Fig. 3. Thermal etch pits seen at 30° incidence in (100) surface after 3 hr anneal at 850°C; (a) unimplanted, (b) implanted.

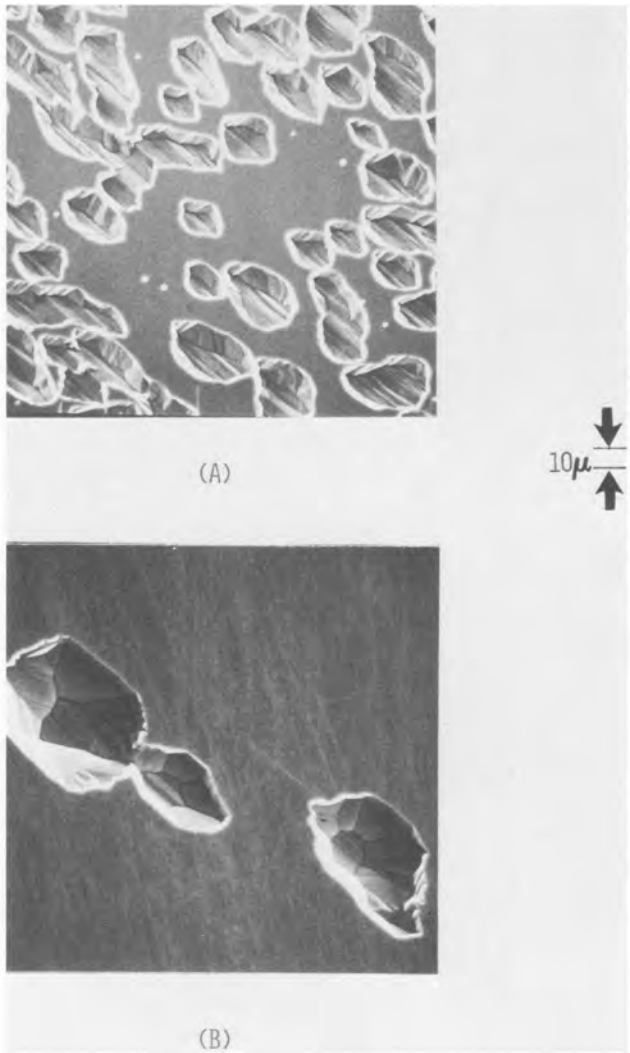

Fig. 4. Enlarged view of thermal etch pits seen at 30° incidence in (100) surface after 2 hr anneal at 850°C. The pits are estimated to be 30-40μ deep; (a) unimplanted, (b) implanted.

Discussion

From the thermal pitting experiment we may draw several conclusions. (*i*) The thermal pit density independence of anneal time indicates that pits nucleate heterogeneously. Increased anneal time causes pit growth but no additional nucleation. (*ii*) If pits nucleate heterogeneously, then we may conclude that the room temperature 8×10^{15} cm^{-2} Zn^+ implant reduces the heterogeneous pit nucleation sites, since the pit density is drastically reduced on these samples. (*iii*) It is obvious that the "contaminated nitride" is a sufficiently poor coating to allow pitting to occur, but the pit nucleation is not correlated with the nitride coating since the same "lossy" coating was simultaneously deposited on implanted and unimplanted samples with a vast difference in pit density.

The photoluminescence experiment allows us to draw the following additional conclusions. (*iv*) The good nitride coating virtually eliminates the formation of thermal pits on all samples though, at 900°C anneal, induced PL degradation still occurs. However, while PL degradation occurs in unimplanted samples the principal radiative recombination mechanism is not changed from that in virgin material; namely donor-to-valence band. Therefore, we conclude that anneal-induced PL degradation results from production of competing nonradiative recombination centers of some sort. (*v*) The 8×10^{15} cm^{-2} Ar^+ implanted samples show a 5-7 times smaller anneal-induced PL degradation while exhibiting essentially the same radiative recombination mechanism as the virgin and unimplanted annealed samples. We conclude, therefore, that the Ar^+ implant reduces the production of competing nonradiative recombination centers in the region sampled by the exciting light. (*vi*) The Zn^+ implant shifts the PL peak by 0.030 eV and doubles the PL peak half-width. By analogy with radiative recombination studies made on Te- and Zn-doped GaAs (6, 7), we would expect the Zn acceptor density in the region sampled by the exciting light to be $\sim 1 \times 10^{19}$ cm^{-3} based on the PL peak shift and half-width change observed. In GaAs the radiative efficiency of 1×10^{19} cm^{-3} Zn acceptor doped-material is about 20 times that of 1.5×10^{17} cm^{-3} Te-doped material (6). By analogy we might expect our Zn-implanted $GaAs_{0.6}P_{0.4}$ to show an increase in PL intensity by a factor of about 20 over the virgin 1.5×10^{17} cm^{-3} Te-doped material. We observe an increase by a factor of 10, very close to that expected. We conclude then that in the 2000-4000Å region sampled by the light very few anneal-induced nonradiative centers have been produced during the anneal.

Interpretation

Matthews *et al.* (8) have shown that lattice misfit strain can be used to remove threading dislocations by a horizontal glide mechanism under proper conditions. They verified this by growing epitaxial $GaAs_{(1-x)}P_x$ on GaAs substrates making appropriate changes in composition variable x during growth so that the lattice misfit strain would drive the "glide-out" of threading dislocations in the thin epitaxial layer at the growth

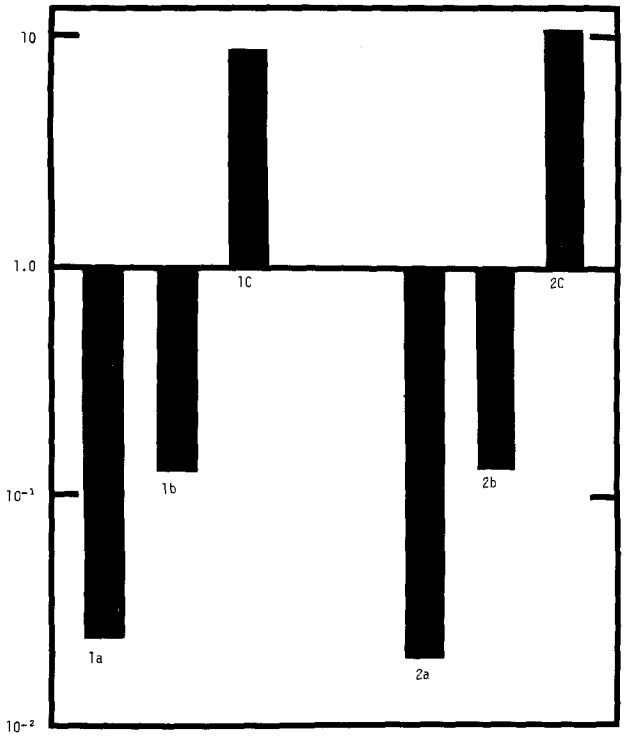

Fig. 5. Photon PL intensities of samples described in Table I relative to PL intensity of virgin (unimplanted, uncoated, unannealed) $GaAs_{0.6}P_{0.4}$ material taken as 1.0 in the figure.

temperature of 750°C. The critical (minimum) film thickness for this mechanism to occur was estimated to be ~60Å.

We propose that a similar mechanism is operating in the ion-implanted samples we studied. The 8×10^{15} cm^{-2} ion implants, of range ~200Å, severely strain the lattice near the surface of the sample and very likely drive it amorphous (9). During the activation anneal, while implant species diffusion and perhaps epitaxial recrystallization occur, the lattice strain resulting from the high dose implant drives threading dislocations laterally out of the implanted region of the sample by glide. It is also possible that vacancies produced by the implant or generated during the anneal are consumed along dislocation lines and assist dislocation removal by a climb mechanism.

We assert that the heterogeneous thermal pit nucleation sites correspond to dislocations terminating on the sample surface. The thermal pit density on unimplanted annealed samples is indeed of the same magnitude as dislocation densities in these materials (8, 10). The strain-induced glide (and perhaps climb) dislocation removal in the implanted samples therefore leads to a decrease in heterogeneous pit nucleation despite a substandard protective coating. The small number of pits which do still form may result from incomplete dislocation removal or from pinholes or other imperfections in the coating.

We propose that the reduction in anneal-induced PL degradation after the inert Ar^+ implant arises in the following way. Ga vacancies generated during the anneal are the most plausible origin of nonradiative recombination (NR) centers (3). We assert that NR center formation on the second set of samples and thermal pit formation on the first set are related and propose that dislocations reaching the surface act as primary Ga vacancy generators. When a high dose implant causes dislocations to be removed from the area implanted (at least not terminated on the implanted area surface) Ga vacancy generation is diminished accordingly, hence PL degradation diminishes.

Anomalous junction depth and curvature.—Junction depth and shape of 12 mil diam (7.3×10^{-4} cm^2) circular diodes were determined by cleaving the sample and staining to delineate the junction. These diodes were fabricated under conditions similar to the PL samples described above (room temperature 8×10^{15} cm^{-2} Zn^+ implant, 2800Å Si_3N_4 coating, 900°C anneal for 15-30 min). Figure 6 shows an electron micrograph of such a junction.

Similar to results reported by Itoh and Oana (12), the junction depth is anomalously large compared to that expected for diffused junctions formed at the same temperatures used for the implant anneal. Normal diffusion would result in 5-20 times shallower junction depths. Indeed, Itoh (11) observed that for $\lesssim 10^{15}$ cm^{-2} Zn^+ implants into $GaAs_{0.62}P_{0.38}$ anomalously large junction depths were observed for implant substrate temperatures $\lesssim$ 100°C. For implant temperatures greater than this (and fixed-anneal conditions) the junction depth decreased with increasing implant temperature to approximately the depth expected for normal diffusion.

Zelevinskaya *et al.* (12) observed similar results for Cd^+ implants into GaAs. In earlier work (13) they had shown evidence that diffusion of Zn implanted into GaAs is slowed by excess vacancies. In both cases Zelevinskaya *et al.* postulate that fast diffusion occurs by interstitial migration of atoms. Excess vacancies trap the Zn or Cd on substitutional sites resulting in slow diffusion. At implant temperatures $\gtrsim$ 100°C vacancy formation and trapping of Zn or Cd occurs during the implant. Most of the implanted atoms already reside on substitutional sites when the anneal is begun, and hence diffusion is slow. At implant temperatures $\lesssim$ 100°C, for high enough doses thermal vacancy generation is slow and most of the implanted atoms are in interstitial sites. During subsequent annealing these interstitial atoms diffuse rapidly. Forcing implanted atoms into fast diffusion interstitial sites may also be associated with recrystallization of a layer driven amorphous by a high dose, low temperature implant (12). Whether or not recrystallization is occurring, considerable stress is built up during high dose, low temperature implants and the fast diffusion is probably indicative of stress release;

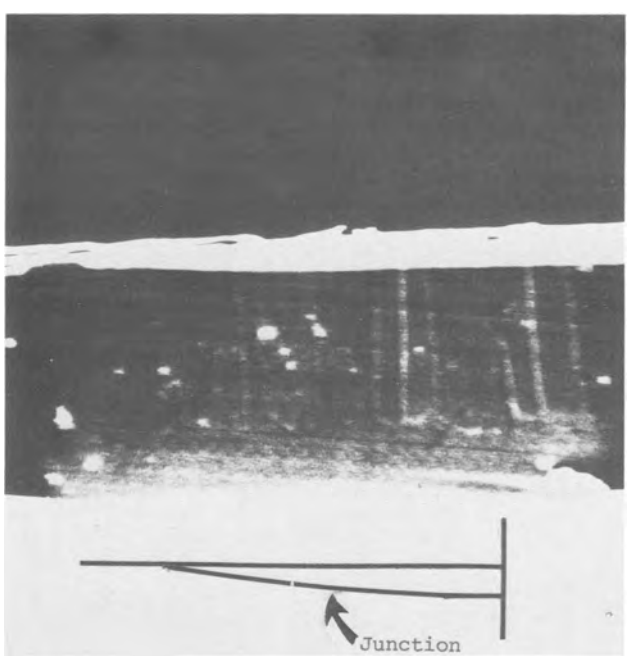

Fig. 6. SEM micrograph of a cleaved junction (white area) which had been annealed 15 min at 900°C. The maximum junction depth is 6.35μ and the curved region extends ~75μ. Magnification 1000X.

the same driving force which apparently drives dislocations out of the surface region.

In addition to anomalously large junction depths we observe a peculiar dish-shape junction for the circular diodes. There is virtually no lateral diffusion outside the implanted region as one might expect to occur in normal diffusion. Instead, the junction curves slowly over a distance of ~75 mm from the edge of the implanted region. This may be due to an anisotropic stress-enhanced diffusion. On the other hand, if vacancy generation during the anneal is higher in the unimplanted surrounding region, as we propose, not only would lateral diffusion of implanted atoms be retarded by vacancy capture, but vacancy diffusion laterally into the implanted area would retard vertical Zn diffusion. This vertical retardation would be greatest at the edge of the implanted region, where vacancy concentration is largest, and diminish toward the center, giving a dish-shaped junction profile.

Conclusion

Correlated observations of thermal pitting, photoluminescence, and anomalous junction profiles in $GaAs_{0.6}P_{0.4}$ on GaAs substrates receiving high dose, room temperature ion implants suggest that thermal pit nucleation sites (causing mechanical surface degradation) and vacancy generation sites (causing photoluminescence degradation) may both be identified with dislocations reaching the surface. Severe strain introduced by high dose, room temperature ion implants may act to remove dislocations which would otherwise terminate at the surface by a glide mechanism similar to that described by Matthews *et al.* (8). We propose that such dislocation removal decreases vacancy generation during anneal, thereby diminishing anneal-induced PL degradation. Anomalous junction depths and shapes offer additional evidence of high strain, low vacancy generation in the implanted region compared to the unimplanted region.

The mechanical and photoluminescence degradation observed here are able to occur only because the Si_3N_4 protective coatings are in varying degrees nonideal. However, the parallel processing of implanted and unimplanted control samples removes from consideration any question that the nitride quality is responsible for the degradation differences between implanted and unimplanted samples.

A Quantitative Model for the Diffusion of Phosphorus in Silicon and the Emitter Dip Effect

R. B. Fair* and J. C. C. Tsai

Bell Laboratories, Reading, Pennsylvania 19604

ABSTRACT

A consistent model of P diffusion in Si is presented which accounts quantitatively for the existence of electrically inactive P, the "kink" and the tail regions of the P profile, and the emitter dip effect. In this model it is shown that three intrinsic P diffusion coefficients exist, each one associated with the diffusion of P with vacancies in three different charge states. In the so-called "anomalous" high concentration region of the profile ($n \gtrsim 10^{20}$ cm^{-3}), it is shown that equilibrium concentration of $P^+V^=$ pairs dominates P diffusion and P electrical activity. At lower electron concentrations when the Fermi level is ~0.11 eV below the conduction band, the $V^=$ vacancy gives up an electron, and the 0.3 eV lower binding energy of the resulting P^+V^- pairs enhances the probability for pair dissociation by a factor of 10-35, depending on the temperature. This effect creates a steady-state excess concentration of V^- vacancies which flow away from the point of pair dissociation. The concentration of excess V^- vacancies created is proportional to the number of $P^+V^=$ pairs created at the Si surface times the enhanced probability for pair dissociation. These vacancies in the V^- charge state interact with P to create the enhanced tail diffusion. In a npn structure, the charge state of the excess vacancies becomes V^+ in the base region, thus enhancing the diffusivity of the base dopant and causing the emitter dip effect. The magnitude by which the P tail diffusivity and the base dopant diffusivity are enhanced is the same and may reach a factor of 135 for a 900°C diffusion.

At high concentrations the diffusion of phosphorus (P) into silicon (Si) produces an impurity atom distribution that differs considerably from the Gaussian or complementary error-function distributions (1-7). Numerous models have been proposed to explain this anomalous deviation from simple diffusion theory. Lawrence (8) suggested that the retardation of P diffusion was a result of the precipitation of P at moving dislocations. Dash and Joshi similarly postulated that the onset of anomalous P diffusion occurred simultaneously with the generation of dislocations in the Si lattice, at a critical integrated P concentration (9). However, the recent results of Sato *et al.* (10) disagree with this model, and Duffy *et al.* (11) found no evidence of dislocations or precipitation following the predeposition of prominently kinked P profiles. Significant numbers of dislocations and accompanying precipitation occur only after the drive-in cycle (11).

Other P diffusion models include the saturated lattice site model of Bakeman and Borrego (12), the thin surface barrier model of Makris *et al.* (13), impurity band effects on the electron activity coefficient (10, 14), the existence of a molten Si-P phase to explain the apparent flattened region of the P profile (15), and Thai's model of enhanced diffusion due to plastic deformation and subsequent generation of excess vacancies (16, 17). All of the above models have been criticized by Hu in a recent review (18), and so additional comments will not be made here.

Since Hu's review in 1972, several additional P diffusion models have evolved which support the idea that P diffuses via an intrinsic defect mechanism. Schwettmann and Kendall (19) observed that the concentration at which the kink occurs in the P profile varies with temperature with a constant activation energy. They suggested a two species mechanism with the faster diffusing species being the neutral phosphorus-vacancy pair (E center). The negative E center was proposed as the slower species, but no mechanism for excess vacancy generation was discussed. The P isoconcentration study of Makris and Masters (20) also suggests that the E center is the dominant diffusing pair.

Peart and Newman (21) have suggested that the high concentration region of the P profile is formed by a simple phosphorus-vacancy mechanism of diffusion where the vacancy is in a single negative charge state. When the Fermi level drops below the vacancy acceptor level of $E_C - 0.44$ eV in the bandgap, the P^+V^- pair breaks up and creates the nonequilibrium vacancy excess that accounts for the enhanced P diffusion in the tail region. This model suffers from the fact that a similar phenomenon is not observed during the diffusion of As in Si, since As diffuses via the As^+V^- pair (22). However, the basic concept of pair dissociation during a charge-state change of the vacancy does apply to the model to be presented in the present work.

Yoshida *et al.* (23) have shown that if at constant surface concentration 900°C P diffusion profiles obtained for different diffusion times are plotted *vs.* $x/\sqrt{t}$ (depth/$\sqrt{\text{time}}$), then the profiles practically fall on top of each other. This means that the diffusivity of P in Si is independent of position or time and depends only upon the local P concentration. This observation negates one of Hu's (18) earlier criticisms regarding the validity of using the Boltzmann-Matano analysis for extracting P diffusion coefficients from measured profiles. This also means that P diffusion in Si is not dominated by processes which involve interactions such as precipitation, generation of nonequilibrium vacancy transients by climbing dislocations, and trapping and complex formations that are far from equilibrium. This result does not rule out processes that generate steady-state concentrations of vacancies that rapidly equilibrate and which remain constant during the diffusion interval. It will be shown that such a process controls the tail region diffusion of P. Additional data supporting the important observation by Yoshida are shown in Fig. 1 for three diffusion temperatures. It can be seen that for the three diffusion temperatures chosen, the profile data plotted with $x/\sqrt{t}$ as the abscissa are independent of x and t. Experimental details will be given below.

Key words: electrical activity, diffusion in silicon, vacancy diffusion.

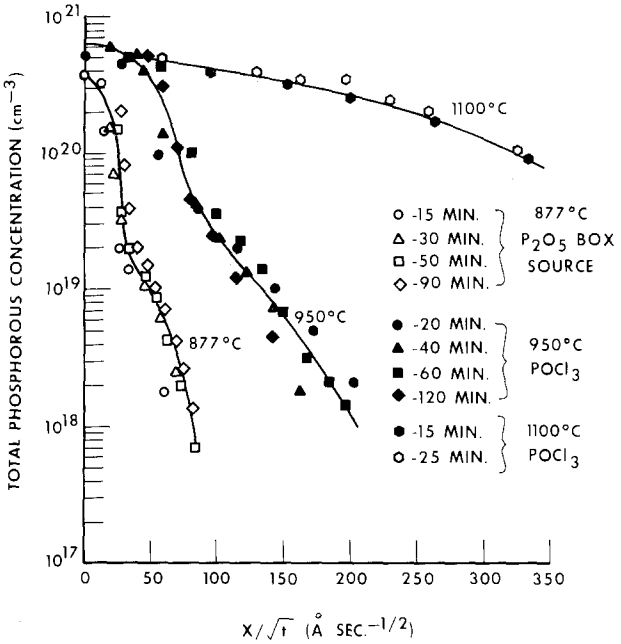

Fig. 1. Total phosphorus concentration *vs.* reduced distance for three diffusion temperatures.

Yoshida proposed that P diffuses only via the diffusion of E centers. His model says that P enters the Si surface in the form of an E center, which then flows into the bulk. Since the energetics of E center formation are more favorable at the Si surface, a supposed excess of E centers results which yields a supersaturation of vacancies due to E center dissociation. This source of vacancies causes the enhanced tail region diffusivity as some of these vacancies diffuse into the bulk. This model is useful since it contains elements which support some experimental facts, but no attempt was made to compare the theory in a quantitative way with experimental results. In addition, there was no mention of the charge state of the vacancies involved in the E center dissociation.

Most recently Shaw (24) proposed that P diffuses in the form of a P-neutral vacancy pair, $(P^+V^\times)$, and also as a P-singly ionized vacancy acceptor pair (P^+V^-). Shaw attributes the kink in the P profile to oxygen donors simultaneously diffusing with P from the surface oxide layer. The disappearance of the kink at lower P surface concentrations is attributed to a reduction of [O] in the crystal. However, the characteristic kink has been observed in ion-implanted P profiles that were diffused in an Ar ambient (25), as shown in Fig. 2. This result also refutes Yoshida's model, since the enhanced tail region can be seen to exist even though no excess E centers were formed via attachment of vacancies at the Si surface during the implantation of P. The fact that the implanted-diffused profile shows the characteristic kink also refutes the thin surface barrier model of Makris *et al.* (13).

In the following sections new experimental data on P diffusivity and P electrical activity in Si are presented, as well as a quantitative model of P diffusion which is supported by experimental measurements. It is shown that P diffuses via the E center as has been proposed earlier, but the diffusion proceeds with the vacancy in three different charge states. Dissociation of the $P^+V^=$ pair at a well-defined Fermi level position of $E_C - 0.11$ eV creates the excess V^- vacancies which enhance the tail region diffusivity. The kink region occurs where the P diffusivity becomes dominated by excess P^+V^- pair formation. For P diffusions in which the surface concentration is less than $\sim 10^{19}$ cm^{-3}, diffusion is dominated by the exchange of P with $V^\times$ neutral vacancies.

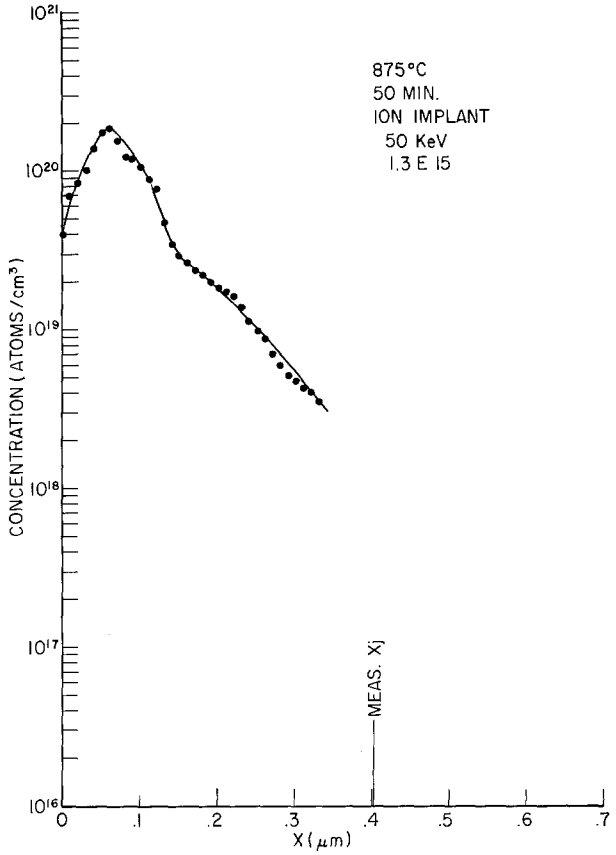

Fig. 2. Ion implanted-diffused phosphorus layer in silicon showing the presence of the kink and tail regions.

Experimental Technique and Results

Starting materials and diffusion conditions.—Diffusions were performed in p-type Si of 0.5-1 Ω/cm resistivity in both <111> and <100> orientation wafers. In most cases the front of the wafers were Syton polished and the backs were chemically polished. The wafers were degreased, cleaned, acid etched, and rinsed in DI water, and spun dry.

The diffusion source was $POCl_3$ for all diffusion temperatures except 875°C. In this case the diffusion source was P_2O_5 + CaO in a platinum box. The $POCl_3$ liquid source was transported into the diffusion furnace with either N_2 or Ar at flow rates typically set at 30 cm^3/min. Mixture with the main gas stream of N or Ar and O_2 occurred in the furnace with flow rates of 1500 and 75 cm^3/min, respectively. No differences in the diffusion profiles were observed when either N_2 or Ar carrier gases were used (25).

Profile determination.—Electron concentration vs. resistivity.—Details of the differential conductivity measurements made on the diffused samples appear in Ref. (7). In the past, Irvin's resistivity *vs.* concentration curve (26) has been used to convert differential conductivity measurements into doping density *vs.* depth. However, recent measurements by Mousty *et al.* (27) and Baccarani and Ostoja (28) indicate that Irvin's curve overestimates electron concentration for a given resistivity for $\rho \lesssim 5 \times 10^{-3}$ Ω/cm in P-doped Si. These authors have also shown that the electron mobility in P-doped Si becomes constant for P concentrations greater than $\sim 2 \times 10^{19}$ cm^{-3}. Tannenbaum (1) has also assumed a constant electron mobility for $\rho < 5 \times 10^{-3}$ Ω/cm. This means that the slope of the ρ *vs.* n curve should be constant in this range. Data from several authors (27, 29, 30) on ρ *vs.* n as determined by Hall measurements on P-doped Si samples are shown in Fig. 3. A "best fit" constant-slope ρ *vs.* n curve is drawn through the data points. It can be seen that Irvin's curve, which is based on radio-

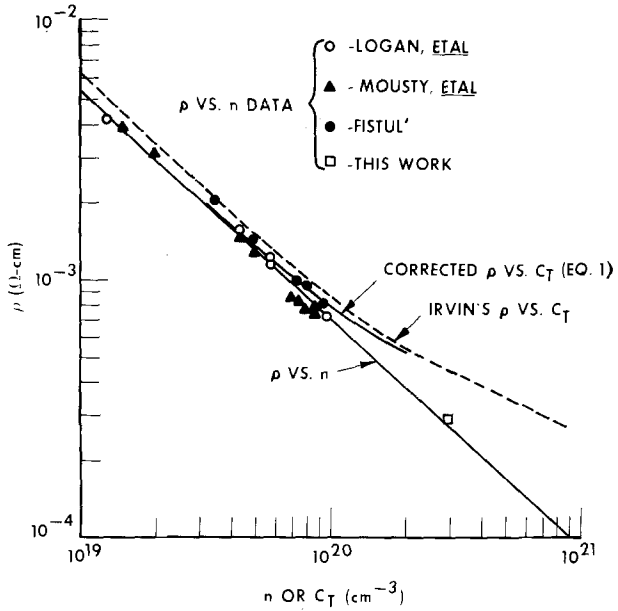

Fig. 3. Resistivity *vs.* phosphorus and electron concentrations in silicon.

tracer P data for concentrations greater than 10^{20} cm^{-3} does not represent the electrically active P^+ concentration. Also drawn in Fig. 3 is a "corrected" curve of ρ *vs.* total P concentration, C_T, based upon data obtained in this study which is discussed below. It can be seen that above $\sim 1.5 \times 10^{20}$ cm^{-3} P doping, good agreement is obtained with Irvin's ρ *vs.* C_T curve.

Total phosphorus concentration.—Secondary ion mass spectrometry was performed on some of the diffused samples in order to determine total P profiles (31). The SIMS data were calibrated using neutron activation analysis (NA) measurements of the same profiled wafers. A typical profile is shown in Fig. 4 of a 1000°C, 60 min diffusion. Also shown is the electrically active

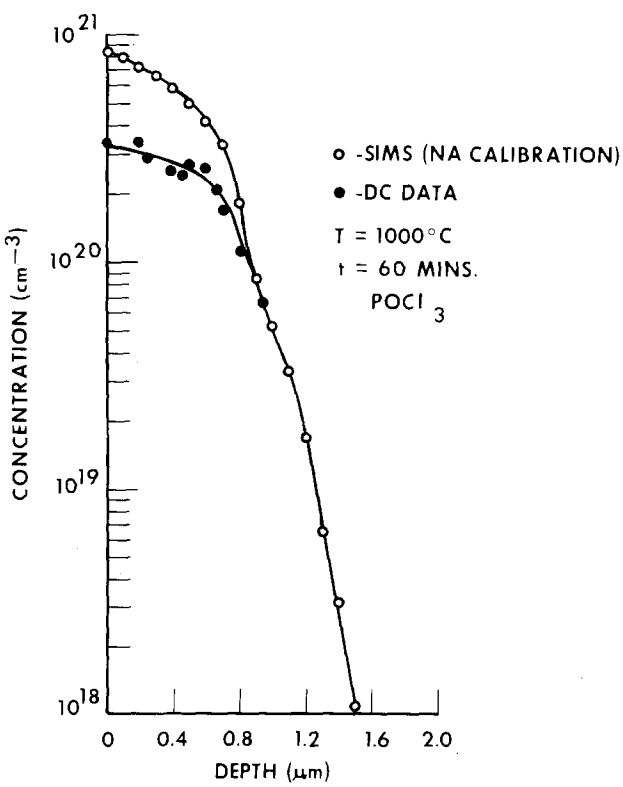

Fig. 4. Total and electrically active phosphorus diffusion profiles obtained by secondary-ion mass spectrometry (neutron-activation calibration) and by differential conductivity measurements.

P^+ profile obtained from differential conductivity (DC) measurements and the ρ *vs.* n curve of Fig. 3. The ratio of total P/cm^2 to n/cm^2 is $Q_T/Q_A = 2$, which agrees with previous results at 1000°C (32).

Additional total P and electrically active P profiles were obtained at 900° and 1050°C. These data are summarized in Fig. 5 where the corresponding n *vs.* C_T data are plotted. Included are the 1050°C data of Tannenbaum (1). These data can be described by an empirical equation relating n to C_T

$$C_T = n + 2.04 \times 10^{-41} n^3 \qquad [1]$$

This expression is plotted in Fig. 3 as the corrected resistivity *vs.* total P concentration curve previously described.

Phosphorus diffusion coefficients.—Since it has been established that the Boltzmann-Matano analysis is valid for P diffusion profiles in Si, this technique was applied to numerous profiles obtained over the temperature range of 875° to 1290°C. The results for 1000°C are displayed in Fig. 6 where D *vs.* n data are plotted. Also plotted are the isoconcentration D *vs.* n data

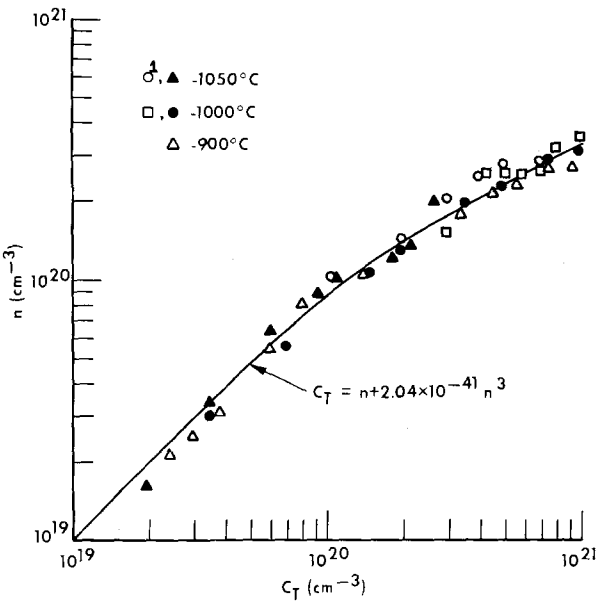

Fig. 5. Total phosphorus concentration *vs.* electron concentration in silicon.

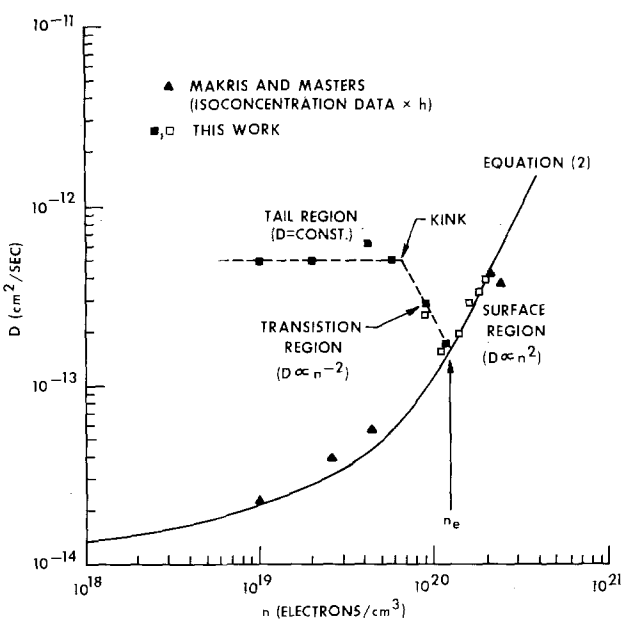

Fig. 6. 1000°C phosphorus diffusivity *vs.* electron concentration in silicon.

(▲ data) of Makris and Masters (20) for 1000°C where the D values have been multiplied by an electric-field enhancement factor (≅2) in order to be comparable with the other data in the figure. Since the data of Makris and Masters were total P data, they were converted to electron concentration *vs.* D by using Fig. 3.

There are several regions of interest in Fig. 6. In the surface region of the P profile, the D *vs.* n data show a slope of 2 when plotted on log-log scales ($D \propto n^2$). When the electron concentration drops to a critical value of $n = n_e$, an abrupt change occurs in the diffusivity by going from an n^2 dependence to a n^{-2} dependence. Finally, by the time the concentration has dropped to the well-known kink region, the diffusivity has increased and remains constant in the tail region (dashed curve). It can be seen that the isoconcentration data do not exhibit the same dependence of D on n as the data taken from profiles of P diffused into 1 Ω/cm Si. However, these data do fall on a curve extrapolated from the surface region data which has the form of

$$D = h\left[D_i^{\times} + D_i^{=}\left(\frac{n}{n_i}\right)^2\right] \qquad [2]$$

where $D_i^{\times}$ and $D_i^{=}$ are diffusion constants and h is the electric-field enhancement factor which approaches a value of 2 at high concentrations (18). D values will be discussed below, but at this point it can be said that $D_i^{\times}$ is the diffusion coefficient usually quoted in low concentration P diffusion studies (20).

The 1000°C data shown in Fig. 6 are plotted in Fig. 7 along with diffusivity data obtained from profiles diffused at 875°-1290°C. The comments applicable to Fig. 6 apply to the data in Fig. 7, except that the transition region ($D \propto n^{-2}$) disappears at 1050°C. However, the constant diffusivity tail region exists for all of the diffusions performed. The solid curves in Fig. 7 are of the form of Eq. [2].

The electron concentration corresponding to the observed abrupt change in D in going from an n^2 dependence to a n^{-2} dependence or n^0 dependence will be called n_e. These n_e data are plotted in Fig. 8 *vs.* $1/T$. Also plotted in Fig. 8 are the electron concentration values from Fig. 5 where the n *vs.* C_T data change slope from a value of 1 to a value of 1/3. It can be seen that the n_e values obtained from Fig. 7 and from Fig. 5 are approximately equal as a function of temperature. Also plotted are data from the D *vs.* n curves of Matsumoto (34). The solid curve drawn through these points corresponds to the electron concentration *vs.* $1/T$ at which the Fermi level is 0.11 eV below the conduction band. The calculation of the electron concentration corresponding to $E_C = 0.11$ eV was based on Fermi statistics with temperature-dependent effective electron mass (33), but with no impurity-band formation. Also shown in Fig. 8 are data of the electron concentration at the kink *vs.* $1/T$ (Δ data) obtained from numerous profiles (7, 19, 25, 35-37). The point to be made here is that the location of the kink, while significant, has far less significance than the concentration n_e. It is argued below that the kink occurs because of phosphorus-vacancy pair dissociations when $E_F = E_C$-0.11 (or $n = n_e$), and that the kink in the P profile exists as a result of these dissociation processes at $n = n_e$.

Sufficient diffusivity data in the tail region were available at 900° and 1100°C to plot D_{TAIL} *vs.* n_s, the electron concentration at the diffused Si surface. The tail region diffusivity at a concentration of 10^{18} cm^{-3} is plotted *vs.* n_s in Fig. 9. It can be seen that above a certain value of n_s, $D_{TAIL} \propto n_s^3$. The solid curves are calculated curves and are described below.

Finally, data representing the temperature dependence of D_{TAIL} for $n_s = 1.5$ to 2×10^{20} cm^{-3} are shown plotted in Fig. 10. These data were obtained from the present study and from other sources (24, 34), and are normalized with respect to the intrinsic P diffusivity at $n = 10^{18}$ cm^{-3}, $D_i^{\times}$. Also plotted in Fig. 10 are enhanced-base diffusivity data obtained on shallow npn structures with P emitters (emitter dip effect) (38-40). These data are normalized with respect to the intrinsic base diffusion coefficients. It can be seen that good agreement with the $D_{TAIL}/D_i^{\times}$ data is obtained, indicating similar magnitudes of enhanced diffusion. The

solid curves in Fig. 10 are calculated and are discussed subsequently.

Analysis of Results

High concentration region.—At electron concentrations greater than n_e (see Fig. 8), the D *vs.* n data in Fig. 6 and 7 have a slope of 2 on log-log scales and the C_T *vs.* n data in Fig. 5 have a slope of 1/3. It is shown in Fig. 8 that n_e *vs.* $1/T$ corresponds to the electron concentration at which the Fermi level is 0.11 eV below the conduction band. Recently, Kimmerling has identified an energy level at $E_C = 0.11$ eV as the second-acceptor level of the Si vacancy (41). His findings are based upon observations of the annealing kinetics of radiation-induced defects in P-doped Si using deep level transient spectroscopy. Therefore, the analysis of the experimental results in this paper will assume the existence of P impurity — $V^=$ vacancy interactions in high concentration phosphorus diffusion.

C_T vs. n.—The reaction between an ionized P^+ atom located on a lattice site and a single negatively charged vacancy whose second acceptor level is unoccupied can be written as

$$V^- + P^+ + e^- \leftrightarrows P^+V^= = PV^- \qquad [3]$$

Reaction [3] is likely to proceed to the right only if the Fermi level position in the bandgap is favorable (close to $E_C = 0.11$ eV). The effect of reaction [3] has been to remove an electron from the conduction band and to bind it to the vacancy. Simultaneously, a hole is created which becomes a free carrier in the valance band. The same reaction product will occur if the P^+ ion reacts with a $V^=$ vacancy, where the second-acceptor level has already been filled.

The equilibrium constant for reaction [3] is

$$K_2(T) = \frac{C_{PV^-}}{\gamma_P \cdot \gamma_V \cdot C_{V^-} \cdot C_{P^+} \cdot \gamma_n \cdot n} \qquad [4]$$

where C_{PV^-}, C_{V^-}, and C_{P^+} are the concentrations of $P^+V^=$ pairs, V^- vacancies, and P^+ ions, respectively, and γ_V, γ_P, and γ_n are activity coefficients. The $\gamma_P \cdot \gamma_V$ product is approximately constant (33) and $\gamma_n \cong 1$ seems to occur in As-doped Si at least up to $n \cong 3 \times 10^{20}$ cm^{-3} (22). The fact that $\gamma_n \cong 1$ is observed at high concentrations supports the fact that impurity-band formation does not significantly affect the Fermi level position in Si at diffusion temperatures, at least up to concentrations of 3×10^{20}, which agrees with Hu's observation (42).

Solving for the concentration of $P^+V^=$ pairs from Eq. [3] using the law of mass action for C_{V^-} and C_{P^+} yields

$$C_{PV^-} = K_2^1(T) C^i_{V^-} \frac{n^3}{n_i^2} \qquad [5]$$

where $C^i_{V^-}$ is the intrinsic concentration of V^- vacancies. The total concentration of P atoms is

$$C_T = C_{P^+} + C_{PV^-} = n + K_3^1(T) \frac{n^3}{n_i^2} \qquad [6]$$

where all the constants in Eq. [4] and [5] are contained in $K_3^1(T)$.

Reference to Fig. 5 shows that Eq. [6] expresses the measured relationship between C_T and n with $K_3^1(T)/n_i^2 = 2.04 \times 10^{-41}$. Actually, this ratio does show a weak temperature dependence since the break in the C_T *vs.* n curve occurs at n_e whose temperature dependence is shown in Fig. 8. This result agrees well with direct calculations of the equilibrium coefficient for reaction [3] (41).

D vs. n.—The general expression for the diffusion coefficient of P in Si can be written as (43)

$$D = h\left[\sum_{r=0} D_i^{r-}\left(\frac{n}{n_i}\right)^r\right] \qquad [7]$$

where h is the self-electric-field enhancement factor, and D_i^{r-} is the intrinsic diffusivity of the P-vacancy pair in the rth charge state. For the present case, $r = 0$,

1, and 2 and $r^- = 0$, $-$, and $=$. Equation [7] arises because the concentration of vacancies in the rth charge state is (from mass action effects)

$$\frac{C_{Vr-}}{C^i_{Vr-}} = \left(\frac{n}{n_i}\right)^r \qquad [8]$$

and the diffusivity of the P^+-V^{r-} pair is proportional to C_{Vr-}. The need for including the electric-field enhancement arises from the fact that Makris and Masters' isoconcentration diffusivity data (20) at high concentrations were a factor of 2 lower than the data obtained in this study (Fig. 6) for the same temperature and doping ($h = 2$ for $n >> n_i$). It is shown in Fig. 11 that the electric-field enhancement is evident at lower concentrations when the dominant diffusing species is the $P^+V^\times$ pair. Since it has previously been shown (22) that electric-field effects are important in the diffusion of As^+V^- pairs, it can be concluded that it is necessary to consider the electric-field effect regardless of the charge state of the diffusing species.

The preceding analysis and the data in Fig. 7 for $n > n_e$ strongly support the existence of the $P^+V^=$ pair, and consequently $D \propto (n/n_i)^2$ is evident. However, the existence of the P^+V^- pair (single negatively charged vacancy) is not evident. In order to try to observe the effect of the P^+V^- pair on D, diffusivity data were obtained on profiles whose surface doping, n_s, was $< n_e$, but greater than n_i ($10^{19} \lesssim n_s \lesssim 7 \times 10^{19}$ cm^{-3}). From these data the D/D_i *vs.* n/n_i relationship was determined. Similar data were obtained for As diffusions with $n_s < 7 \times 10^{19}$ cm^{-3}. Figure 11 is a plot of these data. The recent P data of Matsumoto *et al.* (44) are also included. It can be seen that there is a distinct difference between the P data and the As data. It has been well established that As^+V^- pairs diffuse and cause the observed concentration-dependent diffusion coefficient for As in Si (22). However, in the case of phosphorus, the only concentration-dependent diffusivity observed in this range is due to the self-electric-field enhancement when $n/n_i \gtrsim 1$. Therefore, due to lack of significant enhancement of P diffusivity in this concentration range, the dominant diffusing species must be the $P^+V^\times$ pair with an intrinsic diffusion coefficient, $D_i^\times$. At high concentrations the dominant species is the $P^+V^=$ pair with intrinsic diffusivity $D_i^=$, and the effect of the P^+V^- species is either negligible or nonexistent. Thus, if the presence of the tail is ignored, the total P diffusion coefficient can be written as

$$D = h\left[D_i^\times + D_i^= \left(\frac{n}{n_i}\right)^2\right] \qquad [2]$$

with

$$h = 1 + \frac{n}{n_i}\left[\left(\frac{n}{2n_i}\right)^2 + 1\right]^{-1/2} \qquad [9]$$

The intrinsic diffusivity of the P^+V^- pair must be very small. Its value will be estimated from the tail diffusivity data in the next section.

The diffusivity data for $D_i^\times$ ($P^+V^\times$) pair has been selected from the literature in which the P profiles were directly measured on samples with $n_s << n_i$. The best sources of these data are Ghostagore (45), Makris and Masters (20), and Tsai (46). These data are plotted in Fig. 12 and can be fitted to the Arrhenius equation

$$D_i^\times = 3.85 \exp\left(\frac{-3.66\text{ eV}}{kT}\right) \qquad [10]$$

The diffusivity data for $D_i^=$ can be obtained from Eq. [2] and the data shown in Fig. 7 for $n > n_e$. These data are plotted in Fig. 12. Also, the high concentration diffusivity data of Makris and Masters (20) are plotted in Fig. 12. These results were obtained from isoconcentration studies in which the samples were doped uniformly to 4.5×10^{20}P atoms/cm^3. From Fig. 3 this P concentration corresponds to $n = 2.1 \times 10^{20}$ cm^{-3}. Setting $h = 1$ in Eq. [2] (no concentration gradient; no electric field) and solving for $D_i^=$ using Makris and Masters' measured results gives good agreement with the other $D_i^=$ data shown in Fig. 12. These results can be fitted to the Arrhenius equation

$$D_i^= = 44.2 \exp\left(\frac{-4.37\text{ eV}}{kT}\right) \qquad [11]$$

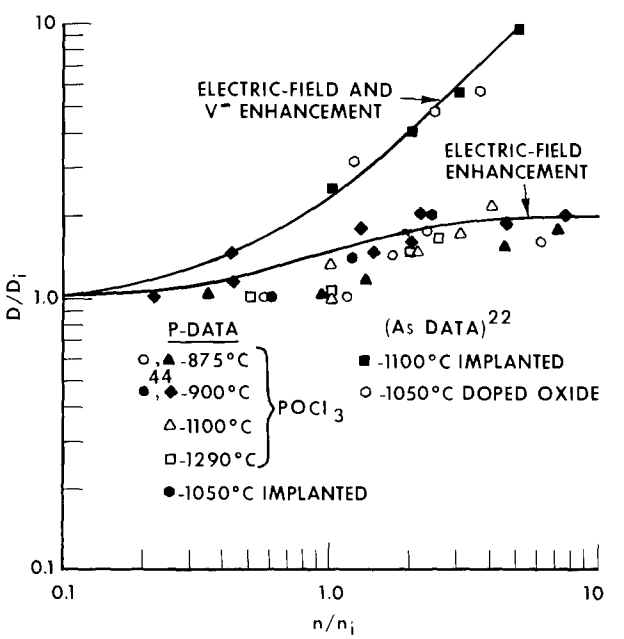

Fig. 11. A comparison between the diffusivities of arsenic and phosphorus in silicon for surface concentrations less than 7×10^{19} cm^{-3}.

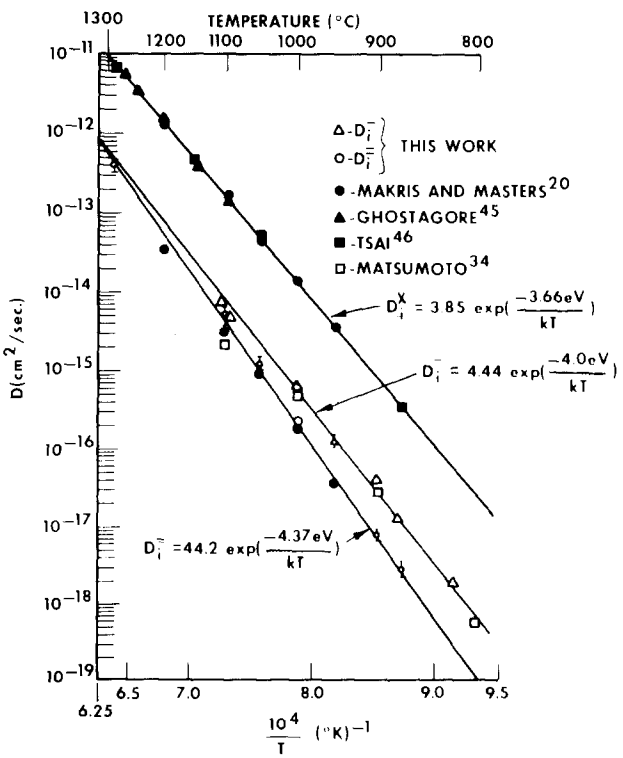

Fig. 12. The three intrinsic diffusion coefficients of phosphorus in silicon.

Equation [2] with $D_i^{\times}$ and $D_i^{=}$ given by the above expressions is plotted in Fig. 6 and 7 (solid curves) for the temperatures shown. Good agreement with the measured data is obtained.

Phosphorus tail region.—In order to understand the processes which contribute to the enhanced P tail region diffusivity, consider the idealized P profile shown in Fig. 13. When P enters the surface, some fraction will become paired with $V^{=}$ vacancies according to the reaction

$$P^{+} + V^{=} \rightleftarrows P^{+}V^{=} \qquad [12]$$

The mass action relation for Eq. [12] at the surface can be written in a similar manner to Eq. [5]

$$\frac{C_{PV^-}}{C^i_{PV^-}} = \frac{n_s^3}{n_i^3} \qquad [13]$$

where n_s is the surface electron concentration or the peak concentration (*i.e.*, for a Gaussian distribution, etc.), and $C^i_{PV^-}$ is the intrinsic concentration of $P^+V^=$ pairs. The condition expressed by Eq. [13] is assumed to hold throughout the highly doped surface region. Referring to Fig. 4 it can be seen that in the first 6000Å of the electron profile, the concentration remains at approximately $n_s = 3 \times 10^{20}$ cm^{-3} (the so-called "flat" region). Thereafter, the measured concentration drops with a doping gradient of 6×10^{24} cm^{-4} to $n_e = 1.3 \times 10^{20}$ cm^{-3}, which occurs at a depth of 8000Å from the surface.

When $P^+V^=$ pairs leave the flat region and diffuse down the steep doping gradient, it is proposed that they do not dissociate significantly until the Fermi level is ~0.11 eV below the conduction band, *i.e.*, until the concentration drops to n_e. This is reasonable in view of the fact that Hirata *et al.* (47) estimated that the phosphorus-vacancy pairs in their annealing experiments underwent $\sim 10^5$ jumps before dissociation. The observation that dissociation is more probable at $n = n_e$ can be understood by noting that the probability for pair dissociation is dependent on the pair binding energy. Thus the pair vibration frequency, γ ($\sim 10^{13}$ Hz), multiplied by exp $(-E_b/kT)$ yields the number of dissociation events/second, N_D (41). The ratio of the

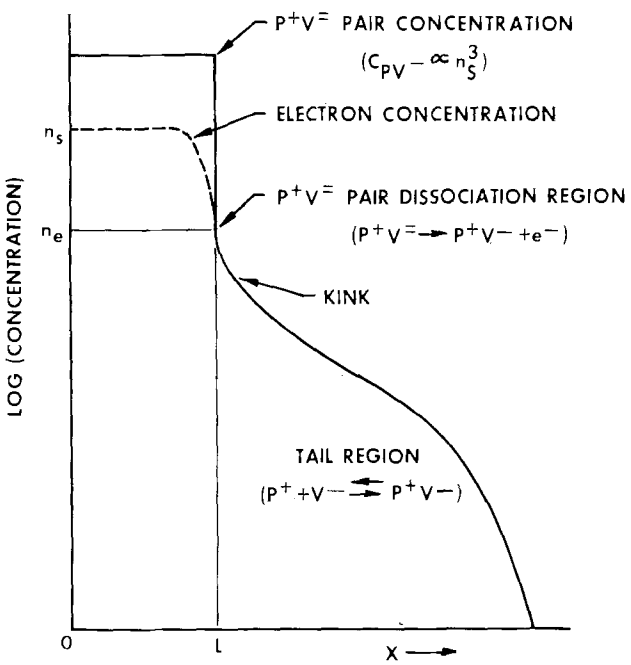

Fig. 13. Idealized phosphorus profile and vacancy generation model. $P^+V^=$ pairs formed in the surface region dissociate when the electron concentration drops to $n = n_e$. At this concentration the Fermi level coincides with the second acceptor level of $V^=$. The freed vacancies diffuse until they recombine with P^+ atoms in the tail region and form P^+V^- pairs.

dissociations/second for the P^+V^- pair to that of the $P^+V^=$ pair is

$$\frac{N_D^-}{N_D^=} = \exp\left(\frac{0.3\text{ eV}}{kT}\right) \qquad [14]$$

This follows since the binding energy, E_b, of the P^+V^- pair is ~0.3 eV lower than the binding energy of the $P^+V^=$ pair (48). Thus, when $E_F = E_C - 0.11$ eV

$$P^+V^= \rightleftarrows P^+V^- + e^- \rightleftarrows P^+ + V^- + e^- \qquad [15]$$

will be favorable as the $V^=$ vacancy loses an electron to the conduction band, and in its new charge state the P^+V^- pair is more likely to dissociate.

The mass action equation at $n = n_e$ for the reaction in Eq. [15] can be written as

$$\frac{C_{V^-}}{C^i_{V^-}} = \left(\frac{n_i}{n_e}\right)^2 \frac{C_{PV^-}}{C^i_{PV^-}} \qquad [16]$$

where C_{V^-} is the concentration of V^- vacancies, and $C_{PV^-}/C^i_{PV^-}$ is given by Eq. [13]. In order to account for the fact that reaction [12] also is generating $V^=$ vacancies which give up an electron to become V^- vacancies, and that reaction [15] is exp (0.3 eV/kT) times more probable than [12], the total concentration of generated V^- vacancies becomes

$$\frac{C_{V^-}}{C^i_{V^-}} = \frac{C_{V^=}}{C_{V^=i}}\frac{n_i}{n_e} + \frac{C_{PV^-}}{C^i_{PV^-}}\left(\frac{n_i}{n_e}\right)^2 \exp\left(\frac{0.3\text{ eV}}{kT}\right)$$
$$= \frac{n_s^3}{n_e^2 n_i}\left[1 + \exp\left(\frac{0.3\text{ eV}}{kT}\right)\right] \qquad [17]$$

Equation [17] represents the steady-state concentration of V^- vacancies referenced to $P^+V^=$ and P^+V^- pair dissociation events with the latter event being exp (0.3 eV/kT) times more probable. Values of the exponential term range from 36 at 700°C to 9 at 1300°C. It is the temperature dependence of the dissociation effect that accounts for the disappearance of the kink at higher temperatures ($T \gtrsim 1100$°C), *i.e.*, the probability for excess V^- generation decreases as temperature increases.

In the tail region the excess, steady-state V^- vacancies interact with P^+ ions to enhance phosphorus diffusion. Assuming that the P diffusivity is proportional to C_{V^-} yields

$$\frac{D^-}{D_i^-} = \frac{n_s^3}{n_e^2 n_i}\left[1 + \exp\left(\frac{0.3\text{ eV}}{kT}\right)\right] \qquad [18]$$

Equation [18] is the expression for the P tail-region diffusivity. In order to find D_i^- as a function of temperature, Eq. [18] can be solved for D_i^-, and measured profiles (known n_s) with known tail-region diffusivities, D^-, provide the required information. The results are plotted in Fig. 12 [Δ data from this work and □ data from Matsumoto, *et al.* (34)]. The Arrhenius equation that best describes these data is

$$D_i^- = 4.44 \exp\left(\frac{-4.0\text{ eV}}{kT}\right) \qquad [19]$$

It is now obvious why the data in Fig. 7 and 11 can be described by Eq. [2] without a D_i^- (n/n_i) term. At no temperature is this term more than 10% of the total P diffusivity. A discussion of this result is presented below.

The total tail-region diffusivity is

$$D_{TAIL} = D_i^{\times} + D^- \qquad [20]$$

with D^- given by Eq. [18]. Equation [20] is plotted in Fig. 9 (solid curves) for $T = 900°$ and 1100°C. Good agreement between the calculated curves and the data is obtained.

Dividing both sides of Eq. [20] by $D_i^{\times}$ gives the diffusivity enhancement factor in the tail region, $D_{TAIL}/D_i^{\times}$. This result is plotted with the data shown in Fig. 10 for $n_s = 1.5 \times 10^{20}$ cm^{-3} and 2×10^{20} cm^{-3}, which is the range of the data also plotted in the figure. Again the agreement between the calculated curves and the data is good.

Transition region.—The transition region is the portion of the D *vs.* n curves shown in Fig. 6 and 7 in which $D \propto n^{-2}$. For the profiles whose diffusivity data are shown in Fig. 7, the width of the transition region varies from 500Å at 1000°C to 1500Å at 875°C. This distance is too small to be associated with the vacancy diffusion length which is reported to be greater than 10 μm at 1050°C (49). This region is probably a result of the additional pair dissociations that occur at concentrations below $n = n_e$. Thus, the concentrations of liberated V^- vacancies and P^+V^- pairs build up with increasing depth into the crystal, but in a region where the concentration gradient is very steep.

Discussion

Vacancy concentrations.—The model presented in the preceding section predicts that a significant excess concentration of vacancies occurs in the P tail region due to $P^+V^=$ pair dissociation. It is assumed that some fraction of P atoms entering the crystal combine with $V^=$ vacancies to form $P^+V^=$ pairs which dissociate at some distance L from the surface and contribute vacancies to the steady-state vacancy distribution (see Fig. 13). It should be pointed out that the reaction which forms $P^+V^=$ pairs does not reduce the concentration of simple single vacancies. More single vacancies are generated at the surface to keep [V] in equilibrium. Thus, the flux of $P^+V^=$ pairs entering the region where dissociation occurs equals the flux of vacancies away from the point of dissociation. If it is assumed that all of the vacancies flow to the surface, then

$$\frac{D_V(C_V - C_V^{\circ})}{L} = D\frac{\partial C_{PV^-}}{\partial x} \qquad [21]$$

where $D_V = 1.4 \times 10^{-4} \exp(-0.33 \text{ eV}/kT)$ is the vacancy diffusivity, and C_V and C_V° are the excess and total equilibrium vacancy concentrations, respectively. D is the P diffusivity given by Eq. [2] and $\partial C_{PV^-}/\partial x$ is the gradient of the total P less the electrically active P distributions at $x = L$. The left-hand term represents the flux of vacancies to the surface where the vacancy concentration is pinned at C_V°. For the 1000°C diffusion shown in Fig. 4, evaluation of Eq. [21] yields

$$C_V - C_V^{\circ} = 2.3 \times 10^{13} (\text{cm}^{-3})$$

At 1000°C, $C_V^{\circ} \cong 1.2 \times 10^{15}$ cm^{-3} when $n = 2 \times 10^{20}$ cm^{-3}, and $C_V \cong 1.2 \times 10^{15}$ cm^{-3}. Therefore, the vacancies generated from $P^+V^=$ pair dissociation at $x = L$ do not significantly perturb the equilibrium vacancy concentration in the highly doped surface region. This result is consistent with the observed equilibrium dependence of C_T on n (Eq. [6]) and D on n^2 (Eq. [2]).

If the same calculation is performed to determine $C_V - C_V^{\circ}$ in the lightly doped bulk where (50, 51) $C_V^{\circ} \sim 5 \times 10^{13}$ cm^{-3} and $L_V \approx 25$ μm, then if it is assumed that all of the generated vacancies flow into the bulk

$$C_V - C_V^{\circ} \sim 8 \times 10^{14} (\text{cm}^{-3})$$

and $C_V \sim 8.5 \times 10^{14}$ cm^{-3}. Both calculations yield C_V values which are reasonably close to each other, *i.e.*, $C_V \sim 1 \times 10^{15}$ cm^{-3}. This value of vacancy concentration is also approximately equal to the $V^=$ concentration necessary to account for the observed flux of $P^+V^=$ pairs entering the Si surface during diffusion. Therefore, the model is entirely consistent with the absolute concentrations of vacancies available in the Si crystal.

In the P tail region at $n = 1 \times 10^{18}$ cm^{-3}, most of the dissociated vacancies will still be in the V^- charge state. The equilibrium concentration of neutral vacancies at 1000°C is (51)

$$C_V^{\times} = 5.5 \times 10^{22} \exp\left(\frac{-2.6 \pm 0.2 \text{ eV}}{kT}\right) \qquad [22]$$

Therefore, $C_V/C_V^{\times} \cong C_V/C_V^{\times} \cong 10$. This result can be compared with the 1000°C $D_{TAIL}/D_i^{\times}$ data shown in Fig. 10. It can be seen that the calculated magnitude of the excess vacancy concentration is of the correct magnitude to explain the observed P tail diffusion enhancement.

P-vacancy binding energy and Si self-diffusion.—The results of the previous sections indicate that P diffuses by interacting with vacancies in three different charge states. At this point it is appropriate to see if these results are consistent with the data available on the diffusion of other Group V impurities in Si and Si self-diffusion. The energy for Group V impurity diffusion is

$$Q_I^r = \Delta H_V^r + Q_E^r - E_b^r \qquad [23]$$

where Q_I^r is the impurity diffusion energy when the dopant interacts with a vacancy in the rth charge state, ($r = x, -, =$), ΔH_V^r is the vacancy formation enthalpy in the rth charge state, Q_E^r is the migration energy of the corresponding impurity-vacancy E center, and E_b^r is the E center binding energy.

From the microscopic cavity model of Phillips and Van Vechten (52), the formation enthalpy of a neutral vacancy in Si is $\Delta H_V^{\times} = 2.66$ eV. When a vacancy is ionized two new carriers of opposite charge are created. One is bound in the vicinity of the vacancy and the other is a free carrier in the valence band for acceptor-type vacancies. Thus, ΔH_V for an ionized vacancy must include the enthalpy of ionization, ΔH_I. The values of ΔH_I have been calculated (53) and yield the result that if the Fermi level is near the conduction band edge

$$\Delta H_V^- = 3.6 \text{ eV}$$

$$\Delta H_V^= = 3.93 \text{ eV}$$

A check on the correctness of these values can be obtained by calculating ΔH_V^- and $\Delta H_V^=$ from Si self-diffusion data. Thus

$$\Delta H_V^r = Q_{Si}^r - \Delta H_m^r \qquad [24]$$

where Q_{Si}^r is the activation energy for Si self-diffusion with a vacancy in the rth charge state, and ΔH_m^r is the corresponding vacancy migration enthalpy. Van Vechten (51) has reviewed the appropriate values of ΔH_m^r in Si and has argued that at high diffusion temperatures, $\Delta H_m^r \cong 1.2 \pm 0.3$ eV. The activation energy for Si self-diffusion with neutral vacancies has been consistently reported to be $\lesssim 4$ eV. Watkins and Corbett (54) reported $Q_{Si} = 3.95$ eV from low temperature annealing of E centers. The N_i precipitation in Si data of Seeger and Chik (55) show a 3.93 eV activation energy for Si diffusion below ~850°C. The recent loop annealing data of Sanders and Dobson (56) show $Q_{Si} \cong 4.1$ eV in intrinsic Si below ~1050°C. At higher temperatures the Q_{Si} energy in intrinsic Si appears to increase to 5.13 eV (57). However, it has been shown (58) that above ~1050°C the intrinsic diffusivities associated with SiV^+, SiV^-, and $SiV^=$ pairs exceed the diffusivity of the $SiV^{\times}$ pair. Thus, the Q_{Si} energy is only an apparent energy and reflects the diffusion of Si with vacancies in multiple charge states. Thus

$$Q_{Si}^{\times} \cong 3.95 \text{ eV}$$

and (58)

$$Q_{Si}^- \cong 5.0 \text{ eV}$$

for Si diffusion via V^- vacancies. Therefore, from Eq. [24] $\Delta H_V^{\times} = 2.75$ eV and $\Delta H_V^- = 3.8$ eV in agreement with the theoretical values.

For the $SiV^{=}$ pair it can be shown that $Q_{Si}^{=} \cong 5.43$ eV (58). From Eq. [24] this yields $\Delta H_V^{=} = 3.93$ eV with $\Delta H_m = 1.5$ eV, in good agreement with the calculated value.

Kimmerling *et al.* (48) have measured $Q_E^{-} = 0.95 \pm 0.03$ eV for the neutral E center migration energy. Thus, from Eq. [23]

$$E_b^{-} = 0.55 \text{ eV}$$

for the P^+V^- pair binding energy.

For the $P^+V^{=}$ pair (negative E center), $Q_E^{=} = 1.25 \pm 0.05$ eV (48). The 0.3 eV difference between Q_E^{-} and $Q_E^{=}$ can be accounted for by an increase in the coulomb energy required to produce a third-neighbor separation between P^+ and $V^{=}$. On this basis $E_b^{=} = E_b^{-} + 0.3 = 0.85$ eV. Using Eq. [23] with $Q_I^{=} = 4.37$ eV and $\Delta H_V^{=} = 3.93$ eV yields

$$E_b^{=} = 0.81 \text{ eV}$$

in excellent agreement. Likewise, the binding energy of the $P^+V^\times$ pair should be $E_b^\times \cong E_b^{-} - 0.3 = 0.25$ eV. Calculations by Swalin (59) indicate that the strain energy released when a neutral vacancy moves into a nearest neighbor position to an impurity atom is about 0.3 eV in Si. The result for $E_b^\times$ is in excellent agreement with this value.

Because the elastic interaction between an impurity and a vacancy in Si is short ranged, varying as r^{-3}-r^{-5} (see Ref. 60-62), the pair migration energy, $Q_E^\times$, is zero since no pair migration occurs. Thus, $Q_I^\times$ for an impurity in Si should be approximately

$$Q_I^\times = \Delta H_V^\times + \Delta H_m^\times - E_b^\times \qquad [25]$$

For the $P^+V^\times$ diffusion with $Q_I^\times = 3.66$ eV and the appropriate vacancy formation and migration enthalpies, $E_b^\times = 0.29$ eV. Again, good agreement is obtained with the previously calculated value.

Diffusion activation energy data obtained from low concentration doping profiles of other Group V impurities in Si are listed in Table I (63, 64) (surface concentration $<< n_i$). The $Q_I^\times$ values of the various $I^+V^\times$ diffusing species average out to 3.69 eV. Also shown is the difference between $Q_{Si}^\times$ and $Q_I^\times$ which averages ~0.32 eV. This difference is due to the impurity-vacancy binding energy which is very short ranged. Therefore, it is expected that $Q_{Si}^\times$ and $Q_I^\times$ should be very close in value, as pointed out by Hu (65).

Q_I^- values for I^+-V^- pairs in Si are also shown in Table I. These data were taken from high concentration diffusion profiles (surface concentration $>n_i$) (22, 66-68). The average Q_I^- value is 4.1 eV. The average difference between the Si self-diffusion energy Q_{Si}^- (with negatively charged vacanices) and Q_I^- is 0.79 eV. This follows since

$$\begin{aligned} Q_{Si}^- - Q_I^- &= \Delta H_m^- - Q_E^- + E_b^- \text{ (eV)} \\ &= 1.2 - 0.95 + 0.55 \\ &= 0.8 \text{ eV} \end{aligned}$$

Table I. Energetics related to diffusion of Group V impurities in silicon

Diffusing pair	Q_E (eV)	E_b (eV)	Q_I (eV)	$Q_{Si} - Q_I$ (eV)
$P^+V^\times$	— (a)	0.25	3.66	0.29
$As^+V^\times$	—	0.33	3.58	0.37
$Sb^+V^\times$	—	0.24	3.65	0.3
$Bi^+V^\times$	—	0.06	3.85	0.1
$SiV^\times$			3.95	
P^+V^-	0.95	0.55	4.0	1.0
As^+V^-	1.07	0.45	4.1	0.9
Sb^+V^-	1.28	0.35-0.57	3.98-4.2	0.9
Bi^+V^-	1.46	0.43	4.12	0.88
SiV^-			5.0	
$P^+V^{=}$	1.25	0.81	4.37	1.06
$SiV^{=}$			5.43	

(a) Short-range elastic interaction only, no pair migration

when the impurity is phosphorus. These results are far more consistent than previous attempts to construct such tables (43, 47, 65) since a proper accounting has been made of the vacancy charge state in Table I.

The P^+-V^- *anomaly.*—It is evident from Table II that the binding energies of the the P^+V^- pair and the As^+V^- pair are approximately the same, as are their activation energies for diffusion. However, it is evident from Fig. 11 that the As^+V^- pair dominates the diffusion of As at high concentrations ($n \gtrsim n_i$), but the P^+V^- pair does not contribute to the diffusion of P except as a result of the dissociation of $P^+V^{=}$ pairs.

The diffusion coefficient of As associated with As^+V^- migration is shown in Fig. 14 to be (22)

$$D_i^-|_{As} = 22.9 \exp\left(\frac{-4.1 \text{ eV}}{kT}\right) \qquad [26]$$

Comparing this result with Eq. [19] for D_i^- for P shows that the ratio of the prefactors is

$$\frac{D_o^-|_P}{D_o^-|_{As}} \cong 0.2 \qquad [27]$$

where D_o^- is the prefactor in the general expression $D_i^- = D_o^- \exp(-Q_I/kT)$. The ratio in Eq. [27] can be written as

$$\frac{D_o^-|_P}{D_o^-|_{As}} = \frac{\gamma_P^- f_P^- \exp\left(\frac{\Delta S_P^-}{k}\right)}{\gamma_{As}^- f_{As}^- \exp\left(\frac{\Delta S_{As}^-}{k}\right)} \qquad [28]$$

where γ^- is the mean vibrational frequency of the impurity atom, f^- is the correlation factor, and ΔS^- is the change in entropy associated with the diffusion process.

Hirata *et al.* (47) have shown that $\gamma^- \exp(\Delta S^-/k)/N_J = 5 \times 10^7$ Hz for P and 2×10^8 Hz for As. Assuming $f_P^- \cong f_{As}^-$ (65), and the number of jumps, N_J, of the P^+V^- pair prior to dissociation is the same for the As^+V^- pair (47), then Eq. [28] predicts

$$\frac{D_o^-|_P}{D_o^-|_{As}} = 0.25$$

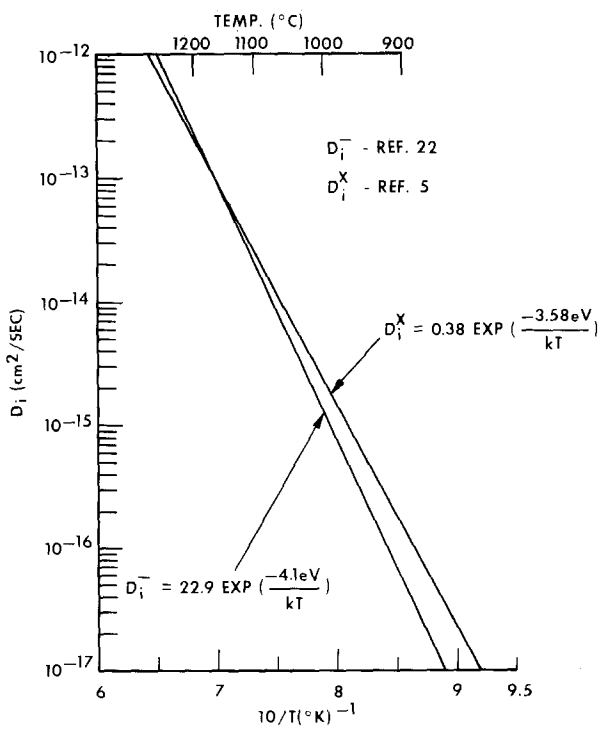

Fig. 14. Intrinsic diffusion coefficients of arsenic in silicon

in excellent agreement with the result expressed in Eq. [27]. Therefore, it can be concluded that the relatively small diffusion coefficient, $D_i^-|_P$ is a result of the lower P atom vibrational frequency and ΔS^- which appears to correlate with the relative size of P compared to As (47). This result gives support to the correctness of the prefactor of D_i^- for P, and the consistency of the 4.0 eV activation energy with the other Group V elements supports the analysis used to calculate the D_i^- data in Fig. 12.

A similar analysis for the $P^+V^\times$ and $As^+V^\times$ pairs shows that their prefactor ratio is

$$\frac{D_o^\times|_P}{D_o^\times|_{As}} \cong 10 \qquad [29]$$

This result reflects the fact that $D_i^\times|_P >> D_i^\times|_{As}$, although a satisfactory explanation is not available. Inspection of Fig. 14 shows that for As, $D_i^\times \cong D_i^-$, whereas the results of this study show that for P, $D_i^\times >> D_i^-$. This observation accounts to a significant extent for the differences in the As and P diffusion profile shapes.

Sample P profile calculation.—It is appropriate at this point to present the initial results of numerical calculations of P diffusion profiles. Detailed aspects of these calculations will be published at a later date. Essentially, the general diffusion equation was numerically integrated after it was expressed as a finite difference equation. The diffusivity of P at concentrations greater than n_e was calculated from Eq. [2], while the tail-region diffusivity was determined from Eq. [18] and [20]. The transition region diffusivity was estimated from its n^{-2} dependence. The results for a 900°C, 30 min diffusion are presented in Fig. 15. The calculation was performed with $n_s = 2 \times 10^{20}$ cm^{-3}, but what is shown in Fig. 15 is the total P concentration curve which was obtained by converting the calculated n *vs.* x curve to C_T *vs.* x from Fig. 3. The data shown were determined from differential conductivity measurements of a 900°C, 30 min $POCl_3$ diffusion. Agreement between the measured data and the calculated curve is quite good, with the calculated kink occurring at $C_T \cong 5 \times 10^{19}$ cm^{-3}.

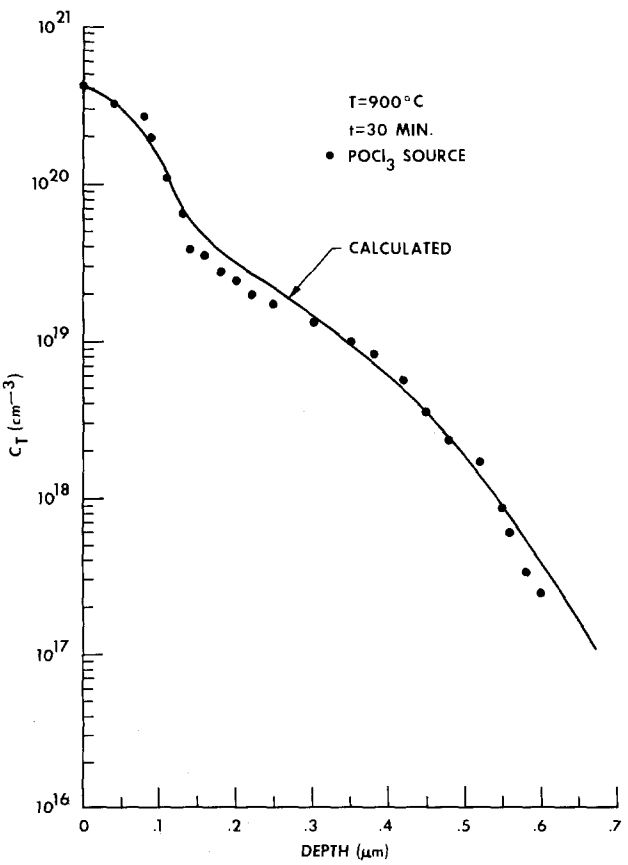

Fig. 15. Calculated and measured total phosphorus profiles in silicon.

Emitter dip effect.—It was pointed out in Fig. 10 that the enhanced base diffusivity resulting from the emitter dip effect of the P emitter diffusion is comparable with $D_{TAIL}/D_i^\times$. The emitter dip effect and the various theories proposed to describe it have been adequately reviewed by Hu (18).

The model proposed in this paper requires that the inner base diffusivity (under the emitter) be

$$D_{in}^B = D_i^B \left(\frac{D_{TAIL}}{D_i^\times} \right) \Bigg|_{phos} \qquad [30]$$

where D_i^B is the intrinsic diffusivity of the base dopant (boron or gallium) under normal diffusion conditions. This result is reasonable since the enhancement factor is measured with respect to $D_i^\times$ which is proportional to the neutral vacancy concentration which, in turn, is constant throughout the n and p regions of the emitter-base structure (indepedent of Fermi level position). Implicit in Eq. [30] is the assumption that the dominant charge state of the vacancies responds to the local Fermi level position which continuously changes with depth into the Si crystal. In the p-type base region, the dominant charge state of the vacancies is assumed to be V^+, which is the type of vacancy that dominates B and Ga diffusion. From Eq. [18] and [20]

$$D_{in}^B = D_i^B \left[\frac{n_s^3}{n_e^2 n_i} \left\{ 1 + \exp\left(\frac{0.3 \text{ eV}}{kT} \right) \right\} \right] \frac{D_i^-}{D_i^\times} \Bigg|_{phos} \qquad [31]$$

If the base is assumed to be Gaussian, then the standard deviation of the initial distribution is

$$W_o = \frac{0.4\, Q_o}{C_{po}} \qquad [32]$$

where Q_o is the integrated doping of the initial base profile and C_{po} is the peak concentration (atom/cm^3). During thermal redistribution

$$W^2(t) = W_o^2 + 2\, D^B t \qquad [33]$$

The amount of base push-out is the difference between the inner base and outer base diffusion distance

$$\delta(t) = W_{in}(t) - W_{out}(t),$$

$$= W_o \left[\sqrt{1 + \left(\frac{2\, D_{in}^B t}{W_o^2} \right)} - \sqrt{1 + \left(\frac{2\, D_{out}^B t}{W_o^2} \right)} \right] \qquad [34]$$

In order to apply Eq. [31] and [34] for the calculation of $\delta(t)$, measured profile data is required to determine n_s and W_o. Becker *et al.* (69) have generated P profile data as a function of $POCl_3$ source flow rates using differential conductivity measurements and Irvin's curve. Base push-out data was also recorded. Converting their data to n_s *vs.* δ using Fig. 3, the results are plotted in Fig. 16. A standard BN base diffusion and oxidation step was employed to establish the initial base layer. This diffusion step has been profiled by Rhoads (35). The initial base parameters are shown in Fig. 16. Substituting the appropriate numbers in Eq. [31] and [34] gives the calculated curve shown in Fig. 16. Excellent agreement with these reliable data is achieved.

At this point it is reasonable to consider the depth to which the generated steady-state flux of vacancies extends, *i.e.*, the vacancy diffusion length. Yoshida *et al.* (23) studied the outdiffusion of an epitaxial P-doped

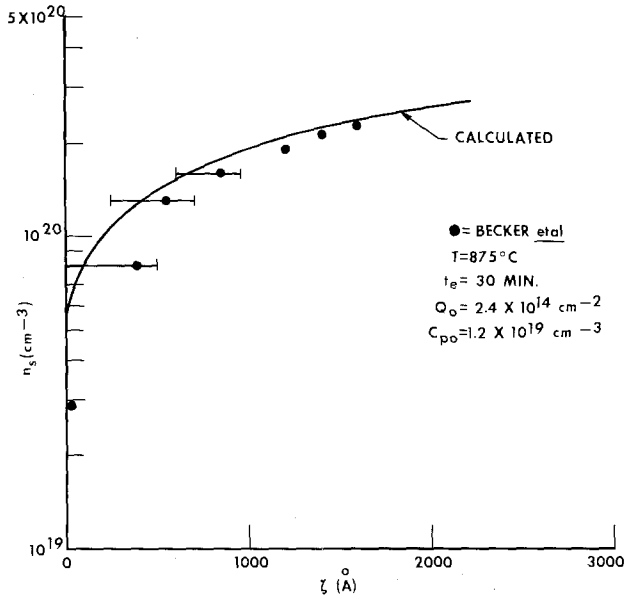

Fig. 16. Base region push-out distance vs. surface electron concentration; the emitter dip effect.

layer located 20 μm from the Si surface. A surface P diffusion was performed over part of the wafer with $n_s \cong 2 \times 10^{20}$ cm^{-3}. Following the 900°C, 1385 min diffusion the portion of the epi under the surface diffused area had itself diffused 1.9 μm. However, the junction at the epi interface in the nondiffused surface portion had not moved appreciably. The diffusion length associated with this latter region is

$$L_{epi} = 2\sqrt{D_i{}^{\times} t}$$
$$= 0.16\ \mu\text{m}$$

for 900°C and 1385 min. From the reported concentrations of the epi ($\sim 2 \times 10^{19}$ cm^{-3}) and the substrate ($\sim 2 \times 10^{16}$ cm^{-3}), the 1.9 μm enhanced diffusion is equal to approximately two diffusion lengths. Thus, the ratio of the diffusion coefficients in the two regions is

$$\frac{D}{D_i{}^{\times}} \cong 35$$

From Fig. 10 it can be seen that for shallow 900°C diffusions with $n_s = 2 \times 10^{20}$ cm^{-3}, $D/D_i \cong 135$. Therefore, in 20 μm the excess vacancy concentration has dropped to $\sim$1/4 of its original value, giving a vacancy diffusion length of $\sim$25 μm and a vacancy lifetime of $\sim$1/4 sec. These results are probably dependent upon the dislocation density of the Si.

Conclusions

A consistent model of P diffusion in Si has been presented which accounts quantitatively for the existence of electrically inactive P, the kink and the tail regions of the P diffusion profile, and the emitter-dip effect. The following points have been made:

1. Phosphorus diffuses in Si by interacting with vacancies in three different charge states: $P^+V^{\times}$, P^+V^-, and $P^+V^{=}$.

2. At high concentration ($n > n_e$) the $P^+V^{=}$ pair dominates. For example, at a total P concentration of 10^{21} cm^{-3}, $\sim$67% of the P is paired with $V^{=}$ vacancies. This pair removes an electron from the conduction band to fill the second-acceptor level of the vacancy, thus accounting for the electrically inactive P concentration.

3. At electron concentrations where the Fermi level is $\sim$0.11 eV below the conduction band ($n \cong n_e$), the $V^{=}$ vacancy has a higher probability of losing an electron to become V^-. The 0.3 eV lower binding energy of the P^+V^- pair enhances the pair dissociation probability significantly, thus creating an excess of V^- vacancies above the equilibrium value. This excess steady-state generation of vacancies accounts for the enhanced P tail diffusion as well as the emitter dip effect to depths greater than 25 μm from the Si surface.

4. When proper account is taken of the charge state of the vacancies, the activation energies for P diffusion are consistent with other Group V elements.

5. The observed differences between P and As diffusion profiles in Si are a result of the differences in the relative importance of the diffusing species. Neglecting pair dissociation, the dominant species in P-doped Si are $P^+V^{\times}$ and $P^+V^{=}$. In As-doped Si, $As^+V^{\times}$ and As^+V^- dominate up to $n \cong 3 \times 10^{20}$ cm^{-3}.

Acknowledgments

The authors would like to thank L. C. Kimmerling and G. H. Gilmer for their helpful discussions, especially regarding the pair dissociation mechanism of P.

ABSTRACT

A new algorithm for spreading resistance measurement data processing is proposed. The method, originally used for solving a thermal resistance problem of a multilayered heat sink, is applied to electrical resistance problems to give fast, exact, multilayer correction factors for converting measured spreading resistances to a profile. The correction factor is calculated by N times multiplication of (2×2) matrices instead of the inversion of a $(2N \times 2N)$ matrix, where N is an arbitrary number changing with the data points of spreading resistances (layers). The computer program, developed on the basis of this algorithm, is applied to impurity profile evaluation of thin (0.5-1.5 μm) epitaxial silicon wafers for millimeter wave IMPATT diode fabrication and affords the results agreeing with capacitance voltage profiling.

Spreading resistance measurement (SRM) is now widely accepted in the semiconductor industry as one of the most convenient methods to measure impurity profiles (1). Multilayer analysis, first proposed by Schuman and Gardner (2), is used for the evaluation of steep impurity profiles as are found in thin epitaxial layers and shallow diffusion layers. On the multilayer analysis, the correction factor C, which is required for converting measured spreading resistance to local resistivity, is expressed for two point probe configuration (3) as

$$C = \frac{4}{\pi}\int_0^\infty f(\lambda)\,\frac{\sin\lambda a}{\lambda}\left[\frac{J_1(\lambda a)}{\lambda a} - \frac{1}{2}J_0(\lambda D)\right]d\lambda$$

where, J_0 and J_1 are Bessel functions of the first kind of zeroth and first order, respectively, a is the probe contact radius, D is the probe spacing, and $f(\lambda)$ is an integration factor, which depends on both the resistivities and thickness of individual layers. In the first developed program, it was necessary to convert a $(2N \times 2N)$ matrix for obtaining an integration factor, where N is an arbitrary number changing with data points of spreading resistances (layers), and required a lengthy computation time (4). Many authors have tried to

ABSTRACT

A new algorithm for spreading resistance measurement data processing is proposed. The method, originally used for solving a thermal resistance problem of a multilayered heat sink, is applied to electrical resistance problems to give fast, exact, multilayer correction factors for converting measured spreading resistances to a profile. The correction factor is calculated by N times multiplication of (2×2) matrices instead of the inversion of a $(2N \times 2N)$ matrix, where N is an arbitrary number changing with the data points of spreading resistances (layers). The computer program, developed on the basis of this algorithm, is applied to impurity profile evaluation of thin (0.5-1.5 μm) epitaxial silicon wafers for millimeter wave IMPATT diode fabrication and affords the results agreeing with capacitance voltage profiling.

Spreading resistance measurement (SRM) is now widely accepted in the semiconductor industry as one of the most convenient methods to measure impurity profiles (1). Multilayer analysis, first proposed by Schuman and Gardner (2), is used for the evaluation of steep impurity profiles as are found in thin epitaxial layers and shallow diffusion layers. On the multilayer analysis, the correction factor C, which is required for converting measured spreading resistance to local resistivity, is expressed for two point probe configuration (3) as

$$C = \frac{4}{\pi}\int_0^\infty f(\lambda)\,\frac{\sin\lambda a}{\lambda}\left[\frac{J_1(\lambda a)}{\lambda a} - \frac{1}{2}J_0(\lambda D)\right]d\lambda$$

where, J_0 and J_1 are Bessel functions of the first kind of zeroth and first order, respectively, a is the probe contact radius, D is the probe spacing, and $f(\lambda)$ is an integration factor, which depends on both the resistivities and thickness of individual layers. In the first developed program, it was necessary to convert a $(2N \times 2N)$ matrix for obtaining an integration factor, where N is an arbitrary number changing with data points of spreading resistances (layers), and required a lengthy computation time (4). Many authors have tried to

* Electrochemical Society Active Member.
Key words: thermal spreading resistance, boundary condition problem, chemical selective etching, capacitance voltage profiling.

shorten the computation time by various methods. The devices utilized to achieve this were (*i*) limitation of layer numbers, taken in the calculation, in a few layers near the surface to keep the matrix compact, ten layers in (3) and two layers in (5); (*ii*) adoption of an approximation for obtaining the integration factor, such as power law (3, 6), instead of using conversion of a $(2N \times 2N)$ matrix; or (*iii*) modification of a correction factor equation derived from the two layer problem, which can afford the results fitting in those measured with independent profiling methods such as capacitance voltage or incremental sheet resistance measurements (7).

In the present data processing procedure, the integration factor is calculated by N times multiplication of (2×2) matrices as a way to exactly solve the multilayer problem. This approach was applied to calculation of the thermal spreading resistance of multilayered heat sinks by one of the authors (8) and is expected to reduce computation time for SRM data processing just as the recurrence formula approach proposed by Leong *et al.* (9).

This paper describes the matrices-multiplication approach which is adopted as an exact way to solve multilayer problems. The results of applying this approach to the impurity profile evaluation of epitaxial wafers used for millimeter wave IMPATT diode manufacture are also presented.

Data Processing

The algorithm for calculating the correction factor is essentially the same as that used in the calculation of heat resistance of semiconductor devices, fabricated with the plated heat sink technology, such as Gunn and IMPATT diodes. In these devices, one or more Si or GaAs chips in a disk shape with about 50 μm diameter are placed on an electroplated metal layer with 50-200 μm thickness. This plated heat sink is then soldered on a metal block with a gold-silicon eutectic alloy layer. The heat resistance calculation of such devices has to take the multilayer effect into account, just as the SRM data processing does.

Correction factor derivation.—The mathematical basis for correction factor computation is explained as follows. As shown in Fig. 1, the potential distribution is considered when current I_0 flows from or collects into a disk electrode set on a multilayer structure, where each layer has specific resistance, ρ_1, ρ_2, -----, ρ_N, moving from top to bottom. In the figure, the sequence of boundaries is z_1, z_2, -----, z_{N_0}, and each layer thickness is h_1, h_2, -----, h_{N_0}, respectively.

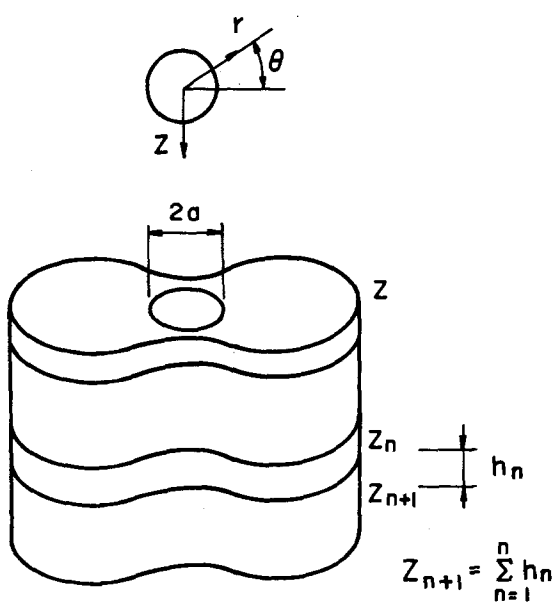

Fig. 1. Geometry for the multilayer problem

Let $V_N(r, z)$ be the potential distribution within the Nth layer. $V_N(r, z)$ is expanded as Eq. [1], using the Bessel function of the first kind of zeroth order, J_0, because $\Delta V_N(r, z) = 0$.

$$V_N(r,z) = \frac{\rho_N}{2\pi a} \cdot I \cdot \int_0^\infty [A_N(\lambda) \cdot e^{-\lambda(Z-Z_{N_0})} + B_N(\lambda) \cdot e^{\lambda(Z-Z_{N+1})}] \cdot \frac{\sin(\lambda a)}{\lambda} \cdot J_0(\lambda r)\, d\lambda \quad [1]$$

where $A_N(\lambda)$ and $B_N(\lambda)$ are functions of λ defined with boundary condition. From the conditions for continuity of potential and current, sequential matrix [2] is obtained

$$\begin{pmatrix} A_N(\lambda) \\ B_N(\lambda) \end{pmatrix} = \frac{\rho_{N+1} + \rho_N}{2\rho_N} \cdot e^{\lambda h_{N_0}} \cdot \begin{bmatrix} 1 & \frac{\rho_{N+1} - \rho_N}{\rho_{N+1} + \rho_N} e^{-\lambda h_{N+1}} \\ \frac{\rho_{N+1} - \rho_N}{\rho_{N+1} + \rho_N} e^{-\lambda h_{N_0}} & e^{-\lambda(h_{N_0} + h_{N+1})} \end{bmatrix} \cdot \begin{pmatrix} A_{N+1}(\lambda) \\ B_{N+1}(\lambda) \end{pmatrix} \quad [2]$$

The boundary condition is assumed at $z = z_1 = 0$

$$-\frac{1}{\rho_1} \cdot \frac{\partial}{\partial z} \cdot V_1(r,z) = \begin{cases} \frac{I_0}{2\pi a} \frac{1}{\sqrt{a^2 - r^2}} & r < a \\ 0 & r > a \end{cases} \quad [3]$$

On the other hand, the boundary condition at $z = z_{N+1}$, where the multilayer slab contacts an insulator, is as follows

$$-\frac{1}{\rho_1} \cdot \frac{\partial}{\partial z} \cdot V_{N_0}(r,z)\Big|_{z=z_{N_0+1}} = 0 \quad [4]$$

Boundary conditions in Eq. [3] and [4] have forms changed according to Eq. [1]

$$\int_0^\infty [A_1(\lambda) - B_1(\lambda) \cdot e^{-\lambda h_1}] \sin(\lambda a) J_0(\lambda r)\, d\lambda = \sin(\lambda a) J_0(\lambda r)\, d\lambda = \begin{cases} \frac{1}{\sqrt{a^2 - r^2}} & r < a \\ 0 & r > a \end{cases} \quad [5]$$

$$\int_0^\infty [A_{N_0}(\lambda) e^{-\lambda h_0} - B_{N_0}(\lambda)] \sin(\lambda a)\, J_0(\lambda r)\, d\lambda = 0 \quad [6]$$

Thus, $[A_1(\lambda), B_1(\lambda)]$ and $[A_{N_0}(\lambda), B_{N_0}(\lambda)]$ has the relationship

$$\left.\begin{aligned} A_1(\lambda) - B_1(\lambda) e^{-\lambda h_1} &= 1 \\ A_{N_0}(\lambda) - B_{N_0}(\lambda) e^{\lambda h_0} &= 0 \end{aligned}\right\} \quad [7]$$

If $A_1(\lambda)$ and $B_1(\lambda)$ are derived from Eq. [2] and [7], the potential distribution at $z = 0$ is

$$V_1(r, z=0) = \frac{\rho_1 \cdot I_0}{2\pi a} \int_0^\infty (A_1(\lambda) + B_1(\lambda) e^{-\lambda h_1}) \frac{\sin(\lambda a)}{\lambda} J_0(\lambda r)\, d\lambda = \frac{I_0 \cdot \rho_1}{2\pi a} \int_0^\infty (2A_1(\lambda) - 1) \frac{\sin(\lambda a)}{\lambda} J_0(\lambda r)\, d\lambda \quad [8]$$

And

$$\langle V_a \rangle - V_D = \left\{ \frac{\rho_1}{\pi a} \int_0^\infty (2A_1(\lambda) - 1) \frac{\sin(\lambda a)}{\lambda} \left(\frac{J_1(\lambda a)}{a} - \frac{1}{2} J_0(\lambda D) \right) d\lambda \right\} I_0 \quad [9]$$

where $\langle V_a \rangle$ is the potential average at $0 < r < a$, and V_D is the potential at $r = D > a$.

In two probe spreading resistance measurements, one probe emits the current I_0 and the other one emits current $-I_0$. The spreading resistance between two probes is

$$R_{SR} = 2 \cdot \frac{\langle V_a \rangle - V_D}{I_0} = \frac{2\rho_1}{\pi a} \int_0^\infty (2A_1(\lambda) - 1) \frac{\sin(\lambda a)}{\lambda} \left[\frac{J_1(\lambda a)}{\lambda a} - \frac{1}{2} J_0(\lambda D) \right] d\lambda \quad [10]$$

From Eq. [7], we can obtain the following expression

$$B_{N0}(\lambda) = A_{N0}(\lambda)\, e^{-\lambda h_{N_0}} \quad [11]$$

and define $\alpha[\lambda]$ and $[P(\lambda)/Q(\lambda)]$ as follows

$$\alpha(\lambda) = \frac{\rho_1 + \rho_2}{2\rho_2} \cdot \text{----} \cdot \frac{\rho_{N0-1} + \rho_{N0}}{2\rho_{N0-1}} \cdot e^{(h_1 + \text{----} + h_{N_0-1})} \cdot A_{N0}(\lambda)$$

$$\begin{pmatrix} P(\lambda) \\ Q(\lambda) \end{pmatrix} = \begin{Bmatrix} 1 & \frac{\rho_2 - \rho_1}{\rho_2 + \rho_1} \cdot e^{-\lambda h_2} \\ \frac{\rho_2 - \rho_1}{\rho_2 + \rho_1} e^{-\lambda h_1} & e^{-\lambda(h_1 + h_2)} \end{Bmatrix} \cdot \text{----} \cdot \begin{Bmatrix} 1 & \frac{\rho_{N0} - \rho_{N0-1}}{\rho_{N0} + \rho_{N0-1}} \cdot e^{-\lambda h_N} \\ \frac{\rho_{N0} - \rho_{N0-1}}{\rho_{N0} + \rho_{N0-1}} \cdot e^{\lambda h_{N_0-1}} & e^{-\lambda(h_{N_0} + h_{N_0-1})} \end{Bmatrix} \begin{pmatrix} 1 \\ e^{-\lambda h_{N_0}} \end{pmatrix} \quad [12]$$

From Eq. [2]

$$A_1(\lambda) = \alpha(\lambda) \cdot P(\lambda)$$
$$B_1(\lambda) = \alpha(\lambda) \cdot Q(\lambda) \quad [13]$$

combined with Eq. [7]

$$A_1(\lambda) = \frac{P(\lambda)}{P(\lambda) - Q(\lambda) e^{-\lambda h_1}}$$
$$2A_1(\lambda) - 1 = \frac{P(\lambda) + Q(\lambda) e^{-\lambda h_1}}{P(\lambda) - Q(\lambda) e^{-\lambda h_1}} \quad [14]$$

Put Eq. [14] into Eq. [10], and spreading resistance R_{SR} becomes

$$R_{SR} = \frac{\rho_1}{2a} \cdot \frac{4}{\pi} \int_0^\infty \frac{P(\lambda) + Q(\lambda) e^{-\lambda h_1}}{P(\lambda) - Q(\lambda) e^{-\lambda h_1}} \cdot \frac{\sin(\lambda a)}{\lambda} \left[\frac{J_1(\lambda a)}{\lambda a} - \frac{1}{2} \cdot J_0(\lambda D) \right] d\lambda \quad [15]$$

Then

$$\rho_1 = 2aR_{SR}/c(\rho_1; \rho_2, \text{-----}, \rho_{N0})$$

where $c(\rho_1; \rho_2, \text{-----}, \rho_{N0})$ is a correction factor, and

$$c(\rho_1; \rho_2, \text{-----}, \rho_{N0}) = \frac{4}{\pi} \int_0^\infty \frac{P(\lambda) + Q(\lambda) e^{-\lambda h_1}}{P(\lambda) - Q(\lambda) e^{-\lambda h_1}} \cdot \frac{\sin(\lambda a)}{\lambda} \cdot \left[\frac{J_1(\lambda a)}{\lambda a} - \frac{1}{2} \cdot J_0(\lambda D) \right] d\lambda \quad [16]$$

Now, the correction factor $c(\rho_1; \rho_2, \text{-----}, \rho_{N0})$ is shown to be obtained by the multiplication of N square matrices and a vector of the second order.

Programming.—In an actual system, measured resistance R_m consists of spreading resistance R_{SR} and contact resistance R_B. It can be assumed that R_B depends only upon first layer specific resistance ρ_1

$$R_B = \frac{\rho_1}{2a} \cdot [K(\rho_1) - 1]$$

Then

$$\rho_1 = 2aR_m/[K(\rho_1) - 1 + c(\rho_1; \rho_2, \text{-----}, \rho_{N0})]$$

$K(\rho)$ is deduced from the calibration line made by some measurements of thick and homogeneous samples having different specific resistances.

In computation of the correction factor [16], it is better to separate the calculation of the term connected with the boundary condition from that composed of a trigonometric function and Bessel function, because the former term changes value according to the number of layers, but the latter does not. Equation [16] is expressed as $\int (\text{DETERM}) \times (\text{JBFUNC}) d\lambda$ for the explanation. For JBFUNC, it is necessary to calculate only for the first layer. The subsequent calculation can use the memory. The derivation described in the prior paragraph makes it possible to obtain $P(\lambda)$ and $Q(\lambda)$ necessary for the term DETERM from only one multiplication of (2×2) matrix and (2×1) matrix. That is

$$\begin{pmatrix} P(\lambda) \\ Q(\lambda) \end{pmatrix} = \begin{Bmatrix} 1 & \frac{\rho_2 - \rho_1}{\rho_2 + \rho_1} \cdot e^{-\lambda h_2} \\ \frac{\rho_2 - \rho_1}{\rho_2 + \rho_1} e^{-\lambda h_1} & e^{-\lambda(h_1 + h_2)} \end{Bmatrix} \cdot \begin{pmatrix} P'(\lambda) \\ Q'(\lambda) \end{pmatrix}$$

where $P'(\lambda)$ and $Q'(\lambda)$ are those used for the $c(\rho_2; \rho_3, \text{-----}, \rho_{N0})$ calculation and are stored in the memory. The present approach requires only the first layer condition for obtaining the correction factor, different from that proposed by others (4, 10). Thus, correction factor is obtained on the flow, as shown in Fig. 2.

Thin Epitaxial Wafer Evaluation

To demonstrate the usefulness of this newly proposed correction factor computation algorithm, the de-

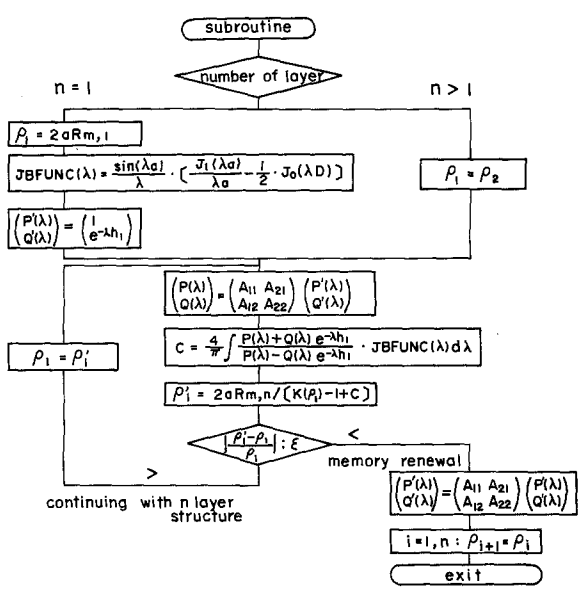

Fig. 2. Subroutine flow chart for correction factor calculation

veloped program is applied to impurity profile evaluation of thin (0.5-1.5 μm) epitaxial silicon wafers for millimeter wave IMPATT diode fabrication.

After SiO_2 deposition of around 2000Å thick, epitaxial wafers were polished with commercial diamond paste (average diameter 0.25 μm) (11) on a plastic plate (12) by a reciprocating lapping machine. The small angles on the beveled silicon wafers, typically 10 to 30 min, were measured with the laser beam reflection method (13) using photodiode as a detector. The spreading resistance equipment used is a commercial two-point probe system, ASR-100. To convert the resistivity to donor density, Irvin's curve was employed (14).

For the epitaxial wafers for IMPATT diodes, there are two important factors to be evaluated. One is the n layer thickness and the other is the n layer donor density. To examine the accuracy of the former factor in spreading resistance method, the epitaxial thickness is measured by the selective etching method. Epitaxial wafer samples lapped in angle by the above described procedures are etched by impurity concentration selective etchant to produce the gap at n layer-n^+ substrate boundary (15). As shown in Fig. 3, the intersection of extrapolation line from the substrate region and that from the epitaxial-substrate transition region, which could be defined as the n layer thickness measured by SRM, agrees well with the thickness obtained by the selective etching method, W_{sel}. The impurity concentration, where the arrow crosses, is a reasonable value, since it coincides with the transition point of etching selectivity, that is around 2×10^{-19} cm^{-3}. In Fig. 3, the results with capacitance voltage profiling method are also plotted. *C-V* characteristics are measured after boron is diffused to 0.12 μm from the surface. Because of the built-in potential and of the avalanche breakdown, the *C-V* method is only applicable to the impurity profile at the depths between about 0.3 μm to about 0.6 μm. Donor densities obtained from the *C-V* method show a good agreement within experimental error.

A few measured profiles of epitaxial wafers used for G-band (40-80 GHz) IMPATT diode fabrication are shown in Fig. 4. CPU time to obtain a complete profile from 30 points of the spreading resistances is around 23 sec by ACOS-700. In order to compare the present approach with Hu's (3), Lee's (6), and Choo's (10) methods, in terms of computation time, some data are obtained (5) or estimated (3, 10). Our computation time would be comparable with other methods, *i.e.*, 60 sec or more (Hu), 16-32 sec (Lee), and 12 sec (Choo). It should be noted that Lee's and ours are the times required for obtaining a profile, for which iteration work[1] is necessary for consistency between $K(\rho)$ and the correction factor. Hu's and Choo's, however, are the calculation times to obtain only correction factors. Additional adoption of our algorithm to Hu's and Lee's approximation analysis should reduce their computation time, since they also need to solve the matrix equations at the points selected as the standards for interpolations.

Conclusion

The spreading resistance measurement for estimating an impurity profile for semiconductors is improved on data processing. A new approach for solving the boundary condition problem is proposed. It requires N times multiplication of (2×2) matrices to obtain the correction factor, but not inversion of the $(2N \times 2N)$ matrix which appears in the computation program of Yeh *et al.* N is an arbitrary number changing with data points of spreading resistances (layers). And Schuman's multilayer structure model for precise impurity profile estimation became more realistic for computation. Average CPU time to obtain a complete profile from 30 data points of spreading resistances was around 23 sec using ACOS-700.

[1] On our data, average iteration number was 2.5.

Role of Grain Growth in the Oxidation of Nickel

Frederick N. Rhines and Richard G. Connell, Jr.

Department of Materials Science and Engineering, University of Florida, Gainesville, Florida 32611

ABSTRACT

The isothermal growth of a NiO scale upon nickel 270 at 800°-1000°C is accompanied by a coordinated growth of the grains of the oxide, wherein the mean intercept of the grains (measured parallel with the scale surface) is directly proportional to the thickness of the scale. The average grain volume of the columnar grains of the scale is directly proportional to the time of oxidation. Correspondingly, the scale thickness and the mean intercept of the grains increase in proportion to the cube root of the time. Markers maintain the same relative positions in the scale as the scale thickens, showing that the scale grows by swelling. These findings are explained by the formation of new oxide, mainly along grain boundaries, where oxygen diffusing inward upon grain boundaries meets nickel diffusing outward through the NiO grains. The sweeping of the grain boundaries that accompanies grain growth serves to distribute the new oxide uniformly throughout the volume of the scale, resulting in growth by swelling.

Although it has long been recognized that the grain size of the oxide scale that forms on metals at elevated temperature is coarser in thick than in thin scales, no importance seems to have been attributed to this fact. The present authors (1) were the first to demonstrate that there is a quantitative relationship between the grain structure and the thickness of the scale upon nickel. They accomplished this by counting the number of grain boundaries crossed by unit length of line (N_L) laid parallel with the surface of the scale, at midthickness of the scale. It was found that any NiO scale on nickel 270 having specific thickness always displays the same value of N_L, irrespective of the temperature of oxidation or of the sequence of atmospheric conditions imposed in forming the scale. It was concluded that the mechanisms of grain growth and of scale growth are interrelated.

Further studies, presented in this paper, have shown that the scale thickness (x) is directly proportional to the reciprocal of N_L, which is a measure of the mean intercept of the grains ($\overline{\lambda}$)

$$1/N_L = \overline{\lambda} \propto x \qquad [1]$$

The scale thickness is also proportional to the cube root of the average grain volume ($\overline{V}_g$), as is the mean intercept of the grains

$$\overline{V}_g^{1/3} \propto \overline{\lambda} \propto x \qquad [2]$$

Key words: oxides, diffusion, quantitative microscopy, stress effects, oxide coatings, metallography.

These relationships apply as well to the kinetics of grain growth and oxidation. The average grain volume increases in direct proportion to the time of oxidation (t)

$$\overline{V}_g \propto t \qquad [3]$$

while the scale thickness and the mean intercept of the grain increase in proportion to the cube root of the time

$$x \propto \overline{\lambda} \propto t^{1/3} \qquad [4]$$

Marker movement observations have made it clear, also, that the NiO scale grows mainly by swelling. New oxide is generated almost homogeneously throughout the volume of the scale, instead of at one of its interfaces, as has been postulated in the familiar theories of oxidation. Nickel ions diffusing outward through the NiO crystals of the scale meet oxygen ions diffusing inward upon grain boundaries of the NiO, and are delivered throughout the volume of the scale by the sweeping of the grain boundaries accompanying grain growth. Thus, both scale growth and grain growth, being limited by the rate of sweep of the grain boundaries, are mutually related in their kinetics.

Experiments and Observations

Nickel 270 (nominally 99.99+% nickel) in the form of rolled sheet specimens, 12.7 × 12.7 × 1.6 mm, was oxidized in pure oxygen at 800°, 900°, and 1000°C, for times up to 225 hr. Prior to oxidation the specimens were annealed 1 hr at 1200°C in air. They were then

ground free of oxide, using SiC grit and finishing with 600 grit in water. Before placing in the oxidizing furnace, they were further degreased with acetone, ethanol, and water and were dried. The furnace and gas-handling systems were constructed entirely of stainless steel and of nickel tubing and fittings, the hot gases being exposed to no material except nickel. During heat-up and cool-down, the furnace was maintained with flowing cold-trapped helium. Pure dry oxygen was admitted for the specified interval of oxidation. The nickel 270 specimens developed regular scales without cracking, spalling, or other physical defects. Some specimens of nickel 200 (commercial purity) that were prepared in the same fashion tended to spall slightly. All speciments were sectioned, mounted, and prepared for metallographic examination using conventional methods. The polishing medium was diamond grit; a hydrofluoric acid, acetic acid, electrolytic etch was employed. Typical microstructures of the scales on nickel 270 and nickel 200 are shown in Fig. 1-4.

Scale thickness (x) was measured directly upon the microscope using a calibrated optical system. The identification of the location of the metal-oxide interface is uncertain in photomicrographs, such as those of Fig. 1-4, because polishing leaves a step in level between the metal surface and the oxide surface. This step, being out of focus, appears wide. By making the readings directly upon the microscope, it is possible to so adjust the focus as to locate the interface with precision. There remains, however, a variation in the true thickness of the scale from point to point. To obtain reproducible readings, therefore, values of x were read at many random sites and averaged. All of the measurements of scale thickness on nickel 270 are reported in Table I. Scale thickness (x) is plotted as a function of the cube root of the time of oxidation ($t^{1/3}$) in Fig. 5. Proportionality of the scale thickness to the cube root of time has been observed by several prior investigators (2), but has yet to be explained adequately.

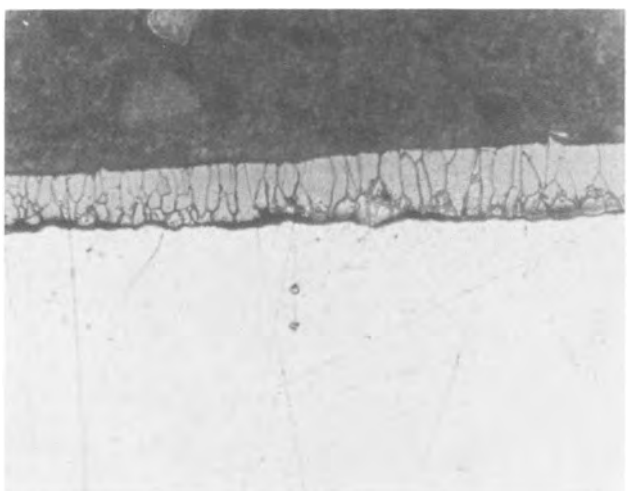

Fig. 1. Ni 270, 1000°C, 4 hr, 700×

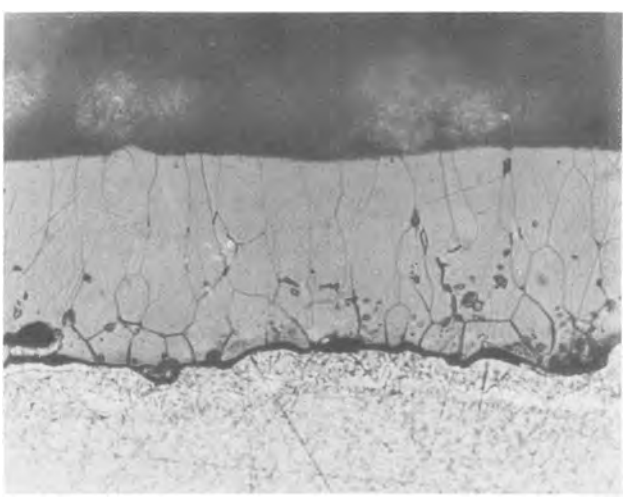

Fig. 2. Ni 270, 1000°C, 49.5 hr, 700×

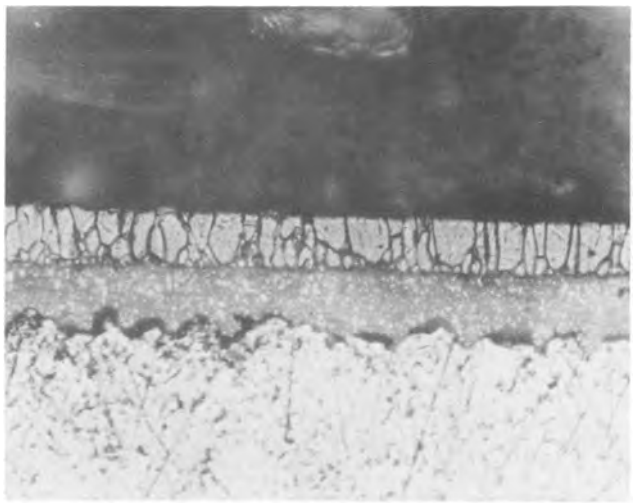

Fig. 3. Ni 200, 800°C, 64 hr, 700×

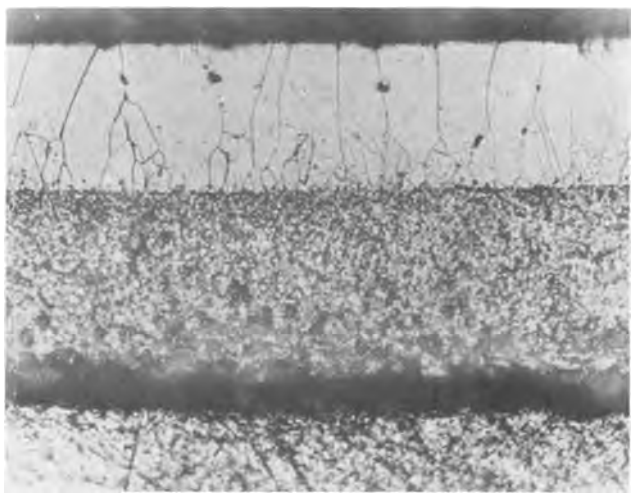

Fig. 4. Ni 200, 1000°C, 49 hr, 700×

Grain mean intercept measurements ($1/N_L = \bar{\lambda}$) were also made directly upon the microscope. As can be seen by reference to Fig. 1-4, the outer portion of the scale is always composed of columnar grains that extend to the oxide-atmosphere interface. A horizontal line drawn at midthickness passes through this columnar zone. The measurement of N_L consists in counting the number of grain boundaries crossed by unit length of such a line. Values of $\bar{\lambda}$ obtained in this way are shown for all of the nickel 270 specimens in Table I. If the grains of the oxide had been equiaxed, $2N_L$ would have been equal to the grain boundary area in unit volume of the scale. Its direct meaning in the case of columnar grains is uncertain, but its reciprocal ($1/N_L$) is equal to the mean intercept ($\bar{\lambda}$) of the columnar grains in a direction perpendicular to their long axes. Values of $\bar{\lambda}$ are plotted as a function of scale thickness (x) in Fig. 6, where it will be seen that a direct proportionality exists.

* The maximum error in the measurement of scale thicknesses and mean grain intercepts is in no case greater than ±7% of the mean values reported as computed at a confidence level of 95%.

The grain structure appears as though optically magnified to maintain proportionality with the scale thickness.

Average grain volume ($\overline{V}_g = 1/N_V$) is usually measured in metals by serial section analysis. This is a laborious procedure, at best, but becomes nearly impossible in application to thin scales of fragile oxides. To the extent that the grains of the scale are truly columnar, however, it is possible to determine their number in unit volume of scale (N_V) by simply counting their ends as they emerge upon the external surface. The oxide grain size is usually too fine to permit such counting by optical methods, but the scanning electron microscope provides both the magnification required and the depth of focus needed for such counts. Five nickel 270 specimens of the 1000°C series were so counted (Table I). In Fig. 7, the average grain volume ($\overline{V}_g$) is plotted as a function of the time of oxidation (t). The linear relationship exhibited by this plot is identical with that found for steady-state grain growth in aluminum (3).

The plots of Fig. 5, 6, and 7, derived as they are from three different kinds of measurements, display a remarkable self-consistency. The average grain vol-

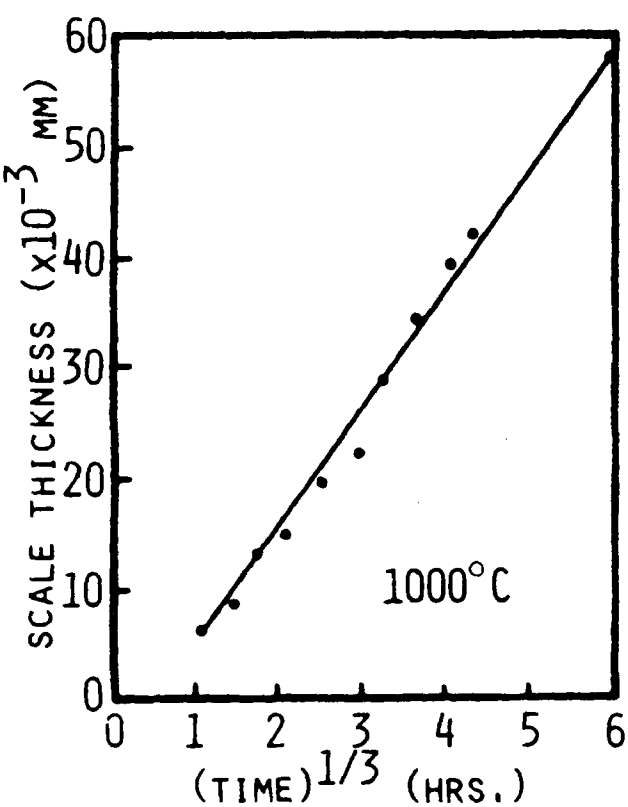

Fig. 5. Scale thickness vs. cube root of time

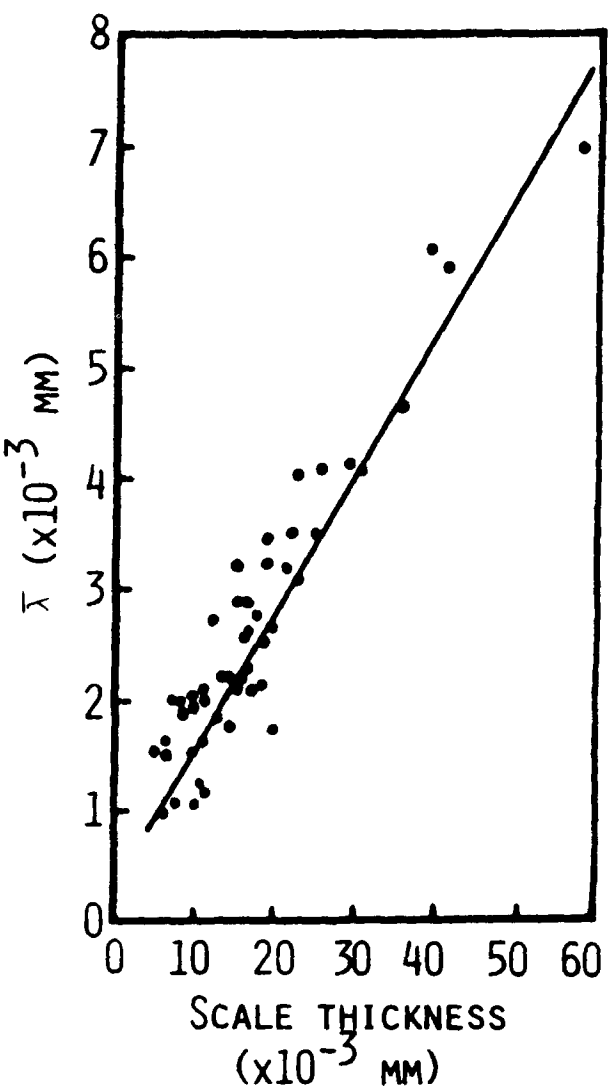

Fig. 6. Mean grain intercept vs. scale thickness

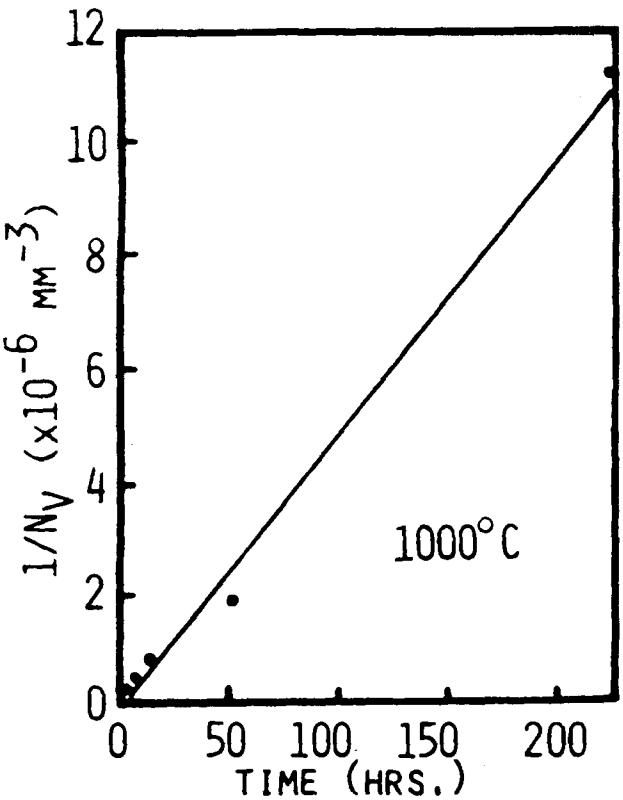

Fig. 7. Average grain volume vs. time

ume ($\overline{V}_g$), being proportional directly to the time of oxidation, implies that any lineal parameter of the grains, such as the mean intercept ($\overline{\lambda}$), should be proportional to the cube root of the time of isothermal oxidation. As anticipated, $\overline{\lambda}$ is proportional to scale thickness, which, in turn, is proportional to the cube root of the time. This leaves little room for doubt that scale and grain growth are functionally related processes.

Two layers can be distinguished in each of the scales of Fig. 1-4. The distinction is mainly one of grain size, the inner layer being finer grained. This difference is much more pronounced and the boundary between the layers is much more distinct in the scale on the less pure nickel 200 than it is in the scale on the purer nickel 270. This structural feature has been noted by almost every investigator of NiO scale microstructure. The presence of the finer grained layer demonstrates that new grains of NiO are nucleated during oxidation. Their absence from the outer layer suggests that they are generated somewhere in the inner layer, probably at the metal-oxide interface. The great refinement of the grains in the inner layer on nickel 200 suggests further that the nucleation of new grains is somehow stimulated by the presence of impurities in the nickel. One possibility is that the impurities in the nickel first form a subscale which is consumed by the growing external scale, each particle of impurity oxide in the subscale giving rise to a new grain of NiO as it enters the external scale.

Probably the most significant characteristic of the layers in the NiO scale is that they maintain a constant ratio of thickness throughout scale growth. This is true not only of the leading front of the boundary between the layers, but applies also to the location of markers within the inner layer. The fine structure of the inner layer formed on nickel 200, Fig. 3 and 4, coarsens with scale growth, so that each marker particle maintains its same relative position in the thickening scale. Such behavior is characteristic of swelling of the matrix in which the particles are embedded.

The texture of the external surface of the NiO scale varies in a regular fashion in the course of scale growth. As soon as any structure becomes visible (with the aid of the scanning electron microscope) the outlines of grains are seen. These outlines develop into ridges which are more pronounced in scales formed at 800°C than at the higher temperatures. At this stage it would be difficult to define the thickness of the scale, because it is much thicker in the neighborhood of the grain boundaries than it is in the central portions of the grains. As oxidation proceeds, the ridges broaden and merge. Thereafter, the grains continue to be distinguishable by virtue of their tendency to form crystalline facets upon their exposed surfaces. Grain growth can be observed by comparing scanning electron microscope pictures of the same locality on the scale surface after successive intervals of heating in oxygen.

Marker Movements During Scale Growth

In 1929 Pfeil (4), studying the high temperature oxidation of iron, reported that inert matter originally upon the metal surface becomes enveloped by the growing scale and is found ultimately near the center of the scale layer. He recognized that this behavior (*i*) denies formation of new oxide by the inward diffusion of oxygen reaction exclusively at the metal-oxide interface; and (*ii*) denies outward diffusion of the metal reaction with oxygen exclusively at the exterior surface. If oxygen alone were to be the mobile species the inert matter should remain upon the exterior of the scale layer. If the metal were to be oxidized only at the exterior surface, then the inert matter should remain at the metal-oxide interface. The inference that the new oxide is generated throughout the mass of the scale was resisted upon the basis that this reaction can occur only at a planar interface, where the diffusing reactants meet. No resolution of this paradox was offered at that time, nor until 1970, when Rhines and Wolf (5) pointed out that the reaction front could reside in the grain boundaries where metal diffusing through the grains meets oxygen entering along grain boundaries. In the light of the new knowledge that grain growth and scale growth are interrelated, it becomes evident that the motion of the grain boundaries that takes place in the course of grain growth also provides a sweeping reaction front that reaches the entire volume of the scale.

From the observation that the scale layer boundary maintains its relative position near the center of the scale it is apparent that almost equal volumes of new NiO are generated on the two sides of this boundary. The further observation that marker points in the inner layer of scales on nickel 200 also maintain constant relative positions with respect to the thickness of the scale means that the same amount of new oxide is being produced everywhere within the scale. Scale growth evidently occurs by swelling, rather than by accretion at the surface of the scale, as had once been supposed. The further fact that the swelling is homogeneous throughout the scale is most remarkable and resists explanation for the lack of more detailed knowledge of the structural behavior of the inner layer.

Plastic Deformation of the NiO Scale

Swelling of the scale develops a shear stress between the metal and the oxide, which was measured by Rhines and Wolf (5) and found to exceed 1500 psi in samples oxidized at 1000°C. If the nickel substrate is thin this stress is sufficient to cause it to bend, or to elongate in creep. When the nickel is too massive to yield the plastic response to the oxidation stress oc-

curs mainly in the scale. At 1000°C the creep stress for NiO is nearly the same as that for nickel. Where the oxidizing surface is flat there is room for scale growth only normal to the plane of the surface. All scale growth in directions parallel with the surface must, therefore, be diverted into growth perpendicular to the surface. This means that the scale must extrude outward as its volume increases.

Although the flow pattern of the oxide cannot be analyzed upon the basis of currently available evidence, some idea of its form is suggested by the grain boundary ridges that develop during early oxidation (1, 6). These ridges represent the outward extrusion of new NiO before sweeping of the boundaries has commenced. The grain boundary contribution to the general oxidation is then limited to the vicinity of relatively static grain boundaries and thrusts outward in place. As the grain boundaries begin to sweep, it may be imagined that each carries with it a wave of extruding oxide that results in a uniform thickening of the scale.

The plastic deformation that results in extrusion of the oxide is also essential in the promotion of oxidation *per se*, because without it grain growth and the accompanying grain boundary sweeping would not occur. The present authors have reported previously that grain growth ceases when oxidation is suspended by substituting helium for oxygen in the oxidizing furnace. This is because the grain boundaries of the scale are normally anchored at the two surfaces of the scale, as well as being pinned upon any impurity particles that may be present in the scale. Only in the presence of deformation can the boundaries break free and migrate under the influence of surface tension. The uniformity of swelling of the scale suggests that plastic deformation is also uniformly distributed through the structure.

Kinetics of Grain Growth and of Scale Growth

If grain growth in the scale were to represent only the increase in the volume of the oxide the columnar grains would simply grow lengthwise, the number of grains in the system remaining constant except for new grains formed at the metal-oxide interface. The average grain volume would be proportional to the volume of the scale (*i.e.*, to its thickness). But the experimental evidence shows that the average grain volume increases as the cube of the scale thickness. In this respect grain growth in the scale is like steady-state grain growth in metals, where equiaxed grains expand three dimensionally. There are, however, the differences that: (*i*) the space into which the oxide grain growth is occurring is increasing and (*ii*) the oxide grains in the outer layer are columnar, rather than equiaxed.

Columnar grains have a minimal energy form wherein their cross sections are two-dimensionally equiaxed. Their longitudinal walls meet the external surface at right angles, a configuration which, though not constituting true pinning, offers no impetus to grain boundary migration. Neither is curvature of the walls of the columnar grains required for space filling, as is true of three-dimensionally equiaxed grains. For these reasons, there is no inevitable grain boundary curvature to promote grain growth under the driving force of surface tension. The curvature required for grain growth is provided, however, by plastic deformation which bends the grain boundaries and disengages them from pinning (7). Thereupon surface tension, tending to straighten and reduce the area of grain boundary, causes it to migrate. The result is grain growth and also growth in the volume of the scale.

It has been shown elsewhere (3) that four grains are lost from unit volume of material each time that grain boundary sweeps[1] this volume once in the elimination of these grains and in restoring the remaining grains to equiaxedness. Thus the volume swept by grain boundary can be computed from the change in the average grain volume, as measured experimentally, and can be associated with the quantity of new oxide deposited through the gain in scale thickness in the corresponding time interval. The results of these computations are shown in Table II for five samples of nickel 270 oxidized at 1000°C, the original data being given in Table I. The computative procedure follows.

From the measurements recorded in Table I, the scale thickness (x) is related to the time (t) of oxidation by

$$x = kt^{1/3} \qquad [5]$$

where $k = 0.01003$, with a correlation coefficient of 0.9978. The average grain volume ($1/N_V$) is related to the time (t) by

$$1/N_V = k't \qquad [6]$$

where $k' = 4.8891 \times 10^{-8}$, with a correlation coefficient of 0.9957. By differentiation, the rate of scale thickening is

$$dx/dt = 3.3433 \times 10^{-3}t^{-2/3} \qquad [7]$$

and the rate of change in the number of grains in unit volume (N_V) becomes

$$dN_V/dt = -2.0454 \times 10^7 t^{-2} \qquad [8]$$

If a unit volume of oxide scale is swept once by grain boundary, four grains per unit volume will disappear as a result of grain growth. Accordingly, the time interval for grain boundary to sweep unit volume of oxide scale can be computed by integrating Eq. [8] and solving for the unknown limit of integration t_2

$$\int_{N_{V1}}^{N_{V2}} dN_V = -2.0454 \times 10^7 \int_{t_1}^{t_2} t^{-2}dt \qquad [9]$$

where: $N_{V1} = 12{,}980{,}000$ grains in 1 mm^3 (unit volume); $N_{V2} = 12{,}979{,}996$ (*i.e.*, $N_{V1} - 4$) grains in 1 mm^3; and $t_1 = 2.25$ hr. Integrating and solving for t_2, $t_2 = 2.25000099$ hr. Thus, the time interval for the grain boundary to sweep one unit volume of oxide scale is $\Delta t = t_2 - t_1 = 9.9 \times 10^{-7}$ hr, or 3.564×10^{-3} sec. The average rate of grain boundary sweep ($V_S/\Delta t$) is 1 mm^3 in 3.564×10^{-3} sec, or $V_S/\Delta t = 280.584$ mm/sec at 2.25 hr.

The corresponding increase in scale thickness can be obtained by integrating Eq. [7]

[1] The term "grain boundary sweeping" refers to the three-dimensional grain boundary migration that accompanies grain growth.

$$\int_{x_1}^{x_2} dx = 3.3433 \times 10^{-3} \int_{t_1}^{t_2} t^{-2/3} dt \qquad [10]$$

where: $x_1 = 9.73 \times 10^{-3}$ mm, $t_1 = 2.25$ hr, and $t_2 = 2.25000099$ hr. Integrating and solving for x_2, $x_2 = 9.730001926 \times 10^{-3}$ mm. Thus, the scale thickness increase in the time interval of one sweep at 2.25 hr is $\Delta x = x_2 - x_1 = 1.926 \times 10^{-9}$ mm. The rate of thickness increase at 2.25 hr is, therefore, $\Delta x/\Delta t = 5.404 \times 10^{-7}$ mm/sec (Table II).

The rate of volume increase of the scale ($\Delta V_o/\Delta t$) at 2.25 hr is 5.554×10^{-5} mm³/sec. This is equivalent to a thickness increase ($\Delta x/\Delta t$) of 5.404×10^{-7} mm/sec. The observed rate of oxidation (dx/dt), obtained by evaluating Eq. [7] at 2.25 hr is 5.4086×10^{-7} mm/sec, showing that the computations are self-consistent. Similar computations were performed for oxidation times of 4, 16, 49.5, and 225 hr, and the results are given in Table II.

These results are of particular interest in the picture that they provide of the behavior of the columnar grain boundaries. Early in oxidation the grain boundary sweeps the volume of the oxide hundreds of times each second. After 225 hr the rate has decelerated to barely 1 sweep/min. At the same time, the quantity of new oxide generated with each sweep is on the increase, producing approximately 100 times as much new NiO per sweep at 225 hr as at 2.25 hr. The net result is, of course, a decelerating rate of oxide growth, because the slowing of grain boundary sweeping dominates. The fact that the grain boundary produces more new oxide per sweep the slower the sweeping rate suggests that the depth of the region about the boundary in which new oxide is being formed is greater the slower the sweeping. Indeed, the values in Table II lead to the conclusion that the rate of new oxide formation ($\Delta V_o/\Delta t$) is proportional to the square root of the rate of grain boundary sweeping ($V_S/\Delta t$)

$$\frac{\Delta V_o}{\Delta t} = 3.3672 \times 10^{-6} \left(\frac{V_S}{\Delta t} \right)^{1/2} - 4.1448 \times 10^{-7} \qquad [11]$$

Correlation coefficient = 0.9996

Some additional relationships which can be derived from Table II follow: The rate of change of the average grain volume

$$\frac{dV_o}{dt} = \frac{d\left(\frac{1}{N_V}\right)}{dt} = 4.8891 \times 10^{-8} \text{ mm}^3/\text{sec} \qquad [12]$$

The rate of sweep *vs.* time in hours

$$\frac{V_S}{\Delta t} = 4.378 \times 10^2 t^{-2} - 67.227 \text{ mm}^3/\text{sec} \qquad [13]$$

Correlation coefficient = 0.9113

The increase in the volume of NiO per sweep *vs.* time in hours

$$\Delta V_o = 6.851 \times 10^{-8} t + 8.8201 \times 10^{-8} \text{ mm}^3 \qquad [14]$$

Correlation coefficient = 0.9999

The increase in scale thickness per sweep *vs.* time in hours

$$\Delta x = 6.540 \times 10^{-10} t^{4/3} - 2.1998 \times 10^{-10} \text{ mm} \qquad [15]$$

Correlation coefficient = 0.9999

The rate of increase in scale volume per sweep *vs.* time in hours

$$\frac{\Delta V_o}{\Delta t} = 1.2695 \times 10^{-4} \left(\frac{1}{t} \right) - 4.065 \times 10^{-7} \text{ mm}^3/\text{sec} \qquad [16]$$

Correlation coefficient = 0.9996

Transport of Reactants

The premise that nickel diffuses outward through the bodies of the NiO grains and that oxygen diffuses inward along grain boundaries is derived from measurements reported in the literature. Moore and coworkers (8), as well as others, have reported diffusion rates for Ni^{++} in single crystals of NiO in the neighborhood of 10^{-3} cm²/sec. Moore (9) found the diffusion of O^{--} to be only of the order of 10^{-5} cm²/sec in NiO single crystals. Volpe and Reddy (10), however, measured the diffusion of oxygen through polycrystalline NiO and obtained a value of the order of 10^{-1}. Thus, the diffusion of oxygen upon the grain boundaries is seen to be very rapid indeed, although it is negligible through the grains.

The delivery of the two reactants throughout the scale layer requires that there be a concentration gradient of Ni^{++} from the metal-oxide interface to the external surface and a concentration gradient of O^{--} from the external surface to the metal interface. These gradients must cross each other because the grain boundary forms a closed network. Such crossing is made possible by the fact that the reaction $Ni^{++} + O^{--} = NiO$ tends to establish equilibrium with the reaction constant (K) everywhere the same

$$K = \frac{p[Ni^{++}] \cdot p[O^{--}]}{p[NiO]} \qquad [17]$$

Near the metal-oxide interface the activity of Ni^{++} is comparatively large and that of O^{--} small, while the opposite prevails near the external surface. Thus, both gradients can exist while producing new oxide all along the grain boundaries.

It should be appreciated that much of the foregoing interpretation is based upon measurements confined to the outer layer of the scale. While the uniformity of scale swelling implies that a common mechanism must prevail throughout the scale, the fact of the finer grain size of the inner layer raises questions that cannot be answered in the absence of more detailed knowledge of the structural behavior of the inner layer. It should be understood, as well, that none of the foregoing is intended to deny the existence of ranges in which oxide growth is dominated by different mechanisms. Graham, Caplan, and Cohen (11) have demonstrated clearly that the growth of NiO as a single crystal is controlled by the diffusion rate of the metal ion. The presently proposed mechanism is seen as applying to that extensive range of scale growth within which the kinetics are dominated by grain boundary oxide generation.

Alternating-Current Properties of Organic Semiconductor Solid Capacitor

Yoshimasa Itoh and Susumu Yoshimura

Matsushita Research Institute Tokyo, Incorporated, Ikuta, Tama-ku, Kawasaki 214, Japan

ABSTRACT

This paper deals with the a-c properties of a new type of aluminum solid electrolytic capacitor in which organic semiconductors are employed as the counterelectrode. Both equivalent series capacitance and resistance (ESR) were measured between 90 Hz and 22 MHz frequencies and their temperature dependence was determined between −55° and +85°C. Excess series capacitance and ESR which were introduced by the use of the organic semiconductor counterelectrode were separated analytically, and the origin of the impedance connected in series of the anodic oxide is discussed. Very stable a-c properties were observed in the high frequency and low temperature regions, which permitted explanation of the a-c properties with simple models, such as a distributed circuit or dispersions owing to various interfaces. In the low frequency region, the capacitance and ESR increased with decreasing frequency and increasing temperature. It is suggested that the low frequency dissipation is dominated by the interfacial polarization due to polymer binder in contact with the anodic oxide.

The solid electrolytic capacitor has been an important passive component in both transistor and hybrid circuitry. The conventional manganese dioxide (MnO_2) counterelectrode has offered great advantage to the capacitor performance, such as a larger capacitance/volume ratio over the thin film capacitors and superior low temperature characteristics over the dry electrolytic capacitors (1). Recently, we have developed a new type of solid electrolytic capacitor in which MnO_2 was replaced by organic semiconductors (2), the ion-radical salts based on 7,7,8,8-tetracyanoquinodimethane (TCNQ) (3). The capacitor has been referred to as the organic semiconductor solid (OSS) capacitor. The organic semiconductor coating was deposited from a solution in a uniform film with polymers. This process is likely to have imposed little or no damage to the anodic oxide as compared with the thermal decomposition of MnO_2, so that the OSS capacitor can be considered to have a simpler structure and superior frequency stability (2).

The a-c properties have been used for many years as a tool for inspecting the nature of the electrolytic capacitors (4). Young (5) and Winkel and de Groot (6) have presented fundamental explanations on the a-c properties of the anodic oxide. The a-c properties of the tantalum solid electrolytic capacitor were examined originally by McLean (7) and lately by a number of workers, Goudswaard (8), for example, and several analytical methods useful for development investigations have been proposed.

Key words: solid electrolytic capacitor, solid electrolyte, tetracyanoquinodimethane (TCNQ).

In this paper, we wish to report the a-c properties of the OSS capacitor and identify the characteristic features of the new type capacitor. We will also present a phenomenological model for the solid electrolytic capacitor which will be a useful tool for the characterization of this kind of capacitor. This paper deals primarily with the equivalent series capacitance (C_s) and resistance (R_s or ESR) in the frequency range between 90 Hz and 22 MHz and also with their temperature dependence between −55° and +85°C.

Experimental

Construction of capacitor.—Foil-type solid Al capacitors were fabricated with processes described in Ref. (2). The Al foils were electrolytically etched in an aqueous sodium chloride solution to about 70 times the apparent surface area and formed to in a boric acid-borate solution to 200V at a rate of 10 V/min or at about 1 mA/cm^2 current density. The counterelectrode consisted of a TCNQ salt, quinolinium $(TCNQ)_2$, and polymers polyvinylpyrrolidone and related polymers, which were deposited from an acetonitrile-based solution. The anode assembly was covered with colloidal graphite and silver paint, and finally packaged with epoxy resin. Comparative studies were made on a conventional Al (foil-type) and solid electrolytic capacitor and a dried anodized Al capacitor with a graphite counterelectrode. The Al solid electrolytic capacitor was fabricated using the same Al anode as the OSS capacitor, so that the effect of the counterelectrode may well be compared between the two cases.

Apparatus.—No single apparatus allowed the measurements of both C_s and R_s over the entire frequency range of interest, because the capacitor studies had relatively large C_s and small R_s. A standard Wien bridge with sharply tuned detector was used between 90 Hz and 10 kHz and a Yokogawa-Hewlett-Packard (YHP) 4342A Q-meter was used between 22 kHz and 22 MHz. In the latter experiment, the Q value and the resonance frequency of a serial network of a test sample and a coil were compared with those of a circuit in which the sample terminals were shorted with a dummy sample having the same reactance as the test sample. As a check, the impedance and the phase angle of each sample were measured between 500 kHz and 100 MHz with a YHP 4815A RF vector impedance meter, and the capacitance at the frequency of resonance between the sample capacitance and the lead reactance ($\theta = 0$) was determined.

The temperature dependence of the a-c characteristics of the OSS capacitor was measured with thermostat equipment, Sigma Electric TE-307S, between −55° and +85°C for frequencies from 90 Hz to 10 kHz. In the Q-meter measurements (from 22 kHz to 22 MHz), a miniature-sized heating attachment was used to attain temperatures above 25°C.

Results

Figure 1 shows the frequency dependence of the relative capacitance and ESR of the two typical OSS capacitors, OSS-A and OSS-B. The OSS-A was chosen as a representative of those capacitors with lowest dissipation factor (about 0.5%) at 120 Hz, while the OSS-B was with higher dissipation factor (about 1.5%). The difference was due mainly to the polymer composition, and the former sample was brought about by polymers with high adhesion force to both Al_2O_3 and the organic semiconductor particles, such as copoly(vinylpyrrolidone-acetate) or polyvinylbutyrale. This figure also includes data on an Al solid capacitor and a dried anodized Al capacitor with a graphite counterelectrode. The capacitance at 120 Hz was 0.16, 0.15, 0.10, and 0.0073 μf for the OSS-A, OSS-B, Al solid, and dried anodized capacitors, respectively. The ESR of each sample was normalized by multiplying its capacitance at 120 Hz. Since the capacitance, *i.e.*, the dielectric constant ϵ, is a weak function of frequency at low frequencies, the normalized ESR, ESR*, roughly corrects for the differences in the actual surface area, S; $C = \epsilon S/d_o$ and ESR* $\propto$ ESR $\times$ S, where d_o is the oxide thickness which is nearly the same for all the capacitors.

The capacitance change and the ESR of the solid electrolytic capacitors had many common features of frequency dependence, irrespective of the kind of counterelectrode. The results are to be compared with

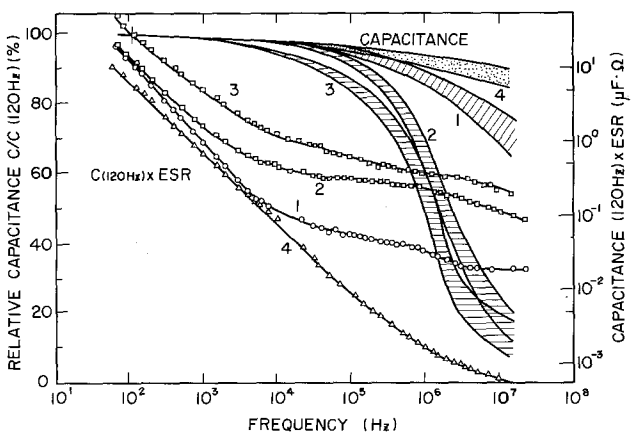

Fig. 1. Normalized equivalent series capacitance and ESR as a function of frequency at room temperature: 1, OSS-A; 2, OSS-B; 3, Al solid; and 4, dried anodized capacitors.

those of Goudswaard (8), McLean (7), and the same authors (2) on conventional tantalum solid electrolytic capacitors. The ESR had a peak or a plateau at intermediate frequencies, from 10 kHz to 1 MHz, and the relative capacitance started to fall rapidly at a frequency roughly corresponding to that of the peak of ESR. The OSS-A displayed the most excellent stability at high frequencies; the capacitance change was smallest of all the electrolytic capacitors, which correlated to a very small value of ESR. With the OSS-B is presented a less satisfactory performance in which the capacitance change and the magnitude of ESR were amplified over those of the OSS-A.

The dried anodized capacitor exhibited a frequency dependence quite different from those of the solid electrolytic capacitors; the capacitance change was smallest and the ESR decreased monotonically until the highest frequency measured. These properties seem to be those of a metal-oxide-metal capacitor and the measured frequency characteristics are thought to be inherent to the anodic oxide dielectric, for the ESR strictly follows a $1/f$ dependence over a wide range of frequency (5, 6). For the OSS-A, the slope of the ESR* was higher than 45° and the ESR* approached that of the dried anodized capacitor at 6 kHz. This result indicates that the incorporation of the organic semiconductor layer has introduced an increasing resistance with decreasing frequency at low frequencies. The comparative studies on the representative capacitors furthermore indicate that the counterelectrode has a general adverse effect of presenting a plateau at intermediate frequencies (9). Goudswaard (8) has ascribed it to the resistance of MnO_2 residing in the pores of anode. The ESR* of the OSS-A capacitor was about one-tenth of that of the MnO_2-based Al solid capacitors at the frequency of the plateau, about 1 MHz. The specific resistivity of the organic semiconductor film was about 1 Ω-cm experimentally, and published data for MnO_2 range from 0.1 to 10^3 Ω-cm (10). However the specific resistivity of the latter in a solid capacitor which is manufactured with usual procedures is estimated experimentally to be higher than 10 Ω-cm due partly to incomplete pyrolysis and partly to the formation of lower exides, so that the small ESR of the OSS-A may be explained by the low resistance of the organic semiconductor film residing in the etch tunnels of the aluminum anode. In case of the OSS-B, it appears that the organic semiconductor film has been deposited into a less dense or less conductive film.

Figure 2 shows the frequency dependence of C_s and R_s of the OSS-A capacitor at various temperatures. In the low frequency region, both C_s and R_s increased rapidly with rising temperature, which seriously affected the dissipation factor at high temperatures (2). In the high frequency region, however, the ESR changed very little with temperature as shown in Fig. 3. At frequencies higher than 22 kHz, the relative capacitance and ESR were independent of temperature within experimental error. The temperature dependence of the OSS capacitor at high frequencies was in apparent contrast to that of the MnO_2-based capacitor. Figure 4 shows the frequency dependence of C_s and R_s at various temperatures for the Al solid electrolytic capacitor. In this case, the capacitance decreased rapidly and the ESR grew very high above 1 kHz at −55°C. Several authors have reported that the conventional solid electrolytic capacitors display an increase in the high frequency ESR at low temperatures (1, 8, 11), and the semiconductive nature of MnO_2 has been thought to be responsible for it. That the OSS capacitor showed virtually no temperature variation in the relative capacitance and ESR at high frequencies may be ascribed to the very low resistivity of the electrolyte film and/or the metallic-like nature of the organic semiconductor (12). This

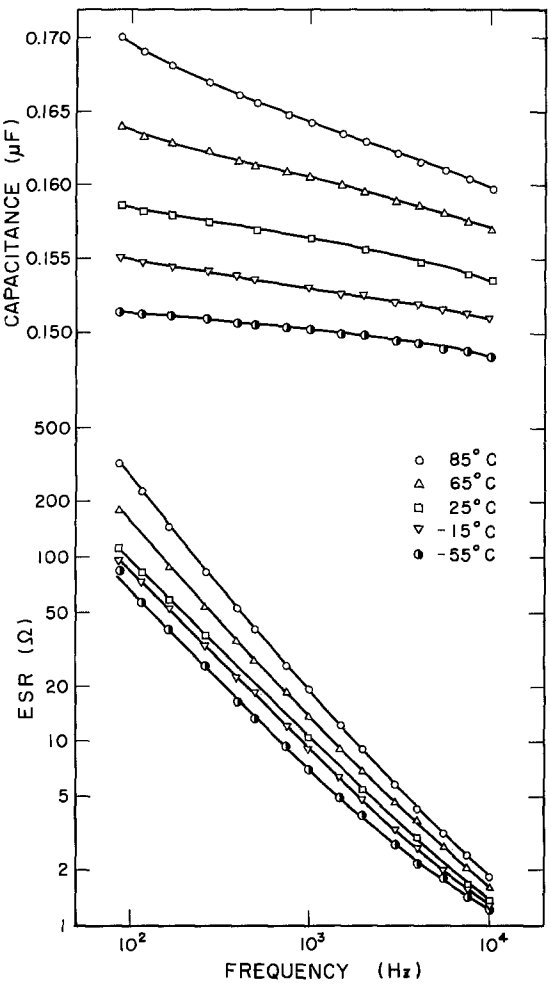

Fig. 2. Capacitance and ESR as a function of frequency for the OSS-A capacitor.

capacitor may have represented the coupled effects of the anodic oxide and the organic semiconductor counterelectrode. In order to obtain an equivalent circuit explaining the a-c properties of the capacitor, we must identify the electrode effects. Generally the impedance of the anodic oxide is explained by Winkel-de Groot theory which is based on an exponential distribution of relaxation time (6)

$$\frac{\partial(1/C_s)}{\partial(\ln f)} = 4\frac{R_s}{1/f} \qquad [1]$$

For special cases, however, each term on both sides can be equated to be a constant b or $4a$ (this is to be defined as a "linealization"), which leads to a set of equations known as the Young equation (5). We will take this approximation for the anodic oxide of the OSS capacitor. The reason for this is multifold: (*i*) the Al-oxide-graphite capacitor displays wide applicability of the linealized equations, (*ii*) the high frequency deviations in R_s and C_s are too large to be explained by [1], and (*iii*) the large oxide thickness (200V forming) and supposed absence of hydrated oxide exclude the possibility of the nonlinear equation. Accordingly, C_s and R_s are described by the following equations

$$R_s = \frac{a}{f} + \Delta R_s \qquad [2]$$

$$\frac{1}{C_s} = b \log f + \frac{1}{\Delta C_s} \qquad [3]$$

$$\frac{b}{a} = 4 \qquad [4]$$

where the extra capacitance and resistance introduced by the counterelectrode are expressed by ΔC_s and ΔR_s, respectively. The capacitance change shown in Fig. 1 was best fitted to [3] with $1/\Delta C_s$ = constant in the frequency range between 90 Hz and about 10 kHz. The constant b was determined from the linear portion of the $1/C_s$ *vs.* log f curve and a was calculated using [4]. Figure 5 shows the extra resistance for the OSS-A and OSS-B capacitors, where the constant a was 5200 and 7400 Ω Hz for the former and the latter, respectively. ΔR_s is enhanced mainly in two frequency regions; a plateau centering at 100 kHz and a rapidly growing resistance with lowering frequency in the

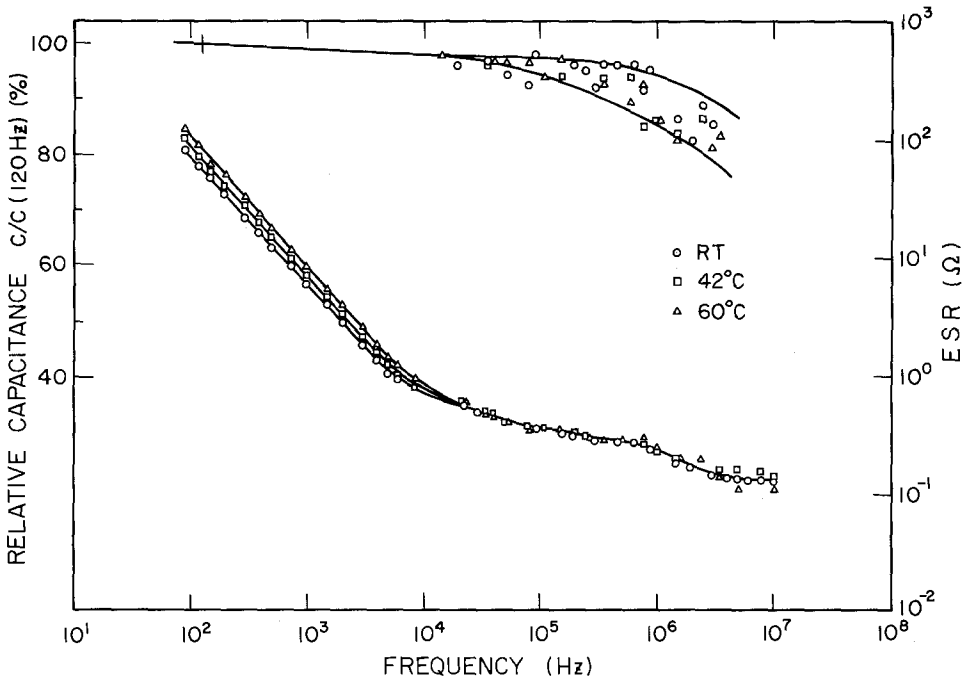

Fig. 3. Relative capacitance and ESR as a function of frequency for the OSS-A capacitor at room temperature (○), 42°C (□), and 60°C (△).

explanation is in accordance with that of Parisi (13) on the temperature dependence of a thin film capacitor with a lead dioxide counterelectrode.

Discussion

Electrolyte effects on the a-c properties.—The experimental data on the a-c properties of the OSS

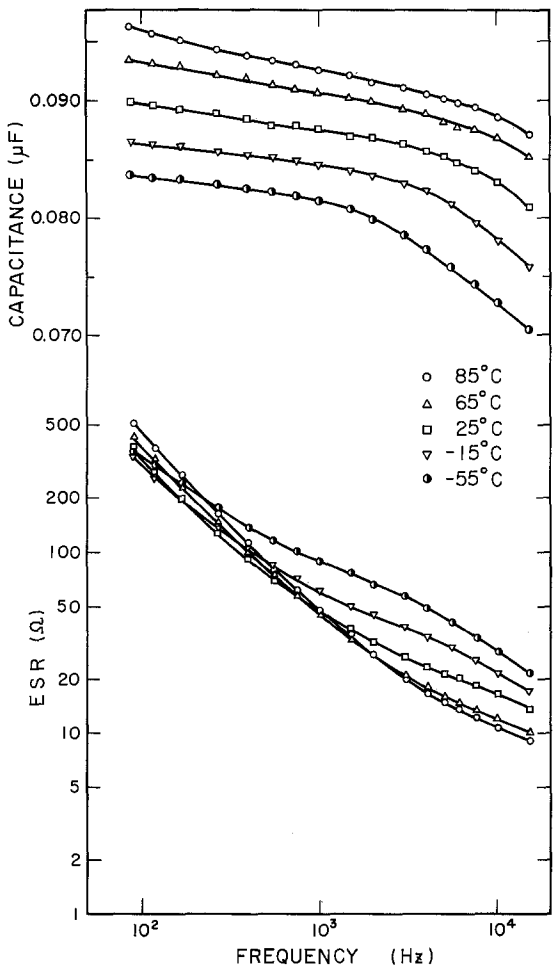

Fig. 4. Capacitance and ESR as a function of frequency for the Al solid electrolytic capacitor.

the other data suggest that the extra ESR is associated with the resistance of the counterelectrode. First we will consider the change in the extra capacitance ΔC_s. Figure 6 shows $1/\Delta C_s$ plotted against frequency for the OSS-A and OSS-B. The diagram implies that the capacitance drops of the OSS-A and OSS-B shown in Fig. 1 need to be interpreted with more than one mechanism. For the OSS-A, the following relationship held from 40 kHz to 10 MHz

$$C \propto f^{-1/2} \qquad [5]$$

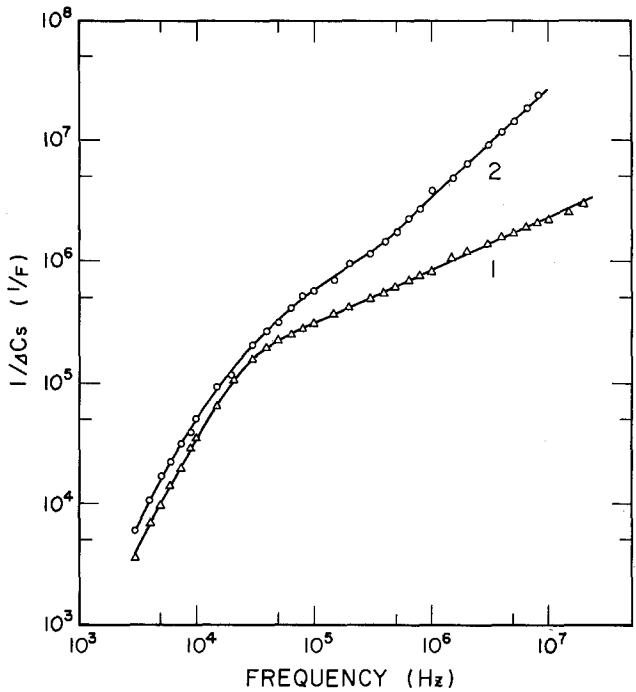

Fig. 6. Inverse extra capacitance (Eq. [2]) as a function of frequency for the OSS-A (curve 1) and OSS-B (curve 2) capacitors.

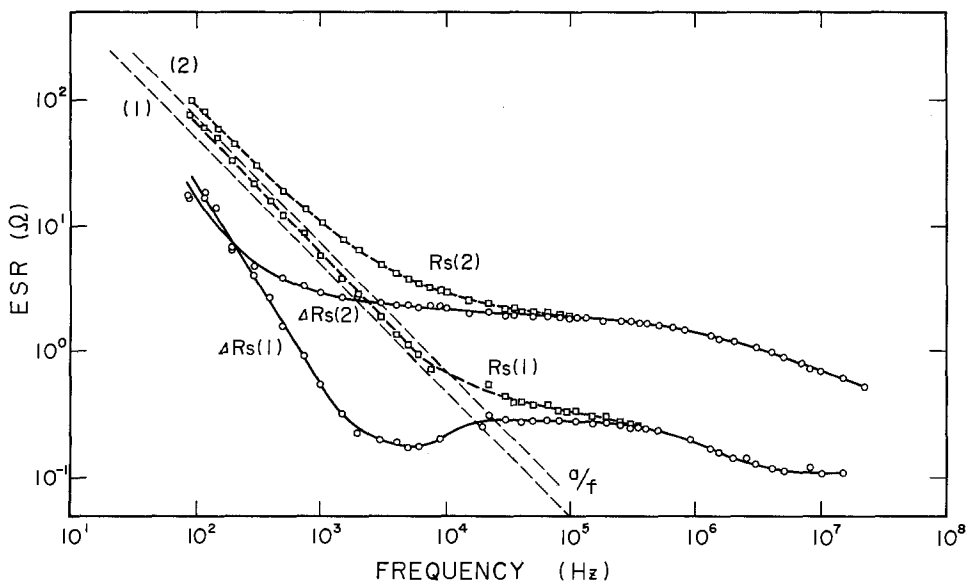

Fig. 5. ESR as a function of frequency at room temperature for the OSS-A (curve 1) and OSS-B (curve 2) capacitors; ΔR_s represents extra ESR due to the solid electrolyte (see Eq. [1]).

low frequency side. Although Fig. 1 seemed to indicate a $1/f$ law of ESR for the OSS-B capacitor, we conclude from this analysis that the $1/f$ dependence appeared accidentally owing to the plateau starting from that low frequency. The same discussion may apply to the apparent $1/f$ dependence of the ESR for the MnO_2-based capacitors.

High frequency properties.—The OSS capacitor has an ESR plateau centering at about 100 kHz, which contrary to the conventional solid electrolytic capacitors was virtually temperature independent. Our and This specific frequency dependence may be understood on the basis of a distributed circuit model. Nishikata (14) has systematically considered the effect of the distributed circuit on the a-c properties of various electrolytic and thin film capacitors and has shown that the capacitance change is generally expressed by [4] in the high frequency region. In view of the fact that ΔR_s did not decrease as $f^{-1/2}$, the model best fitted to our case seems to be that of a counter-lead-type evaporated capacitor where the circuit is distributed on account of its very thin electrode (15).

Since in the OSS-A the semiconductor was deposited in a very dense and thin layer, the distribution model is quite reasonable.

The OSS-B exhibited a complicated frequency dependence of ΔC_s, which was difficult to explain with a simple model. As the OSS-B was composed of less adhesive polymers, polyvinylpyrrolidone, for example, the extra impedance may be ascribed to the resistance of the organic semiconductor film. We will try to describe the data with a combination of several simple equivalent circuits, after which the physical meaning of each equivalent circuit will be given. Figure 7 shows the extra capacitance and resistance of the OSS-B with respect to those of the OSS-A. They were analytically fitted to an equivalent circuit consisting of three serially connected, parallel CR networks as shown in the insertion. The best fitted results were: $R_1 = 0.534\Omega$, $C_1 = 1.65\ \mu f$; $R_2 = 0.570\Omega$, $C_2 = 0.170\ \mu f$; $R_3 = 0.630\Omega$, $C_3 = 0.0158\ \mu f$; and the cutoff frequency of each CR network was 180 kHz, 1.64 MHz, and 16.0 MHz, respectively.

The a-c conductivity of pressed powders of organic semiconductors has been studied by Huggins and Sharbaugh (16). They have represented the a-c properties with two CR networks; one for the organic semiconductor particles and the other for series contacts between particles. This idea led us to measure the frequency dependence of the ESR or capacitance of the organic semiconductor in various forms and to compare the results with those of Fig. 7. Figure 8 shows the ESR as a function of frequency for quinolinium $(TCNQ)_2$ in strongly and lightly pressed pellets with and without polymer, polyvinylpyrrolidone, and also in a solution-deposited film with the polymer. It was demonstrated by the experiments with pressed

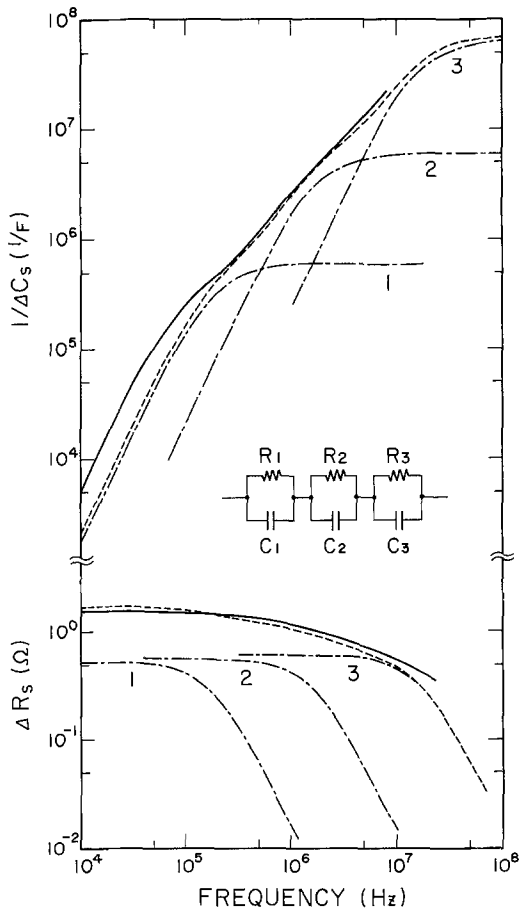

Fig. 7. $1/\Delta C_S$ and ΔR_S for the OSS-B with respect to those of the OSS-A as a function of frequency; solid lines represent experimental data and dotted lines fitted data with illustrated network.

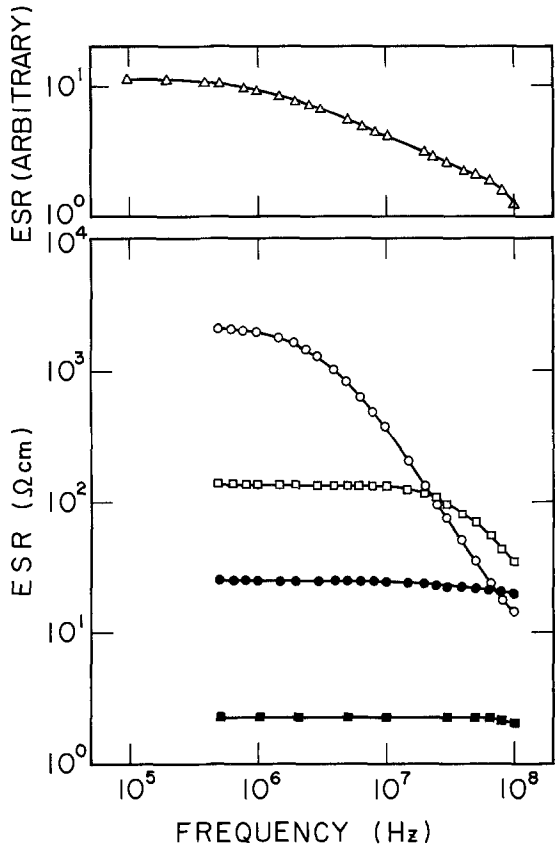

Fig. 8. ESR as a function of frequency for quinolinium $(TCNQ)_2$ at room temperature; points marked ■ refer to the strongly pressed pellet at about 620 kg/cm^2, and □ to lightly pressed pellet at about 11 kg/cm^2. Points marked ● and ○ refer to pellets containing polyvinylpyrrolidone by 10 weight percent pressed at 620 and 11 kg/cm^2, respectively. The top curve marked △ represents solution-deposited film with the polymer.

pellets that two characteristic cutoff frequencies appeared from 500 kHz to 100 MHz frequencies. The lower one (around 2 MHz) was thought to arise from organic semiconductor-polymer effect and the higher (around 50 MHz) from particle-particle effect of the organic semiconductor. The results for the dispersed film are likely to represent the coupled properties of the above two effects. Coming back to Fig. 7 with the results of Fig. 8, we note that two CR networks of the three were simulated by the model experiments. Consequently $(CR)_2$ and $(CR)_3$ are ascribed to the semiconductor-polymer and the semiconductor-semiconductor interfaces, respectively. Since the cutoff phenomena due to the semiconductor particle or more tightly bound interfaces, such as semiconductor-graphite or semiconductor-silver counterelectrodes, do not appear in Fig. 8, the lowest network may be an analog of the electrolyte-oxide interface.

Low frequency properties.—The low frequency deviation in ESR was larger for higher temperatures as shown in Fig. 2 and 3. The capacitance also displayed a slight increase with decreasing frequency at 65° and 85°C (Fig. 2). The increase in C_s and/or R_s at low frequencies has been explained by several mechanisms, but most of them may be ruled out because of their temperature dependence and their relative significance. For example, the blocking of the ionic conduction at the oxide-electrode interface (17) or the dispersion of adsorbed water at the interface has a reverse temperature dependence of R_s and C_s. The d-c leakage current, which has similar temperature dependence as R_s, does not contribute much to the ESR, because the insulation resistance is as high as $10^{13}\Omega$ at room temperature and $4 \times 10^{11}\Omega$ at 85°C. At the present time, we have no definite explanation

of the results, but we suggest that the low temperature impedance is dominated by the interfacial polarization of the polymer which is in contact with the anodic oxide. The trend in the temperature and frequency dependence of C_s and tan δ is indicative of a well-known Debye law or Cole-Cole relation as has been observed for most polymers. Although in case of OSS-A or OSS-B no peak appeared in the tan δ-T or tan δ-f curve, we frequently obtained such peaks for capacitors with much less adhesive polymers, polyacrylonitrile and polyurethane (2). The behavior of the ΔC_s and ΔR_s may be a result of mixed effects of polymers, semiconductor, and the oxide, because the frequency dependences did not entirely coincide with the intrinsic dielectric properties of the polymers.

Conclusions

Both equivalent series capacitance and resistance of the newly developed OSS capacitor were measured over a wide range of frequency and the results were compared with those of the MnO_2-based capacitors. The OSS capacitors exhibited improved a-c properties at high frequencies and low temperatures. The extra capacitance and resistance that were thought to be introduced by the organic semiconductor electrolyte were analytically separated and their origins were considered. The plateau of ESR at intermediate frequencies was ascribed various effects of the electrolyte, such as the distributed resistance and the dispersions due to particle-particle or particle-polymer interfaces.

The improved characteristics of the OSS capacitor may extend the applicability of the solid electrolytic capacitor from the ordinary low frequency use. In view of the extended breakdown voltage in both the forward and reverse directions (2) and higher capacitance density (770 pf/mm^3) of the OSS capacitor, we suggest that the OSS can compete with film capacitors, such as a polycarbonate film capacitor (about 60 pf/mm^3) and a metallized polyester film capacitor (about 150 pf/mm^3). The prominent high frequency stability of the OSS capacitor will be more effective in a leadless device. A thin film capacitor with a screened organic semiconductor counterelectrode is currently being developed, and detailed a-c properties of the capacitor will be reported elsewhere.

Acknowledgments

It is a pleasure to acknowledge Dr. Katsue Hasegawa for his valuable discussions and continual encouragement. We also wish to thank Shohzoh Takahashi and Midori Shinoda for the skill and patience with which they fabricated the OSS capacitors. Most helpful discussions have been made with Mutsuaki Murakami, Masahito Yasuda, and Reiji Sano, to whom we offer our sincere appreciation. We acknowledge various comments made by one of the reviewers, especially on interpretation of the low frequency characteristics.

Technical Notes

Phosphorus Concentration of Chemical Vapor Deposited Phosphosilicate Glass

Kuen Chow[1] and L. G. Garrison*

Burroughs Corporation, San Diego, California 92127

Chemical vapor deposited phosphosilicate glass serves the important functions of passivating the ionic contamination and stabilizing the silicon surface of bipolar and MOS devices. The effectiveness of this passivation function is directly related to the phosphorus concentration in the glass. Therefore a technique which can offer fast and accurate routine monitoring of the concentration of phosphosilicate glass

* Electrochemical Society Active Member.
[1] Present address: Hughes Research Laboratories, Malibu, California 90265.
Key words: silicon, sheet resistivity, neutron activation analysis, etch rate.

will be very desirable for the integrated circuit processing technology.

Many different techniques have been utilized to evaluate the phosphorus concentration in silicate glass. These include neutron activation (1-3), gravimetric (4), infrared spectrometry (5), electron microprobe (5), and etch rate (4-8) techniques. While neutron activation and electron microprobe give accurate absolute measurement of the phosphorus concentration, they are tedious and expensive. On the other hand, infrared and etch rate techniques are fast and inexpensive, but their accuracy is generally not very satisfactory. In this technical note we report the results of an investigation of the CVD phosphosilicate glass concentration using both etch rate technique and neutron activation analysis. The sheet resistivity of the silicon substrate resulting from these glasses being densified at 1100°C for 2 hr in N_2 ambient was correlated with the phosphorus concentration in the oxide obtained from etch rate technique. The etch rate determined dopant concentrations were also compared with those obtained from neutron activation analysis. From these a reliable relationship between the substrate sheet resistivity, the oxide etch rate, and the phosphorus concentration was established which can be used for fast and accurate routine phosphorus concentration evaluation.

CVD phosphosilicate glass was obtained both from the Applied Materials 2640 reactor and Unicorp Pyrox reactor. The deposition temperature was 450°C in the AMT reactor and 400°C in the Unicorp reactor and the oxygen to silane ratio was 11 and 16, respectively. Most of the runs were deposited at 4200Å (±10%) while several runs of 10,000Å were also made. The thickness of the glass before and after etching was measured with a Beckman Model DB spectrophotometer and also with a Gaertner Model 117 ellipsometer. The wafers were positioned carefully so that the area measured was the same in each and subsequent measurement.

The etch rates of as-deposited and densified phosphosilicate glasses as functions of dopant concentration have been reported by Tenney and Ghezzo (8) using infrared spectrometry. The glasses were deposited on chemically polished 10 Ω-cm, p-type 1 in. silicon wafer, by the reaction of argon-diluted mixture of O_2, SiH_4, and PH_3 at 300°-500°C. The oxide was generally 7000Å thick.

Densification at 1100°C for 2 hr was performed in an open tube furnace flushed with pure argon. The etching solutions were prepared by adding deionized water in the desired proportion to buffered HF solution (10 parts 40% NH_4F to 1 part 48% HF by volume) and all etching experiments were carried out at room temperature.

It is well known that the etch rate of as-deposited undensified CVD silicate glass is very sensitively dependent on the deposition parameters (such as flow rate, deposition temperature, growth rate, gas flow pattern, etc.) and the thermal history of the oxide. Consequently etch rates of as-deposited oxide prepared in different conditions are usually not comparable. On the other hand, it is also recognized that after densification at very high temperature, the physical properties of the oxide approach those of the thermal oxide and become uniformly comparable. We can therefore compare the physical properties of the high temperature densified glasses even though they were deposited in different environments. Based on this fact, we have subjected the deposited glasses to a similar 2 hr 1100°C densification, albeit in dry nitrogen ambient instead of argon. The etch rates of the densified glass in 25 and 50% 10:1 BHF were then measured and compared with those measured by Tenney and Ghezzo (8). From this comparison the mole percent (m/o) concentration of P_2O_5 in the densified glass was derived. The etch rate and P_2O_5 concentration results are listed in Table I. In the process of etch rate measurement it was observed that the etch rate generally increases from the surface layer down toward the oxide-silicon interface. The variation ranges from 0 to 40% with an average of 20%. This has been attributed partly to the poor wetting of fresh oxide in diluted HF (7) and partly to the evaporation loss of phosphorus from the surface layer during densification (9). As a result, the etch rate and hence the P_2O_5 concentration inferred at the midthickness of the oxide were taken to be the true average value, respectively.

* The etch rates were measured in 25% 10:1 BHF. Runs No. 1-10 were deposited in AMT-2640 reactor, runs No. 45-93 were deposited in Unicorp Pyrox reactors.

After the etch rates were measured, the residual oxide was stripped clean in 1:1 HF. The sheet resistivity at the point on the wafer where the etch rate and phosphorus concentration were evaluated was then measured with a four-point probe. These sheet resistivity values are listed in Table I and plotted in Fig. 1 as a function of the mole percent of P_2O_5 in the oxide. Large variation was observed in the correlation between the substrate sheet resistivity and the oxide phosphorus concentration arrived from etch rate technique. This indicates the inaccuracy involved when etch rate alone is used to determine the phosphorus concentration.

Since the phosphorus concentration was derived from Tenney and Ghezzo's etch rate data which was only indirectly calibrated with infrared spectrometry, we have also tried to calibrate our result by means of neutron activation analysis. Four 2-in. wafers with as-deposited phosphosilicate glass of varying concentrations were sent to General Activation Analysis, Inc. for neutron activation and radioactive tracing analysis (10). The samples plus comparator standards were irradiated for 30 min in a TRIGA Mark I nuclear

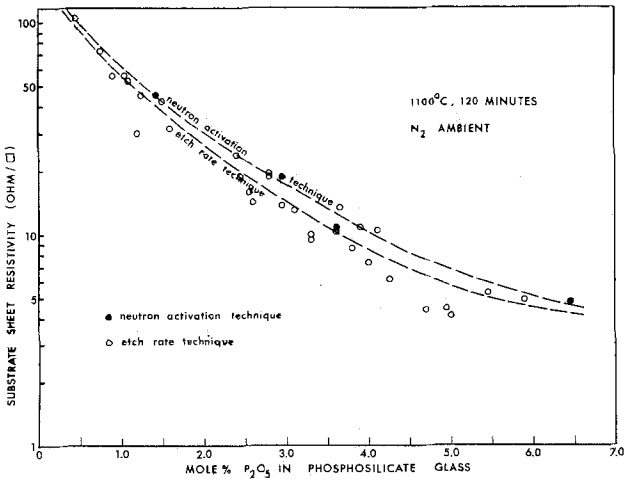

Fig. 1. Substrate sheet resistivity resulting from the 1100°C, 2 hr densification-diffusion in N_2 as a function of m/o P_2O_5 in the glass.

reactor at a flux of 1.8×10^{12} n/cm²-sec. Following the irradiation the surface of the wafer was etched in 1:1 HF. The solution was transferred to a Teflon beaker with 30 mg of phosphorus added. Phosphorus was then precipitated as molybdate. After purification steps the final precipitate was filtered, dried, and weighed to determine recovery. The precipitate was β-counted several times during the next 30 days to determine the amount of radioactive P-32. The weight of phosphorus measured from this radioactive tracing process was then compared with the total mass of the glass which was determined with an assumed density of 2.20 g/cm³ before densification. In the meantime, two other wafers of each composition which were deposited right beside the wafer activation analyzed were densified and used to determine the oxide etch rate and substrate sheet resistivity. The phosphorus concentrations of the undensified, activation-analyzed samples were then correlated with the substrate sheet resistivity obtained on the other two wafers. These four activation-analyzed points are shown as filled circles in Fig. 1. As can be seen, the activation-analyzed data generally indicate a richer P_2O_5 concentration than those arrived at from etch rate technique. Since the activation-analyzed samples have not been subjected to the high temperature densification, this discrepancy probably represents the loss of phosphorus due to evaporation into the ambient flow and diffusion into the silicon substrate. This explanation is also supported by the observation that the etch rate of densified glass usually increases from the oxide surface down toward the oxide-silicon interface.

As a further verification of the correlation between the substrate sheet resistivity and the oxide phosphorus concentration, we have also measured the junction depth of diffusion with the grooving and staining technique. The average conductivity arrived at from the sheet resistivity and junction depth measurements was then used to find the free carrier concentration at the silicon surface from Irwin's curve (11). The resulting free carrier concentrations are plotted in Fig. 2 as a function of the phosphorus concentration in the oxide which were derived from the neutron activation calibrated curve in Fig. 1. These data are compared with the theoretical model proposed by Ghoshtagore (2) which gives the surface concentration of free carrier $C_s(t)$ as

$$C_s(t) = C_{ox}\sqrt{\frac{D_1}{D_2}}\exp\left(\frac{K_{os}^2 t}{D_2}\right)\operatorname{erfc}\left(K_{os}\sqrt{\frac{t}{D_2}}\right)$$

where C_{ox} is the dopant concentration in doped oxide (cm^{-3}), t is the diffusion-densification duration (sec),

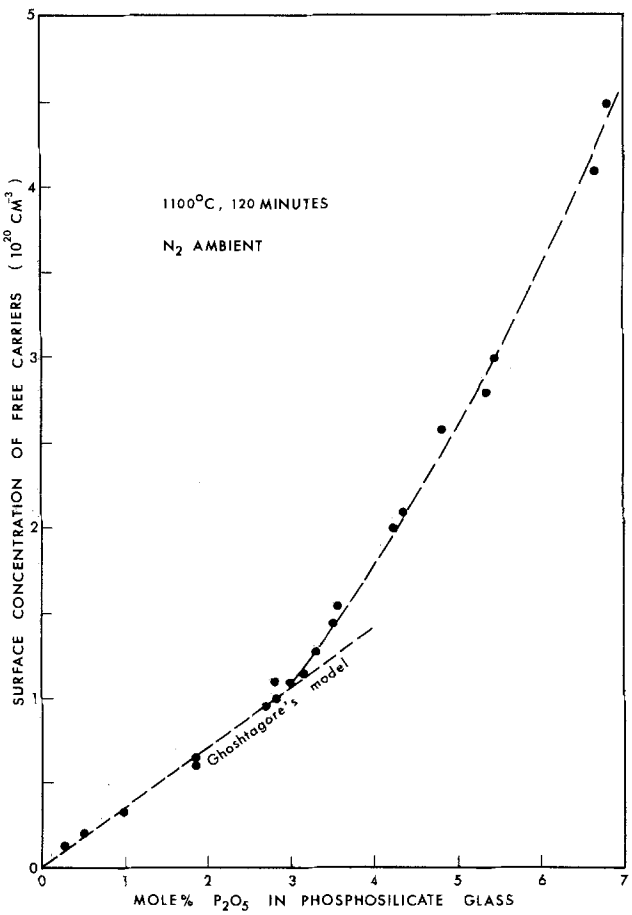

Fig. 2. Silicon surface free carrier concentration from the 1100°C, 2 hr densification-diffusion in N_2 as a function of m/o P_2O_5 in the glass.

D_1 is the diffusivity in doped oxide at concentration C_{ox} (cm²/sec), D_2 is the diffusivity in silicon (cm²/sec), and K_{os} is the surface barrier constant of phosphorus for oxide-silicon interface (cm/sec). As can be seen, with $D_1 = 4.52 \times 10^{-16}$ cm²/sec, $D_2 = 1.47 \times 10^{-13}$ cm²/sec, and $K_{os} = 1.7 \times 10^{-9}$ cm/sec at 1100°C as proposed by Ghoshtagore, the agreement between theory and experiment is very good at P_2O_5 concentrations below 3 m/o. This agreement thus seems to lend further support for the neutron activation calibrated curve presented in Fig. 1. It is however necessary to be cautioned that since Ghoshtagore's model is valid only for surface concentration levels of 1×10^{19} cm^{-3} or less, the fit at higher concentrations should be considered fortuitous.

In conclusion, we have reported in this technical note the evaluation of phosphorus concentration in CVD phosphosilicate glass by means of etch rate, diffusion, and neutron activation analysis techniques. It was shown that etch rate technique alone does not result in very accurate measurement of phosphorus concentration. When compared with data from neutron activation analysis, they are usually 0.2 to 1.5 m/o less than the absolute value. The neutron activation analysis calibration has helped to establish a more reliable correlation between substrate sheet resistivity and the phosphorus concentration in the glass. With this correlation known, it is thus possible to obtain fast and accurate routine determination of the phosphosilicate glass concentration with a 2 hr, 1100°C densification and the subsequent measurement of the substrate sheet resistivity.

Acknowledgments

The authors are indebted to L. E. Kovar for his work on the neutron activation analysis. Helpful

discussions with V. A. Bluhm, C. S. Chen, and Dr. R. N. Ghoshtagore are gratefully acknowledged.

Cathodoluminescent Efficiency

R. C. Alig and S. Bloom

RCA Laboratories, Princeton, New Jersey 08540

Several years ago Kingsley and Ludwig examined the correlation of cathodoluminescent phosphor efficiencies with other material properties (1). In the course of this work they observed that a high plasma resonance energy in a phosphor host is correlated with a low cathodoluminescent efficiency, *i.e.*, all the efficient phosphor hosts have relatively low plasma energies. This observation is illustrated[1] in Fig. 1 where the maximum cathodoluminescent power efficiency η_m ever measured for a phosphor host is plotted *vs.* its calculated plasma resonance energy E_p. In 1970 Kingsley and Ludwig remarked that the upper right-hand region of this graph defined by the dashed lines is devoid of phosphors; only one exception (HfP_2O_7) to this remark is known today even though the number of phosphor hosts with efficiencies above 6% included in the figure has been more than doubled.

It is also quite generally accepted (2) that the efficiency of a phosphor can be expressed as

$$\eta = S E_{ph}/\epsilon \qquad [1]$$

where ϵ is the average energy needed to create an electron-hole pair in the phosphor, E_{ph} is the energy of the emitted photon, and S is the probability that electron-hole pairs are converted to photons. Since E_{ph} is largely fixed by the activator ion, it cannot be related to E_p to explain the correlation illustrated in Fig. 1. Hence this correlation must come either from a relation between ϵ and E_p or between S and E_p^{-1}.

In the early 1960's Lappe empirically found (3) a relation between the electron-hole pair creation energy ϵ and the fundamental electronic bandgap E_g of a semiconductor, *i.e.*

$$\epsilon \approx 2.8\, E_g \qquad [2]$$

This result has been verified repeatedly since then, both theoretically and experimentally, for a broad range of semiconductors (4). Hence, if ϵ and E_p are related, then E_g and E_p must be related, a result we know and expect to be generally untrue of semiconductors.

From Eq. [1] and [2] we expect the efficiency η to be related to E_g^{-1}. Therefore, in Fig. 2 we plotted η *vs.* E_g^{-1} for several phosphors. For phosphors activated by the same impurity ion there does indeed seem to be a relation between η and E_g^{-1}, *i.e.*, for Cu-, Pb-, and Eu^{3+}-activated phosphors, lines from the origin fit the data well. Using measured values[2] of the emitted photon energies E_{ph}, values of the energy transfer probabilities S were calculated from the slopes of these lines; these are listed in Fig. 2. Since S is the same for several phosphor hosts, it is hard to see how it could be related to E_p.

Thus the correlation illustrated in Fig. 1 appears to be inconsistent with Eq. [1] and [2]. The plasma energies used in the construction of Fig. 1 were calculated from the crystal structure of the phosphors, so if the correlation shown there is indeed real, it ought to improve when these calculated values of E_p are replaced by measured values of E_p. Using electron energy loss data measured by Hengehold and Pedrotti (7) for several II-VI compounds, by Yamamoto and Tonomura (8) for several of the more efficient phosphors, and by Best (9) for some alkali halides, Fig. 3 was drawn. In contrast with Fig. 1 there is no hint in Fig. 3 of a relation between maximum phosphor efficiency and plasma resonance energy.

The plasma energies used in drawing Fig. 1 were calculated from the formula $E_p = \hbar(4\pi n_v e^2/m)^{1/2}$ where e and m are the electron charge and mass and n_v is the valence electron density. More specifically, the valence electron density is defined, somewhat

Key words: phosphors, plasma energy, correlations.

[1] Much of the data needed for the figures is summarized in Table I of this paper.

[2] The emission energy data for Cu-activated phosphors come from Ref. (5) and (6), for Pb activation from Ref. (6) and for Eu^{3+} activation from Ref. (1).

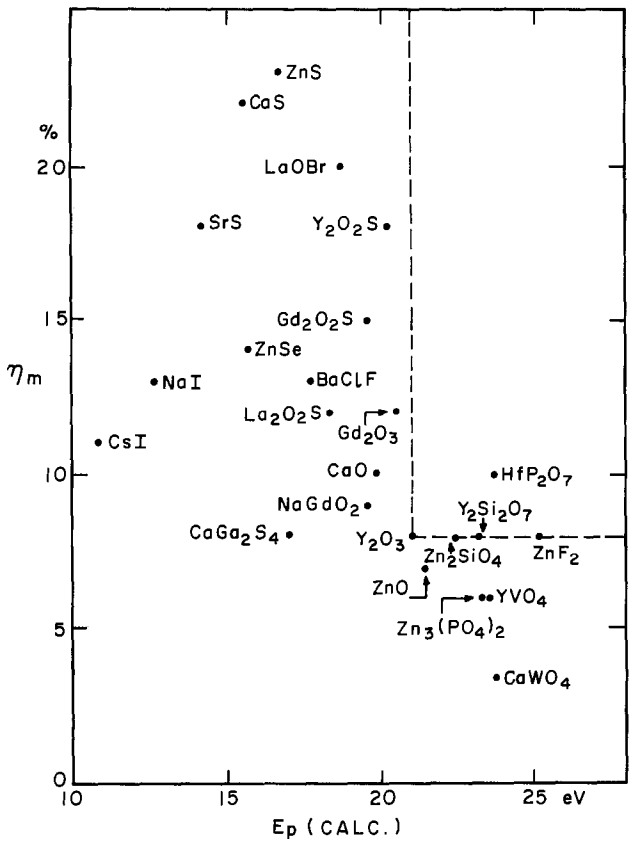

Fig. 1. The maximum cathodoluminescent energy efficiency η_m is plotted *vs.* the calculated plasma resonance energy E_p for selected phosphor hosts. The dashed lines define the region devoid of phosphors.

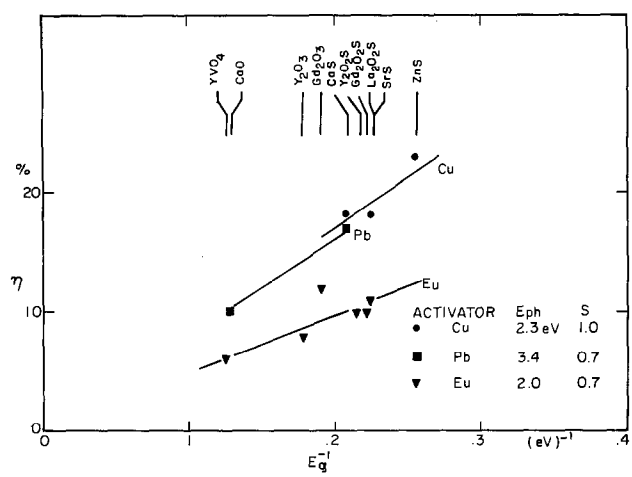

Fig. 2. The measured cathodoluminescent energy efficiencies η of several phosphors, *vs.* the reciprocal of the fundamental band-gap E_g of the phosphor host. The phosphor hosts are indicated at the top of the figure and the activators are indicated by the symbols shown at the right of the figure. Straight lines of slope parameter S, calculated using photon energy E_{ph} and Eq. [1] and [2] have been fitted to selected points associated with the same activator.

arbitrarily, as 8 times the density of halide and chalcogenide atoms in the phosphor host. To establish the existence of a relationship between η_m and n_v, as suggested by the data in Fig. 1, the efficiency η_m is plotted *vs.* n_v^{-1} in Fig. 4. From this figure the relationship does appear to exist; statistically (10) the probability of no correlation lies below 1% for the materials shown in Fig. 4.

If the relation shown in Fig. 4 does indeed exist, then from Eq. [1] and [2] we must expect to find a relation

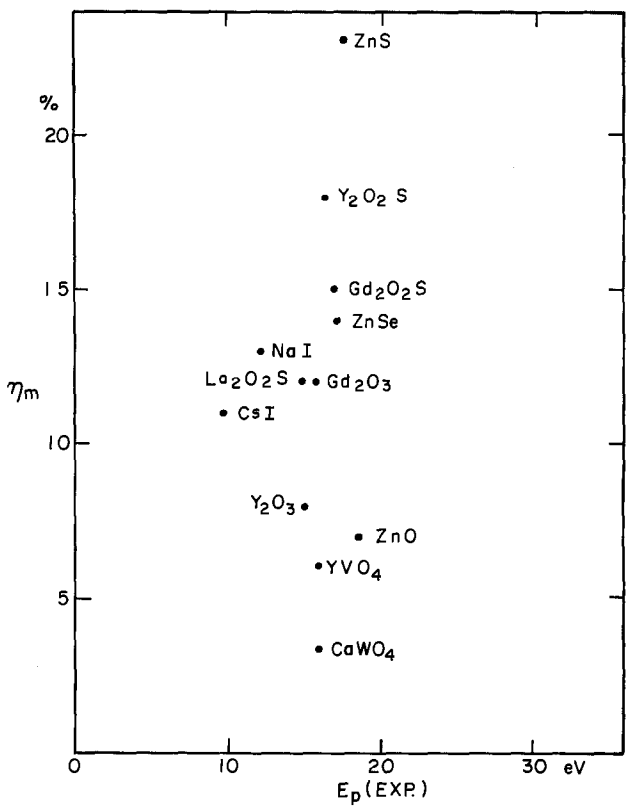

Fig. 3. The maximum efficiency η_m is plotted *vs.* the experimental plasma energy E_p for selected phosphor hosts.

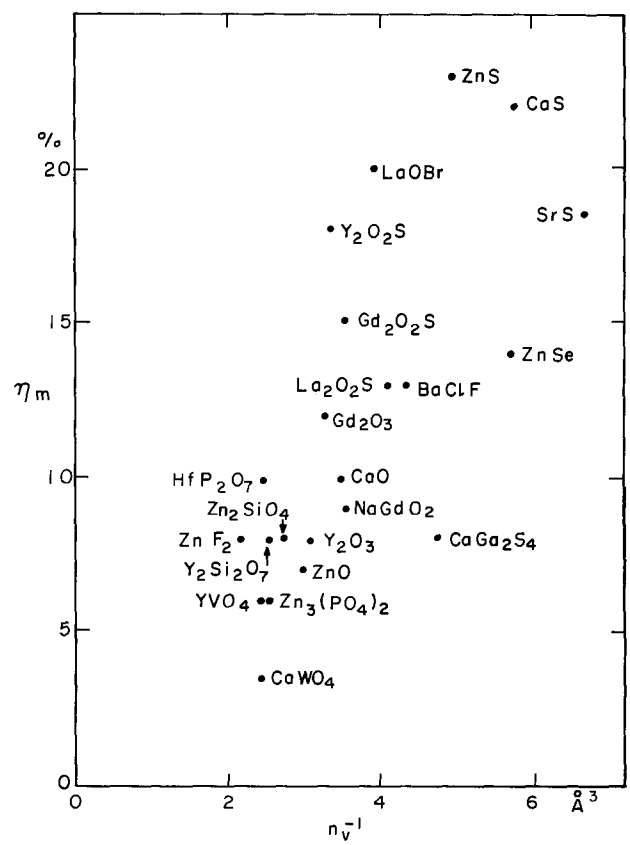

Fig. 4. The maximum efficiency η_m is plotted *vs.* the reciprocal of the valence electron density n_v for selected phosphor hosts.

between E_g and n_v for those materials which host efficient phosphors. This data is plotted in Fig. 5. Indeed there does appear to be a relation, and again the statistical probability of no correlation lies below 1% for the nonhalide materials shown. However, this relation-

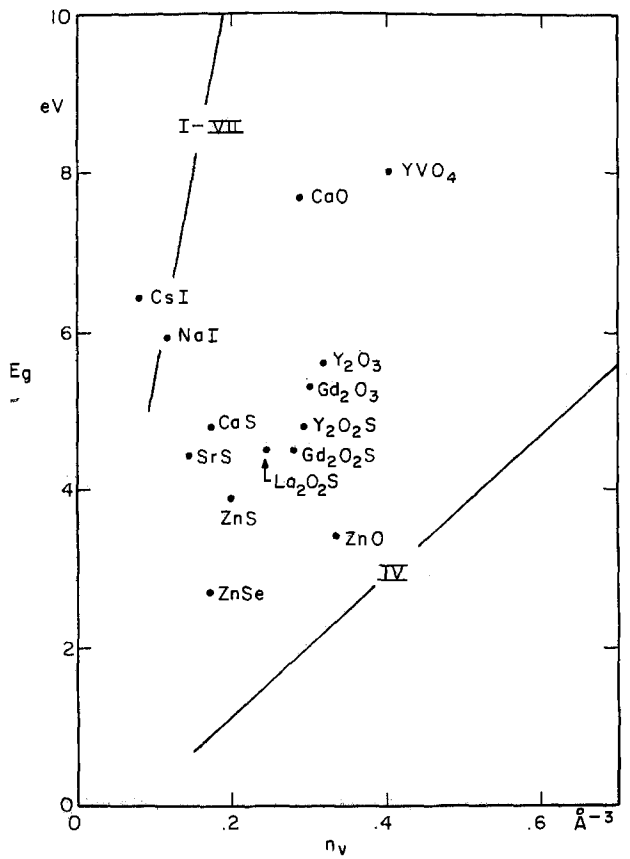

Fig. 5. The fundamental bandgap E_g is plotted vs. the valence electron density n_v for several semiconductors which host efficient phosphors. Similar data is indicated by solid lines for alkali halide and Group IV materials. The valence electron density of the Group IV materials was defined as 4 times the atomic density.

ship is restricted to the efficient phosphors. Similar data for a selection of materials for which bandgap data (11) is available is also indicated in Fig. 5; with this additional data the appearance of a correlation fades.

It can be seen from Fig. 5 that a correlation between the valence electron density and the bandgap does exist for those semiconductors having a similar ratio of ionic to covalent banding. That is, the Group IV semiconductors, which are largely bound covalently, fall on one line, while the alkali halides, which are largely bound ionically, fall on another line. Thus, if most of the popular phosphor hosts had about the same ratio of ionic to covalent bonding, the correlation discovered by Ludwig and Kingsley could be understood. Indeed the two phosphor hosts in which this ratio exhibits the greatest departure from the average, NaI and CsI, had to be excluded from Fig. 4 because they lie far to the right of the right-hand margin of this figure; they depart greatly from the correlations illustrated in Fig. 4 and 5. Therefore, we understand the correlation illustrated in Fig. 1 to be a consequence of the similar ratio of ionic to covalent bonding of the popular phosphor hosts.

Poly(vinylethers) as X-Ray Resists

Saburo Imamura, Shungo Sugawara, and Kei Murase

Nippon Telegraph and Telephone Public Corporation,
Ibaraki Electrical Communication Laboratory, Tokai, Ibaraki, 319-11, Japan

X-ray resist materials for production of microelectronic circuits have recently become subjects of renewed interest (1). In the present work, a series of poly(vinylethers) were studied as new resist materials. The effects of the chlorine-containing side chain and unsaturated groups on x-ray irradiation characteristics were investigated.

Several vinylethers listed in Table I were polymerized in absolute toluene at −70° to −60°C under a nitrogen atmosphere, using a small amount of $BF_3 \cdot OEt_2$ as the cationic polymerization initiator (2). All polymers were purified by precipitation into methylalcohol or water and by washing several times. The intrinsic viscosity of each of the polymers obtained was measured at 30°C in benzene with an Ubbelohde viscometer. Weight average molecular weight $\overline{M}w$ was calculated with Manson's viscosity equation for poly(methylvinylether) $[\eta] = 7.6 \times 10^{-4}\ \overline{M}w^{0.60}$ (3). The polymers were spincoated to about 0.5 μm thickness on silicon wafers from methylethylketone-xylene (4:1) mixed solution. After prebaking at 50°C for 30 min, the resist-coated substrates were exposed to soft x-rays ($\lambda = 5.4$Å, Mo L line). The exposure system was used for evaluation of resist sensitivity and replication of mask patterns. The system was of the two chamber type. In the high vacuum chamber (10^{-6} Torr), a rotating water-cooled Mo target was pumped with a 3.2 kW, 16 kV electron beam. X-rays emitted were passed through a 12 μm polyester window into an exposure chamber vacuum pumped down to 10^{-3} Torr. Resist-coated substrates were held on a fixture mounted 12 cm from the target.

The flux of characteristic x-ray incident on the resist-coated substrate was measured with a gas-flow proportional counter, using P-10 gas at 0.16 kW, 4 kV electron beam, which is within measurable limit of the gas-flow counter. Flux ϕ can be calculated from

$$\phi = 1/T_m \times 1/T_{Al} \times 1/\mu_g \times d_c^2/d_r^2 \times 1/S \times C \times E$$

where T_m and T_{Al} is transparency of the gas-flow counter window [5 μm Mylar (0.805) and 1 μm evaporated aluminum (0.653)], μ_g is absorption of P-10 gas (0.675/2 cm path), d_c (15 cm) and d_r are the distances from target to counter and the resist-coated substrate, S is counter window area (3.4×10^{-6} cm^2), C is photon count (1.3×10^4 counts/sec), and E is photon energy for Mo L radiation (3.8×10^{-13} mJ/photon). The flux was 0.063 mJ/cm^2/sec at 0.16 kW electron beam and was 0.21 mJ/cm^2/sec at 3.2 kW, corrected

with sensitivity-measured resists at 0.16 kW, such as epoxidized polybutadiene and poly(2-chloroethylvinylether-co-vinyloxyethylacrylate). The exposed films were developed by dipping into isoamylacetate for 30 sec. After heat-treatment at 120°C, the remaining film thickness was measured.

Table I shows the characteristics of the polymers studied. Mass-absorption coefficient μ_m is an additive function of the various atomic species present in the material, with consideration of weight percent (w/o) according to

$$\mu_m = \sum_i P_i \mu_{mi}$$

μ_{mi} = mass absorption coefficient of atom i
P_i = weight percent of atom i

Sensitivity is defined as the irradiation dose required to yield 50% of the initial film thickness. Contrast (γ) is defined as the slope of the extrapolated linear portion of the dose-thickness curve and may be expressed as

$$\gamma = [\log_{10}(D_0/D_g^i)]^{-1}$$

where D_g^i and D_0 are the dose of 0 to 100% film remaining (4).

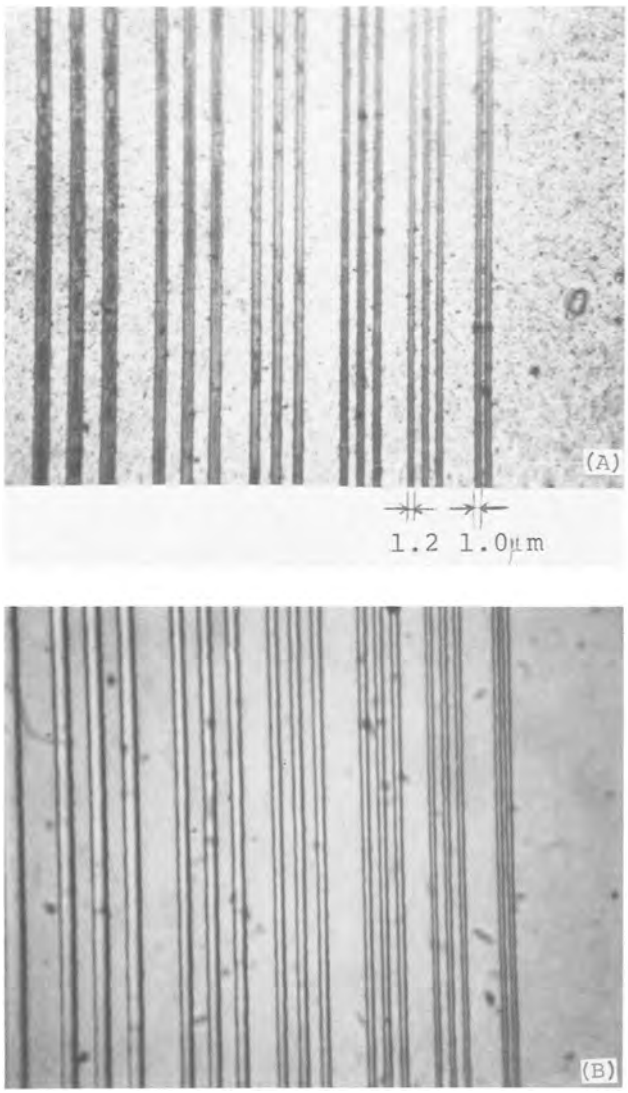

Figure 1 shows sensitivity curves for poly(2-chloroethylvinylether-co-vinyloxyethylacrylate) (CEVE-co-VOEA) and poly(2-chloroethylvinylether-co-isobutylvinylether) (CEVE-co-IBVE).

The results show that (i) The polymers containing chlorine in the side chain have relatively high sensitivities and the polymer containing 1% of vinyloxy-

ethylacrylate has the highest sensitivity; and (*ii*) Polymers containing chlorine also have relatively high contrast; CEVE-co-IBVE is the highest contrast ($\gamma = 2.2$) resist. This value is much higher than contrast values usually observed for negative resists, which can be as low as $\gamma = 0.7$ observed for epoxidized polybutadiene (5). The reason why polymers containing chlorine and an unsaturated group in the side chain have higher sensitivity is considered to be due to its higher reactivity, because differences in the molecular weight and mass absorption coefficient relative to the usual resist materials are small.

Figure 2(A) shows mask patterns and Fig. 2(B) and 2(C) show CEVE-co-VOEA resist patterns on a silicon wafer after pattern replication using soft Mo Lα x-rays emitted with a 1 kW, 10 kV electron beam. Resist-coated substrates were mounted on a fixture below the mask with a 12 μm gap (polyvinylidenefluoride spacer). The mask consists of Si (4 μm thick) with a gold absorber (4000Å thick). It was designed with a minimum line width of approximately 1 μm. The resist was spin coated to an initial thickness of about 0.5 μm. Exposure time was about 7 min. Patterns were developed by dipping into n-butyl acetate and successively rinsed by dipping into isopropanol. The final resist thickness in Fig. 2(A) and 2(C) was 0.25-0.3 μm. It is apparent that this resist has at least 1.0 μm resolution and it could be used successfully to wet etch into SiO_2.

Electrical Properties of $LiFe_5O_8$

Tsuneo Matsui[1] and J. Bruce Wagner, Jr.*

Materials Research Center and Department of Materials Science and Engineering, Northwestern University, Evanston, Illinois 60201

The lithium ferrite spinel ($LiFe_5O_8$) has the inverse spinel structure $Fe^{3+}[Li_{0.5}^{+}Fe_{1.5}^{3+}]O_4$. One-eighth of the tetrahedral (A) sites are occupied by Fe^{3+} ions, and Li^+ and Fe^{3+} ions share one-half of the octahedral (B) sites within the fcc sublattice of oxygen ions (1). There has been considerable interest in lithium compounds for use as solid-state electrolytes and as electrode materials in batteries involving lithium as one reactant. Some measurements of the electrical conductivity of $LiFe_5O_8$ have been made by using d-c (2-4) and a-c methods (5), but the results obtained so far have been inconsistent. The a-c conductivity measurements have been made only at room temperature in air by Samokhvalov *et al.* (5). Accordingly, a study of the electrical properties of $LiFe_5O_8$ was undertaken to contribute to an understanding of this class of materials.

In the present paper, the a-c and d-c electrical conductivity measurements of $LiFe_5O_8$ have been carried out as a function of temperature (22°-850°C) and oxygen partial pressure (oxygen, air, and argon). The samples were polycrystalline pellets pressed from powders and having 94-96% of the theoretical density. The powders were prepared by heating a ferric oxalate ($Fe_2(C_2O_4)_3 \cdot 6H_2O$) and lithium carbonate (Li_2CO_3, 99.999%) mixture at 900°C for 0.5 hr in gold foil, then sintering at 1100°C for 0.5 hr, 1000°C for 2 hr, and finally 700°C for 14 hr in air. The argon gas was purified by passing first over heated copper turnings at 400°C and then through a tube of silica gel to remove water vapor. The oxygen partial pressure in the resulting argon gas was determined to be below 10^{-6} atm by measuring the electrical resistance of a nonstoichiometric cobaltous oxide wire (Johnson Matthey Company reactor grade cobalt) at 1000°C (6-10).

X-ray diffraction patterns of the $LiFe_5O_8$ samples (which were heated in oxygen, air, or argon at 850°C for 15 hr, annealed at 700°C for 15 hr and then cooled slowly to room temperature over a period of 24 hr) were obtained at room temperature by using a Phillips diffractometer with CuKα radiation through a Ni filter. The x-ray results are summarized in Table I. The single α-$LiFe_5O_8$ phase was observed in the samples heated in air and argon, but traces of α-Fe_2O_3 in addition to the α-$LiFe_5O_8$ phase were observed in the samples heated in oxygen. The lattice constant of the $LiFe_5O_8$ sample prepared in air in the present study is in good agreement with that ($a_o = 8.337$Å) of single crystal $LiFe_5O_8$ also prepared in air by Schieber (11).

The a-c conductivity measurements were made using a General Radio 1650A a-c bridge in the frequency range 1-20 kHz using an oscillator (Hewlett Packard Model 202D). Gold foils were used as the electrodes and electrical contact was ensured by spring-loaded quartz glass plates and lava blocks. The results of the a-c and d-c conductivity measurements at 1 kHz are shown in Fig. 1 and summarized in Table II. The a-c conductivity values of $LiFe_5O_8$ were found to vary from sample to sample below 740°C, but reproducible and consistent values (± 3% error) were obtained in all samples above 750°C (in the β-phase whose conduction was 100% electronic). However, even below 740°C the majority of the $LiFe_5O_8$ samples exhibited nearly identical values of conductivity (± 10% error). The inconsistency among the conductivity data of $LiFe_5O_8$ samples is considered to be due to the polarization between sample and electrodes (blocking gold elec-

trodes in this study), and also due to the sluggish transition from the disordered β-phase to the ordered α-phase which was observed by Kato (2) and Schieber (11). To reach equilibrium values of a-c conductivity after transition from β- to α-phase, it was necessary to anneal at 700°C for 15 hr. The a-c conductivity was independent of frequency between 1 and 10 kHz, but at some temperatures a conductivity increase (5 ~ 40%) was observed between 8 and 20 kHz. The a-c conductivity value of $LiFe_5O_8$ at room temperature in the present study is in good agreement with previous data (5).

Wagner's polarization method (12, 13) was not used in the present study to determine the partial electronic conductivity because of the reactivity of reversible lithium electrode with the sample, air, and oxygen. Alternatively Vest and Tallan's method (14) was employed. The polarization potential of the cell with two blocking electrodes (both anode and cathode were gold electrodes) produced by the constant current flow from the current source (Keithley Model 225) was measured as a function of time by a Keithley 610B electrometer and/or Doric digital voltmeter. The applied current to the sample was limited to voltages below the decomposition potential of $LiFe_5O_8$. The d-c potentials used were between 0.01 and 0.60V. However, the polarization potential (i.e., electronic conductivity) still changed with time even after 1 hr. In this polarization cell there was no reversible electrode to fix the chemical potential of the sample, and thus the electronic conductivity changed with time due to the deviation of stoichiometry created by the current flow when the polarization proceeded. The electronic transference number calculated based on the data after 1 hr is summarized to estimate approximately the electronic portion of total conductivity. The difference between Wagner's polarization method and Vest and Tallan's method has been discussed in detail by Joshi and Wagner (15). In the β-phase in air and in oxygen, and both in the β- and α-phase in argon, the polarization potential did not change with time, indicating that in these phases of $LiFe_5O_8$ conduction was 100% electronic. Electrical conductivities calculated from initial transient d-c voltages were in good agreement with those obtained by a-c measurements.

Lithium ferrite spinel contains reducible iron ions (Fe^{3+}) and lithium ions, and therefore it is expected that this material exhibits both electronic and ionic conduction. As seen in Fig. 1, the electronic contribution to the total conductivity increased with decreasing partial oxygen pressure, which is due to the increase of the ferrous (Fe^{2+}) ion concentration reduced from ferric (Fe^{3+}) ions. The same tendency has been observed in potassium ferrite by Roth and Romanczuk (16). The electrical conductivity increased with decreasing partial oxygen pressure (n-type conductor), which is reasonable because p-type $LiFe_5O_8$ is not expected to exist (both Li^+ and Fe^{3+} ions are in their highest valence states). The small activation energy values for the electronic conduction and the linear relation between log σT *vs.* $1/T$ may indicate that the small polaron model of electron hopping motion between Fe^{2+} and Fe^{3+} offer the best possibility for charge-transfer mechanism for $LiFe_5O_8$, which is the same mechanism as that proposed in the potassium ferrite by Roth and Romanczuk (16) and Dudley *et al.* (17).

The phase transition of $LiFe_5O_8$ from α- to β-phase has been found at 750°C by x-ray diffraction (11, 18) and d-c conductivity measurements (2). This is the order-disorder type of transition in the distribution of the Li^+ and Fe^{3+} ions in the octahedral sites (1, 2). In the present study abrupt jumps in the conductivity curves were observed at the phase transitions both in air and oxygen, and the transition temperatures thus obtained were both 740° ± 5°C. There was no difference in the transition temperature within experimental error between samples in air and in oxygen. This is because the $LiFe_5O_8$ phase coexisted with α-Fe_2O_3 in the sample in oxygen and the difference in the composition between samples in air and oxygen was small. At the phase transition the change in conductivity of the sample in air was smaller than that of the sample in oxygen. No significant jump in the conductivity curve was observed for the sample in argon but a change of slope was observed at 550° ± 5°C. It is considered that partial disordering in the distribution of iron ions may occur even in the low temperature phase in argon because of the large concentrations of ferric ions, and thus the jump which corresponds to the change of degree of disordering at the transition was too small to be observed in this study.

Tretyakov and Rapp (19) have proposed the interstitial lithium and interstitial iron model in the lithium ferrite spinel at 1005°C by high temperature electrochemical measurements. In the present study the defect structure was estimated from the partial oxygen pressure (p_{O_2}) dependence of electrical conductivity (σ) in the high temperature β-phase (750° ≦ T ≦ 850°C) where the conduction was 100% electronic. But the dependence between air and argon ($p_{O_2} \leqq 10^{-6}$ atm) was too weak to explain by using a simple defect model (oxygen vacancy model, $\sigma \propto p_{O_2}^{-1/4}$ and $p_{O_2}^{-1/6}$; interstitial lithium model, $\sigma \propto p_{O_2}^{-1/5.5}$; and interstitial iron model, $\sigma \propto p_{O_2}^{-1/5.5}$). To explain the weak dependence, the complex defect model [for example, the clustering and decomposing model of two different types of defects which have been applied for uranium oxides (8, 20, 21)] would be more suitable. However, the detailed determination of crystal structure of $LiFe_5O_8$ in argon at high temperature is required to test such a complex defect model.

Experiments Showing the Absence of Electromigration of As and Al in Peltier LPE of GaAs and $Ga_{1-x}Al_xAs$

J. J. Daniele*

Philips Laboratories, Briarcliff Manor, New York 10510

Peltier-induced LPE is LPE in which an electric current is passed through the solid-liquid (S-L) interface and directly cools it by the Peltier effect. The resulting crystal growth takes place at constant temperature and the electric current is the sole externally applied driving force for growth. Peltier LPE has been performed on InSb, GaAs, and GaAlAs (1-5) and CW GaAs/GaAlAs DH lasers have been grown (6, 7). The growth is characterized by a growth rate (v_p) roughly proportional to the applied current. In addition, the growth rate is too large [v_p observed $\approx$ 1 μm/min, v_p calculated from a diffusion model (8) $v_p \approx 0.05$ μm/min] to be due solely to diffusion. To account for the elevated growth rate, electromigration (3-5) or convection (2-4) have been suggested as possible transport mechanisms. This communication presents recent data which show that electromigration of As and Al does not play a significant role in the Peltier LPE of GaAs and GaAlAs.

The theoretical basis for the present experiment is that electromigration is strongly dependent on (and proportional to) the applied electric field (9) and if the electric potential is reversed then the direction of electromigrative flow of species in solution must also be reversed (see Fig. 1). In order to separate the thermal and electrical effects, it is imperative that the Peltier cooling is the same for both current directions. Identical thermal conditions for opposite directions of current can be achieved in separate experiments by using p- and n-type substrates since these have roughly equal and opposite Peltier coefficients at 800°C (measured with respect to Ga and verified in a separate experiment; $\pi_n \cong -0.30$, $\pi_p \cong 0.35$V). Thus, equivalent Peltier cooling and opposite electromigration effects result when opposite electric currents are applied to p- or n-type GaAs. As a result, if Peltier LPE of GaAs or $Ga_{1-x}Al_xAs$ is performed under identical thermal conditions (except for the current direction and substrate conductivity type) and if electromigration toward the substrate is responsible for the very high growth rates, then electromigration away from the substrate should give a very slow growth or a meltback.

In the present experiments, GaAs and $Ga_{1-x}Al_xAs$ (x = 0.15 and 0.3) were grown by Peltier LPE on p- and n-type GaAs substrates ([100]GaAs, p, n $\approx 3 \times 10^{18}$/cm^3, 2 mm thick). The experiments were identical except for the conductivity type of the substrates, and the current direction. The epilayers were undoped and were thin ($\leq$50 μm) with respect to the substrate thickness so that the substrate dominates the thermal process. The growth took place at 800°C. The growth system and growth procedure have been described previously (3).

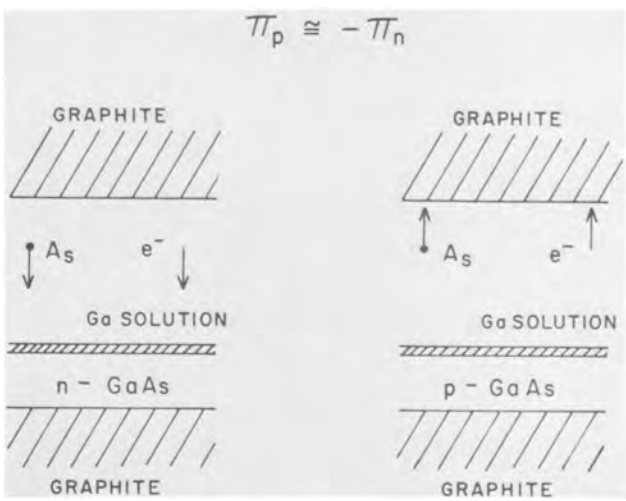

Fig. 1. Schematic of Peltier LPE growth cell showing the solution, substrate and epitaxial layer and illustrating the effects of electromigration on Peltier LPE on p- and n-type substrates. Since $\pi_p \cong -\pi_n$, opposite electric currents are required for cooling in the two cases and thus an opposite electromigration direction must result.

Table I. Experimental results

Substrate type	Normalized current, A/cm^2	X_{Al} (solid)	Average growth rate (v_p), μm/min
p	+10	0	0.5
n	−10	0	0.5
p	+10	~0.15	0.25
n	−10	~0.15	0.4
p	+10	~0.3	0.3
n	−10	~0.3	0.3

* Electrochemical Society Active Member.
Key words: LPE, Peltier effect, growth rate.

The results of these experiments are shown in Table I. From the data it is clear that regardless of current direction the Peltier-induced LPE growth rate is roughly the same for GaAs and $Ga_{1-x}Al_xAs$ ($x = 0.15$ and 0.3). The marked difference indicative of electromigration is not present. Thus, electromigration of As and Al cannot be playing a significant role in the Peltier LPE process and other mechanisms such as convection and boundary layer formation should be more closely investigated. Moreover, preliminary experiments show that the Peltier LPE growth rate of GaAs and GaAlAs decreases with diminishing melt height until a critical height of ~2 mm is reached (10). These experiments indicate that convective stirring and formation of a diffusion boundary layer may be present and can account for the observed elevated growth rate.

Acknowledgment

The author is grateful to Dr. T. S. Hurle of Royal Radar Establishment for suggesting the use of p- and n-type substrates. The author also acknowledges the excellent technical assistance of Robert Peterson.

Investigation of the Formation of Gaseous Sodium Sulfate in a Doped Methane-Oxygen Flame

C. A. Stearns, R. A. Miller,* F. J. Kohl, and G. C. Fryburg#

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio 44135

In hot corrosion research it has generally been assumed that sodium sulfate is formed in the combustion process by reaction of contaminants contained in the fuel and intake air. A commonly proposed reaction is:

$$2NaCl(g) + SO_2 + 1/2O_2 + H_2O = Na_2SO_4(g) + 2HCl$$

Our Knudsen cell study of the vaporization of sodium sulfate has lent credence to such reactions by establishing the existence of gaseous Na_2SO_4 and values for its thermodynamic properties (1).

$Na_2SO_4(g)$ formation was measured at atmospheric pressure in CH_4-O_2 flames. High pressure, free-jet expansion, mass spectrometric sampling was used to identify and measure reaction products. The flame holder and sampler are shown in Fig. 1. The flame was doped by adding SO_2 and by nebulizing aspirated solutions of $NaCl+H_2O$ into the mixing chamber. Burner surface to sampler orifice distance, z, was varied with a precision of 0.025 mm.

Fig. 2 shows measured composition profiles of reaction products for a doped 9.5 mole ratio O_2/CH_4 flame. Weight percentages of reactants were, 4.7 CH_4, 89.0 O_2, 3.5 H_2O, 2.0 SO_2 and 0.35 NaCl. Attachment of the flame to the sampling cone was at z=0.8 mm. The profiles for O_2, H_2O and CO_2 are similar to those reported for CH_4-O_2 flames (2). For the sodium- and sulfur-containing species (except Na_2SO_4) the observed profiles seem reasonable. Results could not be obtained for NaOH because of interference due to an argon peak. We speculate that the Na_2SO_4 profile may have resulted from several interrelated factors: cooling of the flame by the sampling cone at small z (stability of $Na_2SO_4(g)$ increases with decreasing temperature); actual variation of the flame temperature as a function of z; existence of a region of supersaturation for this species. The species $NaSO_2(g)$ and $NaSO_3(g)$ were positively identified and we consider these to be stable reaction intermediates because the respective ions do not appear as fragments in the Knudsen cell vaporization of sodium sulfate (1). Both of these species have been postulated for appropriately doped flame systems (3,4). The composition profiles of these species displayed peaks similar to the Na_2SO_4 at small z, but the intensities decreased to values below our detection sensitivity for z greater than 1.2 mm. The profile shapes of $NaSO_2(g)$ and $NaSO_3(g)$ may have resulted from the same factors that account for the $Na_2SO_4(g)$ profile.

To facilitate a comparison of experimental observations with equilibrium thermodynamic predictions, we calculated the mole fractions of the flame reaction products. Calculations were performed with the NASA chemical equilibrium computer program as described in Ref. 1. Calculations for $NaSO_2(g)$ and $NaSO_3(g)$ were not performed because no thermodynamic data exists for these species. In the calculations CH_4 and SO_2 were labeled 'fuel' while O_2, H_2O and NaCl were labeled 'oxidant'. Experimental results are compared to calculations by noting that according to this labeling convention the ratio of fuel to oxidant for the experimental flame was 0.072. Calculated mole fractions of products are shown on the right-hand side of Fig. 2. The calculated adiabatic flame temperature was 2032K. Considering that the experimental results were not 'calibrated' (Mach number focusing and spectrometer mass discrimination) and that the calculations are for equilibrium conditions, the agreement between experiment and prediction is good for O_2, H_2O, CO_2,

#Electrochemical Society Active Member.

SO_2, and SO_3. Discrepancies with most of the sodium-containing species arose because these are markedly dependent on the fuel to oxidant ratio and the experimental ratio was somewhat uncertain because of the method used to introduce NaCl. Likewise, the stability of $Na_2SO_4(g)$ is a rapidly varying function of temperature and the experimental flame temperature is expected to be significantly lower than the calculated adiabatic temperature. We calculate that for a 200K cooler flame, the predicted $Na_2SO_4(g)$ level would equal the experimentally measured value.

Residence time is a critical parameter in the formation of $Na_2SO_4(g)$. For these experiments we calculated residence times on the basis of cold gas flow velocities. The composition profiles of Fig. 2 indicate that $Na_2SO_4(g)$ was formed in less than one millisecond. This formation time is considerably less than the one reported by Hanby (5) for experimental conditions where sulfide sulfur rather than SO_2 was the reactant.

Mechanism of Beneficial Effect of Tantalum in Hot Corrosion of Nickel-Base Superalloys

George C. Fryburg,* Carl A. Stearns, and Fred J. Kohl

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio 44135

Recently, we reported (1) on a study of Na_2SO_4-induced oxidation (hot corrosion) of the four nickel-base superalloys: B-1900, NASA TRW VIA, 713C and IN738. Oxidations were performed at 900 and 1000°C in slowly flowing oxygen with two doses of Na_2SO_4: 2/3 and 3 mg cm^{-2}. It was found that all of the alloys underwent accelerated or catastrophic oxidation under some conditions. However, several samples of VIA resisted hot corrosion at 900°C when treated with the low dose: specific weight gain was only 0.4 mg cm^{-2} after 100 hr. In addition, preoxidized samples of 738 treated with the large dose resisted corrosion at 900°C for times out to 460 hr, the length of the test: specific weight gain was only 3 mg cm^{-2}.

The oxide scales formed on the samples that resisted hot corrosion were adherent and resisted spallation upon cooling to room temperature. An X-ray diffraction analysis of the scales revealed that all the samples exhibited a prominent $NaTaO_3$ pattern in addition to spinel, tapiolite, and NiO for VIA; and NiO and spinel for 738. The observation of the $NaTaO_3$ was unique and had never been observed for any specimens that underwent hot corrosion.

The specimens were examined in the electron microprobe to determine the distribution of $NaTaO_3$ in the oxide scales. Since $NaTaO_3$ is water soluble, the specimens were prepared for examination by the following procedure: coated with a heavy copper layer in a vacuum evaporator; electroplated additional copper over the layer; cross sectioned very slowly without any coolant; mounted in epoxy and polished in kerosine; polished surface shadowed with carbon.

The most striking set of micrographs were obtained from one of the 738 specimens. This sample had been preoxidized for 100 hours at 900°C prior to the 3 mg cm^{-2} Na_2SO_4-induced oxidation which was continued for 460 hours. Some of the pertinent elemental X-ray micrographs along with the back scattered electron micrograph are presented in Figure 1. The sodium and tantalum maps match up nicely showing the position of the $NaTaO_3$ in the outer layer of the oxide. None of the other elements in the oxide displayed a similar correlation. Sulfur, which appeared to be associated with titanium, occurred below the oxide scale in the alloy substrate. No sulfur was evident associated with sodium. No concentration of molybdenum was observed in the oxide scale.

The VIA samples displayed a thin oxide scale with tantalum distributed evenly throughout. Sodium appeared throughout the oxide also but was concentrated more toward the outer portion. Again, sulfur was situated below the oxide scale in the alloy substrate, and none was evident in the oxide associated with the sodium. No concentration of molybdenum was observed in the oxide. A continuous layer of Al_2O_3 was evident along the inner portion of the scale.

If one accepts the chemical mechanism of Na_2SO_4-induced corrosion of B-1900 proposed in our recent report (1), the beneficial effect of tantalum can be explained within that framework. According to the mechanism, the protective Al_2O_3 scale is dissolved by acid fluxing of MoO_3 (2) after the oxide ion concentration has been lowered by the reaction of MoO_3 with the Na_2SO_4:

$$MoO_3(\ell) + Na_2SO_4(\ell) \rightarrow Na_2MoO_4(\ell) + SO_3(g) \quad [1]$$

Once the scale is breached, the molten $Na_2MoO_4 + MoO_3$ phase undercuts the scale exposing the alloy substrate and initiating a sudden increase in the rate of oxidation. The action of the tantalum oxide is preferential reaction with the Na_2SO_4 forming solid $NaTaO_3$:

$$Ta_2O_5(s) + Na_2SO_4(\ell) \rightarrow 2NaTaO_3(s) + SO_3(g) \quad [2]$$

We estimate that the ΔG for reaction [2] is more negative than for reaction [1].

*Electrochemical Society Active Member.

The absence of MoO_3 in the elemental X-ray micrographs of our hot corrosion resistant samples arises from the fact that $MoO_3(\ell)$ has a very high vapor pressure: $\sim 10^{-1}$ atm at 1200K. In samples that undergo hot corrosion the molybdenum is generally found lying along the oxide-alloy interface. This results from the fact that $Na_2MoO_4(\ell)$ formed by reaction [1] has a much lower vapor pressure than $MoO_3(\ell)$: we estimate that it is around 10^8 less at 1200K.

In brief, the beneficial effect of tantalum with respect to hot corrosion attack arises from the ability of the Ta_2O_5 to tie-up the Na_2O and prevent the formation of a molten Na_2MoO_4 phase.

Evaluation of Porous Paper and Felt Ceramics for Electrode Separators in High Temperature Li-Al/LiCl-KCl/FeS_x Cells

J. P. Mathers, T. W. Olszanski, and J. E. Battles*

Argonne National Laboratory, Argonne, Illinois 60439

ABSTRACT

Porous papers and felts fabricated from BN and Y_2O_3 fibers have been evaluated as electrode separators for Li-Al/LiCl-KCl/FeS_x cells. The physical and mechanical properties were determined, and in-cell tests exceeding 1000 hr were conducted. The papers and felts had adequate strength and flexibility for cell assembly and performed well during cell testing. Results from the property measurements are presented and the performance of these materials in the cell tests is discussed.

High temperature, molten salt Li-Al/LiCl-KCl/FeS_x ($x = 1$ or 2) cells are being developed by Argonne National Laboratory (ANL) for electric vehicle propulsion and for energy storage on electric utility systems (1). One of the requirements for the successful development of cells for commercial applications is the identification of a low cost, porous electrode separator. The primary function of the electrode separator is to prevent direct electron flow between the electrodes without unduly restricting ionic flow through the electrolyte. In addition, separators for Li-Al/LiCl-KCl/FeS_x cells must retain the Li-Al and FeS_x active materials within the electrodes. This requirement is significant because the Li-Al and FeS_x are in the form of powders, and penetration of the separator by these fine particles may lead to a loss in cell capacity or electrical short circuits between the electrodes. The optimum structure and properties desired in the electrode separator have not been fully determined; however, the following general requirements must be satisfied: (*i*) The separator must be a good electrical insulator to prevent direct electron flow between the electrodes. (*ii*) It should be <2 mm thick to permit close electrode spacing, and it must contain a large volume of open porosity, probably >50%. These factors minimize the cell weight and the resistance to ionic flow between the electrodes. (*iii*) The pore channels should be <20 μm diam to prevent penetration of the separator by the active powders in the electrodes. (*iv*) The separator must be chemically stable in the cell environment at the operating temperature (about 450°C). (*v*) The mechanical strength and flexibility must be sufficient to allow easy cell assembly, and to withstand the forces exerted on the separator by the volume changes which occur in the electrodes during cycling. (*vi*) The separator must have a potential cost of <\$22/m^2 if the cost goals for a commercial cell are to be achieved.

A flexible, fibrous ceramic appears to have the greatest potential for satisfying these requirements. At present, interest is centered on two ceramics, BN and Y_2O_3; both of these have proved to be compatible with the cell environment and are available in the form of fibers (2). Boron nitride fabric is currently being used as a separator material, and engineering test cells with BN separators have been operated for periods up to 7800 hr (1, 3, 4). However, it does not appear that the cost goal of \$22/m^2 can be achieved with this material. Also, the fabric weave presently attainable is not tight enough to prevent penetration of the separator by the active powders in the electrodes (5). The latter problem has led to the use of a layer of ZrO_2 fabric which has a much tighter weave over the faces of the electrodes to aid in particle retention. Zirconia fabric becomes electrically conductive in the cell environment, and thus cannot be used as an electrode separator; however, its conductivity does not preclude the use of zirconia as a particle retainer.

Papers and felts made from BN and Y_2O_3 fibers are being developed as alternatives for the BN fabric/ZrO_2 fabric combination. These materials are expected to be considerably less expensive than the BN fabric and to provide more effective particle retention within the electrodes. The results obtained from evaluation tests of three promising separators which appear to have the potential for reaching the cost goal of \$22/m^2 are presented.

Experimental Procedure

The first material tested was a composite paper of Y_2O_3 fibers and 10 weight percent (w/o) asbestos fibers developed at the University of Florida (6). The asbestos was used to provide the strength necessary for handling during cell assembly, however, it was not expected to be stable in the cell environment. The second material was a BN felt, developed by the Carborundum Company,[1] in which BN fibers were bonded with a BN binder. The third material was an Y_2O_3 felt developed by Zircar Products, Incorporated.[2] It was prepared by a process in which fibers of a rayon felt were impregnated with YCl_3 and then converted to fibers of Y_2O_3 by controlled pyrolysis (7, 8).

The candidate paper and felt separators were characterized by measuring the thickness, porosity, air resistance, burst strength, flexibility, and wettability. The

[2] Florida, New York.

thickness was measured with an AMES No. 16 Dial Comparator[3] equipped to provide a contact pressure of 763 Pa. The porosity was calculated from the thickness and weight per unit area of the separator, and from the weight fractions and densities of the component materials. The air resistance was measured with a Model 4110 Densometer.[4] This property is an indication of the volume of open porosity and the lengths of the transport paths in the material. The densometer measures the time for the flow of a standard volume of air through a standard area of the sample under a uniform pressure. The burst strength of each material was measured on a Mullen Burst Testor, Model C.[5] In this test, the material being evaluated is clamped over a rubber diaphragm, and then the diaphragm is expanded against the material by hydraulic pressure until the material ruptures; the pressure at rupture is reported as the burst strength. The flexibility of each separator was evaluated by bending it around a series of successively smaller cylindrical mandrels. The value reported for the flexibility represents the diameter of the smallest mandrel around which the separator could be bent without tearing.

The ability of each material to be wet by the electrolyte was evaluated by immersing a sample in the molten electrolyte (LiCl-KCl eutectic) at 450°C. If the sample could be impregnated by the electrolyte without the aid of a vacuum, the material was classified as having "good" wettability. When vacuum impregnation was required, the wettability was classified as "fair"; when the material could not be vacuum impregnated after 1½ hr of exposure to the molten salt, the wettability was classified as "poor". The amount of material available for determining the above properties was very limited and, as a result, only one measurement was made for each property.

Scanning electron microscope (SEM) examinations were conducted to observe the structure of each separator material and the morphology of the fibers and binders. A small sample (~5 × 5 mm) of each material was mounted on an aluminum specimen mount using a thin layer of silver paint as a glue. After the mounted sample was thoroughly dried, it was sputter coated with 10 nm of carbon followed by 10 nm of gold. This mounting procedure was sufficient to obtain micrographs with magnifications below 1000×; however, to obtain micrographs of higher magnification without electrical charging effects, a second mounting procedure was devised. An aluminum specimen mount was coated with a thin layer of silver paint and individual fibers of the paper or felt were dispersed on the wet paint. After drying, the specimen was sputter coated with 25 nm of gold. Using this procedure, high quality micrographs of individual fibers could be obtained up to 12,000×.

Functional tests of the candidate separators were performed in unsealed Li-Al/LiCl-KCl/FeS cells. The cylindrical test cell, illustrated in Fig. 1, was 7.6 cm diam and 5 cm high. The cell housing, which also served as the lower electrode housing, was made from AISI-1008, low carbon steel, and the upper electrode housing was made from Hastelloy B[6] (Ni-28Mo-5Fe-1Cr). The electrodes were assembled by vibratorily loading powdered Li-Al (48 atomic percent (a/o) Li) or powdered FeS into iron RETIMET,[7] a porous (~5% dense) iron structure which served as a current collector. In the test of the Y_2O_3-asbestos paper, the cell was constructed with FeS in the upper electrode and Li-Al in the lower electrode. The theoretical capacity of each electrode was 31.5 A-hr. In the tests of the BN and Y_2O_3 felts, however, the Li-Al electrode was uppermost, and each electrode had a theoretical capacity of 20 A-hr. Zirconia fabric[8] and 60 mesh stainless steel screens (spot welded in place) were used to retain the active materials in the electrodes. The upper electrode was electrically insulated from the lower electrode and the cell housing by the separator material being tested and by tightly packed BN or Y_2O_3 fibers, as shown in Fig. 1. One layer of the test separator was used on each side of the upper electrode, except in the cell containing the Y_2O_3-asbestos paper where two layers of the separator material were used on each side. This arrangement provided a separator thickness of ~1.8 mm for each of the test cells. The electrical lead to the upper electrode was insulated from the cell housing by a BN sleeve, which was pretreated for 6 hr at 1750°C in a N_2 atmosphere to reduce the oxygen content of the BN and thus improve its compatibility with lithium (2). The top of the cell housing was not welded to the lower portion of the housing; therefore, it was free to move if dimensional changes occurred in the electrodes during cell operation. Openings were provided in the top of the cell housing and in the top of the upper electrode to facilitate loading the cell with the molten salt electrolyte (LiCl-KCl eutectic).

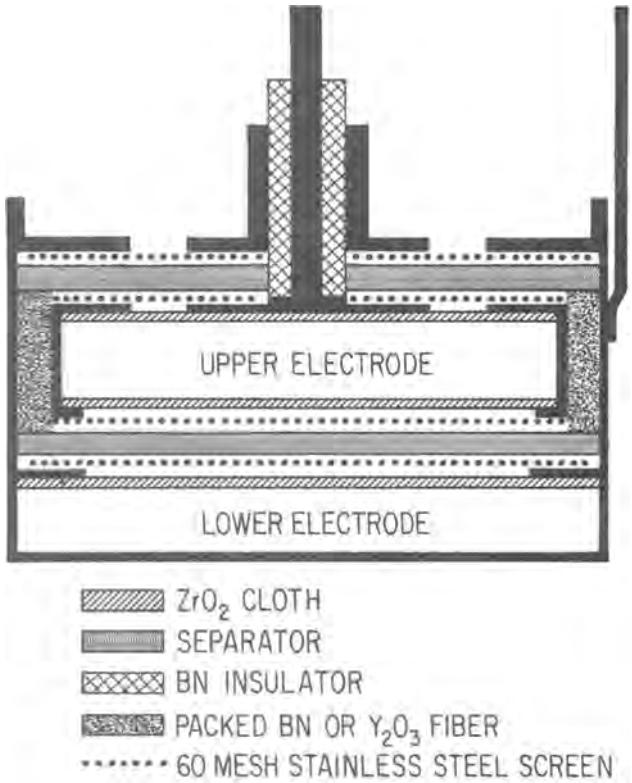

Fig. 1. Test cell design

The cells were assembled in a helium-atmosphere glove box, and were operated at 450°C in a helium-atmosphere furnace attached to the glove box. The cells were cycled continuously between a discharge cutoff potential of 0.9V and a charge cutoff potential of 1.67V (internal resistance included). The cell was placed on open circuit for 10 min after each charge and discharge. The current density was increased in steps from 20 to 76 mA/cm² during the first 200-500 hr of cell operation, and then maintained at 76 mA/cm². After 1000 hr of cycling, cell operation was terminated for post-test examination of the cells and separator materials.

The cells were sectioned in a helium-atmosphere glove box, and samples of the separators between the electrodes were removed for SEM examination and x-ray diffraction analysis. The electrolyte was removed from the separator materials by repeated washing with

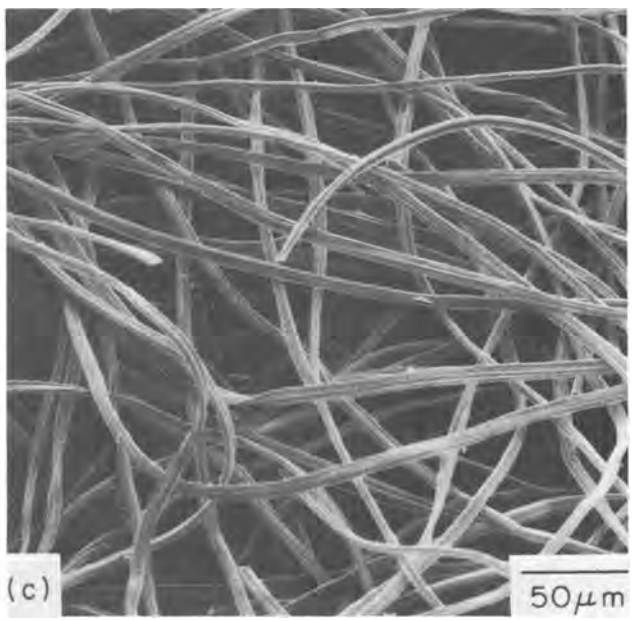
hot water. The SEM mounting techniques described earlier were also found to be suitable for post-test examination.



Results

The physical and mechanical properties of the three separator materials are presented in Table I. The thickness, porosity, and air resistance are useful in evaluating the resistance of the separator to ionic transport and the ability of the separator to retain the active materials of a cell within the electrodes. Thin materials with high porosity and low air resistance should have low resistance to ionic transport, whereas thick materials with low porosity and high air resistance should provide good particle retention. The results obtained for the candidate separators indicate that the BN and Y_2O_3 felts should allow the best ionic conductivity, but the Y_2O_3-asbestos paper should provide better particle retention. However, in the evaluation process, consideration must be given to the possibility that swelling of the electrodes during cell operation, and consequent compression of the separator, may alter the thickness, porosity, and air resistance of the separator.

The burst strength and flexibility are useful in evaluating the ease with which the separators can be handled during cell assembly and, also, how well the materials can maintain their integrity when dimensional changes occur in the electrodes during cell operation. The Y_2O_3 felt had the best combination of strength and flexibility, but all three materials had sufficient strength and flexibility, at least for handling during cell assembly.

The wettability of the separator by the electrolyte is a measure of how easily the separator becomes impregnated with electrolyte when the cell is filled with electrolyte. The wettability of the three separators

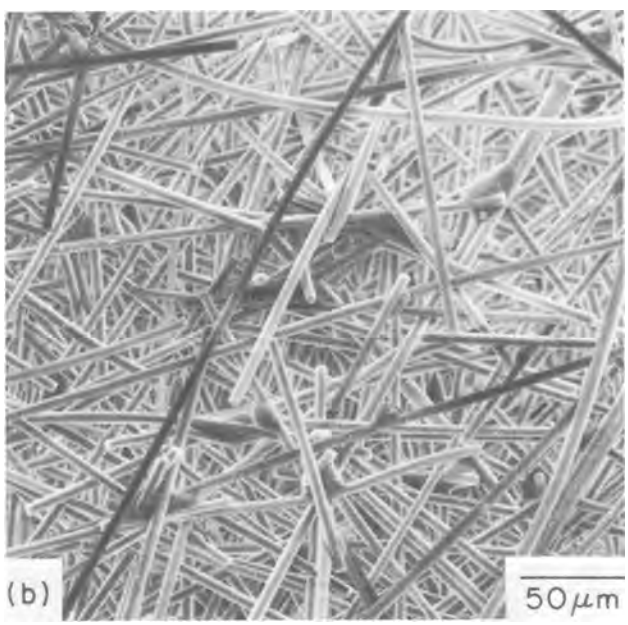


Fig. 2. Paper and felt separators: (a) Y_2O_3-10 w/o asbestos paper; (b) BN felt; (c) Y_2O_3 felt.

ranged from good (Y_2O_3-asbestos) to fair (Y_2O_3 felt) to poor (BN felt), and these evaluations were borne out when the test cells were filled with electrolyte. The cell containing the Y_2O_3-asbestos paper was easily filled with electrolyte, while some difficulty was encountered in filling the cells containing the BN and Y_2O_3 felts. The reason for the superior wettability of the Y_2O_3-asbestos paper compared with that of the Y_2O_3 felt has not been determined. It could be related to differences in the pore structure of the materials or to the presence of asbestos, which is easily wet by the molten electrolyte. The poor wettability of the BN felt is in agreement with the poor wetting characteristics of other BN materials (fabric and paper) in molten electrolyte (9).

The fibrous structure of each separator material is shown in Fig. 2. The Y_2O_3-asbestos paper consists of asbestos fibers (~0.02 μm diam) intertwined around the much larger Y_2O_3 fibers (~10 μm diam). The Y_2O_3 fibers are quite short, thereby allowing them to be closely packed. The average pore opening appears to be 15 μm or less. The BN felt has much longer fibers which are bonded at some intersections by the BN binder. The average pore opening of this material appears to be ~30 μm. The fibers of the Y_2O_3 felt are extremely long and are intertwined; as a result no binder is required to maintain the structure. The average pore opening of the Y_2O_3 felt appears to be ~30 μm. The more open structure of the BN and Y_2O_3 felts compared to that of the Y_2O_3-asbestos paper is consistent with the porosities and air resistances obtained for these materials.

A single Y_2O_3 fiber is shown in Fig. 3. The ridges along the length of the fiber result from the characteristic shape of the rayon precursor fiber. Individual fibers and the binder from the BN felt are shown in Fig. 4. Boron nitride fibers normally have a circular cross section and a very smooth surface; however, the surfaces of the fibers, and to a much lesser extent those of the binder, were covered with small crystallites. A view of these crystallites at higher magnification is shown in Fig. 5. The crystallites are flat hexagons that are insoluble in water. These characteristics suggest that the crystallites are probably BN. The crystallites are believed to have developed during a high temperature heat-treatment used to improve the compatibility of the felt with lithium.

The electrical performance of the test cells is summarized in Table II. The entries for coulombic efficiency and percent utilization represent average values obtained during the last 500 hr of operation at a current density of 76 mA/cm². For the cell that contained the Y_2O_3-asbestos paper separator, utilization after initial start-up was 33% of theoretical, with a coulombic efficiency of 100%. The utilization gradually increased to 56% during the first 700 hr of operation, while the coulombic efficiency remained near 100%. During the final 300 hr of operation the utilization slowly decreased to 41% and the coulombic efficiency to 91%. Post-test examination of the cell revealed that

Utilization (%)	47	35	45

the upper electrode cup had ruptured from swelling of the FeS; this rupture may have caused the decline in cell performance. The structure of the separator had been maintained between the electrodes where it would have been in a state of compression, but the fibers had drifted away from one another in the peripheral areas of the cell. SEM examination showed no evidence of any corrosive attack on the Y_2O_3 fibers, as can be seen from a comparison of Fig. 3 and 6. No asbestos fibers were observed in the separator, but a large quantity of crystalline debris was present. X-ray diffraction analysis of the separator revealed Y_2O_3 and possibly $Mg(OH)_2$, α-Fe, and FeS. The presence of Fe or FeS from the positive electrode is another factor that may have been responsible for the decline in cell performance. It is apparent that the asbestos was destroyed in the cell environment as expected, but the structure of the separator between the electrodes was maintained by the compressive forces exerted on it by the electrodes.

In the test cells containing the BN and Y_2O_3 felts, the FeS was placed in the lower electrode and the loading of both electrodes was reduced to avoid failure of the upper electrode container. The cell containing the BN felt separator had a utilization of only 2% after initial start-up, and a coulombic efficiency of 97%. After the furnace chamber containing the cell was evacuated and repressurized several times to aid in impregnating the separator with electrolyte, the utilization began to increase steadily with a coulombic efficiency of 100%. The utilization reached 42% after 700 hr of operation and leveled off at that value for the remaining 300 hr of operation. Post-test examination of the cell revealed that the upper electrode cup had ruptured owing to expansion of the Li-Al. The separator had maintained its structure in all areas of the cell, even where it was not compressed by the cell components. No evidence of corrosive attack on the fibers or the binder was revealed by the SEM examination, as shown in Fig. 7. However, most of the small crystallites that had been present on the BN material initially were either attacked by the cell environment or removed by mechanical interaction of the fibers.

The test cell containing the Y_2O_3 felt separator had an initial utilization of 24% and a coulombic efficiency of 100%. After the furnace chamber was evacuated and repressurized, the utilization gradually improved to 51% after 800 hr of operation and remained at that level for the final 200 hr. The coulombic efficiency remained >98% during the entire operation of the cell. Post-test examination revealed that the upper electrode cup of this cell had also ruptured. The Y_2O_3 felt separator had maintained its structure in all areas of the cell, just as the BN felt had. SEM examination showed no evidence of any corrosive attack on the fibers, but many of the fibers appeared to have been fractured, probably from the pressure exerted on the separator by the swelling electrodes.

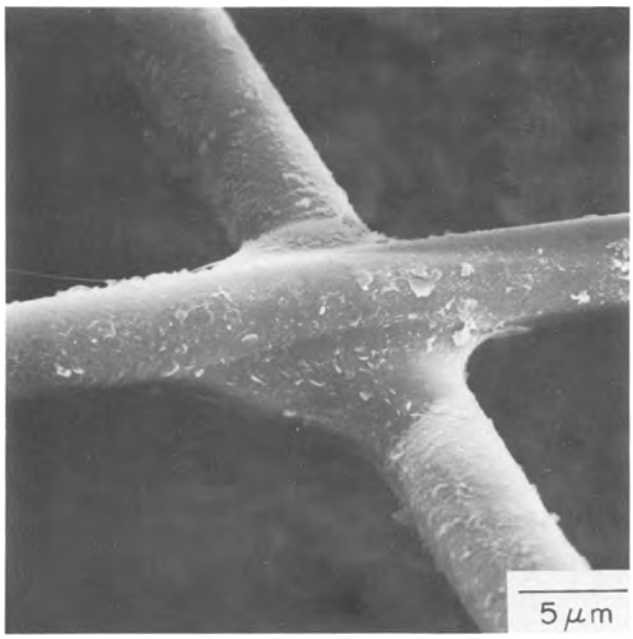

Fig. 7. BN fibers and BN binders after cell test

Conclusions

All three materials tested are good candidates for electrode separators in Li-Al/FeS_x cells. Asbestos is not stable in the cell environment; however, the Y_2O_3-asbestos paper can be used successfully in cells where the separator is maintained in a state of compression. The BN and Y_2O_3 felts have an advantage over the Y_2O_3-asbestos paper because they maintain their structure during cell operation without the need for a compressive stress; thus, a cell-design feature that ensures compression of the separator would be a less important consideration with separators of BN or Y_2O_3 felt.

In all three tests, ZrO_2 fabric was used to retain particles of active materials within the electrodes. Therefore, further testing of all three materials in the absence of ZrO_2 fabric will be necessary to establish the effectiveness of these separator materials as particle retainers. Long-term testing of these papers and felts in larger engineering-scale cells is now in progress, and these tests will provide further information on the suitability of these materials as electrode separators.

Zinc-Bromine Secondary Battery

H. S. Lim,* A. M. Lackner, and R. C. Knechtli

Hughes Research Laboratories, Malibu, California 90265

ABSTRACT

A zinc-bromine secondary battery with circulating aqueous electrolyte showed 80% over-all (round-trip) energy efficiency at a current density of 20 mA/cm^2 for 10 hr charge and 10 hr discharge cycles. The battery characteristics may be attractive for load leveling and other applications if a low cost separator is developed.

The zinc-bromine secondary battery appears to be a potentially attractive battery for energy storage, especially for load leveling applications, because of the low cost and wide availability of the active materials, high theoretical energy density, and low electrode polarizations. The Zn-Br_2 battery has been studied (1-7) for a long time. However, it is not fully developed for commercial applications yet, probably because of its high self-discharge rate (2, 6) and corrosion problems due to bromine. The high self-discharge rate is mostly due to the bromine diffusion from the positive electrode (where bromine is generated during charge) to the negative electrode where it is chemically reacted with zinc.

We have recently developed a new zinc-bromine battery which includes an electrolyte circulation system and an ion exchange membrane as a separator. An energy efficiency of 80% has been demonstrated in a 10 hr charge and 10 hr discharge experiment at a current density of 20 mA/cm^2. Efficiencies are defined throughout the paper as follows

$$\text{voltage efficiency} = \frac{\text{average charge voltage}}{\text{average discharge voltage}}$$

$$\text{coulomb efficiency} = \frac{\text{amount of charge consumed during discharge to 1.0V}}{\text{amount of charge consumed during charge}}$$

$$\text{energy efficiency} = (\text{voltage efficiency}) \times (\text{coulomb efficiency})$$

The electrode reactions in the battery can be described as follows

$$(+)\ \text{electrode:}\quad 2Br^- \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftharpoons}} Br_2 + 2e$$

$$(-)\ \text{electrode:}\quad Zn^{++} + 2e \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftharpoons}} Zn$$

over-all reaction:

$$Zn^{++} + 2Br^- \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftharpoons}} Zn + Br_2$$

Bromine and bromide ions will probably be present in equilibrium with complex species

$$xBr_2 + Br^- = Br_{2x+1}^-$$

Experimental

A schematic diagram of the battery is shown in Fig. 1. Self-discharge due to the direct chemical reaction of zinc and bromine was minimized by using a separator such as a sulfonated Teflon ion exchange membrane (*e.g.*, Nafion 125, manufactured by E. I. du Pont de Nemours and Company) or a polypropylene microporous film (*e.g.*, Celgard 3400, manufactured by Celanese Plastics Company). The electrolyte, which was 1.0-7.7M aqueous zinc bromide ($ZnBr_2$), was circulated through the cell from two separate storage tanks for the catholyte and the anolyte. The electrolyte was either pure $ZnBr_2$ solution or $ZnBr_2$ with additives such as potassium chloride (KCl) or sodium chloride (NaCl). The catholyte initially contained about 0.05M excess bromine in order to promote complete discharge of the negative electrode. Chemicals used were Baker Analyzed Reagents, J. T. Baker Company. The electrodes

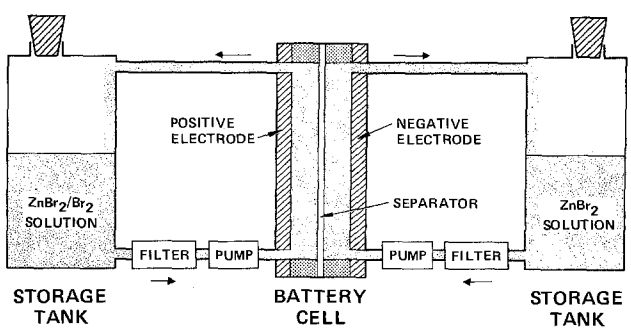

Fig. 1. Schematic drawing of zinc-bromine battery

* Electrochemical Society Active Member.

Key words: Zn-Br_2 battery, bromine electrode, conductivity of $ZnBr_2$ solution.

were carbon electrodes with an active geometrical area of 60 cm^2. The circulation rate of the electrolyte was 0.5-3.2 ml/sec. Electrode separation was about 5 mm with the separator membrane in the middle. All charge-discharge experiments were done with constant currents.

Polarizations of the electrodes and the potential drop across the separator were measured by placing reference electrodes (saturated calomel electrode) right after the cell in the circulation system. Conductivity of the electrolyte was measured with an a-c bridge with 1-10 kHz signal in a conductivity cell. Electrode separation of the conductivity cell was 11 cm and the cross-sectional area of the cell was 0.27 cm^2.

Results and Discussion

Conductivity of electrolyte.—Resistivities of aqueous $ZnBr_2$ solutions at 25° and 55°C, respectively, are shown in Fig. 2 as a function of the concentration of $ZnBr_2$. The resistivity minimum was observed at about 2M. When NaCl or KCl was added to a solution of a given concentration in $ZnBr_2$, the resistivity of the solution was reduced, as shown in Fig. 3. With the same concentration of additive, KCl was much more effective in lowering the resistivity than NaCl. When 4M KCl was added to concentrated solutions of $ZnBr_2$, the resistivity at 25°C was changed by a factor of two, *i.e.*, from 8.4 to 3.7 Ω-cm with 2M $ZnBr_2$ and from 11.4 to 6.3 Ω-cm with 4M $ZnBr_2$. The resistivity of 2M $ZnBr_2$ with 4M KCl at 55°C was as low as 2.5 Ω-cm (Fig. 3).

Polarizations.—The polarization at the bromine electrode was extremely low, *i.e.*, up to a current density of 100 mA/cm^2 the polarizations were less than 20 mV at 25° and 10 mV at 54°C in the concentration range of 1.0-7.7M in $ZnBr_2$. The polarization at zinc electrodes was also very low (see Fig. 4). The polarization stayed less than 100 mV up to the current density of 60 mA/cm^2 at 54°C, even in 1M $ZnBr_2$. Little changes in the polarizations of zinc electrode were observed when the temperature was lowered to room temperature or when KCl was added up to 4M in concentration.

The potential drop in the battery was mostly across the electrolyte and separator. The potential drop was linear with the current density. The slope depended on the conductivity of electrolyte and separator material. The potential drops at various concentrations of $ZnBr_2$ were measured at 54°C as a function of current densities (Fig. 4) when a Nafion 125 cation exchange membrane was used as the separator and the electrode separation was about 5 mm. The potential drop was 85-90 mV at 54°C when concentration of $ZnBr_2$ was 2M and current density was 15 mA/cm^2, while it was 125-130 mV at room temperatures (23°-25°C). When the electrolyte was 2M in $ZnBr_2$ and 4M in KCl, the potential drop was 70-80 mV at 54°C. The slight decrease in the potential drop by the addition of KCl appeared to indicate that the major portion of the potential drop was across the separator rather than across the electrolyte layer. The resistivity across the Celgard

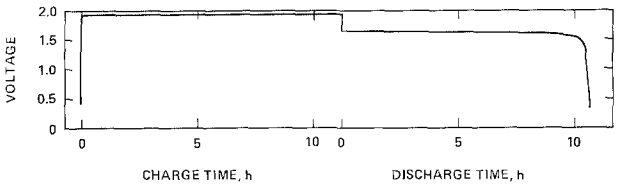

Fig. 5. A typical charge-discharge curve of zinc-bromine battery. Electrolyte: 2M $ZnBr_2$, pH = 1.4. Current density: 15 mA/cm². Temperature: ~25°C. Separator: Nafion 125.

3400 separator in the electrolyte was similar to that of Nafion 125.

Dendrites and hydrogen evolution.—Dendrites were visible on zinc electrodes when current densities were greater than 15 mA/cm². The dendrite growth, however, was cut off when it touched the separator. There was no evidence that the dendrite went through either kind of separator. Loose particles of zinc, however, were collected on the filter of the anolyte when the cell was discharged after a charge at current densities greater than 20 mA/cm². It was speculated that the bases of the dendrites were anodically dissolved during discharge before the dissolution of the main body of the dendrites, thus giving loose particles of zinc. Operating conditions showing poor coulomb efficiency of the battery were accompanied by the observation of loose zinc particles.

Hydrogen evolution at the zinc electrode was observed at low pH's (pH < 3), but it was not a severe problem unless the pH was maintained below one, which was not required.

Performance of battery.—A typical charge-discharge curve of the battery is shown in Fig. 5. The charge potential stayed almost constant during the whole charge period, while the discharge potential was decreased slightly as it was discharged at a constant current. Charge voltages, discharge voltages, and voltage efficiencies of one of the test batteries with a Nafion 125 separator at various current densities are shown in Table I. The voltage efficiency was over 80% at current densities up to 30 mA/cm². During 10 hr charge and 10 hr discharge experiments, coulomb efficiencies as high as 95% at 15 mA/cm² at room temperature and 92% at 20 mA/cm² at 54°C have been observed with over-all energy efficiency of over 80%. When current densities were increased above 20 mA/cm², the coulomb efficiency was decreased rapidly on 10 hr charge experiments. The maximum charge loading was about 200 mA-hr/cm². A similar maximum loading of zinc on negative electrodes of an aqueous zinc-chlorine battery has been reported (8, 9).

The performance characteristics of the batteries with a Celgard 3400 microporous separator were similar to those with Nafion 125 except for coulomb efficiency. Coulomb efficiency of the batteries with Celgard 3400 was usually much lower than with the other separator. This was due to a higher bromine transfer rate through the Celgard separator than through the Nafion 125. The color of the anolyte during battery operation was yellow due to the bromine transfer from the catholyte when the separator was Celgard 3400, while it was colorless when the separator was Nafion 125, indicating that very little bromine was transferred through this separator. The trade-offs between the two separators are the relative cost and possible stability problems in addition to the relative coulomb efficiency. Nafion material should be very stable, while polypropylene may or may not be stable in the battery electrolyte which contains aqueous bromine solution. The Nafion membrane, however, is presently much more expensive than the Celgard microporous film.

Table I. Operation characteristics of the zinc-bromine battery*

Current density (mA/cm²)	Voltage, charge	Voltage, discharge	Voltage efficiency (%)
0	1.785	1.784	100
10	1.854	1.715	92.5
20	1.920	1.647	85.8
30	1.986	1.580	79.8
40	2.052	1.509	73.5
50	2.118	1.438	68.0
60	2.183	1.366	65.5

100	2.444	1.135	46.4

* Electrolyte: 2M $ZnBr_2$, 4M KCl, pH ~ 1.5. Temperature: 54°C. Separator: Nafion 125.

The power needed for the pump of the circulation system is ignored in the discussion. It is generally believed that this power loss can be minimized to a small fraction of the total output of the battery, especially in a large battery system.

Life tests of the battery were very preliminary. No visible sign of degradation nor any change in performance was observed after six full charge-discharge cycles.

Comparison with zinc-chlorine battery.—The zinc-bromine battery was compared with a zinc-chlorine battery (10, 11) which is one of the contenders for load leveling batteries. The basic difference between the two batteries is the difference in active materials, *i.e.*, chlorine *vs.* bromine at the positive electrode. The advantages of the zinc-bromine battery over the zinc-chlorine battery are as follows:

1. Polarization of the bromine electrode is much lower than that of the chlorine electrode.
2. An electrolyte cooling system is not essential in a zinc-bromine battery. It is an essential part of a zinc-chlorine battery where chlorine is stored as chlorine hydrate which requires low temperature (~9.6°C at 1 atm) (10).
3. The electrolyte of the zinc-bromine battery can be stored above the ambient temperature while the chlorine hydrate cannot.
4. Bromine is chemically less reactive than chlorine. Therefore, the corrosion problem may be less severe with bromine than with chlorine.

The probable disadvantages of the zinc-bromine battery are as follows:

1. The zinc-bromine battery has lower emf (1.78V) than the zinc-chlorine battery (2.12V).
2. Bromine is more expensive than chlorine, although the cost of these materials is a minor part of the total battery cost.
3. Bromine is less abundant than chlorine.
4. The zinc-bromine battery needs a separator which may not be required in the zinc-chlorine battery.

An estimate of battery cost.—A complete battery cost estimate is premature at this early stage of development. As a first-order guideline, however, it is possible to estimate the contribution of the active materials and of the separator membrane to the anticipated battery cost. The active materials are zinc and bromine. The cost of either of these elements is below $0.80/kg. With full utilization of the active material and 100% energy efficiency, the energy density of the active material in the battery is 432 W-hr/kg. Our measurements showed that the battery performance was relatively insensitive to zinc bromide concentration changes over a range of from 1 to 4M (Fig. 2 and 4), indicating that the battery operation in this concentration range is reasonable. It is therefore conservative to assume at least 50% active material utilization in a practical zinc-bromine battery, leading to over 200 W-hr/kg of active material. With a cost of less than $0.80/kg, this leads to a cost of active material below $4/kW-hr, which is an attractive figure.

The effect of the separator cost on the battery cost is determined by the current density. Our experiments showed good performance up to a current density of 20 mA/cm² for a 10 hr charge rate. This corresponds to

0.2 A-hr/cm². With a battery voltage in excess of 1.5V, this is equivalent to more than 0.3 W-hr/cm² or about 3 ft² of separator per kilowatt-hour. Present cost of Navon 125 membrane in small quantity is on the order of \$30/ft². This leads to a cost of \$90/kW-hr for the battery using presently available separator material. This cost is about an order of magnitude too high for a low cost battery. If the cost of the present separator can be lowered by a factor of 10 or if another suitable separator which costs less than \$3/ft² is developed, the battery should be attractive for load leveling application. Operation at more than 20 mA/cm² can also reduce the cost of the battery. The total material cost of the battery can be lower than \$15/kW-hr (assuming electrode and other material costs to be \$2/kW-hr), provided that a separator membrane comparable in performance with Nafion 125 can be developed with a cost of less than \$3/ft².

Conclusion

The present zinc-bromine battery is demonstrated to have good performance up to a current density of 20 mA/cm². The life tests of the battery have not yet been made. However, it appears that the battery could be attractive for load leveling application, especially because of the low electrode polarization, low cost, and wide availability of the active materials and electrodes. There is no obvious life-limiting component in the battery for the short term when the Nafion separator is used, although possible slow corrosion of the graphite electrode by aqueous bromine could not be ruled out for the long-term life problem. Overcharge and overdischarge should not damage the battery. Electrolysis of water will take place during overcharge or overdischarge of the battery, changing the water content and the *p*H of the electrolyte, which can easily be compensated by addition of water and acid. The battery should not have the shape change problems of the zinc electrode because the electrode can easily be rejuvenated by complete discharge of the battery.

Acknowledgments

The authors wish to thank Dr. J. D. Margerum for many helpful discussions and Mr. K. Barnett for his help on the dendrite experiments.

Structural Principles for Silver Halide Superionic Conductors

Douglas O. Raleigh*

Rockwell International, Science Center, Thousand Oaks, California 91360

ABSTRACT

The reasons why so many alkali and organic-base iodides form solid ionic conductors with AgI, while others, apparently similar, do not, are discussed in terms of geometric structural principles. It is proposed that the principal functions of the additive cation are to force the structure into a greater degree of face-sharing of the iodide coordination polyhedra than in β-AgI by coordinating more iodide ions than Ag^+, and to relieve tetrahedral distortion in the resulting structures.

There are at present well over 50 solid chemical compounds which have room temperature silver-ion conductivities in excess of 10^{-4} Ω^{-1} cm^{-1}. The reported discovery (1, 2) of the highly conductive MAg_4I_5 group (M = K, Rb, or NH_4) was soon followed by that of the QI · *n*AgI compounds (3, 4) in which Q is one of a great variety of nitrogenous organic bases (tetraalkylammonium, pyridinium, quinolinium, etc.) and in which *n* ranges 4 to 8. Since that time, conductive compounds have been reported from the addition of AgI to silver oxy-salts [phosphates (5), tungstate (6), molybdate (7), chromate (7), vanadate (8), arsenate (8)], cyanides (9), polymethonium iodides (10), sulfonium iodides (11, 12), tropyllium iodides (13), and mercuric iodochalcogenides (14). Takahashi (15) has provided an excellent review of compounds reported up to 1972. More recently, Takahashi *et al.* (16) and Sammells *et al.* (17) have reported room temperature copper ion conductivity in a variety of organic halide-copper halide addition compounds in which analogous structural considerations should apply.

To date, structures have been determined for only several of these compounds. It is clear, however, that more is involved in the AgI-based compounds than the simple addition of a minor component to stabilize the highly conductive α-AgI structure. The structures thus

* Electrochemical Society Active Member.
Key words: solid electrolyte structure, silver halide electrolytes, solid ionic conductors.

far reported are generally highly unique and unlike α-AgI. Also, several of the alkali metal iodides (LiI and NaI) and a large number of the nitrogenous-base QI compounds result either in no addition compound or a stable but nonconductive one. Geller (18) states that the common structural motif in the conductive compounds is the existence of passageways of face-shared iodide ion polyhedra. However, it has not been explained why such a variety of cationic and/or anionic groups produces such structures, while apparently similar groups do not, other than evidence that the ionic size plays a role (4, 19).

Several explanations have been proposed for the apparently unique ability of Ag^+ and Cu^+ ions to result in such structures. Armstrong *et al.* (20) have noted the near-uniqueness of Ag^+ and Cu^+ ions in forming stable 3- and 4-coordinated structures, and the role of $d\pi$ bonding by anions such as iodide in stabilizing such structures. Face-shared iodide ion tetrahedra appear to be a recurrent structural element in these compounds, and the energetics of silver ion migration through shared tetrahedral faces should be lowered if 3-coordinated complexes are stable. Quite recently, Phillips (21) has proposed that the borderline ionic-covalent character of AgI, resulting in comparable stability of Ag^+ in 4- and 6-coordination, permits a large variety of low symmetry "scaffolding" structures because of the low energetics of Ag-I bond-bending. In these structures, iodide complexes of the "minority cation" (M^+ in MAg_4I_5 and Q^+ in QI · nAgI) are said to provide a rigid skeletal framework which is "decorated" by loosely bound quasi-interstitial Ag^+ ions which supply a neutralizing charge sheath enveloping the over-all structure. Geller (22), however, maintains that there is really no crystallographic evidence for the relative rigidity of the minority cation part of the structure and "softness" of the AgI elements.

In 1975, I briefly proposed a basically geometric rationale for the existence of the conductive MAg_4I_5 and QI · nAgI structures (23). The purpose of the present communication is to expand upon this suggestion and offer additional, basically geometric, functions for the M^+ or Q^+ cation. The other categories of Ag^+ ion conductive solids and Cu^+ ion conductors will not be specifically discussed, since no detailed structures have yet been determined and because these geometric considerations are less readily visualized for, *e.g.*, the "anion-stabilized" conductors. Still, similar considerations may well apply.

How to Increase Face-Sharing

In AgI, MAg_4I_5, and the QI · nAgI compounds, it is clear that the geometric arrangement of the relatively large iodide ions determines whether a conductive structure results. The wurtzite and zinc blende structures of β- and γ-AgI, stable at room temperature, result in relatively poor conduction. The body-centered cubic structure of α-AgI, stable above 147°C, permits the highest Ag^+ ion conductivity in existence, despite being actually 5-6% denser than the β- and γ-AgI structures, so that Ag^+ ions should, in principle, have less "room" in which to migrate.

Geller and co-workers have determined the detailed structures of the room temperature Ag^+ ion conductors $RbAg_4I_5$ (24), $((CH_3)_4N)_2Ag_{13}I_{15}$ (25), and the two pyridinium iodide compounds $(C_5H_5NH)_5Ag_{18}I_{23}$ (26) and $(C_5H_5NH)Ag_5I_6$ (27). In each case, the common structural element permitting Ag^+ ion conductivity was identified as the presence of multiple-faced-shared iodide ion polyhedra, partially occupied by Ag^+ ions, which form networks of passageways for Ag^+ ion conduction through the structure. In the first three of these compounds, the polyhedra are tetrahedra; in the last, a mixture of tetrahedra and octahedra.

Figure 1 is a schematic of silver ion migration through a passageway of face-shared iodide ion tetrahedra. If these tetrahedra are only partially occupied, and if the energetics of passing through their shared triangular faces are relaxed by either facile bond-bending or the stability of 3-coordinated Ag^+ ion complexes, then conduction may result by Ag^+ ion hopping from filled to adjacent empty tetrahedra under the influence of an applied electric field. Obviously, at least two faces of each polyhedron must be shared with others to result in a network of conductive paths through the structure. In the $RbAg_4I_5$, $((CH_3)_4N)_2Ag_{13}I_{15}$, and $(C_5H_5NH)Ag_5I_6$ structures, a three-dimensional matrix of multiple-faced-shared iodide polyhedra extends throughout the structure, while in $(C_5H_5NH)_5Ag_{18}I_{23}$ the network is two-dimensional.

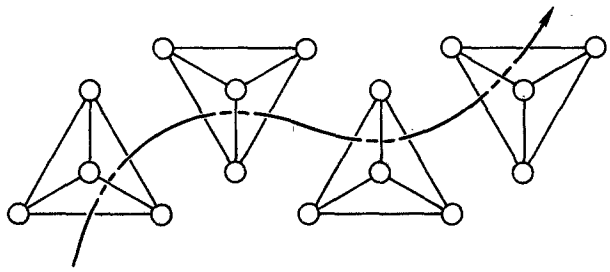

Fig. 1. Schematic of ion migration through face-shared tetrahedra. Though drawn separately for illustration, the ions on the shared faces are identical.

It is the central thesis of this section that an important function of the M^+ or Q^+ ion incorporated into a structure with AgI is to increase the degree of face-sharing by iodide ion coordination polyhedra, resulting in conductive structures, by coordinating a greater number of anions than the Ag^+ ion. To see how this is so, consider the wurtzite structure of β-AgI, from which the conductive MAg_4I_5 and QI · nAgI compounds can be considered to be formed by the addition of 10-20 mole percent (m/o) MI or QI. In this structure, shown in Fig. 2, each Ag^+ ion is coordinated by an I_4 tetrahedron. Each I^- ion "corner" is fourfold shared and each Ag^+-filled I_4 tetrahedron shares a face with one adjacent empty one. This arrangement does not in itself permit bulk conductivity, since the Ag^+ ion could at most hop back and forth between the pair of face-shared tetrahedra, and even this is energetically not permitted by the symmetry of the structure. Obviously the I_4 tetrahedron needs to share faces with at least two neighbor polyhedra, and the symmetry of the structure needs to be low enough to permit some randomness of occupancy without undue energetic "cost."

In solid crystalline compounds, corner-, edge-, and face-sharing of anion coordination polyhedra result as a necessity whenever the average coordination number of the cations is greater than the stoichiometric ratio of anions to cations (28). Only by such sharing are there enough anions to "go around." If, then, a significant mole fraction (*e.g.*, 0.1-0.2) of an iodide MI can form a solid solution with β-AgI in which the M^+ ion has a larger coordination number than the Ag^+ ion (>4), structures must result in which the degree of

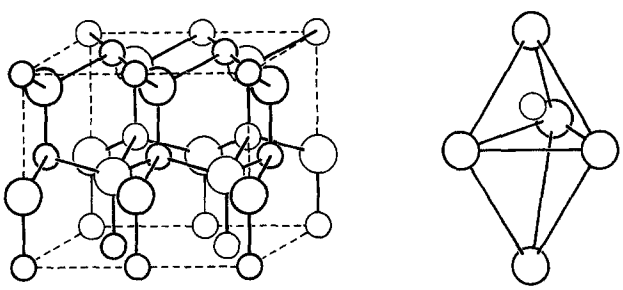

Fig. 2. The wurtzite crystal structure of β-AgI. The large circles represent I^- ions; small circles, Ag^+ ions.

face-sharing by iodide ion coordination polyhedra is considerably increased; very possibly to the point where a conductive structure results. The energetic feasibility of such structures may be argued from factors previously mentioned (polarizability of the large I^- ion, $d\pi$ bonding, low energetics of Ag-I bond-bending), but the driving force for increased face-sharing appears to be the increased coordination "demand" of the M^+ ions upon the available I^- ions.

A multiplicity of low symmetry structures seems permitted by the fact that most of the energy required for distortion from more regular geometric structures is recovered through electronic polarization. Since, in this variety of structures, a number of face-sharing arrangements are possible that greatly increase the "utilization" of the anions, structures can result where there is more anion-sharing than is required to accommodate the coordination numbers of all the cations. The result is that a number of the anion polyhedra are empty, which fulfills the additional requirement of a conductive structure besides face-sharing.

With this picture, the maximum Q^+ ion size and proportion for forming conductive $QI \cdot nAgI$ structures can be understood. For the larger Q^+ ions, the iodide ion coordination number would seem to be less a matter of specific chemical coordination than of the size of the "hole" required to accommodate the Q^+ ion; this hole being composed of the surrounding faces of the adjacent iodide ion polyhedra. If the Q^+ ion becomes too large, it will defeat its original purpose by "using up" in its coordination polyhedron the additional iodide ions made available by the more face-sharing arrangement it was employed to promote. The ultimate, and quite sudden, result is that anions are no longer available for forming empty polyhedra, and one obtains a perfectly stable structure that is an insulator. Owens (19) has reported that an abrupt transition from conductive to insulating structures occurs with few exceptions when the estimated Q^+ ion volume exceeds 85Å^3. This appears to hold for a broad variety of tetraalkylammonium and azacyclic substituted ammonium $QI \cdot nAgI$ compounds.

Owens' conductivity-composition data for the lower tetraalkylammonium compounds (3) show a maximum conductivity at 13 m/o QI for the Me_4NI-AgI system, 12½ m/o QI in the Me_2Et_2NI-AgI system, and 12 m/o QI for the Et_4NI-AgI system. Thus, as the size of the Q^+ ion increases, there is the expected decrease in the amount required to maximize the conductivity. In addition, while results were only reported at $\geq$ 5 m/o intervals for QI contents greater than 15 m/o, a rapid drop-off of conductivity was observed at higher QI contents, resulting in insulating compounds ($\sigma \sim 10^{-8}\ \Omega^{-1}\ cm^{-1}$) at $\geq$ 33.3 m/o QI. Thus, increasing the proportion of QI in compounds formed from the lower molecular weight Q^+ ions would seem to have the same effect as increasing the size of the Q^+ ion at constant mole fraction; that of "tying up" I^- ions needed for the formation of empty polyhedra.

Additional Additive Ion Functions

Another function of the M^+ or Q^+ additive ion appears to be that of reducing distortion energy in the space-filling arrangement of the iodide ions. We have already noted that in the $RbAg_4I_5$, $((CH_3)_4N)_2Ag_{13}I_{15}$, and $(C_5H_5NH)Ag_5I_6$ structures, the multiple-faced-shared iodide ion polyhedra form a three-dimensional network, extending throughout the structure to fill the space not occupied by the M^+ or Q^+ ions, while in the $(C_5H_5NH)_5Ag_{18}I_{23}$ structure, the network is two-dimensional. In all of the structures, Ag^+ ions appear to prefer 4-coordination, resulting in iodide ion tetrahedra for all Ag^+ sites except a minor fraction of those in the $(C_5H_5NH)Ag_5I_6$ structure.

From the viewpoints of coordination and conductivity, then, the "ideal" structure would be a space-filling arrangement of completely face-shared I_4 tetrahedra. Regular tetrahedra, however, cannot by themselves form space-filling arrangements without distortion. Much of this distortion may be removed by replacing an occasional tetrahedron by a higher order polyhedron. Thus, space is completely filled without distortion by a 2:1 arrangement of regular tetrahedra and octahedra of the same size faces (*i.e.*, in the fcc structure) and is filled with only modest distortion if a smaller number of octahedra is employed. The latter appears to be the arrangement in $RbAg_4I_5$, where tetrahedral distortion in an icosahedral arrangement of 56 I_4 tetrahedra per unit cell is reduced by the presence of 4 distorted RbI_6 octahedra in a cubic-symmetry arrangement.

It follows that tetrahedral distortion could likewise be reduced by the substitution of an occasional Ag^+ ion by any of a number of monovalent cationic species that would create a "hole" somewhat larger and more many-sided than an I_4 tetrahedron, or even a continuous structural element such as the hexagonal "tunnel" holes in the $(C_5H_5NH)Ag_5I_6$ structure. We have already discussed the effect of size for the organic-based cations. For the MAg_4I_5 structures, the suitable size range for the alkali cation would seem to be that which is optimal for the distortion-reducing MI_6 octahedral hole.

In the structures with the larger organic-base cations, the "determinative structural role" of the minority cation suggested by Phillips (21) becomes quite evident. Thus, it is not surprising that the pyridinium compounds have the hexagonal symmetry of the pyridinium group and the hole it occupies. In these cases, Phillips' "scaffolding" structures for the minority cation seem reasonable, and one can envision that the cation acts as a "seed site" for a particular space-filling structure of face-shared iodide ion polyhedra.

Summary

In conclusion, the minority cation, M^+ or Q^+, seems to serve several functions in creating ionically conductive structures with β- or γ-AgI. First, AgI is capable of participating in a variety of low symmetry structures because of the small energy differences associated with various Ag-I bonding geometries. Addition of an M^+ or Q^+ ion that coordinates 6 iodide ions or a Q^+ ion that requires an n-hedral iodide ion "hole" with $n > 4$ encourages the formation of structures with the much increased degree of face-sharing by I^- coordination polyhedra required for conductive structures. The increased utilization of the I^- ions in these structures also permits a stoichiometric excess of I^- polyhedra over Ag^+ and M^+ (or Q^+) ions, resulting in the second requirement of conductive structures. However, introduction of too many M^+ or Q^+ ions, or of Q^+ ions that are too large, "uses up" the excess coordination capacity that permits empty polyhedra and results in insulating structures. In addition, the M^+ or Q^+ ion helps stabilize these structures of predominantly space-filling face-shared I^- ion tetrahedra by creating holes that reduce tetrahedral distortion. Also, at least in the case of the larger Q^+ ions, the minority cation plays a determinative role in the symmetry and over-all arrangement of the structure.

EMF Studies of Lithium-Rich Lithium-Aluminum Alloys for High-Energy Secondary Batteries

J. R. Selman,*[1] D. K. DeNuccio,[2] C. J. Sy, and R. K. Steunenberg*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

Emf measurements were made across the lithium-rich half of the lithium-aluminum system at temperatures from 390° to 550°C using a cell of the type Li/LiCl-KCl (or LiF-LiCl-LiBr)/Li-Al. The lithium activity increases from 0.007 to approximately 0.7 over the composition range of 48-56 atomic percent (a/o) lithium (the β-phase region). A compound, Li_3Al_2, rather than Li_2Al, as reported in standard compilations, exists at temperatures up to the peritectic decomposition at 520°C and forms a two-phase region of high lithium activity (>0.85) with the lithium-rich liquid phase. This compound has an estimated free energy of formation of −58 kJ/mole at 700°K. The emf data indicate that the lithium-rich liquidus is about 2 a/o richer in lithium than the composition shown in standard compilations of binary phase diagrams.

The present work was prompted by an interest in lithium-rich alloys as potential electrode materials. Lithium has attracted attention as a negative electrode material in the development of high-energy secondary batteries (Li/Cl_2, Li/S, Li/FeS_x). The metal, which is liquid at the operating temperatures of these batteries (400°-500°C), is usually contained in a porous nickel or stainless steel matrix. Cells containing liquid lithium electrodes pose special materials problems because of the extreme corrosivity of the metal, particularly toward ceramics. These problems are compounded by: (*i*) The solubility of lithium in the molten LiCl-KCl electrolyte (approximately 0.17 mole percent (m/o) at 700°K), and (*ii*) a gradual decrease of the capillary retention of lithium by most matrix materials upon repeated charge-discharge cycling. This "de-wetting" tendency may lead to cell shorting by lithium globules.

These problems can be avoided or alleviated by using a lithium alloy that is solid at the cell operating temperature (1). The most commonly used alloy is β-phase lithium-aluminum, of nominal composition LiAl, which melts at 718°C (991°K). During most of the charge and discharge, the electrode composition traverses a two-phase region consisting of a saturated solid solution of lithium in aluminum (α-phase) and the β-phase.

The potential of the two-phase alloy is approximately +0.3V relative to lithium metal, which corresponds to a lithium activity of 0.007 of the pure metal. This loss of emf over most of the discharge, compared with a cell containing a liquid lithium electrode, and the relatively low weight fraction of lithium, 20 weight percent (w/o) in the β-phase alloy, imply a considerable (15-20%) decrease in the specific energy of the cell. It would be desirable to use alloys having lithium concentrations higher than 50 atomic percent (a/o) to increase the specific energy of the cell, provided that the lithium activity of the alloy does not exceed a value of, say, 0.2.

The compound Li_2Al, which had been reported by earlier investigators (2, 3) and is represented in standard compilations (4), was considered as a potential candidate. Also, the compounds Li_3Al_2 and Li_9Al_4 have recently been identified at room temperature (5, 6) and would be potential candidates, if stable at 400°-500°C.

Little information is available on the lithium activity of solid lithium-aluminum alloys outside the ($\alpha + \beta$) two-phase region. Emf measurements at 300°-380°C by

Key words: high temperature cell, LiAl, Li_3Al_2, Li_2Al, phase diagram.

Yao *et al.* (1) indicate an initial decrease of the emf in the β-phase, relative to the value of +0.3V *vs.* liquid lithium observed in the two-phase region. At 50 a/o lithium, the richest composition reported, the emf appears to be approximately +0.18V.

Consequently, the present work was directed first toward obtaining a lithium-activity profile for the lithium-rich half of the phase diagram at temperatures between 400° and 500°C. It was expected that this would also yield indirect information confirming or contradicting the existence of the various compounds mentioned earlier. Two rather divergent sets of data have been reported for the alloy composition at the lithium-rich liquidus. At 427°C (700°K) the liquidus composition is 84 a/o according to Shamray and Saldau (3), whose liquidus data are adopted in Hansen's standard compilation. Grube *et al.* (2) report the liquidus composition as 86 a/o at 427°C. Therefore, accurate data were sought for the alloy composition at the lithium-rich liquidus using coulometric methods.

We report here electromotive force measurements of lithium-rich alloys using the cell

$$\text{Li (l, in Feltmetal}^{3}) \;\Big|\; \begin{matrix}\text{LiCl-KCl}\\ \text{(eutectic)}\\ \text{or}\\ \text{LiF-LiCl-LiBr}\\ \text{(eutectic)}\end{matrix} \;\Big|\; \text{Li}_x\text{Al}_{1-x} \;\Big|\; \begin{matrix}\text{s}\\ \text{or}\\ \text{l}\end{matrix} \qquad [1]$$

Two types of measurements were carried out: measurements at fixed alloy composition in which the temperature was varied, and measurements at constant temperature in which the composition was varied coulometrically.

Experimental

Materials.—Lithium metal (Foote Mineral Corporation) was premelted in a tantalum cup at 200°C and drawn in droplets from the bottom through a hole stoppered by a conical tantalum spike. This operation, as well as the subsequent alloying and the emf measurements, took place in a high purity helium atmosphere glove box with continuous purification of the recirculated helium. Small drops (0.1-0.3g) of lithium were obtained, and only those which were visibly free of oxide or nitride layers (yellow hue) were used in this study.

Small lithium reference electrodes were made by absorbing lithium drops into porous stainless steel or nickel plaques (Feltmetal) at 600°C. The excess lithium was removed by contacting it with an empty plaque of porous metal at the same temperature.

Samples of the lithium-aluminum alloys were prepared by heating carefully weighed amounts of the metals together at 750°-800°C, stirring the melt, and absorbing it quickly in stainless steel or nickel Feltmetal or in tantalum frits, followed by annealing for 48 hr at 500°C. The aluminum metal (Materials Research Corporation) was of 99.99% purity. The composition of the alloy samples was checked by analysis as indicated below.

The LiCl-KCl eutectic (58.8 m/o LiCl-41.2 m/o KCl, mp 352°C) was obtained from the Anderson Physics Laboratory, Urbana, Illinois. For some of the experiments an all-lithium cation eutectic (22 m/o LiF-31 m/o LiCl-47 m/o LiBr, mp 430°C) was prepared from purified individual salts supplied by the Anderson Physics Laboratory.

Apparatus and procedure.—The cell shown in Fig. 1 was used for the emf measurements at fixed sample composition and varying temperature. This cell design was suggested by the desirability of a large area lithium reference electrode whose activity would not be affected by the inevitable slow reaction with gaseous

[3] A porous metallic material produced by the Brunswick Corporation

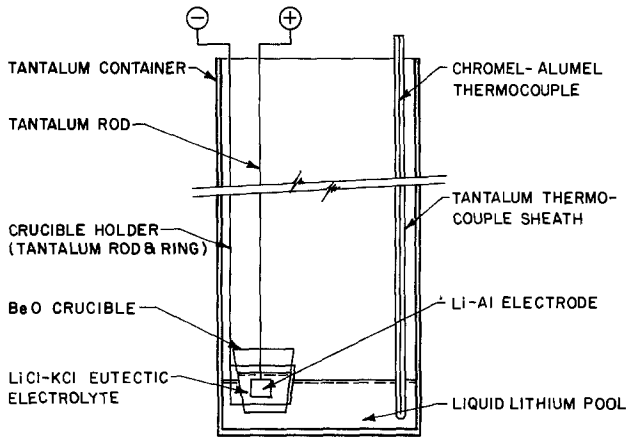

Fig. 1. Schematic diagram of cell for lithium-aluminum alloy emf measurements.

impurities in the helium atmosphere; in addition, temperature uniformity (± 1°C) was maintained in this cell by the liquid lithium pool, of approximately 10 cm diam and 1 cm depth. The lithium was skimmed from time to time to remove surface impurities.

The electrolyte and the alloy electrode were contained in a porous BeO crucible which separated the electrode from the lithium pool electrode. The crucible (National Beryllia Corporation) had a porosity of approximately 20% and was 2.5 cm in diameter and height, with a 0.2 cm wall thickness. Rapid self-discharge of the emf cell occurred in the absence of this barrier because of the high lithium activity of the electrolyte in contact with lithium metal or an alloy of high lithium activity.

Temperature equilibrium was usually attained within 20 min following a 20°C step, so that a series of traverses (390°-520°C) could be made with one sample of alloy in one or two days. Emf equilibrium appeared to follow temperature equilibrium very rapidly.

In the coulometric emf measurements, a weighed sample of liquid alloy was anodically oxidized to decrease the lithium content and the emf was recorded at regular intervals following current interruption. The current level was chosen such that the emf would reach steady state (± 1 mV) in less than 15 min.

In these measurements it was found advantageous to reverse the arrangement of Fig. 1 so that the lithium reference electrode was contained in the porous plaque and the alloy pool surrounded the BeO crucible. Therefore, the sample size of the alloy could be made fairly large (typically 4g) as compared with that contained in a porous plaque (0.1-0.4g).

This arrangement proved advantageous in spite of the longer time required to obtain a desired change in composition of the alloy while using the same current. The lithium initially contained as liquid alloy in a porous plaque electrode was removed at a rate far greater than the coulometric oxidation rate. This effect was apparently the result of appreciable solubility of lithium in the electrolyte, associated with the high lithium activity of the liquid alloy.

In the reverse arrangement of that shown in Fig. 1 the measured emf's were satisfactorily stable and reproducible. Since the ratio of the electrolyte interfacial area to the sample volume is much smaller in this cell arrangement, a likely explanation for the difference in stability is that immersed lithium alloy is oxidized more easily and continuously via impurities in the melt than in lithium alloy in direct contact with the atmosphere.

The cell temperature was measured by means of a tantalum-sheathed Chromel-Alumel thermocouple which had been calibrated against the freezing points of tin (231.9C), zinc (419.5°C,) and aluminum (659.7°C). The thermocouple emf's were read by amplifying and

recording a difference signal with respect to a L&N K-3 universal potentiometer.

The cell emf's were read with a Dana Model 5000 digital multimeter (input resistance greater than $10^{10}\Omega$) to ± 0.01 mV. The reproducibility and accuracy of emf's measured at fixed composition during fairly short periods were ± 2 mV. The uncertainty can be ascribed in part to diffusion potentials of variable magnitude caused by composition changes of the LiCl-KCl electrolyte in the pores of the BeO crucible. The electrolyte, in contact with liquid lithium, undergoes a displacement reaction

$$\mathrm{Li(l) + KCl(l) \rightarrow K(l) + LiCl(l)} \qquad [2]$$

The standard equilibrium constant of this reaction[4] at 427°C is $K = 0.046$, and at 527°C, $K = 0.084$. Since the partial pressure of potassium is appreciable at these temperatures (0.4 Torr at 427°C), reaction [2] can proceed to a considerable extent, especially at temperatures in excess of 450°C, as shown by Seefurth and Sharma (7).

The porous separator prevents rapid diffusion of excess LiCl formed at the interface (lithium/electrolyte) toward the bulk of the electrolyte, and of KCl from the bulk toward the depleted zone. Therefore, a concentration cell emf results, which declines very slowly. In accordance with this picture, a constant-sign bias potential was observed when the alloy electrode in Fig. 1 was replaced by a porous plaque electrode containing pure lithium. Whenever the bias potential was steady over several hours, the alloy emf was corrected for it; however, fluctuations of the bias potential were common, which suggests that other causes of instability were involved.

To avoid the potassium-displacement reaction [2], an all-lithium cation electrolyte was used in part of the measurements. The LiF (22 m/o)-LiCl (31 m/o)-LiBr (47 m/o) eutectic has a mp of 430°C. Stable emf's could be obtained in this electrolyte at temperatures above approximately 460°C. Attempts to use a mixture of LiF (14.7 m/o)-LiCl (35.5 m/o)-LiBr (20.0 m/o)-LiI (29.8 m/o), for which the melting range was 318°-326°C, failed because the stainless steel or nickel substrate of the porous plaque electrode was strongly attacked by the electrolyte. Therefore, measurements in the temperature range 400°-470°C were carried out with LiCl-KCl eutectic.

Chemical analyses.—Chemical analyses were performed on samples of the alloy before and after the emf measurements. The alloy was dissolved in HCl and the aluminum was separated as an oxalato complex by anion exchange (8). Lithium was determined by atomic absorption spectrometry (1-2% accuracy) or by mass spectrometry with isotopic dilution. The latter technique, using standards supplied by Oak Ridge National Laboratory, was used for small samples where a lithium-aluminum separation was impractical; its accuracy is 0.5%. Aluminum was determined by precipitation by 8-hydroxyquinoline (9).

Samples analyzed after the emf measurements contained electrolyte adhering to the alloy; the metallic lithium content was back-calculated from halide-ion or K^+-ion content by subtracting the Li^+-ion concentration corresponding to the known electrolyte composition.

The analyzed composition of the alloy in most cases agreed with the weighed composition within 1 a/o, which is assumed to be the uncertainty of the alloy compositions reported here. No signficant change in alloy composition was detected after the emf measurements (except in the coulometric sample) if the temperature did not exceed 500°C for extended periods.

Results and Discussion

The emf's of eight alloy samples were measured at various temperatures between 390° and 530°C. The analyzed compositions of the alloys, the emf's, and the lithium activities at 427°C (700°K) are listed in Table I. Also included in this table is a value for the emf in the two-phase $\alpha + \beta$ region, extrapolated to 427°C from measurements by Yao *et al.* (1) at 300°, 350°, and 380°C.

[4] Taking solid standard states for LiCl and KCl.

* Extrapolated from measurements in the temperature range 300°-380°C.

The emf data shown in Table I and in Fig. 2 project a consistent picture of the lithium activity as a function of composition: (*i*) The steep decrease in emf as the lithium fraction exceeds 48 a/o, which was already suggested by the earlier work (1), is clearly substantiated by the present results. There appears to be no intermetallic compound with a lithium activity 0.1-0.2, except the β-phase itself over the narrow composition interval of 48-50 a/o lithium. (*ii*) No significant emf discontinuity is observed at 67 a/o Li (composition Li_2Al) or 69 a/o (Li_9Al_4), but a phase transition at 60 a/o Li (Li_3Al_2) is suggested by the data.

Attempts were made to carry out coulometric emf measurements in the range of 50-80 a/o lithium, and thereby establish the location of phase transitions. These attempts were not successful because of a high rate of self-discharge in conjunction with the low current levels necessary to avoid polarization of the wholly or partly solid electrode.

However, the present results are in good agreement with conclusions of a concurrent DTA investigation of

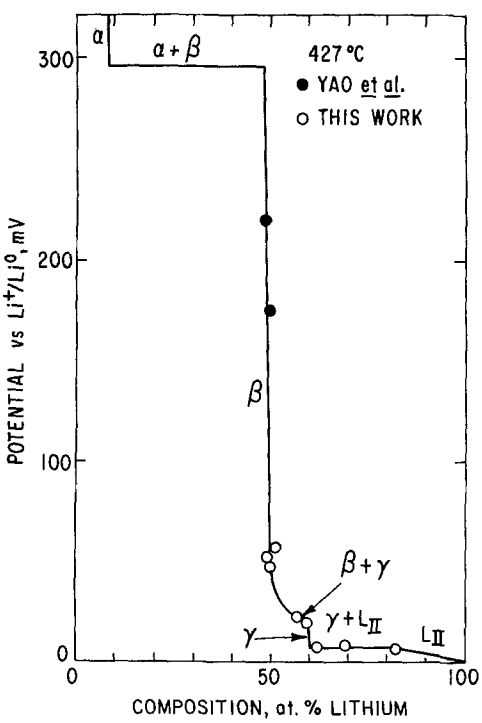

Fig. 2. Emf-composition diagram of lithium-aluminum alloy at 700°K.

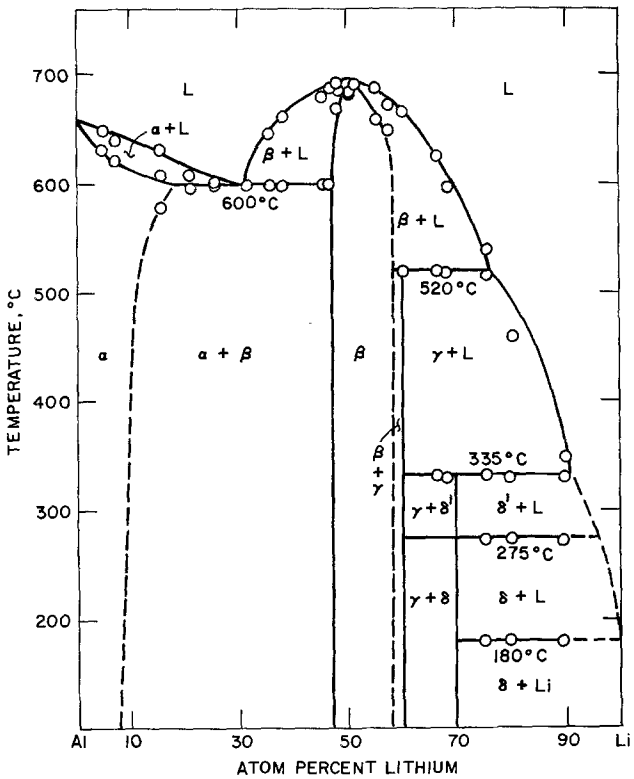

Fig. 3. Revised phase diagram of the lithium-aluminum system according to Myles and Settle (10).

the Li-Al systems by Myles and Settle of Argonne National Laboratory (10) (see Fig. 3). According to their results, the β-phase (nonstoichiometric solid LiAl) at 700°K extends from a composition between 47 and 48.3 a/o lithium to a composition in excess of 56 a/o. [The solid compound Li_3Al_2 exists, but neither Li_2Al nor Li_9Al_4 is present at 700°K. A two-phase alloy, solid Li_3Al_2 + lithium-rich liquid (L_{II}), therefore, is present at compositions in excess of 60 a/o lithium.] As shown in Fig. 3, the compound Li_3Al_2 was found to decompose peritectically at 520°C, while the compound Li_9Al_4 undergoes a peritectic decomposition at 335°C. Thus at 700°K and for compositions in excess of 60 a/o lithium, the stable phases are Li_3Al_2 and liquid lithium saturated with aluminum. The emf results are consistent with this phase diagram.

In the emf-composition diagram at 427°C (700°K), Fig. 2, the composition ranges of the phases and two-phase mixtures are taken from the phase diagram shown in Fig. 3. The lithium-rich boundary of the β-phase at 427°C was assumed to be 48 a/o lithium. A solid-solid, two-phase region, β + $Li_3Al_2(\gamma)$, is indicated in Fig. 2 although its existence and extent cannot be inferred with any certainty from the emf data. Hansen and Anderko (4) indicate 56 a/o lithium as the lithium-rich boundary of the β-phase, based on the work of Shamray (3). The recent DTA investigations do not pinpoint the boundary more accurately (Fig. 3). The lithium-rich liquidus is located at 86 a/o, in agreement with Ref. (3). Two emf data points in the β-phase region (Fig. 2) were obtained from the work of Yao *et al.* (1) by extrapolation to 700°K.

The present data, in conjunction with emf data for the two-phase α + β alloy, allow a rough estimate of the free energy of formation of Li_3Al_2, according to the reactions

$$Li + Al(\alpha) \rightarrow LiAl(\beta) \qquad [3]$$

and

$$Li + 2LiAl(\beta) \rightarrow Li_3Al_2(\gamma) \qquad [4]$$

If the presence of lithium in the α-phase is neglected, and the composition of the β-phase is considered stoichiometric, *i.e.*, LiAl, this yields, at 427°C

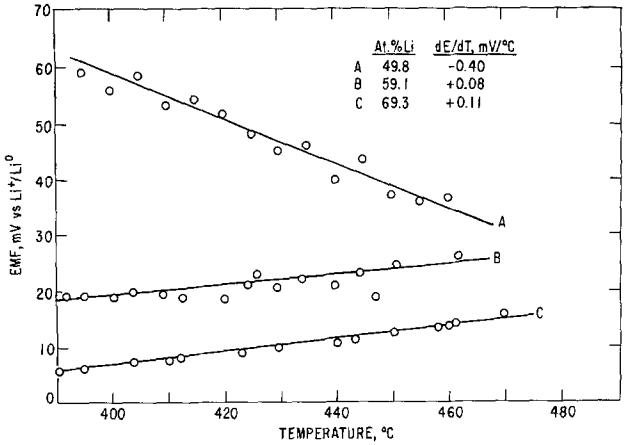

Fig. 4. Temperature dependence of the emf for alloy compositions in three different regions of the Li-Al phase diagram.

$$\Delta G_f\, LiAl(\beta) = -28.6\ kJ/mole$$

$$\Delta G_f\, Li_3Al_2(\gamma) = -58\ kJ/mole$$

The effect of temperature on the emf is illustrated in Fig. 4, for temperatures between 390° and 470°C. In the β-phase the emf temperature coefficient is negative, as is the temperature coefficient found by Yao *et al.* (1), for the two-phase α + β alloy in the temperature range of 300°-380°C (see Table I). At the lithium-rich end of the β-phase region the coefficient becomes positive. Since the temperature coefficient in the two-phase regions is directly proportional to the entropy change in lithium-addition reactions such as [3] and [4], it is apparent that β-phase formation from α-phase involves an entropy decrease, whereas further lithium addition leads to an entropy increase. This behavior appears to parallel the volume change in reactions [3] and [4] which is negative in the formation of β-phase from α-phase, and positive from β-phase to Li_3Al_2, according to room temperature density data (6).

The coulometric emf measurements to determine the lithium-rich liquidus composition started with an alloy sample containing 90.0 a/o lithium at 470°C; in these measurements the LiF-LiCl-LiBr eutectic electrolyte was used. Using the reverse cell design of Fig. 1, the sample was anodically oxidized and emf readings were taken at intervals. As shown in Fig. 5, the emf readings were sensitive to the current level; at the lower current level indicated, the emf curve in the liquid range was satisfactorily reproducible.

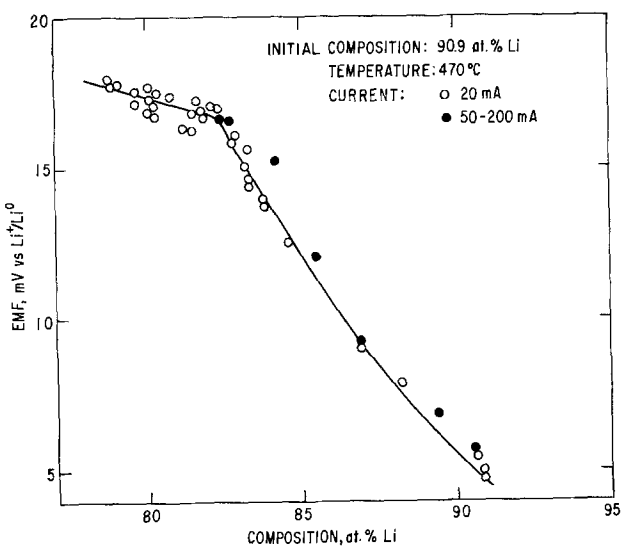

Fig. 5. Coulometric emf measurements on a liquid alloy sample at 470°C.

The discontinuity in the curve at 82.8 (±0.3) a/o corresponds to the phase transition at the liquidus composition. To the left of this point (two-phase region) the emf should be independent of composition; actually, the emf showed a slight tendency to increase but the values were rather scattered and tended to level off upon repeated cycling across the phase boundary. The large spread and the initially high values are probably caused by local formation of alloy containing less than 60 a/o lithium in the pores of the BeO separator.

The liquidus composition, 82.8 a/o at 470°C, agrees more closely with the data of Grube *et al.* (2) than with those of Shamray and Saldau (3), which were adopted by Hansen.

Figure 6 illustrates the relationship between the lithium activity and composition at the lithium-rich liquidus. The triangles are the lithium activities of a two-phase alloy sample (69.3 a/o lithium) measured with a cell as in Fig. 1. Here the emf was measured up to 550°C; the discontinuity at 522°C agrees very well with the peritectic decomposition temperature for "Li_2Al" (actually, Li_3Al_2) given by Hansen and that found by Myles *et al.* (10).

The liquidus composition at 470°C ($X_{Li} = 0.828$) is plotted in Fig. 6 as a black dot. The lithium activity coefficient at 470°C is 0.94; this is in agreement with the negative deviation from ideality recently reported (11) for the entire liquid alloy composition range between 630° and 820°C.

It is seen from Fig. 6 that the liquidus compositions reported by Shamray and Saldau (3) would lead to positive deviation from ideality below 425°C. Although this is not impossible, the evidence presented here strongly suggests that the liquidus compositions reported by Grube *et al.* (2), rather than those of Shamray and Saldau (3), are correct.

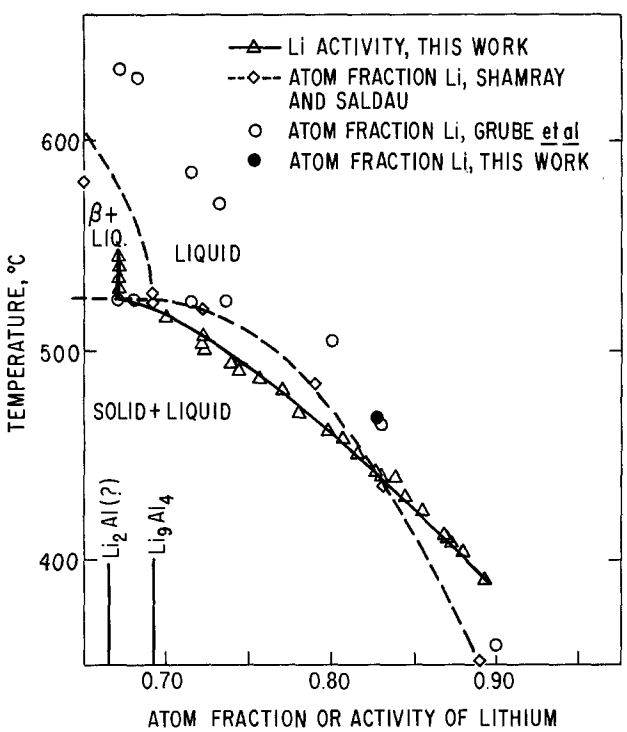

Fig. 6. Lithium activities and mole fractions at the lithium-rich liquidus as a function of temperature.

Conclusions

1. The lithium activity of β-phase lithium-aluminum alloy increases steeply, from 0.007 to approximately 0.7, as the alloy composition changes from 48 to 56 a/o lithium. In view of this high lithium activity, alloys containing more than 50 a/o lithium do not appear to be suitable as substitutes for lithium in the negative electrodes of high temperature batteries.

2. The compound Li_3Al_2, rather than Li_2Al as reported in compilations, is stable at temperatures below 520°C. With lithium-rich liquid, Li_3Al_2 forms a two-phase region of high (>0.85) lithium activity. The compound Li_3Al_2 has an estimated $\Delta G_f°$ from the elements of −58 kJ/mole at 427°C (700°K).

3. Coulometric emf measurements at 470°C and activity measurements over an extended temperature range indicate that the lithium-rich liquidus is approximately 2 a/o closer to the liquid lithium axis than is shown in standard compilations; the liquidus composition reported by Grube *et al.* (2) appears to be correct.

On the Composition of the Passivating Films Formed on Aluminum in Chromate Solutions

Milena Koudelkova, J. Augustynski, and H. Berthou

Département de Chimie Minérale, Analytique et Appliquée, Université de Genève, Geneva, Switzerland

ABSTRACT

The chemical constitution of the passive oxide films formed on aluminum in chromate and chromate/chloride solutions under simple immersion (at open-circuit potential) and under anodic polarization has been investigated by means of x-ray photoelectron spectroscopy. It has been shown that these films, whose thickness is comparable with the mean escape depth of photoelectrons, are composed of a mixture of hydrated chromium (III) oxide, aluminum (III) oxide, and chromium (VI) species. A considerable amount of chloride species has been detected in the films formed in chromate/chloride solutions, independently whether chlorides were initially present in the solution or were added only after 18 hr immersion of the sample in chromates. The extent of chloride incorporation within the oxide film from CrO_4^{2-}/Cl^- solution was not modified by the anodic polarization of aluminum from open-circuit potential up to critical pitting potential. This situation is quite different from that observed in chloride solutions, in the absence of chromates, where the amount of chlorides in the oxide film increases appreciably between E_{st} and E_{cr}. The nature of the inhibiting effect of chromate ions on the pitting corrosion of aluminum is discussed on the basis of these results.

Although numerous studies have been devoted to clarifying the mechanism by which chromate ions inhibit the corrosion of aluminum, the exact nature of this phenomenon is still under discussion. Edeleanu and Evans (1) first attributed the inhibiting effect of chromate solutions to a redox reaction occurring between CrO_4^{2-} ions and aluminum metal to form aluminum oxide and Cr^{3+} ions. Their suggestion was further examined by Pryor (2), and by Heine and Pryor (3), who found that γ-Al_2O_3 films formed on aluminum by passivating chromate solutions exhibited lower ionic resistance and higher electronic resistance than amorphous films of comparable thickness produced by thermal oxidation. According to these authors, the inhibiting effect of chromate ions on the pitting corrosion of aluminum in chloride solutions can be explained by strong specific adsorption of divalent CrO_4^{2-} ions on the film-solution interface, preventing simultaneous adsorption of monovalent Cl^- ions and their entry into the γ-Al_2O_3 lattice. This latter theory has since received indirect support in the investigation of Böhni and Uhlig (4), who showed the existence of a linear relationship between the logarithm of the activity of Cl^- ions, and the logarithm of the activity of CrO_4^{2-} ions required to shift the critical pitting potential of aluminum to an arbitrary noble value of 0.8V *vs.* NHE. Recently, Abd Rabbo *et al.* (5) have studied the changes in the composition of anodically formed aluminum oxide films after immersion in chromate/dichromate solutions, using secondary ion mass spectrometry (SIMS). A layer of uniformly distributed Cr^+ ions[1] was detected in the outer regions of the films on immersed specimens, followed by localized Cr^+-rich areas down to the metal-oxide interface. On the basis of these results the authors have concluded that, in addition to a gradual chromate/dichromate anion entry into the film material from the oxide-solution interface, the $CrO_4^{2-}/Cr_2O_7^{2-}$ species underwent reduction to Cr_2O_3 within flaws in the film. However, the technique of ion microprobe mass spectrometry being unable to distinguish between different oxidation states of a given element, the results of Abd Rabbo *et al.* cannot be considered as direct experimental evidence for the specific incorporation of a Cr(III) species into the surface oxide film on aluminum.

Key words: x-ray photoelectron spectroscopy, inhibiting anions, chlorides.

[1] A secondary ion species produced during analysis of the sample by SIMS.

In the present study, x-ray photoelectron spectroscopy (XPS or ESCA) was used to examine the composition of the surface films formed on aluminum in chromate and chromate/chloride solutions at open circuit and under anodic polarization. The aim of this investigation was, on the one hand, to determine the extent of incorporation of different chromium species into the oxide film and, on the other hand, to clarify the effect of these species on the entry of chloride into the film.

Experimental

XPS spectra were obtained on a Varian IEE-15 photoelectron spectrometer using $MgK\alpha_{1,2}$ x-rays at 1253.6 eV. The pressure in the sample chamber of the spectrometer was in the range of 10^{-6}-10^{-7} Torr. Binding energies were referenced to the carbon 1s electron peak, at 290.0 eV, due to residual pump oil on the sample surface. The relative concentrations of the species detected in the oxide film were calculated from their XPS peak intensities using the relative photoelectron line sensitivities referenced to fluorine 1s signal (6, 7). Measured concentrations were reproducible within 15%.

All analyses were performed on cylindrical aluminum (99.99% purity) samples having a geometrical area of approximately 6.5 cm^2. Before immersion in the solution, the samples were polished with fine emery papers and washed in doubly distilled water. All solutions were made up from AR grade chemicals and doubly distilled deionized water, and were deaerated with argon. Following immersion (polarization) in the solution, the samples were carefully washed in doubly distilled water, dried in a desiccator, and transferred to the spectrometer. The potentiostatic polarization experiments were carried out with a Wenking 68 FR 0.5 potentiostat driven by a Wenking SMP 69 scanning potentiometer: the polarization rate was 3 mV/min.

Results

In order to characterize the initial state of the surface on the aluminum samples employed in this study, the XPS analysis of a freshly prepared, mechanically polished Al specimen was first performed. As expected, the presence of an 10-13Å thick oxide film having a mean composition equivalent to $Al_2O_3 \cdot 3H_2O$ (8) was determined. Exposure of this air-formed aluminum oxide film to 0.2M Na_2CrO_4 solution during 18 hr pro-

* Binding energies are given relative to the zero kinetic energy level, using 290 eV as the carbon 1s binding energy *in vacuo*.

duces a mixed oxide film[2] containing Al(III) oxide, Cr(III) oxide, and Cr(VI) species (Fig. 1 and Table I). As shown in Fig. 1a, two separate peaks were observed in the Al2p region (as in the Al2s region) of the XPS spectrum, indicating that the thickness of the surface film formed on aluminum during the immersion in sodium chromate solution is less than the mean escape depth of photoelectrons, estimated as 15-20Å (9, 10).[3] The positions of the two Al2p peaks (77.6 and 79.8 eV, respectively) were indeed those assigned normally to Al metal (first peak) and to Al(III) of aluminum oxide (second peak).

The $Cr2p^{3/2}$ electron signal (Fig. 1b), as well as the $Cr2p^{1/2}$ signal, showed significant asymmetrical character, indicating the presence of two different chromium species. On the basis of a comparison with the binding energies of various chromium compounds (Table II), the two peaks resulting from the deconvolution of the $Cr2p^{3/2}$ signal were assigned to chromium (III) of Cr_2O_3 (peak at 582.6 eV) and to chromium (VI) in CrO_4^{2-} (smaller peak at 585.2 eV). The large peak observed in the O1s region of the spectrum (Fig. 1c) was quite similar to the O1s signal for hydrated aluminum oxide (14). The abnormal width (1.2 eV) of this peak suggests the presence of at least two oxygen species but, on account of its symmetrical form, resolution was not attempted. The relative oxygen concentration, calculated from the peak intensity,

[2] A series of the XPS analyses performed on aluminum samples immersed in Na_2CrO_4 solution for different periods of time has shown that the oxide film reached its maximum thickness after 18 hr of exposure to the solution.
[3] The fact that the whole oxide film is localized in the outermost region of the aluminum surface examined by XPS, allows true mean concentration of different elements entering the film composition to be determined.

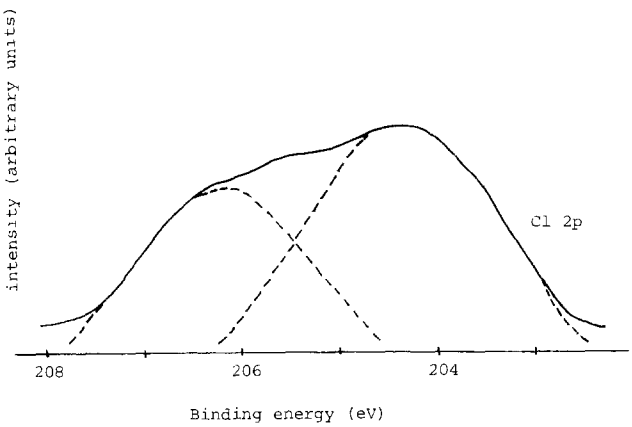

Fig. 2. Chlorine 2p photoelectron signal for the aluminum sample exposed to 0.2M Na_2CrO_4/0.1M NaCl solution.

being distinctly higher than the total amount in Al_2O_3, Cr_2O_3, and CrO_4^{2-}, this additional oxygen was assigned to hydration water. The XPS spectrum shown in Fig. 1 was quite typical of all aluminum samples pretreated in chromate and chromate/chloride solutions. For the latter, in all cases, an additional chlorine signal was detected. Figure 2 shows the Cl2p region of the spectrum obtained for an aluminum sample exposed during 18 hr to 0.2M Na_2CrO_4/0.1M NaCl solution. The position of the $Cl2p^{3/2}$ peak was in this case identical to that previously observed for chloride ions included in an aluminum oxide film, derived from sodium or aluminum chloride solution treatment (15)[4] in the absence of chromates. Another series of analyses was performed on aluminum samples immersed first during 18 hr in 0.2M Na_2CrO_4 solution and then, during a second period of 18 hr, in a solution containing both 0.2M Na_2CrO_4 and 0.1M NaCl. As shown in Table I, the composition of the oxide film formed under these conditions (and in particular the extent of chloride incorporation) was practically the same as that of the film from direct immersion in Na_2CrO_4/NaCl solution.

No significant changes in the surface film structure were observed for aluminum samples polarized anodically at −0.350V *vs.* NHE; *i.e.*, at a potential about 0.1V less noble than the critical pitting potential of aluminum in 0.2M Na_2CrO_4/0.1M NaCl solution. In these experiments, the first set of specimens was immersed directly in 0.2M Na_2CrO_4/0.1M NaCl solution for 18 hr, and then polarized anodically stepwise up to −0.350V, this potential subsequently being kept constant during another period of 18 hr. The second set of specimens was first immersed in 0.2M Na_2CrO_4 solution, and sodium chloride was added only after the initial 18 hr, at the beginning of the anodic polarization. In both cases, the extent of chloride incorporation determined by photoelectron spectrometry was about 6-7 atomic percent (a/o); *i.e.*, the same as that found for samples exposed to CrO_4^{2-}/Cl^- solution at open-circuit potential.

Discussion

The results of surface analyses performed using x-ray photoelectron spectrometry clearly confirm that chromate ions from the solution undergo reduction inside the aluminum oxide film, after being adsorbed on the oxide-solution interface. Indeed, the spectra indicate, for all samples examined, the presence of two different chromium species, which have been identified as Cr(III) in Cr_2O_3 and Cr(VI) in CrO_4^{2-}. However, one can consider rather surprising the fact that the oxide film formed on aluminum under immersion in chromate solution contains such a substantial amount of chromium (III) oxide: almost 60 a/o for 0.2M CrO_4^{2-} solution and even more than 60 a/o for 1M CrO_4^{2-} solution (Table I). Decreasing the *p*H of chromate solution from 9.5 to 7 changes the film composition in favor of an increased proportion of aluminum oxide. This observation corroborates partially the conclusions of an earlier work (2), which indicate that the dissolution rate of γ-Al_2O_3 in chromate solutions is appreciably higher at *p*H 9.5 than at *p*H 7.

[4] From a comparison of the $Cl2p^{3/2}$ binding energies of the different chlorine species it has been suggested that Cl- ions entering the aluminum oxide lattice may form an aluminum oxychloride AlOCl.

Table III. Relative concentrations of the Cl species in the oxide film on Al samples as a function of potential

Electrolyte	Potential, V *vs.* NHE	Relative concentration of Cl (a/o)
NaCl 0.1M	$E_{st} = -0.96$	5-6*
	-0.50	13*
	$E_{cr} = -0.43$	
Na_2CrO_4 0.2M/ NaCl 0.1M	$E_{st} = -0.52$	6-7**
	-0.35	6-7**
	$E_{cr} = -0.24$	6-7**

* Given with respect to Al(III).
** With respect to the sum of Al(III) and Cr(III).

The total film thickness, however, remains practically unchanged,[5] notwithstanding the *p*H modification, which means that the portion of γ-Al_2O_3 dissolved in the surface film (formed in chromate solution of *p*H 9.5) is apparently replaced by chromium (III) oxide. In this connection, it seems interesting to mention the suggestion of Pryor (2), which was based on the results of an electron optical study, and concerned the duplex nature of passive films formed on aluminum in chromate solutions. According to this author, these films would be composed of an underlying layer of amorphous γ-Al_2O_3, being overlaid by a thin layer of microcrystalline γ-Al_2O_3 having very low ionic resistance. Our XPS results strongly suggest that this outer layer consists of chromium (III) oxide, which would be responsible for the diffraction patterns attributed by Pryor to microcrystalline γ-Al_2O_3.

Another point of particular importance with regard to the mechanism by which chromates exert an inhibiting action on the corrosion of aluminum by chloride ions, is the fact that the formation of a layer of chromium (III) oxide, just as the presence of adsorbed CrO_4^{2-} ions on the film surface, has no special merit in preventing Cl^- penetration of the protective oxide film. Indeed, as shown by our XPS results (Table III) the extent of chloride incorporation within the oxide film from CrO_4^{2-}/Cl^- solution (at open-circuit potential) is quite similar to that observed for aluminum samples immersed in chloride solution not containing chromates (16).[6] It must be also emphasized that the amount of Cl^- and the over-all film composition are not visibly modified if the aluminum sample is immersed directly in CrO_4^{2-}/Cl^- solution or if chlorides are added only after the initial period of film formation in chromate solution has been achieved (Table I).

These observations are in good agreement with our previous results concerning nitrate/chloride solutions (17), which also indicate significant incorporation of Cl^- ions in the aluminum oxide film at open-circuit potential (E_{st}), in spite of the presence in solution of inhibiting NO_3^- ions.

Anodic polarization of aluminum in CrO_4^{2-}/Cl^- solution near critical pitting potential has practically no influence on the surface film composition and, in particular, the chloride content remains unchanged with respect to that at E_{st}. The situation is quite different when aluminum is polarized anodically in chloride solution not containing chromates; in this case the amount of Cl^- in the oxide film (Table III) increases

[5] This is substantiated by the presence of a comparable weak signal for metallic aluminum in the Al2p spectra of the samples pretreated in chromate solutions of *p*H 9.5 and 7.

[6] For this comparison, the relative concentrations of Cl species were referenced to the sum of Al(III) and Cr(III) in the first case and to Al(III) in the second.

from 5-6 a/o at E_{st} to about 13 a/o at E_{cr}-0.1V (16).

The above results therefore show that if chromate ions do not prevent the entry of chlorides into the protective oxide film at open-circuit potential, they largely impede their further incorporation at higher potentials. This effect is related, in our opinion, to the fact that CrO_4^{2-} ions are reduced within the oxide film, this reduction process being a film forming (and film repairing) reaction. The reduction of chromate ions[7]

$$2CrO_4^{2-} + 2Al^{3+} + 4H_3O^+ + 6e^- \rightarrow Cr_2O_3 + Al_2O_3 + 6H_2O$$

(over-all reaction)

not only produces both oxides entering the film composition (*i.e.*, Cr_2O_3 and Al_2O_3), but also consumes protons from the oxide lattice. Assuming that the preferential sites by which Cl^- and CrO_4^{2-} ions penetrate the oxide film are the same, the inhibiting action of chromates can therefore be understood in terms of shifting the potential at which a critical concentration of chlorides is established on the metal surface (at the metal-oxide interface).

On the other hand, explanation of increased stability of passive films, formed on aluminum in the presence of chromates, by a competitive adsorption effect [whereby the specifically adsorbed CrO_4^{2-} ions would displace Cl^- ions from the oxide-solution interface (3)] appears hardly compatible with the results of our work. Indeed, the fact that no difference in the extent of chloride incorporation within the protective film (at E_{st}) is observed if 0.1*N* NaCl solution contains, or does not contain, chromates, seems to exclude any significant modification of the amount of specific adsorption of Cl^- ions. This conclusion is also supported by the results of previous work of one of the authors (14), concerning interactions between sulfate ions and oxide-covered aluminum which show that, notwithstanding a large extent of incorporation in the oxide film, they exert practically no inhibiting action in the presence of chlorides. At the same time sulfates are, to our knowledge, the sole oxyanions which are not reduced within the oxide film covering aluminum metal.

[7] This reduction process must be accompanied by an anodic oxidation process occurring at the metal-oxide interface: $Al \rightarrow Al^{3+} + 3e^-$ and, at least, partial diffusion of Al^{3+} ions toward the oxide-solution interface

Mobility of Foreign Atoms during the Anodic Oxidation of Aluminum: As, Sb, and Bi; Se and Te

W. D. Mackintosh, F. Brown, and H. H. Plattner

Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Solid State Science Branch, Chalk River, Ontario, Canada, K0J 1J0

ABSTRACT

Atoms of As, Sb, and Bi; Se and Te introduced into the surface layers of aluminum specimens are shown to be mobile during anodic oxidation. The direction of motion depends on whether the initial distribution of the foreign atoms is located in aluminum metal under the natural air-formed oxide or is entirely within a thin preformed surface film of anodic oxide. The rate of motion relative to aluminum was determined. This investigation complements earlier studies of the behavior of metallic and of halide foreign atoms during anodization.

In two previous papers (1, 2) we described the movement of foreign atoms during the anodic oxidation of aluminum. The metallic elements studied were K, Rb, and Cs; Ca, Sr, and Ba; Cu and Ag; Ga, In, and Tl; Hg; V; Cr; Mn, Fe, Co, and Ni. The nonmetals were Cl, Br, and I. It was shown that when these were introduced into a thin preformed oxide film which was subsequently thickened, the metallic species moved outward while the nonmetals moved inward. However, if introduced into the metal beneath the native air-formed oxide, then metallic species with oxidation potentials greater than that of Al, viz., Ag, Co, Cu, Fe, Ga, Hg,

Key words: aluminum, anodic oxidation, foreign atoms, Rutherford backscattering analysis.

In, Mn, Ni, Tl, and V retreated in whole or in part before the advancing oxide front and were found to be located in the metal after the anodic oxide film had been removed. In all cases where the final location of the foreign atoms was within a specimen (some species, under certain circumstances, were lost to the electrolyte) the distribution of the implanted atoms was largely unaltered, that is to say, the atoms moved as a group.

In this paper we extend these studies to include the Group VA elements As, Sb, and Bi; and Group VIA Se and Te. As before, ion implantation was used to introduce the foreign atoms into the specimen and Rutherford backscattering analysis to locate the ions before and after oxidation.

Experimental

The aluminum specimens were 1.2 cm in diameter and 0.4 cm thick. Surfaces were first prepared by vibratory polishing with 0.5 μm alumina. This was followed by four cycles in which the specimens were anodized then stripped of oxide with a solution of phosphoric and chromic acids at 95°C. Some samples were then exposed to the air at room temperature for a few hours, some were anodized until covered by a much thicker oxide layer.

All anodization was done in a saturated solution (approximately 5%) of ammonium pentaborate in water at 23°C. The current was kept constant at 2 mA/cm^2. The desired oxide thickness was achieved by terminating the oxidation at a voltage corresponding to the desired thickness from a previously prepared calibration curve.

After surface preparation of the specimens covered only with the air-formed oxide, As, Sb, and Bi; Se and Te were implanted at energies of 40 keV. Specimens covered with the preformed oxide were initially implanted at the same energy but the first results indicated that higher energies (300-400 keV) were preferable to avoid ambiguities. In order to ensure that the implanted ions were largely within the oxide layer it was necessary to make the preformed oxides 40-60 μg/cm^2 thick. The number of ions implanted was commensurate with the sensitivity of the Rutherford backscattering method for each species; they were in the range 10^{14}-10^{15} ions/cm^2.

The position of the implanted atoms, the thickness of the oxide films, the profile of the implant distribution, and the number of atoms implanted were then determined by Rutherford backscattering analyses. The principles of this technique for achieving these objectives and the experimental arrangements used were described in Ref. (1).

The specimens were again anodized and the analysis repeated. In many cases second and third oxidations and analysis were carried out.

Results and Discussion

Implants into preformed oxides.—Initially we implanted the foreign atoms at 40 keV into oxides approximately 10 μg/cm^2 thick. On thickening all the implanted material was found at, or very close to, the surface. Although the atoms had obviously moved outward, it was not clear whether the position they occupied was solely due to the rate of movement through the oxide or whether complicated by some surface effect. Consequently, we preformed much thicker oxides and implanted at higher energies, so that they could move a considerable distance before encountering a surface. The position of the implants in the oxide film is illustrated in Fig. 1A, using the case of Sb as an example. Here, the preformed oxide was found to be 42 μg/cm^2 thick and the center of the implant distribution was located at the depth of 25 μg/cm^2. The oxide was then thickened to 64 μg/cm^2. It is known from Ref. (1) that of the 22 μg/cm^2 of oxide grown during the second anodization 4/10 forms over the original oxide and the

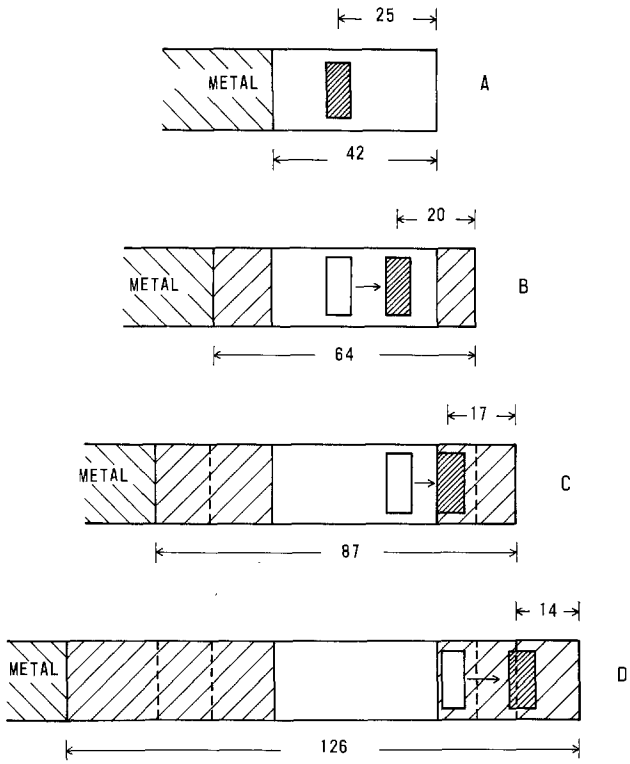

Fig. 1. The movement of Sb implanted in a preformed oxide. A, the position of the implant (solid rectangle) after implantation; B, the position of the implant (solid rectangle) and the "immobile" position (open rectangle) after thickening the oxide to 64 μg/cm^2; C, after thickening to 87 μg/cm^2; and D, after thickening to 126 μg/cm^2. Implant depths are shown in micrograms per square centimeter.

remainder under it. This is shown in Fig. 1B. The center of the implant distribution is 20 μg/cm^2 from the surface. Had the Sb atoms been immobile they would have been located at a depth of $25 + 0.4 \times 22 = 34$ μg/cm^2. This position is indicated by the open rectangle in the figure. It now follows that the Sb atoms have moved $34 - 20 = 14$ μg/cm^2. In Ref. (1) we defined a migration number as the ratio of this distance to the thickness of oxide grown. In this instance the number is 0.63. In Fig. 1C and D we show the results for further thickening. The migration numbers obtained agree with the original within the experimental precision attainable ($\pm$ 2 μg/cm^2 for depths and thicknesses). In Table I we list all these migration numbers together with the averages and the standard deviations for all species except Se. Numbers calculated from the initial experiments with low energy implants were much lower. It is therefore apparent that where the original implant is at such a depth that it can reach the surface, it will remain at the surface rather than dissolving in the electrolyte. Similar observations were made in Ref. (2) for some, although not all, species considered.

Rutherford backscattering spectra give the profiles of foreign atom distributions. The profiles of As, Sb, Bi, and Te remained virtually unchanged throughout the series of oxidations. This indicates that the foreign atoms move as a coherent group during oxidation.

In contrast, Se atoms were found dispersed throughout the preformed oxide and the new layer formed under the original. If any moved into the new layer formed over the original they were too few in number to be detectable. Because the atoms were widely dispersed no migration numbers were calculated for Se. In Ref. (1) it was shown that ions likely to be negatively charged (the halides) moved inward when implanted into an oxide layer which was subsequently thickened while those likely to be positively charged (all metals) moved outward. In this respect the metals Sb and Bi and the near metals As and Te behaved as if

positively charged. Selenium atoms, on the other hand, moved in both directions as if some atoms were of one charge, others of the opposite.

Implants into metal.—In Ref. (2) we reported that many metallic species when implanted into Al under the natural air-formed oxide behaved in a radically different manner than they did when implanted into preformed oxide films. Rather than move outward in a coherent group, some fraction was found at the metal-oxide interface while the remainder was found either in the oxide or to have passed into the electrolyte. All elements in the present study behaved similarly. A fraction of each species was found at the interface. This is illustrated for Te in Fig. 2A and B where we have plotted the backscattered yield against the depth. In A, which represents the as-implanted specimen, the highest concentration of Te is located about 5 $\mu g/cm^2$ below the surface. After anodizing to 30 $\mu g/cm^2$ of oxide the highest concentration lies at the metal/oxide interface while the remainder is distributed throughout the oxide. The profile shown in the figure is approximate only, because the finite resolution of the detector produces some distortion. Table II lists the fractions of all species found at the interface together with the corresponding oxide thickness.

The depth resolution of the Rutherford backscattering technique is not adequate to determine whether the fraction of the foreign atoms at the interface is in the metal surface layers or in the oxide layers adjacent to the substrate. However, when the oxide was stripped from a number of samples with chromic phosphoric acid, the number of foreign atoms found on subsequent analysis was identical to the number found at the interface with the oxide film intact. The foreign atoms are therefore located in the metal close to the metal/oxide interface.

When the oxide film is thickened a second and third time the amount retained in the metal decreases. Table II also lists these amounts with the corresponding oxide thicknesses. It is therefore apparent that as an oxide grows, some of the implanted atoms that were initially moved deeper into the specimen by the advancing oxide front, were transferred across the interface into the oxide.

In all specimens the fraction of the implanted material not held at the advancing oxide front was spread

throughout the oxide film; no detectable amounts were lost to the electrolyte. This is represented qualitatively in Fig. 2B, C, and D for increasing thicknesses of oxide. The change in the distribution profile is consistent with two previous observations. First, in Ref. (2) we found that the rate at which foreign atoms (specifically Tl in the work quoted) were transferred across the interface decreased as the concentration in the metal phase decreased. The dependence was first order. This accounts

for the decreasing concentration in the oxide inward. Second, in an earlier section of this paper it was observed that the foreign atoms of all species implanted into preformed oxide moved outward during oxidation until they reached the surface where they were retained. The pile-up at the surface in Fig. 2D is evidence that the same process is occurring once an atom has been released from the metal and transferred to the oxide.

Conclusions

These experiments have shown that Groups V and VI metals and near metals, like the metals reported in Ref. (2), behave in a manner dependent on the position of the implant. When implanted in a preformed oxide all remain in the oxide but move within it. When implanted in the metal beneath the air-formed oxide all move, in whole or in part, ahead of the advancing oxide front.

The rate of movement within the oxide of As, Sb, and Bi when implanted into a preformed film which is subsequently thickened, increases with the size of the ion. The reverse was noted in the Group I metals, K, Rb, and Cs (1). However, we noted in Ref. (2) that the likely charge on the ion appears to be more significant than size, as the Group IIA metals Ca, Sr, and Ba all moved faster than Group IA. We therefore infer that the charge on Bi is greater than that of As and Sb as it moved appreciably faster.

We have shown that the direction of movement is dependent on the sign of the charge; negative ions move inward, positive ions outward (1, 2). We therefore conclude that some ions of Se are negative, some positive, as the spread of the implant throughout the oxide indicates movement in both directions.

When implanted in metal, As, Sb, and Bi; Se and Te behave in the same fashion as metals with higher oxidation potentials than Al, *i.e.*, retreat before the advancing oxide front (2). This has practical consequences. Anodic oxidation and stripping have been used as a microsectioning technique [*e.g.*, Ref. (3)] to determine range profiles and study diffusion. The present experiments show that the technique cannot be used when Group VA and VIA elements are involved as the movement of the foreign atoms during oxidation will falsify the results. In this respect these elements are similar to many others (2). Although we have not the facilities to check the entire Periodic Table it appears that the microsectioning technique is only safely used with the alkali metals, alkaline earths, halides, and noble gases.

Acknowledgments

We are grateful to O. Westcott, G. Sims, and R. Bellavance for implantation of the specimens and to J. Lori and D. Lanteigne for assistance in the Van de Graaf operations.

Anodic Oxidation of Methane

S. Y. Hsieh and K. M. Chen

Department of Chemical Engineering, National Taiwan University, Taipei, Taiwan, Republic of China

ABSTRACT

The anodic oxidation of methane on a platinized platinum electrode was studied in acidic sulfate electrolytes at 80°C. Results indicate that the reaction proceeds according to $CH_4 + 2H_2O \rightarrow CO_2 + 8H^+ + 8e^-$, with ~100% current efficiency. Effects of potential, methane partial pressure, and pH on current density give the following kinetic parameters, respectively: $(\partial V/\partial \log i) \sim 2.3\ RT/\mathbf{F}$, $(\partial \log i/\partial \log p) \sim 1$, and $(\partial \log i/\partial\ pH) \sim 1$. A mechanism (up to the rate-determining step) consistent with these experimental results was suggested as

$$CH_4 \rightleftharpoons CH_3(ads) + H^+ + e^-$$

$$CH_3(ads) \xrightarrow{rds} \text{intermediates}$$

One of the key problems in fuel cell research is the achievement of high electrochemical reaction rates using cheap fuels, of which the saturated hydrocarbons represent a notable class. The electrochemical oxidation of saturated hydrocarbons has been extensively studied (1-24). Most of the previous works either emphasized the improvements of actual fuel cell performances or approached the studies of adsorption and the formation of various intermediates during oxidation. A study of electrode kinetic parameters to determine the mechanism was only approached by Bockris, Gileadi, and Stoner in the anodic oxidation of propane, n-hexane, cyclohexane, and 2,2-dimethylbutane (24). In this work, the rate and mechanism of methane oxidation on platinum in acidic sulfate solutions were studied by using the electrode-kinetic-parameter approach.

Key words: methane anodic oxidation, fuel cell methane, electrochemical oxidation methane.

Experimental

Cell and apparatus.—Electrochemical measurements were conducted in a three compartment Pyrex cell (capacity 700 ml). The anode compartment was separated from the cathode compartment by a fritted glass partition. A water-sealed stopcock and a Luggin capillary provided contact between the anode and the reference electrode. The anolyte temperature was main-

Table I. Electrode rest potentials in electrolytes bubbled with methane at 80°C

Electrolytes	pH	Rest potential, mV
1N H_2SO_4	0.35	100
1N (H_2SO_4 + KOH)	1.0	50
1N (H_2SO_4 + KOH)	1.7	0
1N (H_2SO_4 + KOH)	3.5	−110

tained at 80° ± 0.1°C except for the activation-energy determinations. Gas-flow rates through the anode compartment were maintained at 200 cm^3 (1 atm, 25°C) per minute. Both the anode and the cathode were platinized platinum gauzes, about 6 cm^2 apparent area. The platinizing procedure reported in Ref. (25) was closely followed, and the resulting anode had a roughness factor about 200. The anode was activated at the start of each run by an electrochemical pulsing technique (alternate anodic and cathodic polarization). The reference electrode was a Hg/Hg_2SO_4 (1N H_2SO_4) electrode. All anode potentials referred to are at the standard hydrogen electrode (SHE) at 80°C (26). Current-potential relations were studied by potentiostatic method. A Wenking potentiostat (Model ST72) and a Wenking scanning potentiometer (Model SMP72) were used. A Hokuto galvanostat (Model HA-104) was used for coulombic efficiency studies. All current-time and potential-time variations were recorded with a MFE 2100 series recorder. The potentials were also monitored with a Keithley 602 electrometer.

Materials.—Potassium hydroxide Baker analyzed reagent and sulfuric acid Hanawa extra pure reagent were used. Double-distilled water was used in preparation of all solutions. Methane gas was prepurified and supplied by the Chinese Petroleum Company. It was further purified by passing through an alkaline pyrogallol solution to ensure the complete removal of oxygen. Only one peak (methane) was observed in several gas-chromatographic analyses of the purified methane gas. The nitrogen used for purging and mixing with methane for partial pressure studies was at least 99.99% pure.

Results and Discussion

Rest potentials.—Table I shows the rest potentials of the platinized platinum electrode in various electrolytes saturated with methane. The electrolytes were 1.0N H_2SO_4 solutions and H_2SO_4 solutions partially neutralized with KOH to the desired pH values. The ionic strength of all electrolytes was kept the same throughout the experiments. The variation of rest potential with pH was approximately 70 mV (Fig. 1). Little effect of methane partial pressure in the range of 0.25-1 atm was noted. Similar pH and partial pressure effects were reported for other hydrocarbons (acetylene and ethylene) and maleic acid on platinum and gold electrodes (27-30), and interpretations as mixed potentials of various possible reactions were fully discussed (27). Schlatter (8) indicated that the rest potentials are probably determined largely by the concentration of hydrogen atoms resulting from dissociative adsorption of the hydrocarbons on the electrode.

Current-potential relations.—Tafel curves for methane oxidation in various electrolytes are shown in Fig. 2. The individual points represent quasi-steady-state values (current change less than 10%/hr) which were usually reached within 5 min for a potential change of 10 mV. Linear Tafel regions were observed with slopes of 70-75 mV which were close to 2.3 $RT/\mathbf{F}$. Above the linear region, mass transfer assumed significance and a limiting current region was found.

pH effects.—Figure 2 also shows that the curves shift in the negative potential direction as the pH increases. Data points taken from Fig. 2 at constant potential and constant current give $(\partial \log i/\partial \text{pH}) \sim 1$ and $(\partial V/\partial \text{pH}) \sim -70$ mV, as shown in Fig. 3 and 4.

Coulombic efficiency.—Any CO_2 contained in methane was first removed by passing the gas through concentrated potassium hydroxide solution. Then the procedure, as described in (26, 31), was slightly modified and used for the determination of the efficiency of CO_2 production. In the modified procedure, the exit gases from the anode compartment were passed through an absorption train which contained a cold trap, concentrated H_2SO_4, and two ascarite absorbers, in that order. The cold trap collected most of the water leaving the cell and the concentrated H_2SO_4 removed the remaining water from the gases before they passed through the ascarite absorbers. Ascarite absorbed CO_2 with the formation of water according to the reaction: $2NaOH + CO_2 \rightarrow Na_2CO_3 + H_2O$. Since ascarite is not a particularly good drying agent, it was therefore followed by a good desiccant $Mg(ClO_4)_2$ in the first absorber to take up any water that might escape. The second ascarite absorber was used for preventing back-diffusion of atmospheric CO_2 and moisture from getting into the first ascarite absorber. For a specified time

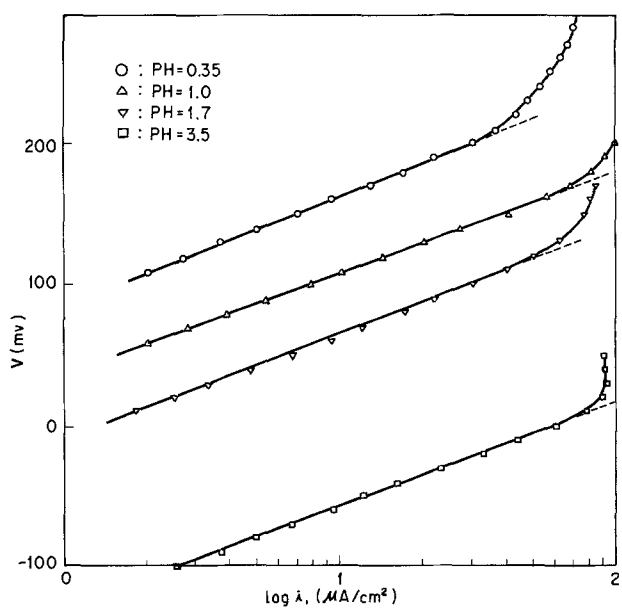

Fig. 2. Current-potential relations in electrolytes of various pH's at 80°C and $P = 1$ atm.

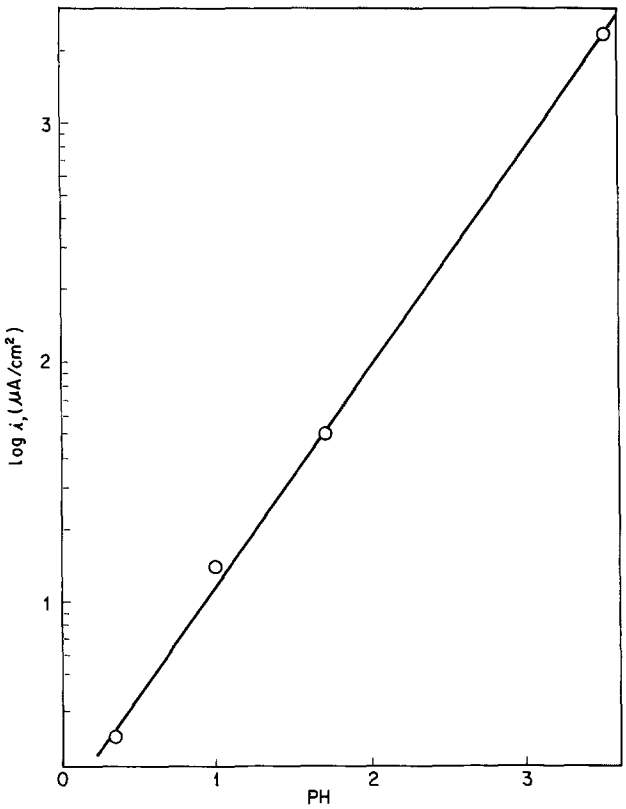

Fig. 3. Current-pH relations at constant potential (120 mV) and 80°C.

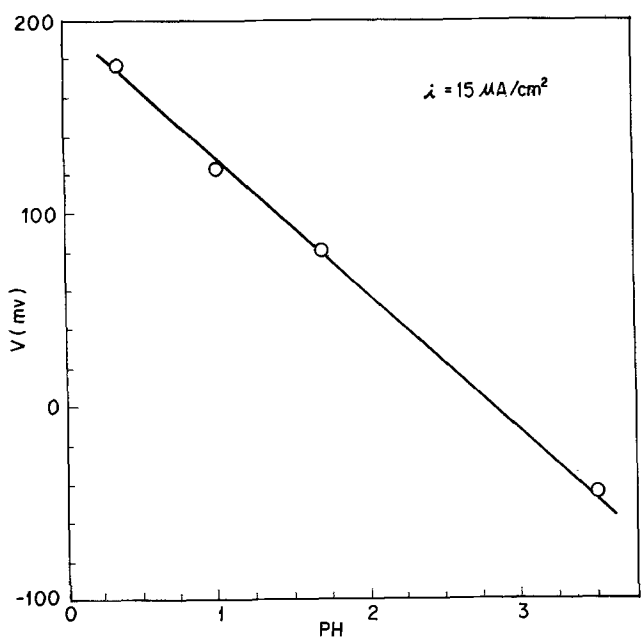

Fig. 4. Potential-pH relations at constant current density (15 μA/cm²) and 80°C.

period the CO_2 production was determined by the weight gain of the first ascarite absorber.

The coulombic efficiency for CO_2 production was determined in 1.0 H_2SO_4 electrolyte. A current density within the linear Tafel region was chosen in the study and a larger electrode was used to allow the use of a higher current. During the galvanostatic runs, anodic potentials were found to agree within 15 mV of the values read from Tafel region. Efficiencies close to 100% were obtained and results are given in Table II.

Temperature effect.—The effect of temperature on current density was measured potentiostatically at potentials within the linear Tafel region. Results are

(1 atm, 80°C, I = 2 mA, i = 22 μA/cm², 190 ± 15 mV, 48 hr)

Run no.	Weight of CO_2 gained (grams)	CO_2 efficiency (%)
1	0.0189	96
2	0.0195	99

Table III. Activation energies for the anodic oxidation of methane on platinized platinum electrode

Electrolyte	Potential, mV	Activation energy, kcal
1*N* H_2SO_4	140	30.0
	190	28.7

shown in Fig. 5. The calculated activation energies are reported in Table III.

Pressure effect.—Methane of a given partial pressure was passed through the anode compartment while the electrode potential was held constant. After a steady-state current was reached, the methane partial pressure was changed to another value and the corresponding change of current was recorded. For methane partial pressure between 0.25 and 1 atm, $(\partial \log i/\partial P)$ ~1.0 was observed (Fig. 6).

Reaction mechanism.—In connection with the reaction mechanism, there are four results of importance. (*i*) The high efficiency of CO_2 production indicates that no branching leading to products other than CO_2 and water occurs to any appreciable extent. (*ii*) With Langmuir-type adsorption, a Tafel slope of 2.3 $RT/\mathbf{F}$ generally indicates that the rate-determining step is a chemical reaction following the first electron transfer. (*iii*) The reaction order with methane is $(\partial \log i/\partial \log P)$ ~1. (*iv*) The pH effect is $(\partial \log i/\partial \text{pH})$ ~1. A mechanism which satisfies the above kinetic parameters may be formulated as

$$CH_4 = CH_3(\text{ads}) + H^+ + e^- \qquad [1]$$

$$CH_3(\text{ads}) \xrightarrow{\text{rds}} \text{intermediates} \qquad [2]$$

The rate expression, assuming Langmuir-type adsorption and a low surface coverage of the electrode, is

$$i = n\mathbf{F}k_2K_1P{a_{H^+}}^{-1}\exp(\mathbf{F}V/RT)$$

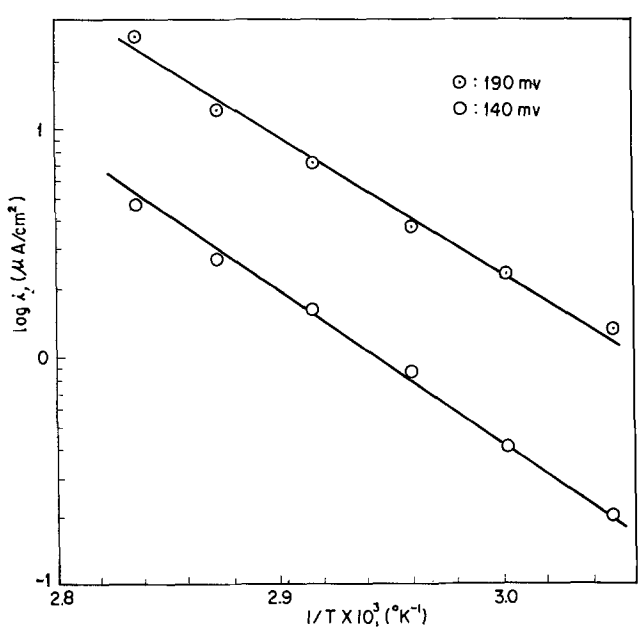

Fig. 5. Effect of temperature on current density in 1.0*N* H_2SO_4 solution, P = 1 atm.

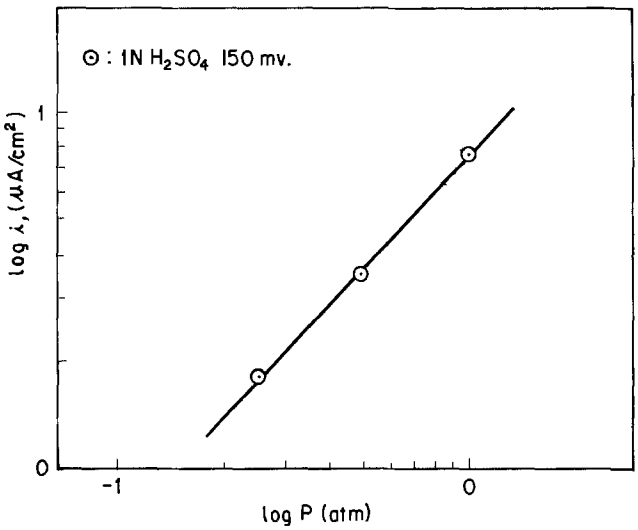

Fig. 6. Effect of methane partial pressure on current density at 80°C.

where n is the number of electrons transferred, k_2 the forward rate constant for [2], K_1 the ratio of forward and reverse rate constants for [1], a_{H+} the activity of hydrogen ion, and p the partial pressure of methane.

Table IV shows a comparison between the theoretical and experimental kinetic parameters. The proposed mechanism in this study is consistent with that described by Bockris, Gileadi, and Stoner from the investigation of other saturated hydrocarbons in phosphoric acid electrolytes (24).

Syntheses with Electrogenerated Halogens

Part I. Phosphorous Acid

D. A. White* and M. J. Dolan

Monsanto Company, St. Louis, Missouri 63166

ABSTRACT

A simple one step conversion of white phosphorus to phosphorous acid based on indirect electrolysis using electrogenerated halogens has been demonstrated.

Presently, the major industrial route to phosphorous acid involves the conversion of white phosphorus to the trichloride

$$1/4\ P_4 + 3/2\ Cl_2 \rightarrow PCl_3 \qquad [1]$$

followed by hydrolysis

$$PCl_3 + 3H_2O \rightarrow HPO(OH)_2 + 3HCl \qquad [2]$$

It should be noted that this route produces more hydrochloric acid than it does phosphorous acid. The disposal of large quantities of hydrochloric acid presents problems, but a closed loop can be achieved by reoxidation of the hydrochloric acid to chlorine. One of the most effective ways of doing this is via electrochemical oxidation (1)

$$3HCl \rightarrow 3/2\ H_2 + 3/2\ Cl_2 \qquad [3]$$

The over-all effect when this regeneration step is included is summarized as follows

$$1/4\ P_4 + 3H_2O \rightarrow HPO(OH)_2 + 3/2\ H_2 \qquad [4]$$

This effect is achieved in three separate steps and the objective of the present work has been to devise a one step route achieving the same results, Eq. [4], using indirect electrolysis involving electrogenerated halogens.

Experimental

Elemental phosphorus and other reagents were obtained from Fisher Scientific Company, Fairlawn, New Jersey. A sample of disodium hypophosphate, $Na_2H_2P_2O_6 \cdot 6H_2O$ was kindly supplied by M. M. Crutchfield.

Analysis.—The aqueous solutions obtained by oxidation of elemental phosphorus were analyzed by a combination of ^{31}P and ^{1}H NMR spectroscopy. For solutions in which the product concentration was less than *ca.* 1*M* (Table I, runs 1-3, 5, and 6), it was found that the ^{31}P NMR bands were broad and not suitable for measurement of the relative amounts of the various species present. However, if these solutions were made strongly basic with aqueous potassium hydroxide (50%), sharp bands were obtained. Sodium hydroxide was not suitable for this purpose, since the sodium salts of the product acids usually crystallized out of the basic solutions. The reason for the broadening in the acidic solutions is not known. After addition of a known quantity of methanol, the acidic solutions were examined by ^{1}H NMR and the quantity of phosphorous acid present was estimated from the relative areas of the $\underline{H}PO(OH)_2$ and $\underline{CH_3}OH$ resonances.

The identification of the products was by comparison of their ^{31}P NMR chemical shifts with those of authentic samples, which are shown in Table II. Because basic conditions were used for examining the reaction product mixture, the authentic samples were also made strongly basic. The doublet ^{1}H NMR resonance of phosphorous acid (7.08 ppm downfield from deuterated 3-trimethylsilylpropanesulfonic acid; $J(PH) = 684$ Hz; measured in the acidic solutions[1]) served to confirm the identity of the major product.

Apparatus.—The electrochemical cell was constructed from a 1 liter flange-jointed glass resin kettle, having a seven necked top (4 × 24/40, 3 × 10/18 standard taper joints). The necks were used for the two electrode connections, a stirrer, a water-cooled condenser, a thermometer, a nitrogen inlet, and for access to the electrolyte. The electrodes were graphite plates (grade 72C, St. Mary's Carbon Company, St. Mary's, Pennsylvania) (10 × 6 × 1.2 cm). They were maintained vertical, parallel, and 3 cm apart by 4 Teflon support rods which passed through the electrodes and fitted tightly against the inner surface of the resin kettle. The tight fit of the support rods permitted very vigorous stirring without moving the electrodes. Electrical contact with the electrodes was made via platinum wires.

A Sorenson d-c power supply, Model DCR 40-35A operating in its constant current mode, was used for the electrolyses. ^{31}P NMR spectra were measured at 40.55 MHz on a Varian Model HA-100 machine and ^{1}H NMR spectra at 60 MHz with a Varian Model A 56/60 machine.

Handling of white phosphorus.—White phosphorus is toxic and spontaneously inflammable in air. It can be safely handled under water. In the present work it was stored under water in a nitrogen-flushed glove box, washed with methanol, and dried in a stream of nitrogen before weighing. The cell was charged in the glove box and returned to it after completion of the electrolysis. Unreacted phosphorus was removed by filtration and destroyed by several weeks' contact with aqueous copper sulfate solution. The copper sulfate reacts almost instantly to form a surface coating of a copper phosphide, but prolonged contact was necessary to consume all of the phosphorus. A spray bottle of aqueous copper sulfate was used to treat accidental spills in air, and the sprayed material was then transferred to a large beaker containing other phosphorus residues. Unreacted white phosphorus tended to adhere to the electrodes. As much as possible was scraped off in the glove box. The last traces were then cautiously removed by sanding with wet emery paper, and finally by scrubbing with bleaching powder.

* Electrochemical Society Active Member.

Key words: indirect electrolysis, white phosphorus.

[1] $J(PH)$ for phosphorous acid varies considerably with *p*H [see Ref. (3)]. Thus, this value is quite different from that observed in basic solution (see Table II).

[c] Doublet, J(PH) = 564 Hz.
[d] Doublet, J(PH) = 585 Hz.
[e] Sample solution made up from $Na_2H_2P_2O_6 \cdot 6H_2O$, others made up from the acid.

Oxidation of white phosphorus.—A mixture of white phosphorus (102g; 3.29 mole) concentrated hydrobromic acid (48%; 20 ml), water (380 ml), and chloroform (200 ml) was added to the assembled nitrogen purged cell. The mixture was heated to 50° to melt the phosphorus. A constant current of 10A was then passed for 25.5 hr. Throughout the electrolysis a steady stream of nitrogen was passed over the electrolyte, and rapid stirring to mix the undissolved phosphorus and the aqueous and organic layers thoroughly was maintained. After a brief initial period the passage of the current maintained a gentle reflux and an electrolyte temperature of 56°.

In a nitrogen atmosphere, the aqueous layer of the cooled reaction mixture was separated and examined by ^1H and ^{31}P NMR spectroscopy, which showed the presence of phosphorous (1.99 mole), hypophosphoric (0.07 mole), and phosphoric (0.42 mole) acids. Unchanged phosphorus (0.65 g-atom) in the chloroform layer and around the walls of the cell was estimated by exhaustive electrooxidation to phosphoric acid, which was determined by ^{31}P NMR. Thus, the conversion of phosphorus is estimated at 80%, the combined yields of phosphorus acids at 96%, and the combined current efficiency for phosphorus acids at 91%.

Evaporation of the aqueous layer afforded a colorless viscous liquid, which was seeded with a crystal of phosphorous acid. The mixture was allowed to stand several hours at room temperature. The now mainly crystalline mass was pressure-filtered under a stream of dry nitrogen to give white crystals (111g) containing phosphorous (96% of P present), hypophosphoric, and phosphoric acids. The crystals were dissolved in water and the solution was evaporated until a mainly solid mass was obtained. Pressure filtration under dry nitrogen afforded white crystals (100g) of phosphorous acid in which no phosphorus containing impurities were detected by ^{31}P NMR. By ^1H NMR the purity was estimated at 97%, and by titration with iodine, 98%. The major impurity appears to be water. However, some hydrobromic acid was still present, since titration, using an ion-selective electrode, indicated a bromine content of 0.2%.

This experiment was similar to run 4 of Table I. That and the other experiments reported in Table I were carried out as described above to the point of determination of the product distributed and yield via ^{31}P and ^1H NMR. For those runs unreacted phosphorus was not measured and the product was not isolated as described above.

Oxidation of phosphorus acid.—Chemical.—Iodine (1.27g; 0.01 g-atom) was added to a solution of phosphorous acid (1.64g; 0.02 mole) in a mixture of water (9.5 ml) and aqueous hydriodic acid (58%; 0.5 ml). The mixture was heated to 60° and stirred at that temperature until all the iodine dissolved and a pale yellow solution was formed. About 1 hr was required. By ^{31}P NMR the phosphorus-containing species present were found to consist of phosphorous acid and phosphoric acid (24%; corresponding to a yield of 98%). No hypophosphoric acid was detected.

Electrochemical.—A solution of phosphorous acid (82g; 1.0 mole) was dissolved in aqueous hydriodic acid (58%; 40 ml diluted to 400 ml) and electrolyzed with a constant current of 10A for 1.4 hr. The solution was light brown during the electrolysis, and the passage of current maintained a temperature of 65°-70°. After switching off the current, the brown color dissipated and the solution was analyzed via ^{31}P NMR, which showed it to contain only phosphorous acid (75%) and phosphoric acid. Complete conversion to phosphoric acid was observed on passage of a current of 10A for a further 4 hr.

Results

Electrolysis of mixtures of white phosphorus and aqueous hydrobromic or hydriodic acids afforded mixtures of phosphorous, hypophosphoric, and phosphoric acids (Table I, runs 1 and 2). No attempt was made to convert all the phosphorus added, since it was considered desirable to have an excess present at all times, so that it, rather than the phosphorous acid produced, would react with the electrogenerated halogen. Nevertheless, higher oxidation state acids were produced. Another problem was the formation of a coating on the droplets of molten white phosphorus, which probably hindered contact of the halogen with the phosphorus. To alleviate the assumed further oxidation of phosphorous acid, subsequent experiments were carried out with a water-immiscible solvent present. The purpose of this was to extract the halogen from the aqueous phase in which it was generated. This should have two desirable effects: first, halogen and phosphorous acid formed would be in separate phases and this would hinder further oxidation of phosphorous acid formed; and second, the solvents used also dissolve white phosphorus, and contact between it and the halogen should be improved. The results did show a marked improvement in both selectivity to phosphorous acid and cur-

rent efficiency. Chloroform was preferred as the solvent because of its noninflammability. Benzene was also effective (Table I, run 6). Reflux of the solvent-water azeotropes (bp 56.3° for chloroform; 69.4° for benzene) provided a stable operating temperature.

Even with the solvent present, higher oxidation state acids were still formed. The presence of hypophosphoric in the product mixture suggests that further oxidation of phosphorous acid may not be entirely to blame. The oxidation of phosphorous acid by halogens is well known and is reported to give only phosphoric acid (4-6). To rule out the possibility that hypophosphoric acid may be a product at low conversions, the partial oxidation of phosphorous with iodine has been examined. At 25% conversion, phosphoric acid was detected as the only oxidation product. The hypophosphoric acid formed is evidently not formed by further oxidation of phosphorous acid. This may also be true of some of the phosphoric acid which is formed.

Discussion

Since phosphorous acid is in the middle of the range of oxidation states normally exhibited by phosphorus, selective oxidation was expected to be difficult. However, the strategy of always having unchanged white phosphorus present and using a water-immiscible solvent leads to quite high (75-80%) selectivities for phosphorous acid when the two heavier hydrohalic acids are used. When hydrochloric acid is used as the electrolyte, the lower selectivity may be due to higher reactivity of chlorine and/or its higher solubility in water. The direct electrochemical oxidation of white phosphorus has been reported (7, 8), but the selectivity to phosphorous acid was low (15-38%).

The conventional process (1, 2) for phosphorous acid achieves an essentially quantitative selectivity by distillation of the phosphorous trichloride. At that point, some pentachloride is removed and recycled to react with further phosphorus, giving more trichloride. This recycle allows quantitative conversion of phosphorus to the trichloride, which is then quantitatively hydrolyzed to phosphorous acid. Although the present process is not so selective, it has the distinct advantage of converting white phosphorus to phosphorous acid without any isolated intermediates in a single step, and without producing hydrochloric acid as a by-product.

Syntheses with Electrogenerated Halogens

Part II. Oxidation of Malonate Esters

Donald A. White*

Monsanto Company, Corporate Research Department, St. Louis, Missouri 63166

ABSTRACT

The indirect electrochemical oxidation of malonate esters (I) to ethane-1,1,2,2-tetracarboxylate esters (II) has been investigated in greater detail than previously reported. With acetonitrile or an alcohol as the solvent, ethenetetracarboxylate (III), propane-1,1,2,2,3,3-hexacarboxylate (IV), and ethane-1,1,2-tricarboxylate (V) esters were also formed. If the conversion of (I) was limited to 70%, by-product formation was low and 98% yields of (II) were obtained. In acetonitrile, current efficiency was comparable with the chemical yield, but with alcoholic solvents it was lower (70-80%) due to competing indirect oxidation of the alcohol to the corresponding alkyl formate (VI). The similar coupling of monosubstituted malonate esters (VII; giving VIII) shows a marked steric effect similar to that observed in some cyanoethylation reactions, suggesting that the coupling occurs via a nucleophilic displacement reaction. The steric effect rationalizes the absence of tetrameric and higher products. The similar cyclization of some bismalonate esters (IX; giving X) is also reported.

The electrochemical conversion (Eq. [1]) of malonate esters (I) to ethane-1,1,2,2-tetracarboxylate esters (II) has been achieved via direct oxidation of the malonate carbanion (1-3) or via indirect oxidation in systems containing a halide (usually iodide) electrolyte (4, 5). This conversion was of interest as a route to tetrasodium ethane-1,1,2,2-tetracarboxylate, which has useful detergent-builder properties (6, 7). The direct oxidation gives a mixture of products (2, 3) in addition to low current efficiencies. At the time this work was initiated, it appeared that current efficiencies were also low for the indirect reaction [24% (ethanol solvent); 35% (acetonitrile solvent)] (4). However, the corresponding chemical oxidations of the malonate carbanion by iodine (8, 9) or bromine (10) have been reported to give ethanetetracarboxylate esters (II) in high yield (9, 10). This suggested that it should be possible to obtain a high efficiency, indirect electrochemical conversion

Key words: indirect electrolysis, carbanion oxidation, alcohol oxidation, cyanoethylation.

and, indeed, during the course of this work Osa and co-workers (5) reported current efficiencies of up to 82% when the solvent was acetonitrile. The present work is concerned mainly with the use of alcoholic solvents, but some experiments [which show even higher current efficiencies than those reported by Osa and co-workers (5)] with acetonitrile as the solvent are reported for comparison with the use of alcoholic solvents. Other work in this laboratory on this conversion (Eq. [1]) has been concerned with a paired system in which acrylate esters are simultaneously converted to adipate esters (11).

Experimental

Solvents, electrolytes, reagents, the majority of the starting materials (dimethyl and diethyl malonate and diethyl methyl and ethyl malonate) and some authentic samples of products (triethyl ethane-1,1,2-tricarboxylate and the formate esters and other products formed by oxidation of methanol and ethanol) were obtained from Fisher Scientific Company, Fairlawn, New Jersey. Sodium bromide and iodide were dried *in vacuo* at 80°. Tetrabutylammonium iodide was recrystallized from tetrahydrofuran and then dried *in vacuo*. The substituted malonate esters were purified by distillation. The remaining compounds were used as supplied. Other starting materials [tetramethyl (12) and tetraethyl (13) propane-1,1,3,3-tetracarboxylate, tetramethyl butane-1,1,4,4-tetracarboxylate (14) and tetramethyl 3-phenylpropane-1,1,2,2-tetracarboxylate (15)] and some authentic product samples [hexaethyl propane-1,1,2,2,3,3-hexacarboxylate (16), trimethyl ethane-1,1,2-tricarboxylate (17), and diethyl bis (2-cyanoethyl) malonate (18)] were prepared by literature methods. Hexamethyl propane-1,1,2,2,3,3-hexacarboxylate was a sample prepared according to a procedure published for the hexaethyl ester (19). For ethanetetracarboxylate esters the present procedures were found to be the most convenient and economical synthetic route. Authentic samples of ethenetetracarboxylate esters were synthesized via a procedure described below.

GLC analyses of the malonate and substituted malonate ester oxidation products were carried out with a 6 ft × ⅛ in. stainless steel column packed with 5% OV-17 on Gas Chrom Q (100° programmed at 10°/min to 300°). For methanol or ethanol oxidation products a similarly sized column packed with Porapak Q (80° programmed at 10°/min to 200°) was used. A Hewlett-Packard F and M Model 5750 machine was used for the GLC analyses. Hexamethyl propane-1,1,2,2,3,3,-hexacarboxylate sometimes underwent decomposition via the reverse Michael reaction (reverse of reaction [3]) in the GLC injection port. The GLC analysis was supplemented by an NMR determination of this compound based on the area of its methine proton resonance. The similar resonance of the hexaethyl ester was obscured (at 60 MHz) by that of the ethyl group methylene protons, and it was not reliably determined. NMR spectra at 60 MHz were obtained using a Varian Model T-60 or A-56/60 machine. Elemental analyses, solution molecular weight measurements, and mass spectra were determined in this department.

For the preparative electrochemical reactions, a Sorenson Model DCR 80-6B power supply operating in its constant current mode was used. Small-scale preparative electrochemical reactions were carried out in the cell (Fig. 1) with platinum electrodes (as shown) or graphite electrodes. The graphite electrodes were 12 × ¼ in. graphite rods (Laboratory Supply and Equipment Company, Chevy Chase, Maryland), and were discarded after both ends had been used. The platinum electrodes were washed with acetone, followed by washing with water, and then heated to red heat in a flame before reuse. For larger scale preparative experiments the electrode assembly used in the small cell was transferred to a commercial 3 necked flask having a central 34/45 standard taper joint. The remaining necks in both small and large cells were used to attach a water-cooled condenser and a thermometer. For runs performed under reflux, the heating effect of current passage was used to maintain reflux. In other cases, the temperature was kept down by placing the cell in a bath of flowing cold water. Analytical data and NMR spectra are shown in Tables I and II, respectively.

Ethenetetracarboxylate esters.—Authentic samples of these compounds were obtained by the following procedure, which was found to be more convenient than that reported in the literature (20). Diethyl bromomalonate (120g; 0.5 mole) (21) was dissolved in dimethylformamide (250 ml). Potassium carbonate (69g; 0.5 mole) was added and the mixture was stirred magnetically for 18 hr (this was convenient, but the temperature behavior of the mixture—a rise to 52° after 45 min followed by a fall back to ambient—suggests that a shorter time period might be used). The mixture was filtered and dimethylformamide was used to wash the white residue. Evaporation *in vacuo* of the combined filtrate and washings yielded an oily residue which was taken up in ether. The ether solution was freed of traces of salts by filtration and then evaporated. The oil obtained crystallized on standing. It was recrystallized from ethanol (30 ml) to give tetraethyl ethenetetracarboxylate (IIIb; 52g; 67%), mp 55°-56° [Ref. (8) mp 56°].[1] Analytical data are shown in Table I.

A similar reaction using dimethyl bromomalonate (106g; 0.5 mole), instead of the diethyl ester, was worked up by addition of water (*ca.* 1 liter) to the filtered dimethylformamide solution. The product, which crystallized out as long needles, was removed by

[1] This value is more typical than the rather low figure in the reference already cited (20).

filtration, washed with water, washed with methanol, and recrystallized from methanol. In this way tetramethyl ethenetetracarboxylate was obtained (IIIa; 56g; 88%), mp 119°-120° [Ref. (22) mp 121°]. Analytical data are shown in Table I.

Oxidation of malonate esters.—Dimethyl malonate.— A 1 liter flask was equipped with graphite rod electrodes inserted in the electrode adaptor shown in Fig. 1. The flask was charged with dimethyl malonate (264g; 2.00 mole), sodium iodide (30g; 0.20 mole), and methanol (500 ml). This mixture was stirred magnetically until homogeneous, and was then heated to 60°. A water-cooled reflux condenser was attached and the remaining neck was stoppered. A constant current of 3A was passed for 19 hr ($2.13F \equiv 1.06$ F/mole of ester). Throughout this reaction time the electrolyte was pale yellow and was maintained at a gentle reflux by the passage of the current. Toward the end of the electrolysis, white crystals separated out. The mixture was allowed to cool to room temperature. More crystals separated and the liquid became brown. The crystals were removed by filtration and washed with methanol, which was chilled to 5°. The crystals

were washed with chilled methanol with agitation in a blender to break up the large crystals. Filtration and air drying afforded a white solid, identified by its NMR spectrum as tetramethyl ethanetetracarboxylate (IIa; 210g; 0.80 mole). A small sample was recrystallized from methanol and had the mp 135.5°-137° [Ref. (2) mp 136°-137°)]. Analytical data are shown in Table I.

The filtrates and washings were combined after separation of this product, and the solvent was removed *in vacuo*. The residue was taken up in chloroform, washed with water, washed with aqueous sodium bisulfite, and water again. The chloroform solution was then dried ($CaSO_4$), filtered, and evaporated *in vacuo*. The solid-liquid mixture (51g) was made homogeneous by heating to 100°, and a sample was removed for analysis by NMR and GLC. The mixture was found to contain unchanged dimethyl malonate (26g; 0.20 mole), tetramethyl ethanetetracarboxylate (IIa; 4.8g; 0.018 mole), tetramethyl ethenetetracarboxylate (IIIa; 6.6g; 0.025 mole), and hexamethyl propanehexacarboxylate (IVa; 13.6g; 0.035 mole). Combining this analytical data with the quantity of isolated product shown above gives the conversion yield, and current efficiency figures shown in Table III, run 1.

Other reactions shown in Table III (runs 2-4, 12) were carried out similarly. In run 12 the material which crystallized out from the cooled electrolyte was a mixture of ethanetetracarboxylate and propanehexacarboxylate esters.

[a] Reactions under reflux except runs 10 (120°) and 11 (55°-60°). Considerable cathode corrosion occurred in run 10. Abbreviations: nd = not detected, nm = not measured.
[b] Combined current efficiencies for all malonate ester oxidation products (II + III + IV + V).

Diethyl malonate.—This reaction was carried out using a 500 ml, 3 necked flask containing diethyl malonate (160g; 1.00 mole), sodium iodide (30g; 0.2 mole), and ethanol (200 ml) as described above for the dimethyl ester. A current of 2.2A was passed for 12.3 hr (1.02 *F*/mole), after which the cell and contents were cooled to 5°. Filtration afforded a crude product (106g), which was recrystallized from ethanol (110 ml) to give pure tetraethyl ethanetetracarboxylate (IIb; 99g; 0.31 mole) mp 74°-75° [Ref. (1) mp 74°-75°]. Analytical data are shown in Table I.

The filtrates and washings from both the original filtration of the reaction mixture and from the recrystallization were combined and analyzed by GLC. Unchanged diethyl malonate (48g; 0.30 mole), tetraethyl ethanetetracarboxylate (IIb; 11g; 0.035 mole), and traces of tetraethyl ethenetetracarboxylate (IIIb) and triethyl ethane-1,1,2-tricarboxylate (Vb) were found. These data are summarized in Table III, run 5.

The reactions shown in Table III, runs 5-10 were carried out similarly, except that in run 9 no product crystallized out from the cooled electrolyte. Triethyl ethane-1,1,2-tricarboxylate was obtained via work up and fractional distillation of run 9, confirming the presence of this unexpected product. Tetrabutylammonium iodide was recovered unchanged from runs 9 and 10. After recrystallization from tetrahydrofuran, the "yield" of recovered material was in both cases *ca.* 90%. It had the mp of 143°-145° [Ref. (22) mp 146°].

Oxidation of alcohols.—Methanol.—The cell shown (Fig. 1) was charged with methanol (64g; 2.0 moles) and sodium iodide (3.0g; 0.02 mole). A water-cooled condenser, solid carbon dioxide cooled trap, and drying tube ($CaSO_4$) were attached in series via one neck, and the remaining unused neck was stoppered. A constant current of 1.8A was passed for 32 hr (2.0*F*). After a few minutes, the electrolyte reached reflux temperature and the cell voltage settled out at 12V. At the end of the electrolysis the cell voltage had increased very slightly to 13.5V. The liquid (15g) in the trap was identified by GLC and NMR as a mixture of methyl formate (13g) and methanol (2.0g). Small traces of methylal and methyl iodide were also detected by GLC. The liquid (47g) remaining in the cell contained methyl formate (6.6g) and methanol (36g). The yield of methyl formate based on methanol consumed is 81%, and the current efficiency is 65% (requires 4 *F*/mole of ester produced).

Ethanol.—In the apparatus used for methanol oxidation, a solution of sodium iodide (60g; 0.04 mole) in ethanol (46g; 1.0 mole) was electrolyzed. The initial current (2.0A), which produced reflux of the electrolyte, could not be maintained due to cell voltage increase (from 10 to 15V after 1 hr). The current was gradually reduced and the reaction terminated after passage of 0.50*F*. Along with the cell voltage increase, precipitation of a gelatinous solid was also observed. The trap liquid (3.05g) contained ethyl formate (2.0g; 27 mmoles), ethanol (0.67g; 15 mmoles) ethyl methyl ether (0.15g; 2.5 mmoles), methyl iodide (0.23g; 1.6 mmoles), and a trace of acetaldehyde. Further ethyl formate (0.35g; 4.8 mmoles) was found in the liquid in the cell. The current efficiency for ethyl formate is, thus, 51% (requires 8 *F*/mole of ester produced). The solid (0.26g) formed was removed by filtration. It was white, water-soluble and evolved carbon dioxide (detected with a drop of saturated calcium hydroxide suspended from a glass rod), on addition of dilute acid.

Chemical oxidation of methanol.—A solution of sodium methoxide (0.83*M*, 100 ml) was "titrated" with a solution of iodine (1.00 g-atom/liter) in methanol until a permanent yellow color developed. This required only 5 ml of the iodine solution (*i.e.*, 0.06 g-atom/mole of sodium methoxide). The experiment was repeated with a refluxing solution of sodium methoxide (0.83*M*, 100 ml) contained in a 3 necked flask equipped with a reflux condenser and burette. In this case, much more iodine solution (73 ml; 0.88 g-atom/mole of sodium methoxide) was required to produce a permanent yellow color. Methyl formate was detected as the product of this latter experiment via GLC.

Oxidation of monosubstituted malonate esters.—Diethyl methylmalonate.—A mixture of diethyl methylmalonate (VIIa; 17.4g; 0.1 mole), sodium iodide (1.5g; 0.01 mole) and ethanol (20 ml) was electrolyzed with a constant current of 1.5A for 4 hr in the cell shown (Fig. 1). The electrolyte quickly reached reflux temperature. After *ca.* 15 min of electrolysis, a solid began to precipitate and the cell voltage to increase (*cf.*, "oxidation of ethanol" above). From that point on, the polarity of the electrodes was reversed every 30 sec, which prevented the cell voltage from getting too high. The cooled, filtered electrolyte was evaporated and the oil obtained was taken up in ether. Washing of the ether solution with aqueous sodium thiosulfate decolorized the ether solution, but, on exposure to air, it became brown again. Consequently, the solution was alternately purged with air and shaken with aqueous sodium thiosulfate until it was permanently decolorized [evidently, a compound liberating iodine on exposure to air was present, perhaps diethyl iodo(methyl)malonate, the formation of which has been observed when the carbanion is treated with iodine (23) or when the ester is electrolyzed in acetonitrile containing potassium iodide (24)]. The ether solution was then washed with water, dried ($CaSO_4$), filtered, and evaporated. The oil obtained was distilled and three fractions [(*i*) 3.2g, bp 45°-50° (0.1 mmole); (*ii*) 3.9g, bp 50°-118° (0.1 mmole); and (*iii*) 8.3g, bp 118°-120° (0.1 mmole)] were collected. Fraction (*iii*) was identified as tetraethyl butane-2,2,3,3-tetracarboxylate (VIIIa) via its NMR spectrum (Table II). It was

redistilled and a center cut was taken for analysis (data in Table I).

Two minor products were tentatively identified by GLC/mass spectroscopic examination of fraction (*ii*) as diethyl ethoxy(methyl)malonate and triethyl butane-2,2,3-tricarboxylate [*cf.* (V), formed in oxidation of unsubstituted malonate esters]. Fraction (*i*) appeared to be a mixture (*ca.* 2:1M) of the starting material and the ethoxy compound, and showed a quartet NMR resonance due to the ethoxy group at 3.60 ppm downfield from internal tetramethylsilane. In a repeat experiment, the current efficiency, after passage of 1.0 *F*/mole, was estimated at 47% using the isolated compound (VIIIa) as a standard.

In a similar oxidation of diethyl ethylmalonate (VIIb), a very small quantity of the expected product appeared to be formed and was tentatively identified via GLC/mass spectroscopy. The current efficiency was crudely estimated by assuming a GLC response factor similar to that of (VIIIa). In this way the current efficiency, after passage of 1.0 *F*/mole, appeared to be *ca.* 0.3%.

Cyclization reactions.—Oxidation of the compounds (IX) was carried out in a manner similar to the oxidation of diethyl methylmalonate described above except graphite electrodes were used, without polarity reversal, and the products were isolated after passage of 1.0 *F*/mole (IXa and b) or 1.5 *F*/mole (IXc). The products isolated were tetramethyl cyclopropane-1,1,2,2-tetracarboxylate [Xa, mp 70°-71° (from methanol), Ref. (25) mp 71.5°-72°], tetraethyl cyclopropane-1,1,2,2-tetracarboxylate [Xb, mp 44°-45° (from ethanol), Ref. (26) mp 43°], and tetramethyl cyclobutane-1,1,2,2-tetracarboxylate [Xc, mp 80.5°-81° (from cyclohexane/benzene, 70%/30%)]. Analytical data are shown in Table I. All three compounds gave mass spectra consistent with their structures. Current efficiencies, after passage of 1.0 *F*/mole, shown in Table III were estimated via GLC using these isolated samples.

Hexamethyl propane-1,1,2,2,3,3-hexacarboxylate.—A mixture of the ester (11.8g; 30 mmoles), sodium iodide (1.5g; 10 mmoles), and methanol (40 ml) was placed in a cell similar to that shown (Fig. 1), but with graphite electrodes. A constant current of 1.8A was passed for 12 hr (27 *F*/mole). Within a few minutes, the electrolyte reached reflux temperature and the solid ester dissolved. After electrolysis, the electrolyte was evaporated to dryness and the residue was taken up in chloroform. The solution was washed (water, aqueous sodium thiosulfate, water again), dried ($CaSO_4$), filtered, and evaporated. The semisolid residue (11.3g) was analyzed by NMR and GLC and was found to contain unchanged starting material (6.3g; 16 mmoles), tetramethyl ethenetetracarboxylate (IIIa; 3.1g; 12 mmoles), dimethyl malonate (Ia; 1.2g; 9.0 mmoles), and tetramethyl ethanetetracarboxylate (0.3g; 1.1 mmoles).

Cyanoethylation reactions.—Tetramethyl ethane-1,1,2,2-tetracarboxylate.—The ester was cyanoethylated by the method of Koelsch and Sjolander (15). A mixture of tetramethyl ethanetetracarboxylate (78.6g; 0.3 mole), acrylonitrile (150 ml), and *t*-butanol (450 ml) saturated with potassium hydroxide was stirred under reflux for 20 hr. The mixture was cooled and the residue partitioned between ether and water. A white solid which dissolved in neither phase was removed by filtration. It was washed with methanol and dried to give tetramethyl 1,6-dicyanohexane-3,3,4,4-tetracarboxylate (XIIIa; 23g; 21%). This material appeared to be pure by NMR, but was recrystallized from methanol (1200 ml) before analysis (data in Table I). The recrystallized sample had mp 169°-170.5°.

After removal of this compound, the ether layer of the filtrate was separated and washed with water until the washings were neutral. Drying ($CaSO_4$), filtration, and evaporation yielded crude tetramethyl 4-cyanobutane-1,1,2,2-tetracarboxylate (XIIa; 65g; 69%). It was recrystallized from methanol (50 ml), giving the pure product (23g), mp 83°-84.5° [Ref. (15) mp 84°-86°].

Similar treatment of tetramethyl 3-phenylpropane-1,1,2,2-tetracarboxylate (XIIb) led to a 25% conversion to tetramethyl 5-cyano-1-phenylpentane-2,2,3,3-tetracarboxylate (XIIIb). A small amount of the latter was separated by 6 fractional crystallizations from methanol, and it had the mp 101°-102°. Analytical data are shown in Table I. The conversion reported was estimated by NMR, using the isolated product as a reference sample.

Hexaethyl propane-1,1,2,2,3,3-hexacarboxylate.—A mixture of the ester (4.76g; 0.01 mole), acrylonitrile (5 ml), and *t*-butanol (20 ml) saturated with potassium hydroxide was refluxed for 20 hr. The cooled solution was acidified with acetic acid and filtered (the solid residue appeared to be acrylonitrile polymer). The filtrate was evaporated to dryness, and the oil (5.7g) obtained was examined by NMR and GLC, which showed it to be an approximately equimolar mixture of tetraethyl ethenetetracarboxylate (IIIb) and diethyl bis(2-cyanoethyl)malonate (XI). The oil was taken up in ethanol (25 ml) and the solution was cooled to −78°. The crystals formed were removed by filtration and identified as the latter compound (XI; 0.5g), mp 61°-62° [Ref. (18), mp 62°]. This isolation of a small amount of one of the products confirms the analytical results, and quantitative separation of the products was not attempted.

Results

Oxidation of malonate esters.—Some typical results, using sodium iodide as the electrolyte and acetonitrile or the alcohol corresponding to the ester (to avoid ester interchange) as the solvent, are shown in Table III, runs 1-8. Ethanetetracarboxylate esters (II) were obtained in excellent (98-99%) yield when the conversion of the malonate ester was limited to *ca.* 70% (*cf.*, runs 1, 2, 7, and 8). Even at conversions up to 90%, yields were still *ca.* 90%. By-products were ethenetetracarboxylate (III), propanehexacarboxylate (IV), and ethane-1,1,2-tricarboxylate (V) esters. Compounds (III) and (IV) have been previously observed as by-products of the oxidation of malonate esters (2, 3, 5). They presumably arise via further oxidation of the major product (Eq. [2]) and via the Michael reaction (Eq. [3]), or cross-coupling of product and starting material (Eq. [4]). Compounds (V) may be formed by attack of iodide ion on (II), as shown (Eq. [5]) [*cf.* similar reactions of other esters (27)].

The conditions of these experiments were similar to those of Okubo and Tsutsumi (4), except that the more soluble sodium iodide was used in place of the potassium salt, and the reactions were carried out at reflux temperature (*vs.* 10°) (4). The effect of temperature is significant, since below 50° iodine generated at the anode [see reaction mechanism [6-10]; note this neglects equilibria involving I_2 and I_3^- and (in alcohol solutions) RO^- and $\overline{C}H(COOR)_2$] accumulated in the solution.

Cathode: $2M^+ + 2e^- \rightarrow 2M$ [6]

Solution:

$2M + 2CH_2X_2 \rightarrow 2M^+ + 2\overline{C}HX_2 + H_2$ [7]

$\overline{C}HX_2 + I_2 \rightarrow ICHX_2 + I^-$ [8]

$\overline{C}HX_2 + ICHX_2 \rightarrow CHX_2CHX_2 + I^-$ [9]

Anode: $2I^- \rightarrow I_2 + 2e^-$ [10]

Over-all: $2CH_2X_2 \rightarrow CHX_2CHX_2 + H_2$ [1]

$$RCHX_2 + e^- \rightarrow R\dot{C}X_2 + \tfrac{1}{2} H_2 \quad [11]$$

Cathodic reduction of dissolved iodine would, of course, lead to reduced current efficiencies. At reflux temperatures the solutions were a very pale yellow. The essentially quantitative usage of current in forming malonate ester oxidation products, when the solvent is acetonitrile (Table III, last column, runs 4, 7, and 8), suggests that this recycling has been minimized. The lower values observed when the solvent is methanol (85-90%) or ethanol (70-75%) appear to be due to competing solvent oxidation, and this is discussed below.

Even though acetonitrile gives the best current efficiencies, the use of methanol has some potential advantages. Inexpensive graphite electrodes may be used; these were considerably corroded when used in acetonitrile solutions. Another feature is that the product (Ia) is not very soluble in methanol and, in fact, crystallizes out from the refluxing methanol solution during the electrolysis, this would lend itself to a means of continuously removing product in a continuous industrial process.

Dimethylformamide was a poor solvent for the present reaction (Table III, run 9), though this may be due partially to poor choice of conditions (rather high temperature, graphite electrodes which were corroded). Ethanetricarboxylate ester (V) was positively identified as a product by isolation from this reaction. Tetrabutylammonium iodide was also effective as the electrolyte in this solvent (Table III, run 10). This was unexpected, since indirect cathodic formation of the malonate carbanion via alkali metal ion reduction (Eq. [6], [7]) had been assumed. With tetraalkylammonium salts as the electrolyte malonate esters, they undergo direct cathodic reduction (11), as postulated by Osa *et al.* (5). This phenomenon will be discussed elsewhere, but it should be noted that direct reduction of other carbon acids has been observed by other workers (28).

Use of tetrabutylammonium iodide in acetonitrile for the oxidation of malonate esters gave results (Table III, run 11) almost as good as those observed with sodium iodide. This reaction presumably involves generation of the carbanion via direct reduction. Sodium bromide was briefly investigated as a possible electrolyte (Table III, run 12), but it gave very large amounts of propanehexacarboxylate ester (IV). The reason for this is not known, but a different mechanism may operate in this case. It was observed in a divided cell experiment that the malonate esters (Ia and Ib) were readily brominated by anodically generated bromine, whereas they did not react with iodine generated in the same way. Considerable quantities of the dibromomalonate ester were formed even at low conversions, which would give rise to large amounts of either (III) or (IV) in the undivided cell, even at low conversions, as is observed

Oxidation of methanol and ethanol.—Electrolysis of refluxing methanol containing sodium iodide in an undivided cell with either graphite or platinum electrodes led to a smooth reaction giving methyl formate in *ca.* 65% current efficiency. Presumably, it is formed via formaldehyde (Eq. [10], [12]-[14]), which is further oxidized via the hemiacetal (Eq. [10], [12], [15]-[17]). The net effect is as shown (Eq. [18]). This reaction shows a temperature effect similar to that observed in the malonate ester oxidation, but more pronounced. In this case there was essentially no reaction of the electrogenerated iodine at room temperature, whereas in the malonate oxidation, the problem was rather that the reaction did not consume all of the iodine formed. The same temperature effect was observed in the chemical oxidation of sodium methoxide in methanol by iodine. There was very little consumption of iodine at room temperature (0.05 g-atom/mole CH_3ONa), but in refluxing methanol the consumption (0.88 g-atom/mole) approached that expected (Eq. [19]). In this latter experiment methyl formate was

$$4CH_3ONa + 2I_2 \rightarrow HCOOCH_3 + 4NaI + 2CH_3OH \quad [19]$$

detected by GLC/mass spectroscopy.

The ethanol oxidation was less smooth than that of its lower homolog; the cell voltage continually increased and a solid precipitated during the electrolysis (in the methanol oxidation the cell voltage was constant once reflux temperature had been attained and the electrolyte was clear throughout). In addition to ethyl formate, other products detected were ethyl methyl ether and methyl iodide. A trace of acetaldehyde was also found. Although the quantities of ethyl methyl ether and methyl iodide were less than would be expected, their presence and that of acetaldehyde suggests the mechanism shown, Eq. [20]-[24], involving oxidation to the aldehyde (Eq. [20]), iodination of the α-carbon atom (Eq. [21]), nucleophilic displacement of CI_3 by ethoxide ion (Eq. [22]), reduction of the iodoform also formed in (Eq. [22]) to methyl iodide (Eq. [23]), and reaction of methyl iodide in a Williamson ether synthesis-type reaction (Eq. [24]). An additional reduction of ethanol (Eq. [25]) is necessary to balance the electron count, and the net effect of Eq. [20]-[25] is summarized by Eq. [26]. As noted, the current efficiency for ethyl formate was low, but the reason for this has not been examined. However the solid which precipitated during the electrolysis liberates carbon dioxide on treatment with acid, and this suggests that oxidation of ethanol to carbon dioxide may also occur.

$$C_2H_5O^- + CH_3I \rightarrow CH_3OC_2H_5 + I^- \quad [24]$$

$$2C_2H_5OH + 2e^- \rightarrow 2C_2H_5O^- + H_2 \quad [25]$$

$$3C_2H_5OH \xrightarrow{M^+I^-,\ 8F} HCOOC_2H_5 + C_2H_5OCH_3 + 2H_2 \quad [26]$$

Electrooxidation of ethanol

The formate esters, which are rather volatile, were collected by passing the cell gas effluent (mainly hydrogen) through a trap at −78°. When a similar trap was attached to a cell in which (Ia) was being oxidized in methanol solution, methyl formate was again found in the trap liquid, suggesting that solvent oxidation may be a source of current efficiency losses when malonate esters are oxidized in alcoholic solvents.

Oxidation of monosubstituted malonate esters.—Oxidation of the simple alkyl substituted compounds (VII) and the cyclization of the bismalonate esters (IX) has been investigated, and the results are summarized in Table IV. Oxidation of diethyl methylmalonate (VIIa) proceeds as expected, Eq. [27], but the current efficiency is low (47%) compared to that of the similar oxidation of diethyl malonate (73%; Table III, run 6). For diethyl ethylmalonate there is almost no reaction; a small amount of the expected product was detected by GLC/mass spectroscopy.

In contrast, the intramolecular reactions (Eq. [28]) proceeded with current efficiencies comparable with (IXa and b) or just less than (IXc) those observed for the corresponding unsubstituted malonate esters.

Since hexaethyl cyclopropanehexacarboxylate has been obtained (29) by treatment of compound (IVb) with base followed by bromine, a similar cyclization of the esters (IV) was expected on electrolysis with sodium iodide as the electrolyte. In fact, what was observed was simply the reverse Michael reaction (reverse of reaction [3]). Some of the malonate ester formed was oxidized to ethanetetracarboxylate ester and perhaps further to ethenetetracarboxylate ester.

IVb

The indirect electrochemical oxidation of malonate esters (Eq. [1]) emerges from this study as a useful high yield synthetic reaction. In addition to the facility with which ethanetetracarboxylate esters are formed, the pronounced detrimental effect of substituents (Table IV, runs 1, 2) serves to minimize further oxidation of the product. This steric effect is consistent with mechanism suggested (Eq. [6]-[10]), which involves a nucleophilic displacement reaction (Eq. [9]) as the actual coupling process. At high conversions the intermediates shown in Table V may be present and available for similar coupling reactions. For the nucleophiles, the relative reactivity indicated is based on their reaction with acrylonitrile reported here and in the literature. Diethyl malonate is very easily biscyanoethylated (Eq. [29]) (18, 30), indicating the high reactivity of the monomeric anion (XIV) toward acrylonitrile. Much more vigorous conditions are necessary for monocyanoethylation of tetramethyl ethanetetracarboxylate (Eq. [30]) (15), indicating the lower nucleophilicity of the dimeric anion (XV). The trimeric anion can be regarded as a compound of the general type (XII). Such compounds have been reported (15) not to undergo cyanoethylation. This is not strictly true since (XIIIa) has been obtained in the present work as a by-product in the literature (15) preparation of (XIIa). Also, (XIIb) has been observed to undergo a 25% conversion to (XIIIb) under similar conditions. The low conversions of (XIIa) and (XIIb) indicate very low reactivity of the carbanions toward acrylonitrile. For the trimeric anion (XVI), itself, the reverse Michael reaction occurs rather than cyanoethylation (Eq. [32]). The parallel between cyanoethylation and the electrochemical coupling reactions is emphasized by occurrence of the reverse Michael reaction on attempted cyclization of propanehexacarboxylate esters, also reported here. Thus, there is no evidence to suggest that the trimeric anion has any nucleophilic activity at all, even toward a very active

Table V. Possible reactive intermediates in malonate ester oxidation reaction mixtures at high conversions

Nucleophile	Relative reactivity	Electrophile	Relative Reactivity
$\bar{C}HX_2$ XIV	Good	$ICHX_2$ XVII	Good
$\bar{C}X_2CHX_2$ XV	Poor	ICX_2CHX_2 XVIII	?
$\bar{C}X_2CX_2CHX_2$ XVI	?	$ICX_2CX_2CHX_2$ XIX	?

electrophile such as acrylonitrile. For the electrophiles (Table V), nothing is known of their reactivity. However, the malonate carbanion reacts with both chloro- and bromo-malonate esters (31, 32), to give (II), and it seems likely that iodomalonate esters would react readily with the same carbanion. Except in special situations (33) tertiary halides are poor electrophiles and the dimeric and trimeric species should be, at best, poor electrophiles. It is noteworthy that observed coupling products (II) and (IV) can be explained by the interactions of (XIV) + (XVII) and of (XV) + (XVII). Compound (IV) could also arise from the interaction of (XIV) and (XVIII), but it seems more likely that this interaction is a source of the olefin (III) [although a poor electrophile, (XVIII) should still function effectively as a carbon acid]. The absence of higher molecular weight products, such as tetramers, is evidently due to the unfavorable nucleophile-electrophile interactions required for their formation.

The noninvolvement of radical coupling in the present reaction is evident from comparison with the reported (2) direct electrochemical oxidation of the carbanion derived from diethyl methylmalonate. Radical coupling appears to be involved in that reaction and a radical disproportionation prior to coupling leads to an additional product not observed in the present indirect oxidation. Also, it has been observed that the present reactions are unaffected by the presence of butadiene, which would be expected to trap any radicals formed.

Breakdown of Oxide Films on Nickel

B. MacDougall* and M. Cohen*

National Research Council of Canada, Division of Chemistry, Ottawa, Ontario, Canada K1A 0R9

ABSTRACT

Oxide films have been formed on nickel by either electropolishing in H_2SO_4 or anodizing at different potentials and times in *p*H 2.8 Na_2SO_4. The 6-8Å film of NiO on electropolished nickel breaks down rapidly on open circuit at *p*H 2.8 with a poorly defined potential arrest structure. In contrast, several distinct potential arrests are observed during open-circuit breakdown of the oxide films on anodized nickel, the number of arrests and their duration being dependent on the condition of film formation and indicative of film stability. The results are interpreted in terms of the anodic formation of a nickel oxide film $\approx$ 12Å thick with a small area (<5%) covered by defective oxide. Breakdown begins at the defect sites by chemical dissolution of the oxide. Oxide undermining is responsible for removal of most of the oxide and starts when the underlying nickel metal at the defect sites has been exposed. Large variations in oxide film stability are associated with very small changes in the over-all character of the film since the small coverage with defective oxide plays the major role in film breakdown.

Thin, protective films of NiO are formed on nickel electrodes either by electropolishing with subsequent air exposure or anodic oxidation in sulfate solutions of various *p*H's (1-4). The thickness of the NiO film after electropolishing and air exposure is 6-8Å, while that formed by steady-state anodic oxidation is 9-12Å. The stability of these films toward cathodic reduction is dependent on the *p*H of the solutions; at a *p*H of 8.4, the film on electropolished nickel can be cathodically reduced but not that on anodized nickel. All the films can, however, be cathodically reduced at *p*H 2.8 and this *p*H was subsequently chosen for studying the mechanism of the anodic oxidation of nickel (2, 3).

Chemisorbed oxygen is formed during the early stages of nickel anodization and is converted to nickel oxide with continued oxidation. The stability of the different oxygen species on anodized nickel was characterized in relation to their cathodic reduction behavior. At oxygen coverages approaching a monolayer, the chemisorbed oxygen can be galvanostatically reduced with almost 100% current efficiency, giving a distinct cathodic arrest structure. Conversion of the chemisorbed oxygen to NiO gives rise to a decrease in the reduction current efficiency, *i.e.*, an increase in the film stability toward cathodic reduction. At the same time, the charge associated with the well-defined cathodic arrest diminishes and the arrest completely disappears when oxide covers the entire surface. For these reasons, the cathodic charging technique did not provide a direct method of determining the stability of oxide films (*i.e.*, NiO) formed under different conditions of anodization.

The open-circuit breakdown behavior of the oxide has also been used in studying film stability. The chemisorbed oxygen is less resistant to open-circuit breakdown than NiO, a result similar to that obtained in the cathodic reduction study. However, unlike the cathodic charging profiles for the oxide, the open-circuit decay profiles for NiO display a distinct arrest structure which varies with condition of anodization. In the present investigation, the open-circuit decay technique is used in studying the films prepared under various conditions. The experimental results are analyzed in relation to the corresponding x-ray emission and anodic coulometry data for anodically polarized nickel electrodes. The structure of the oxide film is discussed in terms of its breakdown characteristics.

Experimental

Polycrystalline specimens, 1 × 2.5 cm, were prepared from zone-refined nickel sheet of 99.996% purity as described elsewhere (1). They were degreased with benzene, chemically polished (1), electropolished for 2 min at 23°C in a 57 volume percent (v/o) sulfuric acid solution at 0.5 A cm^{-2}, and then annealed at 800°C in a vacuum of 10^{-8} Torr. The specimens were electropolished again immediately before use in an experiment. As for the reference electrode, potentials quoted in this paper are referred to the Hg_2SO_4 electrode in 0.15*N* Na_2SO_4 (+0.665V with respect to the standard reversible hydrogen electrode). Deaerated solutions of 0.15*N* Na_2SO_4 had their *p*H's adjusted to 2.8. Experiments were conducted at 25°C. A Wenking fast-rise potentiostat was used to anodize specimens. The galvanostatic cathodic charging curves and open-circuit decay profiles were recorded on a Hewlett-Packard Model 7004B X-Y recorder. A high speed Brush recorder was used to follow the initial rapid decrease of current after an anodic potential step treatment. After electropolishing, the electrodes were immersed in deaerated Na_2SO_4 solutions of *p*H 2.8 under cathodic polarization sufficient to remove the prior 6-8Å film of NiO. The oxide-free electrodes were then anodized using the potential step method. Experiments were also performed where the electropolished specimens were anodized without prior reduction of the NiO film. The anodized electrodes were discharged either on open circuit or with galvanostatic reduction. Surface activities were measured by switching the potential back to the potential of anodization and measuring the anodic charge passed during the first 2 sec. The anodic current fell by about three orders of magnitude during this time, indicating that the measured anodic charge is related to that required to recover passivity. The surface activity is the ratio of this charge to the corresponding change obtained with an oxide-free starting surface. The effect of air exposure, drying, and vacuum pumping in a stainless steel chamber to 10^{-4} Torr on the steady-state oxide films was investigated by comparing the open-circuit potential-time profiles for anodized nickel with and without this treatment.

Results

Figure 1 shows the behavior of electropolished nickel during cathodic reduction at various current densities as well as on open-circuit exposure. The charges associated with the oxide reduction arrests at 20 μA cm^{-2} and 100 μA cm^{-2} are the same and equivalent to the coulombs required to reduce $\approx$ 6Å of NiO. This is in agreement with the thickness as determined by x-ray analysis (1, 2). The film is also removed on open circuit, with a complete activation of the surface occurring within 3 min. The open-circuit potential of the oxide-free surface was −0.85V.

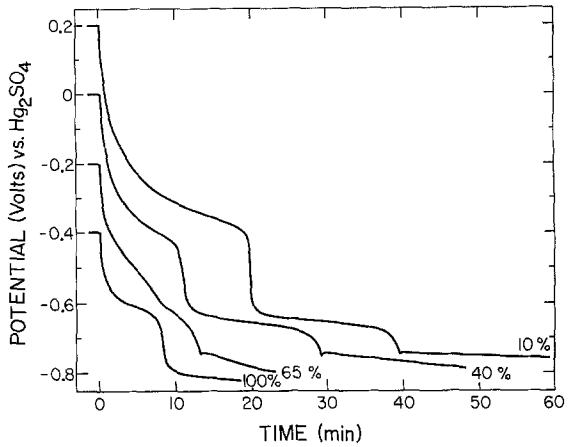

Fig. 3. Open-circuit decay profiles, at pH 2.8, of previously oxide-free nickel electrodes which had been anodized for 1 hr at various potentials. The surface activity after various times on open circuit is also given.

monolayer of chemisorbed oxygen on nickel. The surface activity at the end of the arrest is <100% due to the blocking of active sites by unreduced nickel oxide. Breakdown on open circuit is substantially slower for this film, in comparison with that on electropolished nickel, with *ca.* 7 min required for complete reactivation as indicated by the electrode potential and surface activity measurements. Figure 2b shows that the stability of the film formed at −0.3V is greatly enhanced by increasing the time of anodization to 1 hr. This is in agreement with the fact that 1 hr at −0.3V is sufficient to form a steady-state oxide film on the surface (3).

The open-circuit breakdown behavior of oxide films formed after 1 hr anodizations at different potentials is shown in Fig. 3 and 4. The number of distinct arrests increases from two to three with increasing anodic potential. Also given are measured surface activities. During open-circuit decay, the surface activity does not begin to increase significantly until the sharp potential decrease to −0.75V, this decrease generally giving rise to a potential spike. The open-circuit decay time up to the potential spike will hereafter be referred to as the induction time. In all cases, the surface activity just prior to the sharp potential decrease to −0.75V, *i.e.*, within the induction time, is <5%. For this reason, the surface activities were determined for specific times after the spike, this time being 10 min after anodizations at −0.4 and −0.2V and 20 min for all other anodization potentials (Fig. 3-6). At $V_a \leq +$ 0.2V the rate of potential decay and surface reactivation decreases with increasing anodic potential; however, at $V_a > +$ 0.2V the reverse is true. The same trends are observed after 15 hr anodizations (Fig. 5). Table I gives the corresponding anodic current densities, measured at the end of the various 1 and 15 hr anodizations, as a function of V_a.

The development of the open-circuit decay structure was also studied as a function of time of anodization at 0.0 and −0.4V (Fig. 6 and 7). The variation of the anodic current density with time of anodization at 0.0V is given in Table II. The difference between the 15 and 90 hr anodizations is not significant since the experimental precision is ± 0.01 μA cm^{-2}. At 0.0V, the stability of the oxide film toward open-circuit breakdown continues to increase with time of anodic treatment even after many hours of anodizing (Fig. 6). This increased film stability is manifested by both an increase in the induction time for significant film breakdown and a decrease in the rate of surface reactivation after the potential spike. With an increase in the anodization time from 15 min to 90 hr at 0.0V, the induction time increases by a factor of five while the surface activity recovered during a standard 20 min decay time after

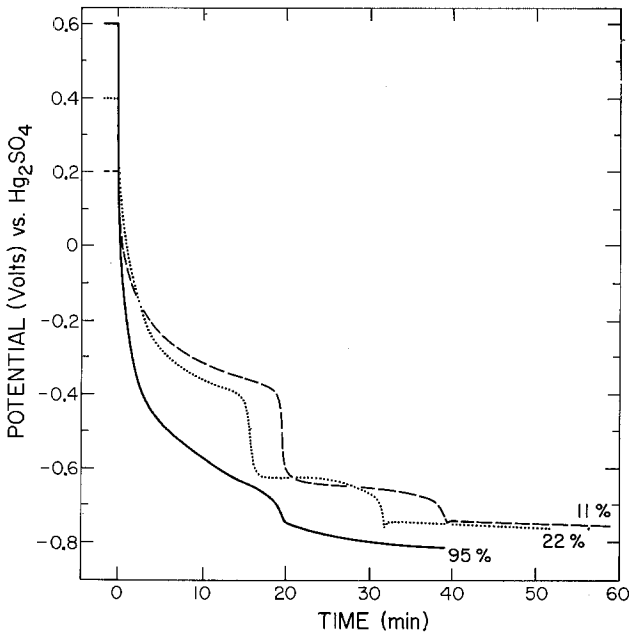

Fig. 4. As in Fig. 3 but with different 1 hr anodization potentials

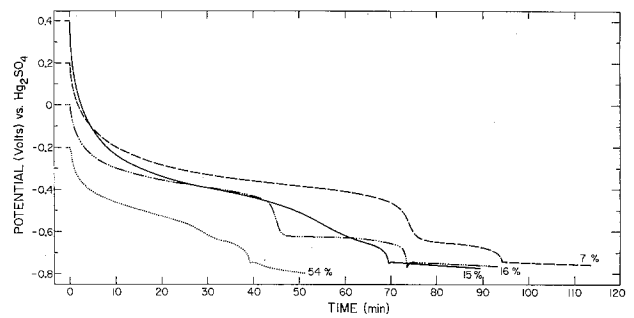

Fig. 5. As in Fig. 3 but with an anodization time of 15 hr

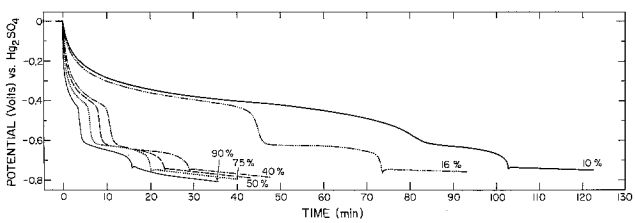

Fig. 6. Open-circuit decay profiles, as in Fig. 3, after vorious times of anodization at 0.0V: (—) 15 min; (· · ·) 30 min; (– – –) 45 min; (– · –) 1 hr; (– · · · –) 15 hr; (—) 90 hr.

the potential spike decreases by a factor of nine (Fig. 6). Clearly, for anodizations at 0.0V, the recovery rate after the potential spike is strongly influenced by the induction time to the potential spike. Although no potential spike is evident after anodizations at −0.4V (Fig. 7), the sharp potential fall to −0.75V indicates the point at which recovery of surface activity commences. In this case, however, the rate of recovery of

Table I. Current density at end of anodization

1 hr at −0.4V	0.40
1 hr at −0.2V	0.27
1 hr at 0.0V	0.22
1 hr at +0.2V	0.35
1 hr at +0.4V	13.1
1 hr at +0.6V	28.0
15 hr at −0.2V	0.11
15 hr at 0.0V	0.06
15 hr at +0.2V	0.15
15 hr at +0.4V	5.8

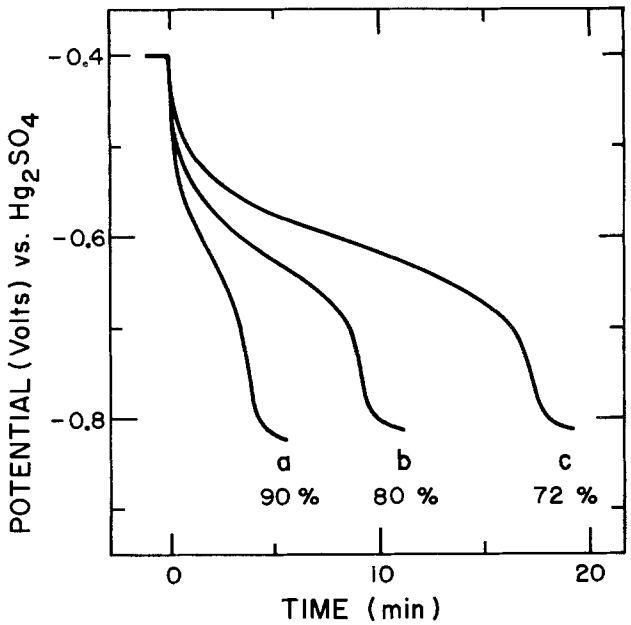

Fig. 7. As in Fig. 6 but with an anodization potential of −0.4V: (a) 15 min; (b) 1 hr; (c) 15 hr.

surface activity after the sharp potential fall is much less influenced by changes in the induction time. Also, the more anodic open-circuit arrest is not observed after the anodizations at −0.4V.

Cathodic galvanostatic charging profiles, at currents from 0.3 to 20 μA cm^{-2}, were obtained on electrodes which had been anodized under conditions known to give rise to significant open-circuit arrests at −0.4 and −0.65V, *e.g.*, 15 hr at 0.0V. In all cases, the potential decreased rapidly to *ca.* −0.75V, *i.e.*, in the region of the most cathodic open-circuit arrest, and no multiple cathodic arrest structure was observed. The sensitivity for oxygen was *ca.* 0.02 monolayer of NiO during galvanostatic cathodic reduction. Experiments were also performed where the system was switched to open circuit soon after initiating the cathodic pulse on the anodized specimen. After 15 hr at 0.0V and subsequent passage of a cathodic charge corresponding to 0.02 monolayer of NiO, the open-circuit potential was *ca.* −0.6V, *i.e.*, the arrest at −0.4V was not observed after passage of this small amount of cathodic charge.

Open-circuit decay profiles were obtained for nickel electrodes anodized at 0.0V for 1 hr both with and without prior reduction of the 6Å of NiO on the electropolished nickel, *i.e.*, the starting surface. The decay profiles were the same in both cases even though the presence of the oxide film on electropolished nickel resulted in a 10-fold decrease in the initial anodic charge which passed after potential-step anodization to 0.0V. The oxide film on electropolished nickel obviously inhibits nickel dissolution but has no substantial influence on the stability of the anodically formed steady-state oxide film.

The open-circuit decay structures obtained after 1 hr at −0.4 and 0.0V were not influenced by air exposure, compressed-air drying, and vacuum pumping of the anodized specimens. The stability of these oxides toward air exposure permitted the use of x-ray

Table II. Effect of time of anodization on final current density

Time of anodization at 0.0V	Anodic current density, μA cm^{-2}

emission spectroscopy in determining oxide thicknesses. Samples were analyzed by the x-ray technique after 1 hr anodizations at −0.4, 0.0, and +0.2V and 15 hr treatments at 0.0 and +0.2V. In all cases, the measured NiO thicknesses were basically the same at 9-12Å.

Discussion

Oxide films on nickel can be removed by electrochemical reduction, chemical dissolution, or undermining. The present paper is mainly concerned with the latter two topics, cathodic reduction of oxide films having been covered in previous papers (1-3). Open-circuit decay profiles, in conjunction with surface activity measurements, are shown to provide an accurate measure of oxide film stability. The results indicate that the rate of breakdown of NiO films is highly dependent on the condition of film formation. From the x-ray emission results, the large differences in film stability observed after various anodization treatments do not appear to be related to changes in oxide film thickness.

The 6Å film of NiO on electropolished nickel breaks down very rapidly on open circuit at pH 2.8 (Fig. 1). However, the arrest charge associated with its galvanostatic reduction is constant at widely varying cathodic charging currents and, hence, times of exposure to the solution. This indicates that on open circuit, undermining of the film by metal dissolution from film-free areas (2), rather than chemical dissolution of the oxide, is playing the major role in film breakdown. The polarized corrosion couple, $Ni \rightarrow Ni^{2+} + 2e$ and $2H^+ + 2e \rightarrow H_2$, is responsible for the steady-state open-circuit potential of −0.85V on oxide-free nickel. During galvanostatic charging, the applied cathodic current protects any exposed metal from dissolution by corrosion and allows the "electropolish film" to be reduced with a current efficiency close to 100%. The oxide-free regions could have already existed on the surface before immersion into the solution (*e.g.*, as pores) or could have resulted from localized chemical dissolution at weak points in the oxide film after immersion. The film on electropolished nickel has a high overvoltage for hydrogen evolution, in contrast with the anodically formed oxide which actually facilitates the reaction, and is mostly reduced at potentials which are more positive than those for hydrogen evolution on oxide-free nickel.[1]

The films on anodically oxidized nickel break down much more slowly on open circuit than the film on electropolished nickel. This is true even when the anodically formed film is thinner than the film on electropolished nickel, *e.g.*, the 1 monolayer film of chemisorbed oxygen with a very small additional coverage by oxide nuclei (3) formed after 90 sec at −0.3V (Fig. 2). This means that the approximately 50% increase in thickness of the steady-state film on anodized nickel over that on electropolished nickel is not the only factor responsible for the relative increase in stability of the former. A difference in oxide composition between electropolished and anodized nickel, indicated by the small change in oxide lattice parameter previously measured by high energy electron diffraction (2), is another possible explanation for the large stability variation. The more stable oxide, *i.e.*, that on anodized nickel, has a lattice parameter which is much closer to that of stoichiometric NiO.

The stability of the oxide films on anodized nickel toward open-circuit breakdown increases with film thickness up to the steady-state value of 9-12Å [Ref. (3) and Fig. 2b]. However, this stability continues to increase substantially with longer times and higher potentials of anodization without a corresponding increase in oxide film thickness (Fig. 3-6). The variation of "steady-state" oxide film stability with condition of anodization can be understood in terms of the detailed structure of the open-circuit decay profiles.

It has previously been shown (2) that two distinct regions of potential decay are present as characterized by the recovered surface activity. The first region is from the beginning of potential decay up to the sharp potential decrease to −0.75V (often accompanied by a potential spike as in Fig. 3) in which no significant increase in surface activity is observed and which can be viewed as an induction period before general film breakdown begins. The second region occurs after this sharp potential fall and is distinguished by an increase in the surface activity with time on open circuit. In the first region, chemical dissolution of a defective oxide ($NiO + 2H^+ \rightarrow Ni^{2+} + H_2O$) occurs at specific defect sites in the film [*cf.*, Ref. (5)].[2] The subsequent exposure of localized areas of the underlying nickel surface causes the potential to rapidly shift from that of a completely oxide-covered surface ($V \geq -0.65V$) to that associated with the galvanic corrosion couple $Ni \rightarrow Ni^{2+} + 2e$; $2H^+ + 2e \rightarrow H_2$ ($V \leq -0.75V$). The resulting nickel dissolution gives rise to undermining of the oxide film (2, 6, 7) with a corresponding increase in surface activity. Obviously the surface coverage with defect sites is small since very little surface activity (<5%) has been recovered up to the end of the first region (*i.e.*, up to the potential spike).

The stability of the steady-state oxide films toward open-circuit breakdown can thus be analyzed in terms of both chemical attack at defect sites and general film breakdown by undermining. With increasing anodic treatment, the time required for chemical dissolution of the oxide at the defect sites increases and, correspondingly, the induction time for commencement of general film breakdown (*i.e.*, undermining) increases. This can be explained by either a small increase in oxide thickness or small changes in the oxide stoichiometry and/or structure at the defect sites. Even large changes in either the thickness or stoichiometry of the oxide at defect sites would probably not be observed experimentally since their surface coverage is extremely small. The rate of reactivation by undermining (*i.e.*, after the potential jump to −0.75V) also decreases with increasing anodic treatment. This can be explained in terms of fewer defect sites breaking down during the previous induction period and correspondingly fewer sites from which undermining can occur, at least initially. If the defect sites are viewed as being nucleation centers (in this case sites for breakdown rather than formation of oxide), the equations for lateral growth of such nuclei (8) in terms of expanding circles suggest that the rate of surface reactivation is dependent on the density of nuclei. The results thus indicate that increased anodic treatment diminishes the number of sites which break down during the induction period and increases the induction time for breakdown of these active defect sites.

The over-all stability of the oxide film does not continue to increase indefinitely with increasing potential of anodization (Fig. 4). The decrease in stability at $V_a \geq +0.4V$ can be directly related to the increased anodic current at the end of the anodization (Table I) which corresponds mainly to oxygen evolution at these potentials. Oxygen evolution disrupts the perfection of the oxide, causing a rapid breakdown at the defect sites and a corresponding rapid surface reactivation by undermining. It may be that the oxide on the outer surface participates in oxygen evolution (9) and may therefore not be present on the surface long enough for the important aging effects (Fig. 6) to occur. At $V_a < +0.4V$, the anodic currents are much smaller because little or no oxygen is evolved (Table I). The general rule that a decreased anodic current is associated with a more stable oxide film (10) is only com-

[1] Although there is some overlap between these two reactions at the latter stages of oxide reduction (Fig. 1), extrapolation of the tangent lines for the two processes seems to resolve the oxide reduction charge component.

[2] It will be shown in a future paper that a general thinning of the oxide film does not occur prior to the spike, *i.e.*, significant chemical dissolution is occurring only at the defect sites.

pletely true at any one particular potential. Thus, after 1 hr at +0.2V the anodic current is actually higher than after 1 hr at 0.0V, even though the stability of the oxide film has increased substantially (Fig. 3). The extra driving force for oxide formation and/or perfection at +0.2V more than compensates for any small amount of oxygen evolution which may occur at this potential. Even at one particular potential, the anodic current at the end of the anodization will only give a direct indication of the oxide stability if it is simply due to oxide chemical dissolution and subsequent anodic reformation of the oxide. Other anodic reactions, *e.g.*, slow oxide thickening over a part of the surface or nickel dissolution through the oxide film, may contribute to the measured i_a and make it difficult to establish a definite quantitative correlation between induction time for oxide dissolution at defect sites and the anodic current density. However, there is a fairly good correlation between change in i_a and induction time with changing times of anodization at specific potentials up to +0.2V which allows the prediction of relative stabilities at one potential from measured i_a's. This is shown for 0.0V in Fig. 6 and Table II.

Increasing anodic treatment leads to the development of an additional open-circuit potential arrest during the induction period prior to general film breakdown. The potential arrest at −0.65V is evident for all anodization treatments but the arrest at −0.40V only occurs after anodization at potentials more positive than this. The absence of corresponding multiple arrests during cathodic reduction of the oxides on anodized nickel probably means that any change in oxide character is only occurring at the defect sites and hence very small reduction charges would be involved. Other workers have observed multiple arrests during the open-circuit breakdown of oxide films on anodized nickel in acid solutions and have postulated the existence of other oxides of nickel besides NiO, *e.g.*, Ni_3O_4 and/or Ni_2O_3 (11-16). Such a higher oxide may possibly explain the stabilization of the oxide defect sites with increasing anodic treatment, the higher oxide forming at and essentially deactivating certain defect sites with respect to breakdown during the induction period. The fact that one has well-resolved arrests would seem to favor such an explanation. However, the reversible potential for formation of the next higher stoichiometric oxide, Ni_3O_4, is +0.08V in the present system, and the arrest at −0.4V is present even after anodizations at −0.2V (Fig. 5).

The two potential arrests during the induction period can also be explained by assuming that the arrest at −0.65V is due to a defective oxide at the breakdown sites and not to the NiO which covers most of the electrode surface. The defective oxide may be noncrystalline NiO or a slightly nonstoichiometric NiO, *e.g.*, cation-deficient NiO, or even $Ni(OH)_2$. The defect sites could be areas of oxide located over metal grain boundaries and/or the regions where the expanding oxide nuclei meet. Although such an oxide species covers only a small area of the surface, *i.e.*, the defect sites, it could control the open-circuit potential if its exchange current were sufficiently high. With increasing extent of anodization, this oxide at the defect sites can be converted to almost stoichiometric NiO, *i.e.*, the same type of species which covers the rest of the electrode surface. This can arise from the injection of Ni^{2+} into the oxide to annihilate the cation vacancies or the expulsion of H^+ from the $Ni(OH)_2$ species, the field being in the correct direction in both cases. When stoichiometric NiO covers the entire surface, the open-circuit arrest occurs at −0.4V. This does not necessarily mean that all the defective oxide has been converted to stoichiometric NiO since the steady-state oxide is 3-4 atomic layers thick and defective oxide may still exist beneath the outer layer at the defect sites. Although the stoichiometry of this oxide is similar to that covering the rest of the surface, *i.e.*, the non-defect site area, it is still probable that the NiO at these defect sites is more reactive toward chemical dissolution. When some of this stoichiometric NiO at the defect sites has chemically dissolved, defective oxide is again exposed and the potential shifts accordingly to −0.65V. This defective oxide then breaks down and the undermining of the entire oxide begins.

To explain the decrease in the number of active defect sites, with time and potential of anodization, it can be postulated that the conversion of defective to stoichiometric oxide occurs to different extents at the various defect sites. During the induction period, those sites at which extensive conversion to stoichiometric NiO has occurred may not break down because of their increased stability. Those sites with the smallest extent of conversion to stoichiometric NiO will break down first and will thus be the ones from which undermining will eventually begin. This would explain the substantial decrease in the number of active defect sites with increasing time of anodization at 0.0V (Fig. 6).

The defective oxide can also be stabilized toward open-circuit breakdown without being completely converted to stoichiometric NiO, *i.e.*, without the involvement of the arrest at −0.4V. This is the situation for anodizations at −0.4V (Fig. 7). In that case, almost all of the defect sites are stabilized to the same extent and therefore the rate of surface reactivation after the potential spike is nearly independent of the induction time. The small changes in rate of recovery of activity can be explained in terms of the deactivation of a very small number of defect sites through the formation of some stoichiometric NiO as discussed above.

The general conclusions are therefore that oxide defect sites play the most important role in film breakdown and that only such defect sites need be stabilized by the increased anodic treatment in order to diminish the rate of over-all film breakdown. These conclusions are in agreement with the x-ray emission, cathodic reduction, and electron diffraction results which indicate that the character of the over-all oxide film does not change substantially with increasing anodic treatment, especially after a steady state has been achieved.

Summary

The results on the breakdown of anodic films formed at various stages of anodization can best be summarized by the use of the composite diagram in Fig. 8. Film formation is shown from the initial stages of oxygen chemisorption, (A), to coverage by a "monolayer" of chemisorbed oxygen, (B), with blocking of active sites by oxide nuclei in both cases. This is followed by lateral growth of the oxide nuclei to give a "flawed film" ≈ 12Å thick with <5% of the surface covered by a defective oxide, such as $Ni(OH)_2$ or nonstoichiometric NiO, in pores (C). Finally, the defective oxide in the pores is repaired, *e.g.*, by dehydration to NiO and possibly slight thickening (D). In (D) it is postulated that conversion to NiO starts at the film-solution interface and proceeds inward.

The breakdown of the film is dependent on the stage reached in the formation process. At condition A the partial chemisorbed film disappears rapidly on open circuit, probably by dissolution, leaving the nuclei at the active areas. These nuclei, although covering only a small area of the surface, can account for 50% of the surface activity. With further exposure the nuclei are removed, probably by undermining, and the surface activity increases to 100%.

The monolayer film shown in (B) takes a slightly longer time to break down and probably does so by dissolution of the chemisorbed layer. The open-circuit decay curves show a single wave and cathodic reduction takes place with high current efficiency and gives a good measure of the total chemisorbed oxygen. After the removal of the chemisorbed layer by either short cathodic reduction or dissolution, the nuclei remain on

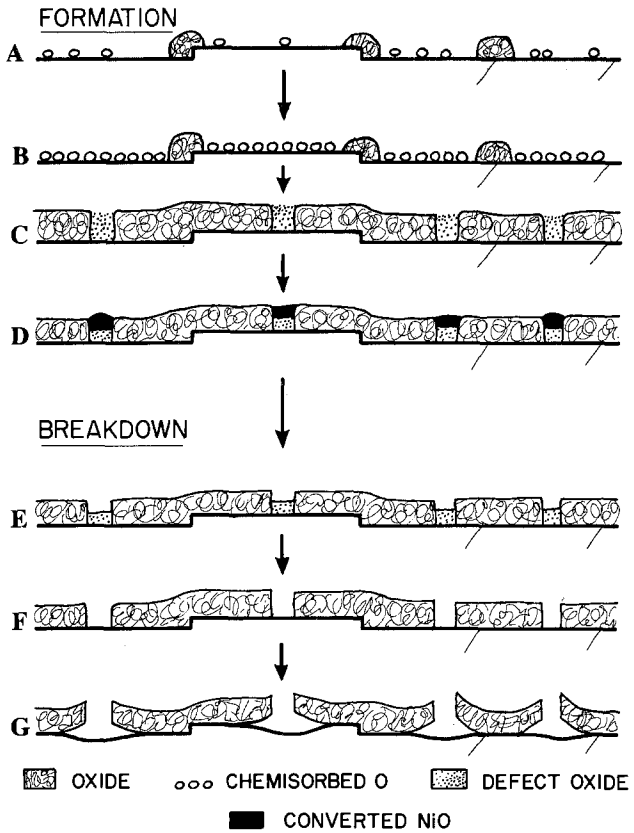

Fig. 8. Schematic diagram of the proposed mechanism of nickel oxide formation (A-D) and breakdown (E-G).

the "active sites" and, on open circuit, are again removed by undermining.

Further anodization leads to the conversion of the chemisorbed layer to oxide. This may take place by expansion of the already present nuclei to cover the whole surface with the formation of nonuniform areas or pores where the expanding nuclei meet. These areas are depicted in C and may consist of $Ni(OH)_2$ or a nonstoichiometric NiO. At this stage the breakdown occurs by dissolution of the material in the pores, as shown in F, followed by undermining of the oxide from the exposed metal side in the pores as shown in G. During open-circuit breakdown only one wave is obtained and this corresponds to the potential of a film of "defective hydrated oxide." The final potential is the nickel corrosion potential, and activity of the surface is increased by the removal of the film by undermining (as shown in G).

In the final stages of anodization shown in D the material in the pores is altered without further thickening of the main layer of oxide. The "defective hydrated oxide" is converted from the outside (film-solution interface) inward, to the metal, to NiO possibly by outward migration of H^+ assisted by the anodic field. The oxide so formed would be less dense than the bulk film oxide and hence probably more readily soluble in the slightly acid sulfate. The NiO in the main body of the film is very resistant to dissolution. The degree of conversion will depend on both the potential and time of anodization; on open circuit, breakdown is slower the longer the anodization time at any potential up to +0.2V. Two potential plateaus are observed, one for the potential of NiO and, as before, one for the defect oxide. Breakdown occurs first by dissolution of the NiO in the pores, and then by dissolution of the remaining defect oxide in the pore to the metal surface, and finally by undermining. In all cases where a full oxide film is formed during anodization, the initial opening of the pores exposes <5% of the metal surface to the solution, as indicated by the low surface activity at the spike in the potential curves. Removal of the film by undermining leads to gradually increasing surface activity until the whole surface becomes reactive.

Low Potential Oxidation of Hydrogen Sulfide on a Rotating Tripolar Wiper-Blade Electrode via Continuous Anode Reactivation

M. Farooque and T. Z. Fahidy

Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

ABSTRACT

The mechanism of anodic oxidation of hydrogen sulfide in an aqueous electrolyte solution was studied by means of a rotating tripolar wiped electrode system; a statistically most likely model taken from six contending models is proposed via likelihood approach. The cell can efficiently be used for the continuous reactivation of the anode surface.

The oxidation of sulfide ions in aqueous solutions is a problem of increasing importance in process metallurgy and pollution control. Although a number of electrochemical studies have been devoted to the understanding of this reaction, passivation and related problems have hindered the development of an electrochemical oxidation process of technological potential. The purpose of this paper is to present the results of a recent study in which the oxidation mechanism has been established and the anode regenerated to warrant possible industrial usefulness of the electrochemical cell employed.

A number of studies involving a wide range of potentials, current densities, and smooth platinum and other metallic anodes (1-4) indicate that, depending on the experimental conditions, elemental sulfur, polysulfides, sulfates, dithionate, and thiosulfate species may be produced during anodic oxidation of sulfide ions. The influence of dissolved H_2S on the oxidation of hydrogen and reduction of H^+ in H_2SO_4 solutions on Pt (5) has also been investigated; the presence of H_2S was found specifically (6) to suppress the reaction of chemisorbed oxygen and hydrogen. Loučka (7) studied the behavior of atomic sulfur bound to the Pt anode surface and found that at a potential of 0.4V, the nonstationary anodic oxidation current drops quickly, indicating rapid buildup of passivation of the apparently two-electron oxidation process. In all experiments, H_2 evolution at the cathode was also observed.

The current investigation began by a preliminary set of experiments in which Loučka's observations at low potentials were quantitatively confirmed via exponential decay of the nonstationary anodic current. In further experiments the mechanism of the oxidation was investigated and a continuous sulfur removal technique was developed.

The Mechanism of Anodic Oxidation of H_2S on Platinum

Experimental.—The experimental apparatus has recently been described in detail (8-10). In this part of the study, the cell was operated in a monopolar fashion without wiping action. The electrolyte was prepared by bubbling technical grade H_2S (O_2, 0.03%; CO_2, 0.25%; N_2, 0.06%; H_2S, 99.6%) through a 0.5 mole/dm^3, analytical grade H_2SO_4 solution made up with doubly deionized water; the impurities in the H_2S gas had previously been found to have no measurable influence on the reaction to be studied. The anode was prepared over a 20 min period in the following fashion, in order to produce a reproducible surface: periodic potential sweep from 0.04 to 1.5V (NHE) at a sweep rate of 0.15 V/sec in the electrolyte solution, interrupted at 0.45V anodic potential. After this sequence the cell was washed and filled with the experimental electrolyte. The concentration of H_2S in the electrolyte was determined by a standard iodometric method (11). After preparation the anode potential was raised to the desired value and the current *vs.* time variation was observed on an oscillograph during the potentiostatically controlled experiment.

Key words: anodic oxidation, rotating tripolar electrode, hydrogen sulfide, likelihood theory.

Typical variations of the anode current with time are illustrated in Fig. 1, obtained at 0.51V anode potential and at 22°C. Rapid passivation occurs during the initial period and is essentially complete within 30 sec. This observation agrees with Loučka's Fig. 1 (7) except at the very start. This apparent disagreement is probably due to a different step at the preparation stage: in his work H_2S was added to the acid solution after the oxidation potential had been raised to the desired value, not before.

More significant for the objectives of this research is Loučka's observation about anode surface reactivation: According to his findings, the anode could be reactivated by successive potential impulses in order to remove the adsorbed "poison" from the Pt surface. In order to identify the nature of this poison, the following experiments were performed: (*i*) The anode potential was raised to 0.51V in the prepared electrolyte and when the transient current had vanished the anode was removed from the cell and washed with doubly deionized water. (*ii*) The anode was put back in the cell and its potential was again raised to 0.51V in the same electrolyte. No current flow was observed; therefore, the surface poison is not a loose layer which would easily be removed by the above treatment. (*iii*) Next,

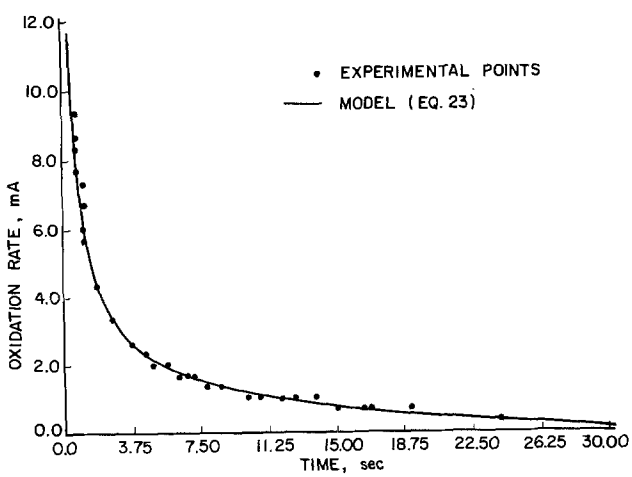

Fig. 1. Comparison of the experimental anodic oxidation rate with prediction via Eq. [23]. Anode potential 0.51V; electrolyte: 0.5 mole/dm^3 aqueous H_2SO_4 solution containing 6.73 mmole/dm^3 H_2S.

the anode was washed with deionized water, then with piperidine (a compound which is a selective solvent for sulfur) and again with deionized water. When the anode was put back in the experimental cell and its potential was raised again to 0.51V, the same transient current as in step (*i*) was observed. This test appears to confirm Loucka's proposition that the poisoning species is chemisorbed sulfur on the Pt surface.

Finally, a small set of experiments was carried out to confirm the proposition that the anodic oxidation of H_2S is a two-electron process, by repeating Loucka's procedure: The results are in agreement with previous findings (7).

It is of interest to examine, before further analysis, the origin of the anode current. It has previously been noted (6) that in a 0.5 mole/dm^3 H_2SO_4 solution saturated with H_2S the electrode reaches a rest potential of 0.165 ± 0.010V (NHE) which depends on the partial pressure of H_2S as -40 ± 15 mV/log$_{10}$ p_{H_2S}. It is also known that elemental (surface-adsorbed) sulfur is not oxidized at potentials below 1.5V (NHE) to a noticeable extent. In our test experiments no significant change in the *I-t* behavior has been observed during the 2-20 min time period in which the electrodes were dipped in the same H_2S solution before the start of the oxidation reaction. Upon introduction of H_2S into the experimental system the potential drifts toward the rest potential and the electrode is finally covered by adsorbed H_2S and possibly some (elemental?) sulfur. As soon as the potential is raised to 0.51V (NHE) or so, the adsorbed H_2S is oxidized to S_{ads} and H^+, the latter being the current source. At this low potential, sulfur on the surface does not take part in any further reaction. Its effect will be to reduce the available active area on the electrode, hence the numerical values of the experimental parameters in the forthcoming analysis will be effected in the same manner. On this basis the anode current observed in the experiments is fully attributed to the electrochemical oxidation of hydrogen sulfide.

Analysis.—In electrochemical studies, mechanistic models describing rate expressions are mainly nonlinear in both independent variables and parameters. There are two powerful statistical approaches available to establish the most likely mechanism: the likelihood approach and the Bayesian approach (12). This analysis was based on a statistical likelihood approach (12-14) whose preferability to the traditional "diagnostic criteria" method (15), in which neglect of the error structure of experimental data, simplifying assumptions, and linearization of the model equation may lead to less reliable conclusions (16), can be demonstrated (17) in electrochemical mechanism studies; the power of the statistical approach has drawn attention in a broad area of chemical kinetics (*e.g.*, 18, 19). The gist of the likelihood discrimination method is to compare the individual probability distribution functions of different competing models for the experimental observations, maximized with respect to their parameters

$$\lambda_{ij} = \frac{\max_{(\underline{a}_i)} F_i(\underline{y}, \underline{a}_i)}{\max_{(\underline{a}_j)} F_j(\underline{y}, \underline{a}_j)} = \frac{\max_{(\underline{a}_i)} L_i(\underline{a}_i)}{\max_{(\underline{a}_j)} L_j(\underline{a}_j)} \qquad [1]$$

where λ_{ij} is the likelihood ratio of model i to model j. The models are generally of the form

$$\begin{aligned} y_i &= f_1(\underline{a}_1, x_i) + \epsilon_i \\ y_i &= f_2(\underline{a}_2, x_i) + \epsilon_i \\ &\cdots\cdots\cdots \\ y_i &= f_j(\underline{a}_j, x_i) + \epsilon_i \end{aligned} \qquad [2a]$$

The error ϵ_i is defined to have zero expectation, constant variance, and a normal distribution. This is usually so, but if not in a given case, proper transformation of the data may make the error, associated with a given model, possess zero expectation, constant variance, and a normal distribution (20). Moreover, methods based on the Bayesian approach, which do not depend on any specific form of the error distribution, are also available (21).

Now, the maximum likelihood function of the jth model may be written as (12)

$$\max_{(\underline{a}_j)} L_j(\underline{a}_j) = \max_{(\underline{a}_j)} \exp\left\{ -\frac{1}{2\sigma^2} \sum_{i=1}^{n} [y_i - f_j(\underline{a}_j, x_i)]^2 \right\} \qquad [2b]$$

$$= \exp\left\{ -\frac{1}{2\sigma^2} R_j \right\} \qquad [2c]$$

in terms of the residual sum of squares, after the parameters have been estimated, and the error variance. It follows, therefore, that the model with its maximum likelihood function closest to unity is the "best" among the contenders considered (*i.e.*, not necessarily the true model in the absolute sense), and its likelihood ratios are measures of its relative preferability to all other models: the larger this ratio, the better. A $\lambda_{ij} \geq 10$ may usually be accepted for preferring model i to model j, when both have the same number of parameters; however, there is no *a priori* assurance that even the most likely model is statistically adequate to test adequacy, a goodness-of-fit analysis is required (22). The power of this approach in electrochemical mechanism studies is in yielding not only point-estimates of the reaction order, transfer coefficient, stoichiometric number, and rate constant(s), but also their probability distributions. Moreover, if deemed necessary, the estimation of parameters may be refined once the preferred model has been established. The number of experimental points required for statistical analysis may be minimized by a careful design of the experiments. Design criteria by different methods, *e.g.*, the criteria of Roth (23), Hill (24), Reilly (12), are also available. It must be emphasized that the above analysis does not decide between "right" and "wrong" mechanisms; it simply finds one (or at worst several) mechanism which is closest to the true one.

On the basis of experimental information hitherto available, the following six mechanisms were considered and subjected to likelihood analysis.

Model 1

$$H_2S \rightleftharpoons HS^- + H^+ \qquad [3]$$

$$HS^- + Pt \rightarrow Pt - SH_{ads} + e^- \qquad [4]$$

$$Pt - SH_{ads} \rightarrow Pt - S_{ads} + H^+ + e^- \qquad [5]$$

If the rate of destruction of the active electrode area by the adsorbed sulfur is a first-order process, and Eq. [4] is a diffusion-controlled process whose kinetics is much slower than that of Eq. [5], one obtains for the anodic current, the relationship

$$I = a\epsilon^{-bt}/\sqrt{t} \qquad [6a]$$

where

$$a = 2z\mathbf{F}C_{SH} - A_o\sqrt{\frac{D}{\pi}} \qquad [6b]$$

and b is the rate coefficient of the destruction of anode process. Nonlinear regression analysis of the experimental current-time data yields $a = 7.8676$ mA sec$^{1/2}$ and $b = 0.084056$ sec^{-1} at 0.51V anode potential in a 6.7 mmole/dm^3 H_2S-0.5 mole/dm^3 H_2SO_4 electrolyte solution. Twenty nine experimental points within the 0.4-32 sec range were employed in the analysis.

Model 2

$$Pt + H_2S \rightleftharpoons Pt - H_2S_{ads} \qquad [7]$$

$$Pt - H_2S_{ads} \xrightarrow{k_1} Pt - SH_{ads} + H^+ + \epsilon^- \qquad [8]$$

$$\mathrm{Pt - SH_{ads} \xrightarrow{k_2} Pt - S_{ads} + H^+ + \epsilon^-} \quad [9]$$

This mechanism corresponds to a typical consecutive reaction scheme in chemical kinetics; the current flow may be expressed as

$$I = a\left[\left(k_1 - \frac{k_1k_2}{k_1 - k_2}\right)\epsilon^{-k_1t} + \frac{k_1k_2}{k_1 - k_2}\epsilon^{-k_2t}\right] \quad [10]$$

Regression analysis yields $a = 2.7528$ mA sec, $k_1 = 0.61109$ sec^{-1}, and $k_2 = 0.079348$ sec^{-1}.

Model 3

$$\mathrm{Pt + H_2S \rightleftharpoons Pt - H_2S_{ads}} \quad [11]$$

$$\mathrm{Pt - H_2S_{ads} \xrightarrow{k_1} Pt - SH_{ads} + H^+ + e^-} \quad [12]$$

$$\mathrm{2Pt - SH_{ads} \xrightarrow{k_2} Pt - H_2S_{ads} + Pt - S_{ads} + H^+ + \epsilon^-} \quad [13]$$

Here the current equation is

$$I = AFk_1(C_{H_2S})_{ads} + \frac{1}{2}AFk_2(C_{SH})^2_{ads} \quad [14]$$

Values of $(C_{H_2S})_{ads}$ and $(C_{SH})_{ads}$ are calculated from the numerical solution of two first-order nonlinear, simultaneous differential equations. This complexity does not hinder the statistical treatment whereas the traditional "diagnostic criteria" approach would be extremely difficult to apply.

Model 4

$$\mathrm{Pt + H_2S \rightleftharpoons Pt - H_2S_{ads}} \quad [15]$$

$$\mathrm{Pt - H_2S_{ads} \xrightarrow{k_1} Pt\text{-}S + 2H^+ + 2e^-} \quad [16]$$

According to Bockris and Reddy (25) the simultaneous two-electron tunneling in Eq. [16] is very unlikely. Regression analysis yields $a = 10.457$ mA and $k_1 = 0.31972$ sec^{-1} for the expression

$$I = a\epsilon^{-k_1t}; \quad a = AzF(C_{H_2S})^{\circ}_{ads}k_1 \quad [17]$$

Model 5

In accordance with Armstrong and Harrison (26), one could visualize instantaneous or progressive two-dimensional nucleation of the $S^=$ species with diffusion control, assuming that the current stops after a poison monolayer has been formed. A somewhat involved derivation yields the current expressions and associated regression parameters

$$I = a\epsilon^{-kt}; \quad a = 10.452\,\mathrm{mA}; \quad k = 0.31972\,\mathrm{sec^{-1}} \quad [18a]$$

(instantaneous nucleation; model 5a)

and

$$I = at\epsilon^{-kt^2}; \quad a = 15.324\,\mathrm{mA\,sec^{-1}}; \quad k = 0.60084\,\mathrm{sec^{-2}}$$

(progressive nucleation; model 5b) [18b]

Model 6

$$\mathrm{Pt + H_2S \rightleftharpoons Pt - H_2S_{ads}} \quad [19]$$

fast

$$\mathrm{Pt + SH^- \rightleftharpoons Pt - SH_{ads}} \quad [20]$$

$$\mathrm{Pt - H_2S_{ads} \xrightarrow{k_1} Pt - SH_{ads} + H^+ + e^-} \quad [21]$$

$$\mathrm{Pt - SH_{ads} \xrightarrow{k_2} Pt - S_{ads} + H^+ + e^-} \quad [22]$$

It is assumed that reactions [19] and [20] occur almost instantaneously as the potential is raised at the experimental value and that current flow is due to reactions [21] and [22]. The current flow in this case may be written as

$$I = a\epsilon^{-k_1t} + b\epsilon^{-k_2t} \quad [23]$$

with regression parameter values of $a = 13.576$ mA, $b = 3.473$ mA, $k_1 = 1.191$ sec^{-1}, and $k_2 = 0.0999$ sec^{-1}.

The likelihood analysis of the six models is summarized in Table I: it is seen that the sixth model is far superior to all others considered here and may, in face of statistical evidence, be considered as the best candidate for subsequent goodness-of-fit analysis. It is instructive to point out that the first mechanism can independently be rejected by computing the apparent diffusivity coefficient from Eq. [6b]: using the numerical values (27) $K_1 = 10^{-7}$ and $K_2 = 1.2 \cdot 10^{-13}$ for the H_2S dissociation steps, $C_{SH} \cong 1.9 \cdot 10^{-9}$ mole/dm^3, and since $A_o = 93.3$ cm^2 under experimental conditions, D is computed to be about $3.7 \cdot 10^4$ cm^2/sec which is a patently absurd value.

The statistical acceptability of the sixth model is further confirmed by subsequent analysis of residues and goodness of fit whose details are described in the Appendix. Equations [19]-[22] constitute, therefore, the most likely mechanism of the anodic oxidation of H_2S in aqueous solutions on the basis of hitherto known experimental inhibition data. Figure 1 compares experimental and predicted oxidation rates, using the sixth model.

Some comments are in order with respect to the question of possible surface adsorption and/or diffusion control. In preliminary experiments, performed in the first stage of the current experimental study, it was found that the oxidation of dissolved H_2S becomes diffusion controlled only at potentials larger than 1.3V (NHE), where experimental current flows were found to be more than tenfold of the highest current flows observed at the low potentials at a given concentration. This finding is, of course, in full agreement with electrochemical theory and practice: Mass transfer becomes the rate-controlling mechanism for an electrochemical process in the neighborhood of its limiting current, *i.e.*, at relatively high potentials. Had additional models been considered (including those based on mass transfer control) the same conclusions would have nevertheless been found because the respective likelihood ratios would have been very high. The foregoing analysis was, therefore, confined to a limited number of models in order to illustrate the approach by means of a manageable number of model "candidates."

Continuous Reactivation of the Anode Surface

The electrolytic cell was operated in a typical tripolar fashion (9) where the anode rotating between three wiper blades forms three separate compartments of the cell. In the first compartment the anode surface was continuously washed with pure piperidine trickling downward along the anode and removed at the bottom of the compartment. In the second compartment the anode was washed in a similar fashion with deionized

* The regression analysis, from which R_j and the parameter values were found, was carried out on an IBM 360 Model 75 computer using Powell's algorithmic procedure (27).

water in order to remove traces of piperidine which might remain adhered to the anode surface. The third compartment was employed as the oxidizing cell where the anode potential was varied between 0.4 and 0.5V. Blank experiments were also carried out with the third compartment containing no dissolved H_2S in the aqueous sulfuric acid electrolyte, in order to establish a (residual) reference current in the absence of H_2S oxidation. The anode rotation rate and the residence time of the anode in the active compartment (*i.e.*, the time for H_2S oxidation at the anode at each pass) are related as

$$\omega = \frac{1.5498}{T} \text{ rad/sec} \qquad [24]$$

Figure 2 shows the dependence of the continuous oxidation rate on anode potential at the anode rotation rate of 0.104 rad/sec ($T \cong 15$ sec), at low potentials, while in Fig. 3 experimentally observed rates are compared at several rotation rates with the model-based predictor equation (see Eq. [23])

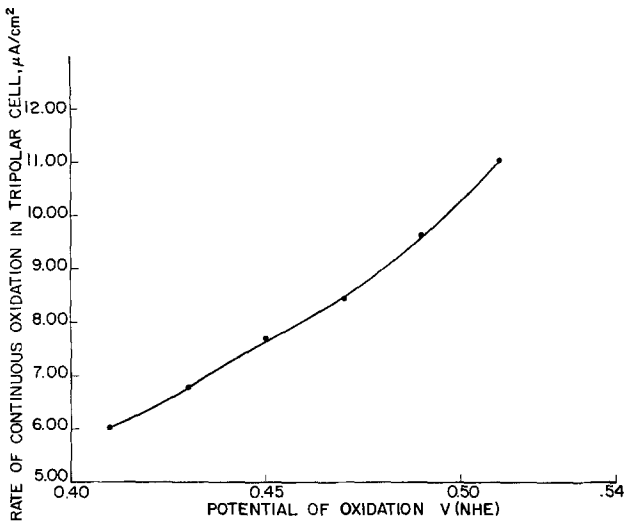

Fig. 2. The effect of oxidation potential on the continuous oxidation rate in tripolar operation (experimental conditions as in Fig. 1).

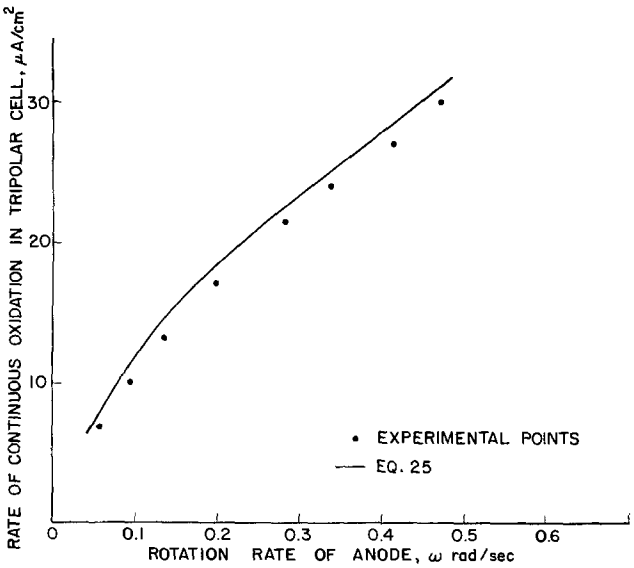

Fig. 3. The effect of the anode rotation rate on the continuous oxidation rate in tripolar operation (experimental conditions as in Fig. 1). The numerical values of parameters in Eq. [25] are: $a = 13.516$ mA, $b = 3.473$ mA, $k_1 = 1.191$ sec^{-1}, $k_2 = 0.09996$ sec^{-1}, $A = 210$ cm^2.

$$\bar{i} = \frac{1}{AT}\int_0^T (ae^{-k_1 t} + be^{-k_2 t})\,dt$$

$$= \frac{1}{AT}\left[\frac{a}{k_1}(1 - e^{-k_1 t}) + \frac{b}{k_2}(1 - e^{-k_2 t})\right] \qquad [25]$$

The theoretical prediction rate is consistently higher than the experimental rate but the two curves are almost exactly parallel, the discrepancy being about 1.15 μA/cm^2, corresponding to a maximum of 16.4% relative error at very low rotation rates and to a minimum of 3.8% relative error at higher rotation rates.

Conclusions

Hydrogen sulfide dissolved in an aqueous electrolyte solution can continuously be oxidized at a rotating platinum anode in a rotating tripolar cell employing wiper blades. The most likely oxidation mechanism involves two first-order consecutive electrochemical reactions with the SH-adsorbate as intermediate product. The oxidation rate can be predicted at an acceptable accuracy via a model equation based on statistical likelihood theory. The approach is applicable to all electrochemical mechanism studies.

APPENDIX

Analysis of Residuals and Goodness of Fit of Mechanism 6

The residual pertinent to the jth model is computed as

$$R_j = \sum_{k=1}^{N} r_j^2(k) = \sum_{k=1}^{N} [I(k) - I_j^*(k)]^2 \qquad [A\text{-}1]$$

where $I(k)$, $k = 1, \ldots, N$ are the experimentally observed values of the anodic current, and $I_j^*(k)$, $k = 1, \ldots, N$ are the corresponding values computed via the jth model. The plots of $r_6(k)$ against the dependent variable of the model $[I(k)]$ and the independent variable (t) show no distinguishable tendency and this finding indicates that the normal distribution of the discrepancy between $I(k)$ and $I_6^*(k)$ may be assumed. In terms of the covariance matrix (28) of the parameter vector $\underline{\alpha}$ (containing the vector elements a, b, k_1, k_2), the likelihood distribution of the parameters is given as

$$\underline{\alpha} : N(\hat{\underline{\alpha}}, (\underline{X}'\underline{X})^{-1}\underline{I}\,\sigma^2) \qquad [A\text{-}2]$$

where $(\underline{X}'\underline{X})^{-1}\underline{I}\,\sigma^2$ is the covariance matrix of the parameters, I is the identity matrix, and $\hat{\underline{\alpha}}$ is the mean value of the likelihood distribution, *i.e.*, the statistically best estimate of the parameters. Pertinent computations give the following numerical distributions: $a = N(13.576;\ 0.20498)$, $b = N(3.473;\ 0.028178)$, $k_1 = N(1.191;\ 3.259 \cdot 10^{-3})$, and $k_2 = N(0.09996;\ 3.5992 \cdot 10^{-5})$.

The goodness of fit of the model was established via the conventional F-test

$$F_{m-p,\,n-m} = \frac{E - s^2(n-m)}{s^2(m-p)} \qquad [A\text{-}3]$$

where E is the sum of all squared residuals $r_6^2(k)$, n is the total number of observations, m is number of replica groups, p is the number of estimated param-

eters in the model tested, and s^2 is the variance estimate computed as

$$s^2 = \frac{1}{n-m} \sum_{i=1}^{m} \sum_{k=1}^{n} (I_{ik} - \bar{I}_i)^2 \qquad [A\text{-}4]$$

$\bar{I}_i$ is the mean in the ith replica group. In the given case, $E = 1.906$, $n = 145$, $m = 5$, $p = 4$, and $s^2 = 0.01338$, thus Eq. [A-3] yields the test statistical value of $F_{11,40} = 2.451$ which is less than any critical value $F_{11,40}^{*}(\alpha)$ for $\alpha \geq 0.90$. It may be concluded that the model shows no lack of fit at any confidence level of 90% and lower.

LIST OF SYMBOLS

a	model parameter; $\underline{a}$ vector of model parameters
A_o	initial active anode area in oxidizing compartment
b	model parameter
C_{SH^-}	concentration of the SH^- ion in the bulk electrolyte
D	diffusivity
$f_j(\underline{\alpha}_j, \underline{x}_i)$	predicted value via model j at the ith observation
$\mathbf{F}$	Faraday's constant (96,487 C mole^{-1})
F_i	probability distribution of model i
I	current flow
k_1, k_2	rate coefficients at a fixed potential
L_i	likelihood function of model i
n	number of observations
p	number of parameters
R_j	residual sum of squares of the jth model after estimating the parameters
T	time spent by an arbitrary point on the electrode surface in oxidizing compartment
t	time
y	dependent variable
y_i	dependent variable at the ith observation
z	valency
e_i	experimental error associated with the ith observation
λ_{ij}	likelihood ratios of model i with respect to model j
σ^2	error variance
ω	rotation speed of the anode

Effect of Orientation, Composition, and Electronic Factors in the Reduction of O_2 on Single Crystal Electrodes of the Conducting Oxides of Molybdenum and Tungsten

Jean Horkans* and M. W. Shafer

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Cyclic voltammetry and steady-state techniques have been used to investigate the electrochemical behavior of single crystals of four conducting oxides of molybdenum, MoO_2, Mo_4O_{11}, Mo_8O_{23}, and Mo_9O_{26}, and one conducting oxide of tungsten, WO_2, in 1*N* H_2SO_4, and the ability of these oxides to serve as O_2-reduction catalysts in H_2SO_4 solution. The behavior of the four oxides of molybdenum was found to be similar due to the formation of a surface layer, the composition of which is more highly dependent on the past history of the electrode potential than on the composition of the bulk of the crystal. Oxygen reduction on all of these oxides occurs, for a given current density, at overpotentials which are high compared to the more common O_2-reduction catalysts such as Pt. The activity of WO_2 toward O_2 reduction is lower than that of MoO_2 because of the greater stability of the less conductive higher oxide on the WO_2 surface. Crystal orientation was found to have a substantial effect on the rate of O_2 reduction. The rate was found to be higher on surfaces which do not include short metal-metal distances. The measurement of the kinetics and mechanism of O_2 reduction is prevented by reactions of the electrode surface which occur in the same potential range.

The interest in finding new materials for fuel cell electrocatalysts has led to recent investigation of the electrochemical properties of a number of conducting transition metal oxides. One of the most extensively studied of these is the tungsten bronze electrode [*e.g.*, (1-5)]. Others include such materials as RuO_2 (6), NiO (7), and some mixed oxides (8-10). Although none of these compounds is competitive with Pt in electrocatalytic activity, these investigations have raised important questions about what electronic and physical factors are important in a good electrocatalyst. Because transition metal oxides exist with such a wide range of chemical and electronic properties, they are an interesting system for the study of these factors.

At least seven different oxides of molybdenum and five of tungsten have been prepared and characterized (11-14). These compounds are fairly stable in acid solutions and many are highly conductive. In addition, most of them can be grown as single crystals of large enough size to investigate the effects of orientation. We have studied MoO_2, Mo_4O_{11}, Mo_8O_{23}, and Mo_9O_{26} in the molybdenum-oxygen system and have investigated the effects of crystal orientation and chemical composition on their electrochemistry and catalytic activity. The oxide WO_2 of the tungsten-oxygen system has also been investigated for comparison between the molybdenum and tungsten oxides, with the aim of elucidating the role of electronic factors in electrocatalysis.

Experimental

Single crystals of the five oxides studied were grown by vapor transport techniques using the metal M and the trioxide MO_3 as starting materials and I_2 as the transporting agent (15). The desired compositions were obtained by varying the M/MO_3 ratio and the growth temperature (which was between 790° and 950°C). The crystals were typically 0.1 cm^2 on the largest faces and differed in morphology with composition. Only natural crystal faces were examined. The best crystals had 4-6 faces which were sufficiently large to allow electrochemical measurements. The crystals were identified and oriented using x-ray diffraction methods.

Contact was made to the oxide crystals by attaching a Au wire with Ag-filled epoxy (Acme Conductive Adhesives). This wire was threaded through a glass capillary, and the wire, the epoxy contact, and all of the crystal except the face of interest were masked off with a polyvinyl ketone which is used as a plater's mask (Miccrostop, Michigan Chrome and Chemical Company). The inertness of this material under the conditions of the investigation was established by partially masking off Au and Pt wires and determining their cyclic voltammetry in 1*N* H_2SO_4. No anomalous features attributable to contamination were observed. There was also no evidence that the solution was able to undercut the mask and come into contact with either the Ag in the epoxy or the Au wire.

All solutions were 1*N* H_2SO_4 prepared from deionized H_2O and reagent grade acid. A three compartment cell was used with a Pt counterelectrode and a Hg, Hg_2SO_4 reference electrode. All potentials will be quoted against the normal hydrogen electrode (NHE). During the measurements, He, N_2, or O_2 was bubbled through the solution from a bubbler slightly above the level of the working electrode. Measurements were made at room temperature.

Both potentiodynamic linear sweep and steady-state measurements were obtained. The surface electrochemical reactions of these oxides are slow, and thus the linear sweep measurements were done at a low sweep speed, 10 mV/sec. Since these oxides typically take long times to reach steady state, each steady-state measurement involved 10-15 min. The background currents, in the absence of O_2, are approximately an order of magnitude lower than the currents in the O_2-saturated solution. The steady-state results given here are the difference between the measured currents in the presence and absence of O_2. The cathodic limit of the measurements was the potential at which the steady-state current in O_2-free solution began to increase markedly. This subtraction procedure results in a small correction to the total current and does not significantly change the shape of the steady-state curves. It has been made in an effort to separate the currents due to reactions of the electrode surface from those due to O_2 reduction.

Results and Discussion

The molybdenum-oxygen system contains five distinct phases, the Magneli phases, with compositions between MoO_2 and MoO_3 (11-14). Magneli phases also exist in the tungsten-oxygen system (14). The dioxides MoO_2 and WO_2 have a rutile-type structure in which MO_6 octahedra share corners and edges. The high electronic conductivity of these materials is essentially due to the short metal-metal bond distance along the direction of edge sharing. The other oxides studied, Mo_4O_{11}, Mo_8O_{23}, and Mo_9O_{26}, have a basic structure of the ReO_3 type, in which the MO_6 octahedra are joined at corners. The oxygen-deficient stoichiometry is accounted for by some of the MO_6 octahedra being joined in other ways or by different metal coordination. In Mo_8O_{23} and Mo_9O_{26} the appropriate fraction share edges; in Mo_4O_{11} there are MO_4 tetrahedra joining the basic ReO_3-type slabs. These oxides are also electronic conductors. A detailed description of these structures is given by Kihlborg (13). The pertinent structural data and the resistivities of these compounds are summarized in Table I.

Although the oxides of molybdenum are relatively stable in acid solution, they can undergo both oxidation and reduction reactions in the region of stability of H_2O. The cyclic voltammetry of five molybdenum oxides in a limited potential region is shown in Fig. 1. Each is the second sweep after the beginning of the potential scan. The shape of the cyclic voltammograms of these oxides will undergo some change with continuous sweeping. The potential region is one in which the observed currents are due to oxidation and anodic dissolution. These samples have never been at potentials more negative than 0.4V. Under these conditions, the two higher oxides, Mo_8O_{23} and Mo_9O_{26} (which were single crystal samples but which were not oriented to determine the identity of the face being examined) do not undergo further oxidation and do not exhibit anodic dissolution.

The anodic behavior of Mo_4O_{11} is highly dependent on orientation. The structure of Mo_4O_{11}, which consists of alternating slabs of MO_6 octahedra and MO_4 tetrahedra, is layered. The [111] direction is parallel to the layers and the [100] direction is perpendicular. The current densities in this potential range are substantially higher for the (111) face than for the (100) face. Both anodic and cathodic currents are observed on the (111) face, but the (100) face sustains little cathodic current in this region. In addition, the dissolution of the (100) face of Mo_4O_{11} results in a number of current peaks which Peekema and Shafer (19) have attributed to the sequential removal of single layers of the Mo_4O_{11} structure.

Table I. Structural data and resistivities of some molybdenum and tungsten oxides

Compound	Symmetry	Lattice parameter	Resistivity 300°K (Ω cm)
MoO_2	Monoclinic[a]	a = 5.61Å b = 4.85Å c = 5.62Å β = 120.95°	1.2×10^{-4}[d]
Mo_4O_{11}	Orthorhombic[b]	a = 24.49Å b = 5.45Å c = 6.75Å	2×10^{-4}[e]
Mo_8O_{23}	Monoclinic[b]	a = 16.88Å b = 4.05Å c = 13.39Å β = 106.19°	6×10^{-1}[e]
Mo_9O_{26}	Monoclinic[c]	a = 16.74Å b = 4.09Å c = 14.53Å β = 95.45°	4×10^{1}[e]
MoO_3	Orthorhombic[b]	a = 3.96Å b = 13.86Å c = 3.70Å	High
WO_2	Monoclinic[c]	a = 5.65Å b = 4.89Å c = 5.50Å β = 120 42°	2.9×10^{-3}[d]
WO_3	Triclinic[c]	a = 7.28Å b = 7.52Å c = 3.84Å β = 90.90°	High

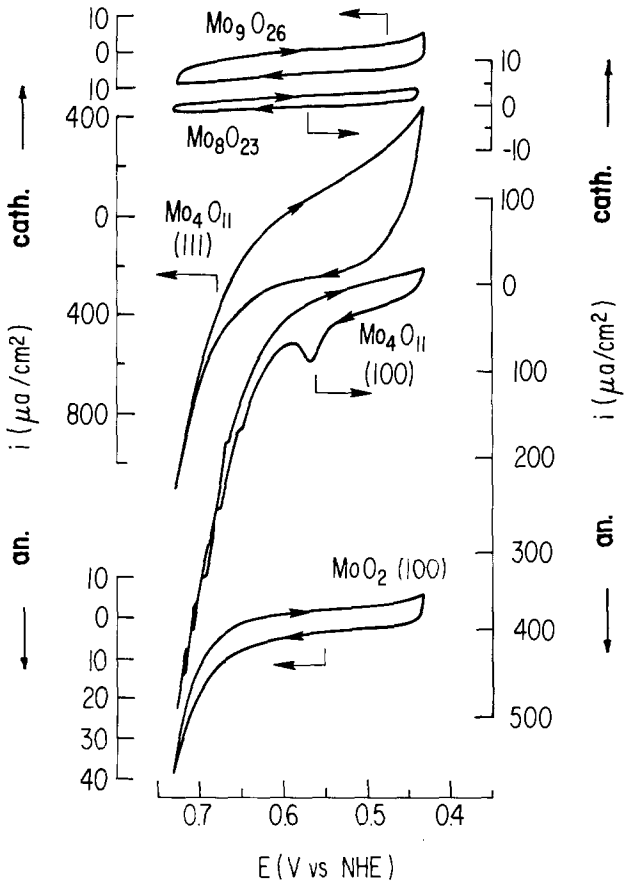

Fig. 1. Dissolution of the molybdenum oxides. Cyclic voltammetry of MoO_2, Mo_4O_{11}, Mo_8O_{23}, and Mo_9O_{26} samples which have not been subjected to potentials more negative than 0.4V. Solution is He-saturated 1N H_2SO_4. Sweep speed is 10 mV/sec.

The lowest of the oxides, MoO_2, also shows some anodic dissolution above ~0.65V. The magnitude of the dissolution current density is dependent on crystal orientation [being low for the (100) face] but the shape is similar for all orientations examined.

The differences in anodic behavior observed in Fig. 1 are thought to be related to the ability of an epitaxial layer of a higher oxide (with composition approaching MoO_3) to form on a given single crystal face. This can vary from oxide to oxide and with orientation on a single oxide. In Mo_8O_{23} and Mo_9O_{26}, most of the molybdenum is already in its highest oxidation state, and further oxidation does not occur in this potential range. However, Mo_4O_{11} and MoO_2 are further removed from MoO_3 in stoichiometry and are much more easily oxidized. Whether oxidation of a given surface results in dissolution or the formation of a stable surface layer may depend on whether the molybdenum in its higher oxidation state finds itself in a stable lattice. On the evidence of Fig. 1, it appears that the higher oxide formed on MoO_2 and on the (100) face of Mo_4O_{11} is not stable and these materials are dissolved anodically. In the case of the (111) face of Mo_4O_{11}, however, a species forms on the surface which does not entirely dissolve, and some of this is reduced during the cathodic sweep.

Very different results are obtained when the potential is swept to a more cathodic potential limit, as illustrated in Fig. 2-4. (These curves were recorded after several sweeps; changes with further cycling are not rapid.) In the potential range 0.0-0.8V, the cyclic voltammetry in He-saturated solutions of all of these molybdenum oxides except the (100) face of Mo_4O_{11} is

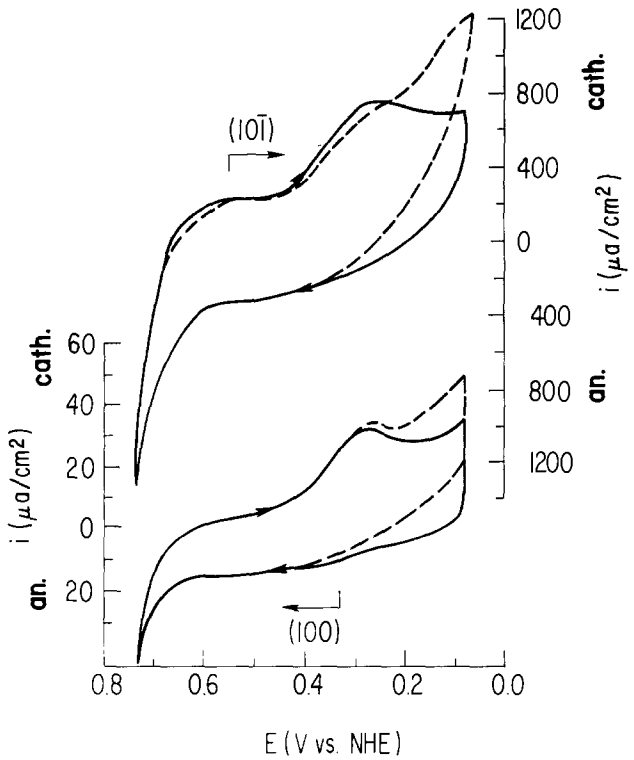

Fig. 2. Cyclic voltammetry of two single crystal faces of MoO_2 in 1N H_2SO_4. The solid curve was obtained in He-saturated solution, the dashed curve in O_2. Sweep speed 10 mV/sec.

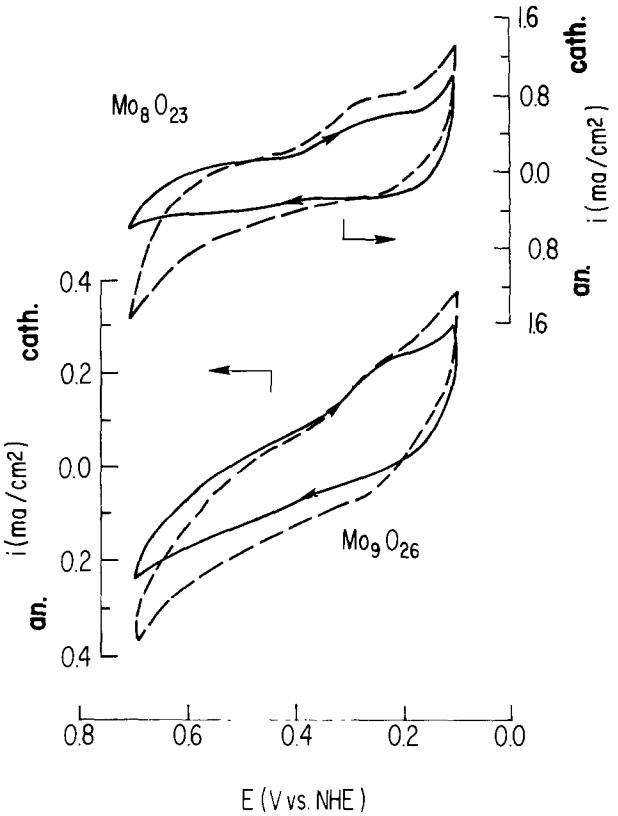

Fig. 4. Same as Fig. 2 for unoriented single crystals of Mo_8O_{23} and Mo_9O_{26}.

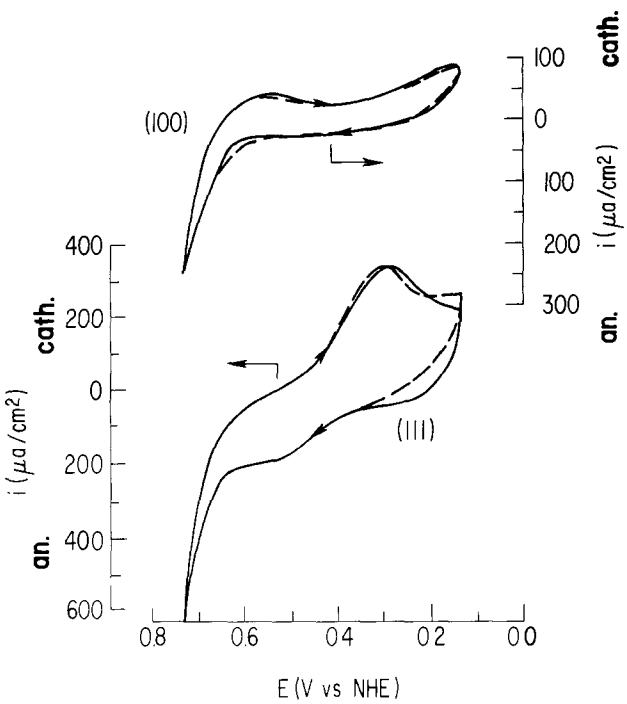

Fig. 3. Same as Fig. 2 for Mo_4O_{11}

similar, showing a broad cathodic peak at ~0.3V, which may be due to Mo(VI) + $2e^-$ → Mo(IV) (20). This behavior is due to the fact that all of these oxides undergo either oxidation or reduction in this potential range and after repeated cycling have a surface composition that is more dependent on the potential and the past history of the electrode than on the composition of the bulk oxide.

The identification of the 0.3V peak with a particular change in oxidation state of molybdenum, based on the available data, remains uncertain. The dangers of using thermodynamic data (20) to assign potential regions of stability in real systems must be kept in mind. More positive assignment of peaks cannot be made without additional, nonelectrochemical evidence. The formation of Mo(V) during anodic processes has been detected using ESR when dissolution rates were high, but it is felt that Mo(V) only occurs in the solution phase. ESCA studies of molybdenum oxide electrodes showed only Mo(VI) and Mo(IV). The solid-state reaction of the 0.3V cathodic peak is thus thought to involve direct conversion of Mo(VI) to Mo(IV).

The behavior of the (100) face of Mo_4O_{11} is somewhat different from that of any of the other crystal faces studied. This is due to the unique crystal structure of Mo_4O_{11} and the fact that the (100) face is parallel to the layers in the Mo_4O_{11} structure. The surface structure may be one with no exposed molybdenum atoms in the +6 oxidation state and thus the peak at 0.3V is not observed. The (111) face has both Mo(VI) and Mo(IV) exposed and exhibits the 0.3V peak. The 0.3V peak appears on the (100) surface after extensive cycling into the region of anodic current, which may roughen the electrode surface.

Figure 2 shows the cyclic voltammetry of two representative faces of MoO_2 scanned between ~0.0 and 0.8V. Cycling in this range results in a broad, somewhat featureless curve. In O_2-free solution, this curve apparently represents the repeated formation and reduction of a higher oxide on the MoO_2 surface. These processes occur over a wide range of potentials and do not result in sharp peaks in the cyclic voltammetry. Since the anodic and cathodic currents are not usually equal, long term changes in the cyclic voltammetry can be observed. Although the general shape of the voltammetry curves for MoO_2 is not very dependent on crystal orientation, the current density can vary by more than an order of magnitude, as illustrated in Fig. 2. The current densities for processes occurring on the (100) face of MoO_2 are much smaller than for those on the (10$\bar{1}$) face. The other faces examined fell between these extremes. The roughness factor of these mirrorlike single crystal faces is expected to be low. The differences in currents between the faces are too

large to be attributable to differences in surface roughness.

When the solution is saturated with O_2 gas, a small increase in the cathodic current on MoO_2 is observed below ~0.3V. Little change is seen at more anodic potentials in Fig. 2. At these high overpotentials, O_2 reduction currents are low on MoO_2 electrodes. The cyclic voltammetry of the (100) and (111) faces of Mo_4O_{11} over this wider potential range is shown in Fig. 3. The characteristic periodic peaks shown in Fig. 1 for the layer-by-layer dissolution of the (100) face of Mo_4O_{11} are no longer observed after continued cycling in this region. The reason for this, discussed by Peekema and Shafer (19), is a surface roughening which exposes other crystal orientations. The addition of O_2 has little effect on the cyclic voltammetry. [The comparison for the (100) face is somewhat obscured by long-term nonreproducibility of the curve.] In general, the behavior is similar to that observed on MoO_2.

Comparable curves for Mo_8O_{23} and Mo_9O_{26} are shown in Fig. 4. These measurements were made on single crystal faces, but due to the fact that crystals of a size and morphology suitable for the examination of several faces were not obtained, no effort was made to orient these crystals. When the potential is swept below ~0.3V for either Mo_8O_{23} or Mo_9O_{26}, the surface is reduced to a lower oxide which is then reoxidized in the anodic sweep to ~0.7V. After repeated cycling, the linear sweep voltammetry in He-saturated solutions is similar to that observed for the lower oxides. The curve for Mo_9O_{26} shows a marked skew with respect to the zero of current, which is probably due to *IR* effects caused by the low supply of carriers in this more highly resistive material. In the presence of O_2, somewhat higher currents are observed at both the cathodic and anodic ends of the sweep. The availability of molecular O_2 apparently promotes the oxidation or dissolution of the oxides above ~0.3V while O_2 itself is reduced at lower potentials.

Oxygen reduction on these oxide electrodes has also been studied using steady-state measurements. Figures 5 and 6 show the steady-state data for MoO_2 and Mo_4O_{11}; these curves represent the difference between the current in O_2-saturated and O_2-free solution, as discussed above. In the case of O_2 reduction on the

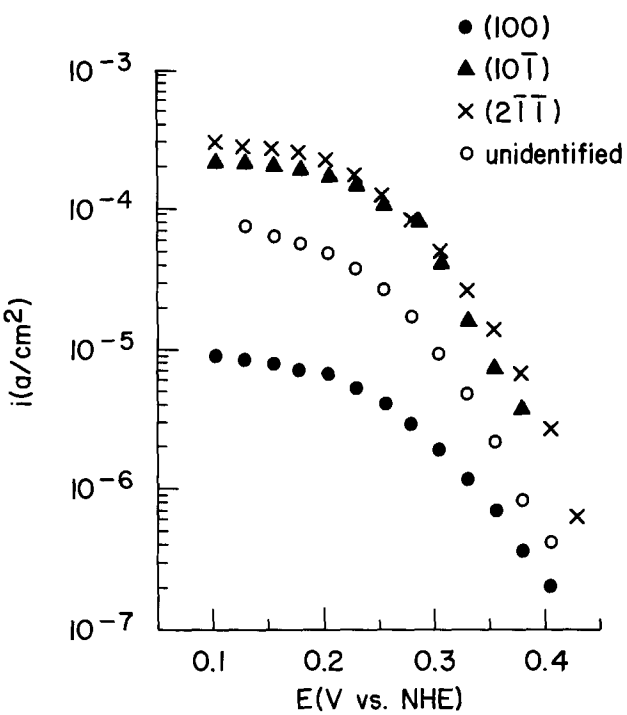

Fig. 5. Steady-state measurements of O_2 reduction on several faces of a single crystal of MoO_2. Electrolyte is 1*N* H_2SO_4.

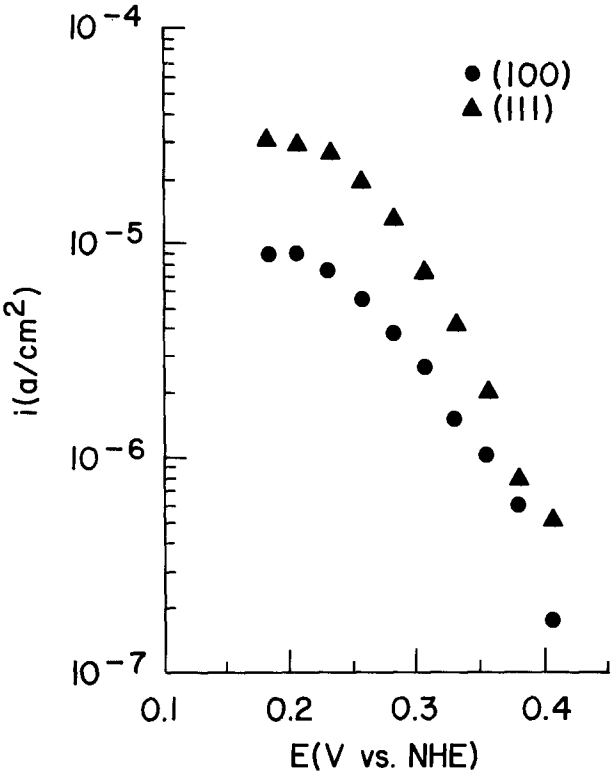

Fig. 6. Steady-state measurements for O_2 reduction on the (100) and (111) faces of Mo_4O_{11} in 1*N* H_2SO_4.

molybdenum oxides, considerable hysteresis in the measurements is observed. The data of Fig. 5 and 6 are taken in the direction of more negative potentials. If the measurements are repeated changing the potential in the anodic direction, the currents are lower than the initial measurements. The initial cathodic-going measurements can be reproduced if the pretreatment of the electrode (*i.e.*, a few cycles of the potential) is repeated. If this cycling is omitted, anomalous anodic currents due to oxidation of the electrode surface are observed at the more positive potentials in subsequent steady-state measurements.

The steady-state data for O_2 reduction on several crystal faces of MoO_2 are shown in Fig. 5. At potentials anodic to ~0.45V the measured currents are anodic and are due to oxidation of the electrode surface. Below 0.4V small O_2 reduction currents are measured. The logarithm of the current shows linear dependence on potential over a relatively narrow range between 0.3 and 0.4V. At lower potentials, the current due to O_2 reduction becomes almost independent of potential. It is difficult to measure the O_2 reduction current below ~0.2V because currents due to surface changes of the molybdenum oxide crystal are of the same magnitude as those due to O_2 reduction; the accuracy of the data in this region is low. The interference of the currents due to reduction of the surface, rather than a limit in the mass transport of species from solution, is thought to cause the change of slope at ~0.25V in Fig. 5.

The data of Fig. 5 show a large dependence of O_2 reduction current on crystal orientation. At a given potential, the current due to O_2 reduction is more than an order of magnitude higher on the (10$\bar{1}$) face of MoO_2 than on the (100) face. This is the same order of dependence of current density on orientation as was measured in the cyclic voltammetry (Fig. 2). This is believed to be a real property of the crystal face and not an artifact, such as the influence of mass transport to the crystal surface. No dependence of the measured O_2-reduction current for a given crystal face on surface area was observed, as would be expected if mass transport accounted for differences in current densities.

Oxygen reduction on MoO_2 occurs at high overpotentials with low measured current densities; the catalytic activity of MoO_2 (Fig. 5) is comparable to that measured by Randin on Pt-free Na_xWO_3 (3). The determination of the mechanism of O_2 reduction is severely complicated by simultaneous changes of the oxidation state of the electrode surface.

The extraction of kinetic parameters from the data of Fig. 5 does not appear justified due to the limited range of linearity, if any, and the extremely long extrapolation that would be required to obtain i_o. Such plots do, however, give useful information in comparing the rate and mechanism of O_2 reduction on electrodes of different composition or on different faces of the same oxide.

Figure 6 shows the steady-state measurements of O_2 reduction on the (100) and (111) faces of Mo_4O_{11}. A behavior similar to that of MoO_2 is observed; at these overpotentials the currents lie in the same range as for MoO_2 and the change of slope at low potentials is again observed. The O_2 reduction currents are lower on the (100) face of Mo_4O_{11} than on the (111) face, the same order observed in the currents in the cyclic voltammetry of Fig. 3. Rest potential measurements in O_2-free and O_2-saturated solutions were found to be not very reproducible. The presence of O_2 results in only a small (~25 mV) change in rest potential, indicating that O_2 is not involved in a reversible couple at the electrode surface. The potential is mainly determined by the composition of the electrode surface. Steady-state measurements of O_2 reduction on the higher oxides Mo_8O_{23} and Mo_9O_{26} also show behavior similar to that in Fig. 5 and 6. The small dependence of the cyclic voltammetry and the steady-state O_2 reduction measurements on the stoichiometry of the crystal is not thought to imply that the electronic properties of the oxide are not important to its electrochemical behavior. Instead, it appears that with pretreatment that includes cycling of the electrode potential over a fairly wide range, all of these materials tend to form similar surface layers. The composition of the surface in contact with the solution is more dependent on potential than on the bulk composition of the crystal.

The results obtained for the molybdenum oxides have been compared with measurements on single crystals of WO_2, which has a rutile-type structure similar to that of MoO_2, with the aim of relating the differences in behavior of these two materials toward O_2 reduction to differences in their electronic properties. However, it was found that the electrochemistry of these materials is dominated by chemical factors, specifically by the stability of their higher oxides in contact with acid solution. In this respect, WO_2 differs substantially from MoO_2.

This difference is illustrated by a comparison of Fig. 7, which shows the cyclic voltammetry of WO_2 in a potential region where mainly anodic currents flow, with Fig. 1, which includes similar data for MoO_2. The curve of Fig. 7 was obtained on an unidentified face of a WO_2 crystal. Similar curves were obtained for other orientations, although the magnitude of the current density was found to depend on orientation. Anodic currents are observed above ~0.4V (a lower potential than that for MoO_2, which does not show significant anodic currents below ~0.65V).

At least two broad current peaks are observed in this range. The WO_2 electrode undoubtedly already has a surface film as a result of storage in air, and this film is thickened during the anodic sweep of Fig. 7 without any significant reduction taking place in the cathodic sweep. This film has a defect structure, allowing charge transfer, but it becomes more highly insulating at higher potentials as its composition approaches WO_3. Further, the thicker oxide films are less likely to form epitaxial layers on the WO_2 crystal. The changes in film stoichiometry and structure probably cause the two broad peaks observed in Fig. 7.

The "WO_3" film which is formed at 1.1V is not significantly reduced above −0.17V. In addition, there is no evidence of formation of a hydrogen tungsten bronze by injection of hydrogen into the surface of the "WO_3" layer. Hydrogen tungsten bronzes are usually formed from amorphous WO_3 [*e.g.*, (22, 23)], and their formation may be energetically less favorable in the highly crystalline film of the higher oxide formed on a WO_2 single crystal in this range. Even at much more anodic potentials than shown here, a large rise in current, indicating active dissolution, does not appear. Repeated cycling shows lower current densities on each subsequent sweep. These results indicate that WO_2 does not dissolve anodically but instead forms a

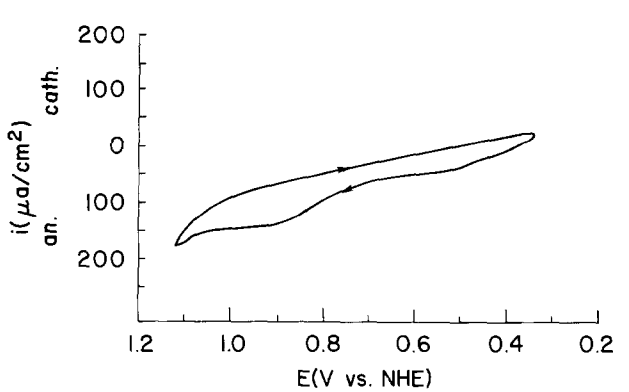

Fig. 7. Oxidation of the surface of WO_2. Cyclic voltammetry of WO_2 anodic to 0.3V. Solution is N_2-saturated 1*N* H_2SO_4. Sweep speed is 10 mV/sec.

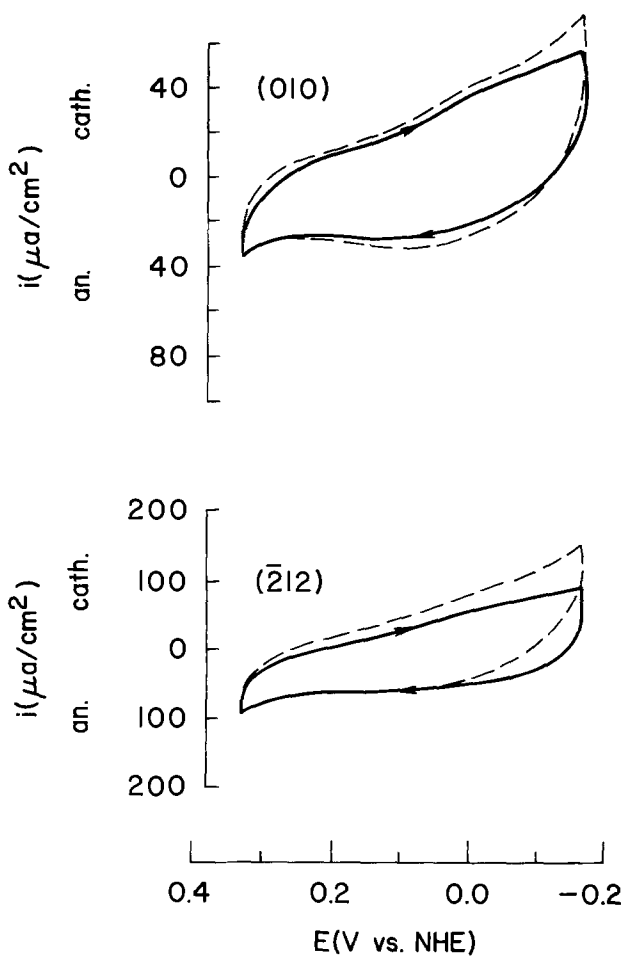

Fig. 8. Cyclic voltammetry of WO_2 cathodic to 0.33V. The solid curve was obtained in N_2-saturated 1*N* H_2SO_4, the dashed curve in O_2-saturated solution. Sweep speed 10 mV/sec.

stable WO_3 layer on its surface. The wide potential range of stability of WO_3 is indicated by Pourbaix (21).

The cyclic voltammetry of WO_2 if the potential range of formation of a higher oxide is avoided is shown in Fig. 8. Results are given for two representative crystal faces in the potential range between −0.17 and 0.33V. An almost featureless current-potential curve is observed in this region. The small hump which is barely distinguishable at ~0.0V can probably be attributed to $W(VI) + 2e^- \rightarrow W(IV)$ (21). If the solution is saturated with O_2, slightly higher cathodic currents are observed.

The steady-state measurements of O_2 reduction on WO_2 are shown for several orientations in Fig. 9. Each point represents the difference between the current density in O_2-saturated solution and that in N_2-saturated solution. The measurements were taken in the direction of more cathodic potentials. As was found to be the case for MoO_2, the measured currents were lower if the direction of measurement was reversed.

The current density due to O_2 reduction is highly dependent on crystal orientation. A given O_2-reduction current occurs at substantially higher overpotentials on WO_2 than on MoO_2. The data of Fig. 9 seem to fall into two groups. For the $(\bar{2}12)$, (010), and (121) faces, the logarithm of current is fairly linear with potential in the range examined. These three curves are approximately parallel with slopes of ~250 mV/decade. The data on the (100) and $(01\bar{1})$ faces, on the other hand, are quite nonlinear, showing a plateau at ~0.2V. The reason for these differences is not clear.

Conclusions

The cyclic voltammetry of the electronically conducting oxides of molybdenum, MoO_2, Mo_4O_{11}, Mo_8O_{23}, and Mo_9O_{26}, and of the tungsten oxide WO_2 in 1*N* H_2SO_4 exhibits broad irreversible current peaks. This implies that multiple oxide phases with compositions intermediate to MO_2 and MO_3 can be formed. A mixture of these oxide phases may exist simultaneously on the surface. If crystals of molybdenum oxides with different bulk compositions are given similar treatment, the surfaces all tend to have the same composition at a given potential. This results in a small dependence of the electrochemical behavior on composition.

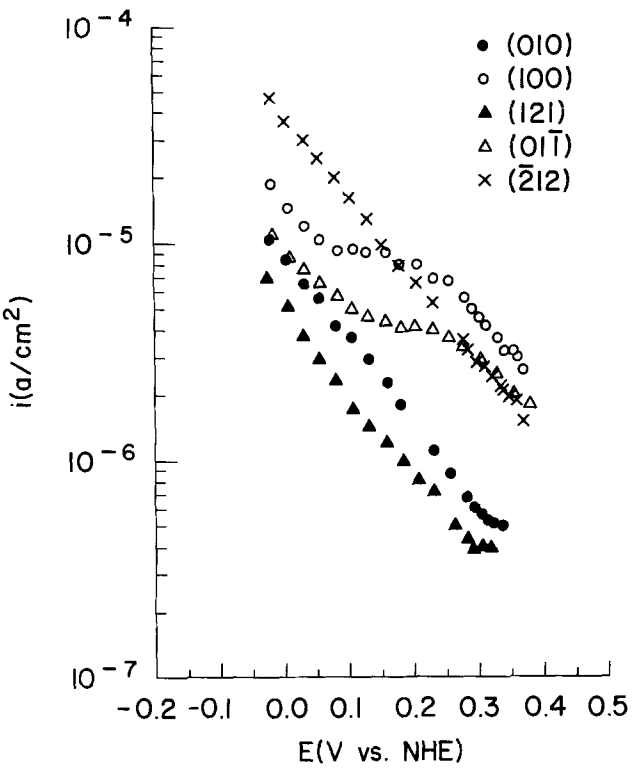

Fig. 9. Steady-state measurements of O_2 reduction on several faces of a WO_2 single crystal. Electrolyte is 1*N* H_2SO_4.

The differences between the electrochemistry of MoO_2 and WO_2 are largely explained by the differences in the stability of the higher oxides MoO_3 and WO_3 in aqueous solutions. The MoO_3 is formed at higher potentials than WO_3 and is much more soluble in acid solution (20, 21). Thus, the MoO_2 surface is more stable in solution than WO_2. The higher overvoltage for a given O_2-reduction current on WO_2 than on MoO_2 can be explained by the inhibiting nature of a less conducting higher oxide on the surface. Since both WO_2 and MoO_2 are excellent metals, *IR* effects in the crystals would not result in the observed behavior. The differences in the potential range of stability of MoO_2 and WO_2 tend to mask any comparisons which could give information about the role of electronic factors in electrochemical reactions, since their surface composition at a given potential is generally quite different.

Reactions of the electrode surface occurring in the potential range of interest interfere with the measurement of O_2 reduction kinetics and the determination of a mechanism for this reaction. Nonetheless, it is clear that the rate of the reaction can vary markedly with crystal orientation.

The feature of these rutile-type oxides which gives them their high conductivity is the small metal-metal bond length in the cathode direction. In some crystal orientations, this small metal-metal bond distance (which is about twice the O_2 bond length) appears in the plane of the surface. Of the crystal faces examined (Fig. 5 and 9), the (100), (010), and (011) have small metal-metal distances in the plane of the surface. These orientations tend to support smaller O_2 reduction currents than the other orientations. The only exception to this order is the (121) face of WO_2 which also gives low current densities without a small metal-metal distance. Thus the absence of the short metal-metal bond appears to be associated with higher rates of O_2 reduction.

Comparison of these data with results on a larger number of MO_2 electrodes with rutile structure are made in the following paper (24).

An Investigation of the Electrochemistry of a Series of Metal Dioxides with Rutile-Type Structure: MoO_2, WO_2, ReO_2, RuO_2, OsO_2, and IrO_2

Jean Horkans* and M. W. Shafer

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Six transition metal dioxides, MoO_2, WO_2, ReO_2, RuO_2, OsO_2, and IrO_2, have been examined as electrodes in H_2SO_4 solution. The oxides MoO_2, WO_2, ReO_2, and RuO_2 have broad current-potential profiles, indicating the formation of a surface layer which can exist over a range of compositions. Steady-state measurements of O_2 reduction showed catalytic activities which were low compared to common O_2 catalysts such as Pt, but of the same order as other oxide catalysts. Activities were lowest for WO_2 and ReO_2, which form resistive surface layers of a higher oxide. The only material studied which was sufficiently stable to allow measurement of both O_2 evolution and O_2 reduction was RuO_2. The current-potential profiles of OsO_2 and IrO_2 are characterized by distinct changes of oxidation state. These two oxides were not sufficiently stable to allow the measurement of O_2 reduction.

A number of transition metal dioxides which have crystal structures related to that of rutile, TiO_2, are as highly conductive as many metals. In spite of the high conductivity of these compounds and their relative stability in aqueous solution, only a few of them have been investigated as electrode materials. A notable exception is RuO_2, which, since its success as an anode in Cl_2 production, has also been studied as a catalyst for other electrode reactions (1-3). The RuO_2 electrodes studied in the past were films prepared by oxidation of Ru(III) salts, supported on another metal, often Ti, and were likely to be nonstoichiometric. Such RuO_2 films were found to be much more stable against dissolution than anodized Ru (1). Oxygen gas can be evolved for extended periods without apparent damage to the electrode; O_2 is reduced on RuO_2 by a different mechanism than that by which it is evolved (3). The O_2 evolution overpotential on RuO_2 is lower than that on Pt but the overpotential for O_2 reduction is higher.

We have examined the electrochemistry of unsupported RuO_2 crystals and compared this with the previously reported data for Ti-supported RuO_2 films. In addition, similar measurements have been made on crystals of MoO_2, WO_2, ReO_2, OsO_2, and IrO_2, all of which are highly conducting oxides with rutile-type structures. The object of examining a series of oxides with the rutile structure was to obtain more definitive information about the role of electronic factors in electrode processes and electrocatalysis. These oxides have a range of d-level occupations without major changes in the environment of the ions in the crystal. The electrode reaction which was chosen to compare these materials was the reduction of O_2, a reaction for which various other transition metal oxides have been examined as catalysts [*e.g.*, (4-7)].

* Electrochemical Society Active Member.

Key words: MoO_2, WO_2, ReO_2, RuO_2, OsO_2, IrO_2, rutile-related oxides, oxygen reduction, oxygen evolution, electrocatalysis.

Experimental

The metal dioxide crystals were grown by a variety of techniques (8) which differ somewhat from the previously published methods (9). The MoO_2 and WO_2 were grown by vapor transport using the appropriate ratio of metal powder and metal trioxide as starting materials, I_2 as the transporting agent, and a growth temperature of 850°-925°C. The best RuO_2 crystals were obtained by heating Ru metal at 1150°C in converging streams of N_2 and O_2. The RuO_2 was transported to a cooler part of the furnace where crystal growth occurred (8). The IrO_2 was prepared in a similar manner using Ir powder heated to 1250°C, the IrO_2 being transported by pure O_2 to a cooler area (~900°C), where crystal growth occurred. A prereacted powder of OsO_2 was transported in a sealed silica tube with a temperature gradient of 1050°-1000°C; no transporting agent was used. The ReO_2 crystals were obtained by transporting ReO_2 powder with I_2 in a sealed tube at 1100°-960°C.

Of the materials studied, only MoO_2 and WO_2 to date have been obtained as crystals large enough to allow

investigation of individual natural faces. Contact was made to these single crystals by attaching an Au wire with Ag-filled epoxy as described in the preceding paper (10). All of the other oxides were examined as clusters of smaller crystals as they had nucleated and grown on the container walls. The Au wire was attached to one end of such a cluster and the contact area masked off. The roughness factors of these samples vary with the size of the crystallites formed. The crystallites were quite small in the case of OsO_2 and IrO_2, fairly large (~0.1 mm on a side) for RuO_2, and even larger for ReO_2. Standard electrochemical techniques were used, which have been described in detail elsewhere (10). The current-potential profiles were recorded after an initial sweep or two. Since surface reactions on some of the oxides are slow, the relatively low sweep rate of 10 mV/sec was used in the potential sweep measurements. The solution in all cases was 1*N* H_2SO_4 prepared from reagent-grade acid and deionized H_2O. All potentials are quoted with reference to the normal hydrogen electrode (NHE).

Results and Discussion

The oxides studied in this investigation, MoO_2, WO_2, ReO_2, RuO_2, OsO_2, and IrO_2, are among the most conductive members of a larger group of transition metal dioxides which have crystal structures related to that of rutile, TiO_2 (9). The main structural units of rutile are TiO_6 octahedra, which share corners and edges in the crystal (9). The dioxides RuO_2, OsO_2, and IrO_2 are isomorphic with tetragonal TiO_2. The other dioxides, MoO_2, WO_2, and ReO_2, are made up of distorted MO_6 octahedra and have lower symmetry than tetragonal. A summary of the crystallographic data of these dioxides is given in Table I. The oxides considered here exhibit high metallic-type conductivity; the room temperature resistivities are given in Table I. This section will discuss in turn the stability of each of these oxides in sulfuric acid solution and the measurement of O_2 reduction on electrodes of these materials.

MoO_2.—The cyclic voltammetry of several crystal faces of MoO_2 and WO_2 electrodes and steady-state O_2 reduction data are given in the preceding paper (10). A broad, featureless current-potential profile is observed, Fig. 2 of (10), the shape being similar on all faces, but the magnitude of the current density varying with orientation. Anodic dissolution of MoO_2 begins at ~0.65V. The broad reduction peak observed at ~0.3V is probably associated with the process Mo(VI) + $2e^-$ → Mo(IV) (15).

Assigning peaks in the cyclic voltammograms of these rutile electrodes to changes in oxidation state of the surface is tenuous based on electrochemical evidence alone. Corroborative nonelectrochemical investigations, such as ESCA measurements, would greatly increase the understanding of these systems. Since such nonelectrochemical evidence is largely unavailable, tentative identification of the oxidation state changes of the surfaces of the rutile-related oxides has been based on the thermodynamic data of Pourbaix (15). However, thermodynamic data may not give direct information about potential regions of stability in real systems. In addition, the Pourbaix diagrams may not consider all the possible species which can form. These considerations should be kept in mind when interpreting the cyclic voltammetry of these oxides.

The broadness of the features in the cyclic voltammetry of MoO_2 indicates that the composition of the surface layer of the crystal can exist over a range of stoichiometries with different Mo(VI)/Mo(IV) ratios. The stable oxides (16) may coexist in discrete layers or patches on the surface to give a virtually continuous variation of composition with potential. The dependence of the current density on crystal orientation is explicable in terms of compatibility of the crystal structures of MoO_2 and the higher oxide forming on the surface. An epitaxial layer of the higher oxide will form much more readily on certain crystal faces than others, resulting in a higher observed current density on those faces.

The cyclic voltammetry in O_2-saturated solution shows small O_2 reduction currents cathodic to ~0.3V. The steady-state O_2 reduction data, Fig. 5 of (10), show a plateau below ~0.2V which is not thought to be due to a mass transport limitation of any species in solution. Below 0.2V, currents due to changes in oxidation state of the electrode surface are nearly as large as those due to O_2 reduction. This illustrates the difficulty of measuring O_2 reduction kinetics on MoO_2, since the composition of the electrode surface is changing in the same potential region in which O_2 reduction occurs. The effect of orientation on O_2 reduction on MoO_2 electrodes is discussed (10).

WO_2.—The chemistries of molybdenum and tungsten compounds show many similarities. The differences in the electrochemistries of MoO_2 and WO_2 can be largely explained in terms of the fact that WO_3 has a much wider potential range of stability than MoO_3, and thus WO_2 is less stable in aqueous solution than MoO_2 (15). The cyclic voltammetry of a WO_2 electrode (Fig. 8 in (10)), is also nearly featureless. A broad peak, probably attributable to W(VI) + $2e^-$ → W(IV) (15), is observed at ~0.0V. A range of possible compositions of the surface layer is likely, similar to the case of a MoO_2 electrode. Anodic currents flow at more cathodic potentials on WO_2 than on MoO_2. The WO_3 layer that forms is expected to exhibit some nonstoichiometry, does not dissolve to a significant extent, and is not reduced above −0.17V. At a given overpotential, O_2 reduction currents are lower on WO_2 than MoO_2, as shown in Fig. 9 of the preceding paper (10). Large dependences of current density on orientation are observed (10).

RuO_2.—All single crystals of RuO_2 which have been grown to date have been slightly too small to allow electrochemical measurements on individual natural faces. The RuO_2 electrodes which have been used consist of small crystallites adhering to a small piece of fused silica. Thus many crystal orientations are simultaneously exposed to the solution. X-ray diffraction analysis of the electrode surface shows an absence of reflections from low index planes. The predominant orientations are (211), (310), (301), and (321). The roughness factor is significantly greater than unity and has been estimated to be on the order of 10.

The cyclic voltammetry of a multicrystalline electrode of RuO_2 in 1*N* H_2SO_4 is shown in Fig. 1. The broad current-potential profile resembles that observed by Galizzioli *et al.* (1) and by O'Grady *et al.* (3) for

Table I. Crystallographic data and resistivities of rutile-type metal dioxides

Oxide	Symmetry	Lattice constants	Resistivity at 300°K (Ω cm)
MoO_2	Monoclinic[a]	a = 5.61Å b = 4.85Å c = 5.62Å β = 120.95°	1.2×10^{-4}[d]
WO_2	Monoclinic[b]	a = 5.65Å b = 4.89Å c = 5.50Å β = 120.42°	2.9×10^{-3}[d]
β-ReO_2	Orthorhombic[c]	a = 4.81Å b = 5.64Å c = 4.60Å	8×10^{-5}[e]
RuO_2	Tetragonal[d]	a = 4.49Å c = 3.11Å	5×10^{-5}[d]

RuO_x films on Ti. However, curves with such broad features would not be expected to be very sensitive to differences in the state of the electrode. The current-potential profile of Fig. 1 differs little from that obtained by continuous cycling of a Ru electrode in the same potential range (1, 17).

Figure 1 indicates that oxidation and reduction of the electrode surface occur over a wide range of electrode potentials. Two broad features are indicated, a nearly reversible peak at ~0.65V and a widening of the curve which indicates another peak above the anodic limit of 1.23V. The more anodic of these peaks has been attributed by Galizzioli *et al.* (1) to $2RuO_2 + 2H^+ + 2e^- \rightleftharpoons Ru_2O_3 + H_2O$ and the more cathodic peak to $Ru_2O_3 + 6H^+ + 6e^- \rightleftharpoons 2Ru + 3H_2O$. These reactions are limited to the surface layers of the electrode. The magnitude of the current density is the same on these crystals of RuO_2 as on the RuO_x films of O'Grady *et al.* (3) if an order of magnitude difference in roughness factor is assumed. The dashed line in Fig. 1 shows somewhat increased cathodic currents below 0.5V due to O_2 reduction when the solution is saturated with O_2 gas. Oxygen evolution is observed if the anodic limit of the sweep is higher than ~1.35V.

Ruthenium dioxide is the only rutile studied which is sufficiently stable to allow investigation of both O_2 reduction and O_2 evolution. Steady-state data for O_2 reduction on RuO_2 are shown in Fig. 2. Each point of Fig. 2 is the difference between the measured steady-state current density in O_2-saturated solution and that in N_2-saturated solution. This correction is very small in the case of RuO_2, where the background currents are smaller than the O_2 reduction currents by nearly two orders of magnitude. The hysteresis observed with reversal of the direction of potential change is small, in contrast to MoO_2 and WO_2. A considerable time is required to reach steady state; each measurement represents ~15 min.

Significant O_2 reduction currents are not observed above 0.6V. Below 0.6V, the plot of ln i *vs.* E is not linear. The extraction of kinetic parameters from Fig. 2 is not justified because of the nonlinearity and the long extrapolation to E_{rev}, as discussed in (10). The bend-over at the lowest potentials may be due to formation of a lower oxidation state of ruthenium. Galizzioli *et al.* (1) suggest penetration of hydrogen into the lattice in this potential range. The potential range of significant O_2 reduction on RuO_2 is comparable to that observed on MoO_2 electrodes.

The data of Fig. 2 are different from those obtained by O'Grady *et al.* (3) in basic solutions. These authors observe cathodic currents at lower overvoltages than those in Fig. 2 and a distinct change of slope in the E-ln i plot. Some of the differences between these two sets of data may be due to a difference in the mechanism of O_2 reduction in acidic and basic solution, to a different surface state of the electrode in acid and base, and to the fact that the present data were obtained using RuO_2 crystal electrodes while those of O'Grady *et al.* involved Ti-supported RuO_2 films. In addition,

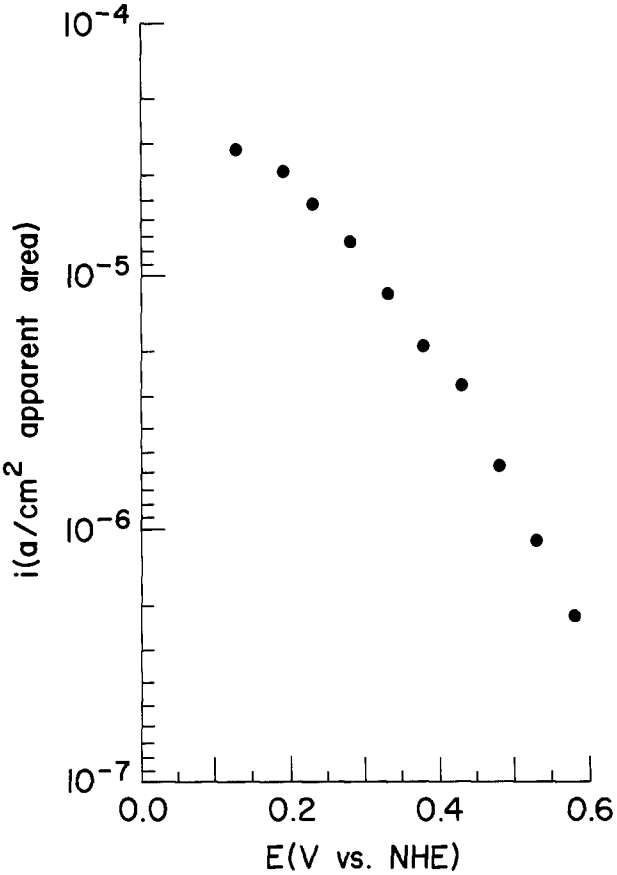

Fig. 2. Steady-state measurement of O_2 reduction on a group of crystallites of RuO_2 in 1N H_2SO_4.

our studies indicate that the 2 mV/sec sweep rate used by O'Grady *et al.* is probably not sufficiently slow to allow steady state to be attained on RuO_x films.

The steady-state data for O_2 evolution on RuO_2 crystals are shown in Fig. 3. Insignificant hysteresis is observed when the direction of measurement is reversed and less time is required to reach steady state than is required for O_2 reduction on the same electrode. The data of Fig. 3 show significant O_2 evolution anodic to 1.33V. The plot of ln i *vs.* E is linear over an order of magnitude in current. The deviation from linearity at low currents may be due to solution impurities, and the deviation at higher currents occurs because neither forced mass transport nor IR correction was used in these experiments. The linear portion of Fig. 3 has a slope of 65 mV/decade and extrapolates to an i_o of 1.4×10^{-6} A/cm² apparent area. O'Grady *et al.* (3) have measured O_2 evolution in 4M KOH on Ti-supported RuO_x and have found linearity over three orders of magnitude of current with a slope of 40 mV/decade. Differences between measurements in acid and base may again be explained by differences in the surface state of the oxide in the two solutions. The RuO_x films would also be expected to have a greater number of defects than the RuO_2 crystals, possibly resulting in a greater number of active sites and increased activity.

If the cyclic voltammetry (Fig. 1) is repeated after extensive O_2 evolution, an apparent increase in surface area is indicated by increased currents. Galizzioli *et al.* (1) report no change in Ti-supported RuO_x electrodes upon O_2 evolution except when gas bubbles do mechanical damage in micropores. However, the crystals used in this work are not expected to be microporous.

The fact that the data of Fig. 2 and 3 do not intersect at E_{rev} shows that O_2 reduction and O_2 evolution occur by completely different mechanisms on RuO_2, as is expected since the electrode surface is in a lower oxidation state in the potential region of O_2 reduction than in the potential region of O_2 evolution. Future

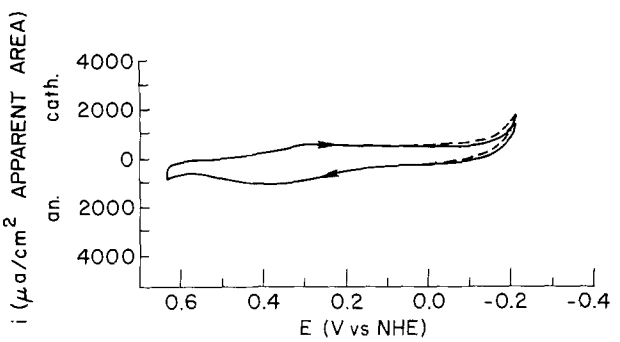

Fig. 4. Cyclic voltammetry of a group of crystallites of ReO_2 in N_2-saturated (—) and O_2-saturated (— —) 1N H_2SO_4. Sweep speed is 10 mV/sec.

work is planned to determine the dependence of O_2 evolution and O_2 reduction on crystal orientation.

ReO_2.—The Pourbaix diagram (15) for the Re-H_2O system indicates that ReO_2 has a very narrow potential range of stability in acid solution and is unstable in base. The data of Fig. 4, however, indicate that an electrode of ReO_2 in 1N H_2SO_4 undergoes neither major oxidation nor reduction in the potential range between −0.17 and 0.63V. The changes in oxidation state of the surface observed in Fig. 4 result in a relatively stable electrode surface. The large size of the ReO_2 crystallites leads to a surface roughness of the multicrystalline ReO_2 electrode significantly greater than that of the RuO_2 electrode of Fig. 1, accounting for the high apparent current densities observed in Fig. 4.

The cyclic voltammetry of ReO_2 is similar to that of the other rutiles, in that changes of oxidation state occur over broad potential regions. A broad peak centered at ~0.35V is observed, which is probably attributable to a reduction of Re(IV) to Re(III) below this potential.

Figure 4 shows that in O_2-saturated solution small O_2 reduction currents are observed below 0.0V. The steady-state data for O_2 reduction on an electrode of ReO_2 are shown in Fig. 5. These data are quite reproducible and exhibit little hysteresis. The behavior is highly nonlinear and probably reflects the fact that the electrode surface is changing over the potential range in which O_2 reduction is being measured. (A parallel reaction, such as H_2 evolution, occurring on an electrode surface of constant composition, should not lead to a slower rate of change of current with potential at more negative potentials.) The O_2-reduction current densities for a given overvoltage are comparable on ReO_2 and WO_2.

OsO_2.—The electrochemical behavior of OsO_2 is quite different from that of the other rutiles discussed so far. The cyclic voltammetry of a multicrystalline OsO_2 electrode in 1N H_2SO_4, shown in Fig. 6, is not featureless, but exhibits two broad and nearly reversible peaks, centered at ~0.95 and ~1.15V. The oxidation state of the surface changes markedly between 0.8 and

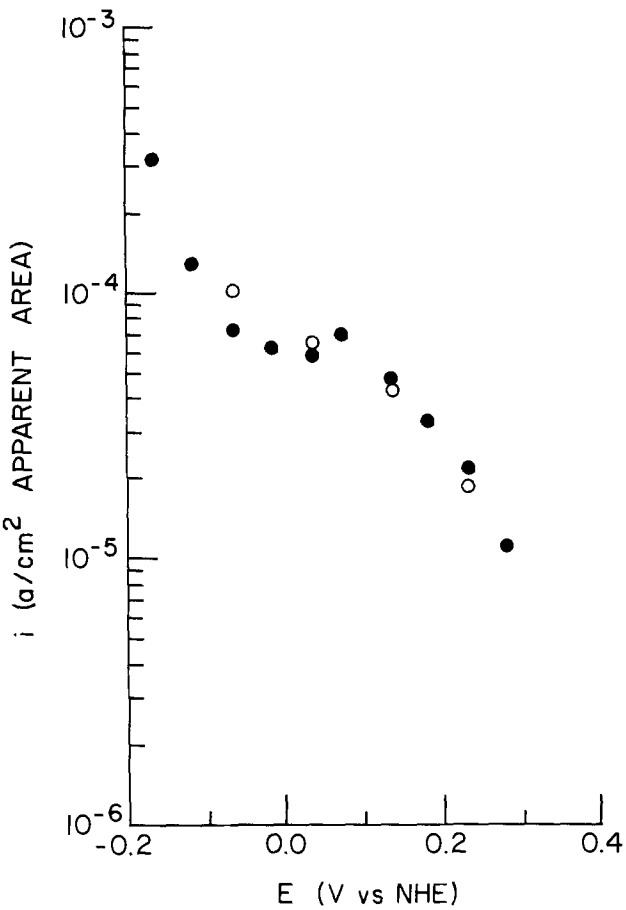

Fig. 5. Steady-state measurement of O_2 reduction on a group of crystallites of ReO_2 in 1N H_2SO_4. The closed and open points represent two sets of measurements made on consecutive days.

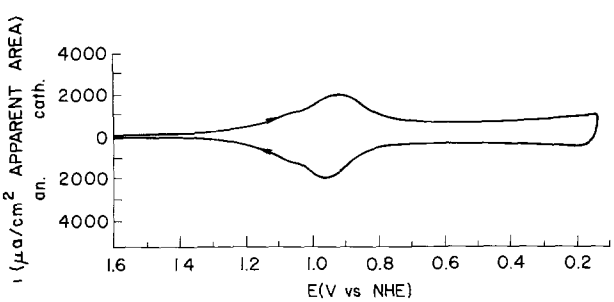

Fig. 6. Cyclic voltammetry of a group of crystallites of OsO_2 in N_2-saturated 1N H_2SO_4. Sweep speed is 10 mV/sec.

1.2V, but above and below this range only small currents are observed. As discussed above, the electrochemical and thermodynamic data do not give sufficient information for the unambiguous assignment of the oxidation state of the surface. Only hypothetical assignments can be made. The higher oxide, stable above 1.2V, is probably not OsO_4, since this compound reacts with H_2O. The surface at potentials more anodic than ~1.2V is postulated to be OsO_2. The composition of the surface at low potentials is more difficult to postulate. The Pourbaix diagram for Os (15) indicates that the surface below ~0.7V should consist of Os metal but does not indicate that two current peaks should be observed on reducing OsO_2. A lower osmium oxide, *i.e.*, an Os(II) or Os(III) species, not considered by Pourbaix, is probably formed in the intermediate potential region. When cyclic voltammetry was run in O_2-saturated solution, no evidence of O_2 reduction was observed. Repeated cycling resulted in an increase in current density, indicating an apparent increase in surface area. The electrode was not sufficiently stable to allow steady-state measurements.

IrO_2.—The cyclic voltammetry of a multicrystalline electrode of IrO_2 (Fig. 7) resembles that of OsO_2, rather than the other rutiles studied, in that it exhibits distinct current peaks. A peak occurs in the anodic sweep at ~0.8V; the cathodic sweep exhibits peaks at 0.55 and 0.6V. The total anodic and cathodic charges passed in Fig. 7 are approximately equal. The limit of the anodic sweep determines the amount of charge. As the anodic limit of the scan is made more positive, further anodic currents flow and the amount of cathodic charge consumed in the retrace becomes commensurately larger.

The Pourbaix diagram (15) for the Ir-H_2O system indicates that IrO_2 is stable in solutions of *p*H 0 from ~0.9V to potentials well above those necessary for O_2 evolution, that Ir metal is stable below 0.9V, and that an Ir(III) oxide is not stable. The observations in the preceding paragraph indicate that a considerable depth of the IrO_2 surface is reduced when the electrode is immersed in H_2SO_4 solution. This reduced surface is reoxidized to Ir(IV) above ~0.7V. The reduction in the cathodic sweep takes place in two steps, as indicated by the two cathodic peaks. The large peak at 0.6V is due to the formation of an Ir(III) species from the reduction of Ir(IV). The broad shoulder like peak at about 0.5V is a further reduction to a lower oxidation state, *e.g.*, Ir(II) or Ir(0).

The cyclic voltammetry of IrO_2, shown in Fig. 7, is quite different from that of Ir metal (18). The current-potential profile of Ir metal shows a fairly reversible peak at ~0.9V, with no major details at lower potentials which would indicate the formation of Ir(III). When the cyclic voltammetry of IrO_2 is run in O_2-saturated solution, some differences are observed. However, the stability of the IrO_2 surface in solution is not adequate to allow measurements of O_2 reduction currents. Large apparent changes in surface area occur upon cycling of the potential.

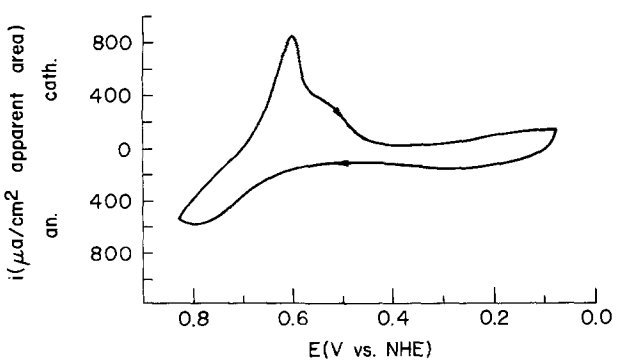

Fig. 7. Cyclic voltammetry of a group of crystallites of IrO_2 in N_2-saturated 1*N* H_2SO_4. Sweep speed is 10 mV/sec.

Conclusions

Six transition metal dioxides with rutile-related structures, MoO_2, WO_2, ReO_2, RuO_2, OsO_2, and IrO_2, were examined as electrodes in 1*N* H_2SO_4 solution. All of these compounds undergo changes in composition of their surface layers as a function of potential. However, the metal dioxides are substantially more stable in acid solution than is indicated by the equilibrium diagrams of Pourbaix (15) and caution should be used in applying these diagrams to such materials.

These oxides appear to show two types of behavior. The cyclic voltammetry of MoO_2, WO_2, RuO_2, and ReO_2 is characterized by broad, featureless current-potential profiles. Such broad profiles indicate that changes of oxidation state of the surface can occur over a range of potentials and that the composition of the surface oxide layer can vary substantially. In contrast, the current-potential profiles for OsO_2 and IrO_2 showed distinct peaks which can be associated with a fairly sharp change in the composition of the surface layer.

The rutiles on which O_2 reduction could be measured showed lower catalytic activity for this reaction than Pt but had activities of the same order as tungsten bronzes. The reaction is least favorable on the dioxides of tungsten and rhenium. This can be correlated with the fact that, of the metals studied, tungsten and rhenium have the most stable higher oxides. Thus, the coverage or partial coverage of the surfaces of WO_2 and ReO_2 by the less conducting higher oxides WO_3 and ReO_3 probably inhibits the O_2 reduction reaction.

The measurement of the kinetics and mechanism of O_2 reduction on these rutile electrodes is prevented by reactions of the electrode surface occurring in the same potential region as O_2 reduction. Only RuO_2 is stable over a sufficiently wide potential range to allow the measurement of the rates of both O_2 reduction and O_2 evolution. These two reactions proceed on surfaces of different compositions and have distinctly different kinetics.

It has been found that a direct evaluation of the role of electronic factors in electrochemistry and electrocatalysis through the examination of a series of metal dioxide electrodes with similar crystal structures but differing electronic properties is precluded by the formation of a surface layer which differs in composition from the bulk oxide. The composition of this surface layer is highly dependent on electrode potential and differs from oxide to oxide, preventing the measurement of a given reaction on several materials under the same conditions. It is this kind of consideration which makes electrocatalysis the empirical science it remains.

Investigation of Lithium Utilization from A Lithium-Silicon Electrode

Randall N. Seefurth* and Ram A. Sharma*

General Motors Corporation, Electrochemistry Department, Research Laboratories, Warren, Michigan 48090

ABSTRACT

A half-cell of the type

Li | in solid Li_2Si or $Li_{21}Si_8$, or $Li_{15}Si_4$ || LiCl-KCl eutectic or LiF-LiCl-KCl melt or LiF-LiCl-LiBr melt | Li | in solid Li_2Si in equilibrium with Si

was used to investigate lithium utilizations (to a 0.5V cutoff *vs.* 40 atomic percent Li-Al) from Li_2Si, $Li_{21}Si_8$, and $Li_{15}Si_4$ at current densities between 20 and 1000 mA/cm^2 and at temperatures between 675° and 750°K. The lithium utilizations from these compounds did not appear to be greatly influenced by current density or temperature variations. For example, 60-80% of the lithium from the Li_2Si-Si plateau, >90% of the lithium from the $Li_{21}Si_8$-Li_2Si plateau, and 80-90% of the lithium from the $Li_{15}Si_4$-$Li_{21}Si_8$ plateau were utilized at current densities between 50 and 400 mA/cm^2. The polarization at current densities up to 500 mA/cm^2 appeared to be mostly ohmic.

In recent years, increasing effort has been devoted to the development of Li/FeS_2 cells for secondary batteries of high specific energy and high specific power (1, 2). Generally, these cells consist of FeS_2 with a current collector of expanded molybdenum or carbon foam as the positive electrode, LiCl-KCl eutectic as the electrolyte, and either lithium entrapped in a metallic matrix (stainless steel or nickel), or Li-Al alloy "β"-phase (3) as the negative electrode.

The liquid lithium electrode, although capable of the highest specific energy and current density, has a problem retaining lithium for a period greater than 1000 hr during repeated charge-discharge cycles. In addition, lithium also severely attacks many insulators and separators of the cells.

The Li-Al alloy electrode with its lower lithium activity is less likely to attack the ceramic components of the cell than is pure Li. In this case, the lithium retention problem is also avoided, but the theoretical specific energy is reduced because of the additional inert weight of aluminum and the lower cell voltage in comparison to a cell using a pure lithium electrode. Current densities are also limited, probably because of the difficulty of lithium transport through the solid alloy electrode.

Lithium-silicon compounds with high lithium content [(*i.e.*, $Li_{22}Si_5$,$Li_{15}Si_4$, $Li_{21}Si_8$, and Li_2Si (4)], seem promising for use as negative electrodes in Li/FeS_2 cells, and work is in progress to develop these electrodes (5, 6). Solid Li-Si alloy electrodes, like those of Li-Al alloy, should not have a retention problem and also may not severely attack ceramic components of the cell, such as separators and feed throughs. However, they have a definite potential for producing a higher specific energy than the Li-Al alloy electrode because of their higher lithium content. In addition, the Li-Si alloy electrode may also be capable of giving higher current densities than those of Li-Al as diffusion of lithium in silicon [$D = 3.0 \times 10^{-8}$ cm^2/sec at 723°K (7)] is faster than that of lithium in aluminum [$D = 1.2\text{-}1.7 \times 10^{-10}$ cm^2/sec at 690°K (8)].

Therefore, a systematic study was initiated to develop a Li-Si negative electrode for Li/FeS_2 cells. In an earlier work (4) results were communicated indicating the reversibility of the Li-Si electrode with respect to lithium at 680°K, the different Li-Si compounds with their respective nonstoichiometry ranges, and the electromotive forces in the temperature range between 650° and 750°K. The activities and the relative partial molar properties of lithium and silicon in the Li-Si system as well as the standard free energies of formation for Li_2Si, $Li_{21}Si_8$, $Li_{15}Si_4$, and $Li_{22}Si_5$ were also reported in this publication.

Our present investigation was carried out to determine the utilization of lithium from three Li-Si compounds ($Li_{15}Si_4$, $Li_{21}Si_8$, and Li_2Si) at different current densities and temperatures. In the case of $Li_{15}Si_4$ (2.95 A · hr/g), three voltage plateaus are observed during charge-discharge cycles; one between $Li_{15}Si_4$ and

* Electrochemical Society Active Member.

Key words: lithium-silicon electrode, high specific capacity, high current density, molten salt battery.

$Li_{21}Si_8$, one between $Li_{21}Si_8$ and Li_2Si, and one between Li_2Si and Si. In the case of $Li_{21}Si_8$ (1.52 A · hr/g), the $Li_{21}Si_8$-Li_2Si and Li_2Si-Si plateaus are observed; while in the case of Li_2Si (1.28 A · hr/g), only the Li_2S-Si plateau is seen.

Experimental

The experiments, including the preparatory work, were carried out in a helium atmosphere dry box. The electrodes were studied using cells of the type

Li { in solid Li_2Si, or $Li_{21}Si_8$, or $Li_{15}Si_4$ } | LiCl-KCl eutectic or LiF-LiCl-KCl melt or LiF-LiCl-LiBr melt | Li { in solid Li_2Si in equilibrium with Si }

in conjunction with 40 atomic percent (a/o) Li-Al reference electrodes.

A schematic diagram of the cell is shown in Fig. 1. The typical cell assembly consisted of a quartz enclosure (70 mm diam, 300 mm high) fitted with a cap which served to position the electrodes and a thermocouple, and a stainless steel cup (50 mm diam, 100 mm deep) to hold the electrolyte.

Electrode preparation.—For the Li-Si test electrode, a chamber was made by heliarc-welding a 304 stainless steel nut onto the side of a 5 mm long piece of 304 stainless steel tubing (25 mm ID, 28 mm OD). A 304 stainless steel rod (3 mm diam, 450 mm long) was threaded into the nut to serve as a current-voltage lead. After cleaning this compartment (vapor-blasting followed by acetone and deionized water rinses in an ultrasonic cleaner), the electrode was completed by inserting a 98% porous nickel current collector into the chamber and vibration-loading it with 60/100 mesh particles of Li_2Si (Appendix A). The chamber was then enclosed by spot-welding a double layer of 304 stainless steel screen (400 mesh followed by 150 mesh) over the open sides. Before assembly into the test cell, the electrode was electrochemically stripped of its lithium in a separate cell using a 80% porous nickel counterelectrode. When recharged to a composition of $Li_{15}Si_4$, these 5 cm^2 working electrodes had a theoretical capacity density of 0.75 A · hr/cm^2.

The Li-Si counterelectrode was prepared in the same manner as the test electrode, except a larger electrode chamber (12.5 mm thick, 25 mm ID, 28 mm OD) was used to increase its capacity and thus prevent it from limiting the test cycles. These 5 cm^2 counterelectrodes had a theoretical capacity density of 1.0 A · hr/cm^2 at a composition of Li_2Si.

The reference electrode also consisted of a cylindrical chamber (5 mm long, 12 mm ID, 16 mm OD) which was completed by inserting a few pieces of 40 a/o Li-Al alloy (4/20 mesh) and spot-welding 150 mesh 304 stainless steel screen disks over the open sides.

Electrolyte preparation.—Three types of electrolyte, 57 mole percent (m/o) LiCl-43 m/o KCl eutectic (9-10), 16.5 m/o LiF-67.5 m/o LiCl-16 m/o KCl [melting point = 723°K-(10)], and 23 m/o LiF-28 m/o LiCl-49 m/o LiBr [melting point = 703°K (11)] were used. They were prepared using 99.6% pure LiCl, 99.9% pure KCl, 99.0% pure LiBr, and a high purity optical grade LiF. The LiCl-KCl mixtures used for making the eutectic and ternary melt with LiF were purified by bubbling chlorine through them at 750°K for 7 ksec, and subsequently scavenging the chlorine by bubbling helium for approximately 3.5 ksec (12). The LiCl-LiBr melt used for making the ternary melt with LiF was also purified by bubbling chlorine through it at 850°K for 3.5 ksec, and subsequently removing the resultant bromine by bubbling helium for an additional 3.5 ksec.

Apparatus.—A tubular furnace (150 mm high, 75 mm diam) was used in conjunction with a proportional band temperature controller to heat the cell. Chromel-Alumel thermocouples and a millivolt potentiometer were used for temperature measurements. The other electrical instruments included a d-c power supply, together with the necessary logic and switching circuitry to cycle the cell automatically according to a preset charge-discharge program, and dual-channel recorders for measuring current and potentials between electrodes.

Procedure.—About 0.2 liter of the electrolyte was placed in the stainless steel container which, in turn, was placed inside the quartz enclosure in the furnace. The electrolyte was heated to a particular temperature and the electrodes were positioned in the melt. After thermal equilibrium was attained, charge-discharge cycles were carried out between the Li-Si working electrode composed of Li_2Si, $Li_{21}Si_8$, or $Li_{15}Si_4$ and a counterelectrode of Li_2Si in three different electrolytes. The cycles were carried out at current densities ranging from 20 to 1000 mA/cm^2 [1] at different temperatures and under conditions where no liquid Li-Si alloy was formed. During the cycles, the working electrode voltages were monitored with a 40 a/o Li-Al alloy reference electrode.[2] A cutoff voltage of 0.5V with respect to the reference electrode was used to terminate discharges, while a cutoff voltage value dictated by the current density and the Li-Si compound under study was used to terminate charge. Voltages with respect to lithium may be obtained by including the 40 a/o Li-Al alloy *vs.* lithium potential obtained from the equation $V_{(mV)} = 464.438\text{-}0.2488T$ (4).

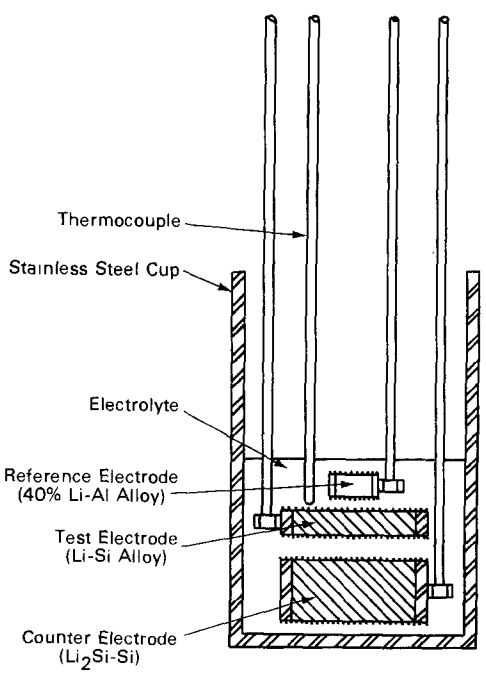

Fig. 1. Schematic representation of the lithium-silicon test cell

Results and Discussion

The results of experiments showing the effects of current density and temperature on lithium utilization (Appendix B) from the Li-Si compounds are presented in Table I and Fig. 2 for the LiCl-KCl electrolyte, Table II and Fig. 3 for the LiF-LiCl-KCl electro-

[1] The reported current densities were calculated using only the facial area of the test electrode opposite the counterelectrode. The contribution by the other face is assumed to be negligible.

[2] The placement of the reference electrode behind the working electrode (Fig. 1) is likely to cause an error in the working electrode voltages. However, voltage measurements using a liquid lithium electrode as both a reference and counterelectrode in subsequent studies indicated that the voltages measured in the present studies differed only by about 50 mV at a current density up to 300 mA/cm^2.

lyte, and Table III and Fig. 4 for the LiF-LiCl-LiBr electrolyte. In these results, the current efficiency, η_E, was calculated from the equation

$$\eta_E = \frac{I_D t_D}{I_C t_C}$$

where I_D and t_D are current and time during discharge, and I_C and t_C are current and time during charge. The current efficiency was observed to be >95% in all cases (tables).

As may be seen from Table I and Fig. 2a, it is possible to obtain a total lithium utilization of approximately 70% from Li_2Si at 675°K in LiCl-KCl eutectic using current densities between 20 and 200 mA/cm². The lithium utilization from this compound appears to remain constant in the above range of current densities, but is found to increase slightly with increase in temperature from 675° to 725°K and decrease again when the temperature is decreased (cell no. 1, cycles 23-33). Charging at lower rates (100 mA/cm²) while maintaining a discharge rate of 200 mA/cm² did not increase the

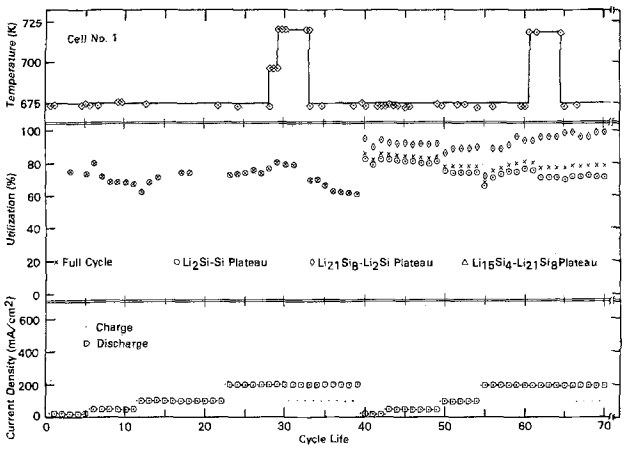

Fig. 2a. Li-Si alloy electrode performance data in LiCl-KCl electrolyte at different current densities and temperatures. Cell no. 1, cycles 1-70.

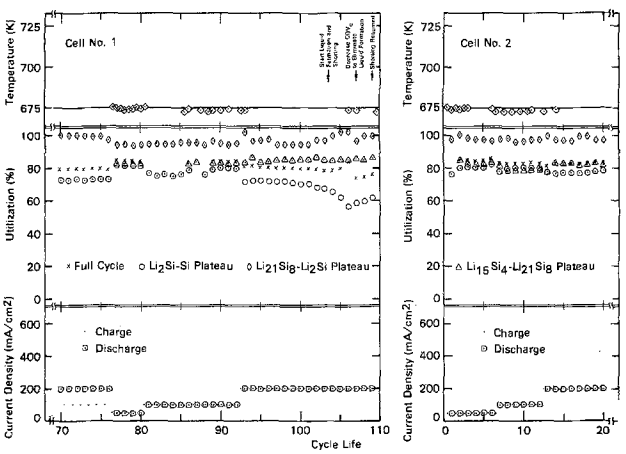

Fig. 2b. Li-Si alloy electrode performance data in LiCl-KCl electrolyte at different current densities and temperatures. Cell no. 1, cycles 70-110; cell no. 2, cycles 1-20.

lithium utilization (cycles 34-39).

It was possible to achieve a total lithium utilization of about 80% from $Li_{21}Si_8$ in LiCl-KCl eutectic at current densities between 20 and 200 mA/cm² and temperatures from 675° to 725°K (cell no. 1, cycles 40-76). The utilization from the $Li_{21}Si_8$-Li_2Si plateau was found to range between 90 and 100% while that from the Li_2Si-Si plateau was found to be between 72 and 80%. The utilization from the $Li_{21}Si_8$-Li_2Si plateau was observed to be unaffected by changes in current density between 20 and 200 mA/cm²; however, the utilization

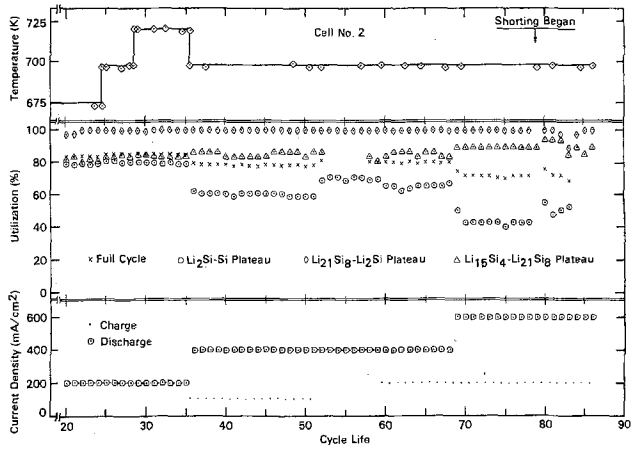

Fig. 2c. Li-Si alloy electrode performance data in LiCl-KCl electrolyte at different current densities and temperatures. Cell no. 2, cycles 20-86.

of the total $Li_{21}Si_8$ cycle and that of the Li_2Si-Si plateau were observed to decrease slightly with increasing current density (cell no. 1, cycles 40-60).

The lithium utilization of the total $Li_{21}Si_8$ cycle at 200 mA/cm² was unaffected by changes in temperature between 675° and 725°K (cell no. 1, cycles 55-66). However, a slight increase in utilization from the $Li_{21}Si_8$-Li_2Si plateau and a slight decrease in utilization from the Li_2Si-Si plateau were noted during these cycles. In addition, charging at lower rates (100 mA/cm²) while maintaining the 200 mA/cm² discharge rate did not affect the utilization (cell no. 1, cycles 65-76).

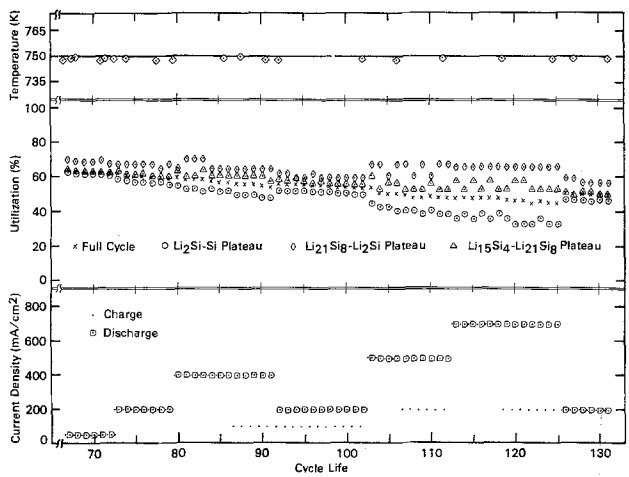

Fig. 4b. Li-Si alloy electrode performance data in LiF-LiCl-LiBr electrolyte at different current densities. Cycles 66-132.

The results presented in Table I and Fig. 2b and 2c indicate that it is possible to achieve a total lithium utilization of about 82% from $Li_{15}Si_4$ in LiCl-KCl eutectic at 675°K using current densities between 20 and 200 mA/cm² (cell no. 1, cycles 77-109; cell no. 2, cycles 1-24). The lithium utilizations from the individual plateaus were found to be approximately 83% for the $Li_{15}Si_4$-$Li_{21}Si_8$ plateau, 98% for the $Li_{21}Si_8$-Li_2Si plateau, and 75% for the Li_2Si-Si plateau during this period. Although current densities below 200 mA/cm² had little effect on the lithium utilization from any plateau, a further increase in discharge current density to 600 mA/cm² caused a decrease in utilization from the Li_2Si-Si plateau, but apparently did not affect the other plateaus (cell no. 2, cycles 69-78).

The lithium utilizations of all the plateaus at 200 mA/cm² increased slightly when temperature was increased from 675° to 700°K, but no further increase was noted when temperature was raised to 725°K (cell no. 2, cycles 13-35). Once again, lowering the charge rate while maintaining a higher discharge rate did not influence lithium utilization (cell no. 2, cycles 36-68).

The data presented in Table II and Fig. 3, which were obtained using the LiF-LiCl-KCl electrolyte at 750°K, indicate that a lithium utilization of 84-68% can be obtained from the Li_2Si-Si plateau in the range of current density between 20 and 400 mA/cm² (cycles 1-34). The utilizations decreased with increasing current density, and charging at lower rates (100 mA/cm²) while discharging at rates of 200 or 400 mA/cm² did not improve the utilization.

The total lithium utilization from the $Li_{21}Si_8$ cycle decreased from 78 to 69% when the current density was raised from 20 to 400 mA/cm² at 750°K in this electrolyte (cycles 46-78). During this current density excursion, the utilization of lithium from the $Li_{21}Si_8$-Li_2Si plateau decreased from 85 to 80% and that from the Li_2Si-Si plateau decreased from 76 to 63%.

The lithium utilization from the total $Li_{15}Si_4$ cycle was found to be about 72% at current densities between 50 and 1000 mA/cm² in this melt at 750°K (cycles 96-161). The utilizations from the $Li_{15}Si_4$-$Li_{21}Si_8$ and $Li_{21}Si_8$-Li_2Si plateaus did not decrease with increasing current density up to 500 mA/cm², but the former was lower than the latter (cycles 96-150). The utilization of lithium from the Li_2Si-Si plateau was found to decrease with increasing current density (cycles 96-154). When the current density was raised above 500 mA/cm², the total utilization was found to decrease, but the different voltage plateaus of the Li-Si compounds could not be readily distinguished. As in all previous cases, lowering the charging rate while maintaining a constant discharge rate did not improve the lithium utilizations. In fact, they appeared to decrease (cycles 158-176, 180-189, and 190-204).

The data presented in Table III and Fig. 4 were obtained using LiF-LiCl-LiBr electrolyte at 750°K. In this case also, the lithium utilization from Li_2Si was observed to decrease from 73 to 58% when current density was increased from 50 to 400 mA/cm² (cycles 1-41).

The total utilization from $Li_{21}Si_8$ and the utilization of the Li_2Si-Si plateau decreased while the utilization of the $Li_{21}Si_8$-Li_2Si plateau increased with an increase in current density from 50 to 400 mA/cm². The total lithium utilization from this compound was between 60 and 66% over the described current density range.

The total lithium utilization from $Li_{15}Si_4$ varied from 63 to 48% with an increase in current density from 50 to 700 mA/cm² (cycles 67-86, 103-106, and 113-118). The utilizations from the $Li_{15}Si_4$-$Li_{21}Si_8$, and Li_2Si-Si plateaus decreased while that from the $Li_{21}Si_8$-Li_2Si plateau remained nearly constant over the above-mentioned increase in current density. Once again, lowering charge rates while maintaining a higher discharge rate did not increase the lithium utilizations (cycles 80-91 and 103-125).

In summary, the lithium utilizations from Li_2Si, $Li_{21}Si_8$, and $Li_{15}Si_4$ showing the effects of temperature, current density, electrolyte, and different charge and discharge rates are given in Table IV.

Selected charge-discharge cycles are also plotted in Fig. 5 as terminal voltage *vs.* capacity density at different current densities in LiCl-KCl eutectic electrolyte. Since the working electrode starting material for these tests was Li_2Si, the voltage-capacity density curves are plotted to coincide at this composition. In this figure, the charge curves are folded back, and the variation of equilibrium voltage with theoretical capacity is shown by the thick solid line. Examination of these curves shows that only a limited amount of the theoretical lithium content of Li_2Si can be removed during discharge and replaced during charge. This incomplete discharge of Li_2Si to Si might be due to difficulty in transport of lithium through silicon once enough silicon is present on the electrode surface area to block diffusion. It was also found that Li_2Si could apparently be charged entirely to $Li_{21}Si_8$ and discharged back to Li_2Si with nearly total lithium utilization. On the other hand, $Li_{21}Si_8$ could not be charged completely to $Li_{15}Si_4$, presumably due to difficulty in transport of lithium through $Li_{15}Si_4$ once the electrode surface area is blocked. However, the amount of lithium charged into $Li_{15}Si_4$ could be completely recovered during discharge.

Terminal voltages *vs.* current densities are plotted in Fig. 6 for the three voltage plateaus at capacity densities of 1.6, 1.05, and 0.6 kC/cm² shown in Fig. 5 by the lines A, B, and C, respectively. As indicated by the slopes of the plots in Fig. 6, the potential shifts from equilibrium values observed in Fig. 5 appear to be mostly ohmic for current densities up to 500 mA/cm².

The results of selected charge-discharge cycles at 750°K using LiF-LiCl-KCl electrolyte are plotted in Fig. 7 as terminal voltage *vs.* capacity density at different current densities. Total lithium utilization from each of the compounds, $Li_{15}Si_4$, $Li_{21}Si_8$, and Li_2Si, as well as individual plateau utilizations are observed to be smaller than the corresponding utilizations obtained when using LiCl-KCl electrolyte at 675°K. However, the polarization during these cycles appears to be less than those observed in the case of LiCl-KCl. The decreases in utilization as well as the reduced polarization may be due to some of the silicon from the Li-Si active material alloying with the nickel current collector at this higher temperature (750°K). Thus,

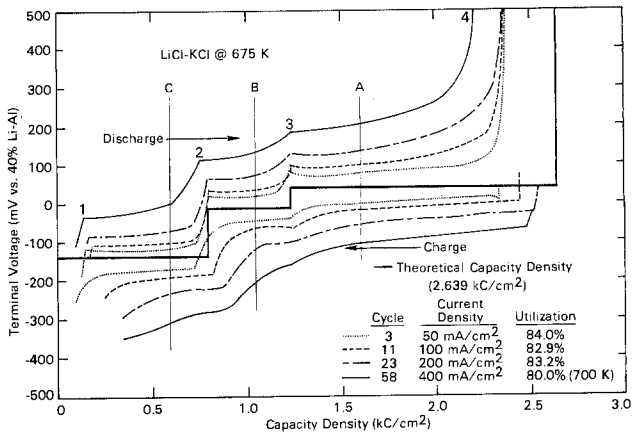

Fig. 5. Voltage-capacity density curves for a Li-Si electrode in LiCl-KCl electrolyte at different current densities.

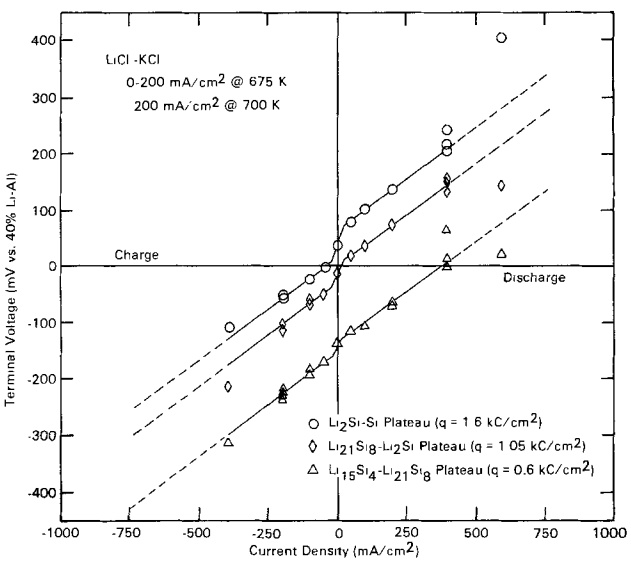

Fig. 6. Voltage-current density relationship for a Li-Si electrode in LiCl-KCl electrolyte.

the silicon would become unavailable for the electrode reaction (lower utilization), but the Ni-Si alloy might lead to better current collection (lower polarization).

In Fig. 8, terminal voltages are plotted *vs.* current density for the Li_2Si-Si, $Li_{21}Si_8$-Li_2Si, and $Li_{15}Si_4$-$Li_{21}Si_8$ plateaus at capacity densities of 1.6, 1.05, and 0.6 kC/cm² as shown in Fig. 7 by the lines D, E, and F, respectively. Once again, the slopes of the plots (Fig. 8) indicate that the potential shifts from equilibrium shown in Fig. 7 are largely ohmic for the current densities studied.

Selected results of charge-discharge cycles in LiF-LiCl-LiBr electrolyte at 750°K are plotted in Fig. 9 as

Table IV. Summary of lithium utilizations from Li-Si compounds under various conditions

Electrolytes	Temperatures (°K)	Current densities (mA/cm²)	Reducing charge current densities	Lithium utilizations (%) Li_2Si-Si	$Li_{21}Si_8$-Li_2Si	$Li_{15}Si_4$-$Li_{21}Si_8$	$Li_{15}Si_4$-Si
LiCl-KCl	675-725 Slight increase in utilization with increase in temperature	20-200 No effect	No effect	69-82	90-100	83-86	80-84
LiF-LiCl-KCl	750	20-400 Slight decrease in utilization with increase in current density	No effect	63-84	79-90	74-78	72-74
LiF-LiCl-LiBr	750	50-400 Slight decrease in utilization with increase in current density	No effect	53-73	67-76	60-64	55-63

terminal voltage *vs.* capacity density at different current densities. At all current densities, the utilizations are smaller than those obtained under similar conditions with the other two electrolytes. This might have happened because some of the silicon from the Li-Si active material alloyed with the nickel current collector or because some of the active material was pushed out of contact with the current collector by this heavier electrolyte. In either case, some of the active material became unavailable for the electrode reaction leading to the lower lithium utilizations.

The slope of terminal voltage *vs.* current density plots (Fig. 10) for the three voltage plateaus at capacity densities shown by lines G, H, and I in Fig. 9 again show the overpotential at these compositions to

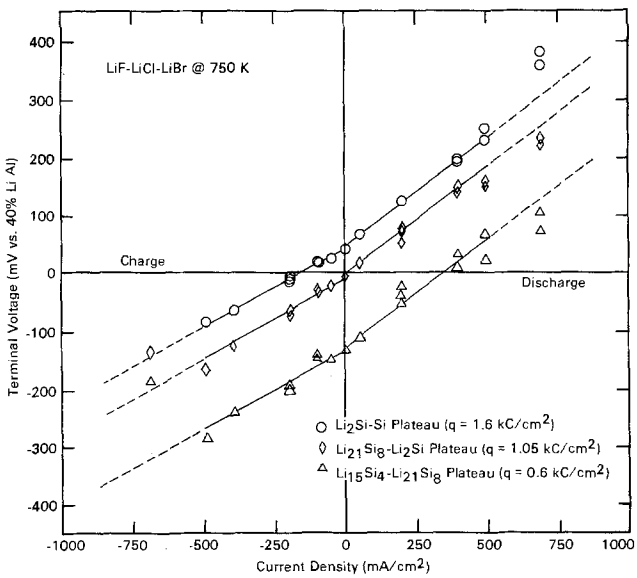

Fig. 10. Voltage-current density curves for a Li-Si electrode in LiF-LiCl-LiBr electrolyte.

be largely ohmic. However, in this case, the potential shifts during discharge are greater than those during charge (*i.e.*, the resistance is greater during discharge than charge). Since lower density Li-Si alloys form during charge, alloy volume increases and may help to develop better contact with the current collector resulting in the lower resistance. The reverse process occurs during discharge, which could increase the resistance.

Summary

Charge-discharge cycles beween electrodes of either Li_2Si, $Li_{21}Si_8$, or $Li_{15}Si_4$ and a Li_2Si counterelectrode at current densities between 20 and 1000 mA/cm² and temperatures from 675° to 750°K indicate:

1. An electrode made of any of the above compounds is promising for use as a negative electrode in Li/FeS_2 cells.
2. Current efficiencies of greater than 95% can be obtained.
3. A lithium utilization of 80-60% can be obtained from a Li_2Si electrode at current densities between 50 and 400 mA/cm².
4. A lithium utilization of 85-70% can be obtained from a $Li_{21}Si_8$ electrode under the same conditions.
5. A lithium utilization of 80-70% can be obtained from a $Li_{15}Si_4$ electrode under the same conditions.
6. The lithium utilizations were not greatly influenced by change in temperature or current density up to 200 mA/cm².
7. The lithium utilizations were observed to decrease with change of electrolyte from LiCl-KCl to LiF-LiCl-KCl to LiF-LiCl-LiBr.
8. Primarily ohmic polarizations were observed in the range of current density between 20 and 500 mA/cm² for electrodes having compositions in the plateaus.

Acknowledgments

The authors are thankful to Mr. Ernest J. Verrier for assistance with the experimental work, and Drs. Elton J. Cairns and John S. Dunning of the Electrochemistry Department for useful suggestions and discussions.

Manuscript submitted Jan. 20, 1977; revised manuscript received April 4, 1977. This was Paper 385 presented at the Philadelphia Meeting of the Society, May 8-13, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

Publication costs of this article were assisted by General Motors Corporation.

APPENDIX A

Preparation of the Li_2Si Alloy

All preparatory procedures were carried out in a helium atmosphere dry box. Approximately 50g of lithium was melted in a clean, preweighed nickel cup at a temperature of 575°K. Impurity scum was scooped off with a nickel screen scoop and the lithium was recooled to room temperature. Remaining impurities at the surface of the solidified lithium were further removed by scraping with a sharp-edged scraper. The lithium was then weighed, remelted, and had its temperature raised to approximately 775°K. A calculated amount of coarse silicon powder was slowly added to the molten lithium. The silicon powder did not sink into the molten lithium, rather it floated on the surface. The molten lithium soaked into the silicon powder, an exothermic reaction was observed, and a solid mass formed at the surface of the melt. The temperature was slowly raised to 1075°K, and the solid mass sank into the melt and dissolved. The melt was then stirred with a nickel rod to insure homogeneity, cooled to room temperature, and powdered.

APPENDIX B

Lithium Utilization

The lithium utilizations were calculated on the basis of the following reactions

$$Si + 2Li \rightarrow Li_2Si \qquad [B\text{-}1]$$

$$Li_2Si + 5/8\ Li \rightarrow 1/8\ Li_{21}Si_8 \qquad [B\text{-}2]$$

$$1/8\ Li_{21}Si_8 + 9/8\ Li \rightarrow 1/4\ Li_{15}Si_4 \qquad [B\text{-}3]$$

The lithium utilization designated as U_1 was calculated by dividing the capacity obtained during the voltage plateau between Li_2Si and Si (reaction [B-1] by the theoretical capacity of that plateau.

The lithium utilization designated as U_2 was calculated by dividing the capacity obtained during the voltage plateau between $Li_{21}Si_8$ and Li_2Si (reaction [B-2] by 5/8 × 96,487 for each gram mole of Li_2Si in the electrode.

The lithium utilization designated as U_3 was calculated by dividing the capacity obtained during the voltage plateau between $Li_{15}Si_4$ and $Li_{21}Si_8$ (reaction [3]) by 9/8 × 96,487 for each gram mole of Li_2Si in the electrode.

The total lithium utilization designated as U_T was calculated by dividing the total capacity obtained for all of the plateaus under consideration by the total theoretical capacity of the electrode.

In the experiments carried out here, the onset of a plateau was marked by a sharp change of slope in the voltage *vs.* time curve. The capacity obtained between two sharp changes of slope at the beginning and end of the plateau was divided by the theoretical capacity of that plateau to obtain the lithium utilization. For example, the lithium utilization, U_3 was calculated by dividing the capacity between points 1 and 2 (Fig. 5) by the theoretical capacity of the plateau between $Li_{15}Si_4$ and $Li_{21}Si_8$. Similarly, U_2 was calculated by dividing the capacity between points 2 and 3 by the theoretical capacity of the plateau between $Li_{21}Si_8$ and Li_2Si, and U_1 by dividing the capacity between points 3 and 4 by the theoretical capacity of the plateau between Li_2Si and Si. U_T was then obtained by dividing the capacity obtained between 1 and 4 by the theoretical capacities of all of the plateaus from $Li_{15}Si_4$ to Si.

Current Distribution in a Tubular Electrode under Laminar Flow: Two Electrode Reactions

Richard Alkire* and Ali Asghar Mirarefi*

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

A computational method has been developed for calculating the current distribution along a tubular electrode when two electrode reactions occur simultaneously. The model is valid for all operating conditions between the secondary current distribution and the limiting current distribution. The model includes the Lévêque equation of convective diffusion, a one-dimensional potential distribution, and Butler-Volmer charge-transfer kinetics for each electrode reaction. Experiments on copper deposition in the presence of a Fe(III)/Fe(II) redox couple were carried out with a sectioned tubular electrode. Current distribution data were compared with theoretical expectations and good agreement was found.

Relatively few electrochemical reactions are carried out with 100% current efficiency. There are several reasons why more than one electrode reaction might occur. For example, the applied current might exceed the limiting current of the most reactive species, or the potential variation along the surface may exceed the rest potential difference between two possible reactions. That is, both mass transport and potential dis-

* Electrochemical Society Active Member.

Key words: tubular electrode, sectioned electrode, mathematical model, multiple reaction, laminar flow

tribution effects can be important in determining what reactions occur as well as where they occur along the electrode surface. Therefore in order to determine the current distribution in the presence of multiple reactions it is usually necessary to take simultaneous account of both the concentration field and the potential field.

Theoretical procedures for predicting current distributions have to date been almost entirely confined to consideration of a single reacting species in the electrolyte. In this study, the role of multiple electrode reactions was investigated with use of a tubular electrode. Theoretical predictions were compared with experimental data obtained with a system which involved copper deposition in the presence of a Fe(III)/Fe(II) redox couple. The investigation reported here (1) extends previous theoretical (2) and experimental (3) work on single electrode reactions in tubular electrode configurations. The purpose of this investigation is to provide experimental data for testing whether current distributions can be predicted accurately at currents below but at an appreciable fraction of the limiting current.

Until recently, current distribution calculations were made with consideration of either the potential field or the concentration field, but not both. For example, Masuda (4) analyzed the mass transfer current distribution at a number of electrode configurations for a variety of multiple reaction sequences, but did not include consideration of the potential field. Klatt and Blaedel (5) studied a mass transfer limited electrode reaction in a tubular electrode followed by a first-order catalytic reaction for which it was not necessary to include potential field considerations. Oesterling and Olson (6) investigated mass transfer controlled deposition of two metals in a tubular electrode.

Procedures for calculating the current distribution with simultaneous consideration of concentration and potential fields in porous electrodes have been applied to multiple reaction systems by Alkire and Gould (7). Similar procedures have been used by Alkire and Nicolaides (8, 9) in the analysis of localized differential aeration corrosion. These one-dimensional analyses are simpler than two-dimensional analyses for which more complex procedures have only recently been developed (10, 11) and applied to tubular electrode systems (2).

Experimental Apparatus and Procedures

The experiment consisted of measuring the current distribution along a sectioned tubular electrode through which electrolyte passed in steady laminar flow. Current distributions were measured at various fractions of the limiting current upon systematic variation of electrode geometry, flow rate, reactant concentration, and counterelectrode placement. The apparatus used in the experimental study was, as described previously (3), designed so that: (*i*) Laminar flow was maintained by limiting the flow rate according to the conditions $Q < 3300R_0$; (*ii*) mass transfer behavior was constrained to the entrance (Lévêque) region by requiring that $Q > 1570LD_1$; and (*iii*) potential distribution was approximately one dimensional by choosing judiciously the tube radius/length ratio.

The electrolytic solution consisted of $CuSO_4$, $Fe_2(SO_4)_3$, and $FeSO_4$ in 1.5M H_2SO_4. Acidified solutions of the copper salt and of the redox salts were prepared and analyzed separately, then combined to give the desired mixed electrolytic solution. The procedure for conducting experiments was the same as described previously (3). A mercury/mercurous sulfate reference electrode was used. Before presentation of experimental results, the theory for multiple reaction systems is described.

Theory

The mathematical model described in this study extends our earlier theoretical work (2) by including the possibility of multiple electrode reactions in a tubular electrode. The enthusiastic reader should examine the earlier papers for a more thorough discussion of the model. Figure 1 illustrates the geometry of the tubular electrode. The electrode, of radius R_0 and length L, is positioned between two long pipe sections made of insulating material. Two coordinate systems were used: one based on the pipe axis (x,r) and the other based along the electrode surface beginning at the upstream edge (z,y). The counterelectrode is placed at a distance L_1 from the tubular electrode either downstream as in Fig. 1 or upstream (not shown).

The theoretical model is based on the assumption that concentration variations are confined to a thin region near the electrode surface so that the electrolyte can be treated as two different regions: (*a*) The diffusion layer region close to the electrode surface in which the concentration of species vary, and (*b*) the bulk region which fills the remainder of the region of the cell.

Transport equations for the two regions are coupled through their boundary conditions and are therefore solved simultaneously. The electrolytic solution moves in steady laminar flow and is assumed to contain a large quantity of supporting electrolyte so that migration of reacting species is negligible.

In the electrolytic solution there are i reactive solute species which take part in j electrode reactions having the stoichiometry

$$\sum_i s_{ij} M_i^{+z_i} = n_j e^- \qquad [1]$$

The rate of arrival of reactive solute species at the electrode surface corresponds to the rate of electrode reaction by Fick's law

$$\left.\frac{\partial c_i}{\partial y}\right|_{y=0} = \frac{s_{ij}}{n_j F D_i} j_j \qquad [2]$$

For the experimental system under study, we denote

$$Fe(II) = Fe(III) + e^-$$

as reaction [1] involving species 1 [Fe(II)] and species 2 [Fe(III)], and

$$Cu(II) = Cu^o + 2e^-$$

as reaction [2] involving species 3 [Cu(II)] and species 4 (Cu^o). With this notation and in conformance with Ref. (5), the reversible reaction rate expression for the redox reaction has the general form

$$j_1 = i_{o,1}\left[\left\{\prod_{i=1,2}\left(\frac{c_{i,s}}{c_{i,\infty}}\right)^{(\delta_i+\alpha_1 s_{i1})}\right\} e^{\frac{\alpha_1 n_1 F}{R_g T}\phi} - \left\{\prod_{i=1,2}\left(\frac{c_{i,s}}{c_{i,\infty}}\right)^{(\delta_i-\beta_1 s_{i1})}\right\} e^{-\frac{\beta_1 n_1 F}{R_g T}\phi}\right] \qquad [3]$$

and the rate expression for the metal deposition reaction has the form

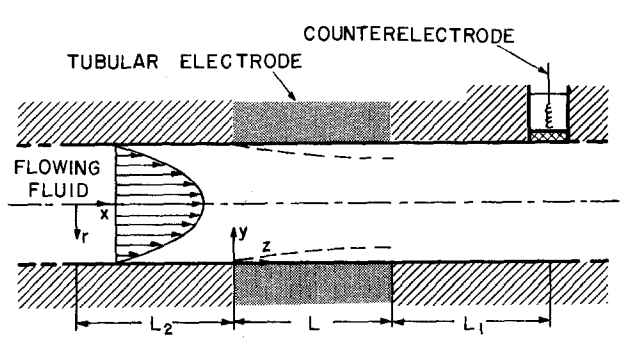

Fig. 1. Schematic diagram of tubular electrode system geometry, with downstream counterelectrode.

$$j_2 = i_{o,2}\left[\left\{\prod_{i=3,4}\left(\frac{c_{i,s}}{c_{i,\infty}}\right)^{(\delta_1+\alpha_2 s_1)}\right\} e^{\frac{\alpha_2 n_2 F}{R_g T}(\phi+\phi_r)} - \left\{\prod_{i=3,4}\left(\frac{c_{i,s}}{c_{i,\infty}}\right)^{(\delta_1-\beta_2 s_1)}\right\} e^{-\frac{\beta_2 n_2 F}{R_g T}(\phi+\phi_r)}\right] \quad [4]$$

with $s_4 = 0$ since the deposited metal does not exist in the solution phase. The potential ϕ is defined as the potential of a Fe(II)/Fe(III) reference electrode placed in the solution, adjacent to the working electrode surface, with respect to the potential of the working electrode. Cathodic processes correspond to negative values of both ϕ and j_j.

Under the assumptions of the model, the surface concentrations appearing in Eq. [3] and [4] were found from the equation of convective diffusion according to the Lévêque approximation (12)

$$\frac{4Q}{\pi R_0^3} y \frac{\partial c_i}{\partial z} = D_i \frac{\partial^2 c_i}{\partial y^2} \quad [5]$$

with the boundary conditions

$$c_i = c_{i,\infty} \text{ at } z \leq 0$$

$$c_i = c_{i,\infty} \text{ at } y = \infty,\ z > 0$$

$$\frac{\partial c_i}{\partial y} = \frac{s_i j_j}{n_j F D_i} \text{ at } y = 0,\ z > 0$$

The reaction rate distribution corresponding to Eq. [5] was determined with Laplace transform methods (1) to be

$$j_j = \frac{n_j F}{s_i R_0 \Gamma(1/3)}\left(\frac{12QD_i^2}{\pi}\right)^{1/3} \int_0^z \frac{dc_{i,s}(z')}{dz'}\frac{dz'}{(z-z')^{1/3}} \quad [6]$$

For the experimental system under study, the ratio of tube radius to tube length was sufficiently small that the potential distribution within the tube was essentially one dimensional (3). Consequently the electrode reaction rates appear as pseudohomogeneous source terms in the charge balance equation

$$j_1 + j_2 = \frac{R_0\kappa}{2}\frac{d^2\phi}{dz^2} \quad [7]$$

The boundary conditions on Eq. [7] depend on placement of the counterelectrode. For example, a downstream counterelectrode would correspond to

$$\frac{d\phi}{dz}(0) = 0$$

$$\phi(L) = \phi_m \quad \text{or} \quad \phi(L + L_1) = \phi_A$$

The applied potential ϕ_m, or ϕ_A, corresponds to the potential of a Fe(II)/Fe(III) reference electrode placed in the solution outside the tubular electrode at $y = L$, or $y = L + L_1$, respectively. The applied potential is negative in all calculations in this study, indicating that the redox reaction proceeds in the cathodic direction. The total cell voltage would be obtained by adding to ϕ_m or ϕ_A the sum of all other voltage losses which arise between the reference electrode and the counterelectrode.

Equations [3], [4], [6], and [7] constitute a set of relationships between the concentration distributions for each reacting species, the reaction rate distributions for each electrode reaction, and the potential distribution. The dimensionless ratios which are convenient for this system are

$$Z = \frac{z}{L} \qquad \rho = \frac{r}{R_0} \qquad \gamma_0 = \frac{R_0}{L}$$

$$\gamma_1 = \frac{L_1}{L} \qquad \gamma_2 = \frac{L_2}{L} \qquad \Phi = \frac{n_r F}{R_g T}\phi$$

$$j_j^* = \frac{2n_r F L^2}{R_g T R_0 \kappa} j_j \qquad \bar{\beta}_j = \frac{2n_r F L^2}{R_g T R_0 \kappa} \langle j_j \rangle \qquad C_i = \frac{c_i}{c_{i,\infty}}$$

$$C_{i,s} = \frac{c_{i,s}}{c_{i,\infty}}$$

The dimensionless model equations are

$$j_1^* = \xi_1\left[\left\{\prod_{i=1,2} C_{i,s}^{(\delta_1+\alpha_1 s_1)}\right\} e^{\frac{\alpha_1 n_1}{n_r}\Phi} - \left\{\prod_{i=1,2} C_{i,s}^{(\delta_1-\beta_1 s_1)}\right\} e^{-\frac{\beta_1 n_1}{n_r}\Phi}\right] \quad [8]$$

$$j_2^* = \xi_2\left[\left\{\prod_{i=3,4} C_{i,s}^{(\delta_1+\alpha_2 s_1)}\right\} e^{\frac{\alpha_2 n_2}{n_r}(\Phi+\Phi_r)} - \left\{\prod_{i=3,4} C_{i,s}^{(\delta_1-\beta_2 s_1)}\right\} e^{-\frac{\beta_2 n_2}{n_r}(\Phi+\Phi_r)}\right] \quad [9]$$

$$j_1^* = \frac{2n_1}{3n_r} N_{1,i} \int_0^Z \frac{dC_{i,s}(Z')}{dZ'}\frac{dZ'}{(Z-Z')^{1/3}} \quad (i = 1 \text{ or } 2) \quad [10]$$

$$j_2^* = \frac{2n_2}{3n_r} N_{2,i} \int_0^Z \frac{dC_{i,s}(Z')}{dZ'}\frac{dZ'}{(Z-Z')^{1/3}} \quad (i = 3 \text{ or } 4) \quad [11]$$

$$j_1^* + j_2^* = \frac{d^2\Phi}{dZ^2} \quad [12]$$

where

$$N_{j,i} = \frac{n_r^2 F^2 L^2 c_{i,\infty}}{-s_i \Gamma(4/3) R_g T R_0^2 \kappa}\left(\frac{12QD_i^2}{\pi L}\right)^{1/3} \quad [13]$$

$$\xi_j = \frac{2n_r F L^2}{R_g T R_0 \kappa} i_{0,j} \quad [14]$$

The parameter $N_{j,i}$ is related to the dimensionless average limiting current density by

$$\bar{\beta}_{lim,j} = -N_{j,i}\frac{n_j}{n_r} \quad [15]$$

while ξ_j is a linear polarization parameter. The physical significance of these parameters has been described in detail elsewhere (2, 3, 13, 14) and will be mentioned again upon presentation of experimental results below. The quantity n_r is introduced only to preserve dimensional consistency, and may be assigned the value of unity.

The model equations were solved by the following numerical procedure in which the potential ϕ is the independent variable. In order to begin the iterative sequence, the potential distribution was assumed to vary linearly between the value 0 (at $Y = 0$) and the value Φ_m (at $Y = 1$).

1. With the trial potential distribution in hand, Eq. [8], [9], [10], and [11] were solved to obtain the surface concentration distribution of all species. That is, Eq. [8] and [10] were combined to eliminate j_1^*, and the resulting integral sums were evaluated by the method of Acrivos and Chambré (15) beginning at the upstream edge and using Newton's method of con-

vergence as outlined previously (2). Thus at each integration point, the trial potential distribution was used to determine the trial surface concentrations of species 1 and 2. Similarly, Eq. [9] and [11] were combined and integrated to obtain the trial surface concentration of species 3.

2. The trial current distributions for each partial reaction were added together and then integrated twice over the surface, in accord with Eq. [12], to provide a new guess for the potential distribution.

3. Steps 1 and 2 were repeated until two successive distributions agreed with each other within 0.1% over the entire surface region.

Because it was found necessary to average new and previous distributions during the iterative procedure in order to achieve convergence, the speed of convergence therefore depended on the skill of the operator.

Comparison of Experimental Data with Theoretical Calculations

In order to compare data with calculated behavior, it is necessary to determine the properties of the electrochemical system. Table I contains the values used in this investigation. Because the reactant concentrations were very low, the mixed electrolyte system was assumed to exhibit no interaction effects; that is, the diffusion coefficients, etc., of the individual solutes were used. Conductivity data were measured by us (3). The exchange current density for the copper deposition reaction has been variously reported and would, following Newman (16), have the value 0.38 mA/cm^2 in the 0.01M $CuSO_4$ solution used in this study (with $\alpha = 0.75$ and $\beta = 0.25$). The presence of sulfuric acid affects the exchange current as has been analyzed by Cabán and Chapman (17) whose model IV would indicate the value 0.041 mA/cm^2 in the 0.01M $CuSO_4$ + 1.5M H_2SO_4 solution used in this study (with $\alpha = 0.54$ and $\beta = 0.19$). In this study, we compared tubular electrode polarization curves (in 0.01M $CuSO_4$ + 1.5M H_2SO_4, no $FeSO_4$) with theoretical calculations (with $\alpha = 0.75$ and $\beta = 0.25$) and found that the value of 0.16 mA/cm^2 gave good comparison for all experimental results (3); we have therefore used the value 0.16 mA/cm^2 in the calculations reported below. That is, we assumed that the copper reaction was not affected by the presence of the Fe(II)/Fe(III) couple. The exchange current density of the redox couple on copper is not reported in the literature and was difficult to measure since the copper surface corrodes except when cathodically protected by current in excess of the limiting current for ferric reduction. With the expectation that the redox exchange current density was high, a value was assigned to it which was one order of magnitude above the copper exchange current density. By this arbitrary procedure, the charge-transfer resistance of the redox couple was forced to be negligible so that errors in the precise value of i_0 were therefore unimportant.

Polarization curves and current distributions were measured over a range of applied potential, solution velocity and electrode aspect ratio as indicated in Table II.

As reported elsewhere (3), experiments on single reaction systems were also carried out in the same apparatus, both at the limiting current and below the limiting current. In the multiple reaction system studied here, it is clear that one partial reaction may proceed at its partial limiting current while the less reactive species may be below its partial limiting current. When all possible reactants are simultaneously at their partial limiting currents, then (*a*) the total current is equal to the sum of the partial limiting currents, and (*b*) all partial reactions proceed with the same current distributions. Experimental data are provided below.

Figures 2 through 5 contain current distribution data which have been normalized in one of two fashions in order to compare them with theoretical calculations. By the first method, the current density from each electrode section is divided by the average total current density over the entire electrode surface

$$J = \frac{\sum_j j_j}{\sum_j \langle j_j \rangle} = \frac{\sum_j j_j^*}{\sum_j \bar{\beta}_j} \qquad [16]$$

By the second method, the current density from each electrode section is divided by the average total current density which would be obtained if both reactions were at their respective limiting currents

$$J_N = \frac{\sum_j j_j^*}{\sum_j \bar{\beta}_{\lim,j}} = \frac{\sum_j \bar{\beta}_j}{\sum_j N_{j,1}} J = fJ \qquad [17]$$

The two methods differ in that $\int_0^1 J dZ = 1$, while $\int_0^1 J_N dZ = f$, where f is the fraction of combined limiting current for both reactions.

Figure 2 provides information determined on a single reaction system (copper deposition) at various applied potentials. The counterelectrode is downstream; electrolyte flows from left to right. On the left side of the figure, the experimentally measured current distributions are given for several applied potentials. The current distributions have been normalized by division by the average current, as in Eq. [16]; as a consequence, the area under each current distribution curve is the same, as indicated in the previous paragraph. It is seen that at low potentials, the electrode is most reactive in the downstream regions, close to the counterelectrode. At intermediate potentials, mass transfer processes become more influential and the current distributions become more uniform since the upstream electrode regions become reactive. At high potentials, at the limiting current, the electrode is most

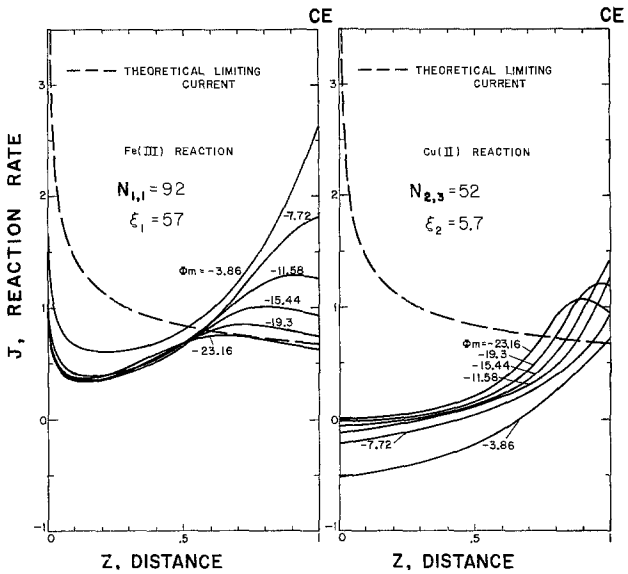

Fig. 4. Calculated current distributions for the individual reactions under the same conditions as Fig. 3. Left side: ferric reduction reaction rate distribution. Right side: copper reaction rate distribution.

reactive at the upstream region, where the diffusion boundary layer is thinnest. For this system, model calculations have been carried out with use of the system parameters given in Table II. The right-hand side of Fig. 2 gives results calculated without any artificial adjustment of parameters to "fit" the data. It is seen that the predicted current distributions agree to within roughly 20% of the data over most of the range measured. The single reaction data of Fig. 2 will now be compared with two-reaction data in the same electrode and at the same flow rate.

Figure 3 shows, on the left side, experimental current distributions for several applied potentials for the mixed cupric/ferric system. At low potentials, both the upstream and the downstream regions of the electrode are more reactive than the center. At intermediate potentials, the current distribution becomes more uniform, exhibiting both a minimum and maximum value. At high potentials, both reactions proceed at the limiting current, and the current distribution is the same as for the single reaction case previously given by Fig. 2. The right-hand side of Fig. 3 provides theoretical calculations for the multiple reaction system at hand.

A more detailed breakdown of the current distribution for each partial reaction is given in Fig. 4. On the left-hand side of Fig. 4 are the calculated results for the ferric reduction reaction; on the right-hand side are results for copper reaction. The current distributions for each reaction are normalized by the total current passing to the electrode. Therefore the area under a current distribution curve for one of the reactions gives the current efficiency of that reaction, the maximum possible area being equal to unity. The ferric partial reaction rate is large on both the upstream surface (thin diffusion layer) and the downstream surface (near the counterelectrode). As the applied potential is increased, the downstream surface becomes less reactive since the ferric ion becomes depleted. The cupric partial reaction rate is anodic on the upstream surface and cathodic on the downstream surface. That is, the ferric ion attacks the copper electrode and dissolves it; the downstream counterelectrode is too far away to provide cathodic protection to the upstream surfaces of the copper electrode. Further downstream, copper is plated onto the electrode. At the higher potentials, the copper current distribution passes through a maximum owing to depletion of copper ions at the electrode surface.

On the basis of these results it is recognized that when one of the two electrode reactions is below its own limiting current, then the multiple reaction system behavior cannot be predicted by simple combination of single reaction behavior. The over-all polarization curve is not the same as the sum of the polarization curves of the single reaction systems because the current distribution is different. In a like manner the over-all (two-reaction) current distribution is not the

sum of the single reaction current distributions because the potential distribution is different.

A less dramatic set of data is shown in Fig. 5. The counterelectrode is downstream, and the electrolyte flow is from left to right. Whereas the flow rate is the same as in the preceding figures, the tubular electrode is shorter in length and larger in radius. For these reasons, the current can penetrate further into the electrode so that the far upstream regions are cathodically protected; corrosion of the copper electrode does not occur. On the left side of Fig. 5 are current distribution data, reported on the basis of the fraction of limiting current for both reactions. On the right-hand side are theoretical calculations for various corresponding fractions of over-all limiting current. The theory underestimates somewhat the upstream reaction rate (ferric reaction), although the over-all comparison is in agreement within less than 10%.

Additional comparisons of experiment with theory (1) have also indicated in each case that the theory underestimated the upstream reaction rate but that the agreement was very good in the downstream surfaces. It seems appropriate to observe that the comparison indicated in Fig. 3 and 5 illustrates that the model can be used to predict behavior to within reasonable engineering tolerances.

Conclusions

Experimental measurements of the over-all reaction rate distribution have been carried out for metal deposition in the presence of a redox reaction. It would be of interest to carry out similar experiments with sectioned platinum electrodes in which case postelectrolysis back-titration of the copper deposition distribution would provide direct measurement of the partial reaction distributions. Other reaction sequences could be studied experimentally, including multiple metal deposition, and coupled homogeneous-heterogeneous reactions.

A theoretical basis has been established for predicting the current distribution in multiple electrode reaction systems. The procedure is sufficiently powerful that simple alterations would permit application to a wide variety of electrode geometries, flow fields, and electrode reactions. The method of calculation may be used to calculate reaction efficiencies as a function of system parameters such as electrode length and fraction of limiting current. It seems likely that the pursuit of such engineering aspects would lead eventually to the establishment of design criteria. The theory can be used to predict behavior in corrosion systems, and could be extended with ease to the prediction of cathodic protection in pipe systems, even to the extent of including a third reaction such as hydrogen evolution.

The electrodeposition of alloys is often constrained to a relatively narrow window of operating conditions. The theory and experimental methods used here could be applied to improve understanding of the complex relation between electrode geometry, fluid flow, current density, and alloy composition.

Although gassing at electrodes involves phase changes and other complications not included in the present theory, it seems clear that detailed pursuit of such effects could be made by extension of the basic framework outlined here.

Studies on Flow-By Porous Electrodes Having Perpendicular Directions of Current and Electrolyte Flow

Richard Alkire* and Patrick K. Ng*,[1]

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

An engineering analysis was carried out on a packed-bed electrochemical reactor in which the electrolyte flowed in the axial direction and current flowed in the radial direction. Experimental measurements with a sectioned porous electrode were conducted to measure the axial current distribution both at and below the limiting current. The experiments involved deposition of copper onto stacks of copper screens with acidified copper sulfate electrolyte. Although the presence of flow channeling caused the mass transfer coefficient to be less than the value reported in the literature, an empirical correlation was established for estimating the mass transfer coefficient. The reactor system gave polarization curves which indicated that the exchange current density was 0.067 mA/cm^2 in 0.001M $CuSO_4$ + 1.5M H_2SO_4. Comparison between axial current distribution data and theory was made with respect to collection efficiency, axial current distribution, electrode polarization, and total current. Agreement was found for a range of reactors having various geometric dimensions, porosities, flow rates, and reactant concentrations. The theory was used to generate criteria for estimating the volumetric reaction rate, as well as for estimating conditions under which the perpendicular configuration reactor gives higher volumetric reaction rates than when the current and electrolyte flow in parallel directions.

By flowing reactants through porous electrodes, it is possible to achieve both high mass transfer rates and large surface areas for electrochemical reaction. Because of limitations on electrolyte conductivity, however, electrical current may not be able to penetrate deep into the porous bed, so that much of the porous electrode may thereby be inactive and, depending upon the potential distribution, reaction selectivity may be poor. That is, the porous electrode may not be effective if it is too thick when viewed from the direction of the counterelectrode.

In many applications of flow-through porous electrodes it is also necessary to provide an adequate residence time by matching the flow rate to the bed length in the direction of flow. Any locally nonuniform flow, or channeling, would be detrimental to the attainment of the desired residence time and would also affect the desired high mass transfer rate. Channeling effects are usually minimized by using uniformly porous beds which are thick when viewed along the direction of fluid flow.

When the direction of fluid flow and electrical current are parallel, then a dilemma can arise in choosing an electrode thickness which balances the need for a uniform potential distribution against the need to avoid channeling. Indeed, in the case of dilute systems of low electrolyte conductivity, there may be no acceptable middle ground whatsoever. Alternatively, when the directions of electrical current and electrolyte flow are perpendicular, then the electrode can often be designed to obtain simultaneously a uniform potential distribution and an adequate residence time. That is, the electrode can be fabricated so that it is thin, as seen by the counterelectrode, and long, as seen by the flowing fluid. The distribution of potential in the "perpendicular" configuration is inherently more complex than in the "parallel" configuration.

The purpose of this investigation was to develop a better understanding of the perpendicular configuration which would assist in engineering design and scale-up. Experiments on direct measurement of the current distribution were performed under a wide range of controlled conditions. A theoretical model was developed for comparison with experimental data, and was used to determine conditions under which the perpendicular configuration should provide a higher volumetric reaction rate than the parallel configuration.

Literature Review

The different concepts and techniques currently used for enhancing mass transport in electrochemical systems have been reviewed recently (1, 2), and porous electrodes in both parallel and perpendicular field orientations were included. A summary of porous electrode studies applicable to battery systems is also available (3). In addition to the publications cited in these review articles, several other studies have been reported on flow-by porous electrodes having the perpendicular field configuration. A fuel cell system of flowing redox solution is under development for pro-

* Electrochemical Society Active Member.

Key words: current distribution, copper removal, porous electrode, channeling, flow cell.

viding electrical power storage (4). Electroanalytical applications have been reported for the separation and analysis of halide ions (5), and for the analysis of free cyanide ions (6). Industrial cells involving flow-by porous electrodes include the Nalco process for tetraethyl lead (7) and the Phillips process for hydrocarbon fluorination (8). A du Pont patent utilizes a series of flow-by electrodes to accomplish removal of heavy metals from effluent streams, and the system has been demonstrated in pilot plant studies (9). A similar cell configuration has been used for electroorganic synthesis reactions and for reduction of hexavalent chromium (10). Experimental studies to date have clarified the over-all behavior of flow-by porous electrode systems. In view of the range of possible industrial applications, a detailed experimental program involving current distribution studies was carried out in order to develop an improved basis for modeling flow-by electrodes (11).

Methods for theoretical prediction of porous electrode behavior were reviewed thoroughly [see Ref. (3)]. There is only one fundamental analysis known for the flow-by perpendicular configuration (12). That model assumes plug flow of electrolyte so that conditions experienced by a fluid packet moving through the porous bed were similar to those experienced during unsteady-state operation of a stagnant porous electrode (13). The model (12) did not include a local mass transfer resistance within the packed bed and was therefore not applicable to limiting current conditions. As reported in what follows, the model has been expanded upon in order to incorporate mass transfer processes which occur under the limiting current condition (11).

Apparatus

The cylindrical electrolysis cell was fabricated from Plexiglas components as shown schematically in Fig. 1. The electrode under study, the cathode, was located in the annular region between the cylindrical anode and the insulating outer wall. The sectioned cathode was constructed from copper screens which were precisely punched out and stacked in the annular region. Electrode sections of equal size were made by insulating groups of screens from each other with a single layer each of filter paper and nylon scarf. Electrical connection to each section was made through small holes drilled through the outer cell wall and fitted with compression gaskets. A 30 gauge copper contact wire was woven into one of the screens in each section. A porous glass annulus was placed downstream from the sectioned electrode to reduce channeling effects. When the cell collar was screwed down, the cathode was compressed by action of the thin-walled piston. Additional holes in the outer wall were drilled to accommodate a reference electrode capillary and a plastic syringe for withdrawing electrolyte samples.

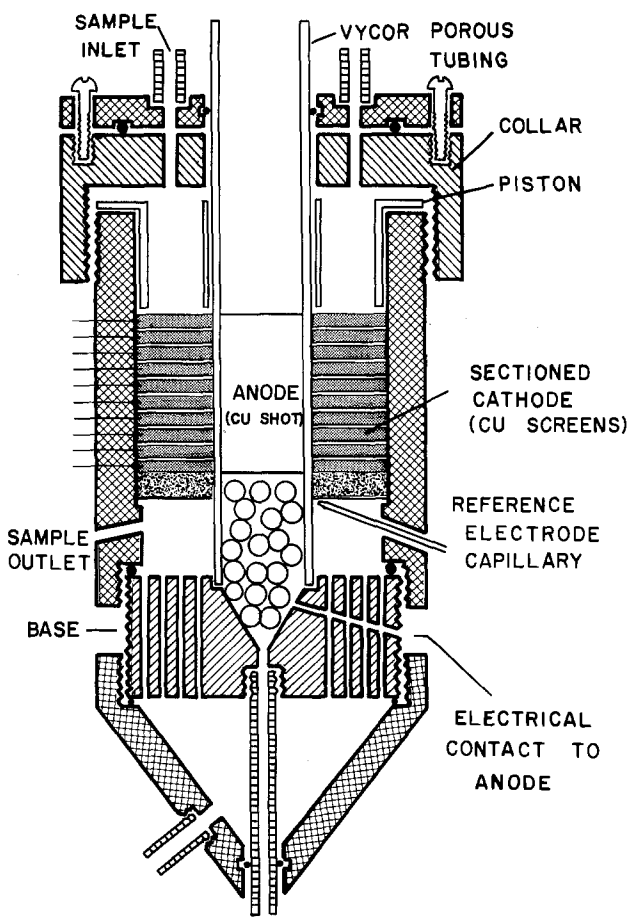

Fig. 1. Segmented porous electrode flow cell, cross-sectional view.

A porous Vycor® tube (Corning No. 7930) separated the cathode and anode compartments. The conductivity of the Vycor® tube filled with electrolytic solution was measured with a four point system and was found to be 0.04 $(\Omega cm)^{-1}$. Because the reference electrode was positioned at the outer periphery of the cell separator, the low conductivity of the separator had no effect on the performance of the sectioned cathode under investigation.

The cylindrical anode was a dumped bed of copper shot (average particle diam 0.05 cm) held between two copper screens and supported on a bed of glass spheres. Electrical contact was made with a copper wire which passed through the solution outlet tube. Auxiliary polarization measurements on the individual electrodes indicated that when the cathode operated at the limiting current, the anode polarization was negligible in comparison with the cathode polarization.

The separate gravity-driven circuits used for anolyte and catholyte flow were constructed from glass components with Tygon connections which had been leached prior to use. The anolyte flow rate was maintained at a sufficiently high level that it did not affect the current distribution in the cathode. The catholyte flow rate was measured with precision rotameters (Gilmont no. 2-5). The overhead catholyte reservoir was fitted within a vacuum device which maintained a constant head independent of the solution level in the reservoir. By this method, the catholyte flow rate remained steady to within 1% during the course of any given experiment.

A potentiostatic power supply (Wenking no. 68TS-3 or 70TS-1) was used to control the cathode potential with respect to a $Hg/Hg_2SO_4/1.5M\ H_2SO_4$ reference electrode. The cell current was monitored with a potentiostatic recorder (Sargent-Welch SRG). Individual section currents were detected with a multichannel zero-resistance operational amplifier device (built in-house) and displayed on a multipoint potentiostatic recorder (Leeds and Northrup Speedomax X). When polarization curves were measured, the potentiostat was driven with a linear ramp generator (built in-house) with display on a X-Y recorder (Houston Instruments no. 2000).

Experimental Procedures

The electrolytic solution used in this study was copper sulfate in sulfuric acid solution, prepared from reagent grade chemicals. Deionized water was distilled once in a tin-lined still and had a conductivity of 4×10^{-6} $(\Omega cm)^{-1}$. Fresh electrolytic solution was placed over clean copper shot to achieve equilibration with Cu(I), and was then deaerated under nitrogen prior to use. Above 0.003M the copper concentration was determined with a spectrophotometer (Beckman Model B); below 0.003M, the neocuproine method was used (14).

The copper screens (Unique Wire Weaving Company) were scrubbed in trichloroethylene, soaked in a hot phosphate/metasilicate solution, pickled in warm acidified ferric sulfate, etched in a mixture of nitric and sulfuric acid, and rinsed in distilled water. The electrolysis cell was assembled under water to avoid

trapped bubbles, placed in the flow circuit, and flushed with copious quantities of deaerated electrolytic solution.

The flow rate was adjusted and the electrical circuit was energized to the desired applied potential. After reaching steady state (usually in 3-4 residence times) the cell current, applied potential, and individual section currents were recorded. The applied potential was then increased and the process repeated. The exit solution concentration was determined from a 5 ml sample of electrolyte which was slowly withdrawn through the downstream syringe while keeping the flow rate constant. The flow rate was then adjusted to a new value and the entire procedure was repeated.

In this fashion, 150 experiments were carried out to refine the cell design and to obtain data under controlled conditions for comparison with theoretical calculations. After several such runs, the cell was disassembled and new electrodes were prepared. It was found that plugging of the porous cathode occurred, for example, upon passing 3500C through twelve 100 mesh screens having an annular flow cross-sectional area of 8.21 cm^2. The life of an electrode assembly was therefore purposefully restricted so as to avoid effects of changing electrode structure.

Theoretical

The mathematical model outlined in this study extends our earlier work by including a mass transfer coefficient to account for behavior at limiting current conditions. Figure 2 illustrates the geometry of the electrolysis cell under consideration. The porous flow-by electrode of interest is annular in shape, bounded on the outside by an insulating wall and on the inside by a separator and cylindrical counterelectrode. In the macroscopic model given below, the discrete structure of the porous bed is not taken into account except through average properties, and the heterogeneous electrode reaction is written as though it were a homogeneous reaction in the species conservation equation. Whereas the average electrolyte flow is in the z direction, it is clear that the microscopic flow field around particles is actually three dimensional. In a similar manner, the flow of current is nominally in the radial direction, although, at a microscopic level, the potential field is actually three dimensional. A theoretical analysis of the microscopic (three-dimensional) variations in potential and solution flow is not necessary for an engineering analysis. The model given below characterizes only the macroscopic nature of the current and velocity flows, which are approximately perpendicular, so that the differential equation can be solved by a numerical analog of the separation of variables technique. Several assumptions have been made concerning electrode operation in order to simplify mathematical treatment: (*i*) the porous electrode is highly conductive and has a uniform porosity and specific surface area which do not change during electrolysis; (*ii*) electrolysis proceeds under isothermal steady-state conditions, with steady plug flow of electrolyte in the z direction; (*iii*) a single reversible electrode reaction occurs; (*iv*) a supporting electrolyte is present which suppresses migration of reacting species, and axial diffusion is negligible; (*v*) current flows in the solution phase solely in the r direction.

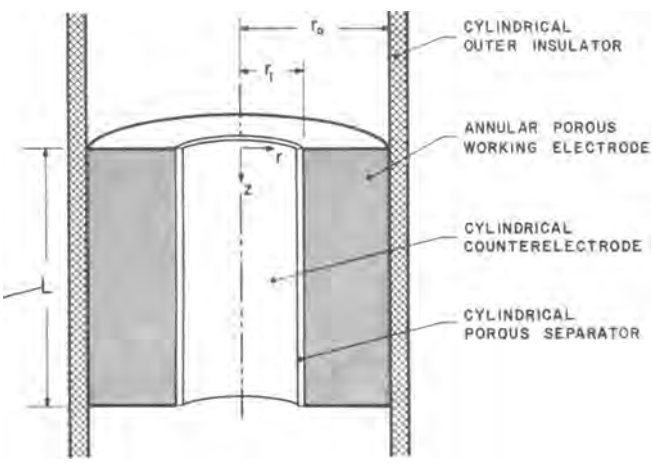

Fig. 2. Geometry and coordinate system used in the theoretical analysis.

The stoichiometry of the electrochemical reaction is defined by

$$\sum_i s_i M_i^{z_i} = ne \qquad [1]$$

In this study, the electrochemical reaction is copper deposition from divalent cupric. Under steady-state conditions, the species conservation equation for copper ion is

$$\nabla \cdot (D\nabla c - vc) = \frac{a\nu_r}{n\mathbf{F}} j \qquad [2]$$

where the source term corresponds to the electrochemical reaction rate which, for the metal deposition system studied here, is

$$j = i_o \left\{ e^{\frac{\alpha_a n\mathbf{F}}{RT}\phi} - \left(\frac{c^s}{c^b}\right) e^{-\frac{\alpha_c n\mathbf{F}}{RT}\phi} \right\} \qquad [3]$$

$\phi(y)$ is the potential difference between a reference electrode and the working electrode that would be measured by placing a Cu/Cu(II) reference electrode in an electrolyte having the composition of the inlet solution and connecting that reference electrode by a capillary to the solution adjacent to the working electrode surface at position y. Because of internal mass transfer limitations, the reactant concentration at the electrode surface, c^s, may be different from the concentration in the core of the flowing electrolyte, c. The two concentrations are related by the mass transfer coefficient

$$j = \frac{n\mathbf{F}k}{\nu_r}(c - c^s) \qquad [4]$$

In the electrolyte phase, the potential field obeys Ohm's law so that the conservation of charge equation is

$$\nabla^2\phi = \frac{a}{\kappa} j \qquad [5]$$

The boundary conditions used in the model are chosen to correspond closely to the experimental conditions described in following sections. At the inlet to the porous electrode, the reactant concentration is uniform. At the inner boundary of the annular electrode, the potential is held constant and the separator membrane is impermeable to the reactant species. The outer boundary of the electrode is an insulator. The equations corresponding to these boundary conditions are given below in dimensionless form in Eq. [12].

The equations of the model were made dimensionless by defining the following quantities

$$C = \frac{c}{c_r} \qquad C^s = \frac{c^s}{c_r}$$

$$R = \frac{r - r_i}{r_o - r_i} \qquad Z = \frac{z}{r_o - r_i}$$

$$\Phi = \frac{n\mathbf{F}\phi}{RT} \qquad J = \frac{(r_o - r_i)aj}{i(z)} \qquad [6]$$

where

$$i(z) = \frac{a}{r_i}\int_{r_i}^{r_o} rj\,dr \qquad [7]$$

As a consequence, the following dimensionless parameters were found

$$\xi = \frac{nFa(r_o - r_i)^2 i_o}{\kappa RT} \qquad \chi = \frac{a(r_o - r_i)^2 i_o}{nFc_r D}$$

$$\zeta = \frac{v_z(r_o - r_i)}{D} \qquad \Gamma = \frac{n^2F^2kc_r a(r_o - r_i)^2}{\kappa RT}$$

$$\beta(Z) = \frac{inF(r_o - r_i)}{\kappa RT} \qquad L = \frac{r_i}{r_o - r_i} \qquad [8]$$

$$\gamma = \frac{c^b}{c_r}$$

The dimensionless equations which describe the model are

$$\zeta \frac{\partial C}{\partial Z} = \frac{\partial^2 C}{\partial R^2} + \frac{1}{R + L}\frac{\partial C}{\partial R} - \frac{\chi\Gamma}{\xi}(C - C^s) \qquad [9]$$

$$\frac{d^2\Phi}{dR^2} + \frac{1}{R + L}\frac{d\Phi}{dR} = \frac{\Gamma}{\nu_r}(C - C^s) \qquad [10]$$

$$\Gamma(C - C^s) = \nu_r\xi\left\{ e^{\alpha_a\Phi} - \frac{C^s}{\gamma}e^{-\alpha_c\Phi} \right\} \qquad [11]$$

with boundary conditions

$$\text{at } Z = 0 \qquad C = \gamma$$

$$\text{at } R = 0 \qquad \frac{\partial C}{\partial R} = 0, \quad \Phi = \Phi_a$$

$$\text{at } r = 1 \qquad \frac{\partial C}{\partial R} = \frac{\partial \Phi}{\partial R} = 0 \qquad [12]$$

The coupled nonlinear model equations were solved by a numerical technique. Integration was carried out in a step-wise fashion along the axial direction beginning at the upstream surface. At each axial step, linearized finite difference equations were written in the Crank-Nicolson symmetric form. The trial matrix was inverted (15) with successive iterative correction until convergence was gained. Complete details may be found in Ref. (11).

The physical significance of the dimensionless parameters in Eq. [8] has been discussed in previous publications (12, 16). ξ contains the ratio i_o/κ and thereby indicates the relative importance of electrolyte resistance and charge-transfer resistances. In the absence of mass transport limitations, ξ is the parameter that controls electrode behavior; ξ can be regarded as a linear polarization parameter. When $\xi < 1$, the conductivity is sufficiently high that the secondary current distribution is uniform. The parameter χ indicates the relative importance of diffusion and charge-transfer resistances insofar as it contains the ratio i_o/D. In the absence of convection or internal mass transfer effects, a large value of χ indicates that slow diffusional transport will lead to nonuniform current distributions in the radial direction. The relative importance of convective transport to diffusive transport of reactants is embodied by the parameter ζ. If ζ is large, the current distribution along the axial direction will be uniform since the supply of reactants will be sufficient to insure against depletion. For lower values of ζ, axial distributions will be nonuniform owing to reactant depletion.

The parameter Γ is a dimensionless mass transfer coefficient, and did not appear in our earlier flow-by analysis in which internal mass transfer limitations were not taken into account. If Γ has a small value, then the surface concentration can be much less than the concentration in the core of the fluid "fingers" which flow through the porous electrode. Equation [11] can be used to estimate conditions under which internal mass transfer effects are appreciable. For high cathodic potentials where the back-reaction is negligible, rearrangement gives

$$C^s = \frac{\gamma}{1 - \frac{\nu_r\xi}{\gamma\Gamma}e^{-\alpha_c\Phi}} \qquad [13]$$

Equation [13] indicates that if

$$\left| \frac{\nu_r\xi}{\gamma\Gamma}e^{-\alpha_c\Phi} \right| << 1 \qquad [14]$$

then $C^s \simeq \gamma$ and our earlier analysis may be used. On the other hand, if

$$\left| \frac{\nu_r\xi}{\gamma\Gamma}e^{-\alpha_c\Phi} \right| >> 1 \qquad [15]$$

then $C^s < \gamma$ and internal mass transfer limitations must be taken into account.

Comparison of Theory with Experiment

The physical properties of the acid copper system are listed in Table I along with the geometrical properties of the porous cathodes. The wire diameters and thickness of stacked screens were measured with a micrometer. The porosity and specific surface area of the screens was calculated by the method of Armour and Cannon (17); the porosity was also measured by weighing. The value of n was determined from the copper concentration difference caused by passage of current, and was found to be 2.0 to within experimental accuracy of 2%. The electrolyte conductivity was measured with a bridge (Leeds and Northrup, no. 4959). Experiments included variation of mesh size of the electrode screen (100, 150, and 200 mesh), electrode length (0.156-2.1 cm), electrode width (0.5-1.1 cm), solute concentration (0.007-0.019M), solution flow rate (0.3-51.0 ml/min), and applied potential (20-800 mV).

Polarization curves for a typical experiment are given in Fig. 3. At low flow rates, the limiting current plateau covered a potential span of about 300 mV in this example. Under conditions of high flow rates, the limiting current plateau was not observed.

Behavior at limiting current.—The dependence of limiting current upon velocity is shown in Fig. 4 for electrodes having the same lengths and mesh size but three different annular widths. At low flow rates, all reactants which enter the reactor are consumed; the straight line on Fig. 4 corresponds to the equation

$$i_{max} = nFc^b v \qquad [16]$$

The collection effectiveness at the limiting current density, defined as

$$\text{collection effectiveness} = CE = \frac{i_{lim}}{nFc^b v} = \frac{c^b - c^l}{c^b} \qquad [17]$$

has the value of unity for the low flow rate (<3 ml/min) range in Fig. 4. At higher flow rates, the collection effectiveness is less than unity at the limiting current owing to restricted mass transport within the porous electrode. Experimental measurement of the limiting current density and the exit concentration

Table I. System properties

Electrodes Mesh no.	Wire diameter (cm)	Screen thickness (cm)	Porosity	Specific surface area (cm^{-1})
100	0.0109	0.0206	0.61	143.0
150	0.0066	0.0140	0.69	188.3
200	0.00533	0.0117	0.67	245.0

Other system parameters
n = 2 g-eq/g-mole
κ = 0.51 $(\Omega\ cm)^{-1}$
D = 5.0 × 10^{-6} cm^2/sec (23)
ν = 1.035 × 10^{-2} cm^2/sec (23)
i_o = 6.7 × 10^{-5} A/cm^2
α_a = 0.75
α_c = 0.25

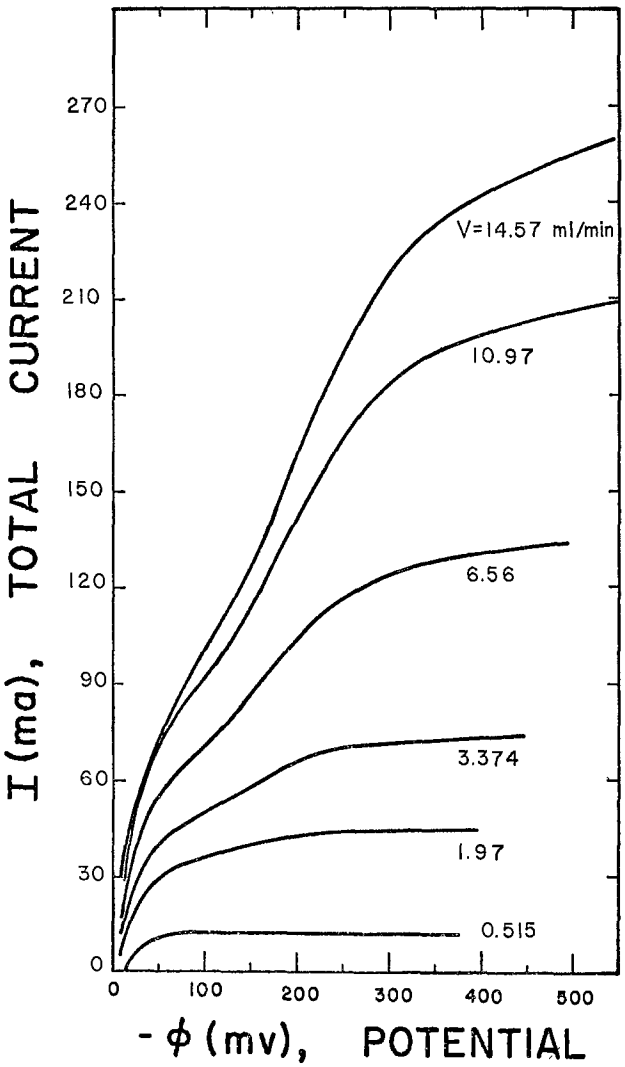

Fig. 3. Effect of catholyte flow rate on cathode polarization. (100-mesh screens, $c^b = 0.0072M$, $r_o - r_i = 0.496$ cm, $l = 0.246$ cm.)

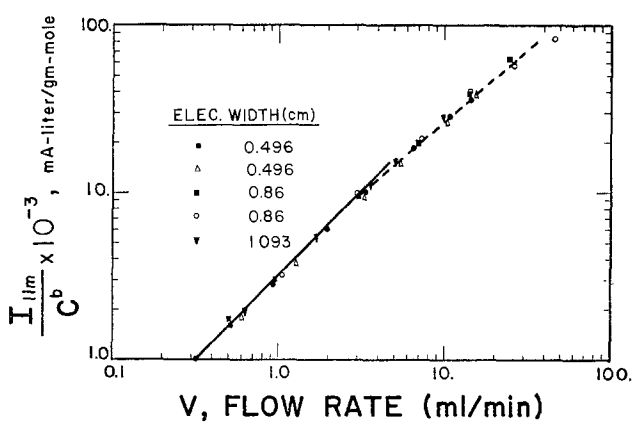

Fig. 4. Effect of catholyte flow rate on cathode limiting current. (100-mesh screens, $l = 0.246$ cm.)

were found by Eq. [17] to be in agreement to within 5%. These data indicate that internal mass transfer limitations are present within the porous electrode. Because the electrode reaction occurs under the limiting current condition without side reactions, the current distribution is controlled solely by the mass transfer characteristics of the packed bed. That is, variation of limiting current with system parameters in this study is qualitatively the same as that observed previously in packed bed reactor systems of different geometric configuration. Therefore, in this study, the mass transfer correlation of Wilson and Geankoplis (18) was used since it had been successful in the parallel flow configuration studied by Alkire and Gracon (16).

Preliminary experiments were conducted in order to demonstrate whether channeling occurred with the porous cathode. For these, prior to cell assembly, the copper screens were silver coated by immersion in a silver cyanide plating solution. After cell assembly, the cathode was operated at the limiting current, the cathode screens were later removed, and the copper deposit was examined. Without the downstream porous glass plate, severe channeling was observed. With the plate in place channeling occurred to a lesser extent. Nevertheless, the screens were more heavily coated with copper along the inner and outer perimeters. Although the channeling effect could perhaps have been further reduced by redesign of the system configuration and reaction chemistry, it was found that the over-all behavior of alternative systems was less amenable to the goal of conducting controlled experiments with known system parameters. As is discussed in detail below, the channeling effect was more pronounced at low than at high flow rates.

Current distribution data for a typical series of experiments are shown in Fig. 5. It is seen that the upstream regions are more reactive to an extent which depends upon the flow rate. At low flow rates, the downstream region of the electrode is unreactive (there being no copper left in the solution) and a collection efficiency of unity is achieved. At high flow rates, the downstream regions are much more reactive, and the collection effectiveness is less than unity. As the flow rate increases the reaction distribution becomes more uniform. Upon comparison of these data with theoretical calculations, two types of discrepancies were observed; at low flow rates the experimental distributions were more uniform than those predicted by the model,

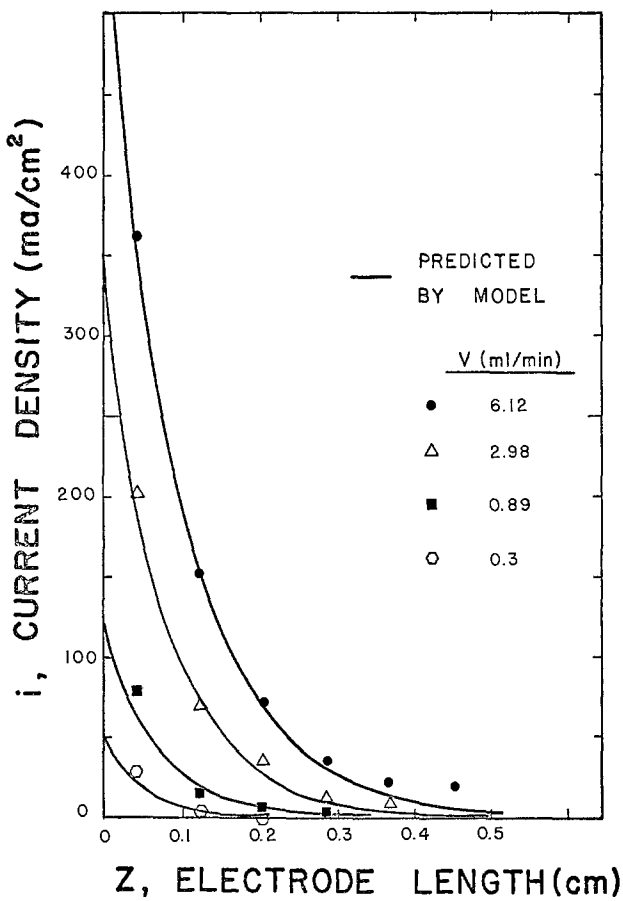

Fig. 5. Axial current distribution measured with segmented porous electrode. (100-mesh screens, $c^b = 0.0188M$, $r_o = r_i = 0.86$ cm, $l = 0.492$ cm.)

while at high flow rates the experimental limiting current was less than that predicted by the model. These discrepancies were attributed to the channeling effect observed in the preliminary experiments mentioned above. Channeling serves to decrease the internal mass transfer coefficient, or effective surface area. Adams *et al.* (19) reported similar circumstances under which channeling apparently served to decrease the effective surface area or mass transfer coefficient.

An empirical method was therefore employed to fit the theoretical model to a single set of limiting current distribution data. Figure 6 shows the correction factor by which the specific surface area in Ref. [18] needed to be multiplied in order that the model fit the predicted limiting current distribution for one electrode. The correction factor depends upon flow velocity and bed porosity as shown. It was found that this single correction was able to fit all limiting current and current distribution data measured for all mesh sizes, electrode widths, electrode lengths, concentrations, and flow velocities studied. For example, the solid lines in Fig. 5 correspond to theoretical results predicted with use of the correction factor. (The data given in Fig. 5 are not the same as those used to obtain the correction factor.) In the same manner, the dashed lines in Fig. 4 correspond to theoretical results predicted with use of the correction factor. The comparisons shown in Fig. 4 and 5 indicate that the correction factor enables one to predict total current and current distribution behavior over the entire range of parameter space studied. At still higher flow rates than those investigated, the data in Fig. 4 would be expected to increase with the cube root of solution velocity.

Electrode behavior under limiting current conditions can depend upon the rate of reactant supply or upon the rate of internal mass transfer. At low velocities, Eq. [16] shows that the limiting current is linearly proportional to the velocity and is independent of the electrode length. Under such conditions, all the entering reactants are consumed within the electrode and the collection efficiency is 100%. The flow rate above which internal mass transfer becomes appreciable may be expressed in dimensionless form as

$$\mathrm{Re}_{cr} = \left[\frac{\Gamma^* d_p \chi^Z}{\mathrm{Sc}(r_o - r_i)} \right]^{3/2} \qquad [19]$$

When the entire porous bed operates under limiting current conditions, the surface concentration of the reactant will be essentially zero throughout the electrode; therefore the radial concentration distribution will be uniform at every axial position in the reactor. For flow rates in excess of Re_{cr}, the axial distributions of concentration and reaction rate are

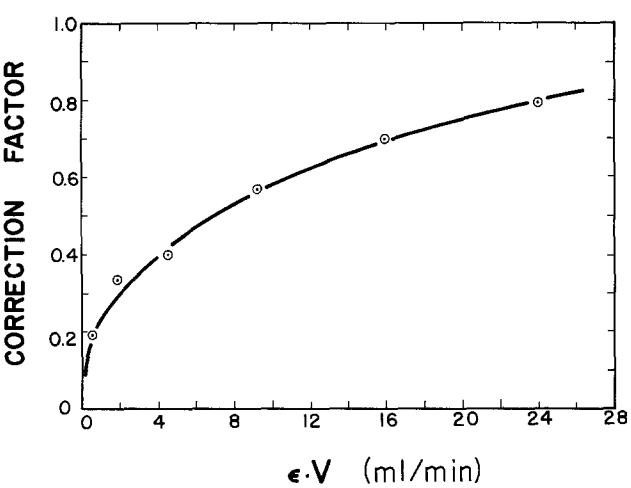

Fig. 6. Factor used in modifying mass transfer coefficient to account for channeling in porous cathode.

$$\frac{\beta(z)}{\Gamma\gamma} \frac{2L\nu_r}{(2L+1)} = C = \gamma e^{-\frac{\chi\Gamma}{\xi} z} = \frac{c^b}{c_r} e^{-\frac{akz}{v}} \qquad [20]$$

In view of the agreement between experiment and theory demonstrated in Fig. 4, it should be recognized that Eq. [20] may be used with confidence in predicting the collection efficiency, provided that the correction factor is used in determining the specific surface area.

Behavior below limiting current.—Current distribution data are given in Fig. 7 for several electrodes having different configurations but having the same values of ξ, χ, and applied potential (50 mV). The four sets of experimental data correspond to different residence times, as obtained by using different electrode lengths and solution flow rates. The data show that the current distribution becomes more nonuniform as the residence time increases. The four sets of data converge at the upstream (left-hand) side of the electrode.

In order to compare data with theoretical calculations, it was necessary to choose the values of ξ and χ which represent the system. The exchange current density for the copper deposition reaction has been variously reported and would, following Newman (20), have the value 0.36 mA/cm² in the 0.009M $CuSO_4$ solution used in this study (with $\alpha_a = 0.75$ and $\alpha_c = 0.25$). The presence of sulfuric acid reduces the exchange current density, as has been found by Cabán and Chapman (21), whose model IV correlation would

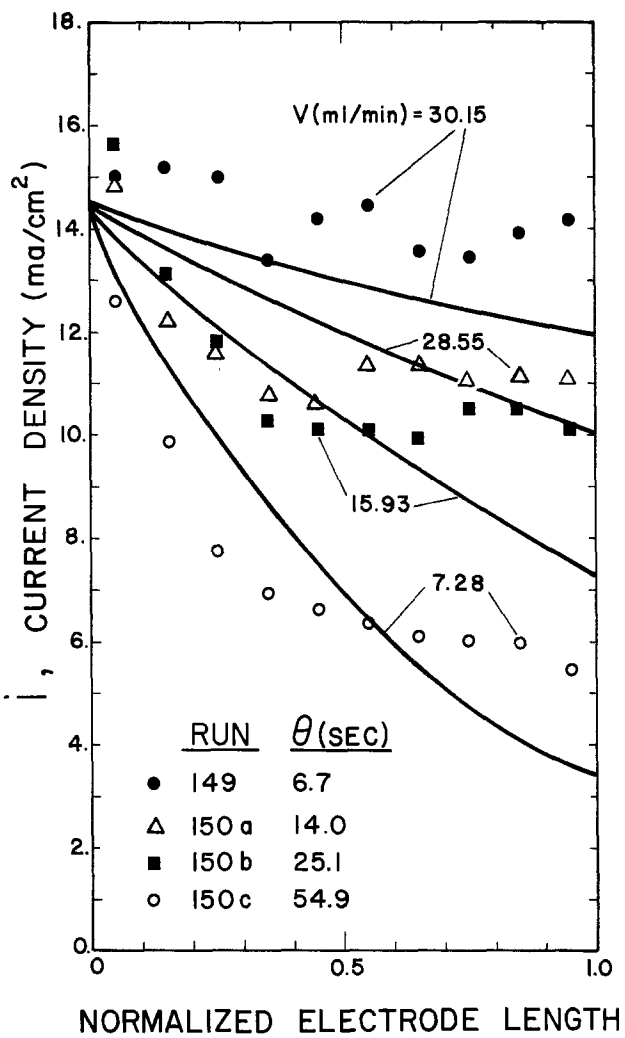

Fig. 7. Axial current distributions measured with segment electrodes under various catholyte flow rates. (100-mesh screens, 50 mV applied, $c^b = 0.0088$M, run 149: $r_o - r_i = 0.496$ cm and $l = 1.04$ cm; run 150: $r_o - r_i = 0.958$ and $l = 2.06$.)

Table II. Comparison of measured cell current with theoretical predictions

Run	Measured (mA)	Predicted (mA)	Deviation (%)
149	135	124	−4.5
150 a	220	226	+2.7
150 b	211	196	−7.1
150 c	139	140	+0.7

indicate the value 0.042 mA/cm² in the 1.5M H_2SO_4 solution (with $\alpha_a = 0.54$ and $\alpha_c = 0.19$). In this study we compared ten sets of packed-bed polarization curves with theoretical calculations made with the values $\alpha_a = 0.75$ and $\alpha_c = 0.25$, and found that the exchange current density of 0.067 mA/cm² gave a good comparison for all packed-bed experimental results. The effect of channeling was not taken into consideration while determining i_0 since the currents were only small fractions of the limiting current, so that mass transport effects were negligible.

Having thus specified ξ and χ on the basis of current-voltage data, calculations were then carried out for determining the current distribution. In these calculations, no adjustment of the mass transfer coefficient was made concerning channeling effects. The results are given by the solid lines in Fig. 7. Comparison between experimental data and theoretical calculations demonstrates agreement to within 15% over the range of cases studied. Table II contains the measured and predicted values of total current for the four cases shown in Fig. 7. It is seen that the model predicts the over-all current to within about 4%.

For the data given in Fig. 7, we compute for the left-hand side of Eq. [14] a value of 0.03, which indicates that the results of our earlier study (12) could be used to predict detailed current distribution behavior. Although the geometry of that earlier work was slightly different from the present study, it seems reasonable to suggest that curvature effects would be relatively unimportant for values of ξ less than 0.5 for which the radial current distribution is relatively uniform. Figure 8 illustrates how the total current passing to the reactor varies with residence time for eight experiments below the limiting current. These experimental data are to be compared with the solid line which was determined in the same manner as had been Fig. 5 of our earlier work. The agreement indicates clearly that the perpendicular configuration model succeeds in predicting experimental behavior to within reasonable engineering tolerances.

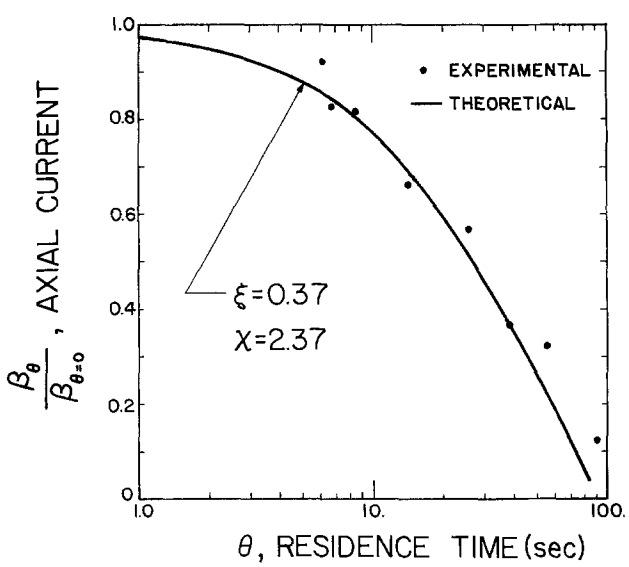

Fig. 8. Dependence of volumetric reaction rate upon residence time. (100-mesh screens, 50 mV applied, $c^b = 0.0088$-0.0096M, $V = 3$-33 ml/min, $l = 1.04$-2.06 cm, $r_o - r_i = 0.496$ cm.)

Discussion

Several aspects of behavior at the limiting current seem worthy of discussion. Consider first the case of operation at high flow rates ($Re > Re_{cr}$) where behavior is controlled by internal mass transfer. In view of the uniform radial current distribution which prevails under limiting current conditions, Eq. [10] may be simplified to

$$\frac{1}{R}\frac{d}{dR}\left(R\frac{d\Phi}{dR}\right) = \frac{\Gamma}{\nu_i}C \qquad [21]$$

Integration between $R = 0$ and $R = 1$ gives the potential drop across the annular width of the electrode

$$\Delta\Phi = \Phi|_{R=1} - \Phi|_{R=0} = \frac{\Gamma\gamma}{4\nu_i}e^{-\frac{\Gamma\chi Z}{\xi\zeta}}\left[(1+2L) - 2(1+L)^2\ln\frac{r_o}{r_i}\right] \qquad [22]$$

By neglecting the curvature terms which give Eq. [22] a complicated appearance, one has

$$\Delta\phi = \frac{n\mathbf{F}kc^b a(r_o - r_i)^2}{\kappa}e^{-\frac{akz}{v}} \qquad [23]$$

This result illustrates that the potential drop across the width of the electrode is largest at the upstream portion and decreases with axial distance downstream since the reaction rate decreases. The radial potential drop across the electrode is only weakly dependent upon the velocity insofar as the mass transfer coefficient varies with the cube root of velocity. Equation [23] may be regarded as the product of a superficial current density ($n\mathbf{F}vc$), with the reciprocal effective conductivity ($1/\kappa$), and an effective penetration depth in the radial direction [$ka(\Delta r)^2/v$)].

Now let us turn to a comparison between the parallel and perpendicular configurations in order to assess the conditions under which one might be preferable to another. As a basis for comparison, we will use the volumetric current density (A/cm³). The reactive regions of the two types of electrodes are confined to the effective depth of penetration as given above for the perpendicular configuration, and by the comments following Eq. [88] of Ref. (3). The volumetric current density over the reactive region is, for the perpendicular configuration

$$\frac{n\mathbf{F}vc^b}{l}e^{-\frac{akl}{v}} \qquad [24]$$

and, for the parallel configuration

$$n\mathbf{F}akc^b e^{-\frac{akl}{v}} \qquad [25]$$

By taking the ratio of Eq. [24] and [25], one finds that the perpendicular configuration gives the greater volumetric reaction rate under the criterion

$$\frac{v}{akl} > 1 \qquad [26]$$

which is a ratio of residence times. By the criterion of Eq. [26] it is seen that the perpendicular field is the preferred choice when design considerations call for high velocities and coarse packing (low specific surface area and low mass transfer coefficients). Equation [26] also indicates a basis for choosing the length of a perpendicular field which cannot be exceeded if the volumetric reaction rate is to remain advantageous. Other bases for comparison could be chosen, such as pumping costs, etc., and it would seem worthwhile to pursue these in future studies.

Conclusions

An advantage often claimed for electrochemical processes is their high degree of selectivity for a particular reaction product. Although high reaction rates are possible with porous electrode reactors, substantial potential variations may occur within the reactor which adversely affect the desired selectivity. The principal advantage of the perpendicular configuration is that it permits large residence times under conditions where channeling effects can be substantially reduced, while simultaneously permitting a uniform potential distribution. The type of systems where its use would be particularly advantageous would be ones in which the reactants are dilute and the conductivity is low, so that not only mass transport is important, but the potential distribution is also important for maintaining reaction selectivity.

Whereas the behavior of reactors with perpendicular flow of current and electrolyte is inherently more complex than the parallel configuration, a mathematical model has been shown to be capable of correlating experimental data at and below the limiting current for systems of various electrode lengths and widths, solution velocities, concentrations, and specific surface areas. In order to account for the presence of channeling effects, it was necessary to develop a correlation for the mass transfer coefficient. Whereas that channeling correlation was adequate over the range of variables investigated here, it is unlikely that it could be used in flow cells of different design or scale.

Should the need arise, the model could be formulated to account for other reaction rate behavior, including multiple electrode reactions and sequences involving simultaneous homogeneous chemical reactions (22). The approximate method of solution, by separation of variables, provides an accurate representation of the reactor provided that axial dispersion or channeling effects are absent (12). The model could not, however, be easily extended to account for axial dispersion or channeling effects in any fundamental manner; a more correct two-dimensional analysis would be exceedingly difficult. The approximate procedure, used here for handling channeling effects by modification of the mass transfer coefficient, provides a simple yet accurate procedure for pursuing engineering aspects of the reactor analysis problem.

The Electroreduction of Air in Trifluoromethanesulfonic Acid Monohydrate

ABSTRACT

The electroreduction of air on a platinum electrode has been investigated in trifluoromethanesulfonic acid monohydrate as part of a study involving the hydrocarbon-air fuel cell. At 135°C, the open-circuit potential of the air electrode was 1.135V (*vs.* the dynamic hydrogen electrode) and the limiting current density was higher than that observed in phosphoric acid under the same conditions. Current density-potential diagrams were constructed over the temperature range of 95°-135°C. The activation energy for the process is low; 1500-4000 cal mole^{-1}.

It has been observed that electrooxidation and electroreduction reactions in direct or indirect hydrocarbon-air fuel cells are influenced by the electrolyte (1, 2). Phosphoric acid has become the accepted acid electrolyte for most fuel cell systems developed in this country for terrestrial applications because of its stability at elevated temperatures and the ease of removal of heat and water. However, when used in direct oxidation hydrocarbon-air fuel cells, phosphoric acid has several undesirable characteristics which are demonstrated by short life and low performance. These shortcomings have been attributed to adsorption of the acid anion and low solubility of air and hydrocarbons.

The investigation of trifluoromethanesulfonic acid monohydrate was based on a consideration of the properties of the material and on the characteristics considered desirable for a hydrocarbon-air fuel cell electrolyte (3). Trifluoromethanesulfonic acid monohydrate has a high conductivity and low vapor pressure in the temperature range of 100°-150°C. The compound melts at 33°C and distills without decomposition at 217°-218°C (4). Trifluoromethanesulfonic acid itself is stable to a least 350°C and its aqueous solution is stable to at least 275°C (5). In the work in our laboratory, individual volumes of the monohydrate have been exposed to temperature cycling, potential cycling, and/or current pulsing, at 135°C, for several months without deteriorating. After several weeks at 135°C some darkening of the monohydrate is observed, but the crystallization temperature is not lowered, suggesting that any decomposition that does occur must be very slight.

The electrochemical oxidation of propane and of hydrogen was found to be significantly enhanced in trifluoromethanesulfonic acid monohydrate when compared with results obtained in 85% phosphoric acid. In the development of hydrocarbon-air and hydrogen-air fuel cells the performance of the air electrode obviously is of as much importance as the performance of the anode. The objective of this research was to investigate the electrochemical reduction of air in trifluoromethanesulfonic acid monohydrate and compare the results with those obtained for the reduction of air in 85% phosphoric acid.

Experimental

Apparatus.—The electrochemical cell and electronic apparatus have been described previously (3).

Materials.—Trifluoromethanesulfonic acid monohydrate was prepared from trifluoromethanesulfonic acid (obtained from 3M Company, Minneapolis, Minnesota), and triply distilled water by the method described by Gramstad and Hazeldine (5). Fisher reagent-grade phosphoric acid was purified and diluted to 85% volume by the technique previously described (3). Water-pumped air was obtained from Air Products, Incorporated. High purity helium (99.995%), obtained from the Matheson Company, was deoxygenated by passing through a bed of copper turnings at 400°C. The gases were humidified to maintain H_3PO_4 concentration at 85% for all cell operating temperatures; the gases were not humidified in those experiments wherein $CF_3SO_3H \cdot H_2O$ was used as the electrolyte.

Experimental technique.—In the development of the current-potential curves, a platinum mesh electrode (99.9%) of approximately 4 cm^2 "real" surface area was utilized. The "real" surface area of the electrode was determined electrochemically by the method used by Brummer (6), and the current density values reported are based on this real surface area. Current density potential diagrams were constructed for the reduction of air at several temperatures from 23° to 135°C, with most of the work from 95°-135°C. In the electrochemical experiments helium was used as a background or nonreactive gas. In performing the current *vs.* potential runs, a potential value was set and the system allowed to equilibrate for 5 min before the current value was recorded.

In conducting an experiment, the air which was previously brought to temperature was bubbled over the electrode. The system used a freely flowing gas which allowed the air to saturate the solution at any flow rate. Due to the design of the electrochemical cell there was no pressure increase at the air electrode. A flow rate of 50 ml/min was arbitrarily selected for the polarization experiments following preliminary experiments wherein the open-circuit potential and the current density were measured as a function of flow rate. This dependency for the trifluoromethanesulfonic acid monohydrate electrolyte is shown at 135°C in Fig. 1. Above a flow rate of 20 ml/min the open-circuit potential attained a steady value of 1.13V; below this flow rate the potential was lower and erratic. The current density was not greatly altered by a change in flow rate, varying only 6 μA/cm^2 from a flow rate of 3 to 40 ml/min.

Results and Discussion

The results for the electroreduction of air on a smooth platinum electrode at 95°, 115°, and 135°C are

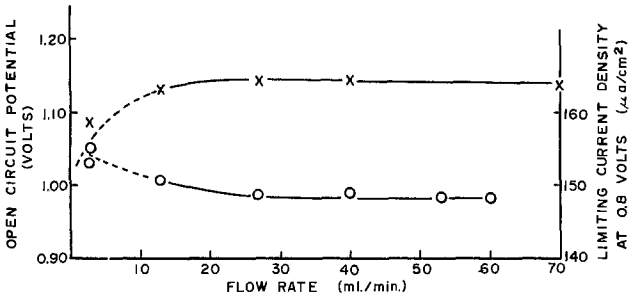

Fig. 1. Influence of air flow rate on the open-circuit potential and limiting current density of the air electrode in trifluoromethanesulfonic acid monohydrate. X = open-circuit potential (volts); O = limiting current density at 0.8V (μA/cm^2).

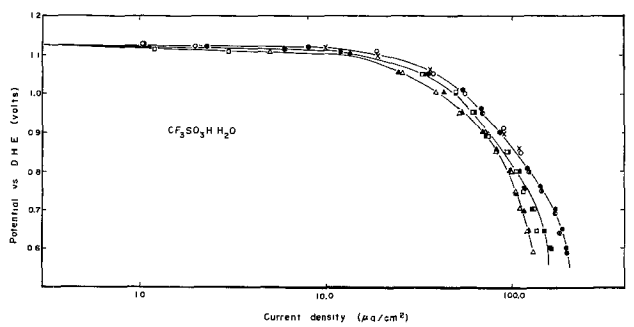

Fig. 2. Electroreduction of air on a smooth platinum electrode in trifluoromethanesulfonic acid monohydrate; at 95°C, △, ▲; at 115°C, □, ■; at 135°C, O, X, ●.

summarized in Fig. 2. These data are also indicative of the precision of the polarization runs, as experiments conducted on three different days at 135°C, on two different days at 115°C, and on two different days at 95°C are given. The curves presented in Fig. 2 represent a minimum of 10 individual polarization runs at any temperature. The potentials reported are on the "dynamic hydrogen electrode" scale (7). The current density values at a set potential increased with temperature as would be expected. Table I gives the open-circuit potentials and the limiting current densities for four temperatures.

The polarization curves of Fig. 2 are characterized by an extended range of reversibility and a short Tafel region, *i.e.*, the current density range in which the overpotential-log current density plot is linear. From the polarization curve an exchange current density of 1×10^{-5} A cm^{-2} may be extrapolated. The activation energy for the temperature range was measured at different potentials from the open-circuit potential (Fig. 3). As the potential moves from the open-circuit potential the activation energy decreases, reaches an extremely low value, and then increases. These energies are given in Table II. Over the whole range the activation energy is low, suggesting a diffusion-controlled reaction.

In Fig. 4 the electroreduction of air in trifluoromethanesulfonic acid monohydrate is compared with that in 85% phosphoric acid at 135°C. Also plotted are some recent results reported by Srinivasen (8) at 80°C for the oxygen electrode in the two electrolytes. The two

studies are in agreement with respect to the higher open-circuit voltage in the sulfonic acid monohydrate of about 150 mV. However, at 135°C the crossover of the polarization curves observed at 0.86V at 80°C is not observed.

The higher current densities observed in the electroreduction of air in $CF_3SO_3H \cdot H_2O$, as compared with those observed in 85% H_3PO_4, following similar observations on the oxidation of propane and H_2, are of vital interest, not only from the practical fuel cell

viewpoint, but also from basic theoretical consideration. Several explanations seem possible, including changes in diffusion coefficients, concentration gradients, and those other factors that are incorporated in the customary limiting current density equation. However, the magnitude of the increase in current density values suggests other effects. It is our present contention that the real explanation lies in the increase in the electroactive area of the electrode in the acid monohydrate electrolyte. It is well accepted that in the adsorption process, which is a necessary preliminary step in the electrode reaction, anions and water molecules compete with the reactant species (propane, H_2, or O_2), for active sites on the electrode surface. It is believed that in the trifluoromethanesulfonic acid monohydrate electrolyte both the acid anion and the molecular "free" water adsorption is less than that in H_3PO_4.

Conclusions

The open-circuit potential for the air electrode in $CF_3SO_3H \cdot H_2O$ is approximately 150 mV closer to the thermodynamic reversible potential than the potential observed in phosphoric acid. At all potentials, at a given temperature, the current density is higher for the air reduction reaction in $CF_3SO_3H \cdot H_2O$ than in H_3PO_4. It is concluded from this and preceding work (4) that the performance of a direct hydrocarbon-air or hydrogen-air fuel cell utilizing this electrolyte would be substantially greater than that of the corresponding cell utilizing phosphoric acid.

In connection with the employment of trifluoromethanesulfonic acid monohydrate as a fuel cell electrolyte, other physical properties such as vapor pressure, the conductivity of H_2O-solutions, and the corrosion of materials that would be used for fuel cell construction, are being measured. It has been observed that the monohydrate wets Teflon, which would create a problem in the employment of Teflon-bonded electrodes in this electrolyte.

Technical Notes

Source of Oscillations in the Anode Current during the Potentiostatic Pitting of Aluminum

C. B. Bargeron and R. B. Givens

Applied Physics Laboratory, The Johns Hopkins University, Laurel, Maryland 20810

Oscillations or pulsations in the anode current during the pitting corrosion of aluminum have been observed by several investigators (1-4). Included in the discussion of this observation has been speculation as to the source of such oscillations. Wood, Sutton, Richardson, Riley, and Malherbe (1) speculated that, among other possibilities, bubble evolution might sometimes be a source of current fluctuations. Videm (2) devoted considerable attention to the current fluctuations and used patterns of pulse generation to distinguish between pit growth and other breakdown events. He discussed several sources of pulse generation including that of gas egress from pits, however, it was finally concluded that the pulsing current was a result of a cyclic oxidation process rather than that the cycles observed were caused by gas evolution. Galvele, De Micheli, Muller, de Wexler, and Alanis (3) mention current oscillations also and note that they are diminished by the presence of a surface active agent. Hübner and Wranglen (4) felt the oscillations were due to the formation and blockage of pits. Current oscillations have also been reported for other metals, for example, high purity zinc (5) and stainless steels (6). Although not mentioning current pulses, numerous other workers have noted gas egress from pits in Al. Using gas chromatography, Hübner and Wranglen (4) identified the gas as H_2.

In this communication we report observations which positively correlate current pulses with gas egress through the oxide cover over a single active pit in aluminum. Earlier work by Masing and Altenpohl (7) on a specimen with more than one active pit reached a similar conclusion regarding the origin of such oscillations. Because there was only one pit in our investiga-

Key words: aluminum, pitting, corrosion, current oscillations, gas egress.

tion, a direct relationship between current fluctuations and gas bubble activity was firmly established.

The aluminum used in this investigation had a purity of 99.999% and was obtained from the Alfa Products Division of the Ventron Corporation. A typical impurity analysis supplied with the 0.25 mm foil was 3 ppm Si, 2 ppm Fe, 1 ppm Cu, and others less than 1 ppm. An annealed disk of this foil was electropolished in a 10% perchloric acid-ethanol mixture for 2 min at +20V at about 24°C. After a thorough rinse with deionized water it was anodized galvanostatically at 1 mA/cm² in 3% ammonium tartrate solution to +60V, which provides an oxide film about 800Å thick according to capacitance measurements and previous literature (8). The counterelectrode was Type 304 stainless steel. The aluminum disk was again washed abundantly in deionized H_2O and placed in a Teflon holder with exposed area of about 0.30 cm². The electrode was then mounted face up in a stainless steel beaker filled with 1M KCl. The beaker served as the auxiliary electrode. A saturated calomel electrode (SCE) was employed as the reference electrode. Using a water-immersible objective, a light microscope was focused on the specimen.

The pitting was performed potentiostatically at −0.1V SCE. Effort was expended in minimizing the noise in the potentiostat circuitry. The anode current was amplified, then both recorded and made audible via a loudspeaker system. After the pitting process the specimen was investigated in a scanning electron microscope (SEM) with an energy dispersive x-ray analysis accessory system.

After several attempts, a specimen was obtained on which there was only one pit for a period of 15-20 min. The presence of the pit was indicated by an abrupt increase in the anode current. The pit location was characterized by vigorous bubble evolution. The nature of the bubbling changed spontaneously from time to time. At times the bubbles were small and escaped through the oxide film in rapid succession. Infrequently, for this specimen, a bubble would adhere to the oxide over the pit near the center and grow quite large. Regardless of bubble rate and size, motion of the bubbles was directly correlated with the audible current noise. At one point the bubble rate slowed to about one per second. The current record during this interval is reproduced partially in Fig. 1a. This string of oscillations continued at about this rate for 328 pulses, which were both seen as bubbles and heard over the speaker as amplitude oscillations. The leading edge of each pulse correlated with a bubble breaking loose from the surface and the trailing edge corresponded to the formation and growth of a bubble at the oxide exit. For comparison, a part of the current record during a period when smaller bubbles were escaping from the pit at a higher rate is shown in Fig. 1b. The entire observation was a convincing display of the one-to-one relationship of gas egress to current oscillations.

After the potentiostat was disconnected, a pumping device was used to direct a jet of electrolyte at the specimen surface. Based on transient light reflections, it appeared that the oxide film was floating perhaps in a torn condition over the pit. After the sample was dried as described above, it was examined in the SEM. A stereo pair[1] of micrographs taken at 20 keV beam voltage is presented in Fig. 2. Although not shown completely in this stereo pair, most, if not all, of the oxide is still present. During pit growth the oxide substantially occluded the pit from the bulk electrolyte. Thus it also impeded the bubbles from leaving the pit immediately. Hence the bubble grows under the oxide until it can escape. In so doing it reduces the area available for ionic conductivity noticeably. This explains the relatively large amplitude of the current oscillations. The above discussion is confined to current pulses observed during pit growth. Shortly before the large increase of current, rather regular oscillations of a much smaller magnitude were also recorded. No source of these pulses was observed.

[1] The pit can be viewed in stereo by placing an opaque sheet of material perpendicular to the page along the line dividing the two micrographs and allowing the eyes to merge the two images. With some luck the sheet is not necessary. However, a stereoscopic viewer is best, if available.

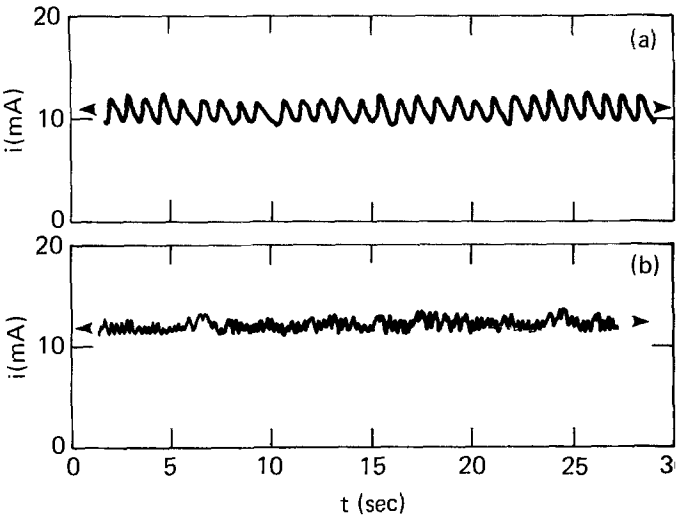

Fig. 1. Partial reproductions of the current vs. time record: (a) a portion of the record during which bubble egress was relatively slow but very uniform, 328 pulses of the type shown were recorded during this interval; (b) a portion of the record during which the bubbles were smaller but escaped at a higher rate.

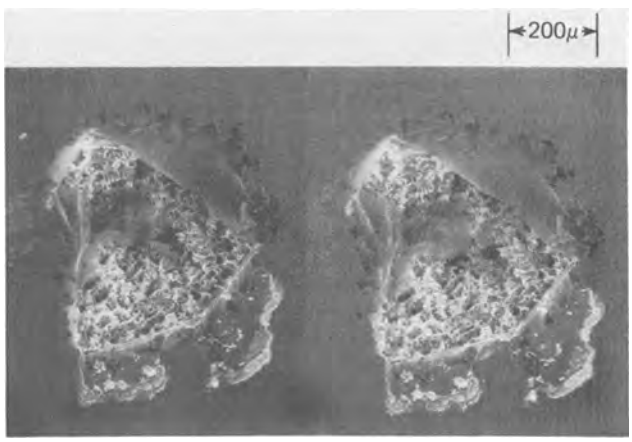

Fig. 2. A stereo pair of micrographs of the pit. The left-hand member was taken at a tilt angle of 37°, and the right-hand at 30°. The beam voltage was 20 keV.

Brief Communications

The Response of an Electrochromic Display with Viologens on a Potential Step

J. Bruinink and P. van Zanten

Philips Research Laboratories, Eindhoven, The Netherlands

The response of an electrochemical process on a potentiostatic voltage pulse is known from literature, *e.g.*, (1). There the current was expected to be proportional to $t^{-1/2}$, a diffusion-limited process. However, in a recent paper (5) it was concluded that convection predominates this diffusion limitation already after 100 msec. Since it could be expected that the display resistance might also play some role, the current-time response of an electrochromic device on a voltage step was investigated.

The electrochromic material we used was an aqueous solution of 10^{-2}M diheptyl viologen dibromide (ABr_2) and 0.3M potassium bromide. The reduction reaction is schematically given by $A^{2+} + e \rightleftarrows A^{+\cdot}$, followed by the chemical reaction $A^{+\cdot} + Br^- \rightleftarrows ABr\downarrow$ where a violet colored layer is deposited (2, 3). The electrochemical cell used had a vertically positioned transparent SnO_2 electrode (10 Ω/□, 0.4 cm²) as a working electrode, a standard Ag/AgCl electrode with a Luggin capillary as a reference electrode, and a large Pt foil separated from the cell solution by a glass frit as a counterelectrode. This three electrode system was driven by a potentiostat (Wenking St 72), and the voltage pulse was delivered by a single shot pulse generator. The response of the current to a voltage step was recorded with a storage oscilloscope.

The current-time response measured with several potential steps is shown in Fig. 1. The observed current-time transient can be divided into three regions. First is the time region directly after $t = 0$. In this region a peak current is observed which is mainly due to double layer charging. This time interval, which varies from 10 to 40 msec depending on the overpotential, was omitted in Fig. 1. The observed charging phenomena are beyond the scope of this paper and, therefore, are not to be discussed here.

In the second region the current is nearly constant, especially at lower voltages. In the third and last region the electrode process becomes diffusion limited and the current shows the familiar $t^{-1/2}$ behavior. This observed current-time response can be explained by considering the current-time relationship for a diffusion-limited electrode process (1) for the reaction $M^+ + e \rightleftarrows M\downarrow$. In this approximation, the coupled chemical reaction is assumed to be reversible

$$I = nAFC^* \left(\frac{D}{\pi t}\right)^{1/2} \left\{1 - \exp\left(\frac{nF}{RT}\eta\right)\right\} \quad [1]$$

Key words: resistance, convection, current-time response.

where I is the current; n, the number of electrons; A, the surface area; F, the Faraday constant; C^*, the bulk concentration of A^{2+}; D, the diffusion coefficient; t, the time; R, the gas constant; T, the absolute temperature; and η, the overpotential. In the absence of ohmic drop, the overpotential η is given by $\eta = E - E_e$, in which E is the applied potential and E_e is the equilibrium potential of the deposited layer in contact with the electrolyte ($\eta < 0$). In our case $E_e = -0.435$V (Ag/AgCl). If an appreciable ohmic drop R_Ω is present, the overvoltage η is given by $\eta = E - E_e + IR_\Omega$ ($I > 0$). Now η has become a function of the current I and Eq. [1] is no longer an explicit relation for I. At small values of η the exponent of Eq. [1] can be expanded in a series, and after neglecting the terms of higher order the following expression for the current is obtained

$$I = \frac{E - E_e}{P\sqrt{t} - R_\Omega} \quad \text{with} \quad P = -\frac{RT\pi^{1/2}}{n^2F^2AC^*D^{1/2}} \quad [2]$$

At short times, where $R_\Omega >> P\sqrt{t}$, the current in this constant current region ($I = I_0$) is approximately given by $I_0 = -(E - E_e)/R_\Omega$. So R_Ω can be determined from this region. The values of R_Ω obtained in this way are in good agreement with values from chronopotentiometric measurements. In our case with transparent SnO_2 electrodes, a representative value for R_Ω

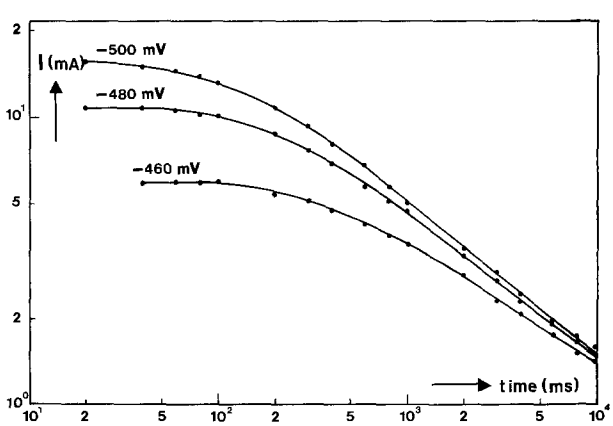

Fig. 1. Current-time behavior at several values of E (vs. Ag/AgCl). 10^{-2}M diheptyl viologen dibromide and 0.3M potassium bromide. SnO_2 electrodes, $R_\Omega = 40\Omega$.

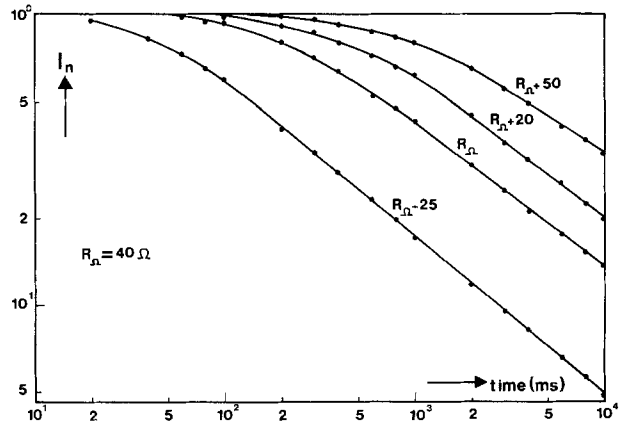

Fig. 2. Normalized current-time behavior with $E = -480$ mV (Ag/AgCl) at several values of R_Ω. 10^{-2}M diheptyl viologen dibromide and 0.3M potassium bromide. SnO_2 electrodes.

is 40Ω. The time during which the current remains nearly constant is, among other factors, determined by the value of the ohmic resistance R_Ω. This is clearly demonstrated in Fig. 2, where the dimensionless parameter $I_N = I/I_o$ is introduced. R_Ω, as given in Fig. 2, is the internal resistance between the reference and working electrode, which is due mostly to the electrode resistance, but also to the electrolyte resistance.

In further experiments, the resistance was increased by inserting an external resistance at the working electrode; decrease of the resistance was obtained by positive feedback. From Eq. [2] it is clear that at longer times ($P\sqrt{t} >> R_\Omega$) the current is diffusion limited: $I = (E - E_e)/P\sqrt{t}$. This behavior is illustrated in Fig. 1 and 2. The value of D can now be determined and is found to be about 7×10^{-6} cm^2 sec^{-1}. This is in good agreement with values obtained from chronopotentiometric measurements. Furthermore, it appears that no distortion by convection takes place up to 10 sec. This is in good agreement with theory (4), which states that the time t_c after which convection distorts the diffusion process is given by $t_c = \delta_N^2/\pi^2 D$, where δ_N is the thickness of the diffusion layer caused by natural convection.

In previous work by Chang and Howard (5, 6) diffusion limitation and convection were indicated as predominant processes in determining the current-time behavior in their electrochromic cells. From the present paper it may be concluded, however, that the current-time response of an electrochromic display due to a voltage step is governed by a combination of resistance limitation and diffusion limitation.

In a practical application, *e.g.*, displays with SnO_2 electrodes, the resistance R_Ω is rather high, varying between 50 and 100Ω. As a result a constant current is observed after a potentiostatic voltage step, especially at higher concentrations of the electroactive species. As a consequence, potentiostatic driving during writing can be more simply replaced by constant current driving. The contrast that can be obtained in a certain time interval in which resistance limitation plays a role, however, is lower than in the case of diffusion limitation only. Enhancement of the maximum attainable contrast can be achieved by means of current driving where the applied current varies proportional to $t^{-1/2}$. In this way the same contrast as with potentiostatic driving without ohmic drop can be obtained in the same time interval.

The Potential of the Gold Overlayer on n-GaP Photoelectrodes

R. H. Wilson,* L. A. Harris, and M. E. Gerstner

General Electric Corporate Research and Development, Schenectady, New York 12301

In recent publications, Nakato *et al.* (1, 2) reported that overlayers of Au on n-GaP photoanodes allowed the photodecomposition of water to proceed while suppressing the corrosion of the GaP. These authors described two different types of behavior; type A obtained with slowly evaporated Au, and type B when the Au was evaporated rapidly.

We have reproduced the I-V curves shown by Nakato *et al.* and have extended their results to include direct measurement of the potential of the Au overlayer during the current-voltage scan. Each GaP electrode was prepared as described by Nakato *et al.* and then coated on its front face by an insulating lacquer (Hunt Waycoat negative photoresist) except for a window area about 3 mm diam. After gold was deposited over the entire surface, the sample was pressed onto a layer of silicone rubber surrounding a small (4 mm) aperture in the side of the electrolytic cell. A fine wire between the silicone and the inactive part of the gold overlayer allowed us to connect a high impedance (10^7Ω) voltmeter between the gold and the saturated calomel reference electrode.

The results shown in Fig. 1 are representative of type A behavior obtained with sputtered Au overlayers about 400Å thick. Figure 2 shows typical type B behavior obtained with rapidly evaporated Au films about 300Å thick. Illumination was provided by a 150W high pressure xenon lamp through a neutral filter which reduced the intensity to about that of the sun (roughly 100 MW/cm^2).

The type A behavior is entirely consistent with the interpretation of Nakato *et al.* (2), who postulated an

* Electrochemical Society Active Member.

Key words: photoelectrochemistry, semiconductor electrodes, photoelectrolysis.

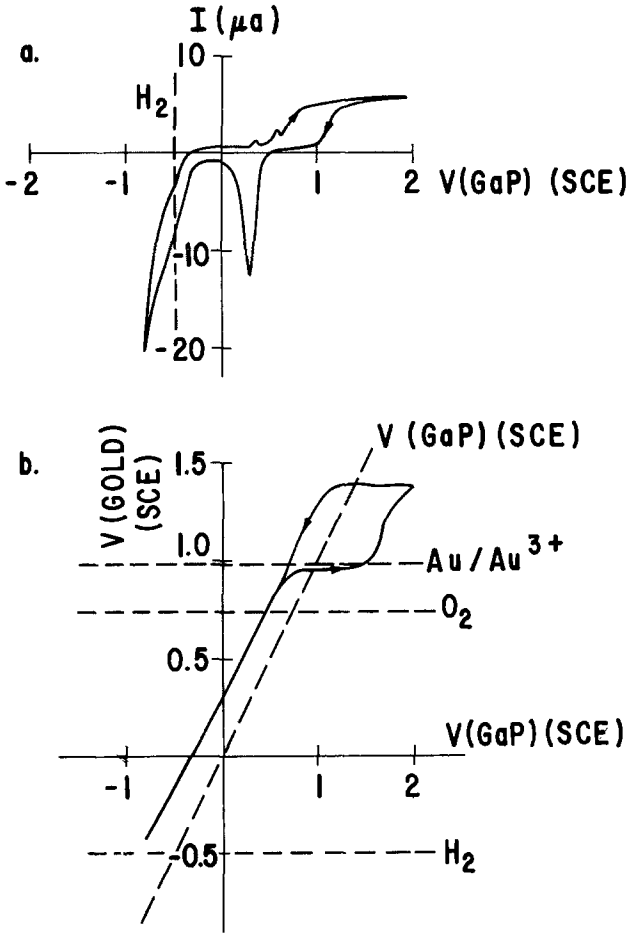

Fig. 1. Type A behavior of 400Å Au film sputtered on n-GaP. Electrolyte is 0.5M K_2SO_4 buffered to pH 4.3. (a) Current-voltage characteristic showing oxidation and reduction waves typical of Au electrodes; (b) potential of Au film with respect to SCE.

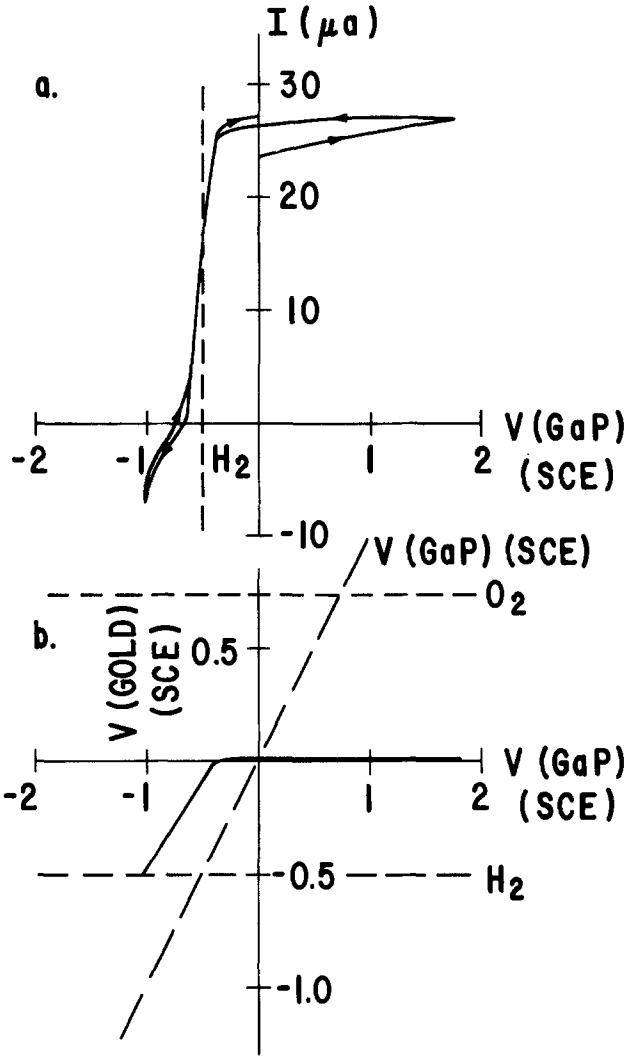

Fig. 2. Type B behavior of 300Å rapidly evaporated Au film on n-GaP. Same electrolyte as for Fig. 1. (a) Current-voltage characteristic; (b) potential of Au film with respect to SCE.

impervious Au layer between the electrolyte and the GaP. The metal-semiconductor interface forms a Schottky photodiode which is in series with a normal gold electrode. As shown in Fig. 1, the Au potential differs from that of the GaP by a constant amount until it becomes limited by an oxidation reaction with the electrolyte (either the decomposition of water or the oxidation of Au).

The above interpretation is confirmed by a second experiment in which such a sample was mounted in a cell, without electrolyte, where it could be exposed to light. The connection from the Au film was brought to a plain metallic gold electrode in contact with the electrolyte of a second cell, thus reproducing the postulated arrangement of a Schottky diode (dry) in series with a conventional electrolytic cell. The I-V curves and measurements of Au potential reproduced the type A results of Fig. 1 in all essential respects.

The type B behavior shown in Fig. 2 duplicates the I-V curves of Nakato *et al.* (2), but we failed to observe any gas evolution except for the blisters formed under the gold film as noted by those workers. It is apparent from Fig. 2 that the Au potential never reaches a value at which water can be decomposed. Indeed, it is difficult to see how at this low potential the Au can be involved in the reaction responsible for the current flow.

The observed type B current is most probably due to a corrosion reaction of the GaP with the electrolyte. This view is consistent with the blister formation, the porous nature of rapidly evaporated metal films, and the tendency of type A behavior to switch to type B after some period of time in contact with the electrolyte.

Further confirmation of this view is afforded by an experiment in which bare GaP is made to exhibit I-V curves resembling those of type B behavior. This is done by reducing the pH of the 0.5M K_2SO_4 electrolyte from about 4.3 to about 3.5 and reducing the light intensity by a factor of 2 or more. At higher intensities, the current is actually decreased after formation of a blocking layer. There is an apparent balance between the rate of formation of a blocking layer governed by light intensity and its dissolution, governed by the pH of the electrolyte.

It has been suggested (3) that if H_3O^+ ions are formed at the GaP surface, their diffusion away from the surface is retarded by the porous gold film, and then the pH near the surface is decreased. Thus the gold film promotes type B behavior by reducing the light intensity and by preventing the formation of a barrier layer through an increase in local acidity.

A more detailed exposition of these observations will follow in a later paper.

Thermodynamics of the Nonstoichiometric β_1-PtZn Phase Exhibiting the $L1_0$ Structure

Yu-Jen Hsiao, Y. Austin Chang, and Herbert Ipser[1]

Materials Department, College of Engineering and Applied Science, University of Wisconsin-Milwaukee, Milwaukee, Wisconsin 53201

ABSTRACT

Thermodynamic activities of zinc in the β_1-PtZn and the α-PtZn phases were determined at 1273°K using an isopiestic method. The theoretical thermodynamic equations by Chang and co-workers for the nonstoichiometric Ll_0 phases were modified to include the different interactions between the first nearest neighbor and the second nearest neighbor atoms. An analysis of the activity data for the β_1-PtZn phase at 1273°K in terms of the modified theoretical equation yields the following values: $\alpha = 3 \times 10^{-4}$, $\eta = 1.0$, and $\ln a_{Zn,o} = -4.65$. The thermodynamic data of the α-phase were evaluated in terms of the subregular solution model. The partial quantities of platinum and the integral quantities for the α- and β_1-phases were obtained by means of the Gibbs-Duhem relationship. A theoretical relationship between the enthalpy of formation and the model parameters for the Ll_0 phases was derived and correlated with the β_1-PtZn data and other data available in the literature.

The three group VIII transition metals, nickel, palladium, and platinum, react with the group II metal zinc to form ordered intermetallic phases with the Ll_0 structure at the equiatomic composition. This structure may be viewed either in terms of a body-centered tetragonal or a face-centered tetragonal lattice. At the stoichiometric composition, in terms of the body-centered lattice, all the A atoms occupy the body-centered positions and the B atoms the corner positions for a perfectly ordered structure. However, at any finite temperature, some degree of lattice disorder prevails. At nonstoichiometric compositions, constitutionally induced lattice disorder occurs in the lattice, in addition to that due to thermal vibration. This lattice disorder contributes to the thermodynamic properties of the intermetallic phases. Chang and co-workers (1, 2) derived theoretical equations to describe the compositional dependences of the activity and the partial molar enthalpy of the Ll_0 phases. The validity of the theoretical equations was verified using the extensive data for β_1-NiZn and β_1-PdZn (3-5). Like these phases, the β_1-PtZn[2] phase also exists over a wide range of homogeneity. The exact range of homogeneity is discussed later in this paper. The objective of the present investigation is to determine the thermodynamic properties of the β_1-PtZn phase using an isopiestic technique and to further test the validity of the theoretical equations of Chang and co-workers. Moreover, these theoretical equations are slightly modified in order to consider the possible difference between the interactions of first and second nearest neighbor atoms, which were assumed to be identical in the original development of the theoretical model (1, 2). Lastly, a relationship between the parameters of the theoretical model and the enthalpy of formation is derived. The validity of this relationship is examined using the data obtained in the present paper for the β_1-PtZn phase, as well as data available in the literature for other Ll_0 phases.

Experimental Method and Results

The isopiestic technique employed in the present study has been described previously (6). Platinum samples of approximately 1g were prepared from a 0.025 mm foil (99.99%; Engelhard, New Jersey). Zinc samples were prepared from a rod (99.999%; United Mineral and Chemical Corporation, New York). Platinum samples were cleaned with aqua regia, while the zinc samples with a solution of 15% HCl, 15% HNO_3, and 70% H_2O. The quartz tubes which contained the samples were evacuated at 5×10^{-2} Pa for 24 hr, sealed, and then placed in the furnace at ~ 1000°C for 10-12 days. The experiments were terminated by quenching the quartz tube in cold water. The composition of each sample was computed from its weight change. During the course of each experiment, the sample temperature T_S was kept constant within ± ¾°K, while the temperature of the zinc reservoir T_R within ± ¼°K. Knowing T_S, T_R, and the vapor pressures of zinc at these temperatures, the activity of zinc in each alloy was computed using Eq. [1] of Ref. (6). The vapor pressure values of zinc used are those selected by Hultgren *et al.* (3, 7). The experimental results expressed in terms of the activity of zinc a_{Zn}, are summarized in Table I. Based on the activity data at 1000°C as shown in Fig. 1, the α-phase boundary of the $\alpha + \beta_1$ two phase field is determined to be 27.5 (± 1) atomic percent (a/o) Zn, while the β_1-phase boundary to be 42 (± 1) a/o Zn. The phase boundaries

[1] Present address: Institut of Inorganic Chemistry, University of Vienna, Vienna, Austria.

Key words: thermodynamic data, platinum-zinc alloys, nonstoichometric β_1-PtZn.

[2] Following the nomenclature in the systems Ni-Zn and Pd-Zn, the Ll_0-phase in the system Pt-Zn is also designated as "β_1".

Table I. Experimental results—standard states: Pt(s) and Zn(l)

No.	a/o Zn	Phase	T_S, K	T_R, K	ln $a_{Zn,1273}$
1	19.95	α	1274	670	−10.10
2	26.23	α	1274	700	−9.14
3	44.33	β_1	1273	726	−8.38
4	46.07	β_1	1271	751	−7.71
5	49.33	β_1	1273	801	−6.54
6	49.96	β_1	1274	881	−4.92
7	50.01	β_1	1273	900	−4.56
8	50.07	β_1	1274	951	−3.73
9	51.03	β_1	1275	1018	−2.75
10	51.61	β_1	1274	1040	−2.46

were estimated by Nowotny *et al.* (8) based on x-ray analysis, microexamination, and magnetic susceptibility measurements of alloys quenched from 750° and 400°C. Extrapolating their estimated values to 1000°C yields the value of ~ 25 and ~ 32 a/o Zn, respectively. While the value of ~ 25 a/o Zn is in reasonable accord with the value of 27.5 a/o Zn determined in the present study, the value of ~ 32 a/o Zn is too low.

All samples in the β_1-phase were examined by x-rays (9) using CrKα radiation in a Debye-Scherrer camera with a diameter of 57.5 mm. The lattice parameters calculated from the photographs were found to be in general agreement with the results of Nowotny and co-workers (8, 10).

Data Evaluation and Discussion

Thermodynamic equations for the nonstoichiometric β_1-PtZn phase.—Chang and co-workers (1, 2) derived theoretical thermodynamic equations to account for the compositional dependence of the activity and the partial enthalpy in nonstoichiometric Ll_0 phases. In this model, Chang and co-workers assumed that the interaction enthalpy between an atom and its eight first nearest neighbors is the same as that between the same atom and its four second nearest neighbors, neglecting all interactions of higher order. Recently, Ipser, Neumann, and Chang (11) found that the influence of second nearest neighbor interactions is also important for some antistructure B2 phases. For this purpose, they introduced a new parameter η into the equations originally derived (2, 12, 13). Theoretical equations are presented for the Ll_0 phases, which now also take into account this new parameter η. In view of the findings for the antistructure B2 phases, it is anticipated that the value of η may deviate from a singular value for the Ll_0 phases. Furthermore, the ratio of the lattice parameters (c/a), which determines the relative distances between first and second nearest neighbors, may also influence the value of η.

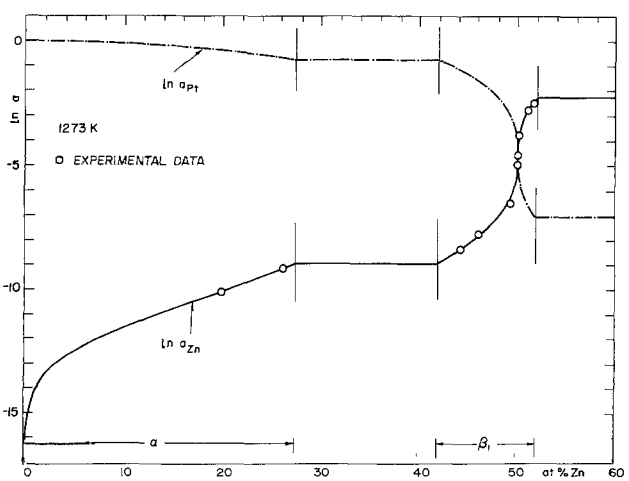

Fig. 1. Activities of zinc and platinum at 1273°K. The standard states are Pt(s) and Zn(l). The smoothed curve for the α-phase was calculated from Eq. [7] with $\epsilon^\alpha = -317.3$ kJ/g-atom and $\eta^\alpha = -209.9$ kJ/g-atom, and that for the β_1-phase from Eq. [5] with $\alpha = 3 \times 10^{-4}$, $\eta = 1.0$, and ln $a_{Zn,0} = -4.65$.

The parameter η is defined as the ratio of the interchange enthalpies between the second nearest and first nearest neighbor atoms

$$\eta \equiv \frac{V'_{AB}}{V_{AB}} \qquad [1]$$

where $V_{AB} = H_{AB} - \frac{1}{2}(H_{AA} + H_{BB})$ and $V'_{AB} = H'_{AB} - \frac{1}{2}(H'_{AA} + H'_{BB})$. The term H_{ij} is the interaction enthalpy for a pair of first nearest neighbors i-j, and H'_{ij} that for a pair of second nearest neighbors i-j. The other basic parameter of the model is the degree of lattice disorder at stoichiometry, α, which is defined as

$$\alpha \equiv \left(\frac{N_A^\beta}{N}\right)_{\chi=0} \equiv \left(\frac{N_B^\alpha}{N}\right)_{\chi=0} \qquad [2]$$

where N_A^β is the number of A atoms on the β-sublattice sites (the wrong sites), N_B^α is that of B atoms on the α-sublattice sites, and N is the total number of atoms; χ is the deviation from stoichiometry in terms of the atomic fraction and is defined as $\chi \equiv x_2 - 0.5$, with x_2 being the atomic fraction of component 2. The degree of lattice disorder at any composition χ is

$$z \equiv \left(\frac{N_A^\beta}{N}\right)_\chi \qquad [3]$$

It reduces to α when $\chi = 0$. Values of z may be computed from the following relationship expressing z as a function of χ and α

$$z = \frac{-\chi + \sqrt{\chi^2 + 4\alpha^2}}{2} \qquad [4]$$

which is Eq. [51] in Ref. (2). Using these parameters and employing the method presented in Ref. (11), the following theoretical equations for the compositional dependences of the activities and partial molar enthalpies can be derived for Ll_0 phases with antistructure defects

$$\ln \frac{a_i}{a_{i,o}} = \epsilon_i \ln \frac{z(1-2\alpha)}{\alpha(1-2z)} + \left(\frac{\frac{1}{2}\eta}{1-\frac{1}{2}\eta}\right)(2\ln 2\alpha)(2\epsilon_i + \chi)\chi \qquad [5]$$

$$\frac{\Delta\bar{H}_i - \Delta\bar{H}_{i,o}}{RT} = \left(2\alpha + \frac{\epsilon_i\chi - 4\alpha^2}{2z+\chi} + \left(\frac{\frac{1}{2}\eta}{1-\frac{1}{2}\eta}\right)2(2\epsilon_i + \chi)\chi\right)\ln 2\alpha \qquad [6]$$

where $a_{i,o}$ and $\Delta\bar{H}_{i,o}$ are the activity and the partial molar enthalpy of the component i at the stoichiometric composition, $\epsilon_i = +\frac{1}{2}$ for $i = 1$ and $\epsilon_i = -\frac{1}{2}$ for $i = 2$, and R is the gas constant.

A comparison of the above two expressions with Eq. [19] and [21] of Ref. (11) shows that the only difference is the coefficient ½ for the quantity η. For the antistructure B2 phases, the coefficient is ¾ if the expression $[3\eta/(4 - 3\eta)]$ in Eq. [19] and [21] of Ref. (11) is written as $(3\eta/4)/(1 - 3\eta/4)$. The coefficients ½ and ¾ represent the ratio of the number of the second and first nearest neighbor atoms in the Ll_0 and B2 structures, respectively. With $\eta = 1$, which is the original assumption made by Chang and co-workers (1, 2), Eq. [5] and [6] reduce to their expressions for the "one-and-half approximation," if the term β in Chang's equation is substituted by its simplified form 2 ln 2α (compare Eq. [105] and [110] in Ref. (2)).

Evaluation of experimental data.—The activity data of zinc in the β_1-phase were analyzed in terms of Eq. [5]. As can be seen from Fig. 2, excellent agreement was obtained between the experimental data and the theoretical curve with $\alpha = 3 \times 10^{-4}$, $\eta = 1.0$, and ln

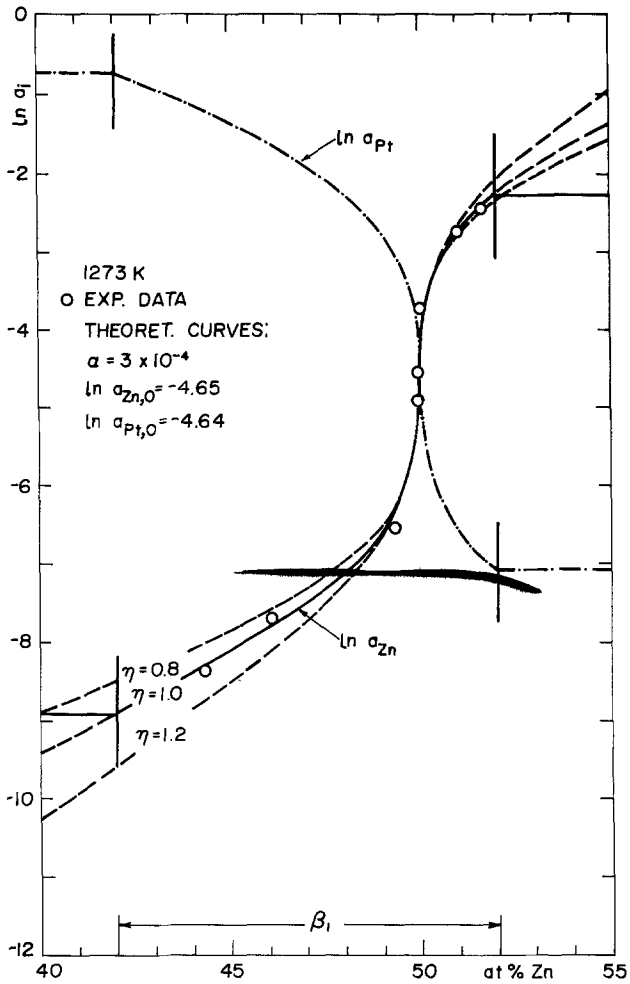

Fig. 2. Activities of zinc and platinum in the β_1-phase at 1273°K with the experimental data points for zinc. The standard states are Pt(s) and Zn(l).

$a_{Zn,O} = -4.65$. For comparison, the curves with $\eta = 0.8$ and $\eta = 1.2$ are also shown in Fig. 2 in the form of dashed lines. It is obvious that a value of $\eta = 1.0$ gives the best fit, which is in agreement with previous findings of Chang and co-workers for several Ll_o phases (2-5). As presented in the previous section, their original model assumes *a priori* that $\eta = 1.0$. Although the agreement between the theoretical predictions with $\eta = 1.0$ and the experimental data was quite good in most cases, an exception was the β_1-NiZn phase, where some deviations were noticed.

In order to obtain the partial molar quantities of platinum in the β_1-phase and the integral quantities of this phase, it is necessary to know the activities of zinc in the α-phase. The subregular solution model (14), which has been used successfully in describing the thermodynamic properties of several terminal solid solutions (3, 6, 15), is used to represent the thermodynamic properties of the α-PtZn phase. The pertinent equation for the activity coefficient of Zn, γ_{Zn}, is

$$RT \ln \gamma_{Zn} = -\Delta G_{Zn}^{\alpha \to l} + [(\epsilon^\alpha - \eta^\alpha) + \eta^\alpha x_{Zn}](1 - x_{Zn})^2 \quad [7]$$

where x_{Zn} is the atom fraction of Zn, and ϵ^α and η^α are parameters which must be obtained from experimental data. The standard states used in the present study are Pt(s) and Zn(l). Using the Gibbs energy of melting of fcc Zn according to Kaufman and Bernstein (16) and the experimental data, values of $\epsilon^\alpha = -317.3$ kJ/g-atom and $\eta^\alpha = -209.9$ kJ/g-atom are obtained. The calculated activity curve for Zn according to Eq. [7] is shown in Fig. 1. The corresponding activity curves for Pt are computed from the appropriate equations and are also shown in Fig. 1 with ln $a_{Pt,O} = -4.64$. The

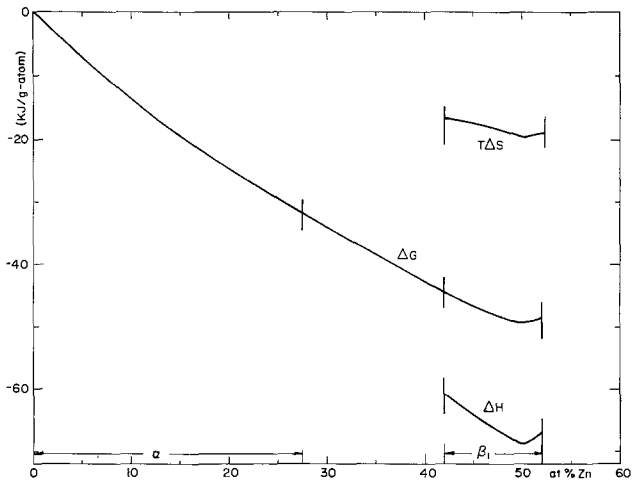

Fig. 3. Integral thermodynamic properties in the platinum-zinc system. The standard states are Pt(s) and Zn(l).

smoothed ΔG values are presented in Fig. 3. These values as well as those of a_{Pt} and a_{Zn} are given in Table II.

In order to obtain an approximate ΔH value for the β_1-phase at the stoichiometric composition, Kubaschewski's empirical correlation was used to estimate the entropy term (17). From the ΔG value given in Table II after converting to Zn(s) as standard state and the known boiling points of Pt and Zn (7), values of $\Delta S^{xs} = -15.8$ J/K g-atom and $\Delta H = -65.0$ kJ/g-atom [referred to Zn(s)] are obtained. When converted to Zn(l) as the standard state, $\Delta H = -68.7$ kJ/g-atom is obtained. The uncertainty in the ΔH value is believed to be less than ±10 kJ/g-atom.

Since the thermodynamic activities of the component elements have practically the same value at the stoichiometric composition (50 a/o Zn), it was assumed that the partial enthalpies are equal referring to Pt(s) and Zn(s). This is to be expected for nonstoichiometric phases with substantially ordered structure. For such phases the enthalpy tends toward a minimum value at the stoichiometric composition. With this assumption, the compositional dependences of the partial molar enthalpies in the β_1-phase are computed from Eq. [6] and presented in Fig. 4. The resulting ΔH values as a function of composition as well as the $T\Delta S$ values are shown in Fig. 3 in addition to the ΔG values. The thermodynamic properties of PtZn alloys at selected compositions between 0 and 52 a/o Zn are summarized in Table II, with the data derived from the estimated value for the enthalpy of formation set in parentheses.

For comparison, a value of ΔH was also computed by means of the theoretical equation derived by Miedema and co-workers (18, 19). Their theoretical model takes into account the following contributions to the enthalpy of formation; the difference in electronegativity,

the difference in the electron density at the boundary between dissimilar atoms, and, additionally, a certain hybridization energy for alloys of transition metals with nontransition metals. A value of $\Delta H = -60.3$ kJ/g-atom [referred to Zn(s)] was obtained, which is in reasonable agreement with the value obtained in the present study.

Relationship between the model parameters and the enthalpy of formation of the Ll_0-phases.—In two recent publications, Neumann *et al.* (20, 21) discussed the relationship between the disorder parameter α and the enthalpy of formation in ordered intermetallic phases with the B2 structure, and Ipser *et al.* (11) investigated the influence of the second nearest neighbor interactions on this relationship. Following the method outlined in Ref. (11) and (21), a corresponding relationship can be derived for intermetallic phases exhibiting the Ll_0 structure

$$\frac{\Delta H}{RT}(1 - \tfrac{1}{2}\eta) = \tfrac{1}{2}\ln 2 + \tfrac{1}{2}\ln \alpha \qquad [8a]$$

For the case $\eta = 1.0$, as was originally assumed by Chang and co-workers (1, 2) in the development of their theoretical equations, Eq. [8a] reduces to

$$\frac{\Delta H}{RT} = \ln 2 + \ln \alpha \qquad [8b]$$

This expression, however, can also be obtained by simplification of Eq. [98b] of Ref. 2 for $\alpha << 1$, if the term $4NV_{AB}$ (where N is Avogadro's number) is identified with ΔH.

The experimental data needed to establish the relationship between ΔH and the model parameters are summarized for convenience in Table III. Of the enthalpy of formation data (which are referred to the solid elements as standard states) listed in the table, the values for α_1''-AuCu and β_1-PdCd were determined calorimetrically, and the value for β_1-NiZn was obtained from the temperature dependence of the Gibbs energy. On the other hand, the values for β_1-PdZn and β_1-PtZn were obtained from the Gibbs energies and the estimated entropies of formation using Kubaschewski's empirical correlation (17).

Table III. Enthalpy of formation ΔH (referred to the solid elements as standard states) and disorder parameter α for Ll_0-phases

Phase	T, °K	α	ΔH, kJ(g-atom)$^{-1}$
α_1''-AuCu	653	3.75×10^{-2} (2)	−8.0 (7)
β_1-PdCd	1350	2.25×10^{-2} (2)	~−40* (22)
β_1-NiZn	905	2.5×10^{-3} (4)	−19.7 (4)
β_1-PdZn	1273	4×10^{-4} (3, 5)	−73.9 (3, 17)
β_1-PtZn	1273	3×10^{-4} (this paper)	−65.0 (this paper, 17)

* This value is the average for the β_1-PdCd phase, since Darby *et al.* (22) indicate a minimum in ΔH at 39 a/o Cd, although one would expect it at or near 50 a/o.

Figure 5 shows the comparison between the theoretical prediction according to Eq. [8b] and the available experimental data. As has been discussed in an earlier section, all of the Ll_0 phases except β_1-PtZn had been analyzed previously in terms of the original model by Chang and co-workers (1, 2), implying an η value of 1.0. However, for the β_1-PtZn phase it has been demonstrated (as shown in Fig. 2) that this particular value of η gives the best agreement between theory and experimental data.

Except for β_1-NiZn, the data points in Fig. 5 fall more or less on the straight line predicted by Eq. [8b]. However, deviations of the experimental data from the theoretical predictions may be reduced if values of η less than 1.0 are used for some of the Ll_0 phases, notably the β_1-NiZn. This is in agreement with the fact that, in the analysis of the thermodynamic data of β_1-NiZn by Lau *et al.* (4), some deviations of the experimental points from the theoretical curves were observed. A reevaluation of these data in terms of Eq.

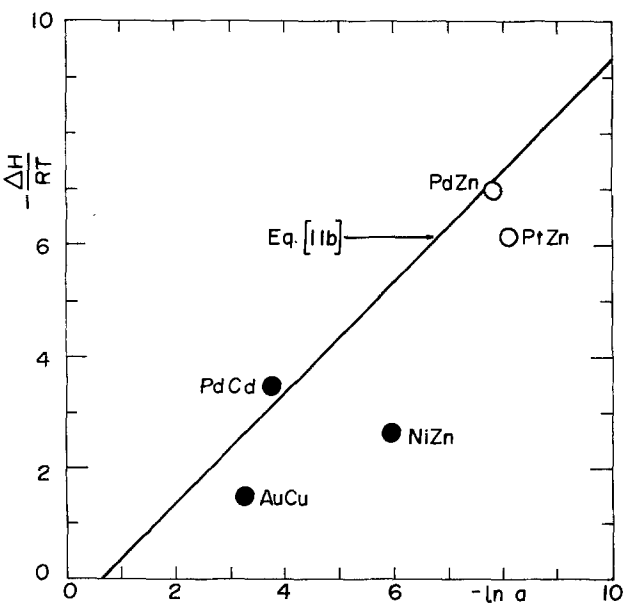

Fig. 5. A relationship between the enthalpy of formation and the degree of lattice disorder at the stoichiometric composition for the Ll_0 phases. The solid circles indicate values determined experimentally, while the open circles indicate those obtained from the experimental Gibbs energy value and the entropy value estimated from Kubaschewski's empirical correlation.

[4] and [5] might help to resolve the discrepancy in Fig. 5.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

LIST OF SYMBOLS

a_i thermodynamic activity of component i in an alloy such as a_{Zn} and a_{Pt}

$\Delta\overline{G}_i$ relative partial molar Gibbs energy of component i, kJ/g-atom; superscript xs refers to the excess quantity

$\Delta G_{Zn}^{\alpha\to l}$ Gibbs energy of melting of α-Zn (fcc), kJ/g-atom

H_{ij} interaction enthalpy for a pair of first nearest neighbor atoms $i - j$, kJ; i and j stand for either the pure A or the pure B atoms

H'_{ij} interaction enthalpy for a pair of second nearest neighbor atoms $i - j$, kJ; i and j stand for either the pure A or the pure B atoms

ΔH, ΔG integral enthalpy and Gibbs energy of formation, kJ/g-atom; superscript xs refers to the excess quantity

$\Delta\overline{H}_i$ relative partial molar enthalpy of component i, kJ/g-atom

ln natural logarithm, *i.e.*, to the base e

N $N_A + N_B$ is the total number of atoms, the Avogadros' number; superscripts for N_A and N_B indicate the sublattices where the atoms are

ΔS integral entropy of formation, J/K g-atom; superscript xs refers to the excess quantity

T absolute temperature, °K; subscripts R and S refer to the reservoir and the sample

V_{AB} interchange enthalpy between the first nearest neighbor atoms, kJ

V_{AB}' interchange enthalpy between the second nearest neighbor atoms, kJ

x_i atom fraction of component i

$z = \left(\frac{N_A^\beta}{N}\right)_x$ number of A atoms on the β-sublattice

Greek symbols

α $\left(\frac{N_A^\beta}{N}\right)_{x=0} = \left(\frac{N_B^\alpha}{N}\right)_{x=0}$

$\gamma_i = \frac{a_i}{x_i}$ activity coefficient of component i such as γ_{Zn}

$\epsilon_i = +\frac{1}{2}$ for $i = 1$; $\epsilon_1 = -\frac{1}{2}$ for $i = 2$

$\epsilon^\alpha, \eta^\alpha$ parameters of the subregular α-PtZn solution, kJ/g-atom

$\eta = \frac{V_{AB}'}{V_{AB}}$

$\chi = x_2 - 0.5$

Ionic Conductivity of Lithium Orthosilicate—Lithium Phosphate Solid Solutions

Y-W. Hu, I. D. Raistrick, and R. A. Huggins*

Center for Materials Research, Stanford University, Stanford, California 94305

ABSTRACT

Lithium ion conductivity in solid solutions formed between Li_4SiO_4 and Li_3PO_4 has been measured as a function of temperature and composition using a-c techniques. Highest conductivities were found at 50 and 60 mole percent (m/o) phosphate. Empirical conductivity parameters are presented and qualitatively analyzed in terms of structural and compositional effects. Unit cell parameters have been determined across the entire range of solid solution by x-ray powder diffraction.

High lithium ion conductivity in solid solutions between lithium orthosilicate (Li_4SiO_4) and lithium phosphate (Li_3PO_4) has been previously reported (1). At that time measurements had been made on compounds varying in composition between pure Li_4SiO_4 and $Li_{3.5}Si_{0.5}P_{0.5}O_4$ (50 m/o phosphate). The highest conductivity, found in $Li_{3.6}Si_{0.6}P_{0.4}O_4$, was several orders of magnitude greater than that of pure Li_4SiO_4 (2-5) at 100°C. Measurements have now been extended to include the entire range from Li_4SiO_4 to Li_3PO_4.

Sample Preparation

Lithium orthosilicate was prepared by solid-state reaction between Li_2CO_3 (Johnson-Matthey Puratronic Grade II) and SiO_2 (Johnson-Matthey Puratronic Grade I or II) at 800°C as previously described (1). Lithium phosphate was purchased from Alfa Inorganics (99+% purity). Intermediate compositions were prepared by hot pressing appropriate mixtures of Li_4SiO_4 and Li_3PO_4 in ⅜ in. diam graphite dies in an argon flow system at 1000°C and 5000 psi pressure. Pressing times varied between 30 and 60 min after reaching the maximum temperature. Carbon was removed from the surface of the disk-shaped samples by heating in air to about 400°C. All starting materials and preparations were routinely checked for completeness of reaction by x-ray powder diffraction.

Conductivity Measurements

Experimental aspects.—Samples were prepared for conductivity measurements by grinding their parallel surfaces on 600 mesh silicon carbide paper, followed by fine polishing. A layer of platinum about 1000Å thick was then sputtered onto each face of the disks. Measurements were made in air using small signal a-c measurements over the frequency range 5-100 kHz, using a General Radio 1615 bridge and a Princeton Applied Research two phase/vector lock-in amplifier. Complex plane methods were used to extract the frequency-independent bulk ionic conductivity, as has been previously described (5, 6).

Results.—Conductivity data for the entire composition range are shown plotted as log (σT) *vs.* reciprocal absolute temperature in Fig. 1 and 2. The data are a good fit to the Arrhenius equation

$$\sigma T = A \exp(-\Delta H/RT) \qquad [1]$$

ΔH is the activation enthalpy, A is a preexponential factor (obtained by extrapolation to infinite temperature T), R is the gas constant. ΔH and A are composition-dependent and their values are listed in Table I. Estimated precision is better than 5% for ΔH and within a factor of 2 for A. Most measurements were repeated on several samples of the same composition; the absolute conductivity values thus obtained were reproducible within a factor of 2. At several compositions it was found that conductivity decreased with decreasing sample density, a sample of only 70% theoretical density having a conductivity up to one order of magnitude less than a 96% dense sample. All results reported here were made on samples of 95% density or better. No corrections for residual density effects have been attempted.

X-Ray Powder Diffraction Results

Lattice parameters were determined by least squares fitting of 10-15 of the strongest reflections for each composition studied. An internal calibrant was included. Consistency of better than 0.1% between observed and calculated d values was achieved. Parameters for Li_4SiO_4 and Li_3PO_4 were within 0.1% of pre-

viously published data (7, 8). Lattice parameters are given as a function of composition in Table II. As Li_4SiO_4 and Li_3PO_4 have different, but rather closely related structures, the coordinate system for Li_3PO_4 was chosen differently from that used in Ref. (8) so that a consistent set of indexes could be compared across the entire range of composition. Over this composition range the structure changes smoothly from the Li_4SiO_4 type to that of Li_3PO_4. The value of c, the only parameter which changes appreciably, is plotted against mole fraction of phosphate in Fig. 3. The largest change in c (and hence in cell volume) occurs between 30 and 50 m/o phosphate. Beyond 50 m/o, the x-ray powder pattern bears more resemblance to Li_3PO_4 than to Li_4SiO_4. The continuous change in lattice parameter is convincing evidence for a complete range of solid solutions between the end members. Li_3PO_4 has two crystallographic forms (9). Powder diffraction showed that although the original material was of the low (monoclinic) form, after hot pressing it transformed to the high (orthorhombic) form. This change has been reported to be monotropic (9), which is consistent with present observations.

Table I. Experimental conductivity parameters A and ΔH

Composition (mole fraction Li_3PO_4)	A (Ω^{-1} cm^{-1} °K)	ΔH (kcal/mole^{-1})
0.0	1.2×10^6	20.1
0.05	1.3×10^6	16.7
0.09	6.3×10^5	14.6
0.2	8.3×10^5	13.7
0.3	1.1×10^6	13.6
0.4	5.8×10^5	12.3
0.5	6.3×10^5	11.9

1.0	10.476*	6.112	4.920	90.0

* Due to the orientation of the PO_4 tetrahedra, the unit cell of Li_3PO_4 is doubled with respect to that of Li_4SiO_4.

Discussion

The relative importance of the two empirical parameters A and ΔH in determining the magnitude of the conductivity changes as the composition is varied. This is illustrated in Fig. 4. From pure Li_4SiO_4 to about 40 m/o phosphate the conductivity shows a strong dependence on the activation enthalpy. Over this range the preexponential factor remains constant within experimental error. Beyond 50 m/o phosphate the change

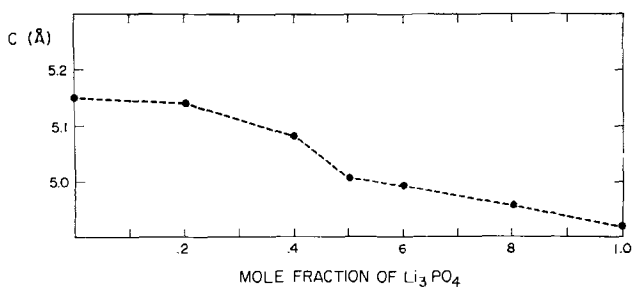

Fig. 3. Variation of c lattice parameter with composition of solid solution.

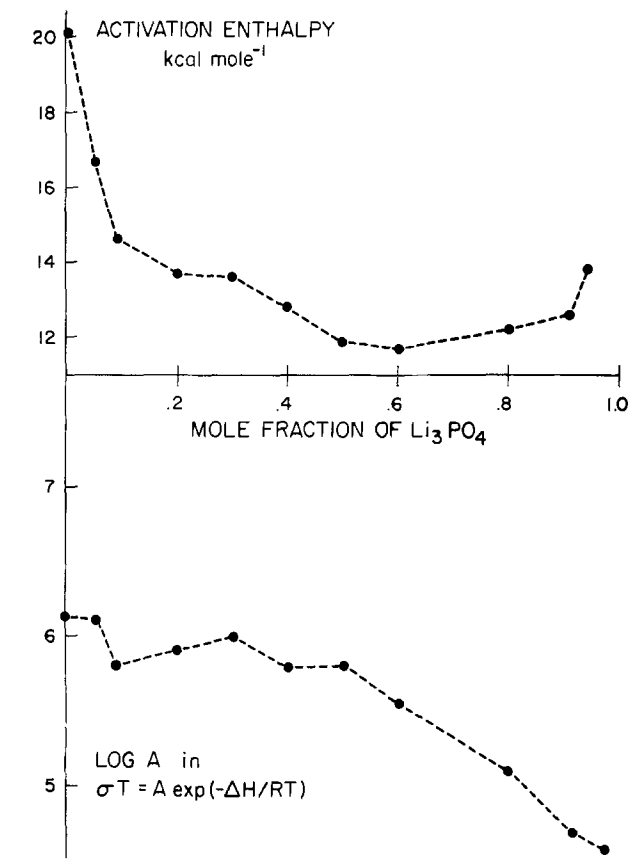

Fig. 4. Variation of experimental conductivity parameters ΔH (activation enthalpy) and A (preexponential factor) with composition of solid solutions.

in preexponential factor dominates the conductivity change; the relative change in activation enthalpy is apparently less important. Following the random walk formulation for a hopping mechanism of conductivity the preexponential factor A can be expanded

$$A = \nu_0 C \alpha d^2 \left(\frac{\mathbf{F}^2}{R}\right) z^2 \exp\left(\frac{\Delta S}{R}\right) \qquad [2]$$

Where C and z are the concentration and charge number of the mobile species, d is the jump distance, α is a geometric factor which depends on the number of available jump directions in the crystal lattice, ν_0 is the attempt frequency, taken to be the vibrational frequency of the mobile species in its potential well, ΔS is the total activation entropy for conduction, and $\mathbf{F}$ and R are the Faraday and gas constant, respectively. The experimentally obtained quantity, ΔH, can be divided into two terms; ΔH_f, which is the heat of formation of the defects necessary for conduction, and ΔH_m, which is the activation enthalpy for motion.

In materials in which there is an excess of lattice sites over ions of the conducting species [in Li_4SiO_4 there are 8 Li ions distributed over 18 sites (7)], the concentration of moving species, $C = C_0 \exp(-\Delta G_f/RT)$, where ΔG_f is the free energy of formation of the defects, is expected to be only very weakly temperature dependent, if at all. C_0 is the total concentration of both static and moving ions of the conducting species. This is because the "defects" necessary for conduction are already present as statistically empty lattice sites. If the mobile species are distributed over several different kinds of lattice sites, ΔG_f becomes equal to the difference in free energy of these sites, and may be assumed to be very small (< 1 kcal/mole) if a distribution over these same sites is crystallographically observable at room temperature. In pure Li_4SiO_4, therefore, it is probably correct to assume that all (or a large fraction of) the lithium ions are contributing to the conduction process, and that the experimentally observed enthalpy ΔH corresponds to the activation enthalpy of motion, ΔH_m, in this structure. In Li_3PO_4, however, this is not true. Two kinds of tetrahedral lithium sites are present, and they are both fully occupied at room temperature (8). Thermal energy is then necessary to create defects before conduction can take place. This presumably accounts for the much higher activation enthalpy observed for this composition. As soon as Li_4SiO_4 is added to the Li_3PO_4, however, interstitial Li ions are introduced, which can contribute to the conductivity. Thus ΔH remains almost constant at 12-13 kcal/mole over a considerable concentration range, and conductivity increases are principally due to changes in A caused by the increase in C_0. Below 50 m/o phosphate, however, A is essentially constant, and conductivity changes are presumably due to structural changes which influence the potential energy contribution to ΔH_m. Parameters contributing to A in Eq. [2], such as ΔS, ν_0, α, and d, are expected to be rather insensitive to small structural changes. ΔH_m, however, will be highly structure sensitive due to rapid changes in such terms as overlap repulsion energy with interionic distance (10, 11).

Without detailed structural information, which would include a knowledge of lithium site occupancies and energies, and a knowledge of how the silicate structure changes into the phosphate structure across the composition range, further interpretation of the data available at present would be speculative.

Electrochemical Properties and Discharge Kinetics of Thin Layer Hydrous Molybdenum Oxide

David Elliott[1]

Department of Chemistry, University of Queensland, St. Lucia, Queensland 4067, Australia

ABSTRACT

Thin layer hydrated molybdenum oxide (oxidation state IV or V) has been deposited electrochemically on a variety of substrates, *e.g.*, polycrystalline tin oxide coated glass. It is capable of existing in an oxidized or reduced form and its equilibrium properties are described by a Nernst-like relationship. Experimentally the activities of the two forms are found to depend on a power function of their concentrations. The equilibrium position is also a function of *p*H. The rate of oxidation is described by a kinetic rate law of at least second order. Slow self-oxidation also occurs over a period of hours possibly due to the reduction of H^+.

Some of the basic properties of hydrous molybdenum oxide have recently been described (1). It is of interest as a solid redox system, as a material capable of receiving and storing charge as a thin layer battery or capacitor, and capable of accepting light-induced charges from a semiconductor and coupling the latter to redox processes in solution. Its composition and oxidation state are at present unknown but it may be identical with some compounds described much earlier by others, *e.g.*, $MoO_2 \cdot 2H_2O$ (2) or $Mo_2O_5 \cdot 3H_2O$ (3). It is here designated "Mo Ox" and the present work describes further basic properties of the material including the charge potential characteristics and the kinetics of the discharge process.

Experimental Technique

Current/potential curves were determined using a three electrode, solid-state potentiostat of conventional design assembled using the Heath ADD system. The integrator and the log amplifier used in the kinetics studies used a single operational amplifier (LM316). A Houston Omnigraphic 2000 X-Y recorder was used to record linear sweep voltammograms. The tin oxide electrodes were cut from commercial infrared reflecting glass and mounted as described earlier (4). The temperature for the experiments described was not controlled and was in the range 22°-23°C.

Preparation of Mo Ox

The material can be generated electrochemically from dilute solutions of ammonium molybdate (10^{-5}-10^{-3}M Mo) in the *p*H range 1-4. Any electrode having sufficient H_2 overvoltage may be used, *e.g.*, mercury, amalgamated silver, doped polycrystalline tin oxide, copper, etc. The observed properties on the first three are identical, whereas the properties on Cu are modified by the limited positive range of the metal (Cu corrosion sets in at about −0.25V *vs.* SCE in 1M NaCl, 0.01M HCl).

The material can also be generated on semiconductor electrodes, *e.g.*, GaAs and Si. In these cases the observed behavior depends much on the particular properties of the substrate, *e.g.*, doping level, carrier type, flatband potential, degree of illumination, etc. There is every reason to suppose, nevertheless, that the intrinsic properties of Mo Ox are not dependent on the substrate except in so far as the latter may affect the precise conditions of its generation.

Figure 1 shows the growth of the material as a thin layer on SnO_2 under the particular conditions shown. Cyclic sweep conditions seem essential for the generation of layers having near reversible properties (oxidation and reduction peaks at similar potentials) and having substantial thickness. Electrolysis at a fixed potential results in a layer of poor reversibility and low charge holding capability. During the process of growth under cyclic sweep conditions there is evidence of a two-stage process both in the oxidation and reduction phases. Eventually the more negative stage becomes dominant resulting in sharper peaks. When transferred to a fresh electrolyte solution containing no molybdenum further refinement of the shape takes place, Fig. 2 (the ultimate shape of this particular scan cycle is shown in Fig. 3a).

Thin layers adhere quite tenaciously but if growth is attempted beyond a certain thickness, the material becomes detached from the substrate and electrical contact is lost. The maximum thickness before this

event varies with the conditions of generation, particularly Mo concentration, stirring conditions, etc. On one occasion, for example, a layer was grown to about 40 mC/cm^2 total charge capacity over 25 hr of continuous cycling at 0.5 V/min before eventually becoming detached. The current/voltage curves obtained with layers as thick as this are rather poorly shaped with a pronounced overvoltage. Layers of up to about 20 mC/cm^2 total charge capacity[2] can be prepared, however, which when matured as shown in Fig. 2 have a peak separation of no more than 30 mV at 0.5 V/min. This separation is a function of the finite charge/discharge kinetic rate; *i.e.*, the degree of reduction of the layer lags behind its equilibrium value on the negative scan and the degree of reoxidation lags behind on the positive scan. At slower scan rates the peaks can be brought more nearly into coincidence.

Basic Properties

The variation of the scan of a matured layer with acid concentration is shown in Fig. 3. Though the layer behaves in a regular way beyond 1.0M acid, it is not stable at this concentration and the current slowly declines. The variation of E_0[3] with acid concentration is 0.095 V/decade (*i.e.*, approximately 0.095 V/pH unit).

The layer is stable indefinitely in solutions of pH 2 and may be dried in an air oven with no apparent change observable when returned to the solution. Heating to 220°C in air for 1 hr, however, degrades the performance of the layer causing a large reduction in the charge capacity and distortion of the I/V characteristics.

Thickness has been measured using multiple beam interferometry. A layer of 20.6 mC/cm^2 had an estimated average thickness of 0.15λ for Na-D, equivalent to 90 nm. This is consistent with layer of composition $MoO_2 \cdot 2H_2O$, density 4.0, and $n = 1$ (equivalent to 87.5 nm). This result is very tentative since the composition and density are no more than guesses based on the very meager information available on the hydrated lower oxides of molydenum. It may be sufficient to suggest, however, that the material probably has a compact rather than an open porous structure and that the charge/discharge phenomenon is a solid-state reaction of a novel type rather than a typical interfacial electrochemical reaction.

Charge/Potential Characteristic

This has been estimated in three ways.

Method (*i*): By graphical integration of the area under the linear sweep I/V curves,[4] up to the potential considered This can only give an approximate result because the curves are distorted by the finite charge/discharge rate This can be partly overcome by taking the total area, both reduction and oxidation, within the cyclic scan up to a given potential and dividing by two. The lag in equilibrium is to some extent then canceled out since it is of opposite sign for the reduction and the oxidation.

Method (*ii*): By charging the layer at a series of fixed potentials, allowing to come to equilibrium, and then scanning positively. The integrated area then represents the total charge absorbed at equilibrium at the potentials chosen, cf. Fig. 4. Since the current does not decline to zero but to a small constant value beyond about +0.1V, the choice of integration limit is somewhat arbitrary.

Method (*iii*): By charging up to a selected potential and reversing back to zero; the charge is taken as equivalent to half the total area.

The data was analyzed according to the Nernst equation

$$E - E_0 = -\frac{RT}{n\mathbf{F}} \ln\left(\frac{\gamma_R}{\gamma_O}\right)$$

where γ_R, γ_O are the activities of the reduced and oxidized forms at the potential E, and E_0 is the "standard potential" (taken as the midpoint of the reduction and oxidation peaks) Clearly the reduced and oxidized forms cannot be separate solid phases for which γ

[2] This is estimated from the charging characteristic as described in the following section.
[3] Defined in the following section.
[4] The charge is independent of scan rate between 0.5 and 0.1 V/min within the limits of experimental error.

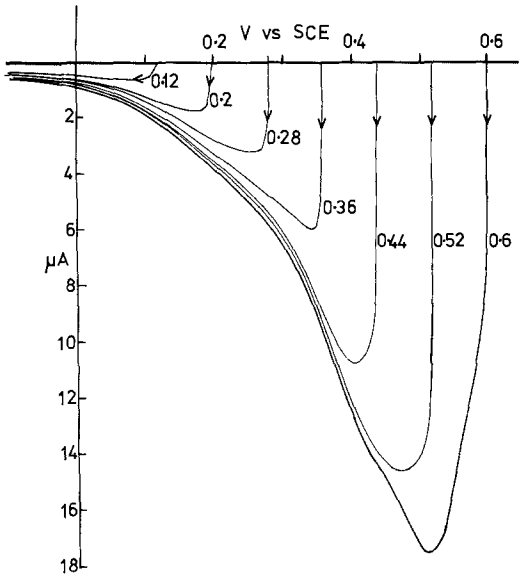

Fig. 4. Discharge current of matured layer. Charging potential indicated on curves (not the same layer as in Fig. 1 and 2). Conditions same as Fig. 2.

would be 1 or 0, otherwise the I/V curve would be a sharp pulse at the potential E_0. The assumption is first made that

$$\gamma \propto q_E$$

where q_E is the charge at potential E

$$\therefore E_0 - E = \frac{RT}{n\mathbf{F}} \ln (q_E/(Q - q_E))$$

where Q = total charge capacity. The value of Q cannot be determined directly since H_2 evolution sets in before reduction is complete. It is therefore assumed that the I/V curve is symmetrical about E_0 and that $Q = 2q_{E_0}$.

Figure 5 shows log $(q_E/(Q - q_E))$ plotted against E for a number of layer samples. The relationship is linear over most of the range with an average slope equal to 0.212 V/decade. This leads to the empirical relation

$$\gamma_R \propto q_E^{3.6} \text{ for } n = 1$$

or

$$\gamma_R \propto q_E^{7.2} \text{for } n = 2$$

Discharge Kinetics

The determination of the discharge rate is attendant with some difficulties.

The most direct method is to observe the discharge current as a function of time, but the dynamic range of this variable is so large (a few milliamperes down to a few microamperes in a few seconds) that a linear display is not sufficiently accurate. A further disadvantage of current measurements is that the current is relatively insensitive to reaction order (row 1, Table I).

Table I.

$\alpha = q/Q$ = fraction of discharge, where q = charge at time t, and Q = total charge capacity of layer.
$\alpha_0 = q_E/Q$, where q_E = initial charge at potential E.
$\alpha_\infty = q_\infty/Q = 0$ for 0.0V *vs.* SCE.
Rate expression $= -d\alpha/dt = K\alpha^n = I/Q$, where K = rate constant, n = "order," I = current at time t.

$n \neq 1$	$n = 2$	$n = 3$	$n = 4$
Current/time $I^{\frac{1-n}{n}} = (n-1)K(KQ)^{\frac{1-n}{n}} \cdot t + I_0^{\frac{1-n}{n}}$	$I^{-1/2} \propto t$	$I^{-2/3} \propto t$	$I^{-3/4} \propto t$
Concentration/time $\alpha^{1-n} = (n-1)Kt + \alpha_0^{1-n}$	$\alpha^{-1} \propto t$	$\alpha^{-2} \propto t$	$\alpha^{-3} \propto t$
Current/concentration $I = (QK)\,\alpha^n$	$I \propto \alpha^2$	$I \propto \alpha^3$	$I \propto \alpha^4$

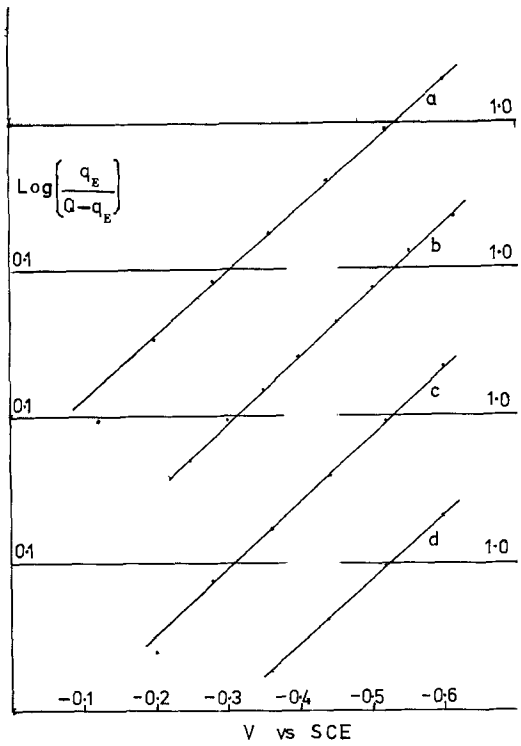

Fig. 5. Variation of log $q_E/(Q - q_E)$ with potential. Vertical axis calibrated in units of $q_E/(Q - q_E)$; successive graphs displaced by 1.0 log units. Solution and area as in Fig. 2. Total charge capacity and method of calculation: (a) 0.826 mC. Data for layer shown in Fig. 4, method (*ii*). (b) 1.45 mC, method (*i*). (c) 2.53 mC, method (*ii*). (d) 0.834 mC, method (*iii*).

An alternative technique is to record the charge flowing as a function of time. This has the advantage of a satisfactory dynamic range and a strong dependence on reaction order (row 2, Table I).

The instantaneous charge, q is now equal to $q_E - \int Idt$ and q_E can in principle be determined from the relationship

$$q_E = \int_0^\infty Idt$$

In practice, however, there is a residual current at zero volts as shown in Fig. 4 and the decline of current is very slow at long times so that the limiting value of $\int Idt$ is difficult to determine. The term q_E has therefore to be determined separately by the procedure described above [method (*ii*)], with the result that the value of q at long times becomes rather uncertain.

Layers were generated under standard conditions (1M NaCl, 0.01M HCl, 10^{-4}M Mo; 0.5 V/min) and then aged by cycling in Mo-free solution. They were then charged at fixed potentials with the potentiostat and switched suddenly to 0.0V. The current was either passed to a logarithmic amplifier or integrated electrically and the output in either case displayed on an oscilloscope.

Figure 6 and 7 show some examples of functions of charge and current, respectively, plotted against time; the assumption is made that $n = 3$ and the appropriate functions are selected from Table I. Although this value of n gives a fair fit for many such measurements, other data have been obtained in which the most appropriate value of n has varied from 2 to greater than 4. Therefore, it is not clear whether n should be an integer or indeed even a constant for different layers. A first-order reaction, which would be expected for a primary electrochemical process, seems ruled out, however. Neither is the charge (or current)/time characteristic obviously dependent on the diffusion of H^+ ions since a tenfold change (10^{-2}–10^{-1}M) has little effect on the observed rate. The rate is however some-

what decreased with increasing thickness (actually charge capacity Q).

Summary

The hydrous molybdenum oxide produced electrolytically under cyclic sweep conditions is an apparently solid and coherent layer of up to approximately 100 nm thickness. It undergoes reversible oxidation and reduction as a whole with a Nernst-like characteristic without any particular evidence of any diffusion of components in or out of it. The discharge rate is of second order or greater but the data is not sufficiently certain as yet to enable a model to be devised.

The Corrosion of Steels in Molten Sodium Hydroxide

R. N. Newman, C. A. Smith, and R. J. Smith

Central Electricity Generating Board, Berkeley Nuclear Laboratories, Berkeley, Gloucestershire, United Kingdom

ABSTRACT

The role of sodium hydroxide corrosion is discussed in relation to the wastage of materials observed in fast reactor boilers under fault conditions in the vicinity of a water leak into sodium. An experimental technique to study the corrosion under varying conditions is described. The results presented are for 2¼ Cr-1Mo obtained in static sodium hydroxide in a closed volume over the temperature range 1033°-1273°K. It is found that the corrosion rate can be followed by monitoring the hydrogen produced by the reaction, which can be written as

$$Fe + 2NaOH = NaFeO_2 + NaH + \tfrac{1}{2} H_2$$

After an initial acceleration period the rate law is parabolic. The effect on the corrosion rate of melt and cover gas composition has been in part investigated, and the relevance of mass flow of reactant is discussed.

The importance of material damage in the vicinity of sodium-water leaks in sodium-cooled fast reactor boilers is well recognized. In order properly to quantify the enlargement of parent tube leaks and the wastage rate of secondary target tubes an understanding of the rate-determining steps in the process is required. A considerable amount of research effort has been applied throughout the world to investigate this phenomenon, of which most has been in the form of small and large scale modeling of the heat exchanger situation, and has provided a considerable amount of empirical data (1-3). This approach, however, has not led to a basic understanding of the processes involved, thus making the interpretation and extrapolation of the data obtained a difficult task.

It has been established that at the boundary of water/steam jets high temperatures are generated by the mixing of sodium and water and their rapid exothermic chemical reaction (1). Sodium droplets entrained from the jet envelope react as they are carried in the jet, thus creating on an adjacent tube a hot corrosive film of sodium and/or sodium-water reaction products (4, 5). It is, therefore, reasonable to assume that the wastage mechanism is integrally connected with the heat generated within this region, the hot products of the chemical reaction, or the flow of the reactants or product droplets over the metal surfaces.

Experiments to measure the relative magnitudes of the corrosive and erosive components of the wastage have been performed. Pure erosion studies have revealed that erosion of the parent material is the least likely mechanism (1, 6). Corrosion tests of boiler materials in sodium hydroxide at 973°-1473°K have been concluded to give lower wastage than found in sodium-water leak tests (1). More recently static corrosion measurements in molten sodium hydroxide were found not to account satisfactorily for wastage rates observed on steel specimens exposed to an inert gas jet containing entrained sodium hydroxide droplets, and an interaction between corrosion and erosion was postulated (6). Corrosion allows erosion to proceed by presenting a continuously weakened surface structure of solid-state corrosion products and/or parent metal whose structure has been weakened by corrosion (6, 7).

A reexamination of previous work shows that even pure corrosion studies can produce wastage rates within a factor of ~3 of that expected at leak sites (1). Modeling studies have given good correlation between extrapolated corrosion rates of steels in molten sodium hydroxide/water vapor and wastage rates of steels exposed in a bench-scale sodium vapor/water vapor jet flame (7). Corroded samples from these studies also show the same surface appearance, *i.e.*, smooth with little or no intergranular penetration, as those from real wastage tests (1). It is therefore apparent that a greater understanding of the corrosion process itself is required in order to comment upon its role in the sodium-water boiler wastage process.

Key words: iron, chromium, sodium, water, caustic melts.

To date, few studies have been made on the reaction of molten sodium hydroxide and iron or iron-based alloys. It has been found that iron, chromium, and ferrous alloys react to form metal oxides or sodium ternary oxides and hydrogen (8). Later studies have shown the enhancing effect of introducing water vapor and the very marked intergranular nature of the corrosion at the metal surface (7). The reaction has not, however, been studied in detail by a kinetic approach under controlled conditions.

This present study is mainly concerned with the corrosion rate of 2¼ Cr-1Mo samples in static molten sodium hydroxide in closed systems, and the kinetic results are presented. Additional work involving the role of water vapor, sodium, sodium oxide, and cover gas flow is at an early stage, but some preliminary findings are presented.

Experimental

Apparatus.—The apparatus for measuring the corrosion rate of metal samples is shown in Fig. 1 and consists of a stainless steel furnace tube, 27 mm internal diameter and 440 mm long, which has a manifold for evacuation and admittance of argon or hydrogen and a removable lid containing a sliding vacuum seal. The sodium hydroxide was held in this tube in a nickel beaker of 20 mm internal diameter and 280 mm long. The sample, of approximate dimensions 24 × 12 × 0.625 mm and containing a 3 mm hole, was tied to a ring on the plunger by a thin ribbon of nickel foil. The lower 130 mm of the plunger was 3 mm diameter nickel wire.

A Bell and Howell 0-3 × 10^5 nm^{-2}, 0-50 mV transducer was used for the pressure measurements. The transducer output was monitored with a Keithley 615 digital voltmeter coupled with a simple potentiometric backing off circuit so that the pressure changes could be traced on a 10 mV recorder, thus resolving a pressure change of ~3 × 10^1 nm^{-2}.

Modification of the system so that the atmosphere over the hydroxide could be continuously purged with purified argon, or other gas mixtures was made by replacing the lid with one having the appropriate inlet line. The hydrogen content of the argon leaving the apparatus was measured with either a mass spectrometer or katharometer. Water vapor can be added to the

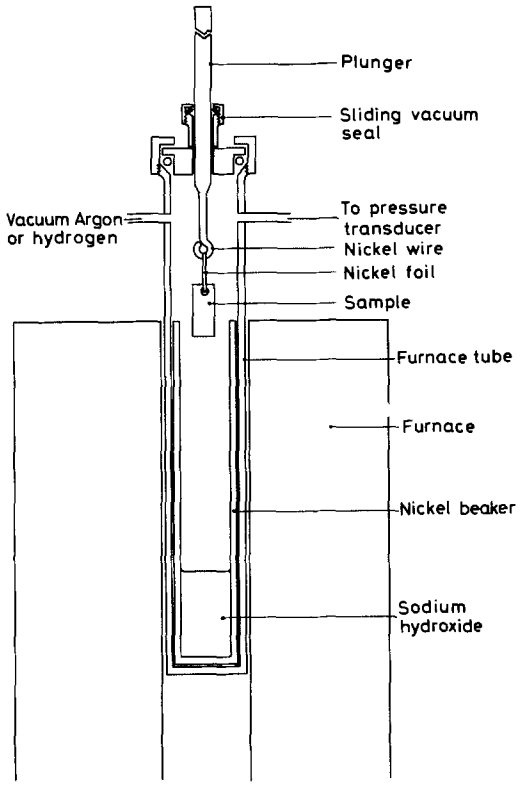

Fig. 1. Apparatus

argon by means of a water bubbler and by heating the appropriate gas lines to prevent condensation.

Experimental procedure.—Forty grams of sodium hydroxide (purity > 98% containing less than 1% sodium carbonate) was placed in the nickel beaker and heated at ~773°K under argon for a few minutes to remove traces of water. The beaker was placed in the furnace tube and the lid and plunger were replaced so that the sample was situated just above the nickel beaker.

The furnace temperature was monitored with a thermocouple placed between the furnace tube and the alumina liner of the furnace at a level near the midpoint of the sodium hydroxide. Independent tests confirmed that the temperature difference between this point and the sodium hydroxide was negligible (<5°K).

The furnace tube was evacuated while being warmed slowly to 523°-573°K before filling with hydrogen to ~1 × 10^5 nm^{-2}. The furnace was heated to the temperature of the experiment and, before immersion of the corrosion sample, the rate of hydrogen diffusion through the furnace tube walls was measured over the pressure range to be covered. This enabled a diffusion correction to be applied to the hydrogen pressures measured in the corrosion experiment. One reason for adopting this procedure was to inhibit the corrosion of the nickel beaker by the hydroxide by having a hydrogen pressure greater than the equilibrium pressure reported for this reaction by Williams *et al.* (8).

To initiate an experiment the plunger was depressed until the sample was immersed in the hydroxide and the increase in hydrogen pressure with time was recorded. At the end of the experiment, the sample was removed from the hydroxide to above the nickel beaker and allowed to cool.

Samples removed from the furnace were washed with excess water to remove sodium hydroxide and dried with acetone before weighing The adherent corrosion products were removed from the metal by etching with 50:50 phosphoric acid:water mixture at room temperature. Etching uncorroded metal samples in phosphoric acid for the same period of time showed that there was negligible attack on the parent metal under these conditions.

To determine the stoichiometry of the reaction, a correction must be applied to the measured gas pressure at the temperature of the experiment to enable its value at 273°K to be calculated. This correction was determined experimentally by filling the apparatus with argon at room temperature, heating to the required temperature, and measuring the gas pressure. A small correction was also required for the small increase in pressure produced by inserting the plunger into the furnace tube. This was measured at the temperature of each run and used to adjust each corrosion pressure trace.

Results

A typical experimental pressure recording is shown in Fig. 2 for a measurement at 1203°K. Part of the hydrogen decay curve from which the diffusion corrections were estimated is shown in the first part of the trace. The sharp trough and peak at the beginning and end of the sample exposure period was found from blank experiments to be due to the sudden cooling and heating of the gas volume, caused by the introduction and exit of the sample plunger.

Using an adaptation of the apparatus shown in Fig. 1, in which up to six small samples could be introduced consecutively to the melt and weight loss and hydrogen release measurements taken, the over-all stoichiometry of the reaction was examined over the time period of the main experiments. Figure 3 shows the consistency of the stoichiometry over the 90 min period. The mass loss is approximated to a loss in gram · atoms of iron, [≈Fe], due to the low percentage of

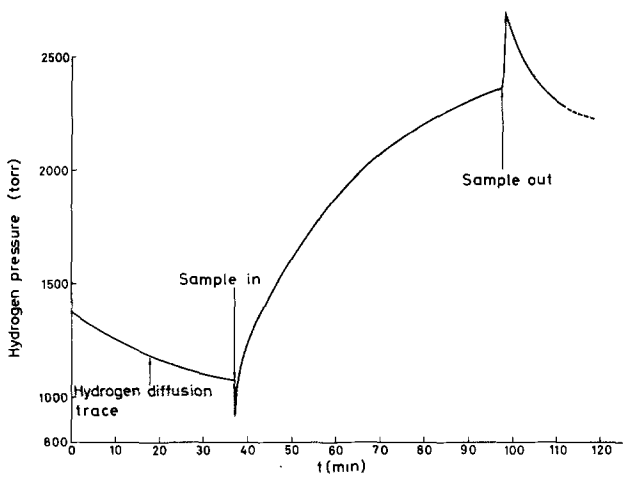

Fig. 2. Experimental pressure recording of corrosion process for 2¼ Cr-1Mo at 1203°K.

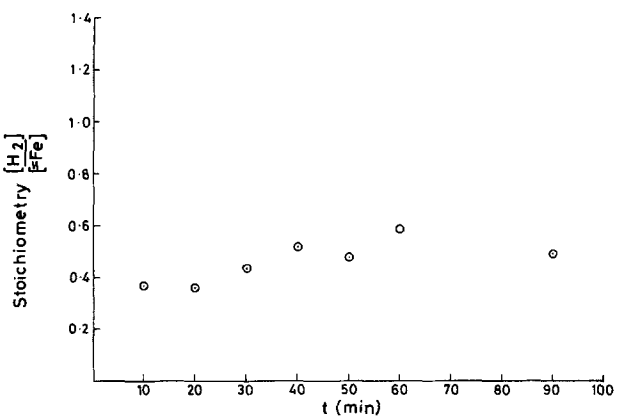

Fig. 3. Ratio of hydrogen produced to metal loss [≈Fe] with time of corrosion for 2¼ Cr-1Mo at 1203°K.

chromium in the steel and the small difference in atomic weights of chromium and iron (52:55.9).

The relationship between the corrected hydrogen pressure p_{H_2} and time was examined by plots of log p_{H_2} *vs.* log t. Beyond an initial period of 10-20 min, the value of d log p_{H_2}/d log t is near to 0.5, *i.e.*, there is a parabolic rate law. The actual values of d log p_{H_2}/d log t are shown in Fig. 4 over the temperature range 1033°-1273°K. Also shown are the values of the over-all stoichiometry after 90 min exposure to the hydroxide.

The parabolic nature of the rate dependence and initial period are illustrated in Fig. 5, where two typical plots of $(p_{H_2})^2/t$ against t at 1203° and 1153°K are shown. The close approximation to the parabolic relationship over the majority of the time period is clearly demonstrated.

Discussion

Static sodium hydroxide corrosion.—Previous work by the authors has shown that the major product of the reaction is a ternary oxide (7) and hydrogen. Williams *et al.* found that the reaction between iron and sodium hydroxide gave a stoichiometric ratio $\{H_2\}/\{\approx Fe\}$ of 3/2 and have interpreted the reaction in terms of the production of Fe_2O_3 and Na_2O or a sodium metalite (8). From examination of the stability of the $Na/H_2/NaOH$ system and identification of the corrosion products ($NaFeO_2$ and $NaCrO_2$) by x-ray powder crystallography (9), the stoichiometric ratio found in these experiments can be accounted for by writing the over-all reaction as

$$2Fe + 4NaOH = 2NaFeO_2 + H_2 + 2NaH \quad [1]$$

Chromium in the steel will react similarly.

The consistency of the parabolic region allows the calculation of a rate constant for the reaction expressed by the relationship

$$[H_2]^2 = kt \quad [2]$$

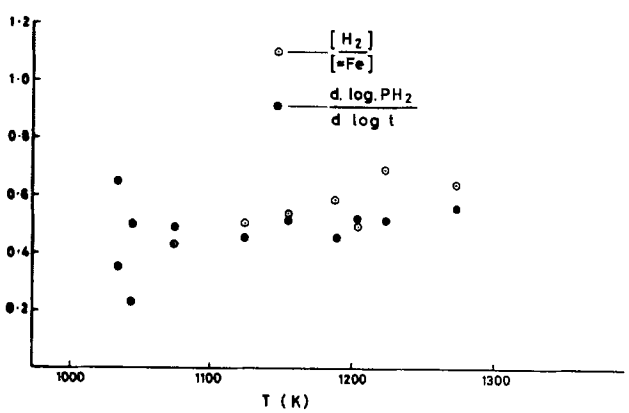

Fig. 4. Variation of stoichiometry of reaction products and d log p_{H_2}/d log t with temperature for 2¼ Cr-1Mo after 90 min exposure to $NaOH_{(l)}$.

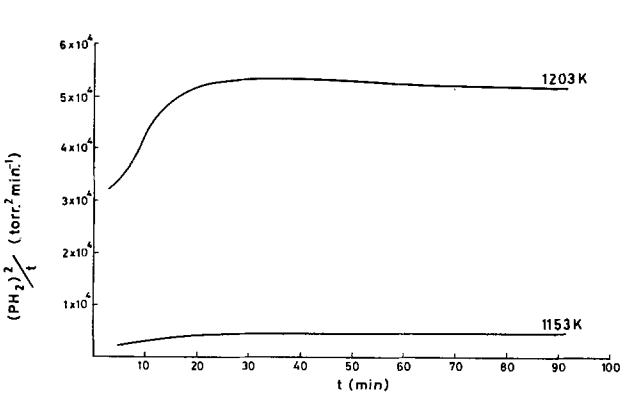

Fig. 5. Typical variation of $(p_{H_2})^2$ with time

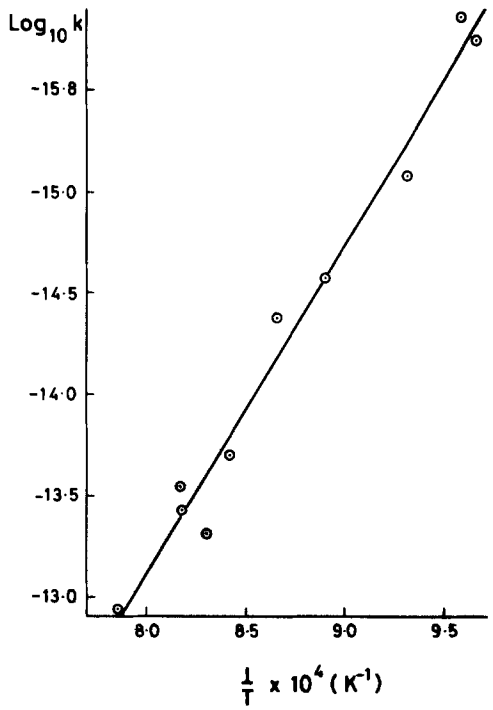

Fig. 6. The temperature dependence of rate constant K

where k has units of (moles of hydrogen $mm^{-2})^2 sec^{-1}$. The calculated values of k are displayed against temperature in an Arrhenius plot (Fig. 6) and show a straight line relationship from which k is derived as

$$k = 0.604e^{-37,000/T} \quad [3]$$

The induction period before the establishment of the parabolic rate law may in part be due to the heating of the sample to the melt temperature and the kinetics of hydrogen release from the melt.

Comparison of the present data with results reported previously (7) in which 2¼ Cr-1Mo samples were exposed to molten sodium hydroxide for periods of 5 min indicates that, in spite of the observed induction period, extrapolation of the parabolic expression to short time intervals gives good agreement with observed corrosion rates.

Hydrolysis of sodium hydroxide melts following the corrosion runs has confirmed the presence of sodium hydride through hydrogen evolution. Measurements of the amount of hydrogen released were consistent with the presence of approximately 1 mole of sodium hydride produced per gram · atom of iron/chromium consumed in the experiment. The stability of sodium hydride in sodium hydroxide was demonstrated by heating a 4 mole percent (m/o) solution of the hydride in the evacuated corrosion apparatus. The hydrogen pressure measured at 1073°K was constant at 1.41×10^5 nm^{-2} for the duration of the experiment, ~1½ hr, and indicated ~12% of the hydride had decomposed according to the reaction

$$NaH + NaOH = Na_2O + H_2 \quad [4]$$

The hydride is therefore apparently more stable than predicted from thermodynamic considerations based on JANAF (10) data with the assumption that the activities of dissolved oxide and hydride can be represented by mole fractions.

The rate of decomposition of the hydride was studied by bubbling argon through a corrosion melt and measuring the hydrogen content of the effluent gas with a katharometer. At 1203°K the process was found to be first order with a half-life of approximately 27 min when the argon flow was 2 ml sec^{-1} which is sufficiently large to give vigorous stirring of the solution. The observed stability of the hydride in the corrosion

runs is consequently a result of either solution interactions or kinetic limitations on its dissociation induced by the small area of gas-liquid interface of the sodium hydroxide and the limited stirring of the melt by convection. Figure 4 indicates that the stoichiometry of the corrosion reaction [1], $[H_2]/[\approx Fe]$ increases gradually with temperature and can be explained by the lower stability of the hydride and its greater rate of decomposition at the higher temperatures.

For reaction [1] to take place the free energy change must be a small positive to a negative value. Summation of thermodynamic data for sodium hydride and sodium hydroxide (10) indicates that the free energy of formation of sodium ferrite is given by the inequality

$$\Delta G(NaFeO_2) \lesssim -181{,}600 + 41T \text{ (cal mole}^{-1}\text{)} \quad [5]$$

The free energy of formation of sodium ferrite can be calculated from data given by Gross and Wilson (11) and Wu (12) to be

$$\Delta G(NaFeO_2) = -168{,}200 + 48T \quad \text{(from Gross and Wilson)} \quad [6]$$

$$\Delta G(NaFeO_2) = -181{,}350 + 47.5T \quad \text{(from Wu)} \quad [7]$$

Both expressions predict a free energy of formation which is less negative than required by Eq. [5], although Wu's data is more closely aligned with our experimental observations and those of Williams *et al.* (8) in which the corrosion reaction was interpreted as

$$6NaOH + 2Fe = Fe_2O_3 + 3Na_2O + 3H_2 \quad [8]$$

The results from other corrosion tests of 2¼ Cr-1Mo steel using sodium hydroxide under argon atmospheres have been reported (1). Maximum penetration was observed to occur mainly at the gas-liquid interface. The mean penetration cannot be derived accurately from the data since the surface area is not known, but estimates indicate that the mean is within a factor of four of the maximum. The maximum penetrations at 1300°K are in good agreement with our extrapolated data, while at 980°K Eq. [2] and [3] predict a penetration which is lower by a factor of ~65. The experimental conditions in the two experiments are dissimilar in the composition of the cover gas and the concentrations of reaction products and these factors may have some bearing on the different activation energies found for the corrosion process. Chamberlain (1) expressed the corrosion reaction as

$$3Fe + 8NaOH \rightarrow Fe_3O_4 + 4Na_2O + H_2 \quad [9]$$

The latter predicts an iron to sodium ratio of 0.91 when the reaction is complete. Reactions [1] and [8] would give ratios of 1.2 and 0.81, respectively, and if the sodium hydride were to distill from the reaction system following reaction [1] the ratio would increase to 2.4. Ratios of 1.3 to 1.9 were observed by Chamberlain at 1480°K, the larger value occurring at longer reaction times. At 1300°K a ratio of 1.1 was found which was virtually independent of time, but rationalization through Eq. [1] is unlikely since sodium hydride would be expected to dissociate and the sodium to distill at this temperature with long reaction times.

It was concluded by Chamberlain *et al.* (13) that as the primary reaction [9] or more generally

$$Fe + NaOH \rightarrow Fe_xO_y + Na_2O + H_2 \quad [10]$$

progressed to the right, a second corroding agent was formed, presumably Na_2O, which then reacted further with the iron according to

$$Fe + Na_2O \rightarrow Fe_xO_y + Na \quad [11]$$

with the evolution of free sodium. Secondary reactions may also take place as the evolved hydrogen reacts with and reduces the iron oxide to a lower oxide or iron

$$Fe_xO_y + H_2 \rightarrow Fe + H_2O \quad [12]$$

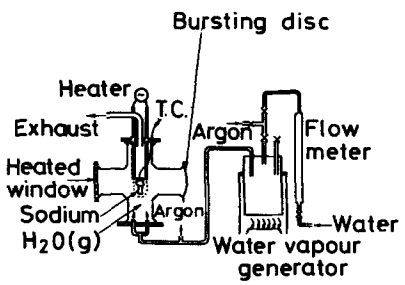
The difference in the experimental observations indicates that species produced in the reaction apart from determining the final product composition are also affecting the rate of the corrosion process. The presence of water vapor had previously been shown to increase the rate of corrosion of 2¼ Cr-1Mo by sodium hydroxide (7). Consequently a series of scoping experiments were performed to obtain comparative data of the influence of possible products and water vapor on the corrosion rate.

Further experiments varying the melt and gas composition.—Initial scoping experiments were to investigate the effect of sodium ferrite and sodium hydride on the corrosion rate. Sodium ferrite was added to the melts prior to corrosion runs at 1200°K. The results were somewhat inconclusive but indicated that at low concentrations (<3 m/o) there was no effect on the corrosion rate as determined from the weight loss compared with that predicted from Eq. [2] and [3] and the known stoichiometry of the reaction. At higher concentrations there was a small reduction in the corrosion rate which was accompanied by a reduction in the hydrogen released by the process. This effect was also observed by successively corroding samples in the same sodium hydroxide so that the ferrite concentration was allowed to rise. Samples removed from corrosion runs normally had a surface layer of adherent sodium ferrite which corresponded to up to 50% of the metal weight loss.

Addition of sodium (~4 m/o) to the hydroxide, followed by its conversion to the hydride by the addition of hydrogen prior to the corrosion run, produced a slight increase in the corrosion at 1200°K over that predicted.

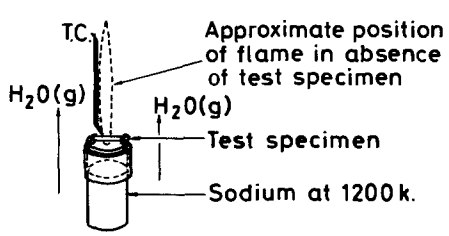
Prior to studying the effect of passing gas mixtures through the hydroxide at 1200°K, control experiments were performed in which hydrogen was bubbled through the melt at ~2.5 ml sec^{-1}. The results obtained were identical with those found in the static system. Passing argon through the melt at the same temperature and flow rate approximately doubled the amount of corrosion. The stoichiometry of the reaction, $[H_2]/[\approx Fe]$ was found to be > 0.5 but <1 when the sample was removed, and hydrogen release from the solution was observed for some time afterward. The increased rate with argon flow may result from the presence of sodium oxide produced by the decomposition of sodium hydride as in reaction [4].

Hydrogen/water vapor mixtures were also found to increase the corrosion rate. The variation with water vapor pressure was difficult to quantify with the design of the water injection system used since raising the water vapor pressure produced a larger gas flow which cooled the sodium hydroxide. However raising the water vapor pressure initially increased the corrosion rate and an increase of a factor of two was observed with a water vapor pressure 8×10^4 nm^{-2} at 1200°K.



The addition of 30 m/o of sodium oxide to the melt resulted in a 5-fold increase in the corrosion rate at 1070°K. Consequently, changing the hydrogen cover gas to argon, the presence of water vapor and sodium oxide produce more rapid corrosion. High concentrations of sodium oxide would appear to be necessary to give larger effects on the corrosion rate.

In these experiments some nickel transfer was observed producing a porous deposit over the corrosion sample. To eliminate the possibility of a reduction in corrosion rate by this effect experiments were performed in alumina, silver, and 2¼ Cr-1Mo crucibles. Results in all cases were identical with those observed in nickel beakers.



Experimental results in other systems have some bearing on the corrosion by sodium oxide. Sodium water flame studies were carried out using the apparatus shown in Fig. 7 in which sodium was boiled into water vapor at 1 atm pressure (7). Five grams of sodium boiled through the burner nozzle in 90 sec and produced a white-yellow laminar diffusion flame some 120 mm long and up to 7 mm in diameter. In wastage tests samples of candidate boiler materials were held ~2 mm above the burner nozzle which was constructed of 316 stainless steel. Thermocouples positioned on the side of the sample remote from the flame indicated temperatures of 1470°K during tests. Wastage of the nozzle was found to be seven times greater than the maximum wastage found on the 316 stainless steel samples. The temperature of the nozzle would be within the range of 1156°K (the boiling point of sodium) to 1470°K and the atmosphere in the nozzle would be sodium rich. If molten sodium hydroxide from the sodium-water reactor were present in this region calculations based on JANAF data (10) indicate that the equilibrium activity ratio for sodium oxide to sodium hydroxide would be >0.6 to >0.1 at the respective temperatures and suggests that the increased corrosion rate of the nozzle may result from the presence of sodium oxide.

Burning sodium in the above apparatus when the water vapor atmosphere had been replaced by air gave laminar sodium-oxygen flames where the product of the reaction was liquid monoxide (14). Wastage damage observed on 2¼ Cr-1Mo specimens exposed to these flames was found to be an order of magnitude smaller, from weight losses, than observed with sodium-water flames. The temperature of the specimens would be expected to be higher than those in the sodium-water flames tests. Sodium oxygen and sodium-water flame temperatures have been measured to be ~1700° and 1570°K, respectively (7, 14). It is possible that as the temperature is raised above the boiling point of sodium, sodium oxide has less effect on the corrosion process.

Rate-determining steps in wastage processes.—The parabolic rate expression implies the rate-controlling step in the sodium hydroxide corrosion of 2¼ Cr-1Mo is limited by diffusion through surface layers and the high activation energy is within the range of values quoted by Kubaschewski and Hopkins for the diffusion of metal or oxygen ions through double oxides (15). Detailed examination has not been made of the corrosion specimen surfaces but preliminary results indicate the strongly adherent corrosion product is chromium rich. Previous studies had shown the flame wastage of steels to vary linearly with their chromium content (7).

(ii) Enlarged view of burner assembly and specimen mounting.

Fig. 7. Sodium-water flame apparatus

The majority of corrosion rates, as found by others (1, 6), are considerably lower than observed in water leak tests in sodium systems unless high temperatures are postulated for the target tubes. The influence of gas atmosphere and reaction products on the corrosion rate in static systems is relatively small in view of the above discrepancy. Consequently the flow of entrained material and sodium-water reaction products plays the major part in increasing the wastage rate observed in fast reactor boilers as modeled by Tregonning *et al.* (6). The detailed mechanism however has not been resolved. It has been suggested by Tregonning that the corrosion rates must be appreciably higher than is implied by the results of static corrosion tests and at least as high as the measured wastage rates, since the sensitivity of the wastage to the velocity of the hydroxide droplets entrained in the jet is low. The results from the present and previous experiments indicate two probable mechanisms for wastage at leak sites.

The surface of the corrosion specimens exposed to sodium-water flames exhibited little intergranular penetration in the region of maximum wastage (7). The surrounding metal showed considerable intergranular corrosion (7, 16) and suggests the enhanced corrosion may be the result of a process where the corrosion loosened metal grains in the maximum wastage area are removed by the erosive action of sodium hydroxide droplets produced in the flame.

The purely chemical aspect of this mechanism was exhibited in the sodium vapor-water vapor jet flames (16) when 316 stainless steel samples were exposed briefly to the flame some 70 mm from the nozzle where any erosive action of the smoke droplets formed would be expected to be minimal (6). During a 20 sec exposure to the flame at a temperature approaching 1473°K marked grain boundary penetrations of up to 5×10^{-3} mm sec^{-1} were observed without a measurable mass loss. It would be reasonable to assume that the grain boundary penetration rate would be dependent on the path length through the metal, thus removal of the overlying grains would shorten the path length and increase the rate.

This process would be more favored in the sodium-water leak jet where the larger entrained droplets would have a greater erosive effect than the smaller ($\lesssim 1$ μm) smoke droplets formed in the sodium vapor-water vapor flame. It would also be expected to occur at high jet temperatures where the proportion of entrained reactants was close to that of reaction [13]

$$Na_{(l)} + H_2O_{(g)} \rightarrow NaOH_{(l)} + \tfrac{1}{2} H_2 \qquad [13]$$

Secondly, corrosion in static systems where erosive forces are negligible has also produced surfaces with little intergranular penetration in the region of maximum wastage at the hydroxide cover gas interface (1, 7). The corrosion rates may be enhanced here by the thinning of the rate-restricting surface layers by solution or chemical processes to produce a transgranular reaction as rapid as the intergranular reaction. In the sodium-water leak jet this thinning would be related to mass flow effects, possibly the flux of entrained material on the target. Using the rate expression in Eq. [3] mass flow or secondary chemical effects

would need to reduce the surface layer to a steady-state thickness of $\simeq 5 \times 10^{-8}$m to maintain a wastage rate of $\simeq 4 \times 10^{-2}$ mm sec^{-1} at 1173°K. At lower temperatures near 973°K much lower thicknesses of $< 5 \times 10^{-9}$m would be required, and the extrapolation of the parabolic rate constant is probably invalid at this level. If the rate of reaction, however, is increased by the presence of sodium oxide, this mechanism becomes more feasible. A reaction between sodium oxide and the rate-restricting layers may produce a compound which is more soluble in sodium hydroxide. Consequently in the sodium-water jet, this mechanism would be favored at temperatures below the maximum jet temperatures when the jet temperature and product composition are controlled by the presence of excess sodium, reaction [14], following the complete reaction of the water

$$NaOH_{(l)} + Na_{(l)} \rightarrow Na_2O_{(s/l)} + \tfrac{1}{2} H_2 \qquad [14]$$

Until the water is completely consumed the amount of oxide present in the jet will be low since the reaction

$$Na_2O_{(s/l)} + H_2O_{(g)} \rightarrow 2NaOH_{(l)} \qquad [15]$$

is balanced appreciably in favor of sodium hydroxide at the temperatures of interest.

Conclusions

The corrosion of 2¼ Cr-1Mo in sodium hydroxide has been studied between 1033° and 1273°K by monitoring the hydrogen produced in the process. The observed chemical reaction in the closed reaction system with a hydrogen cover gas was

$$2Fe + 4NaOH = 2NaFeO_2 + H_2 + 2NaH$$

The rate law after an initial acceleration period was parabolic with

$$[H_2]^2 = kt$$

where the rate constant k has the units (moles of hydrogen mm^{-2})^2 sec^{-1}. The rate constant was found to vary with the temperature according to the expression

$$k = 0.604\, e^{-37{,}000/T}$$

The influence of water vapor, sodium hydride, sodium ferrite, and sodium oxide on the corrosion rate was found to be relatively small when compared with the difference between wastage rates observed in the static corrosion experiments and those in water injection tests. The most likely wastage mechanisms seem to involve both chemical and mass flow components but not necessarily erosion processes.

The Effect of Trivalent Cations on the Conduction Characteristics of PbF_2

A. V. Joshi and C. C. Liang

P. R. Mallory & Company Incorporated, Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

The conduction characteristics of PbF_2 containing large amounts of AlF_3 were investigated in the temperature range between −50° and 300°C. It was found that the inclusion of high concentrations of AlF_3 stabilizes the cubic structure of PbF_2 and the application of a high pressure and/or mechanical stress on the PbF_2-AlF_3 sample does not result in a conversion from the cubic form to the orthorhombic form at ambient temperatures. Furthermore, the conductivity of PbF_2 was substantially increased by the incorporation of AlF_3. PbF_2 containing 12 mole percent (m/o) AlF_3 exhibited a room temperature conductivity of 1.1×10^{-4} $(\Omega\text{-cm})^{-1}$ and an activation energy for conduction of 8.2 ± 0.2 kcal/mole in the temperature range of −50°-70°C. However, the conductivity of this solid decreased substantially after annealing at a temperature above 100°C. Furthermore, the activation energy for conduction was found to be higher after annealing. The rate at which the conductivity decreases and the activation energy increases appeared to depend upon the temperature and duration of the annealing process. Inasmuch as the conductivity of the annealed sample could be increased to some extent by prolonged grinding, and the presence of an orthorhombic phase together with the predominate cubic phase was noted in the x-ray diffraction patterns of the annealed samples, we concluded that the decrease in conductivity by the annealing process may be attributed to (*i*) stress relief at the grain boundary or in the lattice upon annealing, (*ii*) partial structure conversion from the more conductive cubic form to the less conductive orthorhombic form upon annealing, and/or (*iii*) precipitation of AlF_3 or AlF_3-rich PbF_2-AlF_3 complexes from the supersaturated PbF_2-AlF_3 solid solution.

The conduction characteristics of lead fluoride in the orthorhombic form (α-PbF_2) and/or cubic form (β-PbF_2) have been studied by various investigators under a variety of conditions (1-5). It was noted from these studies that lead fluoride is virtually a pure ionic conductor and that the ionic conductivity of lead fluoride can be increased by both the monovalent and trivalent cation dopants indicating an anti-Frenkel defect structure. In view of these interesting conduction characteristics which suggest that lead fluoride may be a solid electrolyte material for solid electrolyte cells, we have widened our scope of investigation to study the effect of high concentrations of aluminum fluoride on the ionic conductivity and crystal structure of lead fluoride. The results of these investigations are discussed in this article.

Experimental

Material preparation.—Alfa Inorganics PbF_2 (99.9+% pure) and Cerac AlF_3 (99.5% pure) were used in this study without further purification. These materials were dried before use by heating in an evacuated flask at about 130°C for a minimum of 3 hr, and then transferred to a Vacuum Atmospheres dry box under argon atmosphere. The oxygen and moisture content of the box was always maintained below 15 ppm. All the sample preparations and some measurements were conducted in the dry box.

The solid solutions of PbF_2 and AlF_3 were prepared by melting in the argon atmosphere well-blended mixtures of appropriate amounts of PbF_2 and AlF_3. The resulting clear melts were quenched to ambient temperature and pulverized using a Fisher mechanical grinder. PbF_2-AlF_3 solid solutions containing 5-25 m/o AlF_3 were prepared.

Total conductivity measurements.—The total conductivities were measured at various temperatures. Graphite electrodes were used in the conductivity cells. The graphite/PbF_2-AlF_3/graphite conductivity cells were fabricated according to the following procedures.

A weighed amount of powder of the PbF_2-AlF_3 solid solution was prepressed at 4000 psi in a 0.6 in. diam steel die. While the prepressed pellet remained in the steel die, the electrode powder (graphite) was placed on both sides of the pellet, and the total assembly was pressed at 100,000 psi to form the conductivity cell. The geometric area of the pellet was calculated from the diameter, and the thickness of the pellet was determined by measuring a pellet of the same weight formed under similar conditions but without the graphite electrodes. The conductivity of the pellet was determined from the resistance of the conductivity cell which was held in a lava cell holder and measured by means of a General Radio Type 1650-B impedance bridge at 1000 Hz. Resistance measurements were also made with square wave excitation from 1000 to 10,000 Hz of a bridge constructed from Helipot precision potentiometers. A Tektronix Type E differential preamplifier made possible the application of only 3 mV peak to peak to the sample. The same results were obtained using both techniques.

A Blue M Model M10A resistance furnace was used to maintain the temperature of the conductivity cell above ambient. For the measurements at temperatures below ambient the conductivity cells were sealed in steel containers using glass-to-metal seals. A Blue M Versa-Range test chamber was used to maintain the temperature of the sealed conductivity cells below ambient.

Electronic conductivity measurements.—A Pb/PbF_2-12 m/o AlF_3/graphite cell was used for electronic conductivity measurements. The cell was constructed in the dry box according to the following procedures. A weighed amount of PbF_2-12 m/o AlF_3 powder was prepressed at 4000 psi in a 1 in. diam steel die. A well-blended mixture of Pb and PbF_2-12 m/o AlF_3 solid-solution powder was placed on one side while graphite powder was placed on the other side of the prepressed

Key words: lead fluoride, ionic conductivity, solid electrolyte, aluminum fluoride, solid solution.

pellet. The assembly was then pressed under a final pressure of 100,000 psi to form the Pb/PbF_2-12 m/o AlF_3/graphite cell. A mercury battery with a voltage divider was used as a constant potential source to furnish the polarization potentials for the Pb/PbF_2-12 m/o AlF_3/graphite cell. The polarization potential was measured by a Keithley 610B electrometer, and the current in response to the polarization potential was monitored across a precision resistor using a Dana Model 5500 digital voltmeter.

X-ray diffraction analysis.—Debye-Scherrer powder patterns of the PbF_2-AlF_3 solid solutions containing various amounts of AlF_3 were obtained at room temperature with CuKα radiation. The lattice parameter of each solid solution was obtained by the Nelson-Riley extrapolation based on the x-ray patterns. The uncertainty in the results was about ±0.01Å.

Results

Lead fluoride can exist at room temperature in either orthorhombic form (α-PbF_2) or cubic form (β-PbF_2) (1, 2). The cubic form of PbF_2 can be converted to the orthorhombic form at room temperature upon the application of pressure or stress. For example, Kennedy *et al.* (2) found that β-PbF_2 was converted to α-PbF_2 at pressures above 30,000 psi, while Liang and Joshi (1) found that the β-PbF_2 powder was converted to α-PbF_2 completely upon grinding in a mechanical grinder for about 2 hr. These characteristics were also observed in PbF_2 containing small amounts of aliovalent cation dopants. It was noted from the x-ray analysis that the PbF_2-AlF_3 (5-15 m/o) solid solutions were in the cubic form. Unlike the pure PbF_2 or PbF_2 doped with small amounts of aliovalent impurities (1, 2), the PbF_2-AlF_3 solid solutions retained the cubic structure of PbF_2 even after grinding for 2 hr and/or pressing the powder in a steel die at 100,000 psi at room temperature.

The lattice parameters of the PbF_2-AlF_3 solid solutions are given in Fig. 1. It was noted that the uncertainty of the measurements made the exact determination of the lattice parameter rather difficult. Nevertheless, the results indicated strongly that within the solubility limit of AlF_3 in PbF_2 the lattice parameter decreased linearly with the concentration of AlF_3.

The incorporation of aluminum fluoride caused a nonlinear increase in the conductivity of the polycrystalline PbF_2. Figure 2 shows the conductivity of PbF_2-AlF_3 solid solution as a function of aluminum fluoride content at 27° ± 2°C. It was noted that the maximum conductivity of about 10^{-4} $(\Omega\text{-cm})^{-1}$ was attained at 12 m/o AlF_3. Furthermore, the conductivity

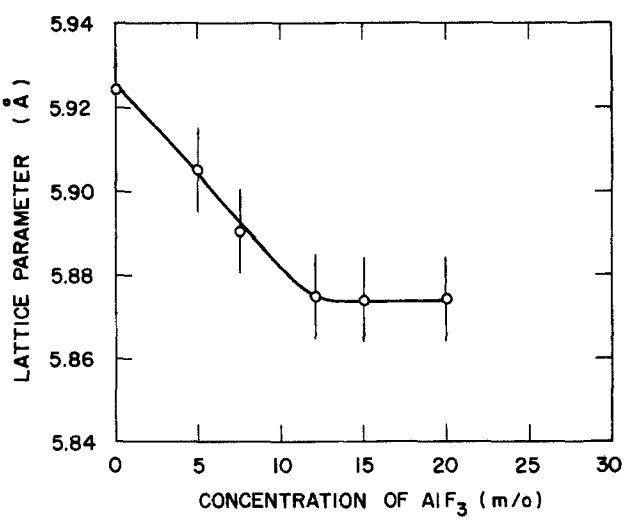

Fig. 1. Lattice parameter of the cubic PbF_2 as a function of AlF_3 content.

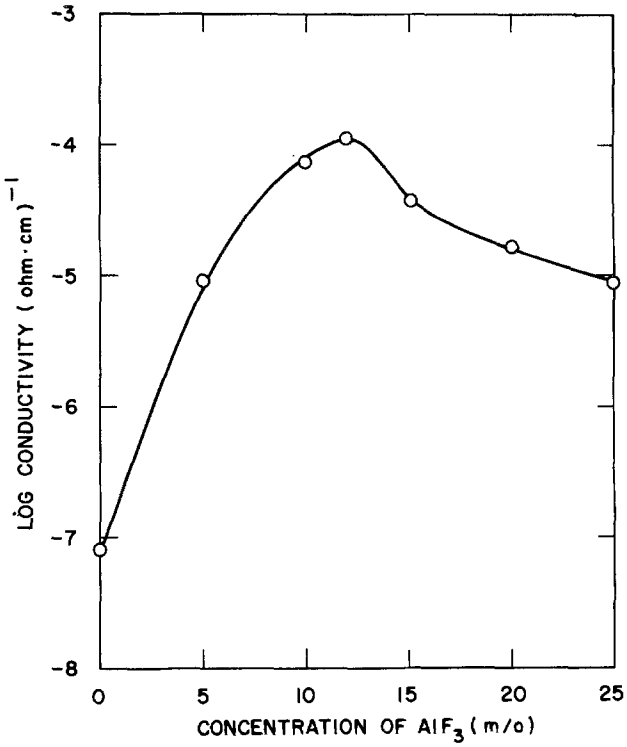

Fig. 2. Effect of AlF_3 content on the conductivity of β-PbF_2 at 27° ± 2°C.

did not change with time on storage at room temperature.

The d-c polarization measurements were carried out on a Pb/PbF_2-12 m/o AlF_3/graphite cell to deduce the partial electronic conductivity of the PbF_2-12 m/o AlF_3 solid solution. Wagner (6) showed that the total electronic current I_T can be related to the polarization potential by the following expression

$$I_T = I_e + I_h = \frac{RTA}{LF}\{\sigma_e^\circ[1 - \exp(-EF/RT)] + \sigma_h^\circ[\exp(EF/RT) + 1]\} \quad [1]$$

where I_e and I_h denote the electronic current due to electrons and electron holes, respectively; A represents the geometric area of the interface between the graphite electrode and the PbF_2-AlF_3 pellet; L represents the thickness of PbF_2-AlF_3 pellet; σ_e° and σ_h° are, respectively, the conductivities due to electrons and electron holes in PbF_2-AlF_3 equilibrated with Pb; and the other symbols have their usual meanings. Figure 3 shows the log I *vs.* E characteristics of the Pb/PbF_2-12 m/o AlF_3/graphite cell. In view of Eq. [1], the present results indicate a predominance of electrons as carriers for the electronic conductivities. Therefore, Eq. [1] can be reduced to

$$I_T = I_e = \frac{RTA}{LF}(\sigma_e^\circ); \text{ for } \exp(-EF/RT) \ll 1 \quad [2]$$

The electronic conductivity was obtained by using Eq. [2]. The value of I_e in Eq. [2] was estimated from Fig. 3 as the average value corresponding to the plateau. Based on these results, it was estimated that the electronic conductivity of the PbF_2-12 m/o AlF_3 solid equilibrated with Pb is 1.1×10^{-9} $(\Omega\text{-cm})^{-1}$ at room temperature. Consequently, the PbF_2-AlF_3 solutions are virtually pure ionic conductors and the value of the total conductivity of the solid solution is to be regarded as that of the ionic conductivity.

The fact that the PbF_2-AlF_3 solid solutions are virtually pure ionic conductors was further demonstrated by the open-circuit voltages of the Pb/PbF_2-AlF_3/AgF, Ag electrochemical cells. In these cells PbF_2-5 m/o AlF_3, PbF_2-10 m/o AlF_3, and PbF_2-12 m/o AlF_3

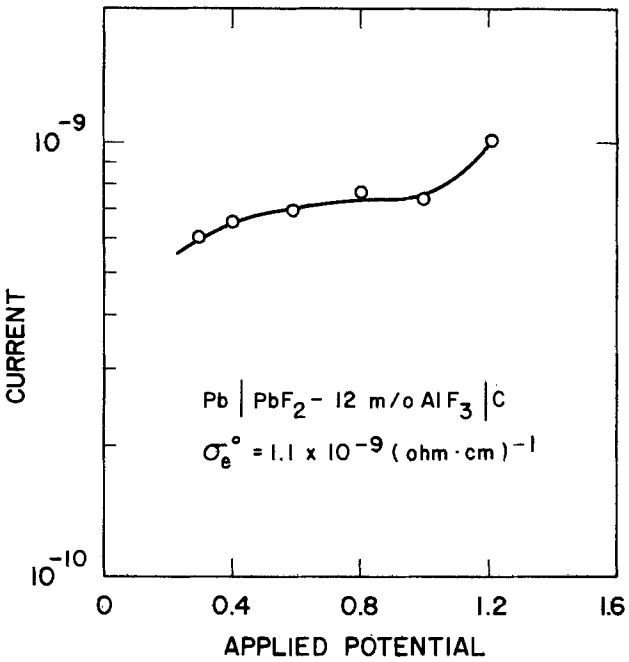

Fig. 3. Electronic current as a function of polarization potential on the Pb/PbF_2-12 m/o AlF_3/graphite cell.

were used as the solid electrolytes; a well-blended powder mixture of Pb and electrolyte was used as the anode material and a well-blended powder mixture of AgF, Ag, and electrolyte was used as the cathode material. The cells were fabricated by pressing the powders in a 0.6 in. diam steel die in a similar manner as the conductivity cells. The open-circuit voltages of the Pb/PbF_2-AlF_3/AgF, Ag cells, measured by a Keithley 610B electrometer, were 1.28 ± 0.01V at 26 ± 3°C. In view of the fact that the measured open-circuit voltage agreed well with the emf value of 1.284V calculated from the thermodynamic data (9) based on the cell reaction Pb + 2AgF → PbF_2 + Ag, we concluded that the PbF_2-AlF_3 solid solutions are virtually pure ionic conductors, and are suitable as solid electrolyte materials.

The conductivities of various PbF_2-AlF_3 solid solutions at temperatures ranging between −50° and +70°C are shown by the log σ *vs.* $1/T$ plots in Fig. 4. From these plots the activation energy for the conduction process in the temperature range between −50° and +70°C was determined to be 8.2 ± 0.2 kcal/mole. Both the log σ *vs.* $1/T$ plot and the value of the conductivity at a given temperature in this temperature range were found to be reproducible and did not depend on the direction of temperature change (descending or ascending temperature). In fact, we found that the value of conductivity at a given temperature was stable at temperatures as high as 100°C. However, when the temperature ascended beyond 100°C we noted that the conductivity decreased with time. Furthermore, the log σ *vs.* $1/T$ plot obtained in the direction of descending temperatures had a higher slope than that in the ascending direction, indicating a higher activation energy as shown by the log σ *vs.* $1/T$ plots in the temperature range between 27° and 150°C (Fig. 5).

It was also observed that the rate of conductivity change in the PbF_2-AlF_3 solid solutions at a given temperature above 100°C depended on the temperature. As a result, the conductivity values in the descending conductivity *vs.* temperature curve in Fig. 5 may not be those at equilibrium. Therefore, the solid solutions were annealed at 400°C for various periods of time and their conductivities were measured at room temperature to determine the required annealing time to reach equilibrium. It was found that the equilibrium

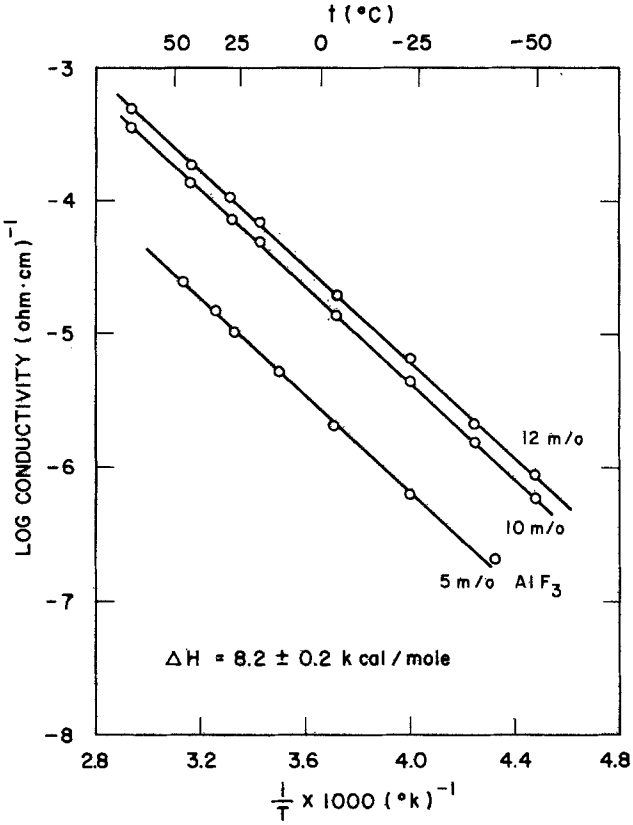

Fig. 4. Conductivity of the PbF_2-AlF_3 solid solution as a function of temperature.

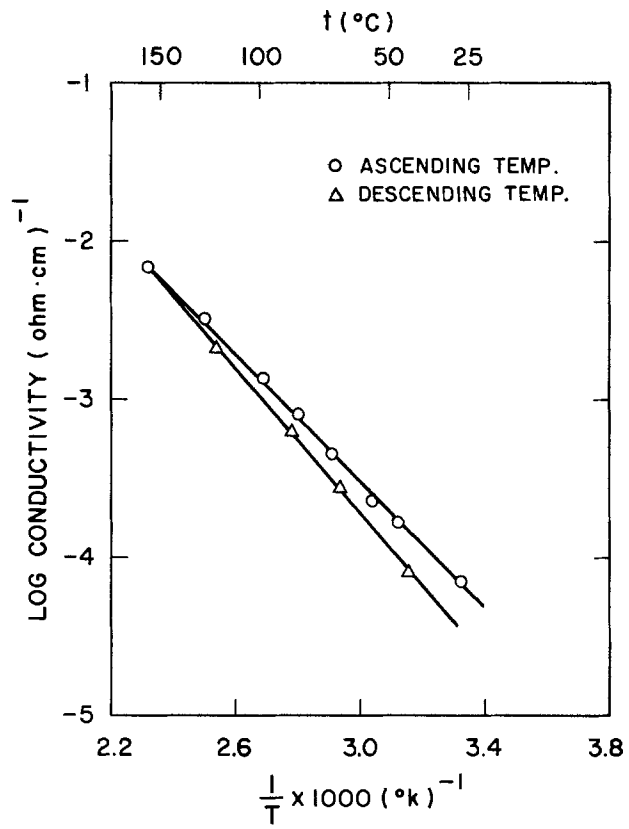

Fig. 5. Effect of the direction of temperature change on the conduction behavior of the PbF_2-10 m/o AlF_3 solid solution.

conditions were attained after a 20 hr annealing treatment. The log σ *vs.* $1/T$ plots for the PbF_2-AlF_3 solid solutions after the 400°C annealing treatment are shown in Fig. 6. It is noted from Fig. 6 that in the temperature range of 27°-125°C the activation energy

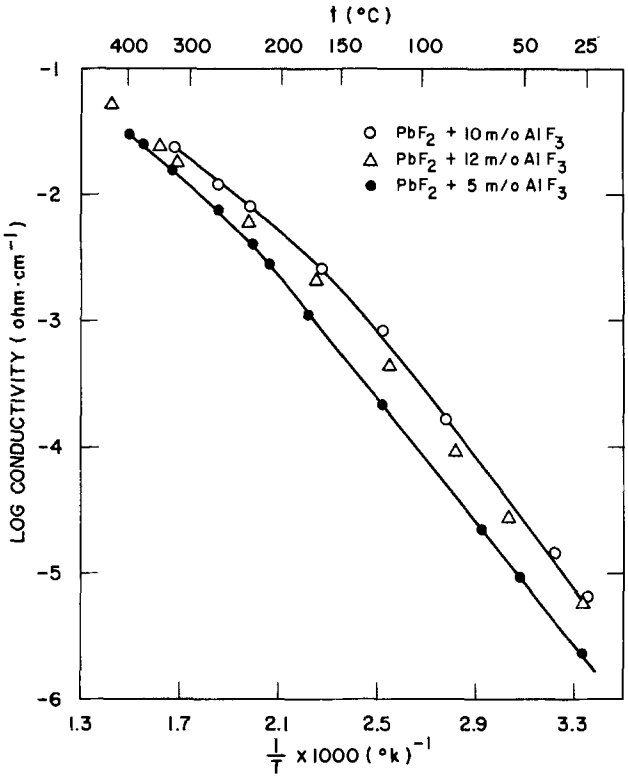

Fig. 6. Conductivity as a function of temperature for PbF_2 containing various concentrations of AlF_3 after annealing at 400°C.

for the conduction process, 12 kcal/mole, agreed well with that of the nominally pure PbF_2 and PbF_2 containing a small amount of YF_3 dopant (1). On the other hand, a decrease in activation energy is clearly noted at higher temperatures. The activation energy in the temperature range of 230°-400°C was found to be 7 kcal/mole.

In order to examine whether or not a phase transition had taken place during the 400°C annealing treatment, we obtained x-ray diffraction patterns on the annealed powder samples. It was noted that the cubic phase was still predominant. However, the patterns did show that some orthorhombic phase was present as a result of the annealing treatment.

It was further noted that the conductivity of the PbF_2-AlF_3 solid could be increased substantially by the application of mechanical stress such as prolonged grinding. For example, the room temperature conductivity of the 400°C annealed PbF_2-12 m/o AlF_3 was increased from 5.1×10^{-6} $(\Omega\text{-cm})^{-1}$ to 4.8×10^{-5} $(\Omega\text{-cm})^{-1}$ by grinding the sample in a mechanical grinder for 3 hr. Table I shows the comparison of the conductivity of the PbF_2-12 m/o AlF_3 solid solution before annealing, after annealing, and after annealing followed by the grinding treatment.

Discussion

In a recent study, Lucat *et al.* (4) found that β-PbF_2 and BiF_3 form solid solutions. Furthermore, these investigators found that the lattice parameters of β-PbF_2 decrease linearly with an increasing BiF_3 concentration in the solid solution. Inasmuch as the ionic radius of Bi^{3+} (0.96Å) is smaller than that of Pb^{2+} (1.20Å), the decrease in the lattice parameter indicates a substitutional dissolution of BiF_3 in β-PbF_2. The experimental results in the present study showed a similar behavior in the β-PbF_2-AlF_3 system. Figure 1 shows that the lattice parameter of the cubic lead fluoride decreases linearly with an increasing aluminum fluoride concentration in accordance with the Vegard law up to 12 m/o AlF_3. The fact that an AlF_3 concentration higher than 12 m/o does not result in a further decrease in the lattice parameter (Fig. 1) suggests that the solubility of aluminum fluoride in cubic lead fluoride is about 12 m/o under the experimental conditions. This conclusion is supported by the fact that the maximum conductivity of PbF_2 containing AlF_3 at room temperature was attained at PbF_2-12 m/o AlF_3, as shown in Fig. 2.

Table I. Effect of thermal and/or mechanical treatment on the conductivity of PbF_2-12 m/o AlF_3

	Treatment	Conductivity at 27° ± 2°C $(\Omega\text{-cm})^{-1}$
A.	Quenched from clear melt to room temperature and ground for about 3 hr	1.1×10^{-4}
B.	(A) followed by annealing at 400°C for 20 hr	5.1×10^{-6}
C.	(B) followed by grinding for 3 hr	4.8×10^{-5}

The cubic β-PbF_2 (both pure or containing small amount of aliovalent cation impurities) can be converted to α-PbF_2 by pressing at a pressure of 30,000 psi or higher (1, 2) or by prolonged grinding in a mechanical grinder (1). In other words, the cubic lead fluoride is not stable under pressure and/or stress. We have found, however, when a large amount of AlF_3 is dissolved in PbF_2, the cubic form is quite stable. Indeed, x-ray diffraction patterns showed that PbF_2-5 m/o AlF_3, PbF_2-10 m/o AlF_3, PbF_2-12 m/o AlF_3, and PbF_2-15 m/o AlF_3 were in the cubic form even after these powders had been ground in a mechanical grinder for more than 3 hr and/or pressed under a pressure as high as 100,000 psi. These results showed that the dissolution of relatively large amounts (5-15 m/o) of AlF_3 stabilizes the cubic structure of PbF_2.

The stability of the cubic form of lead fluoride containing a relatively large amount of AlF_3 enabled us to fabricate the β-PbF_2 conductivity cells by a simple powder pressing process. In previous studies (1) we found that it was necessary to sinter the pressed pellet, followed by a slow cooling process to room temperature to fabricate the β-PbF_2 conductivity cells. These postpressing sintering and cooling processes were no longer necessary in fabricating the β-PbF_2 (AlF_3) conductivity cells at room temperature. It is noted in Fig. 2 that a conductivity as high as 10^{-4} $(\Omega\text{-cm})^{-1}$ at room temperature is attainable at an AlF_3 concentration of 12 m/o. Figure 3 shows that the electronic conductivity of the PbF_2-AlF_3 solid solution is as low as 10^{-9} $(\Omega\text{-cm})^{-1}$ at room temperature, which means that the electronic transference number of the PbF_2-AlF_3 solid solutions is as low as 10^{-5}. Furthermore, the open-circuit voltage value of 1.28 ±0.01V for the Pb/PbF_2-AlF_3/AgF, Ag cell agrees well with the emf value of 1.284V calculated from the thermodynamic data. Therefore, the solid solutions are virtually pure ionic conductors suitable as solid electrolyte materials.

An interesting anomaly is also noted in Fig. 2. The conductivity of the β-PbF_2-AlF_3 solids does not increase linearly with the AlF_3 concentration. In fact, we have plotted in Fig. 2 the log σ *vs.* AlF_3 concentration to show that the conductivity increases at a much higher rate than predicted by the classical defect formation model with respect to the AlF_3 concentration. These characteristics are discussed in detail as follows. It has been shown (1) that β-PbF_2 has a Frenkel-type defect structure and the intrinsic point defects are interstitial fluoride ions and fluoride ion vacancies. Accordingly, upon the incorporation of AlF_3 in the β-PbF_2 lattice, the interstitial fluoride ions are induced according to the following equation

$$AlF_3 \rightarrow Al^{\cdot}_{Pb} + 2F_F^{x} + F_i' \qquad [3]$$

where $Al^{\cdot}_{Pb}$ denotes the aluminum ion at a lead ion site with an effective charge of +1, F_F^{x} and F_i' represent, respectively, the fluoride ion at a fluoride ion site and the interstitial fluoride ion with an effective charge

of −1. Based on Eq. [3] it is reasonable to assume that the concentration of the interstitial fluoride ions is much higher than that of the fluoride ion vacancies in the AlF_3-doped β-PbF_2, and the conductivity, σ, should be a linear function of the AlF_3 concentration in view of the following equation

$$\sigma = n_{F_i'} e \mu_{F_i'} \quad [4]$$

where $n_{F_i'}$ and $\mu_{F_i'}$ denote the concentration and the mobility of the interstitial fluoride ion and e represents the electronic charge. The experimental fact was that upon dissolution of AlF_3 the conductivity of β-PbF_2 increased substantially more than predicted by Eq. [3] and [4]. A similar observation was made by Kennedy and Miles (3), who studied the effect of monovalent cation dopants in PbF_2 and found that at higher doping levels the conductivities of PbF_2 were higher than predicted by the linear increase in the defect concentration. They attributed this behavior to the decrease in activation energy at higher doping levels. This explanation, however, cannot be applied to the present case inasmuch as we have found that the activation energy for the conduction process is constant for all the PbF_2-AlF_3 solid solutions as shown in Fig. 4.

The defect structure of the fluorite solid solutions of CaF_2 and YF_3 was investigated by Cheetham *et al.* (7). Based on the results of the Bragg neutron diffraction studies, these investigators concluded that the dissolution of YF_3 in CaF_2 resulted in the formation of two types of fluoride interstitials (F_I' located along the <110> direction and F_{II}' located along the <111> direction from the cubic position), and a fluoride ion vacancy. Furthermore, based on the observed occupation numbers, Cheetham *et al.* proposed that these defects appeared in various types of defect clusters in the solid solutions. It is possible, according to the cluster model, that in heavily doped crystals the number of vacancies would increase more rapidly with respect to the dopant concentration than predicted by the classical substitutional model Lucat *et al.* (4) applied this model to describe the conduction characteristics of the PbF_2-BiF_3 solid solutions. They attributed the high conductivity of the solid solution to the high mobility of the vacancies.

The conduction mechanism based on the defect clusters cannot be confirmed or denied by the present investigation. Nonetheless, it is unlikely that a straightforward fluoride ion vacancy mechanism prevails in the PbF_2-AlF_3 solid solutions, as shown in the following discussion. It has been shown in a previous investigation (1) that the activation energy for the mobility of fluoride ion vacancies is 4.1 kcal/mole in β-PbF_2. We have observed in the present studies that the activation energy for the conduction process of the PbF_2-AlF_3 solids is 8.2 ± 0.2 kcal/mole. Consequently, the fluoride ion vacancy mechanism cannot be applied to the PbF_2-AlF_3 solid solutions. On the other hand, it has been shown (1) that the activation energy for the mobility of interstitial fluoride ions is 14 kcal/mole in β-PbF_2, which is also considerably different from the 8.2 kcal/mole obtained for the PbF_2-AlF_3 solids. Furthermore, the nonlinearity of the conductivity *vs.* AlF_3 concentration plot (Fig. 1) shows that a simple fluoride ion interstitial mechanism cannot be applied to the present case. Although a detailed conduction mechanism cannot be elucidated for the PbF_2-AlF_3 solid solutions from the available data, it can be concluded that it is a complex one involving both vacancies and interstitials, and possibly even defect clusters.

As we discussed in the previous section, the conductivities of the PbF_2-AlF_3 solid solutions are stable at relatively low temperatures. No change in the values of conductivities is observed even after a prolonged storage period at room temperature. However, it has been observed that annealing the solid solution at a temperature above 100°C results in a substantial decrease in the conductivity and a substantial increase in activation energy (Fig. 5 and 6). On the other hand, the room temperature conductivity of the high temperature annealed sample can be increased, though not to the level of the preannealing sample, by grinding the powder in a mechanical grinder. These characteristics may be due to one or more of the following factors:

1. *Stress factors.*—The solid solution was prepared by heating the PbF_2-AlF_3 powder mixture to 1000°C to form a clear melt then quenched to room temperature. The quenching process may result in a great deal of stress to the solid solution. Another way of looking at this situation would be that a large number of line defects would be frozen in the solid solution. The stress or line defects may contribute to the conduction process, resulting in a higher conductivity. The annealing process would relieve the stress or annihilate the line defects created by quenching. Consequently, a decrease in conductivity was observed after annealing. The annealed sample can be restressed or the line defects in the sample can be reformed by the application of mechanical stress such as grinding in a mechanical grinder for a long period of time. Indeed, after grinding the conductivity was again increased, as shown in Table I. It should be noted that the positions of the lines in the x-ray diffraction patterns of the annealed samples are identical to those of the ground samples. However, the lines in the patterns of the ground samples are broader and less intense, indicating a more glassy or amorphous nature of the solid solutions.

2. *Orthorhombic phase.*—It is possible that a conversion of the cubic phase to the less conductive orthorhombic phase (1) takes place upon annealing. We noted from the x-ray diffraction patterns that indeed some orthorhombic phase along with a prominate cubic phase was present in samples which were annealed at 400°C for about 20 hr. Consequently, a partial conversion upon annealing may also be one of the causes for the decrease in conductivity.

3. *Precipitation of AlF_3.*—It is conceivable that the quenched PbF_2-AlF_3 solid solutions are supersaturated with AlF_3. Upon annealing, AlF_3 may precipitate from the solid solution as AlF_3 or as low conductivity AlF_3-rich PbF_2-AlF_3 complexes (8). As a result, the annealing process decreased the conductivity of the PbF_2-AlF_3 solid solutions. It should be noted, however, that in the x-ray diffraction patterns of the annealed PbF_2-AlF_3 sample we did not observe any lines which may be attributed to a separate phase of AlF_3. Nonetheless, we would not rule out the precipitation of AlF_3 as being a possible cause for the decrease in conductivity upon annealing the PbF_2-AlF_3 solids, in view of the fact that detection of small amount of impurities from x-ray diffraction patterns may be difficult.

Etching Characteristics of Silicate Glass Films in CF_4 Plasma

Kiyokatsu Jinno, Hiroshi Kinoshita, and Yasuo Matsumoto

Toshiba Research and Development Center, Saiwai-ku, Kawasaki, Japan 210

ABSTRACT

In order to delineate doped silicate glass layers, gas plasma etching has been found to be useful. Compared with conventional wet chemical processes, the etching characteristics with gas plasma processes are less dependent on deposition temperature and are more dependent on the dopant concentrations. These results can be explained by the volatility of dopant-fluorine compounds.

The uses of doped silicate glasses as dielectric materials, passivation layers, diffusion sources, etc., have become increasingly important in semiconductor device fabrication.

Conventional wet chemical etching techniques have been used to delineate silicate glass films. The conventional techniques, however, require complicated compositions of chemicals, precise control of etching bath temperature, and sometimes ultrasonic agitation. Further, the conventional chemical etching techniques have inherent disadvantages, such as undercutting caused by poor photoresist adhesion, which reduces the yield and reliability of the devices, and the etching controllability. The etching solutions may also contain harmful dust particles. The refuse chemicals must be treated carefully in order to minimize water pollution. Clean and safe operation environments must be maintained.

Recently, gas plasma techniques for stripping photoresist films in O_2 and etching silicon and silicon nitride films in CF_4 have been extensively developed (1-9). These new gas plasma techniques are found to be very useful for simplifying the wafer process without reducing the resolution capability, and for overcoming the disadvantages inherent in the conventional wet chemical etching techniques.

A freon gas plasma may also be used to etch silicate glass films. It is the purpose of this report to clarify the etching characteristics of the silicate glass films in the CF_4 plasma.

Experimental

The silicate glass films were deposited on chemically polished 20 Ω-cm p-type 2 in. silicon wafers by the reaction of SiH_4 with O_2 in an Ar ambient at 440°-550°C. The silicate glass films were doped respectively with B_2H_6, PH_3, AsH_3, or mixtures of these gases. The films were about 5000Å thick.

The positive photoresist (OFPR-2 manufactured by Tokyo Ohka) was used as an etching mask.

Resolution test patterns were exposed by a projection aligner (Canon FPA-120) and developed in a choline solution. Plasma etching was carried out in the IPC 2005-1813 SC plasma etcher with an 8 in. diam quartz reactor with an aluminum plasma shield. The etching gases were CF_4 and the mixtures of CF_4 and O_2. During the series of experiments the pressure in the reactor was maintained at 0.6 Torr, and the rf power was typically kept at 150W.

Key words: dopant effect, temperature dependency, volatility.

Film thicknesses were determined with Talystep, and the etch rate was defined as the decrement of film thickness per unit time. As the reference, wet chemical etching was performed at 25°C using NH_4F solution.

Results

Effect of silicate glass deposition temperature on the etch rate.—In Fig. 1, the etch rates of undoped silicate glass films in the CF_4 plasma and the NH_4F solution are shown as a function of silicate glass deposition temperature. As can be seen in Fig. 1, the etch rate in the NH_4F solution slightly decreases as the deposition temperature increases, while the etch rate in the CF_4 plasma is nearly constant. The etch rate of the undoped silicate glass films deposited at 550°C was 110 Å/min in the plasma and 3100 Å/min in the solution.

This result indicates that the etch rate in the CF_4 plasma is almost independent of the deposition temperature.

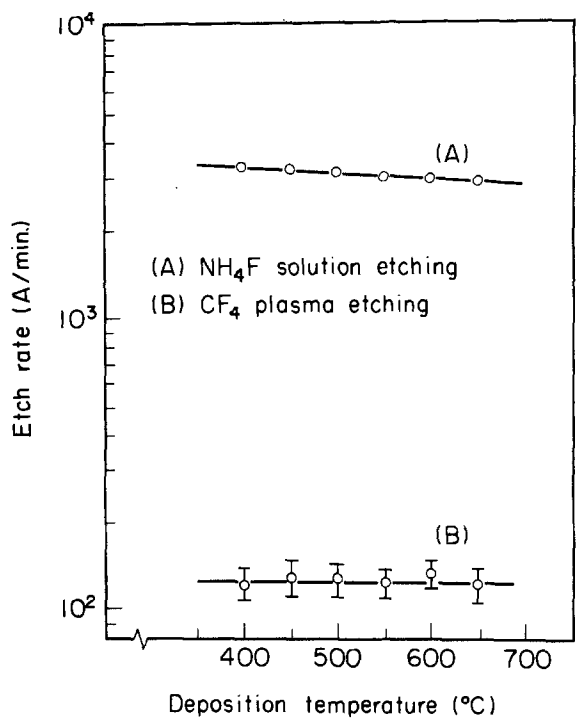

Fig. 1. Etch rate of silicate glass films vs. deposition temperature.

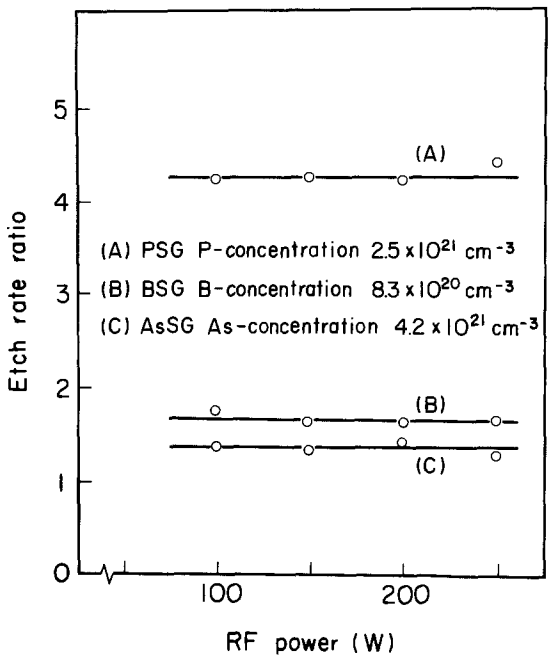

Fig. 2. Etch rate ratio vs. rf power

Effect of rf power on the etch rate.—The etch rate ratios, defined as the ratio of the etch rate of the doped silicate glass films to that of the undoped silicate glass films, are shown in Fig. 2 as a function of rf power.

It is apparent that the etch rate ratio does not depend on the power examined, so that the etch rate ratio can be used for compact representation of our etch rate results.

Effect of heat-treatment after deposition of silicate glass films.—The etch rate in the CF_4 plasma and NH_4F solution of undoped silicate glass films deposited at 500°C was examined after heat-treatment for 10 min in the temperature range 800°-1100°C. The result is shown in Fig. 3. Both in CF_4 plasma and in NH_4F solution etching, the etch rates of undoped silicate glass films decrease as the heat-treatment temperature increases. Therefore, it is concluded that the plasma etch rate depends on the material density.

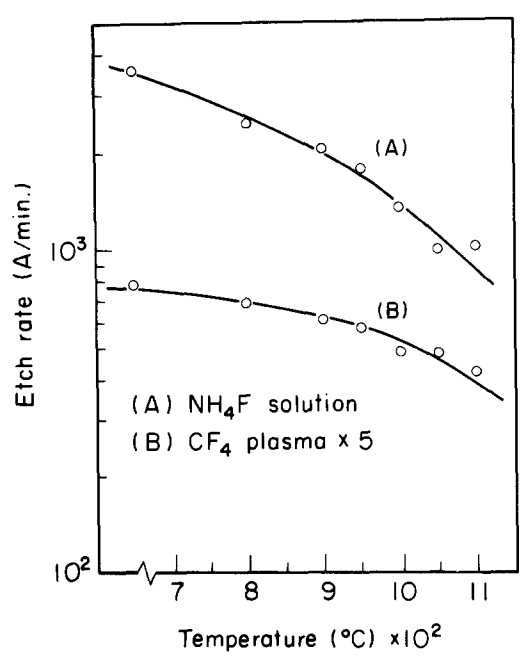

Fig. 3. Etch rate ratio vs. heat-treatment temperature after deposition of silicate glass films.

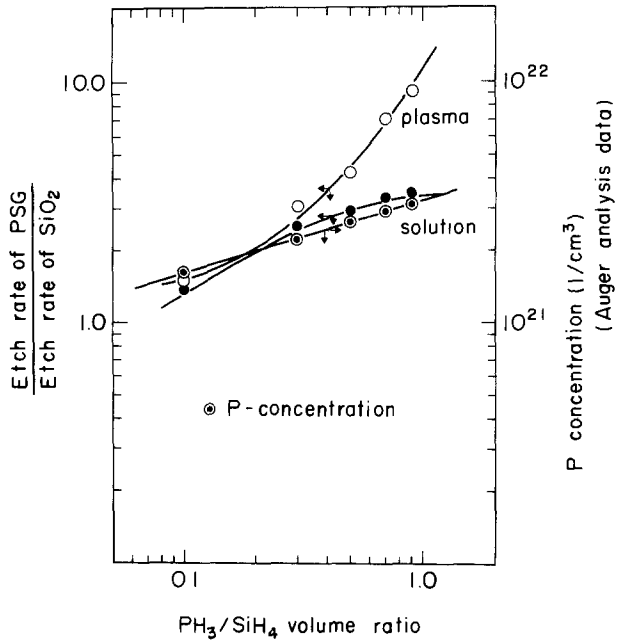

Fig. 4. Etch rate ratio of phosphosilicate glass films vs. PH_3/SiH_4 volume ratio.

Etching characteristics of phosphosilicate glass films.—The etch rate ratios of phosphosilicate glass films in CF_4 plasma and NH_4F solution etching were determined.

In Fig. 4, the results are shown as a function of the flow volume ratio of PH_3 to SiH_4 into the deposition chamber. It is clear that the etch rate ratio of phosphosilicate glass films increases with increasing phosphorus concentration in the glass films. This phenomenon is particularly remarkable in CF_4 plasma etching.

Etching characteristics of borosilicate glass films.—The etch rate ratios of borosilicate glass films in plasma and solution etching were determined as shown in Fig. 5. In NH_4F solution etching, the minimum in the etch rate ratio was reproducibly obtained at a boron concentration of about $7 \times 10^{20}/cm^3$.

In CF_4 plasma etching, the etch rate ratio increases with boron concentration over the entire range examined.

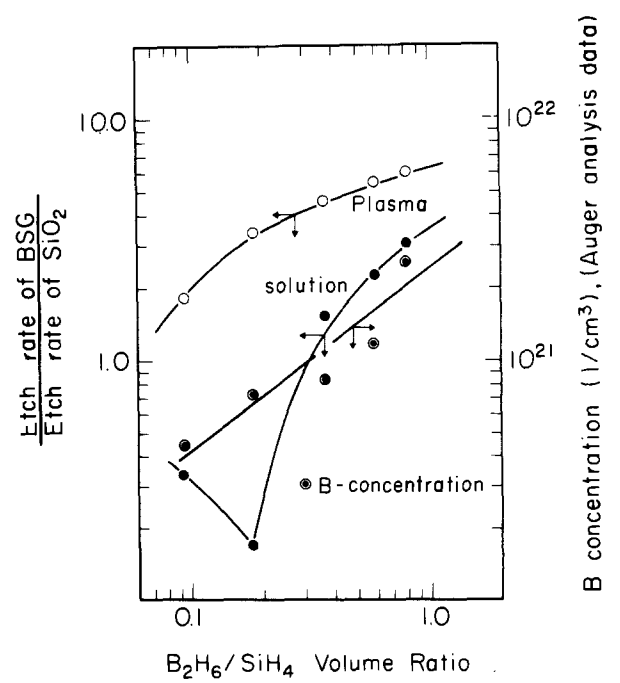

Fig. 5. Etch rate ratio of borosilicate glass films vs. B_2H_6/SiH_4 volume ratio.

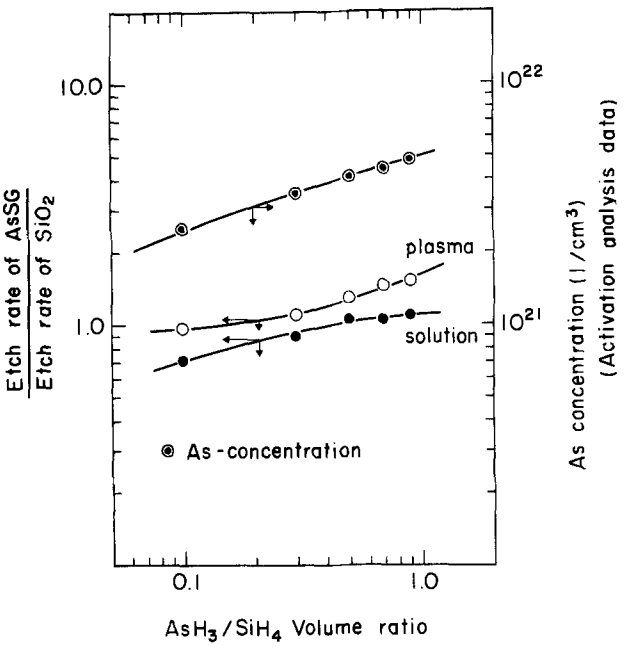

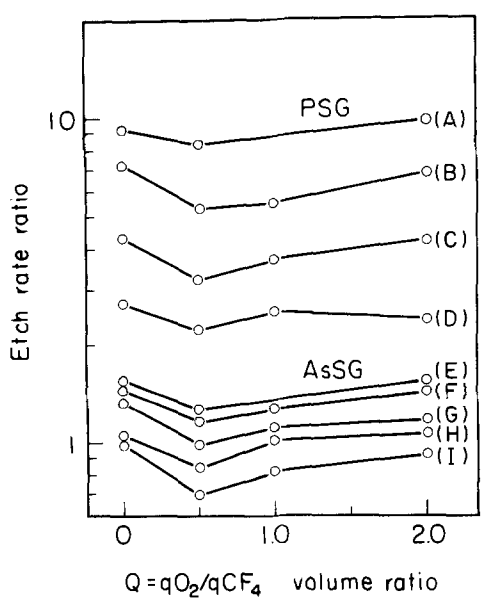

Fig. 6. Etch rate ratio of arsenosilicate glass films vs. AsH_3/SiH_4 volume ratio.

Etching characteristics of arsenosilicate glass films.—The etch rate ratios of arsenosilicate glass films were determined as shown in Fig. 6. The etch rates of arsenosilicate glass films are nearly the same as those of undoped glass films, and increase slightly with arsenic concentration.

Effect of additive oxygen in the CF_4 plasma.—The etch rate ratios of phosphosilicate glass and arsenosilicate glass films were examined as a function Q, the flow volume ratios of O_2 to CF_4, with dopant concentration as a parameter.

(A)	P-concentration	3.1×10^{21}	cm^{-3}
(B)	"	2.9×10^{21}	cm^{-3}

(H)	"	3.5×10^{21}	cm^{-3}
(I)	"	2.5×10^{21}	cm^{-3}

Fig. 7. Etch rate ratios vs. volume ratio (Q) of O_2 to CF_4

As shown in Fig. 7, the plasma etch rate of both silicate glass films are dependent on the additive O_2 concentration. At the range above $Q = 1.0$, the etch rate ratios for these silicate glass films increase with Q value. Each curve has a minimum at $Q = 0.5$.

Effect of plasma etching temperature.—Figures 8, 9, and 10 show the Arrhenius plots for plasma etching of phosphosilicate, borosilicate, and arsenosilicate glass films in the temperature range from 25° to 180°C, respectively. During etching, wafers were heat-controlled by a heating stage in contact with the back-side of each wafer. The activation energies for the etching reaction of phosphosilicate glass, borosilicate glass, and

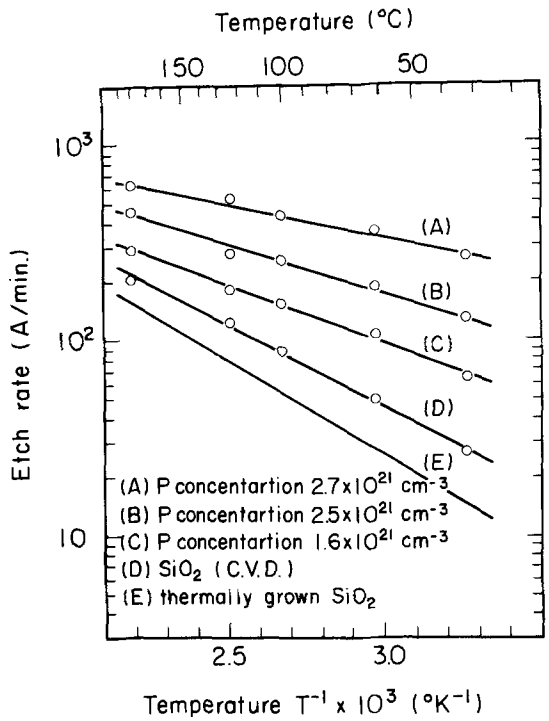

Fig. 8. Etch rate vs. temperature T for various phosphosilicate glass films.

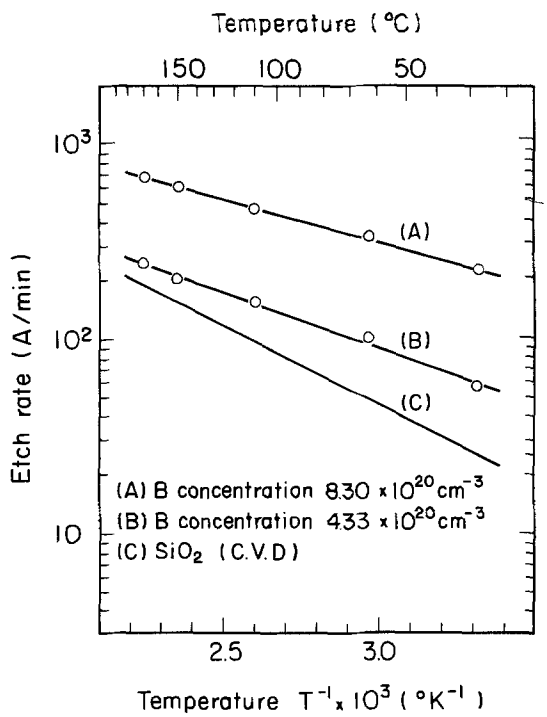

Fig. 9. Etch rate vs. temperature T for various arsenosilicate glass films.

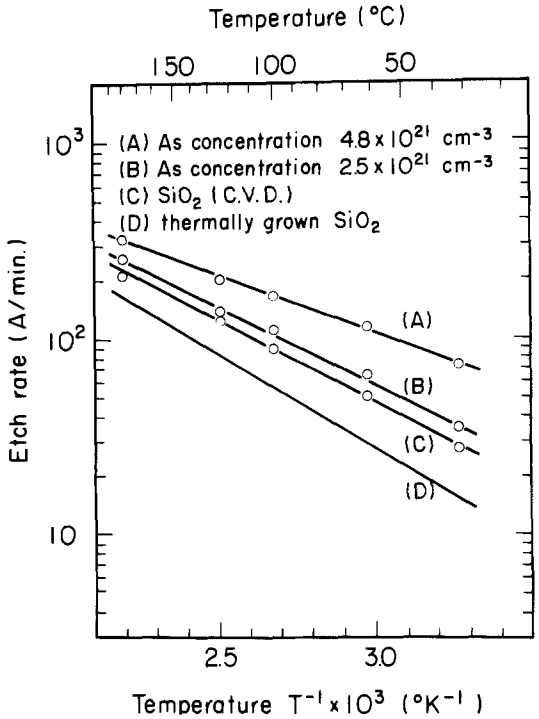

Fig. 10. Etch rate *vs.* temperature *T* for various borosilicate glass films.

arsenosilicate glass films obtained from the above results are summarized in Table I.

The activation energies may be due to differences in the reactions of SiO_2-F*, P_2O_5-F*, B_2O_3-F*, and As_2O_5-F*, etc.

Discussion

From the experimental results shown in Fig. 4-6 it is clear that the etch rate of silicate glass films in a CF_4 plasma is dependent on the dopant concentration in a range from $10^{21}/cm^3$ to $10^{22}/cm^3$, as observed also for NH_4F solution etching.

In solution etching, the effect of dopant concentration is interpreted as follows (10).

The monotonic increase in the etch rates with dopant concentration observed for doped silicate glass films except boron concentration below $10^{21}/cm^3$ suggests that the etch rate is controlled primarily by the dissolution of the SiO_2 in the doped silicate glass, and adding dopant oxide facilitates dissolution.

Thus the etching process can be explained as a combination of the dissolution of the SiO_2 by NH_4F originated species such as F^- in the NH_4F solution, and that of the dopant oxide in water. The etch rates of phosphosilicate glass films increase much more rapidly with dopant concentration than those of borosilicate and arsenosilicate glass films, which apparently are related to the relative solubilities of P_2O_5, B_2O_3, and As_2O_3 in water, respectively. But the relationship between etching characteristics and dopant oxide solubility does not extend to borosilicate glass films with boron concentration below $1 \times 10^{21}/cm^3$. Then the etching is complicated by formation of insoluble boron compounds, for example.

Meanwhile in CF_4 plasma etching, effects were observed for phosphosilicate, borosilicate, and arsenosilicate glass films that were similar to those observed for solution etching. The etch rate of phosphosilicate glass films increases much more rapidly with dopant concentration than those of borosilicate and arsenosilicate glass films. But, a significant difference was observed in the etching of borophosphosilicate glass films. The etch rate ratio of borophosphosilicate glass films in the CF_4 plasma etching was determined to be 3.05 and that in the NH_4F solution, 0.55.

In CF_4 plasma etching, the gas plasma is generated in the chamber by rf power, then silicon compound films begin to react with activated fluorine in the CF_4 plasma.

What seems to happen in the plasma etching process is that fluorine atoms from the plasma are chemisorbed on the silicon surface to form silicon fluoride compounds which are volatile even below room temperature; hence silicon is removed.

From the previous discussion, it is assumed that a large plasma etch rate is obtained for elements which produce fluorides with high volatility.

If we assume that doped silicate glasses are binary mixtures as follow; phosphosilicate glass: P_2O_5-SiO_2, borosilicate glass: B_2O_3-SiO_2, arsenosilicate glass: As_2O_3-SiO_2, the expected fluorides produced in CF_4 plasma are PF_3, PF_5, BF_3, AsF_3, and AsF_5. The vapor pressure of these fluorides are shown in Table II (11).

From this discussion, it is apparent that the plasma etch rate is dependent on volatility of the reaction products, and dopant effect in plasma etching is interpreted to originate in the difference of volatility of the dopant fluorides, *i.e.*, PF_3, BF_3, and AsF_5.

Table I. Activation energy of plasma etching reactions

Substrates	*E*, activation energy (kcal/mole)
Phosphosilicate glass	
p-concentration	
1.7×10^{21} cm^{-3}	2.78
2.5×10^{21} cm^{-3}	2.05
2.8×10^{21} cm^{-3}	1.61
Borosilicate glass	
B-concentration	
4.4×10^{20} cm^{-3}	3.51
8.2×10^{20} cm^{-3}	2.85
Arsenosilicate glass	
As-concentration	
2.5×10^{21} cm^{-3}	3.65
4.8×10^{21} cm^{-3}	2.57
Silicate glass deposited CVD	4.09
Thermally grown SiO_2	4.31

Conclusion

The etching characteristics of silicate glass films in the CF_4 plasma were studied. As a conclusion:

1. The plasma etch rate is almost independent of the silicate glass deposition temperature.
2. The etch rates of undoped silicate glass films decrease as the temperature of the heat-treatment after deposition increases. Therefore, the plasma etch rate depends on the density of materials.
3. The plasma etch rate of silicate glass films is dependent on the dopant concentrations. This characteristic can be explained by the volatility of fluorides such as PF_3, BF_3, and AsF_5, similar to solubility of dopant oxides, P_2O_5, B_2O_3, and As_2O_3 in water in solution etching.

Acknowledgment

The authors express their sincere thanks to Dr. Y. Nishi, Dr. S. Horiuchi, and T. Shinozaki for their useful discussions. They are also grateful to T. Moriya, K. Kirita, Y. Tsuji, M. Yamanaka, and T. Matsuo for their valuable support in the sample preparation, and to T. Inoue for auger spectrometric analysis.

Table II. Vapor pressure data of fluorides

Fluorides	Temperature (°C) 760 mm Hg	1 mm Hg
PF_3	−101.5	—
PF_5	−75	—
BF_3	−99.9	−154.6
AsF_3	−63	s
AsF_5	−53	−117.9
SiF_4	−94.8	−144.0

The Loading Effect in Plasma Etching

C. J. Mogab

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The dependence of etch rate on the quantity of material being etched, often referred to as the loading effect, for plasma etching is analyzed quantitatively with the aid of some simplifying assumptions. The etch rate is related to the quantity of material being etched through three phenomenological parameters β, τ, and G, which are related to the affinity of the etching material for the active species created in the plasma, the lifetime of the active species, and the volume generation rate of the active species, respectively. It is shown analytically that the reciprocal of the etch rate, when N identical wafers are etching simultaneously, is directly proportional to N. Data are presented for the plasma etching of Si in a CF_4-O_2 plasma which confirm the analytical prediction. The significance of loading with respect to the measurement of etch rate, end-point detection, and the interpretation of the temperature dependence of etch rate is discussed. A brief discussion of the physical meaning of the phenomenological parameters and their relation to process parameters subject to control such as power, pressure, and temperature is also included.

Plasma etching refers to the selective removal of a solid by the formation of a volatile compound upon chemical reaction of the solid with an active species created in a low pressure gas discharge. Silicon and its compounds of importance in silicon integrated circuit (SIC) fabrication can be etched, for example, in a low pressure (~0.2-1.0 Torr) rf discharge of CF_4 by virtue of the formation of volatile products such as SiF_4.

The so-called "loading effect" is familiar to anyone who has utilized plasma etching in a batch-type operation where the quantity of material being etched may vary from run to run. In SIC processing, for example, the number of wafers in a batch may vary from a few to as many as 20 or more. The loading effect is characterized by a decrease in etch rate as the quantity of material to be etched is increased, for a given set of etching conditions. The etching conditions subject to control include gas pressure, gas flow rate, rf power density, and the temperature of the solid being etched.

The loading effect is most evident with a rapidly etching material such as polycrystalline silicon. If the etch rate as determined from measurements on a single wafer is utilized to predict the time needed for complete etching of a batch of several wafers, it is invariably found that this time is insufficient to clear all wafers. Obviously, this leads to problems in maintaining dimensional tolerances when fine line patterns are being etched in a material which is partially masked. The etching will be incomplete if the etch time is too short, whereas undercutting of the mask and loss of pattern fidelity will result if the etch time is too long. Moreover, an incorrect etch time may also produce undesirable consequences with respect to the etch profile, that is, the shape of the edge of an etched feature.

If the variation of etch rate with load cannot be predicted, then a time consuming, trial and error process must be used to determine an appropriate etch time for each particular load or some means of end-point detection must be employed. For example, frequency-selective monitoring of the optical emission from the plasma has been suggested and used to determine the end point of certain plasma etching operations (1-3).

The objective of this paper is to analyze the loading effect with particular reference to a plasma reactor employing radial flow as depicted in Fig. 1 (4). We show that by making some reasonable, simplifying assumptions, a phenomenological equation can be developed which predicts the loading effect; that is, the dependence of etch rate on the amount of material being etched. Experimental verification of the predicted effect is given for plasma etching of single crystal silicon wafers in a CF_4-O_2 plasma. A discussion of some of the implications of loading with respect to end-point detection and interpretation of the temperature dependence of etch rates is also included, as is a brief consideration of the physical significance of

Key words: silicon, silicon dioxide, CF_4-O_2, reactor, etch rate, etching end point detection.

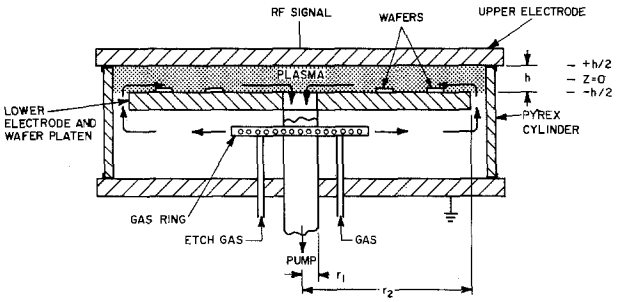

Fig. 1. Schematic illustration of a radial flow reactor

the phenomenological parameters appearing in the expression relating etch rate to the quantity of material being etched.

Theory

It is recognized that plasma etching, while conceptually simple, encompasses several rather complex processes which are, at best, poorly understood. The etching process depends not only on the complicated phenomena occurring in the discharge itself, *e.g.*, the production of ions and radicals, but also on the kinetic details of the interaction of the solid with one or more active species (reactants) adsorbed at the solid surface. One can anticipate that the production of active species in the plasma is dependent on power, pressure, flow rate, and reactor geometry, while the surface processes are sensitive to temperature. A detailed analytical description which could account for the influence of all these variables, however, would obviously be difficult to formulate. Alternatively, by making some reasonable assumptions, a phenomenological treatment is possible. Thus one can introduce certain parameters which, presumably, are related to the aforementioned variables, in order to characterize the process.

We assume that a single species, B, generated in the plasma is actively etching solid A according to the over-all reaction

$$aA + bB = A_aB_b\uparrow \qquad [1]$$

where A_aB_b is a volatile compound (*e.g.*, $Si + 4F \rightarrow SiF_4\uparrow$). Let the concentration of species B in the plasma be C_N. The subscript N refers to the number of identical wafers (substrates, films, etc.) being etched ($N = 0, 1, 2, \ldots$). The rate at which the active species are generated in the plasma, *e.g.*, by collisions between gas molecules and energetic electrons is designated G (the volume generation rate). It is assumed that, when no etchable material, A, is present in the reactor, the lifetime of an active species, B, is determined by adsorption, recombination, and flow processes in a way that can be described by a mean lifetime, τ. Then, if R_N is the etch rate of material A when N identical wafers are etching, the equation of continuity for the concentration of active species B is

$$\frac{\partial C_N}{\partial t} = D\nabla^2 C_N + G - \frac{df}{h}R_N - \frac{C_N}{\tau} - \nabla \cdot (C_N v) \qquad [2]$$

where

$$d = \frac{b\rho N_o}{M}$$

is a constant with b = coefficient in reaction equation [1]; ρ = density of solid A; N_o = Avogadro's number; M = molecular weight of A; h = interelectrode spacing; f = fraction of the wafer platen area occupied by etchable material (Fig. 1); v = gas flow velocity vector; and D = diffusion coefficient of B in the plasma. In general, C_N, G, R_N, and v must be considered to be functions of time and position. However, it is possible to simplify Eq. [2] considerably as follows.

In a reactor of the type under consideration here, the radial flow velocity of the gas is inversely proportional to radial position (5). It can also be shown (6) that the electron density in the plasma takes the form of a zero-order Bessel function with respect to radial position; thus it is maximum at the center of the reactor and drops to zero at the periphery.[1] Consequently, in this type of system the average gas molecule spends most of its transit time where the electron density is low and much less time where it is high. The significance of this fact is that the concentration of active species, created by collisions of gas molecules and energetic electrons, can be made uniform across the wafer platen. That is, the gas velocity and electron density profiles offset each other in such a way that the probability of producing an active species by collision is roughly independent of position. Accordingly, it is assumed that both C_N and G are uniform throughout the plasma volume.[2]

The last term on the right-hand side of Eq. [2] relates to flow effects and vanishes if C_N is uniform (independent of position) since the flow velocity $\vec{v}$ is divergenceless. Thus, for steady-state etching ($\partial C_N/\partial t = 0$) Eq. [2] becomes

$$R_N = \frac{h}{df}\left[G - \frac{C_N}{\tau}\right] \qquad [3]$$

The area fraction, f, is given by

$$f = \frac{A_W}{A}N \qquad [4]$$

where A_W = area of etchable material per wafer and A = total wafer platen area.

Substitution of Eq. [4] into Eq. [3] gives

$$R_N = \frac{hA}{dA_WN}\left[G - \frac{C_N}{\tau}\right] \qquad [5]$$

In order that R_N remain finite as $A_WN \rightarrow 0$ it must be true that

$$G = \frac{C_o}{\tau} \qquad [6]$$

Where C_o is the concentration of B in the absence of etchable material ($A_W \underset{\text{LIM}}{N} \rightarrow 0^{C_N = C_o}$). Thus, substituting Eq. [6] into Eq. [5]

$$R_N = \frac{hA}{dA_WN\tau}[C_o - C_N] \qquad [7]$$

It is reasonable to suppose that the etch rate is directly proportional to the concentration of active species B for a given set of etching conditions, that is

$$R_N = \beta C_N \qquad [8]$$

where β is a proportionality factor whose magnitude depends on the affinity of the material being etched for the active species B. Substituting Eq. [8] into Eq. [7] and combining terms yields

$$\beta^{-1}R_N = C_N = \frac{C_o}{1 + \frac{dA_W}{V}\beta\tau N} \qquad [9]$$

where $V = hA$ is the plasma volume. Finally, using Eq. [6] and [9], we obtain

$$R_N = \frac{\beta\tau G}{1 + \beta\tau\frac{dA_W}{V}N} \qquad [10]$$

From Eq. [10] it is apparent that the etch rate for N

[1] The zero-order Bessel function can be viewed, for qualitative considerations, as similar in form to the cosine function from 0 to $\pi/2$.

[2] This assumption is probably valid, to a first approximation, for other types of reactors, too, since the low viscosity gases employed in plasma etching discourage the formation of sizable concentration gradients in the bulk of the plasma.

wafers is a function of N, that is, Eq. [10] predicts a loading effect. Equation [10] also contains three phenomenological parameters (β, τ, G) which are discussed further on. First, it is shown that Eq. [10] is obeyed for the etching of Si wafers.

Experimental

Single crystal wafers of silicon with both 2 and 3 in. diameters were used in this study. The crystals had a [111] orientation and were polished on the side exposed to the plasma. Etch rate was measured by weight change, with a measurement precision of 0.1 mg. The etch time was selected so that weight changes were of the order of tens of milligrams. Etching was carried out in a 92% CF_4-8% O_2 plasma. The wafers were unmasked.

Relative etch rates were also measured by an optical technique which requires some explanation. The active species for etching Si in a CF_4 plasma is atomic fluorine, and the etch product is SiF_4. This has been ascertained from several observations. First, the reactor effluent was monitored with a quadrupole mass spectrometer during etching. Peaks consistent with the mass spectrum of SiF_4 appear when Si is actively etching. The intensity of the major peak (at measured etch rate = 85) compares favorably with the quantity of SiF_4 expected from the measured etch rate, assuming SiF_4 to be the only etch product. Secondly, a correlation between the intensity of optical emission from electronically excited states of F and the etch rate has been noted in two separate experiments. In the work of Harshbarger *et al.* (3), the etch rate of Si and the intensity of emission from excited F at 703.7 nm were measured as a function of the O_2 content of CF_4-O_2 mixtures. It was found that oxygen enhances the intensity of optical emission from excited states of F in the same proportion that etch rate is enhanced by the addition of oxygen.

Figure 2 illustrates that the emission intensity from the 703.7 nm F line tracks the etch rate of Si, measured by weight change for a single 2 in. diam wafer, as a function of rf power. (Optical emission was measured with a 0.3m Ebert polychromator and a Princeton Applied Research optical multichannel analyzer.) The emission points were measured with the reactor empty ($N = 0$). If one assumes that the intensity of emission for the empty chamber, I_o, is proportional to C_o according to $I_o = \alpha^{-1} C_o$, where α is independent of rf power, then Eq. [9] can be written

$$R_N = \frac{C_o \beta}{1 + \dfrac{\beta \tau d A_W N}{V}} = \frac{\alpha I_o \beta}{1 + \dfrac{\beta \tau d A_W N}{V}}$$

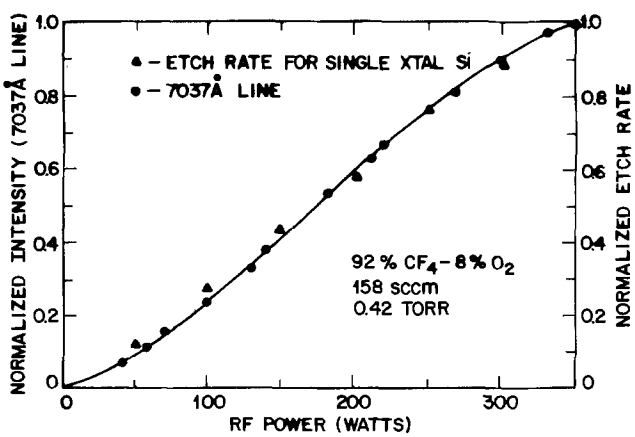

Fig. 2. Variation of etch rate for a 2 in. Si wafer and intensity of emission from electronically excited F as a function of rf power in a CF_4-8%O_2 plasma. The data are normalized to the highest power level.

Therefore the variation of etch rate with power, for a given load, can be determined by measuring the variation of emission intensity with power for an empty reactor. The data of Fig. 2 are normalized to the maximum values of intensity and etch rate to emphasize the strong correlation between etch rate and F concentration. These data confirm the validity of Eq. [8] for this case. Thus, available evidence indicates that F is the active species for etching Si.

It follows from Eq. [8], therefore, that the etch rate of Si is reflected in the intensity of emission from excited states of F. That is

$$R_N = \gamma I_N \qquad [11]$$

where γ is a constant at fixed temperature and pressure.[3] The main advantage in using optical monitoring in this manner is that it is far less time consuming than direct measurement of etch rate. All of the optical emission data reported subsequently, refer to the 703.7 nm F line. Other F lines can be used, however, this one has the maximum intensity for plasma conditions employed in these studies.

Inverting Eq. [10] gives

$$R_N^{-1} = (\beta \tau G)^{-1} + \left(\frac{dA_W}{GV} \right) N \qquad [12]$$

Therefore, the reciprocal of etch rate is linear in N. Moreover, using Eq. [10] and [11]

$$\frac{R_o}{R_N} = \frac{I_o}{I_N} = 1 + \beta \tau \frac{dA_W}{V} N \qquad [13]$$

In order to test the validity of Eq. [12], several runs were made in which only the number of 3 in. diam, bare Si wafers was varied. The wafers were weighed, etched for 15 min, and then reweighed. A fresh batch of wafers was used in each run and the wafers were placed immediately adjacent to one another so that their centers were on a circle concentric with the inner and outer edges of the wafer platen. The circle of centers was chosen such that 10 wafers could just be placed on it with no overlap. The results of this experiment are shown in Table I. The weight changes listed in the second column of Table I are arranged to reflect the position of the wafers on the circle of placement. (The first and last figures are for the wafers on the "ends" of a partial ring; with 10 wafers present the ring is continuous.)

Two observations can be made concerning the data of Table I. First, as the number of wafers increases, the standard deviation, which reflects the nonuniformity of etching from wafer to wafer, increases to a near maximum for a half-full ring, and then decreases again as the ring of wafer sites is filled beyond the halfway point. Second, for runs with an unfilled ring, the "end" wafers ($N \geq 3$) consistently show more etching than inner wafers. These two facts suggest that the concentration of active species is not exactly uniform, except when the etchable material is symmetrically distributed. The concentration of active species is somewhat higher near a wafer which is not surrounded by other wafers. This is not surprising since it is simply a manifestation of loading, *i.e.*, a competition for active species. This same competitive effect can presumably lead to an etch rate dependence on feature size, with small isolated features etching more rapidly than large, less isolated features on a wafer. From a practical viewpoint, it is clear that loads should be distributed symmetrically in order to obtain a maximum uniformity of etching.

The measured weight changes given in Table I were converted to average etch rates across each wafer and then the reciprocal of the average of these values for

[3] The parameter γ must be assumed to be pressure dependent unless it can be demonstrated that the plasma is optically thin at all pressures of interest. This means that the variation of emission intensity with pressure cannot be used to predict the variation of R_N with pressure, other conditions being held constant.

Table I. Dependence of etch rate on loading conditions: 92%CF_4-8%O_2, 300W, 0.3 Torr, 150 SCCM, 100°C, 15 min of etching

No. of wafers etched	Measured weight change (mg)	Average weight change (mg)	Standard deviation (mg)
1	69.3	69.3	0
2	48.8 51.5	50.2	1.91
3	39.9 34.7 42.0	38.9	3.76
4	34.4 29.3 29.3 35.4	32.1	3.26
5	31.0 24.9 24.4 25.8 32.1	27.6	3.62
6	27.2 22.5 20.4 20.0 23.0 28.6	23.6	3.54
8	23.3 20.5 18.2 17.2 19.7 20.5 20.1 24.0	20.4	2.30
10	18.7 16.5 16.6 15.1 16.9 15.9 17.3 16.0 17.4 17.7	16.8	1.03

each run was plotted against the number of wafers in the run, as shown in Fig. 3. It is evident that Eq. [12] is obeyed.

Similar experiments in which the intensity of emission from excited F was measured as a function of N have been run with both 2 and 3 in. diam wafers. Figure 4 illustrates results typical of these experiments.

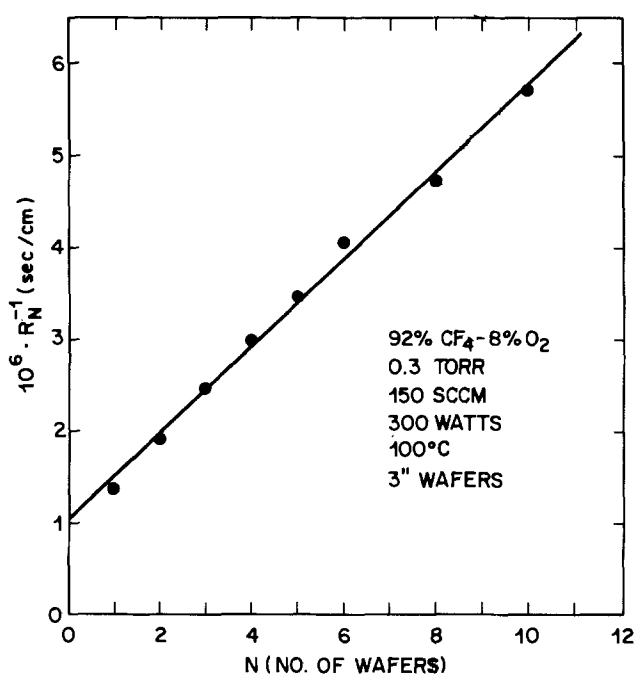

Fig. 3. Reciprocal of average etch rate vs. number of wafers for the data of Table I.

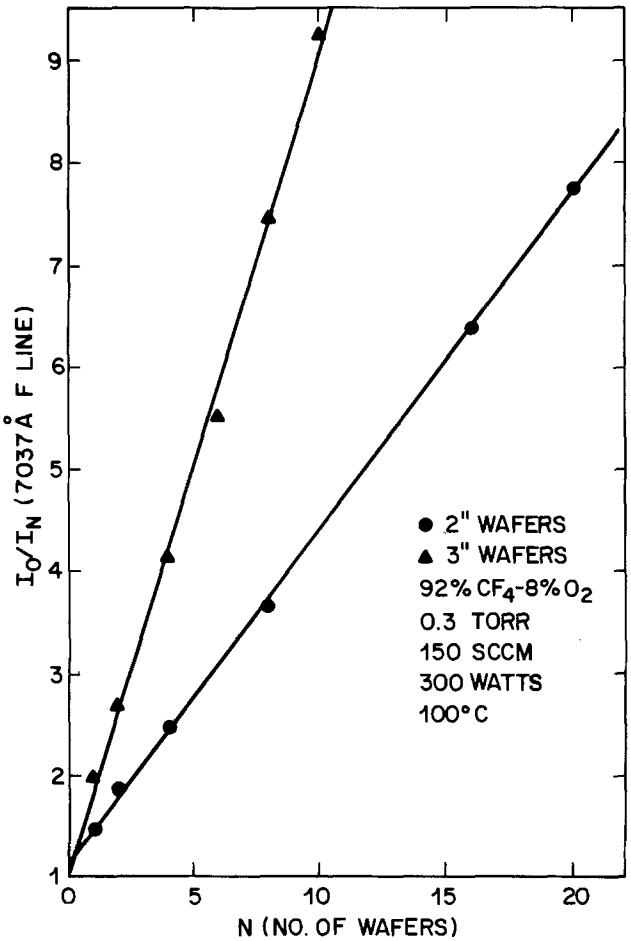

Fig. 4. The ratio of emission intensity of excited F for an empty reactor to the intensity when N wafers are etching plotted vs. N.

The data are plotted in the form suggested by Eq. [13]. Intensities were measured after 5 min of etching to ensure steady-state readings. The lines drawn through the data points are least squares fits. Note that the lines have a unit intercept (within experimental error), as predicted by Eq. [13]. According to Eq. [13], the ratio of the slopes of the lines in Fig. 4 (3 *vs.* 2 in. wafers) should be proportional to the ratio of wafer areas which is $3^2/2^2 = 2.25$. The measured ratio of slopes for the least squares lines is 2.4, which is in reasonable agreement considering that the wafer surfaces roughen somewhat during etching. This has the effect of increasing the surface area in proportion to the geometric area, which would tend to make the ratio of slopes greater than 2.25 as observed.

Discussion

Loading effects.—According to Eq. [10], loading effects can be expected whenever

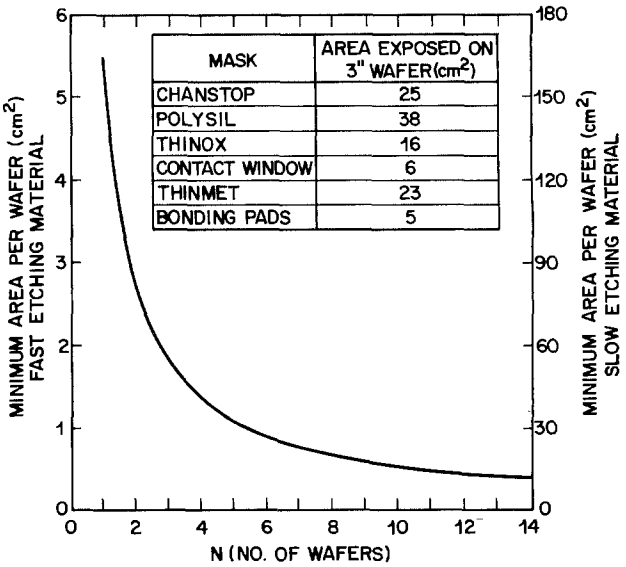
$$\beta\tau \frac{dA_W}{V} N \sim 1 \qquad [14]$$

whereas no loading will occur when

$$\beta\tau \frac{dA_W}{V} N << 1 \qquad [15]$$

It follows that, for a given load and mask pattern, loading can be suppressed only by increasing the plasma volume V. Of course, there are physical limitations to the extent to which this alternative can be pursued. It can also be seen that, for a given amount of exposed material per wafer (A_W), loading will be more prevalent for faster etching materials (large β) and for species with a long lifetime (large τ). This simply reflects the fact that the active species will be

used up more quickly when the higher etch rate material is present. Loading is, of course, a natural consequence of competition for the etchant in what amounts to a very "dilute solution." The plasmas used in plasma etching are rather weak (electron density $\sim 10^9/cm^3$).



When loading effects are present, specification of etch rate should be made with reference to the amount of material being etched. Alternatively, the etch rate for a small quantity of material ($A_W N \to 0$) should be measured and reported as R_o. If the etch rate can be measured for two different loads, the linear relation given by Eq. [12] can be used to predict etch rates for other load sizes by extrapolation or interpolation. This is easily done by plotting R_N^{-1} *vs.* N for two points, and drawing a straight line between them.

Obviously, if there is more than one material etching on a wafer, the material with a maximum βA_W product will dominate loading. Thus when masked wafers with exposed Si backs are etched in a vertical position, typical of some reactor designs, the back of the wafer will cause loading even if the front side contains only a small area of slowly etching material, which by itself, would produce no loading.

End-point detection.—Two means of determining the end point of etching, both based on frequency-selective detection of optical emission from the plasma, have been suggested (1-3). In the first method, emission from an etching product is detected. It is apparent that when a reaction product, unique to the material being etched, can be detected by some means, the end point can be determined with a sensitivity equivalent to that of the detector employed. Alternatively, when the etch-active species generated in the plasma can be identified and detected, changes in the concentration of this reactant can be used as an end-point indicator. In this case, however, the sensitivity of the technique is dependent both on the capability of the detector and the extent to which a loading effect is present. This follows immediately from Eq. [13] and [14], since this method depends on detecting an increase in the intensity of a signal proportional to the reactant concentration at the completion of etching.

It is instructive to estimate the sensitivity of the latter technique for a rapidly etching material such as Si and a more slowly etching material such as SiO_2, assuming that the over-all sensitivity is limited by the extent of loading rather than by the detector. From the slopes of the lines in Fig. 4 we find $\beta\tau \simeq 5 \times 10^{-23}$ cm^4 (at 100°C). For Si, $d \cong 2 \times 10^{23}/cm^3$ and for the present reactor $V \simeq 550$ cm^3. It follows that for loading to be detectable, requiring say a 10% change in intensity, we must have $A_W N \gtrsim 0.1V/\beta\tau d \cong 5.5$ cm^2 for Si.

Atomic fluorine is also the major active species for etching SiO_2 in a CF_4 plasma. For conditions equivalent to those used in etching Si (Fig. 3 and 4), the etch rate of thermally grown SiO_2 is approximately 30 times less than R_o for Si. Thus, to a first approximation, $\beta\tau$ for SiO_2 is 1/30 of that for Si. Accordingly, for SiO_2 etching, $A_W N \gtrsim 165$ cm^2 is required. These conditions are expressed graphically in Fig. 5, which shows the minimum area of etchable material per wafer needed to make end-point detection, by monitoring a reactant, feasible for "fast" (left-hand ordinate) and "slow" (right-hand ordinate) etching materials, as a function of N. Also shown in Fig. 5 is a table listing the approximate area of etchable material per wafer exposed by various masks typical of an SIC fabrication process, using a CMOS technology, for 3 in. diam wafers. These values were obtained from densitometer measurements on working masks. It is evident from Fig. 5 that even a single 3 in. wafer will permit detection with a rapidly etching material such as polysilicon. On the other hand, plasma etching of contact windows through a slowly etching dielectric

MASK	AREA EXPOSED ON 3" WAFER(cm^2)
CHANSTOP	25
POLYSIL	38
THINOX	16
CONTACT WINDOW	6
THINMET	23
BONDING PADS	5

Fig. 5. A plot of the minimum area of etchable material per wafer which must be exposed in order to detect the end point of etching, by a change in the concentration of the active species in the plasma, as a function of the number of wafers being etched. It is assumed that a 10% change in signal is the minimum that can be sensed. The table gives typical values of total exposed area for various mask levels representative of CMOS integrated circuit fabrication for 3 in. diam wafers.

will be difficult to monitor for typical, maximum batch sizes, whereas etching of SiO_2 at the Thinox level would require a minimum load of $\approx$ 10, 3 in. wafers.

In the event that the exposed area is insufficient to allow end-point detection, one might consider including a "monitor wafer" covered with a sufficient area of the material to be etched. This would require that the monitor and device wafers etch at the same rate, despite the absence of masking on the monitor.

The factors β, τ, and G.—The factor β was introduced in Eq. [7] to relate the etch rate to the concentration of etch-active species formed in the plasma. β thus has the form of a kinetic rate constant for the reaction which produces etching. Accordingly, one can anticipate that β will be temperature dependent and, in particular, if the reaction occurs via some thermally activated process, that this temperature dependence will have an Arrhenius form ($\beta = \beta_o e^{-Q/kT}$, where Q is the activation energy, k is Boltzmann's constant, T is the absolute temperature of the etching surface, and β_o is a pre-exponential constant). On the other hand, since β mainly reflects processes occurring on the solid surface, it is likely to be independent of plasma parameters such as power and pressure, provided that the reaction mechanism and the etch-active species do not change with power and pressure. Of course, in reactors where wafer temperature control cannot be maintained, an increase in power will cause wafer heating and thereby indirectly influence β.

The lifetime, τ, will depend on the various processes, exclusive of etching, which consume active species (*e.g.*, bulk and surface recombination, adsorption, and removal by convection). It is likely then that τ will depend on system geometry, materials of construction, reactor temperature, vacuum integrity, and probably other less obvious factors. In any case, one can reasonably expect that τ will vary from reactor to reactor for a particular active species. With respect to flow processes it seems plausible that τ will take the form

$$\frac{1}{\tau} = \frac{1}{\tau_r} + \frac{1}{\tau_f} \qquad [16]$$

where τ_f is the flow-limited lifetime, and τ_r is the lifetime due to all other consumption processes. Thus,

when flow rates become high enough so that $\tau_f << \tau_r$, the etch rate will become flow limited. In this limiting case, active species will be swept through the system too rapidly to accomplish etching. The residence time ($\sim\tau_f$) for the average molecule flowing through the system illustrated in Fig. 1 is of the order of a few tenths of a second at an input flow rate of 200 SCCM. This time is large compared to the expected range for τ_r (7). This implies that, at the maximum flow rates which can be sustained with the pumping speeds normally employed with plasma reactors, an etch rate controlled by convective losses is unlikely. We note, however, that a report on plasma stripping of photoresists indicates a stripping rate inversely proportional to flow rate, at high flow rates (8). [Note that $\tau_f \propto$ (flow rate)$^{-1}$.] In the system used in the present work the etch rate of Si is essentially independent of flow rate up to the maximum flow rate attainable (~300 SCCM) at a pressure of 0.4 Torr.

It is difficult to estimate the effect of parameters such as power, pressure, and temperature on τ except to say that recombination and adsorption processes are likely to show a strong pressure dependence.

It is evident from Eq. [10] that β and τ cannot be determined individually from etch rate data since only the product $\beta\tau$ appears. Experimentally, we have found that while Eq. [12] and [13] are consistently obeyed for plasma etching of Si wafers, the empirically determined values of $\beta\tau$ vary from day to day for experiments made under nominally identical conditions. The variation can be as much as a factor of two. Thus, for example, from the slope and intercept of the least squares fitted line in Fig. 3, $\beta\tau \simeq 3 \times 10^{-23}$ cm^4, while the slopes of the lines in Fig. 4 give $\beta\tau \simeq 5 \times 10^{-23}$ cm^4. It is believed that this may reflect the dependence of τ on the history of the reactor; for instance, on the surface condition of the Pyrex chamber which contains the plasma and is itself etched slowly and roughened.

The generation rate of active species (G) will depend on pressure and power. In order to determine this dependence one must first know the particular mechanism by which the active species are generated. For example, if the active species are generated by collisions of parent gas molecules with free electrons, the rate of generation will depend on the electron density and the frequency of collisions of a type which produce the active species. These parameters, in turn, will depend on the electron energy distribution and the variation of collision cross section with electron energy. A detailed discussion of these factors is beyond the scope of this paper. It suffices to say that if the electron energy distribution and the appropriate collision cross sections were known as a function of power and pressure, one could relate G directly to power and pressure. However, this is not a simple problem even in the limiting case where the plasma is assumed to be in equilibrium.

An empirical value of G can be derived from Eq. [12] and the slope of the line in Fig. 3. Thus, at 0.3 Torr, 300W in a CF_4-8%O_2 plasma, the empirical rate of generation of fluorine atoms is $\sim 10^{16}$ cm^{-3} sec^{-1}. Since the electron density in a plasma of this type is of the order of 10^9-10^{10} cm^{-3} and the collision frequency is of the order of 10^9 sec^{-1}, this implies that about one collision in every 10^2 or 10^3 is effective in producing a fluorine atom.[4]

Determination of activation energy.—Recent results in this laboratory and elsewhere have indicated that the plasma etch rates of several materials exhibit an Arrhenius type of temperature dependence (8-10). Generally, the empirical activation energies are low, being no more than a few tenths of an electron volt per molecule. As regards experimental determination of activation energy, it is important to note that, for materials which exhibit a loading effect, a plot of the logarithm of etch rate *vs.* reciprocal absolute temperature, even if strictly linear, will not necessarily yield the proper activation energy. This is most easily seen by example.

Suppose the temperature dependence of etch rate is determined by etching a single wafer at several temperatures while holding all other conditions fixed. According to Eq. [10] for this case ($N = 1$)

$$R_1 = \frac{\beta\tau G}{1 + \beta\tau d\dfrac{A_W}{V}}$$

It is apparent that if the temperature dependence resides in the parameter β according to $\beta = \beta_0 e^{-Q/kT}$, and if loading is not negligible (*i.e.*, if $\beta\tau d\ A_W/V$ is not $<<1$), then the logarithm of R_1 is not linear in T^{-1}. Nevertheless, the data are likely to produce a reasonable fit to a straight line because of the small activation energies and the characteristics of logarithmic scaling. The activation energy so determined will be in error.

As an illustration of the magnitude of the error, we have measured the etch rates for a single 3 in. Si wafer as a function of temperature and plotted them on a logarithmic scale against reciprocal temperature in Fig. 6. We have also derived values of $\beta\tau$ from the slopes of plots such as shown in Fig. 4 (see Eq. [13]) where the intensity data were measured at several different temperatures. These values are also plotted in Fig. 6.

The activation energy derived from the $\beta\tau$ values is $\simeq$0.1 eV/molecule, whereas the etch rate data when plotted directly yield $\simeq$0.04 eV/molecule. Two conclusions can be drawn from this. First, when loading is present, the magnitude of the apparent activation energy, derived from an Arrhenius plot of each rate, will depend on the size of the load. Second, the parameter β (or at least the product $\beta\tau$) contains the temperature dependence of etch rate as hypothesized previously.

The simplest way to determine the activation energy is to measure the etch rate on a quantity of etchable material small enough to preclude loading. That is, A_W should be reduced to the point where Eq. [15] holds at all temperatures of interest. In that case an Arrhenius plot of R_N will yield the correct value of activation energy.

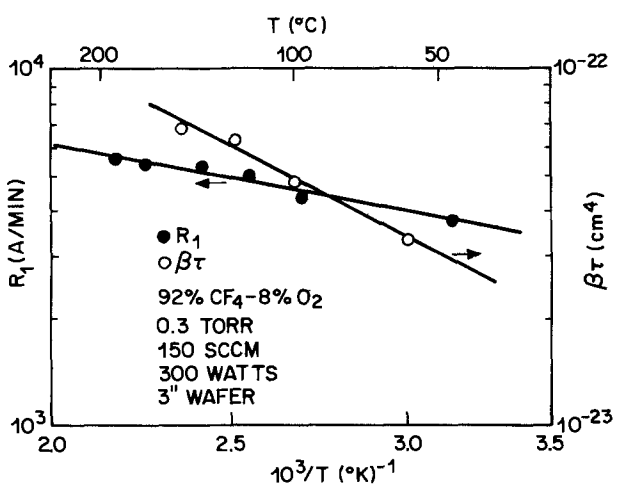


Fig. 6. Variation of the etch rate for a 3 in. diam Si wafer as a function of temperature, displayed on an Arrhenius plot. On the same plot is shown the experimentally determined variation of $\beta\tau$ with temperature. The activation energy, determined from the etch rate plot, is less than the true value, determined from the $\beta\tau$ plot, because of loading.

[4] The mechanism for F atom production in the CF_4-O_2 plasma is not known; however, electron-molecule collisions presumably are an essential part of the production process.

Conclusions

A phenomenological equation has been derived which correctly predicts the loading effect observed in a horizontal, radial flow, plasma etching reactor. This equation relates the observed etch rate to the quantity of material being etched. The loading effect is dependent upon: (*i*) the affinity of the material being etched for the active species created in the plasma; (*ii*) the area of exposed material; (*iii*) the plasma volume; and (*iv*) the lifetime of the active species. Specifically, the reciprocal of etch rate has been shown to be a linear function of the quantity of material being etched. Consequently, linear extrapolation or interpolation can be used to predict the variation of etch rate with load if the etch rates for two different loads are measured for a particular reactor and set of etching conditions (gas composition, power, pressure, temperature, etc.).

Detection of the end point of plasma etching by monitoring the concentration of etch-active species in the plasma is useful only when sufficient loading occurs. In particular, for SIC fabrication, the applicability of this method depends, in part, on the amount of etchable material exposed by a given mask.

In principle, etch rate can be related to the experimental variables, power, pressure, and temperature through three phenomenological parameters β, τ, and G. However, to arrive at the analytical dependence of each of these parameters on the experimental variables would require a detailed mechanistic picture of plasma etching which is presently unavailable. Nevertheless, some reasonable inferences regarding the qualitative dependences of these parameters on power, pressure, and temperature can be drawn.

Finally, it was pointed out that simple Arrhenius plots of etch rate can yield erroneous values for the activation energy of plasma etching when loading occurs.

ABSTRACT

Ionic and electronic conductivity has been measured in $AgCrS_2$ and $AgCrSe_2$. Ionic conductivity was measured by using $RbAg_4I_5$ as a blocking electrode for electronic conduction. Transference numbers were confirmed by cells of the type $Ag/AgCrX_2/X,C$. Ionic conductivities were 3×10^{-4} and $\sim 1\ (\Omega\text{-cm})^{-1}$ for $AgCrS_2$ and $AgCrSe_2$, respectively, at room temperature. The conductivity of $AgCrS_2$ increases abruptly at $\sim 170°C$ to $\sim 1\ (\Omega\text{-cm})^{-1}$. A transition at this temperature was observed by DSC.

A large number of compounds of the general formula AMX_2 (*e.g.*, A = Ag, Cu, Li, Na; M = Cr, Ti, Zr, Ta, Nb; X = S, Se) exhibit structures containing two-dimensional layers of A and M (1). That ionic mobility of A is high in a number of these compounds is evidenced by the formation of a number of them from the MX_2 at ambient temperature. Lithium NMR also indicates rapid Li ion motion in a number of these compounds with A = Li (2). Since many of these compounds form a continuous phase from MX_2 to AMX_2, they are interesting as cathodic electrodes in batteries, especially for A = Li (3). Direct measurement of the ionic conductivity in these compounds has been lacking because of their high electronic conductivity (4).

As a starting point in determining ionic conductivity in AMX_2, we chose to investigate $AgCrS_2$ and $AgCrSe_2$. The electronic conductivity is less than many of the others, and techniques to separate ionic and electronic

Key words: silver, chalcogenide, ionic conductivity.

conductivity exist for Ag ion conductors. Engelsman *et al.* (5) reported that the structure of $AgCrS_2$ and $AgCrSe_2$ contained CrX_2^- sandwiches with the Ag^+ in half of the tetrahedral holes. The structure of the Ag-S layers is shown in Fig. 1. The Ag ions exhibited anomalously large and anisotropic thermal parameters at room temperature, and at higher temperatures (202°C for $AgCrSe_2$ and 397°C for $AgCrS_2$) a reversible phase transition occurred involving a random distribution of the Ag^+ over all tetrahedral sites between the CrX_2^- layers. Thus, it was expected that the ionic conductivity might be large at room temperature and might increase sharply at the phase transition.

The α-phases of Ag_2S and Ag_2Se are known to be superionic Ag ion conductors. The electronic conductivity is appreciably larger than the ionic conductivity (6). The $\beta \rightarrow \alpha$ transitions occur at 180°C (Ag_2S) and 132°C (Ag_2Se), respectively, and a second transition occurs in Ag_2S at 350°C.

Experimental

The $AgCrS_2$ and $AgCrSe_2$ powders were prepared from stoichiometric mixtures of the binary chalcogenides. The mixtures were heated to 700°C for 1 week, then cooled to room temperature over several hours. X-ray powder patterns agreed well with the literature values, and care was taken that no unreacted Ag_2S or Ag_2Se was present.

The conductivity and electromotive cells were formed by pressing the $AgCrS_2$ or $AgCrSe_2$ powder into 2 mm inner diameter thick walled Pyrex tubes of ~4 cm length. Graphite rods were press fit into the tubes for external electrical contact. The powder thickness varied from a few millimeters to greater than 1 cm. The tubes were subsequently annealed for 1-2 hr in N_2 or Ar to 450°C for $AgCrS_2$ and 350°C for $AgCrSe_2$ prior to making electrical measurements. For total conductivity measurements (*i.e.*, cells of the type $Ag/AgCrS_2/Ag$), powdered Ag electrodes were pressed into the Pyrex tubes. For measurements of ionic conductivity (cells of the type $Ag/RbAg_4I_5/AgCrS_2/Ag$) an ~1-2 mm thick layer of $RbAg_4I_5$ was pressed into contact with the sulfide or selenide and was in turn contacted by the Ag. The technique of blocking the electronic component of the conductivity by interposing a layer of AgI or $RbAg_4I_5$ is well documented, and is confirmed in our experiments as discussed below. The Pyrex tubes were then placed in a cylindrical bore aluminum block on which was mounted a Fe-constantan thermocouple, and placed inside a box furnace. Sufficient time was allowed between measurements for the system to equilibrate, and for annealed samples, no hysteresis occurred between measurements made on the up and down heating cycles.

Two point resistance measurements were made with a Hewlett Packard Type 4800 A vector impedance meter, in which the measuring frequency could be varied from 0.5 Hz to 0.5 MHz. For cases in which the resistance was frequency dependent, the resistance was extrapolated to infinite frequency. The frequency-dependent part was attributed to contact capacitance (7), the effects of which disappeared within the frequency range of the instrument. The reproducibility in the electrical measurements between different cells was ~30% for conductivities less than ~1 $(\Omega\text{-cm})^{-1}$ and approximately a factor of 2 or 3 for conductivity greater than ~1 $(\Omega\text{-cm})^{-1}$. This reduced reproducibility was partly due to the error in subtracting lead resistance and the $RbAg_4I_5$ resistance which became a significant fraction of the total resistance.

For measurement of the electromotive force, cells of the type $Ag/AgCrS_2/S,C$ and $Ag/RbAg_4I_5/AgCrSe_2/Se,C$ were formed (8). Twenty-five percent graphite mixed with the sulfur or selenium served to make the electrode both electronically and ionically conducting. The resulting emf (open-circuit voltage) was measured with a Keithley Model 610C electrometer.

Specific heat measurements were performed with a Perkin Elmer differential scanning calorimeter. Several scans were made for each compound under various quenching and annealing treatments.

Results

The total and ionic conductivities of $AgCrS_2$ and $AgCrSe_2$ were measured from room temperature to ~200°C in cells of the type $Ag/AgCrS_2/Ag$ and $Ag/RbAg_4I/AgCrS_2/Ag$. At room temperature, the ionic conductivity of $AgCrS_2$ is moderately high [$\sim 3 \times 10^{-4}$ $(\Omega\text{-cm})^{-1}$] with the total conductivity being about twice the ionic conductivity as seen in Fig. 2. The ionic conductivity increased exponentially with an activation energy of 0.4 eV until ~150°C, where a transition to a highly conducting state begins with a leveling of the conductivity near 170°C. The ionic conductivity above 170°C is of the same magnitude as those for α-AgI and $RbAg_4I_5$. However, the total conductivity above the transition is several times larger than the ionic.

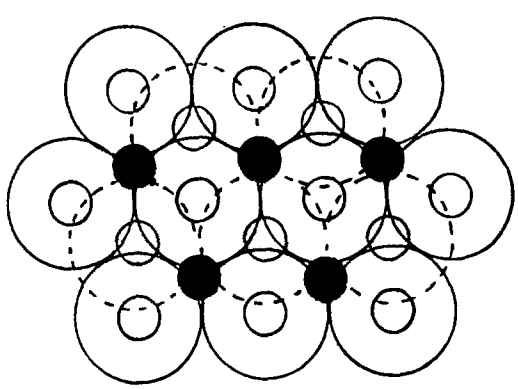

Fig. 1. The two dimensional sites available to Ag. Also shown are X in adjacent layers and alternative octahedral sites occupied by Li in $LiCrS_2$. ●, Octahedral, M directly above and below metal slabs; ○, tetrahedral sites (2 per M).

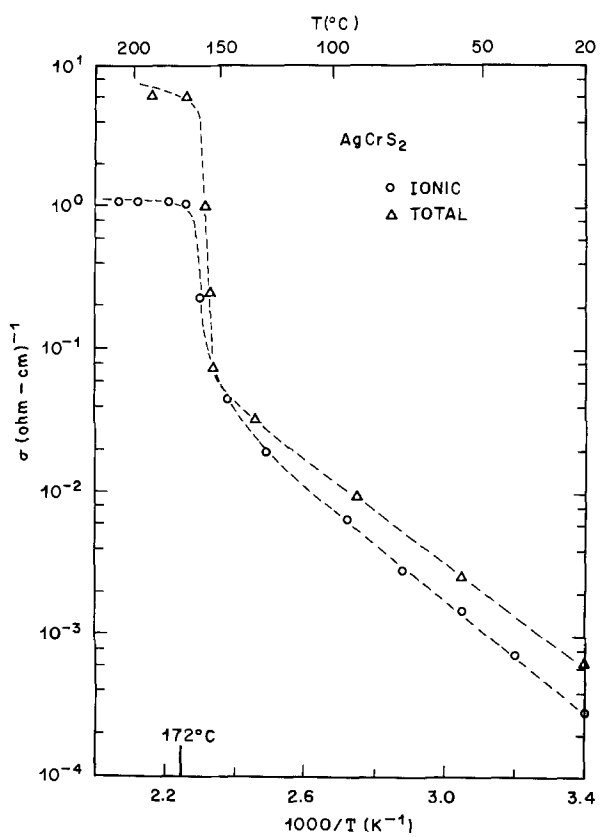

Fig. 2. The ionic and total conductivity of $AgCrS_2$ as a function of reciprocal temperature.

The electrical evidence of a phase transition in $AgCrSe_2$ is not so dramatic, since $AgCrSe_2$ is already highly conducting at room temperature as seen in Fig. 3. The ionic conductivity at room temperature is comparable to that of Ag_4RbI_5, but the electronic component is several times larger than the ionic component. The ionic conductivity increases with an activation energy of 0.11 eV, comparable to those measured for other Ag superionic conductors (9).

Electromotive force measurements serve as a useful complement to conductivity measurements. They confirm the presence of ionic conductivity and can determine the ratio of ionic to total conductivity. The open-circuit voltage of cells of the type $Ag/AgCrS_2/S,C$ and $Ag/AgCrSe_2/Se,C$ were measured from room temperature to ~200°C. The voltage E depends on the ionic transference number t_i by the relationship (8)

$$E = t_i E_0$$

where E_0 is the thermodynamic equilibrium potential and $t_i = \sigma_i/\sigma_t$ is the ratio of ionic conductivity to total conductivity. At room temperature, E_0 equals 0.21V for Ag_2S and 0.26V for Ag_2Se. The room temperature open-circuit voltage for the sulfide cell was in the range of 0.12-0.18V (depending on thermal treatment). This reflects the fact that the magnitude of the ionic and electronic conductivity are comparable. Above room temperature, the voltage decreases slowly until a sudden drop occurs in the same temperature vicinity where the conductivity transition occurs. This is illustrated in Fig 4. The drop is presumably due to the more rapid increase in the electronic conductivity compared to the ionic conductivity at the transition.

For cells of $Ag/AgCrSe_2/Se,C$, the open-circuit voltage was in the millivolt range, reflecting the fact that the electronic conductivity is significantly higher than the ionic conductivity. Cells of the type $Ag/Ag_4RbI_5/AgCrSe_2/Se,C$ were also formed, and the full expected open-circuit voltages (0.26V at 20°C and 0.285V at 200°C) were obtained. This result confirms that the

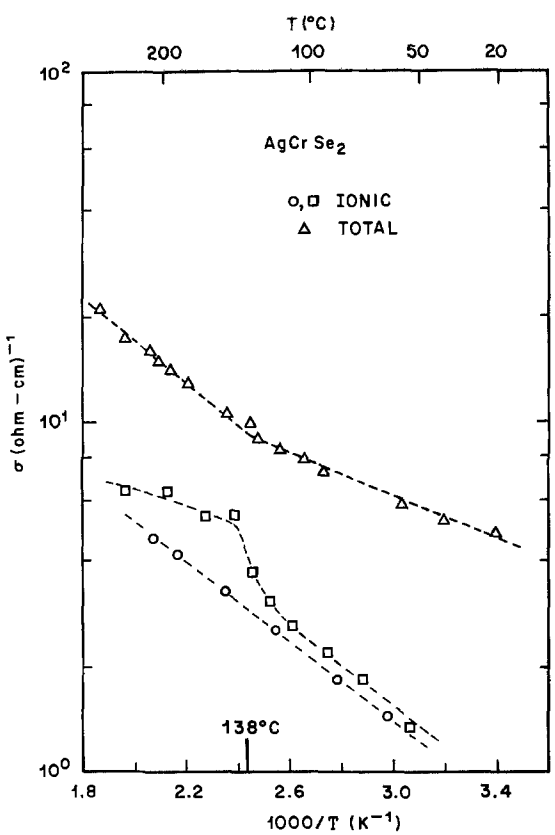

Fig. 3. The ionic and total conductivity of $AgCrSe_2$ as a function of reciprocal temperature. The ionic conductivity is shown for two samples.

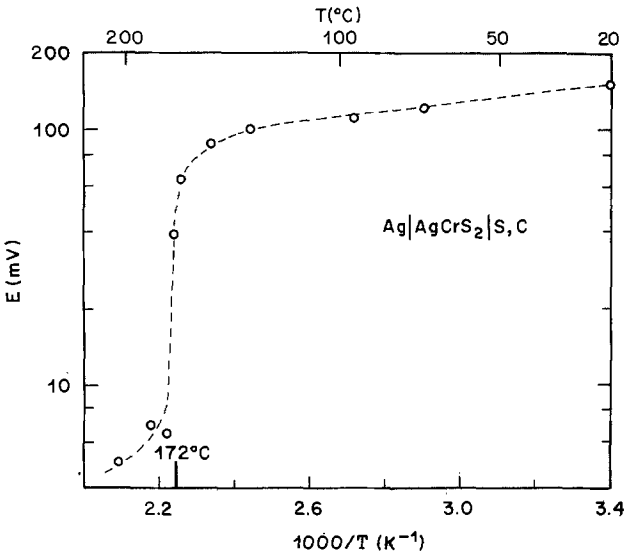

Fig. 4. Open-circuit voltage for the cell $Ag/AgCrS_2/S,C$

Ag_4RbI_5 effectively blocks the electronic component of the conductivity.

The occurrence in $AgCrS_2$ of the rapid increase in conductivity and the rapid decrease in cell potential near 170°C led us to suspect the presence of a phase transition. However, previous neutron diffraction and DTA work did not indicate any anomalies near 170°C in $AgCrS_2$ (5). However, our measurement of the specific heat of $AgCrS_2$ revealed transitions at 172° and 400°C. The 400°C transition corresponds closely to the transition previously attributed to a Ag ion disorder. The latent heat is ~100 cal/mole at 172°C and ~250 cal/mole at 400°C. This is illustrated in Fig. 5a. The specific heat of $AgCrSe_2$ was also measured. Again, as illustrated in Fig. 5b, two anomalies are observed, at 138° and 205°C. The 205°C transition corresponds closely to that previously observed by neutron diffraction and DTA and ascribed to the Ag ion disorder. The total heat involved is around 250 cal/mole, with ap-

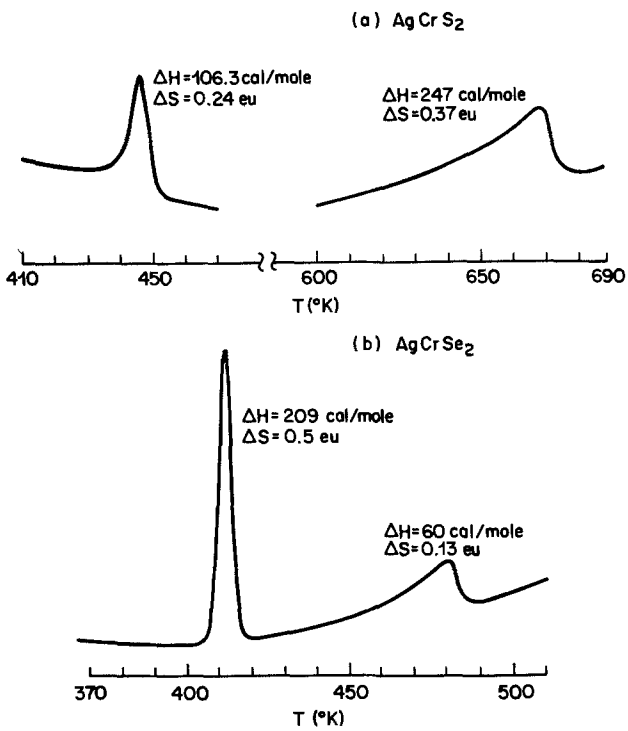

Fig. 5. Differential scanning calorimeter spectra for (a) $AgCrS_2$ and (b) $AgCrSe_2$. The latent heat and entropy of each transition are noted.

proximately 200 cal/mole in the transition at 138°C. The distribution is opposite to the case for $AgCrS_2$ where most of the latent heat is in the high temperature transition.

Discussion

Similar to Ag_2S and Ag_2Se (6), $AgCrS_2$ and $AgCrSe_2$ exhibit both high ionic and electronic conductivity at moderate temperatures. However, the ionic conductivity of $AgCrSe_2$ is high at room temperature as well, in contrast to Ag_2Se. The transformation temperatures as determined by DSC are comparable, but the latent heats are quite different. The low temperature transitions in AgI (9) and Ag_2S (9) (the $\beta \rightarrow \alpha$ transformations) involve significant changes in crystallographic structure, whereas the change in Ag_4RbI_5 (9, 10) is more subtle. These transformations make available equivalent sites for the Ag ions resulting in a large increase in the ionic mobility and consequently the conductivity. As previously mentioned, neutron diffraction data on $AgCrS_2$ and $AgCrSe_2$ did not reveal any structure changes below the complete disordering transformation, but small subtle changes might go undetected.

It is interesting to compare the latent heats for the low temperature transformations which involve crystallographic symmetry changes as given in Table I. For significant changes (AgI from hexagonal to bcc and Ag_2S from monoclinic to bcc) in crystal structure, the latent heat is large, being approximately 1 kcal/mole for both materials. For $RbAg_4I_5$, $AgCrS_2$, and $AgCrSe_2$ the latent heat is less by a factor of 5, indicative of a smaller change in structure. There is also a trend in the conductivity change at the transition temperature. The larger structural changes in AgI and Ag_2S result in larger conductivity changes. These results are also given in Table I.

Table I. The transition temperatures, latent heats, and conductivity increases at the lower temperature transition in several Ag compounds

Compound	T (°K)	Ref.	Latent heat (kcal/mole)	Ref.	Conductivity increase	Ref.
AgI	421	(11)	1.5	(11)	10^4	(12)
Ag_2S	450	(13)	0.95	(13)	10^2-10^3	(6)
Ag_4RbI_5	122	(14)	0.19	(14)	10^2	(15)
$AgCrS_2$	445	*	0.11	*	25	*
$AgCrSe_2$	405	*	0.21	*	1.2	*

* This work.

Conclusion

The ionic conductivity in $AgCrS_2$ and $AgCrSe_2$ is quite similar to that in Ag_2S and Ag_2Se, even though the structure is more open. It is dangerous to extrapolate data for Ag ion mobility in these compounds to Li or Na ion mobility since the sites occupied are different (tetrahedral *vs.* octahedral) and the types of transition states the ions may accommodate are different.

The Thermoluminescence Characteristics of Binary Sulfate Phosphors

M. Sakaguchi, M. Ohta, K. Nakazato, and T. Kondoh

Department of Applied Chemistry, Faculty of Engineering, Niigata University, Nagaoka, Niigata, Japan

ABSTRACT

The effect of the physicochemical structure of the matrices used on the thermoluminescence (TL) characteristics of TL phosphors [$(K_{1-x}Na_x)_2SO_4$:Tl^+, $Ba_{1-y}Mg_ySO_4$:Eu^{3+}, and $K_{2(1-z)}Ca_zSO_4$:Tl^+], has been investigated by using TL analytical, x-ray powder diffraction, and radioactive (^3H-H_2O) methods. All kinds of phosphors exhibited the brightest TL at such matrix compositions as $K_3Na(SO_4)_2$, $BaMg(SO_4)_2$, and $K_2Ca_2(SO_4)_3$ which were thermally stable compounds. On $(K_{1-x}Na_x)_2SO_4$:Tl^+ phosphors, the solubility of the larger Tl^+ ion in the matrix was enhanced due to the presence of smaller Na^+ ions (volume compensation); therefore, the TL intensity increased relative to the K_2SO_4:Tl^+ phosphor. The TL center was destroyed by the escape of bound water released mostly near the temperature at which the rotation of SO_4^{2-} radical becomes activated, and the TL intensity decreased simultaneously. On $Ba_{1-y}Mg_ySO_4$:Eu^{3+} and $K_{2(1-z)}Ca_zSO_4$:Tl^+ phosphors, each TL intensity increased abruptly in the initial stage of firing due to the crystallization of the compounds [$BaMg(SO_4)_2$ and $K_2Ca_2(SO_4)_3$].

One-component crystals of alkali or alkaline earth sulfates have been extensively utilized as a matrix in thermoluminescence (TL) phosphors, however, few binary sulfate crystals have been done yet. Sakaguchi *et al.* (1) have previously reported that β-ray irradiated K_2SO_4:Tl^+ phosphors emitted TL, and in the binary sulfate phosphor [$K_3Na(SO_4)_2$:Tl^+], which was prepared by using as a matrix the crystals obtained by reacting K_2SO_4 with Na_2SO_4, the TL intensified remarkably. Ryan *et al.* (2) and Blasse *et al.* (3, 4) reported that the activated $BaMg(SO_4)_2$ phosphors exhibited optical spectra characterized by sharp fluorescence. Also, Soudagar and Narayana (5) reported that (Ba:Sr)SO_4:Ce^{3+} and (Ba:Cd)SO_4:Ce^{3+} phosphors exhibited an extremely bright TL following x-ray irradiation. These results have suggested that the binary sulfate crystals could have interesting properties as phosphor hosts. In this paper, the TL character of the binary sulfate phosphors such as $(K_{1-x}Na_x)_2SO_4$:Tl^+, $Ba_{1-y}Mg_ySO_4$:Eu^{3+}, and $K_{2(1-z)}Ca_zSO_4$:Tl^+ is studied in connection with the crystal growth of these matrices.

Experimental

The phosphors used, $(K_{1-x}Na_x)_2SO_4$:Tl^+, $Ba_{1-y}Mg_ySO_4$:Eu^{3+}, and $K_{2(1-z)}Ca_zSO_4$:Tl^+, were prepared as follows. In $(K_{1-x}Na_x)_2SO_4$:Tl^+ phosphors, one set of samples was prepared by evaporation to dryness of a mixed aqueous solution of K_2SO_4, Na_2SO_4, and Tl_2SO_4 with various molar ratios followed by vacuum drying at 130°C for 2 hr (unfired phosphors); the other samples were prepared by firing the unfired phosphors at 250°-1000°C for 1 hr in He (fired phosphors). Unfired and fired phosphors which were used to determine the amount of bound water were prepared by the above-mentioned method using ^3H-labeled water as a tracer. Different compositions involving mixtures of $BaSO_4$, $MgSO_4$, and $Eu_2(SO_4)_3$ were prepared by careful blending with methanol followed by vacuum drying at 130°C for 1 hr, then $Ba_{1-y}Mg_ySO_4$:Eu^{3+} phosphors were prepared by firing the mixtures at 600°-1200°C for 0-6 hr in air. $K_{2(1-z)}Ca_zSO_4$:Tl^+ phosphors were prepared by firing mixtures of K_2SO_4, $CaSO_4$, and Tl_2SO_4 (blended by a similar procedure) at 500°-1000°C for 0-8 hr in He, O_2, or air. The time interval required to reach the firing temperature was adjusted to be 30 min in all cases, and the firing time denoted as zero means that the firing was stopped instantly at the given temperature.

He and O_2 used for the firing atmosphere were obtained by further purifying cylinder He or O_2 by passage through a glass tube containing molecular sieve 5A at −196°C for He or at 0°C for O_2.

The static apparatus used for preparing phosphors in He or O_2 was constructed of borosilicate glass tubing except for a reaction tube made of quartz, and a sample vessel was made of quartz for $(K_{1-x}Na_x)_2SO_4$:Tl^+ phosphors or of platinum for $K_{2(1-z)}Ca_zSO_4$:Tl^+ phosphors. Alumina crucibles were used for preparing phosphors in air.

Glow curves were measured using a TL analyzing system composed of the thermoluminescence dosimetry (TLD) (Aloka Company, Limited, Type TLR-101B), electrometer (Takeda Riken Industry Company, Limited, Type TR-8651), and X-Y recorder (Riken Denshi Company, Limited, Type F-3C). Thirty milligrams of phosphor were uniformly spread on the tray (14.5 mmϕ × 2 mm) made of silver, and the glow curve was immediately recorded after the phosphor was exposed to the β-ray source (^{90}Sr, 100 μCi) at a distance of 2 mm at 25°C for 10-180 sec. Furthermore, in order to eliminate the effect of cosmic and other external radiation on TL, all phosphors were preheated up to 260°C prior to the β-ray irradiation.

The crystal structure of the phosphors was examined by x-ray powder diffraction method using nickel-filtered Cu radiation.

The amount of bound water in $(K_{1-x}Na_x)_2SO_4$:Tl^+ phosphors prepared by using ^3H-labeled water was determined by the liquid scintillation countermethod with PCS scintillant (supplied by Amersham/Searle Company).

Results and Discussion

$(K_{1-x}Na_x)_2SO_4$:Tl^+ phosphors.—These phosphors exhibited similar glow curves with two glow peaks at 100° and 160°C. The height of the 100°C peak was selected to compare with that of K_2SO_4:Tl^+ phosphor reported previously (1).

X-ray powder diffraction traces on unfired phosphors showed formation of $K_3Na(SO_4)_2$ (glaserite) (6). Figure 1 shows the relation between the amount of $K_3Na(SO_4)_2$ crystals produced and the TL intensity in these phosphors. The TL intensity increased with the diffraction peak intensity of glaserite, and it indicated a maximum for the phosphor prepared with the matrix composition at x near 0.3. A similar exami-

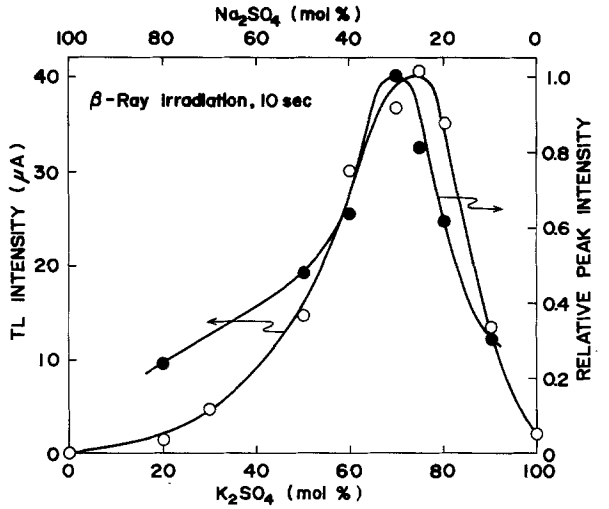

Fig. 1. Relation between the TL intensity and the (110) diffraction peak intensity of $K_3Na(SO_4)_2$ crystals in unfired $(K_{1-x}Na_x)_2SO_4$:Tl^+ (2.5 m/o) phosphors.

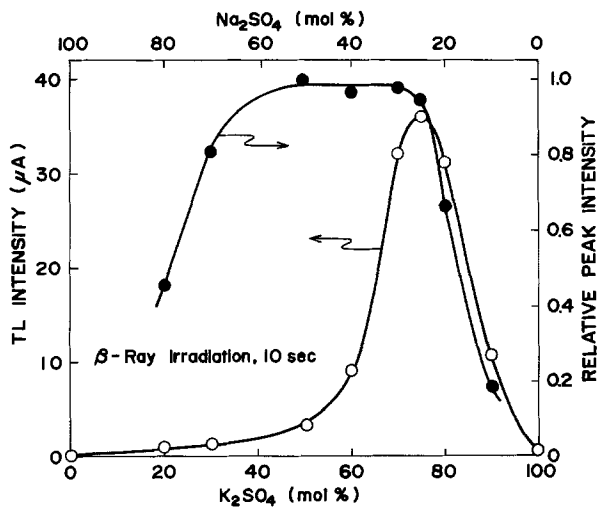

Fig. 2. Relation between the TL intensity and the (110) diffraction peak intensity of $K_3Na(SO_4)_2$ crystals in $(K_{1-x}Na_x)_2SO_4$:Tl^+ (2.5 m/o) phosphors fired at 750°C for 1 hr in He.

nation was carried out on fired phosphors (Fig. 2). A higher yield of glaserite structure was obtained over a wide range of composition, in contrast to the fixed composition in unfired phosphors. Nevertheless, the higher TL intensity was limited to the phosphor prepared at the calculated composition, *i.e.*, $K_3Na(SO_4)_2$. Hence the TL character on both unfired and fired phosphors, which were prepared with $K_3Na(SO_4)_2$ crystals as a matrix, was subsequently investigated.

The phosphors had a maximum in TL intensity at Tl^+ concentration of 2.5 mole percent (m/o). This increase of a factor of 2.5 in the Tl^+ concentration as compared with K_2SO_4:Tl^+ (1.0 m/o) phosphor,[1] is attributed to the increase of Tl^+ solubility where the larger radius of Tl^+ (1.57Å) was compensated by the smaller Na^+ (0.97Å) than K^+ (1.33Å) (volume compensation).

It could be assumed that the unfired phosphor prepared as mentioned above occluded bound water at such active sites in crystals as subgrain boundaries, cracks, and so on, during the crystallization (7, 8). It should be remarked how bound water affects the crystal structure during firing. To investigate this feature, the amount of bound water in unfired phosphor was determined by using water labeled with ^3H as a tracer;

[1] K_2SO_4:Tl^+ phosphor had a maximum in TL intensity at Tl^+ concentration of 1.0 m/o (1).

Table I. Amount of bound water in unfired phosphors

Phosphor	Amount of bound water (mole/mole-phosphor)
K_2SO_4:Tl^+ (1.0 m/o)	3.94×10^{-3}
$K_3Na(SO_4)_2$: Tl^+ (2.5 m/o)	1.46×10^{-3}

the water persisted in the phosphor after vacuum drying at 130°C for 2 hr; this water was defined as bound water.

The data given in Table I show bound water to be clearly present in the unfired phosphors, and the amount of bound water occluded in $K_3Na(SO_4)_2$:Tl^+ phosphor was much less than that in K_2SO_4:Tl^+ phosphor. The decrease of the active sites for occlusion of bound water in $K_3Na(SO_4)_2$:Tl^+ phosphor may result from the release of the strain in the crystal lattice due to the solution of a larger Tl^+ ion in K_2SO_4 crystals in the presence of a smaller Na^+ ion.

The behavior of bound water during firing was investigated by using the unfired phosphors of both K_2SO_4:Tl^+ and $K_3Na(SO_4)_2$:Tl^+ (Fig. 3 and 4), where the 25°C value corresponded to the unfired phosphor. In the case of K_2SO_4:Tl^+ phosphor (Fig. 3), bound water diminished abruptly near 400°C, then could not be detected after firing at 750°C, and the TL intensity decreased obviously with diminution of bound water. On the other hand, bound water in $K_3Na(SO_4)_2$:Tl^+ phosphor was no longer detectable at 400°C, and the TL intensity jumped after removal

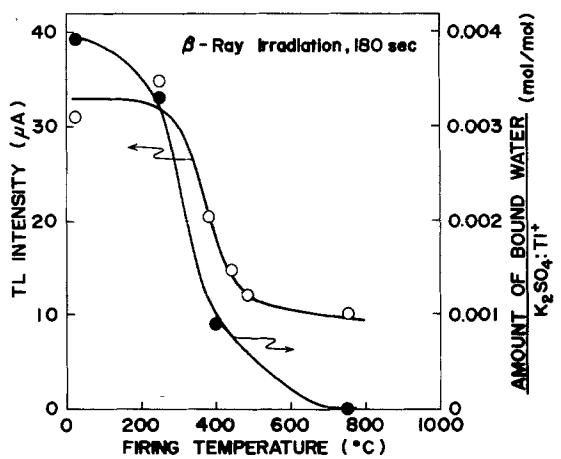

Fig. 3. Relation between the TL intensity and the amount of bound water in K_2SO_4:Tl^+ (1.0 m/o) phosphor fired at various temperatures for 1 hr in He.

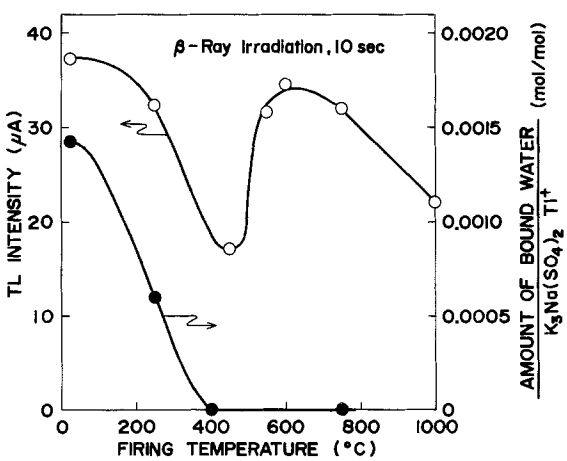

Fig. 4. Relation between the TL intensity and the amount of bound water in $K_3Na(SO_4)_2$:Tl^+ (2.5 m/o) phosphor fired at various temperatures for 1 hr in He.

of bound water (near 550°C) then declined again above 750°C. These facts suggest that bound water in $K_3Na(SO_4)_2$ crystals was more easily desorbed.

It has been already reported that the rotation of SO_4^{2-} radical in K_2SO_4 crystals was initiated at 375°C (9); then bound water must desorb easily when the rotation of SO_4^{2-} becomes activated. Scanning electron micrographs of fired phosphor indicated the existence of many micropores and cracks resulting from a destructive process, which was caused by the escape of both bound water and gases produced by the thermal decomposition of blended Tl_2SO_4 (decomposition point: 632°C). Consequently, the TL center would be damaged during the destructive process. The restoration of the TL intensity on $K_3Na(SO_4)_2:Tl^+$ phosphor which dropped near 400°C (Fig. 4) could be ascribed to the recrystallization of a matrix after desorbing bound water, and the drop in TL intensity above 750°C was caused by the thermal decomposition of Tl_2SO_4. On the other hand, the restoration of TL intensity on $K_2SO_4:Tl^+$ phosphor (Fig. 3) would be impossible due to the presence of residual bound water under the experimental conditions.

$Ba_{1-y}Mg_ySO_4:Eu^{3+}$ phosphors.—These phosphors exhibited similar glow curves with three glow peaks at 100°, 150°, and 230°C. The 230°C peak (main peak) was selected for the investigation of the TL character.

X-ray powder diffraction traces on $Ba_{1-y}Mg_ySO_4:Eu^{3+}$ phosphors showed formation of $BaMg(SO_4)_2$ as found by Ryan *et al.* (2). Figure 5 shows the relation between the amount of $BaMg(SO_4)_2$ crystals produced and the TL intensity in these phosphors. The TL intensity increased with the diffraction peak intensity of $BaMg(SO_4)_2$ crystals, and it indicated a maximum for the phosphor prepared with the matrix composition at $y \simeq 0.5$. The TL intensity in $BaMg(SO_4)_2:Eu^{3+}$ phosphor had a maximum at 10^{-2} m/o Eu^{3+}. From Fig. 6, the degree of crystallization of $BaMg(SO_4)_2$ indicated a maximum on firing at 1000°C for 1 hr. However, the crystals decomposed rapidly for a longer firing interval at 1000°C.

$K_{2(1-z)}Ca_zSO_4:Tl^+$ phosphors.—These phosphors exhibited similar glow curves with two glow peaks; main at 90°C and shoulder at 130°C. The 90°C peak was selected for the investigation of the TL character.

X-ray powder diffraction traces on $K_{2(1-z)}Ca_zSO_4:Tl^+$ phosphors showed formation of $K_2Ca_2(SO_4)_3$ (calcium langbeinite) (10). Figure 7 shows the relation between the amount of $K_2Ca_2(SO_4)_3$ crystals produced and the TL intensity in these phosphors. The TL intensity increased with the diffraction peak intensity of calcium langbeinite, and it indicated a maximum for the phosphor prepared with the matrix composition at z near 0.7. The TL intensity in $K_2Ca_2(SO_4)_3:Tl^+$ phosphor had a maximum at 1.0 m/o Tl^+. From Fig. 8, the degree of crystallization of $K_2Ca_2(SO_4)_3$ increased with

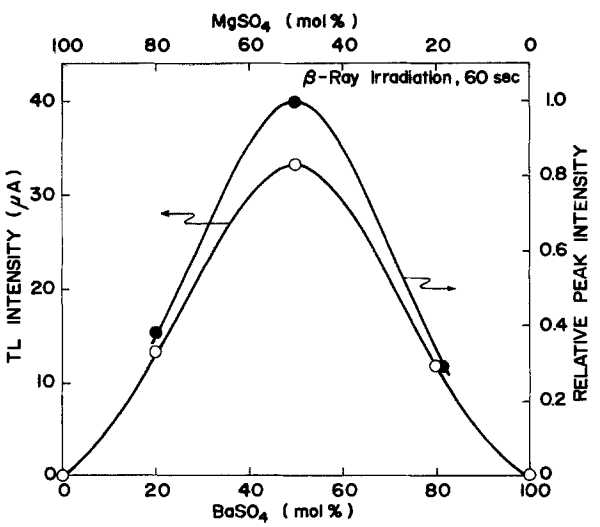

Fig. 5. Relation between the TL intensity and the diffraction peak intensity at $2\theta = 23.6°$ of $BaMg(SO_4)_2$ crystals in $Ba_{1-y}Mg_ySO_4:Eu^{3+}$ (10^{-2} m/o) phosphors fired at 1000°C for 1 hr in air.

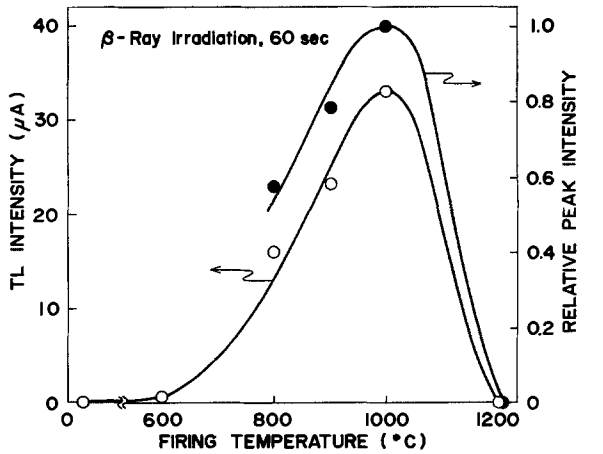

Fig. 6. Effects of firing temperature on the TL intensity and the diffraction peak intensity at $2\theta = 23.6°$ of $BaMg(SO_4)_2$ crystals in $BaMg(SO_4)_2:Eu^{3+}$ (10^{-2} m/o) phosphors fired for 1 hr in air.

the firing temperature, then it did not change above 900°C; however, the TL intensity decreased abruptly. Also, the crystals decomposed gradually for a longer firing interval at 900°C.

Further details on the formation reaction of $K_2Ca_2(SO_4)_3:Tl^+$ phosphor in the mixture of the molar ratio $K_2SO_4:CaSO_4:Tl_2SO_4 = 3:7:0.1$ were investigated by using a high temperature x-ray diffractometer. The result obtained in the 2θ region of 29.0°-33.0° [2] is shown in Fig. 9. On elevating temperature, the diffraction peak intensities of both K_2SO_4 and $CaSO_4$ starting materials diminished near 400°C while the peak of $K_2Ca_2(SO_4)_3$ crystals emerged; the peak intensity reached a maximum near 900°C, then it disappeared above 900°C; this fact suggests melting of $K_2Ca_2(SO_4)_3$ crystals. On cooling, a peak of the crystals emerged again near 900°C.

These facts are explained by referring to Fig. 8 as follows. The diffusion rate of Tl^+ dopant into the $K_2Ca_2(SO_4)_3$ crystals can increase during the noticeable change in crystal structure near 900°C; the phosphor fired at 900°C exhibited extremely bright TL. On the other hand, during cooling, most of Tl^+ dopant in the crystals produced by the recrystallization from the molten salt would be segregated on the grain boundaries, thus the amount of available Tl^+ for the TL center must decrease. Therefore, the TL intensity of the phosphor fired at 1000°C decreased remarkably.

The effect of firing atmosphere on the TL intensity of $K_2Ca_2(SO_4)_3:Tl^+$ phosphor is shown in Fig. 10. The phosphor fired in O_2 was much stronger in TL intensity than that fired in He. This fact may be due to the stabilization of Tl^+ dopant in the crystals by the presence of oxygen.

Conclusion

The phosphors prepared by using binary sulfate crystals as a matrix exhibited a much brighter TL than those prepared by using each crystal which constituted binary sulfate crystals, and the TL intensity of $K_2Ca_2(SO_4)_3:Tl^+$ phosphor prepared by recrystallization from molten salt decreased remarkably. The TL center in $K_3Na(SO_4)_2:Tl^+$ phosphor was destroyed by the escape of bound water.

[2] X-ray diffraction peaks of K_2SO_4, $CaSO_4$, and $K_2Ca_2(SO_4)_3$ crystals are detected in this 2θ region.

Acknowledgment

We wish to thank Mr. K. Uematsu for his assistance with the experimental work.

The Luminescence of Eu^{3+} and Bi^{3+} in the Two Modifications of $CaLaGaO_4$

H. Ronde, D. M. Krol, and G. Blasse

Physical Laboratory, State University, Sorbonnelaan 4, Utrecht, The Netherlands

ABSTRACT

The luminescence of Eu^{3+} and Bi^{3+} in the two modifications of $CaLaGaO_4$ is reported. The Eu^{3+}-activated α-phase (with olivine structure) shows a bright red luminescence at room temperature, whereas the Eu^{3+}-activated β-phase (with K_2NiF_4 structure) shows a red luminescence of much lower intensity at room temperature. This difference in efficiency is discussed and correlated with the dramatic shift of the charge-transfer band of the Eu^{3+} ion to lower energies in going from the α- to the β-phase. Furthermore, additional information on the crystal structure of α-$CaLaGaO_4$ can be deduced from this emission, *viz.*, the Ca^{2+} and La^{3+} ions are ordered with the Ca^{2+} ions on the (4a) and the La^{3+} ions on the (4c) sites. The Bi^{3+}-activated α-phase shows a bright blue luminescence at room temperature. The activated β-phase, however, shows only a very weak blue luminescence at temperatures below room temperature. This difference in efficiency is discussed and correlated with the stiffness of the surroundings of the luminescent centers in the different host lattices. The activated α-phase shows two emission bands peaking at about 420 and 480 nm. The bands are ascribed to electronic transitions on two crystallographically different Bi^{3+} centers, *viz.*, Bi_{La}^{x} and $Bi_{Ca}^{\cdot}$, respectively. The decay time of the two emissions at different temperatures is reported; the temperature dependence of the decay time is described in terms of a three level scheme.

During the course of our investigations we came upon an interesting class of compounds, *viz.*, the gallates $CaLnGaO_4$ (Ln = Y, lanthanide) (1). The normal temperature and pressure modification (denoted by α) of these compounds has an olivine-type crystal structure. At high temperatures (Ln = La, Pr, Nd, Sm) or pressures (Ln = Eu, Gd, Tb, Dy) a β-modification appears with the K_2NiF_4 or a distorted K_2NiF_4 structure. The $\alpha \rightarrow \beta$ transition is irreversible. It seemed interesting to dope one of these compounds with luminescent activators (*e.g.*, Eu^{3+} or Bi^{3+}) to investigate the influence of the crystal structure of the two modifications on the luminescence properties of the activated compounds. Since the high pressure induced phase transitions are far beyond the working range of our piston-cylinder apparatus, we had to choose a substance which shows a temperature-induced transition. Within this class of compounds only $CaLaGaO_4$ has no optical transitions at wavelengths longer than 240 nm, so that we selected $CaLaGaO_4$ as a host lattice. An additional advantage of this choice is the fact that of all compounds which show a temperature-induced transition, only $CaLaGaO_4$ has the regular K_2NiF_4 structure in the β-phase.

The red luminescence of the Eu^{3+} ion has found wide technical application. It has been suggested that the efficiency of this luminescence is determined by the spectral position of the Eu^{3+} charge-transfer band in the u.v. region (2, 3). Hoefdraad (4) has proposed a model which shows that the coordination of the Eu^{3+} ion in oxides is one of the important factors determining the position of the charge-transfer band. In this paper we give further experimental evidence supporting Hoefdraad's model.

The luminescence of phosphors activated with ions with ns^2 configuration is well known (5). Blasse *et al.* have recently shown that the thermal quenching temperature of the luminescence of the Bi^{3+} and Pb^{2+} ion depends strongly on the stiffness of the host lattice (6). In this paper we report another example supporting this general rule.

Experimental

Starting materials were $CaCO_3$ (Merck p.a.), La_2O_3 (Koch Light 99.9%), Gd_2O_3 (Fluka A.G. 99.9%), Ga_2O_3 (Alusuisse 99.99%), $Al(OH)_3$ (UCB), Eu_2O_3 (Fluka A.G. Puriss), and Bi_2O_3 (Baker 99.7%). Samples α-$CaLa_{0.99}Eu_{0.01}GaO_4$ were prepared by firing an intimate mixture of the starting materials for about 50 hr at 1250°C in air. The irreversible phase change occurs at 1310°C, whereas the melting point is at about 1350°C. The temperature range in which we could transform the α-phase into the β-phase is, therefore, rather small. In addition, the phase transition is sluggish. As a consequence we were not able to prepare a completely α-free β-modification. From the x-ray powder diagram the amount of α-phase in our β-phase samples is estimated to be 10% at maximum.

Samples α-$CaLa_{1-x}Bi_xGaO_4$ (x = 0.001, 0.005, 0.03) were prepared by firing intimate mixtures of the starting materials for about 15 hr at 1150°C in air. In view of the difficulties met in the preparation of the pure β-modification in the Eu^{3+} case and the volatility of bismuth oxide, we decided to simulate the β-phase by doping $CaGdAlO_4$ with Bi^{3+}. This compound has the K_2NiF_4 structure (7) and shows some similarity with $CaLaGaO_4$. $CaGd_{0.99}Bi_{0.01}AlO_4$ was prepared by firing the starting materials for about 50 hr at 1300°C in air. Samples were checked by x-ray analysis on a Philips diffractometer using Cu-Kα radiation. The performance of the optical experiments has been described elsewhere (8).

Results and Discussion of the Eu^{3+}-Doped Samples

A careful inspection of the unactivated samples $CaLaGaO_4$ revealed that these samples show a very weak blue luminescence at and below room temperature. Since this very weak luminescence does not disturb our measurements, we will not consider it further.

At 77°K and at room temperature

$$\alpha\text{-}CaLa_{0.99}Eu_{0.01}GaO_4$$

shows a bright red luminescence under u.v. excitation. In Fig. 1 we present the emission spectrum of α-$CaLa_{0.99}Eu_{0.01}GaO_4$ recorded at room temperature. We notice that this spectrum consists of a large number of sharp lines. The $^5D_0 \rightarrow {}^7F_2$ transition is the most intense one. Furthermore, the number of lines resulting from the transition from the $^5D_0$ level is restricted (4-5 for the $^5D_0 \rightarrow {}^7F_2$ transition, 3 for the $^5D_0 \rightarrow {}^7F_1$

Key words: luminescence Eu^{3+}, Bi^{3+}, $CaLaGaO_4$.

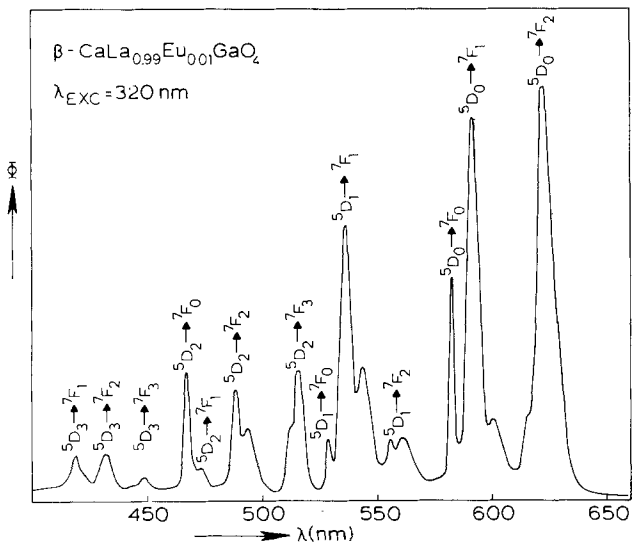

Fig. 1. Spectral energy distribution of α-$CaLa_{0.99}Eu_{0.01}GaO_4$ at room temperature under 254 nm excitation. Φ denotes the spectral radiant power per constant wavelength interval in arbitrary units. Note change in scale at the right-hand side.

transition). In addition, we also observe emission from the $^5D_3$, $^5D_2$, and $^5D_1$ levels.

At 77°K and at room temperature

$$\beta\text{-}CaLa_{0.99}Eu_{0.01}GaO_4$$

shows a red luminescence of much lower intensity under u.v. excitation. The emission spectrum of β-$CaLa_{0.99}Eu_{0.01}GaO_4$ recorded at room temperature is presented in Fig. 2. We notice that this spectrum consists of a large number of lines which are less sharp than the corresponding lines in the α-modification. Also in this case emissions from the $^5D_3$, $^5D_2$, and $^5D_1$ levels are observed. Furthermore, the intensity of the emission from the $^5D_3$ level relative to the intensities of the emissions from the $^5D_2$ and $^5D_1$ levels is much lower in the β-phase than in the α-phase.

In Fig. 3 the excitation spectra of the Eu^{3+} emission (610 nm) recorded at room temperature are given for both the α- and the β-phase. We want to emphasize the fact that we can excite the β-phase selectively at 320 nm, so that the emission spectrum given in Fig. 2 can

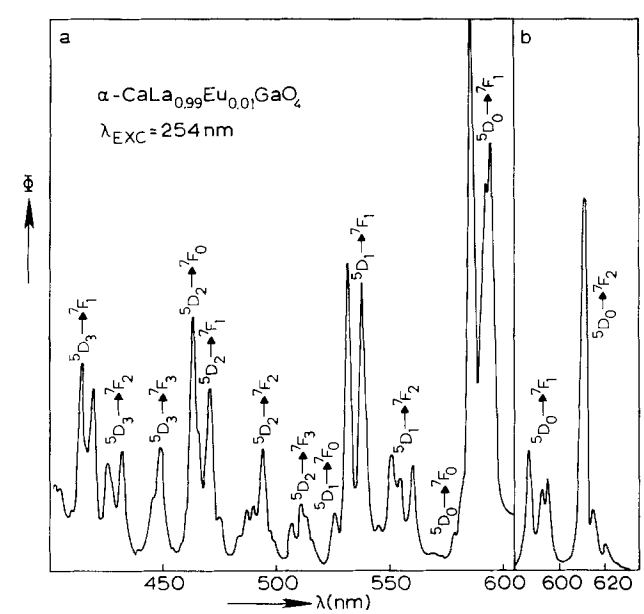

Fig. 2. Spectral energy distribution of β-$CaLa_{0.99}Eu_{0.01}GaO_4$ at room temperature under 320 nm excitation. The slit width in Fig. 1 and 2 is the same.

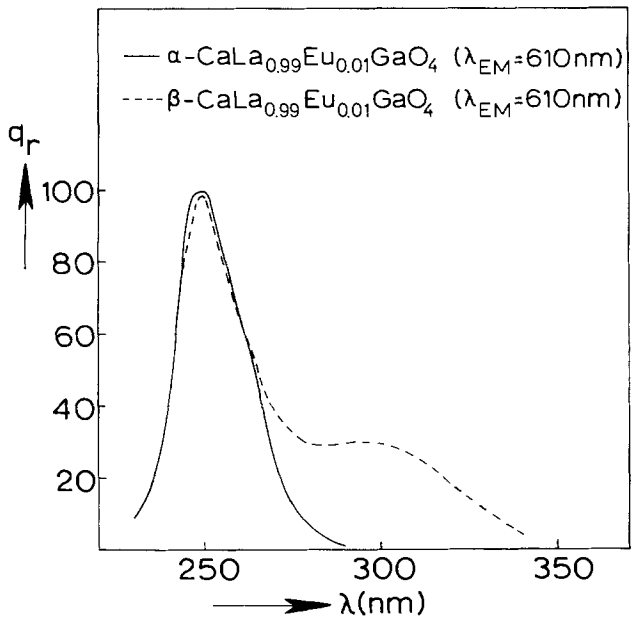

Fig. 3. Relative excitation spectra of the Eu^{3+} 610 nm emission of α-$CaLa_{0.99}Eu_{0.01}GaO_4$ and β-$CaLa_{0.99}Eu_{0.01}GaO_4$ at room temperature. q_r denotes the relative quantum output.

be regarded as the emission spectrum of the pure β-phase. Furthermore, we observed that when we excite the activated β-phase with 360 nm radiation, the $^5D_3$ emission has the same intensity as in the α-phase where the $^5D_3$ emission intensity does not depend upon the excitation wavelength.

In the olivine phase the coordination number of the cations, denoted by roman figures, is as follows: α-$^{VI}Ca^{VI}La^{IV}GaO_4$. There are two crystallographically different octahedral sites, one being centrosymmetric (site symmetry C_i), whereas the other is not (site symmetry C_s). The distribution of the Ca^{2+} and La^{3+} ions among these sites has not been described in the previous paper (1). The sharpness of the lines in the emission spectrum of Fig. 1 indicates a unique crystal field at the Eu^{3+} ion, so that there must be a long-range ordering of the Ca^{2+} and La^{3+} ions among the octahedral sites. The high intensity of the $^5D_0 \rightarrow {}^7F_2$ forced electric-dipole transition relative to the intensity of the $^5D_0 \rightarrow {}^7F_1$ magnetic-dipole transition indicates that the Eu^{3+} ion occupies the noncentrosymmetric site (9). Moreover, the number of lines observed for the $^5D_0 \rightarrow {}^7F_1$ and $^5D_0 \rightarrow {}^7F_2$ transitions is in agreement with the number expected for C_s symmetry. In this way we have obtained additional information on the crystal structure of α-$CaLaGaO_4$, *viz.*, the Ca^{2+} and La^{3+} ions are ordered with the Ca^{2+} ions on the (4a) and La^{3+} ions on the (4c) sites. This ordering is in agreement with an empirical rule given by one of us before (10), *viz.*, in the superstructure of olivine the (4a) sites are preferred by the lower charged octahedral cations.

If we compare the emission spectra of

$$\alpha\text{-}CaLa_{0.99}Eu_{0.01}GaO_4$$

with that of the isomorphous $LiY_{0.99}Eu_{0.01}SiO_4$ (10), a striking difference is noted; the silicate does not show emission from the $^5D_3$, $^5D_2$, and $^5D_1$ levels of the Eu^{3+} ion, whereas the gallate has a considerable amount of emission from these levels. This can be explained as follows. Relaxation from the above-mentioned levels to the $^5D_0$ level occurs via phonon emission. The energy differences between the levels within the ^5D manifold amount to 1750 cm^{-1} or more. In the case of $LiY_{0.99}Eu_{0.01}SiO_4$ this energy can be dissipated by a two phonon relaxation process due to the presence of the silicate group with its high energy phonons. In α-$CaLa_{0.99}Eu_{0.01}GaO_4$ this relaxation can only be achieved by at least a three phonon process, because

the phonon cutoff frequency is about 600 cm^{-1}, as found by us from the infrared spectrum.

The excitation band of the α-modification presented in Fig. 3 corresponds to the optical absorption caused by a charge-transfer transition within the Eu^{3+}-oxygen complex (9). The position of the maximum of this band (40 kK at 300°K, 41.5 kK at 77°K) is in agreement with a model by Hoefdraad (4). For Eu^{3+} in octahedral coordination he predicts this charge-transfer band to be situated at about 42 kK independent of the host lattice. Since oxides containing octahedrally coordinated La^{3+} ions are rare, Hoefdraad could find only one example of Eu^{3+} on an octahedrally coordinated La^{3+} site, *viz.*, $NaLaO_2$:Eu. This substance did not obey the prediction, the charge-transfer band being situated at only 36 kK. We reinvestigated $NaLa_{0.97}Eu_{0.03}O_2$ at room temperature and measured a value of about 38.5 kK for the position of the maximum of the charge-transfer band; furthermore we found a value of 36 kK for this position in the case of Eu^{3+}-activated La_2O_3 at room temperature. We therefore conclude that the value of 36 kK reported earlier (11) is probably due to Eu^{3+}-activated La_2O_3, which originates from hydrolysis of the hygroscopic $NaLaO_2$. The value of 38.5 kK cannot be considered as a serious deviation from the model of Hoefdraad, so that there is now evidence that this model can be extended to Eu^{3+} on an octahedrally coordinated La^{3+} site.

In the K_2NiF_4 structure the cations are coordinated as follows; β-$^{IX}Ca^{IX}La^{VI}GaO_4$. The IX-coordinated sites are crystallographically equivalent (site symmetry C_{4V}), the Ca^{2+} and La^{3+} ions being distributed at random among these sites.

We assign the maximum in the excitation spectrum of the β-modification at 33.3 kK (cf. Fig. 3) to a charge-transfer transition within the Eu^{3+}-oxygen complex. This dramatic shift of the first charge-transfer band of the β-phase with respect to the α-phase can be explained as follows: In the first place the number of ligands increases from six to nine in going from the α- to the β-phase, leading to a lowering of the energetic position of the first charge-transfer state (12). In addition, the position of the charge-transfer band of nine coordinated Eu^{3+} does depend on the host lattice, in such a way that the charge-transfer band shifts to higher energy for smaller lanthanide host lattice ions. This was shown by one of us for the series of compounds $NaLn_{0.98}Eu_{0.02}TiO_4$ (Ln = La, Gd, Y, and Lu) which also have the K_2NiF_4 structure (13). In the case of $NaLa_{0.98}Eu_{0.02}TiO_4$ this charge-transfer band was reported to be situated at about 31 kK. In the case of the smaller Ln^{3+} ions this charge-transfer transition is hidden under the first optical absorption band of the TiO_6 octahedra at about 35 kK. Hoefdraad showed that the variation of the charge-transfer band of the Eu^{3+} ion in VIII and XII coordination is proportional with the Eu-O distance, with increasing bond length the band shifts to lower energies. We conclude that Hoefdraad's reasoning can be extended to Eu^{3+} in nine coordination.

The lower intensity of the emission of the β-modification in comparison with the α-modification is compatible with the above-mentioned shift of the charge-transfer band. From a simple configurational-coordinate diagram it follows immediately that the Mott-Seitz activation energy decreases with a decrement of the energetic position of the parabola for the excited state (9).

Another consequence of a charge-transfer band at low energies is an increase of the relaxation rates of the ^5D_J levels as shown by Struck and Fonger (14) for Eu^{3+} in the oxysulfides. This is due to the fact that a ^5D_J level can be emptied via the charge-transfer state to the $^5D_{J-1}$ level. This is indeed observed here; the $^5D_3$ emission is more intense in the α-phase than in the β-phase upon charge-transfer excitation. If, however, excitation is into the $^5D_3$ level of Eu^{3+} in β-$CaLaGaO_4$ (λ_{exc} = 360 nm), the $^5D_3$ emission has the same intensity as in the α-phase where the $^5D_3$ emission intensity does not depend upon the excitation wavelength.

As mentioned before, the Ca^{2+} and La^{3+} ions are distributed at random among the C_{4V} sites in the β-modification. This is fully confirmed by the emission spectrum of β-$CaLa_{0.99}Eu_{0.01}GaO_4$, the broadness of the bands indicating all sorts of crystallographically different Eu^{3+} ions.

Results and Discussion of the Bi^{3+}-Doped Samples

At 77°K and at room temperature, samples with composition α-$CaLa_{1-x}Bi_xGaO_4$ (x = 0.001, 0.005, 0.03) show a bright blue luminescence under u.v. excitation. We present the emission and excitation spectra of α-$CaLa_{0.995}Bi_{0.005}GaO_4$ recorded at 4°K in Fig. 4. We note that there are two emission and excitation bands. Apparently, the long wavelength excitation band corresponds to the long wavelength emission band and, similarly, the short wavelength excitation band corresponds to the short wavelength emission band. Furthermore, the long wavelength excitation band contains two overlapping subbands. These general features are also observed in the spectra of the 0.1 and 3% Bi^{3+} samples.

In the case of the 0.5 and 3% Bi^{3+}-doped samples, the two emissions are of about equal intensity at all temperatures (4°, 77°, and 300°K) when excited in the maximum of their corresponding excitation bands. The 0.1% Bi^{3+}-doped sample showed considerably more short wavelength than long wavelength emission. Upon exciting the samples with 320 nm radiation, we did not observe any increase in the intensity of the long wavelength side of the short wavelength emission in the sequence x = 0.001, x = 0.005, x = 0.03; this seems to exclude efficient energy transfer processes between the two band systems.

For the sample α-$CaLa_{0.995}Bi_{0.005}GaO_4$ we measured the decay time τ of the emission around 450 nm under excitation with a broad spectrum of u.v. radiation (240-360 nm). Figure 5 presents τ as a function of temperature. Within the experimental error the intensity *vs.* time relations were single exponentials. We emphasize the fact that in the temperature range from 4° to 400°K the total intensity of the emissions remains constant. Therefore the sudden decrease of τ in the region between 40° and 80°K cannot be the result of temperature quenching of the emission.

$CaGd_{0.99}Bi_{0.01}AlO_4$ shows a weak blue luminescence at 77°K under u.v. excitation; at room temperature this luminescence is quenched. At 4°K the emission spectrum of $CaGd_{0.99}Bi_{0.01}AlO_4$ consists of a very broad band peaking at about 400 nm, with a shoulder at about 450 nm. The corresponding excitation spectrum consists of one band peaking at about 290 nm. Because of the low efficiency of this luminescence, we did not perform detailed measurements on this composition.

For the interpretation of the experimental results we will use the atomic energy level diagram of the Bi^{3+}

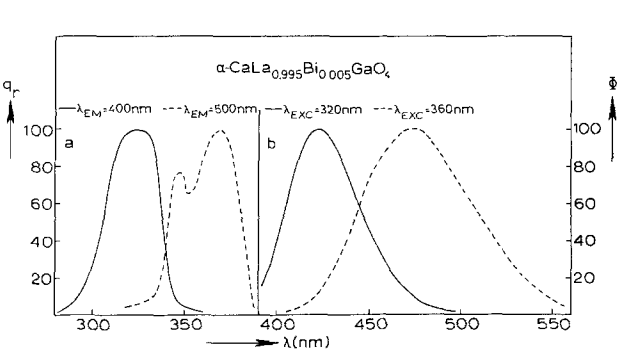

Fig. 4. a. LHeT excitation spectra of α-$CaLa_{0.995}Bi_{0.005}GaO_4$. b. LHeT emission spectra of α-$CaLa_{0.995}Bi_{0.005}GaO_4$.

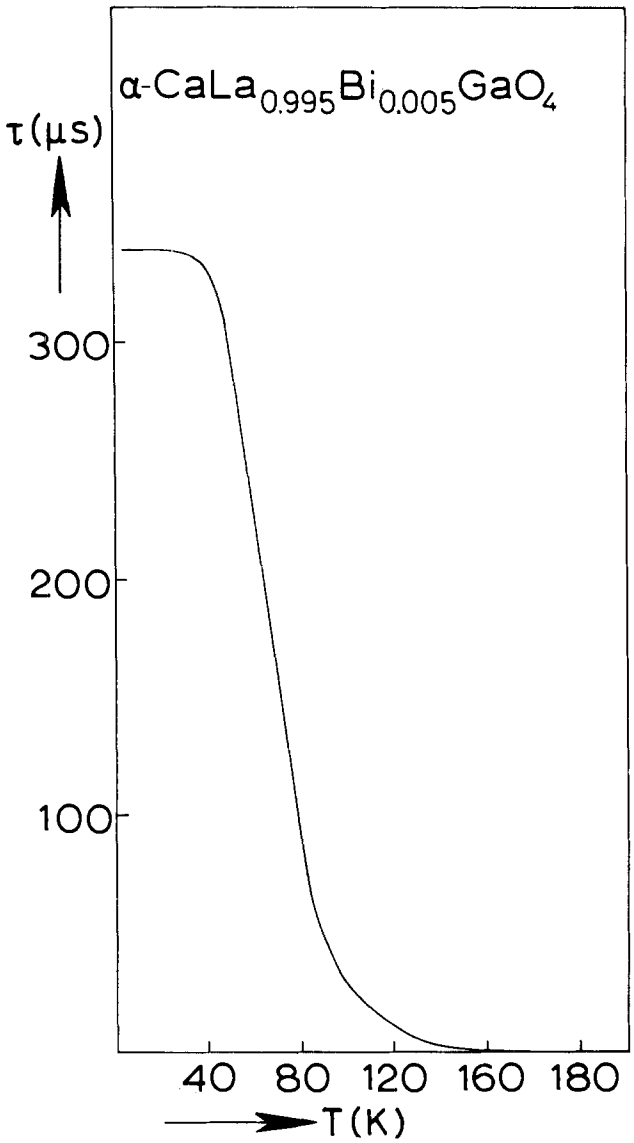

Fig. 5. Temperature dependence of the decay time of the 450 nm emission of α-$CaLa_{0.995}Bi_{0.005}GaO_4$ under a broad spectrum of u.v. radiation (240-360 nm). Above 160°K the decay time amounts to 1 μsec (measurements up to 300°K).

ion. The $6s^2$ configuration of the Bi^{3+} ion gives rise to a $^1S_0$ ground state. The first excited configuration 6s6p gives rise to four states, *viz.*, $^3P_0 < {}^3P_1 < {}^3P_2 << {}^1P_1$ (15). The allowed transitions within this energy level diagram are $^1S_0 \rightarrow {}^3P_1$ and $^1S_0 \rightarrow {}^1P_1$ (15). The distance between the excitation bands of Fig. 4 is about 3.6 kK, which is considerably less than the energy difference between the $^3P_1$ and $^1P_1$ levels. Blasse reports the following values for the distance between the $^1S_0 \rightarrow {}^3P_1$ and $^1S_0 \rightarrow {}^1P_1$ transitions of Bi^{3+} in Y_2O_3, YOCl, and LaOCl; 8, 9, and 7 kK, respectively (5). Moreover, Jørgensen reports this distance to amount to 12 kK and even 15 kK in the case of Bi^{3+} in bromide and chloride complexes, respectively (16). We therefore conclude that the excitation bands of Fig. 4 are lying too close together to correspond to the $^1S_0 \rightarrow {}^3P_1$ and $^1S_0 \rightarrow {}^1P_1$ transitions of one and the same Bi^{3+} ion. We assign these bands to $^1S_0 \rightarrow {}^3P_1$ transitions on two crystallographically different Bi^{3+} centers. An obvious possibility is Bi^{3+} on La^{3+} sites (Bi_{La}^{x}) and Bi^{3+} on Ca^{2+} sites ($Bi_{Ca}^{\cdot}$). In the case of $LiYSiO_4$-Bi, which has the ordered olivine structure, only one emission and excitation band has been reported, the maxima of which lie at about 28.6°K and 35.7 kK, respectively (5). These bands correspond with transitions on the Bi_Y^x center. Comparing these values with those for α-$CaLa_{1-x}Bi_xGaO_4$, the short wavelength excitation and emission bands (maxima at about 31 and 24 kK, respectively) are most likely to correspond with transitions within the Bi_{La}^{x} center. The long wavelength excitation and emission bands (maxima at about 27 and 21 kK, respectively) are then ascribed to transitions on the $Bi_{Ca}^{\cdot}$ center. The position of these latter bands is at rather low energy in comparison with values found for other Bi^{3+}-doped oxides (5). This may be due to the fact that a Bi^{3+} ion on a Ca^{2+} site is effectively positive, so that the Bi-O bond will be relatively covalent and the electronic transitions will lie at low energy (16). Thus accepting the interpretation given above as the simplest model that elucidates the major part of our experimental observations, we assign the emission bands to $^3P_{1,0} \rightarrow {}^1S_0$ transitions on two different Bi^{3+} centers. The lower $^3P_0$ level plays only a role in the luminescence process at low temperatures. This follows from the decay measurements as is now shown.

The experimental conditions for the decay measurements had to be taken so that we excited predominantly in the short wavelength excitation band and measured mainly the decay of the short wavelength emission band. However, since the intensities of the emissions do not differ very much, and in view of the fact that we excited partly also in the long wavelength excitation band and detected for a part also the long wavelength emission band, we certainly would have noticed any significant difference in the decay times of the two centers, if such a difference would have been present. As mentioned before, we measured single exponentials at all temperatures. We, therefore, conclude that the decay times of the two centers are approximately equal. This is in agreement with the fact that the decay time of the Bi^{3+} activator does not depend strongly on the host lattice (17). The temperature dependence of the decay time can be described with a three level scheme; the ground state $^1S_0$ and two excited levels ($^3P_0$, $^3P_1$), the lower of which is metastable ($^3P_0$).

Using the formulas of Boulon (17) for the case that the intensity of the emission is temperature independent in the region in which τ varies, we arrive at the following values for the radiative transition probabilities $P_{^3P_0} \rightarrow {}^1S_0$, $P_{^3P_1} \rightarrow {}^1S_0$ and the energy separation

$$\Delta E = E(^3P_1) - E(^3P_0)$$

$$P_{^3P_0} \rightarrow {}^1S_0 = 3 \times 10^3\ \text{sec}^{-1}$$

$$P_{^3P_0} \rightarrow {}^1S_0 = 10^7\ \text{sec}^{-1}$$

$$\Delta E = 0.05\ \text{eV}$$

These values are in fair agreement with the values found by Boulon (17) for the Bi^{3+} activator in all sorts of compounds.

The broadness of the emission band of $CaGd_{0.99}Bi_{0.01}AlO_4$ indicates that there are several crystallographically different Bi^{3+} centers in agreement with the crystal structure. As in the α-modification, the emission is assigned to the $^3P_{1,0} \rightarrow {}^1S_0$ transitions. Again the lower $^3P_0$ level will only play a role in the luminescence process at low temperatures. The excitation band is likewise ascribed to the $^1S_0 \rightarrow {}^3P_1$ transition.

The efficiency of the Bi^{3+} emission in $CaGd_{0.99}Bi_{0.01}AlO_4$ is low in comparison with that of Bi^{3+} in the olivine phase. Blasse *et al.* (6) have also reported a very low luminescence efficiency for Pb^{2+} in Ba_2ZrO_4 with K_2NiF_4 structure. These authors argued that the stiffness of the surroundings of the PbO_n-center influences strongly the thermal quenching temperature T_q and the efficiency of the Pb^{2+} luminescence.

Here we have found another example supporting this simple model. The increase of the Stokes shift in going from the α- to the β-phase ($\Delta^\alpha E_s = 0.9$ eV; $\Delta^\beta E_s = 1.2$ eV) and the decrease of T_q ($T_q^\alpha > 300$°K; $T_q^\beta << 300$°K) is ascribed to the fact that the lattice of the β-phase is less stiff than that of the α-modification. This

can be easily seen as follows: the K_2NiF_4 structure can be regarded to exist of relatively stiff perovskite layers separated by relatively soft (Ca, La)-O layers; along the c-axis the stiffness of the lattice is low, and this will result in a relatively large value of Δr. The olivine structure, however, is based upon a hexagonal close packing of oxygen ions. The Ga^{3+} ions occupy tetrahedral sites in such a way that a three dimensional framework of GaO_4 tetrahedra is formed. These tetrahedra are bound together by the Ca^{2+} and La^{3+} ions. Further, the lower coordination numbers in the olivine phase will also promote a higher stiffness. We, therefore, expect a small value of Δr.

Manuscript submitted Dec. 28, 1976; revised manuscript received March 21, 1977. This was Paper 136 presented at the Philadelphia, Pennsylvania, Meeting of the Society, May 8-13, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

Publication costs of this article were assisted by the State University at Utrecht.

The Structure Sensitivity of the U^{6+} Ion Luminescence in Oxides

G. Blasse

Physical Laboratory, State University, Sorbonnelaan 4, Utrecht, The Netherlands

ABSTRACT

This paper discusses how the luminescence of the U^{6+} ion in oxides is influenced by the crystal structure and the chemical composition of the host lattice. The vibrational fine structure of the emission band, the decay time, and the thermal quenching temperature of the luminescence are the properties which we concentrate on. Starting point of the discussion is the perfectly cubic UO_6^{6-} group, the emission of which corresponds to a zero-phonon magnetic-dipole transition followed by mainly one-photon vibronics. The influence of symmetry lowering on this emission is described. This influence becomes of striking importance if the U^{6+} ion is introduced in host lattices containing edge-sharing MO_6^{6-} (M = Te, W) groups. Finally some general aspects of the vibrational fine structure, in particular the length of the progression in ν_1, are discussed. The strong dependence of the thermal quenching temperature of the U^{6+} luminescence on the host lattice can be explained using a configurational-coordinate diagram with three parabolas.

The luminescence of the hexavalent uranium ion in oxides is well known and has been studied for many years. A main issue in the discussion has been the nature of the emitting center which has been proposed to be UO_2^{2+} (uranyl), UO_6^{6-} (octahedral uranate), or UO_4^{2-} (tetrahedral uranate) (1). This paper describes the dependence of the hexavalent uranium luminescence characteristics on the symmetry of the uranium site and the chemical composition of the host lattice. In contradiction with the majority of the work up to 1970 the measurements have been extended down to liquid helium temperatures and the decay time of the emission has been measured. This is essential in our interpretation. Because we want to describe a number of luminescence properties and their dependence on the crystallographic surroundings of the emitting center, the approach is of a qualitative nature only. We hope to extend the present ideas in the near future.

Key words: uranium luminescence, uranium activated phosphors, lithium tungstate.

Experimental

All samples were prepared according to the usual methods described earlier in the literature for the appropriate host lattice Firing was performed in an oxygen atmosphere The uranium concentration amounts to 0.3 atomic percent (a/o) relative to the hexavalent metal ion of the host lattice (tellurium or tungsten). All samples were checked by x-ray analysis.

All optical measurements were performed as described in detail previously (2).

Results

The luminescence of the hexavalent uranium ion has been studied in a large number of host lattices.

Part of the results have been published before. The host lattices relevant for the present discussion are:

1. The ordered perovskite structure. In this structure the $[M^{6+}O_6]^{6-}$ octahedra are isolated from each other, *i.e.*, they do not have oxygen ions in common, and the M^{6+} ion occupies a site with cubic symmetry. The results of the study of the uranium emission in this lattice are the basis for the present approach. They have been published elsewhere (2-4) and are summarized below.

2. A number of lattices containing isolated $[M^{6+}O_6]^{6-}$ octahedra, but with lower than cubic symmetry, viz., Mg_3TeO_6 and Y_6WO_{12} (5), $Y_3Li_3Te_2O_{12}$ (6), and finally Li_6WO_6. The crystal structure of the latter compound seems to be a short-range ordered variant of the rock-salt structure but details are still lacking (7, 8). Uranium-doped Li_6WO_6 appears to be a very efficient, green-emitting phosphor at room temperature. At lower temperatures the green emission band shows fine structure and, in addition, a blue band appears (see Fig. 1). The blue band, which is due to the tungstate octahedron in Li_6WO_6, can be excited in an excitation band with a maximum at about 280 nm; the green uranium emission can be excited in a broad excitation band with a maximum at about 340 nm (direct excitation) or in the tungstate excitation band (see Fig. 1). Although energy transfer from the tungstate to the uranate group definitely occurs in Li_6WO_6-U, it is not as efficient as in some ordered perovskites where no tungstate emission is observed for a uranium concentration of 0.3 a/o (9). The reason for this is undoubtedly the very small spectral overlap between the tungstate emission band and the uranium excitation band at 340 nm, so that transfer from the tungstate group to the uranate group occurs straight into the parity-forbidden energy levels of the latter (9).

Table I gives more details on the fine structure of the green emission band at liquid helium temperature. The assignment is discussed below.

The thermal quenching temperature of the emission under 340 nm excitation is high: The luminescence intensity remains temperature independent up to 400°K, above which temperature thermal quenching occurs ($T_{1/2}$ = 450°K).

Table I. The vibrational fine structure in the emission spectrum of Li_6WO_6-U at LHeT (except for the first two lines). All values in cm^{-1}. The vibronics are counted from the zero-phonon transition. The intensity is given between brackets ((very) weak, medium, strong)

Position	Assignment	Remarks
+240 (vw)	ν_3	Only at LNT, not at LHeT
+130 (m)	$\nu_{lat.}$	Only at LNT, not at LHeT
19.970 (w)	0-0	Zero-phonon transition
−150 (s)	$\nu_{lat.}$	
−280 (m)	ν_6	
−410 (m, br)	ν_4	Broad line; shoulder contains probably ν_3

−(800 + 160) (m)	$\nu_1 + \nu_{lat.}$	
−(800 + 260) (w)	$\nu_1 + \nu_6$	
−(800 + 400) (w)	$\nu_1 + \nu_4$	

Figure 2 presents the temperature dependence of the decay time of the uranium emission of Li_6WO_6-U. Note that the luminescence intensity is not temperature dependent in the temperature range of this figure, so that we are dealing with a temperature-dependent radiative transition probability (4).

3. The compound Li_4WO_5; this compound has an ordered rock-salt structure where the tungstate octahedra occur presumably in edge-sharing pairs (10). The luminescence characteristics of Li_4WO_5-U differ markedly from those of the phosphors mentioned under 1 and 2, above, and have been given elsewhere (11).

4. $MgWO_4$ with strings of zig-zag edge-sharing WO_6^{6-} octahedra and in relation with this compound some compounds with WO_4^{2-} tetrahedra (scheelites) (12).

Finally we remeasured the uranium luminescence in Y_2TeO_6 and La_2TeO_6 (13) and $LaAlTeO_6$ (14). It has been suggested in the literature that the efficient uranium luminescence from these lattices would originate from the uranyl group (13) This point is discussed below. Table II shows the vibrational fine structure of the emission of Y_2TeO_6-U and La_2TeO_6-U at LHeT, whereas Fig. 3 gives an over-all view of the emission of La_2TeO_6-U. The fine structure in the case of

$LaAlTeO_6$-U is similar to that of La_2TeO_6 and, therefore, not given in more detail.

The thermal quenching temperature of the uranium emission of Y_2TeO_6-U and La_2TeO_6-U is again high. The $T_{1/2}$ value is about 400°K. The temperature dependence of the decay time is given in Fig. 2 and is less pronounced than in the case of Li_6WO_6-U.

Discussion of the Emission Spectra

The luminescence of the U^{6+} ion in ordered perovskites (2, 3) is easy to interpret and is used as a starting point. At low enough temperatures the fine structure in the emission band consists of a zero-phonon line [relatively low intensity; magnetic-dipole emission (15)], a number of one-phonon lines due to coupling with the ungerade internal modes of the UO_6^{6-} octahedron (ν_6, ν_4, ν_3) and a relatively weak progression of these lines in ν_1 (the symmetrical UO_6 stretching frequency). The radiative decay time is long (about 350 μsec) and temperature dependent. All this shows that the emission transition of the cubic UO_6^{6-} group consists of a parity-forbidden electric-dipole transition. In view of the high intensity of the one-phonon lines the coupling between the electronic and vibrational states must be weak, *i.e.*, weaker than in the case of the uranyl group in the emission of which the more-phonon lines dominate (16).

Figure 4 presents a schematic overview of some emission spectral of oxides doped with hexavalent uranium. Those of the ordered perovskite Ba_2CdWO_6-U and of $SrZnP_2O_7$-U, a compound in which uranium has been proposed to be present as uranyl (17), illustrate the remarks made above

The emission pattern and the low temperature value of the decay time of the uranium emission do not change very much upon symmetry lowering if a center of symmetry remains present. The one-phonon lines still dominate, although their number increases. This is illustrated in Fig. 4 by the case of Mg_3TeO_6-U (5). The site symmetry of the hexavalent ions in this crystal structure is S_6 (18). As a consequence the threefold-degenerate ν_3, ν_4, and ν_6 split resulting in a larger number of one-phonon lines.

The luminescence characteristics of Li_6WO_6-U can be explained in an analogous way. The decay time is long and temperature dependent as required for a parity-forbidden electric-dipole transition. The fine structure in the emission spectrum (Table I) contains a weak zero-phonon line, strong one-phonon lines due to coupling with a lattice mode and ν_6 and ν_4, and a weak progression in ν_1. The one-phonon lines are not split, but somewhat broadened.

Unfortunately the crystal structure of Li_6WO_6 is not known in detail. Hauck (7) has proposed that tungsten occupies 50% of the 2a sites of space group Immm (D_{2h}^{25}) in a short-range ordered way; further the position of two of the six lithium ions is unknown. The symmetry of this 2a site is D_{2h}. Inversion symmetry at the hexavalent ion sites seems, therefore, to be a good first-order approach, but it should be realized that the crystal field at these ions varies from site to site as a consequence of the short-range order. This may explain why the threefold-degenerate vibronics do not split and are a little broad. Note that the progression in ν_1 is as weak as in the perovskites.

In the crystal structure of Li_4WO_5 we have edge-sharing between two WO_6^{6-} octahedra (10). Introduction of uranium into this lattice yields an emission with different characteristics. The low temperature value of the decay time is lower (viz., 160 μsec) than in the systems mentioned above. The fine structure of the emission band is quite simple (Fig. 4). The zero-phonon line dominates in this case. Together with the

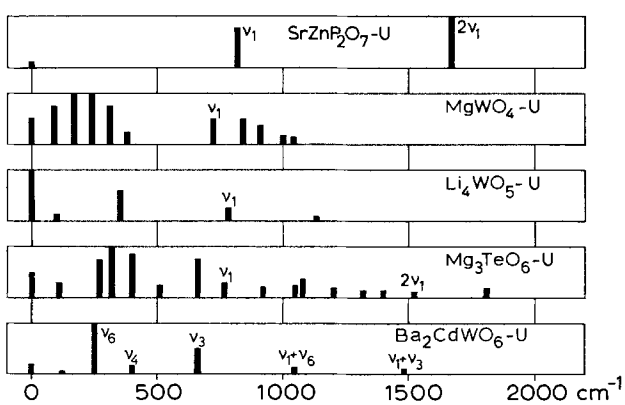

Fig. 4. Schematical representation of the vibrational fine structure of a number of U-activated oxides at 4.2°K. The position of the zero-phonon line is at 0 cm^{-1} and is the origin of the wave number scale. The height of the blocks indicates the peak intensity of the vibronic lines and is, therefore, not a reliable measure for the integrated intensity. Data for $SrZnP_2O_7$-U were obtained at 4.2°K in this laboratory and are not essentially different from the room temperature values reported in Ref. (17). The emission line in the $SrZnP_2O_7$-U spectrum marked $2\nu_1$ is the most intense line in this spectrum. The intensity of $n\nu_1$ ($n > 2$), not shown here, is lower.

shorter decay time this indicates a considerably higher transition probability for this line. This must be connected with the absence of inversion symmetry at the uranium center in a complex like $[WUO_{10}]^{8-}$. Vibronic emission lines are due to coupling with a lattice vibration, with a U-O deformation and with a U-O stretching vibration. Since these vibrational modes have not been studied in detail, we refrain from further discussion.

In $MgWO_4$ the lattice contains strings of edge-sharing WO_6 octahedra. The decay time of uranium in this lattice is much shorter (viz., 35 μsec at 4.2°K) and the vibrational fine structure in the emission band is apparently different (Fig. 4). The latter fact is due to stronger coupling with lattice modes. Similar characteristics have been reported for uranium in the scheelites MWO_4 (M = Ca, Sr, Ba) (19) and Y_2WO_6 (12). The emission band in all these compounds has shifted from the green to the red part of the spectrum, which is not essential for the present discussion. In these compounds inversion symmetry is definitely lacking. As a consequence the number of selection rules on the vibronic lines decreases, so that the decay time becomes shorter and the fine-structure pattern more complicated.

We also investigated some efficient uranium-activated phosphors reported before, viz, Y_2TeO_6-U and La_2TeO_6-U. Their emission characteristics are very much like those of $MgWO_4$-U, *i.e.*, relatively short decay time and high intensity for the zero-phonon and one-phonon lines. Unfortunately, their crystal structures have not been solved up till now. The structure of $LaAlTeO_6$ is an ordered variant of the $PbSb_2O_6$ structure containing isolated TeO_6^{6-} groups (14). The luminescence of U^{6+} in this lattice is similar to that observed for Y_2TeO_6-U and La_2TeO_6-U. This seems to indicate that the U^{6+} ion is in six-coordination in all these tellurates. From the high intensity of the zero-phonon transition and the short decay time of the emission (which in addition shows only a weak temperature dependence in comparison with, *e.g.*, Li_6WO_6-U, see Fig. 2), we conclude that the uranium ion does not occupy a site with inversion symmetry in these compounds. A detailed analysis of these crystal structures would be of great help for the discussion of the uranium luminescence.

All these results together lead to the conclusion that the emission spectra of $U^{6+}(O^{2-})_n$ complexes show fine structure and radiative transition probabilities that depend strongly upon the site symmetry of the uranium. We feel that a detailed discussion of the luminescence characteristics of the U^{6+} ion in oxides should start from these experimental data and not from a discussion on the value of n of the emitting center as has been done many times in the years before.

Two clear phenomena in these emission spectra ask for a further treatment, viz., the pronounced host lattice dependence of the length of the progression in ν_1 and the host lattice dependence of the ratio of the coupling strengths with lattice modes and with internal uranate modes (see Fig. 4).

The latter is not discussed here because we feel that a detailed analysis of the vibrational modes in the relevant host lattices is necessary. Nevertheless we remark that the vibronics due to coupling with lattice modes seem to have higher intensity, if the separation between external and internal modes becomes less meaningful. This is not unexpected.

As far as the progressions are concerned a rough model can be proposed to account for the dependence of the progression length on the host lattice. The exact nature of the emission transition in the uranate group is not known. It is often assumed to be a charge-transfer transition between oxygen 2p and uranium 5f levels (20). Recent Xα-calculations on UF_6 have shown that the uppermost filled orbital of this molecule is the $t_{1u}\sigma$ orbital, made up of U 6d, U 5f, and F 2p functions, whereas the lowest unoccupied orbitals are all predominantly U 5f in character (21, 22). For the moment we assume that the same orbital scheme is valid in principle for the UO_6^{6-} octahedron (and probably also for the other $U^{6+}(O^{2-})_n$ complexes). This implies that the emission transition is in fact a charge-transfer transition from a predominantly nonbonding orbital to a σ-bonding orbital. It also means that the difference between the equilibrium distance in the emitting state and that in the ground state, Δr, must be positive. Using an approximation suggested by Ballhausen (23) it is possible to estimate Δr from the relative intensities of the lines in the progression in ν_1. Taking Ba_2MgWO_6-U with UO_6^{6-} octahedra as a representative sample (2, 3) we arrive at $\Delta r \cong 0.02$Å. The longer the progression in ν_1, the larger the value of Δr will be. In view of the nonbonding character of the emitting state we assume that the host-lattice dependence of the progression length arises mainly from the lattice dependence of the ground state. It is obvious that a relatively short U-O distance (high degree of covalency) in the ground state will involve a relatively large Δr and, therefore, a long progression in ν_1. Taking $\nu_1 = 750$ cm^{-1}, it is an easy task to calculate that Δr should be about 0.04Å in in order to attain that the second repetition in ν_1 has the maximum intensity in the emission spectrum of the UO_6^{6-} octahedron (this is the situation in the emission spectrum of $SrZnP_2O_7$-U, see Fig. 4, where probably the uranyl group is the emitting center). This illustrates that variations of less than 0.01Å in Δr are enough to explain our observations, since the case of $SrZnP_2O_7$-U is an extreme. The observations are the following:

1. The progression is longer in U-activated tellurates than in tungstates (see, *e.g.*, Fig. 4); this becomes especially clear, if isomorphous tungstates and tellurates are compared [*e.g.*, $Ba_2MgM^{6+}O_6$-U (24)]. The most reliable ionic radii for Te^{6+}, W^{6+}, and U^{6+} in six-coordination are 0.56, 0.60, and 0.73Å, respectively (25). As a consequence the U-O distance in the uranate center in the ground state will be smaller in tellurates than in tungstates resulting in a longer progression.

2. The cations surrounding the uranate center have a marked influence on the progression length: The progression becomes more intense and longer if the surrounding cations are smaller and/or higher charged. This follows immediately from our simple model. If the U^{6+} ion is substituted for the Te^{6+} or W^{6+} ion, the surroundings have to expand in view of the larger radius of the U^{6+} ion. If the surroundings are relatively stiff (small and/or highly charged cations), the expansion will be relatively small and the U-O distance, therefore, relatively short. This results in a longer progression. There is experimental evidence for this reasoning. In the series MWO_4-U (M = Ca, Sr, Ba) the progression becomes the more intense, the smaller the M^{2+} ion (19). In the series Ba_2MTeO_6-U (M = Mg, Ca, Sr) the progression becomes more intense, the smaller the M^{2+} ion (3, 24). A stiff lattice like Mg_3TeO_6 yields U^{6+} emission with a long progression if it is activated with uranium (see Fig. 4). Still stiffer seems to be the trirutile Al_2TeO_6 (26, 27). At the moment we are studying the uranium luminescence in this compound. Provisional measurements indicate that in the emission of Al_2TeO_6-U the first repetition of the one-phonon lines is more intense than the one-phonon lines themselves in striking agreement with our expectation (28)

3. Since the U-O distance in a molecule is much shorter than in a solid, we expect longer progressions for molecules or "molecule-like" configurations than for solid solutions. This has been observed: for the molecule UF_6 (29) and for the UO_6^{6-} center in fluorides (30).

We realize the shortcomings of this approach, but we believe that at the moment this is the best that can be done. Quantitative calculations yielding such

Table III. The differences Δ between the position of the excitation and emission bands at room temperature for some U^{6+}-activated host lattices (all values in 10^3 cm^{-1}) vs. the thermal quenching temperature of the emission $T_{1/2}$ (temperature at which the luminescence intensity has decreased to 50% of the low temperature value). Spectral data for the lower two cases are at liquid nitrogen temperature

small variations in the value of Δr are probably not worth the trouble and cost.

Discussion of the Temperature Quenching

The thermal quenching temperature of the emission of U^{6+}-activated oxides depends also markedly on the host lattice. This can be seen in Table III where some of the compounds investigated have been tabulated. As pointed out before (6) it is also clear that this quenching temperature seems to be related to the difference in energy between the position of the intense ultraviolet excitation band and that of the emission band of the U^{6+} luminescence (see Table III).

In view of the small value of Δr between the ground state and the emitting state (see discussion above) it is rather improbable that the process of temperature quenching occurs between the two parabolas for these two states in the configurational-coordinate diagram. The data of Table III rather suggest that a higher excited state plays an important role. Since the optical transition corresponding to the ultraviolet excitation band of the uranium luminescence is an allowed one and its broad band character with only scarce fine structure indicates a relatively large value of Δr between this state and the ground state, a schematic configuration coordinate diagram as drawn schematically in Fig. 5 seems to explain the relation of Fig. 4 reasonably. The emitting state is represented by the parabola BCF, whereas the parabola EFG represents the state to which the system is promoted by excitation into the near-ultraviolet absorption band (AE). At low temperatures the system relaxes from E to C via F followed by emission (CD). At high enough temperatures a radiationless transition via the crossover G is possible, resulting in temperature quenching of the emission CD. It will be clear that the difference Δ in Table III is the difference in energy between AE and CD in Fig. 5, The larger the value of Δ, the higher will be the crossover G resulting in a high value $T_{1/2}$. We aim to make this model more quantitative in the near future.

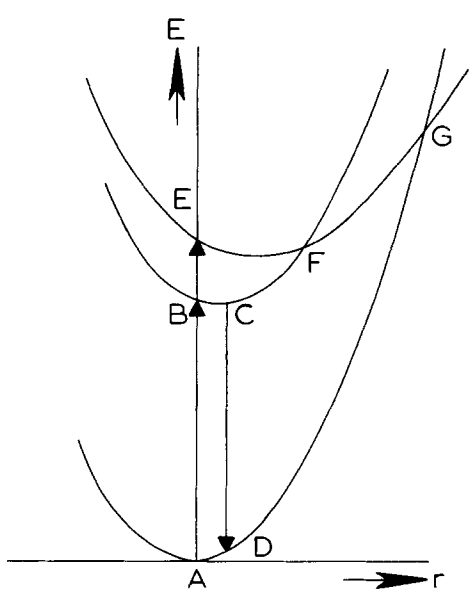

Fig. 5. Configurational-coordinate diagram of the luminescent uranate center. Thermal quenching of the emission CD is proposed to occur via the crossover G. See text.

In closing we remark that the model of Fig. 5 shows a clear resemblance to the model for temperature quenching of the Eu^{3+} luminescence in oxysulfides proposed by Struck and Fonger (33). Here the two lower parabolas relate to the $4f^6$ configuration of the Eu^{3+} ion and the higher one to the charge-transfer state.

GaP Red Light Emitting Diodes Produced by a Rotating Boat System of Liquid Phase Epitaxial Growth

Tatsuhiko Niina

Sanyo Electric Company, Limited, Research Center, Hirakata, Osaka, Japan

ABSTRACT

An improved rotating boat system for liquid phase epitaxial growth has been developed. With this system GaP red light emitting diodes can be mass produced. Its features are that substrates can be fixed by the remarkably simple method of attaching a small volume of melted gallium to the substrate holding plate and pressing the substrate closely against it. It is also suitable for mass production in that the construction of the boat for liquid phase epitaxial growth simplifies the operation for crystal growth; large quantities of substrates of large diameter (30-50 mm) can be treated in one processing batch; the consumption of the Ga melt is small. The growing surface is mirrorlike. A double step process, in which n- and p-type layers are grown in two separate steps is used in the diode fabrication. Another feature is that the same Ga melt is used ten times for the growth of n- and p-type layers, respectively. Encapsulated mesa diodes with efficiencies of 6% (current density = 2 A/cm^2) are routinely obtained from the sequential use up to ten times of the Ga melt and also, the average electroluminescence time decay is 500 nsec. The maximum efficiency is 10% (current density = 2 A/cm^2).

To manufacture low cost GaP light emitting diodes (LED's), it is necessary to develop a p-n junction formation technique using a liquid phase epitaxial (LPE) growth system and a single crystal growth technique suitable for mass production. For the single crystal growth technique, the liquid encapsulated Czochralski (LEC) method was developed in 1968 (1). Improvements in single crystal growth have progressed rapidly, until now it is possible to obtain substrate crystals of large diameter (30-50 mm) on an industrial scale. In the p-n junction formation by LPE (used to obtain LED's of high efficiency) it is necessary to precisely control the concentration of impurities in the neighborhood of the p-n junction and to improve crystallinity. At present, the maximum efficiency of the red LED is 12.6% (2), and in the case of mass production, efficiencies of 6% (3) have been achieved. The major task for the future is to obtain LED's with high efficiencies using an LPE growth system suitable for mass production.

In the rotating boat LPE growth systems suitable for mass production hitherto reported (3-6), the crystal growth is, in most cases, that of the open-flow system (4-6) with a large melt consumption. In the closed type system (3), suspension of the substrate is rather complicated.

This paper describes the process of manufacturing red LED's using the rotating boat LPE growth system. Features of this method are: (*i*) The substrates can be fixed by the simple method of attaching a small volume of molten gallium to the substrate holding plate and pressing the substrate closely against it. (*ii*) It is suitable for mass production in that the construction of the boat for LPE growth makes operation easy. (*iii*) Repeated use of a (Ga + GaP + impurities) melt for the growth of the n- and p-layers minimizes the consumption of gallium. (*iv*) As the boat is sealed, the loss of volatile dopant from the melt is small. Even when the melt is used repeatedly, there is no change in the doped quantity of impurities; thus, it is possible to control the concentration of impurities accurately.

Key words: light emitting diode, crystal growth, junction formation.

This paper first explains the rotating boat LPE crystal growth system, then the doping system of controlling impurities. It also describes changes in the carrier concentration in the neighborhood of the p-n junction due to the frequency of the use of the melt when LED's are made, changes in efficiencies, the growth surface after crystal growth, and various characteristics of the red LED's.

Explanation of the Rotating Boat LPE Growth System

In a method suitable for the mass production of red LED's by an LPE growth method, it is necessary: (*i*) to treat many substrates in one processing batch, (*ii*) for optical characteristics in the same lot to be uniform, (*iii*) to use gallium metal efficiently as it is costly and used in large quantities as a medium of crystal growth, (*iv*) for the substrates to be fixed by a simple method and to simplify the operation for crystal growth. The above (*i*), (*ii*), and (*iii*) have been discussed in Ref. (3). The improved rotating boat system is in principle identical to Ref. (3) but the main features of the improved rotating boat system are (*iii*) and (*iv*), above. As concerning (*iii*), the substrates are held erect by a suitable support, then put into the boat and arranged in a transverse direction. This arrangement of the substrates is a major feature of the rotating LPE growth. If the substrates are arranged vertically, and the melt is run into the space between the substrates, the thickness of the melt will automatically be determined. This is particularly important when making a melt of small thickness. Furthermore, the repeated use of the melt reduces the consumption of the melt per substrate. As concerning the above (*iv*), in the usual system, since the substrates are set in a longitudinal direction, the method of fixing them is difficult. In the existing rotating boat

LPE growth (3), the substrate is fixed by spacer clamps made of quartz. Two substrates are fixed by sticking them together back-to-back with spacer clamps, or quartz plates are put between the two substrates and then fixed with spacer clamps. This method, however, complicates the suspension of the substrate. On the other hand, in the system used here a small volume of melted gallium is placed on the back of the substrate and pressed closely against the quartz plate. One hundred lots were made by this method and there has been no case where the substrate has ever fallen off.

The operation is as follows: Fig. 1a shows the condition before crystal growth. If the boat is turned clockwise from this position, the melt flows out toward the substrates (Fig. 1b). If, after the melt has flowed out sufficiently, the boat is turned counterclockwise, the substrates dip into the melt (Fig. 1c). If the boat is turned counterclockwise after LPE growth, the melt begins to flow out of the substrate portions (Fig. 1d). If the boat is turned clockwise when the melt has fully flowed out, it returns to its original position, and the substrates and the melt are completely separated (Fig. 1a). The above operation is performed either by fixing the boat to a horizontally positioned reaction tube and turning the tube or by turning the boat itself by some outside means.

Figure 2 shows the lid of the boat, the square-shaped vessel, and the screws and nuts for clamping the lid and the square-shaped vessel together. The portion on the bottom of the lid and the portion on the top of the vessel form the joint between the lid and the vessel. This edge is 10-15 mm wide. It is constructed this way so that it can be completely fixed by firmly bonding this portion and clamping it with screws and nuts, thus shutting it off from the outside. The parts are all made of quartz. Figures 3 and 4 show the substrate holders. These are also made of quartz. Two methods of holding the substrate can be used. Figure 3 shows the system wherein quartz columns (1-3 mm in diameter) are welded by fusion in the shape of a (/\) in the lower position on the quartz plate. On this the substrates are installed, parallel to the quartz plate. With this method, by changing the angle of the (/\), it is possible to hold substrates of any size. (By welding 5-10 sheets of these quartz plates together, laid one upon another by fusion, a casette-type substrate holder can be made.) The thickness of the melt is

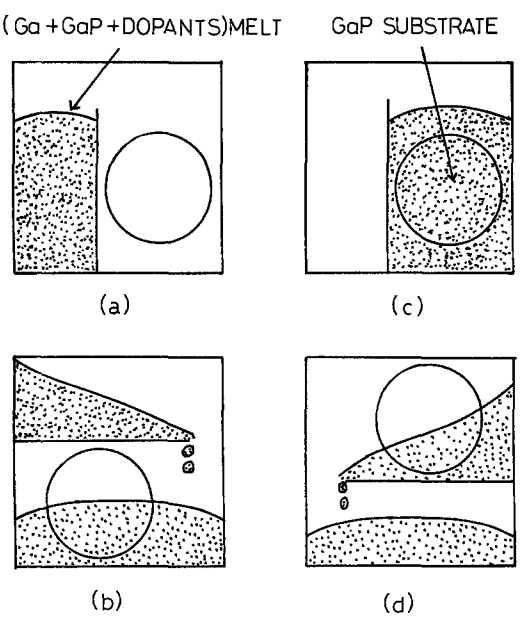

Fig. 1. The schematic representation of the rotating boat system and operation procedure: (a) the condition before crystal growth; (b) the melt flows out toward the substrates; (c) the substrates dip into the melt; (d) after LPE growth, the melt begins to flow out of the substrate portions.

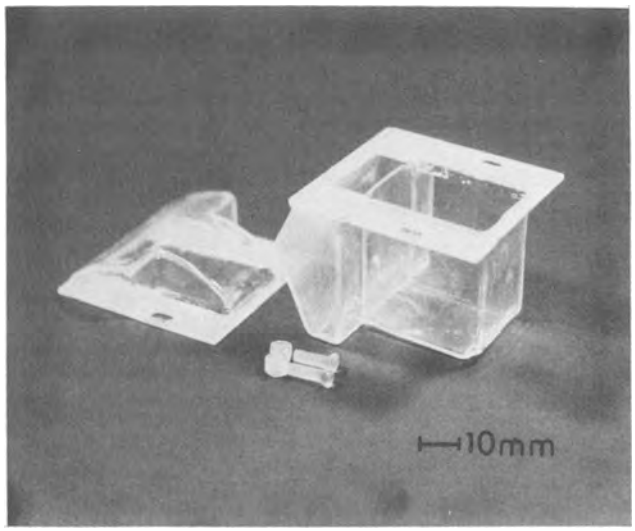

Fig. 2. The lid of the boat, the square-shaped vessel, and the screws and nuts for clamping the lid and the square-shaped vessel together.

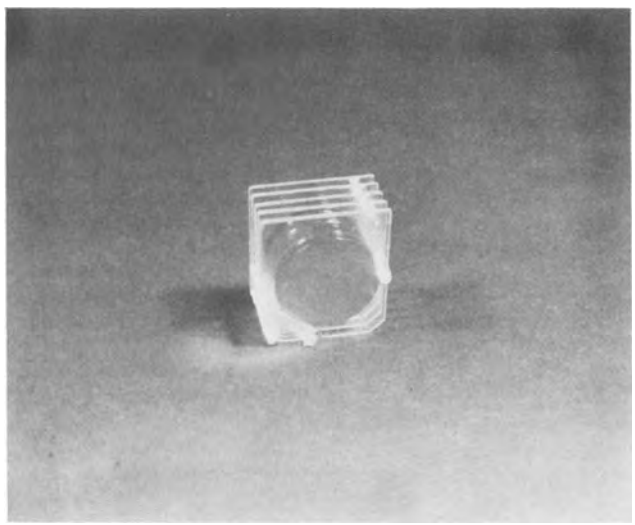

Fig. 3. The substrate holder on which the substrates are fixed

controlled by changing the diameter of the quartz columns. In this experiment, 2 and 3 mm quartz columns are used, and the thickness of the melt is 2 and 3 mm. Figure 4 shows another method for holding the substrates. In this method, a small amount of melted gallium metal is made to adhere to the substrate holding plate and by letting the substrates adhere closely to it, they are fixed. The thickness of the melt is controlled by the height of the quartz column (1-2 mm diam) attached to three corners of the quartz plate.

This experiment is conducted on two kinds of melt, 2 and 3 mm thick. In this method, quartz plates, to which the substrates are fixed on both surfaces, are put successively into the right-hand portion of the square-shaped vessel. It is also possible to use 5-10 quartz plates and to process 10-20 substrates at a time. Either of the substrate fixing methods makes it possible to fix a substrate with up to a 50 mm diameter. Figure 5 shows how the boat is set with the melt and substrate.

Experiment

The electric furnace in this experiment is a horizontal-type resistance heating furnace. Boats are made of quartz of high purity with no copper. These boats can each simultaneously process 10-20 substrates of a 30-50 mm diameter.

First, in order to test the variation of the carrier concentration in an LPE layer for the melt reuse with

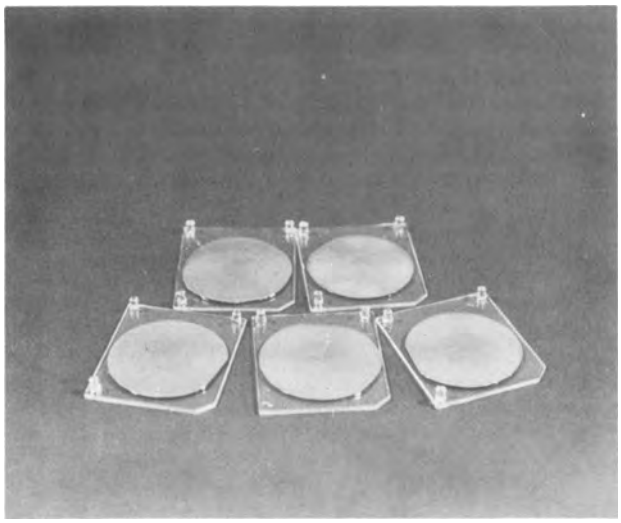

Fig. 4. Another type of substrate holder on which the substrates are fixed.

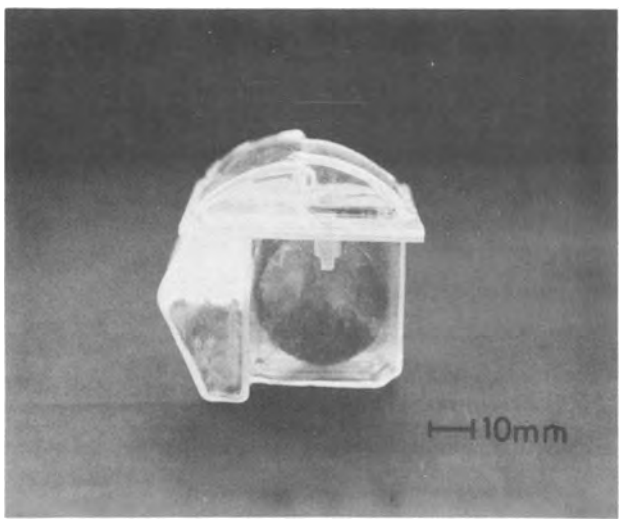

Fig. 5. The boat completely loaded with the melt and the substrates

no added impurities, the same melt is used in the 1st to 10th crystal growth. In the 2nd to 10th growths, only a small amount of GaP polycrystal is added. The procedures are as follows: (*i*) The well-washed boat is heated with nothing in it at 1200°C for about 60 min. The atmosphere is Ar gas, as for crystal growth. (*ii*) In its preparation, Ga metal and GaP polycrystal are first put in the left portion of the boat, and in the right side are put the substrates previously fixed to the substrate holder. The cover is then placed over the boat, which is next inserted in the reaction pipe to bring it to a uniform temperature region. (*iii*) The starting temperature of the LPE layer growth is 1040°C. The cooling speed is 1-3°C/min. The temperature is cooled to 980°C. The substrate used is the n-type (of three kinds) whose carrier concentrations are about $5 \times 10^{16}/cm^3$, $2 \times 10^{17}/cm^3$, and $8 \times 10^{17}/cm^3$. Samples for measuring the carrier concentration are cut equally (5×5 mm) from the wafer in 5 places. Sample surfaces lap by a small angle and Schottky barriers are formed by evaporating Au to the lapped surfaces.

Second, in order to test the variation of the carrier concentration in the case of the addition of impurities, n- and p-layers are grown separately on the substrate. The conditions for the starting temperature, the cooling speed, and the stopping temperature for the n- and p-layer growth are the same as for the undoped layer growth. The dopant is Te for the n-type layer growth and is Zn for the p-layer growth. The quantity of Te added to the melt is 1.6×10^{-2} to 3.3×10^{-1} atomic percent (a/o) and the quantity of Zn added to the melt is 2.8×10^{-3} to 5.4×10^{-2} a/o. The carrier concentration of the n-layer is measured on the grown surface at 980°C and the carrier concentration of the p-layer is measured in the neighborhood of the grown layer at 1040°C.

Finally, to make LED's, the n- and p-layers are continually grown on an n-type LEC substrate with a separate melt. That is, for both the n- and p-layer growth, the first growth is made by adding impurities to the melt beforehand. In the 2nd to 10th growths, the melt used in the first growth is used with no addition of impurities, only a small amount of GaP polycrystal is added. As for O, which is necessary for the formation of the Zn-O complex (the radiative recombination center) O is added to the p-melt in the form of Ga_2O_3. The condition for the n- and p-layer growth is the same as mentioned above. After the crystal growth is finished, the wafers are heat-treated at 550°-600°C for 8-16 hr. After the mesa-type etching is made on the surface of the growth layer, the contacts (small sized dot Zn-Au contacts on the p-side and middle sized dot Sn-Au contacts on the n-side) are evaporated. The contacts are alloyed, then scribing these wafers to the size of $400 \times 400\mu$, the LED pellets are mounted on white ceramic headers, coated with the transparent epoxy resin, and various electrical and optical characteristics are measured. The carrier concentration is found from the C-V measurement. The efficiency is measured with a calibrated integrating sphere. The electroluminescence time decay (τ_D) is measured by a photomultiplier (7102) with a 50Ω load and 1 mA current pulses with 1 μsec width are applied.

Results and Discussion

Carrier concentration in crystals with no added impurities.—LPE crystals are grown using a quartz boat. With a quartz boat, pollution by Si that melts from the boat and pollution of the melt resulting from other impurities gained by moving the holder in and out when replacing the substrate should be considered. A reduction in the efficiency due to these remaining impurities is a problem, especially during the crystal growth of the n- and p-layers with a quartz boat, when using the melt as many as 10 times. There is a fear of the melt being polluted. Without adding impurities, which become carriers, the melt for crystal growth could be used as often as 10 times running as it is at the same growth temperature as when the LED's are prepared. When a quartz boat is used, the growth layer is of the n-type and the carrier concentration is about $5 \times 10^{16}/cm^3$ in the neighborhood of the growth interface and $6 \times 10^{16}/cm^3$ on the growth surface, for the first use of the melt, with a concentration gradient. With the 10th use, this concentration becomes about $8 \times 10^{16}/cm^3$ for the interface and about $10 \times 10^{16}/cm^3$ for the surface. Thus, the carrier concentration tends to successively increase little by little with the number of times the melt is used. No difference in the substrate due to a difference in the carrier concentration is observed. The increase in the carrier concentration toward growth is the same as previously reported (7), and is considered to be due to a gradual increase of Si. The increase in the carrier concentration due to the frequency of the use of the melt is also thought to be due to Si. As seen from the above, the quartz boat is slightly polluted by Si, but because the Ga_2O_3, which becomes the radiative recombination center, is reduced with the use of a graphite boat, and this reduces the quantity of O added to the crystal, a quartz boat is used for red LED preparation.

Control of the concentration of impurities.—In the LED, the carrier concentration of the n- and p-layers affects the efficiency. Therefore, let us consider the

controllability of the concentration of the impurities in the rotating boat LPE growth system.

For LED preparation, Te and Zn are first added to the melt for the growth of the n- and p-layers. Figure 6 shows the relationship between the quantity of Te added to the melt and the carrier concentration of the grown surface at 980°C. For quantities under 4.4×10^{-2} a/o, the gradient is $m = 1$, and for quantities exceeding 4.4×10^{-2} a/o, the gradient is $m = ½$; thus, 4.4×10^{-2} a/o is the fork point. These results show the tendency previously reported (8, 9). Figure 6 also shows the relationship between the quantity of Zn added to the melt and the carrier concentration of the grown layer at 1040°C. In this case, the fork point is 10^{-2} a/o and the gradient (m) is ½ and 1, respectively. These results also show the tendency previously reported (8, 9). Thus, fairly accurate control of the concentration of impurities is possible.

The relationship between carrier concentration and the frequency of the use of the melt.—N- and p-type impurities are added only when the melt is first used; not in the 2nd to 10th uses. Therefore, since the melt is used repeatedly, if the carrier concentration in the n- and p-layers changes, it ought to greatly affect the efficiency.

Figure 7 shows the change in the carrier concentration according to the frequency of the use of the melt when the optimum quantity of Te and Zn (3.28×10^{-2} and 5.38×10^{-3} a/o, respectively) is added. The carrier concentration of the p-layer in the neighborhood of the p-n junction is about $2 \times 10^{17}/cm^3$. This value is nearly constant until the melt is used for the 10th time which, as the quartz boat is sealed, shows that the quantity of evaporated Zn is small. The carrier concentration of the n-layer in the neighborhood of the p-n junction is almost constant ($8 \times 10^{17}/cm^3$) from the 1st to the 10th use of the melt.

Emission wavelength and the frequency of the use of the melt.—The emission spectrum of the red LED has a peak wavelength of 7000Å and a half-value width of 1000Å; neither this peak wavelength nor the half-value width change with the frequency of the use of the melt.

The relationship between efficiency, electroluminescence time decay, and the frequency of the use of the melt.—Figure 8 shows the change in efficiencies based on the frequency of the use of the melt. No change in efficiencies occurs due to the frequency of the use of the melt from the 1st to the 10th use. An average efficiency of 6% (current density = 2 A/cm²) is obtained with good reproducibility at the time of mass production, and the maximum efficiency (current density = 2 A/cm²) of 10% is obtained.

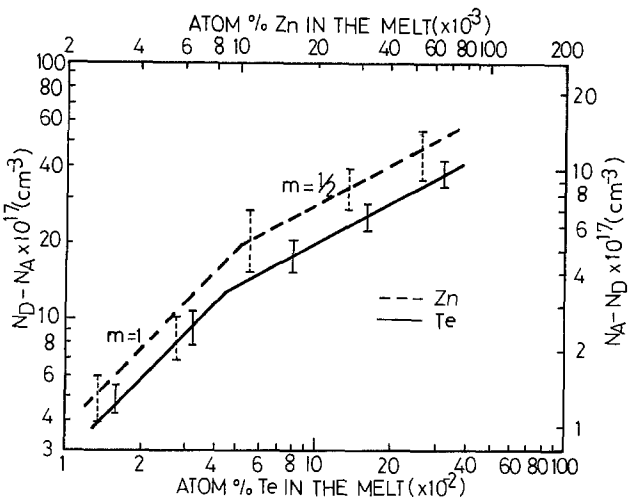

Fig. 6. The relationship between the quantity of added Te and Zn in the melt and the carrier concentration of the grown surface at 980°C and the grown layer at 1040°C.

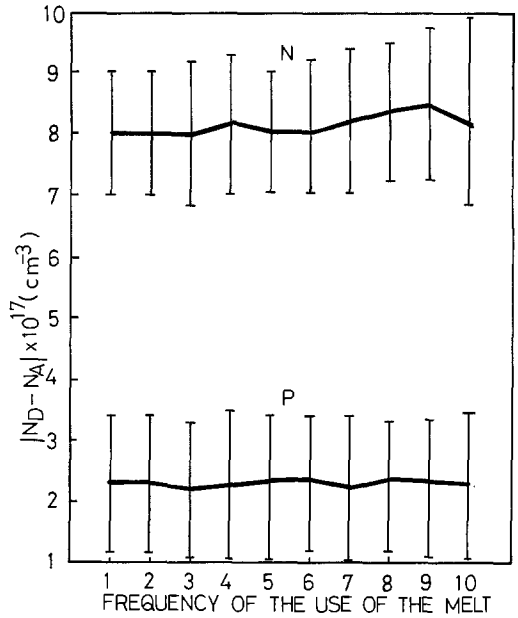

Fig. 7. The carrier concentration with the sequential use of the melt.

Figure 8 also shows the change in the electroluminescence time decay due to the frequency of the use of the melt. In using the n- and p-melts for the 1st to the 10th, the average electroluminescence time decay is about 500 nsec. This also shows that the various contaminations during the LPE procedure are small.

Relationship between efficiency and current.—In the red LED's, at a current density of 2-3 A/cm², the saturation of the efficiency occurs. When the current density becomes higher, the efficiency is linearly reduced. However, the degree of reduction varies with the type of LED; one group having high efficiency and another group having low efficiency. Reduction of the efficiency with the former group is greater. The photoluminescence of the p-layer of these wafers is measured before assembling the LED, and shows no difference in emission intensity.

The difference in the carrier concentration in the neighborhood of the p-n junction is constant. These facts indicate that it is the difference in crystallinity in the neighborhood of the p-n junction that causes

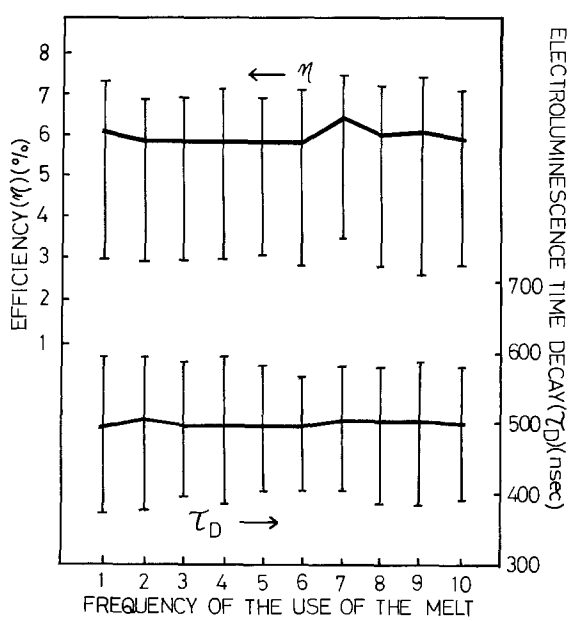

Fig. 8. The relationship between the efficiency (η) of LED's, the electroluminescence decay time, and the frequency of the use of the melt.

the difference in the ratio of the reduction in the efficiency. It is believed that in the LED's with low efficiency, the recombination generation current via the deep levels which exist in the depletion layer becomes predominant with low current. The electron concentration which contributes to radiative recombination is restricted; and the change in the efficiency to the current becomes smaller.

The condition of the surface after LPE crystal growth.—Figure 9 shows the interference microphotograph of the surface of the wafer after the LPE growth. In the rotating boat LPE growth system, the melt is completely removed from the surface of the substrate at the termination of growth, so that a very smooth surface is obtained. This does not change even if the melt is used repeatedly. The surface of the growth layer is mirrorlike, even after the 10th use of the melt.

Conclusion

To lower the production costs of GaP LED's, LPE growth, which is the most important of the production processes, has been considered and a rotating boat LPE growth system has been studied. Results are as follows: (*i*) In the rotating boat LPE growth system, 10-20 substrates can be treated at a time, and the carrier concentration necessary for manufacturing LED's can be controlled quite accurately. In addition, there is little change in the optical characteristics of the same lot and between separate lots. (*ii*) For the red LED, a double step system, which makes the n- and p-layers grow separately, is used. This reduces the consumption of Ga by using the same melt in both n- and p-layer growth up to 10 times. It makes it possible to remove the melt completely after growth is finished, and a mirrorlike growth surface can be obtained up to the 10th use. (*iii*) Red LED's with high efficiencies (average, 6%; maximum, 10%) are obtained with good reproducibility.

Thus, the rotating boat LPE growth system is excellent as a mass production system.

Device Quality GaAs Grown at Low Temperature by the Halide Process

J. Hallais,* D. Boccon-Gibod, J. P. Chané, J. M. Durand, and L. Hollan

Laboratories d'Electronique et de Physique Appliquée, 94450 Limeil-Brévannes, France

ABSTRACT

A study of the parameters which must be controlled to enable the vapor growth of GaAs at low temperature (LT.VPE) using the $AsCl_3/GaAs/H_2$ system has led to routine growth of MESFET layers at 630°C. The source temperature was determined from transport efficiency measurements and set in the range 670°-680°C. The growth rate dependence on temperatures and the $AsCl_3$ mole fraction were determined. The morphology of the layer was optimized as a function of the $AsCl_3$ mole fraction and the misorientation of the substrate. The best value of misorientation is about 6° off (001). These growth conditions were applied to submicron layer growth, and MESFET devices were fabricated. A comparison of the device performances obtained on layers deposited at high (750°C) and low (630°C) temperature shows an improvement on unbuffered layers grown at low temperature. Furthermore, the growth of an n^- buffer layer at low temperature improves the noise figure still further. Typical results without buffer layers, at 10 GHz, are 4 dB NF, 7.5 dB associated gain, and 11 dB maximum gain.

The $AsCl_3/Ga/H_2$ and $AsCl_3/GaAs/H_2$ chemical vapor transport systems, first described by Knight *et al.* (1), are widely used for the epitaxial growth of device-quality GaAs. Most of the work is performed using deposition temperatures T_D in the range 770°-705°C (2-4), but for several reasons it becomes attractive to lower the source and deposition temperatures ($T_D < 700$°C): Firstly, according to Weiner's calculation (5) and Di Lorenzo's data (6), silicon contamination is minimized at low temperatures; the second aspect is related to the thermal stability of GaAs (7). This last factor is of particular interest for MESFET devices for which submicron layers are deposited on semi-insulating substrates and whose rf performances and static characteristics are strongly dependent on the material and interface quality (8).

Several workers (9, 10) have reported on new methods for low temperature epitaxy (< 700°C), but most of their experimental conditions were based on out-of-equilibrium or out-of-steady-state conditions. Their results suggest that undecomposed $AsCl_3$ molecules cause supplementary reactions which allow larger supersaturation.

The aim of this work is: first, to define what can be expected for transport conditions in the temperature range 600°-700°C, and more particularly at 630°C, which is near the congruent evaporation point of GaAs (11); and second, to define an optimum set of conditions for epitaxial growth and to apply it to the MESFET layers.

Experimental Conditions

Both transport efficiency measurements and epitaxial growths are carried out in a classical $AsCl_3/GaAs$ (or $Ga)/H_2$ system described elsewhere (12). Most of the experiments were performed using solid GaAs sources in order to avoid the difficulties associated with Ga melt saturation with As (13). Undoped polycrystalline GaAs was used as the starting material. The transport rate was measured by the weight-loss method (14). The Ga/Cl ratio was calculated from the weight decrease of the source and the mole number of introduced $AsCl_3$.

Semi-insulating chromium-doped GaAs substrates were (001) oriented, a few degrees off, toward the (110) plane. Lens-shaped substrates were also used to study the influence of the misorientation following the technique described by Hollan *et al.* (15). Optical micrographs were used to observe the morphology on the surface plane and to determine the growth rates on stained cleavage surfaces. Electrical assessment was based on C-V measurements using the double mercury Schottky diode (16). Hall data were obtained by the classical Van der Pauw technique (17). A Hall pattern was also incorporated in the masks used for the FET technology. An aluminum layer is evaporated on the Hall sample, which enables measurements to be made at several biases and gives the mobility *vs.* the thickness of the undepleted layer. MESFET devices were fabricated using a previously described technique (18); two geometries of devices are labeled A and B types in Table I.

Experimental Results

Temperature dependence of the Ga/Cl ratio.—According to Watanabe (10) an "anomalous" transport reaction of GaAs by $AsCl_3$ is observed at low temperatures. Figure 1 shows the theoretical variation of the Ga/Cl ratio *vs.* temperature for the H_2 and neutral carrier gas (10, 14) and the experimental data obtained for the H_2 carrier gas. The Ga/Cl ratio dependence on the gas flow rate shows that there is a non-equilibrium phenomenon attributed to the reaction of the GaAs source with both undecomposed $AsCl_3$ and free HCl (10). At 630°C equilibrium is reached in the case of low flow rate values, but a deviation is observed for the high flow rates for temperatures up to 700°C. As the aim is to work at the lowest deposition temperature and with $T_S > T_D$, the flow rates were chosen in the range 30-130 cm^3/min, the source temperature was set in the range 670°-680°C and the source geometry was kept constant. The Ga/Cl ratio variation for a given $\Delta T = T_S - T_D$ is smaller in the low temperature range (680°-630°C) than in the classical temperature range (850°-750°C) and thus should lead to smaller growth rates. An influence of the $AsCl_3$ mole fraction (MF) on the Ga/Cl ratio is also expected

from theoretical calculations (19), but this effect was negligible in these experimental conditions ($10^{-4} \leq$ MF $\leq 10^{-2}$).

Temperature dependence of the growth rate.—Figure 2 shows the experimental results. As expected, a decrease of the growth rate is observed when the deposition temperature decreases for constant values of ΔT (50°C) and of the $AsCl_3$ mole fraction ($1.4\ 10^{-3}$). As previously mentioned (20), it is obvious that no linear dependence can be deduced from the data. It is worth noting that these growth conditions gave a good surface quality (no pyramids) over the whole of the investigated temperature range. Very small growth rates ($\sim$ 2 μm/hr) are interesting in practice for the fabrication of the submicron layers (0.2-0.3 μm) which are required for MESFET devices.

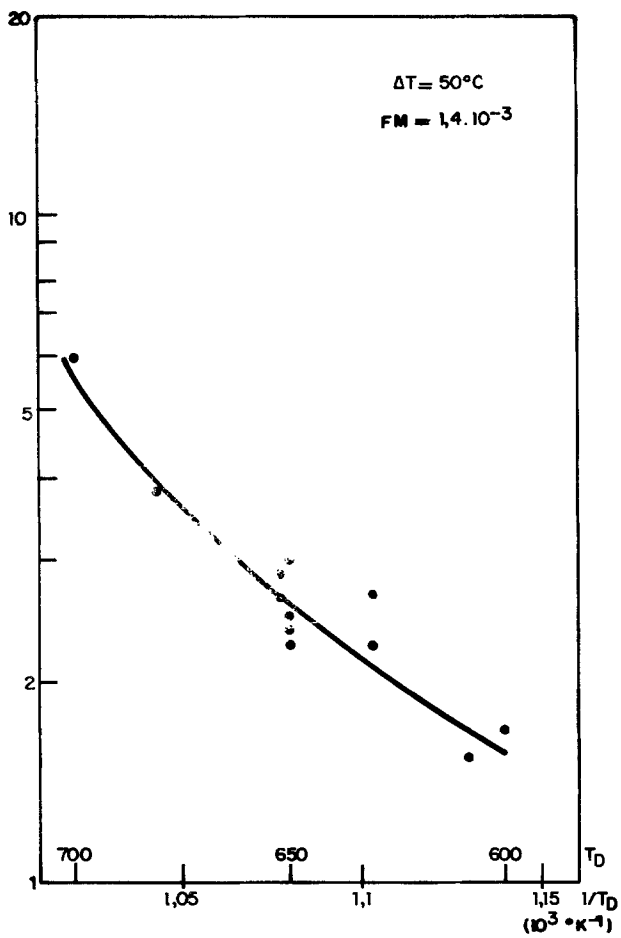

Fig. 2. Growth rate dependence on deposition temperature for constant ΔT and $AsCl_3$ mole fraction.

Growth rate and morphology dependence on the $AsCl_3$ mole fraction.—A large range of $AsCl_3$ MF was investigated for substrate and source temperatures of 630° and 670°C, respectively. The growth rate increased rapidly with the $AsCl_3$ MF (Fig. 3). The same effect has been previously reported (2, 3) for a higher deposition temperature and higher supersaturation. A rough comparison of the data (Fig. 3) shows that the growth rate is almost an order of magnitude higher at 750°C and rather similar at 705°C, but further conclusions cannot be deduced because the growth rate is highly sensitive to several parameters which are quite different for all these experiments (supersaturation, flow rates, misorientation). Surface morphology also depends on the $AsCl_3$ MF (Fig. 4). In practice, mirror-smooth layers are only obtained for $AsCl_3$ MF in the range 1-4 10^{-3}. At lower mole fractions the surface is pitted; at higher mole fractions macroscopic defects appear (pyramids). This effect was mentioned in a study of localized epitaxy (21) and more detailed work on growth anisotropy at low temperatures and high $AsCl_3$ MF's will be published later (22).

Growth rate and morphology dependence on substrate misorientation near (001) plane.—The influence of the misorientation of the deposition surface is conveniently investigated using lens-shaped substrates. The basic plane is (001) and the radius of curvature of 59.25 mm allows a misorientation angle α of about 9°. The other parameters are: $AsCl_3$ MF = $3\ 10^{-3}$, T_D = 630°C, T_S = 670°C. Figure 5 shows the growth anisotropy corresponding to the <110> and <1$\bar{1}$0> directions, and the same phenomenon is mentioned by Hollan (15) at 750°C.

The relative variation of τ, the growth rate, with α seems practically independent of the deposition temperature. The morphologies observed on the lens-shaped substrates are presented in Fig. 6. The two main directions of misorientation were <110> Ga and

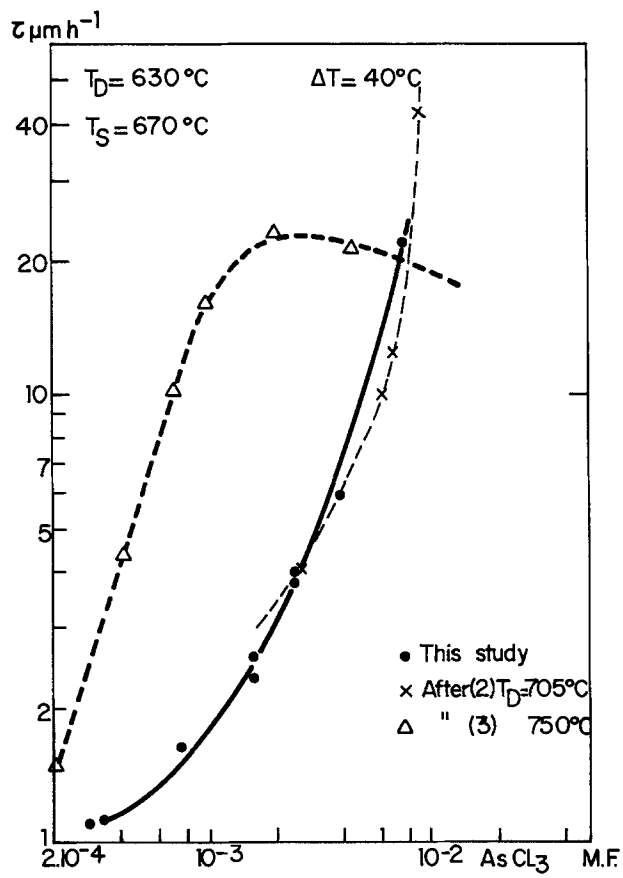

Fig. 3. Growth rate dependence on $AsCl_3$ mole fraction for constant source and deposition temperature. ● This study; x after (2) T_D = 705°C; △ after (3) T_D = 750°C.

<1$\bar{1}$0> As. The exact (001) plane exhibits a high density of pyramids but the density and the dimensions of the defects decrease rapidly with increasing misorientation. For each direction, a misorientation

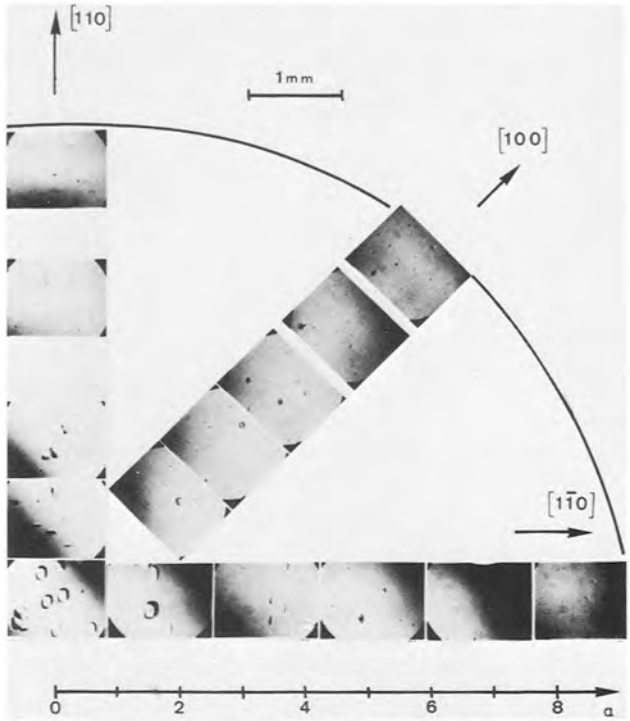

Fig. 6. Morphologies on a lens-shaped substrate for the three main misorientation directions.

angle α of 6°-7° gives a smooth, defect-free surface. This value is two times larger than is usual in high temperature VPE.

Electrical properties.—The residual doping level is n-type and depends on the $AsCl_3$ MF, (Table II). The variation of n is drastic as the $AsCl_3$ MF increases and the low concentration material becomes rather compensated.

Applications of Low Temperature Growth to Devices

Device-oriented epitaxy.— The main results of the last section were applied to the fabrication of practical layers. The experimental conditions are listed in Table III.

The semi-insulating GaAs substrate was cleaned in a dust-free room and directly inserted into the epitaxy reactor. The required layer thickness is in the range 0.2-0.3 μm. Mirror-smooth and macroscopic defect-free layers are routinely obtained. Deliberate sulfur doping is used to achieve the required n^+ level (1-2 10^{17} cm^{-3}). The sulfur mole fraction is about 7 10^{-10}, which is nearly 30 times less than at the high deposition temperature (750°C). Mobility profiles measured on a sample are presented in Fig. 7. By comparison with a high temperature (750°C) layer it appears that there is

an improvement in the mobility at the interface for the low temperature layer. By changing the $AsCl_3$ MF during the growth (see Table II), an $n^+/n^-/SI$ multilayered structure can also be obtained, but the n^- buffer layer, a few microns thick, is rather compensated.

MESFET results.—Defects of the static characteristics such as bumping or looping, which are often related to the interface quality (8), do not appear at all on the present devices (Fig. 8). Table IV shows typical results for several devices. The figure of merit M is defined by the relation $M = \frac{NF - 1}{1 - \frac{1}{G_{NF}}}$ where NF is the noise figure and G_{NF} the associated gain, both expressed with a linear scale. It can be noticed that the performances at 10 GHz for unbuffered layers LT.VPE give a better figure of merit than for the unbuffered HT VPE or MBE layers.[1] Moreover, the results for the $n^+/n^-/SI$ structure are close to the best published data (23).

* Grown at MRL.

Conclusions

It is shown that the $AsCl_3/GaAs/H_2$ epitaxy process can be used at deposition temperatures as low as 630°C. The necessary conditions to grow defect-free layers are an $AsCl_3$ mole fraction of 3-4 10^{-3} and a substrate orientation of 6° off (001) toward <110> Ga. The small growth rates in the range 1-2 μm/hr are very useful for the submicron layers (0.2-0.3 μm) required for MESFET devices.

Until now, on VPE devices the only convenient way to reduce the noise figure was to grow an n^- buffer layer between the SI substrate and the active layer. The present process appears to give an alternative method, which, like the MBE, uses also a low deposition temperature, and could lead to the same results without a buffer layer. The process seems then well adapted to an industrial development.

Kinetics of Titanium Oxidation in Water Vapor Argon Ambient Mixtures

Fradelle G. Fuhrman[1] and Frank C. Collins[2]

Department of Chemistry, Polytechnic Institute of New York, Brooklyn, New York 11201

ABSTRACT

Kinetic studies of the thermal oxidation of polycrystalline and single crystal titanium in ambient mixtures containing water vapor and argon were carried out at atmospheric pressure in the temperature range 400°-500°C. An analytical method was developed utilizing reflectance interference measurements in the u.v.-VIS-*IR* range, which allowed precision of about 2-5% of film thickness, in the range of 5-200 nm of film. In all cases, the kinetics followed a modified parabolic form which implied an initial surface-controlled reaction followed by a diffusion-controlled process complying with a parabolic growth law. Arrhenius plots were made for the growth rates, leading to calculated activation energy of 168.4 ± 0.2 kJ/mole (1.75 ± 0.005 eV) for the parabolic process on both the polycrystalline and single crystal material. No effect on the reaction was observed by either varying the water vapor pressure (above 4.6 Torr) or adding oxygen to the water vapor argon system. This observed zero-order dependence is consistent with the model of a water vapor saturated outer surface which has been observed for rutile in the presence of trace amounts of water vapor. No conclusive evidence has been obtained which would positively identify any single species as the only one migrating.

Oxidation of metals at temperatures below about 300°C usually follows a direct or inverse logarithmic law, and in many cases, ceases with the formation of a protective oxide film. These films are not protective at higher temperatures, and the oxidation then usually proceeds by a diffusion-controlled process which follows parabolic kinetics. At still higher temperatures, depending on the metal involved, other kinetics are obtained.

Oxidation of titanium at temperatures above 350°C has produced growth curves which are generally parabolic (1-6), sometimes indicating the presence of a second process, possibly linear, occurring simultaneously with the parabolic one. However, Hurlen (5) and Kučírek (6) report logarithmic growth below 650°C, while Jenkins (3) and Davies and Birchenall (7) find linear kinetics above 650°C. Tikomirov and Dyach'kov (8, 9) investigated the high temperature (750°-1050°C) oxidation of titanium with dry oxygen and found compliance with a linear parabolic growth equation first proposed by Evans (10)

$$X^2 + (k_p/k_l)X = k_p t$$

where X is the thickness of the oxide film, k_p and k_l the parabolic and linear rate constants, respectively, and t the time. They were able to distinguish for two different temperature regions the separate rate constants for the two processes and to determine activation energies for each. A similar linear parabolic law for the high temperature (850°-1000°C) oxidation of silicon in wet oxygen was analyzed by Nakayama and Collins (11) to give linear and parabolic rate constants and activation energies which they assigned to the separate surface and diffusion processes. Subsequently, Chen (12) showed that the medium temperature (600°-850°C) oxidation of chromium in wet ambients followed a similar linear-parabolic law. In view of the ambiguous results in the literature for titanium oxidation, a precise study seemed necessary to clarify and perhaps more closely define the processes occurring.

Since the study of titanium oxidation in oxygen involves an uptake of dissolved oxygen which is large

Key words: reflectance, interference, spectrophotometry, activation energies.

and difficult to measure (5, 8, 9), particularly with volumetric or gravimetric methods of analysis, and since "dry" oxygen systems may contain small but catalytically active amounts of water vapor (11), particularly in quartz furnace systems, it was of interest to determine the kinetics of oxidation of titanium by water vapor alone, and in the absence of oxygen from the reaction system. Also, since the possible solution of water vapor by the titanium system could not be ruled out, it appeared desirable to use an analytical method directly related to the actual film thickness. A method utilizing reflectance interference was therefore developed for this purpose.

The effect of the state of crystallinity of the surface has not been studied in the case of titanium oxidation. For this investigation, therefore, both single crystal and polycrystalline samples of research grade titanium were used.

The titanium samples for this study were sliced, polished manually and by wheel, and oxidized in a furnace under varying mixtures of water vapor and argon at atmospheric pressure. The samples were removed at intervals, cooled, and analyzed for film thickness in the optical setup described below. After measurements, the samples were replaced in the furnace system for further oxidation. Five to nine measurements were made for each sample, covering an oxidation period of several hours, for the temperature range 397°-549°C. The thickness of the measured films ranged from about 3 nm (the "native" oxide thickness which appears almost instantaneously on the freshly polished titanium) (2, 6) to several micrometers after thermal oxidation.

The data obtained were plotted on straight parabolic plots to give determinations of the parabolic rate constants. From these rate constants at different temperatures activation energies were determined for the process.

Experimental

Preparation of samples.—For the main oxidation studies two types of titanium were used. The polycrystalline material was obtained as a 2 in. long, ½ in. diam bar. The single crystal sample, obtained from Materials Research Corporation as a cylinder 1 in. long and ¼ in. diam, was oriented and sliced by the manufacturer along the long axis parallel to the 0001 plane. An x-ray diffraction image confirmed the single crystal structure, alpha (hexagonal) form, and the 0001 orientation. X-ray diffraction studies on the polycrystalline material showed no preferred orientation.

Since both the oxidation process and the optical analysis required as perfect a surface as possible, attention was focused sharply on the slicing and polishing of samples. Titanium in the pure state is a soft malleable metal, and exhibits a high degree of surface flow under strain. This characteristic led to difficulties in both slicing and polishing. The most successful cut was achieved with a diamond dust wire cutter operating at a very slow speed. The single crystal block was cut into three pieces, each with the 0001 face exposed. The polycrystalline bar was cross cut into slices about 1/8-1/16 in. thick. For the polishing, a relatively simple, although not altogether satisfactory, procedure was developed for both the polycrystalline and single crystal slices which involved the usual hand grinding down to 600 grit silicon carbide paper, wheel polishing with 0.3 and 0.05 micron alumina powder using Gamal cloth, with ultrasonic cleaning in warm acetone between steps to remove adherent grit particles which might cause pitting during wheel polishing. Heavy hand pressure seemed effective, with rapid wheel rotation. Significantly better results were achieved using an aluminum sample holder than either stainless steel or lucite of the same type, the abraded aluminum possibly providing an effective additional abrasive. A number of samples were polished using only abraded aluminum with apparently superior results.

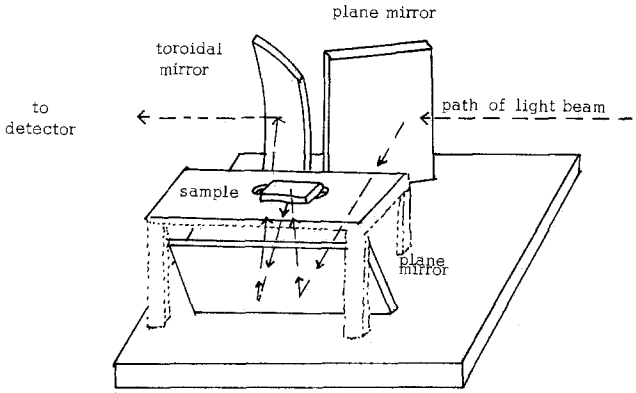

Fig. 1. Sketch of Barnes 134 reflectance attachment (schematic)

All of the holders received polishes far superior to those of the slices they were servicing. Specularity of the sample was judged adequate when the image of a human hair could be distinguished at a distance of about 6 in. Under the low power microscope all polished samples showed many small pits.

Oxidation of samples.—The oxidation system consisted of a gas (argon or argon and oxygen) carrier inlet, several humidiostats to provide water vapor at the proper partial pressures, and a furnace in which the oxidation took place. Analysis was carried out on a Carey 14 spectrophotometer[3] using a specular reflectance accessory in the sample chamber (Fig. 1).

The polished titanium specimens were cleaned ultrasonically with warm acetone for 5-10 min and allowed to stand in air for 1-3 days. The native oxide growth, which begins to form immediately on freshly polished samples except under very high vacuum, seems to be self-limiting, and becomes protective at about 3 nm of film, preventing any additional growth at room temperature.

The oxidation reaction was carried out in a 3 zone single control diffusion furnace which was heated by three helically wound metal rods, with a 10 in. long center section within which control could be maintained to within 1°C. Temperature was determined by a Chromel-Alumel thermocouple placed in the sample position and checked after each run. A calibration of furnace setting number *vs.* temperature gave a straight line with no apparent dependence upon whether the temperature was being lowered or raised. This was a check upon subsequent thermocouple readings.

The furnace tube and all connections were of fused quartz, the tube itself of single wall 2 in. internal diam., and 45 in. in length. All quartz components were connected by 12/5 ball joints with spring clamps. The outlet of the furnace tube was stuffed with glass wool to prevent dust or other solid contaminants from entering the furnace system. The ambient flow during the oxidation runs prevented the entrance of laboratory air into the system. Any absorption of water vapor by the quartz system or diffusion into the interior of the furnace tube was masked by the ambient flow of the water vapor oxidant into the furnace tube.

The quartz boat holding the sample was removed and replaced each time by a fused quartz rod with a hooked end, marked to indicate the position of the sample in the center zone of the furnace. The sample was removed from the boat with forceps and cooled in a glass petri dish before being placed in the sample chamber of the analyzing spectrophotometer.

The ambient argon gas (Matheson, high purity)[4] was controlled by a dual float flowmeter and set for 500 ml/min, corresponding to a linear flow rate of 4.97 cm/sec inside the furnace tube, previous studies having shown that increasing the flow rate beyond this magnitude had no effect on the reaction rates. Water vapor was introduced by first passing the argon through a

[3] Varian Instrument Division, Palo Alto, California.
[4] Matheson Gas Products, East Rutherford, New Jersey.

quartz humidiostat maintained at the required temperature for the desired vapor pressure. For the 0°C water vapor equilibrium (4.6 Torr) an ice bath was employed, with a precooling of the ambient gases in an ice-chilled column. For the higher vapor pressure of 55 Torr a heating unit was used, with a 40W long form light bulb as the heater and a thermistor-controlled regulator which provided temperature control of the bath to within 0.1°C. An infrared heater aimed at the exit tube of the humidiostat prevented water vapor condensation prior to its entering the tube of the furnace.

The furnace temperature was set at least one day in advance, and the ambient gases allowed to flow for 10 min prior to introduction of the sample. The titanium slices, either singly or in duplicate, were placed in the quartz boat and introduced into the furnace. The sample was removed at intervals, cooled, and placed on the sample platform of the reflectance unit inside the spectrophotometer for analysis. The sample was then replaced in the furnace for further oxidation. Three to nine measurements were made during each run, the average being about five, at intervals of 2 min to 2 hr. Readings at given oxidation times did not seem to depend upon whether the sample had been previously removed from the furnace or not.

For the run containing oxygen as one of the ambient gases, a second flowmeter set for 100 ml/min controlled the oxygen flow, which joined the 500 ml/min of argon prior to entering the humidiostat. Mixing was accomplished by turbulent flow through the inlet coils. This yielded an effective pressure of 120 Torr of oxygen within the system. The oxygen was Matheson, ultradry (99.6%).

Prior to the series of oxidation runs, the entire quartz system was cleaned in a dilute hydrofluoric acid-nitric acid mixture, and maintained thereafter as free as possible of contamination.

Analytical Procedure

The quantitative nature of interference phenomena resulting from reflectance at two surfaces is known exactly only for perfect reflectors, where the phase change at the interface is either 0 or pi, depending on the relative index of refraction of the two media. For the case of a real transparent film on an opaque surface, the absorptivity of both the film and the substrate will result in phase changes different from those where perfect reflectors are involved (13, 14). These phase differences will effectively add an apparent optical path to the reflected rays, giving an apparent film thickness greater than the actual value. Although the phase change difference is a function of wavelength, as is the real index of refraction, within a small range of wavelengths we may treat them as effectively constant to a first approximation, particularly if only zero order reflectance minima are used. The thickness of the real film may then be expressed as

$$X_r = \frac{\lambda}{4n} - \delta$$

where X_r is the film thickness, λ the wavelength at which zero order reflectance minimum occurs, n the real film index of refraction, and δ the apparent additional thickness due to the phase change. When the thickness of the real film is zero, then λ will have a positive value equal to $4\,n\delta$, although this is not a measurable value, as there is no interference without a reflecting film. However, the thickness of the real film is never zero, as the native oxide forms immediately on the freshly polished surface. The thickness (X_o) at zero time will therefore be that of the native oxide, and the wavelength zero (λ_o) extrapolated to zero time will consist of two terms, one being due to the native oxide, and the other being due to the phase change difference. The equation may be expressed as

$$\lambda_o = 4\,nX_o + 4\,n\delta$$

We can then write the thermally grown thickness of the oxide film as

$$X = X_r - X_o = \frac{\lambda}{4n} - \frac{\lambda_o}{4n} \text{ or } \frac{\lambda - \lambda_o}{4n}$$

where X_r is the real thickness at time of measurement, and X the thermally grown thickness.

Instrumentation

For the measurement of reflected intensity a Barnes Model 134 reflectance accessory[5] was modified for use in the Cary 14 spectrophotometer. An aluminum platform in the sample chamber of the Cary replaced the usual Cary sample holder, and the reflectance accessory was placed on the platform, after which the mirrors were adjusted to give maximum reflectance (Fig. 1). About 70% of full-scale intensity could be received by the detector with the unit in place and a front surface aluminized mirror in the sample position. Actual reflected intensities were much lower with the sample in place, but since most of the minima went completely off scale there was no real problem in locating them, even with the low light levels present at certain thicknesses. The thin oxide films showed brilliant interference colors, some of which, such as the deep indigo, reflected little visible light. The extended range of the Cary made this instrument extremely useful, as wavelengths from 280 nm to 2.6 μm could be scanned in one reading (three source lamps were available). This covered thicknesses from about 2.5 to about 250 nm. An attempt was made to measure thicker films by use of the reflectance attachment in the Perkin Elmer 21 spectrophotometer in the 2.5-12 μm range, but the reflectance spectra at these wavelengths showed excessive electrical noise, the spectral trace consisting of very jagged lines in which the minima were not readable with any reasonable precision. Beyond about 6 μm absorption bands appear and blank out any interference effects. These absorption bands could be used for the measurement of thicker films, but the method was not developed here.

Precision and Reproducibility

The forms of some spectrophotometric curves are shown in Fig. 2. Although in most cases the actual minimum was off scale, estimation of the minimum wavelength could easily be made to less than 5 nm for the narrower bands, and 50-100 nm for the widest ones. Since 5 nm of λ represents about 0.5 nm of film, it is seen that the precision is on the order of 2-5% of total film thickness, except for perhaps some very early points. The reproducibility of the measurements is better than this. When duplicate runs were made on the same sample area using both visible and u.v. sources within the same low wavelength range, the two curves were usually very closely coincident.

Although separate samples oxidized together under the same conditions varied between themselves as much as 10% of actual film thickness, the measured slopes for the parabolic portion agreed very closely for duplicate samples, indicating that the thickness difference was a function of the initial portion of the oxidation process. Repeat optical measurement of each sample always gave results within the readable precision. It is clear that the analytical method itself is capable of greater precision than the system requires, and shows less variability than the oxidation process itself.

Experimental Results

Computation of growth rates from optical data.— The raw data generated by the interference spectra consists of wavelength readings (λ) at which deep reflectance minima occur, each minimum being a characteristic of a particular oxide film on a particular sample substrate. These minima occur at higher and higher wavelengths as the oxide film increases in thickness (Fig. 3).

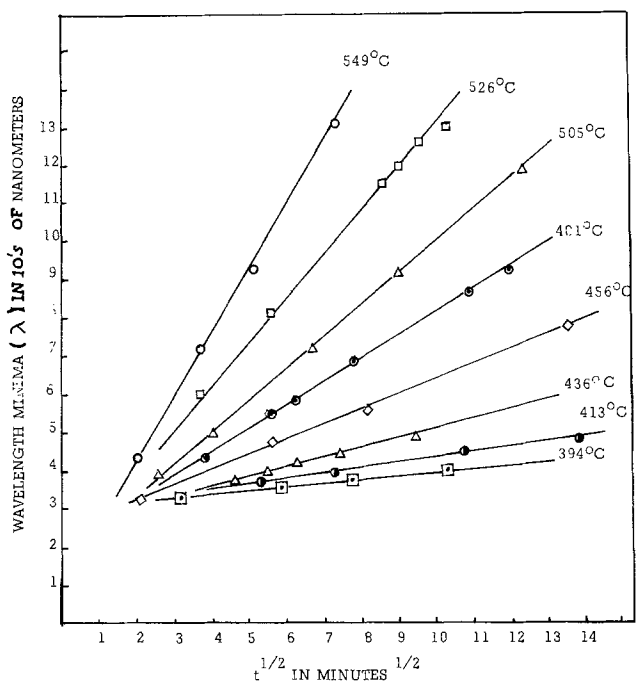

Fig. 3. Typical growth curves of oxide films on titanium in water vapor argon ambient mixtures.

At oxidation temperatures below about 570°C the plot of wavelength minima *vs.* time for any single sample shows a parabolic form with the wavelengths seeming to originate from some λ_o at zero time. Plots of λ *vs.* $t^{1/2}$ show straight lines which intersect not at zero time but at some later t, the form of the curve indicating that an initial term is involved relating to the initial growth process which is probably surface, rather than diffusion, controlled. A parabolic rate constant k_p, may be read directly from the parabolic portion of the curve, with

$$k_p = (dx/dt^{1/2})^2$$

Preliminary runs carried out at oxidation temperatures of 572°C and above showed a breakdown of this parabolic form (Fig. 4) and it was decided to concentrate on the lower temperature range where the simpler and probably more basic kinetics were obtained.

Arrhenius plots of the rate constants *vs.* the reciprocal of the absolute temperature were made on semilog graph paper, and the activation energies were calculated from the slopes. Single crystal runs were indis-

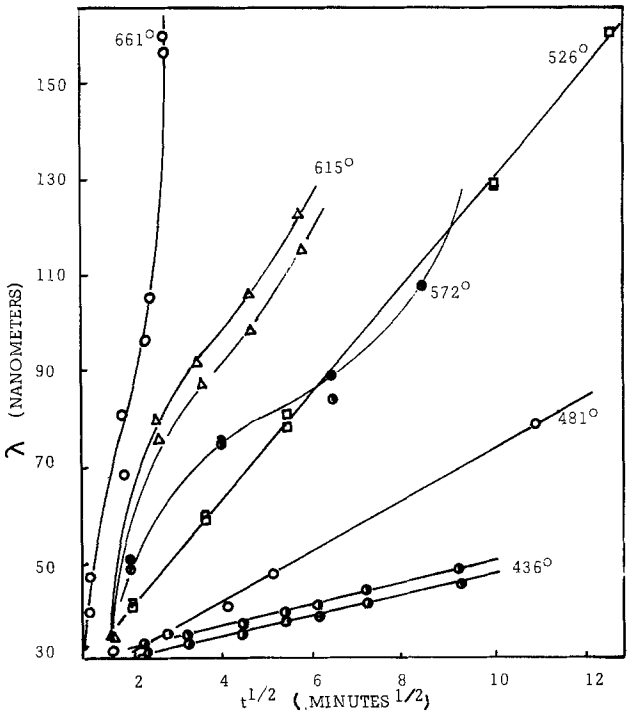

Fig. 4. Plot of preliminary runs showing breakdown of parabolic kinetics at temperatures of 572°C and above.

tinguishable from polycrystalline runs in the parabolic region of the kinetics, although in all cases the initial rates for the single crystal material were lower. The activation energy for the diffusion-controlled region was determined to be 168.4 ± 0.2 kJ/mole (40.3 kcal/mole, or 1.75 eV) (Fig. 5).

Addition of oxygen to the system (about 120 Torr) and the increase of water vapor partial pressure from 4.6 to 55 Torr had no noticeable effect on either the initial or parabolic region of the kinetics. The rate constants fell smoothly on the same Arrhenius plots as those runs with no oxygen, or with lower vapor pressure.

Discussion of Results

The modified parabolic form of the rate curves within the time range of 0-2 hr and at temperatures of 394°-549°C fits a rate law of the form

$$f(X) + BX^2 = t$$

where $f(X)$ represents the initial process, possibly of limited duration, occurring during the first few minutes of reaction, and either ceasing or being dominated thereafter by the parabolic process normally associated with diffusion control as the film builds up to the point where the oxidant species no longer has full free access to the metal surface.

The theoretical basis of the rate law has been investigated by Collins and Nakayama (15). Their results were applied to the data of Nakayama and Collins (11) on the oxidation of silicon, and to that of Chen (12) on the oxidation of chromium. The results of the present study on titanium oxidation may be attributed to the same electrochemical model.

In this model, the oxide layer, which is a semiconductor at oxidation temperatures, separates the substrate from the adsorbed gas. The Fermi potential difference between the energy levels of the electrons in the metal and the adsorbed gas causes a movement of electrons and/or holes through the film. The electrostatic potential difference ΔV set up by this movement of charge causes a drift of ions, the resulting ionic current balancing the mobile carrier current to conserve charge. The growth rate of the oxide layer is proportional to the ionic current which supplies the active species to the reaction systems. Thus

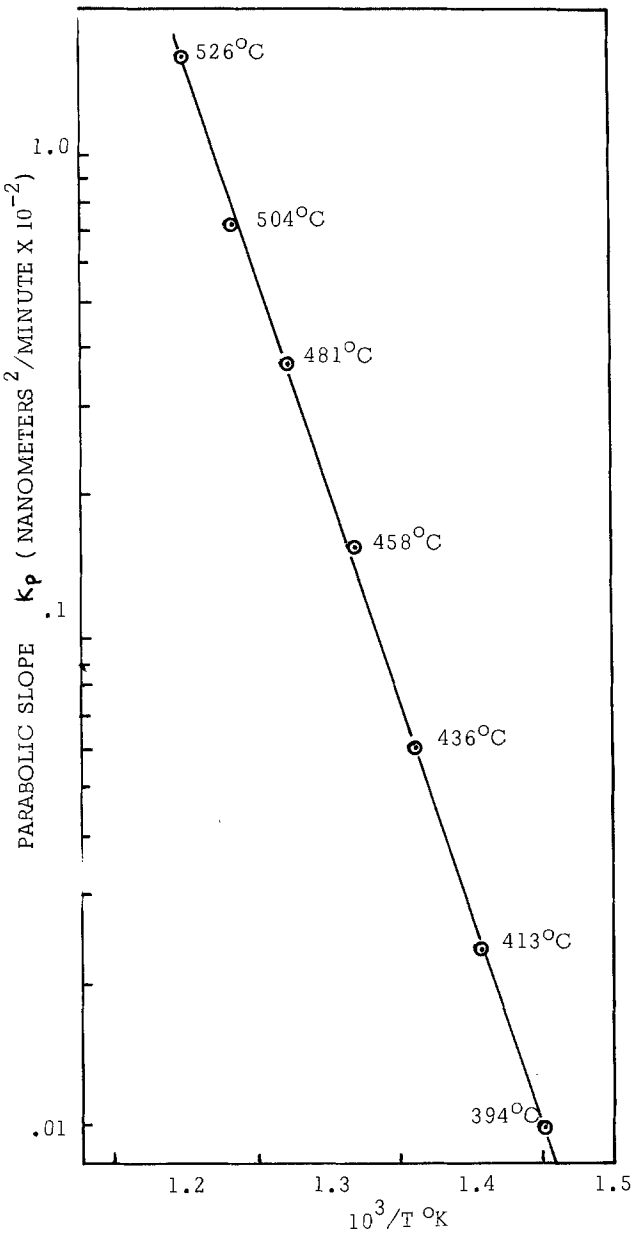

Fig. 5. Arrhenius plot of parabolic slopes k_p read directly from data. All runs on polycrystalline Ti samples with 4.6 Torr H_2O, with argon to 1 atm. E_a = 168.4 ± 0.2 kJ/mole.

$$I = 4q(N/V_m)(dX/dt)$$

where I is the current density, q the electronic charge, N Avogadro's number, V_m the molar volume of the oxide, and dX/DT the rate of increase of thickness of the growing oxide film.

In the absence of space charge, the ionic flux, in terms of numbers of ions per unit area per unit time, may be put into the form

$$J = -\frac{Dq\Delta V}{kTX}\frac{c(X)e^{-q\Delta V/kT} - c(O)}{e^{-q\Delta V/kT} - 1}$$

where D is the coefficient of ionic diffusion, X the thickness of the film, and $c(X)$ and $c(O)$ the concentrations of active species at the two surfaces of the film. It can be seen that in the steady states where $c(X)$ and $c(O)$ are constant, parabolic growth will be observed, assuming ΔV to be constant. Since ΔV depends on the electronic conductivity and the electrochemical cell potential $E°$, this constancy is obtained here at least in the early stages of the reaction (15).

Where an additional term appears in the rate law, the surface concentrations $c(X)$ must be examined for their role in rate control. Nakayama and Collins have applied an adsorption-desorption equilibrium to the system, and derive the rate law

$$\tfrac{1}{2}\left(\frac{k_aP}{k'} + \frac{k_d}{k'}\right)(X_r^2 - X_o^2) + (X_r - X_o) = k_aC_oPt$$

where the k's refer to the process of adsorption, desorption, and diffusion, respectively, with P the partial pressure of the oxidizing species, and C_o the concentration of active sites on the adsorbing surface.

It is seen that the linear rate constant here appears as

$$k_l = k_aC_oP$$

corresponding to adsorption rate control of the growth process at small values of X.

In this study of titanium oxidation no dependence of either initial or parabolic rates on water vapor partial pressure was observed in any of the runs. If, as Hollabaugh (16) has suggested, the rutile surface is saturated with chemisorbed water molecules at all except "trace" ambient pressures, this zero order dependence suggests that both the processes involved in the rate law are supplied with a surplus of oxidant species, even at very low pressures. The adsorption rate control described by Nakayama and Collins for silicon oxidation would be replaced here by some surface process control, the nature of which is not immediately apparent from the data. It could be the surface dissociation of adsorbed water to produce OH^- ions, or perhaps the freeing of Ti^{+4} ions from the substrate metal.

The fact, however, that the initial rates, although not subject to any systematic effect of ambient pressures, did show relatively large variability from sample to sample, indicates great sensitivity of the initial process to the state of the individual surface. These effects could be caused by surface contamination, surface discontinuities, exposure of particular crystal faces, etc. The lower initial rates shown by single crystal samples confirm the role of the surface form in the initial process.

The parabolic rate constants showed no effect of either changing oxidant pressure or crystal form, mono- and poly-crystals showing identical parabolic rate constants and activation energies. The diffusion-controlled process, then, which is involved in the parabolic rate constants, is not affected by surface form or structure, and we may say that the bulk properties of the oxide films are uniform and not dependent upon the surface details, at least for reasonably smooth, polished surfaces. When nonspecular surfaces are involved, however, this may not necessarily hold, and this fact may be responsible for the great variation shown in the literature values of activation energies for these processes.

The lack of response of the reaction system to the addition of oxygen to the wet ambients is consistent with the picture of a water-saturated outer surface of rutile. It also may suggest that the reaction of Ti with water vapor is faster than that with oxygen, which is consistent with Kučírek's (6) suggestion that this may account for his finding that Ti reacts more quickly, under otherwise identical conditions, with air than with dry oxygen.

Brief Communication

Three-Dimensional Distribution of Twins in Epitaxial Silicon on Sapphire

J. Trilhe

Nuclear Studies Center of Grenoble, 38041 Grenoble Cedex, France

Silicon layers in the 0.5μ thickness range are quite interesting for planox technology. We report here transmission electron microscopy observations of 0.4μ epitaxial layers deposited on a sapphire substrate. The silicon, the interface, and part of the sapphire are thin enough to be transparent to 200 keV electrons. Milling of the extra sapphire has been performed from one side, with an argon ion gun at grazing incidence.

Figure 1 is the diffraction diagram of the sample. The interface has been imaged (Fig. 2) in a dark field on a (110) plane of sapphire (spot I). One family of twins is evident (Fig. 3) in a dark field image using twin spot (II) of the same area of the crystal. The edge of the beveled sample is on the left-hand side.

Figure 4 is a schematic of the sample assuming a uniform bevel. The position of the interface is given by the dark field of the sapphire. Twins can be tridimensionally represented, having one (110) direction with no deformation and assuming that twins lie in (111) planes. This classical technique for twin observation in epitaxial silicon layers is shown to be as powerful for this application as the cross-section technique which has been developed elsewhere (1). But it is easier and allows the study of numerous samples.

In the figures of this work we showed a high density of little twins in the first 500Å of the silicon deposit; these twins disappear in the left side of the picture when the interfacial silicon has been removed by ion milling. There is also a random distribution of twins, less numerous, which get through the silicon deposit.

It is interesting to note that these first 500Å in thickness of the silicon deposit are of the same order of magnitude as the thickness needed to reach coalescence of a silicon deposit on a sapphire substrate in the usual conditions for chemical vapor deposition. A possible explanation for twin formation is the outgassing of impurity from the substrate. When the substrate is completely covered, the outgassing comes only from the back side, so the twin density decreases considerably.

Galvanic Corrosion of Al Alloys Monitored by Acoustic Emission

F. Mansfeld* and P. J. Stocker

Science Center, Rockwell International, Thousand Oaks, California 91360

Rettig and Felsen (1) have recently shown that acoustic emission has some promise in monitoring corrosion reactions of unstressed, freely corroding materials and galvanic couples. The data presented were typically taken over a 10 to 30 min. period with emphasis on Al alloys. We have started a program to evaluate the acoustic emission method in more detail, determine the source of the signal monitored and obtain correlations between electrochemical and acoustic data.

The results presented here involve the Al alloys 1100-0 and Al 2024-T851 coupled to Cu (OFHC), 4130 steel, Cd (99.97%) and Zn (99.9%) in aerated 3.5% NaCl. The corrosion behavior of the galvanic couples has been studied in detail earlier (2). The acoustic emission from the sample is detected by a piezoelectric transducer (PZT) which has a peak frequency response in the 150-200 KHz range. Details of the method of counting the individual sound bursts will be described elsewhere (3). The Al alloys were deoxidized in AMCHEM-deoxidizer for 10 min. at 21°C and then immersed in deionized water for one hour. The sample was then immersed in 3.5% NaCl for one hour and the accumulated counts and the corrosion potential ϕ_{corr} monitored on a two-pen strip chart recorder. After one hour the Al alloy was coupled to one of the dissimilar metals and the accumulated counts, the galvanic current measured as described earlier (2) and the potential of the couple ϕ_g monitored for 30 min., after which time the sample was decoupled and acoustic emission and ϕ_{corr} were monitored for an additional 30 min.

Fig. 1 and Table I show the results obtained for Al 2024. The corrosion rates for uncoupled (r_o) and coupled (r_A) Al alloys are from Mansfeld et al (2) for 24 hour tests. The reproducibility of the acoustic emission data was quite satisfactory for the uncoupled alloy with an average rate of 41 ± 5 counts per min. When the Al alloy was coupled to 4130 steel or Cu a sharp rise occurred. The count rate decreased somewhat after about 5 min. and became constant for the rest of the 30 min. When the dissimilar metal was disconnected, the acoustic emission rate increased for a short time and then decreased again to low values. The data in Table I are average values for the 60 min. or 30 min. time periods. For Al 2024 coupled to Cd acoustic emission was very much reduced with a rate of 0.5 counts/min. When contact to Cd was disconnected, the count rate first increased and then decreased again. This phenomenon was much more pronounced when Al 2024 was coupled to zinc. In this case the count rate decreased somewhat when the zinc was disconnected. The potential of the Al alloy became more positive (Fig. 2) and when it reached a maximum of about -0.61V vs SCE the count rate increased sharply. Presumably, at this potential pitting occurs again. About 10 min. after decoupling the count rate decreased again.

Table I. Acoustic Emission from Al Alloys in 3.5% NaCl, 21 ± 1°C

	Uncoupled 60 min.		Coupled 30 min.		Uncoupled 30 min.
	Counts/ Min.	r_o (mdd)	Counts/ Min	r_A (mdd)	Counts/ Min.
Al 2024/Cu	41	5.25	497	68.4	85
Al 2024/Steel	50	5.25	730	43.4	117
Al 2024/Cd	32	5.25	0.5	11.2	97
Al 2024/Zn	42	5.25	50	24.6	385
Al 1100/Cu	1.5	0.24	5200	40.6	1.6
Al 1100/Steel	3.0	0.24	4550	30.4	1.3
Al 1100/Cd	1.1	0.24	1.0	1.5	0.9
Al 1100/Zn	5.0	0.24	3.3	8.8	12

Note: Corrosion rate data r_o, r_A are from Ref. 2.

Al 1100, which is much more corrosion resistant than Al 2024 in 3.5% NaCl (2), produces only very few counts when freely corroding (3 ± 2 counts/min., Table I). When

*Electrochemical Society Active Member

coupled to Cu or steel the count rate increases tremendously (Table I) reflecting the pronounced increase in dissolution rates due to coupling reported earlier. When coupled to Cd or Zn, on the other hand, the count rate did not increase. When Cu or steel are disconnected from Al 1100, the count rate decreases almost immediately returning to the value found initially for the freely corroding Al 1100.

The origin of the acoustic emission is not clear yet. Our observations on steel and stainless steel in acid media suggest, however, that hydrogen gas generated within the pits in the Al alloy is contributing significantly to the acoustic emission. The present preliminary results suggest that acoustic emission can become a valuable tool for corrosion research and monitoring of corrosion reactions. A comparison of the acoustic emission and corrosion rate data in Table I shows that the acoustic measurements reflect accurately the effect of the dissimilar metal and the different corrosion behavior of the two Al alloys. The results of Fig. 2 seem to give information about the pitting process which could not be followed with electrochemical techniques in the same manner.

ACKNOWLEDGEMENT

The authors acknowledge helpful discusions with Lloyd Graham and Dr. Otto Buck. The project was funded by the Science Center IR&D project "Corrosion and Electrodeposition".

Specular Reflectance of Mirrors

R. W. Revie*

Department of Engineering Physics, Research School of Physical Sciences, The Australian National University, Canberra, A.C.T. 2600, Australia

This note describes an experimental method and some preliminary results thereby obtained in an investigation of mirror materials for a solar power station that will employ a distributed array of concentrators (1,2). The mirrors ultimately used in this application must specularly reflect a high percentage of the incident solar radiation and either the reflectance must not irreversibly deteriorate excessively over the lifetime of the power station or the mirror surface must be replaceable.

The apparatus used to evaluate specular reflectance is shown in Figure 1. The light used in the present studies, obtained from a helium-neon laser, has a wavelength of 6328 Å.** Using this apparatus, the scattering of light about the angle of reflection may be evaluated, and the angle of incidence may also be varied. The photomultiplier light detector, with a 0.3 mm slit, has an acceptance angle of 0.55 milliradians. For calibration of the apparatus, the photomultiplier arm is rotated to align with the laser beam directly.

and using a front-surface mirror (45° incident angle) of evaporated aluminium (600 Å thick) with a quartz overcoat (1/20 wave thick).* The degradation of reflectance after natural weathering at an inclined angle of 10°, facing north, in the Canberra, Australia environment for 31 summer days is evident - the specular reflectance (measured by the peak intensity) decreases from 86% to 75%.

To determine the effect of cleaning the surface on increasing the specular reflectance, cleaning was attempted by directing a jet of distilled water and also of a 3% potassium oleate solution from a squeeze-bottle. The effects were negligible. On the other hand, scrubbing with cotton wool soaked in the soap solution, followed by rinsing with distilled water, caused the specular reflectance to increase to 85%. These experiments tend to indicate that cleaning methods - to be effective - will require mechanical action, which may be obtained either by liquid spray operating at high pressure or by wipers similar to those used in window cleaning procedures.

MAY 1977

Reports on Electrochemical Society Summer Fellowship Awards

During the summer of 1976 the following graduate students received $1000 each, representing the three Summer Fellowship Awards of The Electrochemical Society.

Mr. Robert J. Nowak, University of Cincinnati, Cincinnati, Ohio, was awarded the Edward Weston Fellowship.

Mr. John S. Hammond, Purdue University, West Lafayette, Indiana, was designated as the recipient of the Colin Garfield Fink Fellowship.

Mr. Donald L. Feke, Case Western Reserve University, Cleveland, Ohio, received the Joseph W. Richards Fellowship.

The Summer Fellowship Awards are made "without regard to sex, citizenship, race, or financial need, to a fellow or teaching assistant pursuing work between the degrees of B.S. and Ph.D. on a subject in a field of interest to The Electrochemical Society. They are intended to cover a period during which the recipient has no financial support for the continuance of his work.

The Edward Weston Summer Fellowship Report

Mr. Nowak's report is given below.

Anisotropic Highly Conductive Inorganic Polymer as Electrode Material

Recently the characteristics of fully oriented epitaxially grown thin films and crystals of polymeric sulfur nitride [polythiazyl or $(SN)_x$] have been reported (1, 2). An ordered array of parallel fibers makes up the $(SN)_x$ crystal whose d-c electrical conductivity is highly anisotropic with the highest conductivity, about 3.7×10^3 $(\Omega\text{-cm})^{-1}$ at room temperature, along the chain of the polymer (3). The conductivity perpendicular to the chain axis is somewhat less. Thus, the material is classified as a metal.

Studies of the electrode behavior of crystals of $(SN)_x$ in aqueous media were undertaken with the ultimate goal of producing specific surface-modified electrodes. Linear sweep cyclic voltammetry and chronoamperometry were employed for evaluation of $(SN)_x$ with respect to the criteria presented by Mueller and Adams (4).

As $(SN)_x$ is chemically and electrically anisotropic, studies were performed with either parallel (sides of fibers exposed to the solution) or perpendicular (ends of fiber bundles exposed) electrodes. The electrochemical behavior of these two surfaces was found to be quite different in studies using different supporting electrolytes with and without electroactive species present.

Without electroactive species present there was evidence of irreversibly coupled surface redox processes on both parallel and perpendicular $(SN)_x$. Changing the cation from cesium to lithium had a dramatic effect on the anodic and cathodic breakdown limits and surface redox current magnitudes for parallel but not perpendicular $(SN)_x$. Lithium extends the cathodic breakdown current by *ca.* 300 mV and eliminates the hysteresis observed on the reverse (positive) scan for the former.

As the geometric features of the crystals employed for electrochemical studies were quite varied, the ferri/ferrocyanide couple was used in chronoamperometric experiments to determine areas. This system behaved nearly reversibly on both parallel and perpendicular $(SN)_x$ when compared to similar studies at platinum-disk electrodes. The data adhered well to the theoretical equations for the methods employed.

Electrodeposition of lead was also studied on both parallel and perpendicular $(SN)_x$ (5). Voltammograms obtained with perpendicular electrodes appeared much like those obtained on platinum-disk electrodes except they lacked underpotential peaks often seen on the latter. Parallel electrodes yielded more irreversible voltammograms with a marked hysteresis on the reverse (positive) scan. This hysteresis can be totally eliminated by brief pretreatment of the $(SN)_x$ electrode with mercuric ion. These results along with the supporting electrolyte studies seem to indicate that cations with high positive charge densities interact more strongly with parallel than perpendicular $(SN)_x$.

Currently, several irreversible redox couples are being used as probes to investigate the structure of the electrical double layer at $(SN)_x$ electrodes. The results of these studies will be submitted to *This Journal* and will be presented at the 173rd National Meeting of the American Chemical Society in New Orleans.

Acknowledgments

The author wishes to thank Dr. Harry B. Mark, Jr., Dr. Alan G. MacDiarmid, and Dr. Wlodzimierz Kutner for their valuable assistance. and The Electrochemical Society for its financial support through the Edward Weston Fellowship.

Mr. Hammond's report is given below.

ESCA Analysis of Electrochemical Underpotential Deposition

X-ray photoelectron spectroscopy (XPS or ESCA) has recently become a valuable spectroscopic tool for the investigation of electrode surface states (1). The surface specificity of XPS analysis (10-50Å), coupled with the ability to examine the electronic environment of surface atoms through the use of binding energy chemical shifts, permits elemental and molecular analysis of electrochemically prepared surface states. The initiation of electrochemical metal atom deposition on foreign solid metal electrodes produces electrode surface states which have long held the curiosity of electrochemists. In particular, the deposition of metal ions at potentials more positive than that predicted by bulk Nernstian thermodynamics, *i.e.*, underpotential deposition (UPD), has not been fully elucidated by classical electrochemical techniques. The objective of this study was, therefore, to apply XPS to the study of underpotential deposition. The results of this study (*i*) provide valuable spectroscopic information on the nature of the metal adatom-metal substrate bond involved in underpotential deposition, (*ii*) demonstrate the use of unique electrode samples for the testing of the present theories of XPS binding energy chemical shifts, and (*iii*) broaden the scope of XPS analysis of electrode surface states in general.

The underpotential deposition of copper and silver on platinum electrodes was investigated. The clean Pt electrode surfaces were first characterized by cyclic voltammetry. Silver or copper underpotential metal films on the Pt electrodes were then prepared under potentiostatic control. The electrolyte was then removed under potentiostatic control and XPS analysis was performed on the electrode surface. To complement the electrochemical deposition studies, thin metal films on copper and silver were vapor deposited on clean platinum foils in the spectrometer. Details of electrode construction, sample preparation, and XPS analysis have been recently published (2-4).

The results of the XPS analysis have conclusively demonstrated that the silver and copper thin films produced during underpotential electrochemical deposition in H_2SO_4 media are not found as metal oxides or chemisorbed copper sulfate or silver sulfate complexes. Rather, the XPS results indicate that in the absence of an applied electrochemical potential, binding energy shifts are observed in the core photoelectron spectra which are indicative of the copper and silver UPD adatom surface states. The XPS binding energy shift is insensitive to the parameters responsible for the multiple UPD anodic stripping peaks and remains constant with coverage, up to one monolayer.

The *in situ* vapor deposition does, however, produce geometric effects in the XPS binding energy shifts. At very low average coverages (less than 20% of one monolayer thickness), the vapor deposition XPS binding energy shift is equivalent to the electrochemical deposition binding energy shifts. Higher coverages produce XPS results intermediate between UPD and bulk metal deposits. The results, therefore, indicate the metallic nature of the UPD deposits and the capabilities of electrochemical deposition for producing unique samples for surface science investigation.

The interpretation of the observed binding energy shifts is presently not without ambiguity. The binding energy shifts in XPS core level spectra generally correlate with the charge density of the observed atom. However, to provide an interpretation of changes in charge density, the core level binding energy must be referenced to the vacuum level. The XPS experimental binding energies are referenced to the Fermi level, with an unknown work function relating the Fermi level and vacuum level.

One possible approach for dealing with this problem is through the use of the Auger parameter. The kinetic energy for a *kll* Auger transition can be approximated

$$E^V(kll) = E_B^V(k) - 2E_B^V(l) - F + 2E_R + R_e \quad [1]$$

where $E^V(kll)$ is the vacuum level referenced kinetic energy of the *kll* transition, $E_B^V(k)$ and $E_B^V(l)$ are the vacuum level referenced one electron binding energies of the k and l orbitals, F is the hole-hole interaction term due to the double ionization of the final state, $2E_R$ is the intra-atomic "static" relaxation contribution to the second $E_R^V(l)$ binding energy due to the previous creation of a l hole state, and R_e is the extra-atomic relaxation. The binding energy equivalent to the $E^V(kll)$ kinetic energy is $E_B^V(kll)$ where

$$E_B^V(kll) = h\nu - E^V(kll) \quad [2]$$

and $h\nu$ is the x-ray photon energy.

The Auger parameter α is then defined as

$$\alpha = E_B^V(k) - E_B^V(kll) \quad [3a]$$

$$= E_B^F(k) - E_B^F(kll) \quad [3b]$$

$$= 2E_B^F(k) - 2E_B^F(l) - F + 2E_R + R_e - h\nu \quad [3c]$$

The Auger parameter is in fact independent of the sample work function and either E_B^F or E_B^V values can be used. The difference in the Auger parameter $\Delta\alpha$ can then be defined as

$$\Delta\alpha = \alpha_{metal} - \alpha_{UPD} \quad [4]$$

where α_{metal} is the Auger parameter for the bulk metal of the UPD species and α_{UPD} is the Auger parameter for the UPD adsorbate species. For the Ag UPD system, $\Delta\alpha$ is +0.65 eV and for the Cu UPD system $\Delta\alpha$ is +0.95 eV.

These $\Delta\alpha$ terms are not inconsistent with an increase in the cohesive energy of the UPD adatom-metal substrate bonds relative to the respective bulk copper or silver cohesive energies (4). To provide an unambiguous interpretation of Eq. [3c], the $E_B^F(l)$ terms should be spectroscopically measured. This is not possible at present. In addition, the theoretical understanding of extra-atomic relaxation is still in its infancy. Further experimentation and theoretical advances are needed to more fully elucidate the underpotential deposition phenomena.

Mr. Feke's report is given below.

Electrochemical Disposal of H_2S

During the period of the fellowship, significant progress was made in determining the feasibility of electrochemically disposing hydrogen sulfide. The purpose of the research was to determine whether H_2S could be made to decompose by electrolysis to elemental sulfur and hydrogen. A process utilizing this technology could have several applications.

Specifically, work during the fellowship term included the design and construction of an electrolysis cell. This cell withstands pressures up to 2000 psi and enables the experiments to be performed on the condensed phase of H_2S at temperatures up to the critical temperature of 100°C.

Products of the electrolysis reactions were identified. The anodic product was elemental sulfur, which precipitates from solution as crystalline α-sulfur (rhombohedral) when the H_2S is evaporated. The cathodic reaction product was gaseous elemental hydrogen. In these experiments pyridine was used as the electrolyte.

Transient electrodic measurements were taken to determine cell time constants as well as voltage drops across the double layer at the electrodes. Preliminary analysis of these measurements indicates that the total overvoltages depend strongly on electrode material. Of the electrode materials tested to date, nickel appears to have the lowest overvoltages.

Present research is concerned with the measurement of the faradaic current efficiency. Work during the summer also led to the design of a new cell configuration that reduces solution resistance and allows for better product separation. Further experiments will be made using this improved cell design.

Progress in Organic Electrochemistry–1952-1977

Manuel M. Baizer*

Monsanto Company, Corporate Research Department, St. Louis, Missouri 63166

The 1952 review and overview of progress in this field (1), presented when The Electrochemical Society, Inc. was celebrating its fiftieth anniversary, surveyed a fifty-year period. The present article examines progress in the last quarter century. If the number of review papers published in this last decade alone (2-24), repetitious though some of them may be, is any indication of interest or need or activity, the next survey should encompass no more than an eighth century.

The newcomer entering the field today may not be aware of the gap that existed in the presentation of the subject as a whole between 1956 (67) or 1958 (35) and 1969 (34), for in the last few years a number of books both comprehensive and on selected pertinent topics have been published (25-44). In-depth reviews of individual aspects have abounded (47-66). Stimulating new books on general electrochemistry have appeared (39-44) and several series volumes have become established (45-47). Electrochemical engineering has reawakened (69-72). Awareness of organic electrochemistry by undergraduate and graduate students of organic chemistry is also being sponsored by detailed descriptions of experiments (73-74) and by peripatetic "short courses" (75-76). The practitioner of organic electrochemistry has had, in addition to societies within his own country, an abundance of forums at which to present, discuss, and learn of new work (77-97). New research groups in organic electrochemistry have been installed in industry and university. Although the extent of introduction of courses in the subject into the regular curriculum (at least in terms of an option) is still spotty, particularly in the U.S., electrochemical engineering is well established in at least the universities of California (Berkeley), Michigan, Illinois, Newcastle upon Tyne, and the E.T.H. in Zürich. "Working parties" in France and the U.K., the second successive one in the latter country, have recommended programs of research and education to their respective national research councils.

Key Developments

This tremendous upsurge in activity in the last twenty-five years, which has brought with it advances on many fronts, is truly impressive. What influences have brought this about? What components does ghost chromatographic analysis of the Zeitgeist reveal? Organic electrochemists selected at random might draw up similar lists of components but each would probably consider the weighted contributions of his own subdiscipline to be high. (The very existence of so many subdisciplines attests to the fertility of the field.) The following citation listing attempts to exclude conscious bias; no ranking is to be inferred from the order of discussion.

1. *Advances in the science, art, and theory of organic chemistry.*—Particularly germane have been the developing areas of ion radical chemistry, homogeneous electron-transfer reactions, regio- and stereocontrolled synthesis, general acid-base reactions, and derivative work in polymerization (*e.g.*, "living" anionic systems) and homogeneous catalysis by transition metal complexes. Many of these developments have had their counterparts and perhaps their predecessors in organic electrochemistry (*e.g.*, the generation, detection, and reactions of ion radicals).

2. *Instrumental methods.*—The invention, development, and universal acceptance of a host of instrumental methods, particularly chromatographic and spectroscopic, for the rapid detection and quantification of small quantities of organic components has immensely accelerated the pace at which the results of electrolytic experiments can be evaluated and judgment can be made concerning the future direction of a project.

3. *Electrochemical techniques.*—The invention or development and application with increasing degree of sophistication of a variety of electrochemical techniques [polarography, cyclic volummetry, chronopotentiometry and coulometry, pulsing (≡potential step), rotating ring-disk electrodes, electrolysis-cum-spectroscopy, and others] has also been significant. This has had major impact on rational planning of syntheses, characterization of "intermediates," and elucidation of organic electrode processes, particularly the unraveling of sequential electrochemical (E) and chemical (C) steps and the determination of relevant rate constants.

4. *Potentiostats.*—The universal availability and use of potentiostats, now purchasable at moderate cost, could hardly have been imagined a few decades ago. This has been a prerequisite for the development of most of the techniques cited above; in addition, it has facilitated the duplication of results, mechanistic or synthetic, from laboratory to laboratory.

5. *The application of computer science and technology to data processing.*

6. *Electrolyte solvent systems.*—Refinement of the understanding of the role of solvents/supporting electrolytes (particularly salts) has made it increasingly clear that the supporting electrolyte/solvent system serves not only as a means of passing current through a solution containing a nonconducting organic com-

* Electrochemical Society Active Member.

pound; the discharge potentials for the cation and anion, respectively, define the electrochemical domain (electroactivity) range within which an organic compound may be reduced or oxidized. Beyond this, the size, solvation, "softness/hardness," and degree of pairing of (98) the supporting ion may have a determining effect upon the nature of the electrolysis products. With proper choice of solvent and cation, it is now possible to carry out direct reductions to about −3.0V (*vs.* SCE) or, at a less negative potential, to discharge solvated electrons (99) which in solution can "indirectly" reduce substances (*e.g.,* benzene) not directly reducible at a cathode (equivalent of the Birch reduction). At the other extreme, the use of very difficultly oxidizable anions (*e.g.,* BF_4^-, ClO_4^-, $SF_6^=$) permits the oxidation of relatively inert substrates not previously accessible. Likewise, prior protonation (by superacids) (100) or deprotonation (by electrogenerated bases) (101) many produce electroactive species from precursors that have very little, if any, electroactivity as neutral molecules. The greater attention to electrolyses in "aprotic" organic media, in which proton transfers do not intervene as "coupled" reactions in the first electron transfer steps, has greatly expanded our ability to elucidate the mechanisms of organic electrochemical reactions. It has also called to our notice the frequent ability of the organic substrates themselves to act as acids and bases (102).

7. *Large-scale industrial electro-organic processes.*—Announcement was made in the mid-1960's that two industrial organic electrochemical processes had come on stream, Nalco's for tetraalkyllead and Monsanto's for adiponitrile. The former was impressive because it achieved very high yields of R_4Pb and demonstrated that large-scale electrolysis in a nonaqueous medium (of a Grignard reagent) was viable. An alternative electrochemical process for Et_4Pb (103), although not commercialized, using tetraethylaluminates as electrolytes was likewise shown to be technically and economically feasible. The Monsanto electrohydrodimerization (EHD) process not only has been the largest scale organic electrochemical synthesis thus far achieved but has demonstrated that even relatively low cost materials could be economically processed electrochemically. With this impetus (new) industrial groups were encouraged to examine or reexamine the potentialities of organic electrochemistry; utilization of some of the important factors leading to the success of EHD led to great improvements in the sodium amalgam reduction of activated olefins; variants of the Monsanto process, which right from the start (107) described the use of divided and undivided cells and a variety of suitable electrolytes, have demonstrated the presumed successes of electrolyzing emulsions (108) and the utility of a new type of cell, the capillary gap cell (109). The wide scope of EHD, involving as it does olefins $R_1R_2C{=}CCR_3R_4$ in which at least R_1 but also R_1 and R_3 are electron-withdrawing groups, presented mechanistic problems (particularly elucidation of EC *vs.* ECE sequences) which have been brilliantly attacked by academic scientists (104) and have led to increasingly sophisticated use of a battery of techniques for elucidating the mechanisms of organic electrode reactions and to the invention of new techniques (105).

Several other processes, albeit on a smaller scale, have reached actual or near commercialization stage and have served to further arouse the interest of industrial chemists: the reduction of phthalic to dihydrophthalic acid (106); the oxidation (100) of benzene to quinone (with optional further chemical or electrochemical reduction of the intermediate products to hydroquinone); the Crum Brown-Walker oxidation of monoalkyl adipates to dialkyl sebacates (111); the reductive coupling of acetone to pinacol (112).

8. *Catalytic chemistry.*—The explosive pace of development of catalytic chemistry, particularly homogeneous catalysis using dissolved complexes or complexes on supports or more recently complexes bound to polymer backbones, together with the development in the world-wide fuel cell program of electrodes in which catalytic materials were incorporated into conducting matrices is also remarkable.

Selected Bibliographic Items

The bibliography provided with this article offers a fairly complete guide to the developments of the last twenty-five years. The specialist is already familiar with them but may find it convenient to have the items assembled in one place. Those for whom this banquet of information is too lavish may find their appetites whetted by the following limited offering of hors d'oeuvres, limited by the space of this groaning board:

1. The development of the theory and technique of cyclic voltammetry (113) and the wealth of information it provides has led to its universal adoption as one of the major means used early in a study of the mechanism of an electrode reaction. Concurrently, the capabilities of single sweep voltammetry have been expanded (114).

2. Polarography (40a-40d, 65, 68), adopted by only a few for use in organic electrochemistry by 1952 (1), has grown at a fantastic rate (49). Its development in scope and depth has not only led to its universal adoption in analysis but has provided great insight into the mechanisms of organic electrode reactions (34). Coupled with macroelectrolyses, sometimes on a very small scale (115), it has guided immensely useful syntheses and led to correlations and predictions (116). The newest variant of this technique, differential pulse polarography, has become an extremely sensitive analytical method, particularly for the determination of drugs in biological fluids (117).

3. The technique for carrying out an electrolysis in the cavity of an ESR spectrometer (118) has been widely used to observe and record the spectra of anion radicals, particularly those derived from the one-electron reduction of nitro compounds.

4. The presently emerging techniques for attaching chiral reagents to electrode surfaces (119) is opening up new possibilities for preparing chiral products.

5. The discovery that porous carbon under certain conditions may be used as anodes instead of the "classical" nickel for fluorination has opened new prospects for the moderated preparation of a variety of organofluorine compounds (120).

6. A very striking example of how the course of organic electrochemical reactions may be changed by control of concentration, electrode potential, and mass transfer rates was provided in the electrolysis of cyclohexene plus chloride in acetonitrile (121): either 1-chlorocyclohexene or the 1-chlorocyclohexyl carbonium ion can be made the principal initial product.

7. Oxidative couplings with "electron-rich" olefins, undertaken initially to provide the complement to EHD, has, like EHD, been expanded to provide a synthetic method of wide scope (122). More generally, the study of anodic reactions, long relegated to a minor role, has been greatly expanded (52).

8. The demonstration (123) that anodic oxidation of aliphatic carboxylates at carbon leads preferentially to carbonium ion-derived rather than the radical-derived products of the classical Kolbe (and Crum Brown-Walker) reactions at platinum has added considerably to our understanding of the not yet completely resolved mechanism(s) of the Kolbe reaction and has produced, among other results, an electrochemical equivalent of the Ritter reaction (124).

9. The Nalco process mentioned above uses a fixed bed, in this case consumable, lead shot anode. Slurried (125) and, more prominently, fluidized bed electrodes (126) achieve much higher space-time yields than do planar electrodes but their utilization in organic electrochemical synthesis has not yet been as promising as originally anticipated.

10. The electrochemical equivalent of the Birch reduction of aromatic nuclei, using alkali metal salts in amines (127) and, more strikingly, in HMPT plus alcohol (128), has developed entirely since 1963.

11. Electrochemiluminescence (ECL), in which electrogenerated anion and cation radicals undergo mutual annihilation with emission of light, has yielded much interesting theoretical information (129); the present prospects for the fabrication of devices built upon these principles are poor.

12. After uncertain starts in the previous quarter-century, electropolymerization has made firm progress from about 1960 on. The well-known types of initiators have been made electrochemically (130) and used inside or outside a cell (131). Fine control of molecular weights and molecular weight distributions, long predicted, has been realized. Few claims for the superiority of this technique over the conventional one have been made. Electrosustained polymerization, as in the formation of polyesters by reducing of xylylene dihalides in the presence of CO_2, awaits study in depth (132).

13. Imagination and daring are being shown in the design and optimization of new cells and systems (133).

Prospects for the Future

We have been privileged in 1952-1977 to stand upon the shoulders of our illustrious predecessors and get an overview of their era and ours; our lofty perch also allows us to peer into the near future. Excessive empiricism has given way to increasing rationalism; because many of the theories and means for doing so are now at hand, we can look forward to a rapid acceleration of this process. Many of the broad challenges enunciated in 1952 (1) have not yet been very well met (*e.g.*, influence of the nature, structure, and history of an electrode upon the specificity of the electrode reaction; invention of a variety of viable paired organic syntheses). Even so, new ones are upon us, particularly since the emergence of new technological constraints in the last decade: increasing cost and eventual decreasing supply of petroleum-based raw materials; need for synthetic systems which minimize energy requirements and environmental burdens. The newer optimistic assessment of the economics of electrochemical processes in this context augurs well for the future (134).

Progress in the following areas, among others, is virtually mandatory:

1. Further work to bring space-time yields in electrochemical reactors on a par with those in catalytic processes.

2. Characterization of the first intermediate formed after an electron transfer and following its "evolution" to the final product(s).

3. Defining the potentialities of combined photo- and electrochemical techniques.

4. Organic syntheses from nonpetroleum-derived materials (135).

5. Improvement of membranes for use in aprotic systems.

6. Paired syntheses yielding one or two useful products without sacrificial by-products (136).

7. Replacement of many chemical processes which use stoichiometric quantities of redox reagents by electrochemical processes which regenerate these reagents used in catalytic amounts (137).

8. Reexamination in undivided cells of many reductions which have dogmatically been carried out in divided cells.

9. Further exploitation of electroinitiated homogeneous electrotransfers for difficult reductions, initiation of polymerization, etc. (138).

10. More vigorous development of the electrochemistry of transition metal complexes for the preparation of new and old catalysts.

Progress and challenge evolve together and propel us toward an "endless frontier." We are now in a better position than in 1952 to control our direction. The best is yet to be. Professor E. B. Yeager has referred to organic electrochemistry as a "sleeping giant." Those who have been active in this field this past quarter-century will agree with the noun but not with the adjective.

Manuscript received Feb. 7, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by the Monsanto Company.

Correlations Between the Structure and Reactivity at Solid-Gas and Solid-Liquid Interfaces[1]

G. A. Somorjai

Materials and Molecular Research Division, Lawrence Berkeley Laboratory and Department of Chemistry, University of California, Berkeley, California 94720

I am greatly honored to be the Lecturer for the 150th Meeting of this distinguished and successful Society. I would like to start by making a prediction: I assert that *the new developments in the fundamental understanding of electrode processes and of chemical phenomena that take place at the solid-liquid interface will come from correlations with studies of equivalent processes at the solid-gas interface.*

Now let me explain why I believe this to be the case.

Over the past decade there has been a dramatic improvement of our knowledge of surface phenomena on the atomic and molecular scale at the solid-vacuum and solid-gas interfaces. Techniques that use the surface scattering of electrons, ions, and molecules have become available that determine the atomic and electronic structure of the surface monolayer, its composition and valency of surface atoms. Some of the more widely used techniques are listed in Table I. Low energy electron diffraction (LEED) is utilized to determine the structure of the clean surface and of the monolayer of ordered adsorbates (1). Auger electron spectroscopy (AES) (2), and photoelectron spectroscopy (XPS) (3), are used to determine the chemical composition and valency of surface atoms; while ion scattering spectrometry (ISS) (4), and secondary ion mass spectrometry (SIMS) (5), are utilized to determine the composition in the submonolayer region. Although all of these techniques, except LEED, can be used to study surfaces, regardless of their atomic structure (polycrystalline foils, evaporated films, liquids, or powders), many of the major advances in our understanding of the chemistry of surface atoms has come from studies of well-ordered crystal faces of single crystals. Using crystals, we can vary the concentration of different surface sites that are distinguishable by the number of nearest neighbors. The three types of surfaces that exhibit the various surface sites which are important in studies of chemisorption and surface chemical reactions are shown in Fig. 1 (6). Figure 1a shows a low Miller index (111) surface in which most of the surface atoms are in locations where they are surrounded by six nearest neighbors in the surface plane. Although the low Miller index surface may be rough on a macroscopic scale, full of defects that are induced by the presence of dislocations in the bulk, the surface can be prepared in such a way that most of its atoms are in their equilibrium, high symmetry sites. Figure 1b shows a surface with a high density of steps of atomic height. In such a surface there are large concentrations of surface sites of two types: step atoms and atoms in terraces. The former has less number of nearest neighbors. Many high Miller index surfaces exhibit this surface structure (7). Finally, Fig. 1c shows another type of high Miller index surface that has three types of surface sites in high concentrations: terrace and step atoms and atoms at kinks in the steps. Crystal surfaces can be cut and prepared in which every third atom in the step is a kink atom. One example of this is shown in Fig. 1c.

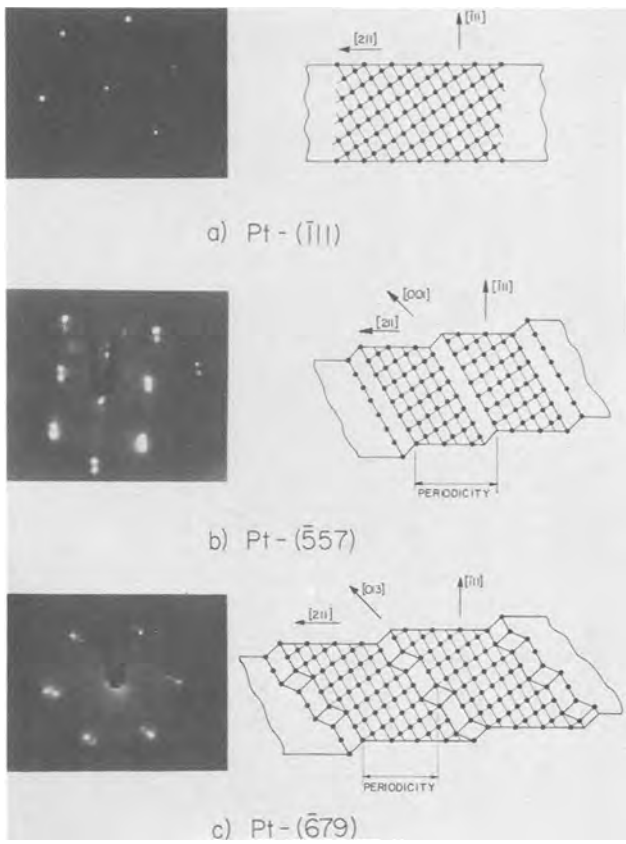

Fig. 1. Diffraction pattern and schematic of mean surface configurations for platinum crystal surfaces exhibiting (a) low defect density, (b) regular step arrays with an average spacing between steps of 6 atoms, and (c) regular step arrays with kink sites along the steps. Note the spot splittings in (b) and (c) indicative of the periodic step arrays.

There is a great deal of experimental evidence accumulating in recent years that indicates that the chemical activity of these various surface sites (kinks, steps, and terrace atoms) is different (8, 9). They form chemical bonds that differ in strength by about ±5 kcal/mole (10) or carry out surface reactions on transition metal surfaces with different rates and selectivity (11). Of course, when a polycrystalline surface (wire or foil

Table I. Techniques of surface analysis that are most frequently employed at present

Technique	Probe	Main output information	Sensitivity (monolayer)	Depth sampled	Commercially available	Depth profile
AES Auger electron spectroscopy	Electrons ~2 keV ~50 μA	Surface composition qualitative & quantitative	$\sim 10^{-2}$-10^{-3}	1-7 layers	Yes	Yes
LEED Low energy electron spectroscopy	Electrons ~100 eV ~10 μA	Surface structure	$\sim 10^{-1}$-10^{-2}	1-7 layers	Yes	No
XPS X-ray photoelectron spectroscopy	X-rays ~1 keV	Oxidation state & composition	$\sim 10^{1}$-10^{-2}	1-7 layers	Yes	Yes
ISS Ion scattering spectroscopy	Ions He, Ne ~1 keV ~10^{-8}A	Surface composition	$\sim 10^{-3}$-10^{-4}	1 layer	Yes	Yes
SIMS Secondary ion-mass spectroscopy	Ions Ne, Ar, O_2 ~1 keV ~10^{-8}A	Surface composition	$\sim 10^{-6}$	1 layer	Yes	Yes

or thin film) is studied, one detects a chemical behavior (heat of chemisorption, reaction rate, and product distribution) that is integrated over all these surface atoms. Thus, identification of the various reactive surface sites cannot be made in this circumstance.

At the same time the surface diagnostic techniques were developing that are listed in Table I that, by and large, scrutinize the surface in static, low pressure conditions, several techniques were developing in my laboratory for kinetic studies of surface reactions under low pressure and high pressure conditions (12, 13). Using suitable apparatus, one can measure the rate and product distribution in surface reactions while also monitoring the structure and composition of the surface using small surface area (approximately 1 cm^2) single crystal samples. This way the relationships between the reactivity of the surface and the structure and composition can be determined.

The apparatus that is used to study high pressure gas reactions and is also suitable to study surface reactions at the solid-liquid interface is shown in Fig. 2 (13). The sample (polycrystalline foil or single crystal) is located at the center of the axis of the ultrahigh vacuum chamber and it is accessible to the LEED, AES, ion bombardment, and mass spectrometry facilities. It is spot-welded to two heating rods which are attached to copper conducting bars in a quartz insulating tube. This is attached to a Teflon compression-sealed stainless steel shaft which allows 180° rotation of the sample at any pressure (10^{-9}-10^{5} Torr). The rotary motion is necessary to clean the sample with the ion gun, then rotate it for LEED, AES, and thermal desorption measurements. The sample may be enclosed by a small high pressure cell which is operated by hydraulic pressure from above and engages a copper sealing gasket below the sample. The internal volume of this isolation chamber is small, about 30 cm^3. Access to the central chamber is made via inlet ports running down the axis of the tube. The sample is heated resistively via the feed-throughs in the lower portion of the manipulator and the temperature is measured with a thermocouple

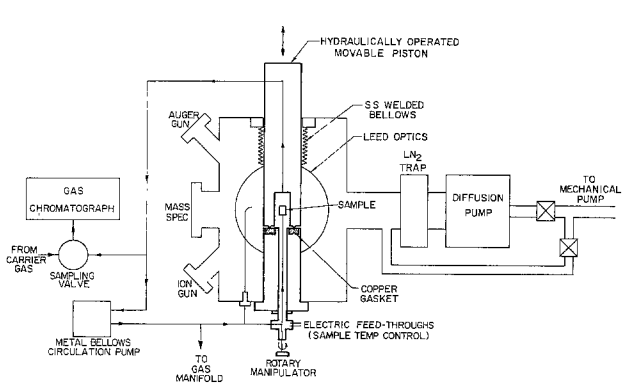

Fig. 2. Surface analysis apparatus for catalytic studies and for studies of the solid-liquid interface at high pressures (0.1-100 atm) with a small volume isolation cell.

spot-welded to the sample. Gases are admitted to the circulation loop and reaction cell from a suction-pumped manifold and a small metal bellows diaphragm pump is used to circulate gases around the loop. The gases pass through a low-internal-volume gas-sampling valve which extracts 0.1 mm of gas for gas chromatographic analysis.

At present this apparatus is being used to study the hydrogenation of carbon monoxide at both low and high pressures (as high as 100 atm) on small surface area metal surfaces (14). There is no reason why an apparatus of this type could not be adapted for studies of the solid-liquid interface. The liquid could readily be introduced and then pumped out after the studies and the surface can be studied by the various surface diagnostic techniques that are listed in Table I. *This apparatus or similar types will be the instruments, I believe, that will permit us to develop the correlations between surface phenomena that occur at the solid-liquid and solid-gas interfaces.*

Below, I briefly review our present view of the atomic and electronic structure of surfaces and adsorbates, and the surface composition of binary alloy systems as it emerges from modern studies of the solid-vacuum and solid-gas interfaces. Then I shall review some of the surface reaction studies that have been carried out recently to correlate the reactivity of the surface with its structure and composition. Finally, I shall propose various research projects that would be of importance in order to begin to correlate surface phenomena at solid-liquid and solid-gas interfaces.

Atomic Structure of Clean Solid Surfaces as Determined by LEED

The atoms at the surface are in an asymmetric environment. They are surrounded by atoms in the surface layer and from beneath but there are no atoms above them. This surface environment also has lower symmetry than that provided for atoms in the bulk. The structural asymmetry experienced by atoms at the surface has a major effect that leads to surface reconstruction: atoms in the surface may move into new equilibrium positions that provide higher symmetry or greater overlay of available positions.

Surface reconstruction.—There are several types of surface reconstruction observed for clean solid surfaces. Many surfaces have atomic structures that are different from that expected from the projection of the x-ray bulk unit cell. The surface atoms assume new equilibrium positions by out-of-plane buckling or by relaxing inward (contraction) that often results in entirely different-ordered surface structures. An example of this is shown in Fig. 3. The diffraction pattern and schematic representation shown here are characteristic of the surface structure of the (100) crystal face of platinum. This surface exhibits the so-called (5 × 1) surface structure (15). There are two perpendicular domains of this structure and there are 1/5, 2/5, 3/5, and 4/5 order spots between the (00) and (10) diffraction beams. The surface structure appears to be stable

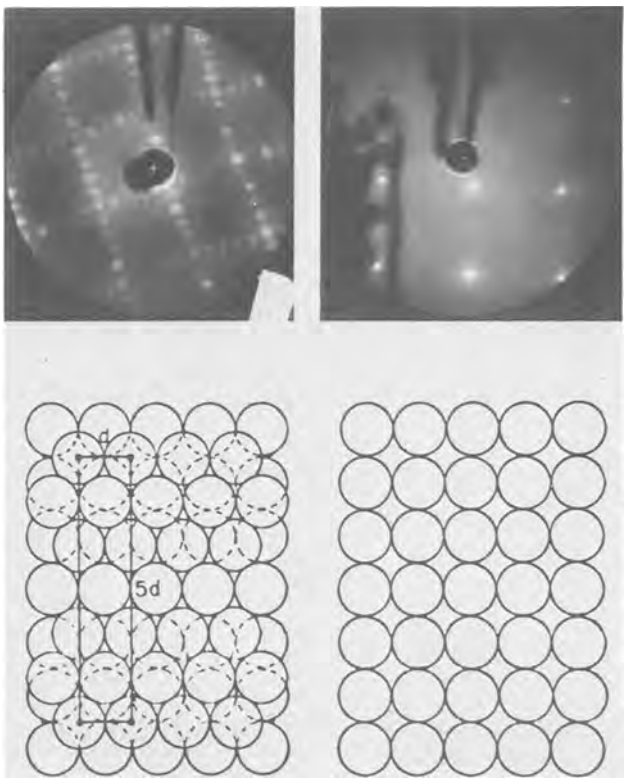

Fig. 3. (a, upper left) Diffraction pattern from the Pt(100)-(5 × 1) structure. (b, lower left) Schematic representation of the (100) surface with hexagonal overlayer. (c, upper right) Diffraction pattern from the Pt(100)-(1 × 1) structure. (d, lower right) Schematic representation of the (100) surface.

at all temperatures from 25°C to the melting point, although at elevated temperatures impurities from the bulk can come to the surface and cause a transformation of the structure to the impurity stabilized (1 × 1) surface structure. Preliminary calculations by Clark *et al.* (16) and in this laboratory indicate that a model for Pt(100) in which the surface atoms assume a distorted hexagonal configuration by out-of-plane buckling is favored. The apparent (5 × 1) unit cell is then the result of the coincidence of the atomic positions of atoms in the surface, *i.e.*, in the distorted hexagonal layer, with atoms of the undistorted second layer below. The (100) crystal faces of gold (17) and iridium (18) that are neighbors of platinum in the Periodic Table exhibit the same surface reconstruction and the same surface structure as that of platinum that is shown in Fig. 3. The (110) crystal faces of these three elements are also restructured (19) and exhibit different unit cells than that expected from the bulk x-ray structure. On the other hand, the (111) crystal face of these three metals appears to have the same surface structure as that indicated by the bulk unit cell.

For semiconductors, most crystal planes that have been studied show reconstruction (20). Monatomic and diatomic semiconductor surfaces have been investigated in large numbers and surface reordering has been observed for most of them. Frequently there are changes of surface structure with temperature that are often irreversible.

For many metal surfaces, the distance between the uppermost two layers, *i.e.*, the z-spacing, is equal to that of the bulk value to within the estimated accuracy of about 5%. However, the Al(110) (21), Mo(100) (22), and W(100) (23) surfaces seem to show substantial contraction in the upper layer z-spacing with respect to the bulk while retaining the (1 × 1) surface unit cell. A simple contraction or expansion of the interplanar z-spacing of this kind is usually termed a "relaxation."

For many diatomic solids there is nonstoichiometry in the surface layer, that is, the surface composition may be different from that in the bulk (20). Nonstoichiometry is apparently a major factor in the observed reconstruction of the polar faces of the III-V semiconductors such as gallium arsenide, GaAs. The (111) face, for example, would ideally have all gallium atoms at the surface bonded to arsenic atoms immediately beneath the surface while the reverse would be true of the $(\bar{1}\bar{1}\bar{1})$ face. However, the $(\bar{1}\bar{1}\bar{1})$ surface has been found to lose arsenic at elevated temperatures and this is associated with the appearance of a new surface structure, while at low temperature another surface structure is arsenic stabilized (24). Similarly, phosphorus is found to preferentially desorb at high temperatures from the gallium phosphide $(\bar{1}\bar{1}\bar{1})$ surface (25). On the other hand, the gallium arsenide (110) surface, which has an equal number of gallium and arsenic surface atoms, does not exhibit reconstruction. A number of studies have pointed to possible nonstoichiometry in alkali-halide crystal surfaces also upon cleavage (26). On oxide surfaces, such as aluminum oxide (27) and vanadium pentoxide (28), changes in chemical composition and valency of surface atoms have been related to the formation of new surface unit cells.

Molecular crystals constitute a large and important group of materials that include most organic solids, but only very recently have the surface structures of some of these materials been investigated on an atomic scale by low energy electron diffraction. Ice and naphthalene have been grown by vapor deposition (29) and ordered surface structures of crystals of many other organic solids such as benzene, trioxene, n-octane, cyclohexene, and methanol have been grown on metal substrates at low temperatures (30). Phthalocyanine crystals have been vapor grown on ordered metal surfaces (31). These large molecular weight, large-size organic crystals exhibit a different kind of surface reconstruction. When copper phthalocyanine was grown on the copper (111) surface, the surface structure of the growing organic crystal layer did not resemble the structure of any of the simpler crystal planes in the bulk structure of the organic crystal. It appears that the ordered metal substrate predetermined the orientation and packing of the phthalocyanine monolayer, which in turn controlled the orientation and packing of the organic layer deposited on top of it. For large molecules, such as phthalocyanine, restructuring into a more stable crystallographic arrangement requires molecular rotation and diffusion processes that are too slow under conditions of crystal growth. Thus the molecules are frozen into a surface structure that is predetermined by the structure of the substrate and the first adsorbed organic monolayer.

Surface irregularities.—The surfaces of real solids are atomically heterogeneous and not smooth as shown schematically in Fig. 4. There are several atomic sites present simultaneously that are distinguishable by their number of nearest neighbors. The symmetry of these low coordination number sites and their charge density are different from that of the sites on the smooth surface and are different from each other. As a result, large variation in chemical bonding of adsorbates at these different sites could occur. Indeed, there is an increasing body of experimental evidence that indi-

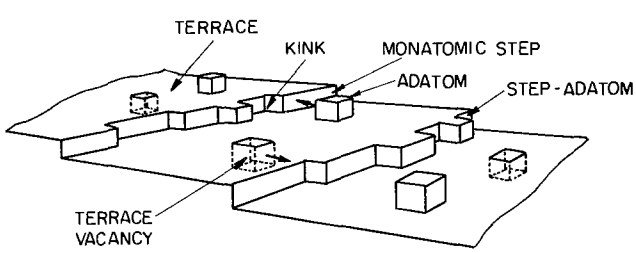

Fig. 4. Model of heterogeneous solid surface depicting different surface sites. These sites are distinguishable by their number of nearest neighbors.

cates that atomic steps and kinks behave as different chemical entities at transition metal (32, 33) and semiconductor surfaces (34), forming chemical bonds of different strengths as compared to that of the atoms on the terraces.

Preparation of surfaces with a large concentration of stable and ordered irregularities (steps and kinks) can be carried out by cutting crystal faces along high Miller index directions. Stepped surfaces of several metals (35), semiconductors (36), and oxide surfaces (37) were prepared this way.

Charge Density at Clean Solid Surfaces

Let us consider an atomically smooth surface where each atom is in the same structural environment. The surface atoms have less nearest neighbors as compared to atoms in the bulk. As a result, electronic orbitals that are used for bonding of bulk atoms are available at the surface, giving rise to increased charge density. These localized unsaturated bonding orbitals are frequently called dangling bonds and the angular distribution of their charge density largely depends on the structural arrangement (packing of atoms, orientation) at the surface. There is excess free electron density at metal surfaces that is not localized at a given atom that gives rise to an induced surface dipole. The presence of this dipole is responsible for changes of the work function of metals from crystal face to crystal face. The formation of the surface dipole can be rationalized and demonstrated using the so-called jellium model. There are strong exchange correlation forces which act on the electrons in the solid due to their many-body coulomb interactions. In the metal interior each electron lowers its energy by pushing others away to form the exchange-correlation "hole." This attractive interaction is lost when the electron leaves the solid so there is a sharp potential barrier at the surface. In the jellium model the positive charge density from the ion cores is smeared out over the atomic volume and the conduction electrons are free to respond to the surface barrier potential. At the surface, however, the electrons are not totally trapped and there is a small probability to leak out in the vacuum. This charge leakage creates a dipole effect which modifies the self-consistent surface barrier potential. This dipole creates an additional electrostatic barrier for the electrons in the solid, V_{dipole}, so that the total barrier, $V_{total} = V_{exchange} + V_{dipole}$. This gives the work function, $\phi = V_{exchange} + V_{dipole} - E_F$, where E_F is the energy at the Fermi level. Variations of the work function from crystal face to crystal face are well documented.

Surface irregularities, like atomic height steps at the surface, exhibit different work functions as determined by Wagner and Besocke recently (38). Recent theoretical studies provide firm foundation of the effect of surface heterogeneity and irregularities on the density of states at the Fermi level (39) and on the angular distribution of charge densities (40) at these low coordination number surface sites. The structural heterogeneity at the surface leads to the chemical heterogeneity, *i.e.*, the ability of the surface to carry out complex chemical rearrangements involving the simultaneous forming and breaking of surface bonds of varied strength at the various atomic surface sites.

The Surface Crystallography of Adsorbed Monolayers of Atoms

The structural asymmetry and excess charge experienced by atoms at the surface have an important effect on the structure of the adsorbate substrate system. In the presence of adsorbates, bonds are formed that make optimum use of the available bonding orbitals. For small adsorbed atoms and molecules this often leads to the formation of a close-packed adsorbate structure in which the adsorbate occupies the high symmetry atomic sites that correspond to the continuation of the bulk structure. We shall review several examples of chemisorbed structures of these types below.

For most of the over 200 surface structures of adsorbed monolayers that have been studied so far, only the two-dimensional symmetry of the diffraction pattern has been determined (41). Thus, only the size and shape of the two-dimensional surface unit cell is known. Determination of the actual positions of the adsorbed atoms requires analysis of the intensity of the diffraction beam and has been performed only on a small number of systems, almost all for atomic adsorption and low Miller index surfaces of face-centered cubic metals. The first of these analyses was carried out by Anderson and Pendry (42), who examined sodium adsorption on the nickel (100) crystal face and reported that the sodium atoms occupy four-coordinated sites at a distance of 0.87Å above the topmost nickel layer. Demuth *et al.* (43) have examined the overlayer structures of oxygen, sulfur, selenium, and tellurium on nickel (100). On this surface they find the adsorbed atom to occupy four-coordinated bonding sites at displacements of 0.9, 1.3, 1.45, and 1.9Å, respectively, from the center of the top nickel layer. Results are also given for nickel (111) and nickel (110). Forstmann *et al.* (44) reported iodine adsorbed on Ag(111) to occupy the threefold sites at a distance of 2.5Å above the topmost layer. Oxygen adsorption on tungsten (45) and nitrogen on tungsten (46) and other body-centered cubic metals has also been studied.

Several general observations appear to be emerging from this work. Chemisorbed atoms seek an adsorption site which allows them to maximize their coordination. The substrate-adsorbate bond length, at least for the strongly chemisorbed systems studied thus far, can be reproduced rather well by adding the metallic radius of the substrate and the single bond covalent radius of the adsorbate. This is shown in Table II which lists the experimentally determined bond length and the predicted bond length obtained by summing the covalent radii. In most cases, the difference is within the 0.1Å accuracy claimed for the experimental determination and in no case is the discrepancy greater than 10%. This result suggests that the chemisorption bond of the small adsorbate atoms studied so far is basically covalent in character, which means that theoretical treatment in terms of localized surface complexes and clusters should be applicable to their chemisorption.

The small adsorbate atoms that are listed in Table II occupy sites of the highest symmetry. These sites would also be the location of the next layer of metal atoms if we were to continue building up the solid layer by layer. The adsorbate-metal atom bond distance is equal, within the experimental accuracy, to the sum of the covalent radii of the two atoms. There are other types of surface bonding, however, that are neither simple nor readily rationalized using simple chemical arguments. For example, when oxygen adsorbs on nickel (110), the best agreement with experiment is obtained assuming that oxygen atoms are lying in a twofold bridge site between 1.41 and 1.51Å above the nickel layer (47). This is clearly not the highest coordination site on the surface. The fact that bridge bonding is preferred suggests that atomic oxygen bonds to two adjacent nickel atoms via the oxygen p_x and p_y atomic orbitals. The bond angles and atomic distances are very

Table II. Adsorbate-substrate bond lengths determined by LEED

Substrate	Adsorbate	Bond length (experimental, Å)	Bond length (predicted, Å)
Ni(001)	O	1.97	1.90
	S	218	2.28
	Se	2.27	2.41

W(110)	O	2.08	2.05

close to what one expects from X_2O compounds, where X is the metal atom.

Another example of unusual bonding has been recently detected in studies of hydrogen adsorption to the nickel (110) surface. A new surface structure forms and surface crystallography studies indicated that this unit cell is a consequence of the restructuring of the nickel (110) surface as a result of hydrogen chemisorption and not due to ordering of the hydrogen adsorbate (48). The surface structure model that gave best fit to the experimental data consists of distorting the nickel surface atoms so as to produce the new (1×2) periodicity. This is carried out by simple depression or raising of every alternate row of nickel atoms in one direction, or a pairwise distortion of every alternate row of nickel atoms in the plane of the surface. The optimal agreement with experimental curves is obtained by a 0.1Å compression of the surface layer and a 0.1Å alternate displacement of the rows of nickel atoms in the $[\bar{1}10]$ direction.

Another example of unusual structure comes from studies of the titanium-oxygen system. It has been reported recently (49) that upon chemisorption, oxygen atoms are located *below* the first layer of titanium atoms in the (0001) surface. There is little doubt that future studies will reveal the richness and complexity of surface bonding and will yield many unexpected bonding configurations.

Studies of Hydrocarbon Bonding to Metal Surfaces

The surface crystallography of acetylene on Pt-(111).—Acetylene, C_2H_2, forms a (2×2) overlayer on the platinum (111) crystal surface. In recent experimental studies, Stair and Somorjai (50), and Kesmodel *et al.* (51) have reported the LEED *I-V* profiles for the acetylene-platinum system. In particular, two different (2×2) structures of adsorbed acetylene were identified, which we refer to briefly as stable and metastable state and which have been interpreted as involving different chemical bonding. The metastable (2×2) structure is observed to form initially at low exposure (one langmuir $= 10^{-6}$ Torr-sec) of C_2H_2 at room temperature but transforms in 1 hr to the stable (2×2) structure upon gentle heating to 100°C. Both structures are characterized by the same (2×2) surface unit cell and involve the same carbon coverage as determined by Auger electron spectroscopic analysis. However, they are readily distinguishable by their different *I-V* characteristics.

Let us examine the various modes of bonding of acetylene to platinum in the context of high symmetry bonding sites available on the (111) face of fcc crystal. As illustrated in Fig. 5, we distinguish four sites designated as: (a) one-coordinate π, (b) di-σ, (c) bridging (sometimes referred to as μ-bridging), and (d) triangular complexes. We have indicated for each site only those surface metal atoms expected to have significant metal-carbon interaction. It is natural to discuss these surface geometries in terms of structural analogies of organometallic complexes. In these terms, the one-coordinate π-complex, (a), involves the interaction of one or both sets of π-orbitals of the acetylene molecule with a single metal surface atom. The bridging site, (c), utilizes both sets of π-orbitals to bond with two surface atoms; both (a) and (c) in principle entail little rehybridization of the molecule since essentially undistorted π-orbitals would be involved. However, the di-σ bond, (b), implies $sp \rightarrow sp^2$ rehybridization and the formation of two carbon metal σ-bonds accompanied by large hydrogen *cis* bending (CCH angle $\simeq 120°$). This possibility has received serious consideration in the catalysis literature. Finally, the triangular structure, (d), commonly found in trinuclear metal alkyne

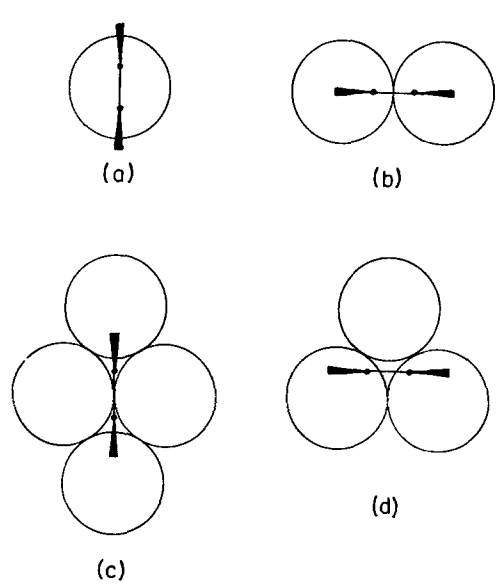

Fig. 5. Schematic indicating various high symmetry local bonding sites for acetylene on the (111) face of a fcc crystal: (a) one-coordinate π, (b) di-σ, (c) bridging, and (d) triangular.

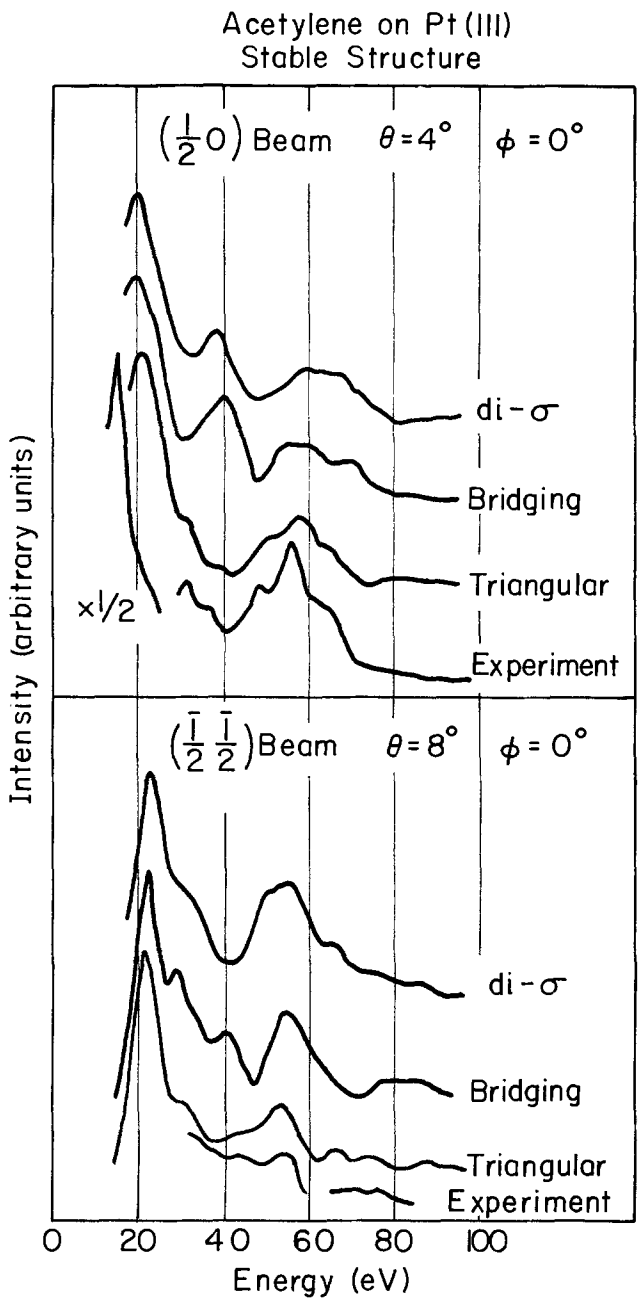

Fig. 6. Comparison of calculated *I-V* profiles for various model geometries ($\zeta = 1.9$Å) to experiment (stable acetylene overlayer) for two fractional order beams.

complexes illustrates a mode of bonding loosely referred to in terms of both σ- and μ-bonds. This triangular geometry is found to be the favored arrangement in the stable structure. Analysis of Fig. 6 and 7 and other data similarly obtained shows that the triangular geometry gives consistently better agreement than either the bridging or di-σ geometries. The metastable C_2H_2 structure exhibits bonding similar to the one-coordinate π complex. The stable C_2H_2 has a z-distance of 1.9Å, and C-Pt distances of 2.2Å for C_2H_2 centered on the triangular site. This value is very close to the predicted covalent bond distance of 2.16Å.

It has been possible to distinguish among various proposed bonding models for acetylene adsorption on the Pt(111) surface using dynamical analysis of low energy electron diffraction intensity profiles. It was found that bonding of acetylene in a triangular site on the Pt(111) surface is the stable and preferred configuration. It is interesting to note that this same bonding geometry is exhibited in trinuclear metal alkyne clusters; moreover, the average C-Pt distance found for C_2H_2 adsorbed on Pt(111) is similar to that determined for the osmium trinuclear cluster, the osmium covalent radius being only 0.04Å shorter than that of platinum. Although one cannot detect a small C-C bond length change, we do anticipate a C-C bond stretch of about 0.1Å to occur for acetylene adsorption judging from the C-C length found in x-ray crystal structure determinations of the metal alkyne clusters.

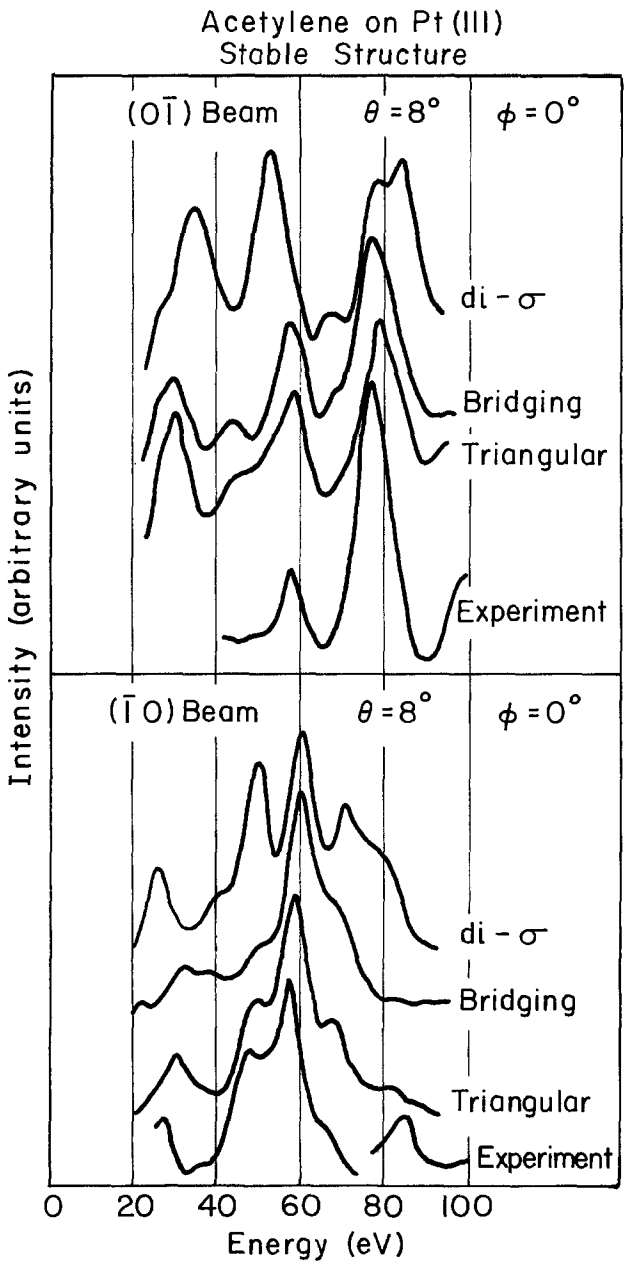

Fig. 7. Comparison of calculated *I-V* profiles for various model geometries (ζ = 1.9Å) to experiment (stable acetylene overlayer) for two integral order beams.

Studies of other hydrocarbons by electron spectroscopy.—The bonding and the composition of C_2H_4 was studied on the nickel (111) crystal face by UPS (52). At 100°K, the organic molecule adsorbs by bonding via its π-orbitals to the metal surface. On heating to 230°K, C_2H_4 dehydrogenates to form C_2H_2 that is bound with even stronger π-bonds to the nickel surface. UPS could monitor changes in bonding caused by the activated dehydrogenation that occurs as a function of temperature. Chemisorption involved predominantly π-d bonding, thus rehybridization of the adsorbed molecule does not seem to occur.

Similar studies were carried out with C_2H_4 adsorbed on the W(110) crystal face (53). At 300°K, the molecule dehydrogenates upon adsorption to form C_2H_2 that π-bonds to the metal. As the surface temperature is increased to 500°K, breaking of the carbon-hydrogen bond occurs and the C_2 fragments are identified by UPS by the presence of C-C and C-W bonds. Upon heating to 1100°K, the C-C bond breaks and carbon atoms remain on the surface in a disordered state.

One of the striking features of the adsorption process is the existence of small (of the order of kT) activation energy barriers in the path of various bond-breaking reactions. As a result an organic molecule may be adsorbed intact even on the most reactive metal surface at sufficiently low surface temperatures. As the temperature is increased, electron spectroscopy can be used to identify the different bond-breaking processes that seem to occur in readily distinguishable steps.

Studies of CO Bonding

The chemisorption of CO was studied on several metal surfaces by electron spectroscopy. Using synchrotron radiation, Shirley *et al.* have found that CO adsorbed in a bridge structure bound through the carbon to the metal on the platinum (111) crystal face, while the oxygen end of the molecule is pointing away from the surface (54). Using the high Miller index (775) surface that has a large concentration of kink atoms of low coordination number, Mason *et al.* (55) found that the CO dissociates at the kink sites, while the carbon monoxide does not dissociate on atoms in terrace sites. These studies were carried out using UPS and XPS techniques. The concentration of carbidic carbon was equal to the kink concentration and was produced at the initial stages of CO chemisorption on this kinked, high Miller index, platinum surface. Thus, the adsorption of CO takes place first at kink sites where the molecule dissociates. Once the kinks are blocked by carbon, CO further chemisorbed in the molecular state on the other atomic sites of the heterogeneous platinum surface. CO adsorbed in several bonding sites, some of them molecular, some of them dissociated on tungsten crystal surfaces (56).

The Surface Composition of Binary Alloys

The composition of alloys in the topmost monolayer is likely to be very different from the bulk composition for several reasons and we shall review briefly each one of them.

1. For systems that exhibit regular solution behavior, the surface free energy (which is always positive) is minimized by the segregation of that constituent with the lower surface tension. For metals that have high tensions as compared to organic surfaces or most oxide surfaces, such surface enrichment is likely to be very marked indeed. For a system obeying regular solution theory, it has been shown (57, 58) that the composition of the surface monolayer is given by

$$\frac{x_l^A}{x_l^B} = \frac{x_b^A}{x_b^B} \exp\left(\frac{(\sigma^B - \sigma^A)a}{RT}\right) \exp\left[\frac{\Omega(l+m)}{RT}((x_b^B)^2 - (x_b^A)^2) + \frac{\Omega l}{RT}((x_l^A)^2 - (x_l^B)^2)\right] \quad [1]$$

Where x_l and x_b are the atom fractions in the surface monolayer and bulk, respectively. In this expression σ is the surface energy, a is the molar surface area, T is the absolute temperature, R is the ideal gas constant, Ω is the regular solution parameter which is given from the heat of mixing ΔH_m by

$$\Omega = \Delta H_m / x_b^B x_b^A \quad [2]$$

The packing parameter l gives the fraction of an atom's nearest neighbors which are in the same plane parallel to the surface as the atom. Similarly m is the fraction of nearest neighbors which are in an adjacent parallel plane. For instance, in a fcc lattice, an atom has twelve nearest neighbors so a (111) plane has six nearest neighbors in the plane of an atom and three nearest neighbors in the plane below the atom. Thus in this case $l = 6/12$ and $m = 3/12$.

Electron spectroscopy techniques, especially Auger electron spectroscopy and photoelectron spectroscopy, have been eminently successful in determining the surface phase diagrams, *i.e.*, the surface composition as a function of bulk composition and temperature, for several binary metal systems. A typical Auger spectrum of an alloy system, that of palladium-gold, is shown in Fig. 8 (59). From the Auger peak intensities one may determine surface composition for a series of bulk compositions and from this data the surface phase diagram is deduced. The most serious experimental difficulty in converting the Auger peak intensities to surface concentrations lies in estimating the depth near the surface from which the Auger electrons of different kinetic energy are emitted and the relative scattering power of the two types of atoms in this volume sampled by the electrons. Since part of the Auger signal is due to atoms below the surface, it is essential to subtract this part from the signal intensities in order to extract the surface contribution. Much of the discrepancy between results reported from different laboratories on the same alloy system can be attributed to difficulties in estimating relative contributions of surface atoms to the various Auger peak intensities.

2. Adsorbed gases or impurities segregating at the surface can markedly change the surface composition. If one of the constituents forms strong chemical bonds with the adsorbate (oxygen, CO, carbon, sulfur, or calcium, most commonly) it will be accumulating on the surface even though it may not be at the surface in the absence of the absorbate. CO, for example, which forms strong bonds with many transition metal atoms, may aid the segregation of these atoms at the surface at the expense of other constituents that form weak CO bonds. In essence an adsorbate converts a two-component system to a three-component system, thereby altering the surface composition at equilibrium.

3. Solute atoms with large or small radii with respect to the size of the solvent (majority) atoms may be "excluded" from the bulk because they introduce excessive strain in the crystal lattice. As a result, surface segregation of one component that is misfit in the crystal lattice can be observed. The strain energy contribution may enhance the surface concentration of that component that would segregate on the surface on account of its effect of decreasing the total surface free energy. Conversely, this strain energy contribution may oppose the effect of surface segregation of one constituent in some cases.

4. There are complex phase diagrams that exhibit the formation of stable compounds of high lattice energy. In this circumstance the energy necessary to exchange the two atoms, A and B, by removing them from their equilibrium lattice site is so large that it overrides the influence of surface forces that would induce surface segregation. Thus the bulk composition pins the surface composition, *i.e.*, the surface and bulk compositions remain identical. We have found in studying the complex gold-tin phase diagram that this phenomenon occurs at the bulk composition of AuSn that forms a compound with high cohesive energy.

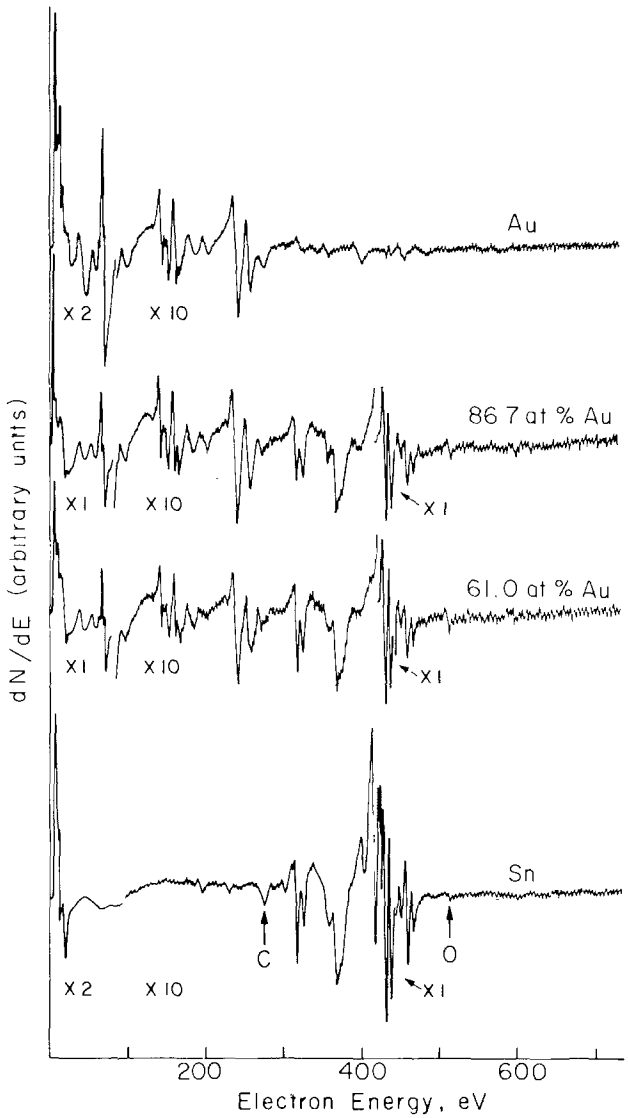

Fig. 8. Derivative Auger spectra for pure gold, pure tin, and two representational alloys.

In Table III we list those metal systems that have been studied by electron spectroscopy and indicate which element is found in excess at the surface. The surface composition is determined by the interplay of three physical parameters: (*i*) the surface free energy difference of the two components, (*ii*) the relative sizes of the two types of atoms in the alloy, and (*iii*) the magnitude of the bond energy between unlike atoms when a compound forms. For regular solutions, *i* and *ii* determine the surface composition. For substitution-

Table III. Surface enrichment of binary metal alloys

Pt-Sn (41)	Sn

ally ordered compounds of high binding energy, *iii* may override the effects of *i* and *ii*.

Studies of Catalytic Reactions

The purpose of these investigations is to understand the mechanism of catalyzed surface reactions on the atomic scale. We have recently developed new instruments for *in situ* studies of the reactivity of crystal surfaces at both low and high pressures. The scheme of one of these apparatus is shown in Fig. 2. At low pressures (10^{-7}-10^{-4} Torr), the reaction rate and product distributions are monitored by a quadrupole mass spectrometer while the surface structure and composition are determined by low energy electron diffraction and Auger electron spectroscopy, respectively. Then a small cup (total volume approximately 10 cm^3) can be placed around the crystal sample that isolates it from the rest of the chamber that can be pressurized to over 100 atm, if desired, using the mixture of gaseous reactants. The high pressure reaction chamber is connected to a gas chromatograph that serves to monitor both rate and product distributions in this circumstance. The structure and composition can be determined *in situ* by LEED and Auger before and after the high pressure experiment once the cup is removed.

Catalysis of Hydrocarbon Reactions by Platinum

Dehydrogenation of cyclohexane or cyclohexene to benzene occurs only on stepped platinum surfaces at an appreciable rate at low pressures. Figure 9 shows the step and kink density dependence of the rate of cyclohexene dehydrogenation to benzene to demonstrate this effect. While the rate increases markedly with increasing step density (Fig. 9a), it is relatively unaffected by changes of kink density (Fig. 9b).

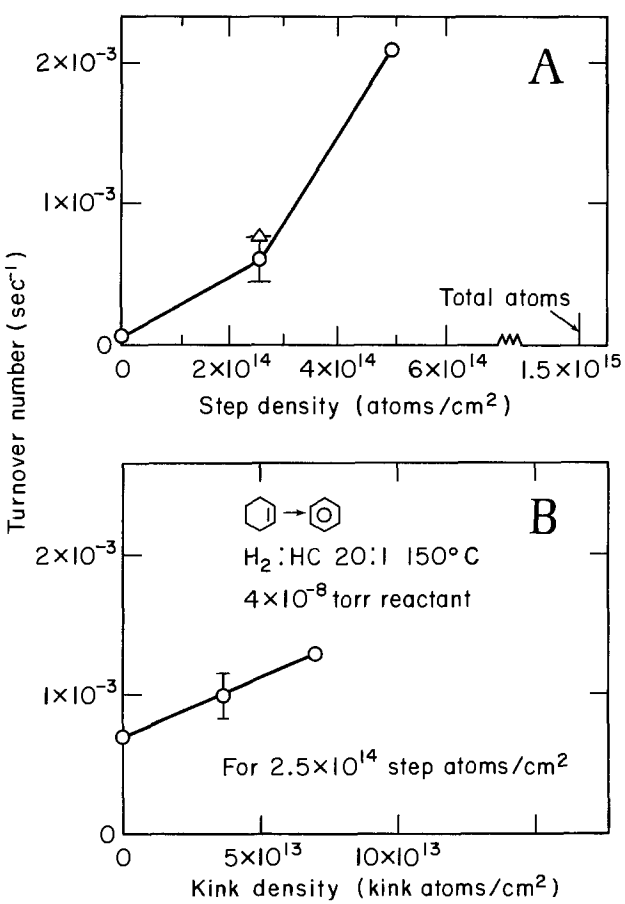

Fig. 9. Initial rate of cyclohexene dehydrogenation to benzene on platinum single crystal catalysts as a function of (a) increasing step density and (b) increasing kink density at constant step density. The reaction conditions are 5 × 10^{-8} Torr of cyclohexene, 1.0 × 10^{-6} Torr of hydrogen, and 423°K catalyst temperature.

The rate of cyclohexane dehydrogenation to benzene is constant as long as there are steps on the catalyst surface, but it is almost an order of magnitude lower on the Pt(111) surface, as seen in Fig. 10a. Thus atomic steps appear to be preferred surface sites for breaking H-H and C-H bonds (H-H bond breaking has been studied by the H_2-D_2 exchange).

Cyclohexane undergoes both dehydrogenation and hydrogenolysis on the stepped Pt surfaces. The relative rates of these two reactions can best be monitored by the ratio of benzene to n-hexane in the reaction product. As is demonstrated in Fig. 10, the rate of benzene production is independent of step and kink density while n-hexane production increases slowly with step density and rapidly with kink density. Rates of cyclohexane hydrogenolysis to n-hexane per kink site is determined by the slope of the line in Fig. 7b representing hydrogenolysis and is 3 × 10^{-28} moles of n-hexane/kink atom/sec. This is almost an order of magnitude higher than the slope in Fig. 8a which is 4 × 10^{-29} moles of n-hexane/step atom/sec. The observed low hydrogenolysis activity on the type of

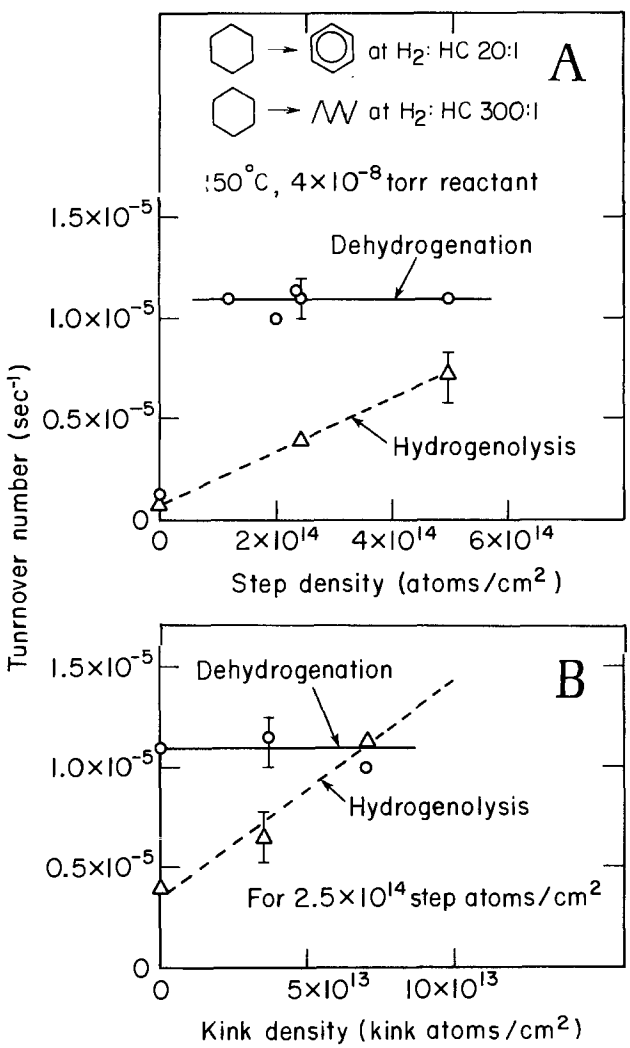

Fig. 10. Initial steady-state rates of cyclohexane dehydrogenation to benezene (o) and hydrogenolysis to n-hexane (Δ) on platinum single crystal catalysts as a function of (a) increasing step density and (b) increasing kink density at constant step density of 2.4 × 10^{14} step atoms/cm^2. The reaction conditions are 5 × 10^{-8} Torr of cyclohexane, 1.0 × 10^{-6} Torr of hydrogen, and 423°K catalyst temperature. The rate of dehydrogenation is constant at 2.8 × 10^{-14} mole cm^{-2} sec^{-1} with steps present but is less (0.3 × 10^{-14} mole cm^{-2} sec^{-1}) one the (111) surface (near zero step density). The rates of hydrogenolysis per surface sites are the slope of the lines representing hydrogenolysis and are 3 × 10^{-28} mole (kink atom)$^{-1}$ sec^{-1} and 4 × 10^{-29} mole (step atom)$^{-1}$ sec^{-1}.

stepped surfaces represented by Fig. 10a may be caused by some thermally regenerated kinks in the steps. n-Hexane formation and the formation of other hydrogenolysis products must be the result of C-C bond scissions. It appears that kinks are very effective in breaking C-C bonds in addition to C-H and H-H bonds. Thus we have been able to identify two active sites of lower coordination number of platinum surfaces: steps with C-H and H-H and kinks in steps with C-C, C-H, and H-H bond-breaking activity.

The Hydrogenation of CO and CO_2 over Polycrystalline Rhodium at 1 Atm (14)

The formation of hydrocarbons from CO-H_2 mixtures is thermodynamically favorable, although higher pressures (in excess of 1 atm) are necessary to facilitate the formation of higher molecular weight products.

The rates of formation of products by this reaction are very low as compared to other hydrocarbon reactions (dehydrogenation or hydrogenolysis). Thermodynamic equilibrium between reactants and the many possible products is not established even at the high pressures commonly employed.

We have studied the reaction of CO and H_2, and CO_2 and H_2 to form hydrocarbons, using polycrystalline rhodium as a catalyst. The kinetics of methanation on this metal foil of about ~1 cm^2 area is in excellent agreement with the results obtained on dispersed and supported rhodium catalysts.

There is evidence for the presence of both molecular and dissociated CO on the surface, during the synthesis. The active rhodium surface develops a carbonaceous deposit, while chemisorbed oxygen is rapidly removed from the surface layer by CO and H_2. Oxygen also appears to be located below the metal surface. By changing the composition and/or structure of the rhodium-carbon surface complex by pretreatment (with acetylene or oxygen), both the reaction rate and the product distribution can be markedly altered. The CO_2-H_2 reaction yielded methane predominantly, in contrast with the much broader distribution obtained from CO-H_2 reactions under the same conditions.

Variation of methanation activity and product distribution on clean and pretreated rhodium surfaces is shown in Table IV.

The high pressure apparatus has been a great asset to correlate the reactivity of the surface with the catalyst surface structure and composition for the important CO-H_2 and CO_2-H_2 reactions. As a result a better physical picture of heterogeneous catalysis emerges. It is my hope that using similar apparatus the reactivity, the structure, and the composition at solid-liquid interfaces will also be explored.

Table IV. Variation in methanation activity and product distributions for the CO-H_2 and CO_2-H_2 reactions on clean and pretreated rhodium surfaces. (Reaction conditions 1:3 ratio, 700 Torr, 300°C.)

Reaction gases	Surface pretreatment*	Methanation rate (300°C) (turnover number)	Product distribution (%)
CO-H_2	None	0.15 ± 0.05	88 C_1 9 C_2 3 C_3
CO_2-H_2	None	0.33 ± 0.05	100 C_1
CO-H_2	O_2	0.33 ± 0.05	87 C_1 10 C_2 3 C_3
CO_2-H_2	O_2	1.7 ± 0.2	98 C_1 2 C_2
CO-H_2	CO	0.15 ± 0.05	88 C_1 9 C_2 3 C_3
CO_2-H_2	CO	0.33 ± 0.05	100 C_1
CO-H_2	C_2H_2	0.07 ± 0.02	78 C_1 18 C_2 4 C_3

* Heated for 15 min in 700 Torr of the particular gas, then thermally desorbed to 1000°C *in vacuo* before reaction.

Correlations of Structure, Composition, and Reactivity at Solid-Gas and Solid-Liquid Interfaces

The same questions that are asked in studies of solid-gas interfaces are also important to answer in studies of solid-liquid interface phenomena. What is the atomic and electronic structure and composition of the solid surface at the liquid interface in the presence of an external electric field and in the absence of such an electrochemical potential? How does this structure and composition correlate with reactivity during an electrochemical reaction or for surface reactions at the liquid interface? Since the solid surface structure and composition cannot be studied in the presence of a liquid with our surface-sensitive techniques that are presently available, just as in the case of high pressure, solid gas studies, the surface structure and composition will have to be determined before and after the solid-liquid interface reaction.

The simplest question that one may ask is whether stable surface structure of adsorbates and the bonding of these adsorbates are the same when adsorption occurs from the liquid face as compared to that from the vapor of the same molecule. Water or organic solvents (n-heptane, benzene, etc.) and ionic substances (sulfates, chlorates, halogens, and alkali metals) may come to mind as likely candidates for these studies. The high pressure apparatus that has been described above is most suitable to carry out these investigations. One may wish to investigate the surface structure of a single crystal face as the external electrochemical potential is changed. Simultaneously, one would wish to determine how the surface composition varies as oxidation or reducing surface conditions are established using an external potential. For example, what is the coverage and bonding of oxygen and hydrogen on the surface as a function of variation of the external electric field. The aim of these early studies should be to discover patterns of similarity and change with studies of the same type at the solid-liquid and solid-gas interface. Once these correlations of changes of surface structure and composition are established, electrochemical and other solid-liquid interface studies can draw on the wealth of information that is available from studies of the solid-gas interface. Then patterns of similarity may emerge for surface reaction studies as well, such as electrocatalysis and heterogeneous catalysis.

Admittedly, during the transient period while the liquid phase or high pressure gas phase is removed from the vicinity of the solid surface to be studied, many of the weakly bound surface intermediates may change their bonding or desorb altogether. Thus, studies of the surface structure and composition before and after the surface reaction may not always yield a complete physical picture of the working surface under reaction conditions. It is feasible, however, to remove or reintroduce a liquid or high pressure gas within milliseconds thereby increasing the probability to detect even weakly bound, short residence time surface species. [The surface residence time (τ) is commonly given as $\tau = \tau_0 \exp(\Delta H/RT)$ where τ_0 is often equated with vibrational times approximately 10^{-12} sec and ΔH is the heat of adsorption.] Such rapid pumping techniques will be developed in the near future no doubt.

Modern surface science developed on account of the atomic and molecular level information that has become available by applications of the new surface diagnostic techniques. Determination of the structure and composition of the working metal catalyst or the corroding surface also presented the opportunity to develop new catalysts and to passivate the surface against corrosion. There are several innovations of commercial significance that owe their birth to modern surface science. It is likely that studies of the solid-liquid interface will yield major advances in the field of elec-

trochemistry and perhaps establish new areas of electrochemical science.

PEOPLE

David G. Thomas has been elected to the grade of Fellow by the Institute of Electrical and Electronics Engineers (IEEE). The honor, conferred upon 133 chosen from nine countries, is given to people with "demonstrated outstanding and extraordinary qualifications and experience" who have made important contributions to their profession. Dr. Thomas, Executive Director of the Transmission Systems at Bell Laboratories in Holmdel, has been selected in particular "for contributions to the understanding of luminescense in semiconductors, and to the development of light-emitting diodes." His studies led to the development of gallium-phosphide light-emitting diodes (LED's), which consume less power and last longer than tungsten lamps. LED's are used extensively in the Bell System as indicator lights on maintenance equipment, central-office control panels, and some new multiline telephones and business telephone consoles.

Dr. Thomas has been an Active Member of the Society since 1968.

Robert Baboian has been honored as a "TI Fellow" by Texas Instruments Incorporated. He was presented with a plaque designating him as such in special recognition of his contributions to Texas Instruments in science and technology during his ten year career with the company. He is the sixth person to receive the award.

Dr. Baboian received his B.S. degree in chemistry from Suffolk University, Boston, and his Ph.D. in physical chemistry from Rensselaer Polytechnic Institute in Troy, N.Y. He did postdoctoral research as a Ford Foundation Fellow at the University of Toronto. He is presently working in the Materials and Electrical Products Group in Attleboro, Vermont, and is Texas Instruments' leading expert on corrosion resistant materials. Some of his earliest work at TI involved the investigation of the use of stainless-steel-clad aluminum trim materials on automobiles. He has developed fundamental principles for galvanic corrosion, established test methods and design criteria for clad metal systems, and has established electrochemical techniques for investigation of corrosion reactions. His work on impressed current cathodic protection has led to wide use of platinum-clad columbium anodes for corrosion protection. Since joining TI in 1956, he has been issued five U.S. patents and 27 international patents.

Dr. Baboian has been an Active Member of the Society since 1934.

Section News cont.

Metropolitan New York Section

On March 16, 1977, the Metropolitan New York Local Section held a joint meeting with the Newark Branch of the American Electroplaters Society. The meeting was attended by 49 ECS and AES members, guests, and students. Professor Rolf Weil, Chairman of this Local Section, presented a talk entitled "The Structure of the Early Stages of Nickel Electrodeposition." Dr. Weil showed how brighteners have not only an effect on the formation of multiple layers of electrodeposited metal, but also have substantial effect on the formation of the initial layer of metal. Under ideal conditions, electrodeposition should initiate at kink sites and spread two dimensionally to form a monolayer. This typically does not occur. Both clumps and pyramids grow from nucleation sites and coverage occurs by coalescence of these islands of atoms. Addition agents such as saccharin reduce the clumping tendency and also decrease mismatch stress caused by the difference between the atomic spacing of nickel and substrate.

The last meeting of the season, Ladies Night, was held on April 27, 1977, at the Stevens Institute of Technology, Hoboken, New Jersey. After a business meeting at which new officers were elected (results to be published in a later issue of **This Journal**) a social evening was held at which there were door prizes, entertainment, and a featured speaker.

John Broadhead
Vice-Chairman

NEW MEMBERS

It is a pleasure to announce the following new members of The Electrochemical Society as recommended by the Admissions Committee and approved by the Board of Directors in April 1977.

Active Members

BOOK REVIEWS

"Silicon Carbide—1973," edited by R. C. Marshall, J. W. Faust, Jr., and C. E. Ryan. Published by the University of South Carolina Press, Columbia, South Carolina (1974). 692 pages.

This volume is a compilation of 75 papers delivered at the Third Silicon Carbide Conference held September 17-20, 1973, sponsored by AFCRL. The papers stress the "glamour" areas of SiC research such as fundamental physical properties, new methods of crystal growth, and electronic devices (especially LED's), but also cover more practical nonelectronic research including, for example, a paper on the production of SiC from rice hulls.

For over twenty years SiC has been a promising material for LED's and other electronic applications because of its wide bandgap, ease of being doped either n- or p-type, and high thermal conductivity and stability. However, the field is still severely impeded by the tremendous difficulty of growing single crystals and diffusing the material to form useful devices, processes which must be carried out at temperatures between 1800° and 2300°C. Because of this, nearly a third of the papers in this volume deal with crystal growth, including liquid and vapor phase epitaxial growth.

The degree of sophistication of SiC crystal growth is seen to parallel that of the more widely used, commercially

successful III-V compounds. An example of perhaps the most sophisticated crystal growth technique is presented in a paper by Rutz and Cuomo of IBM, who grew single crystals of SiC by close-spaced vapor deposition at 1860°C on single crystalline AlN layers grown by reactive sputtering on single crystal tungsten layers deposited on sapphire substrates.

Another very interesting paper is a review of the status of SiC LED's, including a comparison with GaP, a competing material for which an advanced LED technology has been developed. The paper is by two Russian authors, Kholuyanov and Vodakov, who are well qualified because of their heavy involvement in LED research and by the fact that most SiC LED work has been carried out in the Soviet Union. They conclude that at very low current densities (< 0.1 A/cm^2) the best SiC diodes are superior to either Zn, O-doped red, or N-doped green emitting diodes. However, it should be understood that at normal operating current the situation is reversed. For example, at 10 A/cm^2, the GaP:N LED's are a factor of ~ 20 brighter.

In spite of the good and original research presented in this volume, one has the feeling that SiC for electronic applications still remains "subthreshold," as characterized by R. C. Marshall in the opening comments, and is falling further and further behind the rapidly advancing III/V and elemental semiconductors.

This book will be indispensible to workers in the area of SiC. It is also an excellent source for researchers involved in electronic materials research who want a compact compilation of the recent work in SiC and its present status.

"Progress in Solid State Chemistry," Vol. 10, edited by J. O. McCaldin and G. Somorjai. Published by Pergamon Press, Inc., Elmsford, New York (1976). 284 pages; $37.50.

The well-known series on "Solid State Chemistry" has added a new edition, the tenth, which starts a new mode of publication. Camera-ready manuscripts are printed so that faster publication is assured and several volumes per year may be issued. With nine papers covering a wide range of topics, Volume 10 is a welcome addition to this series, as it treats a group of important projects.

Carl Wagner contributes a paper on the transport equations in solid oxides and sulfides of transition metals. As these materials are of technical importance in metallurgical processes, amorphous structures, thin films, electrolytic cells, and semiconductor electronics, the solutions of the transport equations (basically of the Onsager-type) for different cases (ratio between ion and electron conduction, composition gradient, rate of oxidation, defect density) are essential. This paper written by a recognized authority will be of great interest for those working in this field.

A second paper on the oxides of transition metals (W. W. Smeltzer and D. J. Young) contributes to the chemical and structural features of these compounds. Major aspects of the oxide formation are discussed: thermodynamics (metal-oxide equilibria); lattice defect structures (point defects vs. electron concentration); diffusion (self, tracer, defect, and chemical diffusivities); boundary conditions and interfacial processes including defects; and oxidation rate equations and rate control by electron injection and transport. On the experimental side, the authors develop detail of oxide film growth in the case of nickel, copper, and zinc, and discuss conducting oxide films.

Finally, high temperature scale formation is described in the context of the experimental facts (phase diagrams, diffusion coefficients, parabolic kinetics) for the above metals and cobalt, chromium and manganese. There is an intimate connection between scale growth and growth of dislocation networks. (See also: "International Colloquium on Grain Boundaries in Metals," Journal de Physique, Colloque C-4 supplement No. 10, October 1975.)

J. H. Sinfelt contributes an article on heterogeneous catalysis by metals. The great importance of the catalytic potential of the group VIII metals (iron, cobalt, nickel) and copper is emphasized from the outset. Heterogeneous catalysis is discussed qualitatively as a large surface area chemical interaction with specificity for the chemical reaction induced. Particular features or classes of reactions on metals are discussed: hydrogenation, hydrogenolysis, isomerization, oxidation.

A. Rothwarf and K. W. Boer summarize the status in the field of solar cells in their contribution on direct conversion of solar energy through photovoltaic cells. The article is an in-depth review of the field starting with the basic equations for the state density, statistics, band scheme, junction behavior, and diode forms (homojunctions and metal-semiconductor junctions). The more complex cases of heterostructures (Cu_2S-CdS) are discussed and a few practical questions concerning solar cell efficiency (reflection, absorption losses) and the basic set of transport equations are given. Boundary conditions, drift field effects, diffusion length, mobility, and lifetime are part of the general topics leading to a consideration of the solar cell efficiency. After discussion of the important Schottky diode cells (with a practical list of observed barrier heights), some experimental results are given and future forms are discussed. In this fast moving field, it is difficult to stay abreast of the latest development. Thus numbers given and materials quoted are partially outdated already, but the in-depth survey conveys an excellent picture of the technologies involved.

Ivan Haller gives a description of the thermodynamic and static properties of liquid crystals. The review is limited to thermotropic liquid crystals with emphasis on nematic materials, and it pursues the ideas concerning the nature of liquid crystalline phase transitions. Particular topics treated are molecular structure and phase transitions, eutectic compositions, surface chemistry and alignment, refractive index, and the order parameter. The industrial importance of the liquid crystals (displays) and their biological significance (membranes) has resulted in numerous other reviews quoted by the author.

The paper by A. D. Pelton and W. T. Thompson on phase diagrams correlates graphical representations with analytical thermodynamic expressions. The integral molar-free energy of a phase is combined with the expression for the chemical potential. The shape of the isotherms is expressed via the temperature dependence of the integral molar Gibbs free energy of mixing. Numerous binary and ternary systems are calculated and the result compared to experimental phase diagrams. The authors have made great strides to further the understanding of the many parameters influencing phase equilibria.

A. Y. Cho and J. R. Arthur contribute a paper on molecular beam epitaxy. This is the ultimate in localized definition of epitaxial growth; different from CVD (Chemical Vapor Deposition) and LPE (Liquid Phase Epitaxy), individual molecular species are deposited under ultrahigh vacuum conditions. The method allows a submicron control of deposition and so-called superlattices are feasible by subsequent layer deposition. The authors show how the difficulties of monocrystallization can be overcome. Clean deposition conditions plus annealing steps yield very perfect monocrystallinity. Also the doping problem can be solved in most cases. The authors show as proof a number of devices and their performance data.

A paper on surface physics of silver halides (Yen T. Tan) adds interesting information on the structure of AgBr and AgCl. The ionic space-charge model of halide surfaces is addressed specifically and the theory underlying this phenomenon is reviewed. As the vacancy gradient and uncompensated surface charges give rise to a rearrangement of ions near the surface, a type of Boltzmann distribution of excess subsurface charges is postulated. Experimental conductivity vs. thickness results and potentials plotted by the Kelvin probe are discussed. The presence of these space-charge layers is also postulated in emulsions and microcrystals with the additional feature of an even higher conductivity due to interstitial silver

Electrocapillary Curves for Gold

K. F. Lin and T. R. Beck*

Department of Chemical Engineering, University of Washington, Seattle, Washington 98195

Electrocapillary curves have been determinded for gold by measuring the elongation of a thin gold ribbon as a function of potential. Elongation is measured by an extensometer instrument previously described (1,2). Change in surface stress, $\Delta\sigma_s$, of the ribbon is measured which with this instrument is approximately equal to change in surface tension, $\Delta\gamma$.

The gold ribbons had the dimensions 12.5 μm thickness x 0.32 cm wide with about 50 cm length immersed in the electrolyte. The ribbons were rolled from 99.99% gold. The counterelectrode was a ribbon of the same material to minimize contamination to the system. A saturated calomel reference electrode was connected to the measuring cell through a salt bridge containing the electrolyte under study. Electrolyte was prepared from reverse-osmosis purified water and ACS-reagent grade chemicals. Initial experiments were with nondearted solutions. A new purification system has been assembled which continuously deaerates with purified nitrogen, absorbs with activated carbon and preelectrolyzes with ribbons of the same metal as under study.

An electrocapillary curve for gold in 0.1*N* KCl solution was previously shown (1). Similar parabolic-shape curves are also obtained in other solutions. The potential of the surface stress maximum for gold was found to be independent of *p*H in 0.1*N* potassium sulfate and perchlorate solutions. Gold has a high hydrogen overvoltage and a high oxidation potential so that it has a wide electrical double layer region like mercury.

Surface active anions shift the surface stress maximum in the negative direction as shown in Fig. 1. (These curves were moved on the surface-stress scale to bring them tangent on the negative branch.) The order of adsorption of the anions on gold is the same as for mercury (3) but the magnitude of the shift is greater. A similar larger magnitude shift in the point of zero charge of gold measured by double layer capacitance minima and integration of capacitance for dilure halide solutions was observed by Clavilier and Van Huong (4). These data are compared in Table I. The bias between the two sets of data hopefully can be resolved upon more rigorous purification.

Table I. Potential of surface stress maximum and point of zero charge for gold

	ϕ (σ_s max) (V_{SCE})	ϕ_z (V_{SCE})	$\Delta\phi$ (V)
Cl^-	-0.4	-0.18	0.22
Br^-	-0.70	-0.42	0.28
I^-	-0.98	-0.70	0.28

Order of magnitude checks have been obtained between surface stress and double layer capacitance using the Lippmann equation.

The Hydrogen Electrode in Molten Carbonate

W. M. Vogel* and C. D. Iacovangelo*,[1]

United Technologies Corporation, Advanced Fuel Cell Research Laboratory, Power Systems Division, Middletown, Connecticut 06457

ABSTRACT

Open-circuit potentials are reported for the hydrogen (Au) electrode in molten carbonate at 650°C. The data, with few exceptions, agree with thermodynamic values calculated assuming simultaneous equilibrium of the shift and the methane reactions. The exceptions are those instances where methane has to be oxidized almost completely to reach equilibrium, and those where carbon can form during preheating of the gas.

The anodic activation polarization of the hydrogen electrode in alkali carbonate melts should be small because of the required high temperatures. This is evidently true because the nature of the electrode metal has no effect on the polarization (1). Ohmic losses can be estimated from the conductance of the electrolyte and should be generally small even in a porous gas diffusion electrode except when poorly conducting surface oxides are formed on the electrode metal. Thus, with negligible activation polarization and ohmic losses the anode polarization should consist, at potentials below the metal oxidation potential, of concentration overvoltages plus, possibly, some contribution from liquid junction potentials between anode and cathode.

Broers *et al.* (2) have found that the polarization of such anodes results primarily from the accumulation of reaction products (CO_2, H_2O) rather than from a lack of hydrogen. The anode reaction

$$H_2 + CO_3^{=} = H_2O + CO_2 + 2e^- \qquad [1]$$

produces CO_2 and H_2O both of which are acids in molten carbonates. Both enter into acid-base equilibria (3, 4) with the strongly basic $O^=$ ion

$$CO_2 + O^{=} = CO_3^{=} \qquad [2]$$

$$H_2O + O^{=} = 2\,OH^- \qquad [3]$$

The acidity constants, *i.e.*, the equilibrium constants of reactions [2] and [3] are of similar magnitude. Busson *et al.* (5) reported the values $K_{CO_2} = 10^{7.5}$ and $K_{H_2O} = 10^6$ for 600°C. The alkalinity of the melt, expressed as $pO \equiv -\log[O^=]$ in analogy to the pH of aqueous solutions (6), is therefore not determined by the CO_2 pressure alone but by both the pressures of H_2O and CO_2. Because of this simultaneous dependency of the oxygen ion concentration on both pressures, it appears more suitable to use the pO as the measure for acidity rather than the $PCO_2 \equiv -\log p_{CO_2}$ which was suggested by Janz *et al.* (7) for hydrogen-free systems.

A given melt can then be considered acidic if the pO is larger than a certain neutrality value, and alkaline if the reverse is true. Busson *et al.* (5) reported for the solubility of CO_2 the relationship $(CO_2) = 0.1\,P_{CO_2}$ (P_{CO_2} in atmospheres, (CO_2) in mole/liter). Together with the acidity constant of CO_2 we have, at 600°C

$$(CO_2)\,(O^=) = 10^{-8.5} \qquad [4]$$

We consider a melt to be neutral when $(CO_2) = (O^=)$, *i.e.*, at $pO = 4.25$. As long as the water pressure is not extremely high, the OH^- ions can be assumed to be dissolved in molten carbonate and we can use the same pO value for a neutral melt containing both acids, H_2O and CO_2. An equilibrium oxygen electrode can then be used as a pO indicator with the potential

$$E = E_o + \frac{RT}{4F} \ln P_{O_2} + \frac{2.3RT}{2F} \cdot pO \qquad [5]$$

The results of Broers *et al.* (2) indicate, in this terminology, a lack of buffer capacity of the electrolyte (8) as a main cause for the polarization of a hydrogen anode. This explanation assumes that the electrode reaction is, at all current densities, close to equilibrium, *i.e.*, the iR-free electrode potential is nearly identical with the equilibrium potential calculated with the activities of the reactants as they prevail at the metal/liquid interface. However, this explanation is in apparent contradiction to data in Ref. (5) which describes deviations from equilibrium even at open circuit. The discrepancies were as large as 100 mV with the largest differences observed in acidic and alkaline melts, *i.e.*, just where polarized molten carbonate electrodes are assumed to operate.

A number of factors can cause real or apparent discrepancies between calculated thermodynamic potentials and observed open-circuit potentials (ocp). The equilibrium potential of reaction [1] is given by

$$E = E^\circ + \frac{RT}{2F} \ln \frac{P_{H_2O} P_{CO_2}}{P_{H_2}} \qquad [6]$$

If arbitrary mixtures of H_2, CH_4, CO, and CO_2 are used we can calculate the equilibrium pressures of H_2O, CO_2, and H_2 provided that carbon is not formed.

[1] Present address: General Electric Company, Research and Development Center, Schenectady, New York 12301.
Key words: molten carbonates, hydrogen electrode, open-circuit potentials.

However, the actual pressures at the electrode may be different, resulting in discrepancies between calculated and observed potentials.

It is also possible that observed differences are due to fundamental uncertainties which are introduced by the type of reference electrode used in previous studies. The H_2O and CO_2 pressures at a molten carbonate electrode cannot be changed without simultaneously changing the electrolyte composition (Eq. [2], [3]). As written, Eq. [6] assumes that E is measured against a reference in the same medium, and that the reference potential varies with the carbonate ion activity in the same way as that of the hydrogen electrode. An example is an oxygen reference electrode with the same H_2O and CO_2 pressures as the hydrogen electrode. In this case, E is simply the cell voltage for the water reaction and $E°$ can be calculated very accurately. Differences between such calculated values for E and observed ocp have to be due to nonequilibrium conditions of the working electrode. Such experiments are thermodynamically well defined but they are also cumbersome, requiring changes in the gas composition at the reference in concert with those at the working electrode.

It is more common to use a constant reference electrode. Such experiments are simpler to do but they are thermodynamically less well defined, *i.e.*, observed potentials cannot be compared with calculated values without additional assumptions. Assume that an oxygen electrode in a carbonate melt of fixed acidity (CO_2 pressure) is used as reference. Equation [6] can then be applied provided that liquid junction potentials and differences in the carbonate ion activities at the two electrodes are negligible. These conditions should be fulfilled except for very alkaline conditions at the working electrode. Similar restrictions apply to potentials referred to a metal/metal ion electrode such as that of Danner and Rey (9). With such a reference, furthermore, the standard potential $E°$ cannot be calculated from thermodynamic data but has to be determined empirically.

The present study was undertaken in an attempt to identify the reasons for previously reported deviations of ocp from thermodynamic values, and to determine how and under what circumstances the ocp can be calculated.

Experimental

The apparatus used in measuring the ocp is illustrated in Fig. 1. The electrolyte, which was a fused binary eutectic of 62 mole percent (m/o) Li_2CO_3 and 38 m/o K_2CO_3, was contained in a tapered crucible made of Degussit AL-23 (99.5% Al_2O_3, dense).

The working electrode (WE) was a 0.020 in. diam gold wire inside a 0.50 in. diam AL-23 tube with a 1 mm opening to the melt at the bottom. The tube was vented to the atmosphere through a 0.125 in. diam alumina tube.

The initial partial pressures of H_2 and CO_2 in the feed gas to the WE were regulated by flowing each gas through Gilmont Flowmeters (no. 1) connected by a tee to 0.25 in. diam tubing, 2 ft in length, where they were allowed to mix prior to entering the water saturator. The initial water pressure was established by flowing the gas mixture through a saturator maintained at the required temperature. The saturator efficiency was checked by absorbing the H_2O with Dri-Rite. The feed gas was subsequently preheated to 650°C by flowing at 200 ml/min through 0.25 in. diam 316 stainless steel tubing 7 ft in length. The latter was wrapped around the outside of the cell crucible.

The apparatus was heated in a Lindberg furnace. All experiments were done at 650° ± 0.5°C. The temperature was measured inside the cell with a thermocouple contained within an alumina tube.

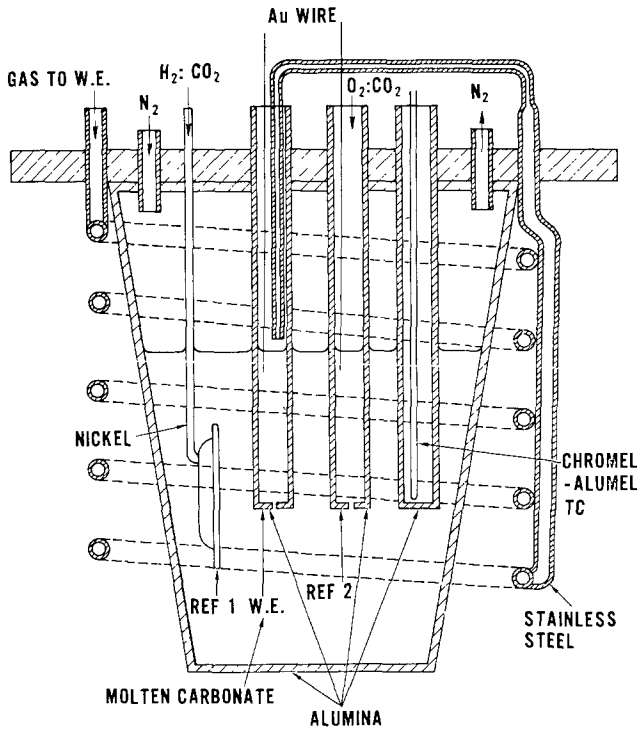

Fig. 1. Cell assembly

Cell voltages were measured with a Newport digital voltmeter having an input resistance of $10^9\Omega$.

For the present study a constant oxygen reference electrode was used [O_2, CO_2 (Au) with $P_{O_2} = 1/3$ and $P_{CO_2} = 2/3$ atm]. This choice of reference introduces fundamental inaccuracies which were described in the introduction. Significant errors of this nature should produce deviations of the ocp from theoretical values. As will be shown later, good agreement was observed which indicates that such errors were small for the range of compositions studied. The reference was checked against a CO/CO_2 electrode of similar melt composition ($P_{CO} = 0.382$ and $P_{CO_2} = 0.618$ atm). The difference between the observed and the calculated voltage of this cell [using data from Ref. (10)] was 2 mV which demonstrates the usefulness of our reference. Similar reliability in a ternary melt of alkali metal carbonates has been reported by Borucka *et al.* (11, 12).

Results and Discussion

The observed open-circuit potentials for initially dry mixtures of H_2 and CO_2 are listed in Table I. Included in this table are the pressures of H_2, H_2O, and CO_2 which were calculated assuming shift equilibrium ($K_p = 1.96$), and also simultaneous equilibrium of the shift and the methane reactions ($K_p = 2.68$). The data are plotted in Fig. 2. We see that neither assumption explains the experimental results.

One likely cause for the differences is carbon formation. If the gases are heated instantaneously to 650°C, carbon cannot form since the potential of the C/CO_2 reaction would be negative relative to the hydrogen potential if either shift or complete equilibrium is assumed. However, in our experiments the gas was heated gradually as it passed through the preheater tubing. At temperatures below 650°C the C/CO_2 potential becomes increasingly more anodic to the hydrogen potential assuming, *e.g.*, shift equilibrium, and carbon formation is likely.

The experiments were repeated with an addition of 14% H_2O vapor to the H_2-CO_2 mixtures. The re-

sults are given in Table II, together with the pressures of H_2, H_2O, and CO_2 again calculated with the assumption that only the shift reaction is in equilibrium. The ocp and the thermodynamic potentials E, derived from these calculated pressures, are plotted in Fig. 3a against the activity term in Eq. [6]. The agreement is better than in Table I. However, at low potentials the experimental data still are more positive than the calculated values. The ocp appears to be a mixed potential with the hydrogen reaction being anodically polarized and some other reaction proceeding cathodically. This electrochemical description is being used because any of the possible chemical reactions (shift, Boudouard, etc.) can be considered as the neutral sum of electrochemical partial reactions. It does not matter, for the present purpose of determining equilibrium potentials, where these reactions occur, *i.e.*, at the metal/liquid interface or somewhere upstream from the electrode.

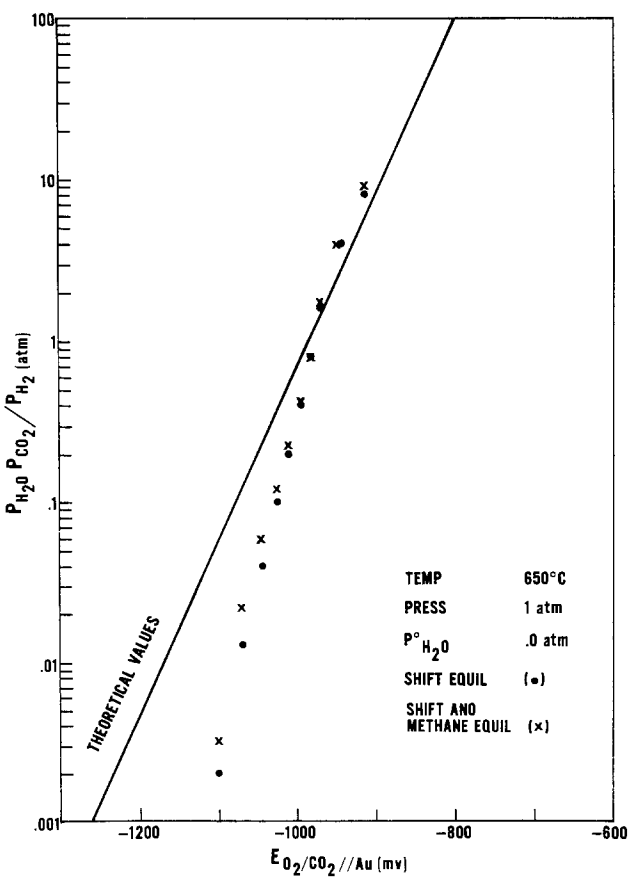

Fig. 2. Open-circuit potentials for dry mixtures of H_2 and CO_2. Partial pressures of H_2, CO_2, and H_2O calculated assuming equilibrium for the shift reaction only.

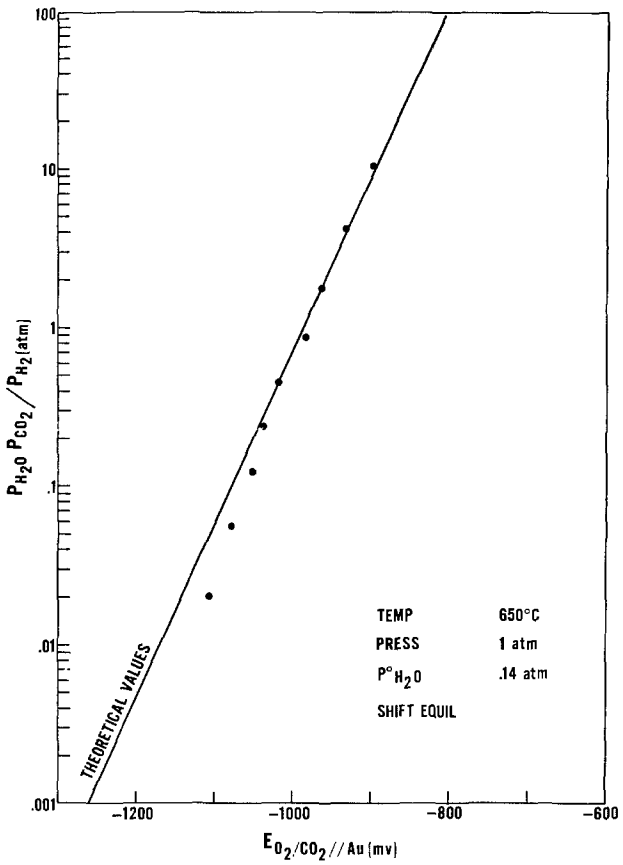
We have the following four reactions, combinations of which yield all other possible reactions (chemical or electrochemical)

$$H_2 + CO_3^= = CO_2 + H_2O + 2e^- \quad [7]$$

$$CO + CO_3^= = 2CO_2 + 2e^- \quad [8]$$

$$C + 2CO_3^= = 3CO_2 + 4e^- \quad [9]$$

$$CH_4 + 4CO_3^= = 5CO_2 + 2H_2O + 8e^- \quad [10]$$



Since, by adding 14% H_2O, we had raised the value of E for reaction [7] above that for reaction [9] no carbon formation was possible. Reaction [8] was accounted for by assuming equilibrium for the shift reaction which is the (electrically neutral) sum of reactions [7] and [8]. It was indicated, therefore, that the cathodic branch of reaction [10] was responsible for the remaining differences in Fig. 3a.

The equilibrium pressures for the gas mixtures in Table II were recalculated assuming that reactions [7], [8], and [10] were in equilibrium. Thus, in addition to the shift reaction, the methane formation, which results from a combination of reactions [10] and either [7] or [8], was assumed to be in equilibrium. The value

$$K = \frac{P_{CO} P_{H_2}^3}{P_{CH_4} P_{H_2O}} = 2.68 \quad [11]$$

was used. The results are given in Table II and Fig. 3b. Agreement between observed and theoretical potentials appears satisfactory.

In Fig. 4 and Table III the results are given for gas mixtures containing a constant initial amount of methane. The experimental and theoretical potentials agree with each other except for those gases for which complete equilibrium requires nearly complete oxidation of methane, *i.e.*, to pressures below approximately 0.0006 atm.

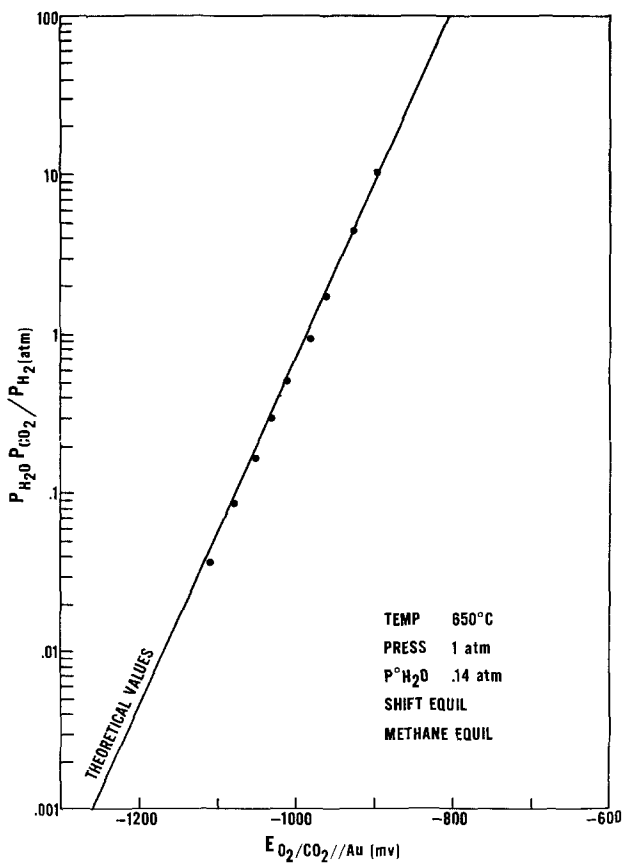


Fig. 3 (a, top; b, bottom) The ocp for humidified mixtures of H_2 and CO_2. Partial pressures of H_2, CO_2, and H_2O calculated assuming equilibrium for shift reaction only (a), and complete equilibrium (b).

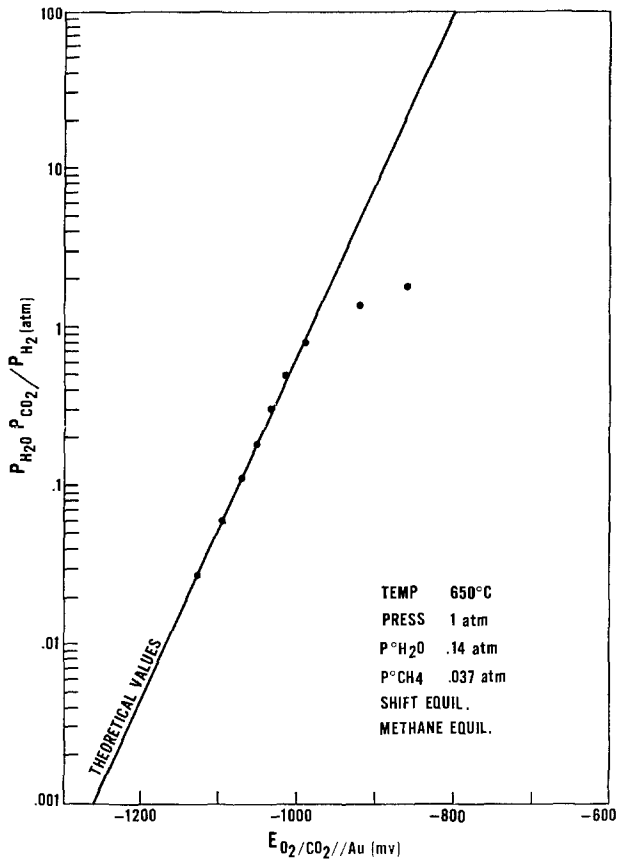

Fig. 4. The ocp for mixtures of H_2, CH_4, H_2O, and CO_2. Partial pressures calculated assuming complete equilibrium.

Conclusions

We conclude that, in calculating the ocp of a hydrogen electrode from the composition of the (initially cold) feed gas, the entire experimental setup has to be considered including the device used to preheat the gas. Large errors can result if complete equilibrium is not achieved. This is particularly true if the initial gas contains insufficient water to prevent carbon formation at lower temperatures encountered by the gas during heating. If, on the other hand, an equilibrium gas mixture is supplied, the ocp in most instances agrees accurately with the thermodynamic value. Exceptions are experiments in which equilibrium can be obtained only by nearly complete oxidation of excess methane in the feed gas.

Equilibrium Properties of Lithium/Niobium Selenide, Nonaqueous Secondary Cells

J. N. Carides and D. W. Murphy*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Equilibrium-open-circuit potentials of Li/$LiClO_4$, PC/$NbSe_x$ (x = 2, 3, 4, 4.5) cells were measured as a function of the state of charge of these cells. For $NbSe_2$ the emf decreased monotonically from ~2.3 to 1.65V at full discharge (1 Li/Nb) and was independent of prior history. With $NbSe_3$ two distinct types of emf curves were found: (*i*) a constant emf of ~1.7V from 0-2Li/Nb followed by a monotonic decrease in emf to ~1.5V at 3Li/Nb, and (*ii*) a "stepped" form with breaks at 1 and 2Li/Nb. Neither type of curve was reproduced on cycling. The emf of $NbSe_4$ and $NbSe_{4.5}$ was nearly constant at 1.83V to ~4Li/Nb. The $NbSe_4$ exhibits a monotonic decrease in emf to ~1.6V at 5Li/Nb. The emf curves obtained on the first charge and subsequent cycles were higher in value. The implications of this data on the chemistry of cell discharge is discussed.

Interest in nonaqueous reversible cells of lithium with metal chalcogenides prompted a study on the equilibrium properties of these cells with the series of niobium selenides $NbSe_2$, $NbSe_3$, and $NbSe_{4+x}$ to determine equilibrium properties, and to better understand the chemistry in this series. The selenides of niobium were chosen because they exhibit a wide range of stoichiometries. Dynamic electrochemical results have been reported for $NbSe_3$ (1) and for $NbSe_{4+x}$ (x = 0-0.5) (2). The class of metal dichalcogenides has been suggested to form reversible cathodes with Li (3, 4), prompting the examination of $NbSe_2$.

Experimental

Materials.—Niobium powder (30 μm, 99.95% purity), selenium shot (5*N* purity), graphite powder (325 mesh), lithium foil (Foote Mineral Company), and polyethylene powder (Microthene 500, U. S. Industrial Chemicals) were used as received. Propylene carbonate (PC) and tetraglyme (TTG) were vacuum distilled from lithium. Lithium hexafluorophosphate (Ventron) and lithium perchlorate (Ventron) were vacuum dried at ~ 150°C. The selenides of niobium were prepared by direct reaction of the elements in sealed vitreous silica ampuls at 750°, 680°, and 450°C for $NbSe_2$, $NbSe_3$, and $NbSe_{4+x}$, respectively. X-ray diffraction patterns agree with those previously reported for these phases.

Construction of Test Cells

Except for $NbSe_3$, cathodes were prepared by hot pressing a mixture of 65-70% active powder (150 mesh), 30-25% graphite, and the balance polyethylene (PE). Pressing was done at ~123°C and 3.5 × 10^4 psi yielding samples of ~ 7 mil thickness that were cut to convenient sizes. The natural growth habit of $NbSe_3$ resulted in a conducting, feltlike material of interwoven fibers, which was cut into sections and used directly. All samples were sandwiched between nickel screen to provide support and external connection.

The cathodes were placed horizontally in a crystallizing dish together with a lithium electrode, separation provided by glass filter paper or glass wool.

With one exception, the electrolyte was 1.0*M* $LiClO_4$ in PC. One cell, using $NbSe_4$, was constructed with 0.1*M* $LiPF_6$ in TTG to determine the significance of the electrolyte.

Cells were constructed in an inert atmosphere box under argon, and were mounted in air-tight Mason jars fitted with electrical feed throughs.

Test Procedure

Voltages were measured using a Keithley 160B digital multimeter. Cells were discharged at low current densities for periods of 8-24 hr, representing a suitable fraction of the theoretical capacity. Typical current densities were of the order of 50 μA/cm^2. Following

* Electrochemical Society Active Member.
Key words: batteries, intercalation, chalcogenides.

discharge the cell was disconnected and allowed to equilibrate for periods of 16-48 hr. Approach to equilibrium was determined by periodic potentiometric readings during the time interval. When voltage readings indicated a change of 0.010V or less over an 8 hr sampling period, the cell was regarded as having attained equilibrium and the voltage at that point recorded; discharge to the next point was then resumed. The same procedure was followed on charging. All voltage readings were made at 24° ± 2°C.

Several cells of each type were tested and the curves derived were the best fit for all points.

At least one representative of each cathode material was cycled several times. Some cells were cycled within a range that represented only a fraction of the theoretical capacity.

After the tests were completed, each cell was dismantled and the cell components visually inspected. None of the electrodes showed any deterioration or other abnormalities.

Results and Discussions

$NbSe_2$.—Lithium is introduced into $NbSe_2$ according to $xLi + NbSe_2 \rightarrow Li_xNbSe_2$ ($0 \leq x \leq 1$) (5, 6). Figure 1 shows a gradual decrease in emf indicating that Li_xNbSe_2 is single phase over the entire composition range. The shape may be understood to arise from a gradual filling of the metallic d band in $NbSe_2$, lithium inserting between Se layers in which only Van der Waals bonding exists. This result is similar to that previously discussed for TiS_2 (3, 7), whose equilibrium emf is compared in the same figure. Upon recharging $NbSe_2$ cells, the equilibrium voltage curve tracks the discharge curve within 3%, confirming that the same composition is obtained from charge or discharge.

These results were reproduced in several test cells and in each case the cells could be discharged to at least 95% of theoretical capacity (1 lithium) while still permitting recovery of at least 90% of the amount discharged.

Previous work (8) on $NbSe_2$ in Li cells containing I_2 suggested that $NbSe_2$ acted as a "host" for I. Reexamination of that cell data shows a substantial capacity in the voltage range observed here for lithium intercalation.

$NbSe_3$.—Results for $NbSe_3$ (Fig. 2) are ambiguous. In some cases the equilibrium emf was similar to that found for slow discharge (9), and OCV data for TiS_3 (3). Other cells behaved quite differently, sometimes even for material taken from the same sample preparation and with identical x-ray powder patterns. After cycling, all the $NbSe_3$ cells exhibited a gradual sloped emf. These differences in various $NbSe_3$ electrodes and the changes in emf on cycling imply that the structure is changing on cycling. Inspection of the structure of $NbSe_3$ (Fig. 3) (10) suggests the possibility that the complex arrangement of chains in the structure may not be unique. Such polytypism has been noted for a number of two-dimensional compounds involving coordination geometry and registry of the layers. The polytype formed at 680°C may not be the most stable at room temperature and also might change via lithiation and delithiation. We have been unable to detect

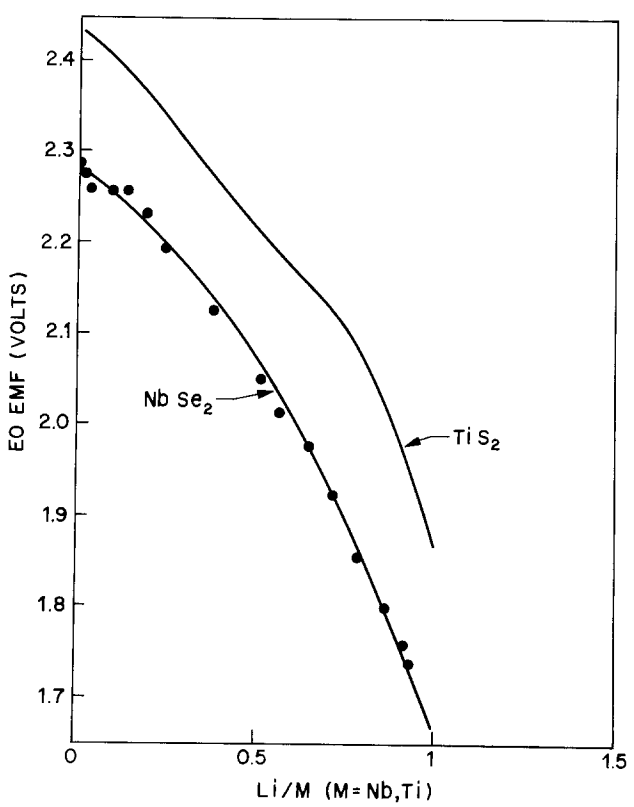

Fig. 1. Equilibrium voltage of $NbSe_2$ as a function of Li composition, compared with results given for TiS_2 (3).

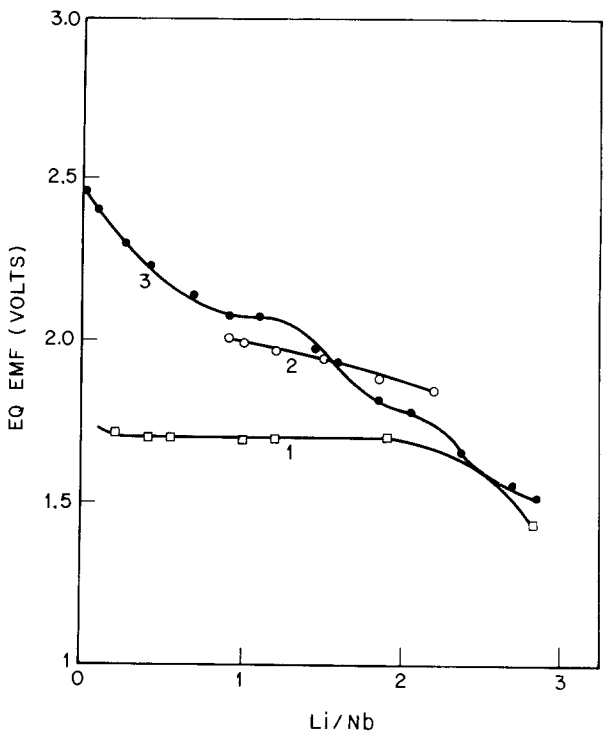

Fig. 2. Equilibrium voltage curves for $NbSe_3$ as a function of Li content. Curve 1 is first discharge curve for one type of behavior; curve 2 is the equilibrium curve for the same type on second discharge. Some $NbSe_3$ cells yielded a "stepped" voltage on first discharge, as shown by curve 3.

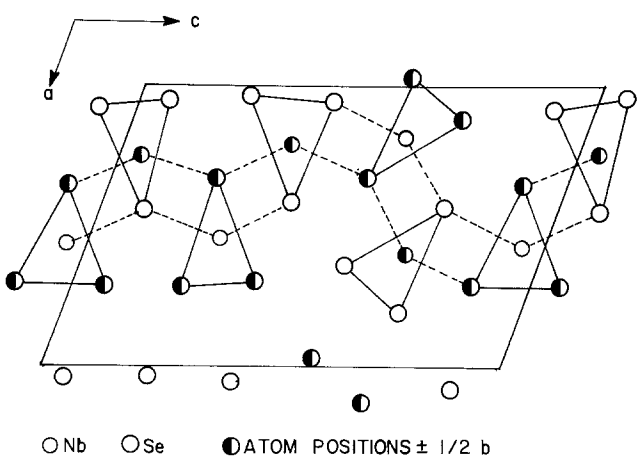

Fig. 3. Structure of $NbSe_3$ (10)

these changes by x-ray powder patterns, the patterns being quite complex, weak, and diffuse.

$NbSe_4$.—Cells were cycled to 2Li/Nb, 4Li/Nb, and 5Li/Nb. The equilibrium emf's are shown in Fig. 4. The curve is almost flat (slightly negative slope) from 1-3Li at about 1.83 ± 0.02V. This curve differs from that reported (2) under dynamic conditions in that a break appears beginning at about 3.5Li, with the voltage remaining above 1.5V at 5Li, as opposed to a sharp drop in voltage at 4Li in the dynamic study. This particular cell was recharged to ~ 84% of amount discharged.

Cells limited to 2 or 4Li showed better rechargeability, ~93% of amount discharged. In the initial part of the first recharge, the 0-4Li emf levels off at ~ 2.07V, and the 0-2Li emf merges with the 0-4Li emf near 1.5Li; therefore, these charge curves tracked each other. When both these types of cells were subsequently discharged (second discharge), they continued tracking each other closely, although at a higher but still flat emf (1.92 ± 0.02V) over the range 1.5-3.8Li. The second discharge curve for the 0-5Li cell started at higher voltages than the first discharge, but ultimately converged with the others in the range ~ 2.8-4Li. This phenomenon of different discharge curves converging to the same emf, and the relative flatness of the composite second discharge curve was true of the $NbSe_{4.5}$ series as well.

Another $NbSe_4$ cell using 0.1*M* $LiPF_6$ in TTG yielded a curve similar to that using $LiClO_4$/PC, but approximately 3% lower in emf, indicating any role played by the electrolyte is minimal.

$NbSe_{4.5}$.—Cells were cycled from 0 to 2Li, and 0 to 4Li. Recoverability was about 90% for all these cells. One cell was discharged to 4.3Li/Nb, but further discharge was not possible without a precipitous drop in the cell voltage below ~ 1.2V (recoverability for the cell was about 87%). The emf remained at 1.83 ± 0.01V to 4.3Li, thus there was no gradual decrease in emf as with $NbSe_4$. The initial equilibrium curve was nearly flat (1.83 ± 0.01V) over most of the range as shown in Fig. 4.

Except for the cell that was discharged beyond 4Li, the various initial charge and second discharge curves

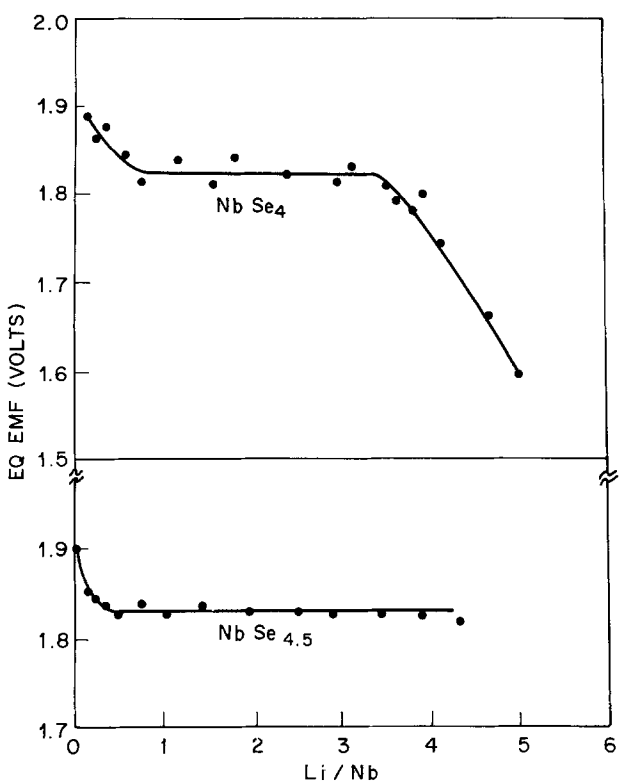

Fig. 4. Composite results for equilibrium voltages of $NbSe_4$ and $NbSe_{4.5}$, as a function of Li content; first discharge.

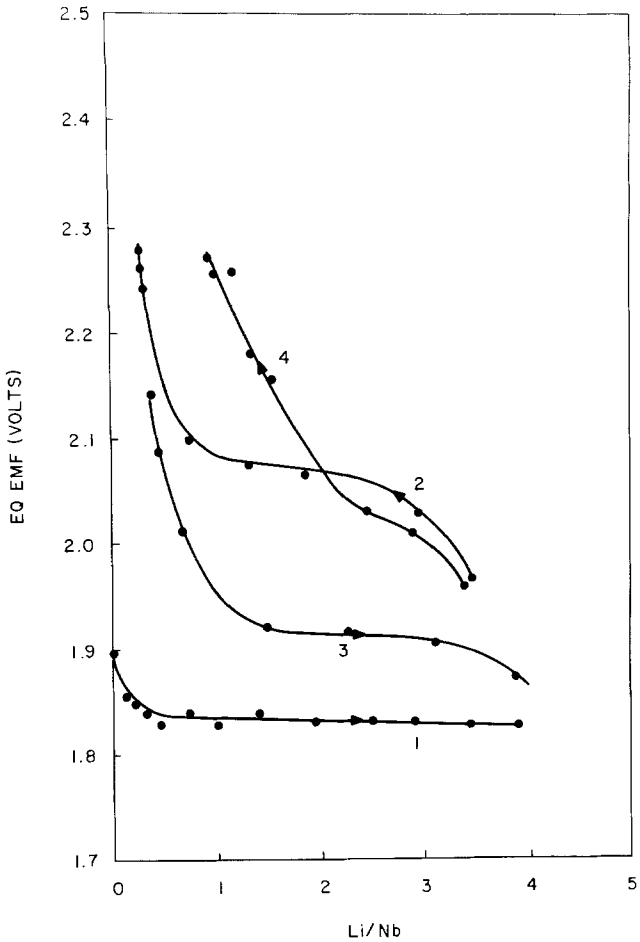

Fig. 5. Equilibrium voltages for two complete cycles of an $NbSe_{4.5}$ cell, as a function of lithium content.

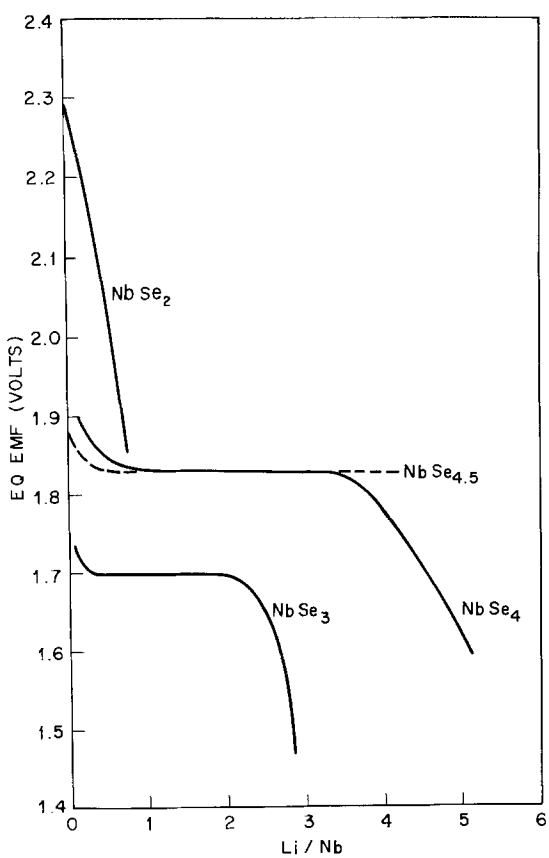

Fig. 6. Composite showing equilibrium voltages for cell $NbSe_x$ compounds studied in this series.

converged in a manner similar to that described for $NbSe_4$. The second discharge curve is flat at about 1.93 ± 0.02V over the range 1-3Li. Typical emf curves for 2 full cycles are shown in Fig. 5.

Discussion

All the initial discharge data are compared and summarized in Fig. 6. For $NbSe_3$ we observed varying initial discharge curves on samples giving identical x-ray patterns. We have included in Fig. 6 the curve resembling that previously published (9).

$NbSe_2$ is essentially fully reversible by the mechanism of lithium intercalation involving virtually no irreversible chemical changes, similar to TiS_2 (3). The shape of the equilibrium emf *vs.* composition curves confirm that a single phase is involved during cycling. The higher selenides of niobium were reversible in varying degrees, but the charge curves were significantly different than the discharge curves. Indeed, the equilibrium charge voltage exceeded the initial discharge voltages by at least 15%. In these cases, the chemistry is obviously more complex and significant changes take place within the first cycle. The very low current densities and long equilibration times minimized effects due to solvent incorporation. The test with 0.1*M* $LiPF_6$ in TTG supports this conclusion.

For $NbSe_3$ (curve 1, Fig. 2) the flat portion of the discharge curve is lost after the first cycle, while in $NbSe_4$ and $NbSe_{4.5}$ level, although higher than original, emf's persist and data points from cells having different cycle history tend to converge during some overlapping parts of the cycle span. This behavior is best reproduced when a composition of Li_4NbSe_{4+x} ($x = 0, 0.5$) is not exceeded.

The changing OCV curves on cycling the higher selenides $NbSe_3$ and $NbSe_{4+x}$ ($x = 0, 0.5$) seems to indicate a multiphase system or a gradual structure change in these cases. Further studies are needed to confirm and elucidate such changes.

The Allotropes of Dibasic Lead Oxide: A Quantitative X-Ray Diffraction Analysis

J. R. Dafler*,[1]

ESB Incorporated, Technology Center, Yardley, Pennsylvania 19067

ABSTRACT

The allotropes of PbO are important in the formulation of positive and negative elements for lead-acid, SLI-battery systems. Recently, there has been renewed interest in making plates rich in tetrabasic lead sulfate [$(PbO)_4PbSO_4$] or tribasic lead sulfate [$(PbO)_3PbSO_4(H_2O)$], with special attention to which species predominates in the fully conditioned plate. The form is, characteristically, related to whether the starting oxide for paste formulation is rich in orthorhombic or tetragonal PbO. A quantitative technique, using x-ray diffractometry, to determine the amount of one allotrope in mixtures of both is given here, with a discussion of sources of probable error and the character of analyses based on linear calibration curves.

Dibasic lead oxide (PbO) occurs in two polymorphic forms: the tetragonal, t-PbO; and the orthorhombic, o-PbO; oxides. Both oxides are important in the lead-acid battery industry, and t-PbO is a major component of most commercial oxides used to make porous, pasted electrodes for storage batteries. The two oxides have slightly different densities and, according to Clark and Kern (1) and others (2-4), differing reactivities. Some battery manufacturers prefer to formulate pastes for electrode manufacture with oxide mixtures that contain no o-PbO. These oxides, the very low yellow (VLY) oxides, are considered by some to be superior for paste production and battery element fabrication. The presence of o-PbO is now considered desirable or undesirable only according to the crystal form sought in cured, pasted, unformed plates. If $(PbO)_4PbSO_4$ [tetrabase] is desired (5, 6), o-PbO rich oxides are selected, while the formation of $(PbO)_3PbSO_4(H_2O)$ [tribase] appears favored by the presence of t-PbO. Pavlov and Papazov (7) have recently summarized the results of a large amount of careful experimental work concerning the interplay of the divalent oxides in yielding the final form of battery plates. Their conclusions with respect to the morphologies of cured plate species disagree with ours, but their summaries of pasting and paste manufacturing do not.

Key words: basic lead sulfates; lead oxides, dibasic; x-ray diffractometry.

Considerable battery practice has been devoted to developing cured plates rich in $(PbO)_3PbSO_4(H_2O)$, and Mrgudich (8), using VLY oxides found a modified or activated PbO that apparently was a distorted t-PbO. Moreover, in his work, mixing and pasting techniques that produced $(PbO)_4PbSO_4$ yielded little of the distorted species, suggesting a special propensity to incorporate into the tetrabase lattice. Clark and Tyler (3) had systematically studied the Pb(II) oxides and found an "active" PbO that had unusual properties which could be indexed by catalytically decomposing hydrogen peroxide, though some of their o-PbO:t-PbO mixtures also had unusual activity for H_2O_2 decomposition. Later Clark and Rowan (9) found that o-PbO could be converted to a distorted t-PbO by grinding. They attributed this to transformations taking place in imperfectly crystallized regions that were undergoing natural o-PbO → t-PbO transitions. Petersen (10) summarized much of the early effort devoted to preparation and identification of the allotropes of PbO.

In agreement with long standing experience, Pavlov and Iliev (11) established that $(PbO)_3PbSO_4(H_2O)$ is the preponderant phase in pastes made at temperatures below 80°C. They suggested that $(PbO)_4PbSO_4$ was formed at higher temperatures by reacting $(PbO)_3PbSO_4(H_2O)$ with t-PbO, but only if o-PbO was present. Pavlov and Papazov contend the necessary o-PbO will be generated by processes in paste mixing, and by oxidizing the metallic lead in commercial oxides when H_2SO_4 is present.

For reasons of older battery practice and craft, and evaluation of treated ores and commercial oxides for purchase, it was necessary to have a fast and reasonably simple technique to quantitatively determine o-PbO in a given oxide sample.

X-ray diffraction of Pb(II) oxides.—Orthorhombic and tetragonal PbO possess distinct, sharply defined x-ray diffraction spectra (12) and, moreover, their most intense diffraction maxima (I_{100}) occur quite close to one another in a spectrum of mixtures, making quantitative diffractometry appear a very promising method of analysis (13, 14). Mixtures of t-PbO and o-PbO, and commercial oxides for lead-acid battery manufacture represent quasi two-component systems in which the mass absorption coefficients, μ_{xi}, are the same, obviating the need to make absorption corrections to the measured intensities (15). Alexander and Klug have shown that the measured intensity, I_i, of a line in a mixture where $\mu_{xi} = \mu_{xj}$, is a linear function of the fraction of the ith component in an i-j mixture (14). Ores and commercial oxides sometimes contain metallic lead in quantities up to 30%, however, this component represents no difficulty, except as a relatively constant matrix diluent.

The method of standard additions is frequently used in atomic absorption spectrophotometry (16) and stripping voltammetry (17), and can be applied to any analytical problem in which matrix interference effects need to be minimized (18, 19). Klug and Alexander adumbrated the use of this method for quantitative diffraction analysis of very small samples (20).

Quantitative diffractometry by the method of standard additions is one depending on linear calibration curves, and the difficulties inherent in such analyses is discussed by Mandel and Linnig (21). The method and treatment of data derived using linear calibrations is treated in detail by Larsen, Hartmann, and Wagner (22). Basically what is done is the unknown matrix is scanned carefully and the ratio of the analyzed, I_{100}-line intensities is determined, preferably in a statistical fashion from several separate, discrete scans. The sample is then "spiked" or diluted with carefully measured amounts of the subject polymorph (in this case o-PbO) to produce two or three calibrating samples. These are mixed with extreme care and the x-ray intensity ratios, R_i, measured.

The standard addition samples are used to generate an analysis, or calibration curve, produced by plotting the appropriate R-values as a function of percent added o-PbO. Since linear regression analysis is available so casually through the use of hand-held calculators, a least squares line can usually be determined within minutes. The line will have a positive slope and a negative intercept on the abscissa. The absolute value of the x-intercept (percent added o-PbO concentration) will be the determined value of the unknown quantity. If the line is translated so that it includes the origin, a recalculation of all points must lie on a straight line parallel the original calibration curve.

The analytical possibilities inherent in the x-ray diffraction spectrum, apparently were first listed by Hull (23). The first practical analysis appears to be that of Clark and Reynolds (19), and since the work of Klug and Alexander and colleagues (14, 15, 20, 24) quantitative diffractometry has found widespread application.

Experimental Procedures

A commercial lead oxide was used for this study. It is a standard "leady" oxide used to prepare $(PbO)_3PbSO_4(H_2O)$-rich elements for positive plate manufacture. It contained 17.6% metallic lead, the rest being t-PbO. This was VLY oxide and contained no o-PbO. The o-PbO was a high purity litharge supplied by Johnson, Matthey and Company, Limited of London. An x-ray diffraction spectrum of a "nonleady" commercial oxide is shown in Fig. 1. The diffraction maxima useful in this analysis are noted.

Portions of the VLY oxide were carefully diluted with small amounts of o-PbO, the additions to represent, approximately 5, 10, 15, and 20%. The carefully measured chemicals were then mixed thoroughly in a SPEX shaker mill with a single alumina ball.

A Philips Electronics, Incorporated x-ray diffractometer, using Cu radiation was used for all intensity measurements. This unit has a curved crystal monochromator (LiF). For analytical measurements the scanning rate was 0.25°/min, with a 0.2° receiving slit, and beam settings of 42 kV:22 mA. These instrument settings yield a natural linewidth of ~0.2°.

Four spectra of the interesting regions were made for each sample. After each scan, the sample was discarded and the storage bottle once more shaken in the SPEX mill. Samples were back-filled into the holders to minimize possible orientation effects.

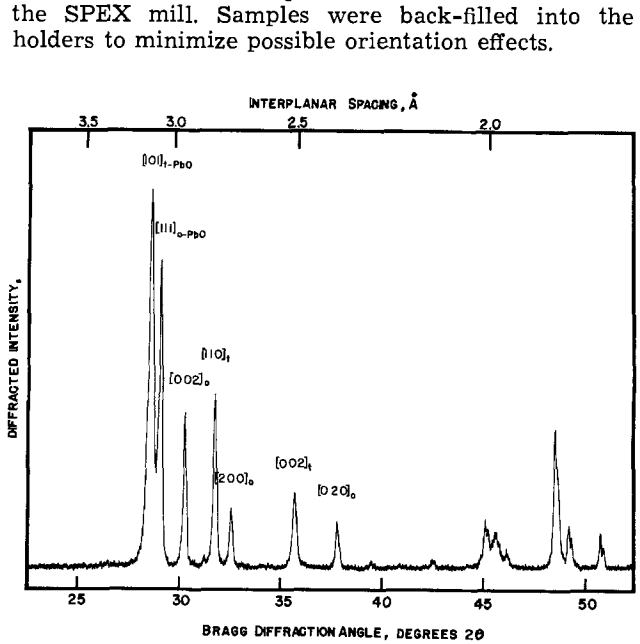

Fig. 1. X-ray diffraction spectrum of a "nonleady" commercial oxide. The principal x-ray diffraction maxima of t-PbO and o-PbO are indicated.

Commercial oxides for lead-acid battery plate manufacturing are generally very fine, and all but a very small fraction of the material used did not pass a 325 mesh ASTM sieve. Crystallite size and particle size in these oxides are so small, generally, that some line broadening is seen. This enhances the practicability of the analysis: Alexander, Klug, and Kummer (24) have shown that reproducibility of intensity measurements is highest if the average particle size is less than $\sim 5\mu$. Wilchinsky has correlated the effects due to crystal, grain, and particle size on diffracted beam power (25).

To simulate unknown analysis and visually establish the linearity of the intensity ratio: percent added o-PbO calibration, all samples were scanned in serial order, After the initial remixing of the samples, each was scanned three more times in random order. The pooled data were then subjected to multiple linear regression analysis using a digital computer to establish the over-all "goodness" of the calibration line, and to obtain a statistically derived standard error of estimate, *Sr*. The data were also processed with a hand calculator that featured linear regression analysis (Texas Instruments SR-51A). The simulated analyses that follow were processed using the hand calculator.

Results and Discussion

The two x-ray diffraction maxima used in this determination are: o-PbO, the [111] line; 3.07Å at a Bragg angle of 29.06°; and t-PbO, the [101] line; 3.12Å at a Bragg angle of 28.58°. The base line for the intensity measurements was established between the steady background at 26.5° and the diffraction minimum at 29.8°. The relative intensity ratio, $R = I(\text{o-PbO[111]})/I(\text{t-PbO[101]})$, is obtained from the uncorrected peak height measurements. The method is illustrated in Fig. 2, which shows two typical scans for samples containing differing amounts of o-PbO.

The values of R calculated from four different "spiked" samples of the commercial oxide are summarized in Table I. The initial, serially obtained values are denoted with asterisks. They are discussed in another section as a simulated unknown analysis. The data in the table are listed in order of increase in R-value to facilitate initial statistical treatment. The line "added o-PbO" is used in a later section to discuss regular analysis of an unknown (in this case the first sample, 6.875% o-PbO, is the simulated unknown).

The sixteen data were subjected to linear regression analysis after examination for gross error. Of the two data that are questionable and do not fit their populations well (underlined in Table I) only the second, the 0.2595, point can be rejected by the ratio test of Crow *et al.* (26).

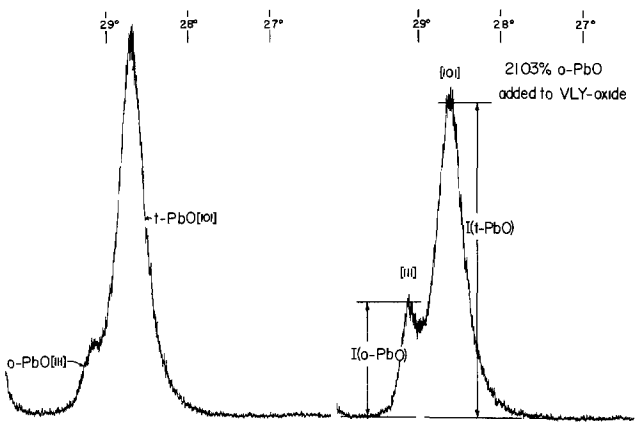

Fig. 2. Two analytical scans of the t-PbO/o-PbO region. The method of measuring line intensities is indicated on the right. The left-hand spectrum represents the simulated unknown.

Table I. Summary of intensity data for "spiked" oxides

Percent o-PbO (%)	6.876	9.128	14.58	21.03
Added o-PbO (%)	0.00	2.253	7.705	14.16
R-values	0.1341	0.1656	0.2595*	0.4003
	0.1365*	0.1729	0.2805	0.4012*
	0.1405	0.1764*	0.2812	0.4072
	0.1410	0.1794	0.2820	0.4097
Average *R*-values	0.1380	0.1736	0.2812	0.4046
Standard deviation	0.00330	0.00594	0.00075	0.00458
Range of *R*	0.0064	0.0138	0.0015	0.0094
Relative error	0.0239	0.0342	0.00267	0.0113

* Initial datum for each mixture.

Linearization: digital computer.—The program used yields a multiple linear regression analysis line that is weighed according to the density and distribution of observations about their mean value. The line obtained gave the percent o-PbO, *Y*, as a function of the intensity ratio, *X*. The *F*-value for the line was ~7000 with a sum of squares, attributable to the regression, of ~480. Statistically, this is a very good calibration curve, and indicates data linearization to be appropriate. The correlation coefficient was 0.9991. The equation is

$$Y = -0.10902 + 52.56X \qquad [1]$$

and the standard error of estimate, *Sr*, is 0.259, which indicates, or suggests that using this calibration will produce determinations, o-PbO = (Y ± 0.259)%, 64% of the time, and o-PbO = (Y ± 0.518)%, 90% of the time, etc.

Linearization: hand calculator.—To analyze the pooled data using the hand calculator, the averaged *R*-values were used, because multiple linear regression is not available on the instrument. The expression for percent o-PbO was

$$Y = -0.19620 + 52.53X \qquad [2]$$

The standard error of estimate calculated for this regression line for the four averaged values was 0.192. When calculated for all fifteen data, the value for *Sr* was 0.257. As expected, the linearization was very good, the correlation coefficient being 0.9997.

The error of estimate for both treatments is quite low but, of course, for low o-PbO contents (1-10%) would represent a fairly large relative error in the determination. For commercial ores and oxides that contain o-PbO this is a sufficiently precise and sensitive analysis.

As Klug (27) and others (28) have pointed out the sufficiency conditions for quantitative diffractometry (linearity in the analytical relationship) is met very well. The necessary conditions that the analytically interesting diffraction maxima intercept the same region of analyzing radiation (29) is, clearly, well met (cf. Fig. 2).

The analysis of an unknown.—To analyze an unknown, the *R*-values for the unknown and the "spiked" samples are plotted on any convenient axis; such as intensity ratio, *R*, *vs.* concentration added o-PbO. The unknown's *R*-value is plotted as 0.0% added o-PbO. To simulate analysis we plotted the values from Table I under the "added o-PbO" heading, on just such an axis. Since we know the correct, measured value of percent o-PbO in the simulated unknown we can discuss the precision and accuracy of this analytical method for the PbO allotropes.

To further simulate laboratory practice we will use the four initial readings only, then analyze the one-time analysis situation compared to the replicated analysis, using the pooled data. In the unknown determination, the *R*-values are treated as the dependent variables, functions of the percent of added o-PbO, *P*.

The data from Table I marked with asterisks were plotted on analysis axes, as shown in Fig. 3. One of the lines is a casual fit made by visually averaging the point splits, and may closely approximate real practice in the laboratory. The other line is the result of linear regression analysis by the hand calculator. The equation of the line is

$$R_{initial} = 0.1320 + 0.01847P \quad [3]$$

with a P-intercept of -7.146 added o-PbO. We can generate a table of residuals and calculate Sr for this line. The standard error of estimate for this determination is 0.671, worse than for the replicated data (0.259 and 0.257). The analysis for o-PbO is in error by 3.94%, nearly twice the error of the answers derived using pooled data (2.20% for the computer linearization and 2.97% for the SR-51A linearization). It is interesting to note the casual, visual linearization led to a determination of 6.55% o-PbO, an error of 4.73%, not much worse than the answer calculated from Eq. [3].

The ordinary expectation is that precision and, presumably, the accuracy will be no worse than the error reflected in the distribution of the replicated data (Table I). The answer obtained in simulated analysis has a larger error than the replicated data, and the answers from pooled data indicate the relative error in the determination is larger than the error in the pooled data. The fact the computer linearization was outstanding (correlation coefficient = 0.9991) appears to offer us a paradox. The data are far better than the answer. This appears to be a property of the calibration line and its relationship to the data (21).

The solution lies in the fact that linear calibration lines are "best fits" of data that randomly fluctuate in the neighborhood of the line. It is, in fact, data scatter about the calibration curve that determines and defines the measure of precision and therefore the accuracy of this analysis (30) and it is always larger than the error in the replicated data. That is so, because, superimposed onto the replication error, as a source of scatter, are the ordinary experimental errors: in this case powder sample packing and mixing, peak height measurement, etc.

The reliability of the calibration line is a two-dimensional problem, and as Mandel and Linnig (21) and Lark (31) have shown, a complex one. The uncertainty in the slope and intercept of the least squares calibration line defines a two-dimensional confidence region, centered on the fitted (slope, intercept)-data pair (21, 26, 32). The area of the confidence region depends on the magnitude of the experimental errors that yielded the raw data, and the width of the confidence band, superimposed onto the linear calibration curve, defines the limits of precision and accuracy of such a method.

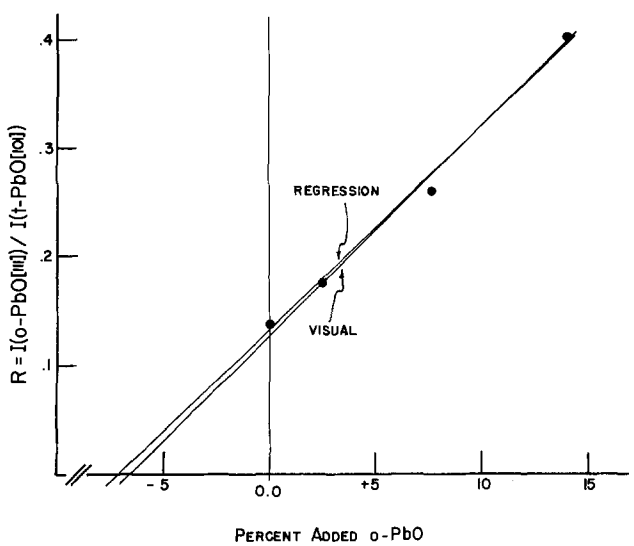

Fig. 3. Analysis plot for o-PbO determination. A casual, visual averaging of the initial points is shown compared to the least squares line.

A deeper analysis would yield the confidence band for any given selected confidence interval (σ, 2σ, 3σ . . .). That is unnecessary at this point, but it has been necessary to indicate how normal distribution of data can lead to unexpectedly large errors in analyses dependent on linear calibrations. This technique for the allotropes of PbO is a sound and useful method, providing normal care in preparation and experimental procedure is taken. The simulated analysis has shown that determinations without replication of observations leads to a less precise answer, with the decision whether or not to do data replication most likely to depend on the need to adjust formulated oxide mixtures for the presence or absence of one of the allotropes. The required degree of preciseness will depend on the required preciseness in the o-PbO analysis.

APPENDIX

To investigate the expectation for accurate analyses from any set of four data we randomized the data pool with the 0.2595 point omitted, then wrote fifteen regressions using data sets made up by randomly selecting four R-values from the data pool. In each case we calculated the percent o-PbO of the "unknown," generated tables of residuals, and calculated the Sr-value for each of the fifteen lines (there are 192 possible combinations of data). These data are shown in Table II. The range in percent error in o-PbO and Sr are 11.44% and 0.435, respectively.

It is instructive to plot the signed percent error in o-PbO analysis as a function of the standard error of estimate of the fifteen lines. This can be seen as Fig. 4. The points from the computer and hand calculator analyses of the pooled data are also plotted. The distribution of the points in Fig. 4 appears strongly to indicate the presence of a systematic error that yields high values for o-PbO, giving regression lines that more frequently yield answers with a positive error. The source is probably a tendency to overestimate the intensity of the o-PbO[101] line, leading to high R-values.

Table II. Analysis of random data set linearization

Index	Intercept	Slope	o-PbO (%)	Sr	Error (%)	C_t

2	0.1380	0.01852	7.452	0.160	8.39	0.9998
3	0.1371	0.01870	7.333	0.123	6.65	0.9999
4	0.1349	0.01927	7.004	0.331	1.88	0.9992
5	0.1319	0.01943	6.789	0.130	−1.25	0.9998
6	0.1315	0.01960	6.710	0.141	−2.41	0.9998
7	0.1372	0.01863	7.346	0.059	7.05	0.9999
8	0.1381	0.01848	7.475	0.171	8.73	0.9997
9	0.1369	0.01914	7.151	0.231	4.01	0.9995
10	0.1368	0.01898	7.207	0.214	4.83	0.9995
11	0.1380	0.01859	7.422	0.166	7.96	0.9958
12	0.1335	0.01890	7.061	0.494	2.70	0.9979
13	0.1367	0.01867	7.320	0.281	6.47	0.9993
14	0.1295	0.01917	6.758	0.335	−1.70	0.9990
15	0.1364	0.01863	7.325	0.264	6.54	0.9994

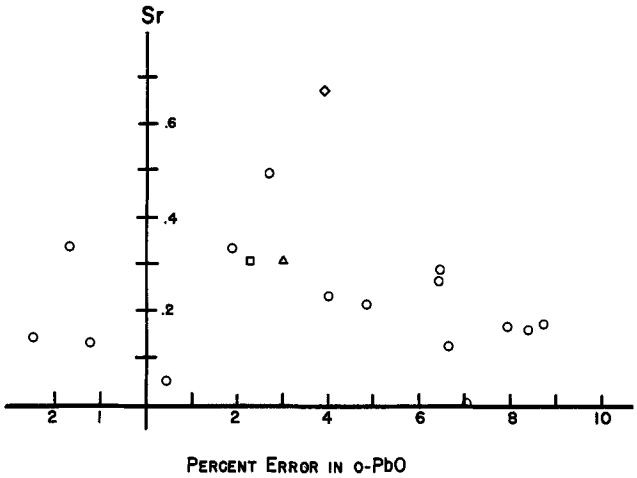

Fig. 4. Scatter diagram for standard error of estimate and signed error in o-PbO determination. The fifteen randomly generated regressions are shown as open circles: ◇ represents the visual averaging, while □ and △ are the computer and hand calculator values for the pooled data.

Figure 4 indicates the occurrence of very large error is coupled to small *Sr*-values, so that empirically the expectation of very large error is small. If we assume $Sr > 0.257$, the smallest value found for the treated, replicated data, then large errors correspond to *Sr*-values that are unrealistically small (outside the confidence band). The largest error in o-PbO analysis seen in this sampling, for $Sr > 0.26$ is ~6.65%.

Study by Auger Spectrometry and Cathodic Reduction of Passive Films Formed on Ferritic Stainless Steels

National Center of Scientific Research, 94400 Vitry sur Seine, France

ABSTRACT

This paper deals with the passivation of ferritic stainless steels (26% Cr) in a 3.5% NaCl solution. The passive state was examined by Auger electron spectrometry and electrochemical reduction techniques. From the chemical composition profiles it appears that the passivation of these alloys is characterized by the formation of a thin oxide film and the development of a chromium-depleted zone in the metallic substrate near the metal-oxide interface. The composition of the passive film changes continuously with the depth. The number of atoms within a given layer of the film is lower than in the layers of the metallic matrix. The thickness and chemical composition of passive films change with the temperature of the corrosive medium. The study by cathodic reduction shows that molybdenum additions especially affect the properties of the inner layers of the passive film.

The great interest in the development of the passive state on iron-chromium steels is due both to the complexity of this phenomenon and to its practical importance. Despite numerous studies on this subject, there are still no definite conclusions relative to the nature and structure of the passive film formed on the surface of the alloys. There is some experimental evidence that the thickness of the oxide film varies from monolayer dimensions near the active-passive transition, up to dimensions of 10-50Å in the passive potential region. However, at present, it is not possible to identify the oxide phase as a single oxide, a duplex oxide, or an oxide not related to any known oxide.

It is obvious that an accurate and extended knowledge of the passivity phenomenon requires further experimentation, especially in connection with the factors affecting the ionic and electronic processes, the local electric potential, and the spatial variation of these through the film. In addition, more quantitative data must be obtained concerning chemical composition and structure.

Further investigation should take advantage of promising new techniques of surface analysis such as electron spectroscopy for chemical analysis (ESCA), low energy ion-scattering spectrometry (ISS), secondary ion mass spectroscopy (SIMS), Mössbauer spectroscopy, nuclear microanalysis, and activation analysis.

This work consists of a study by Auger electron spectrometry and coulometric techniques of passive films formed on very pure ferritic stainless steels exposed to a 3.5% NaCl (*p*H 2.5) solution. The influence of the passivation potential, alloy composition, and temperature of the corrosive medium were examined.

We have developed in a previous paper (1) some quantitative aspects of Auger electron spectrometry, and a general formalism has been given elsewhere (2). Up to now, determinations of surface concentrations have been carried out by resorting to standards. However, studies that have been published in the last 5 years (3-6) indicate the possibility of doing absolute measurements by taking an element of the matrix as a reference element. It is the purpose of this article to demonstrate the use of quantitative Auger analysis in the study of passivating films.

Experimental

Materials.—The alloys investigated were very high purity ferritic stainless steels prepared by plasma furnace melting (7). In these alloys the total content of metallic impurities is less than or equal to about 10 ppm by weight, and that of the nonmetallic impurities is also very low (typically: 10 ppm C, 7 ppm N, 10 ppm O).

The specimens were polished through 600 grade carborundum paper and then vacuum annealed for 1 hr at 900°C. Before introduction into the electrolytic cell the specimens were electropolished in a glacial acetic acid/perchloric acid mixture (3.2:1, by volume).

Electrochemical procedure.—Passivation experiments were carried out in 3.5% NaCl (*p*H 2.5) solution completely deaerated with pure nitrogen. Potentials are reported *vs.* the saturated calomel electrode (SCE). The specimen was polarized in the cathodic region at −700 mV/SCE for 2 min, and then submitted to a slight anodic dissolution: The specimen was put on open circuit for several seconds and then brought to the desired potential in the passive region. According to Frankenthal, this procedure gives the most reliable results (8). After passivation treatment, each specimen was rinsed in distilled water and dried in a stream of dry air.

The passivating films are formed at constant potential in the passive potential range. Passivation treatments correspond to a film growth stage where the log/log plots of the current *vs.* time give a straight line for periods of several hours. This stage occurs after about 30 sec of film growth. The study of the earlier stage of film formation during which the anodic current density decreases abruptly has not been considered here. Furthermore, it must be pointed out that the analytical and cathodic reduction study deals with films formed electrochemically with intermediate exposure to the atmosphere.

Passivation experiments were followed by analytical or coulometric measurements. The study of the cathodic reduction curve was conducted in 18*N* H_2SO_4 solutions deaerated with pure nitrogen (9). The passive film was cathodically reduced at a constant current of 5 $\mu A/cm^2$.

Analytical procedure.—The samples are introduced into the chamber of the Auger spectrometer a few minutes after formation of the passive film. The surface is bombarded under a vacuum of a few times 10^{-9} Torr with a beam of primary electrons having a kinetic energy of 2500 eV. The target current is 200 μA.

The Auger spectrometer operates with a conventional cylindrical mirror analyzer (CMA), *i.e.*, with a coaxial

Key words: passive films, Auger spectrometry, coulometry.

electron gun which bombards the surface of the sample at normal incidence. The emitted secondary electrons enter the CMA with an emission angle θ of 42°18′ with respect to the normal, and an angular aperture of the beam limited to ± 3°. Our spectrometer yields the differential energy distribution curve $dN(E)/dE$ of the secondary electrons emitted from the surface. We assume that the peak-to-peak amplitude of the Auger transition is due to the contribution of the atomic layers in the vicinity of the surface and proportional to the corresponding Auger current. From this hypothesis the peak-to-peak amplitude of the Auger signal due to an element I given by all the i layers, is

$$H_I = \sum_{i=0}^{\infty} h_I^{(i)} = \sum_{i=0}^{\infty} \alpha_I K_I^{(i)} N_I^{(i)}$$

where $N_I^{(i)}$ is the number of atoms I in the layer i, α_I is a sensitivity coefficient (characteristic of the element I), and $K_I^{(i)}$ is the contribution coefficient of the layer i to the total signal given by the whole specimen. (See the Appendix for the formalism leading to a quantization of Auger spectrometry and for more complete information relative to the physical meaning of the various factors.)

In the choice of the appropriate Auger peak for the assessment of the concentration of the various elements, the following conditions have been taken into account: The Auger peak should not involve valence electrons and should not be superimposed on another peak. In the case of iron, we chose the peak at 598 eV, and we converted it to an apparent peak at 703 eV by multiplying the measured height by a coefficient equal to the ratio of the peak heights at 598 and 703 eV, respectively, as determined on a pure iron matrix.

An approximate value of the sensitivity coefficients of iron, chromium, and molybdenum can be obtained from the study of the metallic matrix when the passive film has been completely removed by ion etching. This way the Auger signals are only related to the base elements of the alloy, the concentrations of which are well known. This assumes that sputtering is not selective, which seems to be verified by the constancy of the total number of atoms in every layer. By taking iron as a reference material, we obtain the sensitivity coefficients of the other elements I (I = A, B, C . . .), by satisfying the following relationship

$$\sum_{I=A}^{c} H^* = \sum_{I=A}^{c} \frac{H_I}{\alpha_I} = \text{constant}$$

where H^* is the corrected peak height.

The contribution coefficient K of iron has been calculated from Eq. [2] in the Appendix for different kinds of matrixes (metal or oxides). For the other elements the values of K are obtained by the same procedure (Table I).

Though a statistical approach enables one to show theoretically that the sputtering of atoms does not leave an atomically planar surface, we have nevertheless supposed for the sake of convenience that etching strips a complete layer before attack on the subsequent one. This approximation is more accurate when the number of layers removed is low. The focus of the ion beam is such that the irradiated area is much larger than the one sampled by the primary electrons.

To obtain the depth profile for the various elements, argon ions accelerated by a potential of 600V were used with the ionic current between the limits of 0.3×10^{12}-3×10^{12} ions cm^{-2} sec^{-1}. It has been derived (10) that the number n of argon ions impinging on a 1 cm^2 area of surface is proportional to the sputtering rate, *i.e.*, $n = \gamma(p \cdot t)$, in which p is the argon pressure in Torr, t is the sputtering time t in minutes, and the constant γ is equal to 4.1×10^{18} cm^{-2} $Torr^{-1}$ min^{-1}. If the sputtering rate of one Torr · min is taken as unity, and supposing that the atom density of a surface layer is nearly 10^{15} cm^{-2}, we obtain a sputtering rate of one monolayer for $p \cdot t \sim 0.2 \times 10^{-3}$ Torr · min. This is approximately the case for iron and chromium in the present study, the sputtering yields of which are, respectively, 1.25 and 1.26. This value for $p \cdot t$ is also compatible with the sputtering of monolayers obtained by thermal segregation.

Table I

Elements	Fe	Cr	Mo	O	Cl
Energy, eV	598	529	186	510	181
α	1	0.9	3.1	2.1	1.9
K	0.73	0.70	0.57	0.70	0.57

Our method of quantifying the Auger spectra entails the measurement of the peak amplitude H_I of the characteristic Auger signals chosen for the various elements. The change of H_I as a function of the sputtering rate is plotted and this curve is cut by vertical and parallel lines corresponding to a separation equal to 0.2 $\times 10^{-3}$ Torr · min; this regular interval is consistent with the removal of a monolayer from the surface. The relevant abscissas of the points of intersection H_A^i and H_A^{i+1} permit the determination of the concentration of the element A in the layer i (*c.f.*, Eq. [4] in Appendix).

By applying Eq. [3] in the Appendix to each couple of successive vertical lines, we obtain, knowing the contribution coefficient k, the number of atoms of an element in the monolayer bounded by these lines.

From Table I it is seen that the carbon peak has not been taken into account. That element is only observed during the first sputtering period, and its concentration is considerably reduced in the second atomic layer. Nevertheless it represents the major constituent in the overlayer as the sample is taken from the electrolytic cell and is introduced into the spectrometer. Due to some difficulty in assigning an accurate sensitivity coefficient to carbon, it was decided to ignore that element, which has the drawback of leading to concentration values without physical meaning in the outermost layer of the sample, but does not significantly perturb the concentration profiles of the other elements in subsequent layers.

In addition to Auger electron technique, activation analysis was used to obtain in a quantitative manner the oxygen contained in the passive film; specimens are irradiated in a beam of tritons accelerated in a Van de Graaf generator. The following nuclear reaction has been used: $^{16}_{8}O(t,n)^{18}_{9}F^*$ (T = 110 min). A detection limit of 0.004 $\mu g \cdot cm^{-2}$ may be obtained for a 10 min irradiation with 0.2 μA of tritons at 2 MeV (11, 12).

Results

Passive film formed electrochemically.—Figure 1 shows the composition profiles of the passive film on a ferritic 26% Cr-1% Mo steel that was passivated for 6 hr at a potential of + 650 mV/SCE in a 3.5% NaCl (pH 2.5) solution. Passivation of the ferritic steels is characterized by the formation of an oxide film 8-9 atomic layers in thickness, and by the development of a chromium-depleted zone inside of the matrix at the oxide-metal interface.

The diagram shows that the overlayer of the passive film is principally carbon, the concentration of which decreases abruptly and completely disappears beyond the fourth layer. Chlorine is also found in the first layers of the oxide. The depth of penetration of carbon and chlorine are similar.

From the depth profiles it can be seen that each atomic layer of the passive film has a particular composition. The internal layers of the oxide are richer in chromium than the matrix, while the iron concentration in the same layers is lower. There exist steep gradients of concentration near the metal-oxide and oxide-solution interfaces.

For the 26% Cr-1% Mo steel, the molybdenum concentration in the passive film is very low (Fig. 1 and 2). Nevertheless, the presence of that element in the

steel slightly modifies the depth profiles. Particularly, it appears that the maximum chromium content in passive films on the alloys without molybdenum (Fig. 3) is higher than that in films on alloys containing molybdenum (Fig. 2).

The thicknesses of passive films vary very slightly with potential and with the length of passivation (at least for times greater than 30 min). However, the depth of the chromium-depleted zone increases linearly with passivation time at all passivation potentials (Fig. 4).

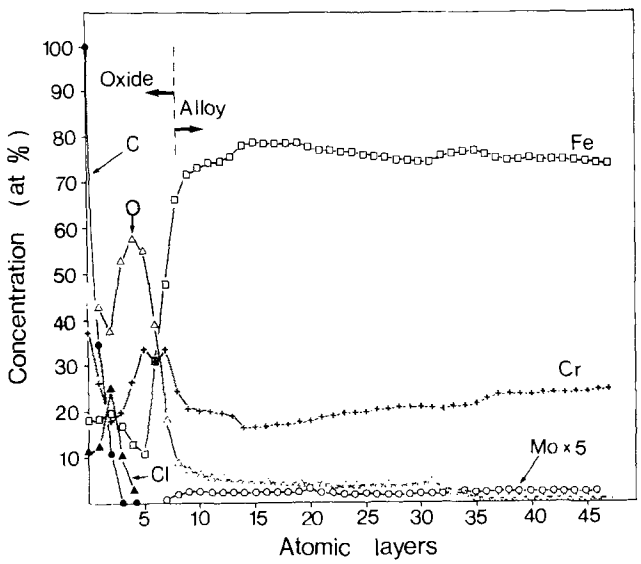

Fig. 1. Composition profiles of the principal elements in the passive film and in the alloy. (26% Cr-1% Mo steel) passivated for 6 hr at a potential of +650 mV/SCE in a 3.5% NaCl (pH 2.5) solution at 5°C.

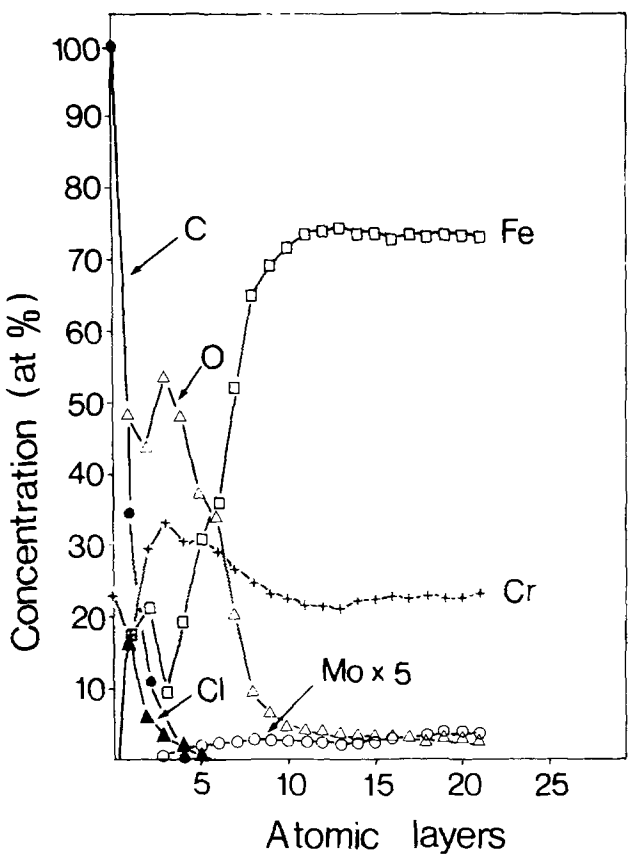

Fig. 2. Composition profiles of the principal elements in the passive film and in the alloy. (26% Cr-1% Mo steel) passivated for 6 hr at a potential of −250 mV/SCE in a 3.5% NaCl (pH 2.5) solution at 5°C.

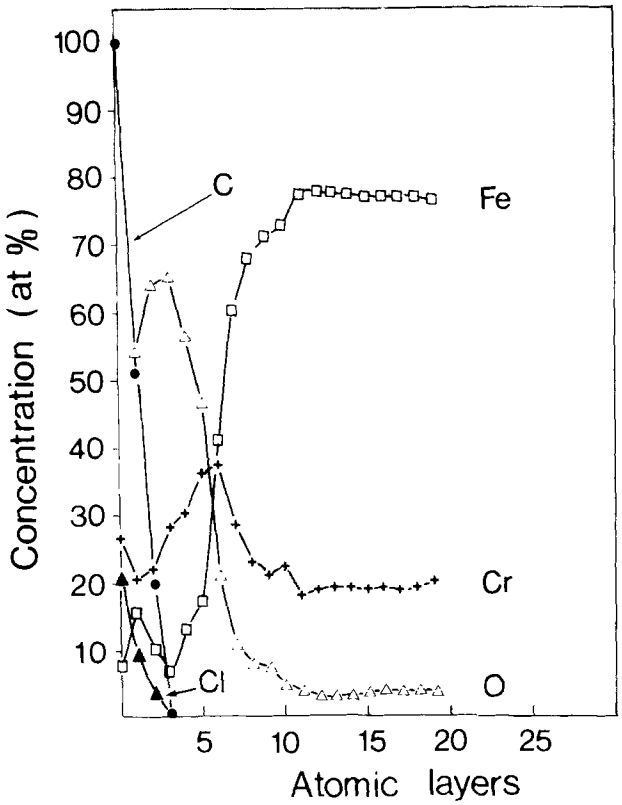

Fig. 3. Composition profiles of the main elements in the passive film and in the alloy. (26% Cr steel) passivated 6 hr at a potential of −250 mV/SCE in a 3.5% NaCl (pH 2.5) solution at 5°C.

The chromium concentration at the minimum of the composition profile is low for short passivation times (30 min), but rises progressively to a constant value as the time is increased. It appears that changes in alloy composition at the film-matrix interface can proceed long after the passive film has been formed.

Figures 5 and 6 show the influence of the temperature of the corrosive medium on the depth profiles of passive films. In the first example (Fig. 5), the potential of the sample was kept at −250 mV/SCE and the chloride solution was held at 98°C. In the second one (Fig. 6), the same alloy was passivated at a potential of +650 mV/SCE and removed from the solution when its temperature reached the critical pitting temperature, *i.e.*, the temperature beyond which localized attack is likely to occur. It can be seen that the films formed under these conditions are generally thicker. It also appears that the penetration of carbon and chlorine is more extensive. Both elements are detected in the film near the oxide-metal interface. In comparison with the experiments carried out at 5°C, the following differences are also noticed: the dip in the iron profile inside the passivating film is not as deep or broad and can hardly be seen for the experiment at 98°C; and the enrichment in chromium affects a much wider zone and is observed as a large hump in the concentration profile.

The curves giving the number of the atoms N_I^i of each element and those giving the total number of the atoms ΣN_I^i in each layer of the passive film are plotted in Fig. 7 as a percentage of the number of the atoms in a layer of the matrix. The number of atoms in each layer of the passive film is generally lower than in the layers of the matrix. This number is relatively low in the layers close to the oxide-solution interface, increases in the first layers, and then decreases at the oxide-metal interface. It also seems that the layers located in the chromium-depleted zone of the metallic matrix have a slightly smaller number of atoms than

in the deeper layers where the alloy reaches its true composition.

Hydrogen atoms are not detected by the Auger effect. This element could be present in the film in the form

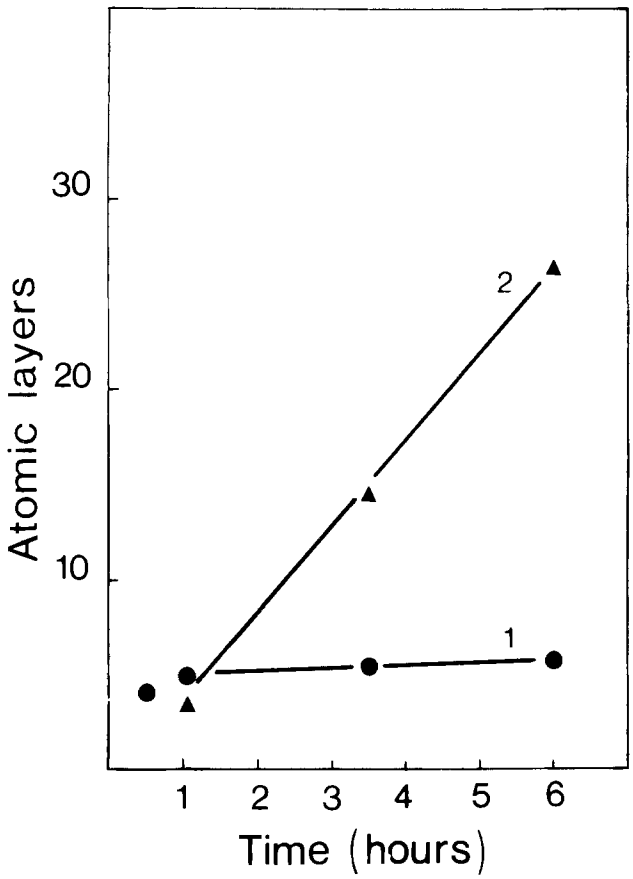

Fig. 4. Number of atomic layers in the passive film (curve 1) and in the chromium-depleted zone (curve 2) vs. the time of passivation. (26% Cr-1% Mo) steel passivated at a potential of +650 mV/SCE, in a 3.5% NaCl (pH 2.5) solution at 5°C.

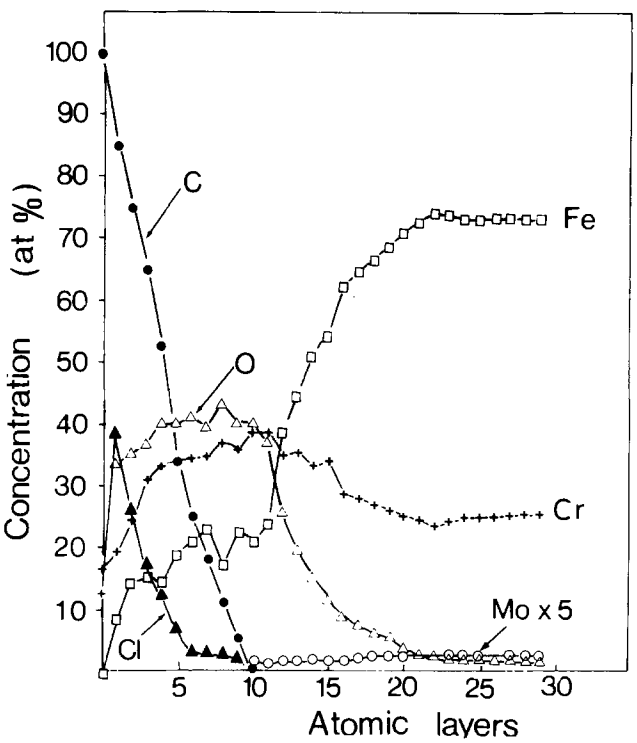

Fig. 5. Composition profiles of the principal elements in the passive film and in the alloy. (26% Cr-1% Mo) steel passivated for 1 hr at a potential of −250 mV/SCE in a 3.5% NaCl (pH 2.5) solution at 98°C.

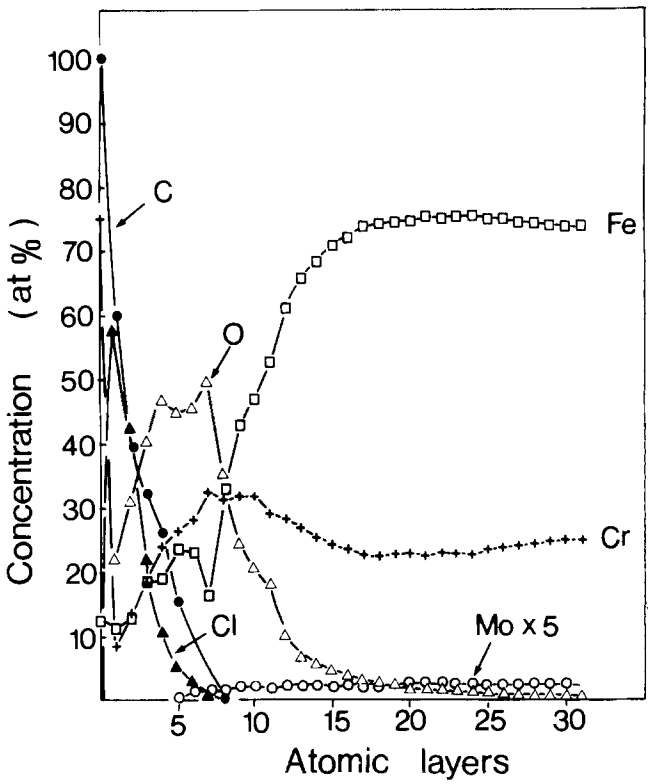

Fig. 6. Composition profiles of the principal elements in the passive film and in the alloy. (26% Cr-1% Mo) steel passivated for 1 hr at a potential of +650 mV/SCE, in a 3.5% NaCl (pH 2.5) solution at 34°C.

of water molecules, as has been suggested for the passive films formed on pure iron (13) and on stainless steels exposed to different solutions (14). Obviously, the presence of hydrogen can affect the total number of the atoms in each layer, and particularly near the oxide-solution interface.

The influence of the temperature of the corrosive environment upon the number of atoms of each element in an atomic layer appears very clearly: The films formed in a chloride solution heated at a temperature of 98°C (Fig. 7b) accommodate fewer atoms in a layer (lower ΣN_i^i) than those growing in the same medium at a temperature of 5°C (Fig. 7a).

Passive films formed in the air.—Passivation in air of a ferritic steel maintained for a fortnight in a desiccator at 25°C (Fig. 8) presents some analogies with that obtained in a chloride solution. The depth profiles show the presence of carbon and chlorine in the first layers of the film, chromium enrichment in the internal layers, and strong gradients of composition at the interfaces. In comparison with the passive films formed in an aqueous solution it appears that for the iron profile the minimum is much wider and its value is much higher. The external ridge of the well is also at a higher level. The concentration gradient for chromium is decreasing towards the surface. The molybdenum in the film is very low as in the films formed in aqueous solution. It is also observed that the number of atoms within a given layer of the film is lower than in the metallic matrix. Nevertheless, in the air-formed films the cations originating from the steel substrate tend to accumulate in the outer layers of the film, as a result of the absence of a dissolution process.

Activation analysis.—Activation analysis shows that oxygen content in the film varies only very slightly with the potential. For the 26% Cr-1% Mo steel passivated 1 hr in a 3.5% NaCl solution, the quantity of oxygen contained in the oxide varies from 0.40 to 0.45 $\mu g/cm^2$ when the potential is changed from −250 to +650 mV/SCE. However the oxygen content increases with the temperature of the solution (0.6 $\mu g/cm^2$ after

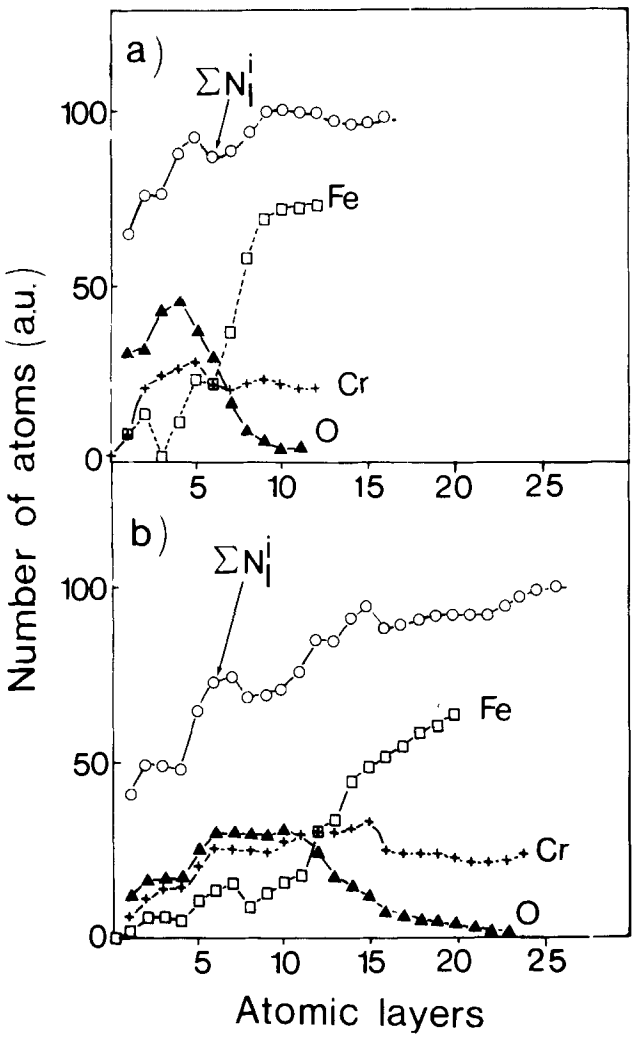

Fig. 7. Composition profiles giving the number of atoms of the principal elements within each layer of the passivated film and in the alloy. (26% Cr-1% Mo) steel passivated for 1 hr at a potential of +650 mV/SCE in a 3.5% NaCl (pH 2.5) solution. a. solution temperature 5°C; b. solution temperature 98°C.

passivation at −250 mV/SCE, when the solution is at 98°C).

Coulometric measurements.—The apparent coulombic thickness of the passivating films has been measured. Further, coulometric measurements have been made to learn more about the influence of molybdenum on the properties of the passive film.

Figure 9 shows the coulometric reduction results obtained with two different alloys (26% Cr and 26% Cr-1% Mo ferritic steels) for 1 hr polarization at a given potential. It appears that the quantity of charge used in the film reduction process increases with the passivation potential. Two different potential regions are indicated: the first is located at lower potentials and the second extends to the higher values. This behavior has been reported by many workers for the passivation of iron (15, 16) and stainless steel (14).

The efficiency of the cathodic process, measured as the quantity of charge required for reduction of the film decreases with molybdenum additions (Fig. 9 and 10). More precisely, the molybdenum content of the alloy has little influence on the reduction of the outer layer of the film (Fig. 9 and 10, curves a). However, the alloys with molybdenum require more charge for the reduction of the inner layers, particularly the layer next to the oxide-metal interface (Fig. 9 and 10, curves c). The quantity of charge for the reduction process increases with the temperature of the corrosive medium. It is also important to observe that the plateau in the potential-time curve disappears at the high temperature (Fig. 11).

Discussion

The analytical study by Auger electron spectrometry indicates that the composition of the passive film changes continuously with depth. This information supports recent ion-scattering spectrometry work for air-formed oxide film on a series of iron chromium alloys (17).

Previous ESCA studies (18) of films formed on chromium steels have shown that chromium is in a trivalent state in all zones of the passivating film, while iron is trivalent in the outer layers with a gradual transition to divalent state in the layers near the metal-oxide interface. These results can be correlated with the iron profile obtained by Auger-spectrometry. The minimum which can be observed in the concentration profile for iron (Fig. 1-3) leads us to consider two zones in the passive film: an inner nonporous oxide which exhibits good electronic conduction and in which cation transport could be expected, and an outer porous oxide in which anions can migrate. A difference between our results and those given by ESCA is worth noting: The

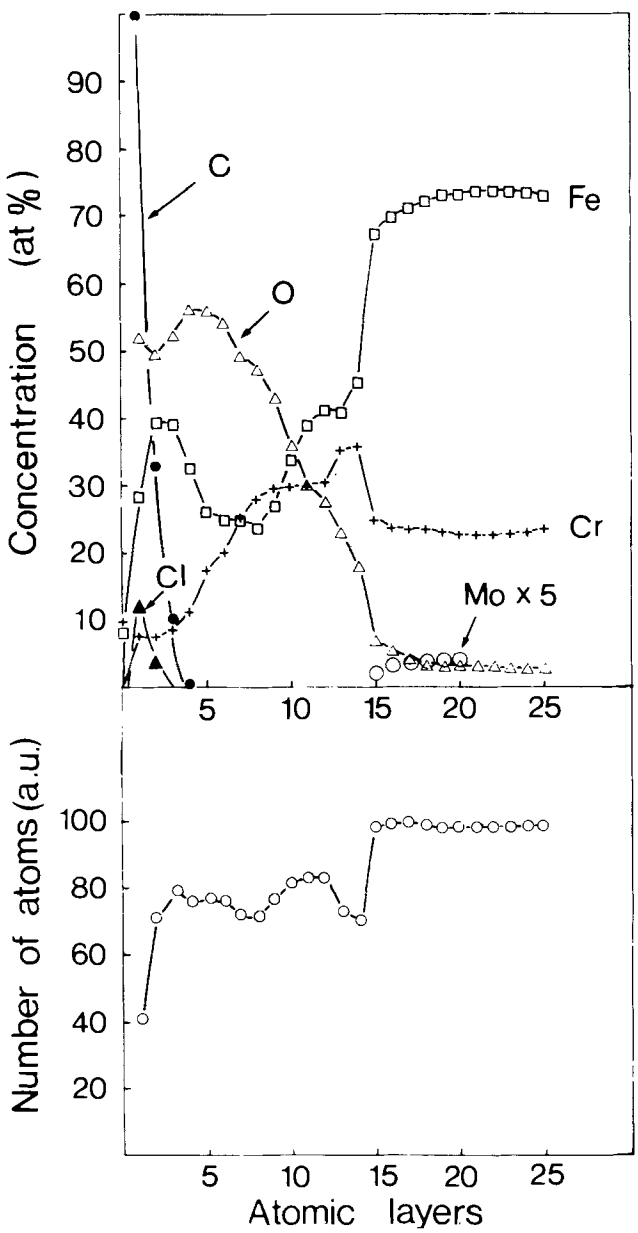

Fig. 8. Composition profile and number of atoms detected in the passive film. Ferritic 26% Cr-1% Mo steel maintained 15 days in a desiccator at 25°C.

chromium concentration gradient in the passive film formed on steels with 4-30% Cr at 25°C in oxygenated water is the inverse of that observed by Auger spectrometry in this work (except for the very first layers, where the sign of the slope is the same). Analytical results show that the thickness of the film does not depend directly on the electrode potential. However it must be recognized that changes in the defect structure probably occur with potential variations (15, 16).

The passive film formed on iron-chromium alloys appears to be a duplex oxide similar to that suggested for passivation of iron (19-23) and austenitic stainless steel (23a). Chlorine penetrates into the outer layers of the film at all potentials. Aggressive ions are stopped only by the inner layers of the film at all potentials. Aggressive ions are stopped only by the inner layers of the film, even when the temperature of the corrosive medium is increased.

In previous papers, the properties of films formed on stainless steels have been associated with an amorphous structure (14, 25). This gel-like structure may be more protective, because it offers a higher resistance to cation transport than crystalline structures (26). In our opinion the amorphous state is characteristic of the outer layers of the passive film. In this zone channels may be formed, and large ions can move (27-30). Further, if we assume that the outer layer forms a poor conductor, anion transfer may be assisted by a high field (16). The less dense matter of the outer zone implies a porous structure, and the presence of Cl^- in the outer layer is consistent with this model.

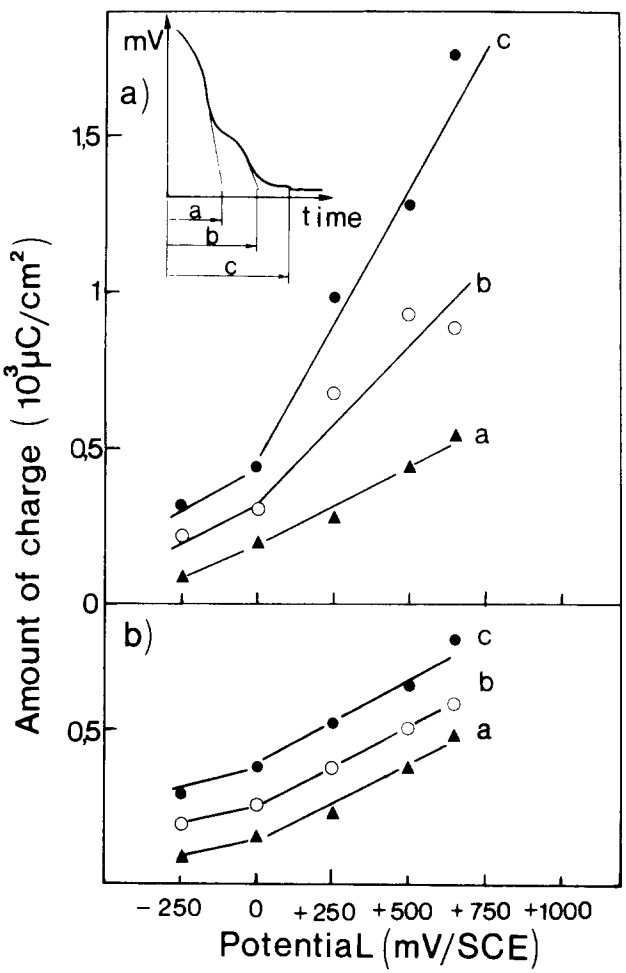

Fig. 9. Quantity of charge associated with the cathodic reduction process for each zone of the passivating film. Films were formed during polarization for 1 hr at different potentials in a 3.5% NaCl (pH 2.5) solution at 5°C. Curves a, b, and are related to the reduction of the outer, transition, and inner layer zones. Coulometric measurements were carried out in 18N H_2SO_4 solutions. a. Ferritic 26% Cr-1% Mo steel; b. ferritic 26% Cr steel.

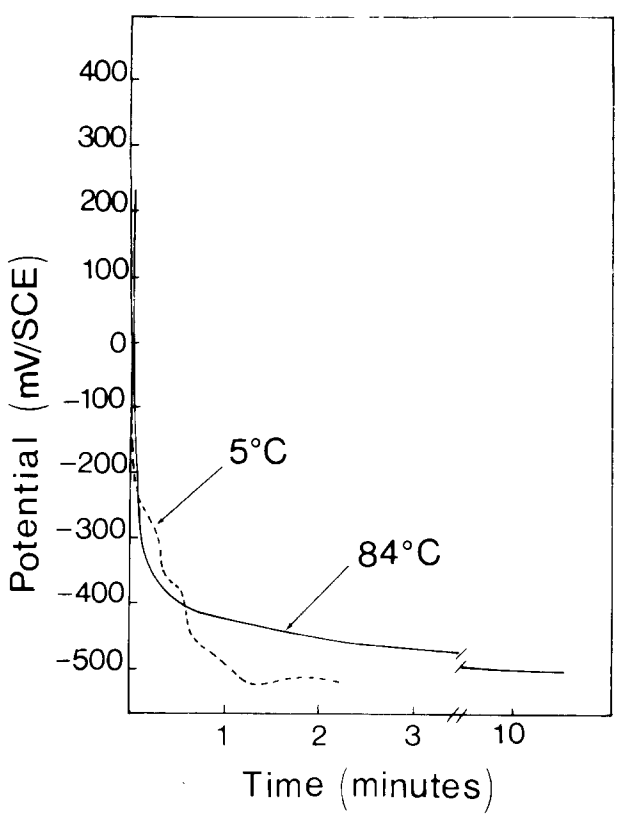

Fig. 11. Potential-time curves obtained during cathodic reduction. Films formed at —250 mV/SCE in a 3.5% NaCl (pH 2.5) solution at different temperatures (Ferritic 26% Cr-1% Mo steel).

The compositional analysis is in agreement with recent results (31), and shows that the molybdenum concentration in the passive films formed on ferritic stainless steels is very low (even in the case of an alloy with 3% Mo) and is only detectable in the inner part of the films. However, coulometric measurements indicate that the passive films formed on Fe-Cr-Mo alloys require a much greater quantity of charge for reduction than do the films formed on Fe-Cr alloys. This electrochemical behavior of the Mo alloys may be associated with their greater corrosion resistance (32-37). It should be pointed out that molybdenum additions have little effect on chromium depletion. This phenomenon, which occurs in high temperature oxidation of iron-chromium alloys (38-41), has not been mentioned as a possible process at low temperatures.

Conclusions

The passive film formed on iron-chromium alloys in NaCl solution is approximately 10 atomic layers thick. The film is enriched in chromium relative to iron. The composition profile of iron in the film shows a deep minimum with a value near to zero in the middle of the film, and a marked increase near the oxide-solution interface. There is a narrow zone inside the film which is only a chromium oxide, behind which molybdenum rises to a level equal to its concentration in the alloy. Further, we observe in the alloy chromium depletion at the oxide-metal interface. On the whole, the total number of atoms per layer is not the same in the oxide film as in the matrix. The less dense matter in the passive film implies a porous structure. Chlorine is always present in the outer zone of the film but does not penetrate into the inner zone. It appears that molybdenum additions increase the stability of the inner layers of the film near the oxide-metal interface.

APPENDIX

Contribution of Each Atomic Layer to the Total Auger Signal: A Quantitative Approach

If we study a heterogeneous sample, the composition of which is a function of the depth in a direction normal to the surface but homogeneous within each atomic layer parallel to the surface, we may consider that the Auger current due to element A given by the whole specimen represents the sum of the contributions of each atomic plane. The peak-to-peak amplitude of the signal $h_A^{(i)}$ corresponding to the Auger current due to the layer i is expressed by the following relationship

$$h_A^{(i)} = \alpha_A k_A^{(i)} N_A^{(i)} \qquad [A\text{-}1]$$

where $N_A^{(i)}$ is the number of the atoms A in the layer i, a fraction of which are excited by the incident electron beam and yield Auger electrons. This proportion is taken into account in the α term. α_A is a sensitivity coefficient, characteristic of the element A, which includes the ionization cross-section, the probability of the Auger transition, as well as many constants of the spectrometer such as the intensity of the incident beam and the collection factor of the analyzer. This term has a fixed value provided the intensity of the beam and the energy of the primaries are well determined. Therefore, it is independent of the matrix insofar as there is no chemical binding resulting in a change of the Auger transition probability. $k_A^{(i)}$ is the contribution coefficient of the layer i to the total signal given by the whole specimen. It takes into account the escape depth of the Auger electrons in the layers before they reach the level i and the backscattering within the matrix.

Owing to these effects, it can be shown that the contribution coefficients are in geometrical progression: 1, K, K^2 ..., with the expression of K given by

$$K = \exp - \left(\frac{d}{D_x \cos\theta} + \frac{d}{D_p} \right) \qquad [A\text{-}2]$$

where d is the thickness of a monolayer, D_s the escape depth of the Auger electrons, D_p the depth of penetration of the primary electrons, and θ, the angle of acceptance of the Auger electrons in the cylindrical mirror analyzer.

If we designate by $H_I^{(0)}$ the initial Auger signal relative to the element I (I = A, B, C ...), when the zero layer is present we may write

$$H_A^{(0)} = \alpha_A (N_A^{(0)} + K_A N_A^{(1)} + K_A^2 N_A^{(2)} + \ldots + K_A^i N_A^{(i)} + \ldots)$$

$$H_B^{(0)} = \alpha_B (N_A^{(0)} + K_B N_B^{(1)} + K_B^2 N_A^{(2)} + \ldots + K_B^i N_B^{(i)} + \ldots)$$

$$H_I^{(0)} = \alpha_I (N_I^{(0)} + K_I N_I^{(1)} + K_I^2 N_I^{(2)} + \ldots + K_I^i N_I^{(i)} + \ldots)$$

and after removal of the zero layer, when layer one becomes the outermost layer, we may write

$$H_A^{(1)} = \alpha_A (N_A^{(1)} + K_A N_A^{(2)} + \ldots + K_A^{i-1} N_A^{(i)} + \ldots)$$

$$H_B^{(1)} = \alpha_B (N_B^{(1)} + K_B N_B^{(2)} + \ldots + K_B^{i-1} N_B^{(i)} + \ldots)$$

$$H_I^{(1)} = \alpha_I (N_I^{(1)} + K_I N_I^{(2)} + \ldots + K_I^{i-1} N_I^{(i)} + \ldots)$$

Hence, if we suppose a layer-by-layer ion etching, the number of the atoms of the element A in the "zero" layer can be deduced

$$N_A^{(0)} = \frac{H_A^{(0)} - k_A H_A^{(1)}}{\alpha_A} \qquad [A\text{-}3]$$

and those contained in layer "one" can be computed from the peak heights $H_A^{(1)}$ and $H_A^{(2)}$. More generally, for any element I (I = A, B, C ...), the number of atoms in the layer i is given by

$$N_I^{(i)} = \frac{H_I^{(i)} - k_I H_I^{(i+1)}}{\alpha_I}$$

The total number of the atoms present in layer i obviously is

$$\sum_{I=A}^{C} N_I^{(i)} = N_A^{(i)} + N_B^{(i)} + N_C^{(i)}$$

If it is certain that this quantity is the same in every layer, its value must be constant. It is therefore possible to choose the sensitivity coefficients α_A, α_B, α_C ... to verify that $\sum_{I=A}^{C} \frac{H_I^{(i)}}{\alpha_I}$ = constant. Inversely, if the values of α_A, α_B, α_C are known, the number of the atoms in each atomic layer can be deduced. The atomic fraction of the element A in layer i is given by

$$C_A^{(i)} = \frac{N_A^{(i)}}{\sum_{I=A}^{C} N_I^{(i)}} = \frac{\frac{H_A^{(i)} - k_A H_A^{(i+1)}}{\alpha_A}}{\sum_{I=A}^{C} \frac{H_I^{(i)} - k_I H_I^{(i+1)}}{\alpha_I}} \qquad [A\text{-}4]$$

The Pb/Pb^{+2} Exchange Reaction in Perchlorate Acidic Solutions

A. S. Gioda, M. C. Giordano, and V. A. Macagno

Department of Physical Chemistry, National University of Córdoba, 5000 Córdoba, Argentina

ABSTRACT

The Pb/Pb^{+2} exchange reaction mechanism in acidic perchlorate solutions has been investigated. Tafel slopes of about 30 mV are found for both Pb dissolution and deposition under steady-state and nonsteady-state conditions, respectively. Empirical rate equations for electrodissolution and electrodeposition are

$$i_a = k_a \mathbf{F} \exp \frac{2\mathbf{F}E}{RT}$$

and

$$i_c = k_c \mathbf{F}\, C^2_{Pb^{+2}} \exp - \frac{2\mathbf{F}E}{RT}$$

respectively. A mechanism with a chemical step as the rds is proposed to explain the experimental results. Although there has been special interest in the study of lead electrodes as anode energy producers in acid and alkali media (1, 2), less is known about the anodic behavior of lead electrodes in acidic solutions without film formation.

The anodic dissolution of lead has been studied (3) in KNO_3, $Pb(Ac)_2$, and NH_4Ac solutions, and a mechanism involving Pb^+ ions was postulated. On the other hand, results of impedance and double impulse measurements (4) have shown that at low Pb^{+2} concentrations the exchange process was controlled by lattice growth and dissolution. A full account of kinetic parameters for the Pb/Pb^{+2} exchange reaction in the presence of different types of electrolyte solutions is compiled elsewhere (2). In $HClO_4$ acid solutions in particular (5) only the passivation time of polycrystalline lead anodes was studied as a function of current density. The authors concluded that the process of anodic passivation is controlled by mass transport in solution.

Recently (6) the anodic oxidation of solid Pb in H_2SO_4 has been investigated and compared with measurements on solid Pb in $HClO_4$ solutions. Although some interesting features are shown, a full account of kinetic parameters are missing. Nevertheless, they concluded that the slow step for surface area changes with $HClO_4$ solutions is located in the surface since the curves do not depend on rotation speed.

This paper reports the results of kinetic studies of the exchange reaction at polycrystalline lead electrodes in acidic perchlorate solutions containing different amounts of Pb^{+2} ions, using several electrochemical techniques under a wide range of experimental conditions.

Key words: electrodeposition, dissolution mechanism, adions.

Experimental

A common three-electrode Pyrex glass cell was used for this investigation. The electrolyte solutions were deareated with purified nitrogen before each run. Temperature was maintained at 25° ± 0.1°C.

Polarization curves were obtained with a fast rise time potentiostat. Linear potential sweep experiments were performed with a specially designed triangular pulse generator (7) provided with electronic ohmic compensation. Potential current curves were recorded with a X-Y EAI Variplotter or with a 545 B Tektronix oscilloscope. Potential/time curves were obtained with a specially constructed power supply of ±0.1% stability. Transients were recorded either with a Sargent MR register or with the oscilloscope. Rotating-disk electrode assembly was previously described (8).

A saturated calomel electrode was used as the reference electrode. It was conveniently isolated from the working solution by an agar plug and glass joint. The reference compartment was in contact with the electrolyte through a Haber-Luggin capillary.

Lead electrodes were prepared from a bar stock of 99.999% Koch-Light Limited. A Teflon electrode assembly was used (9) to support the piece of Pb bar. The seal is produced using the principle of a drill chuck. The collet was made in Teflon, while the truck and the chuck were made in Teflon charged with fiber glass to make it harder. The surface exposed to the solution was a disk of either 4×10^{-3} or 6.1×10^{-2} cm^2. The exposed surface was ground with carborundum paper 600A with distilled water, as the lubricant, washed with distilled water, and then placed immediately in the cell. The same procedure was repeated before each run. Although mechanical polishing for soft metals has been criticized (10), we found that the several electropolished electrodes tested were unable to give reproducible results. The auxiliary electrode was a Pt foil of about 6 cm^2.

Solutions were prepared from $NaClO_4$, Koch-Light crystallized from distilled water, and $HClO_4$ acid Merck pA. $Pb(ClO_4)_2$ was obtained from lead electrolytic dissolution in $HClO_4$-$NaClO_4$ solutions and standardized with EDTA. Concentration range was between 2×10^{-3} and 1.64M for ClO_4^- ions, from 10^{-5} to 10^{-1}M for H^+, and between 2.3×10^{-5} and 1.34×10^{-2}M for Pb^{+2}.

The steady-state rest potential was taken at open circuit until the drift in potential was 5 mV/hr or less, and it was measured with a pH Meter 4 Radiometer potentiometer. The time elapsed to reach the steady state depends on the type of solution and concentration.

Current efficiency for an exchange of two Faradays per mole was verified through quantitative determination of Pb^{+2}. Unless indicated otherwise, all potentials are quoted against the saturated calomel electrode.

Results

Potentiostatic polarization curves.—Two types of solution composition were studied: a mixture of $NaClO_4$-$HClO_4$, and the same mixture with addition of $Pb(ClO_4)_2$. The dependence of the steady-state rest potential with the different species involved are compiled in Fig. 1. It can be seen that E_r appears almost independent of ClO_4^- and H^+ species concentration. On the other hand, in the Pb^{+2} concentration range studied, a plot of E_r *vs.* log $C_{Pb^{+2}}$ shows a slope

$$\frac{\delta E_r}{\delta \log C_{Pb^{+2}}} = 0.03\text{V} \qquad [1]$$

and with an intersect at log $C_{Pb^{+2}} \simeq 0$ very close to $E°_{Pb/Pb^{+2}}$ electrode, indicating that a Nernst's equation for the process

$$Pb \rightleftharpoons Pb^{+2} + 2e \qquad [2]$$

is followed.

Figure 2 shows some of the anodic polarization behavior of Pb electrodes in the two types of solutions. A linear dependence of E *vs.* log i_a is observed over at least two decades of logarithm even for the most dilute solutions. The addition of different amounts of Pb^{+2} produces an increase on the exchange current, but it has no appreciable effect on Pb dissolution. The polarization data obtained with stationary and rotating-disk electrodes were similar except for the region near the rest potential where the effect for the backward reaction becomes important and at high overpotentials where mass transport interferes. Anodic Tafel slopes in both types of solutions are around 30 mV/decade. A similar value was also reported previously (6).

The experimental dependence of anodic dissolution current densities on ClO_4^-, H^+, and Pb^{+2} concentration gives the following results

$$\left(\frac{\delta \log i_a}{\delta \log C_{ClO_4^-}}\right)_{E,H^+,Pb^{+2}} = \left(\frac{\delta \log i_a}{\delta \log C_{H^+}}\right)_{E,ClO_4^-,Pb^{+2}} = \left(\frac{\delta \log i_a}{\delta \log C_{Pb^{+2}}}\right)_{E,ClO_4^-,H^+} = 0 \qquad [3]$$

Although ionic strength was not constant for the first relationship, the effect of ϕ_2 potential on i is minimal when the reaction is independent of the ion concentration, as it seems to be in this case.

The variation of exchange current density with Pb^{+2} concentration obtained by extrapolating the Tafel line to the rest potential is

$$\frac{\delta \log i_o}{\delta \log C_{Pb^{+2}}} = 1 \qquad [4]$$

as shown in Fig. 3. Also, from the dependence of the rest potential on Pb^{+2} concentration, a value of Pb^{+2} concentration at the surface could be calculated in the type solutions. This average exchange current is also included in Fig. 3.

On the other hand, i_o appears as almost independent on H^+ and ClO_4^- ions concentrations as it is shown in Table I. Thus

$$\left(\frac{\delta \log i_o}{\delta \log C_{H^+}}\right)_{Pb^{+2}} = \left(\frac{\delta \log i_o}{\delta \log C_{ClO_4^-}}\right)_{Pb^{+2}} = 0 \qquad [5]$$

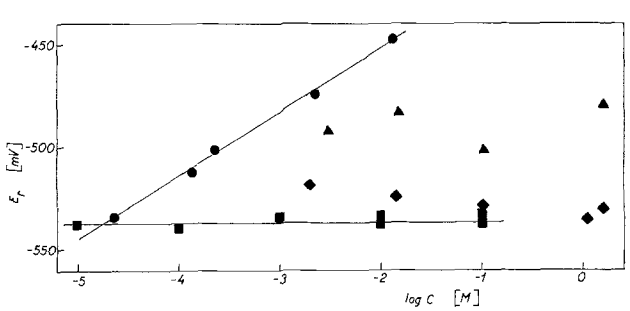

Fig. 1. Dependence of the steady-state rest potential with different species. ● *vs.* $C_{Pb^{++}} - C_{ClO_4^-} = 1.11$M, $C_{H^+} = 0.1$M; ■ *vs.* $C_{H^+} - C_{ClO_4^-} = 1.06$M; ▲ *vs.* $C_{ClO_4^-} - C_{Pb^{+2}} = 0.001$M, $C_{H^+} = 0.001$M; ♦ *vs.* $C_{ClO_4^-} - C_{H^+} = 0.001$M.

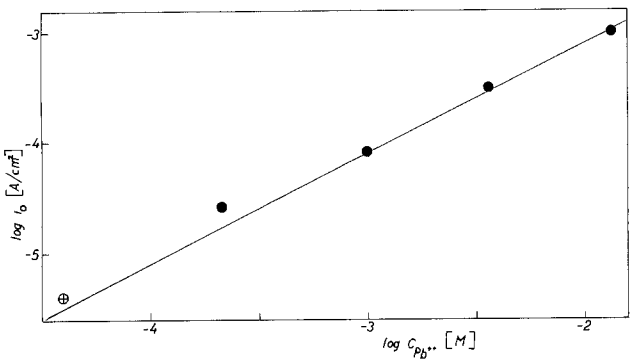

Fig. 3. Dependence of the exchange current density on log $C_{Pb}{}^{+2}$. ⊕ Concentration calculated as is indicated in the text.

Stoichiometric numbers (11) were experimentally obtained from current densities values at low overpotentials, as

$$\nu = \frac{i_o n\mathbf{F}}{RT}\left(\frac{\delta\eta}{\delta i_a}\right)_{\eta\to 0} \qquad [6]$$

Figure 4 gives typical η *vs.* i_a plots. The ν values obtained for the different types of solutions are compiled in Table I, and the average result is 0.5. In order to obtain reproducible results for the cathodic reaction, the electrode was rotated and the potential scanned at a constant rate of 5 mV/sec. Under this condition it is supposed that a quasisteady state is reached since no appreciable change in the E/i curves was found with potential sweep rates up to 20 mV/sec.

Figure 5 shows representative polarization curves for Pb deposition. Limiting currents are obtained which depend linearly on the square root of electrode rotation speed and Pb^{+2} concentration. Taking into account the Levich's equation (12)

$$i_L = 0.62\, n\mathbf{F}D^{2/3}\nu^{1-1/6}\omega^{1/2}C_b \qquad [7]$$

the diffusion coefficient can be evaluated. The average $D_{Pb^{+2}}$ is 4.8×10^{-6} cm² sec^{-1}.

The half-wave potential does not depend on rotation speed, this being an indication that the reaction behaves in a reversible way (13). On the other hand, a plot of η *vs.* log $[(i_L - i_c)/i_L]$ (12) gave a straight line with a slope of about 30 mV/decade.

Galvanostatic potential-time curves.—Representative potential-time curves for Pb^{+2} electrodeposition are shown in Fig. 6. Only one transition time is observed at all current densities studied. Nevertheless, an increase in the transition time was observed in repetitive runs performed at low current densities. This effect together with the increase of the $i_c\tau^{1/2}/C$ ratio as i_c is decreased, Fig. 7, could be attributed to an appreciable increase in the electrode area due to deposition. At moderate and high current densities a linear dependence of $i_c\tau^{1/2}/C$ *vs.* i_c is found.

By applying Sand's equation (14) to the linear region, the diffusion coefficient can be evaluated as

$$\frac{i_c\tau^{1/2}}{C_b} = \frac{n\mathbf{F}\pi^{1/2}D^{1/2}}{2} \qquad [8]$$

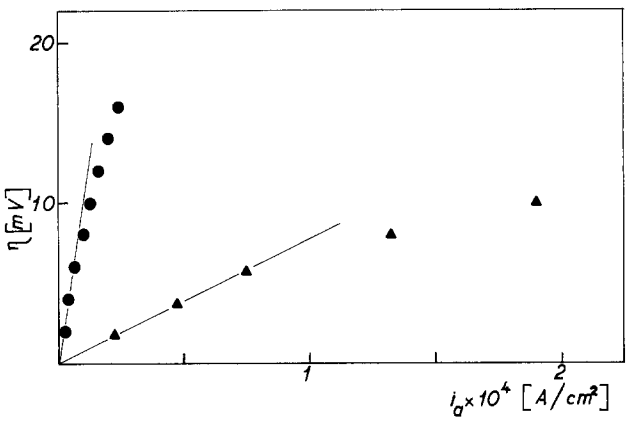

Fig. 4. Plots of overpotential *vs.* current density. $C_{ClO_4}{}^- = 1.64$M, $C_{H^+} = 0.001$M. ● Without Pb^{+2}; ▲ $C_{Pb^{+2}} = 0.001$M.

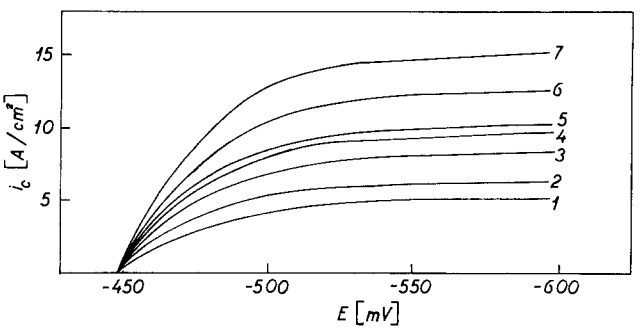

Fig. 5. Polarization curves for electrodeposition obtained at the RDE. $C_{Pb^{+2}} = 0.013$M, $C_{ClO_4}{}^- = 1.64$M, $C_{H^+} = 0.1$M. ω (rad/sec): 1 = 19.8; 2 = 40.2; 3 = 58.2; 4 = 77.4; 5 = 96.9; 6 = 128; 7 = 187.

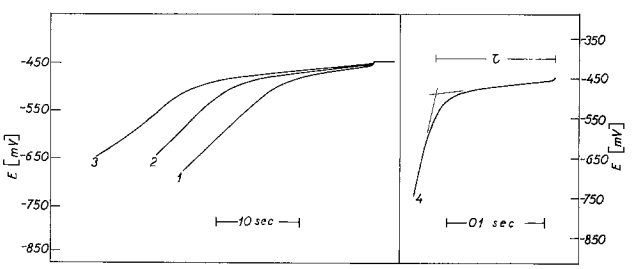

Fig. 6. Galvanostatic potential-time curves. $C_{ClO_4}{}^- = 1.13$M, $C_{H^+} = 0.1$M. 1, 2, and 3 repetitive runs, $C_{Pb^{+2}} = 1.34 \times 10^{-2}$M, $i_c = 2.05 \times 10^{-3}$ A/cm², 4, $C_{Pb^{+2}} = 0.0036$M, $i_c = 4.60 \times 10^{-3}$ A/cm².

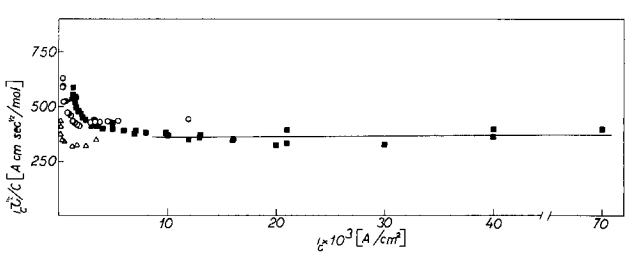

Fig. 7. Dependence of the chronopotentiometric constant on current density. $C_{ClO_4}{}^- = 1.13$M, $C_{H^+} = 0.1$M; ○, ■, △ $C_{Pb^{+2}} = 0.0036$, 0.013, and 0.0009M, respectively.

giving an average value of 4.5×10^{-6} cm^2 sec^{-1}. A plot of E *vs.* log ($\tau^{1/2} - t^{1/2}$) (14) gives a good straight line with a slope of 30 mV/decade.

Linear sweep voltammetry.—The dissolution curve appears as a typical process without film formation with a continuous increase in current as the potential is increased. On the reverse sweep a cathodic current appears near the rest potential. Voltammograms for Pb deposition are shown in Fig. 8. The cathodic i/E curves show a peak current that depends on sweep rate.

A plot of i_p *vs.* $v^{1/2}$, Fig. 9, shows a complex behavior. At low v there is a straight line dependence of i_p with $v^{1/2}$. As sweep rate is increased there is a transition to a lower slope. From the highest slope, the diffusion coefficient for a two electrons reversible process was calculated. The average value results 4.3×10^{-6} cm^2 sec^{-1}.

In Fig. 10, the behavior of E_p *vs.* log v is analyzed. Two different zones are observed depending on sweep rate. At low sweep rates, E_p remains constant independent of v, while after a certain v value the variation of E_p *vs.* log $v^{1/2}$ takes a slope of

$$\frac{\delta E_p}{\delta \log v^{1/2}} = 30 \text{ mV} \qquad [9]$$

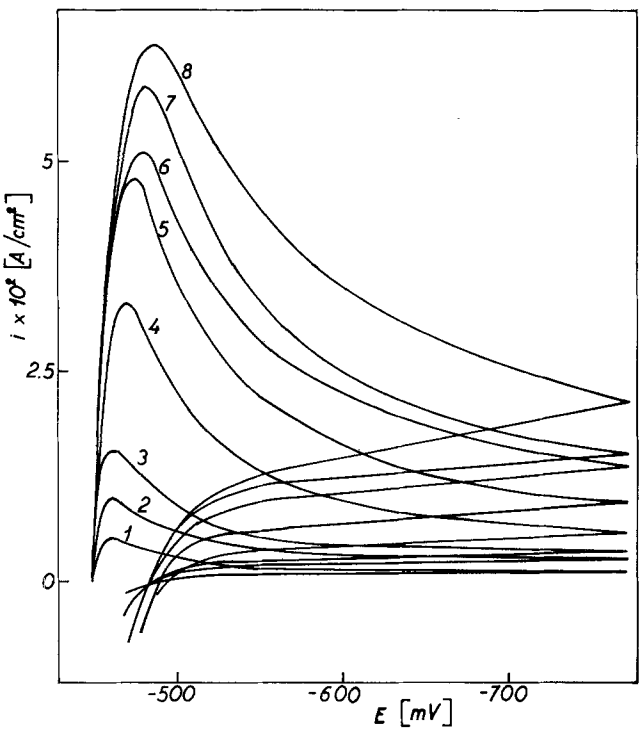

Fig. 8. Voltammograms for Pb^{+2} deposition. $C_{Pb^{+2}} = 0.013$M, $C_{ClO_4^-} = 1.13$M, $C_{H^+} = 0.1$M. Sweep rate (V/sec): 1 = 0.02; 2 = 0.1; 3 = 0.2; 4 = 0.8; 5 = 2; 6 = 4; 7 = 6; and 8 = 10.

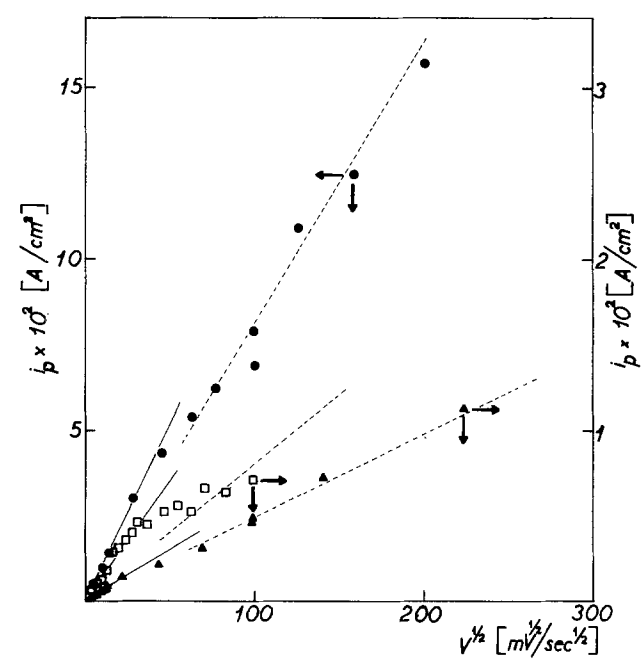

Fig. 9. Dependence of the peak current density on sweep rate for Pb^{+2} deposition. $C_{ClO_4^-} = 1.13$M, $C_{H^+} = 0.1$M. ●, □, ▲ $C_{Pb^{+2}} = 0.013$, 0.0036, and 0.0009M, respectively.

Discussion

From the experimental results given above, the rate for the anodic reaction can be derived from the theoretical expression (15)

$$i_a = \mathbf{F}k_a(\pi_s C_s Z_{a,s}) \exp(\alpha_a \mathbf{F}E/RT) \qquad [10]$$

With the experimental values of $\alpha_a = 2$ and Z_a for all species as zero, the empirical rate equation for the anodic reaction is obtained

$$i_a = \mathbf{F}k_a \exp \frac{2\mathbf{F}E}{RT} \qquad [11]$$

Introducing the overpotential in Eq. [10] as $\eta = E - E_r$, the theoretical rate equation is rewritten as

$$i_a = \mathbf{F}k_a(\pi_s C_s^{Z_{a,s}}) \exp[\alpha_a \mathbf{F}(\eta + E_r)/RT] \qquad [12]$$

when $\eta = 0$, $i_a = i_c = i_o$ and the exchange current results

$$i_o = \mathbf{F}k_a(\pi_s C_s^{Z_{a,s}}) \exp(\alpha_a \mathbf{F}E_r/RT)$$
$$= \mathbf{F}k_c(\pi_s C_s^{Z_{o,s}}) \exp(-\alpha_c \mathbf{F}E_r/RT) \qquad [13]$$

On the other hand, the Nernst equation can be written as

$$E_r = E_o - \frac{RT}{n\mathbf{F}} \ln \pi_s C_s^{m_s} \qquad [14]$$

which according to Eq. [2] takes the form

$$E_r = E_o + \frac{RT}{2\mathbf{F}} \ln C_{Pb^{+2}} \qquad [15]$$

Furthermore, the equilibrium constant of the total electrochemical reaction is related to the anodic and cathodic rate constants (15) as follows

$$\frac{k_a}{k_c} = K^{1/\nu} \qquad [16]$$

Taking into account the above equations, the following relations between kinetics parameters are found

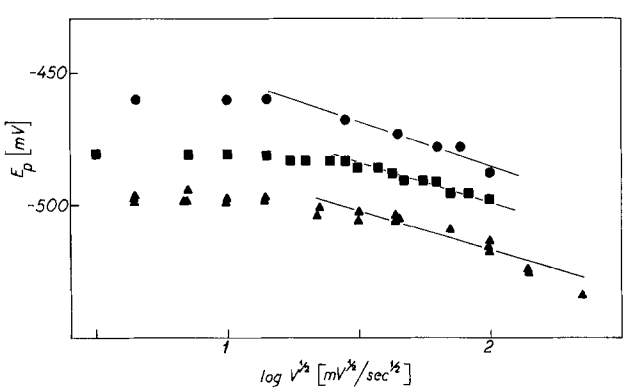

Fig. 10. Dependence of the peak potential on log $v^{1/2}$ for Pb^{+2} deposition. $C_{ClO_4^-} = 1.13$M, $C_{H^+} = 0.1$M. ●, ■, ▲ $C_{Pb^{+2}} = 0.013$, 0.0036, and 0.0009M, respectively.

$$n = \nu(\alpha_a + \alpha_c) \quad [17]$$

and

$$m_s = \nu(Z_a - Z_c) \quad [18]$$

Thus Eq. [13] for the exchange current can be transformed to

$$i_o = (k_c K^{1/\nu})\mathbf{F}\left[\pi_s C_s\left(\frac{m_s}{\nu} + Z_c\right)\right]\exp(\alpha_a \mathbf{F} E_r/RT) \quad [19]$$

Equation [19] shows that from a plot of ln i_o *vs.* ln $C_{Pb^{+2}}$ the cathodic reaction order can be found. Experimentally

$$\frac{\delta \ln i_o}{\delta \ln C_{Pb^{+2}}} = \left(\frac{m_s}{\nu} + Z_c\right) - m_s = 1 \quad [20]$$

hence, as $m_s = -1$ and $\nu = 0.5$, results are $Z_c = 2$. Also, according with Eq. [17], $(\alpha_a + \alpha_c) = n/\nu = 4$ and $\alpha_c = 2$; thus the rate equation for the cathodic reaction results in

$$i_c = \mathbf{F} k_c C^2_{Pb^{++}} \exp -\frac{2\mathbf{F}E}{RT} \quad [21]$$

Deposition of Pb^{+2} behaves as a rather reversible reaction under steady-state conditions. Nevertheless under linear sweep voltammetry a certain degree of irreversibility can be inferred from i_p *vs.* $v^{1/2}$ dependence, Fig. 9, and also from E_p *vs.* log $v^{1/2}$, Fig. 10, at high sweep rates giving a Tafel slope of about 30 mV/decade in agreement with the theoretical $\alpha_c = 2$.

By combining data represented in Fig. 9 and 10 the cathodic reaction order was obtained from log i_p *vs.* log $C_{Pb^{+2}}$ at constant E_p, Fig. 11. The experimental value is in agreement with the kinetic Eq. [21]. In a general case of a multistep reaction (16) the transfer coefficients α are denoted as

$$\alpha_a = \left(\frac{\gamma_a}{\nu} - \beta_r\right) \quad [22]$$

and

$$\alpha_c = \left(\frac{n - \gamma_a}{\nu} + \beta_r\right) \quad [23]$$

where γ's and r are the number of electrons transferred before and during the rds, respectively. β is usually taken as 0.5. On the bases of the kinetic parameters obtained, only one set of numbers of electrons transferred before and during the rds are possible. Thus,

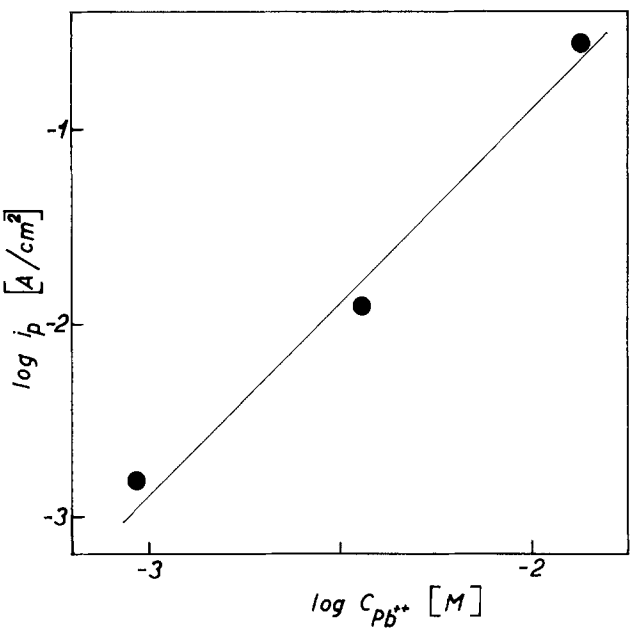

Fig. 11. Reaction order for electrodeposition with respect to Pb^{+2}. $C_{ClO_4^-} = 1.13M$, $C_{H^+} = 0.1M$, $E_p = -500$ mV.

for $\alpha_a = 2$ and $\nu = 0.5$, with $\beta = 0.5$ results $\gamma_a = 1$ and $r = 0$.

Accordingly a mechanism with a charge transfer in quasiequilibrium followed by a chemical step as the rate-determining step could be postulated as the most probable pathway for Pb/Pb^{+2} exchange reaction in acidic perchlorate solutions. Taking into account that Pb^{+2} concentration does not affect the anodic reaction rate, a loop-containing mechanism could be discarded in principle (17). On the other hand, the stoichiometric number of ½ experimentally obtained is an indication that for each occurrence of the rds the total reaction goes twice to completion. Hence, a quasiequilibrium one-electron charge transfer step to form species Pb(I) adion could be postulated for the first step (11). It is more difficult to assign a formal equation for the rds. Nevertheless, a chemical interaction between two Pb(I) adions to form a more suitable specie for the second charge transfer could be a plausible explanation for the $\nu = 0.5$ found experimentally. Formally, a sequence of steps

$$Pb \rightleftharpoons Pb(I) + 1e \quad [24]$$

$$2\,Pb(I) \xrightarrow{rds} [Pb(I)]_2 \quad [25]$$

$$[Pb(I)]_2 \rightleftharpoons 2Pb^{+2} + 2e \quad [26]$$

would be in agreement with the experimental data correlated by the empirical Eq. [11] and [21]. Much work is indicated in order to clarify the complex nature of the rds, but this investigation has shown that the behavior of the Pb/Pb^{+2} exchange reaction agrees with a series of previous results obtained with *sp* metals (18).

The Electrochemical Reduction of Carbon Dioxide, Formic Acid, and Formaldehyde

P. G. Russell,[1] N. Kovac,* S. Srinivasan, and M. Steinberg**

Brookhaven National Laboratory, Department of Applied Science, Upton, New York 11973

ABSTRACT

The prospects for the electrochemical reduction of carbon dioxide to methanol were examined by investigating the intermediate reactions. The reduction of carbon dioxide was carried out in a neutral electrolyte at a mercury electrode. The high overvoltage observed for carbon dioxide reduction to the formate anion reflects a low value for the efficiency of electric energy utilization for this process. Formic acid can be reduced to methanol in a perchloric acid electrolyte (at a lead electrode) or in a buffered formic acid electrolyte (at a tin electrode). The faradaic efficiency for methanol formation is close to 100% at the tin electrode in a narrow potential region corresponding to a low current density. The potential dependence of formic acid reduction to methanol suggests that the adsorption of formic acid on the electrode, near the pzc, may be the rate-controlling step in the over-all reaction. The reduction of formaldehyde to methanol occurs with a faradaic efficiency exceeding 90% in a basic solution. The Tafel slope decreases when either the formaldehyde concentration is increased (at constant pH) or when the pH of the solution is increased (at constant concentration). The polyoxymethylene glycols present as impurities in formaldehyde solutions may influence the mechanism of the electrode process through interaction with formaldehyde molecules and/or other adsorbed species resulting in small changes of the Tafel slope.

The prospects for electrochemical production of methanol from carbon dioxide.—With the increasing possibility of the unavailability of oil in 20-30 years, methanol will probably be the substitute liquid fuel (or fuel intermediate) in the future. New methods for the production of methanol should be economically competitive with existing technology. One approach for the production of methanol from nonfossil sources is by the electrochemical reduction of carbon dioxide. This will be feasible only with a potentially cheap source (*e.g.*, controlled thermonuclear generation) of electrical energy. Methanol may also be considered as a medium for the storage of hydrogen.

The purpose of this work is to evaluate the optimum conditions (electrode, electrolyte, pH, etc.) for the conversion of carbon dioxide to methanol. The high overpotentials observed for the reduction of carbon dioxide and its intermediates result in an over-all low energy efficiency. The reduction of carbon dioxide to formic acid has been studied extensively. However, few studies describe the further reduction of formic acid to methanol.

Previous studies on the electrochemical reduction of carbon dioxide.—The electrolytic reduction of carbon dioxide in aqueous solutions has been the subject of many investigations. According to the earlier papers (1-5) formic acid (or the formate ion) was found to be the principal product with the highest current efficiency being obtained at amalgamated electrodes (see Table I). The electrolyte, containing the alkali salt (bicarbonate, carbonate, or sulfate) was usually saturated with carbon dioxide gas [pressures of up to 50 atm were used in some experiments (4)]. High cur-

rent efficiencies for formate production (~ 99%) were obtained in short-term electrolysis experiments where the diffusion of the formate anion was negligible.

After long-term contact of a solution of sodium bicarbonate with sodium amalgam, appreciable concentrations of formate ion were detected (6). This result led some workers to believe that the bicarbonate and carbonate anions were electroactive species and that the reduction of carbon dioxide occurred on electrodes having high hydrogen overpotentials (2, 3). Polarographic waves observed in solutions containing carbon dioxide were interpreted as being due to the reduction of carbon dioxide (7-9). Later studies (10, 11) confirmed the above interpretation and showed that carbon dioxide, and not the bicarbonate or carbonate anion, is the electroactive species.

Intermediates are formed during the reduction of carbon dioxide. A number of studies have dealt with the properties of a "reduced carbon dioxide" species, $(CO_2)_r$, formed when carbon dioxide is reduced to formic acid in aqueous solution. The results of one study (16) carried out in acid solution show that carbon dioxide reacts with chemisorbed hydrogen (electrochemically formed) on bright platinum in the potential region 0 to +250 mV *vs.* the RHE to form $(CO_2)_r$. The rate of reaction is slow at room temperature, but increases rapidly with temperature. On platinized platinum at 90°C, chemisorbed hydrogen reacts rapidly with carbon dioxide. In another study (17), this reaction intermediate was produced at a platinum electrode and then oxidized at a constant current. The amount of carbon dioxide formed was determined by gas liquid chromatography. The results showed that two electrons are transferred during oxidation of each $(CO_2)_r$ species. In comparison with the results of similar experiments carried out using carbon monoxide, it was suggested that $(CO_2)_r$ is carbon monoxide, chemisorbed in the first layer on platinum.

Previous studies on the electrochemical reduction of formic acid.—The reduction of formic acid is more difficult and thus fewer studies have appeared in the literature. In one study, on the reduction of carboxylic acid esters (18), an ester of formic acid was found to be reduced with difficulty. In 1907, a patent was granted for an electrochemical method of reducing monobasic fatty acids to aldehydes and alcohols (19). Specific mention is made of formic acid reduction. In a 10% sulfuric acid electrolyte solution formic acid was reduced preferentially to formaldehyde at low current densities and to methanol at high current densities. In general, low current densities were recommended for carrying out the reduction. A number of metals were suggested for use as cathodes (lead, spongy nickel, iron, cobalt, and platinized platinum) but the coulombic efficiency for methanol production on the individual metals was not presented. In a recent two-part study (20, 13) tin was found to be a good electrocatalyst for formic acid reduction. In part I (20) formic acid was reported to be reduced to methanol with a 100% current efficiency at low current densities. A selective oxidation and titration scheme of the formic acid, formaldehyde, and methanol present was the analytical method used in the product analysis. However, in part II (13) of this work, significant analytical results showed that the current efficiency is quite low; polished tin (7%), electroplated tin (13%), and Cerrolow 136 (solid phase ~7.4%, liquid phase ~13.7%). The best results (for longer run tests) were obtained with the molten Cerrolow 136 (low melting point alloy containing tin) where the maximum effective current density was only 140 $\mu A/cm^2$.

Previous studies on the electrochemical reduction of formaldehyde.—The reduction of formaldehyde has been studied extensively in classical polarography [see Ref. (21) for a review of the earlier work]. The polarographic wave increases rapidly with the *p*H and temperature of the solution. The low kinetic current is attributed to the fact that formaldehyde is present predominantly in the electroinactive hydrated form, methylene glycol. The limiting current for reduction is governed by the reaction rate for methylene glycol dehydration to formaldehyde, which is the electroactive species. This dehydration appears to be a base catalyzed reaction. In solutions with a *p*H value greater than 12, the limiting current decreases with increase in the *p*H. This decrease probably results from the formation of an anion of methylene glycol, $H_2C(OH)O^-$, in high *p*H solutions which is the intermediate for formaldehyde formation. In a recent study (21) the presence of $H_2C(OH)O^-$ was observed through its u.v. absorption peak at 215 nm. The following mechanism (21, 22) has been proposed for formaldehyde formation in solution at a *p*H between 12 and 13

$$CH_2(OH)_2 + OH^- \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} CH_2(OH)^- + H_2O \qquad [1]$$

$$CH_2(OH)O^- \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} H_2C{=}O + OH^- \qquad [2]$$

Measurement of these rate constants using pulse polarography (22) can explain the sharp decrease ob-

served in the limiting current with an increase in *p*H above a value of 13.2. With lower *p*H values the rate of methylene glycol dehydration determines the available amount of formaldehyde.

In a previous study (23) on formaldehyde reduction evidence was found for a CECE mechanism in the *p*H region of 9 and below while a CEEC mechanism was suggested for the *p*H region of 13 and above. In cyclic voltammetry experiments with 5×10^{-2}M formaldehyde solutions an anodic peak (considered to be the oxidation of the radical anion intermediate resulting from the first electron transfer step) was obtained in a borate buffer (*p*H of 9) at a sweep rate of 100 V/sec. This peak was not observed in a solution of lower *p*H (phosphate buffer, *p*H = 6.8) and it disappeared at a *p*H above 9.5. These results, along with other evidence, suggested that in a neutral solution the chemical reaction following the first electron transfer step is fast enough so that no peak occurs. As the *p*H of the solution increases, this reaction becomes slower and an anodic peak occurs at fast sweep rates. In the absence of any appreciable dimerization of the adsorbed radical anion, the disappearance of this peak with a further increase of *p*H (greater than 9.5) indicated that a second electron transfer step, favored by the increase in the negative potential at the electrode surface due to the higher solution *p*H, occurs prior to the chemical step.

In addition to methylene glycol and a small amount of formaldehyde [$K \sim 10^{-4}$ for $H_2C(OH)_2 \rightleftarrows H_2CO + H_2O$], there are small amounts of polyoxymethylene glycols [$HO(CH_2O)_nH$ where $n \geq 2$], the concentrations of which depend on formaldehyde concentration (24). The amount (mole percent) of methylene glycol decreases while the amount of the polyoxymethylene glycols increases with increasing formaldehyde concentration. A number of equilibria can be written among the different species present in solution (the equilibria involving the anion of methylene glycol discussed above are not included here)

$$\begin{array}{ccc} H_2C(OH)_2 + HO(CH_2O)_nH & \rightleftarrows & HO(CH_2O)_{n+1}H + H_2O \\ \downarrow\uparrow & & \downarrow\uparrow \\ H_2CO + H_2O & & HO(CH_2O)_nH + H_2CO \end{array} \quad [3]$$

Previous studies (25) indicate that with increase in the *p*H of the solution, the amount of methylene glycol increases. Any mechanism study of formaldehyde reduction is complicated by the presence of these species.

Experimental

Types of studies.—Three types of experimental studies (carried out at 25° ± 3°C) were conducted: (*i*) current-potential relations obtained from steady-state potentiostatic experiments at a mercury electrode in electrolyte solutions containing either carbon dioxide or formaldehyde; (*ii*) current-potential relations obtained from nonsteady-state (cyclic voltammetric) experiments in electrolyte solutions at a hanging mercury drop electrode containing formaldehyde; and (*iii*) products formed in long-term electrolysis experiments with formic acid (carried out at both lead and tin electrodes) and formaldehyde (carried out at a mercury pool) as reactants were identified quantitatively, using gas chromatographic techniques.

Electrochemical instrumentation.—A PAR potentiostat (Model 173) and digital coulometer (Model 179) were used for the long-term electrolysis experiments on formic acid and formaldehyde. For the steady-state potentiostatic experiments a PAR potentiostat (Model 173) and a Keithley 160B digital multimeter were employed. The electronic instrumentation for the cyclic voltammetric studies consisted of the PAR potentiostat (Model 173), PAR universal programmer (Model 175), and a Hewlett Packard X-Y recorder (7047A) or Tektronix storage scope (702BA). The cyclic voltammograms obtained at a 10 mV/sec scan rate were displayed on the X-Y recorder while those obtained at faster sweep rates were recorded on the storage scope. The *IR* corrections (for the steady-state polarization curves) were made by the current interruptor method using a mercury relay switch and the storage scope.

Electrochemical cells.—The long-term electrolysis experiments with formaldehyde and the steady-state polarization measurements on formaldehyde and carbon dioxide were carried out in a Pyrex cell having a fine glass frit separating the working and counterelectrode compartments. The counterelectrode was platinized platinum. In these experiments the reference electrode (SCE) was placed 4-6 mm above (and in the center of) the 1 in. diam (5.06 cm^2) mercury pool. The reduction of formic acid was carried out in an enclosed glass cell in order to minimize the loss of any volatile products formed during electrolysis. The three anode compartments were symmetrically arranged and separated from the large cathode compartment (containing an electrode with geometric surface area of 50 cm^2) by fine glass frits each of which is covered with a layer of agar (containing either sodium or tetraethyl ammonium perchlorate). The sealed cell containing a nitrogen atmosphere above the oxygen-free electrolyte, is further isolated in a desiccator, (also containing a nitrogen atmosphere) during the electrolysis which lasted 40 hr or more.

Solutions and materials.—All solutions were made from reagent grade chemicals and distilled water which was redistilled in a Corning apparatus (Model AG-2). The buffer solutions were made in the following way: (*i*) *p*H 6.8, 0.05M KH_2PO_4 + 0.05M K_2HPO_4; (*ii*) *p*H 9.0, 0.1M $NaHCO_3$ + NaOH; (*iii*) *p*H 11.1, 0.1M Na_2CO_3 + NaOH; (*iv*) *p*H 13.0, 0.055M KCl + 0.145M NaOH. The stock formaldehyde solutions were prepared by bubbling the formaldehyde gas (obtained by heating paraformaldehyde) through water. The concentration was determined by the sulfite method (24). In the steady-state polarization experiments with carbon dioxide, good results were obtained with a commercial grade carbon dioxide gas. Reagent grade lead and tin and triply distilled mercury were used for the electrodes.

Gas chromatographic analysis of products.—A Carle analytical gas chromatograph with flame ionization detection modified with a catalytic converter (for reducing small molecules to methane) was used for the analysis of the products in the electrolyte solution. Matheson zero gas grade helium and hydrogen and ultra zero grade air were necessary for maximum sensitivity. A glass column (to minimize adsorption of formic acid) packed with Porapak QS was found to be best for the separation of formaldehyde, methanol, and formic acid in the presence of large amounts of water. Typical chromatograms run on a formaldehyde solution before and after electrolysis are shown in Fig. 1. The initial small amounts of methanol observed in the chromatograms are produced during preparation of the formaldehyde solution. A calibration curve to determine the quantity of methanol obtained during electrolysis is shown in Fig. 2. A similar calibration procedure was used to determine the quantity of methanol produced during the reduction of formic acid solutions.

Results and Discussion

Electrochemical reduction of carbon dioxide.—Detailed kinetic studies have been carried out on the reduction of carbon dioxide at a Hg-pool electrode by Eyring and co-workers (26, 27). Figure 3 shows the polarization curve for the reduction of carbon dioxide to the formate anion in a neutral solution where the faradaic efficiency is 100% (in acid solution the efficiency for formate production is much less because of a

parallel electrode reaction leading to the formation of molecular hydrogen). These results are in good agreement with previously published data (26). The galvanostatic charging curve experiments indicated that the coverage by an adsorbed intermediate is large ($\theta \rightarrow 1$) in region I (low overvoltage region with a Tafel slope of ~91 mV) and is small ($\theta \rightarrow 0$) in region II (with a Tafel slope of ~240 mV). The adsorbed intermediate was suggested to be the formate radical, HCO_{2ads}. In addition the reaction order for the concentration of carbon dioxide was found to approach a value of zero and one in region I and II, respectively. The following mechanism best represents the experimental results (27)

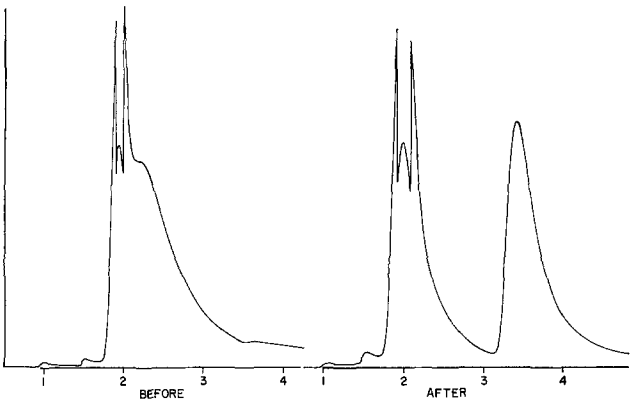

Fig. 1. Chromatograms of 0.1M formaldehyde and 0.1M sodium carbonate solution before and after electrolysis. The concentration of methanol in the solution is obtained from the area under the methanol peak and the calibration curve (Fig. 2).

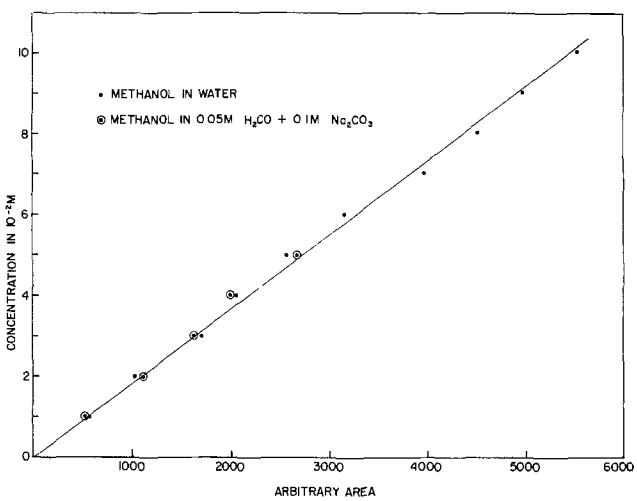

Fig. 2. Calibration curve for methanol detection in the electrolysis of formaldehyde solutions.

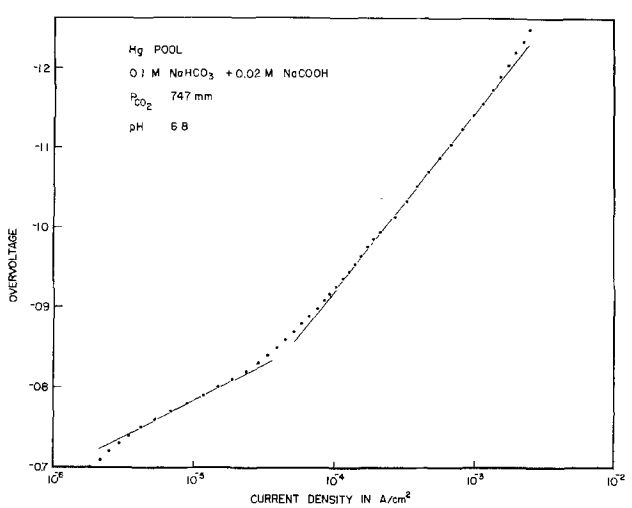

Fig. 3. Polarization curve for the reduction of carbon dioxide to the formate anion in a neutral solution. The overvoltage for the reduction of carbon dioxide is obtained by subtracting out the reversible potential which exists for the conditions of the experiment (26). The curve has been corrected for *IR* effects.

$$CO_2 + e^- \rightarrow CO_{2\cdot ads}^- \quad [4]$$

$$CO_{2\cdot ads}^- + H_2O \xrightarrow{\text{fast}} HCO_{2ads} + OH^- \quad [5]$$

$$HCO_{2ads} + e^- \rightarrow HCO_2^- \quad [6]$$

In region I of the polarization curve, the step represented by Eq. [6] is considered to be rate determining while in region II the first step (Eq. [4]) is the rds. Water may be a reactant in the first step which then leads to the formation of HCO_{2ads}. The variation of the reduction potential of carbon dioxide in DMSO with water content supports this hypothesis (28). For this case, the first step was proposed as the combination of Eq. [4] and Eq. [5] into a single step (26). When a more detailed analysis (which includes adsorption characteristics of the intermediate) is made, it is found that the experimental results (Tafel slope and reaction orders of carbon dioxide) are best explained when the intermediate is assumed to undergo activated adsorption according to the Temkin isotherm (26).

The intermediate may, however, not always be an adsorbed species with a large coverage. In another study (29) the intermediate (generated by a modulated cathode potential at a lead electrode) was found to be the carbon dioxide anion radical, CO_2^-. The technique of modulated specular reflectance spectroscopy was used to detect the presence of this radical by its optical absorption. The optical response of this radical indicated that it undergoes a rapid chemical reaction and that the amount calculated to be present would only form 2% of a monolayer.

The energy efficiency, ϵ, for the reduction of carbon dioxide to formic acid can be expressed in the following manner

$$\epsilon = \frac{\Delta H \times (\text{percent faradaic efficiency})}{n\mathbf{F}\{E_{rev} + \eta_c + \eta_a + \eta_{IR}\}} \quad [7]$$

where $\Delta H = 64.4$ kcal/mole and E_{rev} is 1.43V for the reaction $CO_2(g) + H_2O(l) \rightarrow HCOOH(aq) + \frac{1}{2} O_2(g)$. In a neutral solution (100% faradaic efficiency for formate production) a current density of 1 mA/cm² on mercury requires an overpotential, η_c, of 1.15V (see Fig. 3). Using a value of 0.5V for the value of the overpotential for oxygen evolution at the anode and neglecting all *IR* losses a value of 45% is obtained for ϵ. In a practical cell (with *IR* losses), the value of ϵ would be much less. The efficiency has been found to decrease with current density for a given electrode (12, 14, 30). In one series of experiments (12), a cell potential of 3.5V gave the highest coulombic efficiency (81.5%), at the lowest current density of 20 mA/cm². This yielded an energy efficiency of ~33%.

In order to improve the energy efficiency, it is necessary to test other electrode materials. Recently a number of sp metals (Zn, Pb, Sn, In, and Cd) have been tested as electrocatalysts for the reduction of carbon dioxide (30). The highest faradaic efficiency (92%) for formic acid production was obtained using an In electrode at a current density of 2.9 mA/cm² in 0.1*N* Li_2CO_3 electrolyte. On In, the overpotential is 400 mV lower than on a Hg electrode at the same current density.

Electrochemical reduction of formic acid.—The reduction of formic acid to methanol was carried out at both lead and tin electrodes. Product analysis revealed no detectable amounts of formaldehyde. Table II shows

Table II. Faradaic efficiency for formic acid reduction to methanol on lead (area of electrode, 50 cm^2) in 0.1*N* $HClO_4$ at 25°C

Experiment number	Range of working electrode potential, mV	Range of current, mA (average current density, $\mu A/cm^2$)	Time, hr	Charge, C	Number of moles, methanol		Percent faradaic efficiency
					Maximum	Expt.	
1	−900 to −1000	20 to 5 (155)	68	1900	0.00492	0.00059	11.9

the results of the experiments at a lead electrode using 0.1M formic acid in 0.1M perchloric acid electrolyte. The current efficiency varied from zero to a maximum value of 12% for methanol production. In the potentiostatically controlled experiments, a low current density (for maximum efficiency) was maintained by making periodic adjustments to the working potential (*vs.* SCE) in the range −900 and −1000 mV. In a number of galvanostatic experiments (experiment 3 is an example) carried out at higher current densities, the working potential was always below −1000 mV and no methanol was produced during the electrolysis. The results on lead are not very reproducible. This may be due in part to variations in the chemical polishing procedure of the electrode surface prior to each experiment. In some experiments, an anodic potential was applied in a preelectrolysis step, but this procedure did not appear to stabilize the electrode surface in a way that would lead to consistent results.

Higher efficiencies and stable currents were obtained when the lead electrode was replaced with an electroetched tin electrode (Table III). The electrolyte (0.25M HCOOH + 0.1M $NaHCO_3$) is a formic acid/sodium formate solution buffered to a *p*H of about 3.8. In this case, good results (up to ~100% efficiency) are obtained only in a narrow potential region (with a lower limit of about −720 mV) where the average current density is less than 4.0 $\mu A/cm^2$ (experiments 5, 6, 7, and 9). In some of these potentiostatically controlled experiments, it was necessary to lower the potential occasionally in order to maintain a small electrolytic current density. In galvanostatic experiments (experiments 2, 3, and 4), where the working potential remained below −720 mV throughout most of the electrolysis (the initial potential is given in parentheses), no methanol was produced. In previous work (20), the 100% efficiency reported initially was obtained at a current density of 5 $\mu A/cm^2$, corresponding to a potential of −990 mV *vs.* SCE. In the present experiments, the lower end of the potential region for a high efficiency is more positive by about 270 mV. This discrepancy may be due in part to differences in the surface preparation of the electrodes (higher surface area).

The energy efficiency in an electrolysis cell for formic acid reduction to methanol will be low because of the large overvoltage required at a low current density. The overvoltage has been estimated for the conditions found in experiment 7 (Table III) assuming that $HCOOH_{aq} + 4H^+ + 4e^- \rightleftarrows CH_3OH_{aq} + H_2Ol$ is the half-cell reaction. The equilibrium potential (*vs.* SCE) obtained for this half-cell reaction after 31.4C has passed through a cell containing 20 ml of solution (*p*H ~3.8) is ~ − 0.3V. This corresponds to an overvoltage of ~420 mV at a current density of 3.6 $\mu A/cm^2$.

The present results on both lead and tin electrodes, along with previous results on tin, indicate that the reduction of formic acid occurs in a narrow potential region. On the other hand, the reduction of carbon dioxide and formaldehyde (see following section) occurs over wide potential regions (on a mercury electrode) and are activation-controlled processes. It may be only a coincidence that the reduction of formic acid occurs near the pzc which for lead and tin (*vs.* NHE) are −0.69 and −0.35V, respectively (31). Although these values change somewhat with the electrolyte composition, the maximum efficiency for formic acid reduction occurs at a potential slightly below the pzc (~ 0.1V) on both lead and tin. In this case, the adsorption of formic acid molecules (assuming these are the electroactive species) would appear to be a necessary and potential-dependent step in the reduction mechanism. Further studies (measurement of pseudocapacitance using impedance techniques, etc.) will be required before the role of adsorption in formic acid reduction can be determined.

A number of suggestions have been made (20) for increasing the current density of formic acid reduction: (*i*) increase in the real surface area; (*ii*) increase in the temperature of the reaction; (*iii*) increase in the reaction rate by using metals with lower pzc (a good choice here is cadmium); and (*iv*) application of a pulsed potential profile by which the molecules adsorbed at a potential near the pzc are reduced much faster at a more negative applied potential.

Electrochemical reduction of formaldehyde.—The electrolytic reduction of formaldehyde to methanol occurs, with a better than 90% faradaic efficiency, in a basic solution (*p*H ~11). In each experiment, a 100 ml sample containing 0.1M H_2CO in 0.1M Na_2CO_3 was electrolyzed (~1000C passed through the cell) in the limiting current region (current density ~10 mA/cm^2, see Fig. 10). Product analysis showed that the efficiency

Table III. Faradaic efficiency for formic acid reduction to methanol on tin (area of electrode, 50 cm^2) in 0.1*N* $NaHCO_3$

8	−690	(3.0)	90	48.8		None	0
9	−700	(3.2)	30.5	17.4	0.0000451	0.0000416	92.2

for methanol production was 103 ± 10%. This value includes a correction for the small amount of methanol produced in the initial formaldehyde solution (Fig. 1). No indication was found for the formation of a dimerization-type product such as ethylene glycol.

The energy efficiency in an electrolysis cell for formaldehyde reduction to methanol is low because of the large overvoltage at a moderate current density. The overvoltage was estimated for the conditions found in one electrolysis experiment assuming that $H_2CO_{aq} + 2H^+ + 2e^- \rightleftarrows CH_3OH_{aq}$ is the half-cell reaction. The equilibrium potential (*vs.* SCE) for this half-cell reaction, after 965C were passed through a cell operated in the limiting current region ($E_w = -1.8$V *vs.* SCE), is ~ −0.6V. This gives an overvoltage at the cathode of 1200 mV for a current density of ~10 mA/cm^2.

Cyclic voltammetry experiments have been carried out in 0.11M formaldehyde solutions buffered at different *p*H values (6.8, 9.0, 11.1, and 13.0) at sweep rates from 10 mV/sec to 1000 V/sec. The results of these experiments are in basic agreement with those in a previous study (23). A small anodic peak appears in each solution at sweep rates higher than a threshold value. In contrast to the previous results, however, this anodic peak is found in a solution having a *p*H of 6.8. In this solution it is more easily observed at lower sweep rates where the double layer charging current is less. In addition the anodic peak does not disappear in a solution having a *p*H value greater than 9.5 for fast sweep rates.

The *p*H dependence of this peak is shown in Fig. 4 for a sweep rate of 50 V/sec. It is observed in a solution with a *p*H of 6.8 and 9.0 but not in a solution with a *p*H of 13.0. The threshold sweep rates (in volts/second) are approximately 2, 10, 50, and 100 for solutions having *p*H values of 6.8, 9.0, 11.1, and 13.0, respectively. This peak, which has a longer lifetime in the neutral solution, is most likely due to the oxidation of the radical intermediate and/or its anion. Any methanol formed during the cathodic sweep will not be oxidized at the potential of the anodic peak. A log-log plot of the anodic peak current, I_{PA}, *vs.* the sweep rate, v (volts/second), (Fig. 5), shows that $I_{PA} \propto v^{1/2}$ and the reaction is, thus, diffusion controlled at a *p*H of 9 and below. For *p*H 11 and above, the slope is greater than 0.5 and the amount of intermediate available for oxidation appears to be no longer entirely diffusion controlled. The cathodic peak current appears to be diffusion controlled in a solution buffered at a *p*H of 6.8. The dehydration rate of methylene glycol is relatively slow at this *p*H and the amount of formaldehyde available for reduction can be considered to be fixed during the time interval of an experiment carried out at fast sweep rates (5-500 V/sec). The transfer of formaldehyde molecules across the interphase region to the electrode surface results in a diffusion-controlled current. In a solution of higher *p*H, where the reaction rate for the formation of formaldehyde (either from methylene glycol or its anion) is increased, the amount of formaldehyde available for reduction can no longer be considered constant throughout the lifetime of the cyclic sweep. Instead, it appears that the current is limited by the reaction kinetics of the reduction process at fast sweep rates (100-1000 V/sec). This results in a decrease of the slope (for log I_{PC} *vs.* log v) with increase in *p*H to a value approaching zero in a solution with a *p*H of 13.

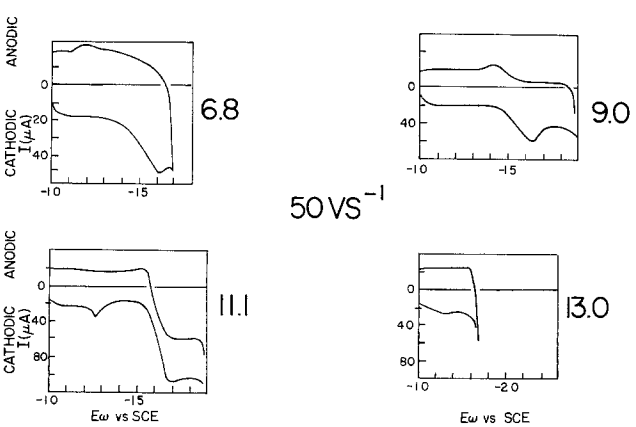

Fig. 4. Cyclic voltammograms obtained at a hanging mercury drop electrode (area ~0.22 cm^2) in 0.11M formaldehyde showing the *p*H dependence of the anodic peak. (An impurity cathodic peak appears in the solutions having a *p*H value of 11.1 and 13.0 in the −1.2 to −1.3V region). In order to observe whether an anodic peak is present in the high *p*H (13.0) solution, the current sensitivity is the same as in two of the other buffer solutions. At this amplification only the current trace in the −1.0 to −1.6V region is shown.

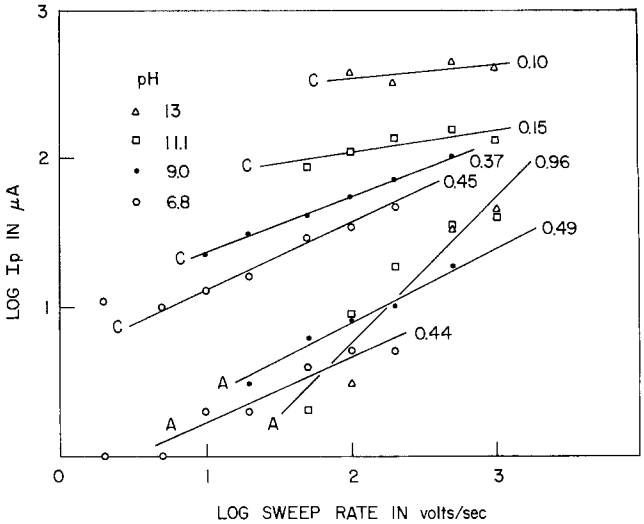

Fig. 5. Log-log plot of cathodic peak current, I_{PC}, and anodic peak current, I_{PA}, *vs.* sweep rate. The value of the slope is given to the right of each anodic line, A, and cathodic line, C. Any value of I_{PA} is one-tenth or less than the corresponding value of I_{PC} and is much less than the double layer charging current at higher sweep rates. As a result, there is more scatter in the data used for the anodic plots. For a *p*H of 11.1 and 13 a line with a slope of 0.96 is shown, whereas a lower value is probably more realistic.

The Tafel slope is observed to decrease with an increase in the *p*H of the solution (Fig. 6). In addition, it can be seen that the limiting current is not a simple function of the solution *p*H over the range of values examined here. In one solution (*p*H 13.0) the limiting current peaks and then it decreases somewhat at higher potentials. This observation may be explained by the mechanism (Eq. [1] and [2]) which accounts for the high *p*H behavior of the limiting current. The rapid generation of hydroxyl ions as the current density increases would momentarily increase the *p*H value in the double layer region. This causes a decrease in the amount of formaldehyde available for reduction (Eq. [2]).

The effect of *p*H on the Tafel slope, along with the cyclic voltammetry results, may be explained in terms of a mechanism change for formaldehyde reduction. The observed Tafel slopes fall in the range of 66-36 mV. The first electron transfer step is therefore not rate determining. A value of 60 mV is expected for the Tafel slope (under conditions of Langmuir adsorption) in the CECE mechanism (Fig. 7) if step 3 is rate determining. A value of 66 mV was observed for the Tafel slope in a neutral solution (*p*H = 6.8). However, step 4 may be the rds. In this case, the radical intermediate and its anion must be stabilized in order for the quasi-equilibrium condition to hold for all except the rds. A fast protonation reaction would produce an intermediate that is more easily stabilized than the

radical anion. Under these conditions, step 4 (with a 40 mV Tafel slope) would be the rds. Temkin adsorption could then account for the increase in Tafel slope observed here. The oxidation of the radical intermediate and/or its anion is controlled by the rate of diffusion of the radical species away from the electrode surface in solutions with a *p*H of 6.8 and 9.0. With increase in *p*H, a second charge transfer step, prior to the chemical reaction is favored due to the decrease in the hydrogen ion concentration and to an increase in the negative electrode potential. A charge transfer to the radical anion should occur at a slower rate since the radical already has a negative charge. However, the experimental results indicate that this electron transfer occurs at a relatively fast reaction rate. The anodic peak is more stable in a neutral solution, since it is observed at a slower sweep rate. The absence of this peak at the slow sweep rates (in the higher *p*H solutions) indicate that a second electron transfer can compete with the protonation reaction to produce a dianion

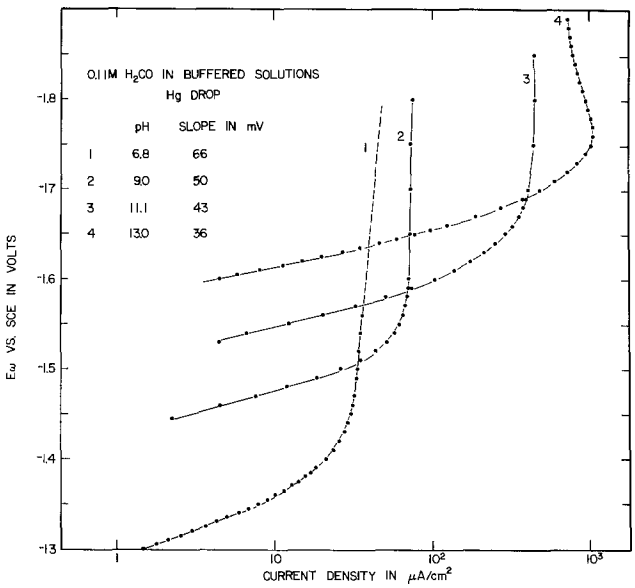

Fig. 6. Effect of *p*H on the Tafel slope. These polarization curves were obtained from the cyclic voltammetry experiments carried out at a 10 mV/sec sweep rate at a hanging mercury drop electrode where the hysteresis is small.

of methanol. Although this species is not expected to be adsorbed at the electrode surface, it may be partially stabilized by one of the adsorbed species. This is necessary if the quasi-equilibrium condition is to hold for step 3 of the CEEC mechanism. In this case, the following chemical reaction (step 4 of the CEEC mechanism, Fig. 8) is the rds with a Tafel slope of 30 mV expected under conditions of Langmuir adsorption. A Tafel slope of 36 mV was observed in a solution with a *p*H of 13.0. The anodic peak current should then result from a diffusion-controlled process. The experimental results (Fig. 5) are not clear in the high *p*H solutions. If the reduction current is limited at fast sweep rates by the reaction kinetics, then a change in the slope, from a value of 0.5 of the I_{PA} *vs.* v plot would be expected. Interactions of the methanol dianion with adsorbed species and/or its repulsion from the double layer region could also affect the slope. In addition to the possibility that changes in the solution *p*H modify the reaction kinetics causing a change in mechanism, an indirect effect may result from a change in the composition of adsorbed species with *p*H. This can influence the Tafel slope through interactions with the electroactive species. The observed values of the Tafel slope are somewhat larger than the values expected under conditions of Langmuir adsorption. Evidence for Temkin adsorption, which could account for the larger values, was found in the steady-state measurements as discussed below.

Steady-state polarization curves were obtained with solutions containing different formaldehyde concentrations (*p*H ~11.3). Some variation of the Tafel slope was observed in different runs on a given sample (Fig. 9). In the first run, the current stabilized quickly above −1.56V but at points below this potential, the current increased slowly for some time before reaching a steady value. Current readings obtained before steady-state conditions gave a low value for the Tafel slope. A 2-3 hr preelectrolysis, carried out prior to the first run, may have conditioned the electrode surface with various adsorbed species. Steady current values were obtained over the entire potential range in the second and third run. In these experiments, a 10% error can be expected in measuring the value of the Tafel slope under steady current conditions. The effect of concentration on the Tafel slope is shown in Fig. 10. Good agreement is obtained for the value of the Tafel slope in the 0.11M solution (47 mV) with the previous result (43 mV) near the same *p*H value at the mercury drop

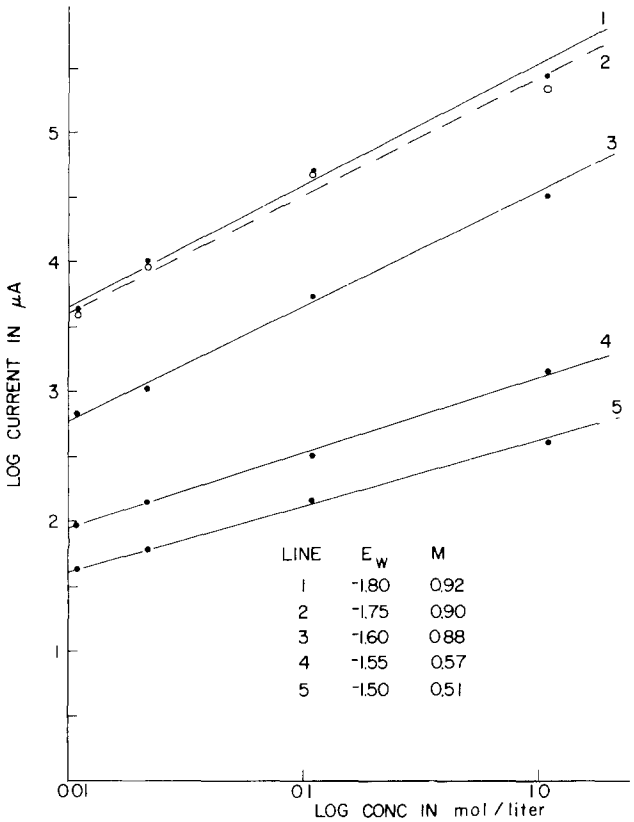

Fig. 11. Reaction order for formaldehyde reduction in the Tafel and limiting current regions obtained from steady-state polarization curves (Fig. 10).

electrode (Fig. 6). The value of the Tafel slope was found to decrease from 60 to 37 mV when the concentration of formaldehyde was increased by a factor of one hundred (0.011-1.09M). Adsorption effects may be partly responsible for this large decrease. A similar though smaller decrease in slope (9 mV) was observed in the reduction of acetophenone (32) at a mercury electrode in a methanol + sulfuric acid solution, containing a small amount of water when the concentration of acetophenone was increased by a factor of 10 (0.045-0.46M). The change in Tafel slope is attributed to adsorption effects.

The reaction order for formaldehyde reduction (Fig. 11) over the above concentration range is close to the expected value of one (0.92) in the limiting current region, but it aproaches a value of one-half in the Tafel region. A fractional reaction order indicates that the coverage, θ, by formaldehyde or an intermediate species is controlled by Temkin adsorption. The reaction order in the limiting current region should be independent of the reaction mechanism. It might be argued, however, that the decrease observed in the Tafel slope indicates a change in the reaction mechanism or a change in the rds (of a given mechanism) when the concentration is increased. Thus, it may not be valid to determine the reaction order over the entire concentration range. However the reaction order remains fractional and constant for a given working potential so that regardless of any mechanism change that might occur with increase of concentration the experimental results most likely indicate conditions for Temkin adsorption over the entire concentration range examined at a pH of 11.3. Temkin adsorption should occur over a wide range of pH values. Some evidence for this was given above.

Coverage by the adsorbed species, formaldehyde, and/or an intermediate, increases with the logarithm

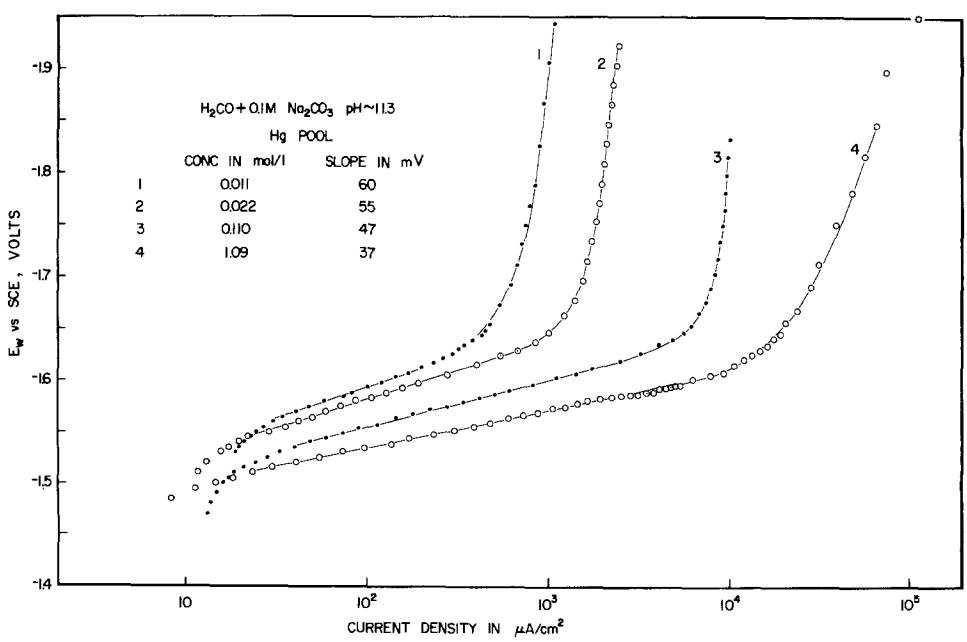

Fig. 10. Steady-state polarization curves for formaldehyde reduction showing the effect of formaldehyde concentration on the Tafel slope for solutions with a pH of 11.3. The curves have been corrected for *IR* effects.

of the concentration under conditions for Temkin adsorption. In addition, coverage by the much smaller amounts (mole percent) of the large species (polyoxymethylene glycols) present in solution may be increased at higher formaldehyde concentrations by preferential adsorption under Langmuir conditions, where the coverage is proportional to the concentration. Coverage by the adsorbed species will increase substantially as the formaldehyde concentration increases by a factor of 100. Normally, the Tafel slope would not be expected to change if this change in coverage remains within the Temkin region. The Tafel slope decreases almost linearly with the logarithm of the concentration (Fig. 12). If the coverage by formaldehyde molecules is predominant, then the decrease in the Tafel slope indicates an attraction between a formaldehyde molecule and nearby adsorbed species. However, the fractional reaction order, the presence of an anodic peak in cyclic voltammetry experiments, and the relatively low Tafel slope values suggest that coverage in the Temkin region is primarily due to an intermediate.

A change in coverage can affect the Tafel slope in a number of ways: (*i*) The adsorption kinetics may change with the increased coverage in such a way that a different step in the reaction mechanism becomes rate determining, and results in a lower value of the Tafel slope. (*ii*) A change in the energy of adsorption may accompany the increase in coverage. The standard free energy (for a coverage equal to θ) when an interaction occurs among the adsorbed species is given by

$$\Delta G^\circ_\theta = G^\circ_{\theta=0} + \alpha r\theta \qquad [8]$$

where r is the interaction parameter and $\alpha < 1$ for activated adsorption and $\alpha = 1$ for nonactivated adsorption (33). A decrease in Tafel slope, with an increase in coverage, requires that a change from activated to nonactivated adsorption occurs. (*iii*) A change in the number of water molecules displaced during the adsorption of the electroactive species will affect the Tafel slope (34). A decrease in Tafel slope requires that the number of water molecules displaced during the adsorption process decreases with increase in concentration (coverage). Small amounts of polyoxymethylene glycols adsorbed on the electrode surface could influence the adsorption process and hence the Tafel slope through interactions with formaldehyde and/or its intermediates. Measurement of double layer and adsorption capacitance will help determine the role of adsorption in the mechanism for formaldehyde reduction.

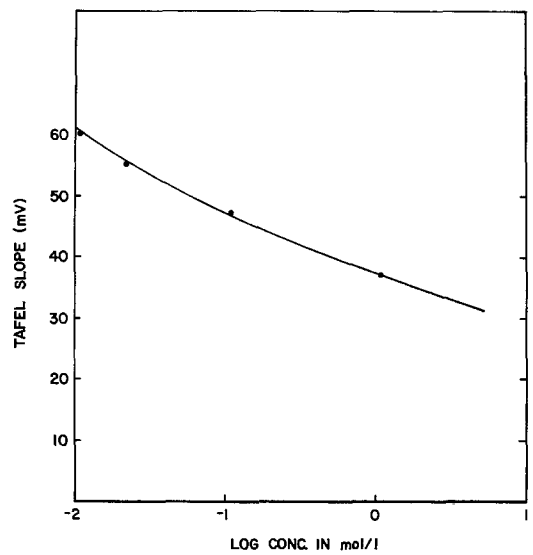

Fig. 12. Change in Tafel slope with formaldehyde concentration

Conclusions

Some conclusions can be made based on the results of this study: (*i*) It is difficult to find conditions for the direct electrochemical reduction of carbon dioxide to methanol. The reduction of carbon dioxide and formaldehyde occur readily in neutral and basic solutions, respectively, while formic acid reduction (assuming the molecule to be the electroactive species) requires an acid or buffered acid solution. (*ii*) The reduction of carbon dioxide to formic acid can be carried out quantitatively on sp-metals having high overpotential for hydrogen evolution at an estimated maximum energy efficiency of ~45% (on Hg). (*iii*) The reduction of formic acid to methanol is difficult to carry out simultaneously at a high faradaic efficiency and high current densities due to the limited potential region for formic acid reduction. (*iv*) The reduction of formaldehyde to methanol was carried out quantitatively on Hg at a current density of ~10 mA/cm^2. The Tafel slope was observed to decrease with an increase in concentration (at constant pH) and with an increase in pH (at constant concentration). The adsorption of polyoxymethylene glycols, which is both concentration and pH dependent, may cause changes to occur in the Tafel slope through interactions with formaldehyde and/or intermediate species.

ABSTRACT

This study describes the combined use of a-c impedance and fast flow techniques to elucidate the mechanism of the fluoride solid-state electrode. By describing fast flow data in the complex frequency Laplace plane and correlating it with a-c impedance data, it has been possible to separate interfacial and mass transport contributions to over-all electrode behavior; and describe the manner in which the electroactive species modifies individual reaction steps. Using this, a preliminary mechanism for the fluoride solid-state electrode involving heterogeneous F^- exchange reactions at two types of sites, one involving electronic and the other ionic conduction, is presented.

Various experimental methods are described for the study of electrode processes of ion-sensitive electrodes. These methods may be classified according to the type of input function applied to an electrochemical cell built up from the electrode of interest and a suitable nonpolarizable reference electrode immersed in an appropriate test solution.

As shown in Table I, two types of experiments may be used. One type of experiment deals with the study of the response signal measured as a function of time when a well-known electrical signal (the driving force or excitation function) is applied to the cell. For example, phase and impedance measurements using small sinusoidal input voltages were employed in this study. The system frequency response is usually represented in a Cole-Cole diagram in the complex plane. From experimental data in a frequency range from 10^{-3} up to 10^5 Hz for various concentrations of the electroactive species an equivalent circuit for the test electrode is obtained. The transfer impedance for this equivalent circuit can be calculated and so the behavior of the system with regard to a specified input is characterized. Physicochemical phenomena associated with the electrode processes are then interpreted in terms of diffusion, double layer, and space charge impedances (1-6).

The second type of experiment deals with the measurement of the transient signal caused by a rapid concentration change of the electroactive species around the sensor surface using fast flow techniques. From these experiments a dynamic response equation for the sensor is obtained. Based on experimental data, rate-limiting processes, as for instance solvation-desolvation (7), adsorption (8), and diffusion (9), were proposed. However, it should be pointed out that the mathematical form of the semiempirical response equation may lead to an erroneous interpretation of the rate-limiting process (10).

As the electrochemical behavior of a sensor is characterized by its transfer function, both types of experiments must supply information about the rate-limiting

* Electrochemical Society Active Member.
Key words: selective electrode, impedance measurements, fluoride.

Table I. Study of electrode processes: mechanistic studies

Method	Driving force	Example	Result
1	Electrical signals of small amplitude excursion	Phase-impedance measurements (10^{-3}-10^{5} Hz)	Linearized electrical equivalent model and transfer impedance
2	Concentration gradients of the electroactive species	Dynamic response studies (fast flow injection experiments)	Transfer function and transfer impedance

process. Nevertheless, fast flow experiments should supply information only about the interfacial process. Indeed, due to the high linear flow rates, the thickness of the hydrodynamic layer is reduced to a minimum (11). Therefore little or no data concerning a Warburg-type process are available from kinetic measurements under these conditions. Moreover, time constants associated with macroscopic electrode kinetics are large compared with those obtained from impedance measurements in a higher frequency range and which are related mainly to space charge impedances. Therefore, a comparison and/or correlation of the results of both kinetic and impedance measurements is valid only in the time constant range obtained in fast flow experiments.

The present paper deals with the equivalent model and rate-limiting processes of the ORION 94-09A electrode. Fast flow studies (11) and impedance measurements (12) were performed. By conversion of the dynamic response equation from fast flow studies into the Laplace domain, the transfer function for this sensor will be calculated. As the transfer function arising from linear networks must be rational, a rational approximation of the experimental and irrational transfer function will be made so that a reasonable comparison of fast flow and impedance data can be made. Making then simple assumptions about the excitation function applied in fast flow studies allows the transfer impedance for the intermediate frequency range to be calculated.

Both transfer impedances or equivalent circuits, one obtained from impedance measurements, the other from fast flow kinetics, contribute to the physicochemical interpretation of the interfacial sensor process.

Experimental Results from Fast Flow Kinetics and Impedance Measurements

The results of kinetic fast flow experiments were reported in a previous paper (11). They revealed that the dynamic response of new fluoride electrodes with an internal reference system of the wick type can be represented by a hyperbol

$$E_t = \frac{t}{a + bt} \qquad [1]$$

where a and b are constants and $t_{50} = a/b$ (*i.e.*, the time required to reach 50% of the steady-state potential); E_t = potential as function of time; $E_{t=0} = 0$, $E_{t=\infty} = 1/b = S \log a_2/a_1$; S = slope of the indicator electrode; and a_1 and a_2 = initial and final concentration of the jump.

The striking discrepancy in rate of response between fast flow and continuous auto analyzer systems (11) is attributed to a rate-limiting film diffusion process in the hydrodynamic layer when the sensor is mounted in a sample processor. In fast flow experiments this layer is reduced to a minimum and hence the response is fast.

From impedance measurements in a range 10^{-3} up to 10^5 Hz, the locus for the same electrode was obtained (12). It is shown in Fig. 1. Three parts can be distinguished. The high frequency and perfect semicircle is due to space charge and to geometrical and wiring impedances. The lowered semicircle is attributed to a slow interfacial charge transfer represented by a time constant related to an apparent transfer resistance and a double layer capacitance. The influence of the concentration of the potential-determining ion on this part of the complex plane plot is obvious. Egorov and Novell'skii (13) proved that a depressed semicircle is also obtained for a series of two parallel networks with R and C of the same order of magnitude.

The very low frequency part of the complex plane plot is characteristic for a film diffusion process. If the slope equals one, it can be interpreted as a Warburg impedance. Deviations from unity slope are attributed to adsorption of intermediate species or to a nonlinear diffusion path at the interface. The latter is related to the surface structure of the membrane, which is far from ideal as was shown by microscopic examination.

Mathematical Treatment of the Dynamic Response Equation

Laplace transform of the dynamic response $r(t)$ of an electrical network to a known excitation function $x(t)$ yields

$$R(s) = G(s) \cdot X(s) \qquad [2]$$

where $R(s)$ = response in the s-domain, s = Laplace variable; $G(s)$ = transfer function of the network; and $X(s)$ = excitation in the s-domain.

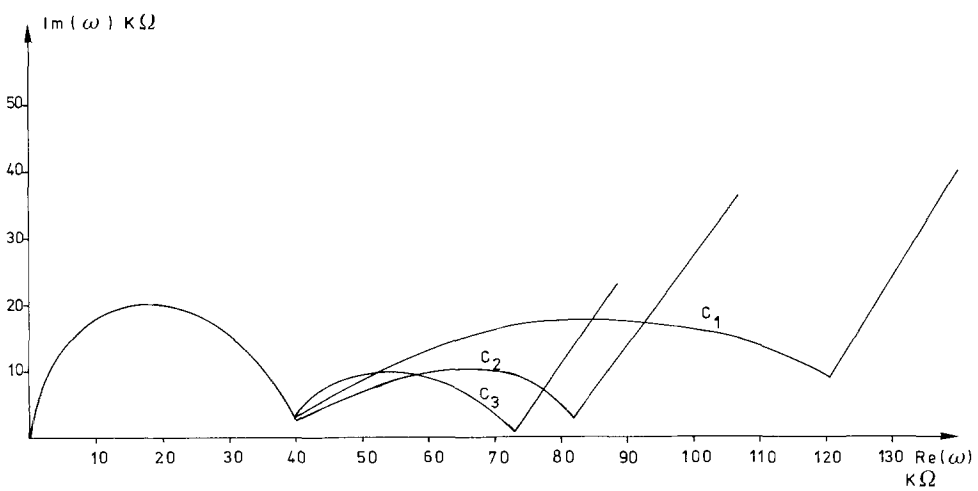

Fig. 1. Indication of the fluoride electrode (Orion 94-09A), influence of the concentration.

With Eq. [1], one obtains

$$R(s) = \mathcal{L}\left\{\frac{t}{a+bt}\right\} = \frac{1}{bs}\cdot\left\{1-\frac{as}{b}\cdot e^{as/b}\cdot E_1\left(\frac{as}{b}\right)\right\} \quad [3]$$

where $E_1(as/b)$ is the exponential integral.

As $1/bs$ represents a step input excitation with amplitude $1/b$, one may put

$$X(s) = \frac{1}{bs} \quad [4]$$

and

$$G(s) = 1-\frac{as}{b}\cdot e^{as/b}\cdot E_1\left(\frac{as}{b}\right) \quad [5]$$

As the transfer function must be rational, an appropriate rational approximation of Eq. [5] must be applied. According to Hastings (14) and with $x = as/b$

$$x\cdot e^x\cdot E_1(x) = \frac{x^2+a_1x+a_2}{x^2+b_1x+b_2}+\epsilon(x) \quad [6]$$

where $|\epsilon(x)| < 5\cdot 10^{-5}$; $a_1 = 2.334733$; $a_2 = 0.250621$; $b_1 = 3.330657$; and $b_2 = 1.681534$.

Neglecting the correction term $\epsilon(x)$ and introducing the numerical values for a_1, a_2, b_1, and b_2 yields

$$G(s) \cong K\cdot\frac{(s+\alpha)}{(s+\beta)(s+\gamma)} \quad [7]$$

with $K = b/a$, $\alpha = 1.43\ b/a$, $\beta = 0.63\ b/a$, and $\gamma = 2.71\ b/a$.

As β and γ are positive, $G(s)$ is the transfer function of a stable network. $G(s)$ is a function of a/b, the half-time potential, *i.e.*, the time required to reach 50% of the steady-state potential $1/b$, and which is an experimental datum. In Fig. 2 the relation between the irrational transfer function and its rational approximation is represented. The agreement is excellent.

Equation [7] may be used either to evaluate an exponential form of the hyperbolic response (Eq. [1]) or to calculate the frequency response of the sensor. The first is accomplished by multiplying Eq. [7] by $1/bs$ (for a step input excitation) and applying an inverse Laplace transform

$$E_t = \frac{t}{a+bt} \cong \mathcal{L}^{-1}\left\{\frac{1}{bs}\left(\frac{K(s+\alpha)}{(s+\beta)(s+\gamma)}\right)\right\} \quad [8]$$

$$= K_0 - K_1e^{-\beta t} - K_2e^{-\gamma t} \quad [9]$$

and $K_0 = 0.851$, $K_1 = 0.226$, $K_2 = 0.625$, $1/\beta = 0.369\ a/b$, and $1/\gamma = 1.613\ a/b$.

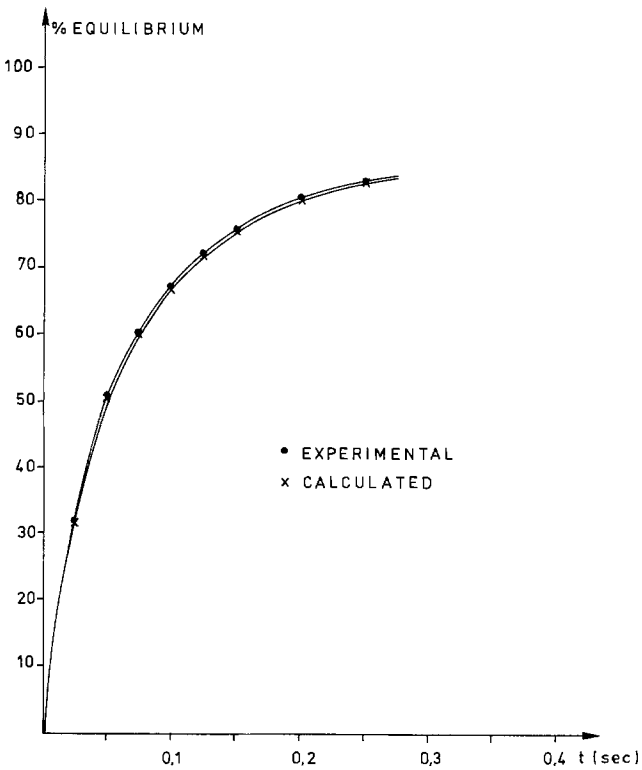

Fig. 3. Concentration jump $10^{-5} \rightarrow 10^{-3}$M F^- in 1/3 TISAB

In Fig. 3 the experimental hyperbolic dynamic response and its calculated exponential approximation for a concentration jump 10^{-5}-10^{-3}M NaF in 1/3 TISAB (total ionic strength adjustment buffer) is shown. As the thickness of the hydrodynamic layer is practically zero in the experimental conditions, the existence of two time constants $1/\beta$ and $1/\gamma$ of the same order of magnitude are most likely associated with interfacial processes. The transfer function $G(s)$ (Eq. [7]) suggests two parallel first-order processes as rate-limiting phenomena. These could be, for instance, exchange reactions of F^- anions at the interface at two types of exchange sites. For LaF_3 crystals doped with Eu(II), these might be

1. $(EuF_2)_c + F^-{}_s \rightarrow (EuF_3)_c + e^-$ (electronic conduction) [10]
2. $(LaF_3)_c + [\,] \rightarrow (LaF_2)^+{}_c + [F^-]$ (ionic conduction) [11]

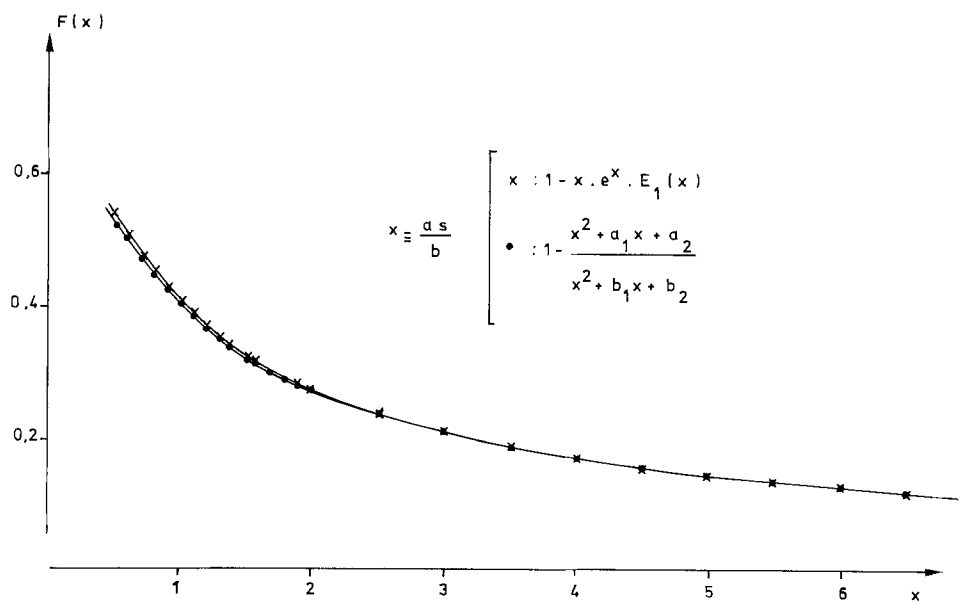

Fig. 2. Rational approximation of the transfer function.

$$(LaF_2)^+_c + F^-_s \rightarrow (LaF_3)_c \quad [12]$$

where c = crystal, s = solution, and [ ] = lattice vacancy.

The first can be interpreted as a semiconductor behavior with a deep donor level of Eu(II), *i.e.*, 0.41 eV energy gap between donor and conduction levels (12). The second reaction involves a crystal F^- anion to jump into a lattice vacancy near the crystal surface followed by the exchange of a F^- with the solution. The fluoride initially trapped in the vacancy then contributes to the ionic conduction of the crystal. To the credit of this mechanism is the remarkable coincidence that the hyperbolic response also holds for other electrodes, *i.e.*, the Ag_2S electrode (15), which exhibit both ionic and electronic conduction (16). Resistance measurements as a function of increasing temperature show increasing conductance in both cases. Therefore the contribution of both types of conduction can be possibly evaluated by Hall effect measurements as a function of frequency or by the square wave method applied by Koebel *et al.* (16).

The calculation of the frequency response of the electrode at lower frequencies can also be done by means of the transfer function $G(s)$ (Eq. [7]), obtained from kinetic fast flow experiments.

Writing the excitation function $1/bs$ as

$$\frac{1}{bs} = \frac{i}{s} \cdot R \quad [13]$$

i.e., the step input voltage excitation is formally treated as the product of a step input current i/s multiplied by a resistor R. Therefore

$$R(s) = \frac{i}{s} \cdot \frac{K \cdot R \cdot (s+\alpha)}{(s+\beta)(s+\gamma)} \quad [14]$$

and the transfer impedance $Z(s)$ is given by

$$Z(s) = \frac{K \cdot R \cdot (s+\alpha)}{(s+\beta)(s+\gamma)} \quad [15]$$

which means that the response in the s-domain is given by the product of a step input current i/s and the transfer impedance $Z(s)$. For low frequencies $s = j\omega \cong 0$. Therefore, neglecting the influence of the concentration change on the transfer resistance

$$Z(o) = \frac{K \cdot R \cdot \alpha}{\beta \cdot \gamma} = R_t \quad [16]$$

with R_t the total transfer resistance. As $K\alpha/\beta \cdot \gamma \simeq 1$, R equals the total transfer resistance as obtained from impedance measurements (see Fig. 1). As a lowered semicircle is the result of two parallel RC networks in series, the components of these networks can be evaluated by identifying the corresponding terms in the expressions [15] and [17]

$$Z(s) = \frac{C_A + C_B}{C_A \cdot C_B} \cdot \left\{ \frac{S + \dfrac{R_A + R_B}{R_A \cdot R_B (C_A + C_B)}}{\left(S + \dfrac{1}{R_A C_A}\right)\left(S + \dfrac{1}{R_B C_B}\right)} \right\} \quad [17]$$

For the given example, the result is represented in Fig. 4. Moreover, the dynamic response to a current step input is a hyperbola and in addition, the values of R_t, K, α, β, and γ allow the complex plane response to be calculated by means of the well-known formulas for phase angle $\phi(j\omega)$ and magnitude $|Z(j\omega)|$

$$\phi(j\omega) = \tan^{-1}\left(\frac{\omega}{\alpha}\right) - \left[\tan^{-1}\left(\frac{\omega}{\beta}\right) + \tan^{-1}\left(\frac{\omega}{\gamma}\right)\right] \quad [18]$$

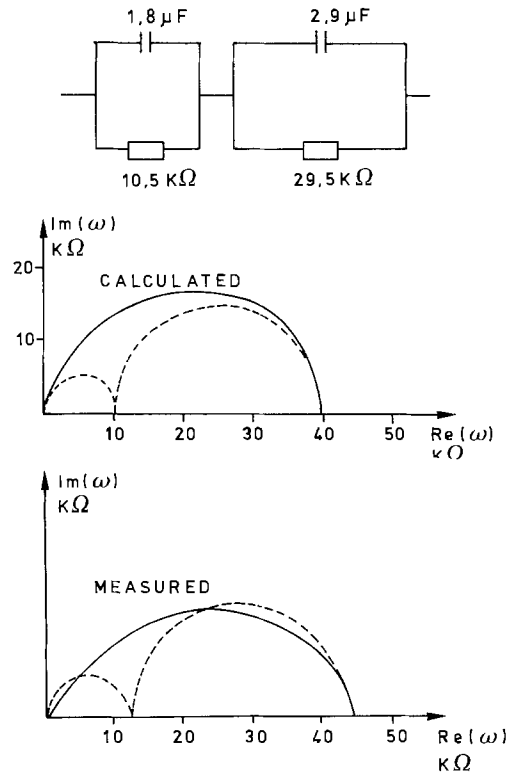

Fig. 4. (a, top) Equivalent circuit. (b, center) (c, bottom).

$$|Z(j\omega)| = R_t \cdot K \cdot \frac{\sqrt{\omega^2 + \alpha^2}}{\sqrt{\omega^2 + \beta^2} \cdot \sqrt{\omega^2 + \gamma^2}} \quad [19]$$

The result is a lowered semicircle which is known to be the result of two perfect semicircles.

Conclusion

From impedance measurements (12) in a frequency range 10^{-3}-10^5 Hz we concluded that the equivalent circuit of the 94-09A fluoride electrode involves: (*i*) a parallel RC network representing space charge and geometrical impedances (R = 100 kΩ, C = 100 pf), (*ii*) a diffusion impedance which is not a pure Warburg impedance due to complex diffusion at the surface, and (*iii*) a series of two parallel RC networks representing double layer capacitance and transfer resistance at both sides of the membrane.

From the present discussion it is obvious that both kinetic fast flow studies and a-c impedance measurements do inform about the rate-limiting process at the electrode-solution interface as evidenced by the lowered semicircle of the complex plane response. Mathematical treatment of kinetic fast flow data allows the evaluation of double layer capacitance and charge transfer resistors and hence allows the elucidation of the electrode process to a greater extent.

An Electrochemical Study of Flavin Adenine Dinucleotide

Robert D. Braun*[1]

Department of Chemistry, Vassar College, Poughkeepsie, New York 12601

ABSTRACT

Flavin adenine dinucleotide (FAD) is examined using polarography, cyclic voltammetry, and controlled potential coulometry. At *p*H less than 6.5 and at *p*H greater than 10, the reaction proceeds in two single electron steps through the semiquinone. At intermediate *p*H the reaction consists of a preceding hydrogen ion addition followed by a two-electron transfer which in turn is followed by a second hydrogen ion addition.

The flavins are an important class of biochemical compounds which are found in both plants and animals. Due to their importance, most of the flavins have been the subject of many studies. In particular isoalloxazine, lumichrome, lumiflavin, riboflavin, and flavin mononucleotide (FMN) have been thoroughly investigated and excellent reviews of these studies are available (1, 2). Although flavin adenine dinucleotide (FAD) occupies a key position in the respiratory transport chain (2), relatively few electrochemical studies of this compound are available (3, 4). These electrochemical studies consisted entirely of polarographic examinations at the dropping mercury electrode (DME). No successful attempt has been made to unravel the electrochemical reaction mechanism or to examine the kinetics of the reaction. In the present study polarography, controlled potential coulometry, cyclic voltammetry, and voltammetry at a rotating platinum disk electrode have been used to study the electrochemical reaction mechanism of FAD throughout a broad *p*H range in aqueous solution.

Experimental

Chemicals.—FAD was obtained from the Sigma Chemical Company and used without further purification. The manufacturer's assay listed the purity of the FAD as 95%. Spectrophotometric analysis at 450 nm assuming a molar absorptivity of 1.13×10^4 l mole^{-1} cm^{-1} (5) resulted in a calculated purity of 92% (14 trials). Any impurity in the FAD was not electroactive within the potential region used in this study. All other chemicals were reagent grade.

Buffer solutions were prepared to be 0.1*M* in their minor constituent except for the *p*H 2.1 HCl solution and the *p*H 11 or greater sodium hydroxide solutions. The ionic strength of each buffer solution was adjusted to 0.5M with KCl except for the *p*H 7.5 Tris buffer and the *p*H 10.0 and 10.2 carbonate buffers which had ionic strengths of 0.8, 0.8, and 1.3*M*, respectively. The buffer solution components were HCl at *p*H 2.1, acetic acid and sodium acetate at *p*H 4-5.1, potassium hydrogen phthalate and sodium hydroxide at *p*H 5.9, potassium dihydrogen phosphate and dipotassium hydrogen phosphate at *p*H 6-8, tris (hydroxymethyl) aminomethane (Tris) and HCl between *p*H 7.5 and 9.2, potassium hydrogen carbonate and potassium carbonate between *p*H 8 and 10.2, and NaOH at *p*H greater than 11.

Apparatus.—Experiments were performed using a Beckman electroscan 30 in its controlled potential mode equipped with an electroscan 30P integrator which was used to integrate the area under controlled potential coulometry current-time curves. The output pulses from the integrator were counted with a Heathkit IM-4100 counter.

Rotating platinum disk electrode (RPDE) studies were performed at 1800 rpm (Sargent synchronous rotator). Cyclic voltammetry experiments were carried out at a hanging mercury drop electrode (HMDE). Polarographic studies were carried out at a conventional dropping mercury electrode (DME). The reference electrode was a saturated calomel electrode (SCE). The auxiliary electrode was made of platinum foil.

All experiments were carried out at 25° ± 0.5° in either a water-jacketed, three-compartment cell, or in a commercially available water-jacketed cell with accompanying cell top (Princeton Applied Research 9300 and 9350). In either case separation between the compartments was effected by medium porosity glass frits and salt bridges containing saturated KCl in agar gels.

Solutions were deaerated prior to examination with Linde high purity dry grade nitrogen which was passed through two wash towers containing acidic ammonium metavanadate and amalgamated zinc, and a final wash tower containing distilled water (6a). All *p*H measurements were made with a Radiometer PHM62 *p*H meter.

Results and Discussion

A cursory polarographic examination of FAD shows a single cathodic wave throughout the *p*H range 2-13. A plot of $E_{1/2}$ *vs.* *p*H yields three straight-line portions corresponding to Eq. [1], [2], and [3] for the acidic, neutral, and basic regions, respectively. The two inflection points in the

Key words: polarography, cyclic voltammetry, coulometry.

$$E_{1/2} = -0.010\text{-}0.0646\,pH \quad [1]$$

$$E_{1/2} = -0.205\text{-}0.0342\,pH \quad [2]$$

$$E_{1/2} = 0.056\text{-}0.0604\,pH \quad [3]$$

plot occurred at pH of 6.4 and 10.0 in fair agreement with previously reported values (3, 4). The first inflection point in the $E_{1/2}$-pH curve has been attributed to the acid dissociation constant of the reduced form of FAD and the second inflection point to the dissociation constant of the oxidized form (1, 3). In the acidic region the slope of the $E_{1/2}$-pH curve was found to be −0.065 V/pH unit. Between the two inflection points in the curve the slope was −0.034 V/pH unit, and at pH greater than 10.1 the slope was −0.060. These values compare to slopes of −0.06, −0.03, and −0.06 reported earlier (3).

Controlled potential coulometry was carried out at several pH's and the results are shown in Table I. In each case the potential was adjusted to a position on the plateau of the polarographic wave and the electrolysis carried out to completion. Throughout the entire pH range a coulometrically calculated value of $n_{\text{redn.}}$ of 2 was obtained. The resulting reduction products were examined polarographically and in a few instances the potential was adjusted on the plateau of the reduced FAD anodic wave and exhaustive electrolysis carried out. The coulometrically calculated values of $n_{\text{oxdn.}}$ obtained in these oxidations are also listed in Table I. After each oxidation the products were examined polarographically and found to have exactly the same $E_{1/2}$ and i_d as did the original FAD sample, *i.e.*, the original FAD was regenerated with no loss to other possible products.

The values of $n_{\text{oxdn.}}$ obtained in basic solutions varied from 0.7 at pH 9.25 to a high value of 1.7 at pH 8.18. These values are all less than the expected coulometric value of 2.0, apparently as a result of air oxidation of the FAD reduction products. Even with nitrogen flowing through the cell it was found that in basic solution the reduced FAD reverts to FAD at a rate that is significant with respect to the relatively long times (about 1 hr) used for the controlled potential oxidations. The pseudo first-order rate constant for the conversion of the reduction products to FAD under the experimental conditions at pH 8.18 was estimated by measuring the increase in the diffusion current of the FAD wave with time and found to be 1.1×10^{-4} sec^{-1}. Consequently after 1 hr about 40% of the reduced substance reverts to FAD.

* The low $n_{\text{oxdn.}}$ values reported here are apparently due to relatively rapid air oxidation of the reduced FAD in alkaline solutions.

Rapid air oxidation of reduced FAD was not observed in solutions of pH 4.08. For convenience the remainder of this report is divided into sections corresponding to the pH range throughout which a particular reaction mechanism takes place

pH 6.6-8.6.—Careful polarographic examination (DME) of the FAD wave in this pH range revealed only a single cathodic wave. The "anomalous" wave at a potential more negative than the main wave observed by Ke (3) was not observed in this study.

A requirement of a reversible electrode reaction is that the half-wave potential of the oxidized species must be identical to that of the reduced species (6b). Half-wave potentials were obtained for the FAD reduction waves from plots of E *vs.* log $(i/i_d - i)$ at the point where the log term was zero. Half-wave potentials for the oxidation of reduced FAD were similarly obtained from plots of E *vs.* log $(i_d - i/i)$. Throughout the remainder of this paper these plots are referred to as log plots. In each case in this pH region the log plots were linear. The average difference between the half-wave potentials of FAD and reduced FAD at the pH's in this range was 0.012 ± 0.006V for five trials at differing pH. The uncertainty is expressed as the standard deviation. A "t" test for significance indicated that at the 90% probability level the confidence limit was identical to the standard deviation. Since the oxidized and reduced forms of FAD do not have identical $E_{1/2}$'s, this system cannot be classified as reversible in this pH range as has been done previously (3). The cathodic FAD wave does overlap with the anodic reduced FAD wave however and consequently this system is best described as quasireversible. A typical FAD cathodic wave and the corresponding reduced FAD anodic wave are shown in Fig. 1.

Slopes of log plots for reversible systems at 25° are given by Eq. [4]. The slopes of log plots obtained

$$\text{slope} = -0.059/n \text{ V/decade} \quad [4]$$

with FAD solutions are listed in Table II. The average

* Log plots are defined as plots of E *vs.* log $(i/i_d - i)$ on the rising portion of the cathodic wave.

slope throughout this pH range was −0.037. This value is closer to the value expected for a two-electron reversible process (−0.030) than to the value for a one-electron reversible process (−0.059). It should be noted that the values of the log plot slopes obtained in this study differ significantly from the value of 0.06 obtained at pH 7.4 by Ke (3). A similar examination of the anodic wave of reduced FAD at pH 8.2 revealed the slope to be 0.030 ± 0.003 (four trials) where the uncertainty is expressed as the standard deviation.

At pH 8.2, i increased linearly with increasing $h^{1/2}_{corr.}$, and $i_d/h^{1/2}_{corr.}$ decreased slightlly with increasing $h^{1/2}_{corr.}$ for solutions of FAD and reduced FAD thereby apparently indicating diffusion control of both the cathodic and anodic FAD reactions (6c). A plot of i_d as a function of FAD concentration was linear and when extrapolated passed through the origin. From the slope of the plot, the diffusion current constant ($I = i_d/Cm^{2/3}t^{1/6}$) was found to be 3.0. The values of m and t used in this calculation were measured in the supporting electrolyte-buffer solution on the plateau of the wave at −0.8V and the diffusion current was measured as the maximum drop current using no recorder damping. This same data was used to calculate the FAD diffusion coefficient from Eq. [5]. The terms in parentheses in Eq. [5] were set equal

$$i_d = (708nD^{1/2}m^{2/3}t^{1/6})C \qquad [5]$$

to the slope of the $i_d - C$ plot and the coulometric value of n of 2.0 used to obtain a value of D of 4.5×10^{-6} cm^2 sec^{-1}. As expected this value is slightly less than the average D of 6.5×10^{-6} which has been calculated for the lighter riboflavin at pH 7.4 (7). Between pH 6.8 and 13, the ratio of diffusion current to concentration never varied by more than 5% (solutions at 10 different pH's examined) and consequently the value of D given above may be assumed to be approximately constant throughout this entire pH range. There was no noticeable variation in $E_{1/2}$ with FAD concentration at the pH's examined.

Similar behavior was observed at the RPDE. A single wave was observed throughout the pH range from 2 to 10. The $E_{1/2}$ of the wave varied with pH in a manner similar to that observed at the DME. The RPDE wave occurred about 0.11V negative of the corresponding DME wave. At pH 8.2 the limiting current increased linearly with increasing FAD concentration. Since the RPDE wave was not as well formed as the DME wave, accurate potential measurements at the RPDE were impossible. Consequently the RPDE offered no particular advantage in studying the FAD system and its use was abandoned after the pH study and an examination of the variation of limiting current with concentration.

Cyclic voltammetry studies were carried out at both the HMDE and at a platinum disk. In order to remove the platinum oxide coating on the platinum disk it was necessary to pretreat the electrode by dipping it in concentrated nitric acid, rinsing with distilled water, and reducing the oxide coating by controlled potential electrolysis at a potential on the platinum oxide peak. Even this procedure was not always adequate at the relatively high current sensitivities used in this study, however, and as a result, after the studies in this pH region, the use of the platinum disk was abandoned.

Between pH 6.8 and 8.6, a single cathodic-anodic peak couple was observed at both the platinum disk and the HMDE (Fig. 2). Application of the diagnostic criteria of Nicholson and Shain (8) to the cathodic peaks resulted in plotted curves (Fig. 3) with shapes characteristic of an electrochemical mechanism consisting of a reversible first-order or pseudo first-order preceding reaction followed by a reversible electron transfer. Since the equilibrium constant for the preceding reaction is not known, it is not possible to use the method of Nicholson and Shain to obtain the rate constant for the preceding chemical reaction.

Reduced FAD in the pH 6.8-8.6 region had a single cyclic voltammetry anodic-cathodic peak pair. Application of the diagnostic criteria to the anodic peak resulted in curves similar in shape to those shown in Fig. 3 for the cathodic peak. This appears to indicate that the oxidation of reduced FAD also follows an electrochemical mechanism consisting of a first-order reaction followed by a reversible electron transfer.

All of the studied flavin compounds have been shown to undergo an over-all reduction to the dihydroflavin compounds (1, 2) as shown in Eq. [6]. As has been previously suggested by Ke (3)

$$F + 2H^+ + 2e = FH_2 \qquad [6]$$

this apparently is also the case for FAD. Between pH 6.8 and 8.6 the cyclic voltammetry data indicate a chemical reaction prior to the electron transfer. For a fast acid-base reaction prior to the electron transfer (Eq. [7] and [8]), if the unprotonated species, O, predominates in this pH range, then the slope of the

$$O + pH^+ = H_pO^{p+} \qquad [7]$$

$$H_pO^{p+} + ne = RH_p \qquad [8]$$

polarographic $E_{1/2}$ − pH curve is given by $-0.059p/n$ (6d). Since n has been shown by both controlled-potential coulometry and by the slope of the log plots to be 2 in this region, and the slope of the $E_{1/2}$ − pH

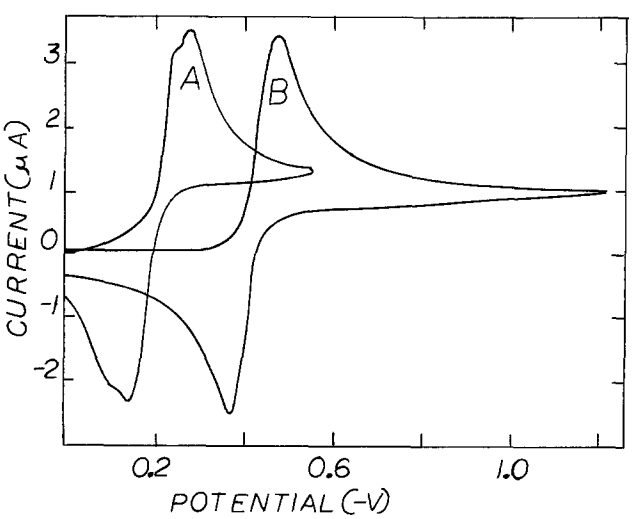

Fig. 2. Cyclic voltammograms obtained at a HMDE. A, 0.53 mmole FAD in pH 4.08 acetate buffer at 0.2 V sec^{-1}; B, 0.72 mmole FAD in pH 8.2 Tris buffer at 0.10 V sec^{-1}.

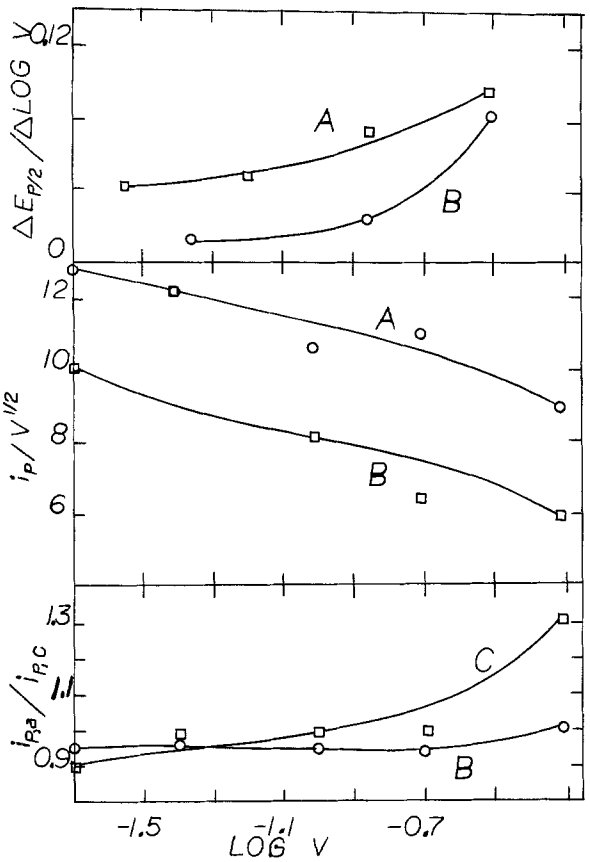

Fig. 3. Application of the diagnostic criteria of Nicholson and Shain (8) to cyclic voltammograms of FAD in pH 8.2 Tris buffer. A, 0.55 mmole at the HMDE; B, 0.87 mmole at the Pt disk; C, 0.87 mmole at the HMDE.

curve was −0.034, then p must be equal to 1. Cyclic voltammetry data also indicates a chemical step prior to oxidation of reduced FAD. The electrochemical mechanism which appears to best explain all of these observations is the three-step mechanism shown in Eq. [9], [10] and [11] where Eq. [9] is the rate-determining step for FAD reduction and Eq. [11] is the rate-determining step for FADH oxidation. In this pH range the present study contains no evidence for semiquinone formation. Semiquinone formation is clearly indicated, however

$$FAD + H^+ = FADH^+ \quad [9]$$

$$FADH^+ + 2e = FADH^- \quad [10]$$

$$FADH^- + H^+ = FADH_2 \quad [11]$$

in other pH ranges (see the following discussion). It should be noted that Eq. [9], [10], and [11] are not meant to imply a specific acidity state of FAD. The K_a values of various flavin compounds are listed elsewhere (1, 9).

Although the reaction apparently does not proceed in the single step indicated by Eq. [6], it is informative to calculate the rate constant for this over-all reaction. The rate constant can be calculated from cyclic voltammery data at the HMDE (10) by assuming n is the coulometrically determined value of 2 and D of FAD is the polarographically calculated value of 4.5×10^{-6} cm^2 sec^{-1}. Several calculated values of the rate constant (k_s) for a 0.21 mmole FAD solution are listed in Table III. The rate of the reaction decreases with increasing pH as would be expected if Eq. [9] were the rate-determining step for FAD reduction.

pH 2.1-6.5.—Polarographic examination at the DME of FAD in this pH region revealed a single cathodic

Table III. Calculated values of the pseudo first-order rate constant (k_s) for the over-all electrochemical reduction of 0.21 mmole FAD

pH	Scan rate, V sec^{-1}	ΔE_p*xn, mV	k_s, cm sec^{-1} × 10^{-3}

* $\Delta E_p = E_{p,\text{anodic}} - E_{p,\text{cathodic}}$.

wave at pH above about 6 which split into two overlapping waves of equal height (Fig. 4) at lower pH's. If a slow scan rate is not employed while recording the polarogram, the split into two waves can be easily overlooked, as was apparently done in the earlier study (3). In this instance a scan rate of 0.5 mV sec^{-1} was used. At pH 2.2 the proximity of the adsorption prewave (11) to the main FAD wave made it impossible to determine whether one or two waves were present.

Log plots at pH 4.08 yielded straight lines from which the half-wave potentials of the two waves could be determined. In drawing the lines through the log plot points it was necessary to neglect those points at potentials on wave I_c which were more than one-fourth of the way up the wave and those points on wave II_c which were less than three-fourths of the way up the wave. The overlapping of the waves in the intermediate region caused the log plots to curve away from the straight line. Using this method the $E_{1/2}$ of wave I_c was found to be 8 mV less negative than the $E_{1/2}$ of wave II_c. The average slopes (three trials) of the log plots were −0.055 V/decade for wave I_c and −0.052 V/decade for wave II_c. Both of these values are only slightly less than the −0.059 V/decade expected for a reversible one-electron process.

At pH's of 6.43, 6.20, and 6.04 the single cathodic FAD waves yielded log plots which were linear but which had two segments of slightly differing slope (Fig. 5). This can be interpreted to mean that two cathodic waves were present which overlapped to an extent which made separate wave identification impossible.

FAD which had been reduced by electrolysis showed only a single anodic wave in the acidic pH region unlike the behavior of FAD prior to reduction. Apparently two waves were not observed since the $E_{1/2}$'s of the waves were too close to each other to allow differentiation. Log plots of reduced FAD at pH 4.08 were linear with a slope of −0.041 V/decade. The

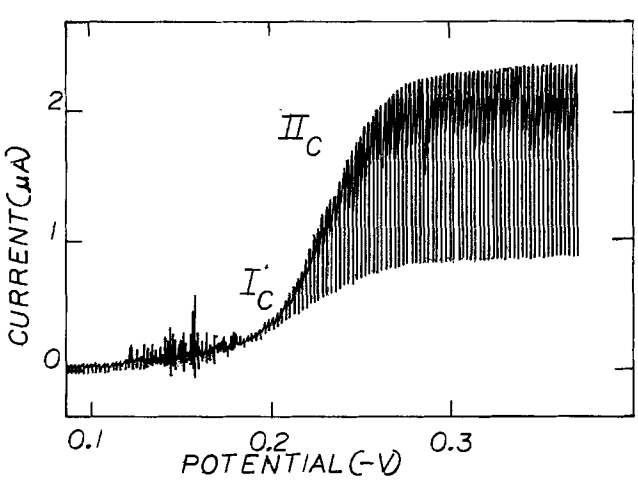

Fig. 4. A polarogram of 0.53 mmole FAD in pH 4.08 acetate buffer. I_c, the first cathodic wave; II_c, the second cathodic wave.

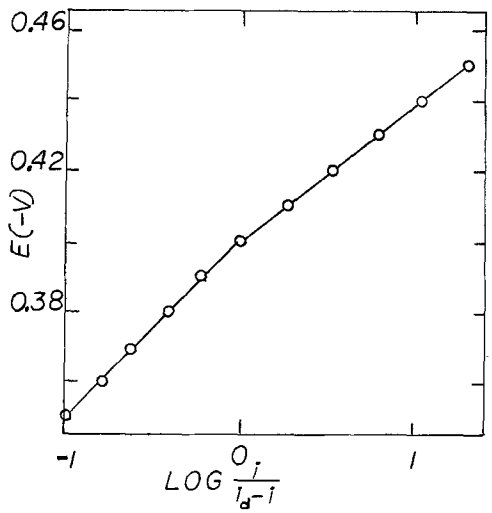

Fig. 5. A log plot of 0.19 mmole FAD in pH 6.04 phosphate buffer

average $E_{1/2}$ of the anodic wave (three trials) was −0.232V. In each case the diffusion current of the reduced FAD anodic wave equaled the total diffusion current of the two cathodic waves of the FAD starting material.

At pH 4.08 the total diffusion current ($i_{d,tot.}$) for the two FAD waves increased linearly with increasing $h^{1/2}_{corr.}$ and $i_{d,tot.}/h^{1/2}_{corr.}$ decreased slightly with increasing $h^{1/2}_{corr.}$ apparently indicating diffusion control of the electrode process. The diffusion current for the reduced FAD anodic wave behaved similarly.

A plot of $i_{d,tot.}$ as a function of FAD concentration at pH 4.08 was linear with a slope of 3.78 μA mmole^{-1}. The single reduced FAD wave behaved identically. From the slope of these straight lines and the measured values of m and t on the plateaus of the cathodic and anodic waves, the diffusion current constants (maximum drop currents used throughout) for FAD and reduced FAD at pH 4.08 were found to be 2.35 and 2.32, respectively. The diffusion coefficients were calculated from Eq. [5] using the coulometrically determined n of 2 and found to be 2.75×10^{-6} cm^2 sec^{-1} and 2.68×10^{-6} cm^2 sec^{-1}, respectively.

Cyclic voltammetry experiments were performed at the HMDE. At slower scan rates in the acidic pH range two overlapping cathodic peaks and two overlapping anodic peaks were observed (Fig. 2). At scan rates above about 0.25 V sec^{-1} the two cathodic and the two anodic peaks merged into a single cathodic-anodic peak pair. Cyclic voltammograms of reduced FAD showed two overlapping anodic peaks which did not completely merge even at 0.50 V sec^{-1}. Scan reversal at potentials cathodic of the anodic peak revealed two overlapping cathodic peaks at scan rates up to 0.05 V sec^{-1} and a single cathodic peak at higher scan rates. Since the cathodic peaks (and the anodic peaks) overlap each other it is impossible to apply the diagnostic criteria used earlier in the neutral pH range.

Controlled potential coulometry data has shown the total n for the over-all reduction of FAD to be 2. Since the polarograms of FAD in acidic solutions exhibit two waves of equal height, FAD must be reduced in two, one-electron steps. The slope of the $E_{1/2}$-pH curve in this pH range has been shown to be −0.065. For a fast acid-base reaction prior to the electron transfer (if the unprotonated FAD species predominates) or for a simultaneous addition of hydrogen ion and an electron, the slope of the polarographic $E_{1/2}$-pH curve is given by $-0.059p/n$ (see earlier discussion). Since n for each individual step is 1, then for each cathodic FAD wave the number of hydrogen ions added (p) is also 1. The electrochemical reaction mechanism which appears to best explain these results as well as the two cathodic cyclic voltammetry peaks is the stepwise reduction of FAD first to the semiquinone and finally to $FADH_2$ (Eq. [12] and [13]). It is not possible from the present data to determine when the hydrogen ions

$$FAD + H^+ + e = FADH^\cdot \quad [12]$$

$$FADH^\cdot + H^+ + e = FADH_2 \quad [13]$$

are added. The data may be interpreted to indicate either H^+ addition prior to or simultaneous with the addition of each electron.

pH 9-13.—Between pH 9.13 and 9.28 a single FAD cathodic wave was observed at the DME which yielded a linear log plot with an average slope of −0.037 V/decade (Table II). Between pH 9.34 and 9.89 the single polarographic wave resulted in a log plot with two linear portions of slightly differing slopes (similar to Fig. 5). Both portions had slopes of about −0.035 V/decade. The more cathodic portion always had the slightly greater negative slope. At pH's of 10.0 or greater two close polarographic waves were observed. By using the log plot method discussed earlier the separation between the $E_{1/2}$'s of the two waves at pH 10.2 (0.97 mmole solution) was found to be 24 mV.

At pH 10.2, 0.51 mmole FAD which had been exhaustively reduced by electrolysis showed two overlapping anodic waves of equal height. The difference in $E_{1/2}$ of the waves was 26 mV. The $E_{1/2}$ of the more positive anodic wave was 6 mV more positive than the $E_{1/2}$ of the more positive cathodic wave of the original FAD. Likewise the $E_{1/2}$ of the more negative anodic wave was 5 mV more positive than the $E_{1/2}$ of the more negative cathodic wave of the FAD starting material. This appears to indicate the presence of two quasireversible electrode reactions. The total diffusion current of the two anodic reduced FAD waves equaled the total diffusion current of the two cathodic waves of the original FAD.

At pH 9.25 i_d increased linearly with increasing $h^{1/2}_{corr.}$ and $i_d/h^{1/2}_{corr.}$ decreased slightly with increasing $h^{1/2}_{corr.}$ for solutions of FAD and reduced FAD. This is normally considered to be evidence of diffusion control of the electrode process.

At pH 12.3 the polarogram of FAD revealed two small waves at −1.1 and −1.4V and two small maxima at about −1.6 and −1.7V in addition to the main FAD wave (Fig. 6). With time the main FAD wave was observed to decrease in height while the wave at about −1.1V grew. The waves at −1.4 and −1.7V also became slightly more prominent (Fig. 6). Apparently the small waves observed in the original FAD polarogram in basic solution were due to FAD decomposition products. The identity of the decomposition products is presently unknown. The "anomalous" postwave observed by Ke (3) may have been due to one of these decomposition products.

Throughout the entire pH 9-13 range, cyclic voltammograms of FAD obtained at the HMDE revealed two overlapping cathodic peaks (*i.e.*, a major peak with a shoulder) and, upon scan reversal, two overlapping anodic peaks (similar to Fig. 2, curve A). In some cases the two cathodic peaks and the two anodic peaks merged to give a single cathodic-anodic peak pair at a scan rate of 0.5 V sec^{-1}. At scan rates of 0.02 and 0.04 V sec^{-1} the cyclic voltammetry traces were erratic making meaningful observations at these scan rates impossible. The overlapping of the peaks made it impossible to apply the diagnostic criteria of Nicholson and Shain to either of the cathodic peaks. Cyclic voltammograms obtained on solutions of reduced FAD showed two overlapping anodic peaks and, after scan reversal, two overlapping cathodic

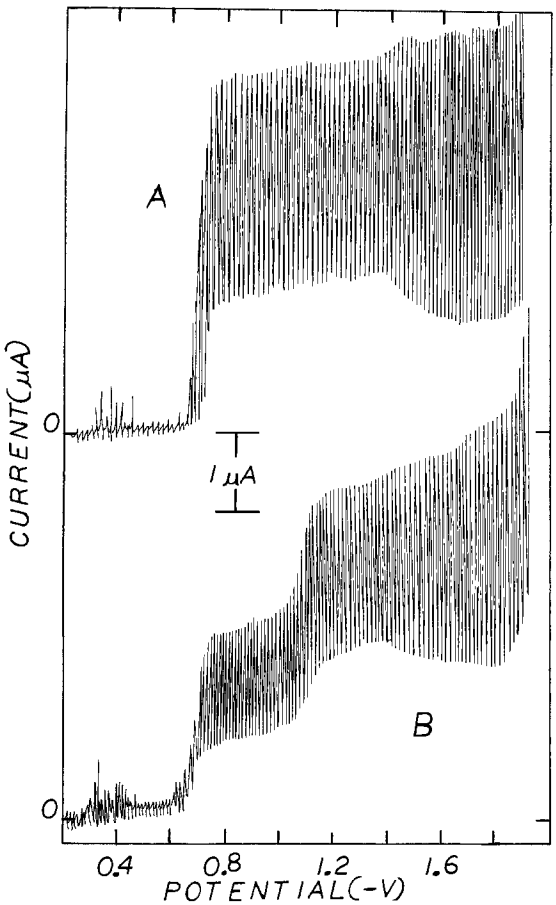

Fig. 6. Polarograms of 0.92 mmole FAD at pH 12.3. A, Immediately after solution preparation; B, 43 hr after solution preparation.

peaks. As with FAD, these peaks often merged into a single anodic-cathodic pair at a scan rate of 0.5 V sec^{-1}.

In the *p*H 10-13 range, reasoning completely analogous to that used in the acidic *p*H region leads to the conclusion that FAD is reduced in two single-electron steps first to the semiquinone and finally to $FADH_2$ (Eq. [12] and [13]). Information concerning the order in which the hydrogen ions are added is not available. In the *p*H region between 9 and 10, the two cyclic voltammetry cathodic peaks indicate two single-electron transfers, however, the single polarographic wave and the slope of the log plots indicate a single two-electron transfer. It appears likely that in the *p*H 9-10 region the actual electrochemical reaction mechanism is a combination of that given by Eq. [9], [10], and [11] and that given by Eq. [12] and [13], *i.e.*, in this *p*H region the reaction mechanism is switching from the mechanism observed at neutral *p*H to the one observed in basic solution.

The Rate of the Photoelectrochemical Generation of Hydrogen at p-Type Semiconductors

J. O'M. Bockris* and K. Uosaki[1]

School of Physical Sciences, Flinders University, Adelaide, Australia 5042

ABSTRACT

The current-potential relations with and without illumination, quantum efficiency-wavelength relations at several potentials, the flatband potentials, the transient behavior, and the stability of seven p-type semiconductors, *i.e.*, ZnTe, CdTe, GaAs, InP, GaP, SiC, and Si, have been measured in 1*N* NaOH and 1*N* H_2SO_4. The position of the photocurrent-potential relations are related to the flatband potential and the energy gap of the semiconductor. The existence of the maximum in quantum efficiency-wavelength relation is analyzed by considering surface recombination. The stability and the transient behavior are analyzed.

Photoelectrochemical production of hydrogen was envisaged by Fujishima and Honda in 1972 (1). To obtain hydrogen, either a *p*H gradient or an external power source in the cell was required (2-4). However, homogenization of the solution would inevitably occur on prolonged functioning in such an arrangement.

The lack of need for single crystals in the photoelectrochemical approach to energy conversion (5, 6) gives the prospect of favorable economics in purely photoelectrochemical hydrogen production from water. The primary aim is the development of a suitable cathode, so that light may be directed both onto the cathode and anode, with the objective of obtaining stable photoelectrolysis in a cell with a uniform *p*H. A previously reported photocathode is unstable (7). We report investigations concerning the stability and efficiency of certain new photocathodes.

Experimental

Apparatus.—The photoelectrochemical cell is shown in Fig. 1. Stopcocks and taps were Teflon. To avoid contact of the metal used to form an ohmic contact with the solution, the back face and side of the electrode were covered with epoxy resin. To minimize contact of this with the solution, a Teflon electrode holder was used. The absence of a leak was verified by the small magnitude of the dark current. All photoelectrode areas were 0.125 cm^2.

A PAR Model 173 potentiostat/galvanostat, with a Model 176 current-potential converter, was used to control the potential. The electrode potential was swept by a Wenking SMP 69 potential stepping motor control. The current-potential relationship was recorded by a Hewlett-Packard Model 7004B X-Y recorder. The time dependence of the photocurrent was recorded by means of a Hitachi QD25 recorder.

A 900W xenon lamp (Canrad-Hanovia 538C1) was used as a light source and a Jarrell-Ash quarter-meter grating monochrometer (Cat. no. 82-410) was employed to obtain monochromatic light. An *IR* absorbing filter (Oriel G-776-7100) was placed between the cell and the light house, when current-potential measurements were carried out without the monochrometer. However, a quartz lens (d = 5 cm, f = 5 cm) was employed to concentrate the light on the electrode surface when the photocurrent was measured under monochromatic light. In this case, two long pass filters (Oriel G-772-3900 and Oriel G-772-5400) were used with an *IR* absorbing filter to eliminate second-order diffraction. The conditions used in this respect were: 3000 ~ 5000Å, *IR* absorbing filter only; 5000 ~ 7000Å, *IR* absorbing filter + G-772-3900 filter; 7000 ~ 7500Å, *IR* absorbing filter + G-772-5400 filter; 7500Å, G-772-5400 filter only.

The intensity of light was measured by means of a Hewlett-Packard Model 8334 radiant flux meter with either a 8334A radian flux detector or a Carl Zeiss vacuum thermocouple (VT Q3/A) with a Keithley 149 millimicrovoltmeter. The error in relative intensity measurement was < 5%. However, absolute intensity measurements had an uncertainty of ± 20% error.

The electrochemical cell and the optical system were set up on an optical bench.

Impedance measurement.—The cell for impedance measurements had a working electrode surrounded by a cylindrical platinized platinum counterelectrode, apparent area 60 cm^2. Hydrogen gas was passed into the solution before and during measurement.

The direct method was employed (8, 9). The circuit contained a dry cell (6V) as a d-c source and the potential was controlled by a ten-turn variable resistor

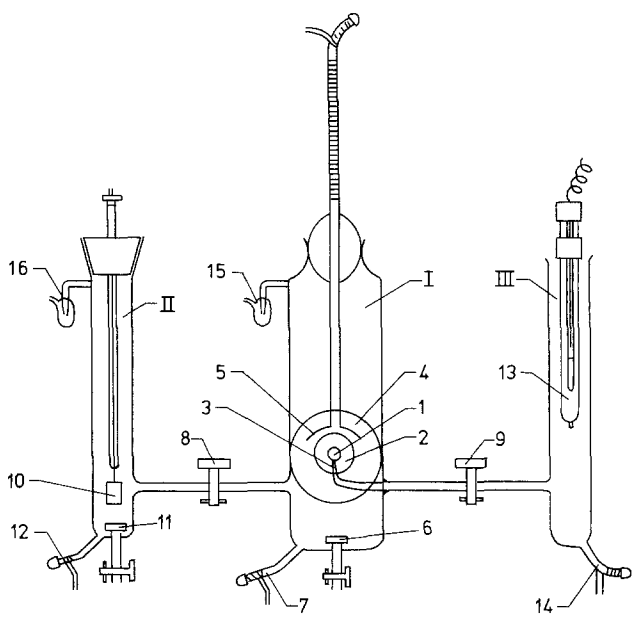

Fig. 1. The photoelectrochemical cell (front view). Key words: hydrogen production, photoelectrochemical reaction, p-type semiconductors, photocathodes.

while being monitored by means of a Keithley 616 digital electrometer. The a-c source was a Mini-Lab Model 603A (B.W.D. Electronics). A capacitor (10 μf) and a choke coil (35 H) were in the circuit. The resistor, the value of which was several hundred times larger than the cell impedance, Z_{cell}, was connected in series to the cell so that the alternating current, I, became constant, and independent of the cell voltage. The impedance of the choke was at least one hundred times larger than that of the cell.

Signals taken from two points in the circuit and applied to the X and Y inputs of a cathode ray oscilloscope (Tetronix 5103N with 5A20N and 5A2IN differential amplifiers) displayed Lissajou's figures. Since the X and Y inputs showed I ($Z_{cell} + R$) and IZ_{cell}, respectively, and $R >> Z_{cell}$, the absolute value of the cell impedance, and phase difference due to the cell, could be ascertained. Assuming a series equivalent circuit (measurements were carried out under nearly ideally polarized conditions), the cell capacitance, which is effectively the space charge capacitance of the semiconductor electrode, can be obtained.

The accuracy of the direct method is low compared with that of the bridge method (8, 9). At metal electrodes the phase difference is small, and hence determination of C is inaccurate by this method.

However, at semiconductor electrodes, capacitance is low so that the phase difference can be measured accurately.

Semiconductors chosen.—Cathodes were selected on the basis of sufficiently low values of energy gap (2.574 $E_G < 1.3$ eV) and electron affinity ($E_a < 4.0$ eV) (28).

Zinc telluride (ZnTe).—A ZnTe single crystal (Ag doped), grown by the Bridgeman method, was cut parallel to the cleaved face (100). After being etched in $K_2Cr_2O_7$-HNO_3 aqueous solution, the specimen was dipped in $HAuCl_4$ solution to make an ohmic contact (10). It was masked with paraffin, later removed in trichloroethylene. The contact was ohmic and the specific resistance was 0.2 Ω · cm. The face of the specimen was polished by means of emery paper to 600 grade. The electrode was etched in HF-HNO_3 (11) solution.

Cadmium telluride (CdTe).—A CdTe single crystal (undoped) grown by the Bridgeman method was cut parallel to the cleaved face (100). The specimen was heated in Te vapor at 500°C for 8 hr to increase nonstoichiometry. Thereafter, the crystal was etched in $K_2Cr_2O_7$-HNO_3 (12), dipped into $AgNO_3$ solution, and heated at 200°C for 30 min. Finally, a gold film was grown on the crystal by dipping it into aqueous $HAuCl_4$ (13). During the processes of etching and dipping into $AgNO_3$ and $HAuCl_4$ solutions, the crystal was covered with paraffin except for the spots where it was intended to make a contact. The specific resistance was 10^3 Ω · cm and the ohmic character of the contact good. The face to be used was polished by emery paper, 400 to 600 grade, and the surface etched in HF-HNO_3 solution.

Gallium arsenide (GaAs).—The GaAs was a single crystal in wafer form, (100) face; Zn doped; carrier density = 2×10^{19} cm^{-3}; 0.5 mm thick. It was etched (12) by dipping into CH_3OH-Br_2 (5%) solution, for 1 min before an ohmic contact was made by soldering with indium (14). The I-V relation was ohmic. The specific resistance was 0.2 Ω · cm.

Indium phosphide (InP).—The InP was a single crystal wafer (100) face, Zn doped; carrier density 5.6×10^{18} cm^{-3}; 0.8 mm thick. Treatment was as for GaAs except that the ohmic contact was by means of an In-Zn alloy (15). The specific resistance was 0.21 Ω · cm.

Gallium phosphide (GaP).—The GaP was a single crystal wafer, Zn doped; carrier density 6.7×10^{17} cm^{-3}; (111) face; 0.4 mm thick. A HNO_3-HCl mixture was used for etching (12). An ohmic contact was obtained by the use of an In-Zn alloy (7). The specific resistance was 2.0 Ω · cm.

Silicon carbide (SiC).—The silicon carbide was a single crystal; (000$\bar{1}$) face; Al doped; carrier density 4×10^{18} cm^{-3}; 0.2 mm thick. "Acme" conductive adhesive gave an ohmic contact if heated in hydrogen at 300°C for 2 hr. The specific resistance was 0.31 Ω · cm. The electrode was dipped in HF for 1 min before each experiment.

Silicon (Si).—The silicon was a single crystal wafer, (100) face; B doped; 0.2 mm thick. An In-Zn alloy was used to obtain an ohmic contact. The specific resistance was 1.2 Ω · cm. The crystal was etched in HF solution before each experiment.

Results

The current-potential relations.—The current-potential relations with and without illumination by means of a 900W Xe lamp were measured in 1*N* NaOH and in 1*N* H_2SO_4. The relations found can be divided into two groups. Results typical of the first group (ZnTe, CdTe, GaP,[2] SiC, and Si) are exemplified in Fig. 2 (ZnTe). Dark curents are low. Typical results of the second group (GaAs and InP) are in Fig. 3 (GaAs).[2] The degree of displacement of the current-potential

[2] In the measurements of Gerischer *et al.* (16), GaAs showed saturation photocurrents at −1.0V, but such saturation was not observed in our work, probably due to a lower intensity of illumination. The current-potential curves observed for GaP were similar to those reported earlier by other workers (17-19).

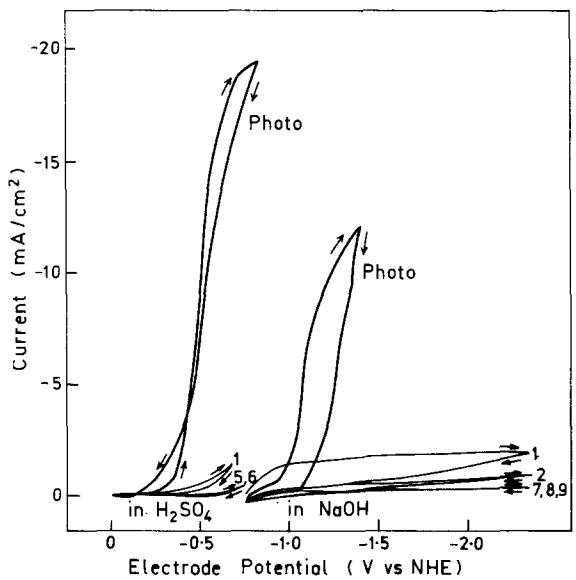

Fig. 2. The current-potential relations of ZnTe in 1*N* NaOH and 1N H_2SO_4 with and without illumination by a 900W Xe lamp. Sweep rate: 1.5 V/min. Intensity of light 0.08 W/cm². Arrows show the direction of the polarization. 1, 1st sweep in dark; 2, 2nd sweep in dark. 5, 6, 7, 8, 9, 5th, 6th, 7th, 8th, and 9th sweeps in dark.

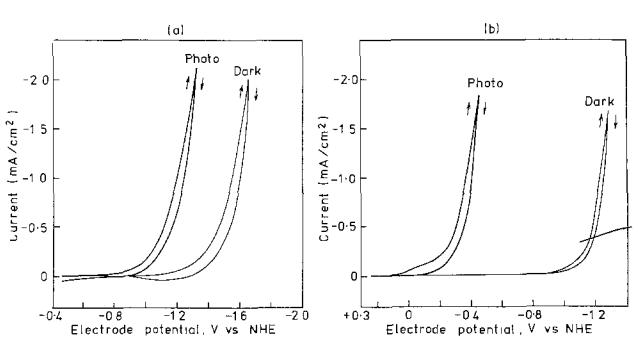

Fig. 3. The current-potential relations of GaAs with and without illumination by a 900 Xe lamp in 1*N* NaOH (a) and 1*N* H_2SO_4 (b). Sweep rate: 1.5 V/min. Intensity of light: 0.08 W/cm².

curves in H_2SO_4 and NaOH respectively is shown in Table I.

At CdTe in NaOH no photocurrent was observed at a potential more positive than −0.75V, when the oxygen concentration in the solution had been sufficiently diminished.

A white film was observed on the InP electrode after measurements in 1*N* H_2SO_4. Mayumi *et al.* (20) observed such white films: Irreproducibility due to them may account for the fact that the critical potential observed by Mayumi was 0.5V more negative than that reported here. No films were observed in 1*N* NaOH.

Photocurrents at SiC electrodes were < 10 μA cm^{-2}.

Quantum efficiency-wavelength relations at several potentials.—Photocurrents were measured under monochromatic light at several potentials. Quantum efficiencies were calculated by using measured values of the photocurrents and the light intensity. Typical results are shown in Fig. 4 (GaP).[3] The spectral response of the quantum efficiency in 1*N* NaOH of the semiconductors examined in this work except for GaP and SiC are shown in Fig. 5. Those in 1*N* H_2SO_4 are as in 1*N* NaOH. Quantum efficiencies at SiC in 1*N* NaOH (Fig. 6) are low.

The flatband potential.—The flatband potentials were determined by using Mott-Schottky plots. A typical plot is shown in Fig. 7 (SiC). Table II shows the flatband potential of the semiconductors in 1*N* NaOH and 1*N* H_2SO_4 and the slopes of the corresponding Mott-Schottky plot. The flatband potentials of InP in 1*N* H_2SO_4 and Si in 1*N* NaOH and 1*N* H_2SO_4 could not be measured due to the instability of these materials in solution.

Gleria and Memming reported (22) difficulties in respect to the Mott-Schottky plot on SiC but none were noted here.

Transient measurement.—Current-time relations at fixed potentials following illumination and interruption of light were measured in 1*N* NaOH and 1*N* H_2SO_4. Typical results are in Fig. 8. When the potential is relatively negative, the current becomes stable just after the light was on or off, but when the electrode potential became relatively positive, it took time to attain a steady state (Fig. 8d).

Stability.—The photocurrents at fixed potentials were measured as a function of time (1-20 hr) at all semiconductors mentioned above in 1*N* NaOH and 1*N* H_2SO_4. Results are listed in Table III in terms of $(1/i)$ (di/dt), which is a measure of the instability.

Discussion

By analogy to well-known behavior at the metal-vacuum interface, the electrode potential corresponding to the commencement of electron emission ("the critical potential") would have been expected to vary with change of the frequency of the exciting source. That the critical potential is not thus dependent for the semiconductor-solution interface is demonstrated in Fig. 9 (ZnTe). An interpretation is that electron-phonon collisions in the semiconductor cause the electrons photogenerated within the semiconductors at various energies (depending on the wavelength of the incident light) to fall to the bottom of the conduction band before they have reached the electrode surface.

The i_{photo}-V relations are Tafel-like (Table IV), whereas, at metals, $i^{0.4}$ is linear with V. Thus, in metals, nearly all the photoactivated electrons decay before the surface is reached. The small fraction ($< 10^{-2}$%) of photoactivated electrons which reach the surface and emit have an energy distribution which is a function of the energy of the exciting source. In the semiconductor, a greater fraction ($\sim$ 1%) of the photogenerated electrons reaches the surface but the energy of nearly all of them is that of the conduction band, Fig. 10. (See above). The variation of the electrochemical photocurrent with potential then becomes subject to the reasoning [*e.g.*, Ref. (23)] which relates the thermal current to potential at metals.

The saturation part of the photocurrent-potential relation can be understood from Fig. 11. When the electrode potential is such that the energy of the emitting electrons is equal to that of the ground state of the acceptor levels in H_3O^+, no further increase in the availability of acceptor levels in solution occurs as the potential is made more negative (24).

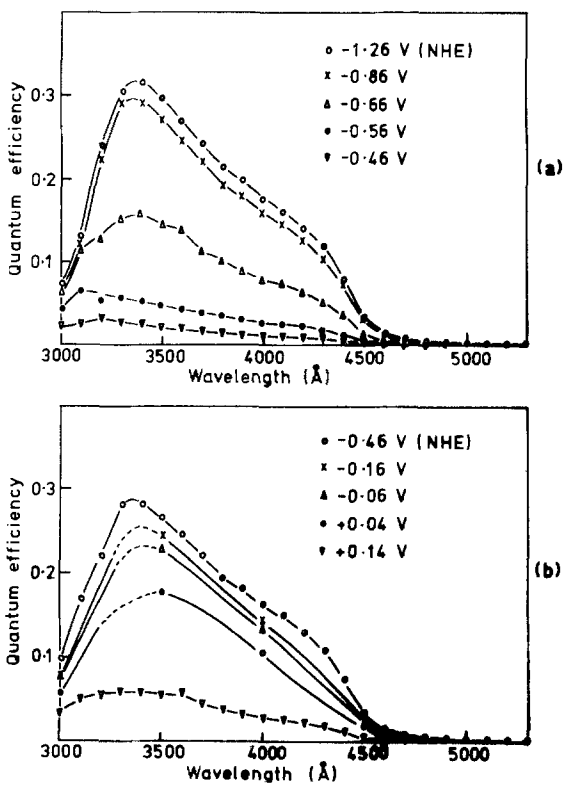

Fig. 4. The quantum efficiency-wavelength relations of GaP in 1*N* NaOH (a) and 1*N* H_2SO_4 (b) at several electrode potentials.

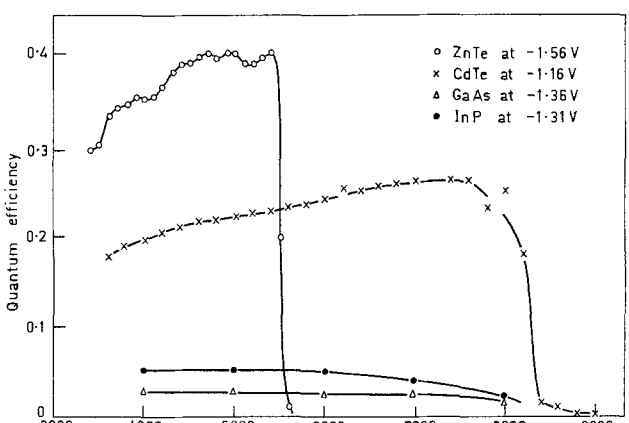

Fig. 5. The quantum efficiency wavelength relations for ZnTe, CdTe, GaAs, and InP in 1*N* NaOH.

[3] Reasonable agreement was observed with the results of Yoneyama *et al.* (21), but the maximum in the quantum efficiency-wavelength relation was at 4500Å in their measurement and at 3500Å in ours. In the Yoneyama work, published data on xenon lamps (instead of calibration) was used.

Table I. The difference in the range of potentials (volts) for photocurrent-voltage relations in NaOH and H_2SO_4

ZnTe	0.6
CdTe	0.5
GaAs	0.8
InP	0.5
GaP	0.6
SiC	Not applicable
Si	0.5

The "critical potential".—$\Delta H'(e)$ (Fig. 12) at the flatband potential is given by (23)

$$\Delta H'(e) = -L_o + E_a - J + A + R + ({}^{S.C}\Delta^{S}\phi)_{fbp} \quad [1]$$

where L_o, E_a, J, A, R, and $({}^{S.C}\Delta^{S}\phi)_{fbp}$ are the hydration energy of the proton, electron-affinity of the semiconductor, ionization energy of hydrogen, adsorption energy of hydrogen, H-H_2O repulsive force, and the potential drop in the electric double layer at the flatband potential.

$({}^{S.C}\Delta^{S}\phi)_{fbp}$ can be estimated as follows.

The flatband potential, V_{fbp}, with respect to normal hydrogen electrode (NHE) is given by

$$V_{fbp} = {}^{Pt}\Delta^{S.C}\phi + ({}^{S.C}\Delta^{S}\phi)_{fbp} + ({}^{S}\Delta^{Pt}\phi)_{\substack{p_{H_2}=1 \\ C_{H^+}=1}} \quad [2]$$

where ${}^{Pt}\Delta^{S.C}\phi$ is the potential difference between the semiconductor and the Pt wire, $({}^{S}\Delta^{Pt}\phi)_{\substack{p_{H_2}=1 \\ C_{H^+}=1}}$ is the potential drop in the electric double layer of the semiconductor at the flatband potential and $({}^{S}\Delta^{Pt}\phi)_{\substack{p_{H_2}=1 \\ C_{H^+}=1}}$ is the potential drop in the electric double layer at the Pt electrode in the presence of 1 atm of hydrogen gas and with $C_{H^+} = 1$. (See Fig. 12).

Since

$$\mu_e{}^{-Pt} = \mu_e{}^{-S.C} \quad [3]$$

where $\mu_e{}^{-Pt}$ and $\mu_e{}^{-S.C}$ are the electrochemical potentials of electrons in Pt and the semiconductor, respectively. Hence

$${}^{Pt}\Delta^{S.C}\phi = (\mu_e{}^{Pt} - \mu_e{}^{S.C})/F \quad [4]$$

where $\mu_e{}^{Pt}$ and $\mu_e{}^{S.C}$ are the chemical potentials of Pt and the semiconductor, respectively. Therefore

$$V_{fbp} = \{({}^{S.C}\Delta^{S}\phi)_{fbp} - \mu_e{}^{S.C}/F\} - [({}^{Pt}\Delta^{S}\phi)_{\substack{p_{H_2}=1 \\ C_{H^+}=1}} - \mu_e{}^{Pt}/F] \quad [5]$$

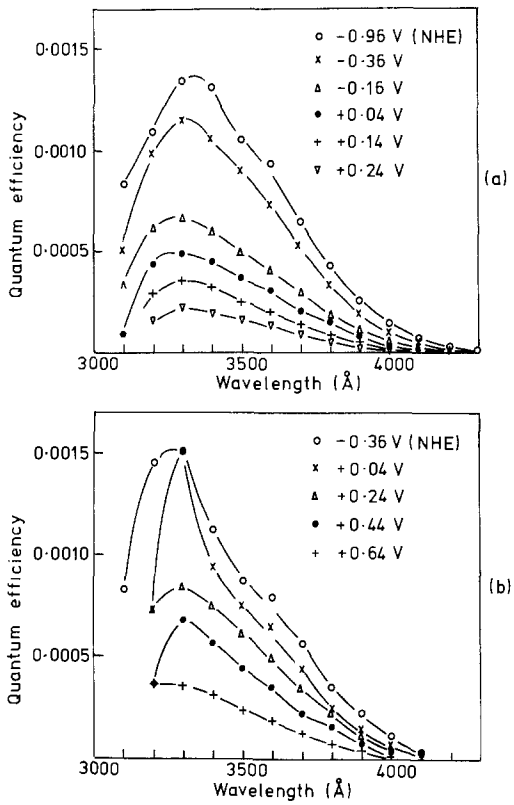

Fig. 6. The quantum efficiency-wavelength relations of SiC in 1*N* NaOH (a) and 1*N* H_2SO_4 (b).

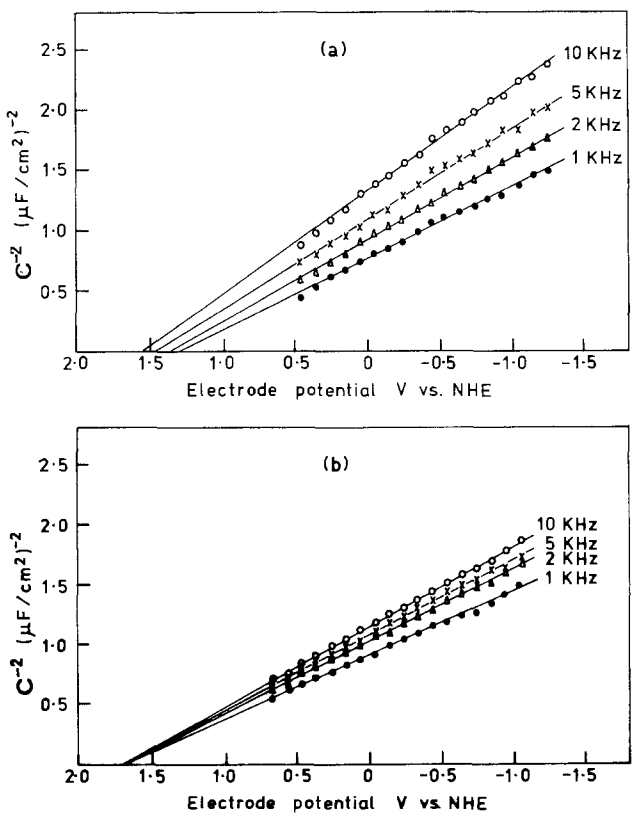

Fig. 7. The Mott-Schottky plots of SiC in 1*N* NaOH (a) and 1*N* H_2SO_4 (b) at several frequencies.

Table II. The flatband potential and slope of Mott-Schottky plots of semiconductors

Semiconductors	1*N* NaOH Flatband potential, V, NHE	1*N* NaOH Slope ($\mu f/cm^2)^{-2}$/V	1*N* H_2SO_4 Flatband potential, V, NHE	1*N* H_2SO_4 Slope ($\mu f/cm^2)^{-2}$/V
ZnTe	−0.79	28	0.04	150
CdTe	0.21	6000	−0.35	2200
GaAs	−0.04	0.12	0.43	0.22
InP	−0.07	0.48	—	—
GaP	0.18	6.0	1.13	4.6
SiC	1.38	0.86	1.68	0.7

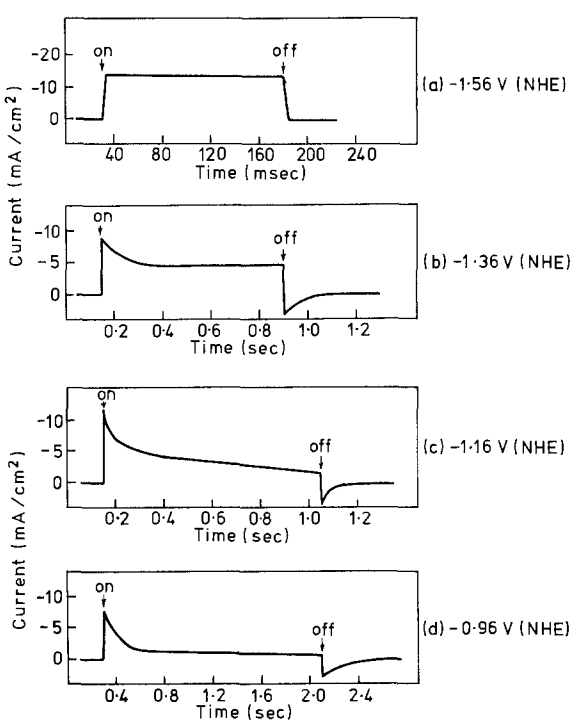

Fig. 8. The transient behavior of the current of ZnTe after illumination and interruption of light in 1*N* NaOH at several potentials. The current before illumination is taken as zero. Intensity of light: 0.08 W/cm².

Table III. The stability of photocathodes, as measured by their change with time at various potentials (given)

Semiconductor	Value of $\frac{1}{i}\frac{di}{dt}$ (sec^{-1}) 1N NaOH	1N H_2SO_4
ZnTe	6×10^{-4} (−1.26V)	5×10^{-5} (−0.56V)
CdTe	2.5×10^{-6} (−1.16V)	1×10^{-6} (−0.76V)
GaAs	2×10^{-4} (−1.36V)	3×10^{-4} (−0.76V)
InP	2×10^{-5} (−1.36V)	2×10^{-4} (−0.46V)
GaP	5×10^{-5} (−0.76V)	5×10^{-5} (−0.26V)
SiC	0* (−1.16V)	0* (−0.76V)
Si	5×10^{-6}** (−1.06V)	1.7×10^{-4}** (−0.41V)

* Current is very small 9 μA/cm² in 1N NaOH and 3 μA/cm² in 1N H_2SO_4.
** After 10 hr in dark, almost no photocurrent was observed.

Thus, the potential drop in the electric double layer of the semiconductor at the flatband potential is given by

$$({}^{S.C}\Delta^{S}\phi)_{fbp} = V_{fbp} + [\,({}^{Pt}\Delta^{S}\phi)_{\substack{p_{H_2}=1 \\ C_{H^+}=1}} - \mu_e{}^{Pt}/F] + \mu_e{}^{S.C}/F$$
$$= V_{fbp} + [\,({}^{Pt}\Delta^{S}\phi)_{\substack{p_{H_2}=1 \\ C_{H^+}=1}} - \mu_e{}^{Pt}/F] - (\Phi/F - \chi^{S.C}) \quad [6]$$

where Φ is the work function of the semiconductor and $\chi^{S.C}$ is potential drop in the semiconductor.

$$[({}^{Pt}\Delta^{S}\phi)_{\substack{p_{H_2}=1 \\ C_{H^+}=1}} - \mu_e{}^{Pt}/F]$$

was calculated by Trasatti (25) using a method suggested by Bockris and Argade (26), as 4.3V. Therefore

$$({}^{S.C}\Delta^{S}\phi)_{fbp} = 4.3/F + V_{fbp} - (\Phi/F - \chi^{S.C}) \quad [7]$$

A schematic of the energy levels of a semiconductor which has surface states in a vacuum is shown in Fig. 13. From this figure, $\chi^{S.C}$ is given by

$$F\chi^{S.C} = \Phi + \Delta E - E_a - E_g \quad [8]$$

where ΔE is the energy difference between the Fermi level and the top of the valence band in the bulk. Hence, Eq. [7] becomes

$$({}^{S.C}\Delta^{S}\phi)_{fbp} = 4.3/F + V_{fbp} - (E_a + E_g - \Delta E)/F \quad [9]$$

As a first approximation, ΔE is assumed to be zero for all p-type semiconductors concerned.

The values of $({}^{S.C}\Delta^{S}\phi)_{fbp}$ were calculated from Eq. [9] for semiconductors listed in Table V. $({}^{S.C}\Delta^{S}\phi)_{fbp}$ is negative in all cases, ${}^{S.C}\Delta^{S}\phi$ in NaOH is more negative than that in H_2SO_4 for most electrodes except CdTe.

From Eq. [1] and [9]

$$\Delta H(e) = -L_o + E_a - J + A + R + 4.3/F + V_{fbp} - (E_a + E_g - \Delta E)/F$$
$$\simeq -L_o - J + A + R + 4.3/F + V_{fbp} - E_g/F + \Delta E/F \quad [10]$$

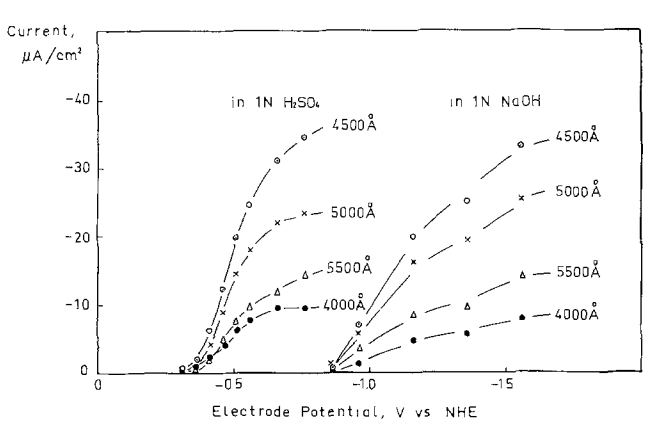

Fig. 9. The photocurrent-potential relations of ZnTe in 1N NaOH and in 1N H_2SO_4 for light of several wavelengths.

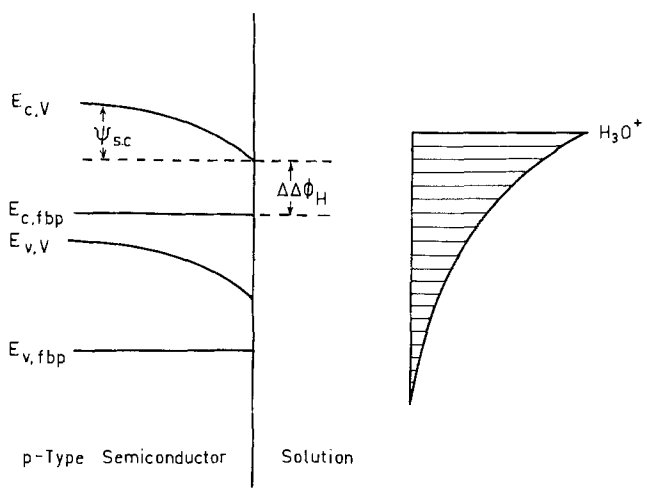
Table IV. Slope of log i_p-V relations

	1N NaOH	1N H_2SO_4
ZnTe	0.165	0.13
GaAs	0.3	0.25
GaP	0.1	0.18
CdTt	Not available because of high resistance	
Si	0.17	0.21



where L_o, J, and R do not depend on semiconductor and the dependence of A on the semiconductor is less than 0.1 eV (27), Therefore, $\Delta H(e)$ is given by

$$\Delta H(e) \simeq \text{const.} + V_{fbp} - E_g/F \quad [11]$$

The probability of the existence of acceptors at energy E, $G(E)$, is given by

$$G(E) = \exp(H(e) - E_v)/kT \quad [12]$$

where E is the energy of the electrons at the surface at a potential V.

$$\begin{cases} V - V_{fbp} = \psi_{s.c} + \Delta\Delta\phi_H \\ \Delta\Delta\phi_H = ({}^{S.C}\Delta^{S}\phi)_V - ({}^{S.C}\Delta^{S}\phi)_{fbp} \end{cases}$$

Fig. 10. The schematic diagram of energy levels of the valence band and conduction band of a semiconductor and of an acceptor.

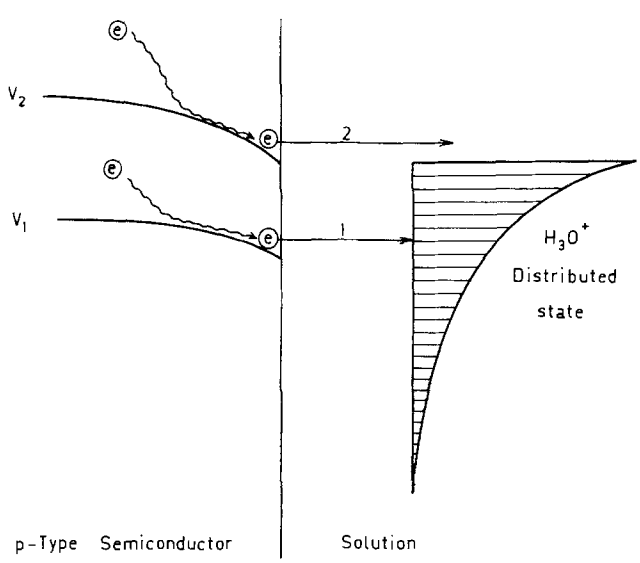


Fig. 11. Schematic illustration of the model proposed to describe the observed photocurrent behavior of semiconductor electrodes.

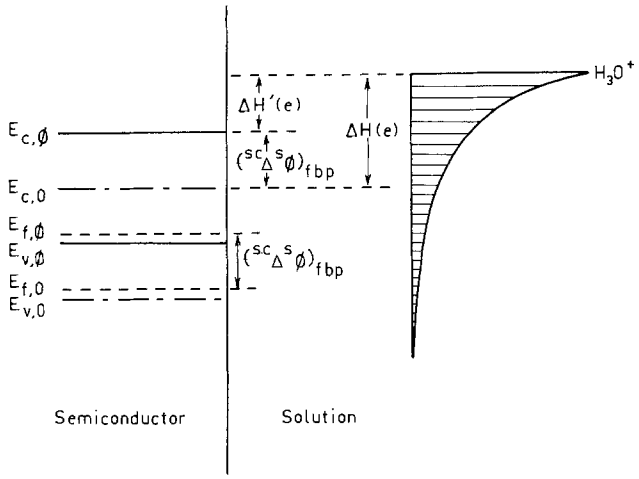

Fig. 12. The energy levels at a semiconductor solution interface

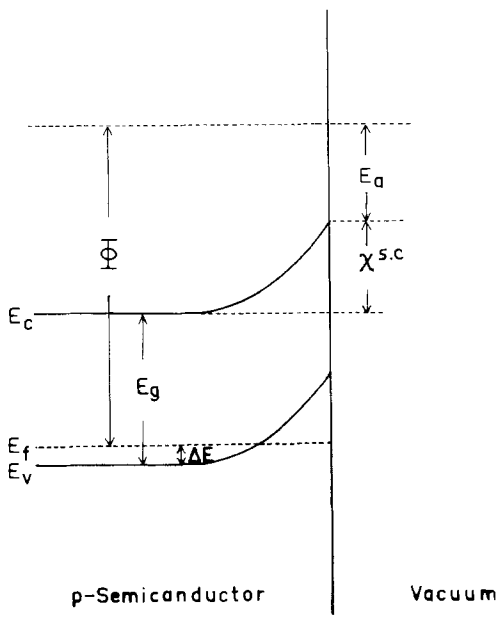

Fig. 13. Schematic diagram of the energy levels of a semiconductor with surface states in a vacuum.

E_v is given by

$$E_v = -F(V - V_{fbp}) \qquad [13]$$

where each of these potentials is on (*e.g.*) the N.H. scale. Therefore, E_v at the critical potential E_{crit} is given by

$$E_{crit} = -F(V_{crit} - V_{fbp})$$

At the critical potential, it can be assumed that $G(E)$ corresponds to an energy value of 0.1-0.2 eV from the ground state of H_3O^+.

Therefore

$$\Delta H(e) \simeq -F(V_{crit} - V_{fbp}) \qquad [14]$$

From Eq. [12] and [14], a linear relation between $(V_{fbp} - E_g/F)$ and $(V_{crit} - V_{fbp})$ is expected. Figure 14 shows this relation. The relation shows the importance of any energy gap in respect to the critical potential. Although a small energy gap is required from the point of solar energy absorption, the smaller the energy gap, the more negative the critical potential (with respect to the flatband potential) and, therefore, the smaller the efficiency of the hydrogen production.

Table V. Calculated values of the potential drop (volts) in the electric double layer at the flatband potential (see Eq. [10])

Semiconductor	1*N* NaOH $^{s.c}\Delta^{s}\phi$, V	1*N* H_2SO_4 $^{s.c}\Delta^{s}\phi$, V
ZnTe	−2.25	−1.42
CdTe	−1.27	−1.83
GaAs	−1.20	−0.77
InP	−1.42	—
GaP	−2.07	−1.12

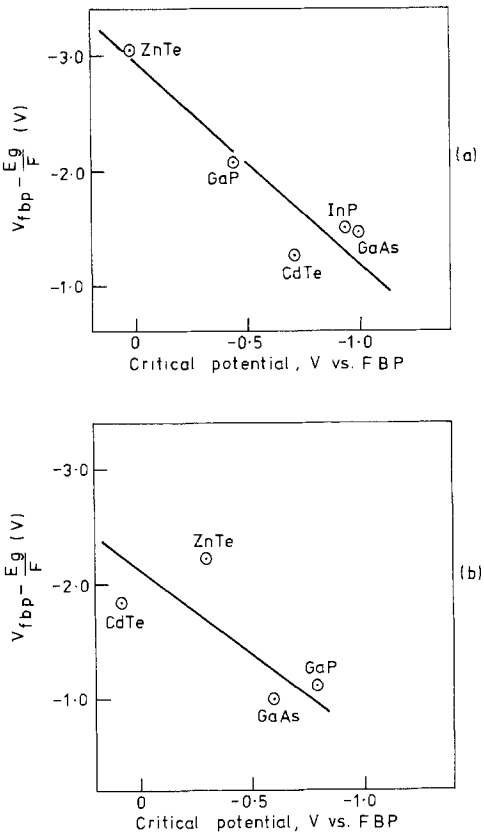

Fig. 14. The relations between $V_{fbp} - E_g/F$, and the critical potential with respect to the flatband potential in 1*N* NaOH (a) and 1*N* H_2SO_4 (b).

The quantum efficiency-wavelength relation.—Quantum efficiency-wavelength relation shown in Fig. 4-6 exhibit two features. (*i*) The quantum efficiency wavelength relation passes through a maximum. (*ii*) The height of the maximum decreases as the potential becomes more positive and therefore nearer to the flatband potential.

The position of the maximum can be interpreted by considering the photocurrent (i_p) as a function of the surface recombination.

Thus, i_p is given by

$$i_p = f(i_{\text{electron arriving at surface}}) - f(v_{\text{surface recombination}}) \qquad [15]$$

As the wavelength decreases, the photon absorption increases and the number of electrons created per average photon increases and therefore the quantum efficiency. At sufficiently small wavelengths, the position of the average absorption of photons gets nearer to the surface. Hence, the effect of surface recombination will become more important and decrease the net current or quantum efficiency.

Stability.—The most outstanding differences in stability (Table III) are for ZnTe and CdTe.

Figures 15 and 16 (drawn for us by Dr. T. Ohashi) show the equilibrium potentials for several reactions relevant to ZnTe and CdTe. For CdTe, the equilibrium potential of hydrogen evolution at pH = 14 is more negative than that of the decomposition of CdTe. Hence, CdTe will not decompose in the potential range of hydrogen evolution. For ZnTe, the equilibrium potential of hydrogen evolution is close to that of ZnTe decomposition.

Transient behavior.—Surface recombination.—The transient behavior may be due to either a process in the semiconductor or a process in the surface of the electrode, or a process in solution.

In the former case, the behavior would be due to time dependence of the electron concentration at the surface. The time constant is 10^{-3} sec and could arise from the recombination process. Then, the number of excess electrons t sec after illumination, $N(t)$, is

$$N(t) = N(1 - e^{-t/\tau}) \quad [16]$$

where N represents excess electrons at the steady state and τ is the lifetime of the excited electron. The number of electrons t sec after illumination is turned off, $N'(t)$, is

$$N'(t) = Ne^{-t/\tau} \quad [17]$$

The time constant of diffusion is less than that of recombination process, so that

$$N_o(t) = N_o(1 - e^{t/\tau}) \quad [18]$$

when the light is on and

$$N'_o(t) = N_o e^{-t/\tau} \quad [19]$$

when the light is off, where N_o is the steady-state concentration of excess electrons at the surface.

Since the photocurrent, $i_p(t)$ is

$$i_p(t) \alpha N_o(t) \quad [20]$$

the time dependence of the photocurrent is

$$i_p(t) = i_{st.}(1 - e^{-t/\tau}) \quad [21]$$

with illumination on, where $i_{st.}$ is the steady-state photocurrent. Also

$$i_p(t) = i_{st.}e^{-t/\tau} \quad [22]$$

when the light is off.

The photocurrent according to Eq. [21] and [22] is shown in Fig. 17. The result of the behavior found in the present work was quite different from these predictions, especially when the electrode potential was near to the flatband potential (Fig. 17).

Hence, since the lifetime of excited electrons is $<10^{-3}$ sec, the transient behavior observed is due to surface electrochemical processes, such as the reduction of oxygen. Thus

$$i_p = i_{p,H_2} + i_{p,red} = k_{H_2}C_{H_3O^+} + k_{red}C_{red} \quad [23]$$

where k_{H_2} and k_{red} are the rate constant for hydrogen evolution reaction and for some other reduction reaction, respectively.

Using Faraday's laws

$$i_p(t) = i_{p,H_2}C_{H_3O^+} + k_{red}C_{o,red} \exp\left(-\frac{M}{\mathbf{F}}k_{red}t\right) \quad [24]$$

where $C_{o,red}$ is the concentration of the species to be reduced at time zero.

From Eq. [24], $\log \dfrac{i(t) - i(\infty)}{i(o)}$ should be proportional to time, as shown in Fig. 18 [see also Ref. (28)].

Chemical Action of Glow Discharge Electrolysis on Ethanol in Aqueous Solution

M. A. Almubarak and A. Wood

Chemistry Department, Liverpool Polytechnic, Liverpool L3 3AF, United Kingdom

ABSTRACT

The action of anodic glow discharge electrolysis (gde) on ethanol in neutral aqueous phosphate buffer gave acetaldehyde, butan-2,3-diol, hydrogen peroxide, and acid. The yields of these products were found to vary substantially with the presence or absence of oxygen and in particular with oxygen flow rate and substrate concentration. A mechanism has been proposed for the reaction of substrate in both the presence and absence of oxygen.

Ethanol vapor and water vapor, over aqueous ethanol solutions, were subjected to glow discharge electrolysis (gde) by Klemenc (1), who examined the gaseous products only. Gde has been performed also on pure methanol (2), with a variety of supporting electrolytes; products were a complex mixture of simple breakdown species. Scholes and co-workers (3) studied the effects of x-rays (200 kV) on ethanol in aqueous solution and found that in the presence of oxygen the products were hydrogen peroxide and acetaldehyde alone. Using deaerated solutions they found acetaldehyde and butan-2, 3-diol, with traces of hydrogen peroxide (under acid conditions). Seddon and Allen (4) studied the hydrogen yields arising from the γ-radiolysis of neutral aqueous solutions of ethanol both in the presence and in the absence of oxygen. Recently Schultze and Schulte-Frohlinde (5) studied the effects of the γ-irradiation of dilute aqueous ethanol under a gaseous mixture of oxygen and nitrous oxide. The products were acetaldehyde, acetic acid, glycolaldehyde, ethylene glycol, and hydrogen peroxide.

A careful study was made of the total yields in the present work to determine the ultimate fates of all the radicals generated by gde: As will be seen, we have accounted for G(OH) in terms of our products. We also studied carefully the proportion of acetaldehyde and hydrogen peroxide since this gives valuable evidence about the reaction possibilities, and we were able to show that in gde under oxygen flow rates high enough to scavenge all the 1-hydroxyethyl radicals (CH_3CHOH) and at ethanol concentrations high enough to scavenge all the hydroxyl radicals, there is a particularly straightforward interaction between the 1-hydroxyethylperoxyl radicals ($CH_3\underset{\displaystyle O_2}{\underset{|}{C}}HOH$) yielding acetaldehyde and hydrogen peroxide in 2:1 proportions.

Experimental

The ethanol solutions were prepared by dissolving the correct amounts of pure absolute ethanol in neutral phosphate buffer solution, except for runs on acid determination under oxygen where very dilute alkali was used. The solutions after gde were analyzed for hydrogen peroxide (6), acetaldehyde (7), butan-2, 3-diol, and acid since these compounds were the products of x-irradiation of phosphate buffer/ethanol solutions (3). Other species sought by the workers who used x-irradiation were acetic acid, ethylene glycol, glycolaldehyde, ethyl hydroperoxide, diethyl peroxide, peracetic acid, and ethyl acetate, but no evidence was found for any of these. The acetaldehyde determination is essentially colorimetric: the absorbance, which declined rapidly, was recorded as a function of time and extrapolated backward to the point of preparation of the final solution. Butanediol was determined by reaction with potassium periodate at about pH 9 (bicarbonate); the unreacted periodate was determined, as I_3^-, by addition of excess potassium iodide.

The acid produced in gde was measured in separate experiments using very dilute alkali to carry the current and also to measure the acid formed as a fall in the pH of the solution during the gde.

The equipment required for rectification and control at the high currents and high voltages required was constructed specially and has been described elsewhere (8). The gde cell and vacuum line were of conventional design (9). The quantity of electricity was obtained by using a sampling digital voltmeter together with the electric clock. Typical run conditions used a current of 30 mA, a vacuum main pressure of 10 cm Hg, a stirring rate of "9" (ideally about 1500 rpm), and an oxygen flow rate of 900 $cm^3\ min^{-1}$. Run times varied from 30 to 300 sec, typically, the quantities of electricity passed being of the order of 10-100 μf. Substrate solutions were degassed with argon or saturated with oxygen, as required. When using argon it was usual to close the system so as to have no gas flow, since the argon flow did not affect the processes (argon not being involved chemically) except at very high flow rates where some arc instability occurred. Manostat gas flow regulation (9) was not always satisfactory and in later runs manual control was used.

Results

Gde on ethanol in neutral aqueous solution produces acetaldehyde, hydrogen peroxide, butan-2, 3-diol, and acid. The yields (in moles per faraday) of these products were found to vary substantially with the presence or absence of oxygen and with its flow rate and with ethanol concentration. Other factors which would affect the yields of the above products are the stirring rate, the gas pressure, the current, and the quantity of electricity.

The original work on the oxygen flow rate effect was reported by Almubarak (10). It was found from preliminary results here that the hydrogen peroxide yield increased with increasing oxygen flow rate. Hence oxygen is involved in the reaction and in the formation of hydrogen peroxide, and the hydrogen peroxide yield was used, therefore, as a convenient measure of the degree of mass transfer of oxygen from gas phase to liquid phase and as an indication of solution-oxygen content. (It was later shown that the hydrogen peroxide comes from two sources: ethanol, involving reactions, and preliminary processes, the first of these being the major source at sufficiently high ethanol concentrations.) This measure of oxygen availability in the solution was confirmed by measurements of

Key words: glow discharge electrolysis, ethanol, mechanism.

the butanediol yield which decreased to zero at very high oxygen flow rates (indicating total scavenging by oxygen of reaction intermediate CH_3CHOH).

Flow rate experiments were repeated, using argon, but no change in hydrogen peroxide yield was observed except at high flow rate values where some discharge instability may be expected.

Increasing the current at a given oxygen flow rate caused the hydrogen peroxide yield to fall (suggesting that the oxygen flow rate was not sufficient to scavenge all the 1-hydroxyethyl radicals): However, the yield could be restored to its original value by increasing the oxygen flow rate. In gde, increases in the discharge current cause increases in the glow spot area; the current density and the radical concentration tend to remain constant. Hence an increase in current at constant hydrogen peroxide yield increases the demand for oxygen. There was a limit, however, to the extent to which the hydrogen peroxide yield could be maintained at its high value by increases in oxygen flow rate; this limit arose from the instability of the discharge at very high gas flow rates. In practice, therefore, a low current (30 mA) was used, together with an oxygen flow rate which was high enough to scavenge most of the 1-hydroxyethyl radicals but not high enough to introduce discharge instability.

Hydrogen peroxide yields varied a little with stirring rate, a fairly rapid rate appearing to be the most suitable. Pressure changes did not affect the peroxide yield significantly at high oxygen flow rates, though it is possible that sufficiently high pressures would improve the mass transfer of oxygen from the gaseous to the solution phases at low oxygen flow rates.

Gde on aqueous ethanol in neutral phosphate buffer at the oxygen flow rate selected produced hydrogen peroxide, acetaldehyde, some diol (none at the highest oxygen flow rates where, however, some arc instability occurs), and acid. The yields of hydrogen peroxide related linearly to the quantity of electricity, showing that there were no peroxide-destruction reactions under the conditions used in this work. Linearity of butanediol yield with quantity of electricity was assumed, when required, since this product is nonvolatile. Acid appeared only in the combined presence of oxygen and substrate.

Under argon, low or zero flow rates were used and the products were acetaldehyde, hydrogen peroxide, and butan-2, 3-diol. It was verified that the yields of the nonvolatiles were linear functions of the quantity of electricity.

The graphs of yield *vs.* quantity of electricity and the results of the acetaldehyde work, whether under oxygen or argon, showed a tendency of the acetaldehyde yield to show a possible stationary state. The effect may arise from chemical decomposition of the acetaldehyde (*e.g.*, reaction with the aqueous electron) but it seems more likely to arise from vaporization because of the high temperature of the arc and the low boiling point of the acetaldehyde. A mathematical analysis, in essence, obtained the initial slopes of the plots of number of moles of acetaldehyde *vs.* quantity of electricity.

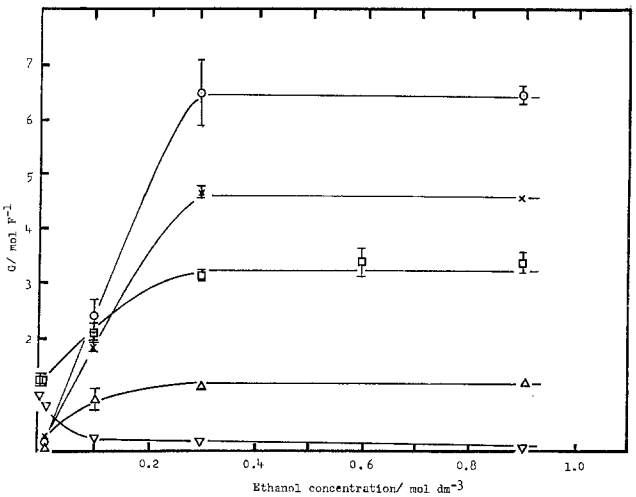

Fig. 1. G *vs.* ethanol concentration: ○, G(CH_3CHO, O_2); ×, G(CH_3CHO, Ar); □, G(H_2O_2, O_2); △, G($C_4H_{10}O_2$, Ar); ▽, G(H_2O_2, Ar).

Discussion

Plots of G-values *vs.* substrate concentration for each of the products are given in Fig. 1 and Table I.

Taking the argon runs first, G(H_2O_2) falls as the ethanol concentration increases, becoming very small. It is possible that at least some of this residual hydrogen peroxide corresponds to the generation of hydroxyl radicals at a rate (represented by 30 mA) slightly too high to permit total scavenging by ethanol within the concentration range used here. G(CH_3CHO) increases sharply, eventually leveling off. G($C_4H_{10}O_2$) increases in a like manner, the plateau value being about 1.16 mole F^{-1}.

In general gde of aqueous solutions may be regarded as producing the following species from the primary reaction zone (9, 11, 12)

$$H_2O \rightsquigarrow e_{aq}^-, H, OH, H^+, OH^-, H_2O_2, H_2, H_2O \quad [1]$$

In the absence of oxygen and in the presence of sufficient ethanol, the initial main reaction was OH + C_2H_5OH. Other radicals, H and e_{aq}^-, undergo slower reactions, under our conditions. The reactions of hydrogen and hydroxyl radicals with ethanol are well known. The hydroxyl radicals abstract hydrogen atoms from ethanol to form CH_3CH_3O (2.5%), CH_2CHOH (84.3%), and CH_2CH_2OH (13.2%) (13). The hydrogen radical abstracts a hydrogen atom primarily from the CH_2 group (14). The rate of reaction of the hydrogen radicals is about 1% of the rate of reaction of the hydroxyl radicals and may be neglected. In the same way reactions between hydrogen radicals and other substrates here are likely to be much slower than reactions between hydroxyl radicals and the same substrates. The CH_3CH_2O radicals pick up hydrogen atoms from ethanol molecules. The CH_2CH_2OH radicals may undergo a similar reaction, so improving the conversion of the hydroxyl radicals to 1-hydroxyethyl radicals, since separate measurements of G(OH, ferrocyanide) agree well with a G(OH) calculated from

Table I. Variation of G-values for acetaldehyde, butan-2,3-diol, and hydrogen peroxide with ethanol concentration and gas

[C_2H_5OH]/ mole dm^{-3}	G(H_2O_2)/mole F^{-1}		G(CH_3CHO) mole F^{-1}		G($C_4H_{10}O_2$)/mole F^{-1}
	Oxygen	Argon	Oxygen	Argon	Argon
0	1.24 ± 0.08	0.89 ± 0 03	0		0
0.01	1.25 ± 0.08	0.79 ± 0.04	0.18 ± 0.02	0.25 ± 0 01	0.05 ± 0.09
0.1	2.11 ± 0.17	0.21 ± 0.05	2.39 ± 0 29	1.83 ± 0 08	0.90 ± 0.19
0.3	3.12 ± 0 08	0.17 ± 0.02	6.47 ± 0.60	4.67 ± 0.11	1.14 ± 0.07
0.6	3.38 ± 0 26	—	—	—	—
0.9	3.39 ± 0.16	0.10 ± 0.01	6.44 ± 0.13	4.56 ± 0.04	1.20 ± 0.05

the product yields discussed here, under both argon and oxygen. Thus the main species formed from ethanol in the secondary reaction zone are 1-hydroxyethyl radicals. We assumed that the reactions of hydroxyl radicals with butan-2, 3-diol [$k = 8.1 \times 10^8$ dm^3 mole^{-1} sec^{-1} (15)] and acetaldehyde (possibly of similar rate constant) do not affect the yields of these two products significantly: The ethanol concentration was much higher than the concentration of these two products, there was no deviation from linearity in the plots of yields of nonvolatile products *vs.* quantity of electricity (suggesting therefore insignificant destruction reactions) and G(OH), ferrocyanide (see below) agrees well with G(OH) calculated from product yields. The reaction of hydrogen atoms with ethanol constitutes the fastest process involving these radicals, but it is still much slower than the rate of reaction of hydroxyl radicals with ethanol.

The products of the gde of aqueous ethanol in neutral phosphate buffer, under argon, are hydrogen peroxide, butanediol, and acetaldehyde, formed according to the following proposed reactions.

$$OH + OH \rightarrow H_2O_2 \quad [2]$$

$$2CH_3CHOH \rightarrow C_4H_{10}O_2 \quad [3]$$

$$2CH_3CHOH \rightarrow CH_3CHO + CH_2OH \quad [4]$$

Formation of acetaldehyde by additional radical/1-hydroxyethyl radical reactions seems unlikely. However, we do know that two 1-hydroxyethyl radicals interact to form butan-2, 3-diol, so we propose that under argon this interaction can yield acetaldehyde also, by disproportionation (reaction [4]).

Of the possible reactions of the aqueous electrons, those with peroxide and acetaldehyde (16) are the most probable

$$e_{aq}^- + CH_3CHO \rightarrow CH_3CHO^- \quad [5]$$

$$CH_3CHO^- + H_2O \rightleftharpoons CH_3CHOH + OH^- \quad [6]$$

$$e_{aq}^- + H_2O_2 \rightarrow OH + OH^- \quad [7]$$

Under oxygen, G(H_2O_2) and G(CH_3CHO) increase with increasing ethanol concentration and level off. G(CH_3CHO, O_2) was always greater than G(CH_3CHO, Ar). No butanediol is detectable at sufficiently high oxygen flow rates. These two facts point to a change of mechanism. Under oxygen G(CH_3CHO) is almost exactly double G(H_2O_2). The actual peroxide:acetaldehyde ratio under oxygen is 3.39:6.46. In the absence of oxygen, and persisting even at the highest ethanol concentrations, there is a small residue of hydrogen peroxide; if we assume that this residue also occurs in the runs under oxygen we can subtract it from G(H_2O_2, O_2), leaving 3.25 mole F^{-1}. The hydrogen peroxide:acetaldehyde ratio is then 3.25:6.46, which is very close to 1:2. Reactions of the 1-hydroxyethyl radicals other than those giving acetaldehyde and hydrogen peroxide in the correct proportions can be neglected. We assume that the 1-hydroxyethyl radicals are scavenged completely by oxygen, under the high gas flow rate

$$CH_3CHOH + O_2 \rightarrow \underset{\displaystyle O_2}{\overset{\displaystyle |}{CH_3CHOH}} \quad [8]$$

and this accounts for the disappearance of the butanediol. The 1:2 hydrogen peroxide:acetaldehyde ratio can be accounted for by

$$\underset{\displaystyle O_2}{\overset{\displaystyle |}{2CH_3CHOH}} \rightarrow 2CH_3CHO + H_2O_2 + O_2 \quad [9]$$

Because of the 1:2 hydrogen peroxide:acetaldehyde ratio we can assume also that the aqueous electron does not react significantly with products (reactions [5]-[7]). However, it could be argued that reactions [5] and [6] regenerate the 1-hydroxyethyl radical and hence, regenerate acetaldehyde. Nevertheless any cyclic process involves losses and the total hydroxyl radical yield, as estimated from the reaction products, would be less than G(OH, ferrocyanide). Reaction [7] would constitute clear loss of hydrogen peroxide also, since the hydrogen peroxide/hydroxyl radical scheme would mean loss of at least half a molecule of hydrogen peroxide at each cycle.

The peroxyl radical, HO_2, is of importance in radiation chemistry

$$H + O_2 \rightarrow HO_2 \quad [10]$$

$$e_{aq}^- + O_2 \rightarrow O_2^- \quad [11]$$

O_2^- is in equilibrium with HO_2. The peroxyl radical could take part in the main acetaldehyde-hydrogen peroxide-generating processes by reactions such as the following

$$2HO_2 \rightarrow O_2 + H_2O_2 \quad [12]$$

$$HO_2 + \underset{\displaystyle O_2}{\overset{\displaystyle |}{CH_3CHOH}} \rightarrow CH_3CHO + H_2O_2 + O_2 \quad [13]$$

Both these reactions would upset the 1:2 hydrogen peroxide:acetaldehyde ratio and therefore are not important here.

An alternative reaction scheme for the 1-hydroxyethylperoxyl radicals is as follows and involves formation of ethanol hydroperoxide (1-hydroxyethyl hydroperoxide) (15)

$$\underset{\displaystyle O_2}{\overset{\displaystyle |}{2CH_3CHOH}} \rightarrow \underset{\displaystyle H}{\overset{\displaystyle OH\ |}{CH_3COOH}} + CH_3CHO + O_2 \quad [14]$$

Ethanol hydroperoxide undergoes various possible reactions, in particular a rapid base-catalyzed decomposition to acetaldehyde and hydrogen peroxide (17)

$$\underset{\displaystyle H}{\overset{\displaystyle CH_3\ |}{CH_3COOH}} \xrightarrow[\text{Heat}]{OH^-} CH_3CHO + H_2O_2 \quad [15]$$

This reaction requires an elevated temperature, as is found under the glow spot (18). Reactions [14] and [15], therefore, are alternatives to reaction [9].

Ethanol hydroperoxide also tends to convert to the di-peroxide in aqueous systems (19). No evidence could be found (3) for this di-peroxide in x-irradiation studies.

The exactness of the hydrogen peroxide:acetaldehyde ratio shows that little, if any, of the product is locked up in the form of organic peroxides. It is possible, on the other hand, that the organic peroxides reacted as mixtures of hydrogen peroxide and acetaldehyde, since time was always allowed for the analytical processes to reach completeness, but the balance of the evidence is against significant organic peroxide formation.

A further possibility is the elimination of the hydroperoxyl radical from the 1-hydroxyethylperoxyl radical, followed by disproportionation of the former species

$$\underset{\displaystyle O_2}{\overset{\displaystyle |}{CH_3CHOH}} \rightarrow CH_3CHO + HO_2 \quad [16]$$

$$2HO_2 \rightarrow O_2 + H_2O_2 \quad [12]$$

This gives the correct product ratio but the possibility of side reactions of peroxyl radicals makes the above scheme less probable. Reaction [12] was investigated

in the absence of ethanol and using dilute aqueous alkali: No change in pH was observed after gde, so no hydrogen peroxide formation was inferred.

Reactions such as

$$CH_3CHOH + HO_2 \rightarrow CH_3CHO + H_2O_2 \quad [17]$$

or

$$CH_3CHOH + HO_2 \rightarrow CH_3\overset{\overset{OH}{|}}{C}HOOH \quad [18]$$

followed by

$$CH_3\overset{\overset{OH}{|}}{C}HOOH \xrightarrow[\text{Heat}]{OH} CH_3CHO + H_2O_2 \quad [15]$$

can be discounted, since they give an unambiguously incorrect product ratio.

If the oxygen flow rate is not high enough the 1-hydroxyethyl radicals are incompletely scavenged and some butanediol appears, possibly with some disproportionation also. The ethanol scavenges most, but not all, of the OH radicals as deduced from our G(OH, ferrocyanide) work and from the small residual peroxide in the argon runs. It was found that the total nonacid yield corresponded very closely to G(OH, ferrocyanide): see Table II. The gde work on neutral and also on alkaline ferrocyanide gave closely similar ferricyanide yields, and no hydrogen peroxide, indicating total scavenging of the hydroxyl radicals by ferrocyanide.

Schultze and Schulte-Frohlinde (5) also postulated the decomposition of ethanol hydroperoxide to acetic acid and water

$$CH_3-\overset{\overset{OH}{|}}{C}HOOH \xrightarrow{H^+} CH_3COOH + H_2O \quad [19]$$

The reaction is acid-catalyzed. Our G-values for acid were very high (of the order of 9 mole F^{-1}). Acid formation as proposed above must involve a chain process, starting from ethanol, since G(acid) is so large: Such a process might involve acetaldehyde, as an intermediate or by-product, and this would upset the 1:2 hydrogen peroxide:acetaldehyde ratio and also the correlation between G(OH, ferrocyanide) and total yields. If acetaldehyde were the source of the acid, then, in order to preserve the acetaldehyde yield, another chain process would be required, consuming ethanol. The gain in acid does not correlate with the loss in acetaldehyde. Further, the acid yield *vs.* quantity of electricity curve flattens off with increasing run time, suggesting some kind of saturation. Acid was found also in gde studies on aqueous isopropanol, involving either a combustion process (yielding carbon dioxide) or C-C bond fission. Acid formation involves the simultaneous presence of oxygen and substrate. The observed hydrogen peroxide:acetaldehyde ratio is consistent with the mechanism proposed above but does not account for the acid. If other reactions occur they must somehow produce acid and the proper product ratio. It is concluded tentatively that the acid arises from combustion processes.

Table II. Total yields under oxygen

	G/mole F^{-1}
G(OH, ferrocyanide)	7.19 ± 0.66
$G(CH_3CHO, O_2)$	6.44 ± 0.13
$2G(C_4H_{10}O_2, O_2)$ (trace)	0.45 ± 0.05
$2G(H_2O_2, Ar)$ (trace)	0.19 ± 0.02
	7.08 ± 0.14

The total yield calculation was repeated for the argon runs, G(OH) being estimated to be 7.145 ± 0.149 mole F^{-1}. It seems we have accounted for all the hydroxyl radicals. Other species may compete, but at a much lower level. We did not find any need to assume loss of products (except for acetaldehyde): Decomposition of products is a main feature of Seddon and Allen's radiolysis work (4).

In the absence of ethanol and in the absence of oxygen, under established conditions, the product-destroying reactions

$$H + H_2O_2 \rightarrow OH + H_2O \quad [20]$$

and

$$OH + H_2O_2 \rightarrow HO_2 + H_2O \quad [21]$$

might occur, but the extent is not clear. The main product under argon and in the absence of ethanol is hydrogen peroxide and possible reactions are

$$H + H \rightarrow H_2 \quad [22]$$

$$H + OH \rightarrow H_2O \quad [23]$$

$$OH + OH \rightarrow H_2O_2 \quad [2]$$

In the presence of oxygen and in the absence of ethanol oxygen/radical or oxygen/aqueous electron reactions compete with radical/radical processes. Perhydroxyl radical formation may be possible, giving some additional peroxide by self-reaction.

It is possible that some or all of the aqueous electrons which may be generated in gde may react with hydrogen ions also generated or with those from water. There seems to be no need to include this species in the yield analyses: For example, under oxygen the aqueous electron has an opportunity to partake via reaction [11] but there is no evidence for this.

The radiation and gde chemistry of aqueous ferrocyanide has been reviewed by Denaro and Owens (20) and further work carried out by others, especially Almubarak and Wood (21). It was found (21) that G(ferricyanide) was independent of pH (from pH 7 upward). In alkali, inorganic peroxide is expected to reduce ferricyanide, *i.e.*, reducing G(ferricyanide); it was concluded that at sufficiently high ferrocyanide concentrations no peroxide occurs and all the hydroxyl radicals are scavenged by the substrate. The absence of any oxygen flow rate effect suggests that reactions involving the hydroperoxyl radical or its anion can be neglected here also. For similar reasons contributions by hydrogen radicals and by aqueous electrons to the reaction system were discounted also. It was concluded that G(ferricyanide) represented G(OH). It is hoped to publish details of this work shortly.

Further work on the gde of aqueous ethanol in selected buffers is proposed in order to investigate the mechanism at various pH values and also to examine the possibility that ethanol itself is decomposed directly by the bombardment processes. This latter may be achieved by analysis for other products, such as ethylene glycol and 1,3-propanediol, arising from C-C fission. The ultimate fate of the hydrogen radicals and the aqueous electrons requires further study also, and substrates likely to show improved reactivities toward these species have been selected.

X-Ray Photoelectron Spectroscopic Studies of Tin Electrodes after Polarization in Sodium Hydroxide Solution

R. O. Ansell, T. Dickinson,* A. F. Povey,[1] and P. M. A. Sherwood

School of Chemistry, The University, Newcastle upon Tyne, NE1 7RU, United Kingdom

ABSTRACT

The surface of tin electrodes after potentiostatic polarization in 0.50 mole dm^{-3} sodium hydroxide solution has been examined by x-ray photoelectron spectroscopy. Stannous oxide and hydroxide are shown to be present in the prepassive region. At higher potentials stannic oxide and hydroxide are formed. The thickness of the layer is evaluated over the potential range −0.95 to +0.40V using various models and is in the range 30-86Å.

X-ray photoelectron spectroscopy (XPS) has been shown to be a valuable tool in the study of electrode surfaces (1-6). Information on the species present and quantitative information on thickness of layers and their distribution may be established. These may lead to proposed mechanisms being disproved or substantiated (7).

In this study tin electrodes have been examined after potentiostatic polarization in 0.5 mole dm^{-3} sodium hydroxide solution. Much of the previous electrochemical work on this system involved galvanostatic methods (8-13) but some workers have adopted a potentiostatic approach (14-18). The anodic polarization curve shows two peaks in the active-passive region. The occurrence of the first passivation has been attributed to the formation of a layer of SnO or $Sn(OH)_2$ by a dissolution precipitation mechanism (13, 15). The second region of passivity has been attributed to the presence of SnO_2 (13, 15).

In this study we have investigated the effect of potentiostatic polarization over a wide potential range. The existence of Sn II and Sn VI species is confirmed.

Experimental

All the spectra were run on an AEI ES200B spectrometer using Mg $K\alpha_{1\alpha_2}$ radiation. Both the analyzer entrance and exit slits were set at their minimum values to give maximum resolution conditions. The electron gun was operated at 120W power for all the studies to give a relatively low x-ray flux [and thus minimize any x-ray reduction (19)] and to enable the intensities of the photoelectron peaks to be compared. No time dependence of the spectra was observed. The spectrometer was operated in the fixed retardation ratio mode for the recording of all the photoelectron peaks. The scan speed used was either 0.05 or 0.02V sec^{-1} depending on the absolute intensity of the peaks. The binding energies are calibrated with respect to the C1s electron peak at 284.6 eV due to residual pump oil on the sample surface. This gave a value of 484.1 eV for the Sn(metal) 3d5/2 electron peak. This was subsequently used to calibrate the spectra where such a peak was clearly observed. The pressure in the sample chamber was, typically, 10^{-8} Torr. This was achieved rapidly after the insertion of the sample probe with the aid of a titanium sublimation pump. The temperature of the samples was maintained at 10°C.

Curve resolution was carried out on a du Pont Model 310 curve resolver using a 50:50 Gaussian-Lorentzian shape fit. For both the tin and oxygen spectra curves were fitted to be within ±0.3 eV of the binding energy quoted and ±0.2 eV of the separation from the tin metal 3d5/2 electron peak where this is observed. In the case of the tin spectra the separation of the 3d5/2 electron peaks due to Sn II and Sn IV from that due to tin metal (when this was observed) was within ±0.2 eV of the difference between their quoted binding energies.

A current-voltage curve was recorded (Fig. 1a), using a triangular voltage sweep at a sweep rate of 10 mV sec^{-1} before any other measurements were made to ensure the system was behaving satisfactorily.

Key words: photoelectron, tin, oxide, passivation.

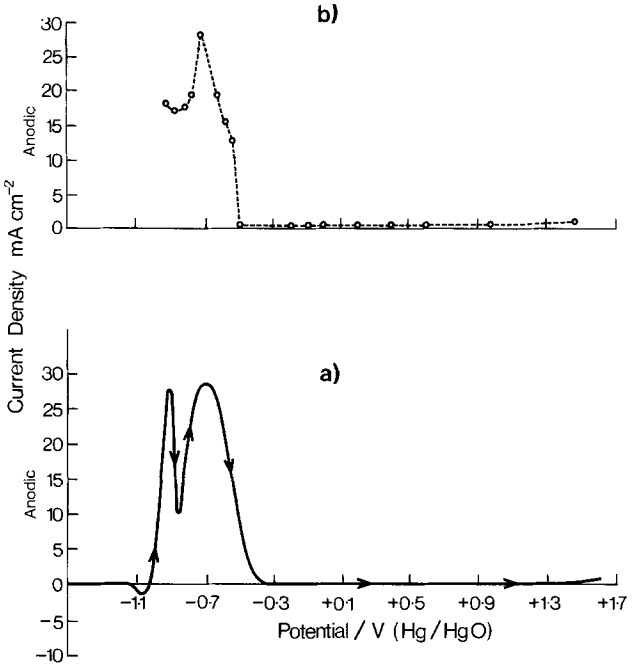

Fig. 1. (a) A current-voltage curve for the tin electrode in 0.50 mole dm^{-3} sodium hydroxide solution at a sweep rate of 10 mV sec^{-1}. Ordinate: Current density mA cm^{-2}. Abscissa: Potential/V (Hg/HgO). (b) The steady-state current-voltage curve for tin electrodes polarized in 0.50 mole dm^{-3} sodium hydroxide solution and subsequently examined by XPS. Ordinate: Anodic current density mA cm^{-2}. Abscissa: Potential/V (Hg/HgO).

Fresh electrodes were used for each measurement to eliminate the possibility of inadequate removal of the electrochemically formed oxide. Ventron (Alpha Products) tin foil (m5N) was used for the electrode studies. The electrodes were degreased in acetone and rinsed copiously before introduction into the cell. They were prepolarized initially for 10 min at −2.00V, the potential was slowly turned to −1.50V, and allowed to rest there for 1 min to allow the hydrogen gas bubbles to disperse. The potential was then either pulsed to the required value or adjusted to the required potential over a few seconds. The electrodes were polarized for 10 min at each potential studied; the current having become steady within this time. These steady-state currents are shown in Fig. 1b.

The electrochemical cell has been described before (7). In this case the electrode was carefully positioned next to the Luggin capillary tip to minimize effects of *iR* drop in the solution. The cell was housed in a nitrogen-filled glove box to enable anaerobic transfer of the electrode to the spectrometer as described previously (5).

All potentials in these experiments were measured and are quoted with respect to the mercury-mercuric oxide electrode in 0.5 mole dm^{-3} sodium hydroxide solution.

— Not present.

Results

The tin 3d5/2, oxygen 1s and sodium 2s electron peaks were studied for the treated electrodes, and were compared with spectra obtained from tin compounds (Table I). The tin 3d5/2 electron peak observed with treated electrodes could be resolved in all cases into two or three peaks at binding energies of 484.1, 485.8, and 486.3 eV corresponding to tin metal, stannous oxide and/or hydroxide, and stannic oxide and/or hydroxide, respectively (Table II). Representative spectra are shown in Fig. 2.

The oxygen 1s electron peak could be resolved into two or three peaks at binding energies of 532.3, 531.4, and 529.9 eV (Table II, Fig. 3). The peak at 532.3 eV is present on all samples introduced into the spectrometer and may be shown to be due to a surface species by angular variation experiments (21). This peak is therefore assigned to adsorbed oxygen or water. In those cases in which the proportion of the total peak area assignable to these species is <5% this peak has not been shown in Fig. 3. The peak at 529.9 eV may be assigned to oxide oxygen by comparison with the tin oxides studied (Table I). A hydroxyl oxygen species would, on a simple basis of charge, be expected to have a higher binding energy and this has been the case for many hydroxide species studied [Table I and previous work (3-7)]; thus the peak at 531.4 eV is assigned to hydroxyl oxygen.

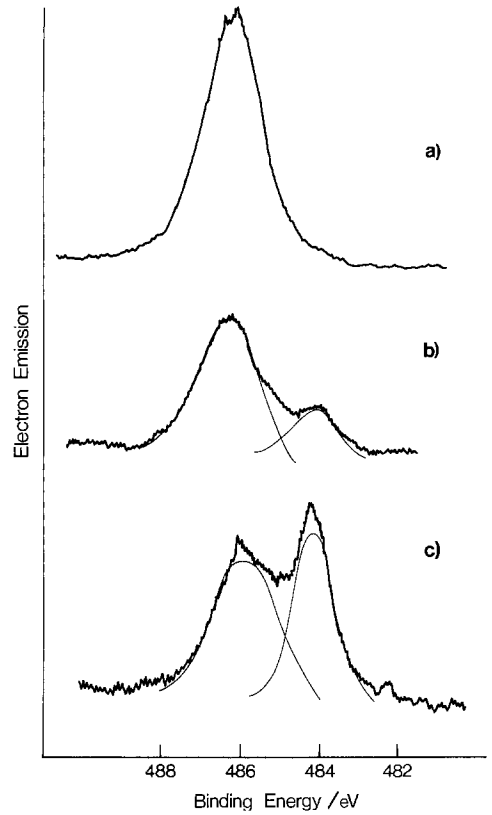

Fig. 2. Representative spectra of the tin 3d5/2 electron region of the tin electrodes after polarization at a potential of (a) —0.90V, (b) —0.10V, (c) +1.50V. Ordinate: Electron emission. Abscissa: Binding energy/eV.

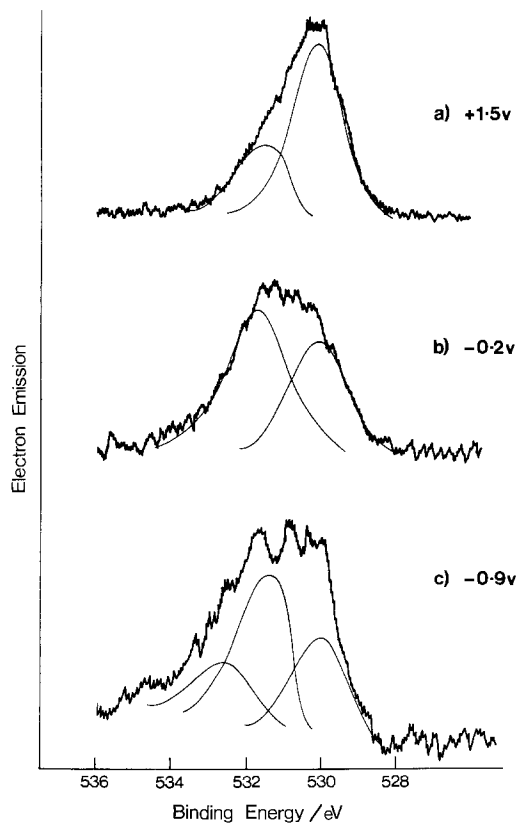

Fig. 3. Representative spectra of the oxygen 1s electron region of the tin electrodes after polarization at a potential of (a) —0.90V, (b) —0.10V, (c) +1.50V. Ordinate: Electron emission. Abscissa: Binding energy/eV.

A single peak at 63.5 eV could be detected at many potentials due to sodium incorporation in the layer. The absolute intensity of this peak in the spectrum of the treated electrodes is given in Table II.

In spite of the precaution taken in transferring the electrode to the spectrometer, even after pretreatment at —2.00V for 10 min the presence of some stannous hydroxide could be detected. Since similar results were obtained after polarizing in the active region no useful information could be deduced from them. At more positive potentials, however, significant differences were observed in the spectra.

Characterization of the layer.—It has been demonstrated previously how the relative intensities of the photoelectron peaks from the surface oxide and substrate metal may be used to derive the thickness of the layer (3-5, 7). When two oxides/hydroxides possibly of different valence states are present a more comprehensive study may reveal how the species are distributed over the surface and thus explain more fully the nature of the passivation process (20).

In this case in order to analyze the intensity data it is convenient to divide the potential range into four sections. The region from —0.95 to 0.80V in which Sn II species are present, from —0.75 to —0.50V in which both Sn II and Sn IV species are present, and —0.20 to +0.40V in which Sn IV species are present. In these three regions the metal substrate is also detectable. In the fourth region, +0.60 to +2.40V the substrate is no longer detectable; this implies the layer is greater than *ca.* 90Å thick (see Table III).

The first and third regions have been analyzed assuming the electrode is completely covered by an oxide/hydroxide layer. The relevant equation is then

$$\frac{I_{ox}}{I_m} = K\frac{(1 - \exp(-x\sigma_{ox}))}{\exp(-x\sigma_{ox})} \qquad [1]$$

where the symbols have the same meaning as before (4, 5, 7). Taking values of 1.81 and 27.7Å for K and $1/\sigma_{ox}$, respectively, arising from our previous angular variation study (21) the thickness of the layer can be evaluated (Table III).

In the second region where two different valency states of tin are present in the surface layer the data may be analyzed in various ways. The results are given in Table IV and discussed below.

Discussion

Assignment of the photoelectron peaks.—The spectra show that oxide/hydroxide species are present on the electrode over the total potential range studied. Assignment of the tin species is based partly on a comparison with the spectra of stannous oxide and stannic oxide. The total Sn 3d5/2 electron peak envelope can be satisfactorily resolved into peaks due to these two species and tin metal. There is no evidence for a chemical shift between stannous oxide and hydroxide in the Sn 3d5/2 electron peak. Thus for the tin foil as received the tin 3d5/2 electron peak is at the same bind-

* Subscript 1 refers to Sn II species. Subscript 2 refers to Sn IV species.

ing energy as that for SnO although the oxygen peaks are shifted. Similarly the spectra of the electrode after polarization at −0.80V show only hydroxide oxygen species and the Sn 3d5/2 peak can be readily resolved into peaks at 485.8 and 484.1 eV. Neither is there any evidence for a chemical shift of the Sn 3d5/2 electron peak between stannic oxide and hydroxide. At very high potentials where there is a high proportion of oxide the tin 3d5/2 electron peak is virtually identical to that at lower potentials where a considerably higher proportion of hydroxide is present.

The assignment of the oxygen 1s electron peak at 531.4 eV to hydroxyl species is based on previous work (5, 7). There is no doubt that there are at least two different oxygen-containing species present in the layer and it seems reasonable to assign one to oxide and one to hydroxide.

The amount of sodium present shows no correlation with potential or with any of the other species present. This is probably due to a small amount of sodium incorporation in the layer and/or some residual NaOH being left on the surface after washing.

Characterization of the layer.—The analysis of the positions and intensities of the photoelectron peaks suggest that in the prepassive region only Sn II species are present.

Both oxide and hydroxide are present in this region and the total thickness is in the range 20-26Å. We have found, previously, that metal dissolution may proceed at a high rate even when the electrode surface is covered by thick layers of oxide/hydroxide (5).

Both Sn II and Sn IV species are present in the region −0.25 to −0.50V. The oxygen 1s electron spectra show only hydroxide is present at −0.80V but at all higher potentials both oxide and hydroxide are present. The total layer thickness is in the range 38-59Å for each of the models chosen for the analysis (Table IV).

In the region −0.20 to +0.40V there is a steady increase in the thickness of the layer which is composed solely of Sn IV species. The oxide/hydroxide ratio also shows an increasing trend with increasing potential (Tables II and III). This trend continues at higher potentials where the substrate is no longer detectable. The film becomes visible at very high potentials suggesting the thickness has increased further.

Correlation with the electrochemical data.—It is important to see if the species identified, the layer thickness, and the distribution of the species can be correlated with the electrochemical data; in particular the current-potential curve (Fig. 1b). In the prepassive region only stannous oxide and hydroxide are present. The current is $\geq$ 15 mA cm^{-2} throughout this region indicating that this layer is not strongly passivating.

The fall in current between −0.95 and −0.90V is probably due to the increased proportion of oxide in the surface layer (Table II). The subsequent increase in current may be tentatively correlated with the decrease in proportion of stannous oxide and of course the more positive potentials.

The true passivation correlates with an increasing proportion of the tin 3d5/2 electron envelope being due to Sn IV species. The intensities have been analyzed using four different models (Table IV). A satisfactory model must explain a slowly decreasing current from −0.75 to −0.55V, followed by a very abrupt decrease at −0.50V to a value of 0.05 mA cm^{-2}. The model must also give a total thickness of about 35Å from −0.75 to −0.55V, since the proportion of the tin 3d5/2 electron envelope due to the metal is approximately constant from −0.80 to −0.55V. A considerably thicker layer (*ca.* 50Å) must be present at −0.50V because, at this potential, the proportion of the tin peak due to the metal falls to a value similar to that observed in the potential range −0.20 to 0.00V.

All models give values for the total thickness which satisfy the requirements described above. This is, indeed, to be expected since, lacking the appropriate data, it has been necessary to assume that $\lambda_1 = \lambda_2$. The slow decrease in current could be explained, by the patchy layer model, as due to an increasing coverage by Sn IV species; as discussed above the Sn II species are not strongly passivating. A fivefold increase in the coverage by Sn IV species (from −0.55 to −0.50V) does not, however, seem a sufficient change to account for the very large fall in the current.

It is difficult to decide whether a homogeneous layer is physically realistic, what properties it would have, and how changes in its composition would affect the degree to which it passivated the electrode.

Both the models involving two distinct layers predict an increase in the thickness of the Sn IV layer with potential, as seems to be necessary to account for the decreasing current. If the lower layer is composed of Sn IV species, it appears that this would have a thickness corresponding to that of at least two unit cells, even at −0.75V (SnO_2 has a tetragonal structure with unit cell dimensions of a = 4.74Å and c = 3.19Å). Since the electrode undergoes rapid dissolution at this potential, whereas Sn IV species appear to be strongly passivating, it seems unlikely that such a relatively thick film would be present. If the upper layer consists of Sn IV species, the thicknesses involved are more acceptable and the fourfold increase in the thickness of this layer between −0.55 and −0.50V would account for the dramatic fall in the current which accompanies this change in potential.

So far as it is possible to analyze this situation, therefore, the balance of evidence suggests that, in the potential range between −0.75 and −0.50V, two distinct layers are present on the electrode surface. It also appears, as is to be expected on thermodynamic

grounds, that the layer nearest the electrode is that of lowest oxidation state.

When the electrode is fully passivated, there is very little dependence of the current on potential (between −0.5 to +0.60V). This can be explained in terms of both the increasing thickness of the layer (22) (Table III) and its progressive dehydration; the oxide/ hydroxide ratio shows a generally increasing trend as the potential is made more positive (Table II). At still more positive potentials the thickness continues to increase but the current rises somewhat. This may be due to the onset of oxygen evolution or to imperfections in the layer.

Diffusion and Charge Transfer Parameters for the Ag/AgCl Electrode

Hiram Gu* and Douglas N. Bennion*

Energy and Kinetics Department, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

Galvanostatic formation and potentiostatic reduction of silver chloride on silver have been studied. Experiments were conducted in 0.5, 1.0, 1.5, 2.0, and 3.0*N* KCl solutions. The effective mass transfer coefficient, k_m^o, for the transport of complex silver ions from AgCl crystals to reaction sites on the silver surface was found to depend on KCl concentrations in the form

$$k_m^o = 1.808 \times 10^3 [\exp(-1.519 \times 10^3 c_e)] \text{ cm/sec}$$

with c_e in mole per cubic centimeter. The apparent cathodic charge transfer coefficient, α_c, was determined to be 0.30, and the exchange current density

$$i_o = 0.15 (c_R^{sat}/10.1 \times 10^{-8})^{0.70} \text{ A/cm}^2$$

with c_R^{sat} (mole per cubic centimeter) being the saturated concentration of complexed silver ions in the KCl solution.

In addition to being used as reference electrodes, silver/silver chloride electrodes have found use as porous electrode plates in batteries such as the seawater battery. Previous studies on porous Ag/AgCl electrodes (1, 2) have indicated that the electrode may be used successfully in secondary storage batteries.

The silver/silver chloride electrode is an electrode with a sparingly soluble reactant, AgCl. Numerous studies have been conducted on the thermodynamics of Ag/AgCl electrodes (3) and the mechanism of AgCl formation and reduction at silver electrodes (4-11). The studies of Kurtz (4) and Lal *et al.* (5) suggested that electrolytically formed AgCl films are porous in nature. Briggs and Thirsk (6) studied the galvanostatic reduction of silver chloride films on silver at different current densities and KCl concentrations. They found that an increase in the initial AgCl layer thickness reduces the number of reduction centers visible at a given percentage reduction. Jaenicke *et al.* (7) found that if a pore-free AgCl layer is reduced by a cathodic current, pores soon appear. Fleishmann and Thirsk (8) studied the growth of AgCl on Ag and concluded that the growth of AgCl is two dimensional. Giles (9), however, believed that the formation of AgCl is by progressive nucleation and growth of three-dimensional centers and that the diffusion of $AgCl_{n+1}^{-n}$ may

Key words: porous electrodes, batteries, exchange current.

be rate determining. The value of n for the complex may be 0, 1, 2, or 3. Katan *et al.* (10) studied the reduction of silver ions from potassium chloride solutions saturated with AgCl. A rotating disk silver electrode was used. Their results also indicate that the formation and reduction of silver chloride involves the solution diffusion of $AgCl_{n+1}^{-n}$. Aleskovskii *et al.* (11) studied the structure of silver deposits with respect to electrode potentials at which the reduction of AgCl takes place. They also suggested that the reduction is via a solution diffusion path.

No information regarding the charge transfer overvoltage of Ag/AgCl electrodes was found in the literature. The absence of charge transfer studies on Ag/AgCl electrodes is probably due to two reasons. First, the overvoltage in the case of solid silver electrodes consists mainly of crystallization and diffusion overvoltage with large exchange current density according to Gerischer and Tischer (12, 13) and Bockris *et al.* (14, 15). Second, the coverage of silver surface by silver chloride adds complexity to the analysis of experimental data.

The present study was conducted with the intention of determining apparent diffusion and charge transfer parameters for the Ag/AgCl system. These parameters are to be used in the mathematical modeling of Ag/AgCl porous electrodes.

The potentiostatic reduction of porous silver chloride films on silver was analyzed. As the silver chloride is being converted to silver, the silver area available for charge transfer increases. The cathodic current increases to a maximum and decreases as the silver chloride is being depleted. The maximum current density reached during potentiostatic reduction was used to construct the current-overpotential curves. From the i-η curves, values of four parameters were deduced. They are: the cathodic charge transfer coefficient, α_c; the mass transfer coefficient of complexed silver ions, k_m^o, for solution phase transport between Ag surface and AgCl surface; the exchange current density, i_o; and the order of dependence of i_o on silver ion concentration, γ.

Qualitative results observed on the galvanostatic formation of AgCl are also presented.

Experimental

The experimental arrangement is shown in Fig. 1. The electrode studied was a circular silver disk 1/8 in. in diameter embedded in Lucite. Another Lucite piece that consisted of the counterelectrode compartment, a 1/8 in. diam tunnel, and a small branch tunnel approximately 1/32 in. diam was spring pressed against the working electrode piece. The 1/8 in. tunnel was aligned with the silver disk allowing uniform primary current distribution on the electrode surface. A thin film of electrolytic solution approximately 10 μm thick existed between the two Lucite pieces which provided a solution connection between the main cell and the reference electrode compartment. The reference electrode was a Ag/AgCl electrode. The same KCl concentration as the main cell was used in the reference electrode compartment. A tube pump was used to circulate the electrolyte so as to maintain a constant electrolyte concentration near the electrode surface. The electrolyte flow rate used during experimental runs was 3.5 cm^3/sec.

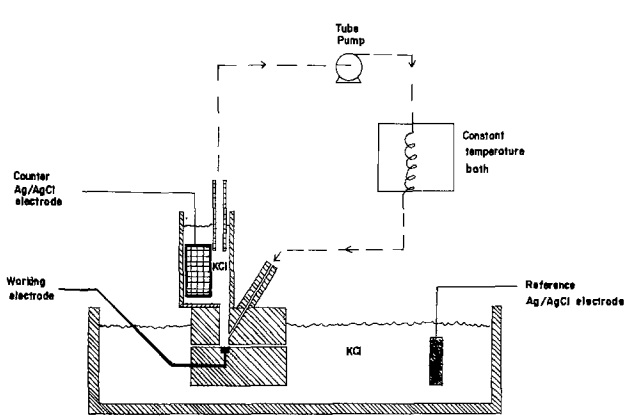

Fig. 1. Experimental arrangement

The KCl solutions used were prepared from doubly distilled water and reagent grade KCl. The initial silver surface was mechanically finished with 4/0 emery polishing paper purchased from Buehler Limited.

The experiments were conducted at 25° ± 1°C in 0.5, 1.0, 1.5, 2.0, and 3.0N KCl solutions. The electrode was galvanostatically charged at 5 mA/cm^2 and subsequently reduced potentiostatically. A PAR Model 173 potentiostat/galvanostat was used to impose the experimental current or voltage.

The overpotential, η, reported in this communication is the potential measured or imposed between the working electrode and the Ag/AgCl reference electrode.

Results

Galvanostatic formation of AgCl.—Typical η-t (overpotential-time) curves for the galvanostatic charging (passage of constant anodic current) of silver electrodes in KCl solutions are shown in Fig. 2. Curve a was obtained when silver chloride was formed on an electrode with a freshly polished silver surface. The curve shows a close to linear rise in potential with time. After the electrolytically formed silver chloride was totally reduced back to silver (either galvanostatically or potentiostatically), galvanostatic recharging of the electrode exhibited a different η-t curve (curve b). The η-t curve has a rather flat portion at the beginning followed by a rapid rise. Additional cycling (charged and discharged) did not seem to have further effect on the η-t curves for galvanostatic charging nor was there any observable dependence (based on scanning electron microscope observation) of the electrode surface roughness on the number of cycles. However, it was observed that the flat portion of the η-t curve was usually lower and the rapid rise in potential was usually earlier (shorter t_p as defined in Fig. 2) when higher concentrations of KCl solutions were used. Figure 3 shows the equivalent amount of charge, Q^* (equal to it_p), at t_p with respect to KCl concentrations. The time t_p is time at which rapid rise in potential begins as defined in Fig. 2. Galvanostatic charging in 1N KCl with current densities from 2.5 to 100 mA/cm^2 indicated that the value of Q^* is independent of the charging current in the range studied.

Fig. 2 are shown in Fig. 4. Figures 4a and 4b give comparison of the surfaces (fresh and cycled) at the same state of charge while Fig. 4b and 4c give comparison of the surfaces at the same electrode potential. The small particles between the AgCl crystallites in Fig. 4c are silver.

Potentiostatic reduction of AgCl.—The current flow during the reduction of AgCl depends on the rate of diffusion of complexed silver ions from the silver chloride surface to the silver surface. As an approximation, one can say that the silver area is θA and the silver chloride area is $(1 - \theta)A$. Here A is the total electrode area and θ is the fraction of silver area exposed. By assuming a linear concentration profile between the AgCl area and Ag area, the reaction rate, based on the area A, can be written as (16)

$$i = n\mathbf{F}k_m^{o}(\theta)^{1/2}(1-\theta)^{1/2}(c_R^{s} - c_R^{sat}) \qquad [1]$$

where c_R^s is the concentration of complexed silver ions at the silver surface where charge transfer reaction takes place and c_R^{sat} is the saturation concentration of complexed silver ions which prevails at the AgCl surface. **F** is the Faraday constant and n is the number of electrons involved in the charge transfer reaction. The mass transfer coefficient, k_m^o, is equal to D/δ where D is the complexed ions diffusion coefficient and δ is the average diffusion length. One can also define an over-all mass transfer coefficient, k_m, such that

$$k_m = k_m^{o}(\theta)^{1/2}(1-\theta)^{1/2} \qquad [2]$$

The over-all mass transfer coefficient thus varies with the amount of surface coverage by AgCl.

The maximum current density reached during potentiostatic reduction was found to depend on the initial coverage of silver surface by AgCl. If the initial coverage, $1 - \theta$, was above 0.5 and below about 0.8 (state of charge in the flat portion of curve b in Fig. 2), the maximum current remained the same over a wide range of initial charge. However, if the electrode was initially heavily covered by AgCl (state of charge corresponding to rising portion of curve b in Fig. 2), lower maximum currents were obtained. Typical i-t curves are shown in Fig. 5. Curve a was obtained with an initially porous silver chloride film. Curves b and c were obtained from initially heavily charged electrodes. Curve c had a more dense coverage of AgCl compared to curve b.

Surface morphology of the electrode at the cathodic current maximum for the cases corresponding to curves a and c in Fig. 5 are shown in Fig. 6. For the case with initial heavy coverage, there were few reduction centers, and the boundaries of the centers expanded in a circular manner as AgCl was being reduced (Fig. 6 d and e). For the case where the initial AgCl film was quite porous, there were many more reduction centers dispersed among the silver chloride crystallites (Fig. 6 a, b, and c). Figure 6c shows the structure of reduced silver after the remaining silver chloride had been removed by sodium thiosulfate. Similar surface morphology was also reported by Briggs and Thirsk (6).

Cathodic i-η curves obtained for KCl concentrations of 0.5, 1.0, 1.5, 2.0, and 3.0N are shown in Fig. 7. Experiments were performed on a cycled electrode with the surface undisturbed between runs. Before each potentiostatic reduction run, the electrode was charged galvanostatically at 5 mA/cm² to approximately 85% of t_b (see Fig. 2). This assured that the AgCl film was porous and the surface coverage was approximately the same for each run. Data points in Fig. 7 correspond to maximum currents reached during potentiostatic reductions. At the maximum current, the fraction of ex-

posed silver area, θ, was 0.5 as determined from microscope pictures.

No limiting current plateau was observed in the 0.5N KCl solution. From the limiting current plateaus in 1.0, 1.5, 2.0, and 3.0N KCl solutions, the over-all mass transfer coefficients for the transport of $AgCl_{n+1}^{-n}$ (at $\theta = 0.5$) were calculated using the following equation

$$\kappa_m = \frac{-i_{lim}}{\mathbf{F} c_R^{sat}} \qquad [3]$$

Values of c_R^{sat} were obtained from experimental results (17). The mass transfer coefficient, k_m^o, was then calculated from Eq. [2] where k_m^o is $2k_m$ at $\theta = 0.5$.

The mass transfer coefficient was found to depend on KCl concentrations (Fig. 8). Examination of Fig. 8 shows that the dependence follows the relationship

$$k_m^o = B \exp(Ec_e) \qquad [4]$$

with $B = 1.808 \times 10^3$ cm/sec and $E = -1.519 \times 10^3$ cm^3/mole.

The kinetic rate expression applied to the present system can be written as

$$i = \theta i_o \left[\left(\frac{c_R^s}{c_R^{sat}} \right)^{\gamma - \alpha_a} \exp\left(\frac{\alpha_a \mathbf{F} \eta}{RT} \right) - \left(\frac{c_R^s}{c_R^{sat}} \right)^{\gamma - \alpha_c} \exp\left(\frac{-\alpha_c \mathbf{F} \eta}{RT} \right) \right] \qquad [5]$$

where γ is the order of dependence of i_o on the complexed silver ion concentration; α_a and α_c are the anodic and cathodic charge transfer coefficients, respectively; R is the gas constant; and T is the absolute temperature. The exchange current density i_o can be written as

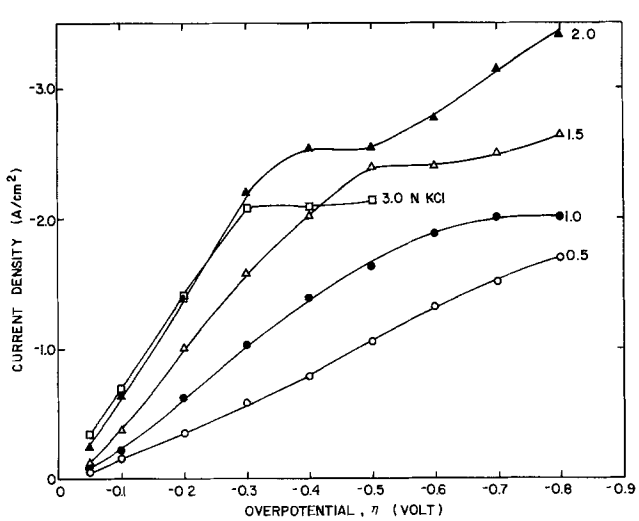

Fig. 7. Current-overpotential curves for the reduction of silver chloride. The current is the maximum current from the i-t curves.

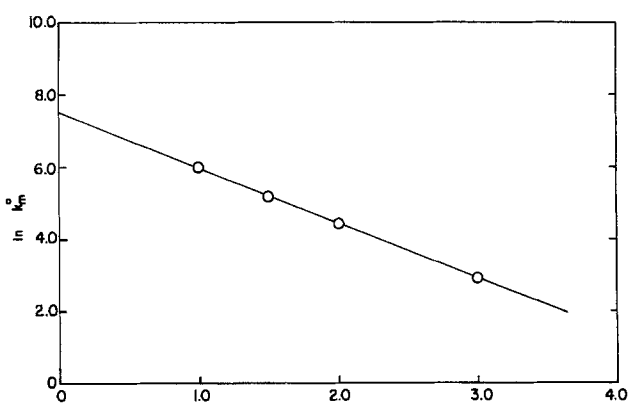

Fig. 8. Dependence of the mass transfer coefficient on KCl concentrations.

$$i_o = i_o^o \left(\frac{c_R^{sat}}{c_R^*} \right)^{\gamma} \quad [6]$$

where i_o^o is the exchange current density corresponding to the concentration of complexed silver ions, c_R^*. In the present investigation, c_R^* was selected as the saturated concentration of $AgCl_{n+1}^{-n}$ in 1N KCl solution, *i.e.*, $c_R^* = c_R^{sat}$ in 1N KCl.

It is believed that the silver dissolution and deposition involves a one-electron transfer elementary step. Therefore, Eq. [5] can be rearranged, with $\gamma = \alpha_a$ and $\alpha_a + \alpha_c = 1.0$, to read

$$\ln \frac{i}{\left[\left(\frac{c_R^{sat}}{c_R^s} \right) \exp \left(\frac{F\eta}{RT} \right) - 1 \right]} - \ln \left(\frac{c_R^s}{c_R^*} \right) = \ln \theta i_o^o - \alpha_c \left[\frac{F\eta}{RT} + \ln \left(\frac{c_R^{sat}}{c_R^*} \right) \right] \quad [7]$$

Using the results from Fig. 7 and 8, values of c_R^s were first calculated from Eq. [1]. The left-hand side of Eq. [7] was then plotted against the terms in the bracket on the right-hand side as shown in Fig. 9. The slope of the plot allowed the detemination of α_c and the intercept gives the value of θi_o^o with $\theta = 0.5$ (since the peak current was used). The values of α_c and i_o^o were determined to be 0.3 and 0.15 A/cm^2, respectively.

The current density, i, can be calculated with respect to θ at a fixed η by solving Eq. [1] and [7] simultaneously. Calculations of i *vs.* θ for several different η indicate that the maximum currents occur at θ around 0.75 instead of 0.5 as was experimentally observed. The solubility of AgCl is quite low and thus the distance from silver chloride sites where $AgCl_{n+1}^{-n}$ ions are reduced is probably quite small. It is possible that the effective charge transfer silver area for the reduction of $AgCl_{n+1}^{-n}$ was actually less than the total exposed silver area when the electrode surface was less than 50% covered by AgCl.

A model was developed to calculate the effective silver reacting area. The model assumes that the effective silver area per silver chloride center is a ring extending a fixed distance from the perimeter of the silver chloride-silver interface. The effective width of the ring is calculated by assuming that all the exposed Ag is effective at θ equals 0.5. At $\theta \leq 0.5$

$$\theta_{eff} = \theta \quad [8a]$$

and at $\theta \geq 0.5$

$$\theta_{eff} = (1 - \sqrt{0.5})\,[2\sqrt{(1 - \theta)} + (1 - \sqrt{0.5})] \quad [8b]$$

An effective silver chloride area was also assumed for the supply of complexed silver ions at $\theta < 0.5$. Similar to the treatment in obtaining effective silver area at $\theta < 0.5$, the effective silver chloride area per center at $\theta < 0.5$ was also assumed to be a ring extending a fixed distance from the silver chloride-silver interface; the distance being calculated by assuming that all the silver chloride area is effective at $\theta = 0.5$. Therefore, at $\theta \leq 0.5$

$$(1 - \theta)_{eff} = 2\sqrt{1 - \theta}\sqrt{0.5} - 0.5 \quad [9a]$$

and at $\theta \geq 0.5$

$$(1 - \theta)_{eff} = 1 - \theta \quad [9b]$$

According to the model, θ and $(1 - \theta)$ in Eq. [1], [2], [5], and [7] should now be replaced by θ_{eff}, and $(1 - \theta)_{eff}$, respectively. The k_m in Eq. [2] is thus in the form, at $\theta \leq 0.5$

$$k_m = k_m^o\,[2\sqrt{1 - \theta}\sqrt{0.5} - 0.5]^{1/2}[\theta]^{1/2} \quad [10a]$$

and at $\theta \geq 0.5$

$$k_m = k_m^o\,[1 - \theta]^{1/2}[2\sqrt{1 - \theta}\,(1 - \sqrt{0.5}) + (1 - \sqrt{0.5})^2]^{1/2} \quad [10b]$$

Applying this revised form of the model, a maximum in current was obtained mathematically at $\theta = 0.5$.

To obtain the variation of θ with respect to Q (accumulated charge) for application in porous battery electrode modeling, the i-θ profiles were first calculated at various η using revised Eq. [1] and [5] for KCl concentration of 1.0N. From the experimental potentiostatic i-t curves at the corresponding η, a set of i-Q curves were then obtained approximately by graphical integration. Comparison of the calculated i-θ curves with the corresponding i-Q curves gave the variation of θ with respect to Q. It was found that the best fitted relationship is of the form

$$\theta = (0.25)^{Q/Q^*} \quad [11]$$

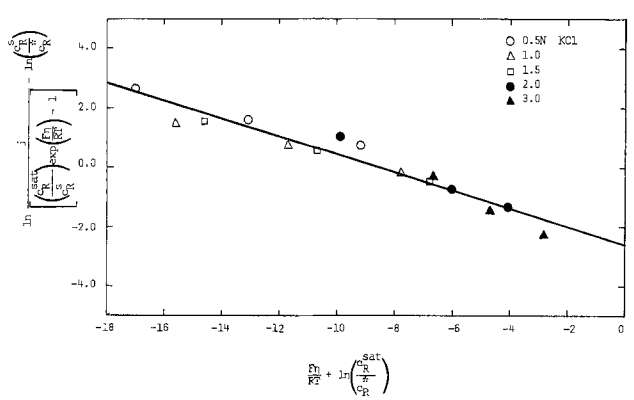

Fig. 9. Plot corresponding to Eq. [7]

Discussion

The two differently shaped η-t curves obtained on two different silver surfaces have also been observed separately by previous investigators. Briggs and Thirsk (6) obtained curves similar to curve a in Fig. 2 on their freshly polished silver surface while Katan *et al* (10) obtained curves similar to curve b on their cycled silver surface. The exchange current densities on a freshly polished silver surface and a cycled silver surface are probably different. The growth of AgCl on the two different surfaces is also different as can be seen from Fig. 4. On a freshly polished silver surface, there are a large number of AgCl nucleation centers formed at the beginning. As more charge is passed, the porous AgCl film thickens with a slow decrease in porosity. On a cycled surface, there are less nucleation centers and more crystal growth of silver chloride (Fig. 4 b and c). In addition, the true silver surface area of a cycled electrode is larger, as has been reported by Giles (9), and can be seen from Fig. 4 b and c. As a result, there is more silver surface available for charge transfer to occur for a longer duration and the overpotential is smaller. Finally, as anodic charging continues on the cycled Ag electrode, the AgCl crystallites begin to grow together, blocking off the silver surfaces, and the rapid rise in overpotential results. These observations support the fact that the formation of AgCl is mainly via solution phase diffusion of $AgCl_{n+1}^{-n}$ followed by crystal growth from a supersaturated solution.

For cycled surfaces, higher KCl concentrations produced lower overpotentials. This is attributed to higher $AgCl_{n+1}^{-n}$ solubility and resulting smaller concentration overpotentials. The shorter time to surface coverage, t_p, at higher KCl concentrations seems to indicate earlier coverage of the silver surface by AgCl in solutions of higher Cl^- content. The earlier coverage can be due to the increase in nucleation sites. Briggs and Thirsk (6) have also observed the earlier surface coverage in higher KCl concentrations. From their η-t curves (which are similar to curve a of Fig. 2), one

can see that the slopes of the curves are steeper in higher KCl concentrations.

The initial higher overpotential of the galvanostatic η-t curves of Fig. 2 are probably due to slow nucleation leading to a "nucleation overpotential" (18).

An electrolyte flow rate of 3.5 cm²/sec was used to keep the KCl concentration near the electrode surface constant. No dependence of current densities on the flow rate was observed during potentiostatic reduction within the flow rate range of 2.0-7.4 cm³/sec. With no circulation of the electrolyte, the measured current densities were higher as a result of the increase in KCl concentrations near the electrode surface as the AgCl was being converted to silver, the increase in KCl concentrations increases the solubility of the silver chloride.

The fact that no limiting current was observed during potentiostatic reduction in 0.5N KCl solution can be explained by nonuniform secondary current distributions and nonuniform concentration distributions of complexed silver ions at the silver surface. The experimental arrangement was designed for uniform macroscopic primary current distribution. However, due to the roughness of the electrode surface and because the reactants are supplied from the silver chloride crystallites, the secondary current distribution and the reactant concentration on a micro scale on the order of 1 μm at the silver surface are not uniform with respect to distance from AgCl crystals. This is especially true in 0.5N KCl, where the solubility of AgCl is lower and the microscale nonuniformity becomes more pronounced. As a result, the diffusion limiting current of silver deposition was not separable from the onset of another reaction (possibly hydrogen evolution) for the 0.5N KCl run.

An increase in silver chloride coverage reduces the number of reduction centers. The lesser number of reduction centers resulted in larger area per reduction center at $\theta = 0.5$ during discharging. For the case with heavy initial coverage of silver chloride, i-η curves similar to those reported by Katan *et al.* [Fig. 7 of Ref. (10)] were obtained. As can be expected, no limiting currents were observed due to the large area per reduction center at $\theta = 0.5$ (see Fig. 6 d and e), which resulted in very nonuniform microscale distribution of complexed silver ions and secondary reaction current across the exposed silver surface. The total effective silver area (boundaries of reduction centers) for the reduction of complexed silver ions was very small as compared to the total exposed silver area. Again, the limiting diffusion current was obscured by the onset of another reaction. The total effective area for the case with a large area per reduction center is also smaller than that for the case with a large number of reduction centers, and resulted in lower currents at $\theta = 0.5$ during potentiostatic reduction (Fig. 5, curve c).

The almost order of magnitude difference in maximum currents between curve a and curve c in Fig. 5 supports the solution diffusion mechanism in the electrochemical formation and reduction of silver chloride. If significant solid phase transport had occurred, there should have been less differences in the magnitude of the maximum currents.

The decrease in k_m^o at higher concentrations of KCl is due to the increased portion of $AgCl_4^{-3}$ present as can be shown from calculations using stability constants (19). The complexed $AgCl_4^{-3}$ has a larger ionic radius and thus a smaller diffusion coefficient than the other complexes. The measured k_m^o which includes all $AgCl_{n+1}^{-n}$, is therfore smaller at higher concentrations of KCl. Katan *et al.* (10), from their rotating disk experiments, also obtained a smaller effective diffusion coefficient for complexed silver ions in 4N KCl compared to that obtained in the 2N KCl solution.

The overpotential η, as measured, includes concentration overpotential, η_c as well as the charge transfer overpotential, η_s. At high overpotentials, η_c becomes important. The terms involving c_R^s/c_R^{sat} were introduced in Eq. [5] to correct for the concentration overpotential. At low overpotentials (less than -60 mV), surface diffusion of adions may become rate determining as was indicated by Bockris *et al.* (14, 15) in their studies of the dissolution and deposition of silver from solutions of silver perchlorate in aqueous perchloride acid. The effect of adion surface diffusion was not included in Eq. [5]. Therefore, in obtaining the slopes and intercepts according to Eq. [7], only data points above cathodic overpotential of 100 mV were used. In addition, since kinetic parameters were to be determined, data in the range where reaction rates might be predominantly solution phase mass transfer limiting were also excluded when constructing Fig. 9. The data excluded were $|\eta| > 0.4$V in 0.5, 1.0, and 1.5N KCl, $|\eta| > 0.3$V in 2.0N KCl, and $|\eta| > 0.25$V in 3.0N KCl.

It might be emphasized that the data in Fig. 7 and 9 are the same with the exceptions noted. The combination of Eq. [1] and [5] correlate the data as shown in Fig. 9. Since Fig. 7 presents the same data, it follows that these same equations yield approximately the curves shown in Fig. 7. The curves in Fig. 7 can be seen to be S shaped, the lower portions being near the inflection point of the S. The data at low η are in the region of exponential dependence of i on η shown in Eq. [5]. However, at larger η the curve in Fig. 7 bends downward due to a decrease in c_R^s as described by Eq. [1].

The overpotential as measured by the reference electrode also contained a small IR or ohmic resistance contribution which was considered negligible. The KCl solutions served as supporting electrolytes with high conductivity. Calculations showed, for example, at a current density of 2.0 A/cm², in 1N KCl, the maximum IR drop was about 20 mV, approximately 3% of the total observed overpotential, η.

Current densities as reported in this communication are based on the apparent electrode area. As mentioned earlier, the true surface area increases after the electrode has been cycled in KCl solutions. To account for the surface roughness based only on scanning electron microscope observations would not be very accurate. It was decided, therefore, that the results should be reported based on the apparent electrode area, keeping in mind that the experiment was performed on cycled electrode surfaces.

The true surface area also varied slightly between runs. Random checks showed that the current densities reported are reproducible to within $\pm 10\%$.

It must also be pointed out that the variation of θ with accumulated charge shown in Eq. [11] is quite approximate. The variation of θ is actually potential dependent. This is because the growth of silver deposits is potential dependent as has been indicated by Aleskovskii *et al.* (11). The result also varied somewhat with the KCl concentration. However, the results shown in Eq. [11] appear to be suitable for purposes of mathematical modeling of porous Ag/AgCl battery electrodes.

Conclusions

The electrochemical behavior of a Ag/AgCl electrode is highly dependent on the surface coverage by AgCl during galvanostatic charging. The η-t (overpotential-time) curves differ widely in shape depending on whether the silver surface is freshly polished or previously cycled.

The number of silver chloride nucleation centers increases with increasing KCl concentrations during galvanostatic charging.

Experimental observations support previous conclusions that the formation and dissolution of AgCl on silver is via solution diffusion of complexed silver ions, $AgCl_{n+1}^{-n}$, with $n = 0$, 1, 2, or 3.

The maximum current density during potentiostatic discharge depends highly on the number of reduction centers. The number of reduction centers in turn depends on the degree of initial coverage by silver chloride. A heavier initial coverage gives lesser number of reduction centers during discharge. A larger number of small reaction sites leads to lower overpotentials at comparable current densities.

The mass transfer coefficient, k_m^o, for the diffusion of $AgCl_{n+1}^{-n}$ was found to depend on KCl concentrations in the form

$$k_m^o = B \exp(Ec_e)$$

with $B = 1.808 \times 10^3$ cm/sec and $E = -1.519 \times 10^3$ cm^3/mole.

The exchange current density was determined to be

$$i_o = 0.15 \left(\frac{c_R^{sat}}{10.1 \times 10^{-8}} \right)^{0.70} \text{A/cm}^2$$

The units of c_R^{sat} are mole per cubic centimeter.

The cathodic charge transfer coefficient, α_c was determined to be 0.30.

Statistical Analysis of Electrode Kinetics Measurements–Copper Deposition from $CuSO_4$-H_2SO_4 Solutions

Reinaldo Cabán[1] and Thomas W. Chapman*

Department of Chemical Engineering, University of Wisconsin, Madison, Wisconsin 53706

ABSTRACT

The kinetics of electrochemical copper deposition from copper sulfate-sulfuric acid solutions have been studied by measuring polarization curves with a rotating-disk electrode. Kinetics models are evaluated and their parameters determined by nonlinear regression analysis of 87 data points. The data are fit within experimental error by a five-parameter model which includes the effects of both copper sulfate and sulfuric acid concentrations. The statistical analysis is made feasible by the rapid simulation of the experimental system by orthogonal collocation. The simulation involves computation of current distribution below limiting current at a specified applied potential for a given kinetics model.

The determination of quantitative electrode kinetics expressions is difficult because of the large number of variables and parameters involved and because of the complicated nonlinear form of the electrochemical kinetics relationships. As a result most kinetic studies focus on only a subset of parameters such as the exchange current density or a reaction order, and do not attempt often to cover a wide range of experimental conditions. For engineering calculations, however, it is necessary to have a fairly complete kinetics expression which can predict local current density over a range of composition and potential.

It is risky to construct a kinetics expression for a given reaction by taking an exchange current density from one experiment and a Tafel slope from another experiment, etc., because there is no guarantee that such parameters are truly independent and that the composite expression will represent properly the behavior of a particular experimental system. For example, the metal surface formed in copper electrowinning probably has quite different catalytic properties from one prepared in the laboratory for a basic mechanistic study. It would be preferable for engineering purposes to determine a complete, empirical kinetics expression with all of its parameters estimated simultaneously from a set of experimental data which cover the ranges of variables to be encountered in a system of practical interest.

Statistical Treatment of Complex Systems

The problem of estimating multiple parameters of nonlinear models from data has been studied in some detail by statisticians (1-3), and methods have been developed for treating many complex phenomena, for example, heterogeneous catalysis (4). The appropriate statistical procedures are indicated in Fig. 1. The form of a kinetics model is postulated and incorporated in a simulation of the experimental system behavior. The parameters of the model are adjusted to make the simulation match the experimental data within experimental accuracy. Figure 1 indicates that least squares fitting of the data yields not only a set of parameters for a given kinetics model but also quantitative measures of goodness of fit and a parameter-estimate correlation matrix. The former may be compared with experimental error as determined by experimental replication to inspect whether or not a postulated kinetics model is adequate to fit the data. The latter indicates whether various parameters characterize independent effects or whether some are superfluous.

In most electrochemical experiments the data are some sort of current-potential relationship, and the simulation of the system behavior requires consideration of mass transfer and potential distribution effects in addition to the specific kinetics model. The major difficulty in applying nonlinear least squares regression analysis to fitting such electrochemical polarization data with a set of parameters is that the data analysis is an iterative procedure in which trial values of the parameters are repeatedly revised until the variance between the observed and predicted data is minimized. At each iteration one must generate not only a simulation or prediction of the experimental system output for each data point but also derivatives of the predicted output with respect to each parameter value, which are used in revising the parameter estimates.

Because electrochemical systems are so complicated these requirements imply a large and expensive computational effort. Recently we have described an approximate procedure for simulating electrochemical cell polarization which is significantly faster in computation time than alternative methods (5). The method known as orthogonal collocation is well suited to the repetitive calculations of nonlinear least squares analysis of electrochemical kinetics data. In this paper we demonstrate the combination of system simulation by collocation with nonlinear least squares estimation of electrochemical kinetics parameters by analyzing

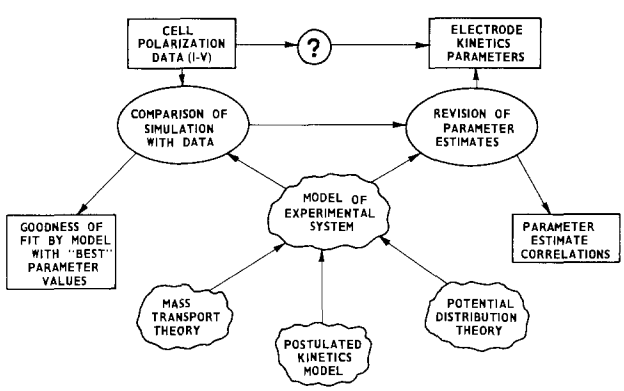

Fig. 1. Schematic representation of information flow in the global least squares fitting of an electrode kinetics model to cell polarization data.

Key words: copper sulfate, sulfuric acid, rotating disk, current distribution, orthogonal collocation.

steady-state polarization measurements on a rotating-disk electrode. Measurements have been made with copper sulfate in sulfuric acid, and the kinetics parameters determined here are compared with earlier results.

Simulation of the Rotating-Disk Electrode

The problem of current distribution on a rotating-disk electrode below limiting current was first solved by Newman (6) in one of the earliest analyses of moderately complicated electrochemical transport problems. The problem was made tractable by a thin diffusion-layer approximation so that potential distribution and mass transfer effects could be treated separately (7). Since the solution to Laplace's equation for the potential in this geometry can be expressed as a series of Legendre functions, a summation of Legendre polynomials was used to describe the current distribution on the electrode. A second series was postulated for the concentration, and the two were matched by relating the current density to the flux of reactant at the surface. It was not recognized at the time that a formal solution for the concentration can be obtained as a superposition integral over the current density, but a later communication clarifies the point (8). Ten approximating functions were required to describe a metal deposition reaction, and a solution to the system of algebraic equations was obtained by repetitive substitution. Numerous convergence and precision difficulties were reported.

It is our purpose to show here how the incorporation of orthogonal collocation concepts in the solution of this problem can result in a faster and more stable computational algorithm. It is important to recognize that we are more interested in computing total current rather than computing detailed current distributions. Since the method of orthogonal collocation renders the solution at Gaussian quadrature points, estimates of the average current density can be obtained with considerably more accuracy than the detailed current distribution at any given order of approximation. Consequently, fewer approximating functions are required, and precision difficulties are minimized. Furthermore, it will be seen that the numerous integrals needed in the nonlinear regression calculations can be evaluated easily by Gaussian quadrature.

Mathematical formulation of the problem.—Newman (7) has presented the mathematical formulation for the current distribution problem for a disk electrode of radius r_0 embedded on an infinite rotating disk with a counterelectrode placed at infinity. According to the usual boundary layer arguments, concentration gradients can be neglected in the bulk of the solution such that Laplace's equation for the potential holds. A solution to the Laplace equation in rotational elliptical coordinates is (7, 9)

$$\phi(\xi,\rho) = \frac{RT}{|n|\mathbf{F}} \sum_{k=0}^{\infty} D_k P_{2k}(\rho) M_{2k}(\xi) \qquad [1]$$

where $y = r_0\xi\rho$, $r = r_0\sqrt{(1+\xi^2)(1-\rho^2)}$, y is the normal distance from the electrode, r is the radial distance, P_{2k} is a Legendre polynomial $[-1, 1]$ of degree $2k$, and M_{2k} is a Legendre function of imaginary argument, zeroeth order, and degree $2k$ (10). The latter is subject to the condition $M_{2k}(0) = 1$ and can be expressed formally as

$$M_{2k}(\xi) = \frac{(-1)^k(k!)^2 i}{(2k)!\pi} \int_{-1}^{+1} \frac{(1-t^2)}{(i\xi - t)^{2k+1}}\, dt \qquad [2]$$

The multiplicative constant in Eq. [1] is included for convenience. For large ξ, far from the disk, the first term in a series solution of Eq. [2] provides a useful approximation

$$M_{2k}(\xi) = \frac{(k!)^2}{\pi(2k)!\xi^{2k+1}} \frac{\Gamma(2k+1)\Gamma(1/2)}{\Gamma(2k+3/2)} \qquad [3]$$

The potential in the solution extrapolated to the surface of the electrode is given by

$$\phi_0(\rho) = \phi(0,\rho) = \frac{RT}{|n|\mathbf{F}} \sum_{k=0}^{\infty} D_k P_{2k}(\rho) \qquad [4]$$

Thus, the normal current density at the electrode is given by

$$\frac{i}{\kappa_\infty} = -\left.\frac{\partial\phi}{\partial y}\right|_{y=0} = \left.\frac{-1}{r_0\rho}\frac{\partial\phi}{\partial\xi}\right|_{\xi=0}$$

$$= \frac{-RT}{r_0\rho|n|\mathbf{F}} \sum_{k=0}^{\infty} D_k P_{2k}(\rho) M_{2k}'(0) \qquad [5]$$

where

$$M_{2k}'(0) = -\frac{2}{\pi}\frac{\{2^k k!\}^4}{\{(2k)!\}^2} \qquad [6]$$

We restrict our discussion to systems with an excess of supporting electrolyte so that the effect of ionic migration may be neglected. The equation of convective diffusion for every minor species in solution reads

$$v_r\frac{\partial c_i}{\partial r} + v_y\frac{\partial c_i}{\partial y} = \mathcal{D}_i\frac{\partial^2 c_i}{\partial y^2} \qquad [7]$$

in cylindrical coordinates, where $\mathcal{D}_i$ is the pseudobinary diffusion coefficient. An analytical solution to Eq. [7] may be obtained for the thin diffusion layer case where the first terms in the small y expansions of Von Kármán's velocity profiles may be used (11, 12). The appropriate approximations for the radial and axial velocity components are

$$\left.\begin{aligned} v_r &= a r y \Omega\sqrt{\Omega/\nu} \\ \text{and} \qquad v_y &= -a y^2 \Omega\sqrt{\Omega/\nu} \end{aligned}\right\} \qquad [8]$$

with $a = 0.51023$ (13). The solution to Eq. [7] corresponding to the limiting current ($c_R(0,r) = 0$) is

$$i_{\lim} = \frac{n\mathbf{F}\mathcal{D}_R c_\infty}{s_R\Gamma(4/3)}\left(\frac{a\nu}{3\mathcal{D}_R}\right)^{1/3}\left(\frac{\Omega}{\nu}\right)^{1/2} \qquad [9]$$

Below limiting current we find it convenient to express the surface concentration as a superposition integral over the prevailing current density which is to be determined. For each reacting species

$$c_i(0,r) = c_{i0}(r) = c_{i\infty} + \frac{n\mathbf{F}\mathcal{D}_i}{s_i\Gamma(2/3)}$$

$$\left(\frac{3\mathcal{D}_i}{a\nu}\right)^{1/3}\left(\frac{\nu}{\Omega}\right)^{1/2}\int_0^r \frac{i_y(\zeta)\zeta d\zeta}{[r^3-\zeta^3]^{2/3}} \qquad [10]$$

which can be obtained as shown in Section 58 of Levich (11) or, more easily, by applying Eq. [40] in a paper by Stewart (13).

Equations [5] and [10] relate the potential and concentration distributions on the electrode to the current distribution function. Another relationship among these quantities is needed, specifically a kinetics expression. Let us consider an electrode reaction

$$\sum_i s_i M_i^{z_i} \rightleftharpoons ne^- \qquad [11]$$

which follows kinetics of, say, the Butler-Volmer type. Many reactions have been shown to follow such a rate expression, which in general can be written as

$$i(r) = {}^0i_0\left[\prod_i c^{\gamma_i}{}_{i0}(r)\right]\left[e^{\alpha_a\frac{\mathbf{F}\eta_s(r)}{RT}} - e^{-\alpha_c\frac{\mathbf{F}\eta_s(r)}{RT}}\right] \qquad [12]$$

where ${}^0i_0$ is the standard exchange current density ($c_{i0} = 1M$, all i), η_s is the surface overpotential, and α_a and α_c are the anodic and cathodic transfer coefficients, respectively. According to the simplified activated complex analysis from which Eq. [12] follows, one should have for a single step redox reaction ($0 + e^- \rightleftharpoons R$) following first-order kinetics, $\alpha_a = \alpha_c = \gamma_0 = \gamma_R = 1/2$.

The surface overpotential in Eq. [12] is related to other contributions to the cell potential by

$$V = U(c_\infty) + \phi_0(r) + \eta_s(r) + \eta_c(r) \qquad [13]$$

where V is the potential applied to the working electrode, $U(c_\infty)$ is the equilibrium cell potential for the conditions prevailing in the bulk of the solution, and η_c is the concentration overpotential given by

$$\eta_c = \frac{-RT}{n\mathbf{F}} \sum_i s_i \ln \frac{c_{i0}}{c_{i\infty}} \qquad [14]$$

In order to reduce the number of independent parameters we define the following dimensionless variables

$$E^* = E\frac{|n|\mathbf{F}}{RT} \qquad E = (V, \eta_s, \eta_c, U, \phi) \qquad [15]$$

$$i^* = \frac{i}{|i_{\lim}|} \qquad [16]$$

$$c_i^* = c_{i0}/c_{1\infty} \qquad [17]$$

$$x = r/r_0 \qquad [18]$$

$$\alpha = \alpha_a/|n| \qquad [19]$$

$$\beta = \alpha_c/|n| \qquad [20]$$

and

$$\mathrm{T} = \frac{|i_{\lim} n| r_0 \mathbf{F}}{\kappa_\infty RT} \qquad [21]$$

Consequently, the basic equations [4], [5], [10], and [12-14] become

$$\phi_0^*(x) = \sum_{k=0}^{\infty} D_k P_{2k}(\rho) \qquad [22]$$

$$i^*(x) = -\frac{1}{\mathrm{T}_\rho} \sum_{k=0}^{\infty} D_k P_{2k}(\rho) M'_{2k}(0) \qquad [23]$$

$$c_i^*(x) = c_{i\infty}^* + \left(\frac{\mathcal{D}_1}{\mathcal{D}_i}\right)^{2/3} \frac{3\sqrt{3}}{2\pi} \left(\frac{s_i}{s_1}\right) \int_0^x \frac{i^*(\xi)\xi d\xi}{[x^3 - \xi^3]^{2/3}} \qquad [24]$$

$$i^* = {}^0i_0^* \left[\Pi(c_i^*(x)/c_{i\infty}^*)^{\gamma_i}\right]\left[e^{\alpha\eta_s^*(x)} - e^{-\beta\eta_s^*(x)}\right] \qquad [25]$$

$$V^* = U_\infty^* + \phi_0^*(x) + \eta_c^*(x) + \eta_s^*(x) \qquad [26]$$

and

$$\eta_c^* = \sum_i s_i \ln \frac{c_i^*}{c_{i\infty}^*} \qquad [27]$$

where $\rho^2 = 1 - x^2$. Simulation of polarization of a rotating-disk electrode requires solution of these equations for the current distribution for given values of V^* and system parameters.

Solution by orthogonal collocation.—We implement the orthogonal collocation procedure by postulating a trial solution as a finite summation of orthogonal polynomials $Q(x)$; that is

$$\overset{(N)}{i^*}(x) = \sum_{k=0}^{N-1} A_k Q_{2k}(x) \qquad [28]$$

for the Nth approximation. The polynomials Q_{2k} are orthogonal over $[-1, 1]$; since $i^*(x)$ is an even function only even polynomials of order 0, 2, . . . , $2N$-2 are included. At this stage the selection of particular polynomials need not be specified. If Eq. [22] and [23] are truncated to the first N terms, and Eq. [28] is substituted into Eq. [24], yielding a finite series of integrals which can be evaluated, the problem is reduced to solving a set of algebraic equations with N unknown coefficients A_k. We obtain a solution by requiring Eq. [22-27] to be satisfied exactly at N discrete points x_i which are selected as the roots of Q_{2N}. The rationale for this choice is that the error contributed by the first neglected term in the truncated series [28] is made identically zero. Also, because such a choice of collocation points corresponds to Gaussian quadrature abscissas, the average error in the approximation is minimized, and the evaluation of integrals involving any of the functions arising in the basic equations can be made with considerable accuracy by quadrature, even with small N. For example, it will be necessary to compute the total current, which is given by an integral. In this problem we take Q_{2k} to be a Legendre polynomial, P_{2k}, defined as (14)

$$\left.\begin{aligned} P_{2k} &= \sum_{m=0}^{k} a_{km} x^{2k-2m} \\ \text{where} \quad a_{km} &= \frac{(-1)^m}{2^{2k}} \binom{2k}{2m} \binom{4k-2m}{2k} \end{aligned}\right\} \qquad [29]$$

This choice is natural because these functions have already arisen in solving the Laplace equation. The total current can now be computed by

$$I = 2\pi r_0^2 \int_0^1 i(x)x\,dx \doteq 2\pi r_0^2 \sum_{k=0}^{N-1} w_i x_i i(x_i) \qquad [30]$$

where x_i and w_i are the points and the weights, respectively, of Gaussian Legendre quadrature (14). The quadrature in Eq. [30] will be exact for current distributions which can be represented by polynomials of degree $4N$-2 or less. The choice of a different quadrature formula may result in a more accurate approximation. For example, Tchebychev quadrature would be more accurate for highly nonuniform current distributions because it would give more weight to the function values near the edge of the disk than does the Legendre quadrature. Depending on the choice of quadrature formula, the polynomials $Q_k(x)$, the points x_i, and the weights w_i are chosen accordingly.

If we consider the reaction $O + e \rightleftharpoons R$ and take O as the reference species, substitution of Eq. [28] into [24] gives

$$\left.\begin{aligned} c_O^*(x) &= 1 + \frac{3\sqrt{3}}{2\pi} \sum_{k=0}^{N-1} A_k E_k(x) \\ \text{and} \quad c_R^*(x) &= c_{R\infty}^* - \frac{3\sqrt{3}}{2\pi} \left(\frac{\mathcal{D}_R}{\mathcal{D}_O}\right)^{2/3} \sum_{k=0}^{N-1} A_k E_k(x) \end{aligned}\right\} \qquad [31]$$

where

$$E_k(x) = \int_0^x \frac{P_{2k}(\xi)\xi d\xi}{[x^3 - \xi^3]^{2/3}}$$

$$= \Gamma(4/3) \sum_{m=0}^{k} a_{km} \frac{\Gamma\left(\frac{2k-2m+2}{3}\right)}{\Gamma\left(\frac{2k-2m+3}{3}\right)} x^{2k-2m} \qquad [32]$$

The coefficients in the potential distribution can be related to those in the trial function in the manner suggested by Newman (7), that is, by requiring Eq. [28] and [23] to be equal, multiplying both sides of the equality by $\rho P_{2s}(\rho)$, and integrating with respect to ρ

$$\sum_{k=0}^{N-1} A_k \int_0^1 \rho P_{2k}(x) P_{2s}(\rho)\, d\rho = \frac{-1}{T} \sum_{k=0}^{N-1} D_k M'_{2k}(0) \int_0^1 P_{2s}(\rho) P_{2k}(\rho)\, d\rho \quad [33]$$

By virtue of the orthogonality condition Eq. [33] becomes

$$D_k = \frac{-T(4k+1)}{M'_{2k}(0)} \sum_{l=0}^{N-1} A_l G_{lk} \quad [34]$$

where

$$G_{kl} = G_{lk} = \int_0^1 \rho P_{2k}(x) P_{2l}(\rho)\, d\rho$$

$$= \sum_{m=0}^{l} a_{lm} \sum_{p=0}^{k} a_{kp} \sum_{q=0}^{l-m} \left\{ \frac{(-1)^q \binom{l-m}{q}}{2q+2k-2p+2} \right\} \quad [35]$$

These coefficients need be calculated only once for a given order of approximation.

Computational procedure and results.—The unknown coefficients A can be obtained by requiring the trial current distribution function to match the current density as given by the kinetic rate expression. That is

$$f(x_i) \equiv \sum_{k=0}^{N-1} A_k P_{2k}(x_i) - {}^0i_0{}^* \left[\frac{c_O{}^*(x_i)}{c_{O\infty}{}^*} \right]^{\gamma_1} \cdot \left[\frac{c_R{}^*(x_i)}{c_{R\infty}{}^*} \right]^{\gamma_2} \cdot \{ e^{\alpha \eta_s{}^*(x_i)} - e^{-\beta \eta_s{}^*(x_i)} \} = 0 \quad [36]$$

at all x_i ($i = 1, 2, \ldots, N$) which are the positive roots of $P_{2N}(x)$. The values of A may be obtained by a Newton-Raphson iteration about an appropriate initial guess. The following order of computation is convenient:

1. Given T, V^* and all kinetic parameters adopt an initial guess for A. For example, obtain the leading coefficient A_0 from the zeroeth order solution (constant current distribution) and set the remaining coefficients to some small number.

2. Calculate $c_O{}^*(x)$ and $c_R{}^*(x)$ from Eq. [31], where x represents the set of N points x_i.
3. Calculate $\eta_c{}^*(x)$ from Eq. [27].
4. Calculate $\phi_0{}^*(x)$ from Eq. [22].
5. Calculate $\eta_s{}^*(x)$ from Eq. [26].
6. Calculate the residuals $f(x)$ from Eq. [36] and the Jacobian matrix of elements $\partial f(x_i)/\partial A_k$. New coefficient values are obtained as

$$A^{(n+1)} = A^{(n)} - [J^{(n)}]^{-1} f^{(n)} \quad [39]$$

where the superscript is an iteration index.

7. Return to step two with the $A^{(n+1)}$ if the rms of the normalized residuals is not less than some specified tolerance, that is, if

$$\left\{ \frac{1}{(N-1)} \sum_{i=1}^{N} \left(\frac{f(x_i)}{i^*(x_i)} \right)^2 \right\}^{1/2} \leqq \epsilon$$

is not satisfied. We have used $\epsilon = 10^{-3}$.

In principle, the procedure outlined above must be repeated for increasing values of N until a characteristic quantity, say $\langle i^* \rangle = I^*/\pi r_0{}^2$, converges to a stationary value. A value of $N = 6$ has been found to be sufficient here to achieve not only a stationary $\langle i^* \rangle$ but also a satisfactory distribution $i^*(x)$. This small number of terms alleviates the numerical precision problems encountered by Newman (7) in dealing with Legendre polynomials of degree 20. The results of our calculations appear to be comparable to those presented by Newman (7). The principle difference in the two computational procedures is that our method exploits the accuracy of Gaussian quadrature in evaluating the integrals involved and allows us to work with fewer unknown coefficients and a small number of discrete points x_i on the electrode.

The complete solution of the current distribution problem for a given set of parameters at $N = 6$ required from 3 to 7 iterations and less than 0.25 sec of computing time on a Univac 1110 computer. Complete polarization curves could be generated economically, and extensive simulations made to study the sensitivity of the polarization curve to the kinetic parameters in the Butler-Volmer kinetics, Eq. [12]. As an example, Fig. 2 shows cathodic polarization curves computed for a redox reaction at various values of $i_0{}^*$ and α_c. It is apparent that the experimental discrimination of ${}^0i_0$ and α_c from experimental polarization curves of this sort requires analysis of data at values of $\langle i^* \rangle$ where variations in the surface concentrations become significant and must be accounted for in the data treatment. With the collocation simulation of the experimental system written for any postulated kinetics model and provided as a computer subroutine, nonlinear least squares regression routines can be used to determine kinetic parameters from a set of cell polarization data.

Statistical Analysis of Polarization Data

A common practice in the study of electrode kinetics is to postulate Butler-Volmer kinetics (Eq. [12]) with a symmetry factor $\beta = 1 - \alpha = 1 - \gamma_1 = \gamma_2$. The two parameters ${}^0i_0$ and β are obtained by comparing data at different degrees of polarization with limiting forms of the model, corresponding to linear and Tafel kinetics, respectively (15). It is also common to fix the value of β at 0.5, thus leaving ${}^0i_0$, or the rate constant, as the only independent parameter. A more reliable approach, at least for engineering purposes, will be to start with a rate expression of the form of Eq. [12] including the possibility that all the parameters are independent. A complete statistical analysis will involve the simultaneous estimation of all parameter values for a postulated kinetic model and an assessment of how well the model describes the data. Investigation of the parameter correlations and the variations of residuals in the experimental space guides one in revising the kinetic model to obtain a better fit of the data.

Consider a set of experimental data consisting of an array of observable quantities y and an array of independent or state variables ζ. A mathematical model is proposed to relate the two in terms of some system parameters θ, namely

$$\hat{y} = g(\zeta; \theta) \quad [40]$$

where $\hat{y}$ is the array of predicted responses. The statistical problem is to obtain estimates of the param-

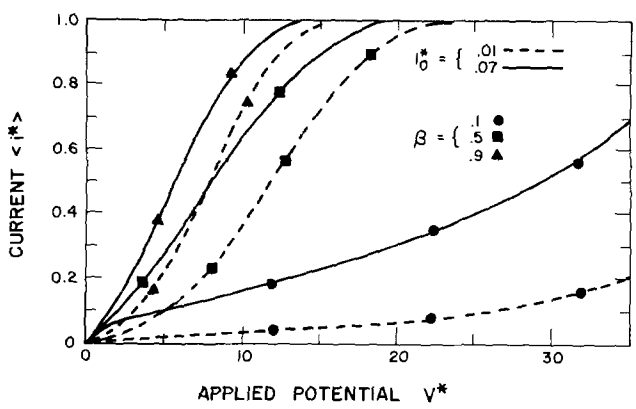

Fig. 2. Simulated cathodic polarization curves for a redox reaction on a rotating-disk electrode for $T = 7$ and various values of ${}^0i^*_0$ and β. $\gamma_O = \gamma_R = \frac{1}{2}$; $\alpha = 1 - \beta$; $n = 1$ (see Eq. [25]).

eters θ such that the best predictions of the observable quantity are obtained according to some optimality criterion. A common approach is to minimize the sum of squares of the errors. That is, values of θ are determined which minimize the quantity

$$\text{SSQ} \equiv \left\{ \sum_{\text{observations}} u_i (y_i - \hat{y}_i)^2 \right\} \qquad [41]$$

where u_i is some suitable weighting function which reflects the distribution of experimental accuracy (4). In polarization experiments, the total current is the observable quantity, and Eq. [40] may be written as

$$\hat{y} = \int_0^1 i^*(x, \Upsilon, V^*; \theta)\, x dx \qquad [42]$$

where the kinetic model for i^* might be of the form of Eq. [12], so that $\theta = (\alpha, \beta, i_0, \gamma_1, \gamma_2)$.

In the least squares fitting of such a model to a set of data, one starts with initial guesses for the parameters θ and computes from the simulation procedure a prediction $\hat{y}_i$ for each experimental point. Then SSQ can be computed according to Eq. [41], and some standard computer algorithm, such as Marquardt's method (16), can be used to find the values of θ which minimize SSQ. Such minimization programs require evaluation of a Jacobian or covariance matrix of partial derivatives of $\hat{y}$ with respect to each of the parameters. It is clear from the form of Eq. [42] that the elements of such a matrix will contain integrals. For example, we would have from Eq. [25] and [42]

$$\frac{\partial \hat{y}}{\partial \gamma_1} = {}^0i_0^* \int_0^1 c_O^{*\gamma_1} \ln (c_O^*)\, c_R^{*\gamma_2} [e^{\alpha\eta_s^*} - e^{-\beta\eta_s^*}] x dx \qquad [43]$$

and

$$\frac{\partial \hat{y}}{\partial \beta} = {}^0i_0^* \int_0^1 c_O^{*\gamma_1} c_R^{*\gamma_2} \eta_s^* e^{-\beta\eta_s^*} x dx \qquad [44]$$

Now, since the collocation simulation generates the value of every term in these integrands at Gaussian quadrature points, the integrals can be evaluated quite rapidly and accurately. An alternative procedure, computing the derivatives by finite differences, would require the complete solution of the current distribution problem at perturbed values of the parameters, and would increase the computation time considerably.

Experimental Measurements and Data Analysis

To demonstrate the application of these methods to electrochemical kinetics, we have studied copper deposition from aqueous $CuSO_4$-H_2SO_4 solutions onto a rotating-disk electrode. This system was chosen because of its industrial importance and because published results (15, 17-19) provide a good basis for comparison.

In order to discriminate the effects of the various parameters in Eq. [12], operation at high overpotentials, and hence at appreciable fractions of the limiting current, is necessary. The collocation method allows the appropriate interpretation of polarization curves in that region by expedient solution of the complete current distribution problem.

Experimental.—Potentiostatic measurements were made on an ESB Research Depak rotating-disk electrode assembly by means of a Princeton Applied Research Model 170 electrochemistry system. Although the ESB Depak indicates rotation speed on a digital meter, more accurate measurement of rotation speed was made by use of a stroboscope.

The working electrode was a 0.1 cm^2 platinum disk embedded in the end of a 1.6 cm diam Teflon shaft. The platinum electrode was covered with copper by deposition from the solution A (see Table I) at 0.2 mA for 2 min.

The cell was made of glass and had a cylindrical shape, 6.4 cm diam and 7.4 cm deep, and was blanketed with nitrogen. The reference electrode was a copper wire placed at 4.5 cm from the disk on the axis. The counterelectrode was a loop of copper wire, 6 cm diam, placed at the bottom of the cell. The reference and the counterelectrodes were covered with fresh deposits of copper from solution A. The solutions were prepared by weight from twice distilled water and reagent grade copper sulfate and sulfuric acid. The temperature was 21° ± 0.5°C. The solutions were thoroughly deaerated with nitrogen before each experiment.

Measurements were made for different levels of metal and acid concentration, the applied potential and disk rotation speeds were varied to obtain currents between 0.45 and −4.25 mA/cm^2, and concentrations were chosen to avoid complications due to varying physical properties and ionic migration. Table I shows the concentrations of the 6 solutions studied and the rotation speeds used. Limiting currents shown are those measured experimentally. Copper diffusivities were estimated from the compilation given by Selman (20). Using the latter, we verified the linear dependance of i_{lim} on $\Omega^{1/2}$ (21). Conductivities were calculated from the correlation given by Hsueh (22)

$$\kappa_\infty = 0.011163 + 0.030798\ (CuSO_4) + 0.423553\ (H_2SO_4) - 0.045224\ (H_2SO_4)^2 - 0.135359\ (H_2SO_4)\,(CuSO_4) \qquad [45]$$

where molar analytical concentrations are used.

Smooth traces of current *vs.* potential were obtained for each of the 16 cases indicated in Table I by scanning the potential from anodic to cathodic at 5 mV/sec. Repeated scans on the same surface provided reproducible traces. The maximum noise was observed at limiting current, where fluctuations were less than 5% of the measured current. Replicate experiments, in which complete cell preparation was repeated, were conducted with solution A. Reproducibility of the current measurements between replicates was within 10%.

Sampled data points from the 16 polarization curves are given in Table II, where the observed currents have been divided by the measured limiting current.

Data analysis.—It has been verified (19) that the copper (II) deposition-dissolution reaction in acid sulfate systems takes place in two steps

Table I. Experimental conditions for Cu(II) deposition studies*

Concentration of $CuSO_4$ (M) \ Concentration of H_2SO_4 (M)	2.0	0.70	0.20
0.100	A 64 (911) 45 (400) 40 (295) 39 (300) $\mathcal{D}_{Cu^{+2}} = 3.82$	x	x

with $\gamma = (2 - \alpha_c/2) = 0.75$ and $\alpha_a = 2 - \alpha_c = 1.5$. Equation [47] may not apply very precisely to the dissolution process because it does not account for diffusion of Cu(I) away from the electrode (23).

Statistical regression analyses of our data with Eq. [47] and several other models were performed with 87 discrete points selected from the 16 polarization curves. Simulation was accomplished by using the algorithm described above with two collocation points ($N = 4$). For lack of a better criterion, these were selected at potential intervals of 0.05 or 0.10V to get about 4 or 5 points from each curve as indicated in Table II. Some observations on the anodic side were necessary for the independent estimation of the anodic transfer coefficient, but these were taken only at currents small compared to the cathodic limiting current. The variable used in the statistical analysis was dimensionless average current density $\langle i^* \rangle = \langle i \rangle / i_{lim}$, and a weighting factor u_i of $1/\langle i^* \rangle^2_{obs}$ was used. This renders the residuals on a percentage basis which is representative of the error distribution in the instrument.

Table III summarizes the parameters estimated from the data for four kinetics models which were tested and their respective sums of squares. Models I and II correspond to those used by the investigators cited earlier. Model II, in which the two transfer coefficients are estimated independently, gives a better fit. However, neither model fits the data within experimental accuracy, and an investigation of their residuals reveals a correlation with sulfuric acid concentration.

To account for the acid concentration effect, we devised semiempirical models III and IV. Because of the precautions taken in selecting the relative concentrations of acid and metal, we can safely neglect the effect of the acid on copper migration. On the other hand, the scant data available on activity coefficients for aqueous $CuSO_4$-H_2SO_4 solutions point to a strong dependence of copper sulfate activity on the concentration of sulfuric acid (24, 25). In view of the large excess of sulfuric acid present, a first-order approximation of the activity coefficient variation should be obtained with an expression of the form $e^{-\delta(H_2SO_4)}$ (26). It is apparent from the results in Table III that the inclusion of such a term reduces the sum of squares considerably, with the model which allows the independent estimation of transfer coefficients, Model IV, being the more likely. Note that the term $\theta_1 e^{-\delta(H_2SO_4)}$ represents the standard exchange current densities for Models III and IV.

In Table II we have listed with the data the residuals corresponding to Model IV. It is seen that the largest percentage deviations occur for very small potentials and that there is no apparent correlation of errors between runs at different concentrations.

The standard deviation obtained for Model IV, about 11%, is roughly equal to that obtained from the replicate runs with solution A, so that within the limits of experimental reproducibility, Model IV describes our experimental observations adequately.

Figure 3 compares two representative experimental curves with the results of the simulation with Model IV shown as discrete points. The results shown here are typical of those obtained for all 16 experimental curves. Although the largest relative error occurs at small currents, the largest absolute discrepancy in the current appears in the intermediate range. In all cases, however, the error is less than 0.3 mA, which should be satisfactory for most practical purposes.

Discussion of Results

It has been found that Model IV in Table III describes our data within the accuracy of the experimental measurements, that is, with a standard deviation of about 11%. On the other hand, Model I with the parameters listed in Table III exhibits a standard deviation of 22% and is not considered to be a satisfactory model for reproducing the data. It appears that sulfuric acid

Table III. Models for Cu (II) deposition and dissolution kinetics

	Model*	Parameters					SSQ (87 observations)
		${}^{c}i_0$ or θ_1 (mA/cm²)	γ	α_A	α_c	δ (M^{-1})	
I	$i = {}^{c}i_0(\mathrm{Cu})^{\gamma}\left[e^{(2-\alpha_c)\eta\frac{F}{RT}} - e^{-\alpha_c\eta\frac{F}{RT}}\right]$	5.51	0.62	—	0.42	—	4.231
II	$i = {}^{c}i_0(\mathrm{Cu})^{\gamma}\left[e^{\alpha_A\eta\frac{F}{RT}} - e^{-\alpha_c\eta\frac{F}{RT}}\right]$	6.78	0.58	1.09	0.36	—	3.051
III	$i = \theta_1(\mathrm{Cu})^{\gamma}e^{-\delta(\mathrm{H_2SO_4})}\left[e^{(2-\alpha_c)\eta\frac{F}{RT}} - e^{\alpha_c\eta\frac{F}{RT}}\right]$	14.5	0.72	—	0.43	0.40	2.117

* Concentrations are analytical concentrations in moles/liter.

concentration has a measurable effect on copper deposition kinetics.

The principal purpose of this work has been to develop a systematic methodology for obtaining kinetic data for practical engineering purposes. Thus, we were content to take our example data at room temperature (21°C) rather than at 25.0°C, and to prepare electrode surfaces in a rather arbitrary way. Nevertheless, it is interesting to compare our experimental results with those of earlier workers.

For the description of kinetic behavior in a solution of fixed composition, the kinetics expression may be written

$$i = i_0\left[e^{\alpha_a\eta F/RT} - e^{-\alpha_c\eta F/RT}\right] \qquad [48]$$

where the preexponential factor is called simply the exchange current density. By comparison with Model IV, the exchange current density i_0 should be

$$i_0 = 1.58(\mathrm{Cu})^{0.67}e^{-0.36(\mathrm{H_2SO_4})}\mathrm{mA/cm^2} \qquad [49]$$

where the concentrations are expressed in moles/liter. Table IV compares kinetic parameters i_0, γ, α_a, and α_c indicated by this work with results reported by earlier workers. Specific concentrations have been chosen in each case to make the i_0 comparison possible. It is gratifying that the i_0 values predicted from Eq. [49] agree so well with the results of the earlier workers, particularly considering the wide ranges of composition involved. Better agreement could hardly be expected among workers who prepared electrodes differently

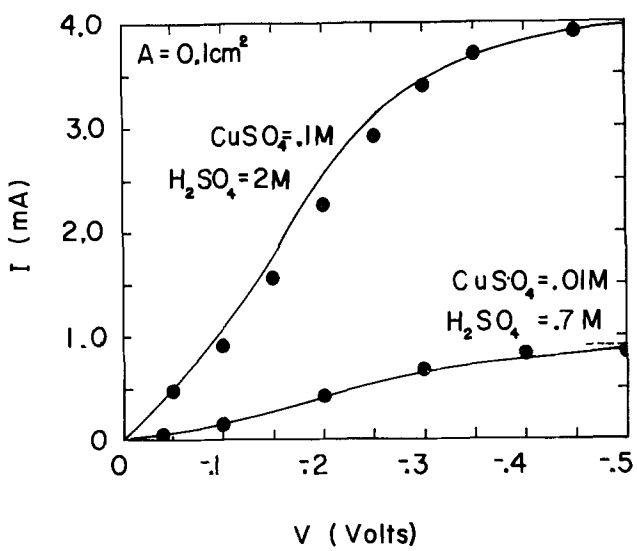

Fig. 3. Comparison of two experimental polarization curves with point values predicted by Model IV and the collocation simulation.

and made different types of measurements. Also, the temperature differences should affect i_0.

The reaction order γ is also in good agreement with earlier work. On the other hand, it is somewhat distressing that our transfer coefficients are significantly lower than those obtained previously. We see no obvious explanation of this discrepancy, but we note that in Models I and III, where $\alpha_a = 2 - \alpha_c$, the statistical analysis yields a larger value for α_c.

Table V shows the correlation matrix for the parameters of Model IV. It is seen that the correlation coefficients are generally small, which means that each parameter is characterizing a different aspect of the kinetics law. The largest correlation, 0.843, is between θ_1 and γ. This probably means that the model is not accounting as well as it might for the dependence of the rate on the copper concentration. Clearly, the use of γ is not redundant as shown by the range of i_0 in Table IV, but the assumed form of the copper dependence may not be satisfactory. For example, a factor for the copper dependence of the activity coefficient might be appropriate.

It should not be surprising that the best empirical parameters for the models tested do not agree with the theoretical values of Eq. [47]. Copper sulfate-sulfuric acid solutions are quite nonideal with $CuSO_4$ ion pair formation likely (24). For engineering purposes it is necessary to obtain experimental kinetics data measured under conditions similar to those where the data will be applied. Measurement on a rotating disk with proper analysis of transport effects satisfies this requirement in the sense that the boundary layer phenomena on the disk should be similar to those in electrolysis cells (27).

It should be noted that the data analysis presented here can be simplified by using a one-point approximation ($N = 1$). In that case, $i^* = A_0$, $c_0^* = 1 + A_0$, $c_R^* = 1 - A_0$, $\phi_0 = \Upsilon\pi A_0/4$, etc., and the statistical parameter determination can be done quite easily. An important point, however, is that this first approximation of the complete model does not correspond to the simple one-dimensional model commonly used.

Summary

Nonlinear regression analysis can be used to determine empirical parameters for a postulated electrode kinetics expression. All parameters are estimated simultaneously from a set of polarization data to obtain an optimal fit of the data. Accordingly, the resulting kinetics model should be useful for engineering analysis of experimental systems where the same range of conditions is encountered.

Practical implementation of the regression analysis requires rapid simulation of the experimental system. Approximate computation of current distribution by orthogonal collocation fulfills this requirement and

facilitates the iterative calculations which yield the parameter values.

We have demonstrated the application of these methods to the rotating-disk system. Because of the flexibility and efficiency of the collocation method it can be applied to other geometries and extended to multiple reaction cases as well (21).

Double Layer Capacitance and Charging Rate of Ultramicroporous Carbon Electrodes

J. Koresh and A. Soffer

Atomic Energy Commission, Nuclear Research Centre-Negev, Beer-Sheva, Israel

ABSTRACT

Adsorption of ions from aqueous solutions into pores, as narrow as 3.7Å was observed, using linear sweep cyclic voltametry. The conductivity of the solution in pores of less than 7Å diameter is several orders of magnitude lower than that of a free 0.1*N* NaCl solution in contact with the carbon electrode. It seems negligibly slow in pores of less than 3.7Å diameter, which are still completely filled with water. Highly oxidized ultramicroporous carbons show much lower double layer capacitance at positive potentials than nonporous carbon surfaces. This is interpreted as repulsive ion-dipole interaction of the anion with the dipole of the chemisorbed oxygen. Ions can penetrate the tiny pores after depletion of the hydration sheath. The double layer charging rate is therefore much slower if 0.1*N* NaCl is replaced by 0.1*N* LiCl. A brief discussion is presented in order to confirm that the electroactive surface groups can be treated in terms of (capacitative) double layer charging.

One of the fundamental requirements of electrochemical power sources are low overvoltage electrodes. Optimization of the physical design of the electrode is partially achieved by increasing the ratio of internal, S_i, to geometrical, S_g, surface area; this lowers the real current density. The S_i/S_g can be increased by using a thicker electrode and/or by increasing the porosity of the electrode. However, since the porous matrix serves as sink for the electrical charge, and due to the resistivity of the solution in the pores, the current decays rapidly on moving away from the counterelectrode. This imposes a limit for the thickness of a practical electrode. The question now is whether the increased active surface area of the porous electrode has also theoretical limitations. Ion mobility in the narrow pores of high internal surface area electrodes may rule out the availability of this surface for the electrode process.

Extensive studies were published on the transport properties of porous electrodes (1, 2), where models of continuous electrode media were used, but the role of pore structure was mostly neglected Only recently has the simplest of these models been satisfactorily matched with experiment (3, 4).

Another property of high surface porous electrodes is their probable usefulness as high capacity electroadsorbent. This idea, which was first put forward by Garten and Weiss (5), was examined experimentally by Murphy *et al.* (6). Much later, the electrosorptive properties were attributed to the electric double layer (7, 8), but again the influence of the fine structure was still disregarded. The pore structure which is characterized by a solid-gas system is being investigated, and several techniques for the characterization of mean pore diameter and pore diameter distribution have been developed (9). The kinetics of adsorption of neutral molecules from solution into porous solids have also been studied (10).

Key words: double layer charging, ultramicropores, carbon electrode.

In the present work pore structure of various carbons and graphites are characterized by means of the well-established methods of gas adsorption, and then the double layer capacitance (C_d) and ion transport through the pore are examined.

An ultramicroporous carbon, with pore size comparable to that of small molecules, is studied. Because of their electrical charge, the rate of transport and adsorbability of ions into narrow pores may have some special features which are encountered neither in solid-gas adsorption systems nor in solid-nonelectrolytic liquid interfaces. As carbon and graphite have polar oxygen surface groups (11), short range ion-dipole interactions influence the behavior of ions in ultramicroporous carbon, unlike flat or wide pore carbon electrodes.

Experimental

The porous carbon electrode was TCM 128 carbon cloth and TGM 389 served as nonporous reference carbon, both supplied by Le Carbonne Loraine, France. Both electrode materials are composed of fibers of cylindrical cross sections of approximately 3 μm for TGM 389, and 6-10 μm for TCM 128 (Fig. 1 and 2). A special feature of TCM 128 and of some other nonactivated fibrous carbons is the complete absence of pores larger than ultramicropores. The diameter of the pores was less than 3.7Å (12). This is the reason that almost all of the surface area results from ultramicropores and only a very small part from the outer surface area of the fibers. The geometrical surface area, S_g, of TGM 389, calculated from an average diameter of 3.2 μm, is

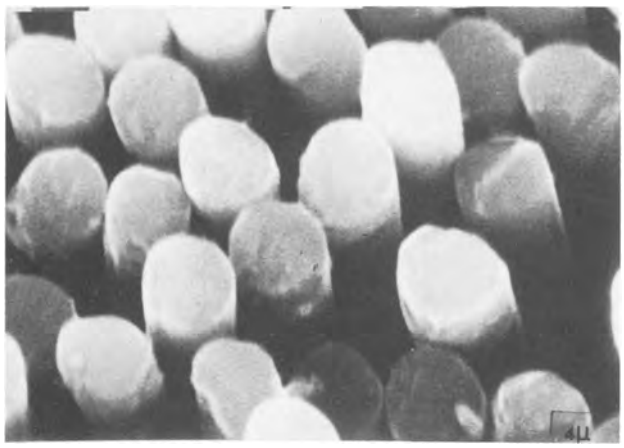

Fig. 1. SEM micrograph of the graphitized carbon fibers TGM 389.

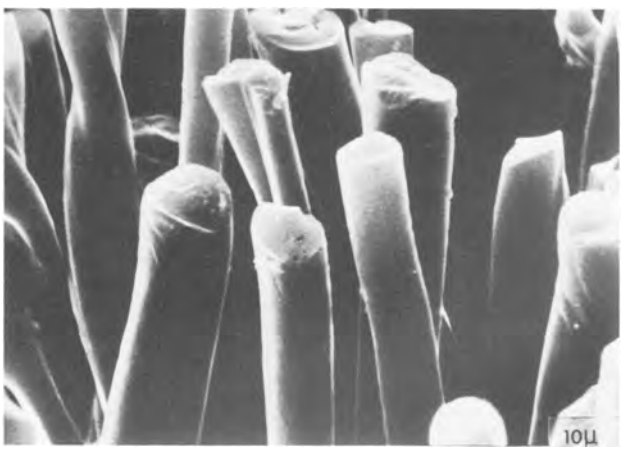

Fig. 2. SEM micrograph of the ultramicroporous carbon fibers TCM 128.

approximately 0.3 m^2/g. The BET surface area (S_{BET}) of TGM 389, measured on a 3g sample, was 1.2 m^2/g. This corresponds to a roughness factor of $S_{BET}/S_g = 4$.

The ultramicropores of the as-received TCM 128 carbon were too narrow to accommodate N_2 molecules (12), therefore the BET surface area obtained from nitrogen adsorption isotherms gave the outer surface area (as for TGM 389) 0.95 m^2/g. From an average diameter of 8 μm we have approximately 0.12 m^2/g for the geometrical surface. This corresponds to a roughness factor of 8. These rough outer surface areas are negligible compared to the much larger (> 250 m^2/g) area of the ultramicropores of TCM 128 (12).[1] Some of the manufacturers' specifications of the carbons are given in Table I.

The electrolytes were sodium chloride and lithium chloride, analar grade. Water was triply distilled.

The electrochemical cell.—Through the openings in the cover of a standard Metrohm cell, three electrodes, deaeration tubes, and a gas outlet were introduced. The reference electrode was a 0.1*N* NaCl calomel electrode half-cell. The auxiliary electrode was a platinum and later a silver rod, enclosed in a glass tube with a sintered base containing the solution. The carbon cloth, working electrode ($\sim 3 \times 3$ cm^2) was stretched across the opening of another glass tube and tightened with gold wire which also served as current collector. The reference electrode was mostly introduced into this tube so that the *IR* drop was screened off by the carbon cloth. At currents below 50 μA the reference electrode was transferred to the main compartment of the cell, since otherwise its complete freedom from *IR* drop at the first mode resulted in an oscillatory response of the potentiostat. This is because the *R*-*C* impedance of the working electrode in the double layer range produces a delay in the potential response at the solution compartment opposite the counterelectrode (4). The electrolytic solution used mostly was sodium chloride 0.1*N*. The maximum value of the *IR* drop was evaluated by interrupting the charging current and measuring the sudden change in potential. It was never above the millivolt range and had thence been neglected.

Instrumentation.—An electromechanical ramp generator, driven by a synchronous motor, was used to obtain very slow voltage sweep rates for following the slow charging rates of the ultramicroporous carbons. For fast voltage sweep a Hewlett Packard function generator, Model 3300 A, was used, and the voltammogram was recorded on a Tektronix, Type 549, storage oscilloscope. A Kepco bipolar operational amplifier power supply was used as potentiostat. Figure 3 is a diagram of the circuitry.

Methods of measurement.—Evaluation of pore diameters and pore surface.—The treatment of the carbon cloth, TCM 128, and the estimation of pore diameters by probe molecules are described elsewhere (12). The probe molecules were H_2 ($d = 3.7$Å), N_2 ($d = 4.3$Å), and SF_6 ($d = 5.6$Å). The molecular diameter was calculated by the equation $d = 2^{1/6}V_L$, where V_L is the molecular volume of a single molecule in the liquid phase, assuming hexagonal packing of spherical molecules. It is well known that pores, almost impermeable to a given molecule at a certain temperature, can become permeable at higher temperatures (13). This was taken into consideration when the various pore diameter ranges were estimated. The amount of chemisorbed oxygen was changed to a certain extent by high temperature, stepwise, evacuation (12) or by limited O_2 chemisorption on oxygen depleted samples.

The internal surface area of TCM 128 was estimated as needed, by BET, Langmuir, and Polanyi-Dubinin models (14).

Evaluation of double layer capacitance (C_d) and kinetic parameter.—Considering the porous electrode as an *R*-*C* network, it can be easily deduced that the application of a constant potential sweep dv/dt starting at time $t = 0$, results in a current transient which decays to the pure capacitor behavior

$$i_\infty = C_d\, dv/dt \qquad [1]$$

where C_d is the total capacitance of the *R*-*C* network. A current transient should similarly occur after the inversion of the linear potential sweep at each end of

[1] A discrimination between roughness and porosity has to be made. Roughness is a property of the outer geometrical surface. It results from shallow pores of a depth not much greater than the diameter. Porosity is a property of the entire solid where the pore length is several orders of magnitude more than their diameter.

Table I. General characteristics of carbon and graphite textiles

Characteristics	Unit	TCM 128	TGM 389

the cyclic voltametry half-cycle. This should result in distortion of the symmetry of the voltamogram *vs.* the potential axis (Fig. 4). The distortion is more pronounced by the edges of the voltamogram when the former transient is well relaxed as compared to the new one produced after the potential inversion. This transient behavior has been thoroughly studied by Austin and Gagnon (15) for the specific model of undimensional distribution of capacitance and resistivity. It can, however, be easily recognized that the same behavior holds qualitatively for any ideally polarized electrode model with resistive restrictions.

Cyclic voltametry on a wide potential range, appeared to be a fast and sensitive method of measuring C_d and for evaluating the double layer relaxation time. It is, however, quite complex for quantitative analysis unless C_d and/or the charging relaxation time are independent of potential, as was the system studied by Austin and Gagnon (15). The slower and less convenient measurements of current transients resulting from small potential steps, are easier to interpret quantitatively, since the C_d and the relaxation time can be assumed to be constant.

The experimental results of cyclic voltametry are given in this work in terms of apparent differential capacitance, C_d via Eq. [1], rather than in terms of the directly measured current. This was found more informative since C_d is the fundamental property which rules the current. One should, however, keep in mind that Eq. [1] is valid only after the decay of the transient, *i.e.*, at the symmetrical portions of the voltamogram. The various plots of C_d are given in two scales: farad per gram (f/g) and microfarad per square centimeter (μf/cm^2) of total surface area. The first unit (f/g) does not take into account the surface area measurements while the second enables comparison of ultramicroporous (3-10Å), with microporous (10-30Å) (8) or nonporous carbon electrodes and also with the classical mercury electrode interface.

Results and Discussion

Nonporous graphitized carbon TGM 389 was investigated in order to have a reference for nonporous carbon surface behavior. The apparent differential capacity obtained from cyclic voltametry is given in Fig. 5 for two very different sweep rates, 1000 and 1 mV/sec. It can be seen that the inversion of the linear sweep produces a very fast current reversal. A slight asymmetry, corresponding to a contribution of slowly charging sites, can be observed at the slower sweep rate. These slow sites are attributed (16) to "slow" electronic surface states which are isolated from the bulk conduction band of graphite by a potential barrier.

The roles of pore diameter and of concentration of oxygen surface groups have been examined in TCM 128 carbon, using thermal treatments under vacuum and in the presence of oxygen or air. The various samples used are given in Fig. 6. The C_d *vs.* potential plot is given in Fig. 7 for carbon I. This sample was activated for 2 hr in air at 450°C in order to obtain relatively large ultramicropores. The slow current inversion indicates a considerably low charging rate com-

pared to the nonporous TGM 389 (Fig. 5), but it is three orders of magnitude higher in capacitance per gram, thereby indicating that the high surface ultramicropores take part in double layer charging and in ion transport.

The carbon II samples were prepared by evacuation at 200°C during 2 days. This caused a slight depletion of chemisorbed oxygen which was removed as CO_2 (18). The lower pore diameter range resulted in a great decrease of C_d. No potential range could be found at which C_d from the increasing voltage sweep is equal to C_d of the decreasing sweep, because the charging rate slowed to such an extent that the C_d-V curve (Fig. 8) was completely distorted. This implies that the relaxation time of double layer charging is considerably greater than the half-cycle time of the cyclic voltamogram. The higher capacitance at negative potentials is connected with chemisorbed oxygen. The role of chemisorbed oxygen is well demonstrated by carbon III in Fig. 9. The pore diameter range of this carbon is much the same as the slightly oxygen depleted carbon II; it was obtained by widening the pores of the original TCM 128 by oxidation in air at 450°C for 1 hr, rather than by prolonged evacuation at 200°C. This is known to result in a highly oxidized surface (19). The C_d retains the high values of carbon I at negative potentials. It corresponds also to the C_d values of microporous (10-30Å) carbons (8). However, unlike these examples, where C_d changes only slightly with potential, it gradually decreases in carbon III by two orders of magnitude at +500 mV (Fig. 10).[2]

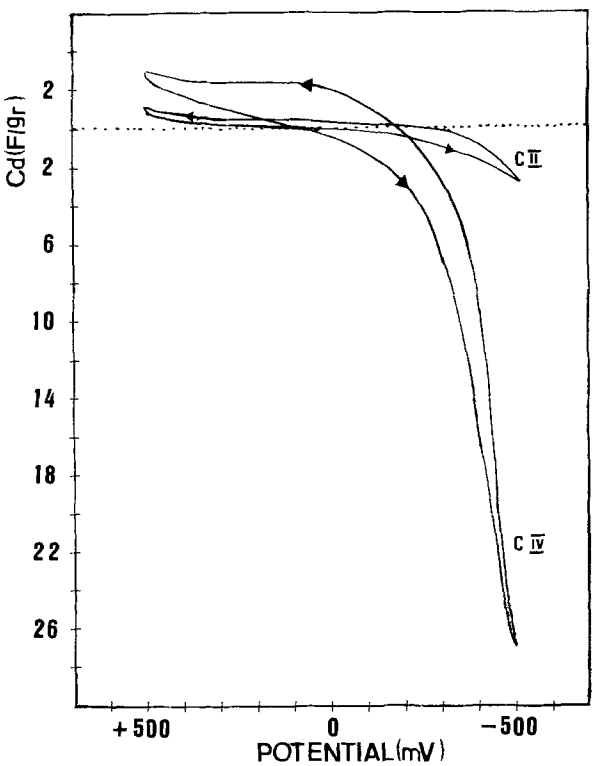

Fig. 8. C_d *vs. V* curve of the carbons C II-PD and C IV-OR in 0.1*N* NaCl; potential *vs.* 0.1*N* NaCl C.E.; 0.5 mV/sec.

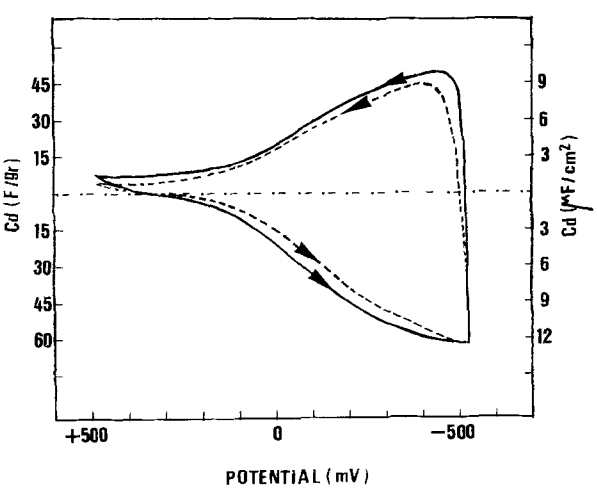

Fig. 9. C_d *vs. V* curve of carbon C III-OR in 0.1*N* NaCl. – – – –, 0.5 mV/sec; ——, 0.166 mM/sec; potential *vs.* 0.1 NaCl C.E.

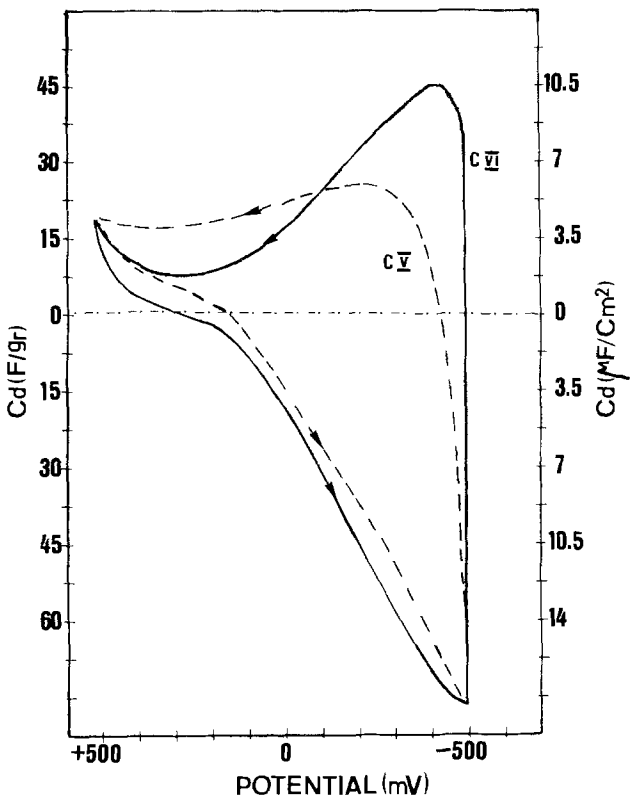

Fig. 10. C_d *vs. V* curve of the carbons C V-OD and C VI-PD in 0.1*N* NaCl; potential *vs.* 0.1*N* NaCl C.E., which shows the influence of reoxidation on double layer behavior; 0.5 mV/sec.

To our knowledge no such extreme change in C_d has been found, with the exception of peaks in C_d for some organic molecules (20). Moreover, the negative branch is almost symmetrical with respect to the potential axis, showing equilibration of the double layer during the half-cycle time, while at positive potentials the C_d-V curve resembles the extremely slow charging rate of carbon II. The fact that the C_d-V curve at a sweep rate of 0.5 mV/sec (Fig. 9) is very similar to that of the threefold slower sweep rate, indicates that the difference in C_d between the positive and negative potentials is due to equilibrium properties and not to different charging rates. A previous study (8) shows that at potentials greater than −190 mV *vs.* 0.1 NCE, cations are repelled from the interface of an oxidized microporous carbon electrode, resulting in a negative cation surface excess. At more negative potentials, anions are repelled similarly. This behavior can be explained by elementary electrostatic considerations, provided there is no specific ion adsorption (21).

Assuming that the oxidized carbon III has a pzc close to that found in a previous work (8), we deduce that the very low capacity at positive potentials originates from repulsive interaction of the anions with the negative dipoles of the surface oxides which, up to +500 mV, is not compensated by the attractive positive electronic charge. The opposite is obviously deduced for cations which penetrate and adsorb into the 3.7-4.4Å pores of the oxidized surface of carbon III. The adsorp-

[2] The capacitance which corresponds to the sweep rates of Fig. 10 is taken to be half the distance between the upper and lower curve.

tion is virtually nonexistent at the slightly less oxidized surface of carbon II, which has the same pore diameter range. The fact that anions are "normally" adsorbed at the carbon I oxidized surface (Fig. 7) is attributed to the larger pores which allow greater ion-interface distance. Here anion adsorption becomes possible again, since the repulsive ion-dipole potential decreases quicker than the attractive ion point charge or the ion-distributed surface charge of the carbon electrode.

The effect of surface oxides can be further demonstrated by starting from the oxygen depleted carbon V and inducing oxygen chemisorption at 300°C which will result in carbon VI, while the pore diameters remain essentially unchanged. The C_d-V curves for these two samples are given in Fig. 10. It can be seen that the charging rate and, to a lesser extent, the C_d increases at negative potentials for the oxidized carbon VI and decreases at positive potentials. This shows that the direct chemisorption of oxygen is the cause of the different double layer behavior. It also shows that the oxidized electrodes favor cation adsorption at the larger diameter (4.3-5.6Å) as well.

A further reduced pore diameter was studied in the original TCM 128 fiber (designated carbon IV). The narrow pores of this carbon could still accommodate water up to 16% w/w. This enabled a minute penetration and adsorption of solvated ions (Fig. 8), resembling the behavior of carbon II. The higher capacitance as compared to carbon II, especially at negative potentials, is due to the slightly larger amount of chemisorbed oxygen. Here again the charging rate is much slower than the potential sweep rate.

The role of the hydration sheath.—The experimental results lead to the conclusion that when the pore diameter is reduced to less than 5.6Å, slowing down of charging rate and dependence of C_d on the amount of surface oxides becomes significant. Since below 5.6Å and especially below 4.7Å (carbons II, III, and IV) ions can penetrate the pores only after partial depletion or distortion of the hydration sheath (22) different behavior could be expected from the various ions. Preliminary results are given in Fig. 11 which shows the effect of exchanging Na^+ by Li^+ on a carbon III ($3.7 < d < 4.3$) electrode. The charging rate of the extensively hydrated Li^+ ion is considerably slower at negative potentials. This is seen by comparing Fig. 9 and 11. Upon a tenfold reduction of the sweep rate, the shape of the C_d curve of LiCl (Fig. 11b) retains the C_d-V curve of NaCl (Fig. 9). This indicates that the equilibrium behavior of Li^+ on carbon III is similar to that of Na^+, but their charging rates differ considerably. This is unlike the difference in equilibrium behavior of cation and anion (negative and positive branches), demonstrated by the two curves in Fig. 9. The apparent selectivity, when accommodating the less hydrated cations, is common to other systems which have molecular size cages, *i.e.*, crown-ether complexes (23), and to highly cross-linked cation exchanger resins (24). In the first case the cation is held by ion-dipole forces, while in the second, interaction with the resin's negative charge takes place. The negatively charged ultramicroporous carbon comprises both types of interaction.

Influence of concentration and voltage sweep rate.—The higher concentration of the electrolyte seems to increase both the charging kinetics and C_d, as is shown in Fig. 12. The effect of the very high 5*N* NaCl concentration needs more study, as there is evidence of pore enlargement during slow charging cycles.

The above porous carbons have at least two different surface areas, that of the ultramicropores which is very large and always charged slowly, and that of the outer surface of the fibers, which should be compared to the nonporous graphite TGM 389 (Fig. 5), concerning C_d and charging rate. Figure 13 shows that the increase of the sweep rate excludes contribution of the micropores to C_d. The remaining much lower capacitance at the

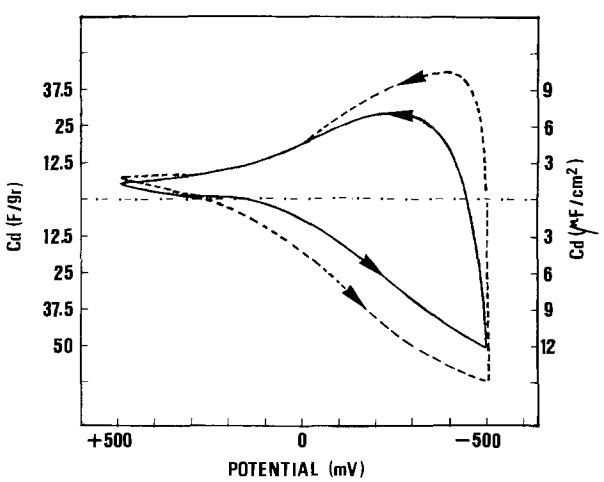

Fig. 11. C_d *vs.* V curve of carbon C III-OR in LiCl 0.1*N*. ----, 0.05 mV/sec; ——, 0.5 mV/sec; potential *vs.* 0.1*N* NaCl C.E.

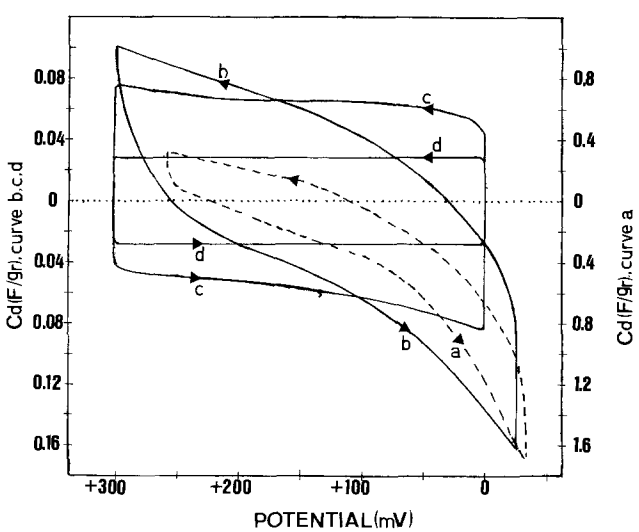

Fig. 13. The influence of potential sweep rate on C_d of carbon C IV-OR in 0.1*N* NaCl, potential *vs.* 0.1*N* NaCl C.E. a, 0.5 mV/sec; b, 10 mV/sec; c, 60 mV/sec; d, 600 mV/sec.

sweep rate of 600 mV/sec (Fig. 13d) corresponds to $2.8 \cdot 10^{-2}$ f/g. A doubled value of C_d, observed at 60 mV/sec (Fig. 13c), and a third charging process was observed (Fig. 13b) at an intermediate sweep rate of 10 mV/sec. All three curves were symmetrical and the current changes sign very fast by inversion of the voltage sweep. They are clearly distinct from the much slower and unsymmetrical ultramicropore charging process (Fig. 13a). The difference in C_d for Fig. 13(d, c, and b) is probably due to the difference between the geometrical and the BET surface area of the fibers. The same shallow micropores which cause the roughness factor might also be responsible for the intermediate rate charging process exhibited by Fig. 13b.

Estimation of ionic conductivity into the pores.—The delay of the current inversion after reversal of the sweep rate may be considered as a measure of restricted transport of ions into the pores. A characteristic relaxation time, τ, of the system could thus be the retention time of the symmetry between the upper and lower C_d-V curves. This value is deduced from Fig. 7 and 9. It could not be obtained from other curves, where no symmetry was achieved, with respect to the potential axis, during the voltametric cycle time. Regarding the porous electrode impedance as an R-C combination, we can write

$$\tau = RC_d \quad [2]$$

from which the order of magnitude of the specific resistivity ρ_P of the solution into the pores can be derived. Considering the radial symmetry of the current flow, the porous fiber is viewed as a solution conductor of a cross-sectional area A and length l. The area A is given by

$$A = A'P \quad [3]$$

where A' is the geometric surface area per gram of the fibrous material and P is the porosity in volume percent, which is about 30% for carbon I and III (12). The approximate length (l) of the ion pathway is expressed by

$$l = \frac{r}{2} \cdot T \quad [4]$$

where r is the average fiber radius and T is tortuosity factor of the conductance path, taken as 2 (4), thus $l \simeq r$. The cylindrical geometry of the fiber is thus approximated to be linear by means of Eq. [4]; therefore

$$R = \frac{\rho_R l}{A} \quad [5]$$

Substituting Eq. [4] and [2] in [5] and substituting the corresponding C_d values from the C_d-V curves at the negative inversion potentials of Fig. 7 and 9, we obtain $\rho_P^{I} = 1.1 \cdot 10^{11}$ Ω-cm and $\rho_P^{III} = 10^{11}$ Ω-cm for carbon I and III, respectively. This is several orders of magnitude larger than the resistivity of the bulk of 0.1N NaCl solution ($\rho \simeq 100$ Ω-cm).

The rough approximation applied renders ρ_P accurately only within the order of magnitude. It is still of value because of the great deviation of ρ_P from ρ. Extension of such studies over wider pore diameter ranges and to solutions used in practical porous electrode systems could provide information about the availability of the tiny pores for electrochemical reactions.

Faradaic and double layer currents.—On studying the electrochemical properties of carbon surfaces, discrimination between faradaic and double layer processes has to be made regarding the various surface groups existing on carbon. Recognizing that electrochemical reactions of surface groups involve the adsorption or desorption (in the thermodynamic, Gibbsian sense of surface excesses) of "aqueous components" (17) such as H^+, OH^-, H_2O_2 as well as electronic charge, we consequently deduce that surface groups fall within the generalized double layer concept. This concept has been put forward by Frumkin and coworkers (25) and later by Soffer (17). It is valid for both ideally polarized and reversible electrodes and makes no fundamental discrimination between them. The surface groups are simply considered as part of the components of the interface or the generalized double layer.

Putting the above argument into more experimental terms: The capacitor behavior of the double layer will not be imparted by the presence of the surface group in the sense that the interface should still acquire, for a finite potential change, a finite electronic charge which corresponds quantitatively with surface coverage constraints. This is unlike true faradaic processes which require an amount of charge according to the concentration and amount of redox components in the solution, regardless of surface coverage constraints.

The differential capacitance C_d (or the current) *vs.* potential function may, however, exhibit certain peaks due to specific surface groups if they are electroactive in a sufficiently narrow potential range. We have not encountered this behavior in sodium chloride solutions here and elsewhere (8, 16), nor in H_2SO_4 solution (26) in the range 0-650 mV *vs.* NHE. Peak-shaped voltamograms have been observed, however, in hot concentrated phosphoric acid (27) and in dilute HCl (28) and it may obviously depend on the type of carbon and surface treatment. In light of the above considerations, however, peak behavior is not necessarily an indication of faradaic response. It may simply be a hump in the C_d-V function.

In this work the electrode potential was always kept far from the thermodynamic potential of water decomposition. The pH was frequently monitored in order to assure, as has been done in a former work (8), that pH changes, if they occur at all, are too small to account for the charge delivered. We found, in fact, that the ultramicroporous electrodes were more immune to capacitance increase and pH changes at extreme potentials, than open structure electrodes.

Last but not least, no conceivable amounts of redox impurities could account for the delivered charges. On the other hand, these charge densities did correspond always to reasonable double layer charge values.

Conclusion

This work is restricted to ultramicropores of dimensions from close to those of water molecules up to 6Å. Qualitative evaluation, using constant sweep cyclic voltametry, showed that the mobility of ions into ultramicropores is several orders of magnitude smaller than in the free solution outside the pores. The surface dipoles have a stronger effect on adsorption and mobility into ultramicroporous carbons than on flat surfaces.

Technical Note

A Method for Direct, Real-Time Display of Q-$t^{1/2}$ Chronocoulometric Data

K. Keiji Kanazawa and R. K. Galwey

IBM Research Laboratory, San Jose, California 95193

In single step chronocoulometry, the time dependence of the charge Q passing through the working electrode in an electrochemical cell due to a step function of applied potential is recorded and studied. This technique was introduced many years ago (1). Even then, the utility of a Q *vs.* $t^{1/2}$ plot was recognized and discussed. The variety of information which can be obtained using this and related techniques has been reviewed by Murray (2).

A linear Q-$t^{1/2}$ dependence is a limiting case of a more general time dependence. To examine the generalized time dependence of charge, the data should be processed using digital computation. This can be done on line, and such systems have been described (3). For less demanding applications however, the necessary time and money investment required for laboratory automation is not warranted. This is particularly true when the functional time dependence is specified and only that dependence is examined. This note describes the technique which we have used to implement a real-time display of Q-$t^{1/2}$ data, permitting a quick assessment of the experimental conditions and eliminating the time, tedium, and possible error involved in manual plotting.

A block diagram of the experimental arrangement is shown in Fig. 1. An analog current-follower potentiostat was used for these measurements. Such instruments have been discussed in detail by Harrar (4). The output of the current follower in the potentiostat is a voltage e_I which is proportional to the cell current. Analog integration of this voltage yields a voltage e_Q which is proportional to the charge Q. Such circuitry is common (5), although special care must be taken in certain coulometric applications (6). Essentially, we want to plot e_Q against a voltage e_T which varies as the square root of time. One could conceivably have used analog techniques to generate this particular function of time. However, to provide maximum flexibility a stored waveform digital generator was used to produce e_T (7). The block diagram for this generator is shown in Fig. 2.

Key words: chronocoulometry, digital function generation, instrumentation.

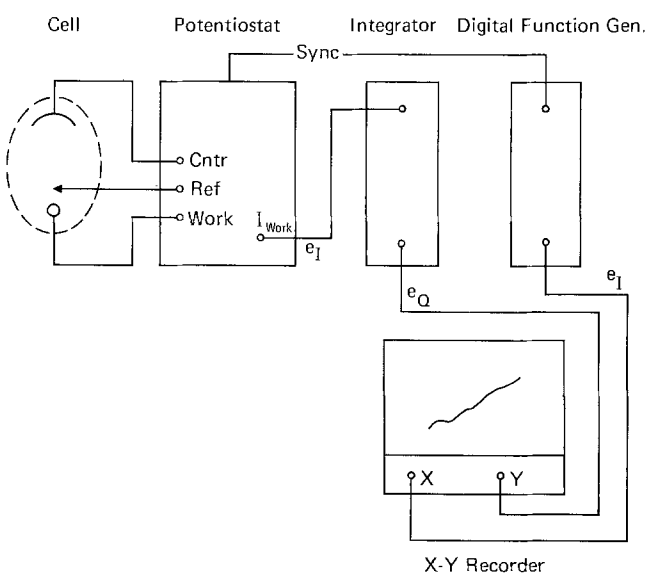

Fig. 1. A block diagram, showing the arrangement of the basic modules.

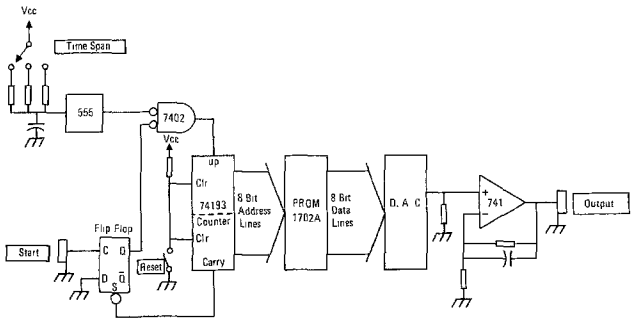

Fig. 2. A functional schematic diagram of the digital function generator.

The requirement on the circuitry is to produce an analog, time-dependent waveform which is digitally derived. The fundamental concepts for this circuit are described below. The digital equivalent of the waveform is stored in an erasable programmable read-only memory (Intel 1702A, 8×256 PROM). By sequentially addressing the PROM, the contents are sensed by the digital to analog converter (Hybrid Systems 371-8, DAC), and converted to the appropriate analog value. The amplifier provides proper scaling and filtering of the DAC output. The filtering is chosen commensurate with the instrument used for recording. In our particular case, where an X-Y recorder was used, the amplifier had a gain of 5 and was rolled off at 40 Hz. The PROM addresses are derived by incrementing an 8 bit binary counter. A clock provides the periodic pulses which increment the counter. We used an NE 555 timer because of ease of operation, simplicity, and cost. Depending on the specific application's needs, different timers may be selected.

Application of the clock signal is controlled by the NAND and the D flip-flop. The intent of these logical elements is to cause the counter to first be reset to address zero (or count zero) when the reset button is momentarily depressed. Simultaneous with the application of the step function voltage to the potentiostat, a "start" pulse must be received by the clock (C) input of the flip-flop. Its "Q" output will then go to a zero state. This zero state is NANDed by the negative-going clock pulses, resulting in positive-going pulses being sent to the counter. The counter will then begin incrementing, causing updated values to be sent to the DAC at the clock rate. When 256 clock pulses (the capacity of the PROM) have been received by the counter, a carry pulse will be generated by the counter. This pulse is received by the flip-flop, causing the "Q" output of the flip-flop to go to a "1" state. This "1" state inhibits any further pulses from incrementing the counter. Thus the cycle is complete.

There are two principal sources of error from the digital function generator. The 8 bit resolution introduces a digitization error. The maximum percentage error is 2% occurring near the beginning of the scan. After the first five points, this error is less than 1%. Since data reduction involves slope and/or intercept determination using a sizable fraction of the sweep data, the error introduced by this is much less than 1%. When the clock is an R-C controlled timer, as in this circuit, a larger uncertainty exists in the clock rate. Use of trimming techniques allows this error source to be reduced to less than 1%. This error is acceptable, being smaller than the 5-10% uncertainties introduced by other sources, such as cell geometry, incomplete IR compensation, and instrument and recorder calibration.

An example of a Q-$t^{1/2}$ plot obtained by us is shown in Fig. 3. This is an actual recording of the signal obtained in a cell using a 0.2 cm^2 Pt button working electrode in a solution containing 0.1M tetraethylammonium fluoborate in acetonitrile. The active species was methoxy pyrazoline, present at 0.001M concentration.

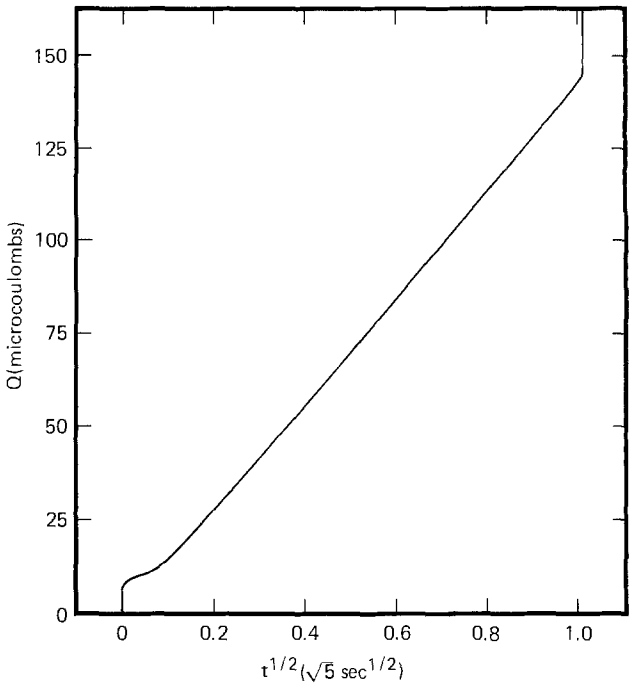

Fig. 3. An example of a direct display of Q-$t^{1/2}$ coulometric data.

For detailed work, the effective electrode area should be evaluated using a known electrochemical system, as was done, for example, by Bacon and Adams (8). The data were plotted using a Hewlett-Packard 7040A X-Y recorder. The hump at the beginning of the plot is due to overshoot in the potentiostat-cell system.

It is clear that this same technique could be used to examine other time dependencies. In fact, any waveform which can be stored with sufficient accuracy in the PROM can be used to drive the recorder X axis. For example, we have generated a $t^{-1/2}$ voltage function to compare these coulometric studies with a direct display of current *vs.* $t^{-1/2}$. We found the Q-$t^{1/2}$ technique to be superior, primarily because it was much less demanding of the recorder response time. We are finding this technique increasingly useful and feel that the versatility of this technique will permit the study of other interesting time behaviors.

Brief Communication

n-Butyllithium–An Effective, General Cathode Screening Agent

M. Stanley Whittingham* and Martin B. Dines

Exxon Research and Engineering Company, Linden, New Jersey 07036

Currently, high energy density lithium storage systems are the focus of intense interest and expectation (1,2). In order to scan and characterize oxidants as potential cathodes, it would be very useful to have a reliable chemical reagent which could, in effect, mimic the half-cell reaction under consideration. Although reagents formed by dissolving alkali metals in ammonia, polyamines, polynuclear aromatic solutions in ethers, or hexamethyl phosphoramide (3) might be used, they have a number of shortcomings. Their reactions are difficult to run, since they involve extremely reactive materials, very dark opaque media, their polar solvents can also partake in the reaction, and it is difficult to separate the product from residual reagent. It would be preferable to have instead an agent whose lithium activity is more on the order of a volt or so below the alkali itself. We report that n-butyl lithium serves as such an agent.

The use of butyllithium to chemically mimic an electrochemical reaction was first mentioned by Armand (4) in connection with work on chromium oxide/graphite compositions. Dines (5, 6) then discovered that the lithium intercalates of the lamellar transition metal dichalcogenides were readily afforded without any of the degradation of their crystalline form previously seen, for instance, with lithium naphthalide (7) or lithium in ammonia, for which it is necessary to subsequently remove, by heating to 250°C, the coincorporated solvent (8). This latter effect, the coinsertion of solvating neutral molecules, has even been observed during electrochemical discharge in organic electrolytes (1). No such complications accompany the inclusion of lithium from butyllithium-hydrocarbon solutions. Because the solution is light and clear, the effect of the reagent on the oxidant can be visually [even microscopically (9)] observed during the process of lithiation.

n-butyl lithium, previously extensively used as an alkylating agent (3), is commercially available as a 1.5-2.0 molarity solution in hexane. In a typical experiment, a known quantity (~100 mg) of the candidate solid oxidant (Ox) was placed in contact with an excess of butyl lithium solution in a dry box and allowed to react for several days at room temperature, after which the solid was filtered, washed with hexane, and examined by x-ray diffraction. The reaction, which is shown schematically (10)

$$C_4H_9Li + (Ox) \rightarrow Li^+ (Ox)^- + (C_4H_9) \rightarrow \tfrac{1}{2}\, C_8H_{18}$$

was followed by acid-base titration of the unreacted butyl lithium and by monitoring the octane formed using gas chromatography. The latter is less reliable because of the possible formation of butene and butane from the butyl radicals. The results are summarized in Table I. A number of materials were found not to react at all, including graphite, aluminum, and antimony.

These results indicate that the reaction is indeed a general one, and that where battery discharge capacity data are available, excellent agreement is obtained. Thus, the carbon fluorides react with the stoichiometric quantity of lithium (11), and cupric sulfide takes up almost two equivalents as expected for formation of lithium sulfide and copper. Tetracyanoquinodimethane (TCNQ) reacts with one lithium to form $TCNQ^-$, in agreement with previous cell data (12). The oxides of vanadium and molybdenum reacted with about 2, and 1.5 equivalent of lithium, respectively, as previously reported (13, 14), and in both cases x-ray analysis indicated that two new phases were being formed. With TiO_2 (anatase form), butyllithium reacted vigorously forming first a blue, then a black compound. The degree of reaction was much higher than that reported by Johnson (19) for rutile, however, preliminary NMR results suggest that the lithium atoms are mobile just as he found them to be. The observed low level of reaction of CuF_2 could be related to the presence of a

Table I. Summary of results

product film of LiF which prevented further reaction. The trichalcogenides, first studied in cells by Broadhead *et al.* (16), all reacted with about 3 moles of butyllithium, and have recently been extensively studied (17, 18). The reactivity of materials such as WO_3 might be enhanced by going to elevated temperatures to overcome kinetic barriers.

The use of butyllithium solutions also allows the rate of the process to be derived. This can be accomplished either by titrating aliquots of the supernatant reagent at appropriate time intervals, thereby following its consumption by the oxidant, or, as depicted in Fig. 1, by measuring the temperature rise of a reaction of the solid on addition to an excess of a molar solution of the reagent. The more rapid the temperature rise, the greater the reaction rate (and the potential discharge current density). As the figure shows, of TiS_2, MoO_3, and V_2O_5, the sulfide holds the greatest rate capability; this is consistent with our finding that current densities of 10 mA/cm^2 and greater can be attained in practical cell configurations (19, 20). In principle, the area under such curves can give a relative measure of the potential energy densities; strictly speaking it is the heat of the reaction which is measured, rather than the free energy. Thus, in the example given in the figure, V_2O_5 would promise the highest energy density. By carrying out the reactions in a calorimeter, a quantitative determination of the heat of reaction could be obtained for those cases where the reaction is rapid (such as TiS_2 and V_2O_5). However, in these qualitative studies, care must be taken in drawing conclusions of comparative behavior, since properties such as particle size obviously influence the results.

A problem in the discharge of cells is that conductive diluents, or other binding agents such as Teflon, must often be utilized in order to allow for the function of the cathode, but these additives are not necessary with the chemical reaction. Thus the butyllithium technique has allowed for the formation of the discharge product of a cell in a form readily amenable to x-ray analysis (21) and other physical measurements (22-24) without the complications of any possible side reactions or additional phases as might be present after disassembly of a battery. X-rays showed that these products were the same as those formed in cells.

That the effective cutoff of the voltage of butyllithium is on the order of *ca.* 1.4V below lithium itself is gathered from the behavior of $NbSe_3$. It has been found that on discharge the triselenide takes up 3 lithiums, with a final open-circuit voltage of above 1.4V (18). This sets an upper limit to the difference in activity between lithium and butyllithium, since the latter also yields Li_3NbSe_3. An approximate lower limit to the activity difference can be inferred from the observation that antimony does not react with butyllithium, and has a voltage relative to lithium of about 1V (25). Therefore, we can say that butyllithium is less active than lithium by 1-1.4V. Since the free energy of formation of octane is +4 kcal/mole (26), one infers a value for the free energy of formation of butyllithium of about 25 kcal/mole (±5 kcal/mole).

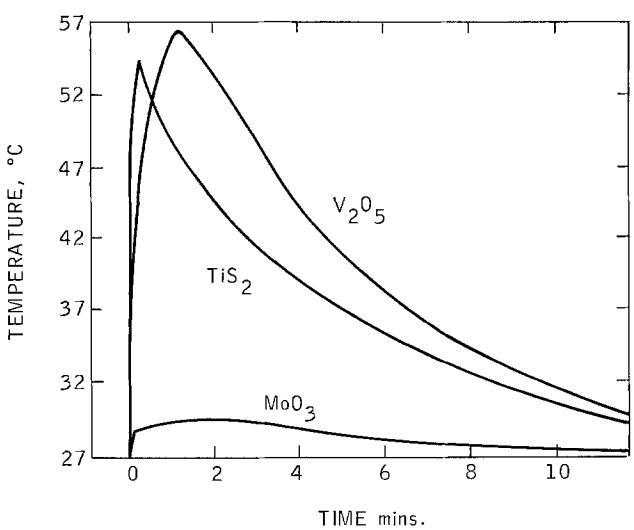

Fig. 1. Effect of the addition of excess butyllithium to equivalent slurries of V_2O_5, TiS_2, and MoO_3.

Electrochemical Properties of Dopants and the D-C Dynamic Scattering of a Nematic Liquid Crystal

H. S. Lim,* J. D. Margerum, and A. Graube

Hughes Research Laboratories, Malibu, California 90265

ABSTRACT

Flow of liquid crystal from one electrode to the other was observed during dynamic scattering of a phenyl benzoate nematic liquid crystal. The direction of the flow depended upon the electrochemical properties of dopants. The flow was from cathode to anode when the dopant was an electron acceptor, and vice versa when the dopant was a donor. A redox dopant gave distinctively different d-c dynamic scattering patterns from a salt dopant, and did not give the Williams domain pattern which was observed with a salt dopant. Charge conduction mechanisms through the liquid crystal are discussed in terms of the electrode reactions of the liquid crystal components and the dopants.

Dopants are commonly used to improve the properties of nematic liquid crystals (LC) for dynamic scattering (DS) displays (1). The conductivity anisotropy (2-4) of a LC depends very much on the dopants which are used. The a-c dynamic scattering characteristics depend strongly on the conductivity anisotropy. Lower threshold voltages (3, 4) and higher scattering levels (4) were observed as the value of the anisotropy was increased. The conductivity anisotropy depends on the structure of the dopant as well as on the liquid crystal material itself (4). The d-c-DS characteristics also depend on the electrochemical properties of the dopant; redox dopants consisting of electron acceptors, donors, or a combination of both, give a low threshold voltage (5, 6) and a high scattering level (6). A combination of an electron acceptor and a donor gives good electrochemical stability (6-8) for long-term d-c-DS of liquid crystals. Redox dopants which can be reduced and oxidized much more easily than the LC compounds minimize the participation of the LC compounds in the electrode reactions which are responsible for their decomposition (6, 9).

In a recent preliminary report (9), we showed that the charge injection and LC flow direction as well as the scattering patterns in a d-c activated LC depended upon the dopants that were used. Earlier, Heilmeier *et al.* (10) reported that in anisylidene-*p*-aminophenylacetate the DS was initiated from the negative electrode and was propagated to the positive electrode. However, they used geometrically dissimilar electrodes and they did not specify the dopants responsible for the observed conductivity and DS of their Schiff base. Lacroix and Tobazeon (11) carried out studies on N-(*p*-methoxybenzylidene)-*p*-*n*-butylaniline (MBBA) in a special cell in which the electrodes were coated with anion-permeable membranes. They observed that the LC motion started at the negative (anion-injecting) electrode and spread toward the positive (collector) electrode, giving a "finger"-type flow pattern followed by a turbulent region spreading toward the collector.

In the present paper we first report studies on the electrode reactions of various dopants and of 4 ester liquid crystal components in solutions of acetonitrile or dimethyl formamide. Then we report studies of the hydrodynamic flow patterns and dynamic scattering effects of these dopants dissolved in the nematic ester liquid crystal mixture when d-c voltages are applied.

Experimental

The LC used was a phenyl benzoate mixture designated as HRL-2N10. It was a four-component mixture of *p*-butylphenyl *p*-toluate, *p*-butoxyphenyl *p*-butoxybenzoate, *p*-butoxyphenyl *p*-hexyloxybenzoate, and *p*-butoxyphenyl *p*-octyloxybenzoate in a weight ratio of 15:5:9:9, respectively. It had a nematic range of about 20°-55°, a dielectric anisotropy of $\Delta\epsilon = -0.12$ (25°C, 500 Hz), and a birefringence of $\Delta n = 0.14$ (25°C, 545 nm). Before dopants were added, the resistivity of the LC at 25°C was greater than 10^{11} Ω-cm at 100 Hz. The resistivity of the LC after doping ranged from 4×10^8 to 1×10^{10} Ω-cm. The individual components of the LC were prepared by the reactions of the corresponding substituted benzoyl chloride and the substituted phenol in pyridine. The reaction products were recrystallized several times. Three types of dopants were used: (*i*) electrochemically inactive salts, tetrabutylammonium perchlorate (TBAP), and tetrabutylammonium trifluoromethanesulfonate (TBATMS); (*ii*) electron acceptors, 7,7',8,8'-tetracyanoquinodimethane (TCNQ), and (2,4,7-trinitro-9-fluoroenylidene)malononitrile (TFM); and (*iii*) electron donors, di-*n*-butylferrocene (DBF) and tetrathiofulvalene (TTF). The acceptor and donor dopants are called "redox" dopants throughout this paper. TBATMS was prepared (12) by reaction of trifluoromethanesulfonic acid and

Key words: redox dopant, salt dopant, liquid crystal, electrohydrodynamic motion, dynamic scattering.

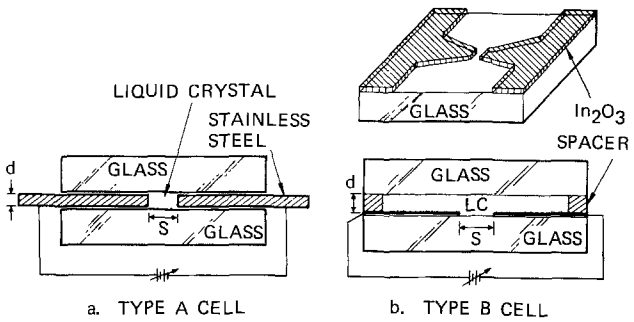

Fig. 1. Schematic drawings of test cells

tetrabutylammonium bromide. The crude product was recrystallized from water and dried. TBAP was the polarographic grade from Southwestern Analytical Chemicals, Incorporated. It was vacuum dried at 50°C before use. TCNQ (from either Aldrich Chemical Company or Eastman Organic Chemicals) was recrystallized more than twice from acetonitrile (AN). TFM (Aldrich Chemical Company) was recrystallized from AN. DBF (Research Organic Chemical Company) was purified by vacuum distillation. The TTF sample was donated by Dr. Fred G. Yamagishi.[1] The solvents AN (Burdick and Jackson Laboratories Incorporated) and spectrophotometric grade dimethyl-formamide (DMF) (J. T. Baker Chemical Company) were used as purchased for electrochemical studies.

The electronic apparatus employed for the cyclic voltammetry was similar to that described earlier (13). The cyclic voltammograms were recorded on an Omnigraphic Model 2000 X-Y recorder (Houston Instrument) using a conventional two-compartment cell. The electrodes used for cyclic voltammetry were either commercially available hanging mercury drop electrodes or a platinum ball attached to a fine platinum wire sealed in glass. Potentials were measured against a saturated calomel electrode (SCE), and solution resistance was not compensated. All experiments were carried out at room temperature.

Two different types of test cells for liquid crystals were used for the microscopic study. Schematic diagrams of type A and B cells are shown in Fig. 1. The LC was restricted to a small interelectrode space in the type A cell. The purpose of the type B cell was to allow enough space so that the liquid crystal could move from one electrode to the other without generating a compensating flow in the area under observation. The electrode separations (S) were varied from 180 to 600 μm, and the thickness of the liquid crystal layer (d) from 25 to 200 μm. The liquid crystal was aligned either perpendicular or parallel to the electric field and parallel to the surface of the glass substrates by manually rubbing the substrate with Kimwipes. The perpendicular alignment was obtained by bonding long alkyl chains onto the surface of the substrates. The microstructure of the DS was observed from a direction perpendicular to the direction of the applied electric field using a Zeiss standard WL polarizing microscope.

Results and Discussion

Electrode reactions in solvents.—The electrode reactions of the liquid crystal components were studied by cyclic voltammetry using platinum and mercury electrodes. The cyclic voltammograms of the LC components in AN are shown in Fig. 2. Anodic oxidations of the compounds occurred at potentials more positive

[1] Preparation of TTF: 1,3-dithiole-2-thione (Strem Chemicals Incorporated) was oxidized with peracetic acid [E. Klingsberg, *J. Am. Chem. Soc.*, 26, 5240 (1964)], and the resulting salt was converted to 1,3-dithialium perchlorate with perchloric acid [D. Leaver *et al.*, *J. Chem. Soc.*, 5104 (1962)]. Deprotonation of this compound with triethylamine [D. L. Coffen *et al.*, *J. Am. Chem. Soc.*, 93, 2258 (1971)] gave TTF in quantitative yield. After recrystallization from hexane, the product was gradient-sublimed (75°C, 10^{-5} Torr) [A. R. McGhie *et al.*, *J. Cryst. Growth*, 22, 295 (1974)] to give orange prisms, mp 118°-119.5°C.

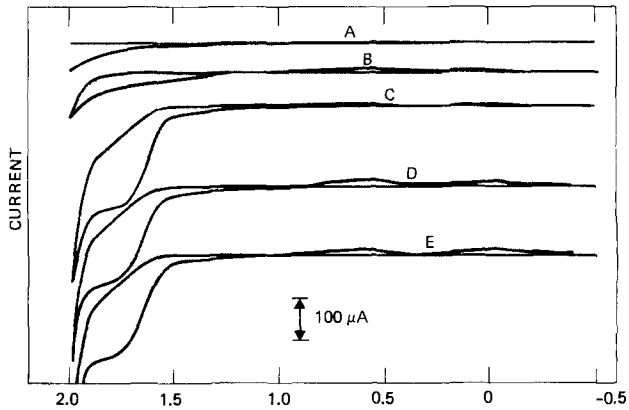

Fig. 2. Cyclic voltammograms of the LC components in 0.1M TBAP solution of AN. Electrode, platinum ball; voltage scan rate, 100 mV/sec; (A) blank solution; (B) 2 mM *p*-butylphenyl toluate; (C) 2 mM *p*-butoxyphenyl *p*-butoxybenzoate; (D) 2 mM *p*-butoxyphenyl *p*-hexyloxybenzoate; and (E) 2 mM *p*-butoxyphenyl *p*-octyloxybenzoate.

than 1.5V *vs.* SCE. A coupled reduction peak of the anodic peak (Fig. 2) of the compounds was not observed, indicating that the oxidation products were not readily rereduced in the experimental conditions. Typical cyclic voltammograms are shown in Fig. 3 of one of the LC components in DMF for the cathodic process. A cathodic reduction of *p*-butylphenyl *p*-toluate (not shown in Fig. 3) occurred at more negative potentials than −2.0V *vs.* SCE, while the reduction of the other three compounds occurred at more negative potentials than −2.1V *vs.* SCE, as in Fig. 3. No coupled oxidation peaks to the reduction peaks were observed at low voltage scan rates [Fig. 3(A)]. As the scan rates were increased above a certain value (*e.g.*, about 100 mV/sec for *p*-butoxyphenyl *p*-hexyloxybenzoate), an oxidation peak which appeared to be coupled with the reduction peak was observed [Fig. 3(B) and (C)]. This observation indicated that a chemical reaction of the primary reduction product might be followed by the cathode reaction to give a reaction product which was not easily oxidizable at the electrode. Primary reaction products of both cathodic and anodic processes would probably be radical ions (14, 15) of the LC esters, which would be unstable in the experimental conditions.

The cyclic voltammograms of the dopants in 0.1M TBAP solution of AN using the platinum electrode are shown in Fig. 4. The cathodic and anodic peaks of all the redox couples in Fig. 4 were separated by about 70-100 mV. The separation of the cathodic and anodic peaks (70 or 80 mV) of the two one-electron reduction steps of TFM appeared to indicate that the electrode reactions were reversible. The values of the peak potential separation (slightly larger than the theoretical

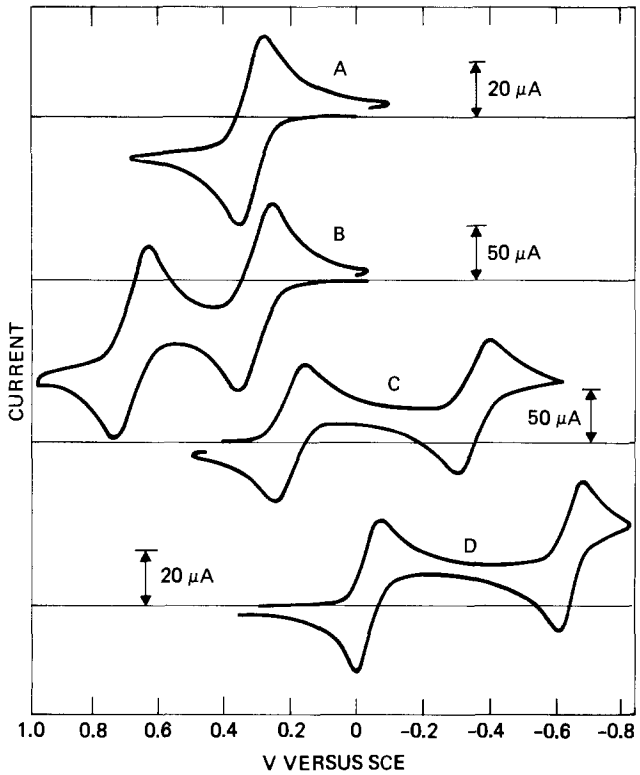

Fig. 4. Cyclic voltammograms of the redox dopants in 0.1M TBAP solution of AN. Electrode, platinum ball; voltage scan rate, 100 mV/sec; (A) 1.0 mM DBF; (B) 3 mM TTF; (C) 2.5 mM TCNQ; and (D) 1.1 mM TFM.

value of 58 mV) might be due to the uncompensated resistance of the electrolyte in the test cell.

Reversible electrode reactions in AN have been reported for the two one-electron oxidations of TTF (16) and also for the first one-electron reduction step of the two one-electron reduction steps of TCNQ (17, 18). Such reversibility has not been reported for TFM and DBF, but in the latter case a similar structure [1,1'-diethylferrocene (19)] was reported to show a reversible one-electron oxidation step.

The redox potentials of the dopants indicate that the electron acceptors such as TFM and TCNQ and donors such as DBF and TTF are expected to dominate cathodic and anodic processes, respectively, in the LC if they are present in sufficient concentrations.

Liquid crystal studies.—The dominating effects of the electrode reactions of dopants on the electrohydrodynamics of the LC have been observed during the microscopic study of DS with applied d-c fields. The characteristic microscopic patterns of DS with various types of dopants are shown in Fig. 5 and 6. Salt dopants [Fig. 5(B) and 6(A)] and redox dopants [Fig. 5(B-D) and 6(B-F)] showed distinctly different DS patterns. When the dopant was salt type and the liquid crystal alignment was perpendicular to the electric field and parallel to the glass substrate, the scattering pattern had a line or channel structure [Fig. 5(A) and 6(A)] which was asymmetric with respect to the polarity of the field but otherwise similar to that previously observed by Chang (20) with MBBA subjected to an a-c signal. (When the alignment was parallel to the electric field, the line structure was spatially very irregular; otherwise, the appearance was similar to the perpendicular case.) Thin flow lines of liquid crystal [Fig. 5(A)] were initiated from both electrodes visibly at the same time and propagated toward the opposite electrodes. The initiation of these flow lines alternated regularly from one electrode to the other. Dust particles moved in one direction along the flow lines originating at one electrode, and in the opposite direction along the flow lines originating at the other electrode, indicating that the lines were caused by LC flow. These particles moved back and forth along the flow channels. This observation is consistent with earlier observations on Williams domain patterns (21). There appeared to be little or no net flow of liquid crystal from one electrode to the other, even with type B cells in which room for net flow was provided.

When the dopant was a redox-type, *i.e.*, an electron acceptor or an electron donor, the general appearance of the scattering pattern was quite different from that observed with the salt dopants. Turbulent motions of liquid crystal were observed at lower voltages, without formation of the regular line or channel structure discussed above. The turbulence was initiated from one electrode and propagated to the other at a visible rate. Except at very high voltages, the turbulence did not reach the opposite electrode and remained localized near the electrode where it was initiated [Fig. 5(B-D) and 6(B-E)]. A surprising observation was that the turbulence was initiated from the cathode when the dopant was an electron donor and from the positive when the dopant was an electron acceptor, *i.e.*, the turbulence was observed at the opposite electrode of

the electrode from which the charge injection was expected through the faradaic reaction of the dopant.

The flow of LC under the influence of the applied d-c field was also observed with the redox dopants. A unidirectional flow from one electrode to the other was observed with these dopants, unlike the case of salt dopants. The direction of the flow was always from the anode to the cathode when the dopant was a donor, and from the cathode to the anode when the dopant was an acceptor. Figure 7 shows an example of microscopic flow patterns with a donor dopant (DBF). As indicated by arrows in the figure, average dust particles moved from the back side of the electrode from which charge injection is expected through the faradaic reaction of the dopants toward the opposite electrode, traveled across the electrode boundary and came back to the starting point by the periphery of the electrodes where the electrical field was weak. The dopant-dependent flow of LC was confirmed by another independent method using a test cell which is shown schematically in Fig. 8. The field was applied across two metal screen electrodes and a net liquid flow in a given direction introduced a pressure which changed the height of the liquid crystal in the capillaries. When voltage was applied to the cell, the LC column was displaced from the anode side to the cathode side when the dopant was an electron donor, and vice versa when the dopant was an acceptor. When the dopant was

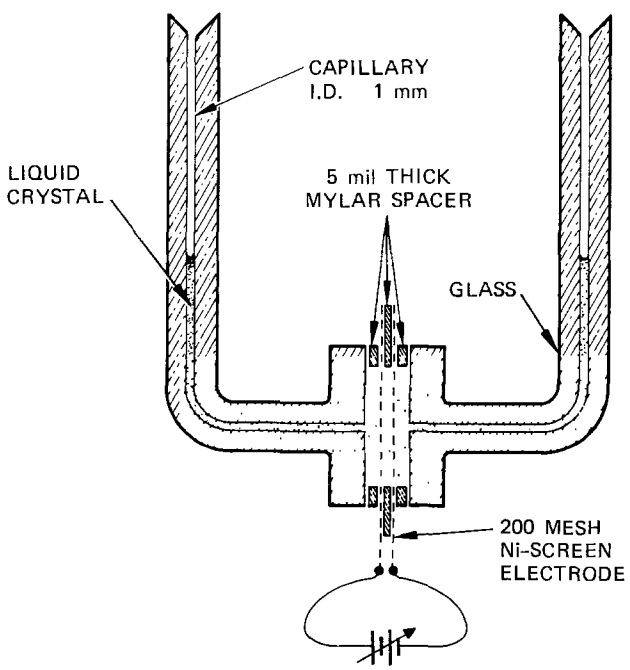

Fig. 8. Liquid crystal flow detection cell.

either a salt or an equimolar mixture of the donor (DBF) and the acceptor (TFM), the displacement was much smaller than previous cases.

The dopant-dependent flow of LC under the influence of the d-c field clearly indicated that the electrode reactions of the dopants played the dominant role in the electrohydrodynamics of the LC. The observation with the redox dopants appears to be consistent with the charge conduction mechanisms, as shown in Fig. 9(a) and (b), which involve a unipolar charge injection through the faradaic reaction of the dopant at our electrode followed by space charge (11) migration to the opposite electrode where the charge is neutralized by the reverse electrode reaction. The space charge should be associated with the radical ions of the dopants. When the dopant is an electron acceptor [Fig. 9(a)], negative charge injection occurs at the cathode ($A + e \rightarrow A^-$), the charge migrates to the anode in the form of a space charge to be neutralized at the anode ($A^- \rightarrow A + e$), and vice versa when the dopant is a donor [Fig. 9(b)]. The LC flow is caused by the migration of ions through it. The alternative mechanisms shown in Fig. 9(c-f) which do not require space charge formation do not explain the unidirectional flow of the LC.

When the redox dopant was a mixture of an electron acceptor and a donor, the direction of the net flow of LC depended on relative amounts of each component. Microscopic studies showed that the over-all flow pattern of the LC was a mixture of regions which were similar to the pattern with an acceptor dopant and those with donor dopant rather than those of a salt dopant with a flow line structure. The patterns contained regions of turbulence which were similar to those with an acceptor dopant and regions which were similar to those with a donor dopant [Fig. 6(F)]. This observation was also supported by the motion of dust particles which moved from one electrode to the other in one region and in the opposite direction in the adjacent region. The charge conduction mechanism appears to involve regions where the mechanism shown in Fig. 9(a) operates, and other regions where the mechanism shown in Fig. 9(b) operates. These two

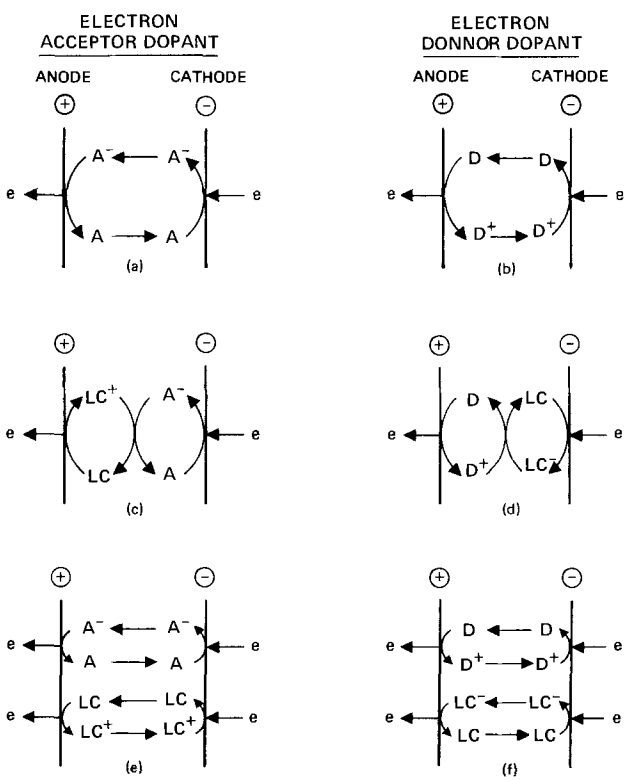

Fig. 9. Charge conduction mechanisms through LC when the dopant is a redox type.

different regions are randomly distributed throughout the conduction area.

When the dopant is a salt, the charge conduction mechanism is probably as shown in Fig. 10(a). The LC components are reduced at the cathode to give a radical anion ($LC + e \rightarrow LC^-$), and oxidized at the anode to give a radical cation ($LC \rightarrow LC^+ + e$). At the same time, channels of cation and anion space charge regions are formed during the charge migrations to the opposite electrodes, and the charge is neutralized at the opposite electrodes by reverse reactions. An alternate mechanism (22) [Fig. 10(b)] which includes a reaction of the cation and anion in the bulk of LC does not explain the alternating flow channels of LC which are observed with the salt dopant.

The hydrodynamic instability of LC with the salt dopants to form the flow channel structure has been theoretically analyzed previously (23). However the reason, why the turbulence pattern is formed during dynamic scattering of LC when the dopant is a redox type and why the turbulence is localized at one particular electrode are not known presently. The reason why two different turbulence regions are formed when the dopant is a mixture of an electron acceptor and a donor, instead of giving the flow channel structure, remains also to be explained.

The turbulent LC flow patterns observed in Fig. 5 and 6 correspond to the dynamic scattering (DS) effects observed in display cells. The DS threshold voltage is considerably higher in the present test cells than in conventional sandwich-type display cells because of the surface boundary conditions. Comparison of the microscopic patterns of salt-doped LC in Fig. 5(A) and 6(A) (no DS was observed at 30 and 40V, respectively) with those of redox-doped LC in Fig. 5(B-D) and 6(B-F) showed that the redox dopants gave lower DS threshold voltage than the salt dopants. Threshold voltages of 2.0-2.1V for a redox dopant and 3-5V for a salt dopant were observed (6) in a comparable resistivity range of the LC in conventional 13 μm thick display cells in which the LC was sandwiched between 2 flat transparent electrodes. The comparison of the microscopic patterns also indicated that the LC doped with a redox dopant would give a higher DS level than the LC with a salt dopant. The scattering levels in a given voltage in the display cells were always higher with the redox dopants than the salt dopants (6).

Our observations (6) of long d-c operational lifetimes of LC with redox dopants as compared to short lifetimes with salt dopants are consistent with the present charge conduction mechanism. In 13 μm thick display cells an operational lifetime of more than 18,000 hr with continuous 20V d-c operation has been achieved when the LC was doped with 0.5% DBF and 0.5% TFM, while the lifetime was shorter by more than two orders of magnitude when the LC was doped with a salt dopant. The shorter lifetime with a salt dopant was probably due to the formation of LC radical ions which are unstable, while in the presence of redox dopants such LC radical ions were not formed.

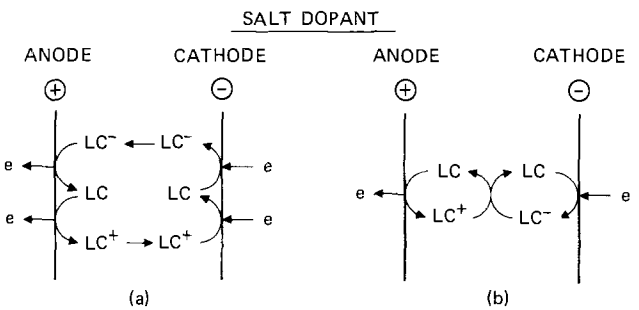

Fig. 10. Charge conduction mechanisms through LC when the dopant is a salt.

Conclusions

1. Discretely different d-c-activated hydrodynamic instabiltities were observed with a redox dopant than with a salt dopant in the same ester liquid crystal. At voltages just above the threshold the liquid crystal with salt dopants showed a flow pattern with periodically arrayed flow channels, while the liquid crystal with redox dopants showed turbulence motion.

2. A unidirectional flow of LC from one electrode to the other has been observed during the DS of the LC which was doped with either an electron acceptor or a donor. The direction of the flow depended on the dopants. The flow was from the positive electrode to the negative when the dopant was an electron donor and vice versa when the dopant was an acceptor.

3. The observations of the flow appeared to be consistent with the charge transport mechanisms which involved a unipolar injection of charge at the anode when the dopant was a donor and at the cathode when the dopant was an acceptor through the faradaic reaction of the dopants and migration of the injected space charge toward the opposite electrode to be neutralized by the reverse electrode reactions.

4. When the dopant was a redox type, dynamic scattering appeared to be initiated and localized (at lower voltages) at the opposite electrode of charge injection.

5. The higher d-c scattering levels (6) of the present liquid crystal with redox dopants rather than with salt dopants appeared to be due to the distinctively different hydrodynamic instability patterns.

Chemical Mechanisms in Photoresist Systems

I. Photochemical Cleavage of a Bisazide System

Shigeki Shimizu[1] and George R. Bird

School of Chemistry, Rutgers University, New Brunswick, New Jersey 08903

ABSTRACT

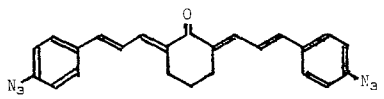
We have investigated the familiar photoresist system of cyclized polyisoprene + bis(4-azidobenzal)cyclohexanone by the methods of infrared and u.v. spectroscopy, solvent extraction, and thin layer chromatography. The principal photoreaction is the simultaneous cleavage of both azido groups on a single molecule by absorption of a single photon with 43% quantum yield. The observed traces of monoazides and or other materials are insufficient to justify a biphotonic mechanism. The reacted bisazide (bisamine and/or by-products) acts as a quencher for neighbor bisazide molecules, producing a complicated kinetic behavior which may simulate a second-order (biphotonic) reaction.

Among the practical photoresist systems used to fabricate printed microcircuits or lithographic plates, symmetrical bisazides have been widely used as the photoactive, cross-link-forming element.[2] It is obvious from the wide acceptance of this class of materials that the quantum yield for formation of cross-links must be high. In describing these systems, Kosar (1) makes repeated mention of the thermal stability of the azide group, a stability which may be contrasted with the relative thermal instability of most photochemical initiators and cross-linking agents (2). Since single-cross-links suffice to bind and immobilize large polymer molecules, a photoresist system must be considered as a chemical image amplifier with a gain roughly proportional to the degree of polymerization of the parent polymer. This amplification applies equally to the desired image of actinic photons and to the undesired thermal initiation of cross-linking reactions.

The high sensitivity of bisazide photoresist systems was called to our attention by John Weigl (3), who indicated that the system described by Clecak, Cox, and Moreau (4) was "a extraordinary fast system described in the literature." This system involves partially cyclized polyisoprene as the starting polymer and 2,6-bis(4-azidocinnamylidene)cyclohexanone as the cross-linking agent (I). Related initiators involving cyclopentanone and methyl substituted cyclic ketones have been described (5). We were initially interested in the question of thermal instability of the cinnamylidene bisazide, but soon discovered that the question of instability could not be approached without a satisfactory understanding of the mechanism of the primary photoreactions of these systems. Conversations with Dr. Moreau indicated that a commercially available material, 2,6-bis(4-azidobenzal)cyclohexanone (II), would be a much more suitable material for investigation, so we began a mechanistic investigation on this compound as a photo-cross-linking agent for partially cyclized polyisoprene.

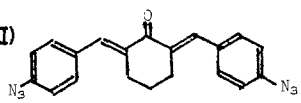
The scientific literature is ambiguous as to the initial step in the photoreaction of a variety of bisazides. It is clear that N_2 is split off and nitrene formed as a highly reactive intermediate, but it is not at all clear whether absorption of a single photon results in the cleavage of one or both of the azido groups. Reiser *et al.* (6, 7) have analyzed the photoreactions of a number of bisazides in frozen matrixes at 70°K, and reported quantum yields for 2 separate steps in the formation of the bisnitrene (stable only in the frozen matrix). One very notable exception in this investigation is the listing of the compound p,p'-diazidobenzophenone at the end of the table of the quantum yields with the single entry $\Phi = 1.00$ and no indication as to whether this refers to the quantum yields of 2 discrete steps or to the simultaneous cleavage of both azido groups by absorption of a single photon. Trozollo *et al.* (8) have reported on the ESR spectra of some bisnitrenes in frozen matrixes, and suggested in the text that these may be formed by simultaneous single photon cleavage in some cases.

In an attempt to settle the distinction between simultaneous, monophotonic cleavage and stepwise two-photon cleavage, we examined the details of light sensitivities reported by Clecak *et al.* (4). Although these workers write an explicit biphotonic equation, their system sensitivity suggests simultaneous cleavage. Thus, the absorption of some 5.0×10^{14} photons/cm^2 suffices to insolubilize over 90% of a film of polymer containing 8.7×10^{14} molecules/cm^2. One could appeal to thermal reactions to make up the difference to at least one reacted azido group per bisnitrene molecule, but such extensive thermal reaction would imply instability on storage, which is not observed.



[1] Present address: Mitsubishi Chemical Industries, Research Laboratory, Midori-ku, Yokohama, Japan.

Key words: cross-linking, energy transfer, infrared spectrometry.



[2] Since the bisazide systems form cross-links and become resistant to solution in exposed areas, they are described as "negative photoresists" by analogy to a photographic negative.

We observed the photoreaction of bisazide (II), monitoring azido group absorption at room temperature in the polyisoprene matrix by infrared spectrometry. This observation was made directly on the actual photoresist composition as coated on high resistivity Si wafers, which allowed us to take advantage of the infrared transparency of pure Si. Photoreaction of quinone diazide (III) which makes a positive[3] photoresist system was also observed by infrared spectroscopy to illustrate the difference of the photoreaction mechanisms between these positive and negative photoresists. In particular, the quinone diazide is a monofunctional reagent, in contrast to the bisazide crosslinking agent. It forms no quenchers in the course of photoreaction, and thus gives uncomplicated kinetic behavior.

(III)

Results and Discussion

Photoreaction characteristic of positive and negative resists.—Figures 1 and 2 show the plot of logarithms of infrared absorbance *vs.* photodosing time at constant intensity. In the case of the positive photoresist (Fig. 1), the logarithmic plot is linear, indicating that the photoreaction is a simple first-order reaction in terms of unreacted quinone diazide (9, 15).[4] No quenching by reaction products is observed, nor was any expected.

In the case of the bisazide photoresist (Fig. 2), the decrease of azide absorbance shows a sharp retardation as the photoreaction proceeds. The reaction curve is more complicated than a simple second-order reaction. We first tried to explain this phenomena by a sequential two-photon process, as proposed by Reiser *et al.* (6). As will be seen, this proved to be impossible to do.

Simulation of photoreaction of bisazide by a sequential two-photon process.—If the bisnitrene is formed through a sequential two-photon process, the decrease of bisazide and increase of intermediate azidoamine can be expressed in Eq. [1] and Eq. [2]. Also, their concentrations (A and B) can be expressed by Eq. [3] and Eq. [4], where K_1 and K_2 are the first-order reaction rate constants for the first and second step, respectively, and are given by products of quantum yields and rates of absorption of photons.

[3] In this system, exposure forms solubilizing groups, so the polymer is removed in exposed areas. Such a system is described as a "positive photoresist".

[4] First-order kinetics are observed when a reaction proceeds at constant quantum yield in an optically dilute sample.

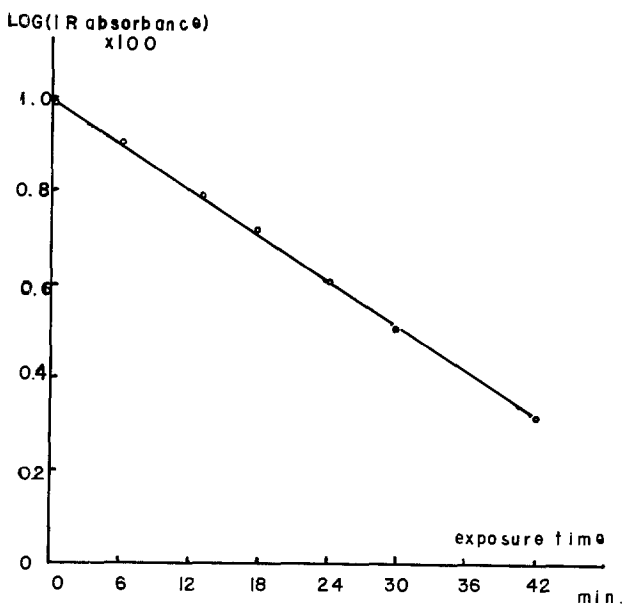

Fig. 1. Disappearance of diazo absorption of positive photoresist (quinone diazide-novolac). Dosing condition, 365 nm, 6.1 mJ/cm² min; photoresist coating, 0.96 μm on Si.

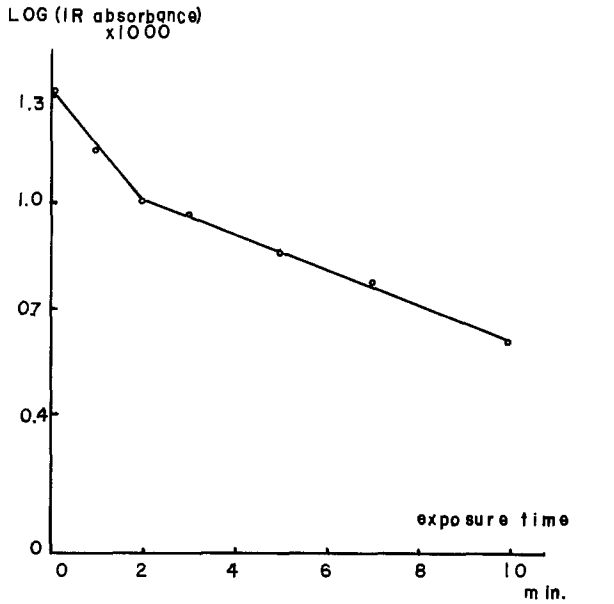

Fig. 2. Disappearance of azido absorption of negative photoresist (bisazide-polyisoprene). Dosing condition, 365 nm, 5.8 mJ/cm² min; photoresist 3 w/o bisazide based on polymer, 1.2 μm coating on Si.

Sequential two-photon mechanism

bisazide (A) $\xrightarrow{h\nu \downarrow K_1}$ $\frac{dA}{dt} = -K_1A$ [1]

azido amine (B) $\xrightarrow{h\nu \downarrow K_2}$ $\frac{dB}{dt} = K_1A - K_2B$ [2]

bisamine $A = e^{-K_1t}$ [3]

$$B = \frac{K_1}{K_2 - K_1}(e^{-K_1t} - e^{-K_2t}) \quad [4]$$

By assuming that the infrared azido absorption coefficient of azidoamine is half of that of bisazide, we can plot the expected azido absorbance ($2A + B$) *vs.* photodosing time at different K_2 values. The dotted line in Fig. 3 shows the experimental data from a 3% wt. bisazide (II) photoresist coated on NaCl. Other solid lines represent simulated data from Eq. [3] and Eq. [4] in which K_1 was determined to be 0.48 min^{-1} from the observed decrease during the first 1 min, and from the assumption that the initial reaction rate involves only cleavage of a single azido group. Figure 4 shows the simulated concentration of the intermediate azidoamine under the same conditions as Fig. 3.

We had searched carefully with a high resolution infrared spectrometer (PE 521) for the expected shift of the infrared band shape and position upon formation of increasing monoazide, and observed none (Fig. 5). The experimental conditions for Fig. 5 are completely the same as Fig. 3.

Extraction of azide from photoresist films.—When it became clear that the observations could not be fitted to a sequential two-photon mechanism, we made a careful analysis of the reaction products in photoresist films. Several mixtures of methanol and benzene were tested to find the conditions for extracting only starting bisazide and low molecular weight reaction products from the photoresist film without removing appreciable

polymer. After extracting the photoresist for 3 min, we analyzed the remaining azide and polyisoprene by the infrared N_3 band and CH band absorbances, respectively. As shown in Fig. 6, an equal volume mixture of methanol and benzene will extract only low molecular weight materials from the polymer layer. All of the uncross-linked polyisoprene is found to dissolve in benzene, so pure benzene can be used for "development" of the exposed photoresist.

We performed extractions from photoresists coated on silicon wafers after different exposure times. The azide remaining in the film was observed by infrared spectrometry. The extracts were separated by TLC (E. Merck, Silica Gel 60 F-254, $CHCl_3$ solvent) and starting bisazide ($R_f = 0.6$) and other colored products ($R_f = 0.0$-0.2) were detected. The R_f (0.6) and u.v. spectrum of the principal extracted material matched the unreacted bisazide (II).

The low mobility colored products were difficult to characterize. They are proved not to be azidoamine (azidonitrene-polyisoprene adducts), but rather by-products of nitrene-bisazide coupling side-reaction from the following observations:

1. The TLC spots of these products can be moved to the solvent front ($R_f = 1.0$) by using polar solvents ($MeOH/CHCl_3 = 5/2$), while cyclized polyisoprene (not cross-linked) does not move at all ($R_f = 0.0$).

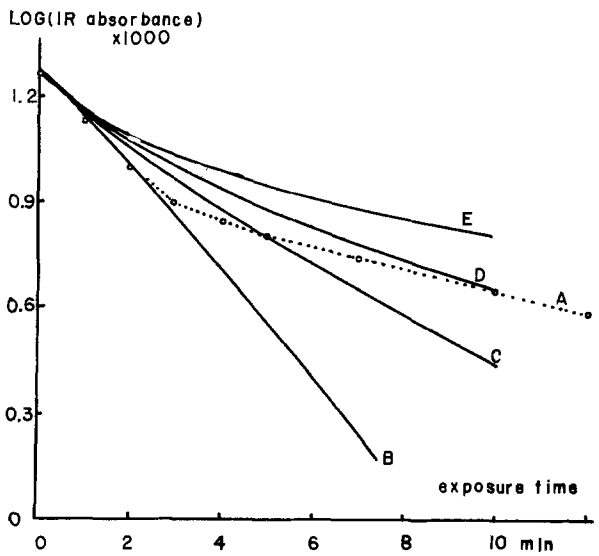

Fig. 3. Simulation of total azido absorbance by sequential two-photon process. Dosing condition, 365 nm, 5.8 mJ/cm² min. A, observed from 3% bisazide photoresist, coated 1.2 μm thick on NaCl; B, simulated from $K_1 = 0.48$ min^{-1}; $K_2 = 0.48$ min^{-1}; C, simulated from $K_1 = 0.48$ min^{-1}, $K_2 = 0.16$ min^{-1}; D, simulated from $K_1 = 0.48$ min^{-1}, $K_2 = 0.096$ min^{-1}; E, simulated from $K_1 = 0.48$ min^{-1}, $K_2 = 0.048$ min^{-1}. K_1 is fixed by observation.

A, bisazide simulated from $K_1 = 0.48$ min^{-1}; B, azidoamine simulated from $K_1 = 0.48$ min^{-1}, $K_2 = 0.48$ min^{-1}; C, azidoamine simulated from $K_1 = 0.48$ min^{-1}, $K_2 = 0.16$ min^{-1}; D, azidoamine simulated from $K_1 = 0.48$ min^{-1}, $K_2 = 0.096$ min^{-1}; E, azidoamine simulated from $K_1 = 0.48$ min^{-1}, $K_2 = 0.048$ min^{-1}. K_1 is fixed by observation.

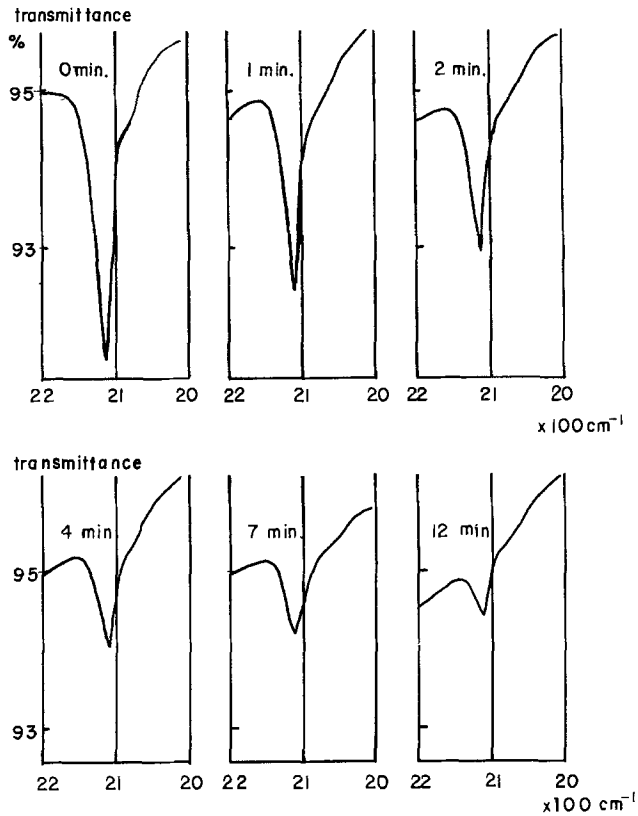

Fig. 5. Infrared spectra (expansion times 10) of photoresist at different photodosing times. Dosing condition, 365 nm, 5.8 mJ/cm² min; photoresist, 3% bisazide, 1.2 μm coating on NaCl.

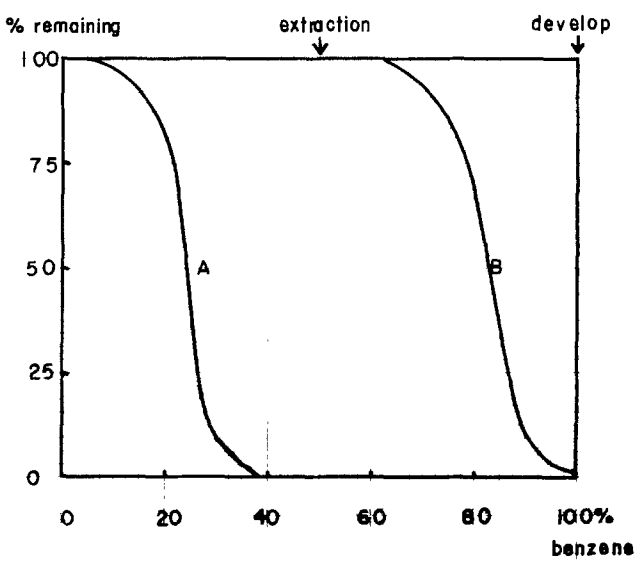

Fig. 6. Extractability of unexposed bisazide and cyclized polyisoprene by methanol-benzene acting for 3 min on a 1.2 μm film containing 3% bisazide. A, bisazide; B, cyclized polyisoprene.

2. The shape, frequency, and especially the relative strength of infrared CH-stretching absorptions are very different from those of cyclized polyisoprene. The ratio of total CH to N_3 absorptions is very low.

3. The low mobility colored spots increased with photodosing time, and never decreased, precluding monoazide intermediates.

4. The infrared spectrum of the mixture of colored products extracted from the low mobility TLC spots by methanol/benzene (1/1) showed a weak azido absorption.

The bisazide spots ($R_f = 0.6$, $CHCl_3$) were scraped from the TLC plate, extracted again by methanol/benzene (1/1), and analyzed by u.v. spectrometer. The results of the extractions are summarized in Table I. In every case almost all the azido compound can be extracted from the polymer layer, as shown by the disappearance of the infrared azido absorption after extraction.

Discussion on the simultaneous single photon mechanism and the sequential two-photon mechanism.— Azidonitrene, which is supposed to be the intermediate product of the two-photon mechanism, is expected to react almost instantaneously with polyisoprene to form polymer adducts (azidoamine) which cannot then be extracted by polar solvent (methanol/benzene = 1/1). These adducts should show an infrared azido absorption, which we have not observed. We can compare the absence of observed azido absorption after extraction with the calculated minimum absorption required to support a sequential two-photon mechanism. The relation between any first-order photochemical reaction rate constant K (min^{-1}) and quantum yield (Φ) and fraction of incident light absorbed (A) can be expressed as follows

$$K = \frac{\Phi \times \text{photon flux for 1 min} \times A}{\text{starting bisazide molecular concentration}}$$

The parameters for a hypothetical biphotonic decomposition (Φ, A) can be approximated from observed infrared and u.v. data which are summarized in Table II.

Φ_1, which is the quantum yield of the hypothetical first process, can be calculated by assuming equal infrared absorbance for all azido groups. Table II shows an infrared absorbance decrease from 0.0179 to 0.0136 for the first 1 min, which would have to mean that 2.46×10^{15} bisazide molecules/cm^2 were decomposed to monoazide. U.V. absorbance shows that the average absorbance is 0.306 at 365 nm for the first 1 min, so the fraction of light absorbed (A_1) is 50.6%, which means that 5.3×10^{15} photons/cm^2 were absorbed in the first 1 min. Therefore the quantum yield (Φ_1) can be calculated at 46.4% in this particular 3% film.

The fraction of light absorbed by half-reacted bisazide existing as monoazide-monoamine (A_2) can be calculated by taking the mean of initial and final u.v. absorption coefficient of bisazide upon exposure. Table II shows that the absorbance of photoresist at 365 nm decreased to 54% of the initial value when almost all the azido groups are decomposed after a massive 50 min dosing. By taking the mean of 100% and 54%, the average absorbance of the photoresist film can be estimated as $0.306 \times 0.77 = 0.236$, which would mean that A_2 is 41.8%.

When the quantum yield of the hypothetical second step (Φ_2) is assumed to be high, smaller amounts of azidonitrene adducts are to be expected in the photoresist after extraction. In the limiting case with $\Phi_2 = 100\%$, K_2 can be estimated as follows

$$K_2 \approx \frac{1.00(\Phi_2) \times 0.418\,(A_2) \times 0.48\,(K_1)}{0.464\,(\Phi_1) \times 0.506\,(A_1)} = 0.85\ \text{min}^{-1}$$

Figure 7 shows the minimum azido absorbance required to agree with a two-photon mechanism in which the infrared absorption coefficient of azidoamine is half that of bisazide. This is a conservative approximation because it has been reported that the infrared absorption coefficient of the azido group increases when conjugated electron-accepting groups are replaced by electron-donating groups, as would be the case if one azido group were converted to a secondary or tertiary amine (10). An azidonitrene would react with polymer to form azidoamine, which can thus be expected to increase the absorption coefficient per azido group.

Figure 8 shows the infrared azido band before and after extraction. The minimum amount of absorbance allowable for a sequential two-photon process is shown aside. The observed absorbance in the polymer after

A, calculated minimum absorbance for sequential two-photon process, $\Phi_2 = 100\%$; I, observed data of photoresist, 3% bisazide based on polymer, 1.2 μm coating on Si, methanol-benzene (1/1) extraction for 3 min.

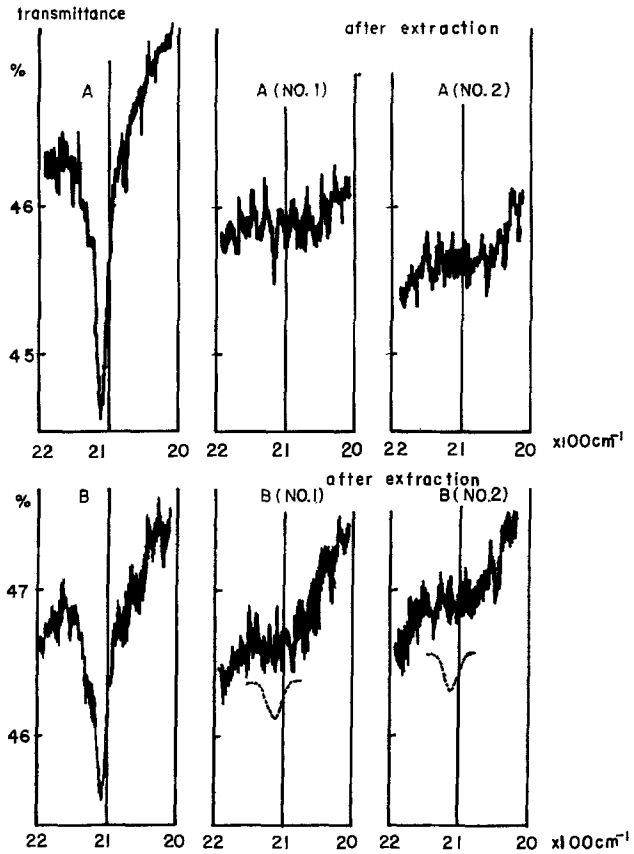

Fig. 8. Infrared spectra (times 20 expansion) of photoresist before and after extraction. A, no exposure, 3% bisazide, 1.2 μm coating on Si; B, partial exposure (remaining azido absorbance is 66%), 3% bisazide, 1.2 μm coating on Si, no. 1 and 2 refer to repeated observations. Note that much of the fine structure (as seen especially clearly in spectrum A-1), is the interference pattern imposed by the high refractive index of the Si wafer (n = 3.4). Fortunately, the azide absorption band is considerably broader than the repeat period of this pattern.

extraction is considerably less than the calculated absorbance.

Thus the two-photon mechanism is inadequate to explain the results and products above mentioned; instead, the simultaneous one-photon mechanism seems much more reasonable. The small amount of azido absorption detected after extraction in Fig. 8 can be attributed in part to unextracted bisazide, because repeated extraction further lowers the intensity of the azido absorption in the polymer while the intensity of the CH absorption is unchanged. Perhaps the over-all cross-linking makes the extraction of bisazide more difficult. The increase in the retained azide with photodosing time (Fig. 7) is thus assigned to cross-linking and reduced swelling of the polymer in the methanol/benzene (1/1) extraction.

The one-photon mechanism also suggests that effective cross-linking occurs at the early stages of photodosing. By measuring the film thickness after development (dissolve in benzene for 3 min), we can estimate the extent of the cross-linking. The results, shown in Table III, give a satisfactory fit for a one-photon mechanism.

Energy transfer.—If we accept a simple one-photon mechanism, the reduced photodecomposition rate of bisazide after *ca.* 50% of photoreaction is still to be explained. We made several coatings with different azide concentration, and observed their azido absorbance decrease upon photodosing. The results are shown in Fig. 9. The decrease of rate with increasing concentration suggests some inhibition of the primary photoreaction by its products. At highest concentration (7% bisazide based on polymer), quenching is observed from the

earliest stages and reaction is completely quenched after about 50% of completion. On the other hand, low concentration photoresist layers (1% bisazide based on polymer) show higher initial rate and only slight quenching.

Figure 10 shows the u.v. absorption of negative photoresist before exposure, after complete photodosing, and after development. During photo exposure, a new long-wavelength absorption around 410 nm appears

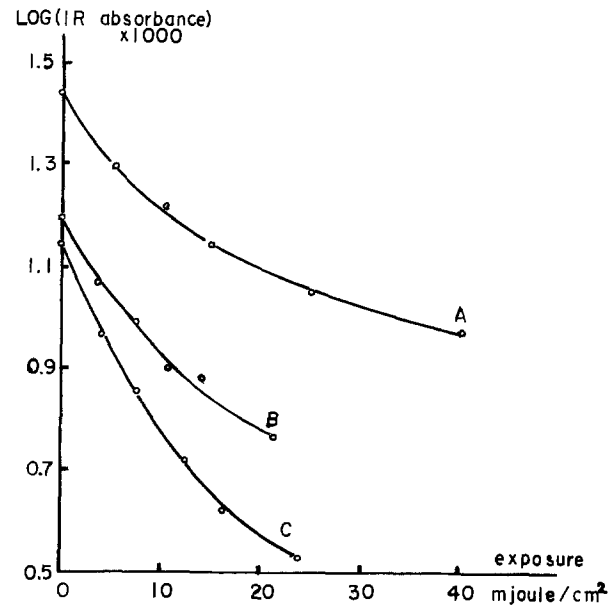

Fig. 9. Rate of disappearance of azido absorbance. Dosing, 365 nm, photoresist A, 7% bisazide, 0.8 μm coating on Si; photoresist B, 3% bisazide, 1.0 μm coating on Si; photoresist C, 1% bisazide, 2.3 μm coating on Si.

and remains fixed in the cross-linked polymer after development. We assign this absorption to reacted bisnitrene, presumably bisamine,[5] which forms the actual cross-links. The absorption decrease (curves B and C in Fig. 10) around 350 nm is due to extractable low molecular weight by-products which have been discussed (the low mobility spots).

For the moment we can only note that both of the absorption spectra (bisamine and byproducts) lie at longer wavelength than the spectrum of the starting material. Thus, direct singlet-singlet intermolecular energy transfer can occur. Further, this is a very concentrated system, and the potential donors and acceptors are nearly in contact. Triplet-triplet transfer may also occur (11), but we have no indication supporting or disproving it. The bisamine appears to be inert to direct photoreaction and to reaction by energy transfer. Thus the retardation of decomposition in this system is explicable in terms of energy transfer to the reaction product.

The u.v. absorption of the positive photoresist shows no long-wavelength absorption in the course of photodosing. The absorbance of every peak decreases according to simple first-order reaction kinetics and no quenching is observed (15). The contrast between the complicated concentration dependence shown by the bisazide system and the single first-order dependence of the quinone diazide system can be examined to emphasize the importance of energy transfer in the bisazide system.

The highest quantum yield of bisazide decomposition observed was 43% (one-photon process). The conditions were as follows: bisazide concentration, 0.56% based on polymer; film coating, 3.5 μm on NaCl; photon flux, 8.22×10^{15} photon/cm^2 min; fraction of light absorbed, 29.7%; decomposed bisazide after 1 min dosing, 1.06×10^{15} molecule/cm^2. An even higher quantum yield is to be expected from shorter exposure times and lower azide concentrations, but these conditions lie beyond the accuracy of the infrared observations.

Experimental

The negative-type photoresist was made by dissolving bis(4-azidobenzal)-cyclohexanone(II) and cyclized polyisoprene in Kodak KTFR Thinner.[6] Cyclized polyisoprene was prepared by refluxing a solution of toluene, cis-1,4-polyisoprene (MW 110,000-150,000, Goodyear NATSYN-200) and p-toluenesulfonic acid for 6 hr (12). Cyclicity (1.7-2.3) and uncyclized isoprene unit (4-6%) were characterized by NMR (Varian T-60). Cyclized rubber was dissolved to 10-15 weight percent (w/o) in KTFR Thinner, and bisazide(II) was added 1-7 w/o based on polymer.

The positive-type photopolymer was prepared by condensing pheno-formaldehyde polymer (Union Carbide, NOVOLAC BRN-5834) with 50 w/o of o-naphthoquinone diazide sulfonyl chloride (III) in the presence of sodium carbonate (13). About 20% of the hydroxyl groups were substituted by the quinone diazide sulfonyl group. The photoresist was made by dissolving this photopolymer to 25 w/o in Shipley AZ-1350 Thinner.[7]

The photoresist films were spincoated on silicon wafers and prebaked at 80°C for 20 min in an oven before use. The film thickness was calculated from the interference pattern obtained by measurement of specular reflectance, using the Model 1413 reflectance attachment of a Cary 14 spectrophotometer.

A medium pressure mercury lamp (100W, GE 100A4/T) was used as the u.v. light source. Specific wavelengths were selected using interference filters (365 nm, 405 nm). During photodosing, light intensity was monitored with an EMI S-10 photomultiplier, which was calibrated by a potassium ferrioxalate actinometer (14). Nitrogen gas was flushed through the photoreaction box during photodosing.

The reactions of bisazide and quinone diazide were monitored by observing the infrared absorption of the azido (2110 cm^{-1}) and diazo (2120 cm^{-1}) group using the scale expansion attachment of the Perkin Elmer 521 spectrophotometer (Fig. 11).

P-doped silicon wafers with a high infrared transmittancy of 45-55% at 2100 cm^{-1}, resistance of 300Ω cm^{-1}, diam of 2 in., thickness of 0.27 mm were obtained from Monsanto Chemical Company, and they were used without further heating. A silver bromide window (blue and u.v. absorbing) was placed in front of the photoresist to protect the bisazide and quinone diazide from any actinic light emitted by the infrared light source. When both infrared and u.v. information was needed, the photoresist layers were coated on sodium chloride plates instead of the silicon wafers.

Conclusions

From the infrared study of azido absorption of photoresist upon exposure, and from the analysis of low molecular weight compounds extracted from exposed photoresists, we obtained the following conclusions:

1. The cleavage of both azido groups of the starting bisazide is brought about by absorption of a single photon. This is established by the following observations: (*i*) Azidoamine, which is considered to be the intermediate of the two-photon process, is not observed in partially exposed photoresists; and (*ii*) bisazide is the principal azido compound still existing after any amount of photodosing.

2. The photodecomposition rate of bisazide is reduced as cross-linking proceeds. This is probably due to energy transfer from unreacted bisazide to reacted bisazide (bisamine cross-link and/or byproducts).

On the Use of X-Ray Screens in Mammography

A. L. N. Stevels

and F. Pingault

Massiot-Philips, 80690 Ailly-Le-Haut-Clocher, France

ABSTRACT

Measurements on $CaWO_4$ screen/film combinations show that in mammography significant speed gains compared with the no-screen film technique can be realized. However, the resolution of such high speed systems is poor. Calculations on recently developed powder phosphors like $BaFCl:Eu^{2+}$, $LaOBr:Tb^{3+}$, $Y_2O_2S:Tb^{3+}$, and $Gd_2O_2S:Tb^{3+}$ show that there are prospects of even faster mammography screens, but the resolution obtained with thinner layers of such new phosphors is expected to be only marginally better. Measurements of the sharpness of imaging phantoms indicate that indeed the resolution is hardly improved by employing new phosphors. The speed gains with respect to $CaWO_4$ are about a factor 2 lower than the calculated ones. New screen technologies have to be found to eliminate the resolution bottleneck. It is found that vapor-deposited CsI:Na and CsI:Tl layers would be very promising candidates for use in mammography. However, hygroscopy is at present a serious obstacle to their application, especially in the CsI:Na case.

The use of x-ray intensifying screens in film radiography is always in the nature of a compromise. On the one hand the speed of the system is increased, so that x-ray exposure can be reduced. On the other hand the quality of the image obtained is reduced by insertion of such an intensification device in the x-ray system.

The choice of an optimum trade-off between speed and image quality depends in the first instance on the type of radiological examination involved. From a technical point of view, not only do all these trade-off points have to be covered by the availability of the corresponding screen-film systems, but also a continuous effort is needed to extend the limits of the system.

As far as the last aspect is concerned, encouraging progress has been made in the last decade. Basically these improvements originate from the availability of new x-ray phosphors (1) which have the potential to replace traditional phosphors like $CaWO_4$ in certain radiological techniques. CsI:Na, CsI:Tl have largely replaced (Zn,Cd)S:Ag in the input screens of image intensifier tubes. For some of the new phosphors (CsI:Na, CsI:Tl) new screenmaking technologies can be applied. Vapor-deposited layers of these materials give rise to less image blurring than comparable ones prepared by the usual powder sedimentation techniques (1-4).

Meanwhile, mainly theoretically (1, 5, 6) and mainly practically oriented (2-4, 7-11) studies have been devoted to the use of new phosphors in x-ray intensifying screens. Almost all of them pertain to the "normal" radiological range, that is to x-rays with energies between 30 and 100 keV.

The present paper pays attention to the use of screens in mammography. Usually in these examinations x-ray films with high silver content are directly exposed to "soft" x-rays with energies between 6 and 30 keV. The main purposes of employing intensifying screens are x-ray dose reduction and economizing on the use of silver in the x-ray film.

First, we compare the properties of $CaWO_4$ screen-film combinations with those of "no-screen" films. After that we calculate what improvements can be

expected from the use of new phosphors and discuss some practical realizations. The results obtained here for soft x-rays are compared with those for the harder x-rays of the 30-100 keV range.

Experimental

The x-ray source used in this investigation was a Rotalix type with W-anode operated at 30 kV. The focus was 0.3 × 0.3 mm², the focus-film distance 1m. No radiation filter was used.

When a double-coated x-ray film is employed, the screen/film combination consists of a front and a back screen with the film in between. With a single-coated film, the screen is placed (with respect to the x-ray source) at the back.

The screens investigated were prepared at our own laboratories or commercially obtained from various sources. For their characterization we use plots of relative speed against resolution. The relative speed is defined as the exposure needed to obtain unit film density above the fog, the mammography no-screen film Kodak PE 4006 being the standard of comparison. All films used in this investigation were processed for 90 sec. The resolution of the system is characterized by the frequency in line pairs per centimeter at which the amplitude of the square wave response of a test grid, consisting of lead strips at varying distances apart, had dropped to 30% of its value at zero frequency. Again the PE 4006 film was used as a standard.

Some Properties of $CaWO_4$ Screen-Film Combinations

In Fig. 1 we have plotted relative speed against resolution for $CaWO_4$ screen/film combinations. The upper curve refers to screens used in combination with double-coated film, type Agfa-Geveart RP3, the lower curve to combinations with a single-coated film, type du Pont "Lo-dose." The points labeled by the subscript 1 represent a standard $CaWO_4$ screen, the Philips Universal type. It is seen that under mammography

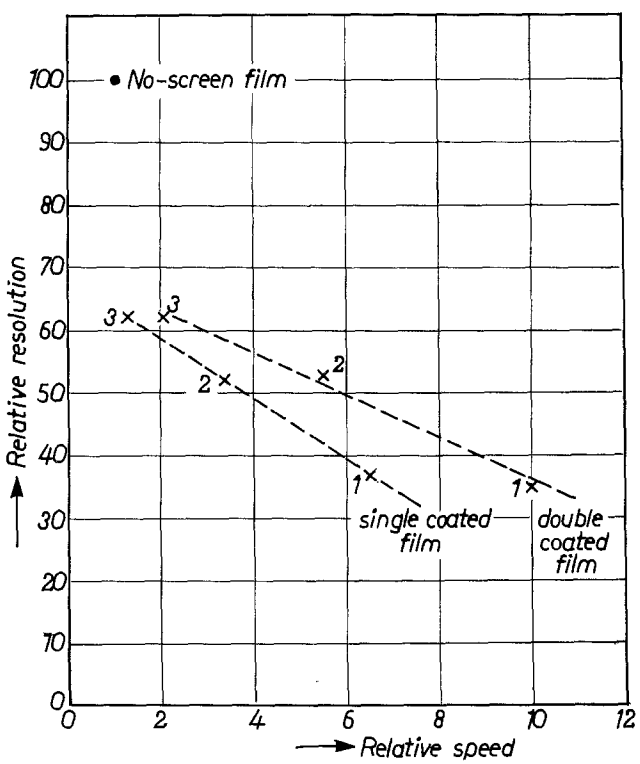

Fig. 1. Relative resolution against relative speed for various screen/film combinations. The no-screen film has a speed equal to unity and a resolution equal to 100. The x-ray source (W-anode) was operated at 30 kV. 1 = $CaWO_4$ standard screen, 2 = $CaWO_4$ high resolution screen, 3 = $CaWO_4$ very high resolution screen (see text also).

conditions its speed is 6.5 (single-coated film) or 10 times (double-coated film) higher than a no-screen film system. The resolution, however, has dropped to about 35% of that of the last-named system. In the literature (12-15) such a deterioration of image quality is stated to be completely unacceptable in mammography. Hence we conclude that with $CaWO_4$ screens maximal speed gains can be achieved which, while preserving a resolution acceptable for mammography, are definitely lower than 6.5× for single-coated film systems and 10× for double-coated film systems.

When a Philips "Micro" screen (points indicated by 2) is used instead of a Universal one the speed is reduced by a factor of about 2, whereas the resolution gain is only a factor of 1.5. It should be noted here that the thickness of the phosphor layer and its packing density are equal to that of a Universal one (≈120 μm and ≈55%). The different properties of the Micro screen have been achieved by adding to the binder some paint which absorbs laterally spread light more than directly escaping light. This method to increase the resolution is more attractive than making the phosphor layer thinner, because in the last-named case the intrinsic x-ray quantum noise of the system increases.

Returning now to Fig. 1, we conclude that also a further reduction of the speed of the system does not result in a compensating increase in resolution: the very high resolution MCD screen (laboratory-made, more heavily colored than Micro), labeled by 3, shows a speed reduction of about 2.5× with respect to the Micro screen, whereas the gain in resolution is only some 20%. Figure 1 suggests that for both types of film there is a limit in resolution of about 65% compared to no-screen film. There are several reasons for this "resolution gap":

1. To a limited extent this gap is due to the fact that the RP3 and the "Lo-dose" films used in combination with the screens contain less silver than the no-screen PE 4006 one. The resolution of the three films is found to be essentially identical. This implies that in Fig. 1 the reference point might shift a bit to the left. In connection with this we note that the speed and the resolution of PE 4006/screen combinations are found to be about equal to those of the RP3/screen combination. Apparently the screen is the limiting factor of the system. This conclusion is also supported by the observation (see Fig. 1) that systems with double-coated films have a speed which is approximately 1.5× that of the ones with single-coated films, whereas the resolution is about equal.

2. A large contribution to the resolution gap is due to geometrical reasons. If, for instance, measurements are made on screens without a plastic protective layer in between the phosphor and the film, the resolution figures are about a factor of 1.2 higher than those given in Fig. 1. If the focus-film distance is increased the resolution gain is small, however.

3. The above-mentioned factors do not bridge the resolution gap indicated in Fig. 1. It is obvious to think that the remaining part is due to the very fact that the $CaWO_4$ phosphor considered is used in the form of a light scattering powder.

On basis of the foregoing section we now formulate several conclusions regarding the use of x-ray screens in mammography:

1. Whatever speed increases can be realized, a resolution drop has to be accepted. Among other things this drop is due to geometrical factors, such as the presence of a protective layer between phosphor and film and the fact that the focus-film distance is not infinite.

2. The use of light scattering powder phosphors gives rise to an additional resolution drop. This makes the image quality marginal in cases where substan-

tial speed gains can be achieved. The impact of laterally scattered light of powder phosphors might be reduced by decreasing the mean grain size of the phosphor and by making the phosphor layer thinner. Regarding the first suggestion we note that in the $CaWO_4$ screens discussed the mean grain size is already low (2.3 μm). Further reduction would entail serious technological problems as well as substantial losses in light output. Thinner phosphor layers would give rise to less x-ray absorption in the screens and hence to increased quantum mottle ("noise") on the film.

3. Screen/single-coated film combinations are disadvantageous from a speed point of view. At present there are no indications that such systems would give a substantially better resolution than those with double-coated films.

4. The use of new powder phosphors instead of $CaWO_4$ gives additional degrees of freedom regarding the realization of screens. Whether this only implies increases of speed or whether it also reduces the resolution drop is a question to be studied. For instance, if a phosphor has higher x-ray absorption per unit length than $CaWO_4$ the phosphor layer thickness can be diminished without increasing the quantum noise above the $CaWO_4$ level.

Calculated Properties of New Phosphors in the Mammography (6-30 keV) Energy Range

A few years ago we studied extensively the properties of new x-ray phosphors in the 30-100 keV energy range (1). We now extend the calculations made in Ref. (1) to the 6-30 keV "mammography" energy range. In order to link up as closely as possible to practical conditions we give data for 100 μm thick powder phosphors screens in contact with u.v./blue sensitive "standard" film or with green sensitive film. We consider 100 μm thick vapor-deposited screens only for CsI:Na (or Tl).

We now discuss the following new materials: $Gd_2O_2S:Tb^{3+}$, CsI:Na (or Tl), $LaOBr:Tb^{3+}$, $Y_2O_2S:Tb^{3+}$, $BaFCl:Eu^{2+}$, and (Zn,Cd)S:Ag. Brief particulars of these phosphors and references to original literature are given in Ref. (1). For $BaFCl:Eu^{2+}$ see also Ref. (8).

The inclusion of $LaOBr:Tb^{3+}$ deserves some special comment. Some two years ago it seemed that this phosphor was not practical because of its hygroscopy and afterglow properties. However, these obstacles to its application now seem to have been eliminated. It should further be noted that the $Gd_2O_2S:Tb^{3+}$, CsI:Tl, and (Zn,Cd)S:Ag phosphors cannot be used in combination with standard x-ray film; green-sensitive films have to be employed instead.

In Fig. 2 we present data on the calculated relative x-ray absorption of the new phosphors, taking a 100 μm thick $CaWO_4$ powder layer as a reference.[1]

Data from tables published by Storm and Israel (16) were used. For the 100 μm powder layers a packing density of 50% was assumed, for the CsI evaporated layers the density was taken to be 100%.

It is seen in Fig. 2 that in the complete 6-30 keV range the x-ray absorption of all the new phosphors considered does not much exceed that of $CaWO_4$. In the case of some well-known candidates for application in standard intensifying screen like $BaFCl:Eu^{2+}$ and $Y_2O_2S:Tb^{3+}$ the absorption in the main part of the mammography range is even substantially lower than that of $CaWO_4$. It is also noted that CsI evaporated layers, which show a superior x-ray absorption in the 40-100 keV range due to their high packing density, need this high density here to have a performance comparable to that of the tungstate.

The fact that, at equal screen thicknesses, the x-ray absorption of the new phosphors is not better than

[1] For reasons of simplicity we have smoothed the curves between 10.2 and 12.1 keV. They would otherwise show small jumps due to L transitions in W at 10.2, 11.5, and 12.1 keV.

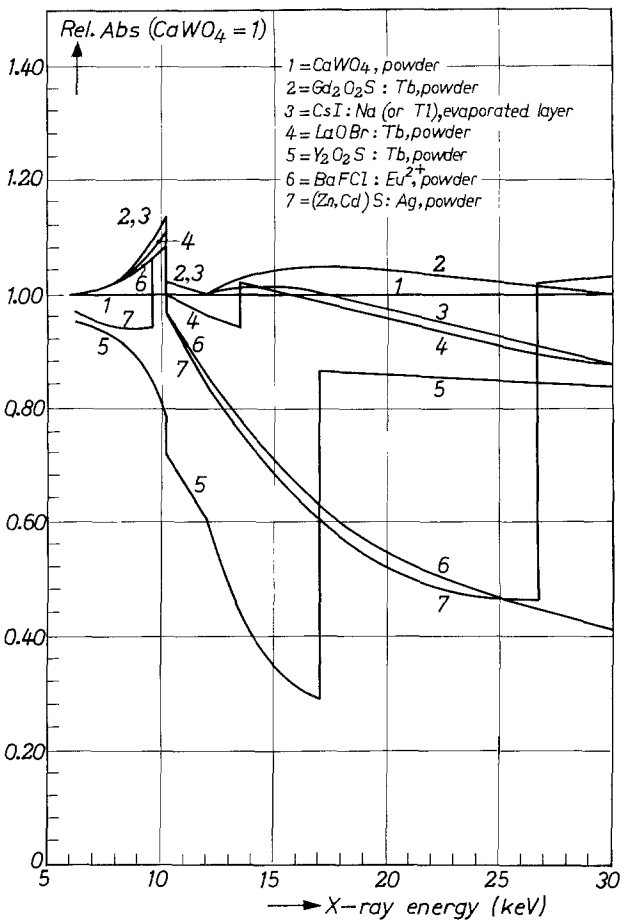

Fig. 2. Calculated relative x-ray absorption ($CaWO_4$ = 1) of various phosphors in the 6-30 keV range. The curves between 10.2 and 12.1 keV have been smoothed (see text).

that of $CaWO_4$ make us conclude that it is probably not possible to improve the resolution of mammography powder screens by decreasing their thickness. The main reason behind this is that the absorption-related [see Ref. (1)] noise properties of the new phosphors are not better and in some cases even inferior to those of $CaWO_4$. At present, the only candidates for mammography screens with improved resolution seem to be those phosphors for which screen technology can be changed, as for instance CsI:Na or CsI:Tl. However, as will be discussed in more detail below, these phosphors have the serious drawback of being hygroscopic, especially in the CsI:Na case.

The speed gains to be expected are shown in Fig. 3, where the relative quantum detection efficiency *QDE* is plotted against x-ray energy. As in Ref. (1) and (6) *QDE* is defined as

$$QDE_E = A_E \cdot \eta \cdot \lambda_{Em} \cdot C_E \cdot D_\lambda$$

where A_E is the x-ray absorption of the screen (as a percentage), η is the luminescence radiant efficiency under cathode-ray excitation of the phosphor[2] (as a percentage), λ_{Em} is the mean wavelength of the detected emission, C_E is a factor representing the energy losses in the screen, and D_λ is the efficiency for detection of the screen luminescence, I_λ, by a detector with response R_λ. D_λ is defined as $\int I_\lambda R_\lambda d\lambda / \int I_\lambda d\lambda$. Details of the calculations are given in Ref. (1).

In Fig. 3, the *QDE* curves of CsI:Na with standard film and of CsI:Tl with green emitting film happen to coincide within 5%. We have drawn data for these two combinations as one curve. As in Fig. 1, the curves have been smoothed between 10.2 and 12.1 keV.

[2] In contrast to efficiencies under x-ray excitation, these are fairly accurately known.

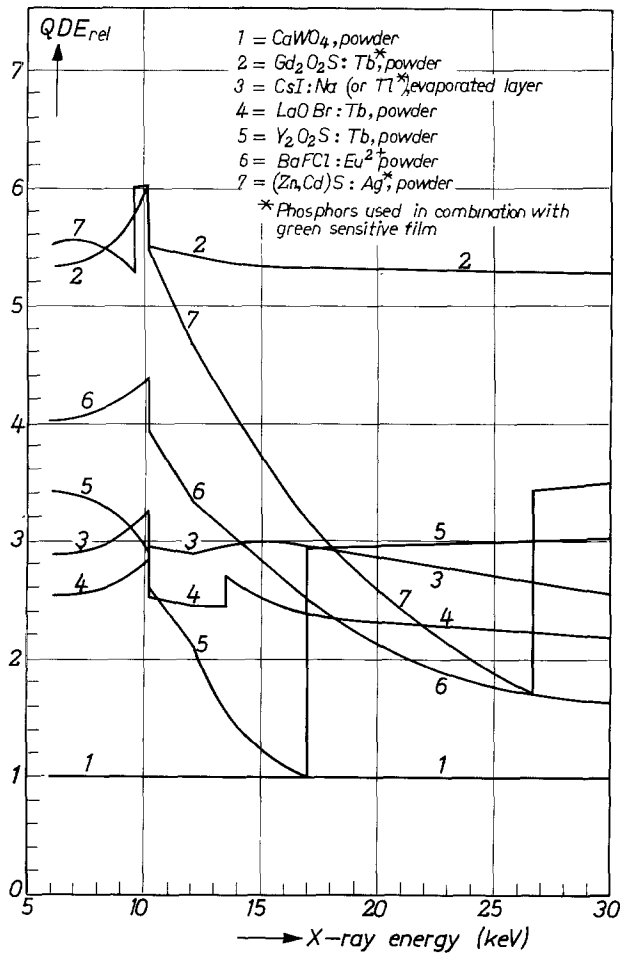

Fig. 3. Calculated relative quantum detection efficiency ($CaWO_4$ = 1) of various phosphors in the 6-30 keV range. The curves between 10.2 and 12.1 keV have been smoothed (see text).

It is concluded from Fig. 3 that the highest *QDE* figures are found at low x-ray energies. In this region the differences in x-ray absorption are small (see Fig. 2) so that the suggested gains almost completely originate from differences in luminescence conversion efficiency and in the match between the spectral distribution of the generated light and spectral sensitivity of the film. Green-emitting phosphors perform especially well in this region, the main reason being that these materials yield more quanta per percent energy efficiency than blue-emitting materials.

The drop in *QDE* above 10 keV is due to the absorption properties of the phosphors. In the most important region for mammography, 15-20 keV (17), the *QDE* lies between 1 and 3 for blue emitting phosphors and between 2.5 and 5.5 for materials to be used in combination with green-sensitive film. In the blue, evaporated layers of CsI:Na are considered to be the best proposal, followed by BaFCl:Eu^{2+} and LaOBr:Tb^{3+} powders. Y_2O_2S:Tb^{3+} performs well above 17 keV but not below that energy. The best phosphor in the green seems to be Gd_2O_2S:Tb^{3+} powder, whereas the promising candidate from a resolution point of view, (see introduction) seems to be CsI:Tl. However, these calculated speed gains with respect to $CaWO_4$ are not as impressive for mammography screens as for screens used at higher x-ray energies. Table I lists some QDE_{rel} data at 15 and 20 keV (100 μm thick screens) and at 60 keV [200 μm thick screen, see Ref. (1)]. It is seen that in most cases the ratio $QDE_{15\ keV}/QDE_{60\ keV}$ or $QDE_{20\ keV}/QDE_{60\ keV}$ is below 1. The more promising candidates even score ratios below 0.5.

Application of the New Phosphors; Measured Properties of Some New Mammography Screens

As concluded in the section on properties of $CaWO_4$ screen-film combinations, an inprovement of the resolution of mammography screens is more urgently needed than a further increase of speed. Therefore CsI:Na and CsI:Tl vapor-deposited screens seem to be the most obvious candidates to replace $CaWO_4$ screens. Impressive resolution gains have in fact been realized for CsI:Na screens used as input screens in an image intensifier tube (1, 3, 4). Good agreement between calculated and measured *QDE* has also been found (6). However, this material can only be used in vacuum devices like the image intensifier tube. Up to now no plastic covers have been found that protect CsI:Na screens sufficiently against moisture, which makes this material unattractive for mammography application.

CsI:Tl is much less hygroscopic than the Na-activated material. A drawback of such screens is, however, that a special green sensitized film should be used in combination with the screen to realize substantial speed gains. In many cases this requires adaptation of existing "dark room" lighting. The strong afterglow of CsI:Tl (1) observed for x-rays with energies of the usual radiological range, might also be a serious application disadvantage. We have found, however, that the soft x-rays used in mammography give rise to a negligible amount of afterglow.

It is concluded that vapor-deposited CsI:Tl layers are candidates for application in mammography screens. We hope to report more details on their properties in the near future.

Regarding powder phosphors, Fig. 4 shows some results of measurements on BaFCl:Eu^{2+} (Philips "Bfc") and LaOBr:Tb^{3+} (Agfa "MR") screens. These screens have thicknesses comparable to those of $CaWO_4$ Universal or Micro screens discussed above. Gd_2O_2S:Tb^{3+} screens, which have to be used with green sensitive films have not yet been considered by us. It is seen in Fig. 4 that, at equal resolution, the speed gains with respect to $CaWO_4$ are only marginal, namely about a factor of 1.2 or 1.3 for use in combination with double-coated film and 1.1 or 1.2 for use in combination with single-coated film. These gain factors are about half of the calculated ones. This result corroborates our conclusion (6) that the screen technology for these new powder phosphors still lags behind the well-established technology for $CaWO_4$.

Table I. Relative x-ray quantum efficiencies (*QDE*) of x-ray screen/film combinations

Screen phosphor	Film	*QDE* at x-ray energies of: (100 μm thick layers) 15 keV	(100 μm thick layers) 20 keV	(200 μm thick layer) 60 keV	ratio $\frac{QDE_{15\ keV}}{QDE_{60\ keV}}$	ratio $\frac{QDE_{20\ keV}}{QDE_{60\ keV}}$
$CaWO_4$	standard (u.v./blue sensitive)	1.0	1.0	1.0	1.00	1.00
Gd_2O_2S:Tb^{3+}	green sensitive	5.3	5.3	12.0	0.44	0.44
CsI:Na	standard	3.0	2.9	14.6	0.21	0.20
CsI:Tl	green	2.9	2.8	14.0	0.20	0.19
LaOBr:Tb^{3+}	standard	2.4	2.3	5.2	0.46	0.44
Y_2O_2S:Tb^{3+}	standard	1.2	3.0	3.5	0.34	0.86
BaFCl:Eu^{2+}	standard	2.8	2.1	5.2	0.54	0.40
(Zn,Cd)S:Ag	green	3.9	2.8	3.2	1.21	0.87

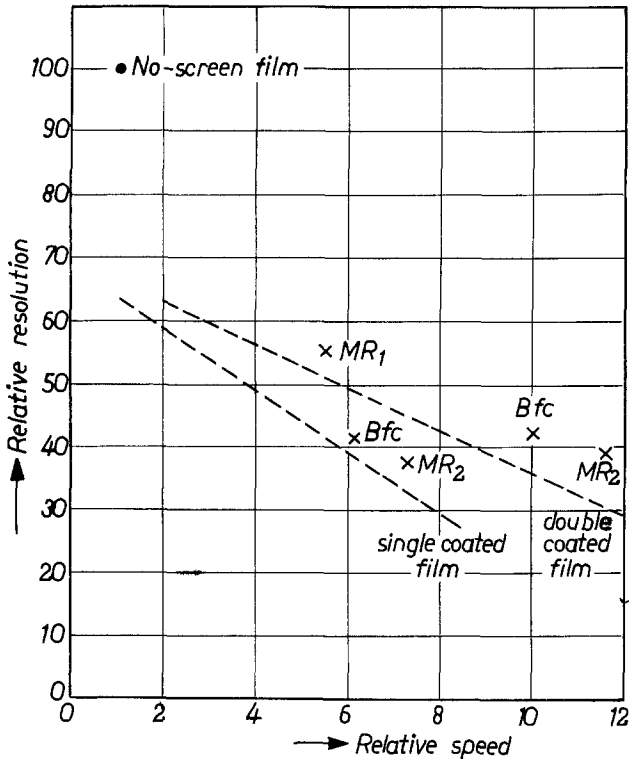

Fig. 4. Relative resolution against relative speed for BaFCl:Eu^{2+} (Bfc) and LaOBr:Tb^{3+} (MR) screen/film combinations. The no-screen film has a speed equal to unity and a resolution equal to 100. The dashed line represents results for $CaWO_4$ screen/film systems, taken from Fig. 1. The x-ray source (W-anode) was operated at 30 kV.

Conclusions

The use of x-ray screens in mammography can give rise to substantial speed gains and hence to x-ray dose reduction. The simultaneously occurring deterioration of the image quality as established by physical measurements, makes the benefits rather questionable. Whether this also holds true from a clinical point of view needs further investigation. Replacement of $CaWO_4$ by more recently developed x-ray powder phosphors like BaFCl:Eu^{2+} or LaOBr:Tb^{3+} does not drastically change these conclusions.

New screen technologies have to be found to give mammography screens better properties. Improvement of the screen resolution is a primary prerequisite, although the resulting improvement of the system may be limited by geometrical factors.

Auger Analysis of Thermally Oxidized GaAs Surfaces

Ikuo Shiota, Nobuo Miyamoto, and Jun-ichi Nishizawa*

Research Institute of Electrical Communication, Tohoku University, Sendai, Japan 980

ABSTRACT

We have investigated in-depth composition profiles of the GaAs crystals with thermally oxidized (100) and (111) surfaces by Auger electron spectroscopy during Ar sputter etching. The Ga depletion is found at two different positions when the oxide thickness is less than about 250 and about 140Å for the closed- and the open-tube oxidation, respectively. One of the positions is within the oxide layer and is always accompanied by the increase in As concentration, while the other is at the oxide-GaAs interface and appears upon the formation of Ga_2O_3 thicker than ~50Å. It is found that the oxide growth rate, the transition layer width, and the composition ratio between As and Ga near the interface strongly depend upon the surface orientation. It turns out that there are three different oxidation kinetics as functions of oxide thickness: the reaction of oxygen with GaAs at the interface, and in- and out-diffusions of oxidizing species and Ga.

GaAs is an important semiconducting material for various optoelectronic and high frequency devices. At the present stage, however, it is still difficult to control the surface properties of GaAs. The difficulty lies in the fact that the surface composition of GaAs easily deviates from its stoichiometry by heating even at lower temperatures and by any chemical treatments. This is due to the high equilibrium vapor pressure of As (1) and the different reactivities of Ga and As with the oxidizing species and chemical reagents (2). This situation does correspond to the thermal oxidation of GaAs surfaces.

The detailed mechanism of thermal oxidation of binary semiconductors (3) such as GaAs (4-9), particularly in relation to the role of As atoms in the oxide, has not been accounted for. In this work, we have investigated the in-depth profiles of thermally oxidized GaAs (100) and (111) surfaces by Auger electron spectroscopy during Ar sputter etching. It has turned out that As plays an important part in the formation of oxide films and exhibits a peculiar compositional distribution in the case of the lower temperature oxidation.

Experimental

Undoped GaAs (100) and (111) wafers were cut from the same boatgrown ingot with a carrier concentration of 1×10^{16} cm^{-3} and an etch pit density of 5000 cm^{-2}. After mechanical polishing, the surfaces were thoroughly degreased using trichlorethylene and methanol cycles in an ultrasonic bath, and then the damaged surface layer was etched off in a solution of 4 parts H_2SO_4, 1 part H_2O_2, and 1 part H_2O, followed by dipping in a concentrated HF solution for 5 min after rinsing with deionized water. The wafers were finally rinsed with doubly distilled methanol.

In the open-tube oxidation system, the flow rate of oxygen gas was about 500 cm^3/min, while in the closed-tube system with the closed inlet and outlet valves of the quartz reaction tube, oxidation took place in a stationary oxidizing atmosphere. The wafers oriented to (100) and (111) were simultaneously oxidized in a resistance heating furnace under identical experimental conditions.

The Auger transitions used for in-depth profiling of the oxide-GaAs system are those in the higher energy states of 1087 and 1228 eV $L_3M_{4,5}M_{4,5}$ for Ga and As, respectively, in order to avoid peak overlapping as observed in the lower energy range (< 100 eV) and also to obtain precise peak-to-peak values of their Auger signals. A 510 eV $KL_{2,3}L_{2,3}$ transition was monitored for oxygen profiling. An accelerating voltage of 4 kV was employed as the primary electron beam to excite the higher energy Auger electrons, the beam current used being 1 μA. The modulation amplitude of the phase-sensitive detector was set at 5 eV, the time constant at 1 sec, and the scanning rate at 6 eV/sec. The peak-to-peak Auger signals were monitored automatically by a physical electronics multiplex control system.

In taking the lower energy part of the Auger spectrum, an excitation voltage of 2 kV was used to avoid sample charging. Furthermore a modulation amplitude of 2 eV, a time constant of 1 sec, and a scanning rate of 1 eV/sec were employed to increase the resolution of the spectrum.

Simultaneous sputter etching was made at a sputtering voltage V_{sp} of 1 or 2 kV, and an emission current of 30 mA under a 5×10^{-5} mm Hg Ar atmosphere. The sputtering rate of the Ga oxide formed in a series of experiments was determined to be 20 and 55 Å/min for $V_{sp} = 1$ and 2 kV, respectively. In this evaluation the oxide thickness measured by a multiple-beam interferometer was divided by the sputtering time when the Auger peak ratio, O/Ga, started to decrease from the value of 1.75 for the bulk oxide. Once the sputtering rate was calibrated, the oxide thickness was determined from the sputtering time defined above. This method was also applied to the oxide in which the interface with the GaAs substrate was not clearly defined and which contained a considerable amount of As.

Results and Discussion

A characteristic compositional distribution in which the amount of Ga is depleted at two different positions has been found in the thermal oxide-GaAs system for the oxides, less than about 250 and 140Å in thickness, formed in the closed- and the open-tube system, respectively. Typical examples are shown in Fig. 1 and 2. Figure 1 shows the GaAs (100) surface oxidized at 500°C for 20 min in the closed-tube system, and Fig. 2 shows the same surface oxidized at 450°C for 60 min in the open-tube system. Two Ga valleys, *i.e.*, the two Ga depletion regions, were observed not only in the (100) surfaces but also in the (111) A and B surfaces. One valley was within the oxide layer 50Å off from the oxide surface [hereafter called the outer (Ga) valley], and the other at the oxide-GaAs interface [hereafter called the inner (Ga) valley]. At the outer valley the amount of As took a peak value and O acted like Ga; that is, the Ga and O distributions showed a tendency opposite to that of the As distribution. It should be further noted that the amounts of Ga and O in the region between the outer and the inner valley are

* Electrochemical Society Active Member.
Key words: composition profile, inner and outer Ga depletion, oxidation kinetics.

smaller than those of the surface layer of the oxide, and that the coexistence of a considerable amount of As is observed between the two valleys. These observations suggest that the total amount of Ga oxide and As remains constant throughout the oxide, and that the close packing of Ga oxide up to its maximum density is impeded by the presence of As. The oxide with the two Ga valleys was more easily created in the closed-tube oxidation than in the open-tube one. For instance, the two valleys were formed by oxidation at 600°C for 10 min or 500°C for 30 min in the closed-tube system, while the outer valley disappeared even by oxidation at 550°C for 10 min in the open-tube system. The inner valley was always observed when the oxide thickness became more than 50Å, as is the case with the oxide formed by violent chemical etching of GaAs surfaces (8, 10). This would mean that the occurrence of Ga depletion at the oxide-GaAs interface is a fundamental phenomenon in the formation of a native Ga oxide on the GaAs substrate by thermal oxidation.

The Auger spectra corresponding to the points indicated by the numbered arrows in Fig. 1 are shown in Fig. 3. The Ga $M_2M_4M_4$ peak and the Ga M_2M_4V peak made chemical shifts of 5 and 5.5 eV toward the lower energy side from their original energies of 54 and 81 eV for the clean GaAs surface. It is obvious that the spectrum at point 1 has a closer resemblance to that at point 3 than the spectrum at point 2. It is evident that at the outer valley (at point 1), a weak but unchemically shifted Ga peak was observed, and the chemical shift of the As Auger peak is much smaller (< 1 eV) throughout the oxide layer compared with that of Ga. These facts indicate the presence of a small amount of the unoxidized Ga at the outer valley, and the presence of the unoxidized As throughout the oxide layer except the uppermost surface layer.

As the oxidation proceeded, the outer valley became shallower, flattened out, and finally disappeared. Thus, only the inner valley remained. With further oxidation, the amounts of Ga and O gradually increased inward from the oxide surface, accompanied by a decrease of the As content in the oxide. Finally the oxide became homogeneous Ga_2O_3. In the single valley oxide formed above 700°C the unchemically shifted Ga Auger peak was observed.

The Auger peak ratio, O/Ga, showed a constant value of 1.75 ± 0.05 throughout the oxide regardless of whether the oxide system had one or both of the Ga valleys, although in the latter case a considerable amount of As was present between the two Ga valleys. It can be inferred from this result that the O atoms around a Ga atom are identical in coordination throughout the oxide layer and only the Ga oxide density varies in it, and that the O atoms are preferentially bound with Ga atoms rather than As atoms. This

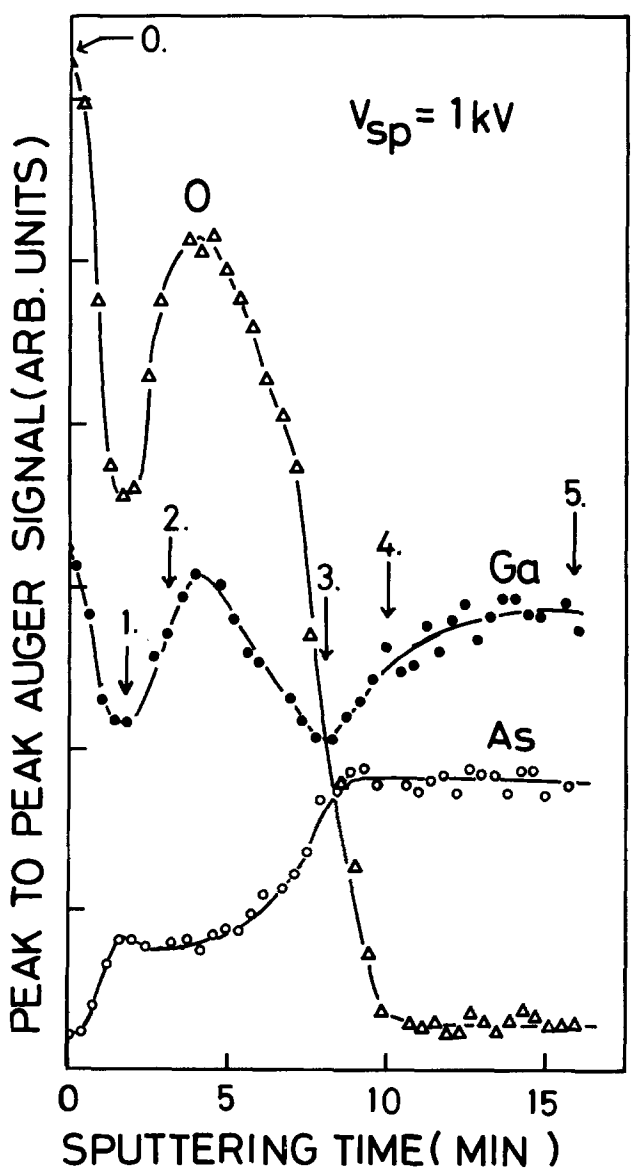

Fig. 1. Composition profile of a thermally oxidized GaAs (100) surface in the closed-tube system at 500°C for 20 min.

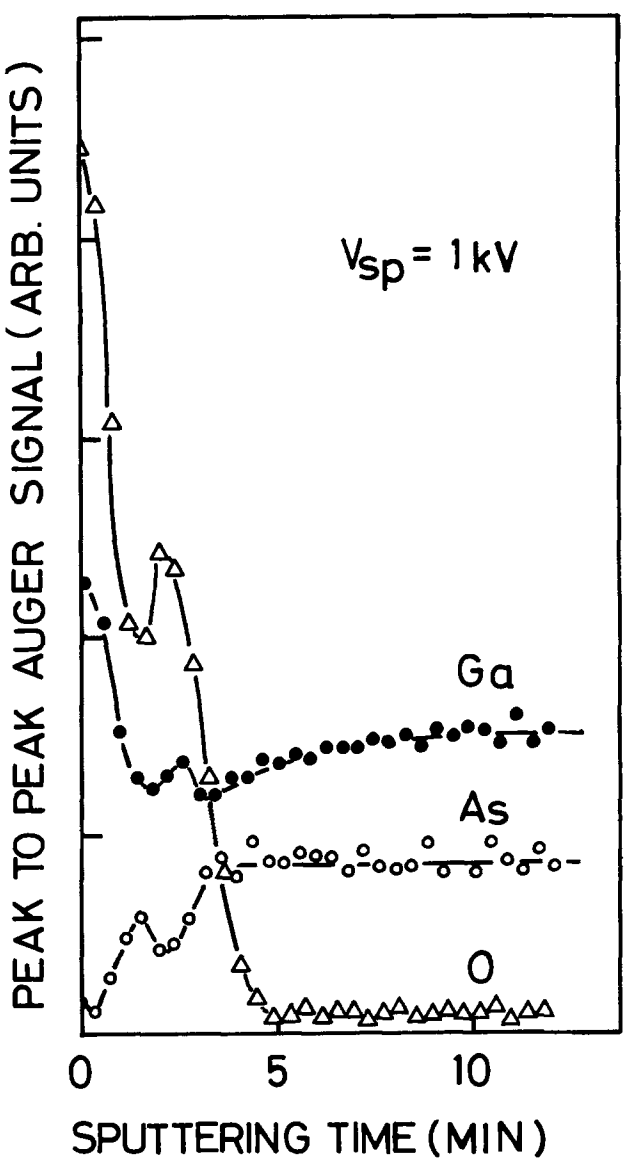

Fig. 2. Composition profile of a thermally oxidized GaAs (100) surface in the open-tube system at 450°C for 60 min.

conception can well explain the previously described result that the chemical shift of the As Auger peak is negligibly small.

The composition profile at the interface shows a large dependence on the crystal orientation and the oxidation condition. Typical examples for the orientation dependence of composition profiles of the (100), (111) B, and (111) A surfaces are shown in Fig. 4, 5, and 6, respectively. Each surface was oxidized at 700°C for 10 min in the open tube. In these figures, the ratios of O and As to Ga Auger peaks are also shown. In the (111) B surface the O penetrated very deeply into the GaAs bulk and the interface was elongated, while in the (100) and (111) A surfaces the interfaces were clearly defined. A remarkable As accumulation appeared only at the (100) interface and increased up to approximately 700°C, beyond which it disappeared. There occurred a weaker As accumulation in the closed-tube oxidation at the (100) interface.

Figures 7 and 8 show the dependence of oxide thickness and Δt on the reciprocal oxidation temperature, where the oxidation was performed for 10 min at each temperature. The quantity Δt is the duration of sputtering time for a half recovery of the Ga Auger peak to the value of the bulk GaAs as indicated in the insert of Fig. 8, and gives a measure of the thickness of the transition layer at the interface. The oxide growth rate is equal between the (100) and the (111) faces below 500°C, but it is greater for the (111) face than that for

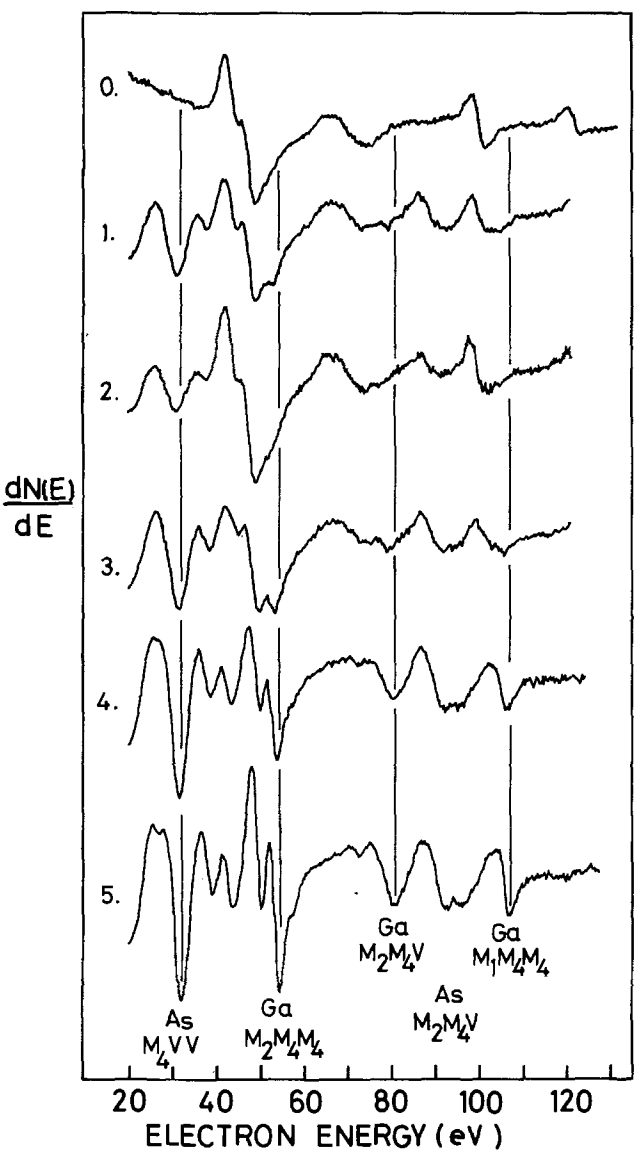

Fig. 3. Auger spectra corresponding to the points indicated by the numbered arrows in Fig. 1.

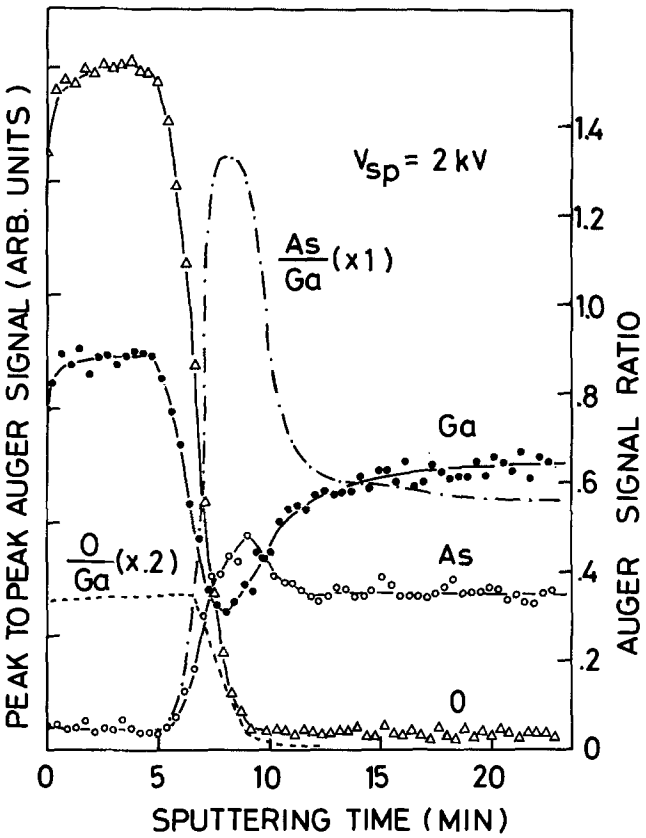

Fig. 4. Composition profile of a thermally oxidized GaAs (100) surface in the open-tube system at 700°C for 10 min.

the (100) face above 500°C. From Fig. 7 and 8, it is obvious that the thermal oxidation has three different rate-limiting processes, depending on the values of activation energy E_a. For the (100) faces, E_a is approximately 0.4 eV between 500° and 700°C, and E_a = 1.3 ~ 1.4 eV at both sides out of that temperature range. For the (111) faces, the temperature range with E_a = 0.4 eV starts from about 550°C.

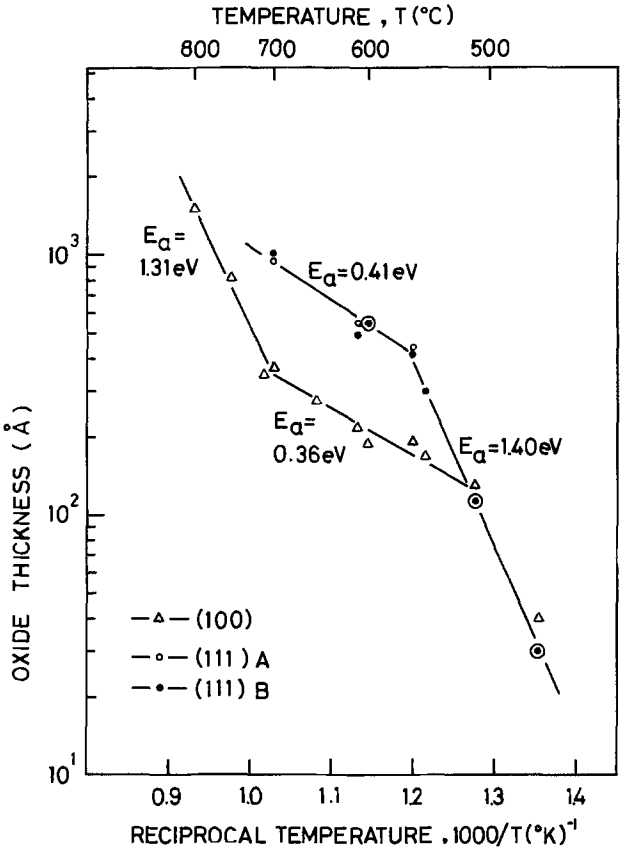

Fig. 7. Oxide thickness as a function of reciprocal temperature. Oxidation was made for 10 min at the specified temperatures.

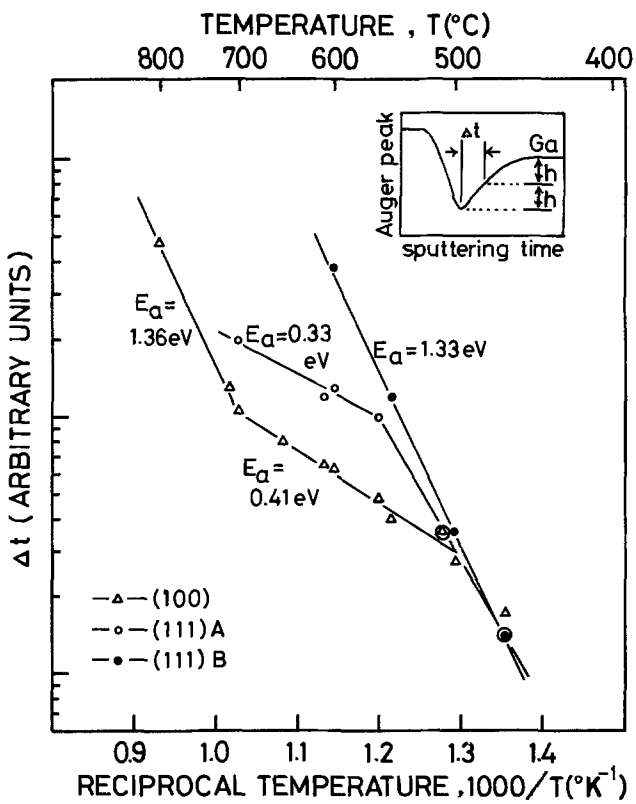

Fig. 8. Δt, the duration of sputtering time for a half recovery of the Ga Auger peak to the value of the bulk GaAs, as a function of reciprocal temperature for the same samples as used in Fig. 7.

In the oxidation at 510°C where E_a falls on 1.3 ~ 1.4 eV for the (111) and 0.4 eV for the (100) face, the relation between oxide thickness and oxidation time is linear for the (111) A and B faces and is parabolic for the (100) face. However, the oxidations at 600° and 730°C with E_a = 0.4 and 1.3 ~ 1.4 eV, respectively, obey an identical parabolic law for both (100) and (111) faces. These results lead to the conclusion that the oxidation in the temperature range where a linear law holds, and E_a = 1.3 ~ 1.4 eV is controlled by the reaction of O with GaAs at the interface. Thus, the remaining As will be distributed in the oxide and near the interface. In the other temperature ranges the oxidation will be controlled by the in- and outdiffusion of oxidizing species such as water and Ga with E_a = 0.4 and 1.3 ~ 1.4 eV, respectively. The diffusion of water is inferred from the analogy with the thermal oxidation of Si in an atmosphere containing water vapor (11). The Δt data plotted in Fig. 8 also show a similar behavior to the oxide thickness for the reciprocal temperature; above 500°C the transition layer at the interface is wider in the (111) surface than in the (100) one. It should be noted here that the width of the transition layer in the (100) surface is narrower than in the (111) surface, but the inner valley is deeper in the (100) than in the (111) surface.

From Fig. 7 and 8, it is apparent that for the same oxide thickness in the range of less than approximately 300Å, the value of Δt is nearly the same regardless of the difference in surface orientation. This suggests that Δt depends solely on the oxide thickness in such a thickness range, and hence the orientation dependence of sputtering may safely be ignored. In the oxide thickness range of more than 300Å, however, Δt becomes dependent not only on the oxide thickness, but on the surface orientation; that is, in the (111) B face Δt is greater than that of the (100) and (111) A faces when the oxide thickness is the same. It is very difficult to understand these results only in terms of such artifacts as selective sputtering and the implantation effect, because the former seems to give the same effect on Δt regardless of the difference in surface orientation when the oxide thickness is the same, and the latter should give an equivalent effect on Δt for the identical surface orientation regardless of the difference in oxidation temperature. Therefore, some other fundamental explanation is indispensable to the understanding of the observed phenomena at the interface. The occurrence of the inner Ga depletion cannot be related to the oxidation kinetics because the inner Ga valley appears inevitably whenever the oxide thickness is in excess of 50Å. Therefore, the cause of the depletion should be sought from the oxide formation itself. A possible explanation may be given as follows. As described above, Ga is preferentially oxidized and consequently As atoms accumulate around the interface, resulting in a relative decrease of the Ga to As ratio in that region. That is to say, the inner Ga depletion is caused by a selective oxidation of Ga and the resulting As accumulation at the interface.

Conclusions

We have obtained new results on the thermal oxidation of GaAs surfaces by measuring in-depth profiles of the compositional distribution by Auger electron spectroscopy during Ar sputter etching. The thermal oxide films can be classified in two groups. One is the oxide with two Ga valleys and the other is the oxide with a single Ga valley. The Ga depletion at the oxide-GaAs interface appears inevitably upon the formation of the oxide layer thicker than ~ 50Å. The Ga depletion in the oxide near the outer surface is always accompanied by the increase in As. The close packing of the Ga oxide up to its maximum density is hindered

by the presence of As. It has been made clear for the first time that the behavior of As plays an important role in the formation of the Ga oxide by thermal oxidation of GaAs surfaces.

Three different oxidation kinetics have been proposed: The first is the reaction of O with GaAs at the interface and dominates the formation of thin oxide films characterized by the two Ga valleys; the second and the third correspond to the indiffusion of oxidizing species, such as water, and to the outdiffusion of Ga. For the (100) surfaces, the second mechanism holds for the temperature range between 500° and 700°C, and the third does above 700°C. In these temperature ranges, the growth rate, the transition layer width, and the composition ratio strongly depend on the crystal orientation.

The Properties of Silica Diffusion Sources under Oxidizing Ambient Conditions and Their Application to Solar Cell Fabrication

T. C. Chandler, Jr.,[1] R. B. Hilborn, Jr., and J. W. Faust, Jr.*

College of Engineering, University of South Carolina, Columbia, South Carolina 29208

ABSTRACT

In this paper a technique for the design and fabrication of silicon solar cells using spin-on silica doping sources is discussed. This technique involves the use of an oxidizing ambient during diffusion which limits the diffusion flux and yields lower surface concentrations of impurities and shallow p-n junctions. It is shown that the uniformity of the film thickness is an important factor in maintaining a uniform surface concentration of impurities in a diffused substrate. Data are given to demonstrate the effects of such silica film thickness variations on solar cell performance.

During the past four years industry and government interest in silica films as diffusion sources in electronic device applications has grown immensely (1, 2). The silica film itself has been in small scale use for some time, but the recent interest in developing inexpensive solar cells has renewed interest in this technology. Doped silica diffusion sources may reduce the cost of solar cell processing and have the advantage of better over-all process control (3).

Silica sources (or doped SiO_2) exist in a variety of forms. Owen and Schmidt (4) have reported on the use of thin anodic silicon dioxide films as diffusions sources, but their analysis is hampered by experimental conditions which are difficult to control. Reactive sputtering has also been investigated (5) but results have not been consistent enough for applications in photovoltaics. A more recent development is the paint-on or spin-on silica film. These films when applied properly, yield excellent p-n junction uniformity, surface concentration of impurities, and minimal surface damage. The silica solutions consist of organic silicates and the appropriate dopant elements dissolved in an alcohol solution. These types of solutions have a typical room temperature viscosity of 25 cp making them well suited for standard photoresist spinning apparatus. Herein lies a primary advantage of the spin-on silica film. The simplicity of the technique and equipment makes this an inherently cheaper process than the anodized or sputtered films mentioned above.

In this paper we describe the diffusion theory and technique used to fabricate p-n junction silicon solar cells using doped, spin-on films. Experimental data are presented to demonstrate the controllability obtained from spin-on silica films.

Diffusion Theory

In a recent paper Barry (3) has demonstrated that in a nonoxidizing ambient, diffusions from doped silicon dioxide films agree with the solutions to Fick's second law to within experimental error and that the surface concentrations of impurities resulting from such diffusions are functions of the silica dopant concentration. It was shown that the surface concentration was independent of diffusion time and temperature for surface concentrations less than or equal to 1.0×10^{20} cm^{-3}. This limitation in Barry's model is an important point. Other studies (6-8) show that for surface concentrations greater than 1.0×20^{20} anomalous diffusion profiles result, leading to regions near the surface of constant impurity concentration having

[1] Present address: U.S. Air Force Materials Laboratory, Electromagnetic Materials Division (LPO), WPAFB, Ohio 45433.
Key words: silicon dioxide, diffusion flux, phosphorus.

a very high diffusion-induced density of dislocations and consequently low minority carrier lifetimes. These are the regions described in the literature as "dead layers" (9). Hence, if one wishes to manufacture silicon solar cells with the highest obtainable efficiencies one must limit the surface concentration to values less than 2×10^{20} cm^{-3} so that the dead layer is eliminated.

Flux limiting.—A method of maintaining a surface concentration at the proper level is to introduce oxygen into the ambient during diffusion (6). The presence of sufficient quantities of oxygen allows oxidation to take place at the silicon surface thus limiting diffusion at the oxide-silicon interface. By proper control of the thermal oxidation rate, one can control the diffusion-limiting process and consequently, the surface concentration. The use of an oxidizing ambient causes deviations from Fick's laws of diffusion resulting in shallow p-n junction depths and, unlike Barry's model, surface concentrations that are functions of the diffusion temperature.

Intuitively, one sees that diffusion in the presence of a retarding mechanism (diffusion limiting due to oxidation) requires changing the boundary conditions of the diffusion model, since the physical boundary (oxide-oxide interface) is in motion.

This moving boundary can be described by two coordinate axes (Fig. 1) X and X'. X is fixed with its origin at the oxide-silicon interface. X' has its origin at the oxide-oxide interface. X and X' are related by

$$X' = X - \frac{R\sqrt{t}}{N} \qquad [1]$$

Where R is the oxidation rate constant in cm/sec$^{1/2}$ and N is the volume ratio of silicon dioxide to silicon (equal to 2.30). (Notice that this formulation of the moving boundary condition is relative in nature. It is just as correct to assume that the oxide-oxide interface is fixed and to allow the oxide-silicon interface to move.) It can be demonstrated by Eq. [1] that in the oxidizing ambient, diffusion is a function of the oxidation rate and not the oxide thickness. It was assumed in this study that the oxide growth followed the parabolic law[2] (5)

$$\alpha = (\alpha_0^2 + R^2 t)^{1/2} \qquad [2]$$

where α is the total oxide thickness, and in practice α_0, the initial oxide thickness, is zero.

Fick's second law can be written for region B and C of Fig. 1 yielding

$$\frac{\partial C_B}{\partial t} = D_B \frac{\partial^2 C_B}{\partial X'^2} \qquad [3]$$

[2] This is a good approximation for temperatures falling in the range 950°C $\leq T \leq$ 1250°C) (5).

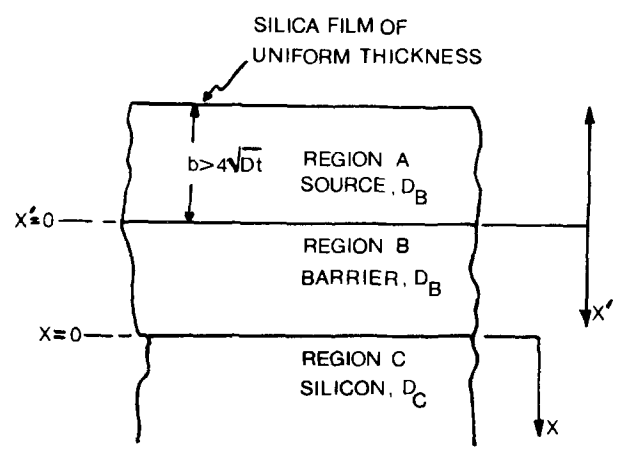

Fig. 1. The three layer diffusion system showing the origin of the X and X' axis.

and

$$\frac{\partial C_c}{\partial t} = D_C \frac{\partial^2 C_c}{\partial X^2} \qquad [4]$$

The solution (10) to Eq. [4] is

$$C_c(X, t) = \gamma C_0 \operatorname{erfc} \frac{X + \dfrac{R\sqrt{t}}{N}}{2\sqrt{D_c t}} \qquad [5]$$

where

$$\gamma \simeq \frac{1}{1 + \sqrt{\dfrac{D_c}{D_B}}} \qquad [6]$$

and C_0 is the concentration of dopant (atoms/cm^3) in the source material. Evaluating Eq. [5] at $X = 0$ the surface concentration is found to be

$$C_s = \gamma C_0 \operatorname{erfc} \frac{R}{2N\sqrt{D_c}} \qquad [7]$$

These equations show that unlike Barry's fixed boundary model, C_s is a function of temperature and also the junction depth is shallower by the quantity $R\sqrt{t}/N$.

Theoretical limitations.—The theory given above is dependent on two basic assumptions. The first assumption is that the oxidation rate constant, R, is independent of time and is only a function of temperature. This assumption is only valid when the silica film is of uniform thickness. Experiments show that oxidation constants for localized regions of thin silica film ($<<$200Å) have somewhat higher values of R and oxidation in these regions is not independent of time. Figure 2 shows a plot of R *vs.* temperature for two different silica layers. Notice that the thin SiO_2 film has a slightly higher R value. This behavior is not completely understood but from microscopic examina-

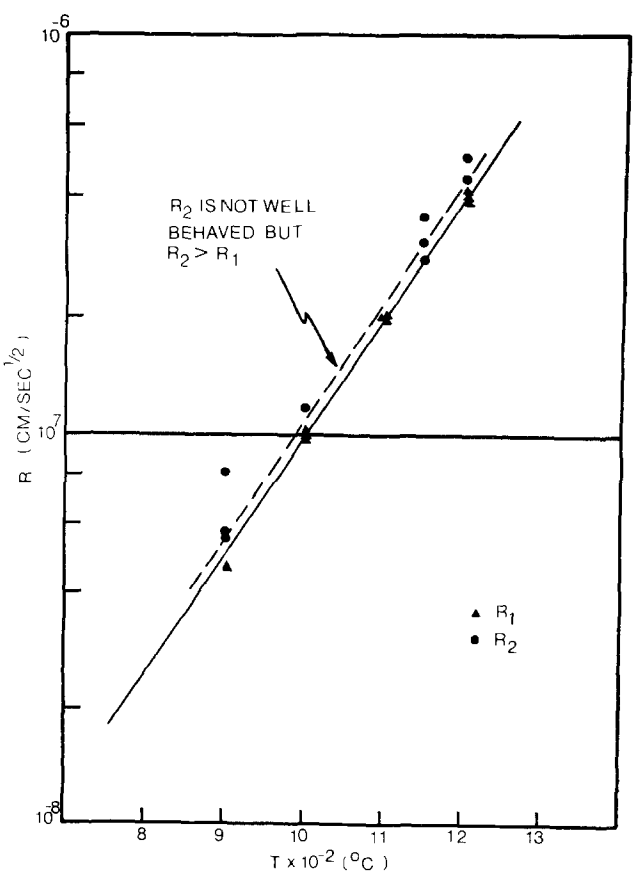

Fig. 2. Plot of R *vs.* temperature. R_1 is measured for thin silica regions and R_2 is measured for thick regions.

tion of such thin regions it is felt that the film has poor oxide integrity, *i.e.*, there are regions which are cracked and porous so that the migration of oxygen ions necessary for the oxidation is somewhat enhanced, unlike the regions of thick SiO_2 coverage (see Fig. 3) which display a reasonably constant R.

The problem of thin regions in the silica film is inseparably linked with the second limitation of the foregoing theory. To maintain the constant source condition of a silica (or deposited SiO_2) film, its thickness must equal or exceed the diffusion length of a dopant atom in the oxide (3, 10), *i.e.*, the silica thickness b must obey the inequality

$$b^2 > 4D_B t \qquad [8]$$

When inequality [8] is not satisfied, the film is quickly depleted of dopant; and, over the extended period during which an ideal erfc profile would have resulted, the profile for such a nonconstant source would be gaussian with a reduced value of C_s. Figure 4 shows the source thickness necessary for a given temperature. Satisfying conditions [8] might seem like a formidable problem, but fortunately the thickness of a spin-on source can be easily controlled by the spin speed and duration.

Solar Cell Processing

Given below is the general procedure for fabricating a silicon solar cell using silica films. The process can be divided into four major segments, prediffusion cleaning, application and examination, diffusion, and metallization. Both prediffusion cleaning and metallization are covered adequately in the literature (1, 5). Application and diffusion are discussed here because they involve implicitly the silica film.

Application.—It has been found by trial and error that silica films, utilizing an alcohol carrier liquid, spin on best at temperatures from 20°C up to 25°C. Spin speeds can vary but the best range is between 2500 and 3500 rpm. Best results are obtained when the substrate is the same temperature as the source liquid; however it cannot have a temperature above the source liquid temperature.

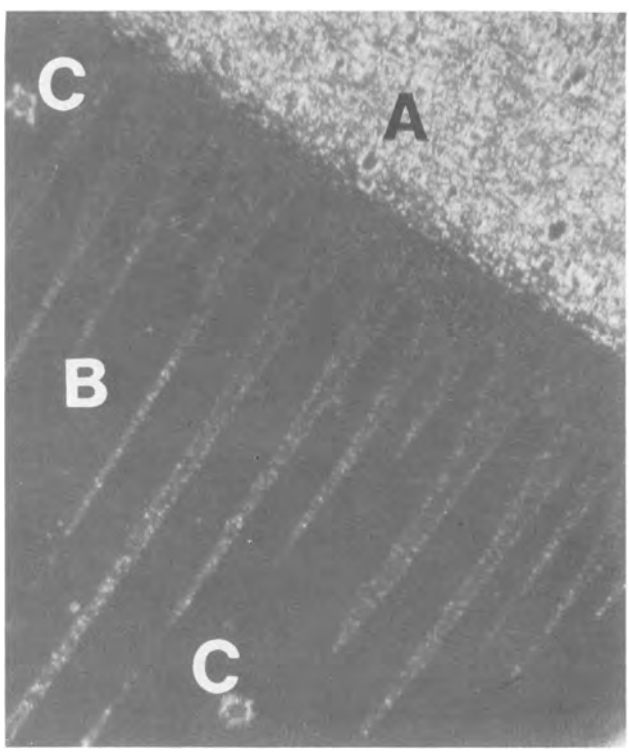

Fig. 3. Purposely induced thin regions of a spun-on silica film. Notice that the thin regions (A) provide poor coverage as opposed to the thick regions (B). C is due to bubble damage. (Magnification 160X.)

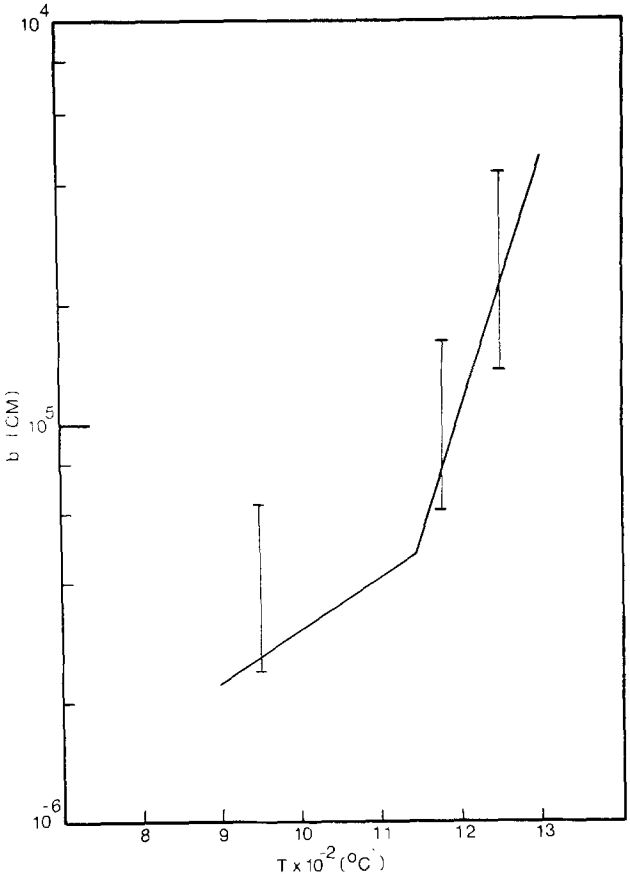

Fig. 4. Plot of source thickness necessary for maintaining constant source conditions as a function of temperature.

To prepare a liquid solution for application, it should be placed in a container so that it fills it completely, with no empty space, and allowed to come slowly to some temperature less than 25°C. If the source liquid is stored for this period in a large partially filled container, evaporation of the alcohol will generate bubbles which can degrade the uniformity of the film, see Fig. 3 and 6.

After the film has been spun on the substrate, it should be examined to see if the source layer is uniform, or if it has thickness variations (12) similar to Fig. 3. (This step is necessary because the properties of commercially available films differ from type to type, batch to batch, etc. Once satisfied that these guidelines are adequate, this step may be deleted.) These variations in thickness can yield thin spots on the order of 200Å or less. The cause is improper film application as described by Chandler *et al.* (12). Similar bad results occur when particles of dust or debris touch the silica film. It has been observed in this laboratory that a particle 1μ in diameter can result in poor silica coverage for a distance of 50μ around the particle. Elimination of these thin areas is essential in view of the theoretical limitation described previously. The silicon beneath a thin area oxidizes faster and the forming oxide, in effect, dilutes the source diffusion. More importantly, one can see from Fig. 4 that a silica thickness of 200Å is far from satisfying inequality [8] for common diffusion temperatures. The cumulative effect is the dilution of a source which itself is growing smaller with time. It has been experimentally confirmed that extremely shallow junctions, if present at all, will form under these thin layers.

If the deposited films have thickness variations, holes, or striation (12), the poor results discussed above will occur; hence the application procedure,

however different from the recommended process, must be altered to insure a uniform silica film. Figure 5 illustrates a ripple formation of the type encountered. During the bakeout cycle the organic compounds are driven off, the film becomes rigid, and the variations are frozen into the silica layer. Hence one means of reducing the thickness variations is to delay the bakeout until the wet film can flow to a more uniform layer. This technique works best below 25°C where evaporation of the alcohol is slow. Delaying the bakeout cycle will not eliminate thickness variations but it will allow thin areas to change sufficiently to satisfy the inequality [8].

Once the film integrity has been established, the substrate should be baked in dry nitrogen at 200°C for 4 hr. This step drives off the organic carrier liquids, leaving a doped silica film on the wafer.

Diffusion.—Diffusion of the substrate was carried out in an ambient mixture of 50% nitrogen and 50% oxygen at a temperature of 1000°C. The doping element was phosphorus at a concentration, C_o, of 4×10^{20}. The values of the oxidation constant R were determined experimentally. These conditions were chosen because they yield a uniform shallow junction.

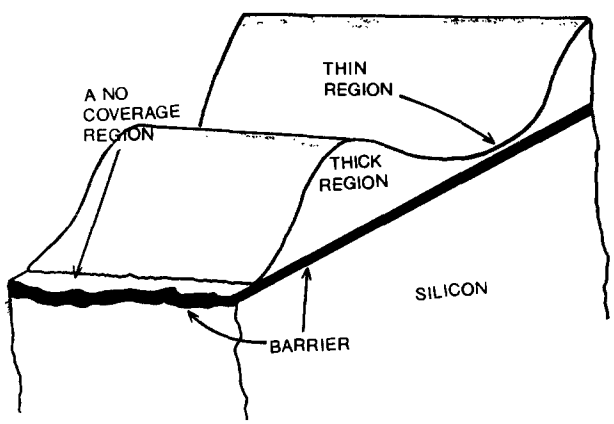

Fig. 5. Artist's conception of a ripple formation in a silica film. The thin regions of the film produce poor p-n junction characteristics.

Fig. 6. Photograph of a silica film with bubbles trapped in the film. If these bubbles remain in the film when it is drying, the damage shown in Fig. 3 results. (Magnification 100X.)

Results

Four series of solar cells were fabricated. Table I gives some data on each series. Each substrate had a background resistivity of 1 Ω cm and a thickness of 200μ. The contact pattern utilized is a common type having a center bar with six fingers. The contact metal was aluminum and the contacts were sintered in an N_2 ambient at 450°C for 10 min. No antireflection coatings were applied. The light source was the sun and the incident solar power was determined by pyranometer measurements.

The first two series were done with no control of the silica film uniformity. The third run utilized the simple temperature/spin guideline given above, and the fourth series was fabricated making sure that the silica film was more uniform by delaying the bakeout. Difference in cell performance is obvious from Table I. Runs 1 and 2 are not encouraging.

The nonuniformity of the film allowed diffusion to take place in a nonuniform fashion so that some regions of the cell display extremely high sheet resistances. In some areas where doping levels were not degenerate, the p-type contact on the n-type diffused region formed p-n junctions. It was found that the level of photon-generated current in the poorly diffused region was low also. Steps were taken to minimize these flaws so run 3 showed that when the uniformity of the silica film improved so did the characteristics of the solar cells.

Series 3 cells were moderately efficient, having fill factors averaging 0.60, but this was greatly improved in series 4.

The solar cells of series 4 were designed using the theory presented in this paper. The diffusion model defined by Eq. [1] through [7] allows the diffusion to take place at a higher temperature and achieve the same surface concentration and junction depth as for the low temperature diffusion. It has been found that diffusion from silica sources is more uniform for temperatures of 1000°C. The results were significant. By eliminating the diffusion inhomogeneities, the series resistance was reduced to tolerable levels. The results of junction depth and surface concentration measurements show good agreement between the theory and the diffused region of the cells.

Figure 7 shows the theoretical junction depth for a surface concentration of 1.2×10^{20} cm^{-3}, and a background concentration of 1×10^{16} cm^{-3}, at various diffusion times. The experimental points show that agreement with theory is good except at very short intervals (less than 5 min). This is probably due to the presence of an unavoidable oxide on the substrate before the source application, such that there is an initial oxide layer which has to be penetrated in a finite amount of time.

In Fig. 8 is an evaluation of the surface concentration for various diffusion times. This figure demonstrates that C_s is not time dependent for periods longer than 5 min and less than 60 min. Inside this time interval the curve of Fig. 8 is in agreement with Eq. [7]. The deviation from simple theory seen here can be explained. The low C_s seen for short diffusion times can be attributed to the residual oxide layer that was evidenced in the junction depth data. Deviations seen for

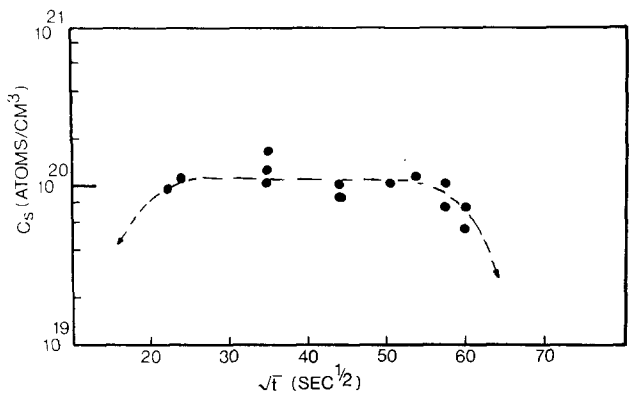

Fig. 8. Plot of surface concentration *vs.* $\sqrt{t}$ for 1000°C and an atmosphere of 50% O_2 and 50% N_2. $C_0 \simeq 4 \times 10^{20}$ cm^{-3}.

periods greater than 60 min indicate that the source material is becoming depleted of its dopant.

Solar cells processed by this technique and described here have better characteristics than those previously reported (12); their series resistances are comparable to standard, commercially diffused cells. These improvements are due to the uniformity of the silica film which results in a homogeneous surface concentration approximately equal to 1×10^{20} cm^{-3} and a shallow, uniform junction.

The uniformity of the degenerate surface concentration is the most important factor. To test qualitatively for uniformity of surface concentration a staining etchant which turns n^+ regions dark (5) was applied. Results show that when the film is uniform the surface concentration of impurities is uniform.

The junction depth was also established by the standard method involving angle lapping and staining (5, 11). The results were consistent with theory.

Conclusions

A model and general technique for fabricating solar cells using silica films is presented. This technique yields predictable, uniform shallow junctions, and acceptable surface concentrations for most diffusion cycle times. Calculations show also that for a given value of C_0 and temperatures between 950° and 1250°C, C_s varies little with the diffusion temperature. This technique is further simplified by the fact that excellent process control can be achieved by varying C_0 and the percent of oxygen in the ambient. It is obvious from the test data that moderately efficient solar cells can be fabricated using spin-on silica sources, and, when care is taken to insure proper film thickness and uniformity, cells comparable to those produced by standard, more expensive diffusion techniques can be manufactured.

The most important feature of this technique is that by introducing an oxidizing ambient, the resulting diffusion retardation allows the diffusion of impurities to be carried out at temperatures exceeding 1000°C while maintaining junction depths which are less than 0.5μ. This is significant because spin-on silica films yield more uniform junctions for temperatures greater than or equal to 1000°C. Although this uniformity could be obtained by using a nonoxidizing ambient, without the benefit of the diffusion retardation, deeper (>0.5 μm) p-n junctions would result. Because this technique also yields degenerate surface concentrations with no dead layer, the resulting solar cells have low series resistance and high blue response.

In view of the data presented in this paper, it seems that there is only one problem related to the full scale use of doped silica films, the rather long bake-out times required for these films. It is felt that the advantages of using silica films probably outweigh this minor difficulty. The original wafer diameters utilized in this research range from less than 2 cm to over 5 cm. No variation in film quality due to wafer size was observed, indicating that the silica films might be applied economically to larger diameter slices. It was also found that once the proper procedure was established for applying these films, the analytical procedures given in this paper could be eliminated. This reduced the somewhat tedious procedures outlined here to mere routine.

The Effect of Growth Rate and Temperature on the Incorporation of Sn in GaAs during LPE

Ulf König[1]

Institüt für Halbleitertechnik Sonderforschungsbereich 56, Technische Hochschule, Aachen, Germany

ABSTRACT

A growth rate dependence of the impurity incorporation has been measured for the first time: average carrier $\bar{n}$, donor $\bar{N}_D$, and acceptor $\bar{N}_A$ concentrations of heavily Sn-doped GaAs layers grown by liquid phase epitaxy (LPE) increase in the range $0.2 < \bar{V}/\mu m/min < 6$. At faster growth rates, the concentrations tend to be constant ($1.4 \cdot 10^{19}$ cm^{-3} for donors, $3.5 \cdot 10^{18}$ cm^3 for acceptors). Growth rates between 0.2 and 35 μm/min have been adjusted by varying the cooling rates of the epitaxial processes between 0.04° and 100°C/min. It can be reported that the relation between $\bar{N}_{D/A}$ and $\bar{V}$ corresponds to the theoretical predictions under surface equilibrium conditions. The most important parameter is the barrier height of the system melt and semiconductor, modified by a concentration-dependent barrier lowering in the case of heavy doping. Based on the same assumptions, the temperature dependence of the measured incorporation $\bar{N}_{D/A}$ (T) is explained. This results from a comparison of the possiole incorporation theories surface and bulk equilibrium.

During epitaxial growth from the liquid phase, the interface between melt and semiconductor can be regarded as a metal semiconductor contact because of the great density of conduction electrons in the melt. The Schottky model is then applicable to the surface. Merten and Hatcher (1) have pointed this out. Later on Zschauer and Vogel (2) and Casey *et al.* (3) used this model. As a consequence of such an electrical model, the thermodynamic equation for the impurity incorporation will have electrical properties like the Fermi level or the barrier height (3, 4).

According to the growth conditions, two aspects have to be distinguished: the bulk equilibrium and the surface equilibrium. If the growth rates of the crystal are slow compared with the impurity diffusion in the semiconductor, there exists a thermal equilibrium between the two phases, melt and semiconductor bulk (bulk equilibrium). This model explains the impurity incorporation of Zn (5, 6) and Cu (7) in GaAs. Where the ratio of the growth rate to the solid diffusion constant is large, the melt is in equilibrium with the surface of the growing crystal only. The important parameter of the surface equilibrium theory is represented by the height of the Schottky barrier. The validity of this theory has been shown for the incorporation of Te (8) and for the Sn donor (4, 9). Panish has found that the incorporation of Sn in GaAs can be better explained if one also assumes a Sn acceptor complex $Sn_{As}2V_{Ga}$ using the surface equilibrium theory again (4). The concentration in the case of bulk equilibrium is almost proportional to the square root of the atomic fraction of tin X_{Sn} in the melt, while in the case of surface equilibrium it is directly proportional to X_{Sn}. In spite of the principal agreement Panish obtained with the surface equilibrium theory, for high Sn concentrations above $4 \cdot 10^{17}$ cm^{-3} there exists a discrepancy between theory and experiment: Experimentally evaluated concentrations indicate a weaker slope with higher X_{Sn} data than expected (4). This can probably be interpreted as a concentration dependence of the barrier height, resulting in a lowering of the barrier (10).

Some authors (11, 12) suspect an additional manifestation of the barrier height or the Fermi level in a cooling rate dependence of the Sn segregation coefficient during liquid phase epitaxy (LPE). As the cooling rate influences the growth rate, this amounts to a growth rate dependence of the impurity concentration. Panish (4), however, did not detect such a dependence of the Sn doping when slightly varying the cooling rate. There is no record of systematic experiments. Zschauer and Vogel (2) predicted a quantitative dependence of the impurity incorporation on the growth rate. Experimental proof has not yet been obtained, partly because the cooling rates, or growth rates, respectively, have not been varied over an extended range large enough to observe this effect. Such a variation is possible, using the epitaxial apparatus and the experimental procedure described in this paper.

Experimental

Crystal growth process.—The heavily tin-doped GaAs layers are grown in a horizontal crucible of high purity graphite, with a fixed chamber for the GaAs-Sn melt and a movable graphite slider for the substrate (13). A radiation heating furnace is used. For the desired experiments, the low heat capacity of the furnace, the small crucible (length 6 cm, diam 2.2 cm), and the small melt (2.5g) in addition, are preferable to allow fast heating and cooling rates. For the rest, this setup corresponds to conventional equipment.

During heating at a constant temperature the GaAs pieces dissolve in the liquid tin. This forms a saturated solution with the liquidus composition of the binary Sn-GaAs cut of the ternary system for the respective saturation temperature. The boat is cooled down to room temperature. The substrate is then positioned in the boat. After a few minutes at saturation temperature, the system is cooled at a constant rate R between 0.04° and 100°C/min. The cooling rate is established by actual measurement of the boat temperature. 2°-10°C below the saturation temperature, the substrate is brought into contact with the melt. As there occurs no spontaneous crystallization during this initial cooling, the result is a supercooled melt of 2°-10°C, or according to the solution diagram of GaAs in Sn, a supersaturation of approximately 2-10%. The cooling continues during the growth period. The growth is terminated by removing the graphite with the substrate from the melt. To avoid strong annealing effects on the average electron concentration during the epitaxial process, the growth times of the examined layers do not exceed 20 min (14).

Two kinds of experiments have been carried out: variation of the cooling rate at an initial process temperature of 650°C, and variation of the initial process

[1] Present address: Forschunginstitut AEG Telefunken, D7900 Ulm, Germany.

Key words: liquid phase epitaxy, impurity concentration, growth rate, gallium arsenide.

temperature from 570° to 710°C. For the later experiments, the cooling rates have to be varied between 0.7° and 1.7°C/min to make sure that the temperature dependence of the growth rate is compensated. The average growth rates of the layers are then approximately 0.6 μm/min for each process temperature.

Growth rate and doping measurements.—The (100) orientated crystals are cleaved in (110) directions, and the cross-sections are etched under illumination with a $HF-H_2O_2-H_2O$ solution. The thickness L of the epitaxial layer grown during the time t is measured optically. An average growth rate of the epitaxial layer is defined as $\overline{V} = L/t$. As it is preferable to grow the layers at an initial supersaturation, actual and average growth rates (V and $\overline{V}$) of a layer decrease with time of growth. $\overline{V}$ is varied over an extended range for the experiments reported here. In a small range, this is attained by varying the growth time at constant cooling rate, in an extended range, however, by varying the cooling rate. [$\overline{V}$ increases approximately linearly with cooling rate R and is a function of temperature (15).] Although it would be better to describe the doping studies in terms of the actual growth rate V, the average growth rate $\overline{V}$, when combined with average doping parameters, is also informative.

The doping data for the epitaxial layers are measured by the Van Der Pauw method. The thicker edges of the layers are removed to avoid errors in the measurements. Ohmic contacts are made by alloying Sn in forming gas at about 400°C. Even the layers grown at 100°C/min are smooth enough to guarantee an accurate measurement of the doping properties.

As the GaAs layers are grown out of a Sn-rich GaAs solution, the expected electron concentration will be in the range of 10^{18} cm^{-3}. Where the materials are heavily doped, the donor and acceptor concentrations can be estimated by the equations of Kressel and Nelson (16), using the measured $\overline{n}$ and $\overline{\mu}$ data at room temperature, and the mobility μ_u of uncompensated material. For μ_u, the highest reported values, extrapolated to carrier concentrations of 10^{19} cm^{-3}, are used (16). To consider the geometrical effects of a nonideal Van Der Pauw structure, a systematic error of +5% for μ and −5% for n was taken into account (17).

Results and Discussion

Growth rate dependence of the Sn concentration.—The average values of carrier concentration $\overline{n}$ (300°K) and mobility $\overline{\mu}$ (300°K) *vs.* the cooling rate R of layers grown at an initial process temperature of 650°C are shown in Fig. 1. The cooling rate varies from 0.04° to 100°C/min. $\overline{n}$ and $\overline{\mu}$ are constant for cooling rates greater than 10°C/min, and decrease or increase, for lower cooling rates. Mobility values of 1200-1400 cm²/Vsec are typical of heavily tin-doped GaAs (4, 18) grown at cooling rates less than 1°C/min. For the higher cooling rate range, no comparable data are available in print. The increase of $\overline{\mu}$ with decreasing $\overline{n}$ is similar to that given by Sze (19), but weaker than that found by Panish (4) with various liquidus compositions of Sn. This can be attributed to a decreasing compensation ratio with $\overline{n}$ or the growth rate, as shown in Fig. 2.

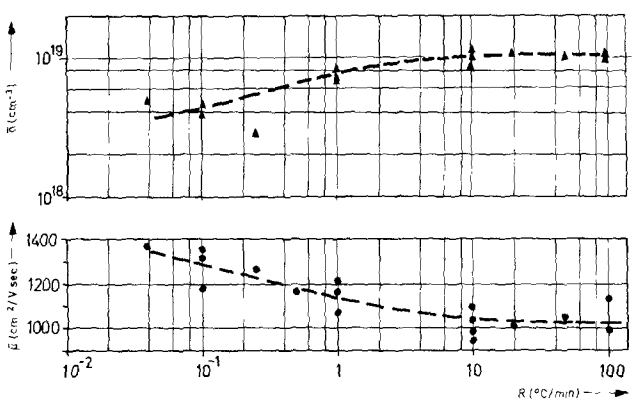

Fig. 1. Average carrier concentration $\overline{n}$ and average carrier mobility at room temperature of several heavily Sn-doped GaAs layers, grown at different cooling rates R.

With the Van Der Pauw data of Fig. 1, the average donor and acceptor concentrations are calculated. As the cooling rate is a process specific parameter only, it is better to use the growth-specific parameter; the average growth rate $\overline{V}$. $\overline{N}_D$, $\overline{N}_A$, and $\overline{N}_A/\overline{N}_D$ are drawn *vs.* the average growth rate $\overline{V}$ in Fig. 2, now showing the uncertainty of the measurements. In spite of a scatter in the experimental data, a significantly steeper increase of $\overline{N}_D$ than $\overline{N}_A$ is observed at slow growth rates. This results in a decreasing compensation ratio with increasing growth rate.

A growth rate dependence can be caused by the redistribution of dissolved Sn in the melt in front of the growing interface because of its small segregation coefficient ($\approx 10^{-4}$). To avoid this effect, $V \cdot L/D_{Sn(m)} < 10^{-1}$ has to be fulfilled (2). This is best guaranteed by the self-diffusion of tin $D_{Sn(m)} \geq 10^{-4}$ cm²/sec (20), the measured epitaxial layers $L < 20$ μm, and growth rates $\overline{V} < 40$ μm/min.

Another possible way of describing a growth rate dependence follows from the surface equilibrium theory. It can be explained qualitatively with the scheme in Fig. 3: in case of surface equilibrium the donor concentration is a function of the electron concentration n_S in the thin surface layer. According to the Schottky theory, n_S depends on the barrier height Φ_{Bn} and the temperature T. It amounts to a varying donor concentration with the parameter Φ_{Bn}/kT at fast growth rates or high ratios of growth rate and diffusion constant (see Fig. 3). For slow rates,

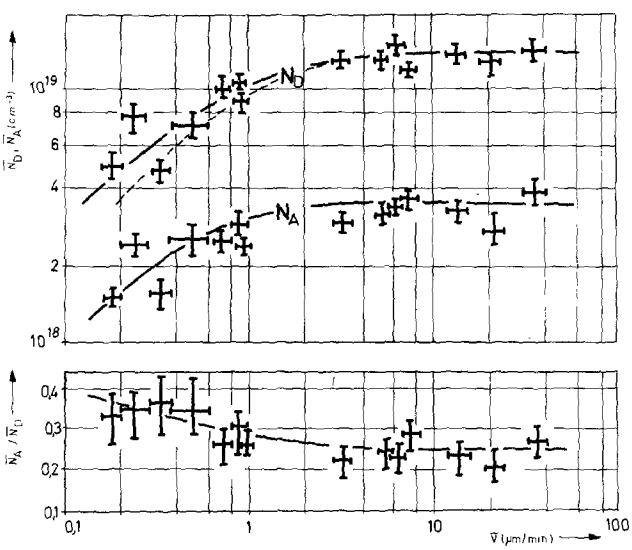

Fig. 2. + Experimental average data $\overline{N}_D$ or $\overline{N}_A$ or $\overline{N}_A/\overline{N}_D$ vs. average growth rate $\overline{V}$. —— Theoretical curves N_D or N_A or N_A/N_D vs. constant growth rate V. Parameter $\Phi_{Bn}(650°C) = 0.51$ eV for donors and $\Phi_{Bp}(650°C) = 0.61$ eV for acceptors at low concentrations. A concentration-dependent barrier lowering is taken into account (*cf.* Table I). Fitting parameter; $\overline{N}_{D/A}$ ($\overline{V} > 6$ μm/min) and $D_{Sn\,D/A} = 3 \cdot 10^{-14}$ cm²/sec. – – – – Theoretical curve $N_D(V)$, to demonstrate the sensitivity of the theory for a larger barrier height $\Phi_{Bn}(650°C) = 0.61$ eV or a 0.1 eV smaller barrier lowering.

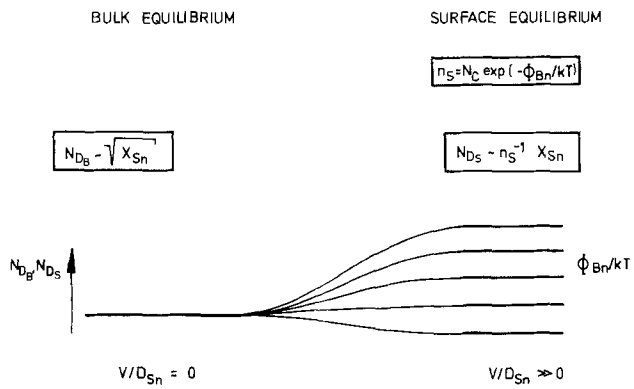

Fig. 3. Scheme for qualitative explanation of the growth rate dependence of the concentration using bulk equilibrium ($V/D_{Sn} \approx 0$) and surface equilibrium ($V/D_{Sn} >> 0$).

on the other hand, in the case of bulk equilibrium such dependence does not exist. Then such transitions as drawn for intermediate V/D_{Sn} values will certainly be possible. Zschauer and Vogel (2) have formulated the corresponding theoretical relationship between impurity concentration N_D, N_A, or in the case of an amphoteric impurity ($N_D + N_A$) and a temporal constant growth rate, on the premises of an intrinsic semiconductor at the epitaxial process temperature. These equations have been derived by Zschauer for donors on Ga and acceptors on As vacancies. In the case of Sn it is not considered that the Sn acceptor is likely to have the more complex structure $Sn_{As}2V_{Ga}$.

For Sn, Zschauer's equation of ($N_D + N_A$) ought to be applicable. Nevertheless, it would be better to regard the growth rate dependence of N_D and N_A separately; by this it is avoided that a characteristic slope of N_A (*cf.* Fig. 2) disappears in the experimental uncertainties of the slope of ($N_D + N_A$). In this case, no mutual influence of donors and acceptors during the incorporation process is assumed. The theory, originally valid for low doping, is modified for heavy doping studied here. The concentration dependence of some properties has to be taken into account (*cf.* Appendix I).

The computation with the equations of Zschauer and Vogel modified with respect to heavy doping, details of which are described in Appendix I, results in the growth rate dependence of donors and acceptors plotted in Fig. 2. (solid and dashed curves). The different slopes of the experimental $\overline{N_D}$ and $\overline{N_A}$ can be fitted by the theoretical curves for N_D and N_A. Consequently, the theory agrees with the increasing compensation ratio at decreasing growth rate (Fig. 2). Satisfactory explanation of the experimental $\overline{N_D}$ and $\overline{N_A}$ by independent theoretical equations points to a separate incorporation of donors and acceptors during the epitaxial growth process.

The fitting parameters for the calculated growth rate dependence are the solid diffusion constants D_{SnD} and D_{SnA} for the Sn donor and the Sn acceptor (see Eq. [1] in Appendix I). The same value for D_{SnD} and D_{SnA} has been found by the fitting. With $3 \cdot 10^{-14}$ cm²/sec, the diffusion constants are relatively large compared with data at 650°C in older literature (21). But new measurements by Peart (22) yield a Sn solid diffusion constant between 10^{-13} and 10^{-14} cm²/sec in the temperature range of 650°-750°C. This confirms the validity of the fitting.

The established growth rate dependence of the concentration does not indicate the transition to constant concentration at slow growth rates (compare Fig. 2 and 3). The bulk equilibrium in this case is not reached before approximately 0.02 μm/min, as it is calculated theoretically. Strictly speaking, the surface equilibrium ($N_{D/A}$ = constant at fast growth rates) is valid only for growth rates above 6 μm/min (Fig. 2), but because of the extended transition region up to bulk equilibrium, it is approximately applicable for some slower growth rates, too.

The transition region is changed at lower doped layers. The equations of Zschauer and Vogel can then be used in their unmodified form. As Zschauer stated, the surface equilibrium theory ought to be applicable for growth rates which fulfil $V/D_{SnD/A} \cdot \lambda_i > 10$ (λ_i intrinsic reciprocal Debye length). Using the fitting parameter D_{SnD} of this work, it is estimated that in the case of low doping the Sn incorporation ought to follow from the surface equilibrium theory already for growth rates above 0.7 μm/min. A possible concentration dependence of the diffusion constant has not been considered. The decrease of the concentration in the transition between surface equilibrium and bulk equilibrium is also much weaker in the case of intrinsic-doped layers. Probably this is the reason why the growth rate influence established for heavily Sn-doped layers has not yet been observed in the case of low-doped layers.

It should be emphasized that the theoretical relationship between temporal constant growth rate V (presumption of Zschauer's equations) and the concentrations $N_{D/A}$ has been compared with the corresponding experimental relationship $\overline{N}_{D/A}(\overline{V})$ for average properties. Strictly speaking this is correct for completely constant doping and mobility within the layer. But this is not valid here because of the established growth rate dependence of concentration and mobility (Fig. 1, 2) and a temporal varying growth rate during the LPE process with a supersaturated melt. In the ideal case of constant profiles, the experiments would have yielded a similar structure, but shifted to faster growth rates and higher concentrations. In addition, the concentration profiles are slightly influenced by the respective process temperature during extended cooling periods, especially at fast cooling rates. To eliminate this effect a constant growth temperature has to be assumed. It is estimated that for this ideal case the expected concentration at fast cooling rates would only be 15% above the experimental value established. For these reasons, the comparison between theory and experiment may be regarded as a first approximation only.

Temperature dependence of the Sn concentration.— The relation between N_D, N_A, and the atomic fraction of tin in the melt X_{Sn} can be described using the surface equilibrium theory at different temperatures above 700°C (4). In this section, however, the temperature dependence $N_{D/A}(T)$ at large X_{Sn} data is deduced. The respective working points for each temperature considered are then positioned on the quasi-binary Sn-GaAs cut of the ternary phase diagram. Experimental data $\overline{N_D}$, $\overline{N_A}$ are compared with the ones expected at surface and bulk equilibrium to examine the validity of the surface equilibrium theory for the heavily Sn-doped layers reported here. All the temperature-dependent values have to be considered, partly computed and partly from literature, while in the case of the $N_{D/A}(X_{Sn})$ dependence, most of the temperature-dependent properties can be comprehended in a normalization constant at each temperature considered (4).

For both possible incorporation theories, surface and bulk equilibrium (S.EQ. and B.EQ.), the theoretically expected concentrations for the Sn donor on Ga vacancies and the Sn acceptor [which is possibly the complex Sn_{As} $2V_{Ga}$ (4)] are plotted in Fig. 4. The essential steps for its calculation are presented in Appendix II. N_D and N_A are normalized on the established concentrations $\overline{N_D}$ or $\overline{N_A}$ at the lowest experimental temperature T_i = 843°K. In the case of surface equilibrium (S.EQ.), an increase in N_D of about 70% is expected. In the case of bulk equilibrium (B.EQ.) a more distinct temperature dependence between 843° and 983°K with an increase of about 400% is estimated.

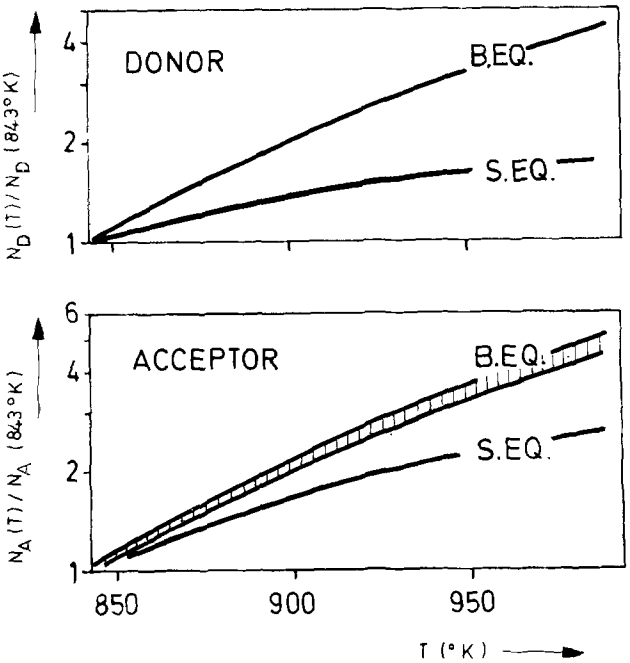

Fig. 4. Semiquantitative computation of the temperature dependence for the Sn donor and the Sn acceptor, normalized at the lowest experimental concentration $\bar{N}_{D/A}$(843°K). B.EQ.: curve for bulk equilibrium; S.EQ.: curve for surface equilibrium.

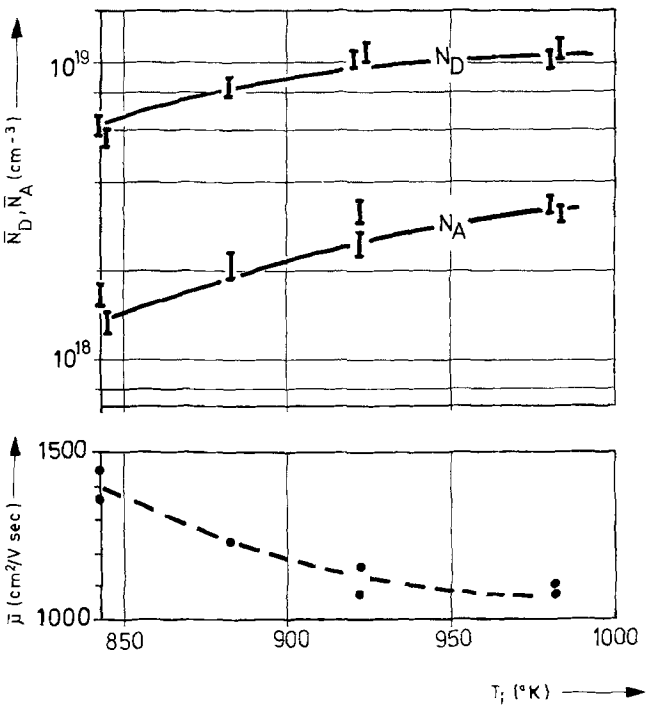

Fig. 5. I Experimental average concentrations $\bar{N}_D$ and $\bar{N}_A$, and ● experimental average mobility vs. process temperature T_i. —— Theoretical curves for N_D and N_A in the case of surface equilibrium.

For the acceptor concentrations calculated with bulk equilibrium, the shaded area has to be plotted in Fig. 4 because of an uncertainty in the transition of the hole activity coefficient between unity and the calculated values at high concentrations (*cf.* Table II in Appendix II). Comparing the curves S.EQ. and B.EQ., a steeper slope was found for the bulk equilibrium both for the donor and for the acceptor.

Experiments at several process temperatures T_i for high Sn contents in melt and solid, for which the calculations are made, are carried out. The layers have been grown at approximately the same growth rate to avoid the influence of different growth rates on the concentrations (see Experimental section). The average donor and acceptor concentration $\bar{N}_D$, $\bar{N}_A$, and the average mobility $\bar{\mu}$ in the range 843°-983°K are shown in Fig. 5. The experimental concentrations are compared with the respectively calculated concentrations in the case of surface equilibrium, as shown in Fig. 4 (solid curves in Fig. 5). Considerable agreement with the temperature behavior expected can then be established. The curves B.EQ. of Fig. 4 instead would be too steep to fit the experiments. According to these experiments at several temperatures, it can be concluded that the bulk equilibrium cannot be responsible for the incorporation of Sn. This conclusion is consistent with the results of $N_{D/A}$ (X_{Sn}) experiments by Panish (4).

As the experimental compensation ratio $\bar{N}_A/\bar{N}_D$ increases, the average Hall mobility decreases with temperature. The measured value of $\bar{N}_A/\bar{N}_D = 0.32$ at 983°K agrees with the one Panish applied to his $N_A(X_{Sn})$ calculations at 973° and 1073°K. According to the increase of the compensation ratio with temperature dealt with in this paper, however, at 1073°K a larger compensation ratio ought to be better. The above values for the compensation ratio may be used for cooling rates of approximately 1°C/min. Otherwise, the cooling rate or growth rate dependence, shown in Fig. 2, has to be considered. The above statements of the compensation ratio reported at high atomic fractions of Sn in the melt should be approximately valid for lower doping, too, if one considers the theoretical results of thermodynamic calculations that the X_{Sn} dependence of N_A is similar to that of N_D and therefore the compensation ratio is independent of X_{Sn}. This is only approximately correct. Regarding the donor and acceptor concentrations found at large X_{Sn} values, different barrier lowerings for donors and acceptors are to be expected which result in different slopes of $N_D(X_{Sn})$ and $N_A(X_{Sn})$ (10). Therefore, the experimental compensation ratio can change slightly in the upper X_{Sn} range.

Summary

The behavior of the concentrations $\bar{N}_D$ and $\bar{N}_A$ for heavily Sn-doped layers indicates the transition region between surface equilibrium and bulk equilibrium, *i.e.*, between fast and slow growth rates of the LPE layers. Donor and acceptor seem not to interact. The increase of the experimental concentrations with the epitaxial process temperature could be explained by surface equilibrium only, in spite of relatively slow average growth rates $\bar{V} \approx 0.6$ μm/min in this kind of experiment. Surface equilibrium, consequently, ought to be applicable for most of the reported epitaxial layers. The barrier height of the system melt-solid is an important property. Attention is drawn to an additional influence of barrier lowering in the high concentration range.

Acknowledgments

I am indebted to Dr. K. Heime for many valuable discussions. I am grateful to Dr. K. H. Zschauer (Siemens, Munic) for suggesting that his calculations might be applicable and for stimulating discussions. I wish to thank A. Dierick for computer programming. APPENDIX I

Details of the semiquantitative computation process for the growth rate dependence with heavy Sn doping and the important parameters tabulated are presented. No interdependence of donors and acceptors during the incorporation process is presumed. This allows the separate consideration of the carriers in the solid.

The growth rate dependence of donors and acceptors $N_{D/A}(V)$ normalized at very slow growth rates $N_{D/A}(V \approx 0)$ were formulated by Zschauer and Vogel for an intrinsic semiconductor

$$\frac{N_{D/A}(V)}{N_{D/A}(V \approx 0)} = \frac{D_{Sn\,D/A}}{V}\left[\int_0^\infty \exp(\mp \psi_{D/A}[l]) \exp\left(-\frac{V}{D_{Sn\,D/A}}\right) dl\right]^{-1} \quad [A\text{-}1]$$

The minus sign stands for donors and the plus sign for acceptors ($l = 0$ the moving interface between melt and semiconductor; dl, differential layer increase; $D_{Sn\,D/A}$, solid diffusion of the donor and acceptor Sn). $\psi_{D/A}[l]$ represents the normalized potentials of the Schottky barrier, only temperature dependent. It contains the intrinsic reciprocal Debye length and the built-in potential.

In heavy doping, however, the concentration dependence of some properties has to be taken into account; the "quadratic" approximation for the Schottky barrier potential

$$\psi_{D/A}(l) = \pm 0.5([2\psi_{D/A}(l=0)]^{1/2} - \lambda_{D/A} l)^2 \quad [A\text{-}2]$$

and the built-in potentials

$$kT\,\psi_{oD} = kT\,\psi_D(l=0) = (\Phi_{Bn} - \Delta\Phi_n) - (E_G - E_{FD})$$
$$kT\,\psi_{oA} = kT\,\psi_A(l=0) = E_{FA} - (\Phi_{Bp} - \Delta\Phi_p) \quad [A\text{-}3]$$

have to be used now (E_G, bandgap), with the concentration-dependent reciprocal Debye lengths $\lambda_{D/A}$ and the Fermi levels E_{FD} (N_D) and E_{FA} (N_A.) The important parameters are the barrier heights Φ_{Bn}, Φ_{Bp} of donors and acceptors. The currently available room temperature barrier height $\Phi_{Bn} = 0.83$ eV for Sn on GaAs (19, 23) seems to be a satisfactory approach for the experimental situation of a Sn-GaAs melt containing 92 atomic percent (a/o) of Sn. The respective barrier heights at the process temperature $T = 923$°K are evaluated with (18, 24)

$$E_G(T) = \Phi_{Bn}(T) + \Phi_{Bp}(T) \quad \text{and}$$
$$E_G(T) - \Phi_{Bn}(T) = \text{constant} \quad [A\text{-}4]$$

i.e., the position of the Fermi level at the surface remains at a fixed energy above the valence band as the temperature varies. The above assumptions that the barrier heights are only metal and temperature dependent is correct for low solid concentrations. In the concentration range of this work, a barrier lowering probably due to a dipole layer at the interface between metal and semiconductor ought to be considered as well for donors ($\Delta\Phi_n$) as for acceptors ($\Delta\Phi_p$). Calculations of Crowell *et al.* (25) for n-Si Schottky diodes lead to a constant barrier height up to a doping level of approximately 10^{16} cm^{-3}, and a decrease of 0.23 eV at $N_D = 10^{18}$ cm^{-3} or 0.33 eV at $N_D = 10^{19}$ cm^{-3}. But these authors also feel that the calculated falling off at large N_D is too rapid. For GaAs Schottky diodes, however, such a distinct concentration dependence is not expected because of a larger density of surface states compared with Si. There are some hints for quantitative values of the Sn barrier heights (10), as already mentioned in the introductory section of this work.

Due to the $N_{D/A}$ dependence of $\lambda_{D/A}$, $E_{F\,D/A}$ and $\Delta\Phi_{n/p}$ at heavy doping, a semiquantitative calculation is performed. According to Eq. [1], [2], and [3], the growth rate dependence is computed for a lot of values of N_D or N_A, respectively (for several concentrations the values used in the calculation are presented in Table I). The highest concentrations, the computations of which are made, are the characteristic experimental data at fast growth rates $N_{D/A}(V > 6\ \mu$m/min) (see Fig. 2). Each curve of the calculated family is presumed to be approximately valid in a small concentration range around the respective values of $N_{D/A}$. A graphical approximation follows. This procedure results in the solid and dashed curves of Fig. 2, evaluated now having taken into account the concentration dependence of all parameters.

APPENDIX II

The important equations for calculating the temperature dependence of the donor and the acceptor concentration with heavy Sn doping (N_D and N_A) and the temperature dependent properties tabulated are shown. The donor on Ga vacancies can be calculated in the case of surface equilibrium with

$$N_{DS} = A_{DS}\,X_{Sn}\,n_S^{-1}\,\gamma_n^{-1} \quad [A\text{-}5]$$

and in the case of bulk equilibrium with

$$N_{DB} = \left(\gamma_n^{-1}\left(1 + \frac{n_i^2}{A_{DB}\,X_{Sn}}\right) A_{DB}\,X_{Sn}\right)^{1/2} \quad [A\text{-}6]$$

Each property depends on the temperature (see Table II). A_{DS} and A_{DB} are the product of the mass-action constant K, the As activity $\gamma_{As}X_{As}$, the activity constant γ_{Sn}, as well as the normalization constants K_{DS} and K_{DB} for surface and bulk equilibrium. K_{DS} and K_{DB} contain a factor, usually temperature dependent, between the atomic fraction of the liquid and the concentration of the solid, that is essentially the segregation coefficient. But in the case of high Sn concentrations in melt and semiconductor the segregation coefficient was found to be approximately independent of the process temperature in the low temperature range (15). This corresponds to theoretical calculations of the segregation coefficient by Stringfellow (26). The normalization constant is evaluated with the lowest experimental concentration $\overline{N_D}$ (843°K). The temperature-dependent properties γ_{As}, γ_{Sn}, X_{As}, and X_{Sn} are determined by the working points on the quasibinary Sn-GaAs cut of the ternary phase diagram (27), where heavily Sn-doped solids are concerned. The other temperature-dependent data, the Schottky barrier concentration

$$n_S = N_C \exp\left[(\Phi_{Bn} - \Delta\Phi_n)/kT\right] \quad [7]$$

including the conduction band concentration N_C and the barrier height Φ_{Bn}, the intrinsic concentration n_i, and the activity coefficient of the electrons γ_n (which is a function of n_S/N_C with surface, or N_{DB}/N_V with bulk, equilibrium), have been computed using published data (19, 23, 28, 29). (As to the concentration dependent barrier lowering $\Delta\Phi_n$, see Appendix 1 and Table II.)

Equations similar to [5], [6], and [7] are used for the Sn acceptor, which is possibly the complex Sn_{As} $2V_{Ga}$. As Panish stated (4), both equations for the donor can be used for the respective acceptor concentrations N_{AS} and N_{AB}; only N_C is substituted by N_V, Φ_{Bn} by Φ_{Bp}, γ_n by γ_p, besides the normalization constants $K_{DS/B}$ by $K_{AS/B}$. Taking into account Eq. [4] of Appendix I, the barrier height for the acceptor in GaAs is found to be independent of temperature. A small barrier lowering $\Delta\Phi_p$, the value of which depends on the respective acceptor concentration N_A in the bulk of the solid, is used. There are some suggestions of a barrier lowering for acceptors with the same value as the one for donors at corresponding concentrations (10).

The properties $\Delta\Phi_n$, $\Delta\Phi_p$, and γ_n, γ_p on the right side of Eq. [5], [6], and [7], and the respective ones for the acceptor depend on the bulk concentrations $N_{DS/B}$ or $N_{AS/B}$. This allows a semiquantitative calculation only. Starting from the properties obtained with the experimentally established bulk concentrations at the normalization temperature 843°K, an iterative calculation for the temperatures considered yields to the parameters listed in Table II and the theoretical concentrations plotted in Fig. 4.

LIST OF SYMBOLS

A_{DS}, A_{DB} constants in the case of surface, bulk equilibrium incorporation
D, A symbols for donors, acceptors
$D_{Sn}, D_{Sn\ D/A}, D_{Sn\ D}, D_{Sn\ A}$ diffusion constants of Sn in the solid (cm^2/sec)
$D_{Sn(m)}$ diffusion constant of Sn in the melt (cm^2/sec)
$E_{F\ D/A}, E_{FD}, E_{FA}, E_F(N_D), E_F(N_A)$ Fermi level of donors, acceptors (eV)
E_G bandgap energy (eV)
k Boltzmann constant
K mass-action constant
$K_{D\ S/B}, K_{DS}, K_{DB}, K_{A\ S/B}$ normalization constants of surface, bulk equilibrium for donors, acceptors
l direction into substrate or LPE layer (μm)
L total epitaxial layer thickness (μm)
$\overline{n}$ experimental average carrier concentration of a layer (cm^{-3})
n_i intrinsic concentration (cm^{-3})
n_S electron concentration in the Schottky surface (cm^{-3})
$N_{D/A}, N_D, N_A$ theoretical donor, acceptor concentrations (cm^{-3})
$N_{D\ S/B}, N_{DS}, N_{DB}, N_{A\ S/B}, N_{AS}, N_{AB}$ theoretical donor, acceptor concentrations in the case of surface, bulk equilibrium (cm^{-3})
$\overline{N}_{D/A}, \overline{N}_D, \overline{N}_A$ experimental average donor, acceptor concentrations (cm^{-3})
N_C, N_V effective concentration of states in conduction, valence band (cm^{-3})
p_S hole concentration in the Schottky surface (cm^{-3})
R cooling rate of the LPE process (°C/min)
t growth time of a LPE layer (min)
T, T_i temperature, initial process temperature (°K)
V momentary growth rate (μm/min)
$\overline{V}$ average growth rate of a LPE layer (μm/min)
X_{As}, X_{Sn} atomic fraction of arsen, tin in the melt (at. fr.)
γ_{As}, γ_{Sn} activity coefficients of arsen, tin
γ_n, γ_p activity coefficients of electrons, holes
$\Delta\Phi_n, \Delta\Phi_p$ barrier lowering of Φ_{Bn}, Φ_{Bp} (eV)
$\lambda_{D/A}, \lambda_D, \lambda_A$ reciprocal Debye length of donors, acceptors (cm^{-1})
λ_i intrinsic reciprocal Debye length (cm^{-1})
$\overline{\mu}$ average mobility of a LPE layer (cm^2/V sec)
μ_u mobility of uncompensated GaAs (cm^2/V sec)
$\Phi_{Bn/p}, \Phi_{Bn}, \Phi_{Bp}$ barrier height of donors, acceptors (eV)
$\psi_{D/A}, \psi_D, \psi_A$ normalized Schottky barrier potential of donors, acceptors (eV)
ψ_{oD}, ψ_{oA} normalized built-in potential of donors, acceptors (eV)

Silicon Nitride Coatings on Molybdenum by RF Reactive Ion Plating

Masao Fukutomi, Masahiro Kitajima, Masatoshi Okada, and Ryoji Watanabe

National Research Institute for Metals, 2-3-12, Nakameguro, Meguroku, Tokyo, Japan

ABSTRACT

Rf reactive ion plating technique has been applied to the preparation of protective silicon nitride coating on molybdenum. All the deposits prepared at deposition temperature of less than 1000°C were amorphous. Silicon in deposits was found to be present as nitride by Auger electron spectroscopic, infrared absorption spectroscopic, and x-ray diffraction analyses. Nearly stoichiometric silicon nitride deposits were obtained at a deposition rate of as high as 1 μm/min. Several factors affecting the stoichiometry of the silicon nitride were discussed. Oxidation test of the coated specimens showed that the silicon nitride layer obtained under optimum conditions protected the molybdenum substrate from oxidation in Ar-1% O_2 gas mixtures up to approximately 1200°C. Typical pitting corrosion was observed in the coating film at the higher temperatures.

Silicon nitride films have received much attention especially for applications in the semiconductor industry because of their excellent chemical stability and resistance to diffusion of impurities. Many authors have studied the preparation of silicon nitride films and their structural and electrical properties. Most of the existing studies are, however, mainly concerned with thin films formed by sputtering (1-4) or chemical vapor deposition (5, 6). Little work on the ion-plated silicon nitride film has been reported in the literature except by Chin *et al.* (7), who dealt with the silicon nitride coatings for thermoelectric couples. On the other hand, the applications of molybdenum as a high temperature material are limited by its severe oxidation at temperatures above 800°C. Considerable effort, therefore, has been made to develop various high temperature protective coatings for molybdenum such as metallic, disilicide-based diffusion, and ceramic overlay coatings (8). The present paper describes a preparation technique of silicon nitride by reactive ion-plating, and the structural and compositional characteristics of the film obtained. An attempt to apply this silicon nitride film to the high temperature oxidation resistant coating for molybdenum is also described.

Experimental

Apparatus.—The apparatus shown in Fig. 1 is specially designed for the rf reactive ion plating of silicon nitride. The rf ion-plating technique was basically the same as that described by Murayama (9). The rf coil electrode (7 turns and 10 cm in spiral coil diam) was placed directly above the evaporation source and connected to a 13.56 MHz, 300-VA rf power supply to make a glow discharge region for the ionization and activation of the reactants. The 6 kW electron beam gun has a 180° bent beam whose spot was swept over the entire source surface for the uniform melt and evaporation rate. The vacuum chamber is separated by the conductance baffle to maintain pressures of less than 10^{-3} Torr around the EB gun, while pressures are as high as 2×10^{-2} Torr in the deposition side. The substrate holder was constructed such that a bias from 0 to −3 kV d.c. could be applied to the substrate for the acceleration of ionized particles toward it. The source-to-substrate distance was approximately 14 cm for all experiments. The substrate was heated by radiation from a tantalum resistance heater to a desired temperature between 400° and 1000°C. The temperature was measured with a Chromel-Alumel thermocouple placed in contact with the back side of the substrate. Gas pressure was measured with a Schulz-Phelps and a Bayard-Alpert ionization gauge and controlled to a desired level by a high vacuum leak valve.

Evaporation source, substrate, and reactive gas.—Semiconductor-grade silicon was used as the evaporation source. Substrate for deposition was prepared from sintered molybdenum sheet and electrochemically polished prior to mounting on the substrate holder. The source for nitrogen was ammonia, supplied by Mathieson Gas Products with a purity of 99.99%. The ultrahigh purity argon was also used for the sputter cleaning of substrate.

Coating procedures.—In a typical coating experiment, the vacuum chamber was evacuated to approximately 5×10^{-6} Torr or lower. Prior to each deposi-

tion, the substrate was sputter cleaned for about 10 min under argon pressure of 2×10^{-2} Torr. As for the evaporation of silicon, uncontrolled splatting of the silicon frequently occurred during melting even after the electron beam power inputs were limited to a low enough level. The same trouble was already reported by Chin *et al.* (7). After examining the vaporization technique, we found that silicon was vaporized significantly without any splatting when it was melted together with several pieces of tantalum sheet. Emission spectroscopic analysis of the deposits obtained by this technique showed traces of tantalum in the film deposited around the crucible but not in the deposited film on the substrate. This is probably due to the very low vapor pressure of tantalum compared with that of silicon. After initiating the evaporation of silicon, the ammonia gas was introduced into a chamber and the rf power supply was increased until a steady glow was observed in the chamber. No apparent changes in the deposited film were observed depending upon the distance between the outlet of ammonia gas feed pipe and the substrate. The shutter was then opened to begin the deposition of nitride under various conditions as given in Table 1. The coating was 7-10 min for most experiments.

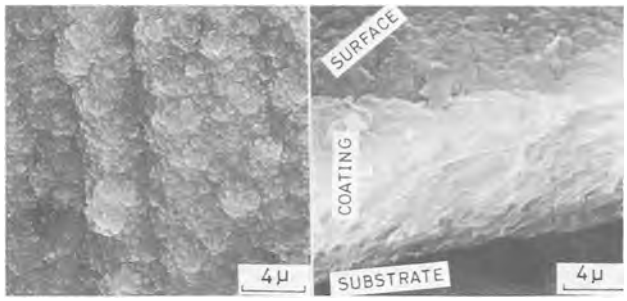

Fig. 2. Scanning electron micrograph of silicon nitride coating (left; coating surface, right; fracture cross section for the same deposit). Deposition rate was 1 μm/min at a substrate temperature of 950°C.

Results

Analysis of ion-plated silicon nitride.—Visual and scanning electron microscopic observations.—The silicon nitride deposits were obtained at a deposition rate of from 0.1 to 1.2 μm/min depending upon the coating conditions. Most deposits showed a dark green color, but some were gray and/or red brown. Figure 2 shows typical scanning electron microphotographs of silicon nitride coatings. Although large primary grains composed of many small grains were observed in the coating surface, no clear grain boundaries in cross-sectional structure were visible. This vitreous structure seems to be characteristic of the deposits obtained in the present work.

Auger electron spectroscopic analysis.—The chemical compositions of the deposited silicon nitride films were determined by means of Auger spectroscopic analysis (Cylindrical Mirror Analyzer, PHI Incorporated). Concentrations were calculated from the peak-to-peak Auger signal height by using relative elemental sensitivity factors given in the literature (10). Table I summarizes the chemical composition representative of the various deposits together with their coating conditions. For comparison, electron probe microanalysis (EMX-SM Shimazu Seisakusho, Limited) was also carried out by using BN as the standard sample for nitrogen. The results are also shown in parentheses in Table I. In certain cases, the results show considerable discrepancy between the two. This can be considered due to the difficulty of quantitative analysis of nitrogen in thin film by electron probe microanalyzer. As for the effect of the deposition temperature, no apparent composition changes in the film were observed in the temperature range from 400° to 1000°C. Nitrogen contents in the film varied over a wide range depending upon the deposition conditions. It should be noted that nearly stoichiometric deposits were obtained in runs 73, 76, and 78, in which silicon was vaporized with EB gun power of about 2 kW under reactant gas pressure of as high as 10^{-2} Torr. Further discussions on this point are made later. Oxygen and carbon were prominent con-

taminants in these deposits. Presumably, they come from the impurities in the reactant gas. As the formation of nearly stoichiometric silicon nitride has been so far ascertained by the compositional data in Table I, the chemical state of silicon in deposits is hereafter examined in some detail. Figure 3 shows an example of Auger spectra for the silicon nitride coatings obtained in this study. After 3 min Ar-sputtering (removing ~300Å), AES signals from silicon and nitrogen increased in intensity, while those from oxygen and carbon became very weak, with an additional peak from argon atoms implanted during sputter cleaning. A detailed comparison of our Auger electron spectra with published data (10-12) revealed that the chemical shift and Auger electron peak shape from silicon in the spectra given in Fig. 3 are completely different from those of elemental Si and SiO_2, but showed a significant agreement with those from silicon in Si_3N_4 and in $Si_{0.54}N_{0.46}$ (10, 12).

Infrared spectroscopic analysis.—Infrared absorption of the deposits was measured by using a double-beam spectrophotometer (JASCO A-3, Japan Spectroscopic Company Limited). The silicon nitride layer removed from the molybdenum substrate was ground to micro-size with potassium bromide and the mixture was pressed into a pellet. In a typical infrared absorption profile shown in Fig. 4, a strong, broad band with its center at 830 cm^{-1} was observed and was identical with the Si-N stretching band reported by many other investigators (1-3, 5). The very weak absorption peaks for N-H and Si-H also were discernible. This hydrogen contamination seems to come from ammonia gas used.

X-ray analysis.—In the as-coated condition, all the coatings obtained in this study proved to be amorphous because no peaks except for the molybdenum substrate were obtained. For further confirmation of the formation of silicon nitride, the coating layer removed mechanically from the substrate was heat-treated at 1400° and 1500°C for about 2 min under 10^{-6} Torr. This caused the crystallization of amorphous deposits. Figure 5 shows the x-ray diffraction profile obtained with Ni-filtered CuKα radiation. All peaks corresponded to those of silicon and Si_xN reported in the ASTM powder diffraction data. The latter substance was originally obtained by Decker (13) together with free silicon when commercial silicon nitride was arc melted. It is obvious from this and previous studies already described that silicon in ion-plated films is present as the nitride. In addition, the deposits were nearly stoichiometric compounds.

Oxidation test of silicon nitride coated molybdenum.—The oxidation resistance of coated specimens was examined by thermogravimeter. Coated specimens of about 1 × 0.5 × 0.07 cm were heated at a rate of 20°C/min in the Ar 1% O_2 gas mixtures with a flow rate of ~200 ml/min. Figure 6 shows the results of oxidation tests for typical coated specimens. Uncoated specimens which were oxidized under the same conditions show a drastic weight decrease at about 790°C. This is because the MoO_3 formed begins to melt at this temperature and has a high vapor pressure. In this test, the edges of the specimens were painted with Al_2O_3 slurry to protect the cut edges and the film defect in the vicinity of edges in specimens. Observation of specimens after oxidation test, however, showed that film failure ascribed to the unprotected cut edges still existed. The oxidation test profiles shown in Fig. 6, therefore, give a rough estimation for the oxidation resistance of silicon nitride coatings. In the coated specimens which showed a marked decrease in weight at relatively low temperature, typical pitting corrosion shown in Fig. 7 was observed. On the other hand, the film adherence to the substrate generally plays an important role in

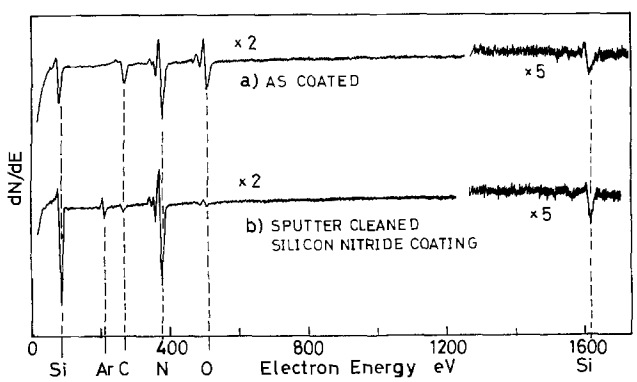

Fig. 3. Auger spectra from a) as coated surface; b) sputter-cleaned surface of silicon nitride coating (Run no. 76).

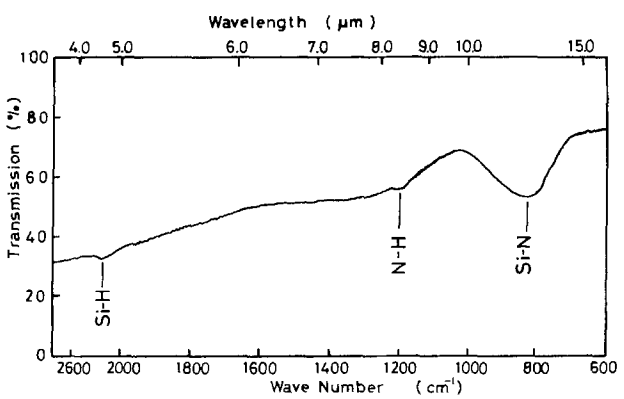

Fig. 4. Typical infrared spectrum of ion-plated silicon nitride film. (Run no. 72), the decrease of transmission in shorter wavelengths is ascribed to the difference in particle size between the sample and KBr reference.

protective coating technology. On this point, silicon nitride layer obtained in this study showed comparatively poor adherence to molybdenum substrate. The bonding was improved to some extent when the substrate was heated during coating. It can still, however, be removed by bending the specimens, even though not as easily as in specimens obtained without the substrate heating. Further investigations concerning the pitting corrosion and the film adherence are needed to obtain more protective silicon nitride coatings for molybdenum.

Discussion

Table I indicates that the ion-plated films vary considerably in their chemical composition, depending upon the coating conditions. For the purpose of examining the several factors affecting the stoichiometry of deposits, another ion-plating experiment was undertaken using a long strip-shaped molybdenum substrate. As shown schematically in Fig. 8, the substrate length is large enough compared with the diameter of rf coil. Evaporation rates of silicon were varied from 0.07 to 0.3 g/min. After the coating experiment, silicon nitride deposits from three different places on the substrate were analyzed by Auger electron spectroscopy. The atomic ratio between silicon and nitrogen in the deposits and the coating thickness measured by scanning electron microscopy are summarized in Table II. A, B, and C in Table II correspond to the three places on the substrate, *i.e.*, directly above the center, close to, and outside of the rf coil, respectively. In each run, as the deposition site was moved closer to the center of the rf coil, namely site A, a smaller value of Si/N was obtained and the deposit became nearly stoichiometric. This is probably because the concentration of ionized reactants is largest in the center of rf coil. On the other hand, when the EB gun power input was increased to as high as 1.8 kW, the deposition rate noticeably increased. Furthermore, the film became close to stoichiometric silicon nitride. This result is consistent with those of run 73 and 76 in Table I. This high rate deposition of nearly stoichiometric silicon nitride can be attributed to the fact that the power of EB gun as well as that of rf discharge is highly effective for the ionization or activation of reactants. The advantage of the use of electron beam evaporation technique for ion plating which was introduced by Chambers and Carmichael (14) has been pointed out by other investigators too (15, 16). From the fact mentioned above, it is concluded that nearly stoichiometric silicon nitride can be ion plated with a rather high speed, as long as the reactants are sufficiently ionized or activated.

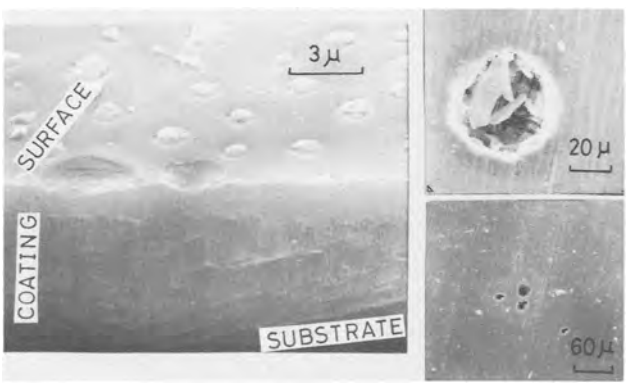

Fig. 7. Scanning electron microphotograph of typical film failure after oxidation test.

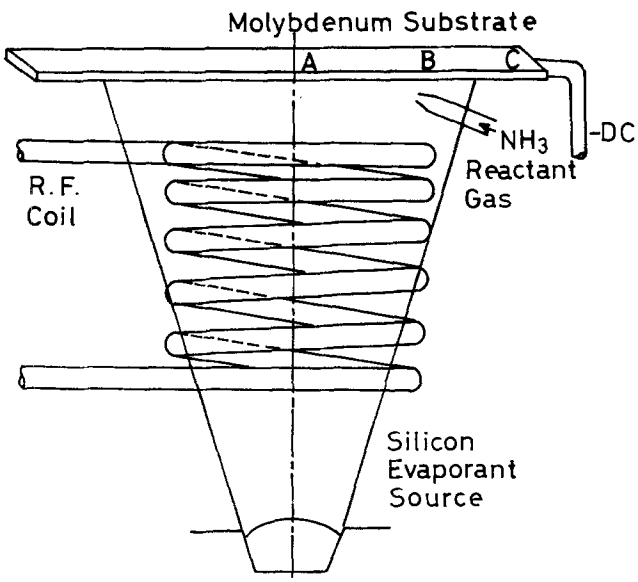

Fig. 8. Schematic illustration of ion-plating experiment using a long strip-shaped substrate.

Conclusions

Nearly stoichiometric silicon nitride coatings on molybdenum can be prepared by rf reactive ion plating from Si and NH_3. The most important factors affecting the stoichiometry of the deposit seemed to be an electron beam power into the Si evaporation source and the condition of rf glow discharge region, where most of the ionized or activated species of the reactants might be produced. The oxidation tests performed on coated specimens showed that the silicon nitride layer restrained the oxidation of molybdenum up to approximately 1200°C, but typical pitting-like failure in the deposited film occurred at the higher temperature.

Precipitation-Induced Currents and Generation-Recombination Currents in Intentionally Contaminated Silicon P^+N Junctions

H. H. Busta[1] and H. A. Waggener

Teletype Corporation, Skokie, Illinois 60076

ABSTRACT

The effects of impurities such as gold, iron, copper, nickel, tantalum, and tungsten on junction reverse *I-V* characteristics were investigated using DLTS (deep level transient spectroscopy), TSCAP (thermally stimulated capacitance), *I-V*, *C-V*, and *I-T* measurements. In almost all cases, the reverse *I-V* characteristics consisted of two components; a normal Shockley-Read-Hall (SRH) generation component and a soft leakage component which dominates the SRH component above a given onset voltage. Only the SRH component can be detected with the DLTS and TSCAP methods. The soft leakage currents were ascribed to the presence of impurity precipitates lying near the metallurgical junction of the devices. Soft leakage currents measured at 80°K were fitted to a Fowler-Nordheim field-emission model. Localized electric field values near the precipitates of the order of 10^6-10^7 V/cm were obtained by this analysis. These values could be correlated with the possible shape of the precipitates. The distribution of the SRH generation centers within the active regions of the devices and the activation energies of the emission rates of above-mentioned impurities were measured using the DLTS technique. The following results were obtained: Au 0.55 eV (c), Fe 0.57 eV (c); Cu 0.2 eV (c), 0.49 eV (*v*), 0.41 eV (*v*); Ni 0.19 eV (c), 0.36 eV (c); Ta 0.21 eV (c); and W 0.25 eV (c), 0.28 eV (c), respectively. Here c and *v* represent measurements from the conduction band and valence band, respectively.

It is well known that point defects distributed in the bulk or at the surface of pn junctions can act as generation centers for electron-hole pairs and thus cause diode leakage. These defects can be process-induced defects, dislocations, radiation-induced defects, or impurities such as gold, iron, copper, manganese, nickel, sulfur, etc. They are characterized by activation energies which lie within the forbidden bandgap of the semiconductor, and by their thermal capture and emission rates for minority and majority carriers, respectively. Their contribution toward diode leakage is governed by the Shockley-Read-Hall generation-recombination theory (1). The most effective centers, in terms of the generation component, lie near the midgap of the semiconductor.

Detection of these defects can be achieved, for instance, by using thermally stimulated current (TSC) (2, 3) measurements. Identification of a given generation center with the above techniques can be achieved in certain cases. Complications arise due to the fact that for some impurities such as gold, iron, copper, sulfur, manganese, etc., the near midgap energy levels are separated by only a few millielectronvolts, which in terms of temperatures, corresponds to only a few degrees difference in the position of the measurement signals. When using the TSC and TSCAP methods, the position of the signals is strongly dependent on heating rates. Therefore, for identification purposes, these rates have to be known precisely. Lang has recently published a paper on deep level transient spectroscopy (DLTS) measurements (4). The advantage of this method is that it is heating rate independent. For a given fixed emission rate window, the position of the signals occurs at the same temperature. Another advantage of the DLTS method is that it is spectroscopic in nature, which means that it has a zero base line. However, this can also be achieved by using the differential TSCAP method (5)

The intention of this work was to identify leakage mechanisms of some diodes fabricated in our facilities using DLTS, TSCAP, *I-V*, *C-V*, and *I-T* measurements. These measurements were performed on planar diodes, gate-controlled diodes, and MOS capacitors. In the course of this work, some devices with known characteristics (6) were intentionally contaminated with gold, iron, copper, nickel, tantalum, and tungsten. It was found that for gold- and tungsten-doped diodes the generation components increased by three orders of magnitude as compared to the precontamination level. This gave rise to large DLTS signals ($N_t \simeq 10^{14}$ cm^{-3}). The reverse *I-V* characteristics of these diodes were almost ideal over the entire voltage range, with *I* varying as $V^{1/2}$. For all the other elements, the generation components increased only moderately, giving rise to weak DLTS signals ($N_t \simeq 10^{11}$-10^{13} cm^{-3}). However,

[1] Present address: Gould Laboratories, Rolling Meadows, Illinois 60008.

Key words: junction leakage, defects in pn junctions, field emission, tunneling, deep level transient spectroscopy.

these diodes showed soft characteristics. In some extreme cases, the onset of the soft current component occurred at voltages as low as 1V. Goetzberger and Shockley (7) attributed this softness to the formation of metallic precipitates, and conjectured that Zener tunneling at localized high field points was responsible for the observed soft leakage currents. They reported leakage currents proportional to V^n, with n ranging from 3 to 7. However, no attempts were made to explain the exponent n in terms of a physical model.

In this paper, the soft component of leakage current is modeled in two ways and experimental results are compared to these models. First, a tunnel or field-emission model is considered. From analysis of the data, values of the electric field at localized high field spots, information about the shape of the precipitates, and estimates of the local extension of the emission sites are obtained. The information gained from this analysis has to be considered more qualitatively than quantitatively, since the expression used for the tunneling current density is only applicable to direct gap tunneling. In the indirect case, such as silicon, effects due to momentum conservation and multiple band effective masses should be included. Second, the possibility that these currents arise from SRH centers is presented. There are other mechanisms which might explain soft leakage currents. Charge multiplication due to impact ionization at localized areas of high electric fields might be one possibility. The reason why a tunneling approach is chosen in this work is due to the experimentally observed fact that leakage currents have a negative temperature coefficient, *i.e.*, at a given voltage the current increases with increasing temperature. Also, in all cases, a temperature-independent component was observed at liquid nitrogen temperatures. Impact ionization has a positive temperature coefficient, *i.e.*, at a given voltage the ionization rate increases with decreasing temperature (8).

Device Fabrication

The diodes were fabricated using Czochralski-grown n-type (111) wafers having an uncompensated phosphorus concentration of approximately 1×10^{15} cm^{-3}. BN disks were used for the p^+ diffusion. Diodes from different stages during the common p-channel MOS process were used for this experimentation. Before testing, all devices were either nitrogen annealed or forming gas annealed at 450°C in order to reduce the surface component of the leakage.

Before the devices were subjected to the impurity diffusion, reverse I-V control measurements were performed. After appropriate cleaning of the slices, the elements under investigation were either filament or electron beam evaporated on the back of the wafers, and diffused in a nitrogen atmosphere. In most cases, a new quartz furnace tube was used for each element. Diffusion temperatures ranged from 800° to 1150°C.

Experimental Results

Leakage mechanisms.—Figure 1 shows the current-reverse voltage characteristics of two diodes. The measurements of Fig. 1 were taken at room temperature and 80°K, respectively. The room temperature plots consist of two distinct regions: a region where the current varies approximately as $V^{1/2}$, followed by a region of very strong voltage dependence. For both junctions, the leakage currents below the onset of the soft knees are governed by Shockley-Read-Hall generation centers. At low temperatures, these currents decrease, due to the exponential temperature dependence of the electron-emission and hole-emission rates (1, 2). The soft component of diode A is almost temperature independent in the range from 80° to 300°K. Diode B does show some temperature dependence of its soft characteristics, however, measurements showed that from 80° to 130°K this component is also temperature independent. Experimentally, it was observed that for a given impurity, both type A and B behavior were present for

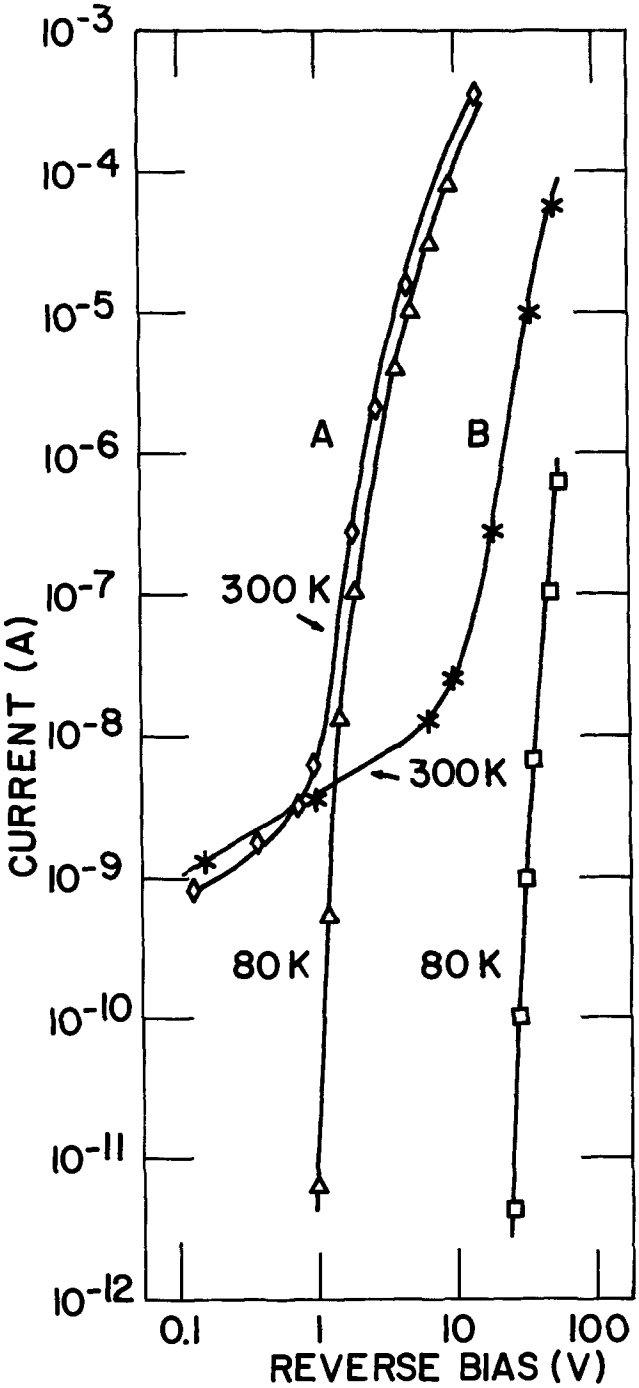

Fig. 1. A: I-V_R characteristics of the tantalum-doped diode C-4 of lot 4521, W-8, chip J-7 measured at 300° and at 80°K, respectively. B: I-V_R characteristics of the tungsten-doped diode C-4 of lot 4521, W-7, chip G-13 measured at 300° and at 80°K, respectively.

a given wafer. Also, the onset voltages of the soft knees varied over wide ranges. In some cases values ranging from 1 to 40V were observed. Due to these reasons, no attempt was made to rank order the influence of the individual impurities upon diode leakage. However, based upon the limited sample size which was investigated, some general comments can be made. Iron, nickel, copper, and tantalum gave rise to the formation of soft diodes with low SRH generation components. The concentrations of generation centers ranged from 10^{11} to 10^{13} cm^{-3}. Tungsten-doped diodes showed softness occurring at voltages of larger than 20V. A large generation component was observed with a concentration of generation centers larger than 10^{14} cm^{-3}. No softness was observed for gold-doped diodes. Their concentration of SRH centers was approximately 10^{14} cm^{-3}. As mentioned, the existence of a temperature-

independent soft leakage component and of a negative-temperature coefficient led to the consideration of a tunnel or field-emission mechanism.,

Tunnel or field emission.—Before discussion of the data, some of the expressions which are used in the analysis of the data are summarized. In this work, only the temperature-independent components of soft leakage currents are analyzed.

The basic law governing field emission is given by the Fowler-Nordheim equation. The current density at temperature $T = 0$ is given by (9)

$$J = \frac{q^3E^2}{16\pi^2\hbar\, q\, \Phi_B t^2(y)} \exp\left(-\frac{4(2m^*)^{1/2}(q\Phi_B)^{3/2}\, v(y)}{3\hbar\, qE}\right) \quad [1a]$$

with t and v being tabulated functions of the argument y, which is given by

$$y = (q^3E)^{1/2}/q\Phi_B \quad [1b]$$

Here E is the applied electric field, $q\Phi_B$ is the barrier height, and m^* is the tunneling effective mass. The function $t(y)$ in Eq. [1a] is almost independent of y. It monotonically increases from 1.00 to 1.11 as y varies from 0 to 1. The barrier-lowering factor $v(y)$ decreases monotonically from 1 to 0 as y varies from 0 to 1. To test if a field-emission process can be used to describe soft leakage currents, the data is plotted in the form $\ln J/E^2$ *vs.* E^{-1} (Fowler-Nordheim plot). A straight line should be obtained, the slope of which is given by

$$-\frac{4(2m^*)^{1/2}\,(q\Phi_B)^{3/2}\, v(y)}{3\hbar\, q}. \quad [2]$$

Near a precipitate it is assumed that the electric field E is enhanced by a factor of β above the unperturbed background field of the junction. A similar assumption was made in Ref. (10), where Fowler-Nordheim field emission from protruding whiskers on nickel cathodes was considered. The electric field is then given by

$$E = \beta E_{\text{unperturbed}} \quad [3]$$

Using the abrupt junction approximation (11)

$$E_{\text{unperturbed}} = E_{\max} = \left(\frac{2qN_D}{\epsilon_s}\right)^{1/2} (V_{bi} + V_R)^{1/2} \quad [4]$$

Here N_D is the donor-doping concentration, ϵ_s is the dielectric constant of the semiconductor, V_{bi} is the built-in voltage, and V_R is the reverse bias voltage. Two further conditions are invoked. It is assumed that one end of the precipitate is located near the maximum field, while the other end of the precipitate extends into the heavily doped region. Therefore, only a small voltage drop can exist between the precipitate and the heavily doped region. With these conditions, the unperturbed field at the tip of the precipitate is the maximum field in the junction, $E_{\max}$. Since under these conditions E is proportional to $(V_{bi} + V_R)^{1/2}$, a Fowler-Nordheim plot should be of the form $\ln J/(V_{bi} + V_R)$ *vs.* $(V_{bi} + V_R)^{-1/2}$ with a slope of

$$-\frac{4(2m^*)^{1/2}\,(q\Phi_B)^{3/2}}{3\hbar\, q\left(\frac{2qN_D}{\epsilon_s}\right)^{1/2}}\,\frac{v(y)}{\beta} \quad [5]$$

By using Eq. [5], it is possible to obtain estimates of the field-enhancement factors at the precipitates. From these values, information about the shape of the precipitates can be deduced.

Since the devices were contaminated with metals, it is assumed that the precipitates are either metallic or in the form of conductive silicides such as CuSi, Ni_2Si, FeSi, $TaSi_2$, WSi_2, etc. Assuming a spherical precipitate imbedded in a dielectric medium, the field inside the sphere is zero; the field outside the sphere is given by (12)

$$\hat{E}(r, \theta) = E(1 + 2a^3/r^3)\cos\theta\hat{r} - E(1 - a^3/r^3)\sin\theta\hat{\theta} \quad [6]$$

Here E is the uniform background field, a is the radius of the sphere, r and θ are the polar coordinates, and $\hat{r}$ and $\hat{\theta}$ are the unit vectors. For $r = a$ and $\theta = 0$, $\hat{E}(a, 0) = 3E$. This means that the field-enhancement factor at the precipitate has a value of 3. As can be seen from Eq. [6] the field-enhancement factor has a strong spatial dependence. In the case of a conducting prolate spheroidal-shaped precipitate, the field-enhancement factor depends strongly on the c/b ratio (10). Here c is the extension of the precipitate in the direction of the field, and b is the diameter. For $c/b = 1$, β reduces to 3, the value of the field-enhancement factor for a sphere. It should be mentioned that field enhancement also occurs for noncontacting precipitates. For instance, the field enhancement for a spherical SiO_2 precipitate is approximately 1.5 (12).

Fowler-Nordheim plots of the temperature-independent components of the two diodes shown in Fig. 1, as well as of one other diode, are shown in Fig. 2 where $V_R^{-1/2}$ is used as the abscissa. From the slopes corresponding to large reverse voltages, (*i.e.*, $V_R + V_{bi} \simeq V_R$), values of $\beta' = (m_e/m^*)^{1/2}v^{-1}\,\beta$ can be obtained. Here m_e is the free electron mass. Using Eq. [5] and taking for $q\Phi_B = 0.5$ eV and for $N_D = 1 \times 10^{15}$ cm^{-3}, these values ranged from 9.4 to 114 for the diodes shown in Fig. 2. Similar values were obtained for iron-, nickel-, and copper-doped diodes. Using Eq. [3] and [4] and assuming that $m^* \simeq m_e$, and $v(y) \simeq 1$, values of the electric field at the precipitates of 0.82×10^6 V/cm for $-V_R = 25$V and of 1.33×10^6 V/cm for $-V_R = 65$V were obtained for diode B of Fig. 1 and 2. This is close to the reported value of 10^6 V/cm for silicon where currents due to tunneling become significant (13). Taking $\beta \simeq 114$ for diode A, values of the electric fields of 2×10^6 V/cm for $-V_R = 1$V and of 6.32×10^6 V/cm for $-V_R = 10$V were obtained. The actual field values are reduced somewhat since $v(y) \leq 1$, and since it is expected that $m^* < m_e$. Since these field values are one to two orders of magnitude larger than the avalanche breakdown field in a junction of approximately 5×10^5 V/cm, they have to be restricted within a small volume, otherwise localized charge multiplication due to impact ionization would take place giving rise to a discontinuous slope in the current-voltage characteristics whenever the multiplication factor reaches the value of one. Using the conditions invoked above, a field-enhancement factor of 9.4 corresponds to a c/b ratio of 3. For $\beta = 114$, the c/b ratio is approximately 20. Again, due to the unknown values of m^*, $q\Phi_B$, and $v(y)$, the c/b ratios have to be viewed more qualitatively than quantitatively. However, by comparing the c/b ratios of diodes A and B of Fig. 1 and 2, it can be concluded that the current contributing precipitates in diode A are more needle-like than the precipitates in diode B. Bearing in mind that the enhanced field at a precipitate can only occur over a small fraction of the junction area, Eq. [1] was used to check if the calculated current densities are consistent with this assumption. The emission area can be estimated from

$$I(V_R) = J(T = 0, V_R)A_p \quad [7]$$

where I is the measured temperature-independent current at a given reverse bias voltage, J is the current density given in Eq. [1], and A_p is the emission area at a precipitate. The results are: $A_p \simeq 10^{-10}A_j$ for diode A, and $A_p \simeq 10^{-3}A_j$ for diode B. Here A_j is the junction area. The value for diode B seems quite large, but since these junctions were intentionally contaminated, it is conceivable that in some cases quite a few precipitates of similar emissivity formed during the cooling cycle.

From Fig. 2 it can be seen that for diode A deviations from a straight line occur at voltages below 3V. This is expected since according to Eq. [4] the electric field is only proportional to $V_R^{1/2}$ for $V_R > V_{bi}$. Incorporating V_{bi} and plotting $\ln I/(V_{bi} + V_R)^{3/2}$ *vs.* (V_{bi}

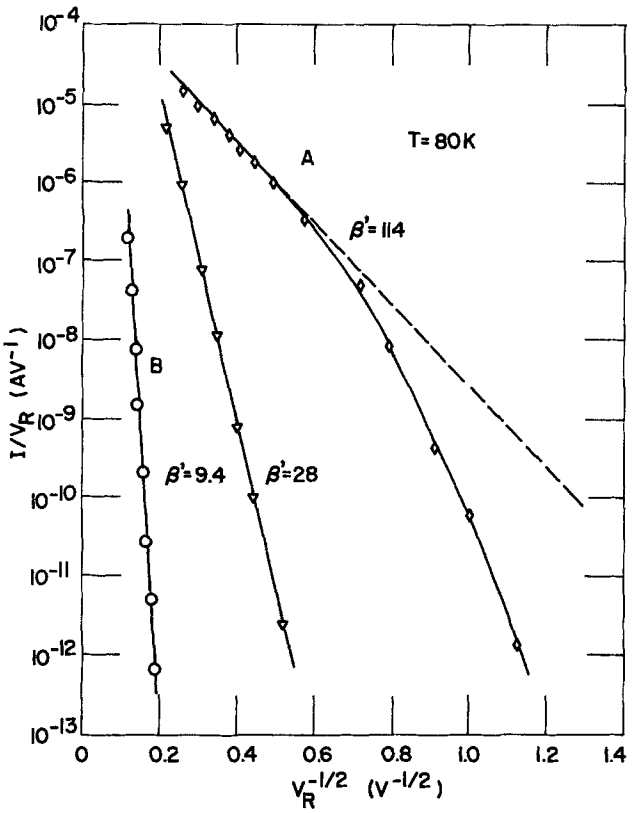

Fig. 2. Log I/V_R vs. $V_R^{-1/2}$ plots of the temperature-independent soft leakage component of several diodes.

$+ V_R)^{-1/2}$, however, did not result in a straight line fit at voltages below 3V.

Detection and distribution of SRH generation centers.—During the early stages of this work, the possibility was considered that the soft leakage component might be due to nonuniform distribution of generation centers or due to field-enhanced emission rates. To investigate this, DLTS measurements were taken at different voltage ranges. Examples of such measurements are given in Fig. 3 and 4. Figure 3 shows the *I-V* characteristics of a soft diode which was contaminated with tantalum. DLTS 1 was obtained for a quiescent reverse bias of −3V which was momentarily reduced to 0V. DLTS 2 was obtained for a quiescent reverse bias of −10V which was momentarily reduced to −6V. The width of the bias reduction pulse was 400 μsec. These two spectra are shown in Fig. 4. From the analysis of the data, the concentration of the near midgap levels were N_t(DLTS 1) $\simeq 1.2 \times 10^{13}$ cm^{-2} and N_t(DLTS 2) $\simeq 1.5 \times 10^{13}$ cm^{-3}, respectively. This moderate increase in N_t from DLTS 1 to DLTS 2 cannot be the cause of the sharp increase in the leakage current from −3 to −10V. From Fig. 4 it can be seen that the maxima of the near midgap peaks of the two spectra occur at the same temperature. This means that the emission rate in the two cases is the same. Therefore the observed large leakage current cannot be explained by a field-enhanced emission rate. The soft leakage component measured at 80°K was subsequently fitted to the precipitation model. From the analysis, a field-enhancement factor of 28 was obtained. It should be mentioned that the near midgap peak in Fig. 4 is due to gold contamination. This was established from control measurements. Therefore only the low temperature peak (0.21 eV, Table I) is associated with tantalum.

DLTS measurements were also used to measure the lateral distribution of generation centers. For this purpose, gate-controlled diodes and in some cases MOS capacitor structures, were employed. In some cases it was observed that up to 40 times more impurities in the form of generation centers were present in the depletion region of the field-induced junction of a gate-

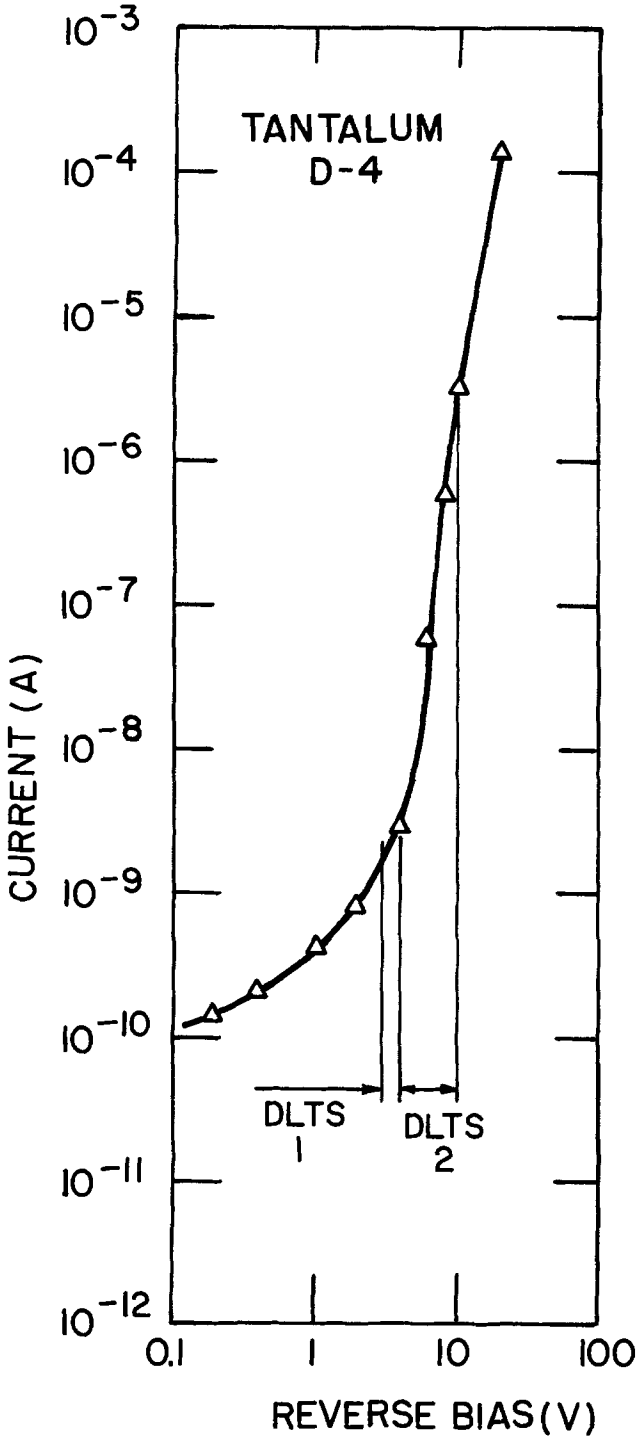

Fig. 3. I-V_R characteristics of the tantalum-doped diode C-4 of lot 4321, W-8, chip D-4, measured at room temperature. Indicated by DLTS 1 and DLTS 2 are the two voltage ranges for which DLTS spectra were obtained in order to measure possible nonuniform impurity distributions and/or field-enhanced emission rates.

controlled diode as compared to the depletion region associated with the metallurgical junction. This was seen for iron- and tantalum-doped diodes, both of which showed soft *I-V* characteristics. Either gettering effects in the p^+ region or formation of precipitates near the metallurgical junction might be responsible for the depletion of generation centers near the metallurgical junction. In the case of the tungsten-doped diodes, an almost uniform distribution of the near midgap impurities in those two regions was observed. An example of such a measurement is given in Fig. 5. It shows the I-V_R characteristics of the metallurgical junction and of the field-induced junction of a tungsten-doped gate-controlled diode. Over most of the

voltage range the current of the metallurgical junction and of the field-induced junction varies as $V_R^{1/2}$. The current of the metallurgical junction was measured at a gate voltage $V_G = 0$. The current of the field-induced junction was obtained by taking the difference of the currents measured at strong inversion and at $V_G = 0$ (or for weak accumulation). V_R was held at a constant value. The measured current change $I_{FIJ}/(I_{FIJ} + I_{MJ})$ at $V_R = -1V$ is 23.2%. Assuming that the leakage is caused by the near midgap center, a similar change in the height of the DLTS peak should be expected. The DLTS spectra are shown in the insert of Fig. 5. The observed change in the amplitude of the signals is 22.2%. This is in excellent agreement with the above value. It should be mentioned that none of the observed soft leakage currents of gate-controlled diodes could be accounted for by surface generation-recombination centers. The surface recombination velocity s_0 of the diodes investigated ranged from 5 to 100 cm/sec.

In the usual treatment of junction leakage it is assumed that the entire contribution of SRH leakage comes from the depletion region which is associated with the lighter doped side of a junction. In practical cases, however, there is a nonzero depletion width which extends into the more heavily doped side of a junction. An indication that SRH centers lying in the p^+ regions contribute to diode leakage was obtained for copper-doped diodes. Figure 6 shows the DLTS spectra of a copper-doped diode and of a MOS capacitor lying adjacent to the diode. (Copper was filament

evaporated on the backs of the wafers and diffused at 1050°C in N_2 for 2 hr. The wafers were then fast pulled to room temperature.) Three peaks are discernible for the p^+n junction. Only one peak is obtained for the MOS capacitor. The increase of the signal of the MOS capacitor spectrum above 200°K is due to the fact that at the temperature where reemission of the trapped electrons would occur, thermal bulk and/or surface generation of minority carriers can invalidate the deep

depletion condition by forming an inversion layer near the insulator-semiconductor interface. The two extra signals in the diode spectrum could also be process-induced defects (3, 14), but since the measured energy values are close to the published values for copper (see Table I), it is believed that these signals come from generation centers which are located in the more heavily doped p region. In principle, soft leakage currents could be explained by assuming a highly nonuniform distribution of SRH centers in the p^+ region. However, the experimentally observed temperature-independent current component does not agree with the exponentially dependent temperature dependence of the emission rates of SRH centers. It should be mentioned that for the chosen biasing conditions of the DLTS measurements (no minority carrier injection), only traps lying in the upper half of the bandgap can be observed with p^+n junction structures, assuming that the signals come from the more lightly doped side of the junction. For n^+p diodes and the same assumptions, only traps lying in the lower half of the bandgap can be detected. Therefore, the energy values of the additional signals coming from the p region of the p^+n diodes have to be measured from the valence band. Table I summarizes the energy values obtained by the DLTS method and compares them to published values (15).

Summary

The effects of impurities such as gold, iron, copper, nickel, tantalum, and tungsten on junction reverse *I-V* characteristics were investigated. In all cases, excluding gold, the reverse *I-V* characteristics consisted of two components; a normal Shockley-Read-Hall (SRH) generation component and a soft leakage component which dominates the SRH component above a given onset voltage. Only the SRH component can be detected with the DLTS and TSCAP methods. In many cases, when the soft leakage component dominated over almost the entire voltage range, only weak DLTS signals were observed ($N_t \simeq 10^{11}$-10^{13} cm^{-3}). In none of the cases investigated could soft leakage currents be associated with SRH centers. They were ascribed to the presence of impurity precipitates lying near the metallurgical junction of the devices. These currents, measured at 80°K, were fitted to a tunneling or field-emission model. It was found that the onset voltage of the soft leakage current depends on the magnitude of the field-enhancement factors and on the magnitude of the SRH component. Assuming that the precipitates are in the form of prolate spheroids and other conditions with regard to their position within a junction, information about the geometry (sphere-like to needle-like) could be obtained from the field-enhancement factors. Local electric fields of the order of 10^6-10^7 V/cm were obtained by this analysis.

DLTS measurements were used to obtain the distribution of the SRH centers within the active region of the devices by employing gate-controlled diode structures and MOS-capacitor structures. Activation energies of the emission rates of electrons and, in some cases, of holes, were measured. Hole emission was observed from impurities lying in the heavily doped p regions of the junctions.

It is expected that soft leakage currents will arise whenever conditions exist in fabrication where impurities are introduced in quantities exceeding the solid solubility at temperatures where sufficient impurity mobility permits precipitation. Clearly, the nature of impurity introduction, stresses, kinetics of precipitation, density, and location of nucleation sites will influence the effects of a given precipitate on junction leakage. For these reasons it has not been possible to systematically determine the relative effects of various contaminants with respect to precipitate-induced leakage.

Acknowledgments

Certain individuals and institutions contributed to the completion of this work. Numerous discussions pertaining to the DLTS and TSCAP measurements with D. V. Lang, L. C. Kimerling (both of Bell Laboratories, Murray Hill, New Jersey) and M. G. Buehler (National Bureau of Standards, Gaithersburg, Maryland) are sincerely appreciated. Properties of CdS Films Prepared by Spray Pyrolysis

Yale Y. Ma[1] and Richard H. Bube*

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

A detailed investigation has been made of the properties of CdS films deposited on amorphous glass substrates by the technique of spray pyrolysis. The variation of the electrical transport properties of these films as a function of substrate temperature has been correlated with variations in orientation, cubic/hexagonal phase ratio, and morphology. Additional effects of cooling rate, spraying rate, heat-treatment in hydrogen, and variations in substrate are also considered. By heat-treatment in hydrogen it is possible to produce films on amorphous glass substrates with an electron density in excess of 10^{18} cm^{-3} and an electron mobility of 90 cm^2/V-sec at 300°K.

The method of spray pyrolysis (or solution spraying) is a convenient and economical method for the deposition of materials suitable for this technique. The production of CdS films by spraying a solution of $CdCl_2$ and thiourea was described by Chamberlin and Skarman (1) following a patent by Hill and Chamberlin (2). The electrical properties of films produced by spray pyrolysis (SP) have been investigated by Micheletti and Mark (3), and by Wu and Bube (4). Solar cells have been produced by the deposition of n-CdS films by SP on p-CdTe single crystal substrates with a solar efficiency of over 6% (5), and SP films of n-CdS are also being used in p-Cu_2S/n-CdS heterojunctions for solar energy conversion (6). The SP technique is convenient for the deposition of ternaries involving sulfides and selenides, and the properties of CdS_xSe_{1-x} and $Zn_xCd_{1-x}S$ films prepared by this method have been described (7).

There is therefore ample motivation to understand the deposition of CdS films by the SP technique. We report here the results of a detailed investigation of the preparation and properties of such films as a function of substrate temperature, cooling rate, spraying rate, postdeposition heat-treatment in hydrogen, and choice of a substrate. By combining measurements of film orientation, cubic/hexagonal phase ratio, morphology, and optical transmission with analysis of electrical transport through thermoelectric and photothermoelectric measurements, it is possible to define some of the correlations between structure and electrical properties of these films.

Preparation of Films

All the films prepared in this paper were prepared by spraying an equimolar (0.1M) solution of $CdCl_2$ and thiourea onto a heated substrate. The solution was sprayed by an atomizer spray nozzle and the liquid spray rate was controlled by a flow meter and the air pressure applied to the nozzle. After the solution is sprayed onto the substrate, thermal decomposition of the complex ion $Cd(CN_2H_4S)_2Cl_2$ takes place, and uniform CdS films are grown on the substrate.

For most of the experiments described in this paper, amorphous glass substrates were used. In order to have a systematic investigation of the effect of substrate temperature on the properties of the films, a series of CdS films was prepared with all the parameters fixed except the substrate temperature. The spray rate used was fixed at 4.2 cm^3/min, and the films were removed from the substrate heater immediately after deposition of a 2 μm thick film. Subsequent portions of the investigation involved using crystalline substrates, changing the spraying rate, or allowing the films to cool slowly on the substrate heater. All spraying was done under air pressure and in an air environment.

It is well known that the electrical properties of CdS films prepared by SP can be affected by chemisorbed oxygen (3, 4). Our previous work, however, has shown that heat-treatment in air lowers the conductivity compared to an as-deposited film, and that subsequent heat-treatment in vacuum restores the conductivity to approximately the same as the as-deposited condition (4). Measurements reported here are primarily on as-deposited films, rapidly cooled and without subsequent heat-treatment in air, and measured by thermoelectric power in 10^{-5} Torr vacuum. For such films oxygen adsorption effects should be minimized.

Effect of Substrate Temperature

A series of films was deposited for substrate temperatures between 320° and 570°C. The room temperature electrical conductivity of these films is shown in Fig. 1a. The dark conductivity is a striking function of substrate temperature, exhibiting fluctuations by three orders of magnitude for differences in substrate temperature of 20°-30°C. Although this conductivity is so strongly temperature dependent, it is still possible to

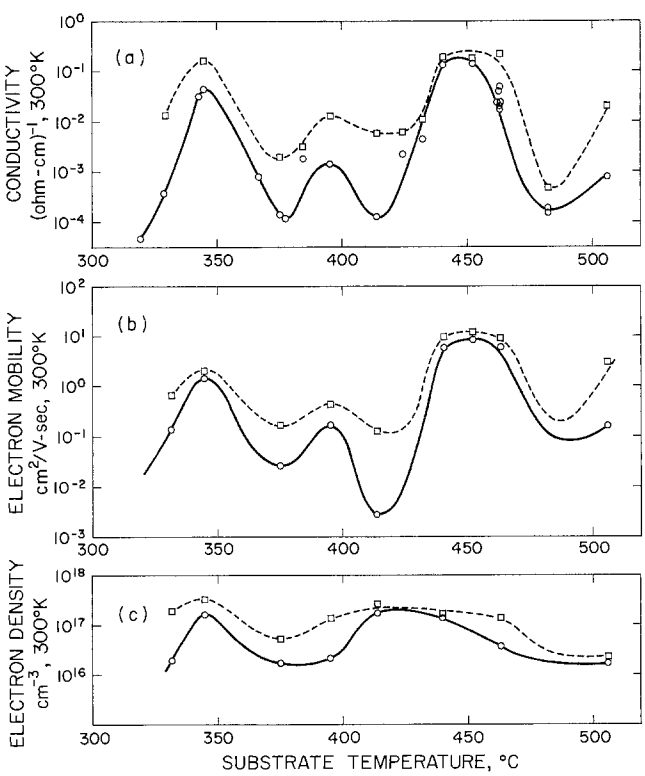

Fig. 1. Dependence of electrical conductivity, electron density, and electron mobility at 300°K on the substrate temperature during CdS film deposition. Solid curves are in dark; dashed curves are under illumination.

Key words: cadmium sulfide, films, spray pyrolysis, solution spraying, transport in films, thermoelectric power of films.

prepare highly reproducible films by carefully controlling substrate temperature, spraying rate, film thickness, cooling rate, etc. Most of the maximum and minimum conductivity points of Fig. 1a have been repeated several times in order to establish that the variations shown are not the consequence of uncontrolled preparation variables. Films prepared at 461°C, for example, have been repeated many times under the same spraying conditions; the reproducibility in conductivity in these films is within a factor of two.

In order to determine the relative contributions to these conductivity variations by changes in electron density and electron mobility, thermoelectric power measurements were made as a function of temperature in the dark and under photoexcitation. Samples subjected to this measurement were mounted on a sample holder, which consisted of two aluminum strips with heaters inserted into each strip. The heaters were used not only to heat the sample above room temperature, but also to establish a temperature gradient across the sample. Cooling of the sample below room temperature was controlled by a Joule-Thomson cryotip system. The temperature gradient and the thermoelectric voltage were measured by thermocouples and electrical leads mounted at the ends of the sample. The electron density n and the electron mobility μ of the CdS films were calculated from the equations

$$\alpha = -\frac{k}{e}[A + \ln(N_c/n)] \qquad [1]$$

$$\mu = \sigma/ne \qquad [2]$$

where α is the thermoelectric power obtained from the slope of the thermoelectric voltage *vs.* temperature gradient curve at each sample temperature, A is a constant taken equal to 2.5 for CdS (4), N_c is the effective density of states in the conduction band, and σ is the measured conductivity of the film.

The variation of the measured electron mobility at 300°K as a function of substrate temperature during deposition is given in Fig. 1b, and the variation of the electron density at 300°K in Fig. 1c. It is evident that the dependence of the electron mobility on substrate temperature is the determining factor in the dependence of the electrical conductivity on substrate temperature. All of the films have relatively high electron densities because of chlorine donors incorporated during preparation from the $CdCl_2$.

Typical light and dark electron density and mobility values as a function of temperature are shown in Fig. 2 as calculated from thermoelectric power measurements for the 441° and the 507°C samples. For both samples the electron density is relatively independent of temperature in both dark and light, as would be expected for totally ionized chlorine donors. The dark electron mobility for both samples is thermally activated with a larger activation energy in the higher temperature range than in the lower, and the activation energies are larger for the lower conductivity 507°C film than for the 441°C film. Under photoexcitation the electron mobility for the 507°C sample ceases to be temperature dependent.

These measured mobility variations can be described at least formally by the fairly universal expression (3 ,4)

$$\mu = \mu_0 \exp(-\phi/kT) \qquad [3]$$

where ϕ can be physically interpreted as the barrier height to electron transport between grains of the film. A summary of values of ϕ as a function of substrate temperature is given in Fig. 3a, and a summary of values of μ_0 in Fig. 3b. Comparison of Fig. 1b with Fig. 3a shows that large values of mobility are in general associated with small values of barrier height ϕ. The major conductivity maxima near 350° and 450°C are associated with values of ϕ approaching zero.

The higher temperature portion of the mobility curves of Fig. 2 can be interpreted as resulting from thermal excitation over the intergrain barriers, and the lower temperature portion of these curves can be

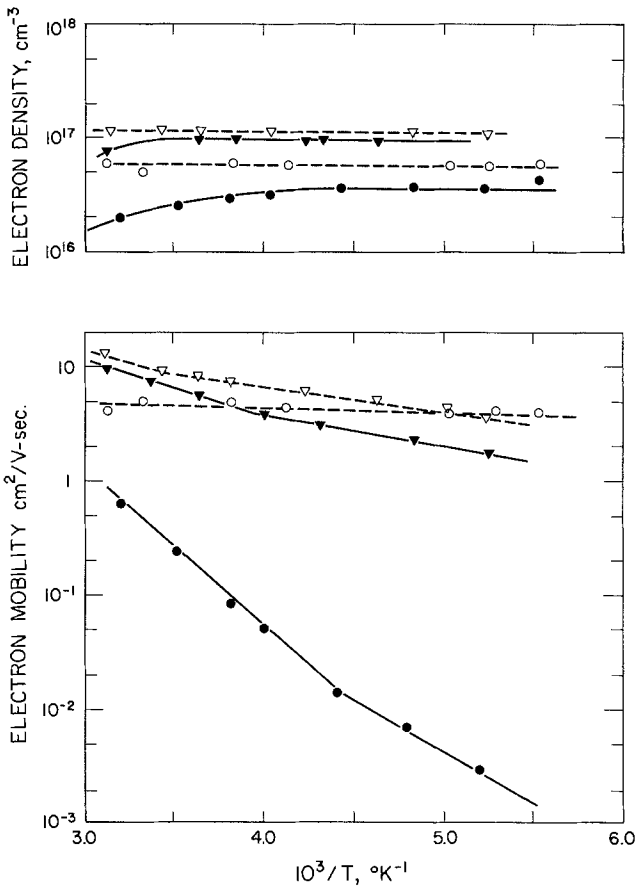

Fig. 2. Temperature dependence of the electron density and electron mobility in CdS films sprayed at 441°C (▼, ▽) and 507°C (●, ○). Solid curves are in dark; dashed curves are under illumination.

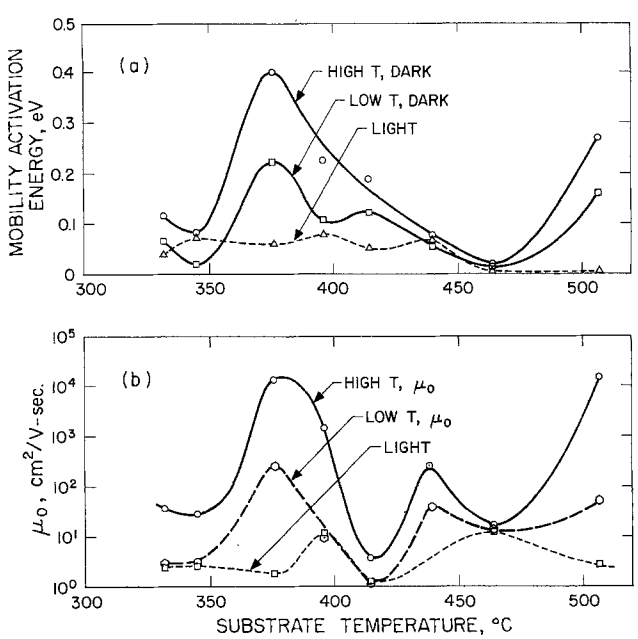

Fig. 3. Values of mobility activation energy ϕ and preexponential term μ_0 as a function of substrate temperature during deposition of CdS films, assuming $\mu = \mu_0 \exp(-\phi/kT)$. Where different values are found at high and low temperatures, both are indicated. Solid curves are in dark; dashed curves are under illumination.

interpreted as caused by thermally assisted tunneling through these intergrain barriers. Under photoexcitation, tunneling without thermal activation dominates in the 507°C film of Fig. 2.

The effect of photoexcitation is to make the variation with substrate temperature less pronounced, in every case causing variations that tend to equalize differences in conductivity, electron density, electron mobility, mobility activation energy, and μ_0 over the whole substrate temperature range explored. Such behavior is consistent with the effect of photoexcitation being both to decrease the barrier height and to enhance tunneling through the barrier, as previously reported (3, 4).

A correlation between the physical properties of the various films produced at different substrate temperatures and these electrical transport properties has been sought with results described as follows.

Orientation effects.—The structure of these films was analyzed by x-ray diffraction techniques. The preferred orientation of the films was determined by using the modified Debye-Scherrer x-ray camera (8) for qualitative analysis, to be compared with the quantitative data obtained from diffractometer patterns. These diffractometer patterns indicate that for substrate temperatures between 322° and 414°C, (11,2) and (10,1) reflections increase in intensity with substrate temperature, whereas (00,2) reflections decrease. Above 441°C the reverse trend is seen with (00,2) reflections increasing and (11,2) and (10,1) decreasing. The Debye-Scherrer patterns of films prepared below 350°C show uniform intensity in (00,2), (11,2), and (10,1) reflections, indicating that the crystallites in the films are randomly oriented. Preferred orientation occurs in the films deposited above 350°C, the degree of preferred orientation depending on the substrate temperature during deposition.

The intensities of the major x-ray reflections, I(10,1), I(00,2), and I(11,2), measured from diffractometer patterns, are plotted as a function of substrate temperature, and are compared with the electrical conductivity of the films, in Fig. 4. It is convenient to divide the temperature range into four regions as indicated. Orientation effects appear to be strongly correlated with conductivity variations in regions II, III, and IV. Between 400° and 483°C, the variation of the conductivity is similar to the variation of the I(10,1), and almost exactly inverse to the variation of I(11,2). In region II between 346° and 376°C, it can be speculated that the inverse variation of conductivity according to I(11,2) dominates over the direct variation according to I (10,1) because of the larger variation of the former with substrate temperature. In region IV, only the (00,2) orientation remains at 507°C; in this range the presence of the cubic phase also affects the conductivity, as described in the following section.

Cubic-hexagonal phase ratio.—CdS can exist in an hexagonal (wurtzite) structure or in either zincblende or rocksalt cubic structures. Cubic phases may be expected in films produced by SP for two reasons: The cubic phase is stable below about 400°C, and may therefore be expected in the films prepared with lower substrate temperatures; and the fast-cooling process can induce stacking faults with cubic structure because of the difference in thermal expansion coefficients of the CdS and the substrate. Such stress-induced stacking faults have been found in the films by observation of the (220) rocksalt cubic reflection in the x-ray diffractometer patterns for films prepared at 397°, 414°, 483°, and 490°C. These rocksalt reflections can also be observed in the modified Debye-Scherrer patterns. The probability of finding the zincblende structure reflections in the diffraction patterns is small since most of the zincblende reflections are superimposed on reflections of the hexagonal hcp phase.

The proportionality of hexagonal hcp phase in the films, called "hexagonality" H, can be calculated from the intensity ratio R of (10,1) to (00,2) reflections in the x-ray pattern, according to

$$H(\%) = \frac{15.9R - 8.1}{13.5R + 25.1} + \frac{33.2 - 2.5R}{32.5 + 71.2R} \qquad [4]$$

This equation was derived by following the suggestions of Smith (9) and Short and Steward (10) in their derivations of the proportion of cubic phase in ZnS and CdS powders. The constants in Eq. [4] are calculated by using the x-ray diffractometer patterns of the SP

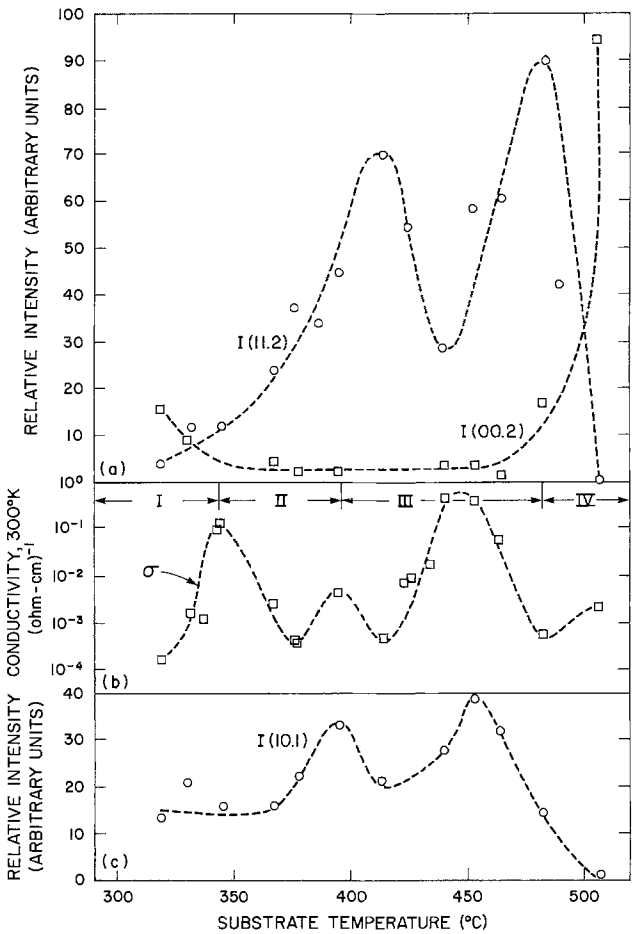

Fig. 4. Relative intensity of (11,2), (10,1), and (00,2) reflections in films of CdS as a function of the substrate temperature during deposition, compared with the electrical conductivity variation with substrate temperature.

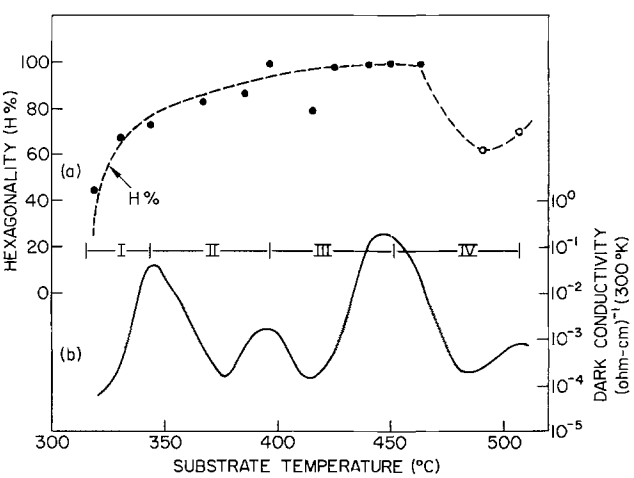

Fig. 5. Hexagonality (as defined in Eq. [4]) as a function of substrate temperature during deposition of CdS films, compared with the electrical conductivity variation with substrate temperature.

films prepared from 322° to 507°C. Detailed derivation of the equation is given elsewhere (11).

Values of H from Eq. [4] are plotted in Fig. 5 as a function of the substrate temperature. In the range of substrate temperatures between 322° and 346°C, H increases from 46 to 71%. Since there is no large change in crystallite orientation in this region the increase of conductivity appears to be associated with this change in phase composition. In region IV, the decrease of conductivity is again associated with an increase in cubic phase. Since the 507°C films are highly oriented in the (00,2) direction, the energy required to generate stacking faults in the close-packed (00,2) plane is small, and thermal or internal stress in the film can generate large proportions of cubic phase.

Surface morphology.—The surface morphology of films prepared at different substrate temperatures was investigated by TEM replica techniques. Figure 6 shows photographs of the surface microreliefs of films prepared at four different substrate temperatures, with different values of H. For the films prepared at 397° and 441°C, for which $H \sim 100\%$, the microreliefs show distinct grains with uniform size. For the films prepared at 332° and 507°C, however, with appreciable proportions of the cubic phase, the microreliefs show a range of grain sizes from less than 0.1 μm to 0.5-0.9 μm. By comparing the electron diffraction patterns of evaporated CdS films to x-ray diffraction patterns of the same samples, Shalimova *et al.* (12) and Galkin *et al.* (13) discovered that the larger grains were hexagonal, while the smaller grains were a mixture of cubic and hexagonal phases. The microreliefs of Fig. 6 are consistent, therefore, with the conclusion that relatively high proportions of the cubic phase are present even at the higher substrate temperature of 507°C.

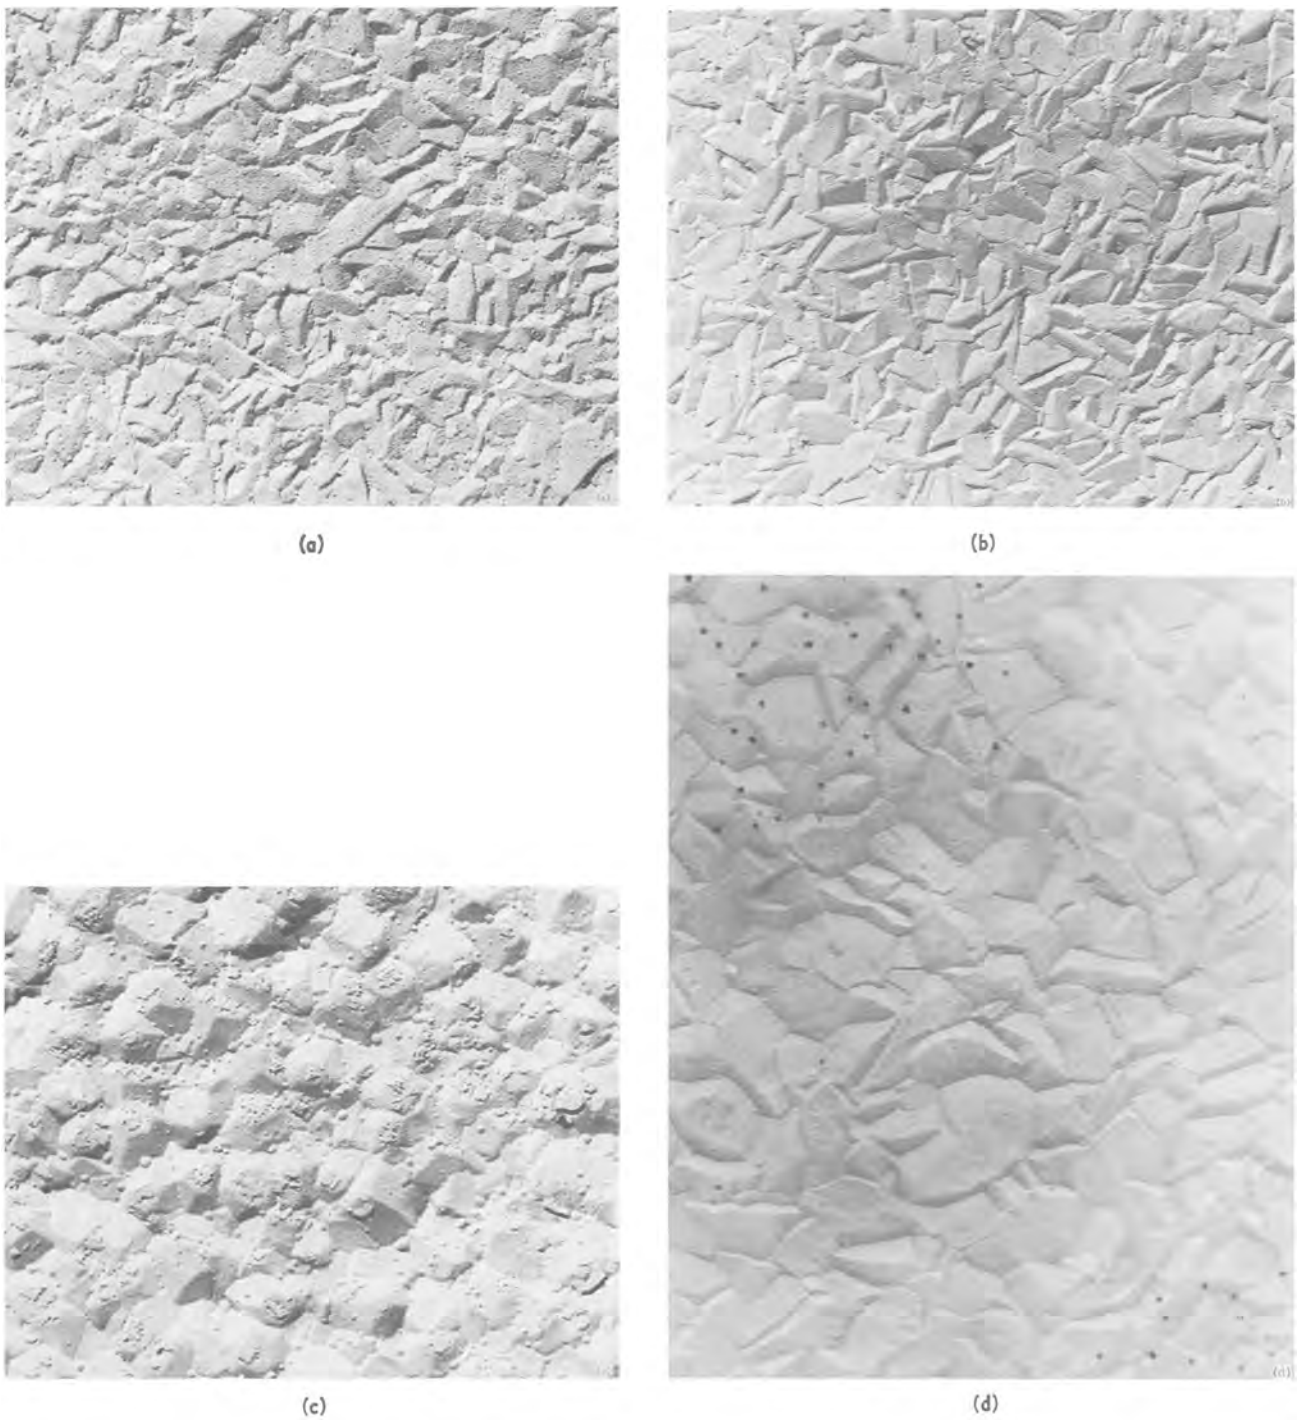

Fig. 6. TEM microreliefs showing surface morphology of CdS films deposited on substrates at (a) 332°C, (b) 397°C, (c) 507°C, and (d) 441°C. Magnification: X44,000.

Optical transmission.—Optical transmission measurements as a function of substrate temperature are summarized in Fig. 7. The film prepared at 332°C has the lowest optical transmittance as well as the lowest electrical conductviity. Auger analysis (14) of this film shows a high concentration of chlorine inside the film, which may contribute to the low optical transmission. Alisoukas *et al.* (15) have also reported that the spectral distribution of photoconducting CdS sintered layers depends on the concentration of $CdCl_2$ used in the sintering and on the sintering temperature. The highest values of optical transmission are for the films prepared at 441° and 451°C, which also exhibit the highest values of electrical conductivity.

Effect of Cooling Rate

The effect of cooling rate was investigated for films prepared at 461°C. One sample was fast-cooled as described above, a second sample was cooled slowly from 461° to 100°C in 80 min, and a third was cooled slowly from 461° to 100°C in 115 min.

Figure 8 compares the electron density and mobility as a function of temperature for these three samples. The slower cooling decreases both the electron density and the mobility compared to the faster cooling, and increases the intergrain barrier height as determined from the mobility activation energy.

X-ray diffraction patterns indicate that the slow-cooled films have a reduced intensity for the (11,2) and (10,1) reflection, and an increase in the intensity of (00,2) reflections, indicating growth of (00,2) crystallites at the expense of others during slow cooling. Since the slow-cooled samples were exposed to air during the long period of cooling, it is likely that the slow-cooling procedure is equivalent to an air bake, causing the chemisorption of oxygen as discussed in the previous section on preparation of films, with related decrease in electron density and increase in intergrain barrier heights.

Effect of Spray Rate

Sensitivity of film properties to the spray rate appears to vary critically with substrate temperature. At

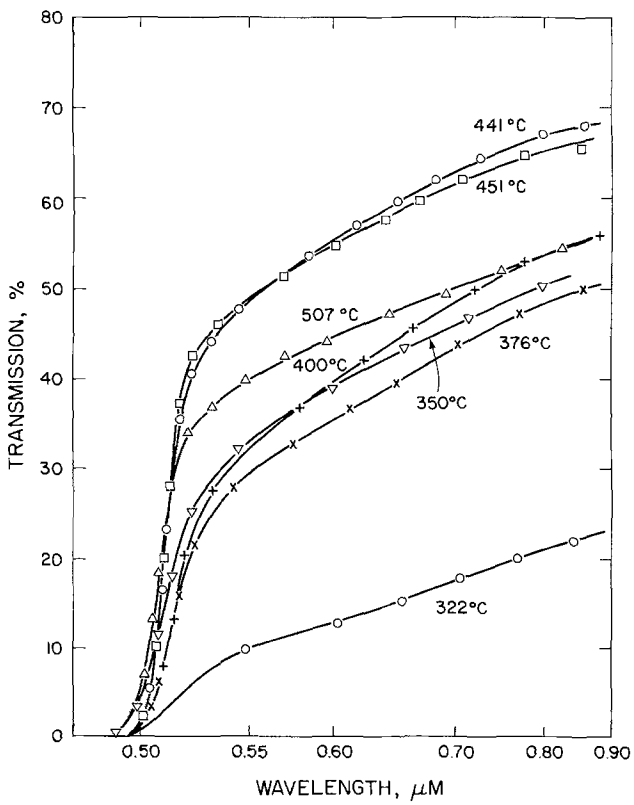

Fig. 7. Optical transmission of CdS films for various substrate temperatures during deposition.

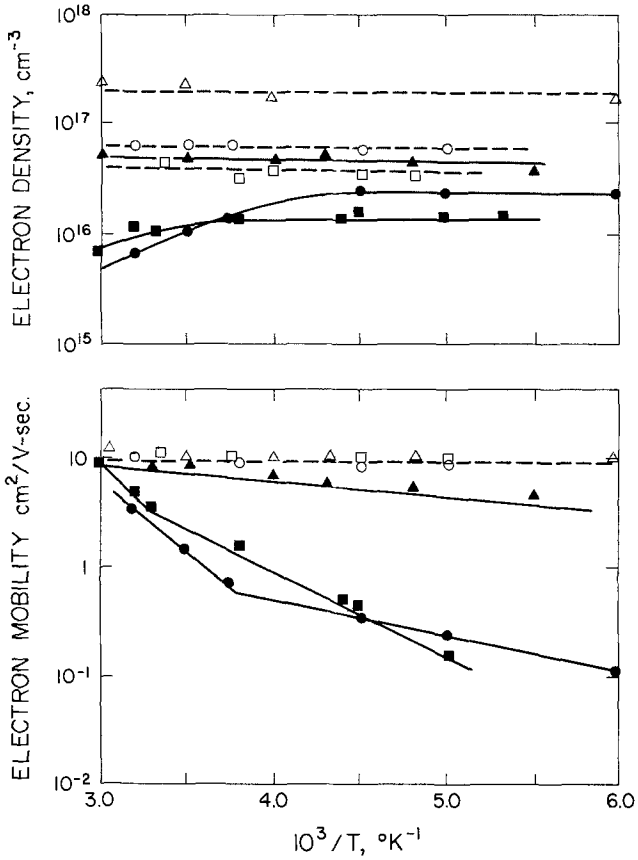

Fig. 8. Temperature dependence of the electron density and the electron mobility of CdS films deposited at a substrate temperature of 461°C for a fast-cooled sample (▲, △), and two slow-cooled samples (●, ○) and (■, □). Solid curves are in the dark; dashed curves are under illumination.

322°C, for example, the conductivity is relatively independent of changes in spray rate from 1.6 to 8.4 cm³/min. At 464°C, the effect is small but detectable; a variation in the spray rate from 4.2 to 10.3 cm³/min produced a decrease in conductivity by a factor of four, attributable to a decrease in mobility by a factor of four because of an increase in the barrier height between grains from 0.016 to 0.049 eV. At 346°C, however, the effect of spraying rate is very strong; the conductivity increases from 5.8×10^{-5} to 6×10^{-2} $(\Omega\text{-cm})^{-1}$ as the spray rate is increased from 1.6 to 4.0 cm³/min, and then decreases again to 4.7×10^{-6} $(\Omega\text{-cm})^{-1}$ as the spray rate is increased further to 8.3 cm³/min.

The major effect of a fast spraying rate is to introduce defects, such as stacking faults, dislocations, and vacancies into the films. Since 350°C is reported to be the phase transition temperature from cubic CdS to hcp (16), these defects generated by the fast spraying rate may increase the internal stress in the films and hence affect the phase transformation, particularly for films deposited at 346°C, close to this critical temperature. The hexagonality for these films shows a dramatic decrease from 83 to 43% as the spray rate is increased from 4.0 to 8.3 cm³/min. Increased spray rate also causes a decrease in grain size observed in TEM micrographs, and a slight peak broadening in x-ray diffraction patterns indicating decreased crystallinity.

Effect of Heat-Treatment in Hydrogen

Heat-treatment of SP CdS films after deposition can increase their conductivity by as much as three orders of magnitude. The results of thermoelectric power measurements on films prepared under the same conditions with and without heat-treatment are given in Fig. 9. After 5 min heat-treatment in H_2 at 400°C, the films become partially degenerate with an electron

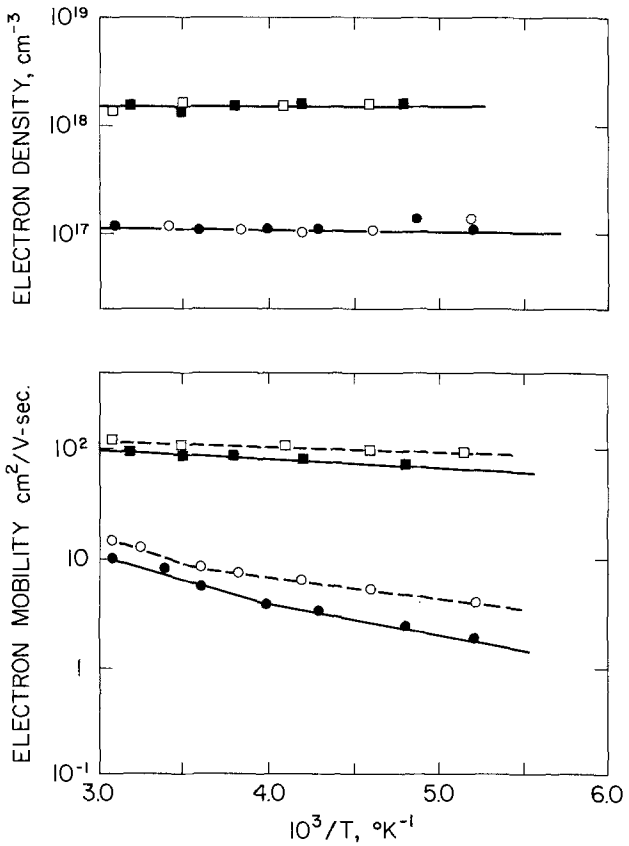

Fig. 9. Temperature dependence of the electron density and the electron mobility of CdS films before and after heat-treatment in H_2 for 5 min at 400°C. Before heat-treatment (●, ○), and after heat-treatment (■, □). Solid curves are in the dark; dashed curves are under illumination. No effects of illumination on the electron density are observed in these films.

density of 1.5×10^{18} cm^{-3}. The electron mobility is also increased by about an order of magnitude to a value of 90 cm^2/V-sec in the dark at 300°K. The dark mobility activation energy decreases from 0.083 eV to 0.015 eV as a consequence of the H_2 heat-treatment. X-ray diffraction patterns indicate both a growth in crystallites with the same orientation as in the non-heated film, and a growth of certain orientations at the expense of others. Heat-treatment in hydrogen is also expected to increase the nonstoichiometry of the film, producing excess cadmium donors, increasing the free electron density in the grains, and reducing intergrain barrier heights. Heat-treatment in H_2 should also remove any vestige of chemisorbed oxygen with similar consequences.

Effect of Substrates

A very limited survey was made of the electrical properties of CdS films deposited on a variety of crystalline substrates, to compare with those prepared on amorphous substrates and described at some length above. In this comparison a single deposition temperature of 461°C was used, together with a fixed spraying rate, cooling rate, etc. Substrates chosen included single crystal CdTe with (110) and (111) orientations, single crystal sapphire with (0001) and (1102) orientations, single crystal quartz, and a (100) oriented polycrystalline film of indium-tin oxide.

All of these films deposited on single crystal substrates have a strong (00,2) orientation, indicating that the c-axis of the film is perpendicular to the substrate, regardless of the specific orientation of the substrate. In spite of this difference, the measured 300°K conductivity of the films sprayed at 461°C was about the same on the crystalline substrates as on the amorphous substrates.

The only additional investigation carried out to date has been the preparation of n-CdS/p-CdTe heterojunctions by the SP deposition of CdS films on single crystalline p-CdTe substrates. As described more fully elsewhere (5), SP-deposited CdS films on substrates at 450°C had an as-deposited conductivity of about 10^{-2} $(\Omega\text{-cm})^{-1}$: This conductivity could be increased to 10^2 $(\Omega\text{-cm})^{-1}$ by heating for 5 min in H_2 at 420°C.

Conclusions

The method of spray pyrolysis for the deposition of thin films of materials like CdS is attractive for its technological ease and economy. This investigation shows that the optical and electrical properties of these films can be strongly influenced by substrate temperature, cooling rate, spraying rate, and postdeposition heat-treatments. It is therefore essential to have carefully controlled preparation conditions in order to achieve reproducible high quality films. With such care it is possible to prepare a wide variety of films with 300°K conductivity between 10^{-4} and 10^2 $(\Omega\text{-cm})^{-1}$, corresponding to electron mobilities between 10^{-3} and 10^2 cm^2/V-sec.

Photoelectrolysis of Water with Semiconductor Materials

Micha Tomkiewicz and Jerry M. Woodall*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

In an effort to find a semiconductor electrode with a bandgap in the visible part of the spectrum that can serve in the catalytic photodecomposition of water, different systems were explored. The first was sputtered thin films of wide bandgap semiconductor materials such as TiO_2, SnO_2, Nb_2O_3, Al_2O_3, and Si_3N_4 on low bandgap, n-type semiconductors such as GaAs and GaAlAs. Scanning electron micrographs showed that corrosion is greatly reduced but continues by diffusion of the electrolyte through the film, undermining the film by pit formation in the low bandgap semiconductor. There was no evidence for hole conduction through the film. The second system employed p-type GaP as the cathode and Pt as the anode. It was observed that this cell catalytically photoelectrolyzes water with conversion efficiency of 0.1%. The efficiency of the device is a strong function of crystal orientation, surface treatment, and purity of the crystal. The results are explained in terms of an energy diagram of the entire system. Areas for possible improvement are mentioned.

Photoassisted electrolysis of water using illuminated semiconductor electrodes has been demonstrated recently in several systems (1-14). In order for such devices to make significant contributions in the conversion and storage of solar energy they must meet two criteria. First, it is essential that a significant fraction of the solar radiation be absorbed by the semiconductor and efficiently converted to electrical energy in the form of charge separation. Second, this electrical energy must be converted into chemical energy that can be stored and then used in any required mode. The first reported photoassisted electrolysis by Fujishima and Honda (1) employed n-type TiO_2 as the anode and Pt as the cathode using either a two-compartment or single compartment device. Since then, many other n-type materials have been tried as anodes.

Two other basic configurations have also been studied. In the first one, a p-type semiconductor is used as the cathode and Pt as the anode (15). This is discussed in the last part of this paper. The other configuration employs n-type semiconductor anode and p-type semiconductor cathode (6, 14, 16) with light being absorbed by both semiconductor electrodes. This last configuration seems very attractive at first glance, since it avoids the highly restrictive condition of matching the flatband potential and the bandgap energies with the potentials of both the hydrogen and the oxygen electrodes. However, it appears that the efficiency of such a device is going to be limited to the lower efficiency of the separate electrodes. This is due to a charge imbalance and, hence, a loss which occurs as a result of the different efficiencies of the two electrodes.

In this paper, we describe some experiments in which we attempted to identify semiconductor systems which absorb visible light, photoelectrolyze water, and will not photocorrode. Our experiments involved both n- and p-type semiconductors. We discuss separately devices based on each kind of semiconductor.

n-type materials.—It has been observed that most small bandgap n-type materials (smaller than 3 eV) tend to corrode in a photoelectrolytic cell, whereas some large bandgap n-type semiconductors will photoelectrolyze water and remain stable. Recently, Fe_2O_3 (9) and WO_3 (13), both with bandgaps smaller than 3 eV, have been shown not to photocorrode. A natural consequence of this is to try to coat the low bandgap semiconductor with a thin protecting film to prevent direct contact between the semiconductor and the electrolyte, and thus prevent corrosion (7). At the same time, it was hoped that such a film would not prevent holes from reaching the aqueous interface.

One choice for such a film is a thin, inert, semitransparent metal film. This approach was tried, (17) and the main conclusion was that light was converted to electrical energy by providing a "negative overpotential" (18) to various electrochemical reactions including water electrolysis. The stability of this electrode system was vaguely mentioned and details about testing this aspect were not given. In our opinion the main drawback in this solution is that it does not appear to offer any advantage over the combination of two already well-established techniques, namely, a standard electrolytic cell connected to Schottky diode photovoltaic device. The reported (17) negative overvoltage is well within the capacity of the direct voltage delivery of metal/semiconductor junctions.

Another choice and the device we investigated will be called the semiconductor insulator electrolyte (SIE) device. This device employs a thin film of photoelectrolytically stable insulator or wide bandgap semiconductor on an efficiently solar absorbing material, with the hope that photogenerated holes, created by illuminating the solar absorbing material, can be transported to the electrode-electrolyte interface.

p-type materials.—Photoinduced hydrogen evolution on p-type semiconductor electrodes has been previously observed (19). However, the potential of this phenomenon in solar energy utilization was realized only recently (14-16). In solar-absorbing n-type materials, photogenerated holes are expected to migrate through the interface to interact with water. Instead they usually break up the crystal structure and form the thermodynamically very stable oxygen-metal bonds that will eventually cause dissolution in the electrolyte and corrosion of the surface. If a chemical change is to take place on p-type materials it will be through reduction of the surface by the minority carriers generated in the conduction band. Those reduction products are in most cases less stable than the parent semiconductor, and the electrons have a greater probability of interacting on the semiconductor electrolyte interface without permanent damage to the crystal lattice.

Experimental

A standard three-electrode electrochemical cell was used with a switch to monitor separately the current-potential and the current-voltage curves. The samples, which were usually in the form of thin wafers, were etched and cleaned. An ohmic contact was then applied. Au-In alloy was used for the n-type materials

* Electrochemical Society Active Member.

Key words: photoelectrolysis, semiconductor electrolyte, interface, photocorrosion.

and Zn-Au was used for the p-type samples. The contacts were alloyed at ~400°C under a forming gas atmosphere. A copper wire was attached to the ohmic contact with silver epoxy. All the nonilluminated areas were masked with polyvinyl ketone. This mask proved to be resistant to both chemical attack and photochemical degradation. This material maintained also constant density even after prolonged exposure to highly basic or acidic solutions. The sample thus prepared was mounted on a Teflon holder and placed in the cell. A 4 cm^2 platinum sheet was used as the counterelectrode, and calomel electrode was used as reference. The light source was a water filtered 75W xenon lamp. Calibrated neutral density filters were used to change the light intensity. Corning, 300Å bandpass intereference filters were used for the spectral measurements. After each measurement, an Eppley thermopile was placed at the same position as the working electrode to monitor the light intensity.

The SIE devices were prepared by either sputtering the insulator (or the high bandgap semiconductor) on the low bandgap material (TiO_2, Al_2O_3, and Si_3N_4 on GaAs and GaAlAs) or by anodic deposition (SnO_2 and Nb_2O_5 on GaAs). The ohmic contact was made to the low bandgap material. The samples were washed with ethanol and distilled water prior to use.

The bulk GaP wafers used throughout this work were prepared by the liquid encapsulation method (20), cleaned with $HF:HNO_3:H_2O$ in the ratio of 1:3:4, and polish etched by mechanical polish in Br_2-methanol solution. The epitaxial GaP was grown on n-type GaP by liquid phase epitaxy. Orientations were determined by x-ray and doping levels by Hall measurements.

Results and Discussion

SIE devices.—The small bandgap, solar absorbing semiconductors that were studied were n-type GaAs and GaAlAs, and the wide bandgap semiconducting films were SnO_2, Nb_2O_5, Al_2O_3, TiO_2, or Si_3N_4. In all cases except TiO_2, the corrosion, as measured by photocurrent of the low bandgap semiconductors (a few $\mu A/cm^2$ for 500 mW/cm^2 xenon lamp illumination), was reduced by a few orders of magnitude compared with unprotected samples. For TiO_2, the photocurrent was about 100-200 $\mu A/cm^2$. However, corrosion was never completely eliminated. At first we believed that the corrosion was initiated by pinholes in the film which enabled the electrolyte to diffuse through localized spots. Corrosion could then continue through lateral diffusion of the electrolyte. However, optical microscopy revealed that the corrosion sites were not localized around presumed pinholes but were scattered uniformly all across the semiconductor surface. In order to reduce the contribution of pinholes to the corrosion, we took special care to prepare films which were pinhole free. This was done by sputtering multilayers of the films and checking them by SEM at magnifications up to 20,000 times.

After determination that within a 300Å resolution, there were no pinholes, the sample was put in the electrolytic cell and the current-voltage characteristics measured. If oxygen and hydrogen were observed, the system was kept electrolyzing water for a short time. Then the electrode was taken out, washed with distilled water, and examined with SEM. The results at two different magnifications are shown in Fig. 1. These pictures suggest that the corrosion can be explained by a mechanism involving diffusion of some species in the electrolyte through the intact film, which then corrodes the surface underneath the film by forming pits in the low bandgap semiconductor. This occurs while the film above the pit is still intact. Eventually the film forms a bubble above the pit which collapses due to surface pressure with the collapsed film hanging toward the interior of the pit. This finding indicates that more care and sophistication in the deposition of the film are not likely to eliminate this problem. Next, it was determined whether or not photogenerated holes were actually being transported to the electrolyte from the small bandgap material. This was done by comparing the photoinduced electrolytic current, using light with photon energies higher than the bandgap of the insulator film with that produced by photon energies less than the bandgap of the film. Specifically, for a 400Å TiO_2 film on GaAs and GaAlAs a cutoff filter of 480 nm was used to distinguish between direct absorption by the film and charge transport due to absorption of light by the low bandgap semiconductor. We found that except for a small corrosion photocurrent, all the observed photocurrent is produced by direct absorption of light by the film. This does not preclude the possibility that a pair might be found with band matching that will allow minority carriers to diffuse through much thicker films than 400Å.

p-type materials.—Current-potential and current-voltage curves were studied on a number of p-type

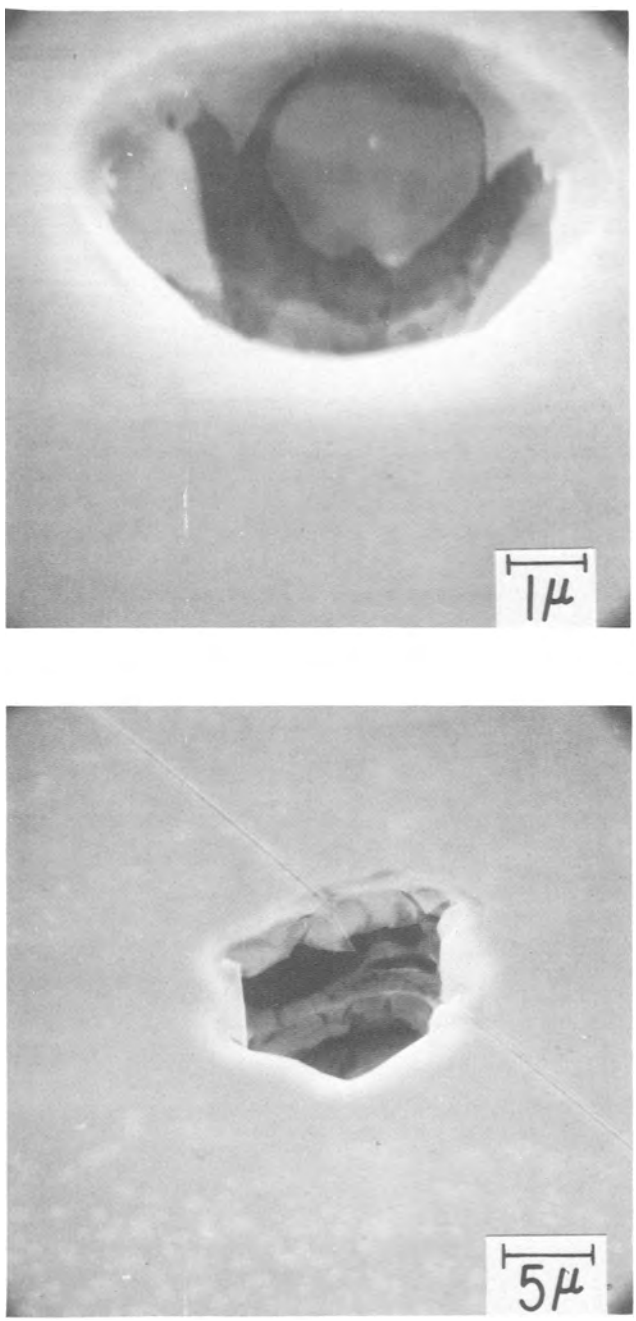

Fig. 1. SEM photomicrograph at two different magnifications of a 400Å TiO_2 film, sputtered on n-type GaAs, after 3 hr of photoelectrolysis in 0.33M phosphate buffer at pH = 7 at an average current density of 0.1 mA/cm^2.

semiconductors which included GaAs, GaAsP, GaP, and InP. It was found that in all cases except GaP the external bias which was needed to start photoelectrolysis exceeded the 'thermoneutral potential" (21), thus making the energy conversion efficiency negative regardless of the generated photocurrent. Only in the case of GaP did we find positive energy conversion efficiency. Thus, this discussion is limited to this semiconductor.

The current voltage behavior of a cell with a p-type $(\bar{1}\bar{1}\bar{1})$ GaP wafer as the cathode and platinum foil as anode in cell with 0.5M Na_2SO_4 + 10^{-2}M NaOH is shown in Fig. 2. When current is flowing through the cell, hydrogen and oxygen could be seen bubbling from the electrode/electrolyte interface for a light intensity as low as 50 mW/cm^2. Figure 2 also shows the conversion efficiency of such a cell when the conversion efficiency is defined as (15)

$$\eta = \frac{I_c \times (1.48 - V) \times 100}{I_a} \quad [1]$$

where I_c is the current flowing in the system, expressed in mA/cm^2, V is the cathodic bias on the GaP electrode, 1.48 is the "thermoneutral potential" (21), and I_a is the intensity of the light incident on the sample, expressed in mW/cm^2.

The current voltage behavior of a GaP (111) wafer from the same crystal is shown in Fig. 3. In this case,

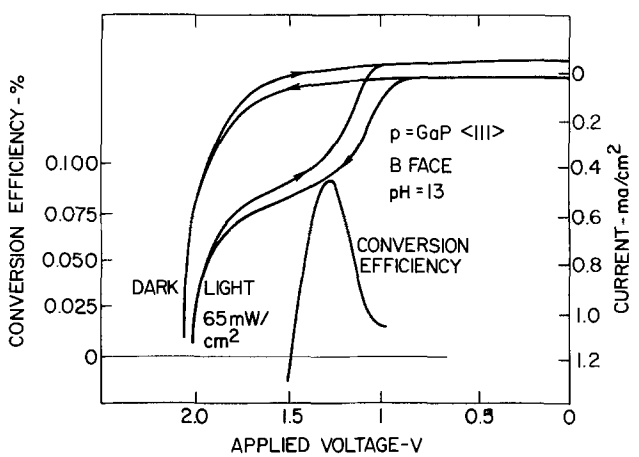

Fig. 2. Current-voltage and conversion-efficiency-voltage diagram for a cell made of Zn-doped GaP $(\bar{1}\bar{1}\bar{1})$ as cathode and Pt foil as the anode. The electrolyte was 10^{-2}M NaOH + 0.5M Na_2SO_4.

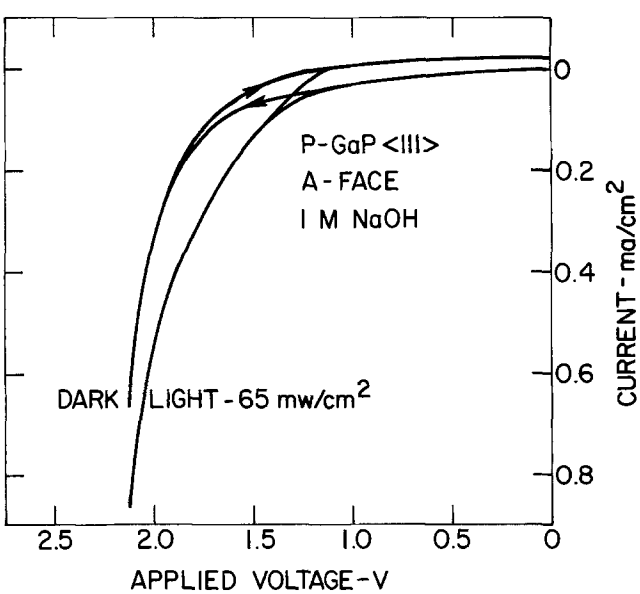

Fig. 3. The same as Fig. 2 except that the (111) surface was exposed. The electrolyte is 1M NaOH.

the bias voltage needed to produce current under illumination is somewhat higher than that needed for $(\bar{1}\bar{1}\bar{1})$ wafers, and, hence, according to Eq. [1], the efficiency will be lower.

The dependence of the light-induced current with light intensity at two different bias conditions is shown in Fig. 4. Above the saturation voltage the current is proportional to the light intensity, while at lower bias the current tends to saturate with light intensity.

Figure 5 shows the spectral response of the quantum efficiency of the photocurrent. The quantum efficiency peaks near 40% at a wavelength which is ~150 nm shorter than the bandgap. We have normalized this spectrum to the condition where only those photons that are absorbed within the first 0.2 μm from the electrolyte interface will lead to charge separation. Any photon that will be absorbed deeper than that will be lost, presumably due to charge recombination. This behavior is not an inherent property of GaP but a very strong function of the particular crystal that is being used.

Figure 6 shows normalized spectrum of two different samples of GaP, one grown by the liquid encapsulation technique and the other epitaxially on GaP. There is a shift of 70 nm in the action spectrum in those two samples. The decline in efficiency at shorter wavelengths is probably caused by increased surface recombination of carriers generated near the surface. If this is so, then the action spectrum should be time dependent, because hydrogen diffusion through the surface is known to have strong effects on the surface recombination rate in semiconductor electrodes (26).

Stability.—The stability of the electrode was checked by passing 100C of electricity through a 1 cm^2 sample

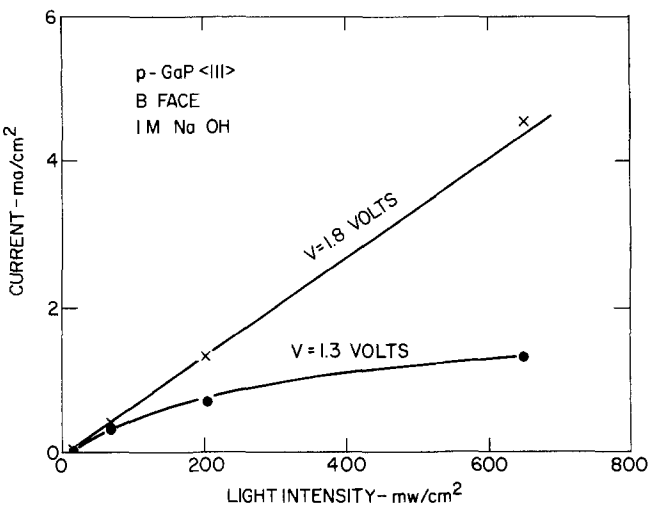

Fig. 4. Dependence of the photocurrent on the light intensity under two different bias conditions.

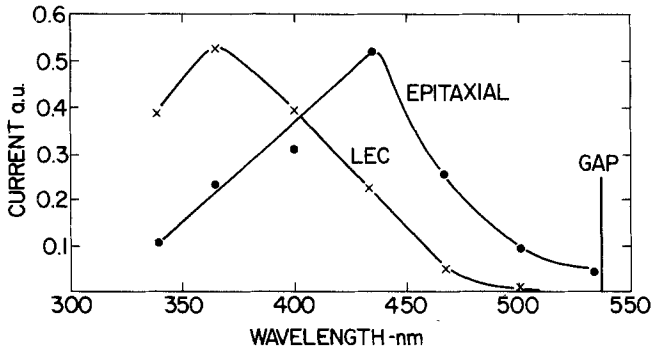

Fig. 6. Normalized spectral response of the photocurrent for two different GaP crystals. One was grown epitaxially on GaP and the other is a liquid encapsulation grown (LEC) wafer.

at an average current density of 5 mA/cm^2 in 0.5M H_2SO_4. Under these conditions the sample did not show any signs of dissolution or corrosion. Optical microscopy did not show any visual change in the surface, and atomic absorption spectroscopy of the electrolyte did not detect any presence of gallium with sensitivity better than 1.5×10^{-7} moles. One additional criterion for the stability of the semiconductor electrode is the stability of the photocurrent with time (14). Figure 7 shows the variation of the photocurrent with time of illumination, under potentiostatic conditions, and under constant bias conditions. It can be seen that under potentiostatic conditions the current is stable, at least for the time period shown here. We found some irregular variations with time over longer periods of illumination. These variations were caused mainly by accumulation of hydrogen bubbles on the electrode. The situation is different when we work under constant bias conditions. The time variation is evident there, but the current could be restored to its original value by turning the light off for a short period of time and then on again. Surface conditions and surface treatment have strong influence on this time behavior. The reversibility of the process indicates that it is not due to any permanent damage to the electrode. The probable cause is formation of surface states due to the hydrogen or metal impurities (22, 23). More studies are needed to explore this important aspect in the performance of the cell.

Energy diagram.—The current potential curve of GaP was measured against standard calomel electrode and agrees with results published earlier (24, 25). The current potential of the platinum electrode was measured and found to be independent of the light. The value of the flatband potential was taken from the work of Memming (24) after correction for the pH. Based on this information, a simplified energy diagram of the cell, under short-circuit conditions and under cathodic bias at the maximum conversion efficiency, was drawn and is shown in Fig. 8. From an examination of Fig. 8,

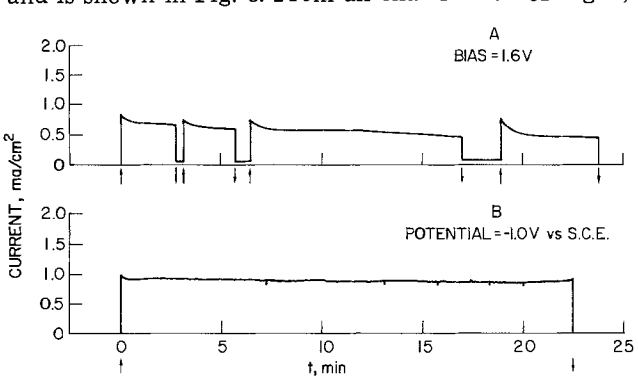

Fig. 7. Variation of the photocurrent with time, at a standard calomel electrode potential of 1.0V. A. under constant bias; B. under potentiostatic conditions. Conditions similar to Fig. 2: ↑ indicates light on; ↓ indicates light off.

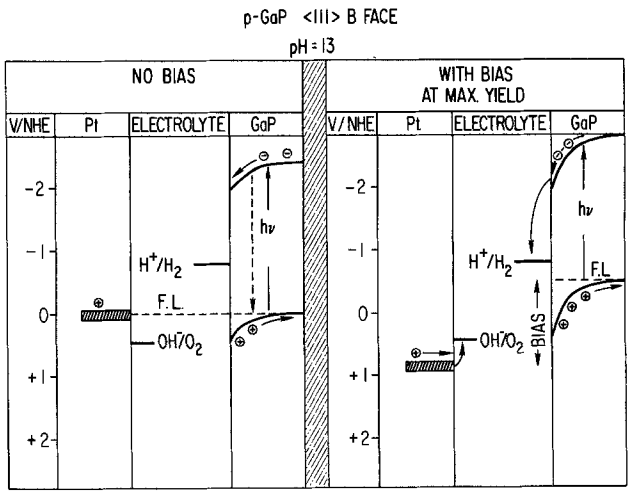

Fig. 8. Energy diagram of the combined cell. All energies are with respect to a standard hydrogen electrode. F.L. is the GaP Fermi Level. 1) under no bias and no photoelectrolysis conditions; 2) under conditions for which the maximum conversion efficiency was obtained.

it appears that the bias which is needed to get the maximum conversion efficiency is divided between the need to raise the potential of the platinum electrode from rest around 0.0V *vs.* a standard hydrogen electrode (SHE) to +0.9V *vs.* SHE. The position of the reversible oxygen electrode is ~ +0.5V *vs.* SHE and the difference is the overvoltage which is required for the evolution of oxygen. This overvoltage could be reduced by platinizing the platinum. The rest of the bias is being applied to increase the band bending of GaP from ~ 0.5V at zero bias to 1V when the light limiting quantum conversion is observed. This relatively high band bending is required to ensure efficient charge separation. A considerable increase in efficiency should be realized if efficient charge separation would occur with smaller band bending.

Conclusions

Two photoelectrolytic devices were discussed in this paper. The first one employed n-type semiconductors as anodes which were embodied in a structure that involved a thin film of insulator or a large bandgap semiconductor, deposited on a solar absorbing n-type wafer. It was shown that in this configuration, even intact films as thick as 400Å could not prevent corrosion of the semiconductor. Furthermore, it was found that these films did not transport charges which were created by absorption of light in the lower bandgap material. It was also shown that p-type semiconductors can serve as stable photocathodes in a photoelectrolytic device. However, among the materials that were studied only p-type GaP showed a positive energy conversion efficiency. The maximum yield that was found was 0.1%. The yield is limited largely by the minority carriers diffusion length and the quality of the crystals used, and by the large overvoltage on the oxygen electrode.

Variation of GaAs Epitaxial Growth Rate with Distance along Substrate within a Constant Temperature Zone

Fujitsu Laboratories, Limited, Kamikodanaka 1015, Nakahara, Kawasaki, Japan

ABSTRACT

On the basis of a model which assumes a laminar boundary layer, a rate equation is derived for the vapor phase epitaxial growth of GaAs within a constant temperature zone. The equation can be used to predict the variation of growth rate with distance along the substrate. The predictions of the equation are shown to be in excellent agreement with the experimental results obtained with the open-tube $AsCl_3$-Ga-N_2 system. It is also shown both theoretically and experimentally that the variation of growth rate decreases with increasing gas velocity and also with decreasing substrate temperature, whereas the initial $AsCl_3$ mole fraction has no effect on the growth rate variation.

One of the requirements for many GaAs devices is to prepare epitaxial layers uniform in thickness. Since a vapor phase epitaxial (VPE) growth method for GaAs was first proposed by Effer (1), many investigations have been reported on VPE growth of GaAs (2-6). However, very little has been published on the variation of growth rate with distance along the substrate. It is of considerable importance for preparing uniform thickness epitaxial layers to understand the growth rate at various positions on the substrate. In order to understand this in the case of growth in a graded temperature zone, which is usually employed in the VPE growth of GaAs, it is convenient to investigate the growth rate variation on the substrate in the gas flow direction in a constant temperature zone.

In the present study, a rate equation for epitaxial growth is obtained from a model based on a laminar boundary layer, and is applied to the calculation of the rate of GaAs epitaxial growth. The epitaxial growth within a constant temperature zone was carried out in the diffusion-limited region using the $AsCl_3$-Ga-N_2 system (7). Good agreement between calculated and experimental values is obtained.

Theory

In the VPE growth of a binary semiconductor, the growth rate, R, can be written as (8, 9)

Key words: VPE, binary semiconductor, reacting species, boundary layer, diffusion coefficient.

$$R = [k_s h_g/(k_s + h_g)](C_t/N_1)nM_f \quad [1]$$

where k_s is the surface-reaction rate constant, h_g is the mass transfer coefficient, n is the number of crystal component atoms in a molecule of the rate-limiting reacting species, M_f is the mole fraction of the rate-limiting species, C_t is the total number of molecules per cubic centimeter in the gas, and N_1 is the number of gallium or arsenic atoms incorporated into unit volume of the epitaxial layer. The value of N_1 for GaAs is 2.22×10^{22} cm^{-3}.

The mass transfer coefficient h_g is defined as

$$h_g = D/\delta \quad [2]$$

where D is the diffusion coefficient of the reacting species and δ is the thickness of the boundary layer (9, 10).

Substitution of Eq. [2] into Eq. [1] leads to

$$R = k_s D C_t n M_f/(k_s\delta + D)N_1 \quad [3]$$

Figure 1 shows a schematic diagram of a horizontal reactor with a boundary layer. According to Schlichting (11), the thickness of the boundary layer along a thin flat plate, $\delta(x)$, is given by

$$\delta(x) = 5.0\ (\mu x/\rho V)^{1/2} \quad [4]$$

where x is the distance from the leading edge of the substrate, μ and ρ are the viscosity and density of the

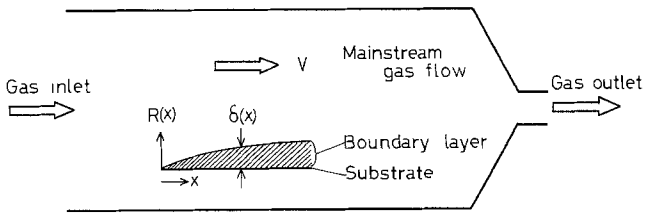

Fig. 1. Schematic diagram of a horizontal reactor with a boundary layer.

gas, respectively, and V is the velocity of the gas outside the boundary layer.

Substitution of Eq. [4] into Eq. [3] yields

$$R(x) = k_s D C_t n M_f / [5.0\, k_s N_1 (\mu x/\rho V)^{1/2} + N_1 D] \quad [5]$$

In order to apply this equation to the actual growth, it is necessary to obtain the temperature dependences of D and k_s.

The temperature dependence of the gaseous diffusion coefficient can be expressed as

$$D_s = D_0 (T_s/T_0)^m \quad [6]$$

where T_s and T_0 are the substrate temperatures (°K) and 273°K, respectively, D_s and D_0 are the diffusion coefficients of the reacting species in nitrogen at T_s and T_0, respectively, and m has a value between 1.75 and 2 (12). In the present study, a value of $m = 2$ is used because most gases diffuse in nitrogen with this m value (13, 14). Thus, Eq. [6] is expressed by

$$D_s = D_0 (T_s/T_0)^2 \quad [7]$$

In the low temperature region, the growth rate increases with increasing substrate temperature. This region is identified as a kinetically or surface-reaction limited region where the over-all epitaxial growth rate is limited by some slow surface process (15). In the case of present system, the apparent activation energy measured in the kinetically limited region is about 1.2 eV. Therefore, the surface-reaction rate constant k_s can be written as

$$k_s = A \exp(-1.2\ \text{eV}/kT_s) \quad [8]$$

where A is a frequency factor and k is the Boltzmann constant (9).

Using Eq. [7] and [8], Eq. [5] can be rewritten as

$$R(x) = nM_f K_1 / [(x/V)^{1/2} + K_2] \quad [9]$$

where

$$K_1 = C_t D_0 (T_s/T_0)^2 \rho^{1/2} / 5.0\, N_1 \mu^{1/2} \quad [10]$$

and

$$K_2 = D_0 (T_s/T_0)^2 \rho^{1/2} / 5.0\, \mu^{1/2} A \exp(-1.2\ \text{eV}/kT_s) \quad [11]$$

Normalizing $R(x)$ by dividing by the growth rate at the point $x = L$ cm, it follows that

$$R(x)/R(L) = [(L/V)^{1/2} + K_2]/[(x/V)^{1/2} + K_2 \quad [12]$$

Experimental

Figure 2 shows the growth apparatus and the temperature profile used for this series of experiments. The apparatus consists of a quartz reactor tube, a Ga source boat, an $AsCl_3$ bubbler, a substrate holder, and a doping tube. The reactor tube had an inside diameter of 44 mm. The purity of Ga and $AsCl_3$ was seven nines and six nines, respectively. The nitrogen gas was purified by a USD nitrogen purifier.

The temperature of the $AsCl_3$ bubbler was varied from 293° to 303°K. The Ga source temperature was held at 1123°K. Constant temperature growth zones of 973°, 987°, and 998°K were employed in the study. The flow rate of nitrogen through the $AsCl_3$ bubbler was kept to 300 cm³/min, and that of nitrogen through the bypass tube was varied from 300 to 1500 cm³/min. It was confirmed that the nitrogen carrier gas was saturated with $AsCl_3$ for the flow rate of 300 cm³/min.

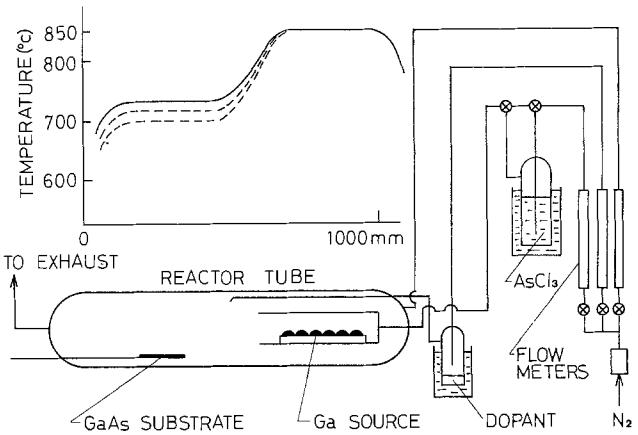

Fig. 2. Schematic diagram of the apparatus and the temperature profile for the epitaxial growth of GaAs.

The substrates used were tellurium-doped GaAs with a resistivity of approximately 2×10^{-3} Ω-cm. Their surfaces were oriented 2° off (100) toward <110>, and the area was 20 × 30 mm. The substrate was placed on a substrate holder in a direction parallel to the gas flow, with a distance between the source and substrate of 20 cm.

The thickness of the grown layer was measured by the infrared interference method (16, 17). The infrared spectrophotometer used was a Beckman IR-18 with a wavelength range of 2.5-16 μm.

Results and Discussion

Diffusion coefficient of reacting species.—In the case of epitaxial growth of GaAs, both gallium- and arsenic-bearing reacting species must arrive at the GaAs surface before the reaction can take place. In the present study, it is assumed that the reacting species bearing both components diffuse through the boundary layer and react at the surface. If, however, one is transported to the surface at a significantly slower rate, it will control the over-all growth rate. Since As_4 is the principal arsenic species and is the largest molecular species in the present GaAs epitaxial growth system, it is reasonable to assume that its diffusion through the boundary layer will be the rate-limiting process. In the present system, GaCl, As_2, and As_4 are considered as the principal reacting species. However, the fluxes of these molecules are in the order

$$F_{GaCl} > F_{As_4} > F_{As_2} \quad [13]$$

over the entire range of growth conditions (18, 19). It is apparent that the process is limited principally by arsenic transport. Thermodynamic considerations (20), however, indicate that F_{As_4} is approximately fifty times as great as F_{As_2} over the range of temperatures employed. Thus, it is reasonable to assume that the over-all growth rate is limited by the process of As_4 diffusion through the boundary layer. Therefore, in order to apply Eq. [9] to the actual growth, the mole fraction of As_4 in the reaction tube must be calculated. The As_4 mole fraction can be calculated from the initial $AsCl_3$ mole fraction; assuming that above approximately 970°K complete reduction of $AsCl_3$ occurs according to the following reaction (20, 21)

$$2AsCl_3 = \tfrac{1}{2}\, As_4 + 3Cl_2 \quad [14]$$

A typical plot of growth rate *vs.* distance along the substrate under a diffusion-limited growth condition is shown in Fig. 3. Values of K_1 and K_2 in Eq. [9] are calculated, by least squares analysis of this plot, to be 7.441×10^{-5} cm/sec$^{1/2}$ and 1.535 sec$^{1/2}$, respectively. The gas viscosity μ and its density ρ at 973°K are taken to be 3.19×10^{-4} g/cm sec and 3.51×10^{-4} g/cm³, respectively (13). Using these values, the diffusion coefficient D_0 and the frequency factor A are calculated as follows

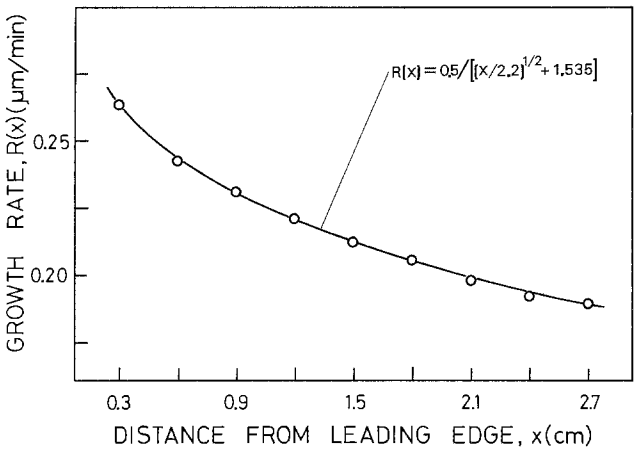

Fig. 3. Growth rate as a function of distance from the leading edge of the substrate. Initial $AsCl_3$ mole fraction 11.20 × 10^{-3}, growth temperature 973°K, gas velocity 2.2 cm/sec.

$$D_0 = 0.083\ \text{cm}^2/\text{sec} \quad \text{and} \quad A = 2.34 \times 10^5\ \text{cm/sec}$$

It is evident that the value of D_0 obtained approximately represents the diffusion coefficient of As_4 in nitrogen. On the basis of the molecular weight of As_4, this value of D_0 seems reasonable (13, 22).

Effect of initial $AsCl_3$ mole fraction.—Figure 4 shows the experimental and the calculated results of $R(x)/R(0.3)$ *vs.* distance x for different initial $AsCl_3$ mole fractions (M_f) at fixed substrate temperature and gas velocity. Variations in the initial $AsCl_3$ mole fraction were obtained by varying the $AsCl_3$ temperature. As can be seen in the figure, there is good agreement between the experimental results and the curve calculated from Eq. [12].

Figure 4 also shows that the variation of growth rate with distance along the substrate is independent of the initial $AsCl_3$ mole fraction M_f. This is because both mass transfer coefficient h_g and surface-reaction rate constant k_s are independent of M_f, since the thickness of the boundary layer is insensitive to variations in M_f, as is evident from Eq. [4]. However, it should be noted here that according to Eq. [9], the growth rate is proportional to the initial $AsCl_3$ mole fraction.

Effect of gas velocity.—The experimental and the calculated results of $R(x)/R(0.3)$ *vs.* x for different gas velocities (V) at a fixed substrate temperature are shown in Fig. 5. The gas velocity was varied by changing the bypass flow so that the efficiency of source

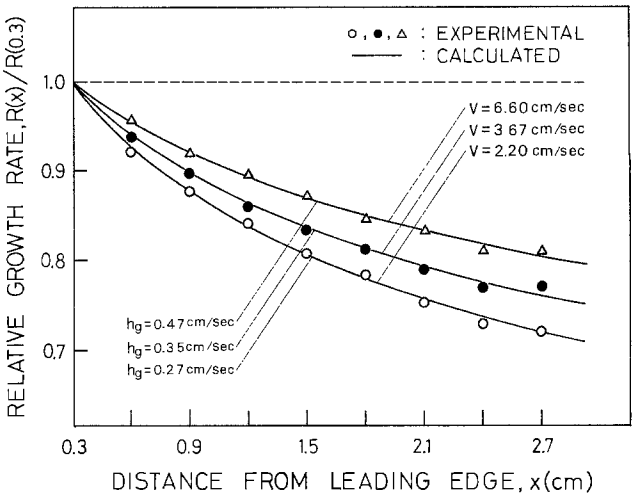

Fig. 5. Comparison of calculated and experimental results of $R(x)/R(0.3)$ as a function of distance from the leading edge of the substrate for different gas velocities (V). Growth temperature 973°K.

reaction did not change. Also given in the figure are the values of h_g at $x = 1.5$ cm for each gas velocity and, as can be clearly seen, there is good agreement between the experimental results and the predictions of Eq. [12].

Figure 5 also reveals that the variation of growth rate along the substrate decreases as the gas velocity is increased. This can be explained by the fact that the mass transfer coefficient h_g increases in proportion to the square root of the gas velocity, which is evident from Eq. [2] and [4], while the surface-reaction rate constant k_s is independent of the gas velocity. It is also evident that further increase in h_g would lead to the kinetically limited region where the growth rate is limited by some relatively slow surface process (adsorption, surface reaction, or desorption). In the kinetic region the growth rate is independent of distance x, as shown by the broken line in Fig. 5. It should also be noted here that the growth rate at each distance x increases as the gas velocity is increased, due to a reduction in the thickness of the boundary layer, provided that the initial $AsCl_3$ mole fraction is held constant.

Effect of substrate temperature.—In Fig. 6 the experimental and the calculated results of $R(x)/R(0.3)$ *vs.* x for different substrate temperatures (T_s) at fixed initial $AsCl_3$ mole fraction and gas velocity are shown. As is evident from the figure, the agreement between

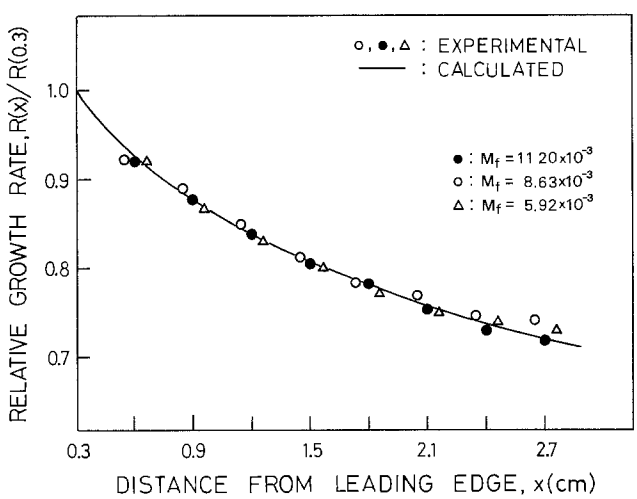

Fig. 4. Comparison of calculated and experimental results of $R(x)/R(0.3)$ as a function of distance from the leading edge of the substrate for different initial $AsCl_3$ mole fractions (M_f). Growth temperature 973°K, gas velocity 2.2 cm/sec.

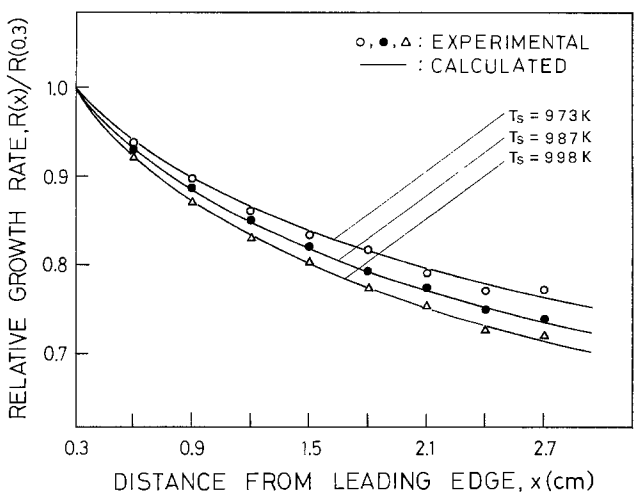

Fig. 6. Comparison of calculated and experimental results of $R(x)/R(0.3)$ as a function of distance from the leading edge of the substrate for different substrate temperatures (T_s). Initial $AsCl_3$ mole fraction 6.71 × 10^{-3}, gas velocity 3.67 cm/sec.

the experimental and the calculated values is very good.

In the figure the variation of growth rate along the substrate is observed to decrease as the substrate temperature is decreased. This tendency is due to the fact that, according to Eq. [8], the surface-reaction rate constant k_s rapidly decreases with decreasing substrate temperature while the mass transfer coefficient h_g is nearly independent of the substrate temperature. Further decrease in k_s would also lead to the kinetically limited region where the growth rate is independent of distance x.

Conclusions

The present investigation has resulted in the following:

1. A rate equation for the epitaxial growth of GaAs has been derived from a model based on a laminar boundary layer. Use of this equation permits the description of the variation of growth rate with distance along the substrate in a constant temperature growth zone. The validity of this equation has been demonstrated by comparison of the calculated growth rate variation with that obtained experimentally.

2. The effects of the initial $AsCl_3$ mole fraction, gas velocity, and substrate temperature on the variation of growth rate with distance along the substrate, in a constant temperature growth zone, have been determined. The variation of growth rate is dependent on the gas velocity and on the substrate temperature, but not on the initial $AsCl_3$ mole fraction.

Oxygen Sensing with $Co_{1-x}Mg_xO$ Ceramics

Kwansuh Park and E. M. Logothetis

Ford Motor Company, Dearborn, Michigan 48121

ABSTRACT

Use of $Co_{1-x}Mg_xO$ ceramics for fabrication of oxygen sensors is reported. The phase stability, electrical conductivity, and thermoelectric power of these solid solutions with $x < 0.85$ have been investigated in the range 700°-1100°C and for oxygen partial pressures in the range $1\text{-}10^{-20}$ atm. The nonstoichiometric defects appear to be singly and doubly ionized cobalt vacancies and give rise to a p-type conductivity. These materials have properties, including stability over a wide range of oxygen pressures and temperatures, that make the $Co_{1-x}Mg_xO$ oxygen sensors particularly suited for monitoring and control of combustion processes. Some results on sensor performance in an internal combustion engine are presented.

In recent years there has been an increased interest in oxygen sensors, particularly those that can be used for the monitoring and control of the combustion process in an internal combustion (IC) engine or a furnace (1-4). The objective of this control is the optimization of the combustion process with respect to fuel economy, emissions, and system performance. Monitoring of the combustion process by means of oxygen sensing is possible because there is a direct relationship between the equilibrium oxygen partial pressure in the exhaust from an engine or furnace and the air-to-fuel ratio (A/F)[1] of the burned mixture. Sensor characteristics that are necessary or desirable for these applications, especially the control of IC engines, include fast response time (generally 1 sec or less), the ability to operate at high temperatures, and the ability to withstand corrosive or contaminating environments. For most furnaces and several IC engine systems, optimization of the combustion process is achieved with air-to-fuel mixtures corresponding to "lean-burn" combustion, *i.e.*, there is more than enough oxygen in the mixtures to convert all the hydrocarbons of the fuel to

Key words: oxygen sensing, combustion process control, ceramics, electrical properties, oxide solid solutions.

[1] A/F is defined as the ratio of the mass of air to the mass of fuel that make up the mixture before combustion.

water and carbon dioxide. Under these conditions, the oxygen partial pressure (P_{O_2}) of the exhaust gas from an engine or furnace is generally in the range of 10^{-3} to 10^{-1} atm.

In a previous publication (5) we reported the use of CoO ceramics as oxygen sensors for lean-burn applications. Pure, stoichiometric CoO is a wide-gap semiconductor with very high resistivity. However, deviations from stoichiometry result in structural defects (cobalt vacancies) that strongly influence electronic conductivity. These properties make the conductivity of CoO at high temperatures depend on the ambient P_{O_2} (5-8). Although CoO ceramic sensors heated at temperatures 900°-1000°C were shown (5) to possess characteristics that make them well suited for lean-burn applications, their usefulness is limited by the fact that CoO decomposes to metallic Co at low P_{O_2}; for example, at 1000°C, the CoO/Co phase boundary occurs at $P_{O_2} \approx 10^{-12}$ atm (Fig. 1); this corresponds to an equivalent air-to-fuel ratio (A/F) of about 14, *i.e.*, a value slightly rich of the stoichiometric A/F ratio. The CoO decomposition does not allow the prolonged exposure of the sensors to very low P_{O_2} such as those corresponding to very rich air-to-fuel mixtures. In the present paper we report the use of solid solutions of CoO with MgO to obtain oxygen sensors with characteristics similar to CoO but without the rich-mixtures-exposure limitation. Since systems operating at high P_{O_2} (lean A/F mixtures) may experience prolonged exposures to very low P_{O_2} (*e.g.*, those corresponding to very rich A/F mixtures) either accidentally or as the result of a certain normal operating mode, the use of $Co_{1-x}Mg_xO$ materials greatly increases the usefulness of these oxygen sensors. Furthermore, the $Co_{1-x}Mg_xO$ sensors can be operated at temperatures lower than CoO.

Properties of $Co_{1-x}Mg_xO$ Materials

The $Co_{1-x}Mg_xO$ materials have been prepared by high temperature reaction of CoO and MgO. Powders of the two oxides were milled together and then fired at temperatures in the range 1400°-1600°C for a few hours. This process was repeated several times until x-ray diffraction measurements indicated that a single phase material was obtained. Ceramic specimens of $Co_{1-x}Mg_xO$ were prepared by standard ceramic techniques involving cold pressing, with or without binder and subsequent sintering.

Figure 1 shows a portion of the P_{O_2}-T phase diagram for the Co-Mg-O system (9). This diagram is

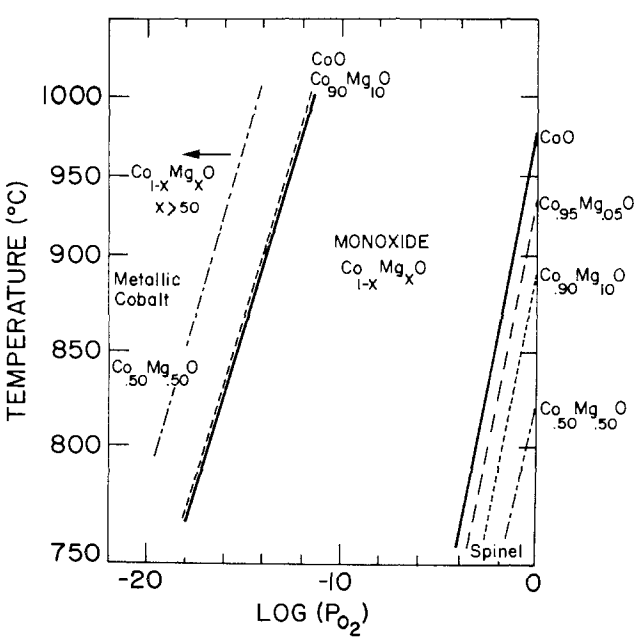

Fig. 1. Approximate P_{O_2}-T phase diagram for the Co-Mg-O system.

only approximate because of difficulties arising from hysteresis phenomena at each phase change; for example, at a given P_{O_2}, the temperature of the phase change from monoxide to spinel is lower than the temperature for the reverse change. The hystereses become more pronounced at lower temperatures and higher rates of change of T (or P_{O_2}). The transition temperature (or P_{O_2}) from one phase to another was determined by monitoring the electrical resistance; this is possible because all three phases (metallic, monoxide, and spinel) have very different resistivities. As Fig. 1 shows, the addition of small amounts of MgO (*e.g.*, $x < 0.10$) into CoO increases the stability range of the monoxide phase by a corresponding suppression of the spinel phase without a noticeable shift in the CoO/Co phase boundary; this boundary, however, shifts substantially to lower P_{O_2} (at a given temperature) for large MgO content (*e.g.*, $x > 0.50$). The wider stability range of the $Co_{1-x}Mg_xO$ materials allows safe exposure of those with $x > 0.5$ to P_{O_2} considerably lower than that for which CoO is decomposed; in addition, at high P_{O_2} (*e.g.*, 0.1 atm) these materials can be maintained at lower temperatures than CoO without transforming to spinel. The spinel composition derived from pure CoO is Co_3O_4; however, when MgO is added, the spinel phase appears to be generally a two phase region consisting of $Co_{1-y}Mg_yO$ and $(Co_{1-z}Mg_z)_3O_4$ (spinel).

The high temperature electrical properties of $Co_{1-x}Mg_xO$ were investigated in the 700°-1100°C temperature range and at P_{O_2} between 1 and 10^{-20} atm. Electrical connections to the ceramic specimens were made by attaching Pt wires with Pt paste. The specimens were mounted inside a quartz vessel that was placed in a furnace. The oxygen partial pressure was established by a continuous flow through the vessel of gas mixtures at a total pressure of 1 atm, O_2 in CO_2 or O_2 in N_2 for high P_{O_2} and CO in CO_2 for low P_{O_2}. At high temperatures, nonohmic behavior and polarization phenomena were absent and 2-probe and 4-probe measurements gave the same results. Figure 2 shows some results on the dependence of the electrical resistivity of the $Co_{1-x}Mg_xO$ ceramics on P_{O_2} at 1000°C. On the high P_{O_2} side the data terminate at approximately the monoxide-to-spinel phase boundary, whereas on the low P_{O_2} side the data terminate at the metal-to-monoxide phase boundary; (for materials with $x > 0.40$, the latter phase boundary extends beyond 10^{-14} atm; see Fig. 1). Complete results on the dependence of the electrical conductivity and the thermoelectric power of $Co_{1-x}Mg_xO$ materials on P_{O_2} and temperature (700°-1100°C) for $0 \leq x < 1$ will be published elsewhere (10).

The behavior of the electrical resistivity of the $Co_{1-x}Mg_xO$ materials appears to be generally the same as that of CoO. In the temperature range of 700°-1100°C, the resistivity is approximately proportional to $P_{O_2}^{-1/4}$ at high P_{O_2} and tends toward a $P_{O_2}^{-1/6}$ dependence for the lower P_{O_2}. These dependences are consistent with a simple model of point defects (most likely Co vacancies) that are predominantly singly ionized at high P_{O_2} and predominantly doubly ionized at low P_{O_2} (6-8, 10). The P_{O_2} range with a $P_{O_2}^{-1/6}$ dependence (doubly ionized defects) widens as the Mg content in the materials increases. At very low P_{O_2}, the resistivity of the materials with $x > 0.5$ tends to saturate. The saturation becomes more pronounced at the lower temperatures and is probably due to donor impurities in the specimens (10). The absolute value of the resistivity increases slowly with x for small x, becoming a strong function of x for large x. The activation energy for the conductivity remains close to that of CoO ($\approx$ 0.5 eV) for $x < 0.20$ and increases strongly for larger x, attaining a value of 1.2 eV for $x = 0.85$. These results in the range 700°-1000°C appear to be generally consistent with the results of thermogravimetric and conductivity studies by Von G. Schwier *et al.* (11, 12)

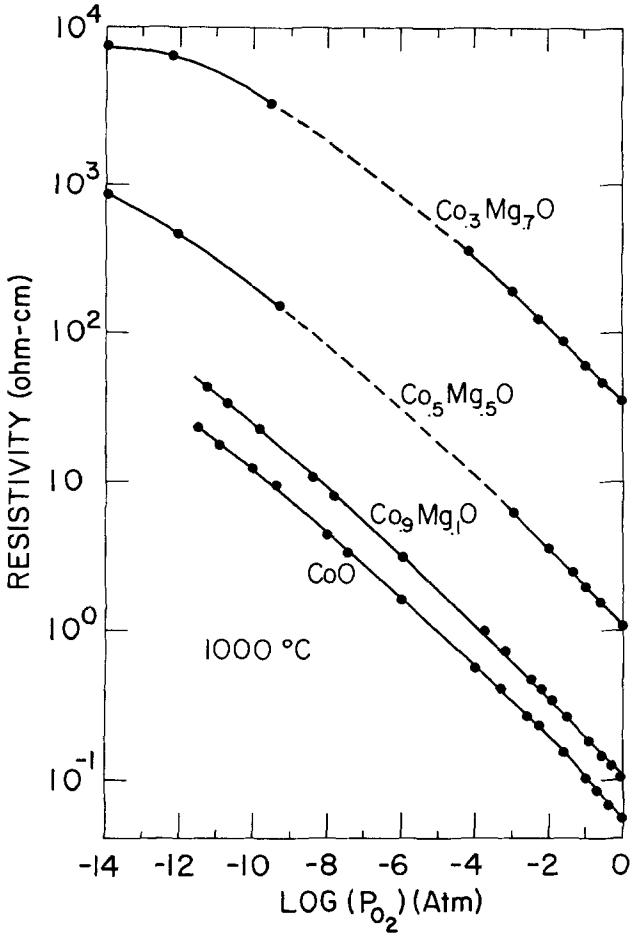

Fig. 2. Dependence of the resistivity of $Co_{1-x}Mg_xO$ alloys on the oxygen partial pressure at 1000°C.

at higher temperatures (900°-1300°C) and at P_{O_2} in the range $1\text{-}10^{-4}$ atm.

For the thermoelectric power measurements, temperature differences ΔT between the two ends of a $Co_{1-x}Mg_xO$ ceramic were established with a small platinum heater near one end of the specimen. Values of ΔT were measured with two Pt/Rh thermocouples, attached to the two ends of the ceramic specimen with platinum paste. The thermoelectric voltage was measured with the platinum legs of the two thermocouples. The sign of the thermoelectric power S shows that the conductivity in all $Co_{1-x}Mg_xO$ solid solutions studied here ($x \leq 0.85$) is p-type, *i.e.*, the charge carriers are holes; this is consistent with the interpretation that the intrinsic defects in these materials are Co vacancies. Furthermore, for materials with $x < 0.5\text{-}0.7$, a plot of S *vs.* $1/T$ gives a straight line having a slope E_S that is equal to the activation energy E_C of the conductivity. This suggests that the exponential increase in the conductivity with temperature results from a similar increase in the carrier concentrations and not from an activated mobility. It thus appears that, as for CoO, the holes in $Co_{1-x}Mg_xO$ with $x < 0.5\text{-}0.7$ are not small polarons but rather itinerant carriers. For $x > 0.5\text{-}0.7$, it was found that $E_C > E_S$ which suggests that the mobility becomes activated. A change from band conduction to hopping conduction is thus indicated at high Mg content. These preliminary results are in disagreement with those of Von G. Schwier *et al.* (11, 12); from combination of mass loss and conductivity measurements these authors concluded that the mobility is activated for all x. It is pointed out that similar discrepancy on the nature of the carrier mobility deduced from mass/loss conductivity and thermoelectric power/conductivity data exists for pure CoO (6-8, 10-13). Experimental uncertainties do not appear to be the source for this discrepancy, since such results for CoO have been obtained consistently by many investigators (6-8, 10-13).

Oxygen Sensor Characteristics

Experimental $Co_{1-x}Mg_xO$ sensors have been fabricated with a configuration similar to that of CoO sensors (5). The ceramic sensing element is in the form of a small bar or disk with two imbedded platinum wires as resistance sensing electrodes. The temperature of the sensor is maintained at some approximately constant value in the range 700°-1000°C by means of a small furnace surrounding the ceramic element.

Figure 3 shows some results on the performance of these oxygen sensors from the specific application of sensing the air-to-fuel ratio of an IC engine. Several sensors were inserted into the exhaust from an 8-cylinder 351 CID (cubic inch displacement) engine and the dependence of the d-c resistance of the $Co_{1-x}Mg_xO$ elements on A/F ratio was investigated. The A/F ratio was determined by conventional gas analysis techniques (14). Figure 3 shows the resistance of the ceramic element of a sensor with composition $Co_{0.3}Mg_{0.7}O$ as a function of the A/F ratio in the range A/F $\simeq$ 15-18 (lean region). The temperature of the sensor was 900°C. The approximate P_{O_2} of the exhaust is also shown at the top of the figure.

Figure 3 shows an approximate two-to-one change in resistance over the range of A/F measured. This change is large enough to be useful in practical applications, provided the materials properties are stable and extraneous changes in resistance (*e.g.*, those due to temperature fluctuations) are small. The resistance *vs.* P_{O_2} relationship and the activation energy of the $Co_{1-x}Mg_xO$ ceramics were found to be very reproducible at least for $T > 800$°C and $P_{O_2} > 10^{-6}$ atm. In addition, they were independent of the porosity of the ceramics in the range 0-50%. These characteristics as well as the absolute value of the resistance remained unchanged after more than 1000 hr of operation at temperatures in the range 800°-1000°C. The tempera-

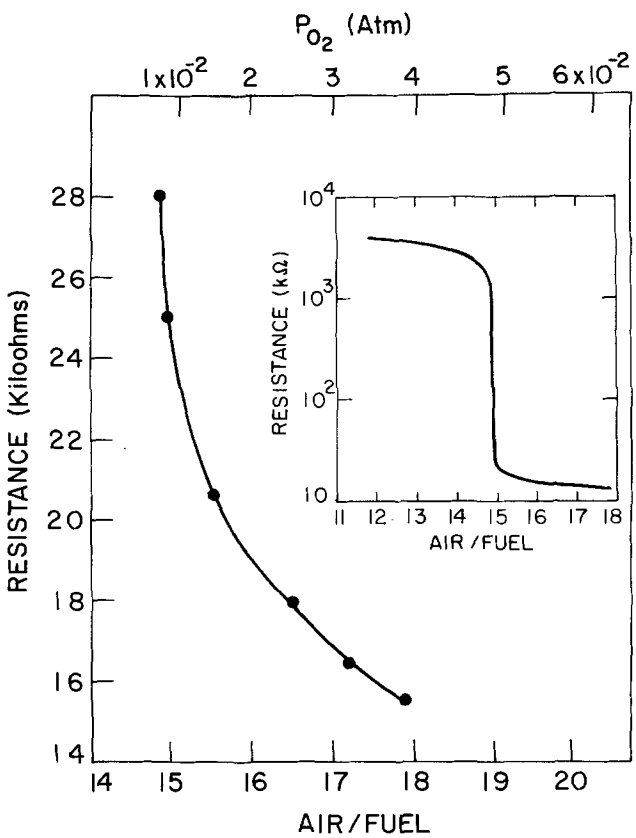

Fig. 3. Dependence of the resistance of a $Co_{0.3}Mg_{0.7}O$ sensor on air-to-fuel ratio (A/F) of an IC engine for A/F > $(A/F)_{stoichiometric}$, and on oxygen partial pressure P_{O_2}. The temperature of the sensor was 900°C. The inset shows the behavior of the sensor resistance for an extended A/F range including the stoichiometric A/F ratio.

ture coefficient of resistance increases with x from 0.3% per °C for CoO to 0.6% per °C for $Co_{0.3}Mg_{0.7}O$ in the neighborhood of 1000°C. These coefficients become about 0.4% and 0.7% per °C respectively in the neighborhood of 800°C.

An important characteristic of an oxygen sensor is its response time. The requirements on response time depend on the application. Sensors made from porous $Co_{1-x}Mg_xO$ ceramics have shown response times similar to the CoO sensors, *i.e.*, of the order of 1 sec or less (5). Shorter response times are expected by optimization of the ceramic structure. It appears that for $P_{O_2} > 10^{-6}$ atm, the response time of the $Co_{1-x}Mg_xO$ sensors is determined by a combination of gas transport through the pores (gas exchange) and the equilibration kinetics (diffusion) within the individual grains.

Since $Co_{1-x}Mg_xO$ materials with $x > 0.5$ do not decompose at very low P_{O_2} (*e.g.*, very rich air-fuel mixtures such as those with A/F = 11), oxygen sensors made from these compositions can be used not only for sensing lean A/F mixtures but also for sensing passage through the stoichiometric A/F mixture. Such "stoichiometric" A/F sensors are presently of considerable interest for the control of engine systems that use a 3-way catalytic converter for the simultaneous removal of all three pollutants (hydrocarbons, CO, NO_x) from the exhaust. Figure 3 (inset) shows the dependence of the resistance of a $Co_{0.3}Mg_{0.7}O$ sensor on A/F ratio for a wide range of A/F ratios, from very rich (A/F = 11) to very lean (A/F = 18). The large step-wise change in the resistance at A/F $\approx$ 14.8 signifies the passage through the stoichiometric A/F mixture and arises from a corresponding large change in the P_{O_2} of the exhaust gas. When the $Co_{1-x}Mg_xO$ is used as an indicator of passage through stoichiometry, the requirements for temperature control are greatly reduced.

Conclusions

Our initial laboratory measurements indicate that oxygen sensors made from $Co_{1-x}Mg_xO$ have electrical properties as well as materials stability over a wide range of P_{O_2} and temperatures, that make them attractive for a variety of applications. The reproducibility and stability of the resistance *vs.* P_{O_2} (or A/F) relationship, the absence of drifts and polarization effects, the relatively small temperature coefficient of resistance, and the fast speed of response, all combine to give a sensor with good performance at high P_{O_2} (lean air-fuel mixtures). More complete evaluation of these sensors for the application of monitoring and control of combustion processes is in progress.

Vapor-Phase Etching and Polishing of GaAs Using Arsenic Trichloride

Rajaram Bhat*,[1] and Sorab K. Ghandhi*

Electrical and Systems Engineering Department, Rensselaer Polytechnic Institute, Troy, New York 12181

A study of the vapor-phase etching and polishing of GaAs substrates using hydrogen chloride gas was presented in a previous paper (1). In that study, it was observed that the etching process critically depended on the purity of the etchant. Arsenic trichloride is readily available in purities better than six nines, and is less expensive compared to HCl gas on the basis of the number of moles of available chlorine. It is, therefore, an attractive alternative for *in situ* etching of GaAs substrates. Knight, Effer, and Evans (2), Hirao and Nakashima (3), and Nozaki and Saito (4) have investigated the etching of gallium arsenide substrates in a $Ga/AsCl_3/H_2$ vapor deposition reactor. Further, DiLorenzo (5) has studied the etching of GaAs substrates with $AsCl_3$ in a helium ambient. However, a detailed information on the effect of temperature, substrate orientation, and $AsCl_3$ mole fraction on the etching and polishing of GaAs substrates, in a H_2 atmosphere, is not available. In this paper, we present results obtained for $AsCl_3$ etching of GaAs substrates in a cold-wall reactor, and compare them with those obtained using HCl gas in the same system. Throughout these etching experiments, a flow of arsine gas was maintained to prevent decomposition of the GaAs. The apparatus and experimental procedure were similar to those used in (1), and the etch rate was defined and determined as in (1).

Experimental Results

Temperature.—The effect of temperature on etch rate was determined for (100) and $(\bar{1}\bar{1}\bar{1})$ oriented, Te-doped GaAs substrates[2] using a flow of 5 liters/min of hydrogen, 30 ml/min of arsine, and 70 ml/min of hydrogen through the $AsCl_3$ bubbler, which was kept at 25°C. Under these conditions, as seen in Fig. 1, the activation energies of the etching reaction and the temperatures at which the etching reaction became mass-transport (type II) limited (6) and independent of crystallographic orientation, were found to be the same as those reported for HCl gas (1). Again, as in (1), GaAs substrate surfaces of both (100) and $(\bar{1}\bar{1}\bar{1})$ orientation were featureless when etched above 870°C, and were faceted with the simultaneous formation of etch pits or hillocks when etched below this temperature. Further, etching experiments with $AsCl_3$ and HCl gas conducted under otherwise identical conditions resulted in equal etch rates for an HCl gas mole fraction which was three times that of $AsCl_3$ in the input gas stream. This indicates that $AsCl_3$ completely dissociates within the reactor before reaching the substrate. The dissociation of $AsCl_3$ produces HCl gas since chlorine is unstable in an atmosphere of hydrogen at the etching temperature (7).

$AsCl_3$ concentration.—Figure 2 shows the etch rate of (100) Te-doped GaAs substrates as a function of the hydrogen flow through the $AsCl_3$ bubbler. These experiments were conducted at a temperature of 900°C, using a total hydrogen flow of 5 liters/min and an arsine flow of 30 ml/min in a reactor tube of 50 mm ID. The etch rate was found to vary superlinearly with HCl concentration. Similar nonlinear dependence of the etch rate on etchant gas flow, under mass-transport (type II) limited conditions, was observed in the etching of Si (8, 9), Ge (10), and GaAs (1). This result differs from the findings of Hirao and Nakashima (3), who observed a linear variation of etch rate with $AsCl_3$ concentration during experiments performed in a hot wall reactor.

Arsine flow.—The effect of arsine flow on etch rate and surface quality under mass-transport (type II)

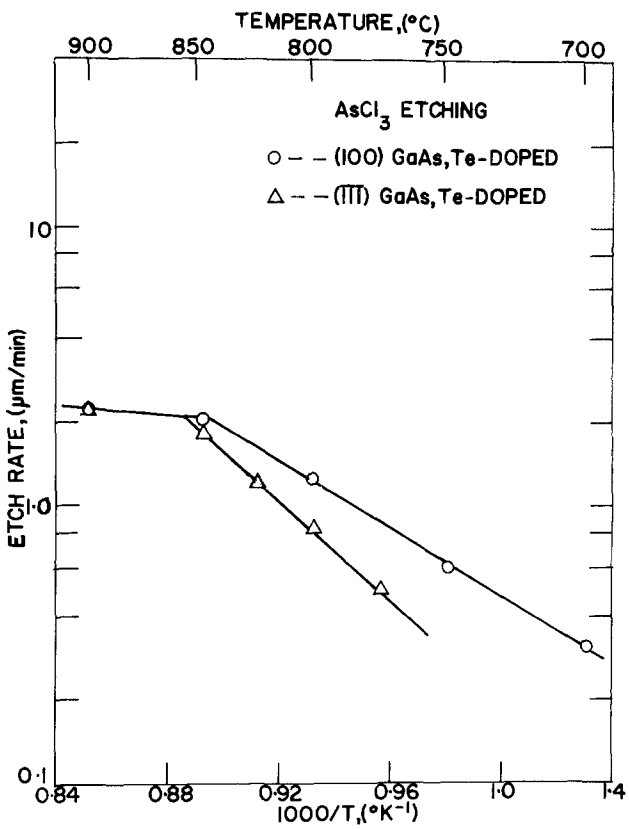

Fig. 1. Variation of etch rate with temperature

Key words: gallium arsenide, arsenic trichloride, etching, polishing.

[2] All (100) substrates mentioned in this paper were misoriented 2° from (100) towards (110).

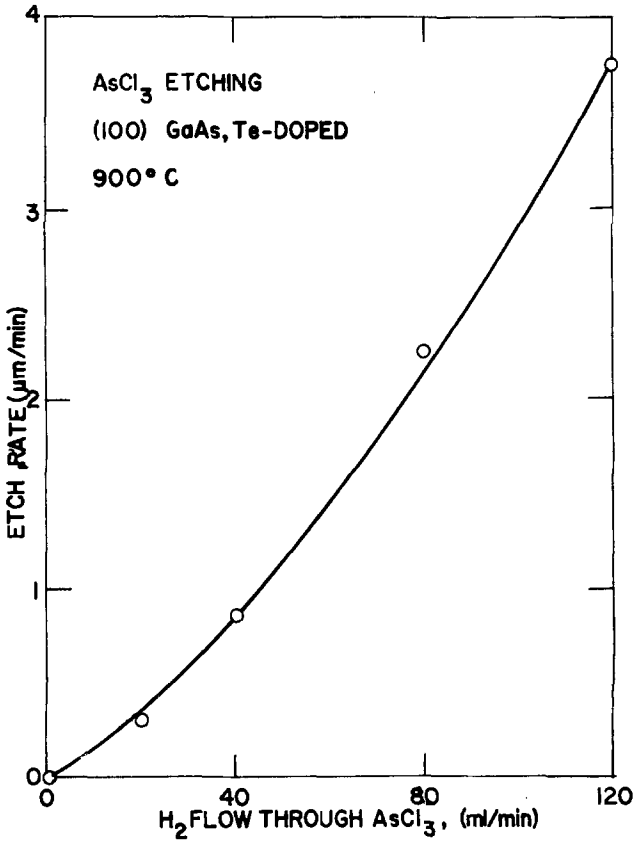

Fig. 2. Variation of etch rate with $AsCl_3$ concentration

limited conditions was investigated at 900°C using a hydrogen flow of 5 liters/min. It was found that at least 15 ml/min of arsine were required to prevent decomposition of the substrate. There was no appreciable change in surface quality for arsine flows between 15 and 30 ml/min, and the etch rate did not change within experimental error. These results are in agreement with those obtained with HCl gas (1).

Orientation and dopant type.—Investigations of the etch rate under mass-transport (type II) limited and kinetically controlled conditions for (100) Cr- and Zn-doped GaAs indicated that it was the same as for their Te-doped counterparts. Therefore, as in (1), the etch rate for $AsCl_3$ etching of GaAs substrates is also independent of dopant type.

It was possible under mass-transport (type II) limited conditions to obtain specular surfaces for (100) Cr- and Zn-doped and $(\bar{1}\bar{1}\bar{1})$ Cr-, Si-, and Zn-doped substrates. In agreement with results obtained in (1), the quality of $(\bar{1}\bar{1}\bar{1})$ Cr- and Si-doped substrates was inferior to that obtained with Te- and Zn-doped GaAs substrates. However, unlike the HCl gas etching study (1), no difference was observed in the quality of (100) oriented Te- and Cr-doped substrates etched with $AsCl_3$. This result is in contrast to that obtained by Hirao and Nakashima (3), who failed to obtain specular etched surfaces for Cr-doped GaAs.

It was noted during the etching of GaAs using HCl gas that the use of a less pure etchant resulted in nonspecular surfaces. Since the $AsCl_3$ was considerably purer than the HCl gas used, we conclude that the difference in the quality of Cr-doped GaAs substrate surfaces etched with HCl gas or $AsCl_3$ was mainly due to the difference in purity of the etchant.

Dopant segregation.—Auger spectra taken on etched and unetched Te-, Si-, and Cr-doped GaAs substrates showed no segregation of dopants on the surface within the limits of detectability.[3] This is in agreement with the results obtained by Moon and James (11) for Te- and Si-doped substrates.

Conclusion

The etching reaction of $AsCl_3$ with GaAs in a hydrogen ambient at temperatures above 700°C has been shown to be identical to that of HCl gas. The ability to obtain equally good specular etched surfaces for both Te- and Cr-doped GaAs substrates makes $AsCl_3$ more attractive than HCl gas in the choice of an etchant.

Lifetime Degradation in Silicon by Emitter Diffusion

R. N. Ghoshtagore*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

The electrical characteristics of silicon devices are critically dependent on wafer processing parameters. Most of these device characteristics are directly derived both from such high temperature process-induced gross internal changes in silicon as resistivity type and level, resistivity gradients and thicknesses of different layers, and such subtle changes in the bulk as heavy metal, vacancy, and oxygen precipitations, minority carrier lifetimes in each doped layer, etc. In this work, the effects of different techniques of one such processing step, namely, $POCl_3$ emitter diffusion, on the minority carrier recombination lifetime of the starting material was investigated.

The starting material in all these experiments was (111) ± 1° orientation, boron-doped, 20-30 Ω-cm, 1-1/4 in. diam, 8 ± 1 mil thick, one-side chem-mechanically polished, < 500/cm² dislocation density, p-silicon, with photoconductivity lifetime of ~225 μsec. The wafers were cleaned by standard techniques with the peroxide process used just before diffusion. They were blown dry with nitrogen before loading into the diffusion furnace. All $POCl_3$ diffusions were done with 4 wafer batches at 1200°C in a 50 mm ID quartz tube for 1-59-1 m (1 preheat time; 59 deposition time; 1 flush time). $POCl_3$ bubbler temperature was controlled to 20° ± 0.5°C by a thermocooler. The carrier gas flow was uniformly N_2 at 2 liters/m. N_2 flow through the bubbler and oxygen flow into the furnace were controlled directly as percentages of the main-line nitrogen carrier gas flow rates. After the emitter diffusion cycle the wafers were cooled by either quenching (by pulling the boat out of the furnace) or slow cooling the furnace (with a programmer) at fixed rates to 600°C and then pulling the boat out of the furnace.

After diffusion, the phosphosilicate glass thicknesses were measured as SiO_2 equivalents, glass stripped in HF, and sheet resistivity and junction depths (angle lap and stain) recorded. The n layer was then lapped off the polished side, and 1/16 in. diam mesa n^+p diodes (1/4 in. apart) fabricated (on the lapped side). Evaporated Al contacts were used on both sides. Open-circuit voltage decay (OCD) lifetime was measured for corresponding diodes under low injection conditions (1 mA forward current) using the relationship (1)

$$\tau = \frac{kT}{q}\left(\frac{dv}{dt}\right)^{-1}$$

All the OCD measurements were made in the dark at room temperature under flowing nitrogen ambients with no further surface passivation of the mesa diodes (1). Surface leakage currents were not a problem in these measurements.

For any particular type of cooling cycle, the phosphosilicate glass thickness on the wafers increased more than linearly with increasing $POCl_3$ concentration in the gas stream, the thicknesses being higher with slower cooling rates. In the entire range of experiments reported here no "bubbles" were observed in the glass. For the experiments where the wafers were pulled out of the furnace after diffusion (quench), junction depths were 6.9 ± 0.8μ. In the slow cool runs, junction depths increased uniformly with decreasing rates of cooling with a 90 ± 5% increase of x_j (over quench) for 0.5°C/min cool rate. Gas phase reactant concentrations (in the range used) had no detectable effect on x_j. Similarly, measured sheet resistivities were primary functions of $POCl_3$ gas phase concentration. Variation of oxygen concentration produced second-order effect that was almost masked by experimental perturbation. All the sheet resistivities were in the range of 0.70-1.33 Ω/□ in. Surface concentrations, calculated from spreading resistance profiles, were also the direct function of only $POCl_3$ gas phase concentration. They ranged from 1×10^{20} to 1.9×10^{20} cm^{-3} in all these experiments. From the spreading resistance profiles, the run conditions with >3.25% $POCl_3$ were difficult to distinguish mainly due to wafer-to-wafer and run-to-run variations.

As we present the OCD lifetime data in Fig. 1-3, the following processing questions will be specifically addressed: (*i*) What is the best $POCl_3$ gas phase concentration for the maximum lifetime preservation? (*ii*) Is there a corresponding O_2:$POCl_3$ ratio? (*iii*) From the same point of view, what is the best range of cooling rates? (*iv*) What deleterious effect, if any, does the thermal preoxidation of wafers have? For a direct basis of comparison of the measured OCD lifetimes, some of the same wafers were used to fabricate 750°C Sb-Au alloyed-in 1/8 in. diam n^+p diodes. The OCD lifetime of such diodes averaged about 60 μsec. The diode size has never been found to have any effect on such measurements.

Minority carrier lifetimes measured by the low injection OCD technique were plotted as a histogram

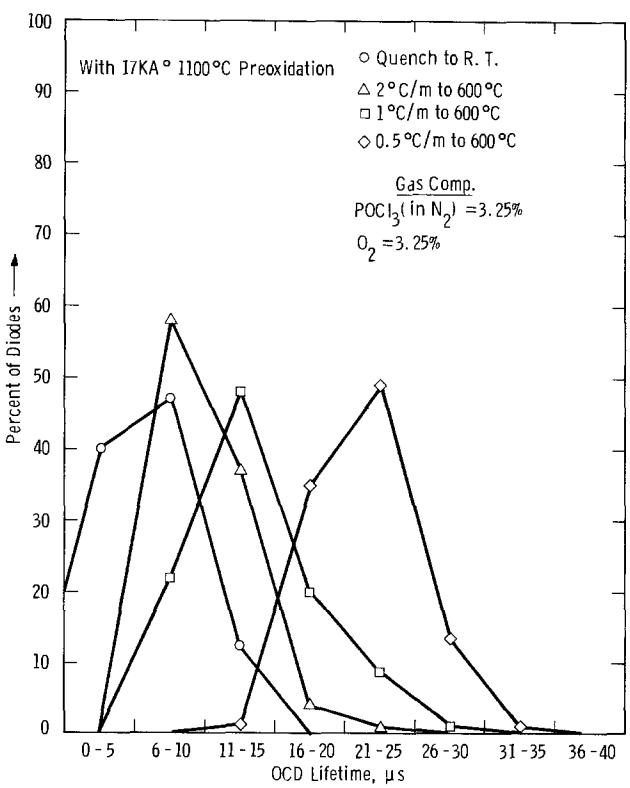

Fig. 1(a). OCD lifetime spectra of 1100°C 17 kÅ preoxidized wafers after the medium concentration emitter diffusion at different slow cooling rates (diffusions at 1200°C).

Key words: silicon, lifetimes, phosphorus, diffusion, degradation, slow cooling.

of the percent of the measured diodes (~100 in each run) as a function of the lifetime divided into 5 μsec groups. Examination of the statistical data in such a form is expected to indicate only the trend of the effect of processing variables experimented. Emitter diffusions were performed for $POCl_3$ gas phase concentrations of 1-10%; O_2:$POCl_3$ ratios of 0.5-3.0 at each $POCl_3$ concentration, and at four primary slow cool rates under any fixed O_2 plus $POCl_3$ concentration condition. Figure 1(a) shows one such set of OCD data illustrating the deleterious effect of wafer preoxidation on the peak OCD lifetime value. Similar effects were observed with unoxidized wafers [Fig. 1(b)]. It should be noted that the maximum programmed slow cool rate of 2°C/min is about equivalent to furnace shut-off condition. Figure 2 shows the peak OCD lifetime data as a function of $POCl_3$ gas phase concentration under two primary O_2:$POCl_3$ ratios. From the trend curves drawn through the data points, it is clear that for the maximum possible lifetime preservation at $\leq$ 2°C/min, cooling rates emitter diffusion must be performed at ~6% $POCl_3$ concentration condition. Under these conditions, peak OCD lifetime initially increases with increasing $POCl_3$ gas phase concentration up to ~6.5%, probably due to heavy metal gettering. But the subsequent drop in each τ value with further increase of gas phase phosphorus concentration must be due to defect generation in the undiffused bulk (2). Both of these gettering and bulk defect generation phenomena become neutralized by the opposing kinetics at low cooling rates (*i.e.*, < 1° C/min). Although Fig. 2 shows that the effect of O_2:$POCl_3$ ratio on the peak τ_{OCD} is very minor, a detailed examination of all the data indicate that the optimum emitter processing should be done at O_2:$POCl_3$ = 2.5-3.0:1.

The topic of the effect of slow cool rate on peak τ_{OCD} is the most controversial one. It has been generally considered to provide considerable time (at different temperatures) for gettering of heavy metals, dissolution of appropriate precipitate centers, annihilation of planar and line-type lattice defects, etc., and thus enhance minority carrier recombination lifetime in heat-treated silicon. As shown in the typical data sets of Fig. 1, all the results obtained in this study

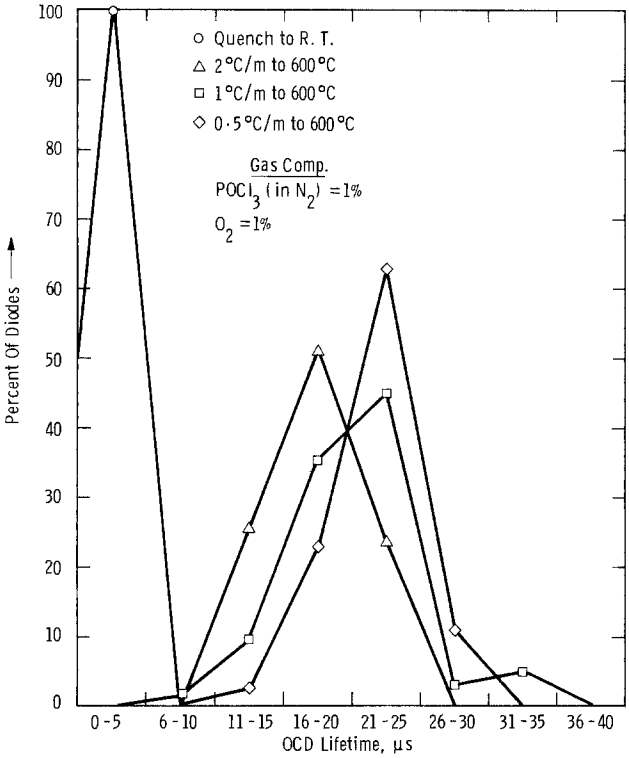

Fig. 1(b). OCD lifetime spectra after low concentration emitter diffusion at 1200°C for different slow cooling rates (no preoxidation).

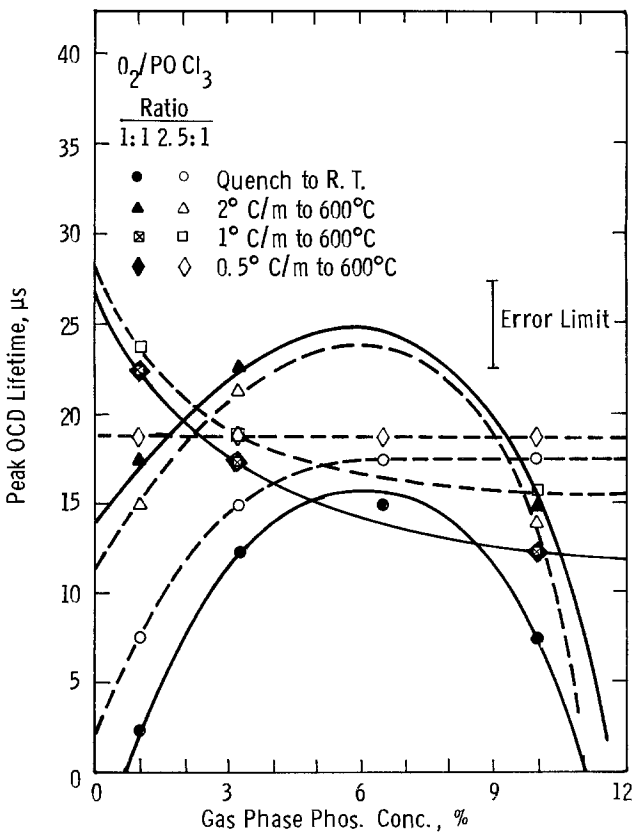

Fig. 2. The dependence of peak τ_{OCD} on the gas phase diffusion conditions at different postdiffusion cooling rates from 1200°C (no preoxidation).

unequivocally indicate longer lifetimes under slow cool conditions, within the aforementioned constraints of gas phase reactant concentrations. As can be seen from Fig. 2, in the case of bare silicon under increasing gas phase phosphorus concentrations, the effects of different slow cool rates on peak τ_{OCD} become minimal. Emitter diffusions under different slow cool rates also drastically alter the distribution of τ_{OCD} values obtainable in any one run. It should be pointed out that in all the data obtained in this study, the trends of the maximum lifetime as a function of slow cooling rates are not monotonically varying. However, with oxidized wafers, the slower the cooling rate the higher is the peak τ_{OCD} [Fig. 1(a)]. Lifetime degradation in preoxidized wafers, being the most relevant to device processing, should determine the best cooling rate (*i.e.*, 0.5°C/min). Slowest cooling rate being equivalent to the maximum x_j immediately raises the question of x_j dependence on τ_{OCD}. Figure 3 attempts to answer that question for an O_2:$POCl_3$ ratio of 0.5:1.0. The set of data with 2°C/min cooling rate (to 600°C) with a 1-89-1 min diffusion cycle is equivalent to that with 1°C/min cooling rate (to 600°C) with a 1-59-1 min diffusion cycle insofar as x_j is concerned (11.0μ). Their lifetime spectra are also nearly identical. This is also approximately the case with that set of data where the slow cool rate was changed from 2° to 0.5°C/min at 1000°C. This latter set of data indicate the importance of the slowest possible cooling rate under 1000°C (0.5°C/min data being anomalous). It has also been observed that the x_j dependence on peak τ_{OCD} ceases to exist after $\sim x_j$ = 12-14μ. Finally, it should be mentioned that all the lifetime data were highly reproducible in the general shape of the spectra. Over 50% of the runs were repeated twice at different times, with some 5-10% being repeated several times.

It is probably appropriate at this point to speculate on the possible mechanisms operating to degrade minority carrier lifetime by emitter diffusion alone. From the clear trend of the data presented, it is not unreasonable to assume that heavy metal contamination is not involved in general, and the wafer cleaning procedure was consistent enough. The presence of optimum $POCl_3$ and O_2 gas phase concentrations probably is consistent with that of least SiP-type precipitation center density production (2). Such incoherent precipitation within the diffused layer is normally associated with dislocation-type recombination centers extending well into the base material. Slow cooling quite possibly could anneal out a fraction of such centers (sessile dislocations). The major effects of slow cooling must, however, be either vacancy annealing (3) and/or oxygen evolution in the silicon lattice as SiO_4-polyhedra. To obtain a clearer idea of the type of thermally induced centers introduced, their densities and locations in the bandgap should be established. Other methods of lifetime determinations could also be usefully employed.

Manuscript submitted Feb. 22, 1977; revised manuscript received May 16, 1977. This was Paper 338 presented at the Las Vegas, Nevada, Meeting of the Society, Oct. 17-22, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1978 JOURNAL. All discussions for the June 1978 Discussion Section should be submitted by Feb. 1, 1978.

Publication costs of this article were assisted by Westinghouse Research Laboratories.

Electrolytic Etching of Aluminum from an Al-Al_3Ni Two-Phase Matrix in Aluminum Chloride Containing Molten Salts

C. L. Hussey,* J. C. Nardi, L. A. King,* and J. K. Erbacher

The Frank J. Seiler Research Laboratory (AFSC), United States Air Force Academy, Colorado 80840

The growth of an aligned microstructure of a controlled eutectic alloy trialuminum nickelide (Al_3Ni) has been investigated by several workers as a means of providing tensile strength enhancement in aluminum (1, 2). A practical method of producing Al_3Ni whiskers in an aluminum matrix utilizes a unidirectional solidification technique (1, 2). In order to properly evaluate the quality of the filament network that has been produced with this growth procedure, it is necessary to remove the solid aluminum phase without causing damage to the filaments. Small diameter fibers composed of Al_3Ni are also expected to find useful application in industrial and military microelectronics if they can be removed undamaged from the aluminum matrix in which they are imbedded. Thus, a practical means of removing aluminum from a two-phase Al-Al_3Ni matrix without damage to the Al_3Ni fibers would be useful to investigators studying the two-phase Al-Al_3Ni system.

Previous attempts using aqueous electrolytes or acid etches for removing or dissolving aluminum from an Al-Al_3Ni matrix have almost always been accompanied by gas evolution, resulting in disordering of the fiber bundles as they are exposed (3). A problem also encountered with aqueous acid etches is low selectivity of attack; *i.e.*, the Al_3Ni fibers are dissolved as well as the bulk aluminum. An electrolyte that would sustain aluminum electrolysis without gas evolution while permitting selective attack on the bulk aluminum phase would be a potential way to circumvent these problems.

Aluminum has been anodized in aprotic media (4, 5), but generally the rate of removal of aluminum is limited by the low electrical conductivity of these media. Application of molten salt media, particularly those containing aluminum chloride, to the anodization of

Key words: aluminum chloride, 1-ethylpyridinium, thin filaments, electrolytic etching, anodization.

aluminum has been demonstrated in both alkali chloride-aluminum chloride (6, 7) and organic salt-aluminum chloride (8, 9) mixtures. Separation procedures using these types of materials provide a number of advantages. Foremost, the method is electrolytic in nature, and therefore provides a great deal of control in the attack. Secondly, the process is not accompanied by gas evolution provided the electrode is not made so anodic as to decompose the melt. Finally, because the electrolyte used is a molten salt the conductivity is high, allowing a rapid removal of material.

King, Brown, and Frayer (6) showed that the anodic dissolution of aluminum proceeds at 100% efficiency at 175°C in a 3:2 molar ratio $AlCl_3$-NaCl melt over the current range 63-500 mA/cm^2. Recently, Gale and Osteryoung (7) found similar results in a 1:1 molar ratio $AlCl_3$-NaCl melt over the current range 0.03-6.30 mA/cm^2 at 175°C. Anodization of aluminum in an organic room temperature molten salt such as 2:1 molar ratio $AlCl_3$-1-ethylpyridinium bromide was also reported to occur with 100% current efficiency (8, 9).

This investigation was undertaken to examine the practicability of using these types of electrolytes to remove the bulk aluminum from a two-phase Al-Al_3Ni matrix.

Experimental

Melts were prepared and maintained and experiments were conducted in a nitrogen filled glove box (Vacuum/Atmospheres Corporation, Model HE 43-6 DRI-LAB). The moisture content was maintained below 10 ppm.

1-ethyl pyridinium bromide (EPB) was prepared by refluxing ethyl bromide (Baker A.R. Grade) with 10% excess pyridine (Baker A.R. Grade) in acetone (Eastman). The resulting white hygroscopic crystals were washed with anhydrous diethyl ether (Baker A.R. Grade) and vacuum dried at 34°C. The melting point of the dried EPB was 121°C and compared favorably with published values of 120°-121°C (10).

A 2:1 molar ratio room temperature melt of $AlCl_3$-EPB was prepared by adding aluminum chloride (Fluka, A.G., iron free) to the EPB. A melt of $AlCl_3$-NaCl saturated with NaCl [49.75 mole percent (m/o) $AlCl_3$] was prepared by fusing aluminum chloride with excess sodium chloride (Baker A.R. Grade) at 175°C. Both melts were purified utilizing a constant current electrolysis procedure (7), and after at least 10 days of electrolysis were clear. They exhibited no evidence of impurities with cyclic voltammetry at a glassy carbon electrode (Fig. 1). The importance of removing impurities from the melt was demonstrated by Gale and Osteryoung (7), who reported that a black deposit forms on aluminum anodes during electrolysis in impure aluminum chloride containing melts.

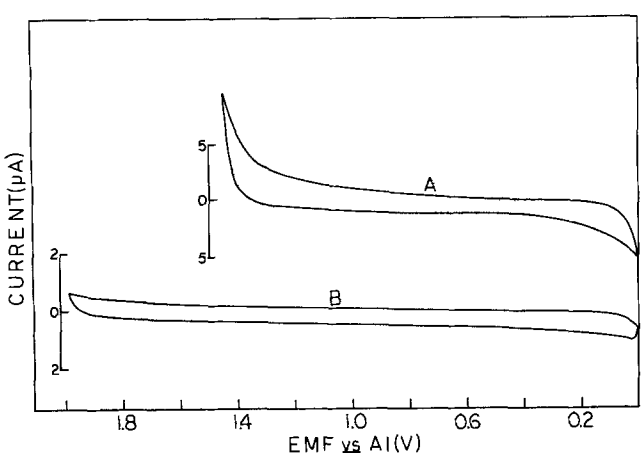

Fig. 1. Cyclic voltammograms at a glassy carbon electrode (A ~ 0.2 cm^2). A is the $AlCl_3$-EPB melt at 23°C and B is the $AlCl_3$-NaCl melt at 175°C. Sweep rate was 100 mV/sec.

Samples of the Al-Al_3Ni matrix were obtained as 3.20 by 0.32 cm diam rods. In addition, a pure sample of Al_3Ni alloy was furnished which had been produced by fusing stoichiometric quantities of aluminum and nickel. This was shaped into a rod of similar dimensions.

Electrodes were fashioned from the samples by wrapping aluminum wire around the ends of the specimens that were not immersed in the melt to provide electrical contact. The immersed area of the Al-Al_3Ni specimen was determined from geometry to be 0.6 cm^2. The Al_3Ni electrode was quite porous, resembling felt metal. A geometrical area, 1 cm^2, was estimated.

Constant current and controlled potential electrolyses were accomplished with a potentiostat/galvanostat (Princeton Applied Research Corporation, Model 173). A voltage programmer (Princeton Applied Research Corporation, Model 175) was coupled to the potentiostat/galvanostat for linear sweep or cyclic voltammetry.

For voltammetry experiments, either a glassy carbon electrode, a pure aluminum wire, or the Al_3Ni electrode was used as the working electrode in a three-electrode cell. The Al_3Ni rod was the working electrode in selective etching experiments. The counter-electrode was a cup-shaped piece of aluminum foil (Research Organic/Inorganic Company, m5n purity), and the reference electrode was a spiral aluminum wire (Alfa-Ventron, m5n purity) isolated from the melt by a 10 mm fine porosity Pyrex frit. The composition of melt in the reference compartment was identical to that of the bulk melt. All potentials described during this investigation were measured against this electrode, *i.e.*, the Al(III)/Al couple.

Cell temperature was maintained at 175°C with a platinum resistance element controlled furnace for experiments with the $AlCl_3$-NaCl melt. Experiments with the $AlCl_3$-EPB melt were conducted at 23°C.

Cyclic voltammograms to determine the melt purity and the $AlCl_3$-EPB anodic limit were constructed by sweeping the glassy carbon electrode between the anodic limit of the melt and the point at which aluminum deposition occurs, *i.e.*, 0.0V at a sweep rate of 100 mV/sec. Linear sweep voltammograms with Al_3Ni or aluminum electrodes were accomplished by sweeping the electrode from 0.0V to the desired anodic potential at a sweep rate of 20 mV/sec.

Results and Discussion

The anodic potential limit of $AlCl_3$-NaCl molten mixtures has been established at *ca.* 2.2V *vs.* Al (11), and was attributed to the oxidation of chloride-containing species to chlorine gas. For the 2:1 $AlCl_3$-EPB melt the limit was determined in this study to be about 1.50V (Fig. 1). Repeated anodization of a glassy carbon electrode in this melt at potentials exceeding 1.50V imparted an orange coloration, suggesting the formation of bromine.

In order that the best electrolysis conditions might be determined, *i.e.*, maximum rate of aluminum removal with minimum fiber attack, it was necessary to know the approximate potential at which significant electrolysis of Al_3Ni took place. For this reason anodic linear sweep voltammograms of aluminum and Al_3Ni were run in both melts. The open-circuit potential of Al_3N was about 0.35V *vs.* Al in both melts.

Linear sweep voltammograms of aluminum and Al_3Ni in the $AlCl_3$-NaCl melt at 175°C (Fig. 2) show that aluminum anodization begins approximately 0.5V before appreciable anodization occurs at the Al_3Ni sample. Therefore, aluminum can be removed in this melt without appreciable attack at the Al_3Ni whiskers, providing the potential of the matrix rod sample is kept below 0.9V. Since this potential is considerably more cathodic than the melt limit, no gas evolution was observed.

The onset of aluminum anodization in this melt is preceded by a reproducible 0.3V overpotential. This

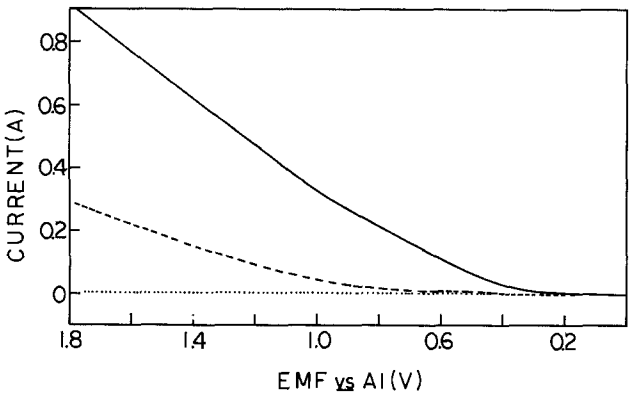

Fig. 2. Anodic linear sweep voltammograms for aluminum and Al_3Ni electrolysis in the $AlCl_3$-NaCl melt at 175°C. Sweep rate was 20 mV/sec. Initial potential was 0.0V vs. Al. —— pure aluminum wire ($A \sim 1$ cm^2); ---- Al_3Ni electrode ($A \sim 1$ cm^2); .... glassy carbon electrode ($A \sim 0.2$ cm^2).

overpotential was not affected by pretreatment of the aluminum electrode. An overpotential of similar magnitude was also observed during steady-state current-potential experiments made in this laboratory. This phenomena is in contrast to the behavior of aluminum in $AlCl_3$ rich $AlCl_3$-KCl-NaCl reported in the literature (12) and in $AlCl_3$ rich $AlCl_3$-NaCl melts observed in this laboratory. Unfortunately a detailed discussion of this phenomena is outside the scope of the present investigation.
