einstein relation, $u_i = D_i/RT$. For the transfer coefficients, $\alpha_{cj} = 0.5$, and the exchange current densities, $i_{oj,ref}$, for reactions [1] and [3] were given the value 10^{-3} A/cm^2 while values of 5×10^{-3} and 5.89×10^{-7} A/cm^2 were used for reactions [2] and [4], respectively.

Results

Results are presented for four cases. In case one, only reaction [1], the reduction of the cupric species to cuprous species, is permitted to occur at the electrode (see Table II). In the remaining cases, reactions [1], [2], [3], and [4] occur at the electrode. These separate cases emphasize the significance of multiple electrode reactions and the significance of the ratio of the bulk concentration of cupric species to ferric species. Table II gives the bulk concentrations for each case.

Figure 2 displays the dependence of the electric potential Φ on the dimensionless distance from the electrode ξ for case one. Two quantities of interest, Φ_o and $\tilde{\Phi}_o$, are illustrated in this figure. The potential in the solution at the electrode surface (just outside the diffuse double layer) Φ_o and the potential of the working electrode V are used to form the potential difference $V - \Phi_o$, which is related to the driving force for the electrode reaction (see Eq. [15]).

The electric potential in the solution outside of the diffusion layer, $\tilde{\Phi}$, extrapolated to the electrode surface

* Taken from Ref. (58).
** Because of a lack of data, the diffusion coefficients of the ferrous and ferric species were taken to be the same as those of ferrocyanide and ferricyanide ions, respectively, as given in table 75-1 of Ref. (22).
† Taken from table 75-1 of Ref. (22).
‡ This value was arbitrarily selected for this work [see Ref. (59)].

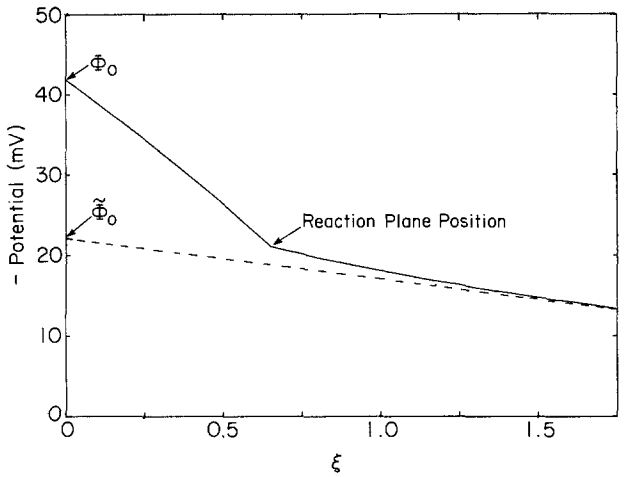

Fig. 2. Dependence of the electric potential on the dimensionless distance from the electrode when $V - \tilde{\Phi}_o = -0.3545$V and reaction [1] alone occurs at the electrode.

is designated as $\tilde{\Phi}_o$. Its value may be obtained by extrapolating Ohm's law

$$i_T = \sum_{j=1}^{m} i_j = -\kappa_\infty \frac{d\tilde{\Phi}}{dy} \qquad [17]$$

to the electrode surface from the bulk by using the previously calculated value of i_T and the conductivity κ_x of the bulk solution. The potential difference $V - \tilde{\Phi}_o$ represents an alternative driving force for the electrode reaction. We might write for the total overpotential

$$\eta_{sj} + \eta_{cj} = V - \tilde{\Phi}_o - U_{j,\infty} \qquad [18]$$

where η_{cj} is the concentration overpotential for reaction j and $U_{j,\infty}$ is the theoretical open-circuit potential for reaction j at the bulk solution composition and the alloy composition of the deposit.

There is a difference between $\tilde{\Phi}_o$ and Φ_o because the conductivity varies with position in the diffusion layer and is not equal to κ_∞ and because there exists a diffusion potential due to the concentration variations and the different diffusion coefficients of the various species [see equation 125-7 of Ref. (22)]. These factors are accounted for when one solves simultaneously the coupled Eq. [6] and [9] across the diffusion layer to obtain the potential distribution in Fig. 2.

Figure 3 depicts the calculated concentration profiles of the ionic species within the diffusion layer that were obtained at the same potential difference. In this figure, the dimensionless distance from the electrode at which the concentration of both the cuprous and the ferric species is zero indicates the position of the reaction plane.

The calculated current density due to reaction [1] alone, i_1, normalized by the current density predicted by the Levich equation (60)

$$i_{LD} = 0.62048 \frac{n_1 F c_{R_\infty}}{s_{R1}} (\Omega\nu)^{1/2} \left(\frac{D_R}{\nu}\right)^{2/3} \qquad [19]$$

is presented in Fig. 4, as a function of the potential differences $V - \tilde{\Phi}_o$ and $V - \Phi_o$.

Figure 5 displays the calculated concentration profiles for case two with $V - \tilde{\Phi}_o = -0.3493$V.

In Fig. 6 the dimensionless position of the reaction plane L/δ is presented as a function of the potential

difference $V - \tilde{\Phi}_0$ for cases 1 and 2.

The total predicted dimensionless current density for case 2 is plotted in Fig. 7 as a function of the potential difference $V - \tilde{\Phi}_0$. The current densities due to reactions [1] and [2] for case 2 are also plotted in Fig. 7. (The current density due to reactions [3] and [4] were too small to be plotted conveniently on Fig. 7.)

These calculated current densities were used to calculate the current efficiency, $100 \times 2i_2/i_T$, as a function of the potential difference $V - \tilde{\Phi}_0$, which is plotted in Fig. 8. Also shown in Fig. 8 are the current efficiencies for cases 3 and 4.

Finally, the dependence of the relative surface concentration of the cupric, cuprous, and chloride species on $V - \tilde{\Phi}_0$ is presented in Fig. 9.

Discussion

The potential profile and the concentration profiles shown in Fig. 2, 3, and 5 are not smooth at the reaction plane because of the assumption that K is infinite.

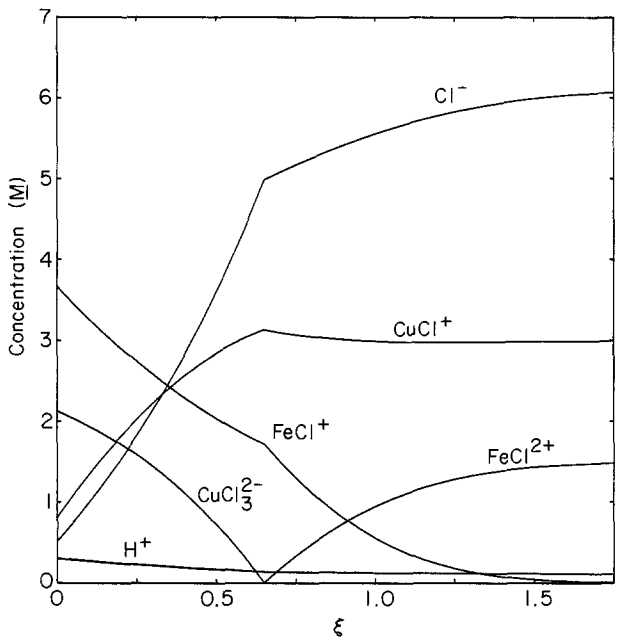

Fig. 3. Dependence of the concentration of the various species on the dimensionless distance from the electrode for case 1 with $V - \tilde{\Phi}_0 = -0.3545$V.

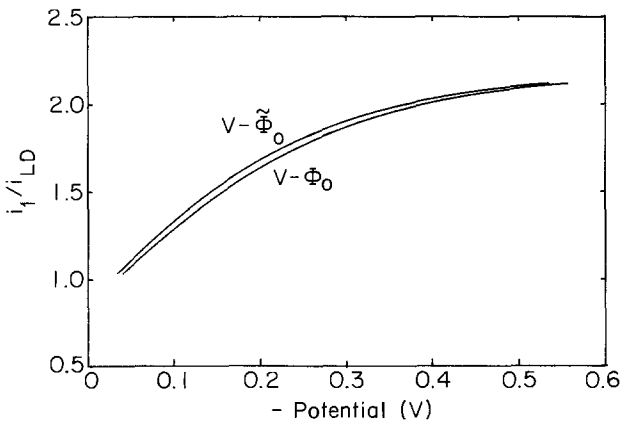

Fig. 4. The dimensionless current density when reaction [1] alone occurs at the electrode as a function of the potential differences $V - \tilde{\Phi}_0$ and $V - \Phi_0$.

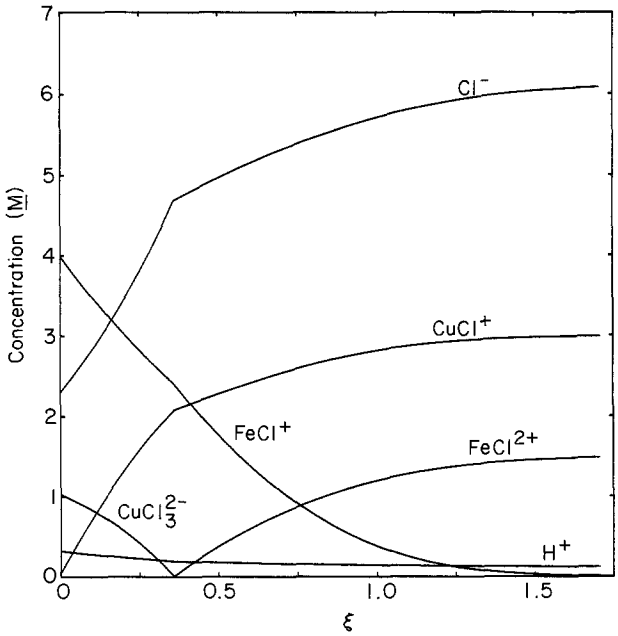

Fig. 5. Concentration profiles of the various species near the electrode for case 2 with $V - \tilde{\Phi}_0 = -0.3493$V.

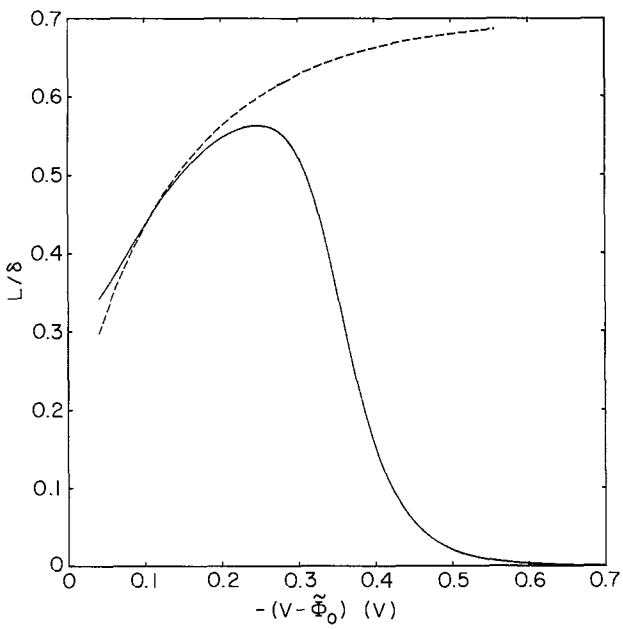

Fig. 6. Dependence of the dimensionless reaction plane position on $V - \tilde{\Phi}_0$ for cases 1 (– – –) and 2 (——).

Consider first case one, where the only electrode reaction is the reduction of cupric to cuprous ions. The latter diffuse away from the electrode to the reaction plane, where they reduce ferric to ferrous ions, with regeneration of cupric. Some of the cuprous species also escape by radial convection. The concentration profiles in Fig. 3 illustrate these processes. As the electric driving force is increased, the concentration of the limiting reactant, the cupric species, approaches zero, and the concentration of the product cuprous species at the electrode increases. Consequently, the position of the reaction plane moves away from the electrode, as also shown in Fig. 6. The position of the reaction plane is determined by a balance of the transport of cuprous species from the electrode and the transport of ferric species from infinity. The ferrous species, the product of the plane reaction, also has accumulated toward the

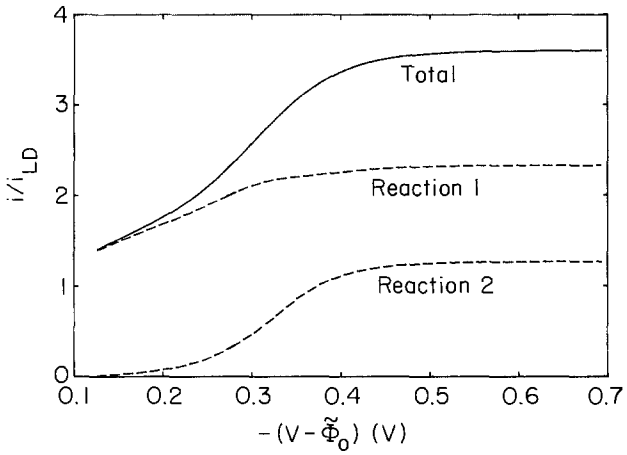

Fig. 7. Dependence of the dimensionless current densities on $V - \tilde{\Phi}_0$ for case 2.

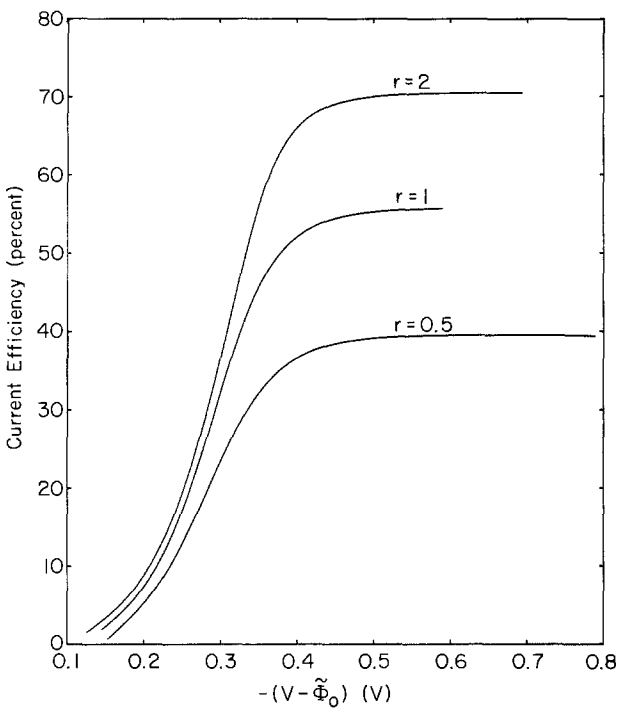

Fig. 8. Dependence of the current efficiency on $V - \Phi_0$. $r = c_{CuCl^+,z}/c_{FeCl^{+2},\infty}$. r = 2, 1, and 0.5 for cases 2, 3, and 4, respectively.

disk surface. The chloride ion is produced by reaction [5] at the plane and consumed by reaction [1] at the electrode, and the consequences of this are observed in the concentration profiles.

The current density for reaction [1] can exceed substantially the limiting value for convection and diffusion of the cupric species as given by the Levich equation. Figure 4 shows ratios as high as 2.12. This enhancement is due to ionic migration of the limiting reactant (55) and the regeneration of the cupric species at the reaction plane. Since the cupric species is positively charged, it is attracted toward the cathode according to the potential distribution in Fig. 2. This effect of migration also accounts for the maximum in the concentration of the cupric species at the reaction plane and for the increase of concentration of the ferrous species toward the electrode (see Fig. 3), where this species is neither produced nor consumed. The effect of the reaction plane is, in essence, to bring

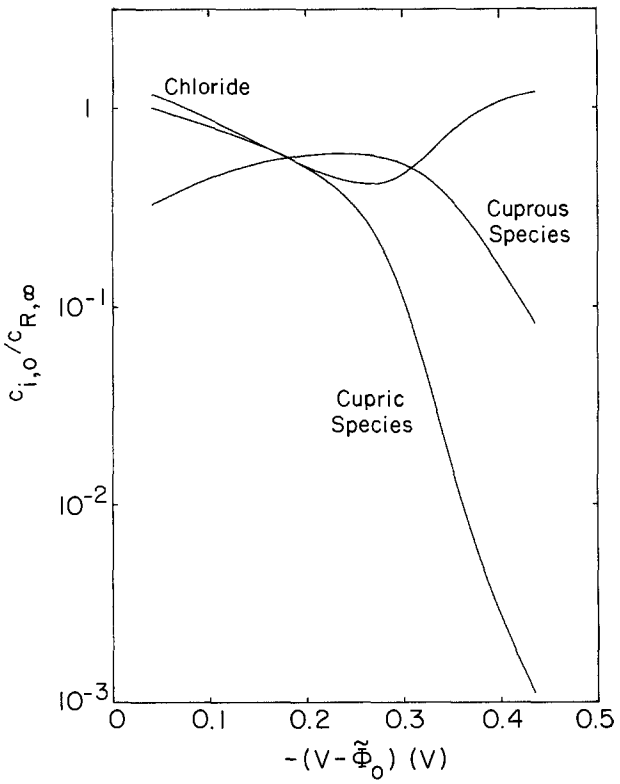

Fig. 9. Dependence of the relative surface concentration of some of the ionic species present in the system on $V - \tilde{\Phi}_0$ for case 2.

the bulk concentration of the limiting reactant closer to the electrode, since the cupric species is produced at the plane by reaction [5], and this serves to increase the concentration gradient at the electrode.

Another way to think about this effect is to realize that the reduction of ferric to ferrous, which occurs at the plane, requires a supply of electrons from the electrode. The indirect supply of these electrons through the transport of cuprous species from the electrode to the plane contributes to a higher current density for reaction [1]. In fact, the reduction of ferric to ferrous requires a smaller electric driving force than the reduction of cupric to cuprous (see Table I). When the reaction-plane distance has decreased to zero, the reduction of ferric to ferrous can proceed directly on the electrode, and the analysis would actually become simpler.

Figure 4 shows that $\tilde{\Phi}_0 - \Phi_0$, the difference between the potential drop through the diffusion layer and that obtained by extrapolation with the bulk conductivity, is relatively small compared with the scale of potentials over which the current rises toward its limiting value. For the situation in Fig. 2, $\tilde{\Phi}_0 - \Phi_0$ has the value of 19.9 mV.

For case two, we must now consider the additional effects associated with the possibility of depositing copper and iron on the electrode and also the possibility of evolving hydrogen gas at the electrode. The deposition of copper by reaction [2] consumes cuprous ions produced through reaction [1], and consequently less of the cuprous species remains to diffuse back into the solution. Comparison of the concentration profiles in Fig. 3 and 5 shows this reduction of the cuprous concentration at the surface. The reaction plane is now much closer to the electrode, as also depicted in Fig. 6. Comparison of the predicted reaction plane positions at small values of $-(V - \tilde{\Phi}_0)$ for cases 1 and 2, as shown in Fig. 6, reveals that the reaction plane is further from the electrode in case 2, a result which is

due to the dissolution of deposited copper according to reaction [2].

The current densities in Fig. 7 reflect the difference in the potentials of the two copper reactions (see Table I). The current density due to reaction [1] is well along toward a limiting current, the same limit shown in Fig. 4, before the current density due to reaction [2] becomes significant. The slight increase in the current density due to reaction [1] above the initial plateau is due to the increasingly larger concentration gradient of the limiting reactant as the reaction plane moves closer to the electrode (compare Fig. 3 and 5). The cupric species produced at the reaction plane can no longer escape by radial convection. Furthermore, the current density due to reaction [2] will increase the potential gradients and enhance further the migration of cupric ions toward the electrode from the bulk solution.

In order to avoid contamination of the deposit with iron, the electric driving force should not be made too large, according to the standard electrode potentials in Table I. For example, the current density for reaction [3] is very small and can be used to estimate that less than 10^{-5} atom percent (a/o) of the deposit is iron for values of $V - \tilde{\Phi}_o$ more positive than about -0.51V. However, this estimate is probably high because the activity of iron was taken to equal the atom fraction, with neglect of the activity coefficient. Since the activity coefficient is greater than unity, the deposition of iron would be further impeded.

For such low rates of reaction [3], the low current efficiencies in Fig. 8 are mainly due to two causes: (*i*) "leakage" of cuprous species away from the electrode by radial convection, and (*ii*) consumption of cuprous species at the reaction plane. The latter is equivalent to the indirect current required for reduction of ferric to ferrous at the plane. Because the reduction of cupric and ferric species occurs at a lower electric driving force than reaction [2], the current efficiency increases with an increase in the electric driving force and approaches about 70.5, 55.7, and 39.5% for cases 2, 3, and 4, respectively. The maximum possible current efficiency is determined mainly by the ratio of ferric and cupric concentrations in the bulk solution. At still larger values of the electric driving force, the current efficiency would decrease due to the deposition of iron by reaction [3] and the evolution of hydrogen according to reaction [4].

For some cases the range of acceptable operating potential differences may be determined by the solubility limit of the cuprous species (approximately 1*M* in the solutions studied here) and the maximum tolerable iron contamination of the deposit or hydrogen gas evolution. For case 2, Fig. 9 (also see Fig. 5) shows that operating at potential differences more positive than about -0.35V could lead to undesirable precipitation of cuprous species. (For cases 3 and 4, $\tilde{\Phi}_o - V$ should be at least 0.32 and 0.275V, respectively, to avoid CuCl precipitation.) At the other extreme in the range of acceptable operating potential differences for case 2, the current density due to reaction [3] may be used to predict that the iron contamination of the deposited alloy would exceed 10^{-5} a/o for $V - \tilde{\Phi}_o$ values more negative than about -0.52V. Further reduction of $V - \tilde{\Phi}_o$ would lead eventually to hydrogen gas evolution. (The value of $V - \tilde{\Phi}_o$ at which this may begin to occur for case 4 was predicted to be approximately -0.789V, for example.)

Another limiting situation is associated with the bulk chloride concentration. Since chloride ions are consumed and liberated at the electrode at rates which depend on $V - \tilde{\Phi}_o$, a minimum in the surface concentration of chloride ions exists, as shown in Fig. 9. The implication of this minimum is that, for some bulk compositions, the chloride ion concentration would vanish at the electrode, a condition which may be considered undesirable because the complexing of the species would be no longer ensured.

Summary and Conclusion

The results of this work are that one can predict for this system: (*i*) the location of a hypothesized reaction plane; (*ii*) reasonable concentration profiles for the ionic species; (*iii*) realistic current-potential curves; (*iv*) current efficiencies of about 70.5, 55.7, and 39.5% for cases 2, 3, and 4, respectively; and (*v*) a copper product that can be at least 99.99999% pure. Consequently, the design of an electrochemical cell to remove the copper directly from the model process stream appears to be feasible provided that problems with the physical structure of the copper deposit can be avoided.

Again, the anlaysis is strictly valid only at the center of the disk.

LIST OF SYMBOLS

a	constant = 0.51023262
a_k	relative activity of metal k in the deposit
c_i	concentration of species i, mole/liter
$c_{i,o}$	concentration of species i at the electrode surface, mole/liter
$c_{i,\infty}$	concentration of species i in the bulk solution, mole/liter
$c_{i,ref}$	reference concentration of species i, mole/liter
D_i	diffusion coefficient of species i, cm^2/sec
D_R	diffusion coefficient of the limiting reactant ($CuCl^+$), cm^2/sec
$\mathbf{F}$	Faraday's constant = 96,487 C/mole
h	mesh size
i_j	current density due to reaction j, A/cm^2
i_T	total current density, A/cm^2
i_{oj}	exchange current density, A/cm^2
$i_{oj,ref}$	reference exchange current density, A/cm^2
i_{LD}	limiting current density due to diffusion (see Eq. [18]), A/cm^2
K	equilibrium constant for reaction [5], (kg/mole)^2
L	position of the reaction plane, cm
m	number of rotating-disk electrode reactions
M_i	symbol for the chemical formula of species i
n_j	number of electrons transferred in reaction j
N_i	normal component of the flux of species i, mole/cm^2-sec
R	universal gas constant = 8.3143 J mole^{-1}K^{-1}
s_{ij}	stoichiometric coefficient of species i in reaction j
T	absolute temperature, °K
u_i	mobility of species i, cm^2 mole J^{-1} sec^{-1}
$U_{j,o}$	theoretical open-circuit potential for reaction j at the surface composition, V
U^θ_j	standard electrode potential for reaction j, V
U^θ_{cal}	standard electrode potential of the calomel reference electrode, V
V	potential of the rotating-disk electrode, V
y	normal distance from the disk, cm
z_i	charge number of species i
α_{aj}	anodic transfer coefficient for reaction j
α_{cj}	cathodic transfer coefficient for reaction j
γ_{ij}	exponent in composition dependence of exchange current density
δ	diffusion layer thickness, cm
η_{cj}	concentration overpotential for reaction j, V
η_{sj}	surface overpotential for reaction j, V
κ_∞	bulk solution conductivity, ohm^{-1} cm^{-1}
ν	kinematic viscosity of the solution, cm^2/sec
ξ	dimensionless distance from the disk

ρ_o pure solvent density, g/cm^3
Φ potential in the solution, V
Φ_o potential in the solution adjacent to the electrode surface, V
$\tilde{\Phi}$ potential in the solution outside the diffusion layer, V
$\tilde{\Phi}_o$ potential in the bulk solution extrapolated to the surface of the rotating-disk electrode, V
Ω rotation speed of the disk, rad/sec

Etch Rates of an Electroplated Alloy (Sn-Ni) Using a Quartz Crystal Microbalance

J. H. Thomas III*

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

Etch rates for electroplated tin-nickel alloy (65 w/o Sn, 35 w/o Ni) in 10% HCl solution have been determined at 25°, 50°, and 75°C using a quartz crystal oscillator as a sensitive microbalance. Sn-Ni electrodeposits exposed to laboratory ambient for 24 hr exhibit linear etch rates (170, 290, and 540 Å/min for 25°, 50°, and 75°C, respectively). Tin nickel (SN-Ni) exposed for more than 6 weeks exhibits nonlinear etch rates initially. An induction period of 25 sec is required before etching begins in 10% HCl for the 6-week exposed samples. These effects are attributed to the presence of a passivating native oxide (30Å thick) which is not observed on the 24-hr exposed Sn-Ni.

Tin-nickel electroplated alloy is presently being investigated for use as an underplate for gold-plated electrical contacts. Many aspects of the physical properties of the polycrystalline tin-nickel deposit, such as corrosion resistance (1) and the buildup of surface passivity (2-4), are presently being investigated. In fabricating gold on tin-nickel contacts, the tin-nickel surface is usually treated in dilute HCl (10%) for a period of between 30 and 60 sec to remove possible oxide buildup prior to gold electroplating. This procedure, called activation, insures good gold film adherence. This practice stems from early investigations into the electrochemical (5, 6) and chemical (7) properties of tin-nickel. Parkinson *et al.* (7) show that the native oxide protects the metal in solutions containing Cl^- with *p*H of more than 1.3. It was also shown that HCl (both 1 and 4*N*) dissolves tin-nickel alloy at a slow rate at temperatures near room temperature. In this paper, etch rates for tin-nickel (65/35) alloy have been determined at room temperature (25°C), 50°, and 75°C using a quartz crystal oscillator as a sensitive microbalance.

Experimental

Polycrystalline tin-nickel samples were prepared by electroplating (3) ~7000Å of tin-nickel on 5 MHz AT-cut circular quartz oscillator plates (supplied by Sloan Technology Corporation, Santa Barbara, California, for use in their film thickness monitors). Quartz crystals were supplied with an evaporated gold film applied to both sides for electrical contact purposes. The gold area was ~1 cm^2 per side. Deposited film thickness is limited by the mass of the total film which subsequently causes the oscillator frequency to shift. On quartz crystal mass monitors of this type, mass loading must be limited to that which will result in less than 100 kHz frequency shift at 5 MHz (9). Frequency change is related to mass change by the following: $\Delta m = 1.77 \times 10^{-8} \Delta f$ g/cm^2 [see Ref. (9)]. To insure a maximum linear crystal response to mass loading, films were not deposited in excess of 7 kÅ per side. At this thickness, Sn-Ni is likely to be porous, but this will not significantly affect the results of this study. Some crystals were allowed to stand in unfiltered laboratory air for 24 hr while a few were aged in this manner for more than 6 weeks. Two coupons (1½ × 1½ in.) were also prepared by electroplating 3 mils of tin-nickel on clean O.F.H.C.[1] copper (supplied by M. Antler). These samples were allowed to stand in laboratory air for about 4 months, which produced a passivating native oxide.

Etch rate and mass loss measurements were performed using a Sloan Crystal thickness monitor (DTM-3) in lab air (see Fig. 1a). A Hewlett-Packard frequency counter was attached to the oscillator output to provide an accurate measurement of the oscillator frequency. Sequences of measurements were typically made to precision of about ±30 Hz.

Contact resistance measurements (10) were made using a gold wire probe (20 mils diameter) (11) at a force of 100g (see Fig. 1b). All measurements were made at a constant current of 1 mA and a maximum open-circuit voltage of 100 mV. Six probings were made for each measurement condition as described below. Contact resistance measurements were per-

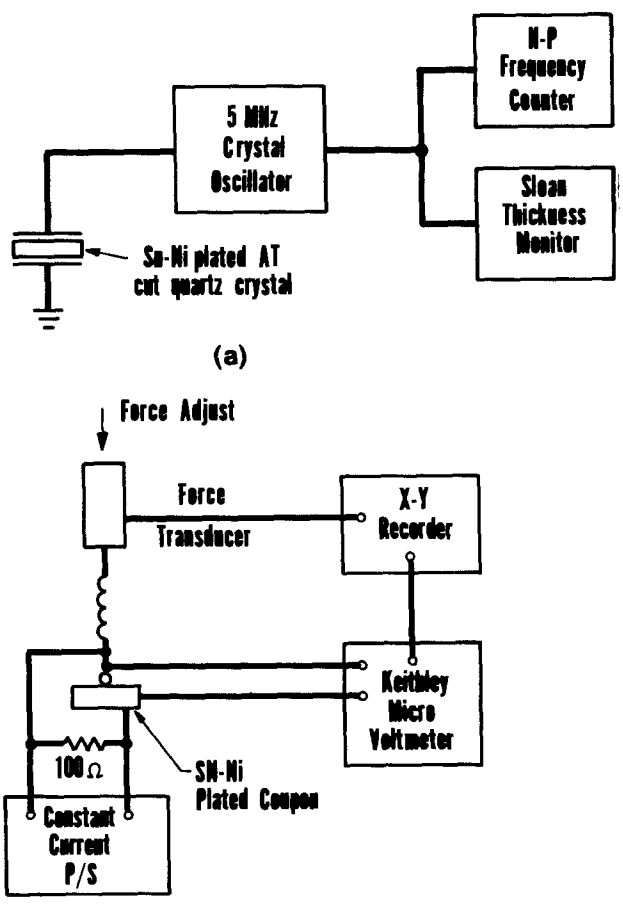

Fig. 1. (a) Block diagram of the mass loss monitor system; (b) block diagram of the contact resistance probe.

formed only on the electroplated copper coupons because the quartz crystals are very fragile.

The 10% HCl solution was prepared using Baker reagent grade HCl (37% HCl) and reverse osmosis deionized water with a resistivity in excess of 5 MΩ-cm. A new solution was prepared before each experiment. Above room temperature measurements were performed by heating 100 ml of solution in a covered beaker on a hot plate. Solution temperature was controlled to within ±1°C.

The following procedure was used to etch the electroplated Sn-Ni samples. The crystals were handled with semi-cleanroom procedures, that is, lint-free gloves, etc. Etching was performed by mounting the crystal (which is approximately ½ in. diameter) on a stainless steel tricep. Only the stainless steel spring fingers of the triceps holding the crystals were immersed in the etchant. During the etch, the samples were vigorously agitated by hand. Upon completion, the etched samples were rinsed in flowing water and blown dry with filtered dry air. All frequency shift measurements were made at room temperature. A similar procedure was used to etch the tin-nickel plated coupons. However, for reference purposes only half of the coupon was exposed to the etchant.

Results

Etch rate vs. temperature (samples aged for 24 hr).—The tin-nickel electroplated crystals which were exposed to lab environment for ~24 hr were used in this study. A number of crystals were etched at room temperature to check reproducibility. Crystals were etched for a given time (30 or 60 sec) using the above procedure, and frequency shift was determined after each etch period. In some cases, up to 5 min were required for the newly etched crystal to stabilize in the oscillator. Transient conditions were attributed to a temperature/humidity differential from the cleaning/drying operation to the crystal mount. Figure 2, curve A shows a typical frequency shift *vs.* etching time at room temperature. Frequency shift is converted to film thickness or mass using a computed density for tin-nickel of 8 g/cm^3 and a crystal constant of 1.77 × 10^{-5} g/cm^2/kHz (5). Mass change is indicated along the right-hand side of Fig. 2. Slight nonlinearities in etch rate (that is, deviations from a straight line in curve A) are likely due to surface contamination in handling or variations in exposure time during successive measurements. AT-cut crystals are more sensitive to mass change near the center of the disk. For these samples (curve A), the 10% HCl appears to attack the tin-nickel at an almost constant rate. When the samples were etched long enough to remove most of the Sn-Ni, the underlying gold on the crystal was exposed more or less uniformly. This indicates that the etchant etched the polycrystalline sample surface uniformly. The slope of the curve can be converted to an etch rate using the crystal constant and the density of tin-nickel. At room temperature, this particular sample etches at a rate of ~200 ± 10 Å/min. The error is estimated from the ±30 Hz inaccuracy in the data.

As mentioned earlier, the etch rate in 10% HCl solution was measured at 25°, 50°, and 75°C. Figure 3 summarizes etch or mass loss data as a function of sequential etch times at these temperatures. In all cases, etching proceeds at a nearly constant rate. Elevated etchant temperature increases the etch rate. Etch rates for the samples shown are 170, 290, and 540 Å/min at 25°, 50°, and 75°C, respectively. However, considering the manner in which etching was performed, that is, exposing the etched surface to lab air between each measurement, the discrepancy in etch rate (170 *vs.* 200 Å/min) at room temperature is not surprising.

Effects of the native oxide (samples aged more than 6 weeks).—Curve B in Fig. 2 shows a typical etch characteristic (that is, mass loss *vs.* etch time). For a crystal which had been exposed to lab ambient for >6 weeks and subsequently etched in room temperature 10% HCl for the various times, no frequency shift was noted (except some variation around the initially measured frequency) for etch times less than 25 sec. An initial etch time of >25 sec produces a measurable frequency shift (for 30 sec, Δf = ~60 Hz) indicating a mass loss. Subsequent 30 sec etches remove considerably more material and the rate becomes linear as shown in Fig. 2, curve B. The linear etch rate is similar to that of curve A indicating that Sn-Ni is being etched. Apparently, the oxide is not appreciably etched for immersion times of less than 30 sec. Unfortunately, higher time resolution measurements were not performed on the quartz crystals.

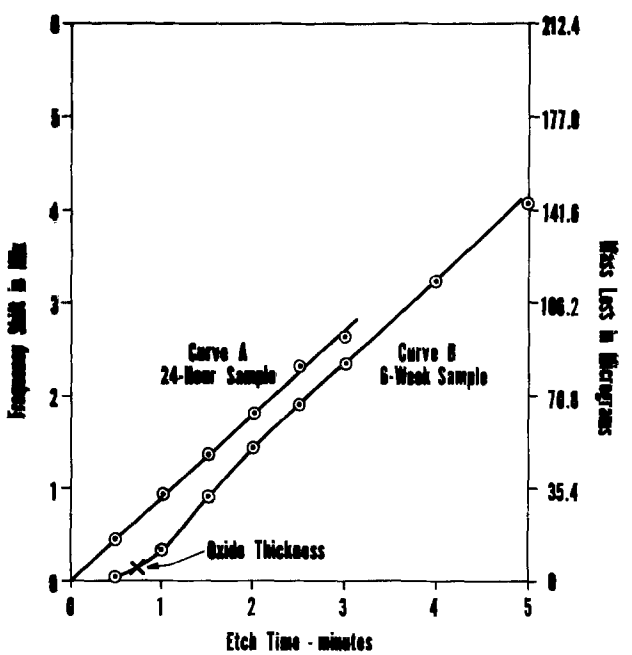

Fig. 2. Curve A: etching characteristics, frequency shift, or mass loss *vs.* etch time for a Sn-Ni sample exposed for 24 hr. Curve B: a similar characteristic for a sample exposed for > 6 weeks.

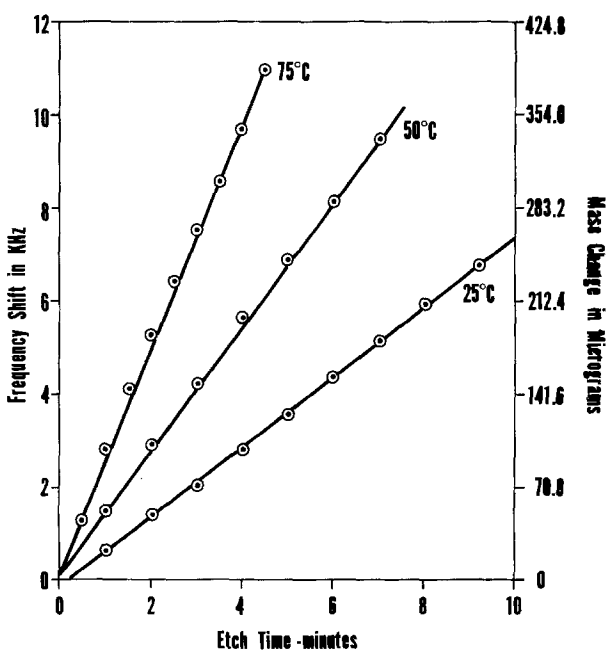

Fig. 3. Etching data, mass loss *vs.* etch time, are shown at 25°, 50°, and 75°C. Etch rates (slopes) are 170, 290, and 540 Å/min.

To study this phenomenon in more detail, contact resistance measurements were performed on a Sn-Ni plated copper coupon as a function of etch time at room temperature. The sample was cleaned and blown dry with clean air and six contact resistance measurements were made at a contact force of 100g. After making initial resistance measurements, the coupon was etched and measured sequentially for two 10 sec periods, four 15 sec periods, two 20 sec periods, and one 25 sec period. The 25 sec etch was followed by four 10 sec etches.

Etching data are summarized in Fig. 4. Bars indicate the range of the six contact resistance values and the dot indicates the median value of contact resistance. Initial contact resistance is near 1000Ω (at 1 mA constant current) and is indicative of an electrically insulating film. Immersion and subsequent etching caused a decrease in contact resistance until a contact resistance of around 100 mΩ was attained. Further etching did not reduce the contact resistance until the etch time was increased to 25 sec. After the 25 sec etch, a marked decrease in contact resistance to around 20 mΩ was observed. Etch times after the 25 sec etch were reduced and repeated until a low repeatable value of contact resistance (~6 mΩ) was attained. This resistance corresponds to a technically clean metallic surface obtained by handling in the laboratory environment. For reference, an abraded gold flat was measured and a value of 3.2 mΩ was measured repeatably.

Discussion

Figure 2, A and B show etch rate data for Sn-Ni which has been aged for 24 hr after plating and more than 6 weeks after plating, respectively. A considerable difference is observed between initial etch rate of the two samples. In the case of the newly plated samples, etching occurs at a near linear rate from the onset. Samples exposed for >6 weeks etch at a slower rate initially and eventually attain a steady etch rate. This suggests that for the samples exposed for a long time the initial nonlinearity is due to the removal of the native oxide. Thus, the oxide appears to etch at a slower rate than the Sn-Ni metal. The oxide which builds up on the Sn-Ni surface after ~24 hr exposure to lab air does not show any evidence of chemical passivity in 10% HCl. Therefore, a clear distinction exists between the long-term oxide and the short-term oxide passivity and etch characteristics. Properties and growth kinetics of both oxides were investigated through the use of analytical surface instruments (ESCA, AES, etc.) (3, 4, 12). The passive native oxide which grows on Sn-Ni was shown to be a form of hydrated nickel stannate (12).

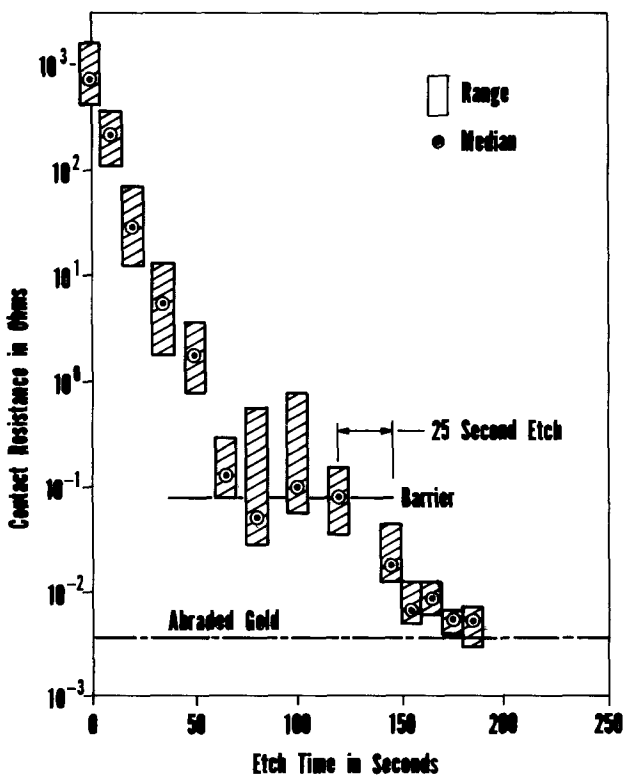

Fig. 4. Contact resistance at 100g force, 1 mA constant current, and 100 mV open-circuit voltage shown as a function of etch time.

From the data shown in curve B of Fig. 2, an approximation of the oxide thickness was made by assuming the point at which the initial slow etch rate begins to increase. A point midway between the first and second data points (indicated by "X") was chosen. Assuming the density of the oxide to be 6.85 g/cm^3 [estimated by averaging the known densities of SnO_2 and NiO (12)], the frequency shift at this point is ~100 Hz which corresponds to a film thickness of ~30Å. Contact resistance data indicate that the oxide film reaches an equilibrium thickness in ~6 weeks exposure to air (2). The thickness estimated from the etch results is in good agreement with the ESCA depth profile results discussed in Ref. (12) (~35Å thick).

Etch rate measurements at various temperatures show that after removal of the native oxide, Sn-Ni metal is removed at a more or less steady rate. The rate is observed to range from ~500 Å/min at 75°C to ~200 Å/min at 25°C. As a practical matter, 10% HCl is a very slow etchant for electroplated Sn-Ni at or above room temperature.

Contact resistance measurements (using a gold probe) show a large initial decrease in resistance with etch time in 10% HCl at room temperature. This may be due to Cl^- incorporated in the oxide which changes its conductivity and is likely related to the breakdown of chemical passivity.[2] Since weight loss was not observed on crystals etched in a similar manner, it is unlikely that the native oxide is being removed in the initial etch stages. The change in resistance is observed to reach a plateau or barrier at ~100 mΩ for etch times of <25 sec. The plateau most likely corresponds to a saturation effect in the oxide film. When the etch time is increased to 25 sec, contact resistance is decreased by a factor of five corresponding to a partial removal of the native oxide. Subsequent 10 sec etches removed the remainder of the passive oxide, exposing the metal surface. Resistance measurements stabilized at ~6 mΩ (compared with 3.2 mΩ Au-Au) at a force of 100g. Lower force contact resistance values tracked the 100g data but exhibited a larger range around the median.

Contact resistance and etch rate data clearly show, in the presence of a passivating native oxide on Sn-Ni, an induction period before which Sn-Ni metal or oxide is not etched by 10% HCl at room temperature. In the case of room temperature etching, the sample must be immersed in the HCl solution for >25 sec before any mass loss is observed. The contact resistance measurements confirm these results. It is likely that shorter times will initiate Sn-Ni etching in 10% HCl at elevated temperatures.

Conclusions

Etch rates for Sn-Ni have been determined using a quartz crystal oscillator as a microbalance. It has been shown that Sn-Ni etches at a linear rate (170, 290, and 540 Å/min, respectively) in 10% HCl solution at 25°, 50°, and 75°C. When a "thick" oxide (samples exposed >6 weeks in lab air) is present, an induction period is required before the oxide or Sn-Ni is etched, that is, the native oxide remains passive for immersion times <25 sec in 10% HCl. These results are confirmed

[2] It is a well-known fact that small quantities of impurities in normally insulating films can change their conductivity drastically. See, for example, J. J. O'Dwyer, "The Theory of Elecrical Conduction and Breakdown in Solid Dielectrics," chap. 2, Clarendon Press, Oxford (1963).

by contact resistance measurements. Room temperature etching of Sn-Ni electroplate exposed for ~24 hr and >6 weeks exhibits different initial etch characteristics. After ~1.5 min in 10% HCl, the "thick" oxide samples etched at essentially the same rate as the thin oxide sample. The initial nonlinearity in etch rate is attributed to the existence of a thick native oxide. Oxide thickness was estimated to be ~30Å.

Acknowledgments

The author wishes to thank E. T. Ratliff for plating the crystals and G. V. McIlhargie for the use of the Sn-Ni plating facility. The author is also indebted to M. Antler for his interesting discussion and the plated Sn-Ni coupons used in this study and to F. E. Bader for his critical reading of this manuscript.

Manuscript submitted Nov. 19, 1976; revised manuscript received Jan. 21, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by Bell Laboratories.

ABSTRACT

The use of heart pacemakers and other implantable electronic devices is increasing. The hybrid cell, as a power source, consisting of a sacrificial anode and a catalytic cathode for tissue oxygen reduction has been successfully employed to pace heart-blocked dogs. The life and biocompatibility of the cell are determined by the anode material loss in the recipient's body. Corrosion rates of Al anodes implanted in dogs have been studied using the d-c polarization technique of Greene and Stern. The difference in the measured apparent corrosion rates is explained. The effect of extensive pitting of Al under galvanostatic loading conditions and its effect on the linear and Tafel curves are discussed. Preliminary data from *in vivo* a-c impedance measurements are presented in an effort to correlate them to the corrosion parameters. Problems associated with the a-c bridge measurements include the elimination of the tissue impedance (exhibiting possible dielectric relaxation) between the measuring electrodes. It is shown that it is possible by careful selection of the electrode geometry to minimize the effects of tissue and auxiliary electrode impedances on the metal-tissue interface parameters of the test electrode.

Hybrid cells consisting of porous palladium black cathodes where dissolved oxygen in the body fluids is catalytically reduced by galvanic coupling to sacrificial anodes which are oxidized have been reported (1). Reduction of available energy due to large overpotentials of the cathodes has been overcome by using powder metallurgy techniques with Pd black (2, 3). Early biocompatibility studies have been previously reported (1). This paper describes further measurements of anode corrosion rates and preliminary a-c impedance studies in an effort to characterize the corroding metal-tissue interface.

Experimental Procedures

Corrosion studies.—Corrosion rates were determined by using the linear polarization technique (4-8); galvanostatic anodic and cathodic polarization curves. The corrosion currents were determined from (8) $I_{corr} = 0.026/R_p$ where R_p is the polarization resistance determined from the linear polarization curves.

The linear polarization technique consists of determining the Tafel slopes β_a and β_c for both anodic and cathodic processes and the polarization resistance, R_{pol}, of the corroding electrode under study. The polarization resistance is the slope of the linear portion of the polarization curve obtained by plotting overpotential *vs.* current density for the first 10-20 mV of overpotential of the electrode.

In the *in vivo* studies, the current was passed between a test electrode and a porous palladium black auxiliary electrode implanted in dogs. The potential of the test electrode was measured with respect to an Ag-AgCl reference electrode placed on the skin of the dog with conductive paste.

The procedure for obtaining a galvanostatic polarization curve was as follows. The constant current (d.c.) was incremented in equal steps (at least ten equal steps per decade on a logarithmic scale) at equal intervals of time, usually between 2-5 min. The change in potential due to the constant current increment was noted at the end of the time interval. This procedure was continued until a complete polarization curve was obtained.

A Keithley Model 225 current source with a Model 160 ammeter was used in the *in vivo* galvanostatic measurements where the current was passed through the test electrode via an auxiliary electrode (9). The electrode voltage was monitored using a Model 610C electrometer and a Digitex 268 millivoltmeter. All electrodes were sterilized in a Bard ethylene oxide gas sterilizer. Electrical connections were made by Teflon-coated multistrand stainless steel wire No. 31A.W.G. (Gooner Wire Company, California) and were percutaneously brought out of the dog. One major problem with previous implants was the permeation of fluids into and beneath the epoxy encapsulation over the sample. However, the present method of applying the epoxy resin by abrading the surface (to remove metal oxide) and the additional PVC-paraffin dip has successfully solved the problem. No ingress of fluids was observed after 5 months of implantation. The implants were given a final coating of Dow Corning medical grade silicone adhesive A for biocompatibility. All samples had a 1 cm^2 area exposed. Metals of 99.99% purity were supplied by A. D. Mackay and Company, New York. An Ag-AgCl standard 16 mm Beckman biopotential electrode was placed on the skin with conductive paste for the duration of the experiment.

Electrical impedance studies.—Test electrodes of Al were made similar to those used in corrosion studies, but of 0.22 cm^2 exposed area. These implanted "impedance cells" had the Al electrode facing, approximately 1-2 mm apart, a parallel plate porous palladium auxiliary (counter) electrode. For *in vitro* measurements, in addition to the above, electrodes of 99.99% purity Al wire 0.005 cm^2 area embedded in epoxy were used. The cross-sectional area (of the wire) was polished with 0.05 μm alumina and inspected for flaws with a low power microscope. Reagent grade chemicals and doubly distilled water were used to make the chloride solutions. The a-c bridges included the Wayne Kerr B201 for 0.1-5 MHz and B221 for 0.25-50 kHz in conjunction with a Wayne Kerr SR 268 source detector, G.R. 1312 decade oscillator, and G.R. 1232A null detector, for measurements of 20-200 Hz, with a G.R. 1608-A bridge.

The total measured impedance between the electrodes includes the solution and tissue impedance. The measuring electrodes consist of a porous palladium counterelectrode whose interfacial impedance (10, 11) is significantly lower than the test electrode. The equivalent circuit employed to represent the measured impedance Z_m is given in Fig. 1.

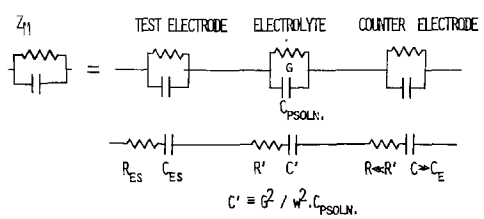

Fig. 1. Equivalent circuit used to represent measured parallel capacitance and conductance as Z_m.

Results and Discussion

Corrosion.—Gross pitting studies.—Two dogs were used with one set of samples in each, loaded to the range of current densities shown in Table I. The set S samples upon removal showed that epoxy adhesion was lost allowing fluid ingress beneath the masked area up to the lead connection. This is ascribed to electrolyte passage through the epoxy resin (12) since this set did not have the PVC-paraffin coating as on set M. In this confined region beneath the epoxy capsule, brightening of the electrode and uniform corrosion had occurred. Under a low power microscope shallow hemispherical and saucer-shaped pitting over the entire area was seen.

Three of the electrodes of set S showed the dark original oxide on the unmasked area intact with micropitting. The electrodes were presumably under cathodic protection (13) by the uniformly corroding parts elsewhere on the electrode. Three other S samples showed brightening of the exposed area as well as that masked by epoxy wherein fluids had permeated. The exposed surfaces had thick crusts of corrosion products. Some pits approximately 20 on one sample of 0.1-0.5 mm opening and up to 0.4 mm depth were present, with innumerable micropits.

The three samples in set M which were implanted and loaded to the currents shown in Table I had the epoxy well adhered. Corrosion was seen only on the exposed area where varying amounts of deep pitting were observed. The area under such macropits was roughly proportional to the loading; the rest of it was covered by the original darker oxide which had undergone micropitting of various geometrical shapes. This area was evidently acting as a cathode (13) for O_2 reduction to the anodic dissolution areas in the pits. Due to the absence of a freely flowing electrolyte in *in vivo*, the corrosion products were again deposited on the surface, especially over the pitted areas. The pits were large, up to 0.7 mm in opening and equally deep with extensive lateral growth. Ob-

servations under a low power microscope clearly showed that the areas under crevice corrosion and the surface of the pits were totally covered with small bright hemispherical pits.

There is difference of opinion as to the morphology and initiation (14, 22) of pitting of Al in solutions containing Cl^- ions. According to Kaesche (15) and Wood *et al.* (16), Al polarized to or below the pitting potential E_p shows crystallographic pitting which turns to electropolished pits as the potential is raised (more +eV); whereas Galvele *et al.* (17) claim that brightened hemispherical pits are not a general rule. They showed the transition from purely spherical polished to a crystallographic pitting as the NO_3^-/Cl^- concentration ratio is decreased. This study shows that the pits (*i*) are crystallographically not well defined but tend to be more or less hemispherical and (*ii*) show a degree of electrobrightening described as polished pits, which is what Hoar (20) found for metals with an oxide undergoing pitting at the breakdown potential. Given Cl^- containing organic fluids as the medium (18, 19), it is not surprising to note during galvanic corrosion at constant current that Al anodes undergo severe pitting at approximately −0.62V *vs.* Ag-AgCl and show brightened hemispherical pit surfaces.

Two electrodes implanted under no load for 5 months showed very little sign of visual corrosion. One sample showed evidence of the beginning of crevice corrosion, with some micropitting and one large pit of 0.1 mm opening. The other electrode showed a similar surface with an additional 0.4 mm wide and deep pit. The exposed area showed numerous micropits of irregular shapes under a low power microscope.

A scanning electron microscope, SEM, micrograph is shown in Fig. 2 and 3. This proves that loading of the electrode results in large pits which propagate extensively with time.

Electrodes of set S of Table I were observed to have undergone uniform metal dissolution under the encapsulating epoxy due to fluid ingress because of bad epoxy adhesion, rather than deep pitting. As a result, galvanic coupling to the copper rivet for the lead wire was established, enhancing the corrosion. These samples showed more active potential (Table I); −0.9V as compared to those of set M (≈ −0.6-

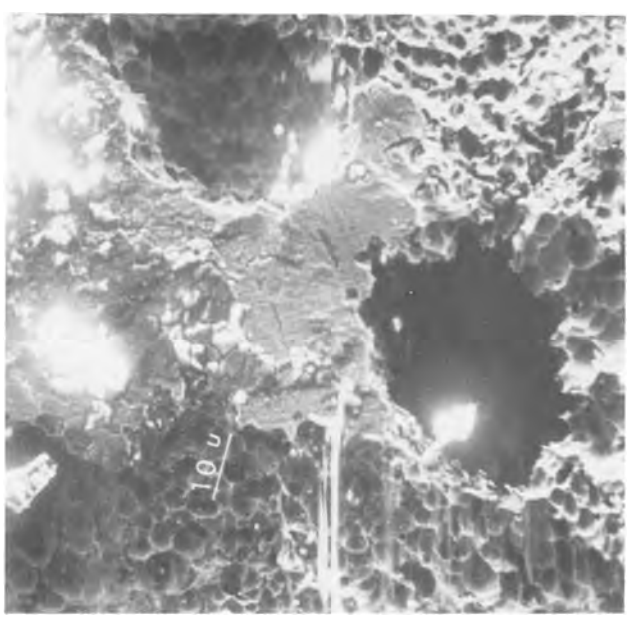

Fig. 2. Scanning electron micrograph showing brightened hemispherical pits and pit surfaces on a loaded aluminum electrode after removal.

Fig. 3. Scanning electron micrograph showing unloaded aluminum electrode surface after removal.

0.65V). Craig (21) has shown that the potential of a corroding metal is an indication of the nature of the metal dissolution process thus indicating that for the above potential ranges sets S and M were undergoing uniform and pitting attack, respectively.

Pitting potential.—Figures 4-6 show anodic polarization curves taken on Al samples *in vivo*. The curves generally do not show a linear Tafel region (see below), however, the interesting feature is the plateau region of apparent nonpolarizability, occurring at an average potential of −0.60V *vs.* Ag-AgCl. The shape of the curve with the hump before the apparently nonpolarizable region is characteristic of the type of galvano-kinetic method used (22). In this study the quasi-stationary method, where a constant current was changed stepwise and a certain rate was used.

Various investigators (34) have given an explanation of the plateau region part of the *E-I* curves. The potential maximum on the hump is called the pitting potential E_p and the potential at the plateau the pitting protection potential, E_{pp}. de Wexler and Galvele (23) have proposed from data on strained Al samples that a critical pitting potential definitely exists for Al and is independent of the oxide.

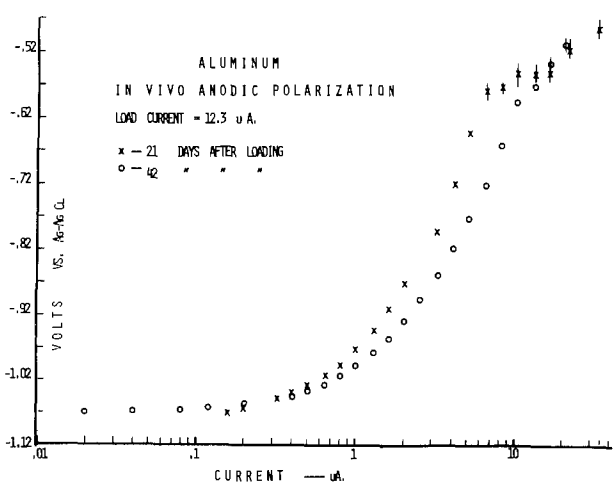

Fig. 4. Anodic polarization curves of aluminum electrodes (set M) showing changes with time under load. Vertical bars indicate oscillations of potential.

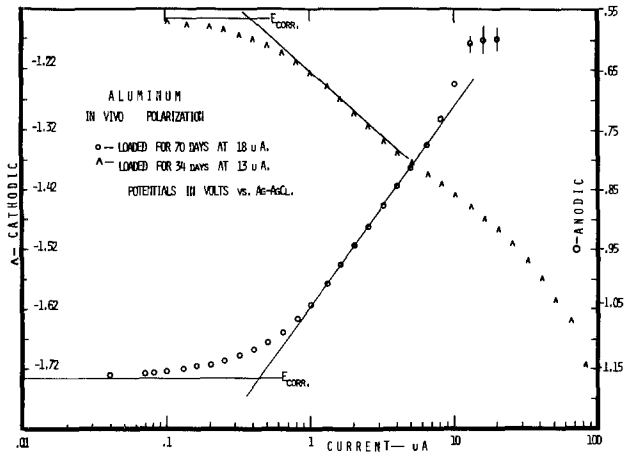

Fig. 5. Polarization curves of aluminum electrodes. ○ = anodic polarization curve taken at 5-8 min time intervals between current increments showing linear Tafel region.

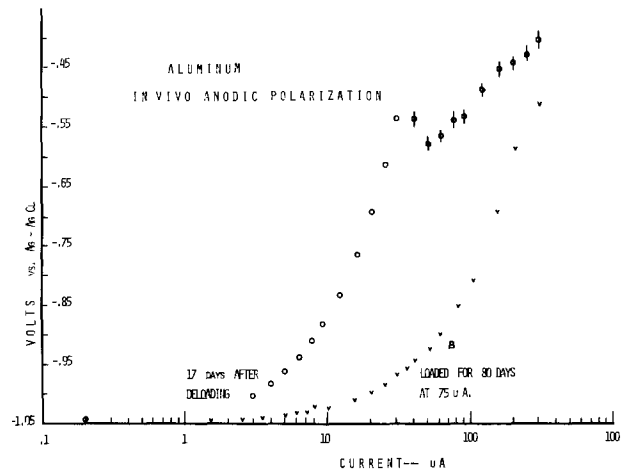

Fig. 6. Aluminum electrode (of set S) polarization curve showing effect of partial passivation due to removal of load current.

Broli *et al.* (22) have shown that there is only one critical potential of Al, and have given reasons for differing values obtained by different types of potential and current controlled *E-I* curves. According to Wood *et al.* (16) the breakdown or pitting potential only represents that stage in the pitting process at which the combined effects of increasing active surface area and decreasing ability of local cathodic activity to support that area require a sudden increase in current supply. On the other hand, Pryor (24) has claimed that at and above the critical potential the Al ions migrate through the oxide by a high field mechanism.

Figure 4 shows that with time, under load, the plateau region is somewhat shortened. This was observed in most of the loaded samples. One explanation of this nonpolarizable region is that it occurs when the external current increases at a rate proportional to the area increase due to propagating pits (15) supporting the anodic process and new pits initiated on any cathodic area. Thus a constant true anodic current density maintains the potential of the specimen constant. During polarization in the plateau region, the potential oscillates rapidly between ±100 mV. This could be due to the activation and increase in "new anodic" and cathodic areas (16) which may momentarily supply a supporting cathodic current. The new "anodic areas" could be the mentioned passive areas supporting O_2 reduction (see above) which are not activated due to breakthrough type of current across the Al oxide of ions as proposed by Pryor (24). The reduction in the nonpolarizable region with time under load is then due to a decrease in the availability of passive (cathodic) area supporting O_2 reduction since more of this area is attached by pitting with increasing time and load.

The above effect is well demonstrated in Fig. 6, where the sample is from set S. The sample had undergone uniform dissolution over its entire surface. Curve B shows no evidence of a plateau, since little or no new anodic area is available (no large pits propagating) nor oxide-covered cathodic area which could undergo breakdown. After deloading, part of the anodically active area passivates, the breakdown of which manifests as the reappearance of the apparent nonpolarizable region. Table II gives some values of the E_p which were observed. Some electrodes showed more +V values of the breakthrough potential after several weeks under load. As to why the breakdown consistently occurs in the range −0.52-0.62V *vs.* Ag-AgCl is yet unknown.

The above curves were obtained by open-circuiting the loaded electrodes, and the polarization was then begun after a time period during which the potential decreased (more −V) to a steady-state value of approximately −1.1V from the value of −0.64 under load. The decrease in potential is explained as follows. Upon removal of the load current, the anodic current density through the true dissolution area (inside pits) decreases (due to repassivation), causing a fall in E_{corr}.

Tafel regions.—The time between current increments was 1-2 min. The electrode potential had reached a near steady state in this interval. As the breakthrough potential was approached, this time was observed to be insufficient and the potential was still increasing

Table II. Values of potentials corresponding to the nonpolarizable region of the anodic polarization curves observed with time after loading. (Note zinc electrode No. 2 was not loaded, and the load on No. 3 was removed after 37 days.) All potentials are −V measured relative to Ag-AgCl reference electrode

(→ +eV). In some cases even though 5-8 min were allowed, a steady potential was not reached, although this resulted in the appearance of a linear Tafel region as shown in Fig. 5. The breakthrough potential, however, still occurred between −0.52 to −0.62V *vs.* Ag-AgCl.

The cathodic polarization curves give β_c values between 0.2 and 0.25 while the β_a values were greater than 0.3.

Since the samples of set M had substantial areas of the original oxide on the surface intact (under cathodic protection by the pits), the curves in Fig. 4 and 5 show a smaller change with time under load as compared to those of set 5 as seen in Fig. 6.

Linear polarization and zinc electrodes.—High purity 99.99% solid zinc electrodes were also implanted and loaded. Figure 7 shows two polarization curves. The nonpolarizable plateau region is obtained for all unloaded. Zn electrodes at approximately −0.92V *vs.* Ag-AgCl (Table II). This region disappears when the electrodes are loaded, leading to the conclusion that Zn, like Al, has a protective oxide or hydroxide layer which undergoes breakdown upon anodic polarization. The unloaded zinc sample showed a layer of products of corrosion on the surface, with a few areas along the edges showing the beginning of crevice corrosion. The loaded electrode showed an uneven surface marked by large shallow pits due to random metal dissolution. Upon deloading the electrode, the polarization resistance increases with time, indicative of repassivation. It remains to be determined if this is caused by a *p*H change at the interface due to loading.

Figures 8 and 9 show the linear polarization curves for loaded Al and Zn samples. Due to loading of the

electrodes, the time changing anodic area inside the pits and crevices caused nonlinearities in the first 10 mV of overvoltage *vs.* applied current plots. The corrosion current calculated from the data, therefore, gives an approximate value for the whole electrode (25) and not per unit area of originally exposed area. The loaded zinc electrodes showed a consistent flattening of the curve after the first few millivolts overvoltage as shown in Fig. 9. The unloaded Zn electrodes did not show this tendency. The unloaded zinc electrode polarization resistance, R_p, increased with time, due possibly to increased passivation by a layer of products of corrosion on its surface. Unloaded Al electrodes behave similarly until some large pitting starts. Due to the changing true area undergoing dissolution, the apparent R_p for Al electrodes changes with time, whereas for Zn electrodes the change in true area is not as large and therefore the R_p tends to show less change with time (see Table III).

We conclude that Al shows extensive and severe pitting of the bright hemispherical morphology when loaded. The corrosion current measured by linear polarization is approximately proportional to loading as the area under dissolution in the enlarging pits increases. During such galvanic corrosion the potential is approximately −0.64V and the anodic polarization curve shows a breakthrough or pitting propagation potential of approximately −0.60V. Due to changing area, Tafel regions are not generally obtained. Unloaded electrodes show a plateau region at approximately −0.92V. The area change is less in Zn electrodes and occluded cell pitting is not seen.

During this study the tissue surrounding the implant material was excised and histopathological studies

were performed, with results similar to those previously reported (1). These results indicate that for loaded zinc electrodes there is an adverse tissue reaction characterized by dilated capillaries, infiltrate of neutrophils, lymphocytes, and plasma cells. Unloaded zinc samples that have been well passivated by the hydroxide-oxide layer on the electrode are free from macroscopic inflammation. Histologic examination of aluminum electrodes under no-load conditions revealed a well-formed relatively thick (550 μm) mature fibrous connective tissue capsule with only mild aggregate of lymphocytes. Aluminum electrodes loaded up to 18 $\mu A/cm^2$ showed little inflammatory reaction and acceptable biocompatibility. Although the body fluids buffer changes in *p*H at the site of implantation, it is to be expected that the *p*H at the metal-tissue interface will be different from neutral *p*H depending upon the rate of electrode reaction and the degree of encapsulation. The local *pH* changes at the metal-tissue interface could not be monitored. Attempts are being made to implant a *p*H sensitive electrode. In the *in vitro* experiments the *p*H was continuously monitored and adjusted if necessary by adding the appropriate acid-base solutions.

A-C electrical impedance measurements.—From the discussion on corrosion, it is evident that to characterize the metal-tissue interface it is necessary to supplement the d-c polarization data by some other technique. The linear a-c polarization technique can be used, as shown by Richardson and Wood (26) and Heine and Pryor (27).

The impedance of the test electrode was measured on a conductance-capacitance a-c bridge. A porous palladium counter (or auxiliary) electrode was implanted near the test electrode. The measurement was effected by the connection of the bridge leads to the test and auxiliary electrodes. The d-c potential of the electrode was monitored with respect to an Ag-AgCl reference electrode as described above by disconnecting the bridge leads.

The following electrode parameters determined by d-c polarization can also be obtained by linear a-c polarization impedance:

1. The d-c linear polarization resistance, R_{pol}, is equivalent to the a-c R_{pol} as the frequency approaches zero.

2. The type of electrode reaction can also be determined from the frequency variations of the a-c impedance at a given potential, *i.e.*, whether it is under activation or diffusion control. In addition, a-c linear polarization impedance measurements are sensitive to the adsorption of electroactive species.

In the particular case of aluminum electrodes, the a-c linear polarization impedance data were obtained for the equilibrium potential only, since any potentiostatic control results in a difficulty of balancing the bridge due to the fluctuations in the surface changes on the electrode caused by the breakdown-repair events of the oxide layer.

For an electrolyte such as physiological saline, the impedance is determined at a sufficiently high frequency, *e.g.*, 1 MHz, where the electrode impedances can be neglected. This value may be used to correct for the background electrolyte. A typical measured conductance *vs.* frequency curve for saline is shown in Fig. 10. The conductance reaches an asymptotic value at approximately 20 kHz, below which electrode polarization decreases the measured conductance. Figure 11 shows a similar plot for tissue excised from around an implant and measured between Pd-black electrodes.

Tables IV and V show average values of data obtained for *in vivo* Pd-Al impedance cell. It is clear that in the frequency range of interest, *i.e.*, below 20 kHz, the solution and Pd counterelectrode series

capacitances may be neglected. If the solution resistance is measured accurately it can be subtracted from the measured resistance, and the Pd resistance neglected. Figure 12 shows how geometrical factors may be altered to minimize the impedance contribution of the solution and counterelectrode.

When biological tissue is the medium between the measuring electrodes, its electrical impedance has been shown (28-30) to exhibit a dielectric relaxation which extends over a wide range of frequencies. It

is, therefore, more difficult to correctly account for tissue impedance. In the implanted impedance cells, the body fluids and partial tissue ingrowth between Al-Pd electrodes did not show appreciable relaxation up to 1 MHz. The tissue parameters were, therefore, assumed to introduce little error as the series Al impedance is generally much greater at low frequencies.

The double layer capacitance, C_{dl}, is difficult to determine for pitted corroding electrodes. Heine and Pryor (27) and Wood *et al.* (16) have approximated this by C_{dl} of an equal area Pt electrode, which in our opinion is not truly representative of the C_{dl} on an oxide-coated electrode like Al of considerably lower (—V) potential.

Figure 13 shows typical data of measured parallel conductance and capacitance *vs.* frequency plotted on the complex impedance plane as developed by Sluyters and co-workers (31). It has been shown that if the measured impedance, $Z_m = A' + jZ''$, is plotted on this plane, a straight line of 45° slope is obtained at low frequencies if the electrode reaction is diffusion controlled. If the reaction is charge transfer controlled, then a semicircle is obtained with its center on the A' axis. Figures 14 and 15 show that the measured angles lie in the 60°-70° range, *i.e.*, neither of the above-mentioned mechanisms controls the reaction. For such reactions it is possible that they are adsorption controlled (11). The method of obtaining parameters for this plot derived by Timmer is given by DeRosa (11). Figure 16 shows the transformations used to obtain R_a and C_a. Figure 17 shows a polarization-capacitance curve. According to Timmer's theory, $R_a = X_a = \gamma/\omega^{1/2}$ where R_a, X_a represents the impedance due to the adsorbed species. Hence a plot of R_a, X_a *vs.* frequency produces a linear

relationship. Figure 18 shows a plot obtained from R_a, X_a for Al *in vivo*.

The electrodes after removal showed extensive micro and large deep pitting with brightened hemispherical pitted surface. In spite of this, the complex plane plots give consistent angles of 60°-70°. Figure 18 thus

shows reasonable agreement with the adsorption theory, though it remains to be determined if this is an effect of the oxide alone.

Protein combines with metal interfaces to increase the electrical resistance and decrease the exchange current. Svare (32) and Korostoff observed that cystine in physiological concentrations passivates Ni. Aragon and Hulbert (33) demonstrated that *in vivo* corrosion rates are lower than *in vitro* due to plasma and interstitial fluid constituents.

Further impedance measurements on polished Al electrodes *in vivo* and *in vitro* are in progress. For coarsely polished electrodes, complex plane angles of the data taken *in vitro* lie in the range obtained for *in vivo* measurements. Polished electrodes *in vitro* show complex plane angles of the order of 80°; the Cole-Cole plots of the parameters show a distinct relaxation phenomenon. Since the complex plane plot does not indicate an electrochemical reaction relaxation, it is likely that the air-formed oxide exhibits a dielectric relaxation of probably the inhomogeneous Maxwell-Wagner type since the conductance part of the complex dielectric constant shows a large increase as the frequency tends to zero. Present measurements are being analyzed to determine the nature of the relaxation and will be reported.

Photogalvanic Cells
II. Current-Voltage and Power Characteristics

W. J. Albery
Physical Chemistry Laboratory, Oxford OX1 3QZ, England

and M. D. Archer
Department of Physical Chemistry, Cambridge CB2 1EP, England

ABSTRACT

A general treatment is developed for the current-voltage characteristics of photogalvanic cells containing two identical electrodes and operating by virtue of the homogeneous reactions

$$A + Z \underset{\text{in dark}}{\overset{\text{in light}}{\rightleftharpoons}} B + Y$$

where A, B, and Y, Z are redox couples. The treatment is in terms of the electrode and homogeneous kinetics, the relative magnitudes of the diffusion and reaction layers, and the position of the photostationary state. Power cannot be drawn from the cell if both couples are either highly reversible or highly irreversible. The best performance is obtained if one couple (A, B say) is highly reversible, and the other (Y, Z) highly irreversible, and this case is explored in detail. If the homogeneous kinetics are rapid, we find an important contribution to the current delivered by the cell from catalytic currents due to the presence of Y and Z close to the electrode.

A previous paper (1) discussed the open-circuit potential of photogalvanic cells. In order to obtain useful work from such a cell, current must be drawn from it, and this paper explores the current-voltage power characteristics of a common type of photogalvanic cell, illustrated in Fig. 1. It contains two identical electrodes of equal area, one immersed in illuminated solution, and the other immersed in dark solution. The differentiation between the dark and illuminated solutions may be achieved either by a black barrier that permits electrical contact, as in Fig. 1, or more gradually by the absorbance of the solution itself, causing the light intensity to drop from the front to the back of the cell. We shall consider the power obtainable from such a cell in terms of the same variables as before, namely, the electrode kinetics of the redox couples, the concentrations of the redox species, and the position of the photostationary state. We do not consider the influence of the over-all cell length, but assume throughout that it is rather greater than the sum of the diffusion layers at the two electrodes. If this is so, then the cell performance is independent of cell length, except in so far as this may affect the collection efficiency, *i.e.*, the number of electrons flowing per photon absorbed. Moreover, we do not consider the variation of light intensity throughout the cell, but simply assume that the dark electrode is always genuinely in the dark and that the solution is optically fairly dilute, so that the photostationary state is uniform in the region of the illuminated electrode.

As in part I (1), the analysis assumes that the solution contains two components. A and Z, which on irradiation undergo a photoredox reaction to form B and Y. A, B, and Y, Z are redox couples. B and Y undergo a second-order thermal back reaction, to reform A and Z. The equilibrium in the dark lies heavily on the side

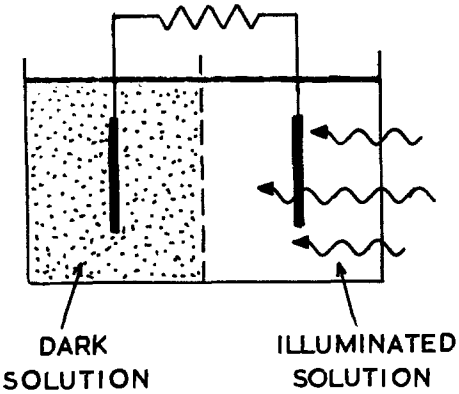

Fig. 1. The photogalvanic cell

of A and Z. The two electrodes are conventional redox electrodes.

System and Notation

We use the same system and notation as in the previous paper (1)

Solution:

$$A + Z \underset{k_{-H}}{\overset{k_H}{\rightleftarrows}} B + Y \qquad [1]$$

where $k_H << k_{-H}$ (liter mol^{-1} sec^{-1})

Electrodes:

$$A + e \underset{k_{-A}}{\overset{k_A}{\rightleftarrows}} B \qquad [2]$$

$$Y + e \underset{k_{-Y}}{\overset{k_Y}{\rightleftarrows}} Z \qquad [3]$$

where k_A, k_{-A}, k_Y, and k_{-Y} (cm sec^{-1}) are electrochemical rate constants.

Photochemistry:

$$A \xrightarrow{h\nu} A^* \xrightarrow{k_*} A$$

$$A^* + Z \xrightarrow{k_Q} B + Y$$

giving over-all

$$A + Z \xrightarrow{g} B + Y \qquad [4]$$

where g (in dimensions of concentration per unit time) is the rate at which B and Y are generated by the photoelectron transfer reaction.

Using lower case letters to denote the concentrations of the various species

$$g = \frac{I\epsilon a z k_Q}{k_* + k_Q z}$$

where I (einstein cm^{-2} sec^{-1}) is the light intensity in the region close to the illuminated electrode, and ϵ is the extinction coefficient of A. To simplify the algebra, we assume that

$$g = g'' a z$$

where

$$g'' \simeq I\epsilon k_Q / k_* \qquad [5]$$

The use of the full expression for g leads to more complicated algebra in the description of X_k but does not otherwise affect our conclusions.

We use a subscript D to denote the bulk concentrations in the unilluminated solution, and a subscript L for bulk concentrations in the photostationary state in the illuminated solution. Both electrodes will perturb the concentrations from these bulk values and we use a subscript zero for concentrations at the electrode surface and a subscript ∞ for the bulk values. Thus $c_\infty = c_L$ or c_D depending on whether the electrode is illuminated or not. The perturbations to the concentrations near the electrodes are described by a' and z'

$$a = a_\infty - a' \qquad b = b_\infty + a' \qquad [6]$$

$$y = y_\infty + z' \qquad z = z_\infty - z' \qquad [7]$$

We assume that the diffusion coefficients of all species are the same and this means that we only need two functions a' and z', since $(a + b)$ and $(y + z)$ must remain constant at all points in solution [1]. We define the following dimensionless quantities which describe the concentrations (with respect to A) of B and Y in the dark solution and Z in the illuminated solution

$$B_\infty = b_D / a_D \qquad [8]$$

$$Y_\infty = y_D / a_D \qquad [9]$$

$$Z_\infty = z_L / a_D \qquad [10]$$

Three further dimensionless quantities P, ι, and θ are used to describe the voltage, current, and power produced by the cell

$$P = \mathbf{F}(E - E^\theta_{A,B})/RT \qquad [11]$$

where $E^\theta_{A,B}$ is the standard redox potential of the A, B couple

$$\iota = i/(A\mathbf{F}Da_D X_{tr}^{-1}) \qquad [12]$$

where A is the area of the electrodes and X_{tr} is the thickness of the diffusion layer. The current is normalized with respect to a_D and X_{tr}^{-1} as the diffusion-limited currents in the cell are usually proportional to these parameters

$$\theta = |\iota \Delta P| = |\iota (P_L - P_D)| \qquad [13]$$

where P_L and P_D are the dimensionless potentials of the illuminated and dark electrodes.

The power, W, produced by the cell is given by

$$W = \theta A D a_D R T X_{tr}^{-1} \qquad [14]$$

The fractional conversion achieved by the photochemistry is described by f, where

$$a_L = a_D(1 - f) \qquad [15]$$

$$b_L = b_D + f a_D \simeq f a_D \qquad [16]$$

$$y_L = y_D + f a_D \qquad [17]$$

$$z_L = z_D - f a_D \qquad [18]$$

We have assumed that the concentration of B generated photochemically is much larger than its concentration in the dark. The relationship between f and g'' is readily found by substitution into the equation governing the composition of the photostationary state

$$(k_H + g'')az = k_{-H} by \qquad [19]$$

to be

$$g'' = \frac{f}{1 - f}\left(\frac{k_H(1 + Z_\infty) + k_{-H}(f + B_\infty + Y_\infty)}{Z_\infty}\right) \qquad [20]$$

Diffusion and Reaction Layer Thicknesses at the Electrodes

The concentration changes in the region of the two electrodes extend into the solution for a distance which may be determined by the transport of species to the electrode, or by the kinetics of the homogeneous reactions [1] and [4]. The shorter of these two will be the effective boundary layer at the electrodes. Currents at planar electrodes of large area in unstirred solutions do not decay away to zero according to the equations of semi-infinite linear diffusion but they reach a steady value. This is because natural convection maintains a reasonably uniform stagnant layer of thickness $\sim 3 \times 10^{-2}$ cm (2). At the illuminated electrode additional convection may be caused by the thermal effects of the absorbed radiation.

The kinetic length, X_k, depends upon the reaction kinetics. The general expression is

$$X_k = D^{1/2}[(k_H + g'')(a_* + z_*) + k_{-H}(b_* + y_*)]^{-1/2} \quad [21]$$

where the subscript asterisk denotes concentrations at the edge of the reaction layer. In many cases, simpler expressions for X_k suffice. For instance, in some photogalvanic solutions, one couple (A, B) is present in lower concentrations than the other (Y, Z). Moreover, $k_H << k_{-H}$. Therefore, at the dark electrode (at which $g'' = 0$)

$$X_k \simeq D^{1/2}(k_{-H}y_\infty)^{-1/2}$$

and at the illuminated electrode

$$X_k \simeq D^{1/2}(g''z_\infty + k_{-H}y_\infty)^{-1/2}$$

The reaction layer thickness may therefore be different at the dark and illuminated electrodes, and both can be varied by adjusting the concentrations of the species.

As the smaller of the two lengths X_{tr} and X_k normally determines the boundary layer across which species must diffuse to the electrodes, we consider the current-potential relationships for the cases $X_{tr} < X_k$ and $X_{tr} > X_k$ separately.

Electrode where $X_{tr} < X_k$.—We deal first with the case where $X_{tr} < X_k$. Under these conditions reactions [1] and [4] are too slow to take place to any significant extent in the diffusion layer. We normalize the electrochemical rate constants in reactions [2] and [3] by writing

$$\lambda_N = k_N X_{tr}/D \quad [22]$$

where

$$N = \pm A \text{ or } \pm Y$$

The transport of the species to the electrode is related to electrode kinetics by

$$D\left(\frac{\partial a}{\partial x}\right)_o = D\frac{a_\infty - a_o}{X_{tr}} = k_A a_o - k_{-A}b_o \quad [23]$$

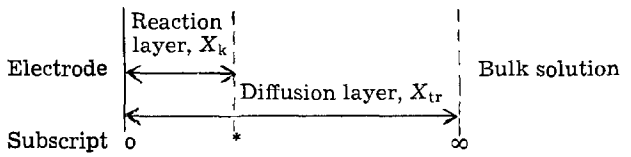
and

$$D\left(\frac{\partial z}{\partial x}\right)_o = D\frac{z_\infty - z_o}{X_{tr}} = k_{-Y}z_o - k_Y y_o \quad [24]$$

In our nomenclature, these equations become

$$a'_o = \lambda_A(a_\infty - a'_o) - \lambda_{-A}(b_\infty + a'_o)$$

$$z'_o = \lambda_{-Y}(z_\infty - z'_o) - \lambda_Y(y_\infty + z'_o)$$



and the general expression for the current-potential curve is

$$\iota a_D = a'_o - z'_o = \frac{\lambda_A a_\infty - \lambda_{-A}b_\infty}{1 + \lambda_A + \lambda_{-A}} + \frac{\lambda_Y y_\infty - \lambda_{-Y}z_\infty}{1 + \lambda_Y + \lambda_{-Y}} \quad [25]$$

(The sign convention adopted for i and ι is positive for a cathodic current, negative for an anodic one.) The current is simply the sum of the currents due to the A, B and Y, Z couples, and both of these may be subject to diffusion control (across X_{tr}), charge transfer control, or mixed control, according to whether ($k_A + k_{-A}$) and ($k_Y + k_{-Y}$) is greater than, less than, or comparable with D/X_{tr}. In other words, the couples behave reversibly if $(\lambda_N + \lambda_{-N}) >> 1$ and irreversibly if $(\lambda_N + \lambda_{-N}) << 1$.

When no current flows, then [25] reduces to our previous result (Eq. [24] and [25] of Ref. (1)), which relate the open-circuit potential to the composition of the solution: in the dark solution, an equilibrium potential is obtained, but in the illuminated solution, a mixed potential is observed. The concentration perturbations at the illuminated electrode extend over the diffusion layer X_{tr}.

Electrode where $X_{tr} >> X_k$.—In this case there is time and space for the homogeneous reactions [1] and [4] to take place in the diffusion layer and so we must introduce a subscript asterisk to denote the concentrations at the outside edge of X_k

X_{tr} remains an important parameter even if it is much larger than X_k because, as we shall show later, supply of species to the outer edge of the reaction layer by transport across the diffusion layer can be the current-limiting process.

The differential equations describing the steady-state concentration profiles of A and Z are

$$\mathrm{Tr}(a) - (k_H + g'')az + k_{-H}by = 0$$

$$\mathrm{Tr}(z) - (k_H + g'')az + k_{-H}by = 0$$

where Tr is an operator describing transport by diffusion and possibly convection. We solve these equations by the method of Koutecky and Levich (3). Substitution from [4] and [7] gives

$$\mathrm{Tr}(a' - z') = 0 \quad [26]$$

and

$$\mathrm{Tr}(a') - (k_H + g'')(a'z_\infty + z'a_\infty - a'z') - k_{-H}(a'y_\infty + z'b_\infty + a'z') = 0 \quad [27]$$

Equation [26] has no kinetic terms and solving it with the boundary conditions that $a' = 0$ and $z' = 0$ at $x = X_{tr}$ we obtain

$$a' - z' = (a'_o - z'_o)(1 - x/X_{tr}) \quad [28]$$

Since $X_k << X_{tr}$, we can then write for $x < X_k$

$$a' - z' \simeq a'_o - z'_o \simeq a'_* - z'_* \quad [29]$$

This approximation implies that $a'_* \simeq a'_o$ and $z'_* \simeq z'_o$, or that the concentrations at the outer and inner boundaries of the reaction layer are roughly the same. This remains a good approximation even though there is a significant gradient when the small difference $c'_* - c'_o$ is divided by the small length X_k, to give the fluxes to the electrode. Equating the transport of the species to the electrode with the electrode kinetics, we obtain

$$D\left(\frac{\partial z}{\partial x}\right)_o = D\frac{a_* - a_o}{X_k} = k_A a_o - k_{-A}b_o \quad [30]$$

$$D\left(\frac{\partial z}{\partial x}\right)_o = D\frac{z_* - z_o}{X_k} = k_{-Y}z_o - k_Y y_o \quad [31]$$

These equations are similar in form to [23] and [24], but transport occurs across the reaction layer rather than the diffusion layer. In this case, we normalize the electrochemical rate constants by writing

$$\lambda_N = k_N X_k/D \quad [32]$$

and in our nomenclature, [30] and [31] become

$$a'_o - a'_* = \lambda_A(a_\infty - a'_o) - \lambda_{-A}(b_\infty + a'_o)$$

$$z'_o - z'_* = \lambda_{-Y}(z_\infty - z'_o) - \lambda_Y(y_\infty + z'_o)$$

and eliminating a'_o and z'_o between these two equations and [29] we obtain

$$\frac{\lambda_A a_\infty - \lambda_{-A}b_\infty - (\lambda_A + \lambda_{-A})a'_*}{1 + \lambda_A + \lambda_{-A}} = \frac{\lambda_{-Y}z_\infty - \lambda_Y y_\infty + (\lambda_Y + \lambda_{-Y})z'_*}{1 + \lambda_Y + \lambda_{-Y}} \quad [33]$$

Again, the couples behave reversibly or irreversibly according to whether $(\lambda_N + \lambda_{-N})$ is greater or less than one, but this time reversible behavior requires higher values of $(k_N + k_{-N})$ because X_k is smaller than X_{tr}.

The concentrations of species in the reaction layer also depend on their supply across the diffusion layer. The current is given by

$$\frac{i}{AF} = D\left[\left(\frac{\partial a}{\partial x}\right)_0 - \left(\frac{\partial z}{\partial x}\right)_0\right]$$

and differentiating [28] and using the approximation in [29] we obtain

$$\iota a_D = (a'_0 - z'_0) \simeq (a'_* - z'_*) \qquad [34]$$

A further relationship between a'_* and z'_* can be obtained from [27] by noting that outside the reaction layer, the kinetic terms are in balance and so we have

$$(k_H + g'')(a'_* z_\infty + z'_* a_\infty - a'_* z'_*) + k_{-H}(a'_* y_\infty + z'_* b_\infty + a'_* z'_*) = 0 \qquad [35]$$

Thus we now have two equations, [33] and [35], to determine the two unknowns, a'_* and z'_*, which are required to find the current from [34]. However, the general solution of the quadratic Eq. [35] does not serve either for entertainment or instruction, so we shall instead discuss various special cases in the next section. First we note that when no current flows at the electrode, $a'_* = z'_* = 0$ (from [34] and [35]) and Eq. [33] also reduces to our previous result (1). However, in this case, the concentration changes caused by the existence of partial anodic and cathodic currents at the illuminated electrode are confined to the reaction layer.

The Effect of Electrode Kinetics on Cell Performance

In part I (1), we showed that the change in potential of the open-circuit electrode on illumination of the photogalvanic solution depended on the electrode kinetics of A, B and Y, Z: No change is found if both couples are reversible, and the largest change is found if one couple is reversible and the other very irreversible. If both couples are electroactive, with different k° values, then intermediate potential changes are obtained. We now consider the effect of electrode kinetics on the closed-circuit performance of the cell for the three different cases given in Table I.

The rate constants for the electrochemical reactions [2] and [3] of the couples A, B and Y, Z are normalized by [22] or [32]; the shorter of the two lengths X_{tr} or X_k is used in this normalization. If $\lambda_N + \lambda_{-N} >> 1$, then the species will be more likely to react on the electrode than to diffuse across X_{tr} or to react in the solution within the distance X_k. The couple will be reversible and the surface concentrations will obey the Nernst equation. On the other hand for $\lambda_N + \lambda_{-N} << 1$ the electrochemical reactions do not perturb the concentrations from the values fixed by the homogeneous reactions [1] and [4]; the couple is irreversible. Figure 2 shows schematically how the concentration profiles across the cell on open and short circuit depend upon the electrode kinetics. These profiles have been drawn for the particular case where $a_D = z_D >> b_D = y_D$ and where there is a high degree of conversion in the photostationary state.

In case a, the electrode kinetics are so rapid that the photochemical perturbation to the concentrations in the bulk solution is destroyed on the illuminated electrode; the concentrations at the electrode surface return to their thermodynamic values and the electrode

Table I. Electrode kinetics

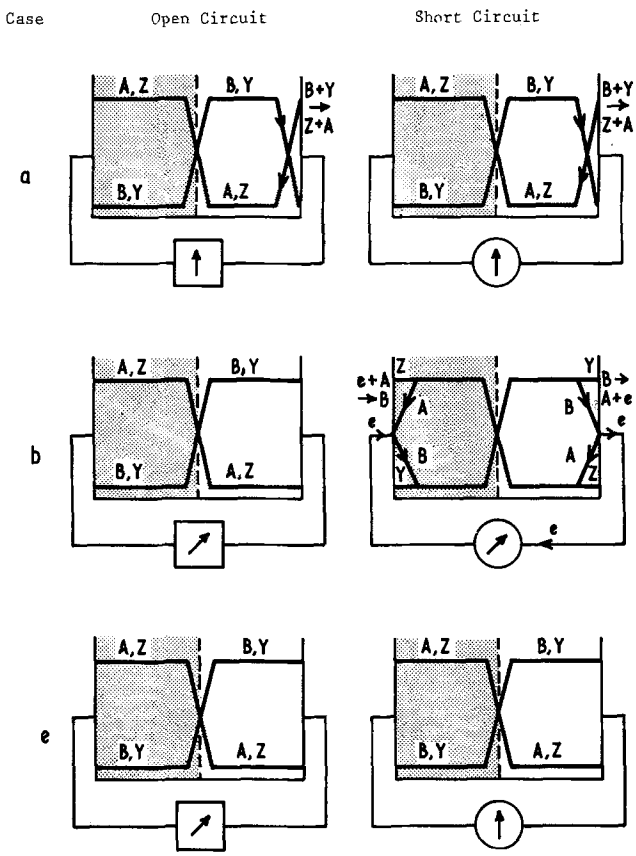

Fig. 2. Concentration profiles across a photogalvanic cell on open and short circuit for cases a, b, and e of Table I. The dark electrode is on the left and the illuminated electrode on the right. The potential difference for case b and e on open circuit is given by the Nernst equation for the A, B couple.

acts as an efficient catalyst for the reaction

$$B + Y \rightarrow Z + A$$

No power can be obtained under these conditions. This is further illustrated in Fig. 3, which shows typical current-potential curves at the dark and illuminated electrodes, when both couples are reversible. Figure 3 has been drawn for the particular case that $E^\theta_{Y,Z} - E^\theta_{A,B} = 0.2$V, so that $a_D/b_D = z_D/y_D = 50$; the composition of the photostationary state has been taken as $a_L/b_L = z_L/y_L = 0.02$. This rather symmetrical case illustrates the general conclusion clearly: The total current-potential curve is the same at the dark and illuminated electrodes, although the two are made up of different components.

In case e, a potential develops if no current is passed but the electrode kinetics are now so slow that neither couple reacts efficiently on the electrodes and hence again very little power can be obtained. This is further illustrated in Fig. 4, which is drawn for the same conditions as Fig. 3, except that A, B has been made rather irreversible ($\lambda^\circ = 10^{-2}$) and Y, Z very irreversible ($\lambda^\circ = 10^{-4}$). The total current-potential curves at the dark and illuminated electrodes differ only at extreme potentials, and negligible current is obtained in the working region of the photogalvanic cell, between E_D and E_L.

The optimal case for current production is case b, for which the A, B couple is reversible and the Y, Z couple very irreversible or better still totally unreactive at the electrodes. The electrode processes then involve only the A, B couple. As shown in Fig. 2, A is reduced to B at the dark electrode, and B is oxidized to A at the illuminated electrode.

In part I, we showed that case b was also optimal for the open-circuit potential of the cell: It is clearly

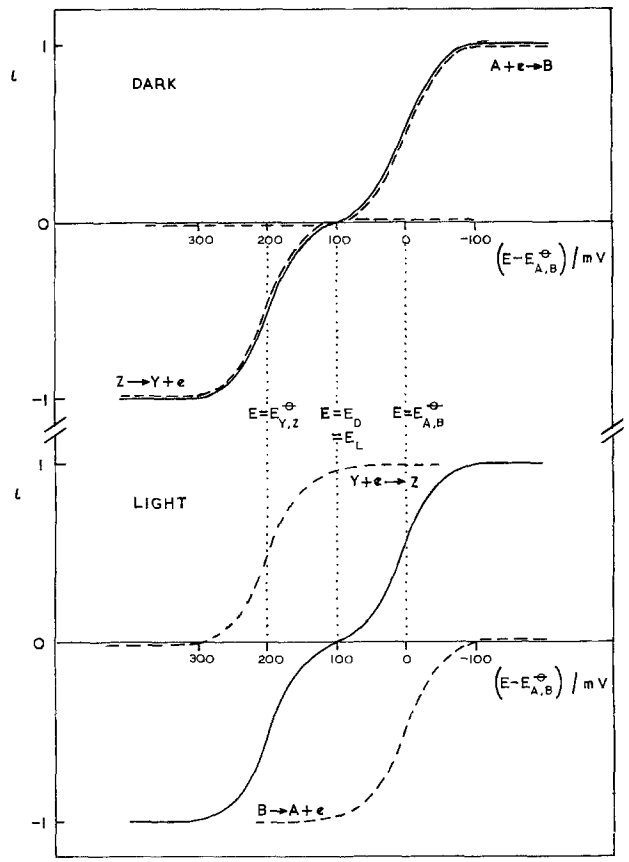

Fig. 3. An example of current-potential curves for the dark and illuminated electrode when both couples are reversible (case a, Table I); $a_D/b_D = z_D/y_D = 50$, $a_L/b_L = z_L/y_L = 0.02$. ι, the normalized current, is defined in Eq. [12]. The broken lines are for the A, B and Y, Z couples separately and the full line is the sum of these components. Note that E_D and E_L, the open-circuit potentials of the dark and illuminated electrodes, are the same for the two electrodes.

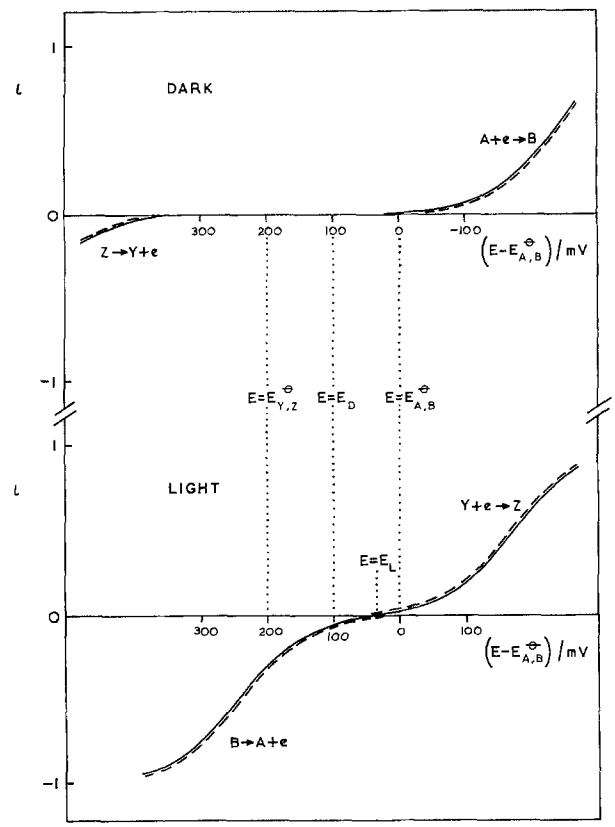

Fig. 4. An example of current-potential curves when both couples are rather irreversible (case e, Table I). $\lambda^{\circ}_{A,B} = 10^{-2}$, $\lambda^{\circ}_{Y,Z} = 10^{-4}$. Other conditions as for Fig. 3. E_L is slightly displaced from E_D, but negligible power is obtained from this cell.

therefore also optimal for power production, and we consider it in more detail in the next section.

The optimal case; A, B reversible and Y, Z irreversible.—With the approximations for case b in Table I, we obtain from [25] and [33]-[35] a general expression for the current-potential curves at both the dark and the illuminated electrodes, which covers the two different conditions $X_k > X_{tr}$ and $X_k < X_{tr}$

$$\iota a_D = S\left[\frac{1+C}{1+CX_k/X_{tr}}\right] \qquad [36]$$

where

$$S = \frac{k_A a_\infty - k_{-A} b_\infty}{k_A + k_{-A}} = -\frac{b_\infty \exp(\tfrac{1}{2}P) - a_\infty \exp(-\tfrac{1}{2}P)}{\exp(\tfrac{1}{2}P) + \exp(-\tfrac{1}{2}P)} \qquad [37]$$

and for $X_k > X_{tr}$

$$C = 0$$

while for $X_k < X_{tr}$

$$C = \frac{[(k_H + g'')z_\infty + k_{-H}y_\infty](k_A + k_{-A})}{[(k_H + g'')k_{-A} + k_{-H}k_A](a_\infty + b_\infty)} \qquad [38]$$

In deriving [36] the term in X_k/X_{tr} arises from including the x/X_{tr} term which was previously neglected in deriving [29] from [28]. In order to simplify the treatment we have assumed in Eq. [37] that the charge transfer coefficient is one-half.

Examination of the general Eq. [36] shows that, depending on the size of X_k/X_{tr}, three different cases, listed in Table II, can be distinguished and we next discuss the "simple" case.

The simple case.—When $X_k > X_{tr}$, $C = 0$ and the only term on the right-hand side of Eq. [36] is the "simple" term S. This term describes the reversible current-potential curve for the A, B redox couple. The same expression is obtained from Eq. [25] if λ_Y and λ_{-Y} are set equal to zero. At the dark electrode the ratio a_x/b_x is large; this ratio is smaller near the illuminated electrode; here its value depends on the light intensity and homogeneous kinetics according to [19].

In Fig. 5, we have plotted current-potential curves for a particular case where in the dark $B_\infty = b_D/a_D = 10^{-1}$ and in the light this ratio is reversed, $b_L/a_L = 10$ (*i.e.*, $f = 0.9$). Figure 5A shows the usual current-potential curves for each individual electrode. Power can only be obtained when a cathodic current ($A + e \rightarrow B$) flows at the dark electrode and an anodic current ($B \rightarrow A + e$) at the illuminated electrode. Hence in Fig. 5B the relevant parts of the current-potential curves are again plotted; this time a logarithmic scale is used for the current so that small currents can be displayed. Now when current flows through the cell, since we have taken the electrodes to be of equal area

$$\iota_D = -\iota_L$$

This condition is satisfied by drawing horizontal tie lines on Fig. 5B. The length of the tie line gives the

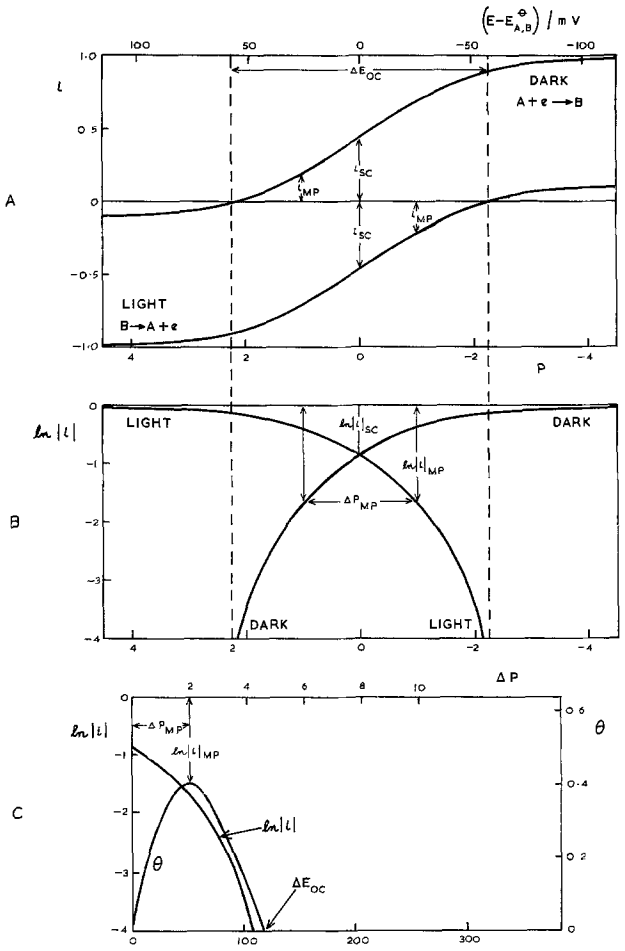

Fig. 5. Current-potential (ι-P) and (θ-P) characteristics for the simple case defined in Table II, when one couple (A, B) is reversible, the other irreversible (case b, Table I). $b_D/a_D = a_L/b_L = 10^{-1}$. The normalized current, potential, and power (ι, P, θ) are defined in Eq. [12], [11], and [13]. ΔE_{oc} = open-circuit voltage of cell, ι_{sc} = short-circuit current, ΔP_{MP} and ι_{MP} = normalized voltage and current at the maximum power point. Figures 5A and 5B display the current-potential curves for each electrode, on a linear and logarithmic scale, respectively, and Fig. 5C shows the current-voltage and power characteristics of the cell.

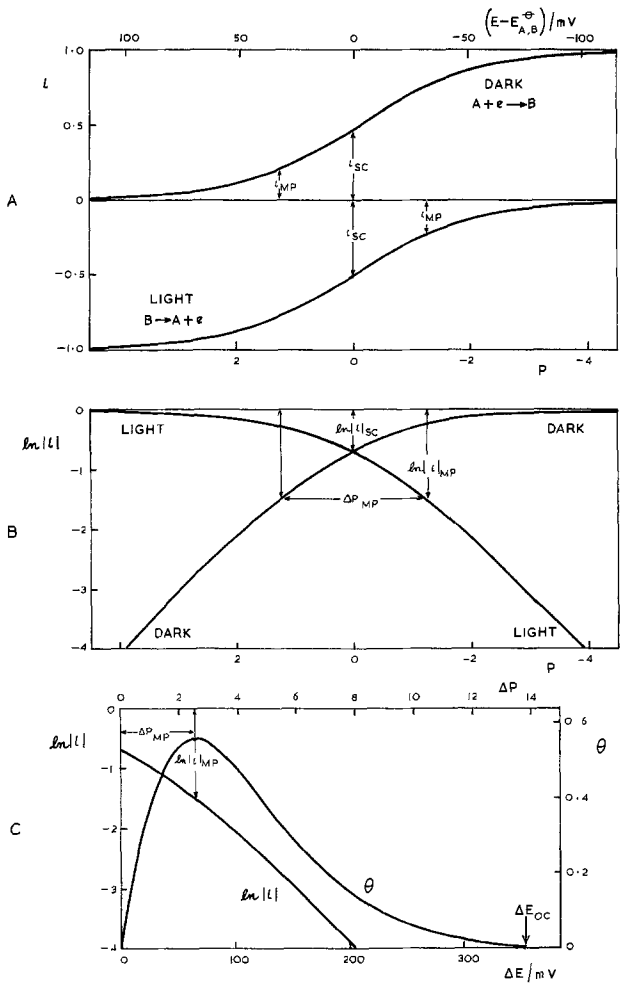

Fig. 6. Current-potential and power characteristics for the same conditions as in Fig. 5, except that $b_D/a_D = a_L/b_L = 10^{-3}$.

voltage developd by the cell. For instance where the curves intersect at the top of the "Gothic" arch we have the short-circuit condition that the equal and opposite currents are as large as possible but no voltage is developed at all. This is indicated by ι_{sc} on Fig. 5A and 5B. As $|\iota| \to 0$, ($\ln |\iota| \to -\infty$), the potential difference, ΔP or ΔE, rises to its maximum value, the open-circuit potential ΔE_{oc}, given by the zero current points in Fig. 5A, or by the distance between the asymptotes in Fig. 5B. The power developed by the cell is proportional to $\theta(=\iota\Delta P)$ and can be calculated from the curves shown in Fig. 5B. Figure 5C shows the current-voltage ($\ln|\iota|$) and power (θ) characteristics of the cell as a function of the cell voltage (ΔE). The power function passes through a maximum value of $\theta = 0.4$ and the currents (ι_{MP}) and potential difference (ΔP_{MP}) corresponding to this maximum power point are shown on Fig. 5A and 5B.

Figure 5 was calculated for moderate ratios of 10^{-1} for b_D/a_D and a_L/b_L. In Fig. 6, the same functions are plotted for the case that these ratios are equal to 10^{-3}. The open-circuit voltage of the cell is three times larger than for Fig. 5, but the power function at its maximum has only increased from 0.40 to 0.55. This is because the currents associated with the increased potential difference are small and one merely obtains a useless tail to the power function: The current-potential curves do not start to rise toward their transport limited values until the potential is in the neighborhood of $E^{\theta}_{A,B}$.

Further decrease in the ratios b_D/a_D and a_L/b_L below 10^{-3} makes no difference to the maximum in the θ function and the maximum value of θ that can be obtained is

$$\theta_m = 0.55 \qquad [39]$$

In Fig. 5 and 6 we took symmetrical examples; in Fig. 7 we show an unsymmetrical example for which $b_D/a_D = 10^{-3}$ and $b_L/a_L = 1$ (*i.e.* $f = 0.5$); the latter condition means that the illuminated solution is half-bleached in the photostationary state. For these conditions, although the open-circuit potential is greater than for the case shown in Fig. 5, the maximum value of θ is only 0.18. The performance of this cell is limited by the dark electrode, which shows severe concentration polarization in its working potential range.

It can be seen that for this type of cell the open-circuit voltage is not very relevant to the amount of power that can be obtained from the cell. Quite large potential differences can be developed by a concentration cell, providing that no current is passed, but as soon as current is drawn, concentration polarization tends to equalize the concentrations at the two electrodes and reduce the potential difference. In all cases the conditions for maximum power are found fairly close to the short-circuit condition, with a cell voltage at maximum power of only $\sim 2.5\ RT/\mathbf{F}$.

Therefore the nominal power (short-circuit current $\times$ open-circuit cell voltage) is not a good estimate for the power that can be obtained for this type of cell.

The intermediate case.—Next we consider briefly the intermediate case of Table II. In this case, the cur-

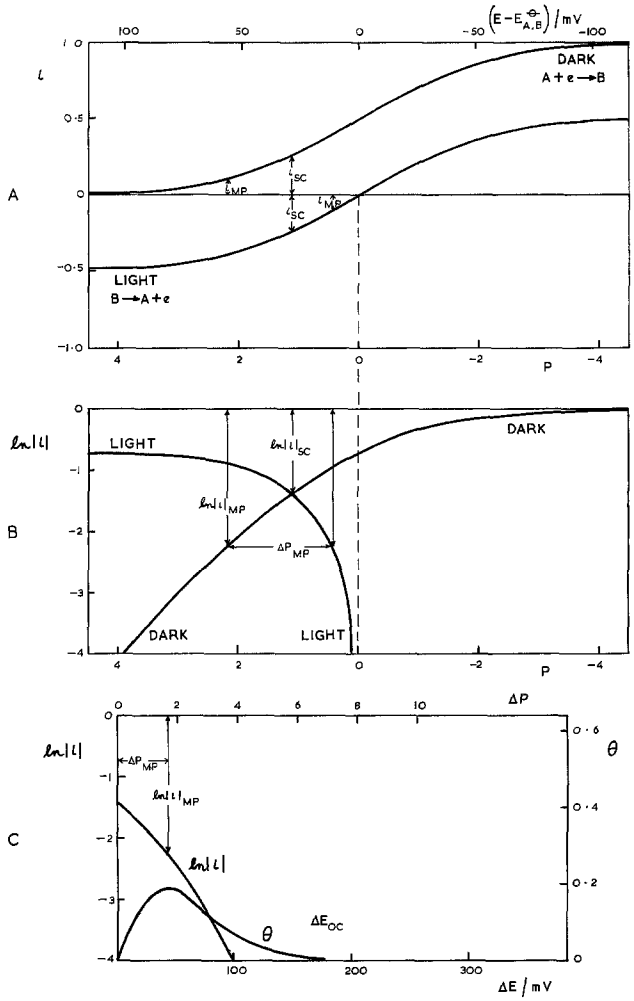

Fig. 7. Current-potential and power characteristics for the same conditions as in Fig. 5, except that $b_D/a_D = 10^{-3}$, $a_L/b_L = 1$.

rents given by [37] are merely modified by the factor X_{tr}/X_k, which is greater than 1. Hence larger currents are found than in the simple case. This is because the concentration polarization at the electrodes takes place over the smaller distance X_k defined by Eq. [21]. Apart from this factor, the shapes of the current-voltage and power characteristics are the same as for the simple case.

The catalytic case.—The current-potential curves for the "catalytic" case of Table II are rather different from those for the simple or intermediate cases. The currents are modified by the expressions for C given in Table III. In Fig. 8 we show the current-potential curves for an example of the catalytic case, in which we have taken

$$Y_\infty = y_D/a_D = Z_\infty = z_L/a_L = 10^2$$

and

$$B_\infty = b_D/a_D = (1 - f) = a_L/b_L = 10^{-2}$$

The limiting currents are 100 times larger than those

Table III. Expressions for S and C in [36]

	Dark electrode	Illuminated electrode
S	$\dfrac{1 - B_\infty \exp(P_D)}{1 + \exp(P_D)}$	$\dfrac{1 - f - f\exp(P_L)}{1 + \exp(P_L)}$
C	$\dfrac{Y_\infty(1 + \exp(P_D))}{1 + \exp(P_D - \Delta P^\theta)}$ where $\Delta P^\theta = P^\theta_{X,Y} - P^\theta_{A,B} = \ln(k_{-H}/k_H)$	$\dfrac{Z_\infty(1 + \exp(-P_L))}{f(1 + \exp(P_* - P_L))}$ where $P_* = \ln\left(\dfrac{(1-f)Z_\infty}{f(Y_\infty + f)}\right)$

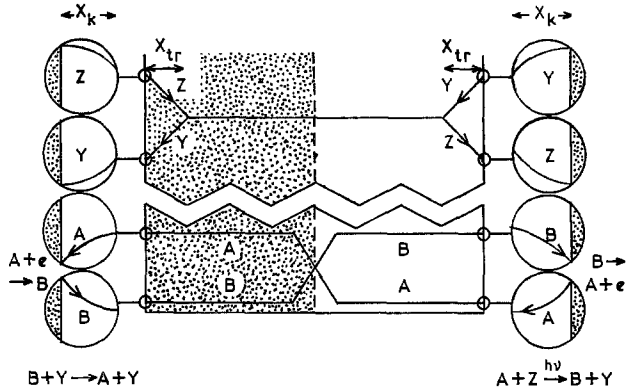

Fig. 8. Current-potential and power characteristics for the catalytic case defined in Table II. Electrode kinetics are the same as for Fig. 5-7 (case b, Table I). The concentration ratios have been taken as $y_D/a_D = z_L/a_L = 10^2$, $b_D/a_D = a_L/b_L = 10^{-2}$. Note the greatly increased values of ι and θ, compared with those in Fig. 5-7. The open-circuit cell voltage ($P = \ln 10^4$) is, however, the same as it would be in the simple case.

for the simple case, since at the electrodes, there are catalytic currents reducing Y or oxidizing Z, even though Y and Z are themselves electrochemically inactive. At the dark electrode the reduction of Y takes place by the sequence

Electrode: $e + A \rightarrow B$

Solution: $Y + B + A \rightarrow Z$

Over-all: $e + Y \rightarrow Z$ [40]

while at the illuminated electrode the oxidation of Z occurs through the sequence

Solution: $Z + A \xrightarrow{h\nu} B + Y$

Electrode: $B \rightarrow A + e$

Over-all: $Z \rightarrow Y + e$ [41]

The current-potential curves in Fig. 8B now meet in a flat arch ("Stonehenge") rather than the Gothic arches of Fig. 5 and 7. The cell voltage remains near its open-circuit value until the cell current is quite near its short-circuit value, and hence more power can be obtained than in the simple or intermediate case. The maximum value of θ of 400 is about 700 times larger than θ_m (=0.55). The current at the maximum power point is approximately 300 times larger than for the simple case and the potential difference is about 2.3 times larger, for this particular case. The reason for this great improvement is that the sequences [40] and [41] of catalytic reactions prevent the electrodes becoming polarized with respect to A and B. Figure 9 shows schematic concentration profiles for the catalytic case. Comparing these profiles with those in Fig. 2 we see that the surface concentrations of A and B remain very different at the two electrodes and this maintains the potential difference. Furthermore, the current is not limited by the transport across X_{tr} of A and B but rather by the transport of Y and Z, which for the catalytic case are present in much larger concentrations.

The General Behavior of the Current-Potential Curves

Having examined each case and shown some particular examples, in Fig. 10 we display the general behavior of current-potential curves calculated from Eq. [36] for the simple and catalytic cases. The curves are plotted in the same way as the B sections of Fig. 5-8. The current-potential curve for a dark electrode starts in the bottom left-hand corner at a potential determined by B_∞. As P becomes more negative the

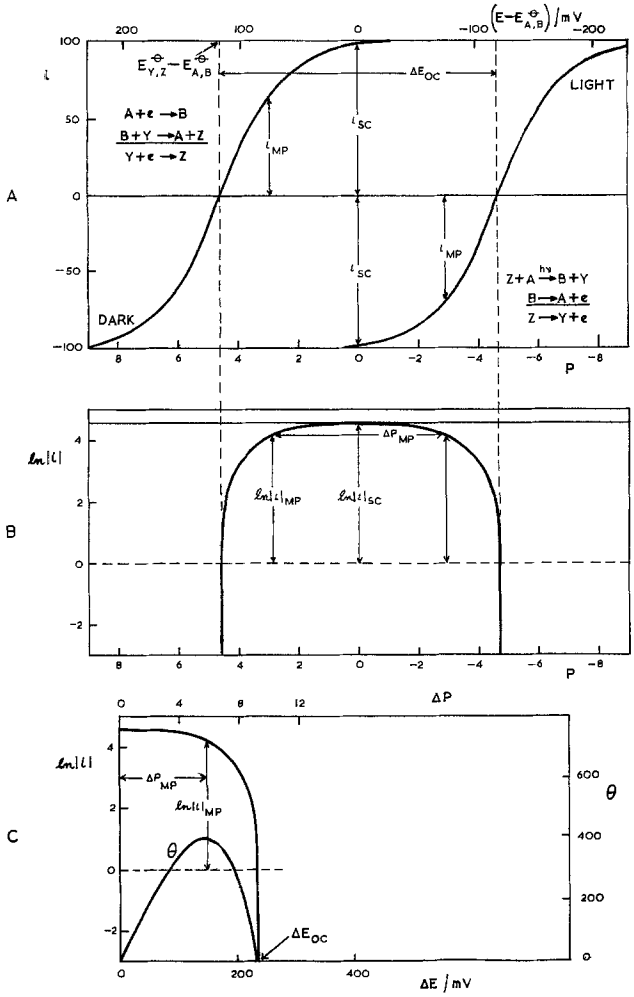

Fig. 9. Concentration profiles across a photogalvanic cell for the catalytic case where $Y_\infty = Z_\infty >> 1$ and $X_k << X_{tr}$.

dark current eventually rises to a limiting value on the right of the diagram which depends on Y_∞. For the catalytic case, the exact route for the crossover between the "vertical" asymptote on the left and the "horizontal" asymptote on the right depends on the value of Z_∞. If $Y_\infty \gtrless Z_\infty$ then the transition is sharp and almost right angled (*e.g.*, $Y_\infty = 10^2$ or $Y_\infty = 10^4$). If on the other hand $Y_\infty > Z_\infty$, then a more gradual transition is found with a region where the slope is 45° (*e.g.*, $Y_\infty > Z_\infty = 10^2$). Similarly the curves for the illuminated electrode start in the bottom right-hand corner at a potential determined by f (the fraction of A that is bleached) and they cross over to a limiting value on the left of the diagram determined by Z_∞ or f. For the catalytic case, the transition depends upon the value of Y_∞ and is sharp for $Z_\infty \gtrless Y_\infty$ (*e.g.*, $Z_\infty = 10^2$ or $Z_\infty = 10^4$) and gradual for $Z_\infty > Y_\infty$ (*e.g.*, $Z_\infty > Y_\infty = 10^2$). As in the examples we have discussed the two curves (dark and illuminated) for any particular cell creates an "arch" which determines the power characteristics of that cell. In Fig. 10 we have outlined a typical Gothic example (S) of the simple case illustrated in Fig. 5-7, and a piece of Stonehenge (C) for the catalytic case as illustrated in Fig. 8. Figure 10 displays the current-voltage behavior of a cell in such a way that the power characteristics can be easily estimated and it shows how these characteristics vary with the concentrations of the species (B_∞, Y_∞, and Z_∞) and the fraction of A that is bleached (f). The three variables B_∞, Y_∞, and Z_∞ are however not independent since they are related for $Z_\infty >> 1$ by

$$B_\infty Y_\infty / Z_\infty = \exp(-\Delta P^\theta)$$

where

$$\Delta P^\theta = (E^\theta_{Y,Z} - E^\theta_{A,B})\mathbf{F}/RT$$

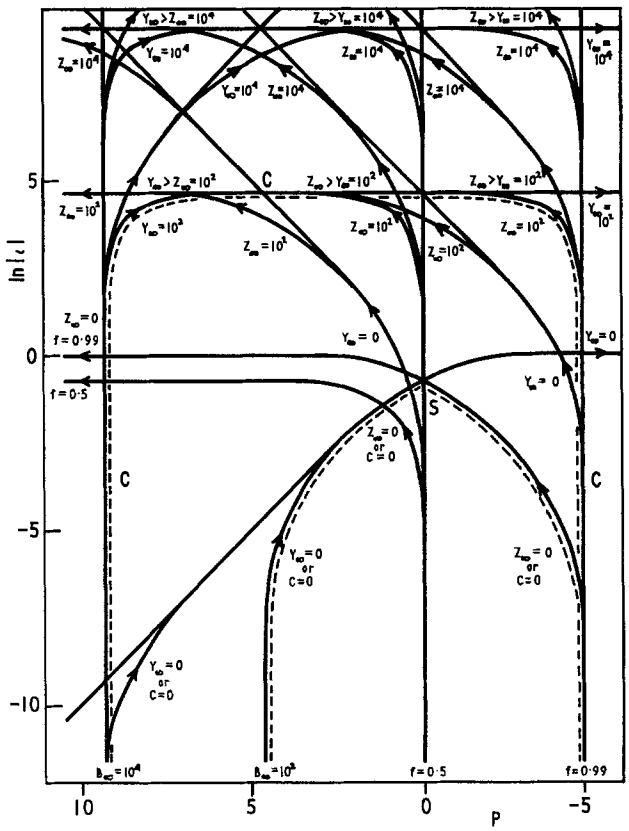

Fig. 10. Current-potential curves given by Eq. [36] for a cell containing a reversible *A, B* couple and an irreversible *Y, Z* couple. See text for discussion.

Limitations on the values of Y_∞ and Z_∞.—The theoretical behavior illustrated in Fig. 10 suggests that it would be desirable to have Z_∞ and Y_∞ as large as possible. Unfortunately there is a practical limitation. The increased performance arises from the A and B species catalyzing the reduction and oxidation of Y and Z. We have assumed that the A, B couple is reversible but there is a limit to the amount of Y or Z it can handle at each electrode. Combining the condition for reversibility ($\lambda > 1$), the definition of λ in [32], and the condition for the catalytic case in Table II, we find

$$Y_\infty \text{ and } Z_\infty < X_{tr} k^\circ_{A,B}/D < 10^2 \qquad [42]$$

The estimate of 10^2 in [42] is obtained by taking $X_{tr} = 10^{-2}$ cm, $D = 10^{-5}$ cm^2 sec^{-1}, and $k^\circ_{A,B} < 10^{-1}$ cm sec^{-1}, where $k^\circ_{A,B}$ is the standard electrochemical rate constant for the A, B couple. If Y_∞ or Z_∞ is increased above ~10^2, no improvement in cell output will result, because charge transfer overvoltage will cause power losses, unless A, B is extraordinarily reversible.

Variation of Power with X_{tr} and X_k

In our discussion so far we have been concerned with how the power varies with the load on the cell and with the electrode kinetics. We now explore how the maximum power from a cell with a matched load varies with X_{tr} and X_k. At constant X_{tr} the power, W, is proportional to θ, as shown by Eq. [14], and Fig. 11 shows the variation of θ/θ_m with (X_k/X_{tr}), where $\theta_m = 0.55$ (Eq. [39]). We have taken for the catalytic case the curve labeled C in Fig. 10, where Z_∞ and Y_∞ have their maximum value of 10^2 (Eq. [42]). Like Table II (or Gaul) the figure is divided into three parts. On the left-hand side we have the catalytic case; the homogeneous reactions are fast enough for reaction sequences [40] and [41] to take place. The difference between θ_m and the maximum value of θ for curve C ($= 852$) is shown by the vertical arrow. On the right-hand side we have the simple case. Under these

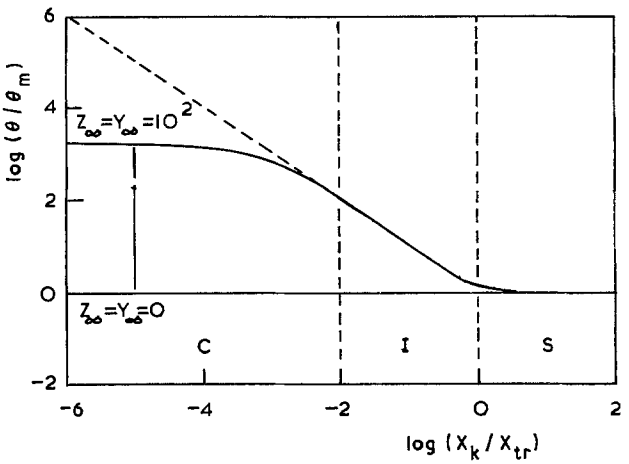

Fig. 11. Variation of maximum power with X_k. The catalytic case illustrated is for $Z_\infty = Y_\infty = 10^2$; the broken line shows the maximum possible power from [43].

conditions the homogeneous reactions are too slow for the catalytic currents to be developed in the diffusion layer. In between we have the intermediate case, for which from Table II

$$\theta = \theta_m(X_{tr}/X_k) \qquad [43]$$

Here θ decreases with increasing X_k. Under these conditions there are catalytic currents. These currents, however, are not limited by the transport of Y or Z across X_{tr} but rather by the transport and reaction of A and B in the reaction layer.

To examine how the maximum power varies with X_{tr} we have to define a new function ϕ where

$$W = \phi\theta_m A D a_D R T X_k^{-1} \qquad [44]$$

and

$$\log \phi = \log (\theta/\theta_m) - \log (X_{tr}/X_k) \qquad [45]$$

In [44] as opposed to [14] the power output, W, is normalized with respect to X_k rather than X_{tr}. Figure 12 shows how ϕ (and hence W) varies with X_{tr}/X_k. Figures 11 and 12 are complementary; the former shows the behavior for constant X_{tr} and varying X_k, while the latter shows the behavior for constant X_k and varying X_{tr}. The same catalytic case (curve C in Fig. 10) is shown.

Three regions are again found in Fig. 12. For the intermediate case from [43] and [45], $\phi = 1$. In this region the power produced is independent of X_{tr}. The reason for this is, firstly that Y and Z are not being consumed rapidly enough for their concentration polarization to be important, and secondly that the concentration profiles of A and B are determined by what happens in the reaction layer rather than by their diffusion across X_{tr}. In both Fig. 11 and 12, more power is produced the smaller is X_k or X_{tr}. In particular on the right of Fig. 12, as X_{tr} becomes large, very little power is produced. In the limit, a cell operating under conditions of semilinear infinite diffusion would not produce any power in the steady state. This is because the concentration polarization reduces the current to zero.

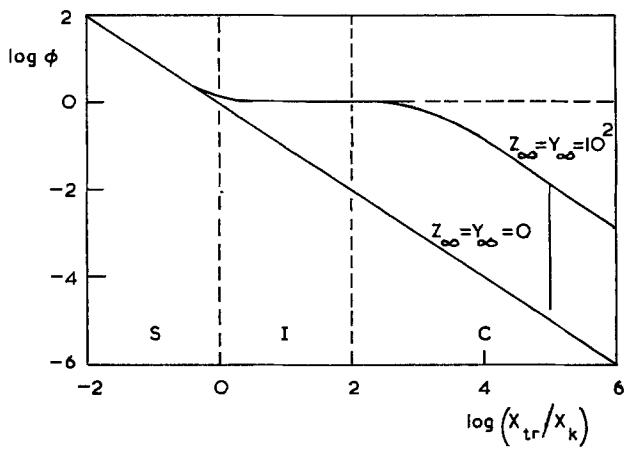

Fig. 12. Variation of maximum power with X_{tr}. The catalytic case illustrated is for $Z_\infty = Y_\infty = 10^2$; the broken line shows the maximum possible power from [43].

The broken lines in Fig. 11 and 12 show the maximum possible power that can be obtained from the intermediate and catalytic cases, even if the restriction on the size of Y_∞ and Z_∞ given in [42] was removed. The transport and reaction of the electrochemically active couple will always ultimately limit the current and the line given by [43] is the maximum value of θ that can be obtained in the catalytic case. As C is increased, although θ is larger in the catalytic region, the boundary between this region and the intermediate region moves to the left in Fig. 11, so that values of θ greater than those given by [43] cannot be found.

Photogalvanic Concentration Cells as Practical Solar Energy Converters?

The broken lines of Fig. 11 and 12, representing the maximum power that can be found, correspond to $\phi = 1$ in Eq. [44] and hence we derive the following simple expression for the maximum power obtainable from the type of photogalvanic concentration cell discussed in this paper

$$W_{max} = 0.55 A D a_D R T X_k^{-1} \qquad [46]$$

The former is limited by the solubility of A. Furthermore in deriving Eq. [46] we assumed that there was sufficient light intensity to convert nearly all the A to B in the photostationary state. The maximum conversion is given by

$$\frac{b_L}{a_L} = \frac{I_{o\epsilon}}{k_{-H}y}$$

and taking $b_L/a_L > 10$ with typical values for I_o for solar radiation of 10^{-7} E cm^{-2} sec^{-1} (4), and $\epsilon = 10^8$ cm^2 mol^{-1}, we find that

$$k_{-H}y < 1 \text{ sec}^{-1} \qquad [47]$$

But for the catalytic case we require

$$y/a_D \sim 10^2$$

and so

$$(a_D/M) < 10^{-2}(k_{-H}/\text{M}^{-1}\text{sec}^{-1})^{-1} \qquad [48]$$

If this condition is violated then sunlight will be unable to convert all the A to B in the photostationary state and less power will be obtained than predicted from Eq. [46].

Returning to consideration of Eq. [46], the other variable, X_k, will be limited by the condition in Eq. [47], giving $X_k > 3 \times 10^{-3}$ cm. Taking $D = 10^{-5}$ cm^2 sec^{-1} and $a_D = 10^{-3}$M (implying from Eq. [48] $k_{-H} \sim 10\text{M}^{-1}$ sec^{-1}) we obtain from Eq. [46]

$$W_{max}/A \sim 10^{-6} \text{ W cm}^2$$

Most real systems will not fulfill all the necessary conditions in [42], [47], and [48], and in the next paper of this series we shall explore how the power varies with the kinetics of the reaction of B and Y and with the concentrations of A and Y. However it is clear that the power output of the cell depends on a complicated interplay of the parameters describing the photochemistry, the homogeneous kinetics, the mass transport, and the electrode kinetics. Conclusions based on simple concepts like the "power conversion efficiency" may well be misleading. For instance, if the power output is limited by mass transport, increasing the light intensity will not increase the amount of power from the cell.

Conclusions

1. Photogalvanic concentration cells will be most efficient when one electrochemical couple is reversible and one irreversible.

2. As shown in Fig. 11 and 12, the efficiency of photogalvanic cells is improved by reducing both X_k and X_{tr}.

3. If $X_{tr} > X_k$, the maximum power that can possibly be obtained is given by [46]. Under these conditions the homogeneous kinetics are sufficiently rapid to suppress the concentration polarization of A and B at the electrodes and to produce catalytic currents from the larger concentrations of Y and Z. The maximum power is unlikely to be $> 10^{-6}$ W cm^{-2}, if sunlight is used to drive the cell.

In this treatment we have made the following assumptions:

(*i*) The electrodes are of the same material and are of equal area.

(*ii*) All diffusion coefficients are equal.

(*iii*) The photochemical generation obeys a relation, $g = g''az$.

(*iv*) Except for conclusion 1 the electrode kinetics follows case b in Table I, so that the A, B couple is reversible and the Y, Z couple irreversible.

(*v*) The concentration of photochemically generated B is much larger than that in the dark.

Spectral Response and Efficiency Relations in Semiconductor Liquid Junction Solar Cells

A. Heller,* K. C. Chang, and B. Miller*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

States due to imperfections at or near surfaces of semiconductors in liquid junction solar cells can be identified by changes in the photoresponse spectra under short-circuit current conditions. These effects become dominant features in two-beam experiments with an intense pumping (laser) source and a weak modulated probing beam. The presence of these states can be correlated with drastic decreases in short-circuit currents, open-circuit voltages, fill factors, and maximum power conversion efficiencies of the cells. Elimination of the damaged surface regions by suitable etching allows AM2 solar conversion efficiencies of 1.3 and 7.2%, respectively, in the cells n-CdS/0.1F Na_2S-0.02F S-0.1F NaOH/C and n-CdSe/1F Na_2S-1F S-1F NaOH/C.

Semiconductor liquid junction solar cells (1) consist of the bulk semiconductor phase, the interface between semiconductor and solution, the redox electrolyte, and a counterelectrode. The motion of carriers in photoexcited semiconductors and in solutions and the transfer of charge at (metallic) counterelectrode interfaces are reasonably understood. The unique features and the problems of semiconductor liquid junction solar cells derive from the chemistry and physics of the semiconductor-electrolyte interface first described by Brattain and Garrett (2). The critical dependence of the stability of such cells on this interface has been discussed by Gerischer (1). That the power conversion efficiency also depends on the properties of the interface as controlled by prior chemical etching was noted by Kaiser, Ellis, and Wrighton (3) in the case of CdSe.

The importance of proper preparation of the semiconductor surface became evident to us in early phases of work on the efficiencies of both single crystal and polycrystalline semiconductor based cells. In fact, efficiencies were found to vary by as much as three orders of magnitude with the method of preparation of the semiconductor surface. Such variations were also expected from experience with solid-state cells where the loss of efficiency has been attributed to the trapping of carriers in surface states, followed by recombination (4).

The significance of surface imperfections in controlling the efficiencies made necessary a fast and simple technique for the monitoring of the quality of the semiconductor surface *in situ*. Byvik (5) recently showed the presence of states within the "forbidden" gap by measuring the photovoltaic response of semiconductors immersed in electrolyte solutions. We have observed distinct changes in the photoresponse spectra of many semiconductors *in situ* with the mode of surface preparation. These changes can be correlated with the level of power conversion efficiency of these semiconductor liquid junctions in solar cell use. The spectral response behavior provides a sensitive indicator for optimizing surface preparation conditions for given semiconductor-redox electrolyte combinations.

We present here the results for two solar cells with n-CdS and n-CdSe single crystal anodes. Similar behavior was observed with other cells utilizing both single crystal and polycrystalline electrodes.

Experimental

Hexagonal (wurtzite) n-CdS and n-CdSe single crystals cleaved into 1 mm thick plates with the surfaces perpendicular to the c axis were purchased from

* Electrochemical Society Active Member.

Cleveland Crystals Incorporated, Cleveland, Ohio. The conductivities of the crystals were at least 0.1 Ω^{-1}-cm^{-1}. Ohmic contacts were formed to the back of each plate with evaporated indium. A copper lead was attached to the indium layer with silver epoxy. Epoxy resin was used to seal the copper wire in a glass tube and to insulate all but the exposed face of the semiconductor electrode.

Pyrex test cells were equipped with Pyrex flat windows. The active crystal face was brought to 1 ± 0.5 mm of the window to minimize solution light absorption. Typical crystal area was 0.2 cm^2. The counterelectrode was a ~ 10 cm^2 geometric surface area carbon ring attached to a graphite rod. Provision was made for a calomel reference electrode. Nitrogen was bubbled through the solution which was also stirred by a magnetic bar.

The electrolytic solutions were 0.1F Na_2S-0.02F S-0.1F NaOH (CdS experiments) and 1F Na_2S-1F S-1F NaOH (CdSe experiments). A 1 mm thick layer of these solutions cuts off 50% of the light at 350 nm in the case of the first solution and at 490 nm for the second.

CdS crystals were etched for 20 sec in conc HCl and CdSe for 20 sec in 5:1 (v/v) HCl-HNO_3. The initial spectra and voltammetric characteristics of the crystals as supplied could be changed by etching and restored by polishing with Linde A (0.3μ alumina).

Current-voltage characteristics of the cells were measured with a PAR Model 173 potentiostat-galvanostat programmed by a PAR Model 175 universal programmer.

The light source was a 100W tungsten-halogen lamp (Oriel Corporation). The beam was chopped at 100 Hz with a Bulova tuning fork and then focused on the entrance slit of a 0.25m Schoeffel grating monochromator. Both entrance and exit slits were set at 0.5 mm. Part of the exit slit was masked to define a spot of 2 mm height as focused on the electrode face.

The lasers used were a Spectra Physics Model 310A argon-ion laser (10 mW at 488 nm) and a Spectra Physics Model 155 helium-neon laser (1.8 mW at 632.8 nm). The spot diameter of the argon laser was brought to 4 mm and that of the helium-neon laser to 2 mm using concave lenses. Thus the irradiance of CdS at 488 nm was about 80 mW/cm^2 and of CdSe at 632.8 nm about 60 mW/cm^2. The beam from the laser was not chopped. The image of the monochromator slit on the crystal was completely overlapped by the light spot from the laser. The irradiance of the crystals by the light that passed through the monochromator varied with wavelength but was never more than 1 mW/cm^2.

Photoresponse spectra under "short-circuit" d-c load conditions were obtained by connecting the cell electrodes to the "transformer mode" input of a PAR Model 116 differential preamplifier plugged into a PAR Model 124A lock-in amplifier. The d-c resistance of this input was measured as 2.2Ω. This synchronous detection method also served to reject the unchopped laser radiation response.

The spectra were corrected for the number of photons reaching the cell at the various wavelengths and normalized to unity at their maxima. Thus the short-circuit current photoresponse spectra represent relative quantum yields. Corrections for solution light absorption were not made.

The energy conversion efficiencies were measured using a calibrated Eppley thermopile and direct sunlight with irradiances close to 75 mW/cm^2.

Results

Figure 1 shows the normalized short-circuit current photoresponse spectra of an as polished (unetched) n-CdS electrode, with and without laser irradiation. In addition to the response at wavelengths shorter than 512 nm, the wavelength corresponding to a 2.42 eV bandgap (6), the spectrum shows a peak at 536 nm (2.31 eV) when the laser is off. Exposure of the CdS to the 488 nm laser light reduces the photocurrent almost to zero on the short wavelength side until the absorption edge is approached. The photocurrent then peaks at 512 nm (the wavelength equal to the 2.42 eV bandgap) and shows a shoulder at longer wavelengths.

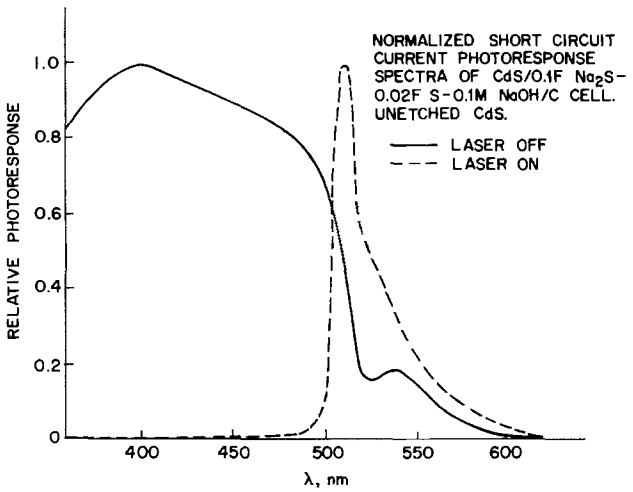

Fig. 1. Effect of laser pumping on unetched n-CdS single crystal electrode spectra.

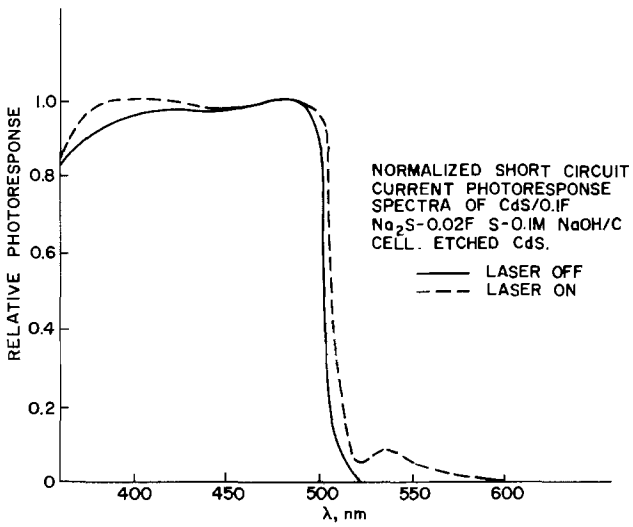

Fig. 2. Effect of laser pumping on etched n-CdS single crystal electrode spectra.

Figure 2 shows the equivalent spectra after etching of the CdS. The drastic difference between the spectra in Fig. 1 produced by the laser irradiation no longer exists. The response of the etched crystal is nearly flat at photon energies exceeding the bandgap in both Fig. 2 spectra. With the laser on a small peak at 536 nm is still observed. This reflects both the sensitivity introduced by the laser pumping and the fact that the etching step is insufficient to provide a "perfect" surface.

The spectral difference between the unetched and etched CdS without the laser irradiation is shown in Fig. 3. Two maxima are observed; 515 nm (2.407 eV) and 537 nm (2.309 eV). These correspond to transitions located 0.014 and 0.112 eV below the bandgap energy.

The current-voltage characteristics of the solar cells with unetched and etched CdS crystals, respectively, are shown in Fig. 4 for a solar irradiance of 76.6 mW/cm^2. Comparison of the performance of the unetched and the etched cells shows that the respective experimental short-circuit currents are 0.68 and 4.1 mA/cm^2. Under AM2 conditions these currents are estimated to be 0.65 and 4.0 mA/cm^2, respectively. The corresponding open-circuit potentials are 0.41 and 0.59V. The maximum power density measured for unetched CdS is 0.34 mA/cm^2 × 0.21V = 0.07 mW/cm^2, translating to an AM2 efficiency of 0.09% and to a fill factor of 0.25.

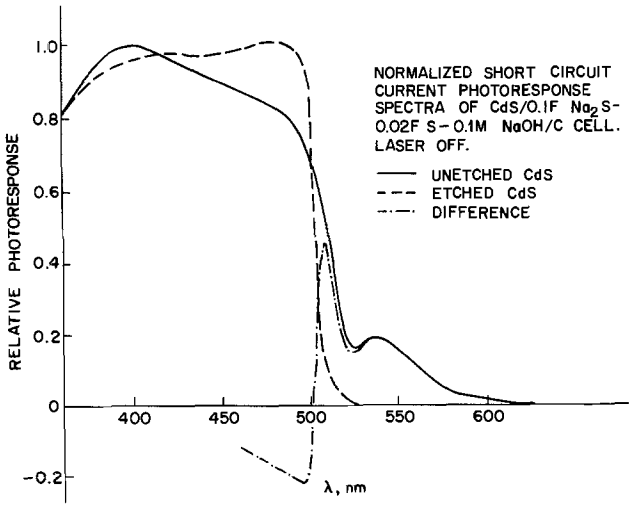

Fig. 3. Effect of surface defects on n-CdS single crystal electrode spectra. Laser off.

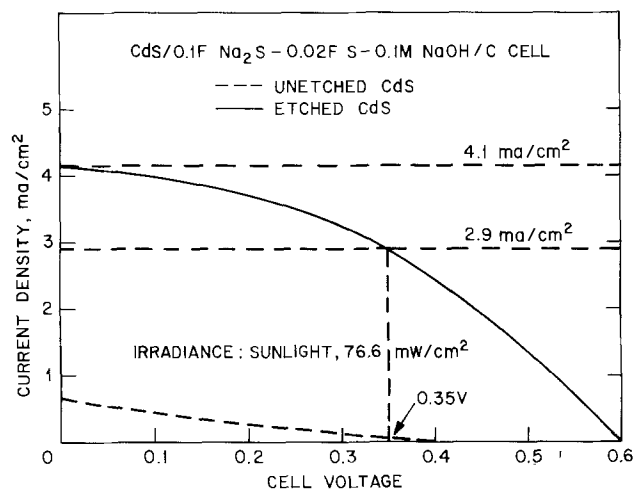

Fig. 4. Current-voltage characteristics of n-CdS/0.1F Na_2S-0.02F S-0.1F NaOH/C cell with etched and unetched n-CdS electrodes.

Etched CdS delivers 2.8 mA/cm² × 0.35V = 0.98 mW/cm² or an AM2 efficiency of 1.3% at a fill factor of 0.41.

The data for the single crystal n-CdSe electrodes are shown in Fig. 5-7. Figure 5 compares the photocurrent spectra of the polished CdSe left unetched, and the same surface etched in 5:1 HCl-HNO_3. The photoresponse of the unetched electrode extends beyond the 727 nm (1.705 eV) bandgap (7) with a maximum at

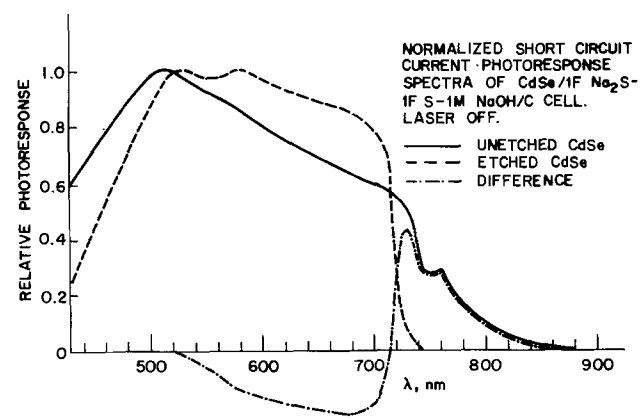

Fig. 5. Effect of surface defects on n-CdSe single crystal electrode spectra. Laser off.

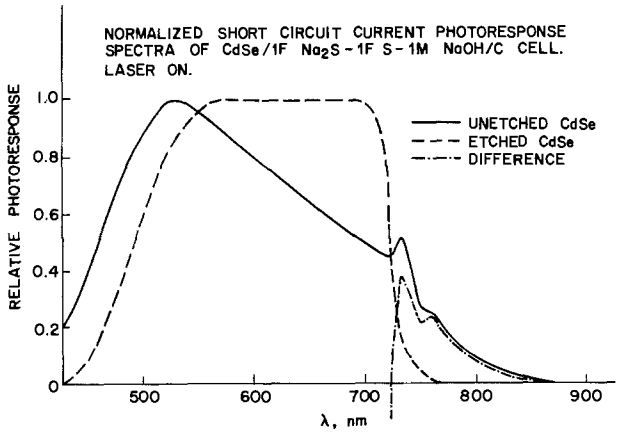

Fig. 6. Effect of surface defects on n-CdSe single crystal electrode spectra. Laser on.

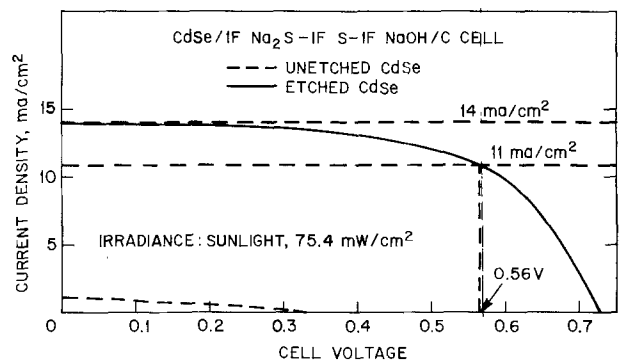

Fig. 7. Current voltage characteristics of n-CdSe/1F Na_2S-1F S-1F NaOH/C cell with etched and unetched n-CdSe electrodes.

757 nm. The difference spectrum in Fig. 5 shows two transitions; 731 nm (1.694 eV) and 757 nm (1.638 eV). These transitions define two states differing by 0.011 and 0.067 eV from the band edge.

The photocurrent spectra obtained with light from the He-Ne laser (632.8 nm) flooding the CdSe crystal are shown in Fig. 6. The etched CdSe displays a sharp band edge at 727 nm (1.705 eV) and a flat response at shorter wavelengths down to the uncorrected region of polysulfide absorption. The spectrum obtained with unetched CdSe is different, extending to longer wavelengths with a peak at 731 nm and a shoulder at 757 nm. In contrast to that of the etched CdSe, the photoresponse peaks near the polysulfide absorption region and decreases as the photon energy approaches that of the bandgap. The difference spectrum between unetched and etched CdSe also shows maxima at 731 and at 757 nm.

The current voltage characteristics of the CdSe cells are shown in Fig. 7. The measured short-circuit current density is 1.2 mA/cm² for unetched CdSe and 14 mA/cm² for etched CdSe. The open-circuit voltages are, respectively, 0.33 and 0.73V. The measured power density maximum for the unetched cell is 0.6 mA/cm² × 0.16V = 0.1 mW/cm², and the fill factor is 0.25. The corresponding values for the etched CdSe cell are 11 mA/cm² × 0.56V = 6.1 mW/cm² and fill factor 0.60. The over-all power conversion efficiency, η, for the etched electrode cell is

$$\eta = \frac{6.1 \times 100}{75.4} = 8.1\%$$

This result is the best of four obtained on different occasions with sunlight near 75 mW/cm² with four different electrodes. The data are virtually identical in short-circuit current and open-circuit voltage and vary only in fill factor to give an average η of 7.2 ± 0.7% (std dev.).

Discussion and Conclusions

The results establish a simple correlation between the presence of the states which are within the forbidden gap and the efficiency of semiconductor liquid junction solar cells. These states are responsible for the 515 and 537 nm transitions in CdS and for the 732 and 757 nm transitions in CdSe. That these states are due to imperfections near or at the surface is evident from the fact that they are removed by a brief etching. Such etching simultaneously reduces or eliminates the spectral transitions within the bandgap and increases the short-circuit current, fill factor, open-circuit voltage, and thus the over-all power conversion efficiency.

The additional states are introduced by mechanical polishing and its attendant surface or bulk dislocation generation. The fact that wurtzite actually undergoes a phase transition to sphalerite upon grinding is well known (8). Lattice defects produced by abrasion have also been reported by Gerischer *et al.* (9) in ZnO where the damage depth is found comparable to the particle size of the abrasive. Similar considerations for our experiments would produce a defect layer of 0.3μ.

Surface and near-surface defects are well known to affect the performance of solar cells by introducing states which act as carrier traps and recombination centers (10). Recombination centers lead to saturation of photocurrents at low light levels and to changes in the photoresponse spectrum both above and within the bandgap. Saturation at moderate light intensities is evident both in CdS and CdSe where laser input drops the response of the unetched crystals to the modulated beam by more than an order of magnitude. Removing the defects by etching makes the modulated photoresponse insensitive to the laser beam.

The origin of the saturation effect can be explained by assuming that the new states are traps for one of the carriers. Whether they are electron or hole traps, they are populated by exposure of the crystal to an intense beam of light. Minority carriers moving toward the interface or majority carriers moving to the bulk thus meet a greatly increased probability of recombination.

Such processes also account for the shape of the photoresponse spectra at higher light intensities in unetched CdS (Fig. 1). Light of short wavelengths is absorbed closer to the surface where the density of populated traps is high. Because of the resulting high recombination probability, such light produces virtually no photocurrent. On the other hand, light near the band edge penetrates deeper to more perfect regions of the crystal where little recombination takes place. As a consequence, substantial photocurrent is produced by wavelengths near the absorption edge.

Upon removal of the top layer with the dislocation generated recombination sites, the performance of the cells is dramatically improved. It is notable that the 4.0 mA/cm^2 short-circuit current for CdS and the 14 mA/cm^2 short-circuit current for CdSe represent 80% of the theoretical limits of these materials for AM2 conditions (11). The quantum efficiency is probably close to unity and the losses are primarily reflection losses at both the semiconductor-liquid and glass-air interfaces and solution absorption losses.

Whether the defects manifest themselves as donor or acceptor levels is not established herein but is under investigation by capacitive techniques.

It may be noted that similar photoresponse techniques with laser irradiation on anodically formed CdS surfaces (12) show the same minimal effects of the laser beam observed in studies of etched single crystals. Unlike the single crystal spectra, those obtained on anodized surfaces have a tail at wavelengths longer than 512 nm (the 2.42 eV bandgap).

The sensitivity of the technique of photoresponse spectra with superimposed laser irradiation confirms it as an excellent diagnostic tool for evaluating surface preparation methods for semiconductor electrodes in liquid junction solar cell investigations.

Current Distribution on a Rotating Ring-Disk Electrode below the Limiting Current

Peter Pierini and John Newman*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Ring-disk electrodes have been used in the literature to simulate experimentally the nonuniform current distribution across a rotating disk electrode operated at a fraction of the limiting current. The analogy of a sectioned disk to a ring-disk electrode is difficult to substantiate since both the limiting current and primary current distributions are radically different. Thus a detailed knowledge of the distribution of current and concentrations is developed to compare rationally the differences in nonuniformity for the ring-disk and disk electrodes. Integral measures of the degree of departure from the limiting current and primary current distributions are developed and related to the measurement of throwing power.

The ring-disk electrode system is one of the most convenient arrangements of two working electrodes in a common cell. The concentric, rotating electrode structure is relatively easy to fabricate and is available commercially. The device has drawn attention recently, as both the object of theoretical analysis and experimental applications. Bruckenstein and Miller (1) and Smyrl and Newman (4) have performed experiments with ring disks to assess the nonuniform current distribution on a disk electrode utilizing the sectioned-electrode approach. Miller and Bellavance (2) have reported a number of experiments with the system, including measurement of interrupter and steady-state resistances and interactive resistances between the ring and the disk. Smyrl and Newman (3, 4) have presented data for ring-disk electrodes operated at and below the limiting current, along with a detailed analysis demonstrating the limiting current calculations. The primary current distribution was recently computed by Miksis and Newman (5). The limiting current (4, 11) and the primary current (5) densities of a ring electrode are not uniform, so the current density on a ring operated at some fraction of the limiting current, where kinetics also must be taken into account, does not approach the uniform distribution (12) that prevails near the edge of a disk electrode as the fraction of the limiting current approaches unity. The current distribution across a ring-disk electrode tends to be more nonuniform than for an equivalent disk.

Newman's (6) approach to the computation of the concentration and current density distributions across a rotating disk electrode has been applied successfully to a number of other electrode geometries (7-9, 24-26). Parrish and Newman (8) investigated the current distributions on two plane parallel electrodes in channel flow, the only application to two interactive working electrodes. The ring-disk geometry contains two working electrodes and can utilize a counterelectrode, which would be considered infinitely far from the working electrodes. The working electrodes interact through the potential distribution, which is described by an elliptic Laplacian equation giving global effects, and through the parabolic concentration boundary-layer equations which allow a downstream influence on the ring electrode by the disk. The ring implicitly affects the disk concentration profile by modifying the potential which enters into the kinetic expressions, thus changing the flux boundary conditions that would exist on the disk from the situation prevailing if no ring were present.

Current can flow between any of the three electrodes in the cell, but common experimental objectives usually attempt to limit the possibilities. The ring and the disk can be operated potentiostatically with the current from each electrode being collected by the counterelectrode. The disk can be used to produce a species not in the bulk solution which can then be collected by the ring electrode, usually one electrode being driven cathodically and the other anodically. The disk electrode can be driven as a bipolar electrode where a current loop exists in the solution over the electrode. The analysis presented here applies to all these cases, but the results are restricted to the sectioned disk, with the ring and the disk maintained at the same potential. Results for the other situations will be reported in a subsequent paper.

The kinetics of the surface reaction to be considered are of three types, a product-independent metal deposition from a single salt solution (6), a product-independent reaction with a supporting electrolyte (6), and a reaction depending on all reacting species with a supporting electrolyte (10). These reactions are representative of plating from a solution with and without a supporting electrolyte, and of redox reactions or organic synthesis with a supporting electrolyte. The analysis is restricted to laminar flows, high Schmidt numbers, and dilute solutions with constant physical properties.

The method of computing current densities and concentration profiles is developed for a ring-disk system operated potentiostatically. Integral measures of the way in which these profiles deviate from the limiting current and primary current distributions are discussed. The design of ring-disk electrodes for the purpose of measuring the throwing power is shown.

Overpotentials

Let a single electrode reaction be expressed by

$$\sum_i s_i M_i^{z_i} \rightarrow n\, e^- \qquad [1]$$

where s_i is the stoichiometric coefficient, M_i is the symbol for the chemical species, z_i is the species charge number, and n is the number of electrons participating in the reaction. The potential applied between each of the working electrodes and a single counterelectrode located at infinity is

$$V_d = U + \Phi_{o,d} + \eta_c + \eta_s \qquad [2]$$

$$V_r = U + \Phi_{o,r} + \eta_c + \eta_s \qquad [3]$$

The applied potentials are separated into the equilib-

* Electrochemical Society Active Member.

Key words: sectioned disk, throwing power, potential distribution.

rium potential U which is associated with reaction [1], a concentration overpotential η_c, a surface overpotential η_s, and an ohmic potential Φ_o for each working electrode which is extrapolated to the surface of the electrode. The expression for the concentration overpotential (13) is

$$\eta_c = -\frac{RT}{ZF}\left[\sum_i s_i \ln\left(\frac{c_{i,\infty}}{c_{i,o}}\right) - t\left(1 - \frac{c_{1,0}}{c_{1,\infty}}\right)\right] \quad [4]$$

Equation [4] applies approximately to metal deposition from a single salt where t is the transference number of the metal ion, species 1. Z is then equal to $-z_-z_+/(z_+ - z_-)$. For the case in which the reactants and products are minor components in a solution containing an excess of supporting electrolyte, t is zero, and Z is equal to $-n$. The surface overpotential can be related to the current density by

$$i = i_o\left[\exp\left(\frac{\alpha ZF}{RT}\eta_s\right) - \exp\left(\frac{-\beta ZF}{RT}\eta_s\right)\right] \quad [5]$$

The kinetic parameters α and β are determined by the reaction taking place. The local exchange current density i_o is taken to have a composition dependence given by

$$i_o = i_{o,\infty}\prod_i\left(\frac{c_{i,o}}{c_{i,\infty}}\right)^{\gamma_i} \quad [6]$$

The γ_i's are specified by the particular reaction taking place and the condition of the surface upon which the reaction occurs, and $i_{o,\infty}$ is an exchange current density evaluated at the composition of the bulk solution. The parameter γ_i can be considered a pseudo reaction order, the values are usually determined experimentally and can be fractional. Newman (27) suggests rules for the estimation of the exponents γ_i.

Potential Distribution

The potential variation in the region of constant concentration is described by a solution of Laplace's equation which matches the current at the surface of the electrode with the mass flux through the boundary layer for a faradaic process. The particular solution found to be most suited for the ring-disk configuration operated below the limiting current is (14)

$$\Phi_o(r) = \frac{2}{\pi\kappa_\infty}\int_o^{r_2}\frac{i(r')}{r + r'}K\left(\frac{4rr'}{(r + r')^2}\right)r'dr' \quad [7]$$

The integral is evaluated at all points r' on the electrode surface where there is a nonzero value of the normal component of the current density i, K is the complete elliptic integral of the first kind (15), and r is the radial position on the surface at which Φ_o is desired. The behavior of the elliptic integral K when r is equal to r' requires special care in the numerical evaluation of Eq. [7]. The integral technique for the ring-disk system when mass transfer and kinetic effects must be considered offers real computational advantages over previously used series solutions (6) and a combination of series and integrals (5).

The primary advantage in using an integral equation rather than the combination of series and integral solutions, which is also applicable, is programming efficiency and lower computing costs. However, if the current distribution on the disk approaches the primary current distribution, the series solution can be used to compute the potential without modification. The integral technique requires the same careful handling of singular points as used in Newman and Miksis (6) for the primary current on a ring. The series solution when applied across both the ring and disk electrodes suffers from the serious inability to cope with discontinuities in the current distribution where the insulator meets the active electrode in three places.

Concentration Profile

The Lighthill transfomation has been successfully applied to the problem of evaluating the concentration profile through the diffusion boundary layer in previous examples of the calculation of current distributions below the limiting current (4, 7-10, 24, 25). The flux at the electrode surface, either the ring or the disk, can be expressed by (4)

$$\frac{\partial c_{i,o}}{\partial\zeta} = \frac{-r}{\Gamma(4/3)}\int_o^r \frac{dc_{i,o}}{dr'}\frac{dr'}{(r^3 - r'^3)^{1/3}} \quad [8]$$

and inverted to give

$$c_{i,o} - c_{i,\infty} = \frac{-1}{\Gamma(2/3)}\int_o^r \frac{\partial c_{i,o}}{\partial\zeta}\Big|_{r=r'}\frac{r'dr'}{(r^3 - r'^3)^{2/3}} \quad [9]$$

Equation [8] is equated to a flux specified by Eq. [2] or [3] and Eq. [4] and [5] and then solved for the concentration at the electrode surface. Equation [9] is used to track the surface concentration variation across the insulating annulus Equation [9] can also be manipulated to yield

$$\frac{c_{i,o} - c_{i,\infty}}{c_{j,o} - c_{j,\infty}} = \frac{s_i}{s_j}\left(\frac{D_j}{D_i}\right)^{2/3} \quad [10]$$

One species can now be chosen and conveniently designated to be subscripted as i equal to 1, then Eq. [8] need be solved for only the value of $c_{1,0}$. All other surface concentrations needed in the expression of the electrode kinetics may be computed by Eq. [10] as long as the only reaction occurring is Eq. [1].

The total current or mass transfer rate to the electrode is a quantity which must be computed as accurately as possible if a good comparison with experimentally measured currents is desired. The ratio of the ring current to the disk current is very sensitive to errors in computing the integral values. A quantity, j, proportional to the total flow of a species to the electrode surface between the limits of integration, 0 and r, is

$$j = \int_o^r \frac{\partial c_{i,o}}{\partial\zeta}r'dr' \quad [11]$$

which becomes upon substitution of Eq. [8] and one integration

$$j = \frac{-1}{2\Gamma(4/3)}\int_o^r \frac{dc_{i,o}}{dr}(r^3 - r'^3)^{2/3}dr' \quad [12]$$

Equations [8] and [12] are Stieltjes integrals, so the points at the center of the disk and the leading edge of the ring must be taken into account when evaluating the integrals. Equation [12] can be easily solved by using the method of Acrivos and Chambre (19) utilizing the same mesh points that are generated in the solution of Eq. [8].

Numerical Solution

A set of equations is now established which can be solved numerically by the same techniques given in previous work (6, 8-10). The parameters that the solution depends on are α, β, γ_i, t, r_o/r_1, r_1/r_2, Z, D_j/D_i, and

$$N = -\Gamma(4/3)\frac{nFr_2i_{LIM,DISK}}{RT\kappa_\infty} \quad [13]$$

and

$$J = \frac{i_{o,\infty}r_2nF}{RT\kappa_\infty} \quad [14]$$

and

$$\delta = |i_{avg}|\frac{r_2nF}{RT\kappa_\infty} \quad [15]$$

N is referred to species 1 so $i_{LIM,DISK}$ is the limiting current density on a disk electrode for species 1. There is a δ for both the ring and the disk, with the ap-

propriate average current density being substituted in Eq. [15]. J represents a dimensionless exchange current density.

Measures of Nonuniform Current Distributions

The problem of assessing the effect of nonuniform ohmic potential drop on arbitrarily shaped electrodes has long been of interest to electroplaters. A specific solution which will deposit an even thickness of metal over a range of current densities has been the goal of many experimental investigations and is the basis of a portion of the plating industry. Haring and Blum (16) introduced the concept of defining throwing power by a well-chosen experiment. Parallel, rectangular electrodes of equal area were connected by a solution contained within insulating planes normal to the electrode surfaces, which would give a uniform primary current on the electrodes and an easily defined primary resistance. Two cells with a primary current ratio of 5 were polarized with the same voltage, and currents were measured. The throwing power can then be computed by applying (17)

$$\text{T.P.} = \frac{\frac{I_{P1}}{I_{P2}} - \frac{I_1}{I_2}}{\frac{I_{P1}}{I_{P2}} + \frac{I_1}{I_2} - 2\frac{A_1}{A_2}} \times 100 \qquad [16]$$

I_1 and I_2 are the measured currents, I_{P1} and I_{P2} are the primary currents, and A_1 and A_2 are the areas of the electrodes. This measurement does not characterize the solution independently of the measuring device. In an unstirred cell, natural convection becomes a significant factor as the current densities are increased (23). Throwing powers measured with cells having the same electrode spacing ratio but different electrode areas are usually different. The effect of natural convection can be minimized by stirring the cells, but the effect of the stirring rates must then be assessed. Studies on membranes (18) have shown that stirring can totally obscure the measurement of desired membrane properties at a surface in a well-stirred tank. Thus it seems difficult at best to describe theoretically the Haring-Blum cell well enough to measure a throwing power that could be related to solution properties only.

The throwing power is a measurement of the deviation of a current ratio from the primary current ratio on two electrodes with different geometries. A rotating ring-disk electrode system is a good device to make this type of measurement since the primary current distribution is now known (5), and the effects of stirring are well characterized by N. Figure 1 shows the radius ratios necessary to construct a ring-disk electrode with a given average primary current density ratio. The average current density ratio must be used instead of the current ratio as in the Haring-Blum cell because the electrode areas are not equal. Throwing powers for ring-disk systems can be computed as a function of the electrode and solution parameters by setting $V_r = V_d$.

Another measure of nonuniformity is a deviation from the limiting current distribution, which is uniform on the disk but not on the ring. A useful parameter f_2 can be defined (4) as the ratio of the current to the ring, divided by the area of both the ring and the insulating gap, to the average current density on the disk.

$$f_2 = \frac{I_r}{I_d} \frac{r_0^2}{r_2^2 - r_0^2} \qquad [17]$$

The value of f_2 compared to the value for the limiting current distribution

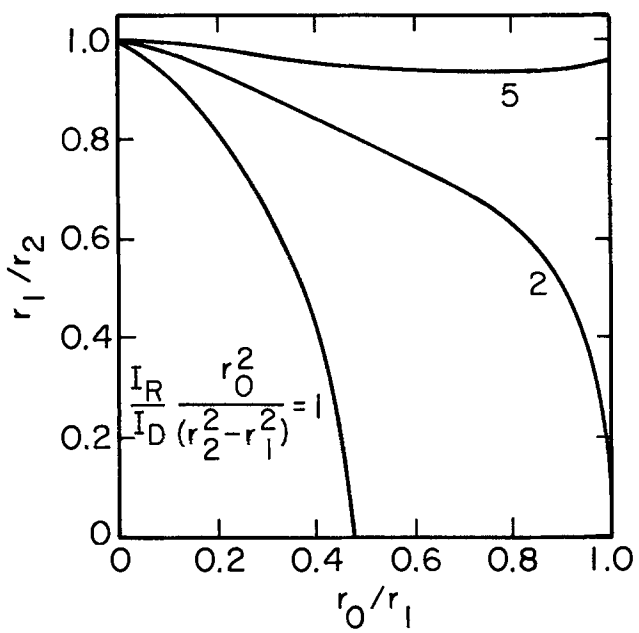

Fig. 1. Design curves for ring-disk electrodes with a given average primary current ratio.

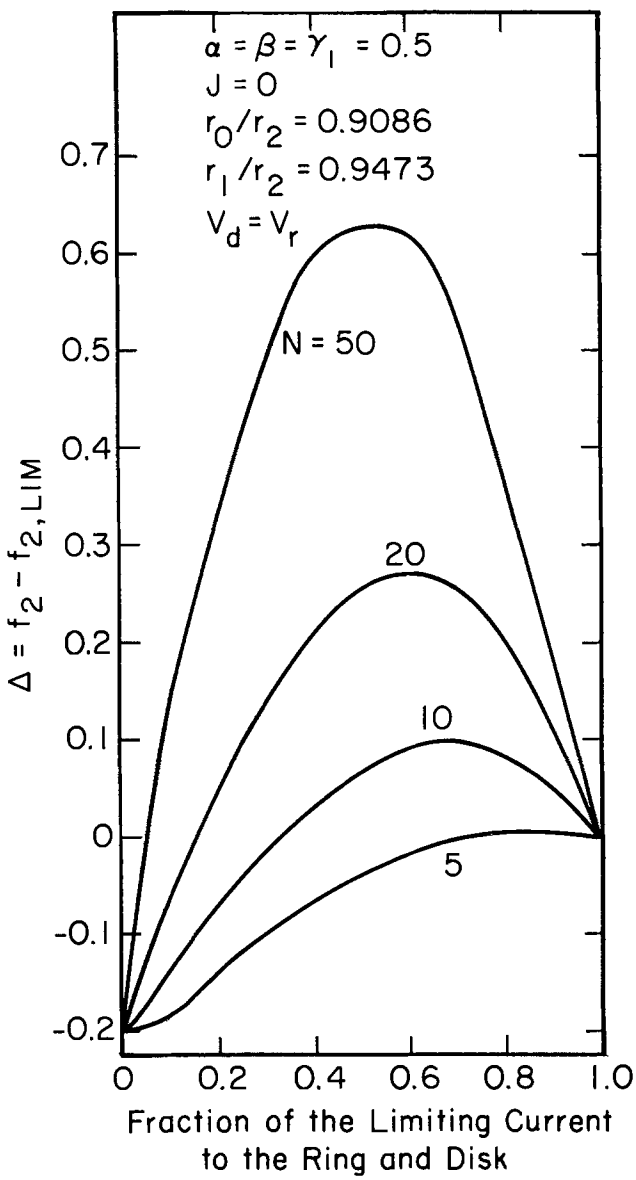

Fig. 2. The variation of Δ calculated for metal deposition from a solution with supporting electrolyte for Tafel kinetics and several stirring rates.

$$\Delta = f_2 - f_{2,\mathrm{LIM}} \qquad [18]$$

then provides the measure of deviation from the limiting distribution.

Results and Discussion

The number of possible combinations of reaction, solution, and electrode parameters is enormous. The discussion is restricted to two electrode geometries, two limiting cases, and the results of an experiment.

Tafel kinetics.—When $|i| >> i_o$, one exponential term in Eq. [5] becomes negligible in comparison to the other. For cathodic current densities, Eq. [5] may then be represented by

$$\eta_s = -\frac{RT}{\beta Z\mathbf{F}}(\ln|i| - \ln i_o) \qquad [19]$$

The other term of Eq. [5] would be retained if the current were anodic.[1] Figure 2 shows the variations of Δ for a ring-disk operated potentiostatically, with V_d set equal to V_r. At low rotation speeds or smaller values of N, little deviation from the limiting current ratios appears until the electrodes are operating appreciably below the limiting current. However, for the higher values of N, there exist large variations in Δ over the entire operating range. At very low currents, all the curves on Fig. 2 come together at $\Delta = -0.205$. Here the Tafel kinetics force the current density to be uniform and equal on the disk and ring electrodes.

Figure 3 gives the values of the throwing power for the same electrode and solution. The effect of N is reflected in the same over-all manner by Δ and by the throwing power. N becomes smaller as the electrical conductivity increases, illustrating the effect of increasing κ_∞ on the throwing power. N is proportional to r_2 and therefore gives a qualitative idea of how the characteristic dimensions of irregularly shaped objects would influence the throwing power of a given plating bath. Another interesting feature is the approximate location of the minimum in the family of throwing power curves. Limits on allowable current densities in a plating situation would be placed on either side of this point to minimize the variation of deposit thickness.

Intermediate kinetics.—The situation in which no single aspect of the concentration or surface overpotential expressions is dominant may be termed intermediate kinetics. For the same electrode used to demonstrate Tafel kinetics, a moderate dimensionless stirring rate N was chosen, and five values of the dimensionless exchange current density J were used to show the effect of concentration and surface overpotential on Δ in Fig. 4 and the throwing power in Fig. 5. When J is small and the reaction is considered slow, the current

[1] Z will be negative for reduction of an anion or oxidation of a cation. In such a case, the words anodic and cathodic should be interchanged in the text.

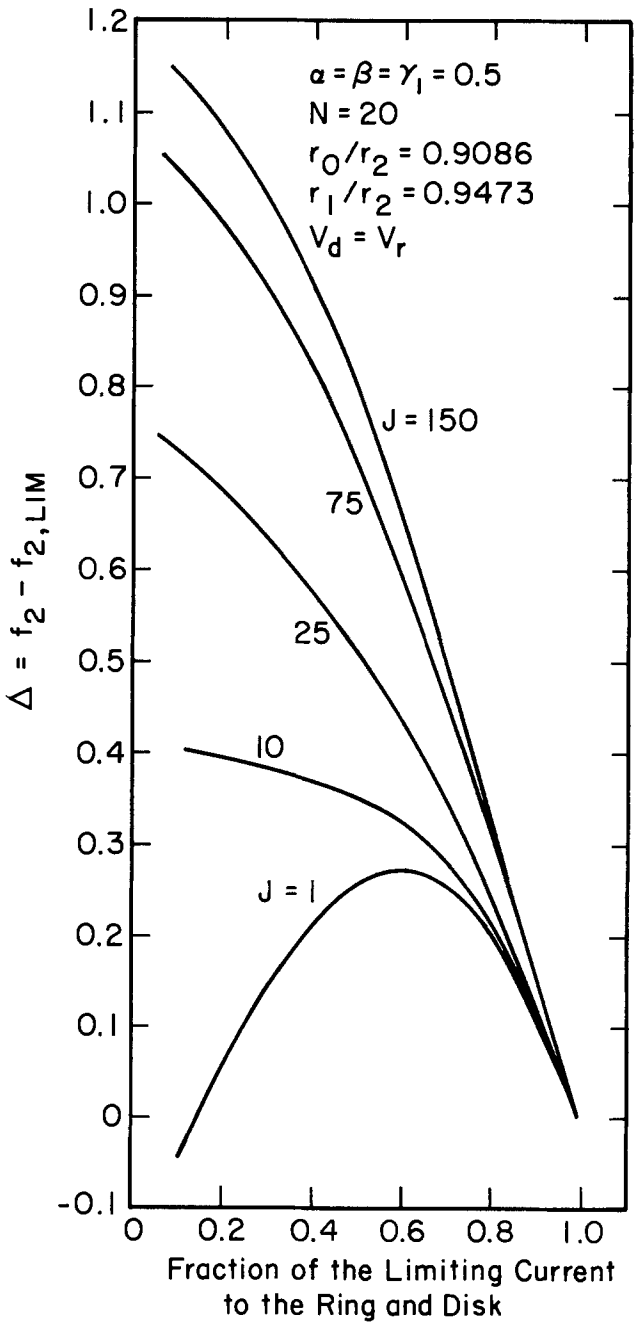

Fig. 4. Computed values of Δ for metal deposition from a solution with supporting electrolyte for a fixed stirring rate and for five values of the dimensionless exchange current density.

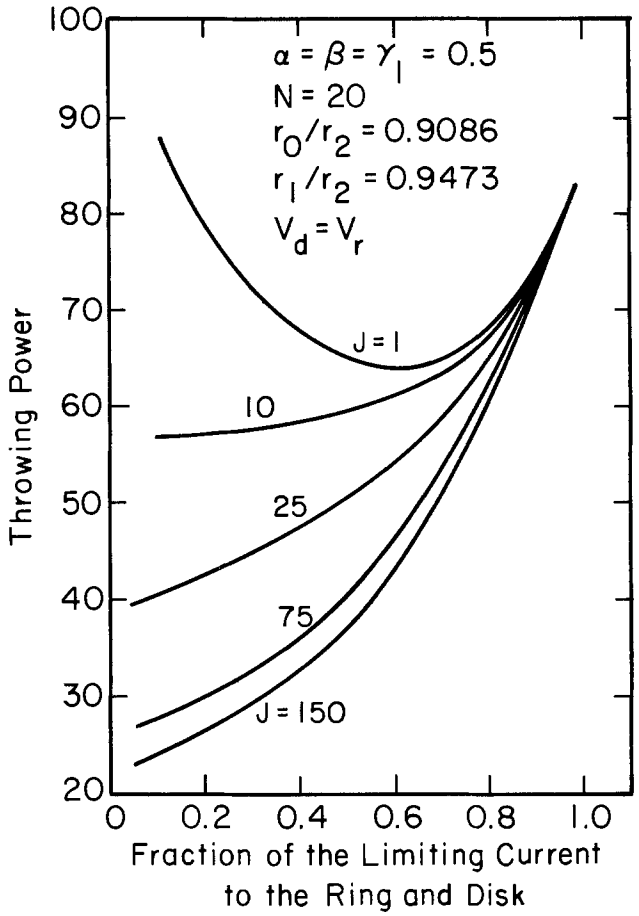

Fig. 5. Computed values of the throwing power for metal deposition from a solution with supporting electrolyte for a fixed stirring rate and for five values of the dimensionless exchange current density.

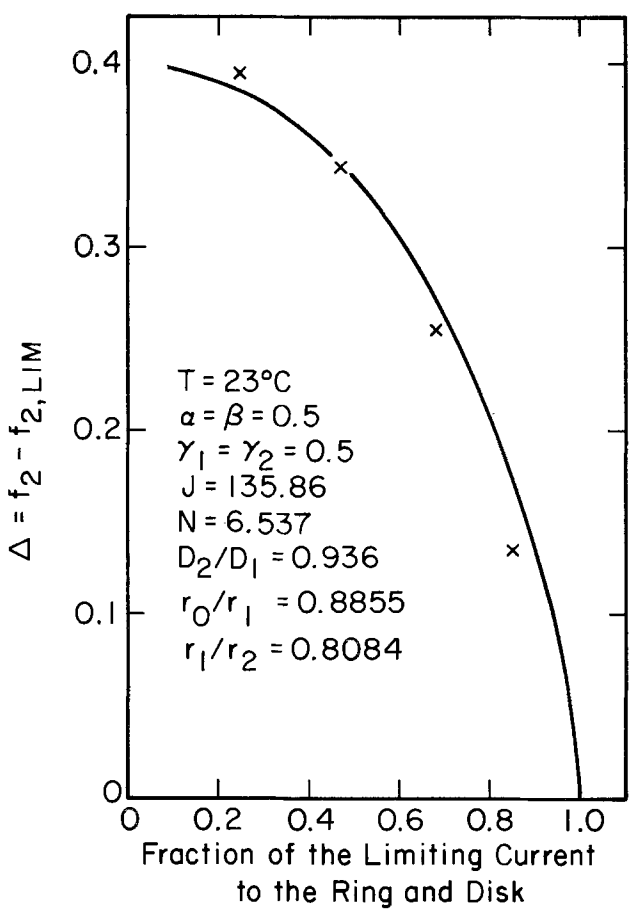

Fig 6. Δ shown as a function of the fraction of the limiting current with $V_d = V_r$. Points are measured and the smooth curve computed for a 1M KNO_3, 0.05M $K_3Fe(CN)_6$, 0.05M $K_4Fe(CN)_6$ solution. Ferrocyanide is the reference species and is being oxidized at the electrodes.

distribution is quite uniform for small fractions of the limiting current. This corresponds to $\Delta = -0.205$ for this geometry. For larger values of J, the surface overpotential becomes less important. The current distribution would approach a primary distribution for smaller values of the average current (and high rotation speeds). This corresponds to $\Delta = 1.977$ and a throwing power of zero for this geometry. The behavior at high average currents is determined more by the effect of mass transfer, and the influence of kinetic parameters decreases.

Comparison with experiment.—The smooth curve in Fig. 6 is the computed variation of Δ for curve A of Fig. 1 in the work of Smryl and Newman (4), and the points are experimentally determined (20). The values of α, β, γ_1, and γ_2 are taken from the literature (21) for the ferricyanide-ferrocyanide redox couple. The value of the exchange current density used to compute J was estimated with Eq. [6] from the experimentally determined value reported by Vetter (22). The conductivity of the bulk solution was determined to be 0.0894 Ω^{-1}-cm^{-1} in our laboratory, thus yielding a somewhat different value of N from that estimated earlier (4). The remaining parameters were measured (20). Good agreement between the computation and the experiment is shown.

Electrochemical Removal of Silver Ions from Photographic Fixing Solutions Using a Porous Flow-Through Electrode

John Van Zee and John Newman*

Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Silver ions were removed from a simulated photographic fixing solution by using a porous flow-through electrode. A feed of 1000 mg/liter of silver was reduced to less than 1 mg/liter in a 5.5 cm thick bed and to less than 10 mg/liter in a 4.0 cm thick bed. The flow rate in both cases was 22 cm^3/min across a superficial area of 61 cm^2. Side reactions reduced the current efficiency to 45% at these low product concentrations. Optimization of incremental power costs and recovered silver value suggests that further reduction of silver concentration is economical.

Motion-picture laboratories remove silver from fixing baths by electrochemical methods because (*i*) the operations can handle large volumes, (*ii*) the fixer can be reused, and (*iii*) the recovered silver is of high purity. Existing electrolytic systems categorized as low current density operations (about 0.1 mA/cm^2) require extensive space to accommodate large volumes of fixing solution. So-called high current density systems (about 10 mA/cm^2) require additional electricity for solution agitation; this agitation is produced by internal paddles, external pumping, or moving electrodes.

Although not specifically investigated here, waste-stream quality standards provide another incentive for silver recovery. Current practice (1) is to dump effluent stream with a silver concentration of up to 100 mg/liter while existing California standards (2) specify 0.02 mg/liter. Hence economical recovery of silver to satisfy this thousandfold discrepancy would be welcome.

The use of porous, fixed, flow-through electrodes for trace metal recovery is suggested by Bennion and Newman (3). The porous electrode provides a large plating area per unit volume with flakes and chips of graphite. A low flow rate allows the solution to be gravity fed. The application of the porous elec-

* Electrochemical Society Active Member.
Key words: waste-water treatment, metal recovery.

trode to silver recovery in motion-picture laboratories realizes the space advantages of high density systems without requiring operating expense for agitation.

Design Problem

It is desirable to maintain the silver concentration of fixing baths below 5000 mg/liter, and many present-day systems are capable of maintaining a concentration of 500 mg/liter. Tailing cells are used to reduce the 500 mg/liter to less than 100 mg/liter in the plant effluent. Thus, a reasonable cell design objective is the reduction of silver ion concentration from 1000 to 10 mg/liter.

Current efficiencies of 75% are considered high in existing operations due to the presence of side reactions. The silver deposition reaction

$$Ag(S_2O_3)_2^{-3} + e^- + 2H^+ \rightarrow 2HS_2O_3^- + Ag \quad [1]$$

must compete with reduction of thiosulfate (4)

$$S_2O_3^{-2} + 8e^- + 8H^+ \rightarrow 2HS^- + 3H_2O \quad [2]$$

which may lead to an alternative mechanism of silver removal

$$HS^- + 2Ag(S_2O_3)_2^{-3} + 3H^+ \rightarrow Ag_2S + 4HS_2O_3^- \quad [3]$$

To reduce the occurrence of the side reactions, the porous electrode is designed for a specified ohmic potential drop in the solution phase. A value of -0.1V is used in the following design calculation. The electrode is designed by using the equations of Bennion and Newman (3) and the parameters in Table I. The Wilson and Geankoplis correlation (5) is used for calculation of the mass-transfer coefficient. The design results are also shown in Table I.

Experimental Equipment and Procedure

The experimental cell used varies only in size from the porous electrode built by Bennion; the bed diameter is 8.8 cm. The cathode was packed with irregularly shaped carbon particles (Union Carbide granules plus powder, GP-22), and the anode was packed with a mixture of carbon and copper powder. Two sheets of Whatman 40 filter paper backed the feed-side Plexiglas plates and facilitated tight packing of the beds.

A saturated calomel cell was used for measurement of the potential between the reduced silver product stream and the cathode (VDP). The circuit consisted of a d-c power supply with the ground attached to the cathode. The power lead went to a 1Ω resistor and then to the cell anode. The potential drop across the resistor was measured and recorded on a strip-chart recorder. The potential drop between the dilute product stream and the cathode (VDP) was measured and recorded on another strip-chart recorder. A multimeter was used to measure the potential drop across the power supply. A digital voltmeter was used to verify and calibrate the recorders and multimeter. The two recorders were used to observe trends and to establish when steady state was attained.

Flow rates of the feed, reduced silver product, and anolyte streams were controlled with needle valves. Float-type glass flowmeters were used to measure relative fluctuations in the flow rate. A graduated cylinder and a stopwatch were used for verification of the reported flow rate. The cathode flow rate was about 99% of the feed flow rate. Flow was induced by gravity. The room temperature fluctuated between 21° and 25°C.

Table I. Sample design calculation

Input parameters		Design results
c_{in} = 1000 mg/liter	ρ = 1.18 g/cm³	v = 7.9 × 10⁻³ cm/sec
c_{out} = 10 mg/liter	D = 10⁻⁵ cm²/sec	L = 1.32 cm
κ_0 = 0.123 mho/cm	μ = 0.018 g/cm-sec	Re = 0.087
ϵ = 0.3	ρ_{Ag} = 10.5 g/cm³	t = 0.7 day
$\Delta\Phi_2$ = −0.1V	M_{Ag} = 107.87 g/mol	k_m = 1.10 × 10⁻³ cm/sec
a = 25 cm⁻¹	Sc = 1525	

Table II. Feed composition

	Grams
Sodium thiosulfate ($Na_2S_2O_3 \cdot 5H_2O$)	20
Sodium bisulfite ($NaHSO_3$)	1
Silver nitrate ($AgNO_3$)	0.16
Sodium bromide (NaBr)	0.13
Water (78.9 ml)	78.7

The feed composition is listed in Table II. Actual fixing baths contain gelatin due to dissolution of film material. If actual bath solutions cause plugging of the porous electrode, it would be necessary to use a filter in the feed line. Nitrate ions, which were introduced with the silver when preparing the simulated photographic fixing solution, are not present in typical commercial fixing baths.

The feed and product concentrations were analyzed with a Perkin Elmer Model 303 atomic absorption spectrophotometer. Concentrations below 20 mg/liter were measured directly. Concentrations above 20 mg/liter were diluted by volume to the 20 mg/liter range. Two samples were analyzed for each run, and the maximum variation was ±3%.

In all experimental runs the cell was oriented with the cathode above the anode. The cell was inverted to change the cathode thickness from 5.5 to 4.0 cm. The cell was inverted after all the initially packed copper powder had been dissolved and the oxidation of thiosulfate ($S_2O_3^{-2}$) to tetrathionate ($S_4O_6^{-2}$) dominated the anode reaction for eight runs. By inverting the cell, the feasibility of a third anode reaction, dissolution of silver metal, was verified.

Results

Figure 1 shows the relationship of total cell current and VDP for the two bed thicknesses. Dilute product concentrations (in milligrams of Ag/liter) are shown below the experimental points. The theoretical limiting current is sketched to illustrate the

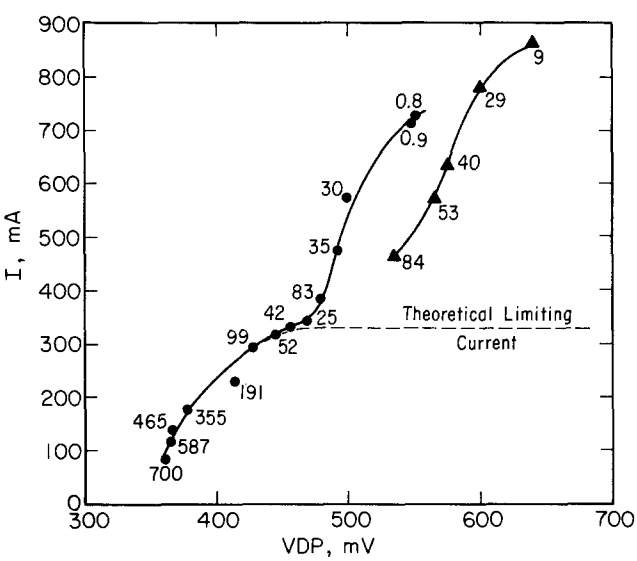

Fig. 1. Current-voltage curves. Superficial electrode area = 61 cm². Flow rate = 22 cm³/min. Electrode thickness: ● = 5.5 cm, ▲ = 4.0 cm. Feed concentration = 1000 mg Ag/liter. Numbers below points are dilute product concentration in milligrams of Ag/liter. VDP is the potential of a saturated calomel cell in the dilute product stream vs. the cathode.

extent of side reactions. The feed concentration increased by 6% due to evaporation losses. Approximately 2 hr were required to reach steady state after each change in the power source potential. Steady state was observed when the total current and VDP remained constant for 1/2 hr.

Discussion

The current-voltage curves for both thicknesses display the same general shape. The large VDP shift between the curves is unexplained at present. The interruption of decreasing dilute product concentrations between VDP of 460 and 490 mV is also unexplained.

The extent of side reactions is shown by the graph of current efficiency *vs.* total current (Fig. 2). (The current required by reaction [1] is calculated from the measured inlet and outlet concentrations of silver and the flow rate. The ratio of this result to the total current is the current efficiency.) The general shape of the graph is expected; that is, current efficiency drops as total current is increased. Current efficiencies greater than 1 may point to inaccuracies in velocity, concentration, or current measurements.

The specific side reactions were not identified; however, no gassing was observed, and hence evolution of hydrogen is doubtful. Reaction [2] has been cited in the literature. The characteristic black suspension of silver sulfide (Ag_2S) was not evident in the dilute product stream. It is possible that Ag_2S was filtered from the dilute product stream by the graphite bed. There was no discernable adverse plugging of the electrode. Another possible side reaction is the reduction of thiosulfate to $S_2O_4^=$.

It is feasible to calculate the superficial area per unit volume, a, by using the correlation of Wilson and Geankoplis, Bennion and Newman's limiting current expression, and the experimental data. With $D = 10^{-5}$ cm²/sec. the value of a ranged from 8 to 13 cm^{-1}. This is about half the value assumed in the design calculation. Another interpretation is that the correlation of Wilson and Geankoplis predicts too high a value of the mass-transfer coefficient, at least for deep beds where aL is greater than 100. The design equations used by Bennion and Newman actually give values of a closer to 25 cm^{-1}.

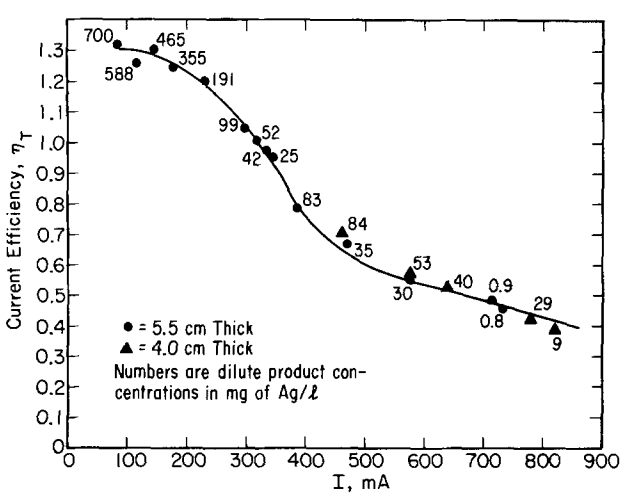

Fig. 2. Current efficiency-total current curves

Optimization.—The presence of nongassing side reactions permits an interesting optimization of the operating current such that incremental power costs are just balanced by the incremental value of recovered silver. The optimum current can be determined by differentiation of the total cost, with the result

$$C_p d(VI) = -C_{Ag} Q d(c_{out}) \quad [4]$$

where C_p = power costs (\$/J), C_{Ag} = silver value (\$/g), Q = flow rate (cm³/sec), VI = power applied to cell (W), and c_{out} = effluent Ag concentration (g/cm³).

The resistance of the cell was on the order of 5Ω; that is, $V = 5I$. An optimum current greater than 2A was determined from the experimental flow rate and typical costs. This optimum indicates that the effluent silver concentration can be economically reduced further despite the low current efficiencies.

Mauscript submitted Nov. 5, 1975; revised manuscript received Nov. 22, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

LIST OF SYMBOLS

a	effective interfacial area of electrode packing per unit volume of electrode, cm^{-1}

Current Distribution on a Continuous Moving Sheet Electrode

K. Viswanathan* and D-T. Chin†

Department of Chemical Engineering, Clarkson College of Technology, Potsdam, New York 13676

ABSTRACT

A theoretical study has been made to characterize the electrochemical behavior of a continuous moving flat surface. The current distribution on the electrode is calculated by taking into account concentration polarization, activation overpotential, and ohmic potential drop in the electrolyte. Numerical results are presented for the Butler-Volmer electrokinetics. It is shown that the current distribution depends on the magnitude of the limiting current. A uniform current distribution can be achieved if the current level is less than 78.5% of the limiting current.

Continuous moving electrodes are used in moving cathode processes such as electrolysis of brine and in electroplating of sheet metals and wires (1). The flow on a continuous moving sheet electrode is of a novel type which has characteristics opposite to the boundary layer on a stationary flat plate (2). The rate of laminar mass transfer to the electrode is proportional to the square root of the Schmidt number instead of a cube root relationship for most known electrolyte flow systems (3). This gives the continuous moving electrodes a higher limiting current density at large Schmidt numbers; at Sc = 1000, for example, the limiting current is enhanced by a factor of $Sc^{1/6} = 3.2$. In this study the nature of a continuous moving sheet electrode is further characterized with a theoretical study. Using the method illustrated by Newman (4), the surface concentration and the potential and current distribution on a continuous moving sheet electrode have been calculated on a digital computer. Numerical results are presented for the Butler-Volmer electrokinetics. This paper describes the details of the study.

Mathematical Analysis

To set up a mathematical model for current distribution we consider one side of a continuous flat sheet electrode which is moving with a constant velocity U_s through an otherwise undisturbed electrolyte as shown in Fig. 1. The velocity of the electrode is high such that the boundary layer approximation can be used to describe the flow of electrolyte near the electrode surface. The counterelectrode is located at a distance b from the moving electrode, and the cell walls are made of an insulation material. To simplify the analysis, we shall make the following assumptions: (*i*) The continuous moving electrode and the counterelectrode are of equal potential bodies; (*ii*) the concentration overpotential and the activation overpotential at the counterelectrode are zero; (*iii*) there is a supporting electrolyte present in the solution so that migration of the reactive ions is negligible; (*iv*) the ohmic potential drop across the concentration boundary layer is negligibly small compared to the ohmic potential drop across the bulk of the electrolyte; (*v*) the electrolyte flow in the vicinity of the moving electrode is laminar in nature; (*vi*) the presence of the cell wall and the counterelectrode does not affect the flow boundary layer on the continuous moving electrode; and (*vii*) the physical properties of the electrolyte are constant. The governing equations describing an electrochemical process at the continuous electrode are

voltage balance

$$E = \eta_a + \eta_{conc} + \phi_{ohm} \qquad [1]$$

Butler-Volmer equation of electrode kinetics

$$i = i_0\left(\frac{C_s}{C_\infty}\right)^\gamma \left[\exp\left(\frac{\alpha n\mathbf{F}}{RT}\eta_a\right) - \exp\left(-\frac{\beta n\mathbf{F}}{RT}\eta_a\right)\right] \qquad [2]$$

concentration overpotential

$$\eta_{conc} = \frac{RT}{n\mathbf{F}} \ln \frac{C_s}{C_\infty} \qquad [3]$$

Here E is the difference between the applied cell voltage and the thermodynamic equilibrium cell voltage, i_0 is the exchange current density based on the bulk concentration of the reacting ion. All the other notations have their usual meanings.

To calculate the surface concentration C_s one needs a convective diffusion equation to describe the transport of the reactive ion from the bulk to the electrode surface

convective diffusion

$$U\frac{\partial C}{\partial x} + V\frac{\partial C}{\partial y} = D\frac{\partial^2 C}{\partial y^2} \qquad [4]$$

The boundary conditions are

$$C = C_\infty \quad \text{at} \quad x = 0 \quad \text{and} \quad y = \infty \qquad [5]$$

$$\frac{\partial C}{\partial y} = \frac{i}{n\mathbf{F}D} \quad \text{at} \quad y = 0 \qquad [6]$$

Here x is the surface distance from the inlet of the continuous moving sheet electrode, y is the perpendicular distance from the electrode surface, U and V are the velocity components of the electrolyte along the x and y directions, respectively. Equations [4]-[6] would give a variable surface concentration along the x direction. The standard procedure for the solution is (*i*) to obtain a solution for the case of a constant surface concentration, *i.e.*, a solution with Eq. [6] replaced with $C = C_s$ at $y = 0$ for all x; and (*ii*) to apply a superposition integral to the resulting equation to obtain a solution for variable surface concentrations. Chin (3)

† Electrochemical Society Active Member.
Key words: convective diffusion, limiting current, electrode kinetics.

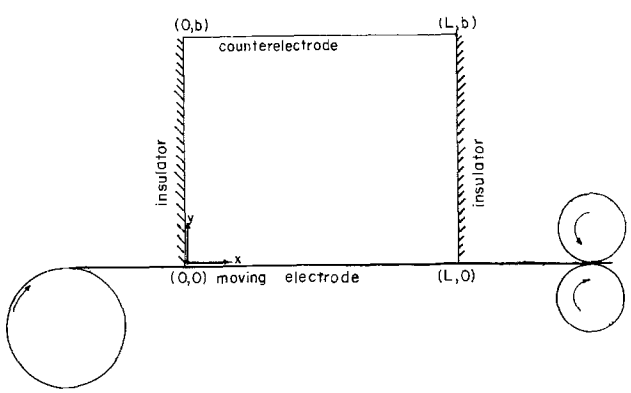

Fig. 1. Schematic diagram of the continuous moving sheet electrode.

has obtained an asymptotic solution of Eq. [4] for the uniform surface concentration conditions. At high Schmidt numbers, his result can be expressed as

$$C = C_\infty + (C_s - C_\infty)\,\mathrm{erfc}\left(\frac{y}{2}\sqrt{\frac{U_s}{Dx}}\right) \qquad [7]$$

(for uniform surface concentration and Sc >> 1) where erfc designates the complementary error function. It is interesting to note that this result coincides with the well-known penetration theory of a falling liquid film (5). By applying Duhamel's superposition integral theorem (6) to Eq. [7], one has a pair of stieltjes integrals

$$i(x) = n\mathbf{F}\sqrt{\frac{U_s D}{\pi}}\int_0^x \left(\frac{dC_s}{dx}\right)_{x=t}\frac{dt}{\sqrt{x-t}} \qquad [8a]$$

or

$$C_s(x) = C_\infty + \frac{1}{n\mathbf{F}\sqrt{\pi U_s D}}\int_0^x i(t)\,\frac{dt}{\sqrt{x-t}} \qquad [8b]$$

(for variable surface concentrations and Sc >> 1). Here i is the local current density at the electrode surface and t is a dummy variable.

In addition, one needs a Laplace equation to calculate the ohmic potential drop in the cell, ϕ_{ohm}

Laplace equation

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} = 0 \qquad [9]$$

The boundary conditions are

$$\left.\begin{aligned} \phi &= 0 && \text{at } y = b \\ \frac{\partial\phi}{\partial x} &= 0 && \text{at } x = 0 \text{ and } x = L \\ \frac{\partial\phi}{\partial y} &= -\frac{i}{\kappa} && \text{at } y = 0 \end{aligned}\right\} \qquad [10]$$

where ϕ is the electric potential in the electrolyte, κ is the electrolyte conductivity, b is the distance between the moving and the counterelectrodes, and L is the length of the moving electrode inside the cell. It should be noted that the boundary conditions are so chosen that ϕ_{ohm} is equal to $\phi(x, 0)$. Equations [9] and [10] have been solved with the method of separation of variables. The solution for the ohmic potential drop across the cell can be expressed in terms of a Fourier cosine series

$$\phi_{ohm}(x) = \frac{b}{L\kappa}\int_0^L i(t)\,dt + \sum_{m=1}^{\infty}\frac{2}{m\pi\kappa}\tanh\frac{m\pi b}{L}\cos\frac{m\pi x}{L}\int_0^L i(t)\cos\frac{m\pi t}{L}\,dt \qquad [11]$$

We now have five equations to describe the electrochemical reaction at the continuous moving sheet electrode. They are Eq. [1], [2], [3], [8], and [11]. These equations are strongly coupled and simultaneous solution is required to find the five unknowns, *i.e.*, the activation overpotential η_a, the concentration overpotential η_{conc}, the ohmic potential drop ϕ_{ohm}, the surface concentration C_s,and the local current density at the electrode i. In order to obtain a more generalized solution and to reduce the number of parameters for the calculation, we introduce the following dimensionless quantities

$$X = x/L; \qquad b^* = b/L; \qquad C_s^* = C_s/C_\infty$$

$$\eta_a^* = \frac{n\mathbf{F}}{RT}\eta_a; \quad \eta_{conc}^* = \frac{n\mathbf{F}}{RT}\eta_{conc}; \quad \phi_{ohm}^* = \frac{n\mathbf{F}}{RT}\phi_{ohm}$$

$$E^* = \frac{n\mathbf{F}}{RT}E; \qquad i^* = \frac{n\mathbf{F}}{RT}\frac{L}{\kappa}i \qquad [12]$$

Substituting Eq. [12] into Eq. [1], [2], [3], [8], and [11] we have

voltage balance

$$E^* = \eta_a^* + \eta_{conc}^* + \phi_{ohm}^* \qquad [13]$$

Butler-Volmer's rate expression

$$i^* = \xi C_s^{*\gamma}[\exp(\alpha\eta_a^*) - \exp(-\beta\eta_a^*] \qquad [14]$$

concentration overpotential

$$\eta_{conc}^* = \ln C_s^* \qquad [15]$$

surface concentration

$$i^* = N\int_0^X \left(\frac{dC_s^*}{dX}\right)_{X=t}\frac{dt}{\sqrt{X-t}} \qquad [16]$$

ohmic potential drop

$$\phi_{ohm}^* = b^*\int_0^1 i^* dt + \sum_{m=1}^{\infty}\frac{2}{m\pi}\tanh(m\pi b^*)\cos(m\pi X)\int_0^1 i^*\cos(m\pi t)\,dt \qquad [17]$$

Here t is a dummy variable. The transfer coefficients α and β are usually equal to 0.5. For the first-order electrochemical reactions the parameter γ is equal to 0.5. There are two significant parameters in the above equations; they are

average dimensionless limiting current density

$$N = \frac{n^2\mathbf{F}^2 DC_\infty}{RT\kappa\sqrt{\pi}}\sqrt{\mathrm{Re_L Sc}} = -\frac{1}{2}\int_0^1 i_{lim}^*\,dX \qquad [18]$$

dimensionless exchange current density

$$\xi = \frac{n\mathbf{F}L}{RT\kappa}i_o \qquad [19]$$

where $\mathrm{Re_L} = U_s L/\nu$ and $\mathrm{Sc} = \nu/D$.

The average limiting current density N represents the ratio of ohmic potential drop to the concentration overpotential at the electrode. A large value of N implies that the ohmic resistance tends to be the controlling factor for the current distribution. For small values of N, the concentration overpotential is large and the mass transfer tends to be the rate-limiting step of the over-all process. The dimensionless exchange current density ξ, on the other hand, represents the ratio of the ohmic potential drop to the activation overpotential. When both N and ξ approach infinity, one obtains the geometrically dependent primary current distribution.

Numerical Results and Discussion

Using the method illustrated by Newman (4), we have solved Eq. [13]-[17] numerically on an IBM 360/44 digital computer for the unknowns η_a^*, η_{conc}^*, ϕ_{ohm}^*, C_s^*, and i^*. We considered a simple first-order cathodic reaction with $\alpha = \beta = \gamma = 0.5$.

Figures 2 and 3 show the current and the surface concentration distributions for various current levels at the leading edge for $N = 50$, $\xi = 1$, and $b^* = 1$. The vertical axis in Fig. 2 is the local current density divided by the geometric average limiting current density at the electrode. The horizontal axis is the dimensionless surface distance from the entrance point of the continuous moving electrode. The average current density of these curves is also shown in the figure. It is seen that at a low current level of $i/(i_{lim})_{avg} = 0.096$, the current profile is almost flat. This is because the concentration polarization is small, and one has a secondary current distribution which is uniform for this geometry. As the average current density increases, the profile has a pronounced steep region near the leading ($X = 0$) and the trailing ($X = 1$) edges. The current density is highest at the leading edge where the concentration boundary layer is thin and the rate of mass

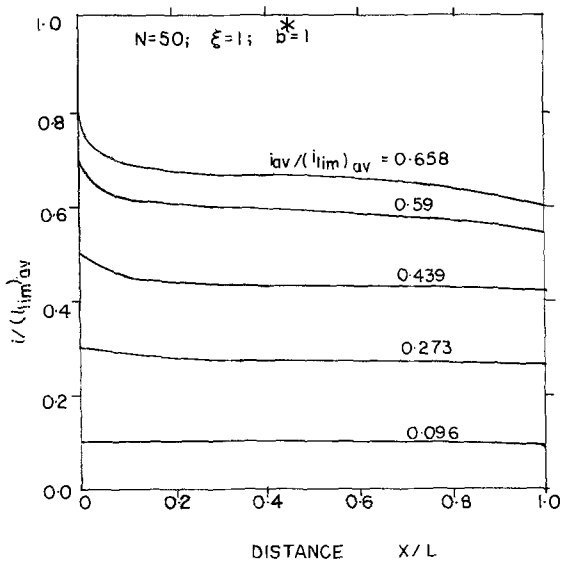

Fig. 2. Current distribution for $N = 50$; $\xi = 1$; and $b^* = 1$ at various specified current levels.

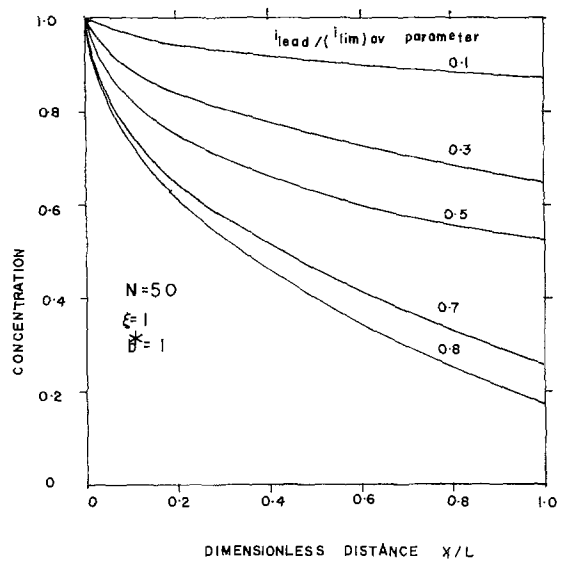

Fig. 3. Surface concentration distribution for $N = 50$; $\xi = 1$; $b^* = 1$ at various specified current levels.

transfer is high. At the trailing edge, the effect of concentration polarization is important, and the current density becomes smaller than the average value. Figure 3 shows that the surface concentration is equal to the bulk concentration at the leading edge and decreases sharply with increasing distance along the electrode surface. As expected, the surface concentration distribution is most uniform for the smallest current level.

Figure 4 shows the effect of N on the current distribution for $\xi = 100$, $i(0)/i(_{\text{lim}})_{\text{avg}} = 0.8$, and $b^* = 1$. Also shown in the figure is a limiting current curve designated by $i_{\text{avg}}/(i_{\text{lim}})_{\text{avg}} = 1$. It is interesting to note that for large values of N, the current densities exceed the limiting current density locally near the trailing edge. The same phenomena is also reported for the rotating spherical electrode (7). As the value of N increases, the mass transfer proceeds faster, and the current distribution becomes more uniform.

For this geometry, the primary current distribution is uniform; the secondary current distribution which is obtained by letting $N \to \infty$ is also uniform. As a consequence, the dimensionless exchange current density ξ, is not an important parameter. Our calculation for different values of ξ ranging from 0.0001 to 100 in-

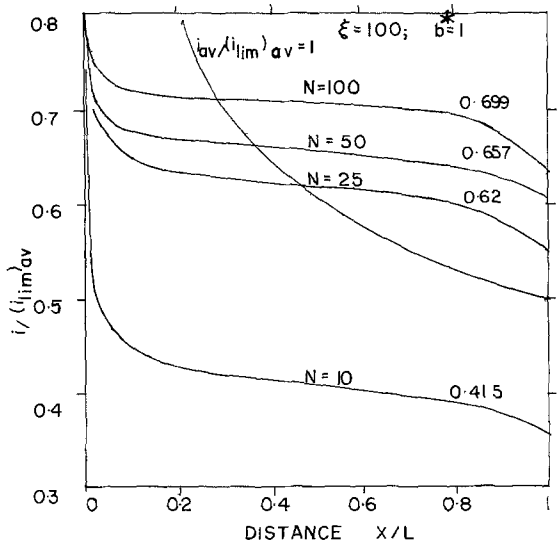

Fig. 4. Current distribution for $\xi = 100$ and $b^* = 1$ for various values of N when $i_{\text{leading}}/(i_{\text{lim}})_{\text{avg}}$ was set equal to 0.8.

dicates that the current distribution is virtually independent of ξ at $N = 100$. For smaller values of N, the effect of ξ is greater; in general, the smaller the value of ξ, the more uniform is the current distribution. The effect of electrode spacing on the current distribution at the continuous moving electrode is shown in Fig. 5. It is seen that the current density becomes more uniform as the value of b^* increases. This is because the ohmic drop in the solution tends to be the dominant term when the electrode spacing is large. The effect is more pronounced when N is large. For smaller values of N, the process tends to be mass transfer limited and the concentration overpotential becomes more important.

Conditions for uniform current distributions.—The results shown in Fig. 4 suggest that a uniform current

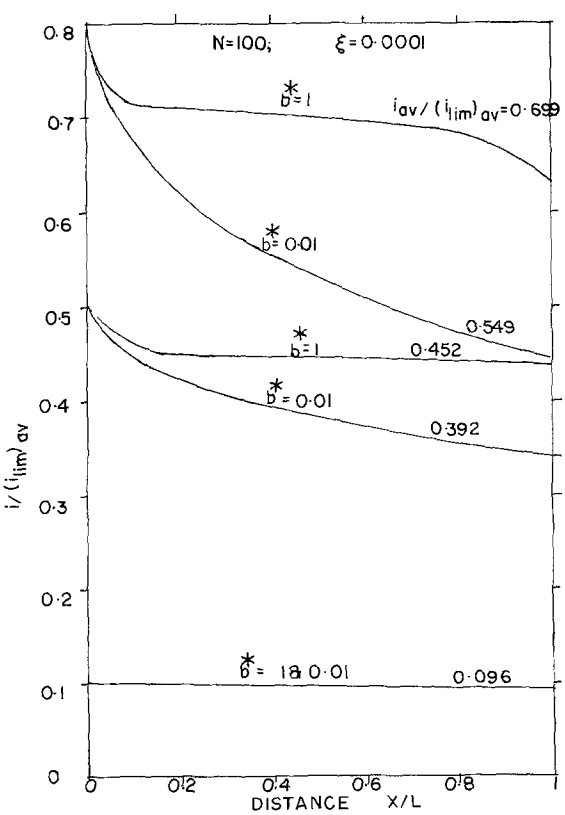

Fig. 5. Effect of electrode spacing on current distributions

distribution can be achieved at the continuous moving sheet electrode when the values of N are large. It can be shown from Eq. [8b] that at a constant flux condition, the surface concentration is described by the following relation

$$C_s^* = 1 - \frac{4}{\pi} \frac{i^*}{(i_{lim}^*)_{avg}} \sqrt{X} \qquad [20]$$

Here $(i_{lim}^*)_{avg}$ is the geometric average of the dimensionless limiting current density; according to Eq. [18], it is numerically equal to $-2N$. Since C_s^* cannot have negative values, there is a limited distance from the leading edge over which i^* can be maintained at a constant value. Letting $C_s^* = 0$ at $X = 1$, we have

$$\frac{i^*}{(i_{lim}^*)_{avg}} \leq \frac{\pi}{4} = 0.7854 \qquad [21]$$

Equation [21] suggests the possibility of attaining a uniform current flux if $i^*/(i_{lim}^*)_{avg} \leq 0.7854$. If this condition is not met, the surface concentration C_s^* becomes zero at a certain value of $X = X_c$, beyond which the current is limited by mass transfer due to zero concentration at the surface. The value of X_c can be determined by letting $C_s^* = 0$, in Eq. [20], and solving for X. To calculate the current distribution in the region between $X = X_c$ and $X = 1$, we evaluate dC_s^*/dX from Eq. [20], substituting it into Eq. [16], and evaluate the integral for $X \geq X_c$. The result can be arranged to give

$$i^*(X) = \frac{2}{\pi} i^*(X_c) \sin^{-1} \sqrt{\frac{X_c}{X}} \qquad [22]$$

(for $X_c \leq X \leq 1$). Numerical results calculated from Eq. [22] are plotted in Fig. 6 for various constant current levels. It is seen that the uniform current distribution cannot be achieved if the current level is greater than 78.5% of the average limiting current density. It should be noted that the results in Fig. 6 are given for $N \to \infty$. Most industrial electrochemical processes are carried out under the condition of large N. This condition is imposed by a low electrolytic conductivity

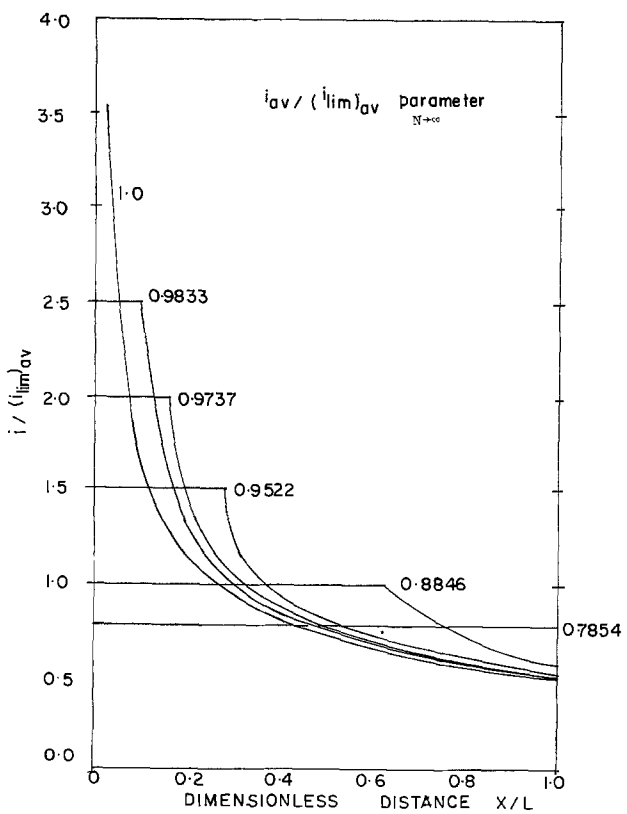

Fig. 6. Current distribution for high values of N

and a high limiting current density. A typical acid copper sulfate bath, for instance, contains 0.75M $CuSO_4$ and 1M H_2SO_4 with a specific conductivity of 0.4 mho/cm (8) at room temperature. The diffusivity of cupric ion in dilute sulfuric acid has been found to be 5.2×10^{-6} cm²/sec (9) at 25°C, giving the Schmidt number of the system equal to 2000. Thus at an operating Reynolds number of 10^5 (corresponding to a typical cell of 4m long and a sheet velocity of 0.026 m/sec), the value of N for the copper deposition reaction on the continuous moving electrode can be calculated to be 1610 at 25°C. This is a large value and can be considered to be close to infinity. Our calculation indicates that Eq. [20]-[22] give a good approximation for the system with N greater than 100.

Conclusions

A theoretical study has been made for the current distribution on a continuous moving sheet electrode. Numerical results are presented for the first-order electrokinetics. It is shown that the current distribution depends strongly on the magnitude of the limiting current. A uniform current distribution can be achieved if the average current density at the electrode is less than 78.5% of the average limiting current density.

Mass Transfer to a Continuous Moving Surface

D-T. Chin,* K. Viswanathan,† and R. Gutowski

Department of Chemical Engineering, Clarkson College of Technology, Potsdam, New York 13676

ABSTRACT

Asymptotic correlations are presented for the rate of mass transfer to a continuous moving flat surface in laminar flow. A laboratory cell has been developed to test the theory for uniform surface concentrations. The limiting current measurement was carried out for the reduction of ferricyanide ion over the range of $1,500 < Re < 70,000$ and $1,800 < Sc < 29,300$. The experimental value agrees well with the theory for $Pe < 1.5 \times 10^8$.

The continuous moving surface is widely used in the manufacture of sheet glasses, fabrication of steel sheets, extrusion of thin films and fibers, drying of papers, and electroplating of metallic sheets and wires. Sakiadis (1-3) and Koldenhof (4) calculated velocity profiles for the system. Numerical solutions of laminar thermal boundary layers were obtained by Tsou *et al.* (5), Erickson *et al.* (6), and Rhodes and Kaminer (7) for continuous moving flat plate, and by Rotte and Beek (8) for continuous cylinders. A mass transfer correlation was obtained by Chin (9) for the condition of constant surface concentrations. For electrochemical applications, mass transfer under a condition of varying surface concentrations has been treated numerically by Viswanathan and Chin (10) for a continuous flat surface and by Alkire and Varjian (11) for a continuous resistive wire. The theory suggests that the rate of mass transfer is proportional to the square root of the Schmidt number when the value of the Schmidt number is large. This is in contrast to the cube root relationship for the other geometries such as pipe flow, flat plate, and rotating disk (12).

There have been few heat and mass transfer experiments reported for the continuous moving surface. Griffin and Throne (13) used the Schmidt shadowgraph method to observe the thermal boundary layer on a continuous moving flat belt in ambient air. Their results indicate that the rate of heat transfer is proportional to $Pr^{1/3}$ when the Prandtl number is in the neighborhood of 0.7. Tvarusko (14) and Rott, Tummers, and Dekker (15) have made the limiting current measurements for the continuous moving cylindrical wire. Tvarusko's result for the deposition of copper from an acid cupric sulfate solution is an order smaller than the theory prediction. Rott *et al.* measured the limiting current for the reduction of ferricyanide at two Schmidt numbers: $Sc = 700$ and $Sc = 1800$. Their result indicates that the theory for the continuous flat plate is also valid for the continuous cylinders, if the wire diameter is large. For smaller size wires, their data are 10-15% lower than the theory prediction.

In this study, we have extended Chin's asymptotic correlation (9) to the case of a constant flux at the surface. This condition is prevalent at the surface of a continuous moving sheet electrode if the reaction rate is below 78.5% of the limiting current (10). It is also of interest to heat transfer engineers. Experimentally, we developed a laboratory cell to determine the rate of mass transfer to the continuous moving sheet electrode at a constant surface concentration. The limiting current is measured for the reduction of ferricyanide ion over a wide range of Schmidt numbers from 1,800 to 29,000. The data agree with the laminar theory for $Pe < 1.5 \times 10^8$. This paper summarizes the results of these studies.

Analysis

Under the steady-state conditions, the convective diffusion equation takes the form

* Electrochemical Society Active Member.
† Electrochemical Society Student Member.
Key words: convective diffusion, limiting current, asymptotic analysis.

$$U\frac{\partial C}{\partial x}+V\frac{\partial C}{\partial y}=D\frac{\partial^2 C}{\partial y^2} \quad [1]$$

in the laminar boundary layer of a continuous moving flat plate, where x is the axial distance from the leading edge of the boundary layer, y is the perpendicular distance from the continuous surface, and U and V are the velocity components of the fluid along the x and y directions, respectively. For the case of a constant surface concentration, Chin (9) has made a curve fitting of Sakiadis' (2) tabulated stream function and substituted it into Eq. [1] to obtain a mass transfer correlation. His results can be summarized as

$$\mathrm{Sh}=\mathrm{Re}^{1/2}\mathrm{Sc}^{1/2}\left(0.56419-\frac{0.094167}{\mathrm{Sc}^{1/2}}-\frac{0.030573}{\mathrm{Sc}}+\frac{0.0035082}{\mathrm{Sc}^{3/2}}\right) \quad [2]$$

(uniform surface concentration)

For mass transfer under the uniform flux at the wall, Eq. [1] may be reduced to an ordinary differential equation with similarity transformations

$$\frac{d^2\phi}{d\eta^2}+\frac{1}{2}\mathrm{Sc}\left[f(\eta)\frac{d\phi}{d\eta}-f'(\eta)\phi\right]=0 \quad [3]$$

$$\phi'(0)=-1 \quad [4]$$

$$\phi(\infty)=0$$

where

$$\phi=\frac{(C-C_\infty)\sqrt{\frac{U_w x}{\nu}}}{\frac{j_w x}{D}} \quad [5]$$

$$\eta=y\sqrt{\frac{U_w}{\nu x}} \quad [6]$$

$$\frac{df(\eta)}{d\eta}=f'(\eta)=\frac{U}{U_w} \quad [7]$$

The stream functions $f(\eta)$ can be represented by the following relation (9)

$$f(\eta)=1.61605[1-e^{-\eta}(1+0.381207\eta+0.0185019\eta^2-0.00543507\eta^3)] \quad [8]$$

To obtain an analytical solution for Eq. [3] and [4], we assume that the dimensionless concentration, ϕ, can be expanded in an asymptotic series of Sc

$$\phi=\mathrm{Sc}^{1/2}\phi_0(\xi)+\phi_1(\xi)+\frac{1}{\mathrm{Sc}^{1/2}}\phi_2(\xi)+\frac{1}{\mathrm{Sc}}\phi_3(\xi)+\cdots \quad (\mathrm{Sc}\gg 1) \quad [9]$$

where

$$\xi=\mathrm{Sc}^{1/2}\eta=y\sqrt{\frac{U_w}{Dx}} \quad [10]$$

Substituting Eq. [8]-[10] into Eq. [3], expanding the functions $f(\eta)$ and $f'(\eta)$ in Taylor series, and equating the terms having the same power of Sc, we have

$$\frac{d^2\phi_0}{d\xi^2}+\frac{1}{2}\xi\frac{d\phi_0}{d\xi}-\frac{1}{2}\phi_0=0 \quad [11]$$

$$\frac{d^2\phi_1}{d\xi^2}+\frac{1}{2}\xi\frac{d\phi_1}{d\xi}-\frac{1}{2}\phi_1=0.113938\xi^2\frac{d\phi_0}{d\xi}-0.221854\phi_0 \quad [12]$$

$$\frac{d^2\phi_2}{d\xi^2}+\frac{1}{2}\xi\frac{d\phi_2}{d\xi}-\frac{1}{2}\phi_2=0.113938\xi^2\frac{d\phi_1}{d\xi}-0.221854\phi_1 \quad [13]$$

$$\frac{d^2\phi_3}{d\xi^2}+\frac{1}{2}\xi\frac{d\phi_3}{d\xi}-\frac{1}{2}\phi_3=0.113938\xi^2\frac{d\phi_2}{d\xi}-0.221854\phi_2-0.00580312\xi^4\frac{d\phi_0}{d\xi}+0.0232125\xi^3\phi_0 \quad [14]$$

$$\left.\begin{aligned}\phi_0'(0)=-1,\ \phi_1'(0)=\phi_2'(0)=\phi_3'(0)=0\\ \phi_0(\infty)=\phi_1(\infty)=\phi_2(\infty)=\phi_3(\infty)=0\end{aligned}\right\} \quad [15]$$

Equations [10]-[14] have been integrated numerically on a digital computer. The results for the local mass transfer coefficient at the wall may be given as

$$\mathrm{Sh}=\frac{\mathrm{Re}^{1/2}\mathrm{Sc}^{1/2}}{1.12838+\frac{0.135623}{\mathrm{Sc}^{1/2}}+\frac{0.0530111}{\mathrm{Sc}}+\frac{0.0117658}{\mathrm{Sc}^{3/2}}} \quad [16]$$

(uniform wall flux)

where Sh and Re are the local Sherwood and the Reynolds numbers, respectively, based on the distance from the leading edge of the boundary layer.

Numerical solutions of thermal boundary layers have been obtained by Tsou *et al.* (5) and Rhodes and Kaminer (7) for laminar flow on a continuous flat surface. Figure 1 is a comparison between the present results and those of the previous computations. The asymptotic results of Eq. [2] and [16] are plotted in the figure $(\mathrm{Sh}/(\mathrm{ReSc})^{1/2}$ *vs.* Sc) as the solid curves; the dashed lines are the numerical solution. It is seen that the agreement between the solutions is excellent except in the region of low Schmidt numbers. Although the present analysis is based upon $\mathrm{Sc}\gg 1$, the theory does not deviate from the numerical solution until the Prandtl number becomes less than 0.7. At Sc = 0.7, the difference between the two solutions is less than 0.8%.

Experimental

At large Schmidt numbers, Eq. [2] can be integrated to give the average Sherwood number

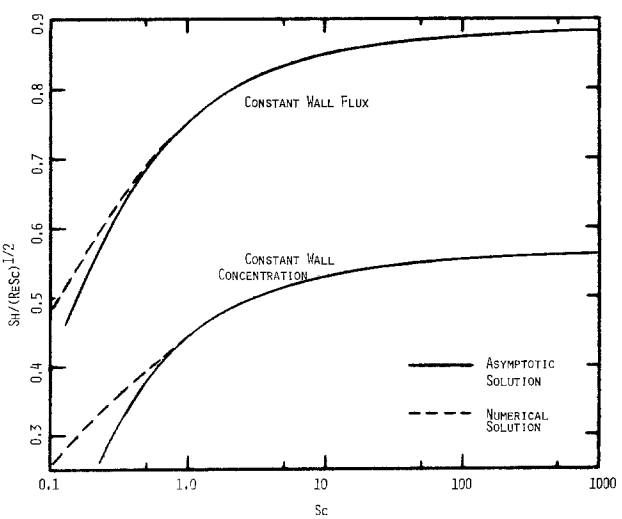

Fig. 1. A comparison between the asymptotic results and those of the numerical solutions.

$$Sh_{avg} = \left(\frac{Kx}{D}\right) = 1.128 Re^{1/2} Sc^{1/2} \quad (\text{for } Sc >> 1) \text{ [17]}$$

Here K is the geometrical average mass transfer coefficient; it is related to the average limiting current density by

$$K = \frac{(i_{lim})_{avg}}{nFC_\infty} \quad [18]$$

In this study, the square root dependence of the Schmidt number has been further tested over a wider range of Schmidt numbers. We used a rotating cylinder to simulate the flow over the continuous moving surface. As shown in Fig. 2B, the working electrode was a metallic cylinder rotating inside a cylindrical container and against a stationary skimmer plate made of an insulation material. The flow near the inner cylinder is similar to that induced by the continuous moving surface. The effect of curvature can be neglected if the cylinder diameter is much greater than the thickness of the concentration boundary layer. Such a system has been used successfully by Tsou, Sparrow, and Goldstein (5) to determine the thermal boundary layer and the velocity profile on the continuous moving surface. The rotating bipolar electrode recently developed by Nadebaum and Fahidy (16) also has a similar arrangement. Their results indicate that the rate of mass transfer is enhanced by the presence of the skimmer plate.

Figure 2A is a schematic diagram of our experimental setup. The working electrode was a piece of copper tubing, 5.08 cm OD and 2.82 cm high, embedded on a Teflon rod of the same diameter. The Teflon rod was placed vertically inside a cylindrical Plexiglas cell container of 19 cm ID and 18 cm deep. It was held by two ball bearings, one on the top plate and the other on the bottom plate of the container, which permitted the rod to rotate smoothly without oscillation. The top of the Teflon rod was attached to a brass shaft-timing pulley assembly and powered with a d-c motor (Minarik 3/4-56C). The electric contact to the working electrode was made by two carbon brushes as shown in the figure. Within the cell container, a spring-loaded Teflon skimmer plate of 1.3 cm thick and 18 cm high, was fastened on the container wall. The skimmer pressed tightly against the Teflon rod and the working electrode while in operation. The counterelectrode was a stainless steel screen located at the container wall; it had a surface area much greater than the working electrode. A saturated calomel electrode inserted through a hole on the top plate into the cell container was used as the reference electrode.

The system was originally designed to measure the limiting current for the reduction of cupric ion to copper at the working electrode, with a copper plate of a large surface area used as the anode. The subsequent experiments with a solution containing 1.5M H_2SO_4 and 0.05M $CuSO_4$ were not successful. The reproducibility for the limiting current measurements was very poor. A careful examination revealed that the copper deposited at the limiting current densities gave a rough coating to the working electrode, which in turn scraped off Teflon particles when rotating against the Teflon skimmer plate. Thus the surface of the working electrode became contaminated, and no accurate measurement was possible.

A ferricyanide-ferrocyanide system with sodium sulfate as the supporting electrolyte was found satisfactory for the limiting current measurement. The reaction at the working electrode was the reduction of ferricyanide to ferrocyanide ions. It was found that a prolonged exposure of the copper working electrode to the solution leads to the corrosion of copper with the formation of brown precipitates. The problem was alleviated by making the solution slightly alkaline. A typical solution used for the experiments was: potassium ferricyanide, 0.01M; potassium ferrocyanide, 0.01M; sodium sulfate, 0.5M; sodium hydroxide, 0.01M; glycerol, 0-5.1M; kinematic viscosity, 0.00983-0.0333 cm/sec; and diffusivity of ferricyanide ion, 5.40-1.139 $\times 10^{-6}$ cm^2/sec. To change the Schmidt number of the system, glycerol was added to the solution to increase the solution viscosity and to decrease the diffusivity of ferricyanide ion. The concentration of glycerol was varied from 0 to 5M; this covered the range of the Schmidt numbers from 1,800 to 30,000 at room temperatures. If the concentration of sodium hydroxide was too high, the copper electrode would become black due to the formation of copper oxide on the electrode surface; also glycerol would react with ferricyanide ions. With 0.01M sodium hydroxide, there was no change of ferricyanide concentration during the run.

For each run the concentration of ferricyanide ion was determined with an iodometric titration. The solution viscosity was measured with an Ostwald viscometer, and the density with a specific gravity bottle. A rotating disk electrode was used to determine the diffusivity of ferricyanide ions. The limiting current measurement was performed with a Wenking HP 72 potentiostat. All the runs were made at a constant room temperature of 22°C.

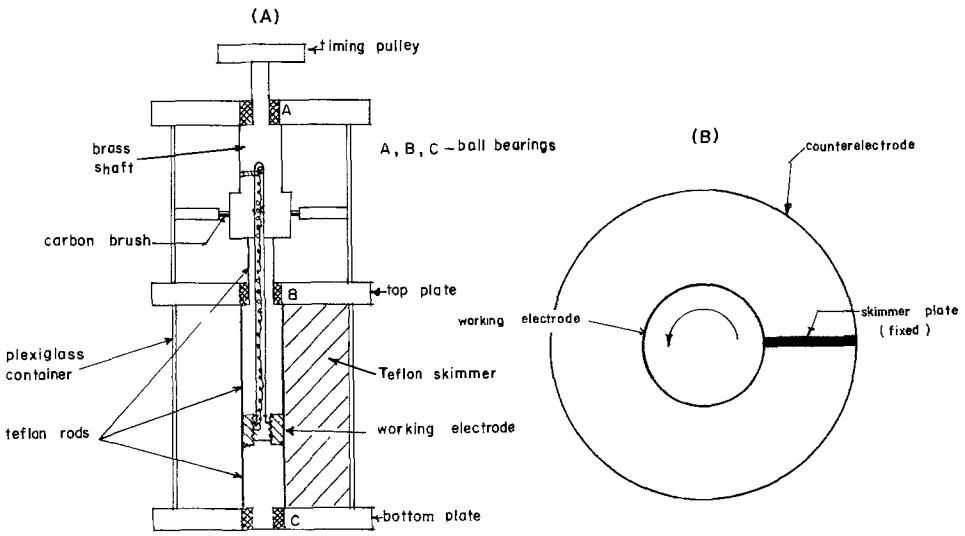

Fig. 2. Schematic diagram of the experimental apparatus.

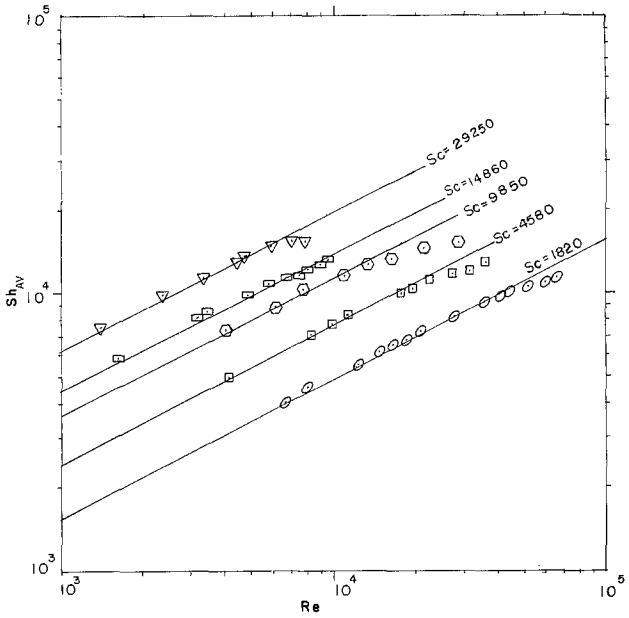

Fig. 3. Results of the limiting current measurement presented in the form of Sh_{avg} *vs.* Re.

Results and Discussion

The results of the limiting current measurements are given in Fig. 3, where the average Sherwood number is plotted against the Reynolds number in a log-log scale for five different Schmidt numbers. For each Schmidt number, the data exhibit a linear relation in the low Reynolds number region with a slope equal to one-half. The data deviate from the linear portion at higher Re. The point of deviation depends on the Schmidt number. The higher the Schmidt number, the earlier is the deviation.

In accordance with Eq. [17], these data are replotted logarithmically in Fig. 4 in the forms of Sh *vs.* Pe. Here the Peclet number, Pe, is the product of the Reynolds number and the Schmidt number. In this way, all the data points as represented by various hollow symbols converge into a single curve. The solid line in the figure is the theoretical prediction as calculated from Eq. [17]. The points of deviation from the theory for various Schmidt numbers also converge into a common point; it takes place approximately at Pe = 1.5×10^8. The agreement with the theory in the linear portion is found to be better than 97%. For comparison, the data of Rott *et al.* (15) obtained with the continuous cylindrical wires are also plotted in the figure as the solid dots. It is seen that their data continue to agree with the theory for Pe greater than 1.5×10^8.

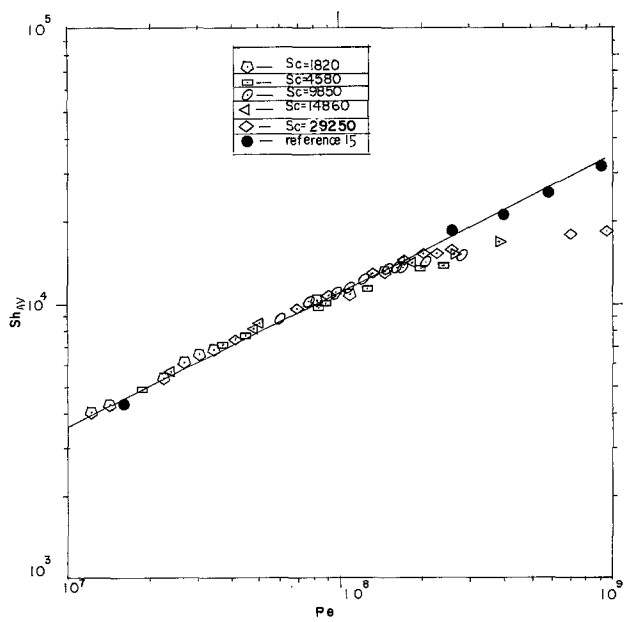

Fig. 4. Comparison with the laminar mass transfer theory. The solid line in the figure is the theory prediction of Eq. [17].

It is interesting to note that for the Peclet number greater than 1.5×10^8, the present experimental mass transfer rates are consistently less than the theory prediction. If the deviation was caused by the transition from laminar to turbulent flow, one would expect the experimental points lying above the laminar theory. Also, the point of deviation should occur at a fixed critical Reynolds number, not the Peclet number. If this was due to the effect of the surface curvature of the experimental device, one would expect that the disagreement takes place in the region of low Peclet numbers not at high Peclet numbers. This is because the thickness of the concentration boundary layer decreases with increasing Peclet number, and the effect of surface curvature is greater if the boundary layer is thick. We exclude the possibility that this might be caused by the chemical nature of the redox reaction or passivation of the copper working electrode. It was found that in the flatten region of Fig. 4, the polarization curves were well behaved and had clear-cut limiting current plateaus for the reduction of ferricyanide ions. One possible explanation is that according to the theory, the thickness of the concentration boundary layer is inversely proportional to the square root of the Peclet number

$$\delta = \frac{1.77x}{\sqrt{\mathrm{ReSc}}} = \frac{1.77x}{\sqrt{\mathrm{Pe}}} \qquad [19]$$

Here δ is the local thickness of the Nernst diffusion layer. The concentration boundary layer at the trailing edge would become thinner and thinner as the Peclet number increased. Eventually, the thickness became smaller than the physical gap between the working electrode and the Teflon skimmer. When this happened, the concentration boundary layer at the trailing edge would be carried by the rotating copper cylinder across the gap to the leading edge of the flow boundary layer. The thickness of the concentration boundary layer near the leading edge region would then be increased by this carry-over effect, and the over-all mass transfer rate would be decreased. For the present apparatus, the surface distance between the leading and the trailing edges was 15.96 cm. Using the value of Pe = 1.5×10^8 as the point of deviation in Fig. 4, the thickness of the Nernst diffusion layer at trailing edge can be calculated to be 0.002 cm when the carry-over phenomena started to affect the limiting current measurement. Whether the apparatus was able to maintain a gap less than 0.002 cm between the working electrode and the stationary skimmer when the electrode is rotating at high speeds, remains to be determined. The analysis, nevertheless, indicates that the discrepancy might be caused by the mechanical tightness of the apparatus rather than a breakdown of the mass transfer theory in the laminar region. It seems that further investigation is necessary to resolve the problem

Conclusions

1. Asymptotic correlations are presented for predicting the rate of mass transfer to a continuous moving flat surface. The result is valid for laminar flow over a range of Schmidt numbers from 0.7 to infinity. The maximum error which occurs in the neighborhood of Pr = 0.7 is less than 0.8%.

2. A laboratory cell has been used to test the theory for uniform surface concentration. The limiting cur-

rent was measured for the reduction of ferricyanide ion over a range of Reynolds numbers from 1,500 to 70,000 and Schmidt numbers from 1,800 to 29,300. The data agree with the theory for $Pe < 1.5 \times 10^8$. The deviation above $Pe = 1.5 \times 10^8$ was probably caused by a mechanical flaw of the experimental cell rather than the breakdown of the theory in the laminar region.

Technical Notes

Dibasic Lead Sulfate in Lead-Acid Battery Pastes

B. P. Varma* and C. W. Fleischmann*

Eltra Corporation, C & D Batteries Division, Plymouth Meeting, Pennsylvania 19462

The process is well known by which commercial lead oxides are partially sulfated to form stiff pastes for subsequent application onto metallic grids to compose electrodes for lead-acid cells. After pasting, and prior to electrochemical formations, these electrodes are allowed to stand or "cure" to develop various basic sulfates and to oxidize any free lead (1). The cured pastes, in addition to the unreacted starting materials, principally PbO, may contain the monobasic lead sulfate, $PbO \cdot PbSO_4$, and the tribasic lead sulfate hydrate, $3PbO \cdot PbSO_4 \cdot nH_2O$ (1-6). Depending on the composition of the starting commercial oxides, unreacted metallic lead or Pb_3O_4 may also be present (1-6). In pastes cured at higher temperatures (>70°C) and humidities, the tetrabasic species, $4PbO \cdot PbSO_4$, is developed in significant amounts (1, 2). It will also form slowly at lower temperatures (5, 7, 8). The dibasic lead sulfate, $2PbO \cdot PbSO_4$, is a well-recognized high temperature phase (9-11), but it has been discounted in battery pastes on the basis of thermodynamic arguments (3). Nevertheless, it has been reported at times (5, 12).

In the course of our investigations on lead-acid battery pastes (13), dibasic lead sulfate was observed in pastes. These observations are discussed.

Experimental

Pastes were prepared from the three commercial oxides described briefly in Table I by blending 9.07 kg of the oxide with 1-1.3 liters water and then slowly adding 460-960 ml 7.02M H_2SO_4. The pastes were subsequently cured at low temperatures (25°-55°C) and over a wide range of humidities (cure I) or, alternatively, for 3 hr at higher temperatures (80°-85°C) in steam (cure II). The compositions of the oxides and the cured plates were determined by comparing their x-ray diffraction patterns to published data (9, 11, 14). The free lead content of pastes made from leady oxides was reduced to 0.5-5% during cure I, depending on the particular conditions, and to 1-2% during cure II. The free lead content was determined by wet methods.

Results and Discussions

Cure I products.—The pastes cured via cure I and humidities were found to contain tribasic lead sulfate, monobasic lead sulfate, and tetragonal lead oxide, PbO(t). Dibasic lead sulfate was not found in any of the cured pastes.

Orthorhombic lead oxide, PbO(o), was not detected in any of the cured pastes including the paste made from oxide A, which contained PbO(o) as a component. The absence of orthorhombic PbO in the pastes after curing is in accordance with past reports (15, 16) that this phase converts to the tetragonal phase in the presence of moisture and/or mechanical working.

Cure II products.—The products found in pastes cured via cure II are given in Table II. The composition depended on the starting oxides, but every cured paste contained both tetrabasic lead sulfate and tetragonal PbO. Differences, however, were observed as to the development of the other basic sulfates. The paste of oxide A also developed both monobasic and tribasic lead sulfates, whereas the cured pastes of the other three oxides contained dibasic lead sulfate. Dibasic lead sulfate was found in one of the leady oxides (oxide C) but not in the other (oxide A). All the literature reports (5, 12) in which the dibasic species was observed were for pastes prepared from leady oxides. Oxides B and D, both nonleady oxides, however, also developed the dibasic species. Hence, the presence of free lead in the starting oxide does not appear to be a requirement for the formation of dibasic lead sulfate.

Table I. Compositions of starting oxides

Oxide	Description	Compositions as found by chemical analysis	Compositions* as found by x-ray diffraction
A	A commercial leady oxide, Barton process	PbO 80.93% Pb 19.07%	PbO(o) PbO(t) Pb
B	A commercial nonleady oxide, followed by mechanical furnace	PbO 90.54% Pb_3O_4 9.46%	PbO(o) PbO(t) Pb_3O_4
C	A commercial leady oxide, Ball-Mill process (Schimadzu)	PbO 76.66% Pb 23.34%	PbO(t) Pb
D	Tetragonal PbO, laboratory preparation	PbO 100%	PbO(t)

* PbO(o) indicates orthorhombic modification.
* PbO(t) indicates tetragonal modification.
* Pb indicates free bulk particles of lead.

Table II. Products after steam curing

Oxides	Products
A	$4PbO \cdot PbSO_4$ $3PbO \cdot PbSO_4 \cdot nH_2O$ $PbO \cdot PbSO_4$ PbO(t)
B, C, D	$4PbO \cdot PbSO_4$ $2PbO \cdot PbSO_4$ PbO(t)

Double cure II products.—A double cure by cure II for pastes made from oxide A changed the principal products to $4PbO \cdot PbSO_4$, PbO(t), and $2PbO \cdot PbSO_4$. These products were the same as those which developed after one cure in the pastes made from the other oxides.

Several mechanisms may be suggested for the formation of dibasic in the pastes. It may develop as a result of tribasic disproportionation on extended cure II conditions. If that is the case, however, it is not immediately apparent why the pastes of oxide A should have

* Electrochemical Society Active Member.
Key words: lead oxides, basic lead sulfates, tetragonal PbO, orthorhombic PbO.

behaved differently than the others. Perhaps the mechanism involves PbO, which is known to have different reactivities depending on both the polymorph and its past history. The effects of the polymorph on the product basic sulfates have been reported by Bode and Voss (17), Ikari *et al.* (18), and Biagetti and Weeks (19). Effects of mechanical working on the reactivity (15, 20) and structure (21) of PbO(t) are also known. Since both oxides B and C were mechanically worked during preparation, the nature of the products formed in the cured pastes may be a function of the distortion, hence the activity, of the PbO(t) in these oxides. Further research is needed to define the reaction mechanisms occurring in battery pastes during curing.

Conclusion

Although dibasic lead sulfate is not commonly reported in battery pastes, it may develop under some curing conditions which also develop $4PbO \cdot PbSO_4$.

Suppression of Surface Dissolution of CdS Photoanode by Reducing Agents

Tooru Inoue, Tadashi Watanabe, Akira Fujishima, and Ken-ichi Honda

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, Japan

and Koichi Kohayakawa

Department of Applied Chemistry, Faculty of Engineering, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221, Japan

Electrochemical photocells (1-21) have recently drawn the attention of a number of investigators primarily in connection with solar energy conversion. The following three criteria appear to be of crucial importance for a semiconductor material to be used as a photoanode in an electrochemical photocell: (*i*) sufficient stability, (*ii*) sufficient light absorption in the visible wavelength region, and (*iii*) sufficient band bending under the conditions used. The third point implies that the flatband potential is sufficiently cathodic, and has been emphasized in several papers (13-15). At stable photoanodes such as TiO_2 (1-12), $SrTiO_3$ (13-15), SnO_2 (16, 17), $KTaO_3$ (18), WO_3 (19, 20), and Fe_2O_3 (20, 21), the electrode reaction is the direct oxidation of water resulting in oxygen evolution by the action of holes produced in the valence band. However, these semiconductors possess relatively wide bandgaps (exceeding 3.0 eV) except WO_3 and Fe_2O_3 and hence do not efficiently utilize solar energy. In this respect, cadmium sulfide (CdS) seems to be a promising material since it shows a strong absorption of wavelengths shorter than 520 nm. However, the anodic reaction at illuminated CdS electrode is the dissolution of the electrode surface (22-24) according to

$$CdS + h\nu \rightarrow h^+_{val} + e^-_{cond} \quad [1]$$

$$2h^+_{val} + CdS \rightarrow S_{ad} + Cd^{2+} \quad [2]$$

where h^+_{val}, e^-_{cond}, and S_{ad} denote a hole in the valence band, an electron in the conduction band, and a sulfur atom deposited on the electrode surface, respectively. For the application of CdS as a photoanode in an electrochemical photocell, the dissolution process [2] should be minimized. This problem has been

Key words: electrochemical photocell, semiconductor electrodes, solar energy, rotating ring-disk electrode.

partly solved by adding appropriate reducing agents such as I^- (25), hydroquinone (26), and S^{2-} (27, 28) into the electrolyte solution. Attempts have also been reported on the dissolution suppression of CdSe (27), Bi_2S_3 (28), and CdTe (29) photoanodes by addition of S^{2-}, Se^{2-}, and Te^{2-}, respectively. However, a more systematic investigation appeared necessary for a better choice of the reducing agent applicable to a practical electrochemical photocell. In the present study we investigated the photoelectrochemical processes at CdS single crystal electrode, mainly focusing upon the suppression of its dissolution, by addition of a variety of reducing agents differing widely in their redox potentials. The rotating ring-disk electrode (RRDE) technique served as a useful tool for the *in situ* determination of the dissolution rate of the electrode surface.

Experimental

The CdS single crystal (n-type) (Teikoku Tsushin Kogyo Company, Limited) employed in the present study was undoped, with the carrier density of 7.4×10^{16} cm^{-3} (determined by measurement of the Hall effect by this company). The crystal was shaped into a disk 6.0 mm in diameter and 1.0 mm in thickness. Indium was vacuum-evaporated onto a face of the crystal in order to insure an ohmic contact with the conducting wire. Then, the CdS disk was assembled in a Teflon rod using epoxy resin together with an amalgamated Cu ring 7.0 mm in inner diameter and 9.0 mm in outer diameter, thus constructing a ring-disk electrode. The (0001) crystal face of CdS exposed to the electrolyte solution was polished with alumina powder, etched in concentrated HCl for 10 sec, and then washed with water. The ring-disk electrode thus prepared was set in a RRDE measurement system (Nikko Keisoku) as is schematically shown in Fig. 1. The potentials of the disk and ring electrodes were controlled independently by means of a dual potentiogalvanostat (Nikko Keisoku). The light source was a 500W high pressure mercury arc lamp and the wavelength of the illuminating light was fixed at 440 nm with an interference filter (Koshin Kogaku) having a peak transmittance of 40% and the half-band width of 10 nm. The CdS-electrolyte interface was uniformly illuminated through a quartz window attached at the bottom of the cell. The supporting electrolyte was 0.2M Na_2SO_4 and all the reducing agents used were reagent grade. In most of the RRDE experiments, the potential of CdS disk electrode was kept at 1.0V *vs.* SCE where a saturation photocurrent occurs, and the potential of the Cu(Hg) ring electrode was swept at a rate of 30 sec/V in order to analyze the products of the photoelectrochemical reaction on the CdS disk electrode. The rotation rate of the RRDE was set at 1000 rpm.

Results and Discussion

Figure 2 shows the currents at the CdS disk and Cu(Hg) ring electrodes as a function of the ring potential, with and without illumination. I_D, I_R, and V_R denote the disk current, the ring current, and the ring potential, respectively. In the dark, the disk current is negligibly small at the fixed potential of 1.0V *vs.* SCE, and hydrogen evolution occurs at potentials more cathodic than −1.5V *vs.* SCE at the Cu(Hg) ring electrode. Under illumination in the absence of a reducing agent, SO_3^{2-} in the present case, an anodic photocurrent flows at the CdS disk electrode. At the same time, a reduction current appears at the Cu,(Hg) ring electrode in the potential range more cathodic than *ca.* −0.6V, which corresponds to the reduction of Cd^{2+}. By addition of Na_2SO_3 into the electrolyte solution, the magnitude of the disk photocurrent undergoes practically no change, whereas that of the ring current for Cd^{2+} reduction shows a decrease. In what follows, the limiting current at the ring electrode corresponding to the reduction of Cd^{2+} is expressed as $I_{R,Cd}$ for the electrolyte containing a reducing agent, and as $I°_{R,Cd}$ for that free of reducing agents. For the SO_3^{2-}-free electrolyte solution, it was found that the ratio of the magnitude of $I°_{R,Cd}$ to that of the anodic photocurrent at the CdS disk coincides fairly well with the theoretical collection efficiency for the RRDE employed. This implies that in this case the dissolution of the CdS electrode surface due to reaction [2] is totally responsible for the anodic photocurrent. From this it follows that the value of $(I°_{R,Cd} - I_{R,Cd})/I°_{R,Cd}$ represents the fraction of the anodic photocurrent by which the reducing agent is being oxidized in competition with the reaction [2]. Below we call the quantity 100 $(I°_{R,Cd} - I_{R,Cd})/I°_{R,Cd}$ the percentage of dissolution suppression.

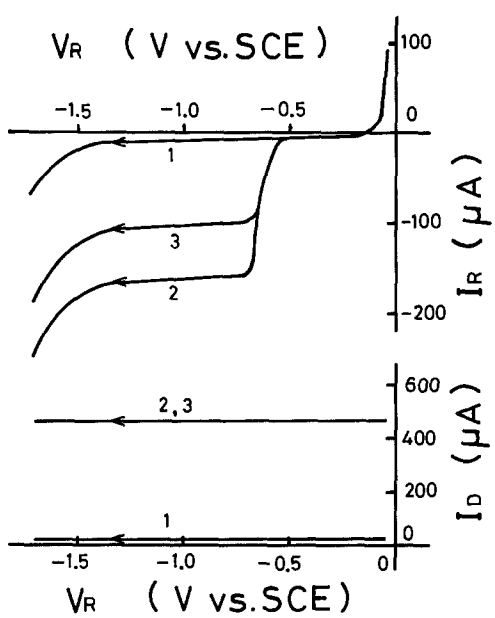

Fig. 2. Dependences of (a) ring current at Cu(Hg) and (b) disk current at CdS, on the ring potential. The disk potential is fixed at 1.0V *vs.* SCE. 1, In darkness. 2, CdS illuminated; $[SO_3^{2-}] = 0$. 3, CdS illuminated; $[SO_3^{2-}] = 10^{-3}$M.

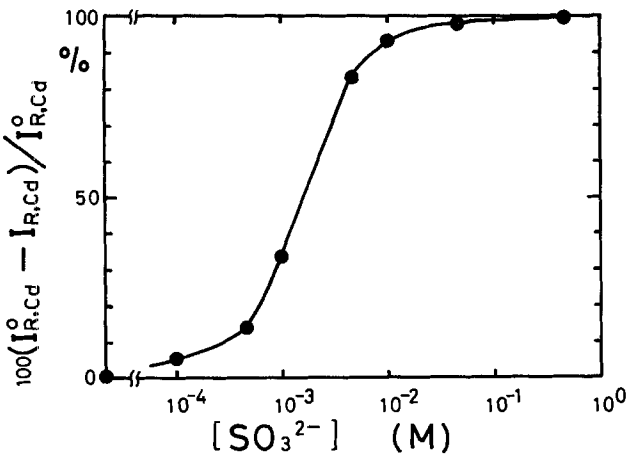

Fig. 3. Percentage of dissolution suppression as a function of SO_3^{2-} concentration.

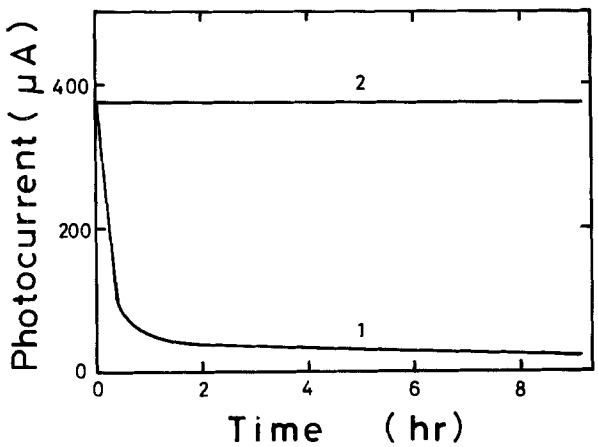

Fig. 4. Decay characteristics of the photocurrent at CdS electrode. 1, In 0.2M Na_2SO_4; $[SO_3^{2-}] = 0$. 2, In 0.2M Na_2SO_4; $[SO_3^{2-}] = 1.0$M.

For SO_3^{2-}, $S_2O_3^{2-}$, and S^{2-}, the determination of $I_{R,Cd}$ was straightforward, since their oxidation products did not undergo reduction at the ring electrode, due presumably to the irreversibility of the oxidation process (*e.g.*, Eq. [3] and [4] below). With Cl^-, Br^-, Fe^{2+}, I^-, and $Fe(CN)_6^{4-}$, on the contrary, the reduction of both Cd^{2+} and the oxidized species of these reducing agents proceeded at the Cu(Hg) ring electrode, and hence a double reduction wave was recorded as the ring current. In this case a simple subtraction was required for the determination of the value of $I_{R,Cd}$.

Figure 3 shows the percentage of dissolution suppression by added SO_3^{2-} as a function of its concentration. Note that the suppression efficiency increases with increasing concentration of the reducing agent, and is almost complete at concentrations above 0.1M.

In the absence of reducing agents in the electrolyte solution, the photocurrent at CdS single crystal electrode usually shows an abrupt decay with time. This phenomenon is attributed to the deposition of sulfur, which acts as a light filter on the electrode surface, produced according to reaction [2]. If the dissolution process [2] is suppressed by added reducing agents, the decay characteristic is also expected to decrease. This is shown in Fig. 4, where the current-time curves for electrolyte solution with and without 1.0M Na_2SO_3 are illustrated.

Concerning the oxidation reaction of SO_3^{2-}, which should proceed in competition with the dissolution of the CdS surface, the following two mechanisms are equally possible

$$2SO_3^{2-} + 2h^+_{val} \rightarrow S_2O_6^{2-} \qquad [3]$$

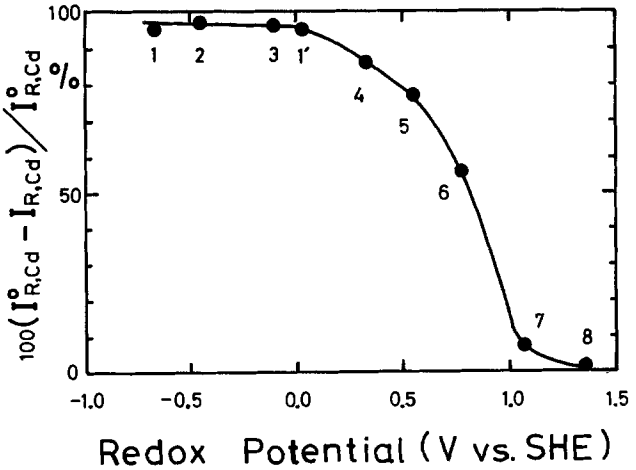

Fig. 5. Percentage of dissolution suppression by reducing agents (0.01M) as a function of their redox potential. 1, SO_3^{2-}/SO_4^{2-}; 1', $SO_3^{2-}/S_2O_6^{2-}$; 2, S^{2-}/S; 3, $S_2O_3^{2-}/S_4O_6^{2-}$; 4, $Fe(CN)_6^{3-/4-}$; 5, I^-/I_2; 6, $Fe^{2+/3+}$; 7, Br^-/Br_2; 8, Cl^-/Cl_2.

$$SO_3^{2-} + 2\,OH^- + 2h^+_{val} \rightarrow SO_4^{2-} + H_2O \qquad [4]$$

These schemes have been confirmed by a number of authors (30-32) in aqueous alkaline solution such as that used in the present study (pH 9.3).

Gerischer and Meyer (22) demonstrated that in the case of I^- one of the reaction products (I_3^-) attacks the electrode and causes a chemical dissolution of the CdS surface, according to

$$CdS + I_3^- \rightarrow Cd^2 + S + 3I^- \qquad [5]$$

Based upon the results shown in Fig. 3 and 4, however, we conclude that such a chemical dissolution is impossible, or at least sufficiently slow, for the present CdS/SO_3^{2-} system. If a reaction similar to [5] occurs effectively, the percentage of dissolution suppression cannot reach almost 100%, and the decay characteristic of photocurrent would appear, even for the case of a concentrated sulfate electrolyte solution.

Measurements of the percentage of dissolution suppression were carried out for a total of eight reducing agents differing widely in their redox potentials: SO_3^{2-}, S^{2-}, $S_2O_3^{2-}$, $Fe(CN)_6^{4-}$, I^-, Fe^{2+}, Br^-, and Cl^-. The results are summarized in Fig. 5. Two different redox potentials were taken for SO_3^{2-} ($SO_3^{2-}/S_2O_6^{2-}$ and SO_3^{2-}/SO_4^{2-}), since two oxidation processes are possible, as mentioned above. From this figure it is seen that the reducing agent whose redox potential is more negative suppresses more effectively the dissolution of the CdS surface. In particular, the percentages of dissolution suppression by SO_3^{2-}, S^{2-}, and $S_2O_3^{2-}$ are quite high, exceeding 95% at such a relatively low concentration.

The flatband potential of CdS single crystal electrode (and hence the vicinity of the conduction band edge of CdS in an energy level diagram) is situated in the potential region around −0.5V *vs.* SHE (33). Therefore, the results given in Fig. 5 are rather surprising, since the interfacial charge transfer concerned (oxidation of reducing agents) may proceed via the valence band by the action of photogenerated holes, and not via the conduction band. However, recently using TiO_2 electrode in acetonitrile with a large number of electroactive compounds, Frank and Bard (34) detected intermediate energy levels between the conduction and valence bands capable of mediating electron transfer. It is felt that further investigations will be necessary for a quantitative interpretation of our experimental results.

Above we have investigated the stabilization of the surface of CdS photoanode by the addition of suitable reducing agents to the electrolyte solution. For a practical application of such systems in the electrochemical

photocell, however, the effect of additives on the cell performance must be clarified. An investigation along this line has been reported by Gerischer and Gobrecht (35), who studied the power characteristics of CdS electrochemical photocell containing $Fe(CN)_6^{4-/3-}$ and $S_2O_3^{2-}/S_4O_6^{2-}$ as redox couples. They found a smaller photo-emf for the latter redox couple than the former, and elucidated such a result on the basis of the difference between the redox potential of the additive and the Fermi level of CdS. Taking these findings into account, we feel that detailed investigations will be required before an ideal electrochemical photocell is realized.

Brief Communication

The Thermodynamics of Arsine Evolution

H. J. Davis*

Noranda Research Centre, Pointe Claire, Quebec, Canada H9R 1G5

The widely published and accepted values for the arsine evolution potential in acid solutions appear to be in error. In view of the very hazardous nature of arsine and the industrial significance of arsenic cementation and removal by electrolysis, a reassessment of the available thermodynamic data relating to this process has been undertaken.

Latimer (1), de Bethune and Loud (2), and Pourbaix (3) give the standard aqueous electrode potential for the reaction

$$As + 3H^+ + 3e^- = AsH_3(g)$$

as -0.608V. This result is based on a value of 42 kcal/mole for the free energy of formation of AsH_3 calculated from an enthalpy of formation of 41 kcal/mole at 298.2°K (4) and an estimate of 52 cal/mole deg for the standard entropy (1). [This value for the enthalpy is based upon the work of Ogier (5) in 1878 and its validity was questioned by Latimer (1)]. These data give the arsine evolution potential at 298.2°K as

$$E_{298.2} = -0.608 - 0.0591\,pH - 0.0197 \log pAsH_3 \quad [1]$$

More recent data on the enthalpy of formation of $AsH_{3(g)}$ have been obtained as follows:

$$\Delta H^\circ_{f298} = 18{,}000 \pm 1{,}500 \text{ cal/mole (1956) (6)}$$

* Electrochemical Society Active Member.
Key words: arsine, standard potential, arsenic, safety.

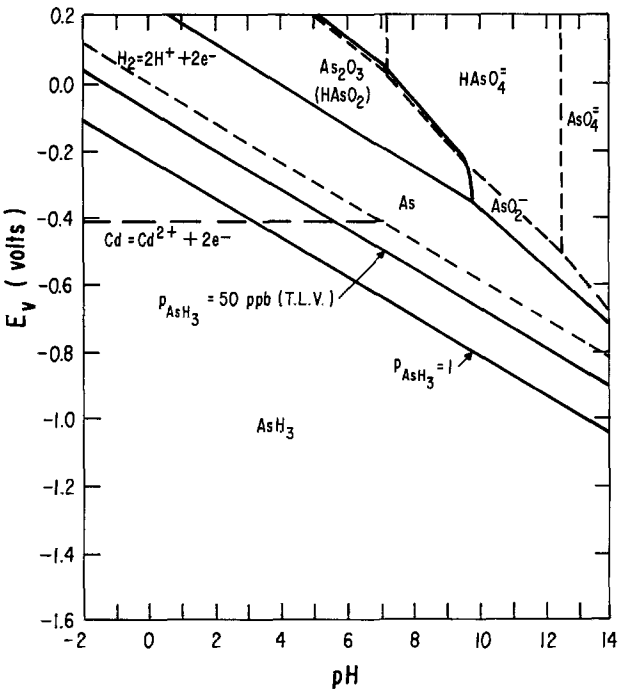

Fig. 1. Potential-pH equilibrium diagram for the system arsenic-water at 25°C, showing voltage-pH ranges capable of giving rise to arsine generation in excess of the threshold limit value.

$$\Delta H°_{f298} = 15{,}870 \pm 250 \text{ cal/mole (1960) (7)}$$

$$\Delta H°_{f298} = 15{,}000 \text{ cal/mole (1961) (8)}$$

$$\Delta H°_{f298} = 14{,}900 \pm 400 \text{ cal/mole (1972) (9)}$$

The standard entropy of arsine has been obtained as follows

$$S°_{298}(AsH_{3(g)}) = 53.21 \pm 0.1 \text{ cal/mole deg (1955) (10)}$$

$$S°_{298}(AsH_{3(g)}) = 53.22 \pm 0.1 \text{ cal/mole deg (1961) (11)}$$

From the above, values of 15,000 cal/mole for the standard enthalpy of formation of arsine and of 53.2 cal/mole deg for the standard entropy of arsine have been used to recalculate the standard free energy of formation of arsine from solid arsenic and gaseous hydrogen. Using a value of 8.4 ± 0.2 cal/deg mole for the standard entropy of arsenic (11) and the accepted value of 31.2 cal/deg mole for the standard entropy of hydrogen (4), the standard free energy of formation for arsine according to the following equation

$$As_{(s)} + 3/2\ H_2 \rightarrow AsH_{3(g)}$$

is given by

$$\Delta G°_{f(AsH3)} = \Delta H°_f - T\Delta S°_f$$

$$= 15{,}000 - 298.2\ (-2.0)$$

$$\Delta G°_{f(AsH3)} = 15{,}596 \text{ cal/mole}$$

This value is lower than the value of 26.4 kcal/mole given by Gunn *et al.* (7) and quoted by Dewalens *et al.* (12). The difference is due to the necessity of using solid arsenic as representative of its standard state at 25°C, Gunn *et al.* (7) apparently using the entropy of arsenic vapor in their calculation of $\Delta S°_f$. The value of 15,596 cal/mole for the free energy of formation of arsine agrees well with the data published by Hopper *et al.* (13) on the free energy of arsine as a function of temperature.

Using this value for $\Delta G°_{o(AsH3)}$ the standard aqueous electrode potential for the arsine/arsenic couple in acids is given by

$$E°_o = \frac{-15{,}569}{3 \times 23{,}060} = -0.225\text{V}$$

At other pH and arsine partial pressures, the reversible potential at 25°C for the reaction

$$As + 3H^+ + 3e^- = AsH_3(g)$$

is given by

$$E_o = -0.225 - 0.0591\ pH - 0.0197 \log p(AsH_3)$$

Figure 1 shows the modified pH-potential diagram for arsenic reduction in aqueous solutions at 25°C. It is now apparent that arsenic cementation with such metals as iron or cadmium does not preclude the evolution of arsine and recent suggestions in the literature (14, 15) that cadmium can be used to safely cement arsenic are not consistent with the data presented here and must be viewed with extreme caution.

Manuscript received Dec. 6, 1976; revised manuscript received Jan 7, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Thermal Desorption of Hydrogen Electrochemically Adsorbed on a Carbon Electrode

W. Warren and J. T. Kummer

Ford Motor Company, Engineering and Research Staff, Dearborn, Michigan 48121

A completely inert electrode (one that does not react with water or chemisorb H_2) charged in a dilute acid solution (HCl, H_2CO_3) to some voltage less than the hydrogen evolution voltage will, in addition to neutral adsorbed species, consist of excess electrons in the electrode surface together with the compensating positive charge due to an excess of hydrated protons at or near the solution electrode interface. Upon removing from solution and heating to a sufficiently high temperature the excess hydrated protons will dehydrate, combine with the excess electrons in the electrode, and, if they are sufficiently mobile, combine and be evolved as hydrogen gas.

Satisfactory inert electrodes would be gold or mercury since they are inert to water and do not chemisorb hydrogen. We are dealing with a surface phenomenon so that the magnitude of any experimental results will increase linearly with the surface area of the inert electrode. High surface area gold electrodes stable toward sintering at high temperature (up to 1000°C) are not available. Experimental work with gold electrodes of low surface area would require sensitive hydrogen detection equipment and equipment to monitor the cleanliness of the gold surface. Since this type of equipment is not available to us, we have used high surface area carbon as the electrode. This simplifies the analytical problems but complicates the interpretation of the results because the electrode is not inert to water and hydrogen. Using carbon electrodes, we have nevertheless obtained results that are consistent with an explanation based on proton dehydration and these results are the subject of this brief note.

Experimental

The carbon electrode used (~0.6 × 0.6 × 5 cm) was obtained from Stackpole Carbon Company, St. Marys, Pennsylvania. It weighed ~2g and its surface area was ~200 m^2/g. The electrode was treated with concentrated HCl + HF at 100°C and then, after washing, with hydrogen at 800°C before use in order to reduce oxygenated surface groups. The ash content was <0.2 weight percent (w/o).

The apparatus used is shown in Fig. 1. For these experiments a 0.5M HCl solution was used as an electrolyte, and helium gas was used to manipulate the solutions and also as a carrier gas for the evolved hydrogen when the carbon electrode was heated. The helium carrier gas was analyzed for hydrogen and other constituents by a Consolidated Engineering Corporation 615 mass spectrometer constructed for continuous on-stream analysis.

Procedure

Before the run, the apparatus and solutions were purged with helium. With stopcock A and B closed, the top part of the apparatus was evacuated through stopcock C to a few Torr and then the degassed HCl solution was allowed to rise and cover the electrode. The evacuation is importnt in order to allow the solution to penetrate the carbon. The carbon electrode was charged by a variable voltage d-c source in an arrangement that permitted continuous monitoring of the current and of the potential difference between the carbon and calomel electrode. The electrolyte resistance and the small overvoltage of the calomel electrode as a function of current had been previously determined so that the zero current potential of the carbon electrode *vs.* the calomel electrode as a function of coulombs charged could be obtained. The charging current was typically between 0.5 and 1 mA. The charging time was overnight. During charge the carbon electrode was negative and the calomel electrode positive.

After charging was completed, the electrolyte was drained away from the charcoal and a helium flow of about 30 cm^3/min was established. The charged electrode was dried by heating to about 120°C for at least 15 min, followed by heating to about 250°C for at least 10 min. Longer heating did not produce any additional removal of electrolyte from the electrode. The helium

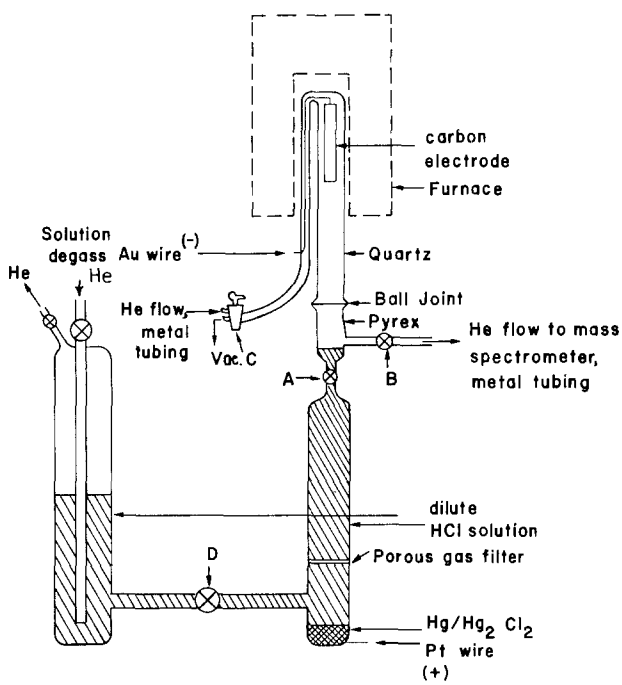

Fig. 1. Apparatus used for the experiments

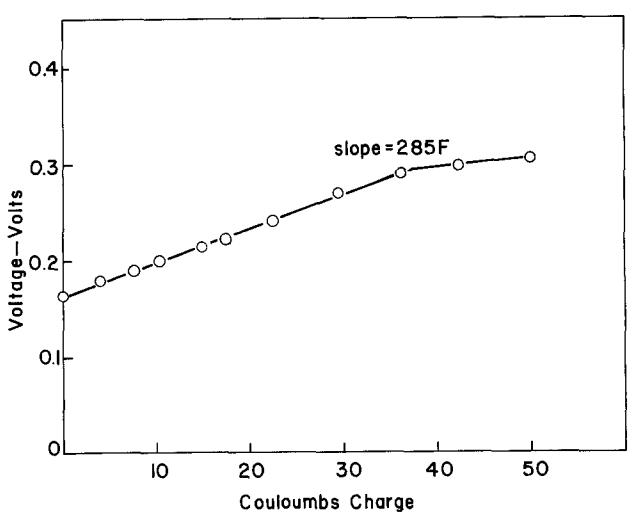

Fig. 2. Open-circuit voltage vs. charge during charging

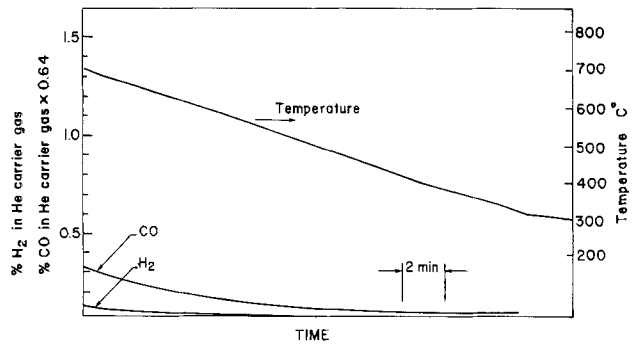

Fig. 3. Thermal desorption of an uncharged electrode

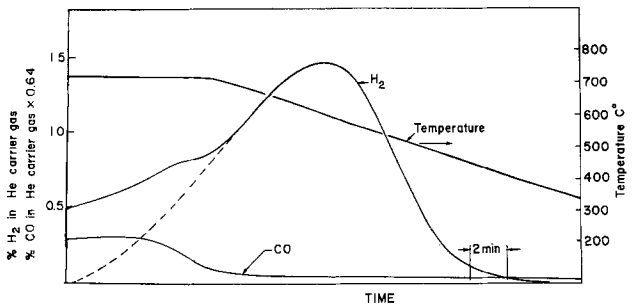

Fig. 4. Thermal desorption of a charged electrode

flow was then continuously sampled by a Consolidated Electrodynamics mass spectrometer as the electrode was heated by a small furnace controlled by a linear programmer. The temperature was generally raised from about 250° to about 700°C in ~15 min, and was constantly monitored by a thermocouple wrapped around the apparatus less than 5 mm away from the surface of the charcoal. The electrode could then be cooled and recharged without ever exposing it to the atmosphere.

Temperatures much greater than ~700°C were avoided since at 650°C the water-gas reaction was found to be measurable and the expected proton dehydration will produce water vapor. Above 600°-700°C CO was evolved from the carbon.

Results

After a helium purge at 700°C, the voltage of the uncharged carbon electrode with respect to the calomel electrode was from −0.13 to −0.16V. This, according to Frumkin *et al.* (1) is the potential of zero charge. The charging curve of voltage *vs.* charge was linear in all cases up to ~ −0.30V. The calculated hydrogen evolution voltage (1 atm H_2) is ~ −0.33V. See Fig. 2 for a representative charging curve. The electrode behaved as a nearly perfect capacitor up to ~0.30V or up to a charge of 30-35C. It was possible to raise the carbon electrode potential past that voltage but deviation from ideal capacitor behavior was observed and became quite pronounced with increasing charge. The average of five runs showed an implied capacitance of 290 ± 20 farads. The total H content of the carbon electrode before use was 0.2 w/o and after eight runs, during which a total charge of 400C was passed, was 0.4 w/o.

During the heating process, the mass spectrometer was used to check all mass numbers from 12 to 100, as well as mass number 2. However, with few exceptions the only mass numbers that showed any temperature variation corresponded to hydrogen and carbon monoxide. Although water was certainly present at some temperatures, it was trapped out with Dry Ice before reaching the mass spectrometer so that any HCl evolved would not corrode the machine. Methane peaks were also occasionally detected, but the total amount of methane given off in any single run never exceeded about 0.1 ml. Similarly, small amounts of CO_2 were sometimes seen.

Evolution of hydrogen and carbon monoxide followed a constant pattern. See Fig. 4. CO evolution began when the electrode reached about 600°C. Hydrogen evolution began around 350°-400°C, reached a peak between 500°-550°C, and began to rise again around 650°C as CO evolution began.

A blank run made by heating the carbon electrode after exposure for 16 hr to the dilute HCl solution in the apparatus of Fig. 1, but without charging, did not evolve H_2 below 600°C, (2) and only small amounts at 650°-700°C. See Fig. 3. When the electrode was charged, evolution of hydrogen at <600°C was observed. See Fig. 4. The results of four charging runs are shown in Table I. In calculating the total amount of hydrogen evolved, the hydrogen evolution during the last part of the run at high temperatures was estimated using the dashed line, as illustrated in Fig. 4. After several charging runs in which ~100C of charge had been passed, the HCl electrolyte was analyzed for total carbon content (not CO_2) and found to contain only 0.37 mg C.

Discussion

The evolution of hydrogen, upon heating, by the charged electrodes but not by the uncharged electrode shows that hydrogen is evolved thermally as a result of the prior electrochemical process. At the end of charge, a measured number of electrons have been moved into the carbon electrode and an equal number of Cl^- ions removed as Hg_2Cl_2 from solution at the mercury electrode (very visible). As a result, at the carbon electrode, there will be an excess of hydrated H^+ ions over the anions present at or near the electrode surface, or there will be neutral chemisorbed H species on the electrode surface of various kinds produced from the solution protons, or there will be produced compensating anions in solution ($HCOO^-$, for example) produced from neutral species at the carbon electrode surface. These are required because of the necessity of charge neutrality. A hydrogen ion, even in a tight double layer, would be hydrated because a proton has essentially no size and because the hydration is thermodynamically necessary in order for the H^+ to exist at the usual electrochemical voltages (3). The hydrated hydrogen ions could be electrostatically attracted to the basal and prismatic planes of the carbon as a result of the excess electrons in the electrode. On an inert electrode that does not chemisorb hydrogen, and at a volt-

age less than the thermodynamic hydrogen evolution voltage and in the presence of H_2 gas this is what occurs.

If a hydrogen atom can form a stable covalent bond to the carbon electrode surface (or to an O atom chemically bound to the surface) then the hydrogen can exist as an essentially neutral (modified by its dipole behavior) surface chemisorbed species after charge. On carbon these chemisorbed H atoms would probably occur at the prismatic faces where there are unsaturated valences rather than on the basal planes (4). These could be formed at less than the evolution voltage if their free energy of formation were negative. Since the voltages we used on charge are just less than sufficient to produce H_2 molecules (not H atoms) in a thermodynamic sense, then we can assess the probability of chemisorbed H species occurring by measuring the chemisorption of H_2 on degassed carbon when exposed to molecular H_2 under conditions where the chemisorption is not rate limited. Hydrogen chemisorption on degassed carbon at 350°C has been observed by Boudart and co-workers (5) so that this type of surface species could be present on our carbon surface after charge. From Boudart's work one could estimate that ~10% of the graphite crystal edge atomic sites could be covered with chemisorbed hydrogen atoms if there were no kinetic inhibitors to this process. One cannot say from Boudart's work if the chemisorbed H would form in the presence of water or that they would evolve H_2 in the temperature range that we observed. The apparent capacitatorlike behavior of the charging curves would argue for electrostatically adsorbed hydrated hydrogen ions rather than the formation of a covalent surface compound, but the present experiments are not conclusive in this respect.

The formation of acid anions in water solution free from the electrode in the absence of O_2 appears chemically unlikely (6). In addition, the absence of significant amounts of carbon compounds in the electrolyte would argue against such an interpretation.

The low yield of hydrogen (~60-70%) with respect to the charge passed has been of great concern to us. It is possible that, upon heating, some H atoms are incorporated into the carbon lattice rather than combining with another H atom. This is qualitatively consistent with hydrogen analysis data of the carbon before and after use. It is also possible that our inability to experimentally observe hydrogen evolution from the electrochemical process above 700°C could be important. As stated before, however, the fact that carbon is not inert to hydrogen and water makes precise quantitative results difficult to obtain.

On the onset of this work, which was a summer project for an undergraduate student, it was hoped that we could determine if the temperature required for hydrogen evolution was affected by the final charging voltage. This might be expected from thermodynamic considerations. Such data may help in understanding electrode processes, and could conceivably be of practical interest in the production of H_2 from a part electrochemical, part thermal process. Because of time limitation and the difficulty of working with carbon, this goal was not realized.

The Speed of Response of Solid Electrolyte Galvanic Cells for Gas Sensing

L. Heyne* and D. den Engelsen

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

The factors affecting the speed of response of solid electrolyte gas sensors are considered. The uptake or release of sample material (gas) by such cells is the main reason for sluggishness in response and for variation with time in the emf developed. Special attention is given to the effect on the emf caused by the presence of a second phase with electrical properties different from those of the main material. For a model cell, consisting of a solid electrolyte containing an intergrain phase with mixed conductor properties, the diffusion equation is solved numerically. The ambipolar diffusion coefficient is used in the calculations. The numerical parameters required for the calculation of concentration profiles and emf as a function of time are those of a typical calcia-stabilized zirconia. The results have a more general validity.

When the concentration of the active component at one of the electrodes of an electrochemical concentration cell is suddenly altered, the response of the open-cell voltage on this change shows some delay. One common reason for such a delay is that a certain, finite, amount of material is taken up (or released) by the electrolyte-electrode system, and it takes some time before the material required is supplied (or extracted) by the medium to be measured. During this transition period the emf developed by the cell may have a value deviating from that in the final stationary state. This represents a slow electrical response.

In the idealized galvanic cells usually considered in textbooks only the extra material adsorbed on the surface of electrolyte and electrode is involved, inducing a change in double layer charge. But with practical electrolytes there is also penetration into the electrolyte because its composition depends on the pressure of the active component of the gas sample. In solid electrolyte cells the active component usually forms a main constituent of the electrolyte material. Consequently, variations in gas concentration induce changes in the composition of the electrolyte. These compositional changes give rise to small deviations from the exact stoichiometric ratio.

During each transition from one concentration in the medium to another one, the amount of material equivalent to the aforementioned changes must be supplied (or taken up) by the medium. Although these amounts usually are very small, they nevertheless may give rise to an appreciable sluggishness in response if the supply is hampered in one way or another.

So we recognize the two key parameters which determine the speed of response. The first is the amount of active material involved in the change from one condition to the other. The second is the density of material flux with which the required amount can be supplied. In each of the several mechanisms that may be speed limiting for the emf response, we have to consider the nature and magnitude of these two key parameters.

It is the aim of the present paper to study the influence on the emf of the takeup of active material by the electrolyte and its diffusion into the bulk of the electrolyte. Therefore, we neglect other factors such as adsorption and double layer charging. In the first instance we further assume that the rate of the material takeup is determined by internal diffusion only ("reversible" electrodes). Later on we relax these restrictions and discuss the influence of polarization effects.

The diffusion in the bulk of the electrolyte is an example where the model of so-called ambipolar diffusion can be applied. In this concept two types of charged particles flow simultaneously with their fluxes adapted in such a way that no net charge transport takes place. Consequently, the resulting mass transport represents the flow of a neutral chemical component only. This type of diffusion is also known as chemical diffusion to stress the difference with self-diffusion or tracer diffusion, where only one particle type is involved and where no "chemical" concentration gradients exist.

In the following, calculations are made for several models of the solid electrolyte in a galvanic gas sensor. The cell considered is schematically represented in Fig. 1a: A sample gas space and a reference gas space are separated by a solid electrolyte which is provided with porous inert electrodes on both sides. Figure 1b illustrates the penetration of the active species into the electrolyte when, after a long period of equal partial pressures at both sides, the sample pressure is suddenly increased. Since, as is shown below, the effective diffusion coefficient is concentration dependent, exact integration of Fick's diffusion laws presents difficulties. Although some methods for dealing with these problems are treated in the literature (1, 2), we preferred to use a numerical integration method right from the start. This has the advantage that not only the exact law for the concentration dependence of the diffusion coefficient can be used, but also any nonuniformity in the

electrolytic properties can be introduced at will. In this way it became possible to study the influence of a foreign compound with mixed conductor properties present within the electrolytic sample at grain boundaries.

Basic Equations

There exist two methods that give a simple quantitative description of the combined diffusive motion of two types of charge carriers. One is due to Wagner and stems from his treatment of the growth of "scaling layers" on metal surfaces (3-5); the other is the so-called "ambipolar" treatment which is used extensively in many fields, such as semiconductors, gas discharges, and electrolytic solutions (6). We quote only the results of both descriptions and show that for the case of interest here they lead to practically the same value for the effective diffusion constant. A more detailed analysis of the assumptions and approximations involved will be given in a separate paper.

The formulas take a simple form if transport numbers t_k are introduced where index k indicates the type of charge carrier. They are defined as the ratio of partial conductivity σ_k and total conductivity as follows

$$t_k = \frac{\sigma_k}{\sigma_1 + \sigma_2} \quad \text{where} \quad k = 1, 2$$

Using the proportionality between mobility and diffusion coefficient D_k (Einstein relation) these equations can also be written as

$$t_k = \frac{z_k^2 c_k D_k}{z_1^2 c_1 D_1 + z_2^2 c_2 D_2} \quad \text{where} \quad k = 1, 2 \qquad [1]$$

Here c_k and z_k denote charge carrier concentration and relative charge, respectively.

In the ambipolar treatment the diffusion process is described as the simultaneous flow of the two types of charge carriers. Their local concentrations are adapted to each other by the condition of electroneutrality. The expression arrived at for the common effective diffusion coefficient is

$$\tilde{D} = \frac{(z_1^2 c_1 + z_2^2 c_2) D_1 D_2}{z_1^2 c_1 D_1 + z_2^2 c_2 D_2} \qquad [2]$$

Identifying index 1 with electronic carriers and 2 with ionic defects and introducing transport numbers according to Eq. [1] yields

$$\tilde{D} = t_e D_{ion} + t_{ion} D_e = t_e D_{ion} + (1 - t_e) D_e \qquad [3]$$

This ambipolar diffusion coefficient refers to the neutral combination of ionic defects and electronic carriers and thus to the neutral active component considered earlier. In solid electrolytes or mixed conductors t_{ion} is not very small and, since usually electronic charge carriers are much more mobile than ionic defects ($D_e >> D_{ion}$), the second term in Eq. [3] dominates strongly. Therefore this equation can be written

$$\tilde{D} \approx t_{ion} D_e \qquad [4]$$

Wagner's type of treatment leads to an effective diffusion coefficient which can be written in the form

$$\tilde{D} = t_{ion} D_e \left(\frac{1}{kT} \frac{\partial \mu}{\partial \ln \tilde{c}} \right) \qquad [5]$$

Here μ is the chemical potential per atomic unit of one (neutral) component of the substance considered, $\tilde{c}$ the excess concentration over the stoichiometric composition of the same component (in atomic units), and k and T have their usual meaning. For solid electrolytes and mixed conductors with high ionic defect concentrations, the factor in parenthesis, the so-called thermodynamic factor, appears to be close to unity, so that Eq. [5] becomes identical with Eq. [4]. For such materials the ionic conductivity is independent of the components' chemical potential (partial pressure), so the transport numbers t_e and t_{ion} are only variable through the variation of the electronic conductivity σ_e.

Numerical Method

In this section it will be shown how the diffusion process following a jump in sample pressure as indicated in Fig. 1b can be evaluated numerically and how the resulting emf changes with time.

To avoid unnecessary complexity of the presentation, we restrict our considerations to oxidic materials with mixed conduction, where electron holes and oxygen vacancies are the relevant charge carriers. In concordance with the final remark of the previous section, the concentration V of the latter type of charge carriers is independent of oxygen pressure (chemical potential), and consequently independent of position in a diffusion experiment. We restrict oxygen pressure variations to that range, where the electronic conductivity always remains p-type.

However, it must be recognized that these choices do not represent a restriction of the applicability of the method to be discussed. With the appropriate, and straightforward, modifications it can be applied at oxygen pressures where the conductivity is n-type, or to galvanic cells with different types of electrolytes of mixed conductors as well.

The concentration of holes h is a measure of the deviation of stoichiometry (excess oxygen).[1] It will be considered as the time and position dependent variable in Fick's second diffusion law. To obtain this parameter in a dimensionless form it is expressed in units of the hole concentration at a certain standard condition (h_{st}), for instance that prevailing in the equilibrium state before the jump in sample pressure took place

$$c_\xi(t) = h(t, \xi)/h_{st} \qquad [6]$$

where t denotes time and ξ is the one-dimensional position coordinate.

Because of the defect mechanism postulated (V = constant), see for instance (8), h depends on the oxygen partial pressure p_{ox} as a quarter-power law

$$h \sim p_{ox}^{1/4} \qquad [7]$$

So, *e.g.*, a jump by a factor 10 in c corresponds to a jump by a factor of 10,000 in the oxygen partial pressure.

Solution of Fick's second diffusion law, which in one dimension reads

[1] Stoichiometry is defined as that composition where the charges of all constituent positive and negative ions, in their normal valency state, balance to zero.

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial \xi}\left(\tilde{D}\frac{\partial c}{\partial \xi}\right) \qquad [8]$$

can be done by replacing it by the following difference equation

$$\Delta c = \frac{\Delta t}{(\Delta \xi)^2}\Delta(\tilde{D}\Delta c) = \Delta(\tilde{D}'\Delta c) \qquad [9]$$

Here Δt and $\Delta \xi$ denote small steps in time and in position and

$$\tilde{D}' = \tilde{D}\cdot\frac{\Delta t}{(\Delta \xi)^2} \qquad [10]$$

is a normalized dimensionless diffusion coefficient. Here ξ-space is thought to be divided into a grid of integer ξ-values, denoted by x, ranging from 0 to n (the sample boundaries) and spaced by $\Delta\xi$ cm. Expression [9] allows one to calculate a new concentration distribution c_x^{new} at time $t + \Delta t$ from a known one c_x at time t

$$c_x^{new} = c_x + \Delta c = c_x + \tilde{D}'_{x+1}(c_{x+1} - c_x) - \tilde{D}'_x(c_x - c_{x-1}) \quad x = 1, 2 \ldots (n-1) \qquad [11]$$

The indexed values of c and $\tilde{D}'$ denote concentrations and normalized diffusion coefficients at the position indicated by the index.[2] At the boundaries ($x = 0$ and $x = n$) the concentration values are kept fixed; c_0 at the value corresponding to the new oxygen pressure in the sample atmosphere, c_n at the value equivalent with the reference pressure (see Fig. 1). From the new values of c_x, new local transport numbers can be computed according to Eq. [1] and, using Eq. [3], new local diffusion coefficients can be found also

$$t_{h,x}^{new} = \frac{c_x^{new} h_{st} D_h}{c_x^{new} h_{st} D_h + 4VD_V} \quad x = 0, 1 \ldots n \qquad [12]$$

$$\tilde{D}_x^{new} = t_{h,x}^{new} D_V + (1 - t_{h,x}^{new}) D_h \quad x = 0, 1 \ldots n \qquad [13]$$

Here the values 1 and 2 have been introduced for z_1 and z_2 of Eq. [1].

It has been indicated in a previous paper (9) that a second phase between the grains of a ceramic electrolyte sample may have a pronounced effect on its transient behavior used as a galvanic cell. This is so because oxygen potential drops over such second-phase layers give rise to emf contributions different from that of a good electrolyte. A second phase can be introduced in the present model calculations in a very straightforward way. The constants h_{st}, V, D_h, D_V of Eq. [12] and [13] are given values different from those of the main compound in a certain, limited region of x-values. In this way a layer of different properties is simulated. The set of values chosen for the calculations to be presented below are also indicated in Table I.

For each concentration profile calculated using Eq. [11], the emf developed can be calculated from the well-known equation (3)

$$E = -\frac{1}{ze}\int_{'}^{''} t_{ion}\, d\mu \qquad [14]$$

Using the relative hole concentrations $c_x(t)$, Eq. [7], and assuming ideal thermodynamic behavior of holes this equation here takes the form

$$E = \frac{kT}{e}\sum_{x=0}^{n-1}(1 - t_{h,x})(\ln c_{x+1}(t) - \ln c_x(t)) \qquad [15]$$

To enable a simple comparison with the value expected from the ideal Nernst law, we introduced a temperature of 1008°K which with $t_V = 1$ yields an emf value of exactly 200 mV per decade in c_0 (50 mV per decade in p_{ox}).

A sequence of computations was started by setting all concentrations c_x equal to unity except the first one, c_0, which was set corresponding to the new situation in the sample space [for instance (10)]. To illustrate this procedure a simplified example is shown in Fig. 2 for the special case that $\tilde{D}' = 1/2$ (and thus is constant), and for only five values of x. Here the initial and right-hand boundary concentrations are taken as zero, the left-hand boundary is set at unity. It can be easily shown, that as long as $\tilde{D}' \leq 1/2$ such a repetitive process yields smooth solutions. However, if $\tilde{D}' > 1/2$ gradients develop into steeper ones during successive steps and numerical "explosion" results, see for instance Ref. (11). However, this restriction presents no difficulties, because by choice of $\Delta\xi$ and Δt, see Eq. [10], $\tilde{D}'$ can always be made smaller than 1/2 so that good convergence is obtained and, as practice shows, with reasonable computing time. To obtain sufficient accuracy, the calculations reported below have been carried out using 50 values for x and 3200-9600 concentration profiles were calculated successively.

Numerical values for material parameters and experimental conditions are required for the calculations. Such parameters are well known for calcia-stabilized zirconia, and, moreover, cells in which this compound is used are of great practical importance. As our model electrolyte we therefore chose a ceramic containing this compound as its main constituent. Its relevant data are represented in the left-hand column of Table I.

[2] The $\tilde{D}'$ values are chosen as the values at the right-hand side of each grid element instead of averages over the elements to simplify introduction of an inhomogeneity.

Table I. Data used for calculations at $T = 1008°K$

	Stabilized ZrO_2 at $p_{ox} = 1$ bar (10)	Second phase at standard condition (c = 1)
σ_{ion}, Ω^{-1}-cm^{-1}	10^{-3}	2×10^{-5}
σ_h, Ω^{-1}-cm^{-1}	2×10^{-7}	4×10^{-5}
t_h	2×10^{-4}	0.67
V, cm^{-3}	5×10^{21}	5×10^{19}
D_V, cm^2-sec^{-1}	3×10^{-8}	5.4×10^{-8}
h, cm^{-3}	10^{18}	10^{19}
D_h, cm^2-sec^{-1}	10^{-7}	22×10^{-7}
$\tilde{D}$, cm^2-sec^{-1}	10^{-7}	7.6×10^{-7}

	$C_x^{new} = 1/2\,(C_{x-1} + C_{x+1})$				
$t < 0$	0	0	0	0	0
$t = 0$	1	0	0	0	0
$t = \Delta t$	1	1/2	0	0	0
$t = 2\Delta t$	1	1/2	1/4	0	0
$t = 3\Delta t$	1	5/8	1/4	1/8	0
$t = \infty$	1	3/4	1/2	1/4	0

Fig. 2. Simplified example of numerical method. Numbers represent excess concentrations over the original value, upper row, at 5 positions in sample. Boundary values are 1 (first column) and 0 (fifth column). New c-values are obtained by taking the average of the neighboring previous values as indicated by the arrows. This corresponds to $\tilde{D}' = 1/2$ in Eq. [11].

They were taken from our earlier work (10) and have been confirmed, at least in order of magnitude, by later research [see for instance the recent surveys by Fouletier *et al.* (12) and by Fischer and Jahnke (8)].

Note that, because t_V is very close to unity, $\tilde{D} = D_h$ (see Eq. [4]). Consequently, both $\tilde{D}$ and $t_V = t_{ion}$ are independent of the oxygen pressure, and the latter parameter is irrelevant as far as the stabilized zirconia part of the ceramic electrolyte is concerned (staying always in the p-type region).

If a second phase is simulated in the model electrolyte, the set of values given in the second column of Table I is used for that region. These values are not based on actual measurement, but are postulated as possible values. They were intentionally chosen in such a way that the results from the calculations showed interesting features. This aspect is discussed more extensively later on.

The calculations are carried out with a dimensionless parameter x for position. To keep a link with practice, a value of 5 μm was chosen for $\Delta\xi$ to convert the dimensionless x-values to realistic position coordinate values ξ. A time interval of $\Delta t = 0.1$ sec in Eq. [10] then yields $\tilde{D}'$ values below 1/2 when c_0 (the left-hand boundary value after the pressure jump) is kept below 10 and when the data of Table I are introduced via Eq. [12] and [13].

Results

In Fig. 3 and 4 the results of such model calculations for a uniform zirconia sample are given as direct computer plots for a few profiles. The curves are constructed by drawing straight connections between the 50 calculated concentration values. Since in this case the diffusion coefficient is constant and the material uniform, the well-known error function or Fourier's series solution of the diffusion equation (13) could be used to check the accuracy of the result. It appeared that as long as the kinks in the curves are not obvious, the accuracy of the graph is better than the line width of the drawing. Only at the start of the calculation the gradients at the left-hand boundary are so steep that kinks are visible and appreciable errors occur.

In Fig. 5 the curves numbered 1 show that the emf developed is constant and has the value corresponding with Nernst's law right from the beginning. This is so notwithstanding the fact that a diffusion process is still

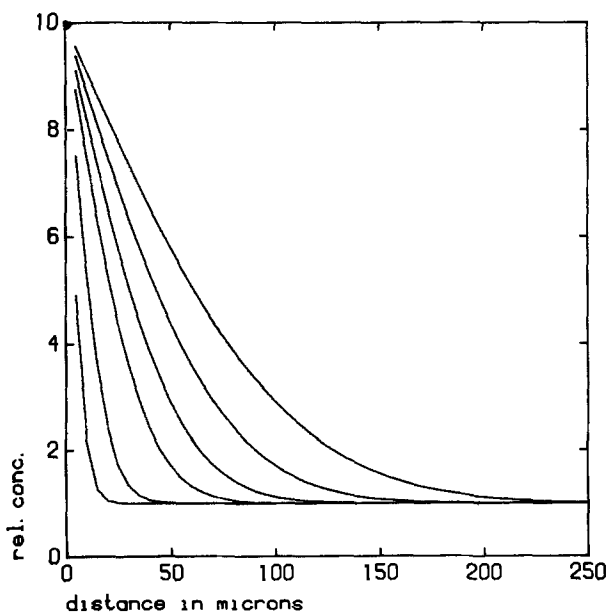

Fig. 3. Concentration profiles in pure stabilized zirconia 2, 10, 40, 80, 160, and 320 sec after a pressure increase at left electrode by a factor of 10^4.

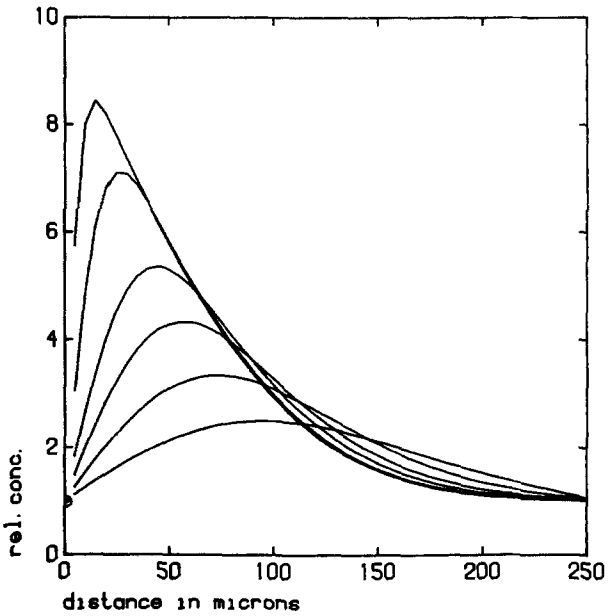

Fig. 4. Concentration profiles 2, 10, 40, 80, 160, and 320 sec after a return to original pressure at left electrode directly after the last profile of Fig. 3.

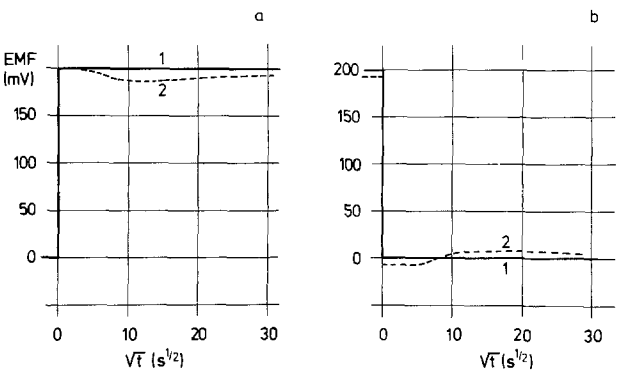

Fig. 5. Time response of emf ($-E$) after pressure increase a, and return to original pressure b. The square root time scale is chosen to be able to span a large period without losing the zero point. going on, and that a stationary state has not been established even at the times of the last profiles shown. The reason is that t_{ion} in Eq. [14] is constant, in fact equal to unity, and can be put in front of the integral. Consequently E becomes independent of the μ-distribution (or c_x-distribution) and is determined by the boundary values only. It is important to realize that these boundary values are assumed to be constant and are determined by the fixed oxygen content of the neighboring gas atmospheres by a gas-solid equilibrium. This equilibrium situation is only present if the contacts behave as perfectly reversible electrodes. The latter may not be true in many practical situations however. If the electrodes are not ideally reversible, then the oxygen flux, caused by the concentration gradient inside the solid, leads to a difference in chemical potential of oxygen at both sides of the gas-solid interface. This is larger in the beginning, because of the steep gradients present then, see Fig. 3. In the situation of Fig. 4 fast desorption takes place in the beginning. For a given gradient the oxygen flux can be calculated from Fick's first law. Figure 6 gives this takeup as a function of time expressed in terms of the equivalent electrical current. The infinite value which theoretically should occur at $t = 0$ is not pictured due

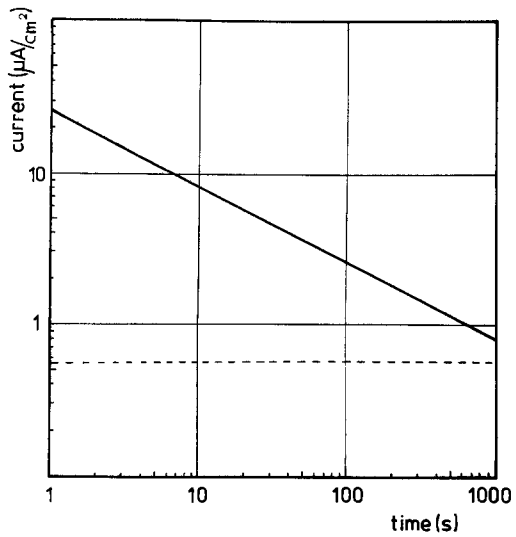

Fig. 6. Uptake of oxygen expressed in terms of current density for uniform zirconia sample and a pressure increase equivalent to a hole concentration rise from 10^{17} to 10^{18} cm^{-3} (10^{-4} to 1 bar in p_{ox}). The dashed line gives the steady-state penetration level for 250 μm sample thickness.

to the logarithmic scales chosen. In the final steady state a linear concentration profile is established leading to a permanent oxygen penetration through the electrolyte wall (8, 10, 12, 14). Its value corresponds to 0.57 μA in the case considered and is also indicated in the figure. Polarizable electrodes generate overvoltages as a result of this flux which, at the left-hand electrode, are large at short times and which modify the emf measured. The resulting time response curves then take the shape of those shown in Fig. 13 (to be discussed later on) instead of the fast response curves 1 of Fig. 5.

The results of calculations on a more complicated model are represented in Fig. 7 and 8. In the ξ-range between 50 and 75 μm the material properties are taken different from those of zirconia according to Table I. The emf shown in Fig. 5a, curve 2 starts with the ideal Nernst value. But as soon as the diffusion front reaches the "second phase," which occurs after about 16 sec, the latter starts to contribute to the emf and deviations

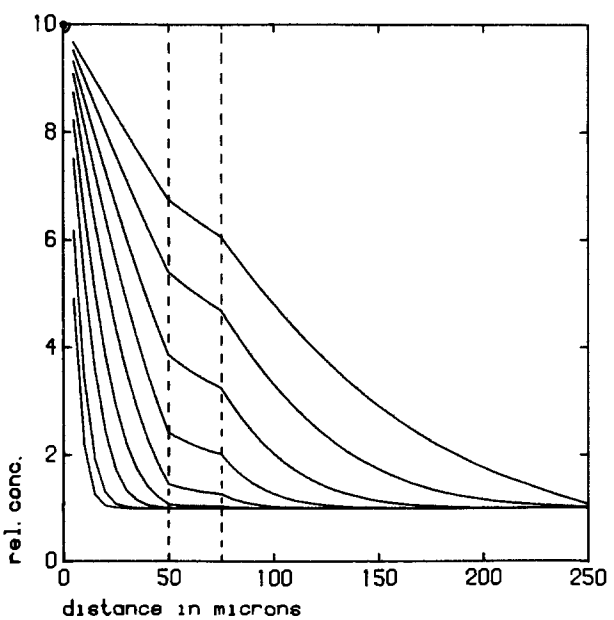

Fig. 7. Concentration profiles in electrolyte with second phase layer with mixed conduction in region indicated by dotted lines. Time after pressure increase at left electrode 2, 4, 10, 20, 40, 80, 160, 320, and 640 sec.

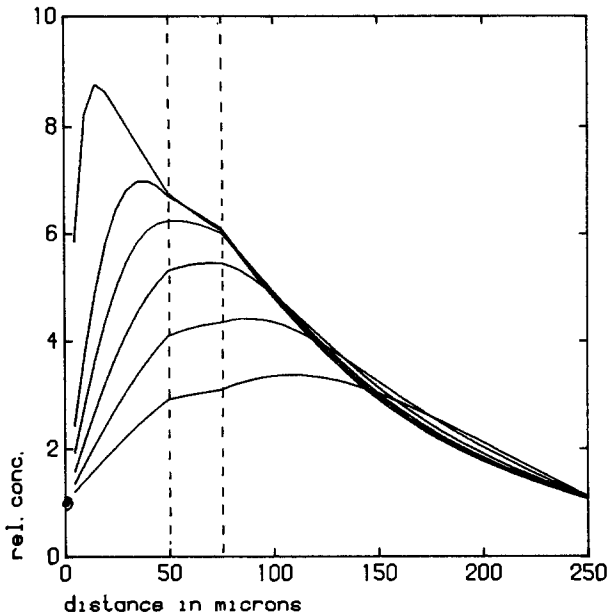

Fig. 8. Concentration profiles 2, 20, 80, 160, and 320 sec after return to original pressure at left electrode directly after last profile of Fig. 7.

occur because the ionic transport number is lower than unity. The deviations grow as the gradient in this region increases; they fall again when the steady state is approached. This is so because the effective diffusion coefficient of the second phase is somewhat higher than that of the electrolyte proper at the concentration occurring in the steady state.

When after 640 sec the sample pressure is returned to its original value (Fig. 8), the first drop in concentration takes place in the electrolyte again. The resulting emf drop is thus exactly 200 mV, the Nernstian value, which means that the voltage starts below zero volts, Fig. 5b, curve 2. It remains practically stationary during the first 20 sec, but then the profile in the second-phase region becomes affected again and slow changes in emf take place. Eventually the concentration drop over the region becomes zero and a point of zero deviation from Nernst's law occurs, which means that the emf passes through zero after about 30 sec. But later on the gradient inverts and a positive error builds up which reaches a maximum. Only after a very long time, of the order of 1 hr, which is much longer than that covered by the computation, zero is approached again. Then the excess concentration built up inside the electrolyte wall has leveled out completely.

Since the effective diffusion constant and transport numbers of the mixed conductor depend strongly on the oxygen pressure, we expect an influence of the pressure range where the electrochemical cell is used. To see this effect a calculation was made with the same parameters as before, but representing a jump down in the oxygen pressure of the sample atmosphere, followed by a return to the original value. A factor of 10 in c is used again corresponding to 10^4 in oxygen pressure. Figure 9 gives the resulting concentration profiles, Fig. 10 the corresponding emf responses after the jump. It is obvious that the effects on the emf are much smaller than in the previous case, the reason why the voltage scale has been expanded. But the same trend and the same time delay are found again. On jumping back to the original pressure a behavior similar to that depicted by curve 2 in Fig. 5b is found. Again the deviations from Nernst's law are smaller but the time delay is the same. The effects are so small because the concentration profiles in the second-phase region stay almost horizontal and this must be a consequence of a higher effective diffusion coefficient.

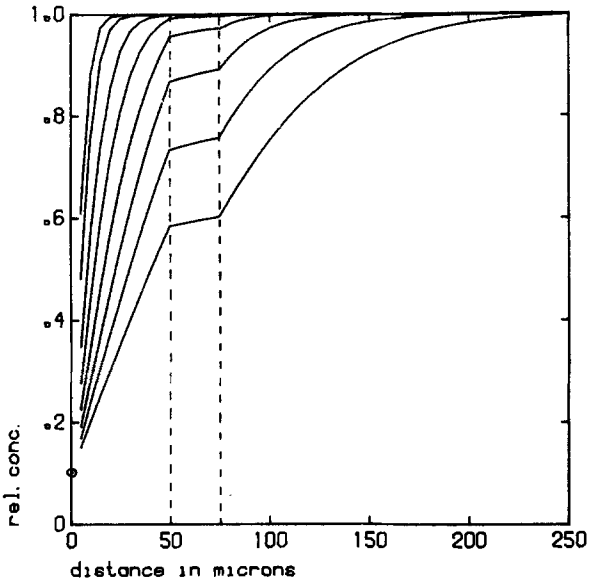

Fig. 9. Concentration profiles in electrolyte with second phase layer 2, 4, 10, 20, 40, 80, 160, and 320 sec after a pressure decrease at left electrode.
